ANALYTICAL APPLICATIONS OF ARSENAZO III—II*

DETERMINATION OF THORIUM, URANIUM, PROTACTINIUM, NEPTUNIUM, HAFNIUM AND SCANDIUM

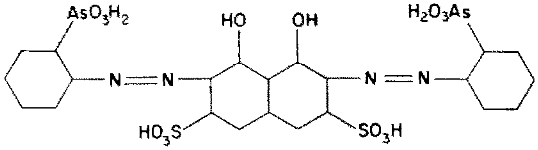
(*Received* 30 *January* 1963; *Accepted* 27 *June* 1963)

Summary—The particular analytical utility of arsenazo III is its capacity for forming especially stable complexes with certain elements. This permits determinations to be carried out in strongly acid media (for quinquevalent and quadrivalent elements—Pa, Np^{IV}, Th, Zr, Hf, U^{IV}—up to 10MHCl or H_2SO_4), which ensures good reproducibility, ease of working, and little interference by anions. The high sensitivity (0·1–0·01 μg/ml, molar absorption coefficient 50–150 × 10^3) is a result of the good contrast effect of the reaction (pink → emerald-green, displacement of the absorption maximum 125 mμ), the nature of the spectrum, and the possibility of reaching extreme dilutions without dissociation of the complex.

THE reagent arsenazo III, produced[1] in 1959, is widely used at the present time for determining thorium,[1–10] uranium,[1,2,11–13] zirconium,[2,14–16] hafnium,[17] protactinium,[18] scandium,[19,20] neptunium,[21,22] and the rare earth elements.[19] Some of the papers mentioned,[3,4,6,8,13,14] having been considered in a previous review[2] are not discussed in the present paper.



PROPERTIES OF ARSENAZO III

Arsenazo III is a dark red powder, moderately soluble in water to give a pink solution. The solutions are stable for an unlimited time in air. Arsenazo III gives colour reactions (violet, blue, and green) in the range from pH 4 to 10M HCl or H_2SO_4 with more than 20 elements.[2] The main distinguishing characteristic of the reagent is its capacity for forming particularly stable metal chelate complexes, their stability exceeding that of the corresponding arsenazo I complexes by more than two or three orders of magnitude.[23]

The high stability of the complexes permits the elements to be determined in strongly acid media at high dilution and in the presence of complex-forming anions—phosphates, sulphates, fluorides, complexone III, and the like. All this permits the analysis to be considerably simplified, making it more reliable and selective. In many cases, it is not necessary to isolate in the pure state the element to be determined; the determination is carried out directly on a solution obtained by dissolving in acids the sample to be analysed.

---

* Part I—see ref. 2.

The sensitivity of the colour reactions is of the order of 0·1–0·01 μg/ml of the element. The molar absorption coefficient for multiply charged elements is of the order of 50–150 × 10^3. Methods for ensuring the necessary selectivity of the reactions have been discussed previously.[2]

METHODS FOR DETERMINING THE ELEMENTS

Thorium

Methods have been previously been described for determining micro-amounts down to 0·01 μg of thorium,[3] thorium in zircons,[4] in rocks (down to 0·0001% of Th),[6] and in Nb-containing products, *etc.*[8]

In the determination of thorium in the presence of zirconium, oxalic acid is added to bind the latter[1]; the determination is carried out in 2·5–3*M* HCl. In the absence of zirconium, the determination is carried out in 1:1 HCl (~6*M* HCl) and no oxalic acid is added. The maximum sensitivity is found in 8*M* HCl. In view of the high acidity, the presence of oxidising agents, for example, nitric acid or chlorine, which are sometimes present in technical acids, is inadmissible (decomposition of the reagent). It is best to use distilled hydrochloric acid. Sometimes powerful reducing agents (for example, Ti^{III}) which also decompose the reagent, may be formed in the process of decomposing and treating the material to be analysed. In this case these must be oxidised by adding, for example, a small crystal of $KMnO_4$ followed by ascorbic acid to decolorise the solution.

In recent papers a method has been described for determining thorium in silicate rocks with a high content of Zr, Ti, rare-earth elements, and the like. The method is based on the separation of Zr, Ti, and the rare-earth elements by ion exchange on KU-2 cation-exchange resin in the H form. Titanium is not sorbed from 1*M* HCl; the rare-earth elements are eluted by 2*M* HCl, and Zr by a 0·5% solution of oxalic acid. The thorium is then eluted quantitatively by means of a saturated solution of ammonium oxalate, and is determined photometrically with arsenazo III in 5*M* HCl without separation of the oxalates. The sensitivity of the method is 10^{-3}–10^{-4}%, and the relative error is ±4%; 6–8 parallel determinations can be completed in 10 hours.[7]

A method has been reported for determining thorium in metallic tungsten, and in natural and other materials.[9] The concentration and photometric determination of thorium in natural waters in which it is present in ultra-high dilution has been described.[5] The thorium is co-precipitated with methyl violet tannate, and the precipitate is filtered off and decomposed by wet ashing. The residue is dissolved in 6*M* HCl, and phenylarsonic acid is added to precipitate the zirconium. The thorium is determined photometrically in hydrochloric acid solution containing lithium chloride (to bind UO_2^{2+}) and oxalic acid. The smallest amount of thorium which can be determined in 5–20 litres of river water is 0·5–1 μg.

Uranium

Uranium may be determined after its preliminary reduction[11] to U^{IV}. An extraction-photometric method consisting of the extraction with butanol of the diphenylguanidinium salt of the complex of UO_2^{2+} with arsenazo III, from a solution containing complexone III, has been described.[13] A method has been developed for determining uranium in rocks, minerals, and solutions of complex composition. UO_2^{2+} is extracted with a 20% solution of tributyl phosphate in carbon tetrachloride from a solution containing ammonium nitrate and Complexone-III; the uranium is re-extracted with a solution of arsenazo III and is determined photometrically. The method permits the determination of uranium when its concentration in the solution to be analysed is 0·002 μg/ml and above.[12]

UO_2^{2+} is determined photometrically at pH 1·5–3·5 and U^{IV} in 6–9*M* HCl.[1,2]

Zirconium

Zirconium is determined under approximately the same conditions as thorium—in 6–9*M* HCl.[2] If a high sensitivity is not required, the determination of Zr can be carried out at a lower acidity, for example, in 2*M* HCl. Various methods of determining it in ores, in concentrates, and in Al, Cu, Mg, Ti, Nb, and Fe alloys have been described.[14–16]

Hafnium

Hafnium is determined under approximately the same conditions and with the same selectivity as zirconium.[2] When Zr and Hf are present simultaneously, a two-pH method is possible.[2,24]

The method of determining Zr in metallic Hf is as follows: 10–20 g of metallic hafnium are dissolved in HF. The solution is fumed off with H_2SO_4. The residue is dissolved in 4*M* HCl and is transferred to a 500-ml measuring flask. An aliquot is taken containing not more than 50 μg of Hf, the solution is heated and, after cooling, 2 ml of a 0·05% solution of arsenazo III is added. The solution is made up to 50 ml with 4*M* HCl and is subjected to photometry. The content of zirconium is found from a calibration curve. Th, U^{IV}, and Ti^{IV} interfere with the determination. The accuracy of the method is ±20% at a Zr content of 0·5% and ±10% at a Zr content of 1%.[17]

Scandium

The determination of scandium is carried out in a fairly acid medium—pH 1–2—, *i.e.*, under conditions where no formation of polynuclear scandium cations takes place. This is of particularly great importance for Sc—almost as much as for Zr—to ensure reproduceability of the results and the reliability of the determinations.[19]

A method has been described for the photometric and complexonometric determination of Sc with arsenazo III as metal indicator.[20] The possibility of working in an acid medium ensures that the reaction takes place rapidly and, at the same time, that the selectivity is greater.

Lanthanum and the lanthanides

In weakly acid solutions with a pH of the order of 1·5–3·5, Y, La, and the lanthanides form an intense blue-green coloration with arsenazo III. The sensitivity is 0·01 μg/ml of the element. A method for determining the individual rare-earth elements has been described by Savvin and Muk.[19]

Protactinium

Arsenazo III gives a colour reaction with Pa^V over a wide range of acidities—from slight acidity up to 5*M* H_2SO_4, 10*M* HCl or more. The complex is green, and it is stable for more than 1 day. The reaction may also be carried out by an extraction-photometric method: the complex of Pa with arsenazo III is extracted almost completely by an equal volume of isoamyl alcohol from sulphuric acid solutions with concentrations of the acid greater than 2*M*. In order to increase the selectivity of the determination of the protoactinium, the organic phase is used for the photometric measurements.[18]

The molar absorption coefficient of the Pa–arsenazo III complex is 22 × 10^3 at $\lambda = 660$ mμ; in the range of concentrations investigated (0·3–3·1 μg/ml of Pa), Beer's law is applicable. The accuracy of the determination is ±3·5%. With a slight excess of reagent, the composition of the complex is 1:1.

The possibility of extracting the Pa–arsenazo III complex from strongly acid media ensures that the determination of protactinium is highly selective. Other elements reacting with arsenazo III either do not pass into the extract at all (Fe, Ti, La, and the like) or are extracted to only a slight extent (Th, U, Zr). The effect of Th, U, and Zr is eliminated by washing the extract with a solution of oxalic acid in 3·5M H_2SO_4. The oxalic acid does not affect the formation and extraction of the complex of Pa with arsenazo III. Mention must be made of the favourable action of sulphuric acid itself, which binds many elements in the form of stable complexes, and, consequently, increases the selectivity of the determination of protactinium.

The chemical analogue of protactinium—niobium—does not react with arsenazo III under these conditions. There is therefore a possibility of determining protactinium in the presence of elements (Nb, Zr, *etc.*) which are always present in uranium ore, and which accompany protactinium when it is isolated.

The procedure is as follows:[18] 0·2–1 ml of the initial sulphuric acid solution containing 1–10 μg of Pa is placed in a 5-ml tube with a ground-in stopper and is treated with 0·8 ml of a $10^{-4}M$ aqueous solution of arsenazo III and concentrated H_2SO_4 in such an amount that the final acidity is 3·5–4M with respect to H_2SO_4. Extraction is carried out with 2 ml of isoamyl alcohol previously saturated with 3·5M H_2SO_4.

After separation of the layers, the extract is transferred into a centrifuge tube and the aqueous phase is extracted with a further 1 ml of isoamyl alcohol. The extracts are combined and centrifuged in order to achieve complete separation of the phases. After centrifuging, the extract is transferred to a 10-mm cuvette and is examined photometrically at 660 mμ against an extract of the reagent alone obtained under the same conditions as the extract of the material to be analysed. The content of protactinium is found from a calibration curve (Fig. 1).

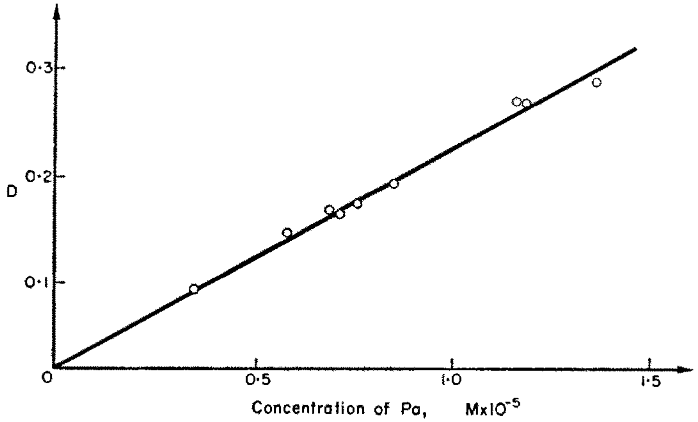


FIG. 1.—Calibration curve for the determination of protactinium. (Concentration of arsenazo III, 2·3 × $10^{-5}M$.)

When Pa is determined in the presence of Th, U^{IV}, and Zr, the extract is washed before centrifuging with one or two 1-ml portions of a 0·5M solution of oxalic acid in 3·5M H_2SO_4. The amount of reagent is increased by a factor of 1·5–2.

Neptunium

A method has been described for determining quadrivalent neptunium with arsenazo III.[21] Np^{IV} with arsenazo III in 1–5*M* HNO_3 forms a green complex, an excess of reagent causing the colour to change to violet. At a concentration of nitric acid of more than 5*M* the coloration of the complex is pale blue and in 8*M* acid it is dark blue. Colorations are formed instantaneously, and are stable for at least some hours. In the presence of iron sulphamate no decomposition of the reagent in concentrated nitric acid solutions takes place. Over the range 4–6*M* HNO_3 the intensity of the coloration changes little with a change in the acidity. The molar absorption coefficient at 665 mμ is approximately 100,000.

Since other quadrivalent elements—U^{IV}, Pu^{IV}, Th, Zr—also form coloured compounds in strongly acid media, these must be removed. This is achieved by extracting the elements with appropriate organic solvents, the NpO_2^+ ions, which are not readily extracted, remaining in the aqueous phase. The neptunium is then reduced to Np^{IV} and is determined with arsenazo III.

For the extraction of U, Pu and Th, Chudinov and Yarkoplev[21] have used a 0·25*M* solution of di-2-ethylhexyl orthophosphate in carbon tetrachloride, which extracts these elements from 0·5*M* nitric acid with a partition coefficient of the order of 100–1000. When quinquevalent neptunium stabilised with sodium nitrite is extracted under the same conditions, only about 2% of the original amount of Np passes into the organic phase. At a ratio of Np to interfering elements of about 1:2000, extraction must be carried out three times to eliminate the latter completely. About 10% of the original amount of Np is lost during the extraction process.

The stabilisation of Np^V is carried out by oxidising it to NpO_2^{2+} with potassium permanganate, and subsequently reducing it to NpO_2^+ with sodium nitrite. Oxidising agents (for example, potassium dichromate) and large amounts of reducing agents interfere with this operation, and they must therefore be removed beforehand.

The following cause no interference in the determination of 1–10 μg of Np: 4 mg of Pu, 3 mg of U, 0·5 mg of La, 2 mg of Th, 1 mg of Zr, 0·2 mg of Cr, and up to 5 mg of Mg, Al, Ca, Co, and other elements. The lower limit for the determination of Np is 0·04 μg/ml ($D = 0{\cdot}02$ at $l = 20$ mm, photoelectric colorimeter, red filter). The accuracy of the determination is between 1% and 7% relative.

In the reaction of Np^V with arsenazo III a green coloration[22] is produced over the pH range 4·4–7·4. The complex has a 1:1 composition, and its molar absorption coefficient is 70,800. Complex-forming substances weaken the coloration. Since the coloration of the complex vanishes on acidification to pH 3, it may be concluded[22] that no change in the valency of the Np compound takes place during complex formation.

Zusammenfassung—Der besondere analytische Nutzen von Arsenazo-III besteht in seiner Fähigkeit, mit bestimmten Elementen besonders stabile Komplexe zu bilden. Das erlaubt Bestimmungen in stark sauren Medien (bei fünf- und vierwertigen Elementen—Pa, Np(IV), Th, Zr, Hf, U(IV)—bis 10 m HCl oder H_2SO_4), was gute Reproduzierbarkeit, leichtes Arbeiten und geringe Störung durch Anionen garantiert. Die hohe Empfindlichkeit (0,1–0,01 μg/ml, molarer Extinktionskoeffizient 50–150 . 10^3) rührt vom guten Kontrasteffekt der Reaktion (rosa–smaragdgrün, Verschiebung des Absorptionsmaximums um 125 mμ), der Natur des Spektrums und der Möglichkeit, extreme Verdünnungen zu erreichen, ohne daß die Komplexe dissoziieren.

ANALYTICAL APPLICATIONS OF ARSENAZO III—III*

THE MECHANISM OF COMPLEX FORMATION BETWEEN ARSENAZO III AND CERTAIN ELEMENTS

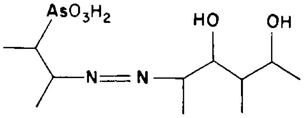
S. B. SAVVIN
V. I. Vernadskii Institute of Geochemistry and Analytical Chemistry
U.S.S.R. Academy of Sciences, Moscow, U.S.S.R.

(*Received* 30 *January* 1963. *Accepted* 27 *June* 1963)

Summary—The two functional-analytical groups of the molecule of arsenazo III are present in two almost isolated conjugated systems. Complex formation with the elements takes place through only one of these: this leads to the appearance of two absorption bands in the visible region of the spectrum. The composition of the complexes for Me^{II} and Me^{III} correspond to MeR; and for Me^{IV} to MeR or MeR_2 (according to the acidity and the concentrations of the components.) Elements whose ionic radii are less than 0·7–0·8 Å give no colour reaction with arsenazo III. The stabilities of the complexes formed by reagents of the type of arsenazo III (bis-azo derivatives of chromotropic acid) with elements depend on the nature of the Me—N bond, and are determined by the extent of the system of conjugated bonds of the molecule of the reagent and the nature of the substituent.

IN recent years the attention of investigators has been attracted to analytical reagents forming particularly stable complexes with elementary cations. Among these are reagents such as complexone III (EDTA) and its analogues, forming colourless complexes and reagents giving coloured complexes—arsenazo III and its analogues, bis-azo derivatives of chromotropic acid containing various salt-forming groups.[1,2] The theory of the analytical action of reagents of the type of complexone III has been studied in relatively great detail, but that of reagents of the type of arsenazo III quite inadequately. Some preliminary observations on the mechanism of complex formation between arsenazo III and various elements have been made by the present author.[3]

The functional-analytical group responsible for the formation of complexes between arsenazo III and elements (as with the other reagents of the arsenazo class, *i.e.*, those containing arsenic and an azo group) is the following:



I

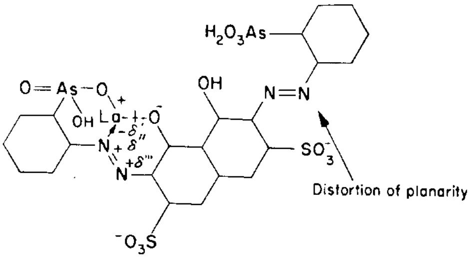
Two such groups are present in the reagent arsenazo III.

Now that further experimental material is available, the mechanism of the formation of complexes of the elements with the functional group is fairly clear.[4–18] Analogies can be drawn with similar reactions between simple inorganic compounds and other organic compounds having the same grouping.[4,13,14] Elements such as UO_2^{2+}, Th, U^{IV}, Zr, Hf, TR form a direct covalent bond with an AsO_3H_2 group and an OH group. For Al, Ti, and some other elements, chromotropic acid is also

---

* Part II—see ref. 2

specific and for Zr even one azo group together with a labile hydrogen atom. Depending on the nature of the reagent and, for a given reagent depending on the conditions, complex formation may take place at different groups. Earlier, for example, by analogy with the corresponding complexes of arsenazo I and thoron I[6,11–13] the following structure was proposed for the complex between La and arsenazo III:



II

A special role is played by the Me—N co-ordinate link. Besides the considerable increase in stability resulting from the formation of two six-membered rings possessing almost aromatic properties, complex formation leads to the transfer to the chromophoric centre of the molecule—the azo group—of some charge, resulting in a marked deepening of the colour of the complex. The same effect is favoured by the transfer of some negative charge to the residue of the hydroxyl group of the naphthalene ring of the reagent.[4,5] The dipole arising at the ends of the system of conjugated bonds, including the chromophoric centre—the azo group—(the magnitude of which depends to some extent on the nature of the metal and the conditions) causes a marked change in the colour of the reagent, *i.e.*, the corresponding colour reaction. A metal cation therefore here plays the role of a peculiar extremely powerful positive auxochrome. This is in complete agreement with modern views, developed, in particular, for azo dyes,[9,15,16] on the theory of the colour of organic compounds.

In the case of arsenazo III, this scheme, which is generally accepted in the literature, is again but only one of the two functional groups is capable of reaction.

Coloration of the reagent and coplanarity

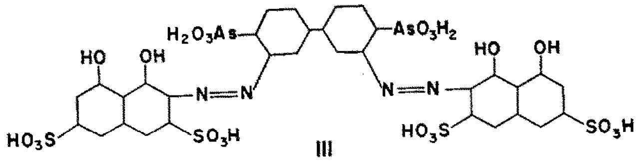
The bis-azo derivatives of chromotropic acid, in contrast to its mono derivatives, and as a result of the conjugation of the two parts of the molecule and the associated planar structure, usually possess deep colours—violet and dark blue. These compounds are unsuitable as photometric reagents. The pink coloration of arsenazo III in acid solutions is the result of a disturbance of the planar structure and the conjugation (consequent on the presence in the *o*-position to the azo group of such voluminous substituents as AsO_3H_2 groups.) The same colour effect is found in the case of certain other substituents: —NO_2 and —SO_4H.

The steric hindrance due to the arsono group is also shown by the considerable difficulty in synthesizing arsenazo III if this is carried out by the methods usually used for azo-coupling reactions.

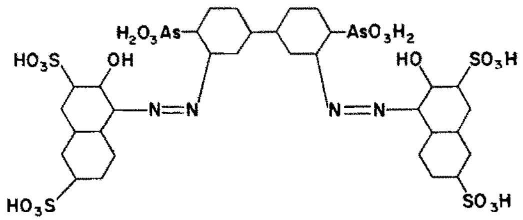
The coloration of arsenazo III in alkalis (dark blue) and in concentrated H_2SO_4 (green) is connected, in the first place, with the ionisation of the hydroxyl groups of the naphthalene nucleus and, in the second place, with the protonisation of the azo groups; this agrees well with views given in the literature.[4–6]

Absorption spectra of the reagent and the complexes

In acid solutions the absorption maximum of arsenazo III in the visible region is located at 540 mμ. The absorption spectra of complexes of arsenazo III with the elements have two maxima in the visible region—$\lambda_1 = 665$ mμ and $\lambda_2 = 610$ mμ (Figs. 1 and 2). The latter circumstance is quite unexpected: with the overwhelming majority of photometric reagents and with all reagents of the arsenazo-thoron group, including the bifunctional reagents arsenazo II and thoron II [Reagents (III) and (IV)], only one absorption band is found in the visible region. It is an essential feature that the characteristic shape of the spectra of the complexes of arsenazo III is retained for all the elements investigated over wide ranges of pH and ratios of the concentrations of the metal and the reagent (Fig. 2). Hence this cannot be a consequence of the simultaneous presence in the solution of two different complexes of dissimilar composition or structure. The two maxima can only be connected with the presence of two weakly interacting (dissociated) chromophoric systems in a single molecule of the reagent, different in magnitude or present in different ionic states. Similar phenomena—*i.e.*, the presence of two absorption bands in the visible region—are known for certain complex cyanine dyes having two dissociated chromophoric systems.[17]



III



IV

In the case of a molecule of arsenazo III not bound in a complex, which is obviously symmetrical, both chromophoric systems, consisting in the present case of functional-analytical groups, are identical, and their absorption spectra coincide, giving a single maximum. Complex formation at *one* group disturbs the symmetry of the molecule and if the system (molecule) does not consist of a single optical unit, *two* absorption maxima appear. The maximum corresponding to the greater depth of colour, $\lambda_1 = 665$ mμ, we ascribe to the functional-analytical group directly linked with the metal and the second maximum at $\lambda_2 = 610$ mμ to the chromophoric centre (conjugated system) not directly connected with the element but, owing to a definite and, apparently, considerable, influence of the first functional-analytical group passing into a different ionic state. To be precise, we assume the transfer of some positive charge to the azo group, more in the first case and less in the second.

It is interesting that the absorption spectrum of the reagent in concentrated

H_2SO_4, where protonisation of the azo group takes place, has a single maximum at the same wavelength as in the case of a complex—665 mμ. In dilute H_2SO_4, protonisation is apparently possible at only one azo group; the symmetry is disturbed and two maxima appear, the first remaining at the same wavelength, 665 mμ. Both for the reagent and for a complex, the first maximum is considerably higher than the second. In alkaline solutions where no protonisation of the azo group takes place, the depth of the coloration is less, the absorption maximum being between 580 and 610 mμ.

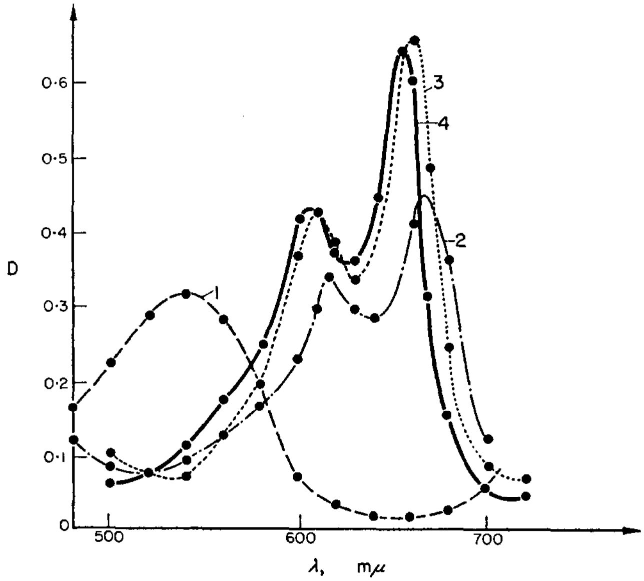


FIG. 1.—Absorption spectra.

(3) Uranyl–arsenazo III complex, pH 1·5;
(4) Lanthanum–arsenazo III complex, pH 3
(SF-4 spectrometer: 10-mm cell: recorded against water)

There is, of course, also the possibility that the extremely large bathochromic effect on complex formation (from pink to green, displacement of the maximum by 125 mμ) is also connected in part with some divergence of the molecule from the non-coplanar state because of the "drawing together", as it were, of the benzene and naphthalene nuclei by the forces of the chemical bond between the metal and the complexing agent; and especially through the quite strongly expressed aromatic character of the two six-membered rings formed with the participation of the metal.

Composition of the complexes

With elements forming doubly charged cations (UO_2^{2+}, Cu, Pb, *etc.*) arsenazo III forms only complexes with a 1:1 composition. This is confirmed by data on the spectrophotometric titration of an element and the reagent, by curves of isomolar series (graphs not given here), and also by the non-dependence, in practice, of the nature of the spectrum of the complex (two absorption bands) on the Me:R ratio in the reaction medium. For example, for molar ratios UO_2^{2+}:R of 1:1 and 10^5:1 the nature of the spectrum remains unchanged; even a 10^5-fold excess of the metal does not give rise to the formation of a complex of the composition Me_2R which, because of its symmetry, would have one absorption maximum. The two absorption maxima are retained at any acidity at which the existence of a given complex is possible.

With elements forming triply charged cations, arsenazo III again forms complexes with a 1:1 composition. This is confirmed by the same methods. With elements forming a quadruply charged cation arsenazo III forms complexes both of the composition MeR and MeR_2. A greater ratio of R to Me is impossible, not so much because valency saturation has been reached, but because of steric considerations which do not permit the co-ordination about Me^{IV} of more than two molecules of so large a ligand. However, Nemodruk and Kochetkova[18] have discussed the possibility of the formation of more highly saturated complexes.

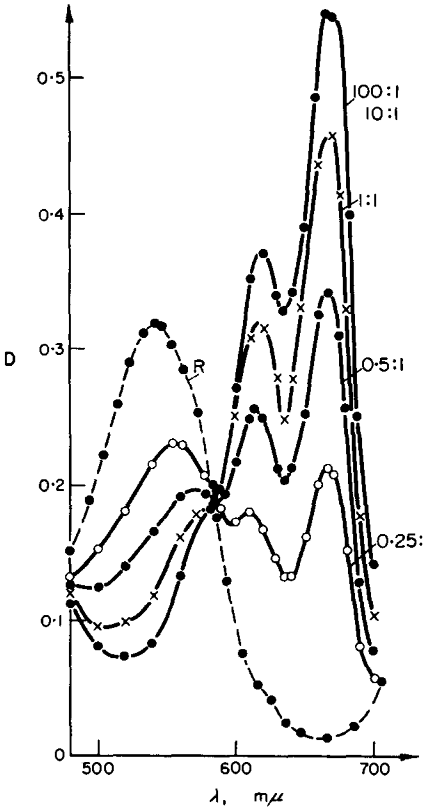

FIG. 2.—Absorption spectrum of thorium–arsenazo III complex at various M:Re ratios ($8M$ HCl: concentration of reagent 0·9 × $10^{-5}M$)

In the spectrophotometric titration of elements forming quadruply charged cations, the point of inflection corresponding to the 1:1 and 1:2 (and, even more, the 1:3 and 1:4) compositions are not clearly expressed; the results obtained by this method are difficult to interpret. It is possible, however, to use the method of determining the absorption of the saturated complexes. It can be seen from Fig. 3 that at a 100–1000-fold excess of thorium (composition known to be 1:1) D = 0·520. The same number of moles of thorium with a 10–20-fold excess of reagent give D = 1·15, *i.e.*, approximately twice as great. In the second case, the formation of a complex ThR_2, having a molar absorption coefficient approximately twice that of ThR may be assumed. This follows from the fact that at a high acidity, when the Th^{4+} ion has appeared quite strongly, the ionic state determining the coloration of the two co-ordinated molecules of arsenazo III is similar, and corresponds to the ionic state of the residue of the arsenazo III molecule in the 1:1 complex.

The same state of affairs is found for zirconium. At an arsenazo III concentration of $0{\cdot}9 \times 10^{-5}M$ and an excess of zirconium in 9*M* HCl, D = 0·5. At a zirconium concentration of $0{\cdot}9 \times 10^{-5}M$ and an excess of reagent in 9*M* HCl, the extinction is approximately twice as high, at D = 1·1.

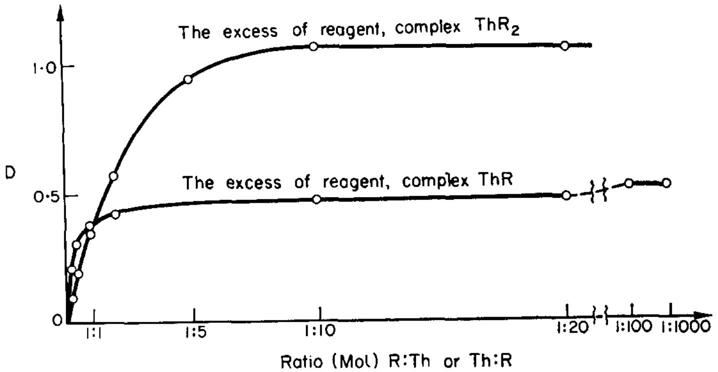

FIG. 3.—Spectrophotometric titration producing saturated complexes for the thorium–arsenazo III system
(Concentrations of MeR and MeR_2, $2{\cdot}2 \times 10^{-7}M$: recorded against reagent)

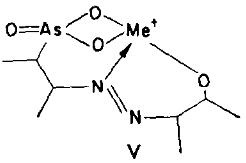
*Influence of the p*H

For arsenazo III and a number of elements (Th, Zr, Hf, U^{IV}, UO_2^{2+}, La, Sc, Cu) curves of isomolar series have been constructed at various values of pH. For triply and doubly charged cations, over the whole range of pH values, the composition corresponds to 1:1. For Th in 0·1*M* HCl, without an excess of reagent there is a 1:1 composition. In 1*M* HCl and at other values of pH, with an excess of reagent the composition is ThR_2, *i.e.*, the more stable form is apparently the ThR_2 complex.

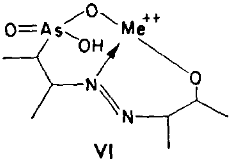
The same thing is found in the case of zirconium. In 0·25*M* HCl and 0·84*M* HCl the composition determined by the Ostromyslenskii—Job method is close to 1:1; but when the acidity is increased (in 2·0 and 5·0*M* $HClO_4$) the composition is close to 1:2.

For Zr and Hf at comparable ratios of Me to R, as the acidity is increased a marked deepening of the coloration is found (violet → dark blue → green). This is apparently connected with a gradual conversion of the Zr ions from a partially hydrolysed to a purely ionic state, which leads to a marked enhancement of the positive auxochromic action of the cation. The same increase in the absorption intensity (at $\lambda = 665$ mμ), but considerably less marked, is found for Th, U^{IV}, and UO_2^{2+}—in the case of UO_2^{2+} right down to those values of the pH (~1) at which the complex begins to decompose.

On the basis of the determination of the compositions of the Me^{II}, Me^{III}, and Me^{IV} complexes and the literature data on the structure of complexes of the elements with reagents of the arsenazo group cited above, two possible structures of the complexes of arsenazo III with the elements may be assumed, fragments of which, for Me^{IV}, are illustrated in (V) and (VI):



V



VI

Structure of the complex in limits of the functional-analytical nucleus

M. P. Volynets and the author[35] have carried out experiments with Th and La to determine the number of protons liberated in the reaction with arsenazo III at various ratios of Me to R. The method of high-frequency titration was used, which permits inflections on the titration curves of the metal and addend to be determined more accurately.[19] The experiments were carried out on the VU-2A apparatus of GEOKhI AN SSSR[20] with a cell in the form of a thin-walled beaker (capacity 30 ml, diameter 23 mm), coated on the inside. The results of the titration were converted into graphs of microammeter reading versus ratio of the components in the solution (the curves are not given here). The use of this apparatus involved some limitations on the conditions of carrying out the experiment: the apparatus is sufficiently sensitive only for the titration of 10^{-2}–$10^{-4}M$ solutions. At such a concentration, and at high acidity, the separation of precipitates is possible; consequently, complex formation was studied at pH 3. Two preparations of arsenazo III were used—in the form of the Na salt and in the form of the acid. In the latter case the reagent, in the form of a mixture of the free acid and the salt, was passed through a column of KU-2 cation exchanger in the H-form. The concentration of the solution to be titrated was generally $0{\cdot}001M$, and the concentration of the titrating agent was 10 times greater.

The results obtained are given in Table I.

TABLE I.—DETERMINATION OF THE NUMBER OF PROTONS LIBERATED WHEN THORIUM AND LANTHANUM FORM COMPLEXES WITH ARSENAZO III

Ratio, *Me:R*, of components	KOH, *equivalents*			
	Th		La	
	Arsenazo III Acid	Arsenazo III Na salt	Arsenazo III Acid	Arsenazo III Na salt
1:1	3·1	2·95; 3·1	2·0	2·1; 1·9
1:2	3·85	4·2; 4·2	—	—

The results in Table I show that three protons are liberated in the formation of a 1:1 thorium complex and 4 protons in the case of a 1:2 complex. In the formation of a lanthanum complex, two protons are liberated.

Thus, the thorium complex of composition ThR has structure (V) (with one positive charge) and the ThR_2 complex has structure (VI), the remaining two valencies being compensated by a second molecule of arsenazo III. The complex of La with arsenazo III has structure (VI). Elements forming doubly charged cations apparently also form complexes of type (VI).

Results for complexes extracted in the form of their diphenylguanidinium salt confirm the conclusions drawn. The ThR_2 (excess of reagent) and UO_2R complexes are extracted considerably more readily than the LaR and ThR complexes. In the latter case, to compensate for the positive charge of the complex, heavy hydrophobic anions must be added to the solution.[21]

Selectivity

It is possible to distinguish selectivity determined by the chemical properties of the element and selectivity determined by the nature of the reagent. In the first case, for reagents of the type R—OH the selectivity is based on the different tendencies of the ions of the elements to hydrolyse. In strongly acid media, a colour reaction is given by elements the ions of which have a considerable tendency to hydrolyse: Zr, Hf, U^{IV}, Th, Np^{IV}; in moderately acid media by UO_2^{2+}, rare earths, Bi, Fe^{III}; and in the weakly acid media by Pb, Cu, Ba, Ca, and NpO_2^+. Thus, in the determination of Me^{IV} a high selectivity is attained. The same case includes the possibility of increasing the selectivity by using masking complex-forming substances, extraction-photometric methods, and the like.[21]

The selectivity of a reagent, as is well known, is determined by the nature of the functional-analytical group. The more simple its structure, the higher its selectivity. To explain the different selectivities of reagents utilising one particular functional-analytical group, supplementary conceptions must be brought in.

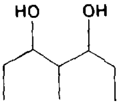
Arsenazo III gives colour reactions with a smaller number of elements than arsenazo I or arsenazo II. It is found that no colour reactions are observed for elements the cations of which have a radius less than 0·7–0·8 Å. In Table II the first column gives the element, the second the ionic radius[22] in Å, and the third the molar absorption coefficient at $\lambda = 665$ mμ.

TABLE II.—RELATION BETWEEN IONIC RADIUS AND MOLAR ABSORPTION COEFFICIENT

E^{II}	r, Å	K	E^{III}	r, Å	K	E^{IV}	r, Å	K
Be	0·314	~ 0	Al	0·55	~ 0	Ge	0·55	~ 0
Zn	0·566	~ 0	Ga	0·65	~ 0	Ti	0·60	~ 0
Pb	1·28	10×10^3	In	0·95	~ 0	Sn	0·65	~ 0
Ca	1·051	10×10^3	Sc	0·81	19×10^3	Hf	0·77	95×10^3
Sr	1·175	10×10^3	Y	0·93	55×10^3	Zr	0·80	120×10^3
Ba	1·395	10×10^3	Ce	1·18	47×10^3	U^{IV}	1·02	100×10^3
UO_2^{2+}	—	53×10^3	La	1·14	45×10^3	Th	1·10	130×20^3

The figures suggest that apparently no ring-closure takes place when the radius of the metal ion forming the complex is relatively small. The values of K in Table II are approximate.

For some elements, complex formation may not take place through the functional-analytical group comprising the AsO_3H_2 group. For example, with Al and Ti the chromotropic acid grouping may form the complex:



VII

In the case of arsenazo I, arsenazo II, and unsymmetrical analogues of arsenazo III [reagents (VIII)–(XIV)], or even of reagents not containing salt-forming groups in the *o*-position to the azo group [(XV), (XVI)] this leads to the formation, within the framework of the conjugated system, of a molecule with some dipole character; and with this is associated a deepening of the colour. In the case of symmetrical reagents—arsenazo III and reagent (XVII)—no dipole is formed and no visible

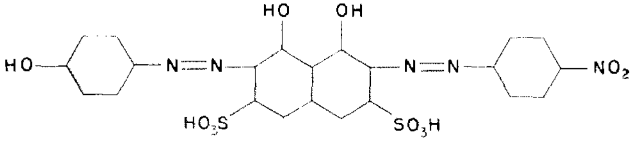
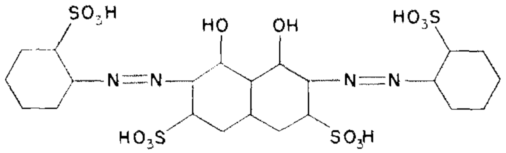
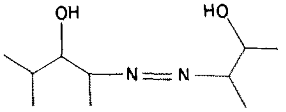
XVI



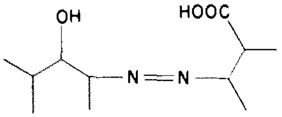
XVII



effects are found. With reagents (VIII) and (IX) complex formation may also take place through the second functional-analytical grouping:



XVIIIa

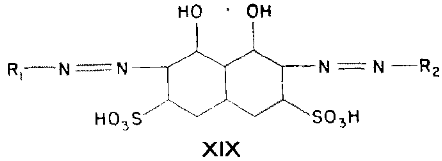


XVIIIb

which also leads to the appearance of a colour reaction.

Analogues of arsenazo III

In order to study the formation of complex formation by arsenazo III, more than 100 bis-azo derivatives of chromotropic acid and various amines of the type of



XIX

have been synthesized, no full list of them being given here. Many of the compounds obtained proved to be extremely interesting analytical reagents in themselves, and may be of interest in the determination of Nb, Zr, Hf, Th, Be, Pb, Cu, and some other elements.

Previously, results have been given (masking coefficients or specific instability indices[23]) showing that all the bis-azo derivatives of chromotropic acid containing even one *o,o'*-azo-hydroxyarsono group form considerably more stable complexes with elements than, for example, arsenazo I.[24,25] This is also found where the second benzene ring completely lacks a salt-forming group [reagents (X), (XI)]; or the group is not specific for thorium (XIII); or it is not located in the *o*-position to the azo group (XII, XIV). This shows that the marked rise in the stability of the complexes observed with arsenazo III and other bis-azo derivatives of chromotropic acid cannot be caused by the simultaneous participation in complex formation of two functional-analytical groups and by the formation of closed rings, as is the case with EDTA.

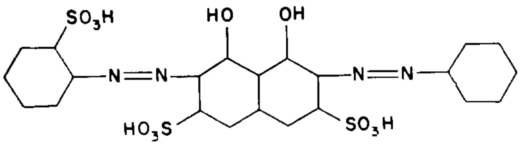
An indirect influence of the second substituent (possibly by enhancement of the tendency to protonisation of the azo group of the functional-analytical nucleus, and the marked stabilisation of the Me—N bond connected with this) is more probable. In addition, a definite effect is also attributed to the repeated occurrence in the reagent molecule of a grouping specific for a given element—if this does not lead to a marked deepening of the colour (through an enlargement of the system of conjugated bonds), to diminished solubility, and other undesirable features.

Somewhat unexpected is the extremely pronounced reduction in the reactivity of the second functional-analytical group when the first takes part in complex formation. It may be assumed that a certain mutual influence of the two conjugated systems leads, when the first group takes part in complex formation, to the transfer of some positive charge to the second azo group, thus lessening the possibility of the formation of a second Me^{n+}—N bond. The lengthening of the conjugated chain in arsenazo III as compared with arsenazo I, and the associated possibility of the distribution of a positive charge transferred to the first azo group, is possibly one of the causes of the increased tendency to protonisation of one of the azo groups and, in the end, leads to a stabilisation of the Me^{n+}—N bond and of the whole complex.

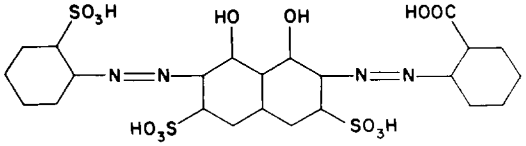
The other bifunctional reagents—arsenazo II and thoron II [reagents (III) and (IV)] have almost completely isolated conjugated systems. These reagents can form with Me^{II} a complex of the composition Me_2R having only one absorption band in the visible region, and having a considerably lower stability than the arsenazo III complexes, although higher than those of arsenazo I. The latter apparently indicates some slight interaction between the systems.

Marked stabilisation of the complexes is also found with the analogues of arsenazo III—bis-azo derivatives of chromotropic acid—containing other salt-forming substituents in place of AsO_3H_2: $-PO_3H_2$, $-SO_3H$, —COOH, —OH. The mechanism of complex formation for these compounds does not apparently differ in principle from the mechanism of the formation of arsenazo III complexes, with the essential limitation that the nature of the salt-forming substituent determines the selectivity of the action of the reagents.

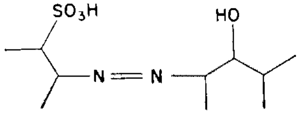
A reagent[26] containing two—PO_3H_2 groups—chlorophosphonazo III—gives a colour reaction in acid solutions with U^{VI},[27] with Pa,[28,29] and with Th, Sc, Ti, and Zr.[30,31] Reagents containing —COOH and —OH groups are specific for Al, Ti, Cu, Nb, and Ta; reagents containing $-AsO_3H_2$, —COOH, and $-SO_3H$ groups have been proposed as metal indicators for the barium ion in the determination of sulphates.[32,33] Examples are reagents (IX) and (XIII). The following reagents are also promising as metal indicators:[33]



XX



They all contain as the complex-forming group of atoms:



XXI

Reagents with two of these groupings [(XVII), *etc.*[33]] form particularly stable complexes with Ba and Sr. The stability of the complex formed by reagent (XVII) with barium can be judged by the simple fact that an intensely coloured complex is formed even in acid media—down to pH 1—which is completely non-specific for barium and is not decomposed by sulphates. The sensitivity is 0·1–0·5 μg/ml of the element.[33]

SYNTHESIS OF ARSENAZO III

In the synthesis of arsenazo III, the method of increasing the activity of chromotropic acid, by treating it in the form of its cyclic salts,[4,34] is used.

Synthesis

Dissolve 60 g (0·276 mole) of *o*-aminophenylarsonic acid in 100–200 ml of water and 60 ml of concentrated hydrochloric acid. Treat the solution with 100–200 g of ice and add slowly, with vigorous stirring, a solution of 20 g of sodium nitrite (0·29 mole) in 50–100 ml of water. Destroy the excess if nitrous acid by the addition of *o*-aminophenylarsonic acid.

Dissolve 26 g (0·0717 mole) of chromotropic acid (mono- or disodium salt) in 200–300 ml of water, and add a mixture of 40 g of calcium oxide and 200–400 ml of water. Treat the mixture with 300–400 g of ice, and add the solution of diazotised *o*-aminophenylarsonic acid with stirring. Allow the mixture to stand for some hours at room temperature.

Then add 4–5 litres of water and 0·5 litre of concentrated HCl, stir the mixture carefully, and set it aside. Then filter, wash the product on the filter with 1:5 hydrochloric acid, water, and ethyl alcohol, recrystallise 2–3 times. Check the purity of the product by the quantitative reaction with thorium salts. Yield of arsenazo III 53–56 g.

Zusammenfassung—Die zwei analytisch wesentlichen funktionellen Gruppen des Arsenazo-III-Moleküls liegen in zwei fast voneinander isolierten konjugierten Systemen. Die Komplexbildung findet nur an einem davon statt; dies führt zu zwei Banden im sichtbaren Spektralbereich. Die Zusammensetzung der Komplexe für Me(II) und Me(III) entspricht MeR, bei Me(IV) MeR oder MeR_2 (je nach Acidität und Konzentration der Komponenten). Elemente mit einem Ionenradius unter 0,7–0,8 Å geben keine Farbreaktion mit Arsenazo-III. Die Stabilität der mit Reagentien vom Typ des Arsenazo-III (Bisazoderivate der Chromotropsäure) gebildeten Komplexe hängt von der Natur der Me-N-Bindung ab und wird durch die Größe des konjugierten Systems im Reagens und der Natur des Substituenten bestimmt.

Résumé—Les groupes à deux fonctions analytiques de la molécule d'Arsenazo-III sont présents dans deux systèmes conjugués presque isolés. La formation de complexe avec les éléments n'intervient que dans le cas d'un d'entre eux. Ceci donne l'apparence de deux bandes d'absorption dans la région visible du spectre. La composition des complexes pour Me^{II} et Me^{III} correspond à MeR et pour Me^{IV} à MeR ou MeR_2 (selon l'acidité et les concentrations des composants). Les éléments à rayon ionique plus petit que 0,7–0,8 Å ne donnent pas de réaction colorée avec l'Arsenazo-III. La stabilité des complexes formés par les réactifs du type Arsenazo-III (dérivés bis-azo de l'acide chromotropique) avec des éléments dépend de la nature de la liaison Me-N et est déterminée pat la proportion de liaisons conjuguées dans la molécule du réactif et par la nature du substituant.

A SYSTEMATIC SCHEME FOR THE IDENTIFICATION OF POLYATOMIC ANIONS BY INFRARED SPECTROSCOPY

FARAJ R. HABA and CECIL L. WILSON
Department of Chemistry, The Queen's University
Belfast, Northern Ireland

(*Received* 22 *May* 1963. *Accepted* 7 *July* 1963)

Summary—Using infrared absorption spectroscopy, a systematic scheme has been established for the identification of the following 16 anions: ferrocyanide, ferricyanide, thiocyanate, arsenite, periodate, salicylate, benzoate, bromate, iodate, silicate, oxalate, tartrate, phosphate, arsenate, chromate and sulphate.

INFRARED spectrophotometry has been established for some time as a popular—indeed well nigh indispensible—method for the identification and determination of organic compounds. Although it has also been used for the investigation of inorganic anions, only one application to systematic qualitative analysis has been attempted.[1]

In the present work infrared spectroscopy has been applied to the systematic identification of the following polyatomic anions: ferrocyanide, ferricyanide, thiocyanate, arsenite, periodate, bromate, silicate, iodate, salicylate, benzoate, oxalate, tartrate, phosphate, arsenate, chromate and sulphate. The above anions are separated into five groups according to the M.A.Q.A. Scheme of semi-micro qualitative inorganic analysis.[2-4] A few mg of each group of anions, after being separated by its selective group precipitant, are washed with a suitable reagent, and dried; the precipitate is mixed with KBr, and a suitable disc is made. The infrared spectrum obtained permits the identification of the anions present.

EXPERIMENTAL

Apparatus and reagents

The infrared spectra were recorded on a Perkin-Elmer "Infracord" spectrophotometer, model 137. The KBr discs were prepared with a Perkin-Elmer die using an "Apex" hydraulic press with a 10-ton capacity on a ram of 2⅛ inch diameter. Before use, the KBr, which was Analytical Reagent grade, was dried at 150° for at least 24 hr. All other chemicals used in the work were AnalaR.

Procedure

The procedure, technique, and equipment have already been described elsewhere.[1,2]

RESULTS

Characteristic absorption of the various anions

Slight differences were found when the characteristic frequencies of the various anions, determined using the KBr disc technique, were compared with those obtained as mulls. These shifts can, in general, be attributed to the short range crystal forces operating on the anions when pressed into the KBr lattice, thus perturbing the vibrational levels. These effects do not occur in the mull, where the material under investigation preserves its own crystal structure and is merely dispersed in an inert medium.

Among the compounds studied here by the KBr disc technique, were some originally investigated by the mull technique,[5] such as silica gel, silver bromate, calcium orthoarsenate, calcium phosphate (dibasic), and barium chromate.

The characteristic absorptions observed were as follows:

(1) Silver ferrocyanide: very strong, sharp absorption at 4·9 μ with two other intense bands at 6·12 μ and 6·2 μ. A deep shoulder is noted at 4·95 μ on the 4·9 μ peak.

(2) Silver ferricyanide: a very strong, sharp band at 4·73 μ, (m. and sp. with sh.)* band at 4·90 μ, and two intense bands at 6·12 μ and 6·2 μ. The main and characteristic absorption band for ferricyanide is that at 4·73 μ; some of the others probably arise from ferrocyanide, produced on grinding the precipitate of silver ferricyanide with KBr. The fading of the orange colour of silver ferricyanide in the grinding process is evidence of this reduction.

(3) *Silver thiocyanate*: a very strong, sharp band at 4·77 μ, with a shoulder at 4·82 μ.

(4) *Silver arsenite*: strong bands at 6·92 μ and 13·5 μ, with two (s, b) bands at 12·5 μ and 14·5 μ. A deep shoulder is observed at 11·3 μ and a weak band at 6·1 μ.

(5) *Silver periodate*: a strong band at 6·92 μ, two (b, s) bands having maxima at 13·65 μ, 14·45 μ.

(6) *Benzoate* (as benzoic acid): (vs. sp) 14·05 μ, 5·92 μ; (s, sp) 7·55 μ, 7·75 μ; (m, sp) 6·9, 7·04 μ, 14·9 μ; (m) 10·66 μ; (w. sp) 14·55 μ, 9·74 μ, 9·32 μ, 8·86 μ, 6·34 μ; (w) 12·3 μ, 8·46 μ; (v, w) 10·0 μ, 9·1 μ, 6·7 μ, 6·18 μ, 6·25 μ, 6·12 μ, 5·6 μ, 5·22 μ, 4·8 μ, 3·9 μ, 3·74 μ, 3·54 μ, 3·35 μ, 3·1 μ.

(7) *Salicylate* (as salicylic acid): (vs, sp) 14·25 μ, 13·1 μ, 8·65 μ, 8·26 μ, 8·02 μ, 7·75 μ, 6·95 μ, 6·85 μ, 6·75 μ, 6·05 μ; (m) 11·15 μ; (m, sp) 12·68 μ, 11·68 μ, 9·7 μ, 8·42 μ, 7·58 μ, 6·22 μ; (w) 11·48 μ, 10·35 μ, 9·2 μ, 7·25 μ, 6·35 μ, 3·85 μ, 3·5 μ, 3·35 μ, 3·1 μ; (v, w) 12·35 μ, 10·05 μ, 7·15 μ, 6·58 μ, 5·72 μ, 5·48 μ, 5·22 μ, 5·15 μ, 5·06 μ, 4·82 μ, 4·62 μ.

(8) *Silicate* (as silica gel, $SiO_2 \cdot xH_2O$): a very strong band at 9·2 μ and a weak band at 10·4 μ.

(9) *Silver bromate*: a very strong band at 12·55 μ with a shoulder at 12·75 μ.

(10) *Silver iodate*: a very broad, strong band, having maxima at 13·0 μ, 13·75 μ and 13·3 μ. Medium shoulders at 12·5 μ, 14·0 μ and 14·2 μ are also observed.

(11) *Calcium oxalate*: (vs) 6·18 μ; (s, sp) 7·25 μ; (s, sp) 7·6 μ; (s, sp) 12·72 μ.

(12) *Calcium tartrate*: (m) 3·86 μ; (vs) 6·3; (vw) 6·75; (s, sp) 7·24, (sh) 7·0, (sh) 7·15, (m, sp) 7·52, (m, sp) 7·82; (w, sp) 8·1, (vs, sp) 8·72, (vs, sp) 9·42, (m, sp) 9·9, (m) 10·4, (vw) 10·82, (vw) 11·28, (vw) 11·76, (m, sp) 12·2, (m) 14·0.

(13) *Calcium orthoarsenate*: a (vs, vb) band at 11·9 μ with a shoulder at 11·3 μ.

(14) *Calcium phosphate* (*dibasic*): a very broad, strong band, having maxima at 9·7 μ, 9·35 μ and 8·9 μ.

(15) *Barium chromate*: (s) 10·60 μ, (vs) 11·10 μ, (vs) 11·45 μ, (vs) 11·60 μ.

---

* m = medium sp = sharp sh = shoulder s = strong b = broad w = weak v = very.

(16) *Barium sulphate*: (vs) 8·48 μ, (vs) 8·95 μ, (vs) 9·25 μ, (m, sp) 10·15 μ.

Note: Absorption bands caused by reagents used in the course of analysis, such as the bands at 6·1 μ, 6·2 μ and 7·25 μ, are neglected.

Qualitative studies on mixtures of anions in groups

It would appear from the foregoing results that the infra-red absorption spectra of the anions under study could provide a useful method for their identification either alone or in mixtures:

Group 1: *Ferrocyanide, ferricyanide, thiocyanate, arsenite, periodate*: In a mixture containing all of these anions, identification of either arsenite or periodate was found impossible; however, if only one of these two is present alone [Fig. (1)] identification is possible. Ferrocyanide, characterised by its 4·9 μ absorption band, is always found wherever ferricyanide is present in the mixture. This band shows itself either as a shoulder on the thiocyanate peak, or separate, when present in higher ratio.

Ferricyanide, characterised by its 4·73 μ absorption band, may give a separate band or a shoulder on the thiocyanate peak, depending on the ratio of ferricyanide to thiocyanate.

Thiocyanate is identified either by its 4·77 μ absorption band; by the twin bands with ferrocyanide; or by the shoulder at 4·82 μ which at increased concentration develops into a new peak. This depends on the ratio of thiocyanate to the complex cyanide in the mixture and on the increase of the transmittancy of the disc.

Group 2: *Salicylate, benzoate*: For a mixture of salicylic and benzoic acids, the spectrum shows the characteristic absorption bands of the individual anions (Fig. 2), particularly at 7·04 μ, 10·66 μ, 12·3 μ, 14·55 μ, for benzoic acid; 13·1 μ, 12·68 μ, 11·68 μ, 11·15 μ, 8·65 μ, 8·26 μ, 8·02 μ, 6·75 μ for salicylic acid.

Group 3: *Bromate, silicate, iodate*: In a spectrum of a mixture of these three anions, only the presence of silicate and iodate can be detected, because the bromate peak is masked by the broad iodate band. When the bromate-iodate ratio in the mixture is increased, a change in the shape of the iodate band is observed which may be taken as evidence of the presence of bromate. Fig. 3 shows a spectrum of a mixture of silicate and bromate.

Group 4: *Oxalate, tartrate, phosphate, arsenate*: In a spectrum of a mixture of oxalate, phosphate and arsenate, the three anions can be identified (Fig. 4) from their characteristic absorption bands. Although a spectrum of all four anions of this group showed overlap of some bands, identification of the four individual anions is, however, possible by the following: oxalate by the 12·72 μ band; tartrate from the 14·0 μ band; phosphate and arsenate from their characteristic absorption bands (which may undergo slight modification in mixtures.)

Group 5: *Chromate, sulphate*: A spectrum of these two anions exhibits (Fig. 5) the characteristic absorption bands of the individual anions. No overlapping of the bands is observed.

DISCUSSION

Although attempts were made to use other existing schemes for the separation of anions[6–8] as the basis for this study, none of them proved satisfactory. This was caused by the accumulation of the spectral bands of many anions when precipitated in one

group, and the impossibility of identifying the individual anions in the resulting spectrum. The effect of the reagents added during the course of analysis is very limited and the bands associated with them produce no interferences. Because of the decomposition at 100° of the silver salts (especially of Group 1) and the consequent accumulation of silver oxide, which tended to produce deformed spectra with poor transmittance, an alternative drying process, therefore performed in a vacuum desiccator, is recommended for this Group. Drying of Group 2 salts was done under a funnel attached to a water pump. Other groups may either be dried in an oven at 100°, or under vacuum. For oxalate and tartrate, vacuum drying is preferable. Under the above drying conditions, calcium dibasic phosphate, and calcium orthoarsenate are produced.

Washing is necessary for the elimination of strong absorptions by adsorbed reagent. Water is used for washing Group 1 precipitates; $0{\cdot}04M$ HNO_3 for Group 3 precipitates; $0{\cdot}04M$ ammonia for Group 4 and 5 precipitates. Washing is carried out by stirring the precipitate with the wash liquid, using a glass rod, discarding the washings after centrifuging.

The transmittances of the KBr discs of the compounds studied, were better than 80%, except for those made from silver arsenite and periodate; reasonable transmittance for these is only obtained when they are present in lower concentration in KBr. The decomposition of these two compounds, with the production of silver oxide, was also observed when their discs were subjected to infrared radiation, the discs being blackened at the end of each experiment. It is unlikely that the decomposition is brought about either by the grinding of the material with potassium bromide, or in the actual disc preparation, because clear discs could be made and stored successfully. The blackening of the disc during the duration of the experiment might be ascribed to either or both of thermal decomposition because of temperature rise of the disc, or photochemical decomposition of the material, since the disc is exposed to a wide range of wavelengths of light. The minimum wavelength given out by the source is of the order of 1000 Å, and these wavelengths could result in the partial decomposition observed.

Halides and sulphides are, of course, unsatisfactory for spectroscopic investigation, being transparent to infrared radiation. One possible further application, however, is the identification of those anions which, when treated with acid, evolve gases: a multiple-path cell could be used to achieve enhanced sensitivity. Such anions include sulphite, carbonate, hypochlorite, hypobromite.

Zusammenfassung—Mit Hilfe der IR-Absorptionsspektroskopie wurde ein systematisches Schema zur Identifizierung folgender 16 Anionen aufgestellt: Hexacyanoferrat(II) und -(III), SCN^-, AsO_3^{3-}, IO_4^-, Salicylat, Benzoat, BrO_3^-, IO_3^-, Silicat, Oxalat, Tartrat, PO_4^{3-}, AsO_4^{3-}, CrO_4^{2-} und SO_4^{2-}. Die Methode ist einfacher, schneller und empfindlicher als die orthodoxen Identifizierungsmethoden.

Résumé—L'emploi de la spectroscopie d'absorption infra-rouge permet d'établir un tableau systématique d'identification des 16 anions suivants: ferrocyanure – ferricyanure – thiocyanate – arsenite – périodate – salicylate – benzoate – bromate – iodate – silicate – oxalate – tartrate – phosphate – arseniate – chromate et sulfate. Cette méthode est supérieure aux méthodes d'identification habituelles car elle est simple, rapide et sensible.

RE-ACTIVATION ANALYSIS OF VANADIUM

Y. KAMEMOTO and S. YAMAGISHI
Division of Chemistry, Japan Atomic Energy Research Institute
Tokai, Ibaraki, Japan

(*Received* 5 *June* 1963. *Accepted* 16 *September* 1963)

Summary—Re-activation analysis is applied to the determination of vanadium. After the addition of vanadium carrier to the irradiated sample, vanadium-52 is separated radiochemically pure by extraction with benzene as vanadium oxinate. The γ-ray spectrum of the vanadium-52 is recorded; the height of the photopeak at 1·44 MeV is measured and compared with that of a vanadium standard. The chemical yield of the purification step is decided by re-irradiation of the separated vanadium oxinate solution and comparing the activity of the vanadium-52 with that of a further vanadium standard. The vanadium content of the sample is determined from the activity of the vanadium-52 induced by the first irradiation and corrected for the chemical yield from the second irradiation.

IN previous papers[1,2] the authors reported on the method of re-activation analysis and its application to the determination of aluminium. This method has the advantage of determining precisely the chemical yield after counting without loss of the sample.

In a normal destructive activation analysis using short life nuclides, the chemical yield is determined by weighing a suitable precipitate of the element being analysed after counting its activity. For the precise determination of chemical yield it is not desirable to treat the irradiated sample after being counted.

On the other hand, when the element to be determined does not have a suitable precipitate for weighing, the chemical yield is determined using a radio-isotope tracer. This method has the disadvantage of producing an error from the difference of chemical yield in each separation.

In re-activation analysis, the chemical yield is easily corrected by re-activation of the counted sample and thus the source of error mentioned above can be eliminated.

The re-activation technique consists of several typical steps, *viz.* the first irradiation of the sample, addition of a carrier, radiochemical separation, counting of the induced activity from the first irradiation, sealing the counted sample in a polyethylene tube, cooling, a second irradiation and counting the induced activity from the second irradiation. The element is determined by measuring the induced activity from the first irradiation, which is corrected for the chemical yield calculated from the induced activity from the second irradiation.

In other words, the technique of non-destructive activation analysis is applied to determine the yield of radiochemical separation in normal destructive activation analysis. This method has now been satisfactorily applied to the determination of vanadium.

THEORETICAL

Solvent extraction was adopted for the radiochemical separation of vanadium because of its rapidity. In this method, the carrier to be added is limited to a rather small amount. Therefore, the amount of the element to be determined in the sample cannot be neglected in the calculation of the chemical yield. From these considerations an equation for determining an element in the sample from the induced activities from the first and second irradiations has been derived:[2]

$$W = \frac{A_{sam} \cdot W_c \cdot W_{st}}{\dfrac{A_{st} \cdot A'_{sam} \cdot W'_{st}}{A'_{st}} - A_{sam} \cdot W_{st}} \qquad (1)$$

where W = weight of vanadium in the unknown sample (g),

A_{st} = induced activity of vanadium-52 in the standard sample from the first irradiation,

W_{st} = weight of the standard sample for the first irradiation (g),

A_{sam} = induced activity of vanadium-52 isolated from the unknown sample after the first irradiation,

W_c = weight of vanadium carrier added to the irradiated unknown sample (g),

A'_{sam} = induced activity of vanadium-52 from the unknown sample after the second irradiation,

A'_{st} = induced activity of vanadium-52 in the standard sample from the second irradiation,

and W'_{st} = weight of the standard sample for the second irradiation (g).

The calibration curves of vanadium for the first and second irradiations (Figs. 2 and 3) were not linear and therefore the amount of vanadium could not be determined from equation (1).[2] However, if the calibration curves are used to find the weights of vanadium corresponding to A_{sam} and A'_{sam}, then A_{sam} and A'_{sam} become equal to A_{st} and A'_{st}, respectively, and equation (1) can be simplified to:

$$W = \frac{W_c(W_{st})_{obs}}{(W'_{st})_{obs} - (W_{st})_{obs}} \qquad (2)$$

where $(W_{st})_{obs}$ = weight of vanadium corresponding to A_{sam} as observed from the calibration curve for the first irradiation (Fig. 2),

and $(W'_{st})_{obs}$ = weight of vanadium corresponding to A'_{sam} as observed from the calibration curve for the second irradiation (Fig. 3).

EXPERIMENTAL

Standard samples

224·5 mg of ammonium vanadate (G.R.) were dissolved in 100 ml of water. This solution was further diluted to give vanadium solutions of several different concentrations. 1 ml of each standard solution was sealed in a polyethylene tube and placed in the centre of a capsule by packing with soft paper.

Samples

Samples containing different amounts of vanadium, manganese, sodium and potassium were prepared in the same way as the vanadium standard samples.

Apparatus

The JRR-1 reactor was used as a neutron source and the RCL-256 channel pulse height analyser with a 1·75 × 2 inch NaI (Tl) crystal (well-type) used as a counter.

Neutron irradiation

All irradiations were made in the No. 16 experimental hole (pneumatic tube) at a neutron flux of about 3×10^{11} neutrons.cm^{-2}.sec^{-1}. The first irradiation was continued for 3 min and the second irradiation for 10 sec.

Procedure

After irradiation in the reactor for 3 min, the unknown sample solution was transferred to a separating funnel. 1 ml of vanadium carrier solution (48·889 μg of vanadium) was added, followed by 50 ml of 0·1M ammonium tartrate solution (pH 4·6). Vanadium was then extracted with 5 ml of a 1 % w/v solution of oxine in benzene. The benzene phase was transferred to a polyethylene tube, which was mounted in the NaI (Tl) crystal 5 min after the end of irradiation, counted for 2 min and the resultant γ-ray spectrum plotted. The polyethylene tube containing the benzene phase was sealed and allowed to cool sufficiently for the vanadium-52 activity to decay to a negligible amount. It was then irradiated for 10 sec, cooled for 110 sec, counted for 1 min and the resultant γ-ray spectrum plotted. The γ-ray spectra of the irradiated standard samples for the first and second irradiations were recorded under the same conditions as for the unknown sample. Vanadium carrier solution was not added to either standard sample nor was the solvent extraction carried out. In each of the resultant γ-ray spectra, the height of the photopeak at 1·44 MeV from the vanadium-52 was measured.

Calibration curves were prepared for the first and second irradiations using the data of standard samples. $(W_{st})_{obs}$ and $(W'_{st})_{obs}$ were determined from these curves as the weights of vanadium producing the same activities as A_{sam} and A'_{sam}, respectively. The amount of vanadium in the unknown sample was then calculated by equation (2).

RESULTS AND DISCUSSION

γ-Ray spectrum

An example of the γ-ray spectrum of vanadium-52 measured after the extraction with oxine-benzene solution is shown in Fig. 1.

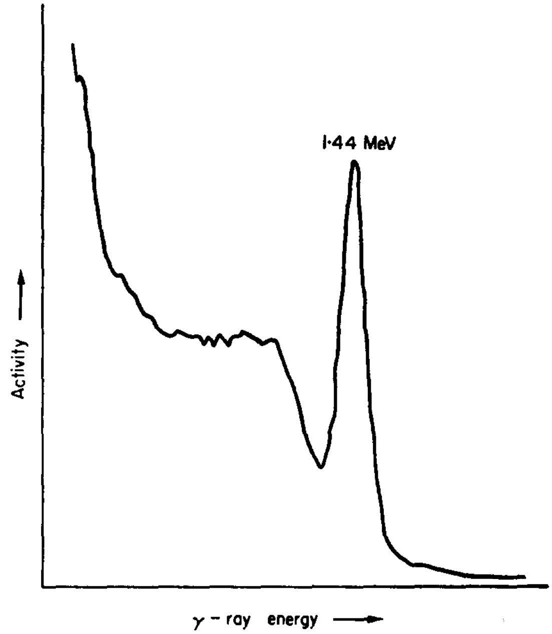

FIG. 1.—γ-Ray spectrum of vanadium.

Calibration curves

The calibration curves of vanadium for the first and second irradiations are shown in Figs. 2 and 3, respectively

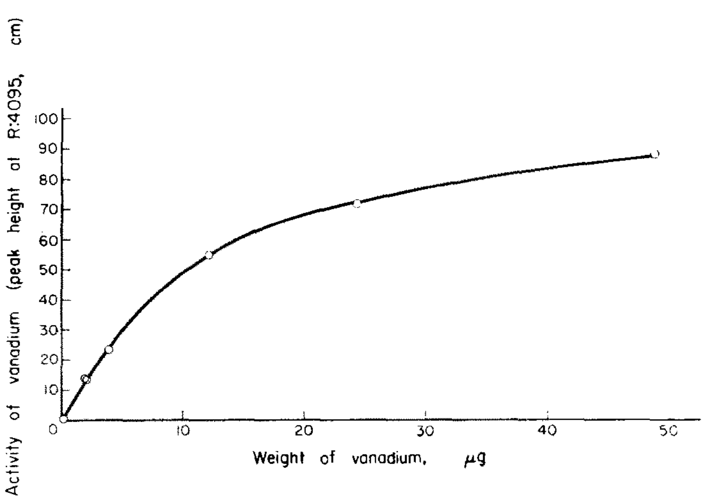

FIG. 2.—Calibration curve of vanadium for the first irradiation.

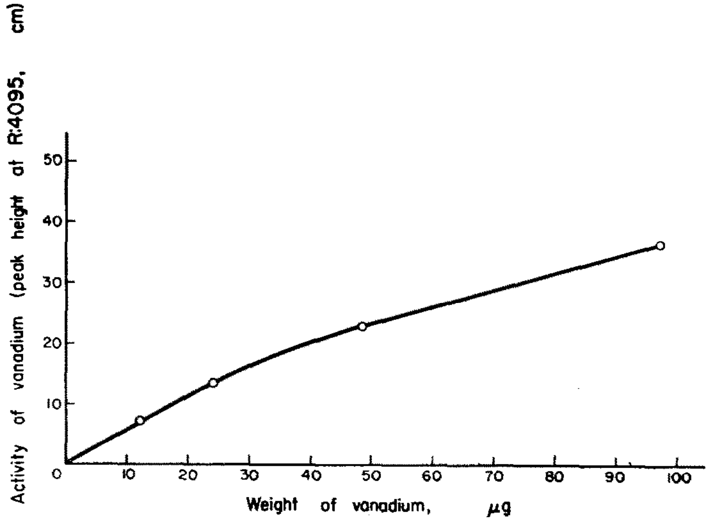

FIG. 3.—Calibration curve of vanadium for the second irradiation.

Results

Some results of analyses by this method are shown in Table I. The upper and lower limits of determination of vanadium are 25 μg and about 0·05 μg, respectively. The coefficient of variation of analysis for 3·91 μg of vanadium is 3·81% (6 results).

Interferences

γ-Rays which may be confused with the 1·44 MeV γ-ray of vanadium-52 are the 1·368 MeV of sodium-24, 1·37 MeV of holmium-166, 1·479 MeV of molybdenum-93m, 1·49 MeV of nickel-65 and 1·53 MeV of potassium-42. Also, the 1·81 MeV γ-ray of manganese-56 would affect measurement of the height of the 1·44 MeV vanadium-52

peak. The interference from manganese-56, sodium-24 and holmium-166 must be taken into account because of their high activation cross sections and saturation factors.[3]

Because sodium and potassium are not extracted with oxine-benzene solution, these elements do not affect the determination of vanadium by the present method. Manganese should not affect it either, because of its non-extractability with oxine-benzene solution, but some interference was found. Some precipitation of manganese hydroxide takes place at the pH of the sample solution at the extraction stage and part of this precipitate is presumably carried into the benzene phase. No method of overcoming the interference from manganese was found.

Zusammenfassung—Die zweistufige Aktivierungsanalyse wird auf die Bestimmung von Vanadin angewandt. Nach Zugabe von Vanadinträger zur bestrahlten Probe wird ^{52}V radiochemisch rein als Oxinat durch Extraktion mit Benzol abgetrennt. Das Gammastrahlenspektrum des ^{52}V wird registriert; die Höhe der Linie bei 1,44 MeV wird gemessen und mit der eines Vanadiumstandards verglichen. Die chemische Ausbeute des Abtrennungsschrittes wird durch erneute Bestrahlung der Vanadiumoxinatlösung bestimmt; deren ^{52}V-Aktivität wird mit der eines weiteren Vanadiumstandards verglichen. Der Vanadingehalt der Probe wird aus der durch die erste Bestrahlung hervorgerufenen ^{52}V-Aktivität berechnet und für die auf Grund der zweiten Bestrahlung bestimmte chemische Ausbeute korrigiert.

Résumé—L'analyse par réactivation est appliquée à la détermination du vanadium. Après addition d'un porteur de vanadium à l'échantillon irradié, le vanadium-52 est séparé sans impureté radiochimique par extraction au benzène sous forme d'oxinate de vanadium. On enregistre le spectre de rayon γ du vanadium-52; la hauteur du pic à 1,44 MeV est mesurée et comparée à celle d'un spectre étalon de vanadium. On détermine le rendement chimique de la purification en irradiant à nouveau la solution séparée d'oxinate de vanadium et en comparant l'activité du vanadium-52 à celle d'un autre étalon de vanadium. On détermine la quantité de vanadium contenue dans l'échantillon à partir de l'activité de vanadium-52 provenant de la première irradiation et la correction due au rendement chimique est calculée à partir de la deuxième irradiation.

SEPARATION OF THE OLIGOPHOSPHATES

(*Received* 15 *August* 1963. *Accepted* 16 *September* 1963)

Summary—Mixtures consisting of orthophosphate, its linear polymers up to and including tridecaphosphate, and three cyclic polymers have been separated by ion-exchange chromatography. One of the cyclic polymers (found in polyphosphate glasses of $\bar{n} \simeq 10$) is probably pentametaphosphate. Its cyclic nature has been demonstrated by end-group titrations and by paper chromatography, but attempts to determine the number of phosphorus atoms in the ring failed because of the very small amount of the compound available. Evidence is presented in support of the common assumption that the linear phosphates above the tetramer are eluted in the sequence of their increasing degree of polymerisation.

INTRODUCTION

THE oligophosphates consist of two homologous series of reasonably stable compounds. The linear polymers can be represented by the general formula $Na_{n+2}P_nO_{3n+1}$, while the cyclic polymers have the general formula $Na_nP_nO_{3n}$.[1] In the latter case, the trimer and tetramer are commercially available. Evidence for the existence of the higher cyclic phosphates in partially degraded Graham salt (long-chain linear polymers) has been obtained by paper chromatography,[2] but these compounds have been isolated only in trace quantities.

In dilute aqueous solution, all of the oligomers undergo slow degradation to orthophosphate. However, at room temperature and at pH levels near 7, the degradation is slow enough to permit the analysis and the study of the properties of the individual polymeric species.

The properties of adjacent members of the polymeric series are so similar that the analysis of mixtures of these polymers is a difficult task. Classical, wet chemical methods are not able to distinguish between oligomers greater than the trimer.[3] Two-dimensional paper chromatography has isolated "spots" for both the linear and cyclic polymers through the tetramers and has partially resolved spots for higher compounds of both types.[4] Quantitative applications of this technique are subject to relative errors of several per cent because of the small samples and the relatively harsh elution conditions. Ion-exchange chromatography has been utilised for the separation and determination of each constituent in mixtures of phosphates.[5–9] The fundamental theory of this approach, applied to the phosphates, was published in 1954,[6] and succeeding papers have extended the original separation to higher oligomeric species. A description of a device for the automatic recording of the elution graph in the analysis of phosphate mixtures has been published.[10]

Matsuhashi[8] extended the range of the ion-exchange method as far as the dodecaphosphate. However, his separation of the linear polymers above the trimer was not quantitative and the cyclic polymers would have overlapped the linear in any single elution. Jameson[9] achieved a quantitative separation of the linear polymers through the dodecaphosphate by gradient elution, but he did not separate the cyclic polymers from the linears.

RESULTS AND DISCUSSION

Anion-exchange chromatography

Previous work in this laboratory[5,7] had indicated that moderately crosslinked polystyrene resins with the ionic group $-CH_2N^+(CH_3)_3$ are best for the separation of the condensed phosphates. Amberlite XE–119 (analogous to IRA–400 but with a mesh range of 400 to 600) was selected.

In the previous work,[5] the pH of the eluent had been chosen with the aid of equations (19) and (20) of reference 6 (or similar equations) so as to give maximum separations between neighbouring members of the polymeric series.

A difficulty was experienced in the present work in applying these equations because the values of the ionisation constants and the selectivity coefficients are not known for the polymers above the tetramers. Therefore, the following semi-empirical method was used to predict the elution behaviour of the higher linear polymers at pH 5.[11]

From the data of Irani and Callis,[12] it seems likely that for any oligophosphoric acid, $H_{n+2}P_nO_{3n+1}$, the last three ionisation constants will have the values: $K_{Z-2} \cong 10^{-2}$, $K_{Z-1} \cong 10^{-6}$, $K_Z \cong 10^{-8}$ $(Z = n + 2)$. It can then be calculated that at pH 5·0, almost 91% of the polymer is present as H_2A^{-Z+2}, 9% as HA^{-Z+1} and negligible amounts as other species. By neglect of all species except the predominant H_2A^{-Z+2} it can be proved[6,11] that at pH 5·0

$$C = \frac{WQ}{V} \cdot \frac{E_{Z-2}}{[Cl^-]^{Z-2}} \tag{1}$$

W is the dry weight of the resin in the column (g); Q is the exchange capacity of the resin (mequiv/g); V is the interstitial volume of the column (ml); E_{Z-2}, the selectivity coefficient, is the classical equilibrium constant of the exchange reaction between the ions $H_2A^{-(Z+2)}$ and Cl^-. For any given ion-exchange column, WQ/V is constant over a range of eluent concentrations. Then equation (1) indicates that each linear phosphate in Fig. 1 should have a slope of $-(Z - 2) = -n$. The actual slopes from $n = 1$ to $n = 3$ are about 10% steeper than the predicted values. The data for these species were taken from the work of Lindenbaum and coworkers.[5,6] Furthermore, E_{Z-2} for these linear phosphates did not vary much over the range of eluent concentrations used nor from one polymer to another.[11] Therefore the graphs for the species larger than the trimer were drawn with slopes of $-1{\cdot}10\,n$ and with $E_{Z-2} = 6 \times 10^{-2}$ in all cases.

Because all ionisation constants of the cyclic phosphates are very large, their elution behaviour is not affected by the pH of the eluent. Their C values vary with the concentration of the eluent[6] approximately according to the equation

$$C = \frac{WQ}{V} \cdot \frac{E_Z}{[Cl^-]^n} \tag{2}$$

For cyclic phosphates, $Z = n$.

The position of any peak in an elution graph with only one concentration of eluent is given by the equation

$$U^* = CV + V \tag{3}$$

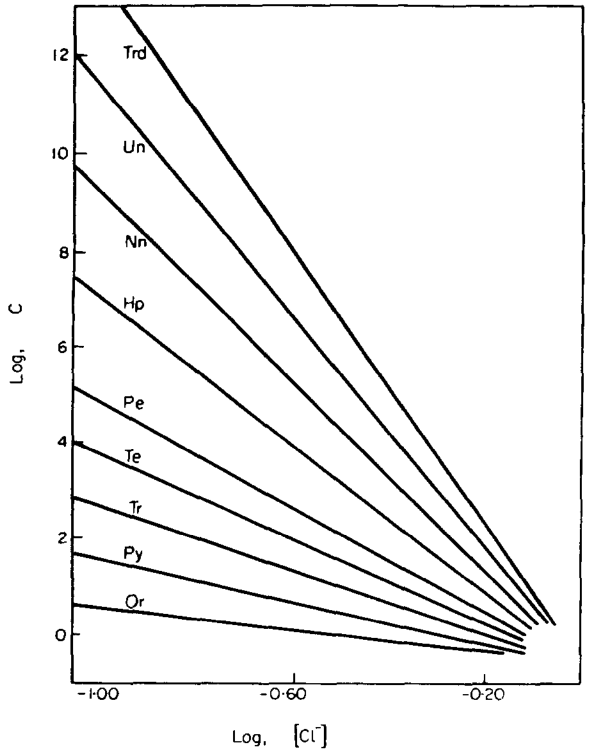

FIG. 1.—Values of log C for various linear phosphates eluted by potassium chloride at pH 5·0:

Trd—tridecaphosphate,
Un—undecaphosphate,
Nn—nonaphosphate,
Hp—heptaphosphate,
Pe—pentaphosphate,
Te—tetraphosphate,
Tr—triphosphate,
Py—pyrophosphate,
Or—orthophosphate.

Log C is plotted against the logarithm of the eluent concentration. The curves for ortho- through triphosphate were determined experimentally,[5,6] while those for tetra- through tridecaphosphate were determined as described in the text.

where U^* is the volume of effluent at the peak. The separation factor for any two adjacent polymers is the ratio of their C values, C_2/C_1. Thus the facility with which any two phosphates may be separated is given by $\Delta \log C = \log C_2 - \log C_1$, *i.e.*, the vertical distance between the appropriate graphs in Fig. 1. Obviously, the separation is very difficult (requiring very long columns) at large concentrations of eluent and much easier at small concentrations. On the other hand, small concentrations of chloride cause large values of C and U^* and hence lengthy elutions. In order to obtain a satisfactory elution, it is necessary to use an eluent less than 0·30M until several of the lower polymers are eluted, then to increase the concentration in several steps (or gradiently) to about 0·40M.

Several preliminary elutions were performed in which unsatisfactory separations were obtained. In each elution, the concentration or the volume of one or more of the eluents was changed to improve the separation according to the principles discussed above. Minor changes in pH of some of the eluents were also made in order to improve the separation of overlapping pairs consisting of one cyclic and one linear polymer. The elution shown in Fig. 2 was finally obtained. This shows a nearly perfect separation of the linear polymers as far as trideca and three cyclic compounds. The peaks of the compounds with four or less phosphorus atoms per molecule were identified by running elutions with known compounds under the same conditions. The identity of the other peaks, especially the "unknown cyclic phosphate" is discussed in the next section.

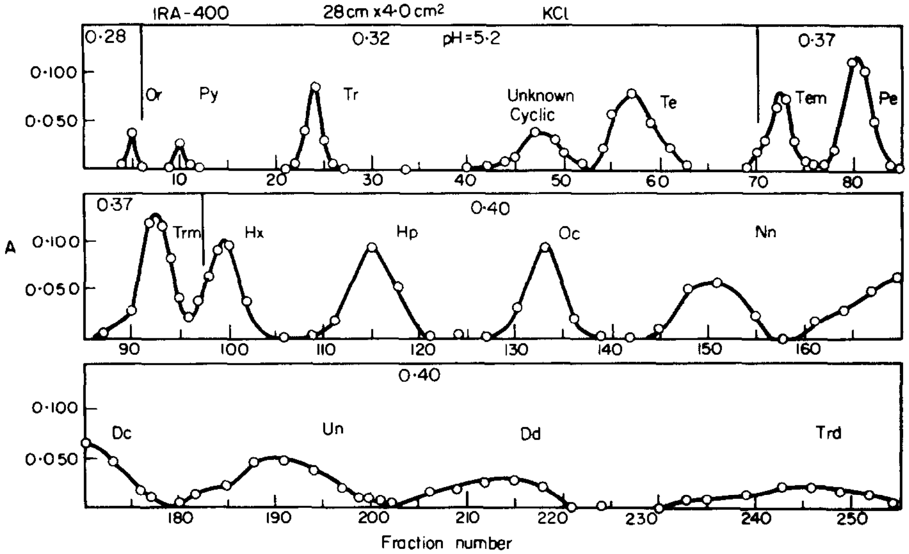

FIG. 2.—Separation of the oligophosphates by anion-exchange chromatography. Absorbance, A, at 400 mμ plotted against fraction number. Each fraction equals 26 ml. A flow rate of 0·42 cm/min was maintained. The sample contained 62 mg of a polyphosphate glass with $\bar{n} \simeq 8$. Trm and Tem denote trimetaphosphate and tetrametaphosphate, respectively.

"Unknown cyclic phosphate"

In several preliminary elutions, a "shoulder" appeared on the left side of the peak of tetraphosphate, indicating that another compound was being eluted at this point. As indicated in Fig. 2, conditions were found that gave a very good separation of these two compounds.

In attempting to identify the compound causing the new peak, the fraction of eluate containing it was collected and freed of the acetate buffer used in the eluent to control the pH. The solution of the unknown compound was then adjusted to a pH of about 4 and subjected to a potentiometric micro titration with sodium hydroxide solution. Under these conditions, linear phosphates above the tetramer give two jumps at pH values about 5 and 8; the base used between the jumps corresponds to the two weakly ionised hydrogens on the end groups. This titration in conjunction with a determination of total phosphorus furnishes the data needed to calculate the degree of polymerisation of the linear compound[1]

$$n = \frac{2G}{\theta} \tag{4}$$

where θ is the number of mequiv of weakly ionised hydrogen and G is the number of mg atoms of phosphorus present as linear polymer. The titration graph of the unknown compound showed only one jump[11] (Table I), indicating that it has no weakly ionised hydrogens and is therefore cyclic.

Further confirmation of the cyclic nature of the unknown compound was obtained by two-dimensional paper chromatography. Because the ratio of potassium chloride to phosphate in the eluate was too great for satisfactory paper chromatography, the major part of the potassium chloride was removed as described subsequently.

Total phosphorus = 14·8 μmole

Under conditions very similar to those recommended by Karl-Kroupa,[4] the unknown cyclic gave a spot in the region where pentametaphosphate would be expected. It was moved very little by the acidic solvent; in the basic solvent, its R_f value was 0·35 compared with 0·39 for tetrametaphosphate. These facts indicate that the unknown compound was probably pentametaphosphate. However, positive identification by chromatography, either on paper or through ion-exchange columns, requires the use of known cyclic polymers above the tetramer, which are not available.

Hydrolysis of cyclic phosphates by base results in large quantities of the corresponding linear phosphates.[13] Several attempts were made to apply this technique to determinations of the unknown cyclic phosphate.

Reasonably large quantities of this compound were isolated by successive elutions and subsequent removal of acetate ion. The samples were hydrolysed with various concentrations of sodium hydroxide solution. The temperature and time for the hydrolysis were also varied. After hydrolysis, cations were removed by the technique for the removal of potassium chloride. The neutralised solution was then subjected to anion-exchange chromatography under conditions similar to those of Fig. 2 in order to identify and determine the products of degradation. Large quantities of tetraphosphate were isolated along with smaller quantities of ortho-, pyro-, tri- and the unknown cyclic phosphate. Although pentaphosphate was not found in the hydrolysate, it is possible that this compound was formed during the hydrolysis, then was itself degraded. The small amounts of unknown cyclic compound present in these samples did not allow a detailed investigation of its properties. Because this sort of hydrolysis data is generally indicative rather than conclusive, this approach was not pursued further.

The compound is certainly cyclic as is evidenced by both its titration behaviour and its behaviour in paper chromatography. It is impossible to state, at the present time, the number of phosphorus atoms per ion. For this reason the compound has been designated "unknown cyclic phosphate".

Identification of peaks in the elution graph

The oligophosphates through the tetramer are easily prepared or obtained commercially. The peaks corresponding to these compounds have been identified by eluting the known compounds. Higher oligomers through the octamer have been identified by paper-chromatographic analysis of their degradation products.[14] In this laboratory, peaks corresponding to linear oligomers were identified by end-group titration, on the micro scale, of the appropriate fraction of eluate.

A titration of the phosphate contained in fractions 78 to 85, obtained from two successive elutions similar to that in Fig. 2, is summarised in Table II. Several of these micro end-group titrations are summarised in Table III. The phosphate had been degraded somewhat between the time of elution and the titration. The procedure for

acetate removal also removes oligomers smaller than the trimer; thus a major source of error in the titration was the presence of trimetaphosphate which resulted from the degradation.[14] This was corrected by precipitation of the linear phosphates by barium ion and the quantitative determination of the soluble trimetaphosphate.[15] The procedure differed in that the volume of the solution before precipitation was adjusted to 40 ml and 10 ml of $1{\cdot}5M$ barium chloride were added. The solution volumes were about one-fifth of those used in the other study.[15]

EXPERIMENTAL

Reagents

Reagent-grade chemicals and de-ionised water were used throughout this work.

Preparation of phosphate glasses: Samples of glassy sodium polyphosphate were prepared by mixing sodium pyrophosphate decahydrate with sodium dihydrogen phosphate monohydrate. The quantities of the two compounds were adjusted so that phosphorus was present in a 15% excess of the desired sodium to phosphorus ratio in order to compensate for the hydrogen that is not expelled by the fusion.[16] The mixture was placed in a platinum boat and inserted in an electric oven where it was kept at 600° for 17 hr. The mixture was removed and cooled rapidly between steel plates. The glassy buttons were broken and dissolved in water. The solution was filtered into a 100-ml volumetric flask, diluted to the mark and stored in a refrigerator at about 5°. A new sample of glass was prepared every month because of the degradation of the polymer.

Eluents: Preparation of the buffered eluents has been described previously.[7]

Procedure for ion-exchange chromatography

Preliminary treatment of resin. The resin was slurried with an excess of water and allowed to settle. The fines were removed by decantation. This process was repeated until the resin settled homogeneously. Supernatant water was poured off and the resin was slurried with $0{\cdot}1M$ hydrochloric acid. The slurry was then poured into a Pyrex tube with a fritted-glass plug at the bottom. A short piece of Tygon tubing was attached to the bottom of this tube and a Hoffman screw clamp was used to regulate the flow of liquid through the tubing. The resin was allowed to settle and was then washed with 1 litre of $0{\cdot}1M$ hydrochloric acid. This was followed by a washing with water until the acid was completely removed from the column.

The resin, in the chloride form, was converted to the hydroxide form by elution with $0{\cdot}1M$ sodium hydroxide solution until the eluate gave a negative test for chloride. Interstitial base was removed by washing with water and the resin was reconverted to the chloride form by the addition of $3M$ hydrochloric acid. After 12 hr the exchanger was washed with 1 more litre of acid.

The resin was then equilibrated with the first eluent. Experience in this field has shown that the first elution with a "prepared resin" is seldom satisfactory. In order to avoid this, a "pseudo elution" was performed, *i.e.*, an elution was carried out with a sample of phosphate glass, but the fractions, instead of being analysed, were discarded. The column was washed with $3M$ hydrochloric acid, allowed to stand overnight, and again eluted with the acid.

The purpose of these washings is to remove impurities which are trapped by the resin during the synthetic process. The forgoing eluents should remove iron$^{\mathrm{III}}$ ion, soaps, any phosphates originally present as well as most other materials.

Chromatography. The eluent was drained to within 1 mm of the resin bed. A 1- to 5-ml sample, was delivered to the top of the bed by means of a pipette. The solution was once again drained to the bed. Collection of fractions was started after this step. The wall of the tube was washed twice with 5-ml portions of the first eluent and drained to the bed between washings. Delivery of eluent was started at this point. The flow rate was maintained at 0·42 cm/min by means of a chromatographic "Minipump"(Milton Roy Company, Chestnut Hill, Pennsylvania, U.S.A.). The pump was connected to Tygon delivery tubes by means of "Vari-grip" fittings made of Teflon (Beckman Instruments, Inc., Mountainside, New Jersey, U.S.A.). The fraction-collecting assembly has been previously[6] described.

Upon completion of an elution, the pump was disconnected and the resin was equilibrated with $3M$ hydrochloric acid delivered with the aid of hydrostatic pressure. The resin was allowed to stand overnight in contact with the acid, then eluted with 1 litre of the $3M$ acid. High polymeric phosphates are removed by this procedure.

End-group titrations

Removal of acetate buffer. Fractions containing the desired phosphates were obtained by elutions similar to that in Fig. 2. The fractions were combined and diluted with water to give a solution

0·25*M* in potassium chloride. This was adjusted to pH 7·0 ± 0·3 by the addition of 0·1*M* sodium hydroxide solution. The entire solution was passed through a column of the resin in the chloride form which measured 6·0 cm × 3·8 cm^2. Potassium chloride (0·25*M*, pH 7·0 ± 0·3) which was free from acetate was passed through the column at a flow rate of 0·6 cm/min until the effluent gave a negative test for acetate. After removal of the acetate, the elution was continued with 0·70*M* potassium chloride which was at pH 7·0 ± 0·3. The desired phosphate was contained in the first one or two 26-ml fractions of this eluent.

These elutions condensed the volume of phosphate-containing solution from about 170 to 26 ml. The amount of potassium chloride present was decreased from about 42 to 18 mmoles.

Test for acetate. A 2·0-ml sample of 1·0 × 10^{-3}*M* hydrochloric acid was added to a 26-ml fraction of effluent and the pH was compared to that of a solution prepared from 26 ml of eluent and the acid. Identity of pH after the removal of carbon dioxide with nitrogen indicated the absence of acetate.

Titration procedure. After removal of the acetate buffer, the phosphate-containing samples were titrated with the aid of a Gilmont micro burette (Manostat Corporation, New York, U.S.A.) The sample was contained in a polyethylene bottle. A glass electrode and a fibre-type calomel electrode were inserted through a hole in the shoulder of the vessel. They were connected to a Beckman pH meter, model G. A thin Pyrex tube which was connected to a tank of nitrogen was introduced, through the plastic wall, into the solution. The microburette was similarly introduced into the liquid. The pH of the solution was adjusted to less than 4·0 by addition of 1*M* hydrochloric acid. The bottle was stoppered with a one-hole rubber stopper through which a short piece of glass tubing was inserted for the escape of gas. Nitrogen was bubbled through the solution for 15 min, expelling any dissolved carbon dioxide. The bubbling was maintained throughout the titration to afford mixing.

Sodium hydroxide titrant. The base was prepared from an aliquot of 18*M* reagent-grade sodium hydroxide and was diluted with freshly prepared de-ionised water. The solution was stored in a polyethylene bottle and protected against carbon dioxide by Ascarite. The solution was standardised against potassium hydrogen phthalate and potassium dihydrogen phosphate.

Determination of total phosphate in a fraction. Standard solutions of the phosphate were used to prepare a "Beer's-Law curve." Total phosphorus was determined after titration and separation by the use of this spectrophotometric technique.[5,6]

Paper chromatography

Elimination of potassium chloride eluent. A 26-ml sample of 0·70*M* potassium chloride, which contained a particular phosphate, was prepared by the procedure for the removal of acetate. A column of Dowex 50-X4, 200–400 mesh, which measured 6 cm × 3·8 cm^2 was converted to the hydrogen form with 3*M* hydrochloric acid. It was washed with water to remove the interstitial acid. The solution was passed through the column, the wall was washed with cold water and additional water was used as an eluent. The first 50-ml portion contained the desired oligophosphoric acid, some hydrochloric acid and no cations other than hydrogen ion. This procedure was carried out in the refrigerator to minimise degradation of the polymer.

The 50 ml of effluent were evaporated to about 2 ml *in vacuo*. A trap with a Dry Ice-acetone mixture was placed in the line. The rapid evaporation maintained the temperature of the solution at 5 to 10° and prevented serious degradation. The small aqueous residue in the flask was treated with a slight excess of 0·1*M* sodium hydroxide solution so that the resultant solution was basic.

The procedure was performed as soon as possible after the isolation of the phosphate by anion-exchange chromatography. As a result, only small amounts of its degradation products along with sodium chloride and hydroxide were also present. The quantities of these contaminants are probably not great enough to interfere seriously in the later experiments.

Paper-chromatographic procedure. This technique has been previously described.[2,4] Twenty μl of the phosphate solution, from which the potassium chloride had been removed, were applied to the paper in increments of 3 μl or less. Samples of tetraphosphate and tetrametaphosphate were similarly applied to the paper at some distance from the origin to serve as standards.

Acknowledgements—The authors are indebted to the Atomic Energy Commission for financial support of this investigation and to the Rohm and Haas Corporation for a donation of a quantity of ion-exchange resin. The authors wish to acknowledge some preliminary work by Helmut Lutsep and Nels Ralph Nelson.

Zusammenfassung—Mischungen aus Orthophosphat, seinen linearen Polymeren bis einschließlich Tridekaphosphat und drei cyclischen Polymeren wurden durch Ionenaustauschchromatographie getrennt. Eines der cyclischen Polymeren (das sich in Polyphosphatgläsern mit $\bar{n} \simeq 10$ findet), ist wahrscheinlich Pentametaphosphat. Seine cyclische

Natur wurde durch Endgruppentitrationen und durch Papierchromatographie bewiesen, aber Versuche zur Bestimmung der Anzahl der Phosphoratome im Ring schlugen fehl, da nur eine sehr geringe Menge der Verbindung zugänglich war. Es wird über Ergebnisse berichtet, die die übliche Annahme stützen, daß die linearen Phosphate oberhalb dem Tetrameren in der Reihenfolge ihres Polymerisationsgrades eluiert werden.

DETERMINATION OF TRIMETAPHOSPHATE ION IN THE PRESENCE OF LINEAR PHOSPHATES

HERBERT L. ROTHBART and WM. RIEMAN III®
Ralph G. Wright Chemical Laboratory, Rutgers—The State University,
New Brunswick, N.J., U.S.A.

(*Received* 15 *August* 1963. *Accepted* 16 *September* 1963)

Summary—A method for the determination of trimetaphosphate in the presence of linear oligophosphates above the trimer has been developed. It has been demonstrated that ortho-, pyro- and triphosphate are incompletely precipitated by barium ion, while higher oligomeric linear phosphates are precipitated quantitatively. The latter species have been isolated from phosphate mixtures by anion-exchange chromatography, mixed with known quantities of cyclic phosphate, and precipitated with barium ion. A mean error of +0·8 and a standard deviation of ±3 μmole of phosphorus as the cyclic ion have been found for mixtures containing from 0 to 203 μmole of phosphorus as trimetaphosphate in the presence of 0 to 81 μmole of phosphorus as the linear polymers.

A NUMBER of cases has been found in which there was a need for a rapid method for the determination of trimetaphosphate in the presence of linear phosphates.[1,2]

It is well known that the barium salts of linear phosphates are sparingly soluble while those of the cyclics are much more soluble. There was doubt, however, that a quantitative separation of these species was possible by precipitation. Jones[3] attempted to precipitate the degradation products of trimetaphosphate at pH 9 using barium chloride, while Healey and Kilpatrick[4] reported that the precipitation of orthophosphate was incomplete under these conditions. The determination of trimetaphosphate, by this technique, in the presence of ortho-, pyro- and triphosphate has been shown to be erratic.[5]

The following study was made to find out whether trimetaphosphate can be determined in phosphate mixtures by precipitation of the linear polymers by barium ion.

RESULTS AND DISCUSSION

All attempts to precipitate quantitatively the phosphates from solutions of phosphate glasses failed when the average degree of polymerisation ($\bar{n}$) was about 4. In these cases, the method described in the next section left 10 to 15 μmole of phosphorus in solution. Varying the pH from 5 to 9, precipitating from the solutions at 5° and "gathering" with sulphate did not improve the results appreciably.

On the other hand, the precipitation was nearly quantitative with samples of phosphate glasses with $\bar{n} \simeq 6$. The slightly low results were probably because of the presence of small amounts of cyclic compounds in these glasses.[6] It was, therefore, postulated that the method of precipitation is not quantitative with linear phosphates of $\bar{n} \leq 3$. In order to test this hypothesis, two samples of sodium triphosphate were treated with barium chloride, one in the presence and one in the absence of a phosphate glass of $\bar{n} \simeq 8$. In both cases, the same amount of phosphorus remained in solution.

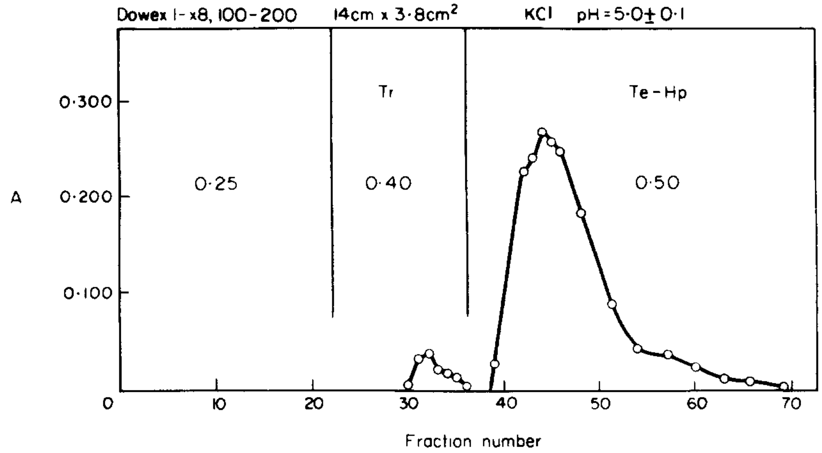

FIG. 1.—Elution of a phosphate glass by potassium chloride eluents at pH 5·0:
Tr—triphosphate,
Te—tetraphosphate,
Hp—heptaphosphate.

Absorbance, A, at 400 mμ plotted versus fraction number. The total number of μ mole of phosphorus in a fraction is equal to 39·0 A. Each fraction equals 10·8 ml. The concentrations of the potassium chloride eluents are indicated on the graph. Fourteen mg of a phosphate glass, with an $\bar{n}$ of about 4, were utilised.

TABLE I.—SUMMARY OF PRECIPITATIONS OF LINEAR PHOSPHATES BY BARIUM ION

Sample no.	P taken, *μmole*		P found, *μmole*		Error, *μmole*	
	Linear	Cyclic	Linear	Cyclic	Linear	Cyclic
1	65	0	61	4	−4	+4
2	66	26	61	31	−5	+5
3	68	71	67	72	−1	+1
4[a]	70	117	54	133	−16	+16
5	73	180	70	183	−3	+3
6	72	0	72	0	0	0
7	73	34	72	35	−1	+1
8	75	68	74	69	−1	+1
9	78	136	84	130	+6	−6
10	81	203	85	200	+4	−3
11	0	0	0	0	0	0
12	0·5	13	0	14	−1	+1
13	3·3	75	4·8	73	+2	−2
14	4·9	112	6·0	111	+1	−1
15	8·2	188	0	196	−8	+8
16	29	0	28	0	−1	0
17	29	0	30	0	+1	0
18	60	0	60	1	0	+1
			Mean		−0·7	+0·8
			Standard deviation		±3	±3

[a] Omitted in the calculation of the mean and the standard deviation.

As a further test of this hypothesis, linear phosphates below the tetramer were removed from phosphate glasses by anion-exchange chromatography. A typical elution is shown in Fig. 1. The fraction containing the polymers from the tetramer to about the heptamer was isolated and immediately used as a source of linear polymers. A known amount of trimetaphosphate was added to this fraction or an aliquot thereof. The resultant mixture was subjected to the precipitation procedure described below.

The results are given in Table I. The second column is the quantity of phosphorus in the glass plus the small amount of non-cyclic phosphorus present as an impurity in the recrystallised sodium trimetaphosphate (see next section). The third column is the corrected quantity of trimetaphosphate present. The fifth column is the quantity of phosphorus found in the filtrate after the precipitation. The fourth column is the total quantity of phosphorus less that in the fifth column. Except for one sample, the results are satisfactory.

EXPERIMENTAL

Reagents

De-ionised water and reagent-grade chemicals, except for sodium trimetaphosphate, were used. Commercial sodium trimetaphosphate (Victor Chemical Works) was recrystallised[7] and analysed by the method of Peters.[8] The analysis indicated that 96·0, 1·2, 1·4 and 1·6% of the total phosphorus were present as trimeta-, ortho-, pyro- and triphosphate, respectively.

Preparation of phosphate glasses. This has been described in a previous paper.[1]

Apparatus

All pH measurements were made with a Beckman pH meter, model G, to which a glass electrode and a fibre-type calomel electrode were attached.

Precipitation procedure

Low linear polymers were removed from solutions of fresh phosphate glasses by anion-exchange chromatography. The phosphate glasses had degrees of polymerisation of about 4. The fraction containing the linear phosphates from the tetramer to about the heptamer was isolated and diluted with water so that the resulting concentration of potassium chloride was 0·4*M*. Two-hundred ml of the solution were delivered into a 250-ml volumetric flask. A known quantity of a solution of sodium trimetaphosphate was added. The solution was diluted to the mark and a 25-ml aliquot was taken. Total phosphorus in the solution was determined from this aliquot. A 200-ml aliquot was removed, its pH was adjusted to 7·0 ± 0·1 with 0·1*M* sodium hydroxide solution, and the solution was transferred to another 250-ml volumetric flask. The phosphates were precipitated by a slow addition of 40 ml of 1·5*M* barium chloride which was at a pH of 7·0 ± 0·1. The solution was diluted to the mark and allowed to digest for 15 min. It was filtered through a fritted-glass funnel of fine porosity, and a 25-ml aliquot was taken for the determination of unprecipitated (cyclic) phosphate.

Phosphate determination

Total and unprecipitated phosphorus were determined by a spectrophotometric method.[7] Ten ml of 0·4*M* potassium chloride were added to the unprecipitated fractions before they were heated. The inside surface of the vessels, which are heated during the colour-development, should be extremely clean and smooth, otherwise a precipitate is noted during this step.

Acknowledgment—The authors thank the Atomic Energy Commission for the financial support of this work.

Zusammenfassung—Eine Methode zur Bestimmung von Trimetaphosphat in Gegenwart linearer Oligophosphate oberhalb des Trimeren wurde entwickelt. Es wird gezeigt, daß Ortho-, Pyro- und Triphosphat durch Barium unvollständig gelfällt werden, wogegen höhere oligomere lineare Phosphate quantitativ gelfällt werden. Diese wurden aus Phosphatmischungen durch Anionenaustauschchromatographie isoliert, mit bekannten Mengen cyclischem Phosphate gemischt und mit

Barium gefällt. Ein mittlerer Fehler von +0,8 und eine Standardabweichung von ±3 Mikromol Phosphor als cyclisches Ion wurden für Mischungen mit 0 bis 203 Mikromol Phosphor als Trimetaphosphat neben 0 bis 81 Mikromol Phosphor als lineare Polymere gefunden.

TITRIMETRIC DETERMINATION OF QUINOL

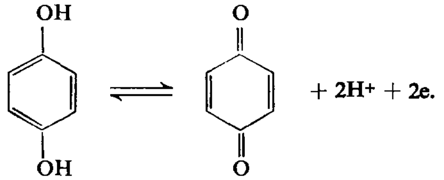
U. A. TH. BRINKMAN and H. A. M. SNELDERS
Chemical Laboratory, Free University, Amsterdam, The Netherlands

(*Received* 13 *September* 1963. *Accepted* 18 *September* 1963)

Summary—A critical review is presented of the literature on the titrimetric determination of quinol. For the standardisation of pure quinol solutions the cerimetric titration procedure can be recommended, but in the presence of various organic contaminants vanadate, hexacyanoferrate(III) plus zinc and dichromate are the best titrants.

INTRODUCTION

IN the literature many publications have appeared concerning the titrimetric determination of quinol (hydroquinone). The principle of these methods lies in the possibility to oxidise quinol quantitatively to quinone according to the equation:



The reason for the many different oxidimetric determinations is undoubtedly the fact that many of the impurities which can be present in quinol, *e.g.*, phenolic compounds, are oxidised partly or quantitatively by most of the common oxidimetric titrants. Accurate results for the analysis of low purity mixtures of quinol are therefore *a priori* impossible. It must be stated, moreover, that many of the titration procedures recorded in the literature are not very easy to carry out.

The use of quinol as a reductimetric titrant has increased of late, especially since the work of Zýka and coworkers[1,2]. Advantages connected with the use of quinol are that it can easily be obtained analytically pure, it is relatively inexpensive and, especially, its solutions in a weakly acidic medium (*ca.* 0·01 *N* sulphuric acid) show a constant titre for periods of up to 8 weeks; in contrast with the solutions of nearly all other reductimetric titrants, solutions of quinol are hardly subject to air oxidation.[3]

In view of these facts it seems useful to present a critical literature survey of the titrimetric determination of quinol. The survey has been arranged according to the various titrants which have been used.

Iodine[4,5]

The oldest known titrimetric determination of quinol originates from Valeur[6] and has been adopted in a sometimes more or less altered form by many authors;[4,5,7–9] independently, Gardner and Hodgson[10] reported an analogous method.

The great difficulty of the iodometric determination lies in correctly adjusting the pH of the solution to be titrated. In order to obtain quantitative reaction the pH must be at least 6;[4] at pH 8–9 (bicarbonate), however, one must take into account the air oxidation of quinol, the velocity of this oxidation being proportional to the square of the hydroxyl ion concentration in the solution.[11,12] Moreover, quinone may undergo disproportionation reactions in an alkaline medium, giving rise to the formation of coloured products and therefore a less sharp end-point; an extra consumption of iodine may also occur.[12,13]

The procedure which involves back-titration of excess iodine has the disadvantage of possible oxidation of thiosulphate to sulphate because of the excess iodine present in the alkaline solution:

$$I_2 + 2OH^- \rightleftharpoons OI^- + I^- + H_2O.$$

It is therefore recommended to use only a small excess of iodine and to use arsenite instead of the more usual thiosulphate.

When carrying out a direct titration it is not possible to use carbon tetrachloride or chloroform as indicator, because the quinone formed during the titration dissolves in the organic layer and forms a compound with iodine. According to Kolthoff[4] a direct titration is possible using a potentiometric end-point.

A serious drawback of the iodometric determination of quinol lies in the fact that many organic compounds are partly or wholly oxidised under the same conditions.

Potassium dichromate

The use of potassium dichromate for quinol determination has been recommended by Kolthoff,[4] who employed a redox indicator (diphenylamine) as well as potentiometric end-point detection. According to Kolthoff it is not possible to carry out the titration at room temperature. The solution must be warmed to 40–60° and even then the titration must be carried out slowly towards the end or over-titration will occur. This statement of Kolthoff has been corroborated by other investigators,[14] but it does not correspond with the conclusions of Casolari,[9] who carried out the titration at room temperature long before Kolthoff. In this connection it is remarkable that the Czech investigators,[3] who use quinol as a reductimetric titrant, standardise it according to Kolthoff, although it must be concluded from the procedures given that they work at room temperature! From experiments carried out by Brinkman and Snelders,[15] it follows that warming the solution has not much influence on the velocity with which the titration can be carried out and that, moreover, the results are practically the same.

According to Kolthoff the quinone formed during the titration poisons the platinum electrode in the potentiometric determination. In more recent investigations on cerimetric titrations in non-aqueous solvents (see below) Prabhakar Rao and Murthy[16] have had somewhat analogous experiences, but on the other hand, Furman and Wallace[8] contradict Kolthoff's statements for cerimetric titrations. In our potentiometric determinations[15] no indication of quinone poisoning was ever found. Instead of diphenylamine, *N*-phenylanthranilic acid has been recommended as an indicator for the direct titration with dichromate,[17] as well as the chemiluminescence indicator siloxene.[18]

Although the titration mentioned above is time-consuming and tedious (50°, slow titration), the use of dichromate is advantageous because it is an easily obtainable high-quality primary standard. A recent investigator[14] has, therefore, proposed an indirect titration in which an excess of ammonium iron^{III} sulphate is added to the solution in a weakly acidic medium; after reduction of iron^{III} to iron^{II} the equivalent amount of iron^{II} formed is titrated with dichromate using barium diphenylamines sulphonate as indicator. In this titration, of course, iron^{III} is the real oxidant, but for the sake of simplicity the method has been included under the heading of potassium dichromate.

As regards the dichromate titrations it can be stated that phenol and cresols do not interfere, whereas they do interfere in the iodometric titrations. Compounds like oxalic acid, citric acid, lactic acid and glycerol, which are normally not attacked by dichromate are, however, partly oxidised in the presence of quinol as inductor.[17]

Bromine water

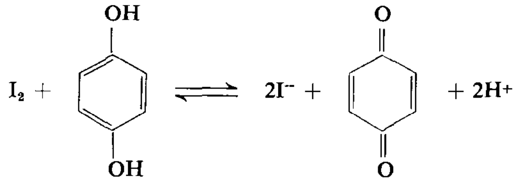
Rosenthaler[19,20] has recommended the use of an aqueous bromine solution for quinol titration; the hydrobromic acid liberated in the reaction can be titrated with a base using methyl red as indicator. The oxidation of quinol occurs immediately: the excess bromine can be blown out of the solution after some minutes, then the hydrobromic acid can be titrated. In the presence of much quinol, which consequently means the presence of much quinone in the neighbourhood of the end-point, the colour change in the acid-base titration is not very sharp.

Freshly prepared solutions of bromine water do not contain any free hydrobromic acid; nevertheless, it is necessary to correct the values found by the amount of alkali consumed by an equivalent amount of bromine water freed from bromine by blowing air through it. This corresponds with *ca.* 0·2 ml of 0·1M hydroxyl ion/100 ml of bromine water. For titration procedures in non-aqueous solvents, see reference 21.

Potassium bromate

Bromination with bromate-bromide mixtures in an acid medium yields titration procedures for many derivatives of benzene. Depending on the *o*- *p*- or *m*-directing influence of the substituents, in many instances di- or tribromo-substitution products are formed. In some instances, however, the reaction proceeds in a different way. With dihydroxy- and diaminobenzenes the *m*-compounds are brominated in the normal way yielding a tribromo product, but the *o*- and *p*-isomers do not take up any bromine. The two strongly *o*-*p*-directing groups present in the quinol molecule do not allow *m*-substitution.

Using the procedure given by Francis and Hill,[22] in which an excess of bromate-bromide is added to the acidified solution, after which potassium iodide is added, whereupon the iodine liberated is titrated with thiosulphate, no difficulties arise because of the temporary oxidation of quinol to quinone. Although this oxidation occurs initially, after the addition of potassium iodide the reaction:



proceeds quantitatively to the left.

Kolthoff,[4] who titrated quinol with bromate-bromide using a direct potentiometric procedure so that quinol was really oxidised to quinone, found in contradiction with the authors mentioned above, that at the equivalence-point free bromine reacts with the quinone present to form an addition or substitution product, so that sharp end-points were not possible.

Brinkman and Snelders[15] have found that in a titration of quinol with bromate-bromide at room temperature some bromination does indeed occur. This not only means a direct titration is difficult to carry out, but also that a titration of other benzene derivatives in the presence of quinol is subject to significant errors. When the titration is carried out, however, at about 0° there is very little bromination; although the results are not very accurate, they give a good indication of the ratio quinol/impurity, especially when this ratio is not too extreme.

Cerium^{IV} sulphate

Extensive investigations concerning the cerimetric titration of quinol have been carried out by Furman and Wallace.[8] According to these authors, the rapid and direct cerimetric titration that can be carried out in about 1*N* sulphuric acid is in many respects superior to the titrations with iodine or dichromate. In potentiometric determinations there is not the slightest indication of quinone poisoning of the platinum electrodes. Methyl red is not a very suitable indicator, but the use of ferroïn, diphenylamine or diphenylamine sulphonic acid is completely satisfactory. Recently, the iron^{II}-2,2′-dipyridyl complex[23] has been used as an indicator in a cerimetric titration. Other indicators mentioned in the literature are *e.g.*, brucine,[24,25] siloxene,[18] copper phthalocyanine tetrasulphonic acid[26] and such triphenylmethane dyes as erioglaucine A, eriogreen B and xylene cyanol FF.[27] Resorcinol and catechol are oxidised by cerium^{IV} farther than the quinone stage, although oxalic acid is not oxidised at all. Attention is called to the fact that both Gopala Rao and coworkers[28] and Brinkman and Snelders[15] have found results 0·3–0·5% too low in cerimetric determinations of pure quinol solutions.

Cerimetric titrations have also been carried out in non-aqueous solvents,[16] using ammonium nitratocerate(IV) as oxidant and acetonitrile as solvent. To obtain a reproducible and fast adjustment of the potential it is necessary to add glacial acetic acid to the solvent. The potentiometric determinations[8,29] can only be carried out when cerium^{IV} is titrated with quinol. In the reverse case quinol exhibits a curious behaviour in contact with the platinum indicator electrode; the results are much too low and, moreover, not reproducible. There is no satisfactory explanation of this fact.

The titrations in non-aqueous solvents can also be carried out with visual end-point determination, using ferroïn, diphenylamine, Janus Green or methyl red as indicator. Ferroïn and diphenylamine are reversible redox indicators under the conditions; with diphenylamine and methyl red the results are about 0·7% high.

An indirect titration of quinol with cerium^{IV} sulphate has been described by Singh and Singh,[30,31] who back-titrate the excess cerium^{IV} sulphate with the iron^{II}-EDTA complex using ferroïn as indicator.

Potassium permanganate

As far as has been investigated, potassium permanganate is the only oxidant that oxidises quinol further than quinone, the end-products in this case being carbon dioxide and water. Under the most favourable circumstances, *viz.* an alkaline medium and excess of permanganate, the time-consuming oxidation takes place almost quantitatively,[32] but many phenolic and other organic compounds are over 90%

oxidised under the same conditions. This very unselective titration can therefore hardly be recommended.

Hypobromite

Generally speaking, titrations with hypobromite are not very suitable because this titrant is not very stable for any length of time; moreover, the results are nearly always high because of the conversion of hypobromite into bromate. A procedure recommended by Kolthoff and Stenger[33] consists in the use of a calcium hypochlorite solution in a weakly alkaline medium, which is added to the solution to be titrated after the addition of potassium bromide. The oxidant hypobromite is generated *in situ*. In most instances, however, not only oxidation but also bromination occurs, *e.g.*, with phenol, oxine and aniline. This hypobromite titration is therefore only suitable in isolated cases, one of these being with quinol.[34] Under favourable conditions (passing of carbon dioxide) the results are not more than 0·2% high. Without carbon dioxide the error increases to about 1%. Most probably this oxidation is brought about by a partial bromination of quinone. It has been proved that the error is not caused by air oxidation.

Sodium metavanadate

Cerium^{IV} sulphate oxidises phenol, cresols and analogous compounds to coloured substances insoluble in concentrated sulphuric acid. Therefore Gopala Rao and coworkers[28] have investigated the use of vanadate as an oxidant for quinol. It appears that vanadate does not oxidise the above-mentioned phenols nor catechol, although it does attack resorcinol.

According to Gopala Rao the quinol concentration of the solution to be titrated must be below 0·01 M (0·02N) and the total acid concentration must be at least 1·0N in order to ensure a sharp end-point. A large quantity of oxalic acid is necessary as a catalyst. The results of the titration are 0·2–0·3% low. Diphenylbenzidine and *N*-phenylanthranilic acid are used as indicators.[28,35]

Hexacyanoferrate(III)

In the literature a potentiometric titration of hexacyanoferrate(III) with quinol in 50% sulphuric acid has been described, which can also be carried out with visual end-point detection.[36] Brinkman and Snelders[15] found that this titration can be carried out in the reverse direction, giving good results for quinol itself and for quinol in mixtures with oxalic acid. In the presence of, for example, phenol, catechol or resorcinol, the colour of the acid solution darkens considerably, however, thereby making titration impossible. Good results are obtained according to these authors,[15,37] when a large excess of hexacyanoferrate(III) is added to an acid quinol solution, whereupon the hexacyanoferrate(II) formed is titrated with a standard solution of zinc using diphenylamine as indicator. The titration can also be carried out potentiometrically, giving results that are about 0·5% high, but it can be used in the presence of oxalic acid, phenol, citric acid and tartaric acid; resorcinol and catechol must be absent, however.

Miscellaneous

In the literature titration procedures are also recorded for quinol with chloramine-B in a weakly acid medium,[38–40] chloramine-T,[41] *N*-bromosuccinimide,[42] manganese^{III}

pyrophosphate,[43] potassium copper^{III} periodate,[44] iron^{III} chloride,[45] potassium periodate[46-48] and iodine monochloride.[49,50] Beranová and Hudeček[51] describe a titration of quinol with barytes using a differential potentiometric titration technique. Tomiček and coworkers[21,52] have carried out titrations with various oxidants, *e.g.*, bromine, chromic acid, sodium permanganate and lead tetra-acetate in glacial acetic acid. They all give good results and the titration with lead tetra-acetate is even used for the standardisation of this substance.

Zusammenfassung—Es wird einen kritischen Überblick gegeben von den in der Literatur beschriebenen Methoden für Quinol Bestimmung. Für die Bestimmung von reinen Quinol Lösungen wird die cerimetrische Titration empfohlen, aber bei Anwesenheit von organischen Verunreinigungen sind Vanadat, Ferrizyanid mit Zink und Dichromat am besten geeignet.

Résumé—On présente un résumé critique de la littérature concernant les méthodes titrimétriques pour détermination d'hydroquinone. Pour le dosage des solutions pures d'hydroquinone, le titrage cérimétrique est recommandé; en cas de présence d'impuretés organiques au contraire, vanadate, ferricyanure avec zinc et dichromate sont les meilleurs titrants.

SHORT COMMUNICATIONS

The determination of thiourea using chloramine-T

(*Received* 18 *August* 1963. *Accepted* 14 *October* 1963)

METHODS are available for the determination of thiourea by oxidation with hypoiodite[1] and hypobromite[2] reagents. Eight equivalents of the oxidant are utilised for each mole of thiourea. In the present study, chloramine-T and sodium hypochlorite were examined as oxidants and a procedure evolved for the determination of thiourea using chloramine-T, which takes less time than the other hypohalite methods. Earlier work on the oxidation of thiourea with chloramine-T relates to acid media, in which the authors[3-5] have claimed quantitative results. However, our results indicate that the oxidation in acid medium is unreliable and unsuited for quantitative work.

EXPERIMENTAL

Reagents

Thiourea solutions of desired molarity (*M*/50–*M*/80) were prepared from dried, recrystallised solid and the strengths were checked by the hypoiodite method.

Chloramine-T was purified, dissolved in water (approx. 0·1*N* solution) and the solution was standardised by the method of Bishop and Jennings.[6]

Sodium hypochlorite solution (approx. 0·1*N*) was prepared from chlorine and sodium hydroxide,[7] and its strength was determined iodometrically.

The other chemicals used were of standard purity.

The extent of reaction between thiourea and chloramine-T, thiourea and sodium hypochlorite, ammonia and chloramine-T, and urea and chloramine-T was studied under different conditions and order of addition of reagents. The mixtures of known amounts of reagents were set aside for the

requisite periods of time, potassium iodide was added (and only then was added sufficient excess of acid if the main reaction was being carried out in neutral or alkaline medium) and the liberated iodine was determined with thiosulphate. The difference between the amount of chloramine-T or hypochlorite taken and the remaining excess, found iodometrically, gave the amount of oxidant used up in the main reaction.

In Table I are recorded typical results obtained for the thiourea-chloramine-T (T-CAT) system. The results indicate that exactly 8 equivalents of oxidant are consumed by 1 mole of thiourea when neutral or alkaline conditions prevail during the addition of chloramine-T to thiourea. The reaction is completed, in contrast with the other hypohalite methods, almost immediately after the reagents are mixed. The presence of free acid during the reaction, however, causes erratic results, the number of equivalents of chloramine-T used up being less than 8 when it is taken in small excess and more than 8 when it is taken in considerable excess over the thiourea. The titre of chloramine-T becomes less with time in acid medium, and corrections were made accordingly, using blank experiments run under identical conditions. Later addition of excess alkali to a T-HCl-CAT system does not yield good results. Invariably, a slight amount of the oxidant seems to be lost by side reactions in acid medium.

The oxidation of thiourea by chloramine-T in neutral or alkaline medium may proceed as follows:

$$NH_2CSNH_2 + 6H_2O \rightarrow 2NH_4^+ + CO_2 + SO_4^{2-} + 8H^+ + 8e \qquad (1)$$

(NH_3, HCO_3, CO_3^{2-} may also be present depending on the pH of solution); *or*

$$NH_2CSNH_2 + 10OH^- \rightarrow NH_2CONH_2 + SO_4^{2-} + 5H_2O + 8e \qquad (2)$$

The oxidation of ammonium chloride and of urea with chloramine-T was studied in order to ascertain the particular course of oxidation of thiourea. The results are recorded in Table II. This indicates that oxidation of NH_4^+ occurs rapidly in neutral medium and sluggishly in acid medium. At pH 10 and above, the ammonia (and NH_4^+) is not oxidised by chloramine-T. Urea is not oxidised in either alkaline or neutral medium; the NH_4^+ produced on very slow hydrolysis of urea in acid medium during 30 min consumes a low amount of chloramine-T. However, it was observed that hydrolysis of urea under similar conditions, for a keeping period of 10 min or less, was negligible, and no loss in the titre of chloramine-T occurred. The results indicate that thiourea is oxidised by chloramine-T according to the reaction (2), and that for the quantitative evaluation of thiourea in the presence of ammonium salts it is imperative that the oxidation be carried out in alkaline medium.

* NaOH added = 30 ml of 1*M* soln.
† HCl added = 10 ml of 1*M* soln.

Attempts to utilise the reaction between ammonium ion and chorlamine-T for the determination of ammonium did not yield promising results.

The oxidation of thiourea by hypochlorite was found to be very rapid and to proceed even beyond the stage of 8 equivalents in neutral and alkaline media. The presence of excess of potassium bromide slowed down the reaction appreciably, as expected, since the hypochlorite is converted to the hypobromite, but the reaction was of little analytical interest.

Procedure for determination of thiourea

To a solution containing 0·1–0·3 mmole of thiourea, add sufficient alkali to raise the pH to about 10. Add a known excess (*a* ml) of chloramine-T solution. After about 2 min, add 15 ml of 20% potassium iodide solution, acidify the solution with dilute hydrochloric acid, and titrate the liberated iodine with zN thiosulphate (V ml.) Carry out a blank with *a* ml of chloramine-T ($\equiv V_1$ ml of thiosulphate). The amount of thiourea in the sample is equal to $(V_1 - V).z/8$ mmole. Urea does not interfere, and large amounts of ammonium salts are tolerated.

Acknowledgment—The authors wish to express their grateful thanks to Prof. M. V. C. Sastri for his interest in the work.

Summary—Chloramine-T oxidises thiourea quantitatively to urea and sulphate ion in neutral and alkaline media. The oxidation is completed within 2 min, even with a very small excess of the oxidant. Urea and ammonium ion do not interfere if the oxidation is carried out in an alkaline medium.

Zusammenfassung—Chloramin-T oxydiert Thioharnstoff in neutralen und alkalischen Medien quantitative zu Harnstoff und Sulfat. Die Oxydation ist in 2 Minuten beendet, selbst bei sehr geringem Überschuß von Oxydationsmittel. Harnstoff und Ammoniumionen stören nicht, wenn die Oxydation in alkalischem Medium ausgeführt wird.

Titration of anthranilic acid with electrolytically generated bromine: Application to coulometric determination of copper

(*Received* 23 *September* 1963. *Accepted* 23 *October* 1963)

Although the coulometric titration of inorganic substances has been rather extensively investigated in recent years,[1,2] the application of coulometric titrimetry to the determination of organic substances has been somewhat limited. A discussion of the application of coulometric titrimetry to organic substances has been given by Lingane,[3] DeFord[4] and Bard.[5] The use of electrolytically generated bromine to oxidise thiodiglycol to thiodiglycol sulphoxide[6] and isonicotinic acid hydrazide to isonicotinic acid[7] are illustrations of oxididative reactions involving this reagent. Substitution bromination reactions for olefins[8] and 8-quinolinol[9] have been investigated. Aniline has been brominated by a back-titration technique in which the excess electrolytically generated bromine was titrated with electrolytically generated copper^I.[10] A study of the feasibility of titrating fifteen organic compounds of possible analytical significance by electrolytically generated bromine was undertaken

Attempts to utilise the reaction between ammonium ion and chorlamine-T for the determination of ammonium did not yield promising results.

The oxidation of thiourea by hypochlorite was found to be very rapid and to proceed even beyond the stage of 8 equivalents in neutral and alkaline media. The presence of excess of potassium bromide slowed down the reaction appreciably, as expected, since the hypochlorite is converted to the hypobromite, but the reaction was of little analytical interest.

Procedure for determination of thiourea

To a solution containing 0·1–0·3 mmole of thiourea, add sufficient alkali to raise the pH to about 10. Add a known excess (*a* ml) of chloramine-T solution. After about 2 min, add 15 ml of 20% potassium iodide solution, acidify the solution with dilute hydrochloric acid, and titrate the liberated iodine with zN thiosulphate (V ml.) Carry out a blank with *a* ml of chloramine-T ($\equiv V_1$ ml of thiosulphate). The amount of thiourea in the sample is equal to $(V_1 - V).z/8$ mmole. Urea does not interfere, and large amounts of ammonium salts are tolerated.

Acknowledgment—The authors wish to express their grateful thanks to Prof. M. V. C. Sastri for his interest in the work.

Summary—Chloramine-T oxidises thiourea quantitatively to urea and sulphate ion in neutral and alkaline media. The oxidation is completed within 2 min, even with a very small excess of the oxidant. Urea and ammonium ion do not interfere if the oxidation is carried out in an alkaline medium.

Zusammenfassung—Chloramin-T oxydiert Thioharnstoff in neutralen und alkalischen Medien quantitative zu Harnstoff und Sulfat. Die Oxydation ist in 2 Minuten beendet, selbst bei sehr geringem Überschuß von Oxydationsmittel. Harnstoff und Ammoniumionen stören nicht, wenn die Oxydation in alkalischem Medium ausgeführt wird.

Titration of anthranilic acid with electrolytically generated bromine: Application to coulometric determination of copper

(*Received* 23 *September* 1963. *Accepted* 23 *October* 1963)

Although the coulometric titration of inorganic substances has been rather extensively investigated in recent years,[1,2] the application of coulometric titrimetry to the determination of organic substances has been somewhat limited. A discussion of the application of coulometric titrimetry to organic substances has been given by Lingane,[3] DeFord[4] and Bard.[5] The use of electrolytically generated bromine to oxidise thiodiglycol to thiodiglycol sulphoxide[6] and isonicotinic acid hydrazide to isonicotinic acid[7] are illustrations of oxididative reactions involving this reagent. Substitution bromination reactions for olefins[8] and 8-quinolinol[9] have been investigated. Aniline has been brominated by a back-titration technique in which the excess electrolytically generated bromine was titrated with electrolytically generated copper^{I}.[10] A study of the feasibility of titrating fifteen organic compounds of possible analytical significance by electrolytically generated bromine was undertaken in order to delineate the stoichiometry involved in colorimetric methods for bromine, and also to circumvent gravimetric methods in the determination of small amounts of metal ions when organic precipitants are employed. This paper reports the results of the investigation involving anthranilic acid (*o*-aminobenzoic acid).[11]

EXPERIMENTAL

Reagents

Double-distilled water was used throughout the investigation.

Electrolyte solution. Dissolve 11·9 g of reagent-grade potassium bromide in 370 ml of distilled water and dilute to 500 ml with 95% ethanol. This solution is 0·2*M* in potassium bromide and 25% by volume ethanol.

Anthranilic acid. Anthranilic acid (Eastman, technical grade) was recrystallised three times from ethanol-water solutions. Only the first crop of crystals was used in each successive recrystallisation. The melting point was 145–145·5° (uncorrected).

Standard anthranilic acid solution. Dissolve 10 mg of the recrystallised material in 27 ml of 95% ethanol and dilute with distilled water to 100 ml in a volumetric flask. One ml of this solution contains 0·1 mg of anthranilic acid.

Precipitant solution. Dissolve 1·0 g of recrystallised anthranilic acid in 50 ml of water containing 0·3 g of sodium hydroxide. Adjust the pH of this solution to 5–6 with dilute hydrochloric acid and dilute to 100 ml with distilled water.

Standard copper^{II} solution. Dissolve 0·5 g of reagent-grade copper sulphate pentahydrate in 1 litre of distilled water. Standardise gravimetrically by precipitating copper anthranilate.

Apparatus

A Leeds and Northrup coulometric analyser was used as the constant current source and timing mechanism. Constant current outputs of 64·3, 6·43 or 0·643 mA are available with this apparatus. The cell contained a platinum generating anode and a platinum counter electrode which was protected from the solution by a glass sleeve which made electrical contact through a fritted disc. A Beckman micro calomel electrode served as the reference electrode while a rotating platinum electrode was used as the indicator electrode. The micro electrode was driven at 1800 rpm by a Sargent synchronous stirrer. A Sargent Ampot was used for the amperometric measurements.

General procedures

The platinum micro electrode and generator electrodes were pretreated by the procedure described by Kolthoff and Tanaka.[12] The electrodes were immersed in concentrated nitric acid for 10–15 sec, washed with distilled water, immersed in a solution of 0·01*M* iron^{II} sulphate and 0·05*M* sulphuric acid for 5 min, then again rinsed with distilled water. The sleeve containing the cathode was filled with 0·2*M* potassium bromide solution.

The desired volume of sample or standard solution was pipetted into the cell and the electrolyte solution, which had been adjusted to the desired pH, added. The electrodes were inserted and the magnetic stirrer and synchronous stirrer motor for rotating the platinum micro electrode was started. A potential of 250 mV *vs.* S.C.E. was applied to the micro electrode. After 10–15 min the indicator current reached a constant value and the titration was started using a generating current of 6·43 mA. The generating current was interrupted periodically in order to obtain current readings of the indicator electrode. Several readings were taken before and after the equivalence point, the exact equivalence point being determined graphically.

In determining copper the following procedure was followed: Transfer the desired volume of copper^{II} solution to a 100-ml beaker and adjust to pH 4. Heat the solution to boiling and add 1% anthranilic acid reagent until a ten-fold excess is present. Maintain the solution just below boiling point for 5 min, then allow to cool for 5–10 min. Collect the precipitate on a filter stick, rinse repeatedly with small volumes of 0·005% anthranilic acid solution and finally twice with a few ml of distilled water. Dissolve the precipitate in 4 ml of 2*M* hydrochloric acid, drain through the filter stick into the suction flask and transfer to a 25-ml volumetric flask. Dilute to volume with distilled water and mix thoroughly. Transfer 5 ml of this solution to the coulometric cell for bromination and follow the previously described procedure.

RESULTS

Preliminary investigation showed that anthranilic acid reacted fairly rapidly with bromine to give tribromoaniline.[13] Ultraviolet absorption spectra confirmed the absence of a carboxylic group in the product. The effect of acidity on the rate and extent of bromination was investigated. The rate becomes slow in both very acidic and basic solutions. Quantitative bromination takes place in the pH range 1 to 6 with the optimum rate occurring at a pH of about 4.

When titrations were performed in strictly aqueous solution the results were found to be about 1% low, possibly because of some incompletely brominated product precipitating. When a 25–40% ethanolic solution was used, however, the stoichiometry was in accord with the calculated values.

When a generator current of 64·3 mA was used, the bromine was generated much faster than it was consumed by the anthranilic acid. A lower rate of 0·643 mA was also tried and found to be acceptable although a much longer time was required for the titration. Using the 6·43-mA current output, 0·1–2·0 mg of anthranilic acid can be titrated within 25 min. The coulometric method is sensitive to about 0·1 mg of anthranilic acid.

Some results of determining copper by precipitating copper anthranilate, dissolving the precipitate and titrating the liberated anthranilic acid with electrolytically generated bromine are given in Table I.

TABLE I. ESTIMATE OF ACCURACY AND PRECISION IN DETERMINATION OF COPPER

Copper taken, *mg*	No. of determinations	Copper found, *mg*	Relative standard dev., %	Relative error, %
0·099	3	0·019	11	−81
0·494	4	0·487	1·9	−1·4
0·988	3	0·994	0·26	+0·6
1·976	12	1·998	0·65	+1·1

When less than 0·5 mg of copper^{II} is present in about 50 ml of solution the solubility losses are too significant for quantitative results. The determination of larger amounts of copper (>2 mg) is not practical because of the time required for the bromination process. Other metals whose ions form precipitates with anthranilic acid should be determinable by this proposed coulometric titration method.[14]

Summary—Anthranilic acid when brominated by electrolytically generated bromine requires 3 moles of bromine per mole. Amperometric detection of the equivalence point is utilised. Small amounts of copper (0·5–2 mg) can be determined by precipitating copper anthranilate, dissolving the precipitate and titrating the liberated anthranilic acid with electrolytically generated bromine.

Zusammenfassung—Bromiert man Anthranilsäure mit elektrolytisch erzeugtem Brom, so verbraucht sie 3 Mole Brom pro Mol, was durch amperometrische Äquivalenzpunktsbestimmung festgestellt wurde. Kleine Mengen Kupfer (0,5–2 mg) können durch Fällung als Kupferanthranilat, Lösen des Niederschlags und Titration der Anthranilsäure mit elektrolytisch erzeugtem Brom bestimmt werden.

Résumé—La bromuration de l'acide anthranilique par le brome généré électrolytiquement nécessite 3 moles de brome par mole. On a utilisé la détection ampérométrique du point d'équivalence. De petites quantités de cuivre (0,5–2 mg) peuvent être dosées par précipitation à l'état d'anthranilate de cuivre, dissolution du précipité, et titrage de l'équivalent d'acide anthranilique au moyen de brome généré électrolytiquement.

A simple separation of large quantities of 8-hydroxyquinoline from trace gallium

(*Received* 11 *October* 1963. *Accepted* 23 *October* 1963)

DURING an investigation of the precipitation of gallium with 8-acetoxyquinoline, a method was required for the determination of the unprecipitated gallium ($<0{\cdot}2$ mg) in each filtrate (*ca.* 300 ml). The presence of the very large excess of 8-hydroxyquinoline (*ca.* 0·9 g) seriously interfered with the three methods attempted, *viz.* polarography, or extraction of the gallium 8-hydroxyquinolate followed by a spectrophotometric or fluorimetric measurement.

It was therefore necessary to remove almost completely the 8-hydroxyquinoline without loss of gallium. Because of the volatility of gallium compounds, evaporation to dryness and subsequent ignition of the residue was considered unsuitable. Wet ashing of 8-hydroxyquinoline with a perchloric-nitric acid mixture[1] resulted in "... rapid clearing at end of period; beaker caught fire with hissing noise." Berg[2] has sublimed ammonium 8-hydroxyquinolate.

The simplest procedure seemed to be steam volatilisation.[3] Although Wegner[4] has used this technique to separate 8-hydroxyquinoline from other organic materials, it has not previously been used to separate the compound from aqueous metal-ion solutions.

When a filtrate (pH *ca.* 4·0) was slowly evaporated in a 400-ml beaker on a steam bath, most of the 8-hydroxyquinoline was removed, except occasionally some colourless needles crystallised on the upper parts of the vessel. Two repetitions with 30–50 ml of water completely eliminated the compound, as was evidenced by the absence of its characteristic spectral peak[5] at 3,180 Å in a chloroform extract of the residue in the beaker.

Furthermore, in four experiments with 0·1–0·8 mg of gallium in the presence of 0·9 g of 8-hydroxyquinoline, a gallium recovery of $>97\%$ was experienced. It was also established that most of the gallium in the residue was in the form of its water-insoluble 8-hydroxyquinolate.

LETTER TO THE EDITOR

The reaction of copper^{II} and copper^{I} with 8-mercaptoquinoline

SIR,

Mercapto compounds are usually considered sufficiently strong reductants to reduce Cu^{II} to Cu^{I}. The assumption that this is true with all mercapto compounds can lead to erroneous conclusions. For example, Bankovskis and coworkers[1,2] found that the reaction of both Cu^{II} and Cu^{I} with 8-mercapto-quinoline led to the formation of the same dark brown complex having a ligand:metal ratio of 2:1. They proposed the following reaction scheme:

$$6C_9H_6N{-}SH + 2Cu^{II} \rightarrow C_9H_6NS{-}SNH_6C_9 + 2Cu^{I}(C_9H_6NS)(C_9H_7NS) + 4H^{+} \qquad (1)$$

and concluded that the complex involves 4-co-ordinate Cu^{I} in which one ligand is bonded in the anionic form and the other ligand as the neutral thione tautomer. This reaction scheme correctly describes the stoichiometry of the copper complex as well as the number of protons released per metal ion on complex formation.

In the course of an investigation of the metal chelate stabilities of 8-mercaptoquinoline[3] we have carried out potentiometric titrations of 8-mercaptoquinoline both in the absence and presence of Cu^{II} and have found that the amount of base consumed at the end-point corresponding to the neutralisation of the mercapto group is unchanged by the presence of Cu^{II}. Because equation (1) predicts that only ⅔ of a mole of protons is released for every mole of reagent involved in the reaction, the amount of base consumed in the titration must vary with the amount of Cu^{II} present. Thus, unless the postulated copper complex loses protons in exactly the same pH region as the free reagent, the above reaction scheme is incorrect.

In order to investigate the alternative possibility that the complex obtained from the reactions of Cu^{II} and Cu^{I} with 8-mercaptoquinoline is $Cu^{II}(C_9H_6NS)_2$, the electron spin resonance spectrum of a chloroform solution of the complex was examined. The signal obtained was characteristic of a Cu^{II} complex, and it was possible to account quantitatively for the copper content of the complex as Cu^{II}.

Therefore a mercapto containing ligand is capable of reacting with a metal in a higher oxidation state without reducing it. This probably results from the greater stability of the complex of the metal in the higher oxidation state.

IZAAK MAURITS KOLTHOFF

JAMES J. LINGANE
Department of Chemistry, Harvard University, Cambridge 38, Mass., U.S.A.

IZAAK MAURITS KOLTHOFF, son of Moses and Rosetta (Wysenbeck) Kolthoff, was born on February 11, 1894, in Almelo, Holland.

In 1911, after graduation from Hoogereburger School, young Kolthoff's interest in chemistry already had been aroused, and the next logical step would have been graduate study of chemistry in a university. However, although he was fluent in English, French and German, in addition to his native Dutch, Kolthoff was barred from academic work in the "pure" physical sciences because he lacked the knowledge of Latin and Greek which at that time was a pre-requisite. As an alternative he enrolled in the chemical engineering curriculum at the University of Delft, but only a fortnight's stay convinced him that his real interest was elsewhere. Accordingly, he transferred to the school of pharmacy at the University of Utrecht. Here he came under the tutelage of Professor Nicholas Schoorl who guided him into his true vocation in analytical chemistry.

In retrospect, it might be said that one of the most important circumstances that has shaped the development of analytical chemistry over the past fifty years was Kolthoff's failure to acquire a knowledge of Latin and Greek during his high school days! If he had done so he probably would have gone on in the usual way to a university course in the "pure" physical sciences, he would not have come under the influence of Professor Schoorl, and, more than likely, analytical chemistry of our time would have been deprived of one of its most influential architects.

Kolthoff's first diploma at Utrecht was that of "Pharmacist", but the six-year curriculum on which it was based actually provided an education in chemistry as good as any available at that time. Indeed, the education in analytical chemistry offered by Professor Schoorl would have been hard to match anywhere, because Schoorl employed the approach (then rare) of emphasising the fundamental science underlying analytical chemistry and also had the gift of being able to inculcate in his students an appreciation for the equally important factual aspects of the subject. Schoorl's motto "Theory guides; experiment decides." has been the cardinal guiding principle of Kolthoff's scientific life.

In 1918, following an enlightened change in Dutch academic laws pertaining to the role of the classical languages in science education, Kolthoff was awarded the Ph.D. degree in chemistry from Utrecht for a thesis entitled *Fundamentals of Iodimetry*. This was not his first piece of original scientific investigation; actually, he had published his first research paper in 1915, and by 1918 it had been joined by 32 more papers all on subjects different from his Ph.D. thesis. His Ph.D. thesis itself certainly was not "thin", when one considers the series of nineteen papers on iodometric methods based on it which he published during 1919 and 1920. All this by the age of 26!

Dr. Kolthoff served as Conservator of the Pharmaceutical Institute at the University of Utrecht from 1917 to 1927, and concurrently as *privat docent* in applied electrochemistry from 1924 to 1927. Apparently a *privat docent* at that time was one who worked very hard in a university as teacher and investigator without being distracted by a salary! That this arrangement was well suited to Kolthoff's love of original investigation is evident from the fact that during this brief ten-year period he published 270 more research papers and wrote three books.

By 1927 not merely the amazing volume of his publications, but rather their high degree of originality and importance in analytical chemistry, had earned for Dr. Kolthoff an international reputation and he was invited on a lecture tour to Canada and the United States. Following this tour he accepted the position of Professor and Chief of the Division of Analytical Chemistry at the University of Minnesota. During the next 35 years, under his influence, the University of Minnesota became renowned as a leading research centre in analytical chemistry. In June 1962 Professor Kolthoff "retired", but for him this word is meaningless and his contributions to analytical chemistry continue unabated.

Kolthoff began his scientific life at the time when analytical chemistry was just emerging from its age of empiricism, and when applications of the principles of physical chemistry to analytical problems were appreciated only vaguely, and even vaguely by only a few. When he took his first course in quantitative analysis in 1913, S. P. L. Sörensen's definition of pH was only four years old, and even Arrhenius' theory of electrolytic dissociation was still a novel idea. Kolthoff began to demonstrate how these then new principles of solution physical chemistry could be applied to interpret, rationalise, and improve titrimetric analytical methods.

His earliest studies were in the field of acid-base titrimetry, and, beginning about 1914, he instituted a series of investigations of the dissociation equilibria of various weak acids and bases, the functional mechanism and characteristics of acid-base indicators, the use of indicators and indicator test-papers for pH measurement, and the properties of standard buffer solutions. He not only carried out studies in this field which were truly fundamental, but he also applied the knowledge thus gained to the development of many practical procedures. This combination of fundamental theory and practical application has been a characteristic of all his work ever since. These studies led to the publication in 1922 of his first monograph *Der Gebrauch von Farbenindicatoren*. That this book satisfied a real need is shown by the fact that it went through four editions between 1922 and 1932, and was translated into English by N. Howell Furman in 1926. In 1932 in collaboration with Harry Fischgold it was revised as *Säure-Basen Indicatoren*, and in 1937, with the assistance of Charles Rosenblum, it was again revised as *Acid-Base Indicators*.

Electrometric methods of analysis owe much of their development to Kolthoff, who appreciated their potentialities and began to exploit them when they were still virtually unknown to most analytical chemists. Starting about 1918 he carried out many studies of the application of electrolytic conductance to end-point detection in titrations, and these culminated in the appearance of his second monograph, *Konduktometrische Titrationen*, in 1923. This book was one of the first to systematise the theory and applications of the conductometric method. It also illustrates another of Kolthoff's characteristic traits, namely, that whenever he devotes himself to a particular subject a good monograph soon appears!

Another subject pioneered by Kolthoff was the field of potentiometric measurements and titrations. In connection with his investigations of protolytic equilibria and pH measurements he published many papers on the hydrogen, quinhydrone, antimony and other pH electrodes. Characteristically, these were particularly valuable because they emphasised the limitations and sources of error of the then relatively new potentiometric method of pH measurement. Kolthoff's approach to analytical problems *via* fundamental theory proved especially fruitful in his many studies of potentiometric equivalence-point detection in precipitation, complexation and redox titrations. In 1926, in collaboration with N. Howell Furman, Kolthoff published *Potentiometric Titrations*, the first monograph on this subject published in the United States. A second revised edition appeared in 1931, and even after 30 years it is still a most useful source of information on the practical performance of potentiometric titrations and on actual procedures.

The studies cited above, which engaged Kolthoff's attention during the period from 1915 to about 1926, would have been more than sufficient to satiate the scholarly impulses of any ordinary scientist. But during this same decade he had also found time to cultivate many other aspects of classical titrimetric analysis, and he recognised the need for a treatise on titrimetric analysis which would provide a comprehensive treatment of the theory of the subject and a critical evaluation and description of its manifold specific applications. Accordingly in 1927, with H. Menzel, he published the first volume of his famous *Massanalyse* (*Die theoretischen Grundlagen der Massanalyse*), and a year later this was followed by the second volume *Die Praxis der Massanalyse*. In 1928 the first American edition under the title *Volumetric Analysis* was made available with the translational assistance of N. Howell Furman. Kolthoff did not merely edit this book; he created it by personally testing nearly every procedure which it contained. During the period from 1942 to 1957 a revised edition was published in three volumes with the co-authorship of Vernon A. Stenger, George Matsuyama and R. Belcher, and it stands today as the most authoritative monograph on its subject.

Influenced by the great Dutch chemist H. R. Kruyt, Kolthoff had early acquired an interest in colloidal phenomena and surface chemistry. When he came to Minnesota in 1927 he intensified the investigations on coprecipitation and adsorption by precipitates which he had begun in Holland. He directed these studies to such analytically important precipitates as those of the Hydrogen Sulphide and Ammonia Groups, calcium oxalate, barium sulphate and the silver halides. The results obtained have done much to rationalise the practice of gravimetric analysis, and have added very significantly to knowledge of the mechanisms involved in the formation of micro-crystalline precipitates, and to the behavioural mechanism of adsorption indicators. In these studies Kolthoff, in collaboration with Charles Rosenblum, was among the pioneers in the use of radioactive indicators (Th B for Pb). At that time (1930) only the natural radioactive isotopes were available, and the activity was measured with a gold leaf electroscope.

During the fall of 1934 Kolthoff's interest was again attracted to electometric analysis, this time to polarographic analysis with the dropping mercury electrode. Polarography had been invented about a decade previously by Jaroslav Heyrovský at the Charles University in Prague, and the reader will recall that this discovery was rewarded recently by the award of the Nobel Prize in Chemistry to Professor Heyrovský. Although European analytical chemists had been quick to realise its potentialities, polarography was still unknown in the United States in the middle

1930's. Approaching this subject in characteristic fashion, Kolthoff's first concern was the theoretical basis of the method, and he carried out important studies of the various factors which influence the diffusion current, polarographic maxima, and the current-potential inter-relationship. At this same time, in collaboration with Herbert A. Laitinen, he instituted a series of studies on polarographic (voltammetric) analysis with stationary and rotated platinum microelectrodes. He was quick to recognise the potential utility of amperometric titration, and he played a major role in bringing this method to its present well-developed state. It was quite in character that he was not content merely to contribute to polarographic analysis by his own investigations. Realising the need for correlation and systematisation he published in 1941, with this writer's assistance, the monograph *Polarography*. This was the first comprehensive and critical treatment of the subject in the English language and it was a potent factor in the accelerated development of polarographic analysis which began in the early 1940's. A second, much enlarged edition of *Polarography* in two volumes appeared in 1952, and Professor Kolthoff currently is busy with the preparation of a third edition.

With the advent of the war in 1942, Kolthoff forsook his academic interests to direct a research project for the Office of Rubber Reserve. From pure analytical chemistry to synthetic rubber did not entail as drastic a change in Kolthoff's activities as might be supposed. The acquisition of detailed knowledge of the kinetics of polymerisation reactions in solution was an essential part of this programme, and, because the experimental study of such kinetics depends primarily on analysis, Kolthoff was eminently qualified for this task.

After the war Kolthoff again picked up the many irons which he had had to let cool by the fire's edge, although several years passed before the odour of styrene finally disappeared from the atmosphere of his laboratory. (As recently as 1957 he was still publishing results of his studies of the emulsion polymerisation of styrene.) He returned to his studies of polarography and amperometric titrations, and a steady stream of communications from his laboratory continues to enrich this field.

A complete list of Kolthoff's research publications up to about the end of 1963 is appended (p. 351). This list is restricted to original research papers, and it does not include routine writings such as book reviews, *etc.* No attempt will be made here to analyse in detail the amazing volume and variety of these contributions. The reader will appreciate that to do so adequately would require a book-length discussion, and I leave this task to some future historian of analytical chemistry. It is quite evident that analytical chemistry has never been served by a more original mind, nor a more prolific pen, than Kolthoff's.

Quite recently Professor Kolthoff was able to implement a long-held urge to provide practicing analytical chemists with a comprehensive, multi-volume reference monograph covering all phases of analytical chemistry. In partnership with Philip J. Elving, and with the collaboration of Ernest B. Sandell, several volumes of this *Treatise on Analytical Chemistry* have already appeared.

It is not uncommon for a gifted research scholar to be indifferent to educational aspects of his field, but here again Professor Kolthoff has been exceptional. Although his chief preoccupation has always been the education (not "training") of graduate students, and during all the years at Minnesota he never taught the elementary analytical course, he has not neglected undergraduate instruction in analytical chemistry. His elementary *Textbook of Quantitative Inorganic Analysis*, co-authored with Ernest B. Sandell, originally published in 1936 and since revised twice, is the comparison standard among American texts on this subject. Kolthoff's classroom teaching has been confined to seminars and to an advanced course devoted chiefly to electrometric methods of analysis. For use in the latter course he published in 1931 a textbook, *The Colorimetric and Potentiometric Determination of pH. Outline of Electrometric Titrations*, and a German translation was prepared the following year with the assistance of Oskar Schmitt. In 1941, in collaboration with Herbert A. Laitinen, a second revised edition appeared under the title *pH and Electro Titrations.*

Kolthoff has been outstanding as a teacher of graduate students; a list of those who earned Master's and Doctor's degrees under his guidance is appended. The analytical chemistry faculties of a surprisingly large number of American universities and colleges (as well as several in other countries) are composed of his former students, by their students in turn, and even by a third generation. His laboratory has also been a Mecca for many foreign post-doctoral fellows, which has further extended his influence in the educational sphere, because most of them returned to academic posts in their own countries.

Professor Kolthoff's deep-rooted concern for freedom of thought and expression, and his abhorrence of dogma in any guise, have always underlaid his relationships with his students. Each student was made to feel that he was a partner, not just a useful pair of hands, and he was given every opportunity to learn to behave as an intellectual equal. Kolthoff kept in close contact with each student's progress by daily, informal conferences. On occasion, these sessions with the "Chief" could be embarrassing, because nothing that the student had (or had not!) done ever escaped his incisive scrutiny. But a knife cannot be sharpened on butter, and the whetting of the younger against the experienced mind was education in its finest sense. Kolthoff never exerted the authority of his experience to "silence" a student, but rather the spirit of these discussions was always "Not *who* is right, but *what* is right". Small wonder that Kolthoff's students became and remain his enduring friends.

The intensity with which Kolthoff concentrates on scientific problems, and on his other intellectual pursuits, demands periodic release in physical activity, and for many years tennis was a favourite means of "letting off steam". Although his highly individualistic style, including ambidextrous use of the racket, may have been more baffling than "polished", it kept his opponent very busy. He enjoys swimming, whether in the bucolic surroundings of a pasture pond on a Minnesota farm, or in the North Sea off a Netherlands beach. Horseback riding has been a lifelong hobby, and his disdain of anything "lukewarm" applies to his choice of mount. On one occasion some years ago the horse won the bout, and the resulting fall produced a crippling spinal injury. However, even before he was able to discard crutches, he was back in the saddle.

Kolthoff's extra-professional contributions to analytical chemistry include service for many years on the editorial boards of Analytical Chemistry and the Journal of the American Chemical Society. He was active in the creation of the Section on Analytical Chemistry of the International Union of Pure and Applied Chemistry, and he has served as President of that section as well as Vice-President of the Union.

In addition to ordinary membership in the American Chemical Society, the Dutch Chemical Society and the Dutch Pharmaceutical Society, Kolthoff is an honorary member of a number of other scientific societies, including the American Pharmaceutical Association, the Society for Analytical Chemistry, Phi Lambda Upsilon, the Spanish Chemical Society, the Finnish Chemical Society, the Peruvian Chemical Society, the Czechoslovak Chemical Society and the Israeli Chemical Society. He is a Fellow of the American Academy of Arts and Sciences, and he has the distinction of being one of the few analytical chemists to achieve election to the United States National Academy of Sciences. He is a foreign member of the Royal Bohemian Academy of Sciences and Fine Arts, of the Royal Flemish Academy of Sciences in Amsterdam, and of the Academy of Sciences in Lisbon.

In 1938 the Netherlands government knighted Dr. Kolthoff an Officer in the Order of Orange-Nassau, and in 1947 he was made a Commander in that Order. He holds the Charles Medal of Charles University in Prague. In 1949 the New York Section of the American Chemical Society conferred on him its Nichols Medal, and in 1950 he was the recipient of the Fisher Award in Analytical Chemistry of the American Chemical Society. In 1954 he became an Honorary Professor of San Marcos University, and in 1955 he was awarded an honorary doctor's degree by the University of Chicago. He received the Anachem Award of the Association of Analytical Chemists (Detroit) in 1961.

Happily, this is only a progress report. May God grant Professor Kolthoff many more years of fruitful labour.

GRADUATE STUDENTS OF IZAAK MAURITS KOLTHOFF

1. E. J. Amdur	M.S.	1941
2. Madolyn Youse Babcock	M.S.	1950
3. Cyrus P. Barnum	Ph.D.	1940
4. Gordon H. Bendix	M.S.	1938
5. R. A. Bovey	Ph.D.	1948
6. R. C. Bowers	Ph.D.	1953
7. Stanley Bruckenstein	Ph.D.	1954
8. Albert H. Bushey	Ph.D.	1940
9. Marion Bushey	Ph.D.	1940
10. E. M. Carr	M.S.	1952
11. Chi Chang	Ph.D	1958
12. M. K. Chantooni, Jr.	Ph.D.	1960

THE STATUS OF AND TRENDS IN ANALYTICAL CHEMISTRY

I. M. KOLTHOFF
School of Chemistry, University of Minnesota, Minneapolis 14, Minn , U.S A.

THE DEVELOPMENT OF ANALYTICAL CHEMISTRY AS A SCIENCE

BEFORE a subject becomes a science its development is empirical in nature. Facts must be collected before generalisations in the form of laws and interpretations of the facts can be made. Before chemistry had reached the stage of a science, the empirical work in its early days was mainly analytical in nature. With the spectacular development of physical chemistry in the last quarter of the nineteenth century, analytical chemistry started to lose its historic lustre because analytical chemists continued to practice their subject in an empirical way, without making use of the new laws and theories developed by physical chemists. Academically, analytical chemistry became discredited. It was the famous German chemist Wilhelm Ostwald who, at the end of the last century, established analytical chemistry as a scientific discipline. In the preface of his stimulating book, *Die wissenschaftlichen Grundlagen der analytischen Chemie*, published in 1894, Ostwald made it clear that analytical chemistry was doomed to continue to occupy the subordinate position of a maid-servant for the other branches of chemistry unless the analytical chemists would discontinue teaching their subject solely as an empirical technique and art which requires skill, and would start making use of the experimental developments and theories of physical chemistry. Infrequently physical chemists would describe analytical applications of certain physico-chemical principles, but analytical chemists in those days lacked the background to comprehend their significance. At the end of the last century papers describing the principles of voltammetry, of amperometric, potentiometric and conductometric titrations already were found in the chemical literature, to be "rediscovered" and developed much later, after education in analytical chemistry had become scientific in nature. In fact, most of the early scientific fundamentals of analytical chemistry and the analytical applications of theoretical chemistry have been developed by non-analytical chemists. In addition to the early papers on what is now modern electroanalytical chemistry, the development and understanding of acid-base indicators may be mentioned. At the very beginning of this century analytical chemists empirically knew that weak acids are titrated with a strong base using phenolphthalein as an indicator and weak bases with a strong acid using methyl orange as an indicator. It was only after the introduction of the concept of pH and the detailed description of its colorimetric and potentiometric determination in 1909 by the famous Danish *bio*chemist, S. P. L. Sörensen, that the fundamentals of aqueous acid-base titrations could be understood. Sörensen's paper still belongs to the most fundamental publications on the concept and determination of pH with the hydrogen electrode and with acid-base indicators, and it is as important now as it was in those days. Sörensen also made clear the significance and the meaning of buffer action and he developed a set of buffer solutions, covering the entire pH range in aqueous medium. For many years Sorensen's buffer solutions have served as standards for the colorimetric determination of pH and several other purposes. Again, analytical chemists did not comprehend the significance of Sorensen's pioneer work, and it was not until 1914 when the famous Danish *physical* chemist Niels Bjerrum published his classical monograph, *Die Theorie der alkalimetrischen und azidimetrischen Titrierungen*, that a quantitative interpretation of acid-base equilibria and titration errors in aqueous media became available. In the same year the German *bio*chemist L. Michaelis published his book, *Die Wasserstoffionenkonzentration*, and soon thereafter a monograph on oxidation and reduction potentials. This latter book allowed us to give a quantitative interpretation of oxidation-reduction titrations. It was the well known American *physical* chemist, Joel H. Hildebrand, who published in 1913 his important paper on potentiometric titrations with the hydrogen electrode. It was not an analytical chemist but the American *physiological* chemist, W. Mansfield Clark, who in 1917 added the sulphophthaleins to the series of acid-base indicators.

It is not surprising that the fundamentals of analytical chemistry in those early days were developed by non-analytical chemists. Analytical chemistry was still looked down upon as a maid-servant for the other disciplines of chemistry, and no formal education in analytical chemistry was offered by European universities. All students in chemistry had to learn the practice of gravimetric and titrimetric analysis, which was offered as a laboratory course under the supervision of a teaching assistant. Technical universities in Europe and in several American universities had a chair for analytical chemistry, but the subject was taught in a classical way and its aims were mainly to provide instruction in the technique of the analysis of inorganic constituents and of ores, rocks, industrial products, food stuffs, *etc.*

It was only after about 1920 that analytical chemistry gradually became established as a scientific discipline of chemistry. With some notable exceptions, most universities in the world have chairs now in analytical chemistry, and all students in chemistry now receive education both in classical analytical chemistry and—after a course in physical chemistry—in the principles of physicochemical methods of analysis. Those students who major in analytical chemistry for the Ph.D. are exposed to all aspects of modern analytical chemistry, which includes the determination and study of such properties and quantitative characterisation of such systems which aid, and often are essential in, the solution of analytical problems, and which guide in the development of new analytical methods. "Theory guides and experiment decides."

Complaints are sometimes heard that there is overlapping between teaching and research in analytical and other fields of chemistry. Actually, this is not only an unavoidable but rather a desirable situation. A few examples may illustrate this claim. Chemical equilibria is a subject of importance to inorganic, physical, organic, industrial and biochemists. Its principles are now taught in beginning general chemistry, but the significance of this subject in the various specific fields of chemistry is taught in courses for students specialising in these fields. Before scientific analytical chemistry was recognised in the academic curriculum, principles of chemical equilibria were being taught by physical chemists; such courses did not emphasise their primary importance in, and application to, analytical chemistry. Nowadays the subject has rightfully become part of the curriculum in modern analytical chemistry.

Quite generally, in quantitative chemical analysis we make use of properties which can be measured. All other chemists are interested in properties, but again, courses in modern analytical chemistry must include instruction in the understanding of properties which are important analytically, and laboratory instruction on the measurement of these properties.

All experimental scientists must be acquainted with the fundamentals of instrumentation. In view of the fact that an instrument is needed for the measurement of a property, the subject of instrumentation is of special importance to analytical chemistry. Instruction in instrumentation is now a recognised subject in the analytical curriculum.

All chemists are concerned with various aspects of separations, a subject completely analytical in nature. The Dutch word for chemistry is "Scheikunde," meaning the art and ability of separating. It originated in the sixteenth century when chemistry was mainly analytical in nature. The present chemical literature is replete with papers by organic, inorganic, analytical, industrial, and biochemists dealing with the application of chromatography, ion-exchange, distillation, extraction and other methods of separation in the preparation of pure compounds and the identification and determination of constituents. All chemists, including physical chemists, for their own purposes are concerned with an understanding of the factors which determine the degree of completeness of separations. Would it not be desirable that the theoretical and experimental principles of separation—a subject which is analytical chemistry *par excellence*—be taught to all chemists by analytical chemists? The late Professor Ehrenfest once said that everything which is understood in chemistry is physics. Considering the various disciplines of chemistry it is fair to state that the theoretical fundamentals of analytical, inorganic and organic chemistry are physicochemical in nature. But for obvious reasons we need chemists with a major interest in analytical chemistry to teach analytical chemistry, just as we need inorganic chemists to teach inorganic and organic chemists to teach organic chemistry.

THE STATUS OF MODERN ANALYTICAL CHEMISTRY

It seems fair to state that analytical chemistry started to develop as a science towards the end of the first quarter of this century. Analytical chemists became fully conscious of the fact that for the further growth and expansion of analytical chemistry they had to remain up to date with the discoveries and new theories by other classes of chemists and of physicists, and had to consider their significance for and applicability to analytical chemistry. In the last quarter of a century a host of new nuclear, subatomic, atomic and molecular properties have been discovered, most of which already find analytical applications. Radioactive methods, especially activation analysis in trace analysis, are becoming more and more popular. Nuclear techniques have been introduced for analytical purposes. For example, a new instrument has been made available commercially for the rapid and continuous measurement of moisture in bulk materials, based on the reflection of two different kinds of nuclear radiation. X-ray spectroscopy and fluorescence, microwave spectrophotometry, ion-scattering methods, mass spectroscopy and nuclear and electronic magnetic resonance are some of the modern developments which find analytical use. Most of these new techniques originate with physical chemists or physicists, but analytical chemists play an important part in their further development. Numerous symposia organised jointly by physical and analytical chemists are indicative of the role which analytical chemists play in the development of these new techniques.

These advances in techniques are being made possible, not only by new discoveries and theories, but also by the phenomenal progress of instrumentation. This progress has its impact both on the development of techniques based on new discoveries, and also on the development of techniques based on the measurement of a host of classical properties. Many of these properties were known and measured more than a century ago. However, their application to analytical chemistry remained limited, mainly for the reasons that a thorough knowledge and understanding of the instruments was necessary, and the measurements themselves were very time-consuming. Modern instrumentation has changed all this and has even provided us with a host of automatically indicating instruments.

A few examples may illustrate how modern instrumentation has made possible daily measurement of classical properties and their much expanded use in analytical chemistry. Some twenty-five years ago many of us strained our eyes with a Duboscq or another visual colorimeter, or with a polarimeter or refractometer. Accurate spectrophotometers were available as far as colorimetry was concerned, but they were not suitable for routine work. Nowadays modern spectrophotometers for measurements in ultraviolet, visible and infrared light, and also self-recording instruments, are found in all modernly equipped analytical laboratories. Similarly, the analytical application of emission spectroscopy probably dates back to Fraunhofer, who in 1817 combined a slit, a glass prism and a theodolite. This same scientist may be considered the father of atomic absorption (Fraunhofer lines). Bunsen is usually credited as the chemist who introduced spectroscopy in analytical chemistry when he wrote with Kirchhof his classical paper in 1860 entitled *Chemische Analyse durch Spektralbeobachtung*. Much later the spectrograph was developed, but did not acquire popularity until 1939 when excellent optical instruments were produced which allow comparison of spectra with a microphotometer that can be coupled to a recorder—the latter in turn automatically recording the intensity of a whole series of lines.

Quite generally, recorders are now being used in analytical chemistry for automatic registration. Classical photometric, potentiometric, coulometric, conductometric, amperometric, turbidimetric and thermometric titrations are now being carried out with automatic end-point determination. Principles of coulometry, including stripping analysis, and coulometric titrations were laid down more than a hundred years ago in Faraday's second law, but their practice has become popular only after the development of convenient instruments.

Most modern methods of separation are classical in nature. The first evidence of the use of paper chromatography as a separation technique is found in the dye industry of the 1800's. Dyes were tested by spotting vat solutions on paper and observing the number of concentric rings formed as the liquid migrated. The German dye chemist, F. Runge, developed this technique and described the results in two books, *Farbenchemie* (1850) and *Der Bildungstrieb der Stoffe*, the latter being prefaced by actual chromatograms developed by Runge.

Schönbein, around 1860, showed that if a paper is dipped into an inorganic salt solution the liquid migrating through the paper carries the salt with it. However, the water moves faster than the inorganic salts, which travel with different rates. F. Goppelsröder developed the method further for the detection and determination of inorganic and organic constituents, and called the technique capillary analysis. This technique is closer to adsorption than to partition chromatography. Columnar chromatography was discovered in 1897 by the American, J. T. Day, who used it for fractionating petroleum by preferential adsorption on columns of Fuller's earth. Ion-exchange chromatography is classical in nature, and has been made use of in soil studies since the middle of the last century. Liquid-liquid extraction was used already in the 19th century as a method of separation. All these methods of separation have been greatly perfected in the last 25 years, and new techniques, like partition chromatography (Martin and Synge, 1941) and gas chromatography (James and Martin, 1952) have been added. In spite of the great popularity of all these methods of separation, and the great number of papers on the subject in contemporary chemical literature, many phases of these techniques are still incompletely understood.

It is hardly necessary to mention that modern analytical chemistry is still actively engaged in the further development of classical analytical principles. Organic reagents for the detection and determination of inorganic constituents had already been introduced in the 19th century. Many analytical chemists have been searching since for organic reagents with such functional groups that they become selective and/or specific for any given cation. That goal probably never will be reached because, considering the structure of the ions, it would seem impossible that there is a reagent which is truly specific for one particular ion and the reaction of which is not interfered with by some other element. However, the ideal goal may be approached with the aid of masking reagents and modern methods of separation. There is already a considerable literature on the use of ethylenediaminetetra-acetate (EDTA) and similar compounds for masking purposes. Frequently, reports on the discovery of known reagents, or the introduction of known compounds as reagents for use in various types of methods of chemical analysis, are found in the modern literature. Some of these reagents may have been known for years but had not been tested for their analytical usefulness. With our increasing knowledge and understanding of chemical bonding, of steric hindrance and of co-ordination in particular, it is now often possible to predict which groups may have desirable properties for particular analytical purposes, for example, for complexation. Although EDTA and related compounds had been known for some time, it is only as a result of the pioneer work of Gerold Schwarzenbach that they are now in daily use in complexometric titrations and for masking purposes. A large chapter has been added to analytical chemistry after the introduction of these reagents.

RESEARCH IN ANALYTICAL CHEMISTRY

Academic and industrial analytical research deals with the theoretical and experimental development of classical and modern techniques, including micro and submicro techniques, the interpretation and improvement of existing methods of analysis, the development of new methods of analysis to replace existing ones, and the assay and evaluation of new industrial products.

As far as research dealing with theoretical fundamentals is concerned, there naturally is again overlapping with some phases of research carried out by physical, inorganic and organic chemists. As a matter of fact, in the last quarter of a century there has been a definite shift of the activities of classical physical chemistry to analytical chemistry. In the beginning of this century the determination of the dissociation constants of acids and bases by potentiometric, conductometric and colorimetric methods, the determination of distribution equilibria, of solubility products, of the stability constants of complexes, of oxidation-reduction equilibria, of electrode potentials, *etc.*, belonged to the activities of the physical chemists. Nowadays this type of information is obtained mainly by analytical and inorganic chemists. A great many phases of electrochemistry have become the domain of the analytical chemist. In order to interpret and further develop empirical methods of analysis it is essential that the physical chemistry involved in the behaviour of the components of the systems under consideration be fully understood. For example, acid-base titrations in non-aqueous media have experienced wide analytical application after the publication of the fundamental papers by Conant *et al.* on the behaviour of bases in pure acetic acid. Titrations of acids and of bases in a host of other solvents have been described since. However, although the results can be understood qualitatively, much work on acid-base equilibria remains to be done to arrive at a quantitative understanding. The same is true for many phases of extraction analysis as far as a quantitative interpretation of distribution equilibria is concerned. Electroanalytical methods in non-aqueous media, including fused salts, require much fundamental research before they can be fully developed. A host of problems in all kinds of solvents demands much fundamental research before they are completely understood and the results can be applied to further improvement of analytical methods.

Consider, for example, our understanding of the formation and growth of precipitates, of coprecipitation and aging. In spite of the numerous publications dealing with these subjects, a quantitative understanding of the factors determining or affecting the size of the particles of a precipitate and of coprecipitation is still lacking. This is also true with regard to an understanding of the value of the distribution coefficient (or constant), λ, in the formation of heterogeneous mixed crystals. Theoretically, λ should be equal to the thermodynamically defined homogeneous distribution coefficient, D. But even under conditions of *kinetically controlled precipitation*, a term which I prefer to "precipitation from homogeneous solution," λ can be much greater or much smaller than D, even though in many systems studied, especially by L. Gordon, λ is found to be sensibly constant during the precipitation. Apparently, supersaturation during the growth of crystalline particles is mainly responsible for the difference between D and λ (J. A. Hermann, 1956). In unpublished work we have found that λ closely approaches D in the kinetically controlled formation of mixed crystals of barium and lead sulphate, with barium sulphate as the host crystal, when the system is seeded with a relatively large amount of small and well aged crystals of barium sulphate. These crystals serve to overcome to a large extent the supersaturation during the formation of mixed crystals.

In the development of new chelating agents, including metal ion indicators, the modern investigator is actively interested in the nature of reactive groups and the structure of chelates. In order to predict and interpret complexometric titration curves he must have data on stability constants and quantitative knowledge of the effect of pH and other constituents on equilibria. In addition, knowledge of the kinetics of formation of the dissociation of metal chelates, of the chromatographic (ion exchange) and other characteristics of metal chelates, are essential in the further development of the application of complexation in analytical chemistry. Research on ion exchange, chromatography, solvent extraction, electrodialysis and migration, again, is being carried out not only by analytical chemists but also by physical, inorganic, organic, industrial and biochemists. This overlapping of research activities is a fortunate situation, because all disciplines of chemistry profit from each other's contributions, and together we can fill up the gaps in our understanding of the fundamentals of chemistry. It would be deplorable if the scope of research in analytical chemistry were limited to the more typically classical topics.

ACADEMIC AND INDUSTRIAL ANALYTICAL CHEMISTRY

From what has been said in previous sections we may define academic analytical chemistry as the science concerned with the study and interpretation of all aspects of existing methods of analysis and the development of new methods of analysis. This definition apparently has neither the sympathy nor the approval of industrial analytical chemists. In his thought-provoking Fisher Award Address, H. A. Liebhafsky[1] refers to a definition of analytical chemistry which I stated twelve years ago:[2] "The aims and objectives of analytical chemistry are to determine the composition of any complex compound or mixture of compounds." Generously Liebhafsky adds: "From a university point of view of twelve years ago, this is an excellent definition," I would like to maintain that academically the definition is as valid now as it was a century ago. Liebhafsky then refers to R. C. Chirnside's interesting address[3] entitled *The Enlargement of Horizons in Analytical Chemistry*, in which Chirnside quotes E. B. Hughes as having defined our discipline to be "the examination of a material to ascertain its composition, its properties, its qualities." Liebhafsky finds this definition too restrictive and sees "modern analytical chemistry as the characterisation and control of materials—no more, and certainly no less." Liebhafsky further makes the statement (p. 26A): "Analytical chemistry has lost prestige as a research activity and has not yet gained prestige commensurate with its great and growing importance as a *service in industry*." (Italics mine). I would infer from this statement that Liebhafsky expresses himself on the *role* of analytical chemistry and the *use* of analytical chemistry in *industry*. His views are in close sympathy with those of Chirnside, another recognised analytical-chemical leader in industry, who states: "... he would be a brave man who would today attempt a proper definition of analytical chemistry or chemical analysis, or indeed a description of the analyst himself."

If it is admitted that the classical definition of analytical chemistry has remained unchanged but that the aims and objectives for which the analytical chemist is used in industry have changed and are continuing to change, the question arises whether our education of majors with an advanced degree in analytical chemistry satisfies the needs of industry. If the present education of our majors for the Ph.D. in analytical chemistry does not provide adequate background for the industrial analytical chemists, our institutions of higher learning might consider the introduction of a new minor in "materials characterisation and control" for our majors in analytical chemistry. As far as the loss of prestige as a research activity is concerned, I would like to claim that particularly during the last twenty-five years analytical chemistry has gained great prestige as a research activity, thanks to fundamental contributions by both academic and industrial analytical chemists. To a large extent the empiricism has gone out of analytical chemistry.

RECENT AND FUTURE TRENDS IN ANALYTICAL CHEMISTRY

Education in chemistry

In this era of spectacular advances in the natural sciences, and in chemistry in particular, each discipline of chemistry must periodically reappraise and modify its curriculum in order to keep it up to date with the developments. During the last few years we have witnessed and are still witnessing such a reappraisal and modernisation of courses, especially in the U.S.A. In order not to extend the number of years required now for earning a bachelor's or an advanced degree, all disciplines must curtail their "classical" programmes so that justice can be done to the teaching of modern developments. Reluctantly, analytical chemists internationally agree that the scope of the classical programme in gravimetric and titrimetrc analysis, and in particular the laboratory work, must be curtailed, in order to include the theoretical and experimental fundamentals of physicochemical methods of analysis in the curriculum of all students in chemistry. With further scientific developments periodic modernisation of courses will remain necessary.

However, training in elementary gravimetric and titrimetric analysis should remain a requirement in the curriculum for all chemists, as these subjects have not outlived their usefulness. In experimental research in all fields of chemistry these methods find frequent application, *e.g.*, in testing for purity of and assaying reagents, and in following the course and rate of reactions. Moreover, gravimetric and titrimetric analysis are still indispensable in the accurate determination of major constituents in many types of samples. Also, in several physicochemical methods standards are necessary whose composition is often determined by classical analysis, while some "instrumental methods" also involve classical methods, like gravimetry in activation analysis.

As far as majors for the Ph.D. in analytical chemistry are concerned, it is still desirable to include the essentials of classical analytical chemistry and it is possible to cover the essentials of modern analytical chemistry in the curriculum. Considering however, the almost frightening expansion of the literature, the appearance of a host of new journals in specialised fields of analytical chemistry, it will become necessary to add more specialists to the teaching staff. Even so, the education should remain fundamental in nature, and should provide such background that the Ph.D. can later become a specialist in particular fields. Many of us know by experience that education does not stop at the Ph.D. level. A recent Ph.D. is a novice in the field who has such knowledge and understanding of all aspects of analytical chemistry that it serves him to develop into a creative academic or industrial analytical chemist. Only those of our graduate students who exhibit great ability and creativity in research—and their percentage is rather small—should be encouraged to work for the doctor's degree. Society has a great need for advanced technicians who might be encouraged to earn a new degree of "Chem.D." (chemical doctor).

Future trends in analytical chemistry

The Dutch have a saying: "In the past lies the present, and in the present what is going to be." Considering the past and present development of analytical chemistry it is possible to forecast future trends without becoming speculative. In this era of concentration on the natural sciences, discoveries of new properties, especially in the field of radiation, will continue to be made. Modern instrumentation will quickly provide the instruments with which these properties can be measured and recorded. Thus, we will experience a further expansion of "physical analysis." This, combined with continued automation of new and classical methods of analysis may create social problems. However, for the development of scientific analytical chemistry the further perfection of instrumentation is most welcome, because the results of measurements will become more readily available and more time and effort can be devoted to the solution of unsolved problems.

More and more use will be made of computers in the solution of several analytical problems. In titrations involving complicated equilibria exact equations can be derived for the calculation of the titration error and titration curves, for example, in many complexation reactions or acid-base equilibria and titrations in solvents of low dielectric constant. Such equations may be so involved that they require computers for their exact solution. The same is true in the analysis of complex organic mixtures by measuring a host of physical properties, or in the further development of "kinetic" analysis based on different rates of reaction of various constituents, or the determination of particle size and particle size distribution by light scattering and other methods.

In the previous sections a few examples of the application of chemical reactivity have been given. Several methods based on reactivity are awaiting further development; others have hardly been explored yet. The search for more selective reagents, including complex-formers, particularly those with mixed ligands, and for metal ion indicators is not nearly finished. In organic analysis, research continues on specific reagents for functional groups, and on making more analytical use of the kinetics of formation of compounds obtained by reaction of functional groups with suitable reagents, and of the kinetics of the dissociation of these reaction products into the original reactants. Further studies on the expansion of oxidation-reduction analysis to solutions in solvents much more difficult to oxidise and/or reduce than water, remain to be done.

Our quantitative knowledge of the fundamentals of the titration of Lewis acids with bases is still extremely incomplete. The formation constant of the "neutralisation product" AB formed by reaction of the Lewis acid A with a base B, its ionic dissociation constant, its molecular dissociation constant, and the association constants of the ionic dissociation products of AB with AB in a variety of solvents, should be known before a successful interpretation and exhaustive development of thermometric, conductometric, potentiometric (search for indicator electrodes), amperometric, coulometric and visual titrations of Lewis acids (including many inorganic ions or compounds) with bases can be made.

For further development of extraction analysis, much more research remains to be done on formation constants of ion pairs, of ion triplets and quadruplets in solvents used for extraction, and on the effects of pH and of structural characteristics of the cations and anions on distribution and extraction coefficients.

Little work has been done on reactivity at very high and at very low temperatures, on the use of various radiations to bring about chemical reactions, on the quantitative measurement for analytical purposes of the energy involved in breaking chemical bonds.

Organic, inorganic and industrial chemists continue to make available a host of new organic and inorganic compounds. In consequence, analytical chemists are being called upon continuously to devise methods of analysis for these compounds. In addition, analytical chemists are interested in the possible use as reagents of the new products, like organo-metallic compounds. Continuously industry is producing new complex products, like inorganic and organic polymers, and semiconductors, which demand the development of analytical methods for their characterisation and evaluation, and the solution of analytical problems during the production process. Semiconductors are an example *par excellence* to illustrate the increasing demand for the development of new methods for trace analysis, and for the preparation of substances of extremely high degree of purity. Modern biochemistry requires the further development of sub-micro techniques of analysis.

The above review of present and future activities in analytical chemistry is sketchy in nature. In an essay of this kind it is not possible to present either an exhaustive or complete discussion of these activities. However, the examples given substantiate the thesis that analytical chemistry will continue to flourish as one of the scientific disciplines of chemistry as long as there are unsolved chemical problems and the chemistry remains in chemistry.

DETERMINATION OF URANIUM AT MICROGRAM LEVELS BY DERIVATIVE POLAROGRAPHY*

CLEMENS AUERBACH and GEORGE KISSEL
Brookhaven National Laboratory, Associated Universities, Inc
Upton, L.I, New York, U S A

(*Received* 19 *June* 1963 *Accepted* 4 *October* 1963)

Summary—The incremental method of derivative polarography has been applied to the low-level analysis of uranium in acetate-buffered EDTA electrolyte. Optimum conditions are shown for the rapid determination of $2 \times 10^{-6}M$ uranium in the presence of $0{\cdot}01M$ bismuth and of $5 \times 10^{-6}M$ uranium in the presence of $0{\cdot}01M$ molybdenum, with a precision $\leq 2\%$ and without prior separation Uranium in amounts $\leq 10\,\mu g$ may be detected in a 10^4-fold excess of bismuth. The method has been used successfully for the analysis of a bismuth alloy containing 0·1% of uranium.

URANYL ion is one of the few electroactive species which are only weakly complexed by ethylenediaminetetra-acetate (EDTA) and related chelating agents. This fact has prompted Přibil and Blažek,[1] in the course of systematic studies, to investigate the polarography of uranium in an EDTA-containing medium; procedures were reported for determining uranium in the presence of several elements whose half-wave potentials are markedly displaced towards negative values by virtue of chelation with EDTA. Davis[2] has made a more fundamental study of the uranyl-EDTA system. Conventional techniques were used in these earlier investigations and the various elements were present at comparable levels. Derivative polarography, on the other hand, with its enhanced sensitivity and resolving power, has proved ideally suited for the determination of minor constituents in the presence of a less easily reduced major constituent. It was felt, therefore, that derivative polarography in solutions containing EDTA could be made the basis of a simple and rapid analytical method for micro amounts of uranium in a variety of matrices, without prior separation. It is shown in the present paper that the incremental polarograph[3] may be used to determine less than $5 \times 10^{-6}M$ uranium in the presence of $0{\cdot}01M$ bismuth or molybdenum, with a precision $\leq \pm 2\%$. This application is typical of the analytical problems created by developments in nuclear technology.

EXPERIMENTAL

Apparatus

The incremental polarograph has been described in detail,[3] and shown to provide an excellent novel approach to derivative polarography. The present work was carried out using a modified version, which includes transistorised operational amplifiers (Philbrick P2) of exceptionally low inherent noise level and a timing section of greatly improved precision and versatility. The current amplifier provides sensitivities ranging from 0·25 to 50 μA full-scale, and the current differences stored in the memory capacitor can be amplified by factors ranging from 10 to 500. The modified instrument also incorporates optional circuitry for controlled-potential polarography,[4] involving the use of a three-electrode system.

---

* This work was performed under the auspices of the U.S Atomic Energy Commission.

In the present work, unless otherwise specified, the current was sampled during the period from 3 0 to 3 6 sec after drop fall (drop time *ca* 5-5 5 sec, m = 1 46 mg/sec). The voltage was scanned in 10-mV increments Polarograms were recorded by means of a Leeds and Northrup Speedomax recorder (Model G, 0 25-sec pen speed), using the duplex readout mode, which allows simultaneous recording of the current amplifier output over the sampling period and of the difference amplifier output corresponding to the end of the sampling period. This feature is of interest because it allows measurements, on the same polarogram of both the peak incremental response (*i e*, the slope of the current-voltage curve at the half-wave potential) and the instantaneous diffusion current, at the same instant in the drop life, the relationship between these quantities is useful either as a criterion of reversibility or as a means for determining *n* in reversible systems

Reagents

Stock solutions of uranyl perchlorate were prepared from U S Bureau of Standards U_3O_8 and standardised coulometrically Bismuth stock solutions were obtained by dissolving analytical reagent bismuth trioxide in excess nitric acid, and $(NH_4)_6Mo_7O_{24}$ $4H_2O$ served as a source of molybdenum. Solutions of EDTA were standardised titrimetrically against standard magnesium chloride Triple distilled mercury was passed through a nitric acid purification column before use.

Because of the necessity for minimising the level of copper impurities (*vide infra*), the available distilled water was purified further using a commercial distilling-refluxing unit

General procedure

The polarographic cell consisted of a jacketed beaker, placed on a triple shock mount and maintained at 25° by water from a circulating constant temperature bath. This was preferable to direct immersion in a water bath because it was found essential to minimise sources of electrical noise The cell was covered with a polyethylene stopper containing appropriate openings. Contact to the saturated calomel reference electrode was made through a fine porosity frit The three-electrode configuration, with a platinum spiral counter electrode, was used in most of the work, although *iR* corrections were, as expected, wholly negligible at concentrations less than $2 \times 10^{-4}M$. Oxygen was removed from the solutions with prepurified nitrogen which was bubbled through dilute vanadium[11] perchlorate.

Incipient maxima interfered with measurements of the peak incremental response even in $2 \times 10^{-5}M$ uranium solutions; thymol was therefore used at a concentration of 0 001%, which suppressed the maxima without producing distortion in the diffusion current region. Use of Triton X-100 cannot be recommended, despite its masking effect on the interfering copper wave[8] (*vide infra*), because it was found to attenuate the uranium wave markedly as well.

In order to minimise introduction of impurities, no effort was made to maintain the ionic strength constant by adding excess inert salt. The work was performed at ionic strengths varying from 0 1 to about 0·3, and it was ascertained that this variation had no noticeable effect on the behaviour of uranium. All EDTA concentrations quoted refer to the excess over the stoichiometric amount required by the metal ion(s) present Potentials are referred to the saturated calomel electrode.

RESULTS AND DISCUSSION

Uranium alone

Some of the interesting aspects of the polarography of uranyl-EDTA complexes have been discussed by Davis,[2] who worked in a self-buffered 0·1*M* EDTA-1*M* sodium perchlorate supporting electrolyte. He obtained a single wave, the shape of which points to a reversible *one-electron* reduction. His results in a weakly acidic medium, however, led to diffusion current constant values substantially larger than would be expected on this basis, and he also found that massive reduction at a mercury pool proceeds by a *two-electron* step, *i.e.*, to uranium^{IV}. We have observed similar behaviour in a supporting electrolyte consisting of either 0·001*M* or 0·01*M* excess EDTA and 0·1*M* acetic acid—0·1*M* sodium acetate buffer (referred to hereafter as "0·1*M* acetate buffer"). In fact, the presence of acetate buffer was found to enhance the diffusion current constant still further. This is shown in Table I; the diffusion current constants, *I*, were calculated from instantaneous diffusion currents, i_d, corresponding to time t (the end of the sampling period), and converted to average values

$$I = \frac{\frac{6}{7} i_d}{Cm^{2/3}t^{1/6}}.$$

From an analytical viewpoint, a medium containing 0·1M acetate buffer provides an appreciable gain over the sensitivity attainable with EDTA alone, and it was used throughout most of this work. The half-wave potentials of uranium under these conditions are —0·30 V and —0·31 V in 0·01M and 0·001M excess EDTA, respectively. Indications are that the slight negative shift is caused by competing acetate complexation at the lower EDTA concentration. Further work is in progress on the significance of these findings.

The relationship between peak incremental response and concentration was found to be linear over a range of uranium concentrations from 5 × $10^{-6}M$ to 8 × $10^{-4}M$, the slope being (0·47 ± 0·01) μA/mM per 10-mV step. Within this range, concentrations were determined with a precision of ±1%. Below 5 × $10^{-6}M$ the presence of copper impurities in the water interfered to a degree with the quantitative determination of uranium, although concentrations as low as 1 × $10^{-6}M$ could be detected. Copper forms an EDTA complex which is reversibly reduced to the metal;[6] thus, copper peaks were observed in the supporting electrolyte at —0·24 V and —0·27 V, respectively, with 0·001M and 0·01M EDTA. Regular distilled water proved entirely inadequate for work below 2 × $10^{-5}M$ uranium. Even by using redistilled water it was impossible to reduce the height of the residual copper peak beyond a value about 40% in excess of the base line level (0·0015–0·002 μA per 10-mV step[8]). This corresponds to an estimated decrease in copper concentration from 5 × $10^{-6}M$ to 8 × $10^{-7}M$. The limitation introduced by residual copper is illustrated in Fig. 1. In 0·001M EDTA, where the half-wave potentials differ by 0·07 V, an indication of a copper shoulder can be seen on the ascending edge of the uranium peak, producing slight asymmetry. In 0·01M EDTA, however, the half-wave potentials are separated by only 0·03 V; here the waves essentially overlap, and copper definitely contributes to the uranium peak height. It should be noted that the 0·03 V separation in half-wave potentials produces a shift of the observed peak from —0·30 V towards —0·27 V as the uranium concentration approaches the residual copper level; errors will result under such conditions if the incremental response is measured at the composite peak location rather than at the true half-wave potential as established at higher concentrations.

Uranium-bismuth and uranium-molybdenum-mixtures

Fig. 2 shows a polarogram of a solution containing $1 \times 10^{-4} M$ each of uranium and of bismuth in the EDTA electrolyte. The bismuth wave is seen to be composed of two separate waves under these conditions; the same behaviour was observed with $1 \times 10^{-3} M$ bismuth. It may be noted that, although the bismuth-EDTA complex is known to be reduced irreversibly,[7] the existence of two nearly overlapping waves of this type can only be established by a derivative technique. Neither location nor height of the uranium peak, however, were affected by the presence of bismuth, and the separation between the uranium half-wave potential and the first bismuth peak is more than 0·2 V. The irreversible nature of the bismuth wave makes quantitative calculations difficult, but it is apparent that large bismuth/uranium ratios can be tolerated without causing appreciable interference with the uranium peak. Fig. 3 illustrates the polarographic behaviour of a solution containing $1 \times 10^{-5} M$ uranium in the presence of 0·01M bismuth and 0·01M excess EDTA. Excellent resolution is achieved between the uranium peak and the ascending edge of the bismuth wave. The resolution is slightly less satisfactory with 0·001M EDTA, where the uranium half-wave potential is 0·01 V more negative. No further improvement was noted at EDTA concentrations higher than 0·01M in either the presence or absence of acetate buffer.

Curve (A) in Fig. 3 shows the extent of interference of the aforementioned residual copper wave. In the presence of 0·01M bismuth the copper wave was found to behave irreversibly; the copper peak was displaced to —0·29 V, *i.e.*, to within 0·01 V of the uranium peak, and its location became independent of the excess EDTA concentration. This observation was not investigated further at this time; however, the effect facilitates low-level uranium analysis, as does the relatively flat region beyond the

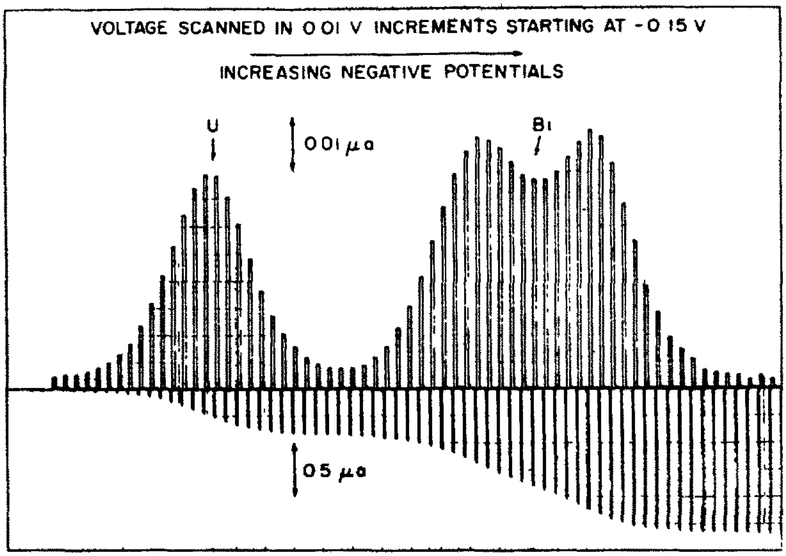

FIG. 2.—Polarogram of a Uranium-Bismuth Mixture (0·82 × 10^{-4}*M* U, 1 × 10^{-4}*M* Bi; 0·01*M* EDTA, 0·1*M* CH_3COOH–0·1*M* CH_3COO Na, 0·001% thymol)

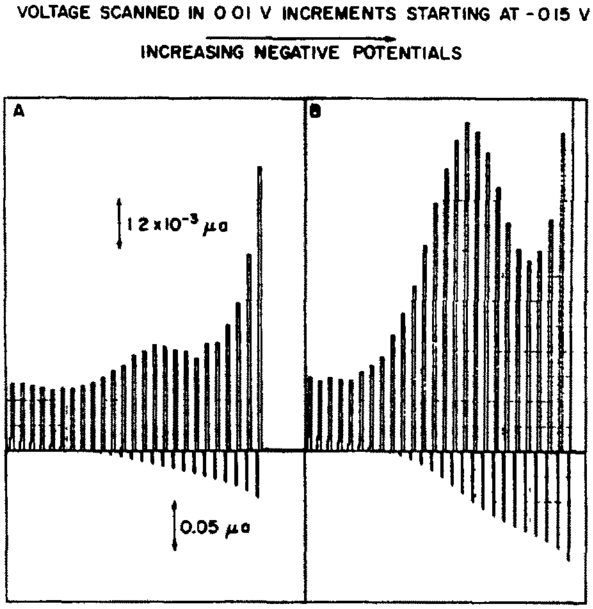

FIG. 3.—Polarogram of Uranium in Presence of Excess Bismuth:

0·1*M* CH_3COOH–0·1 *M* CH_3COONa, 0·001% thymol
(B) Same, plus 1 × 10^{-5}*M* U.

copper peak, caused by the onset of the bismuth wave Thus, $2 \times 10^{-6}M$ uranium in $0{\cdot}01M$ bismuth could be determined with a precision of ±1%, and $1 \times 10^{-6}M$ uranium (corresponding to a 25% increase over the residual copper peak) could easily be detected. Linearity of the peak incremental response, to within ±2%, was established over the $2 \times 10^{-6}M - 1 \times 10^{-4}M$ concentration range, the slope was found to be *ca.* 7% lower than in the absence of bismuth

Molybdenum in the same supporting electrolyte was found to give two fairly well-resolved peaks, between −0·55 V and −0·75 V. This observation basically confirms the findings of Pecsok and Sawyer,[8] and again serves to demonstrate the utility of the incremental approach in analysing complex waves. The presence of $10^{-5}M$ molybdenum did not affect either location or height of the uranium peak. Molybdenum at a concentration of $10^{-2}M$, however, caused difficulties because of the onset of a drawn out wave at −0·26 V, *i.e.*, 0·04 V more positive than the uranium peak. The situation could be improved by increasing the excess EDTA concentration to $0{\cdot}05M$ ($0{\cdot}1M$ acetate buffer), thereby shifting the onset of the molybdenum wave to −0·33 V. Under these conditions $5 \times 10^{-6}M$ uranium could be determined in the presence of $10^{-2}M$ molybdenum with ±2% precision, using the peak observed at −0·31 to −0·32 V; this corresponded to a 50% increase over the residual response. Linearity was established up to $1 \times 10^{-4}M$ uranium, with a slope of 0·42 μA/mM, *i.e.*, 10% lower than for uranium alone.

Practical application

To test the practical utility of the technique described, uranium was determined in an alloy containing more than 99·8% bismuth. This material has been studied extensively as a potential liquid homogeneous reactor fuel. It also contains 0·035% of zirconium, 0·025% of magnesium and smaller traces of steel corrosion products. The following procedure was employed:

Dissolve a 6 to 8-g sample in excess nitric acid Transfer the solution to a 200-ml volumetric flask and make up to volume. The final solution should contain *ca.* $1M$ nitric acid to prevent hydrolysis of bismuth on standing Transfer a 5·0-ml aliquot to a 100-ml volumetric flask containing 10 ml of $1M$ acetate buffer. Add enough $1M$ sodium hydroxide to neutralise excess nitric acid. Add 10 ml of $0{\cdot}10M$ EDTA *in excess* over the amount required (*ca.* 10 ml) to dissolve the precipitate formed in the neutralisation step. Add 0·5 ml of 0·2% alcoholic thymol solution and dilute to the mark The final pH should be 4·6 ± 0·1 Transfer a portion to the polarographic cell, de-aerate and obtain the incremental polarogram. Measure the incremental response at −0·30 V *vs.* S.C.E Calculate the uranium concentration with the aid of a blank and appropriate uranium standards, both containing the same concentrations of bismuth, EDTA and buffer as the sample. Double or triple distilled water should be used for both preparation of reagents and all other operations.

Four separate portions of an alloy of this type (kindly provided by Dr. J. R. Weeks) were analysed by the above procedure, yielding 0·096% of uranium with an average deviation of ±2%. A modified version of the spectrophotometric dibenzoylmethane method[9] gave 0·102%, with comparable precision. It should be noted that the spectrophotometric procedure includes a preliminary extraction step. By contrast, the present method involves only the most elementary chemical steps; it is therefore easily applicable to a highly radioactive material, as would be exemplified by the above prospective reactor fuel.

In conclusion, it is shown that the incremental technique of derivative polarography can be applied to rapid and precise low-level uranium analysis in systems of high electrochemical complexity, without the need for prior separations.

Zusammenfassung—Die Methode der Inkremente in der Derivativpolarographie wurde auf die Bestimmung geringer Uranmengen in acetatgepuffertem EDTA-Elektrolyten angewandt. Die optimalen Bedingungen fur die Schnellbestimmung von 2 10^{-6}m Uran neben 0,01m Wismut und 5 10^{-6}m Uran neben 0,01m Molybdan werden angegeben Die Genauigkeit ist besser als 2%, vorherige Abtrennung nicht notwendig Uranmengen unter 10 μg lassen sich neben der 10^4-fachen Menge Bi nachweisen. Die Methode wurde mit Erfolg auf die Analyse einer 0,1% U enthaltenden Wismutlegierung angewandt

Résumé—La méthode à incréments de la polarographie dérivée a été appliquée à l'analyse de traces d'uranium dans un électrolyte constitué par de l'EDTA tamponné par de l'acétate. Les conditions optimales sont indiquées pour la détermination rapide d'uranium 2 . 10^{-6} M en présence de bismuth 0,01 M et d'uranium 5 . 10^{-6} M en présence de molybdène 0,01 M avec une précision <2% et sans séparation préalable. L'uranium en quantité inférieure ou égale à 10 μg peut être détecté dans un excès de 10^4 de bismuth La méthode a été utilisée avec de bons résultats dans le cas de l'analyse d'un alliage de bismuth contenant 0,1% d'uranium

PROPERTIES OF BASES IN ACETONITRILE AS SOLVENT—III*

HYDROGEN BONDING BETWEEN PROTONATED AND FREE NITROGEN BASES

J. F. COETZEE® and G. R. PADMANABHAN with G. P. CUNNINGHAM
Department of Chemistry, University of Pittsburgh,
Pittsburgh 13, Pennsylvania, U.S.A.

(*Received* 19 *June* 1963. *Accepted* 4 *October* 1963)

Summary—In acetonitrile as solvent, the stronger nitrogen bases, *B*, form 1:1 and also higher hydrogen-bonded complexes with their conjugate acids, BH^+. Formation constants for these complexes have been determined by glass-electrode measurements in buffer solutions consisting of a constant concentration of the perchlorate or picrate of the base and varying concentrations of free base. The results show that the degree of complexation increases with increasing strength of the base and increasing number of hydrogen atoms in the ammonium group of the conjugate acid, and also that it has severe steric requirements, as expected. Thus, complexation is most extensive for the lower aliphatic primary amines and aliphatic cyclic secondary amines, such as piperidine, and does not occur with non-cyclic tertiary amines, except trimethylamine. The significance of these complexation reactions in potentiometric and conductimetric titrations and in studies concerned with the relative strength of bases is discussed.

INTRODUCTION

NON-AQUEOUS solvents have been used extensively in acid-base titrations, mainly in those cases where replacement of water by another solvent results in a desirable increase in solubility of the (organic) solutes, or improved sensitivity of the titration, or better differentiation of the components of mixtures, or where the use of a non-aqueous solvent avoids undesirable hydrolytic reactions. The subject has been thoroughly reviewed on several occasions by Riddick, and recently by Streuli.[1]

In the majority of cases the selection of solvent and titrant involved largely an empirical procedure of trial and error, because little theoretical information was available about the exact nature of the various solute species present and their interactions in these solvents. However, in recent years there has been an increasing interest in the theoretical aspects of acid-base reactions in non-aqueous solvents, particularly in solvents such as acetic acid and ethylenediamine, and in non-hydrogen bonding solvents of intermediate dielectric constant, such as the nitriles. Evidence is accumulating that probably no solvent is truly inert, and non-aqueous solvents provide a broad spectrum of conditions over which such solute-solvent interactions can be studied. However, certain non-aqueous solvents are much more inert in particular respects than water, and therefore provide suitable media for the investigation of the more subtle intrinsic properties of solutes, which are masked in water. Acetonitrile is such a solvent. It is a weaker base and a much weaker acid than water,

---

* Part II: see reference 2.

and its dielectric constant is lower (36·0, as compared to 78·5 for water). The cumulative effect of these three factors is that acetonitrile is a much more differentiating solvent than water, as is reflected by its much smaller autoprotolysis constant (3×10^{-27}, as compared to 1×10^{-14} for water[2]). Nevertheless, the dielectric constant of acetonitrile is sufficiently high to allow extensive electrolytic dissociation of ionic solutes and to permit the study of such solutions by conductimetry and other electrometric methods.

An important consequence of the extremely weak acidic (hydrogen bonding) properties of acetonitrile is the fact that in solutions of many weak Brönsted acids, HA, the anions, A^-, are not stabilised sufficiently by solvation (which for the majority of anions must occur mainly by hydrogen bonding) and therefore resort to hydrogen bonding with undissociated acid instead, producing complexes such as $A^- \ldots HA$. Naturally, if such complexation reactions occur, the treatment of data obtained with hydrogen ion indicator electrodes, and by methods involving conductimetry, spectrophotometry, *etc.*, will be more complex than for the same solutes in water. The complexation reactions of Brönsted acids in acetonitrile have been studied thoroughly by Kolthoff and his coworkers.[3]

Analogous hydrogen bonded complexes between free and protonated amine-type bases are also produced in acetonitrile, although not to the same extent as for Brönsted acids. Nevertheless, some of these complexes are sufficiently stable to be important in acid-base titrations and particularly in theoretical studies concerned with the relative strength of bases. This communication is concerned with the formation of such complexes.

EXPERIMENTAL

Apparatus

Electromotive force measurements were made with a Beckman Model G pH meter and an *H*-type cell containing a Beckman "general purpose" No. 1190-80 glass electrode in conjunction with an Ag/(0 010*M* $AgNO_3$ in acetonitrile) reference electrode, and with 0·1*M* tetra-ethylammonium perchlorate in acetonitrile as salt bridge. This apparatus has been described elsewhere.[2]

Reagents

Technical grade acetonitrile (from two sources, Matheson and Sohio) was purified by a sequence of operations described before,[4] including fractional distillation, first from phosphorus pentoxide and then from calcium hydride.

The bases used were generally purified by distillation from sodium hydroxide and sodium metal (under reduced pressure for high-boiling bases). Full details will be presented elsewhere.[5] Boiling points agreed with literature values.

The perchlorates and picrates of the bases studied were generally prepared by potentiometric titration with the appropriate acid to the equivalence point (glass electrode) in water or ethanol as solvent, followed by evaporation of the solvent if necessary, and recrystallisation of the product from ethanol, isopropanol or ethyl acetate. Again, detailed information will be given elsewhere.[5]

RESULTS AND DISCUSSION

Cells containing glass electrodes in acetonitrile give a reversible response, provided the solutions are adequately buffered, a proper reference electrode is used, and liquid junction potentials are controlled, as described before.[2] For each base (B) studied, we have measured the potential of a glass electrode in a series of 8 to 14 buffer solutions consisting of a constant concentration ($C_s = 5 \times 10^{-4}M$) of the perchlorate or picrate of the base and varying concentrations (C_b) of free base. The salt concentration was deliberately kept low to minimise activity effects, changes in liquid junction potential and complications from $BH^+ClO_4^-$ and BH^+Pi^- ion pair formation, even though a higher concentration of salt would facilitate (qualitative) detection of B·BH$^+$ and higher complexes.

For the dissociation of a protonated amine in a solvent *S* which has some proton acceptor power, the following equilibrium relationships apply:

$$\mathrm{BH^+_{solvated}} + \mathrm{S} \rightleftharpoons \mathrm{SH^+_{solvated}} + \mathrm{B_{solvated(?)}}$$

$$K_a = a_{SH^+} \cdot \frac{[B]}{[BH^+]} \cdot \frac{f_B}{f_{BH^+}}$$

where K$_a$ is the thermodynamic dissociation constant of *BH*$^+$, and [X] denotes the molar concentration, a_X the activity and f_X the molar activity coefficient of species *X*. At constant ionic strength, f_B/f_{BH^+} is constant, so that

$$\frac{[B]}{[BH^+]} = \frac{\text{constant} \times K_a}{a_{SH^+}}.$$

If the electrode responds reversibly to a_{SH^+}, it follows from the Nernst equation that a plot of *E vs.* log ([B]/[BH$^+$]) or *vs.* log [B] at constant [BH$^+$], will be linear with a slope of 59 mV at 25°. If no complexation occurs between *B* and *BH*$^+$ and if the degree of dissociation of *BH*$^+$ is negligible compared to unity (as it is in all cases studied), [B] and [BH$^+$] are given by the total (analytical) concentrations C_b and C_s, respectively. However, if some *BHB*$^+$ formation occurs, it follows that

$$[B] = C_b - [BHB^+]$$

and

$$[BH^+] = C_s - [BHB^+]$$

so that a plot of *E vs.* log (C_b/C_s) will deviate from linearity. In the limiting case where formation of *BHB*$^+$ is virtually complete over the range of base concentrations studied, the plot will again be linear, but now with a slope of 118 mV.

In all cases formation constants of B·BH$^+$ and B$_2$·BH$^+$ complexes were evaluated from *E vs.* log (C_b/C_s) plots, such as those given in Figs. 1–4. In a relatively ideal case, such as that of piperidine (Fig. 2), only one complex (*BHB*$^+$) is produced and, furthermore, formation of this complex is virtually complete over a wide range of free base concentrations, so that calculation of the formation constant is straightforward. However, with the majority of bases studied the situation is more complicated, because either the species *BHB*$^+$ is insufficiently stable to be formed virtually exclusively even at the highest base concentrations studied (see below, pyridine), or else higher complexes such as B$_2$·BH$^+$ (Fig. 1, n-butylamine) and even B$_4$·BH$^+$ (Fig. 3, hydrazine) also are produced.

As an illustration of the calculations carried out, the case of pyridine will be considered. Pyridine forms a relatively weak complex B·BH$^+$, and gives no evidence of forming higher complexes. Experimental data are given in Table I. For the last measurement listed, it follows from the Nernst equation that

$$\log \frac{0{\cdot}812 - x}{5 \times 10^{-4} - x} - \log \frac{0{\cdot}812}{5 \times 10^{-4}} = \frac{39}{59} = \log 4{\cdot}58$$

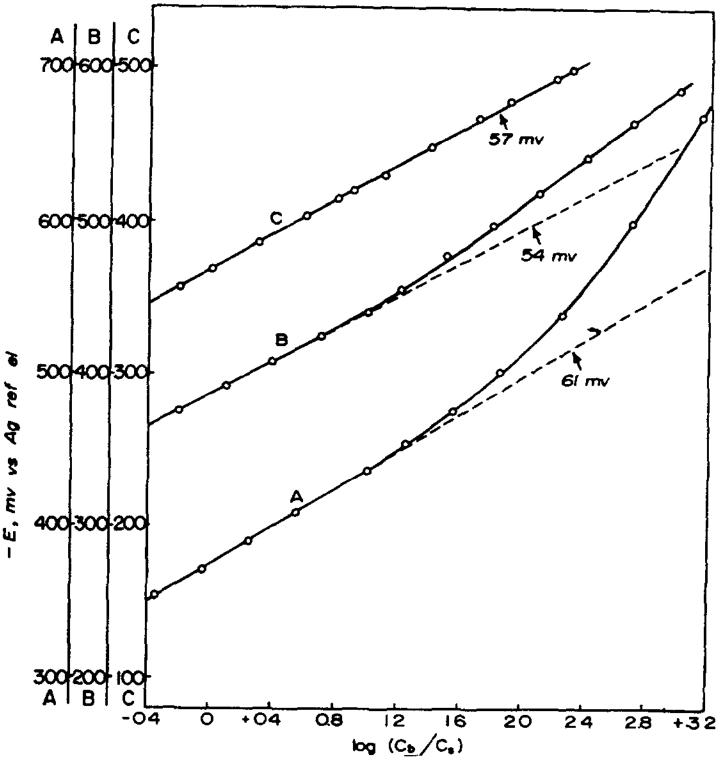

Fig. 1.—Potential of glass electrode in buffer solutions of n-butylamines and their perchlorates at a constant salt concentration of $5 \times 10^{-4}M$. (*A*) n-Butylamine, (*B*) Di-n-butylamine, (*C*) Tri-n-butylamine.

where x represents the molar concentration of the BHB^+ complex. Hence,

$$\frac{0{\cdot}812 - x}{5 \times 10^{-4} - x} = 1624 \times 4{\cdot}58 = 7{\cdot}44 \times 10^3$$

so that

$$x = [BHB^+] = 3{\cdot}91 \times 10^{-4}$$

and

$$[BH^+] = 5{\cdot}00 \times 10^{-4} - 3{\cdot}91 \times 10^{-4} = 1{\cdot}09 \times 10^{-4}.$$

Hence,

$$K = \frac{[BHB^+]}{[B][BH^+]} = \frac{3{\cdot}91 \times 10^{-4}}{0{\cdot}812 \times 1{\cdot}09 \times 10^{-4}} = 4{\cdot}4.$$

Considering a more complicated example, that of n-butylamine, similar calculations give values of K that increase with increasing concentration of base: $K = 26{\cdot}3$, $25{\cdot}4$, $32{\cdot}2$, $41{\cdot}6$ and $70{\cdot}4$ for $C_b = 0{\cdot}0174, 0{\cdot}0348, 0{\cdot}087, 0{\cdot}261$ and $0{\cdot}696M$, respectively. It is clear that (weak) higher complexes also are formed. In such cases the stepwise constants were computed by a series of approximations. For example, assuming as a first approximation that for n-butylamine $K_1 = 26$, it follows for the last measurement listed ($C_b = 0{\cdot}696M$) that

$$[B{\cdot}BH^+] = 26\,[B][BH^+].$$

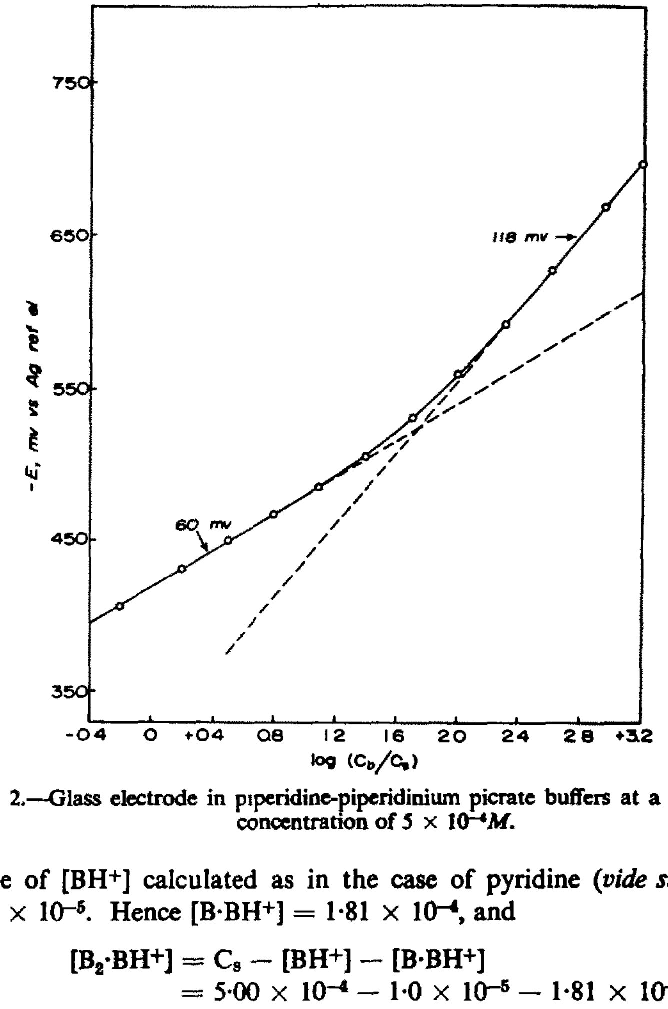

FIG 2.—Glass electrode in piperidine-piperidinium picrate buffers at a constant salt concentration of 5 × $10^{-4}M$.

The value of $[BH^+]$ calculated as in the case of pyridine (*vide supra*) was found to be 1·0 × 10^{-5}. Hence $[B{\cdot}BH^+] = 1{\cdot}81 \times 10^{-4}$, and

$$\begin{aligned}[B_2{\cdot}BH^+] &= C_s - [BH^+] - [B{\cdot}BH^+]\\ &= 5{\cdot}00 \times 10^{-4} - 1{\cdot}0 \times 10^{-5} - 1{\cdot}81 \times 10^{-4}\\ &= 3{\cdot}09 \times 10^{-4}\end{aligned}$$

so that

$$K_2 = \frac{[B_2{\cdot}BH^+]}{[B][B{\cdot}BH^+]} = \frac{3{\cdot}09 \times 10^{-4}}{0{\cdot}696 \times 1{\cdot}81 \times 10^{-4}} = 2{\cdot}5.$$

Similar calculations are carried out for all other points where formation of $B_2{\cdot}BH^+$ is apparent. For $C_b = 0{\cdot}261$ and 0·087, $K_2 = 2{\cdot}3$ and 2·7, respectively. The average value of K_2 (2·5) is then used to correct all preliminary values of K_1, which yields even for the last 3 measurements listed above a reasonably constant value of $K_1 = 26{\cdot}6$, 25·8 and 26·3, respectively. For cases where it was necessary, this sequence of calculations was repeated until (self-consistent) constant values of K_1 and K_2 were obtained. In the case of hydrazine (Fig. 3), where even higher complexes are also formed, an approximate value of K_2 was obtained by using the data for intermediate concentrations of base. Evaluation of K_3 and K_4 for hydrazine is too uncertain to be reported. More precise e.m.f. measurements (perhaps with a vibrating-reed electrometer as null detector) would be required for this purpose.

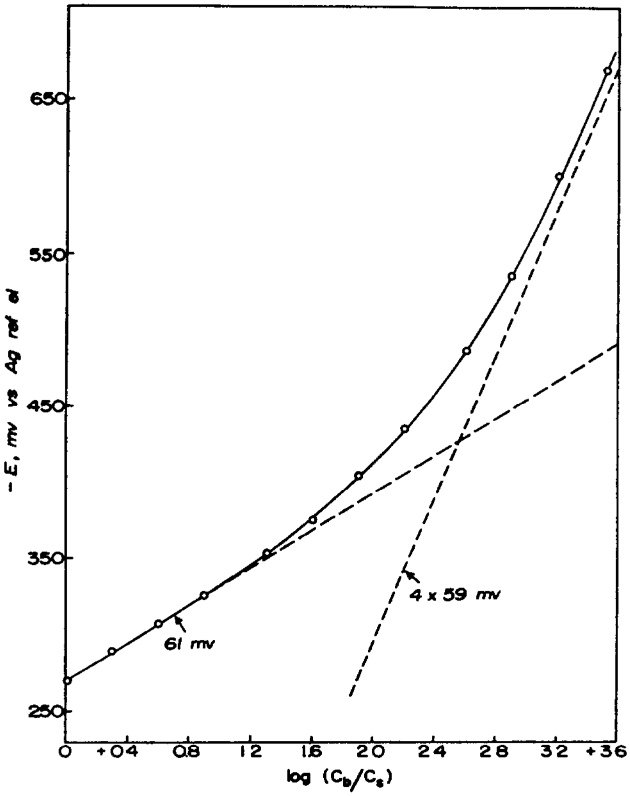

FIG. 3.—Glass electrode in hydrazine-hydrazonium monoperchlorate buffers at a constant salt concentration of 5 × $10^{-4}M$.

Formation constants for the complexes produced by a variety of nitrogen bases in acetonitrile as solvent are reported in Table II.

The main features of the results listed in Table II and in Figs. 1–4 are the following.

A. Non-cyclic aliphatic amines

1. The tendency of these amines to form 1:1 hydrogen bonded complexes, BHB^+, increases in the order tertiary, secondary, primary.

2. The tendency of the same amines to form higher complexes increases in the same order. Furthermore, it is to be expected that the highest complex that can be formed in any given case will be the species $B_n \cdot BH^+$, where n is the number of hydrogen atoms in the ammonium group and therefore represents the maximum number of hydrogen bonds that can be formed. The results are in agreement with this requirement.

3. However, steric factors are very important, as is most apparent from the behaviour of tertiary amines. Thus, while trimethylamine does form a 1:1 complex, triethylamine and its higher homologues form none. Similarly, the higher non-cyclic secondary amines do not form complexes.

B. Aromatic and cyclic aliphatic amines

1. The strength of the complex formed increases with increasing strength of the base. Thus, the relatively weak primary amines aniline and *p*-toluidine do not form

* Range over which total added base concentration was varied, while keeping salt concentration constant (at $5 \times 10^{-4}M$, except where indicated otherwise).

† K_1 and K_2 are stepwise formation constants:

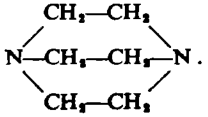
$$K_1 = \frac{[BHB^+]}{[B][BH^+]} \quad \text{and} \quad K_2 = \frac{[B_2BH^+]}{[B][BHB^+]}.$$

For diamines, the data refer to monoprotic species only.

‡ Salt concentration $= 5 \times 10^{-2}M$.

§ Higher complexes, up to $B_4.BH^+$, also formed. Value of K_2 uncertain.

¶ Triethylenediamine:



complexes, while pyridine and especially benzylamine (Fig. 4) do. A similar correlation between the base strength and hydrogen bonding ability (acceptors: chloroform and methanol) has been observed with pyridines in the pure bases as solvent.[6]

2. The cyclic amines pyrrolidine and piperidine form complexes that are much more stable than those of the corresponding non-cyclic secondary amines. Similarly

the cyclic tertiary amine triethylenediamine (Table II) and even the relatively weak base pyridine form 1:1 complexes. Clearly, in these cases steric hindrance is less marked than for the corresponding non-cyclic amines.

C. Other generalisations

1. For the diamines, $H_2N{\cdot}(CH_2)_n{\cdot}NH_2$, *BHB*$^+$ formation decreases as *n* increases from 2 to 4, even though the base strength *increases* in this sequence (in both water and acetonitrile). In the cases where $n = 3$ and 4 internal hydrogen bonding (N—H . . . N) may stabilise the cation, thereby reducing its desire to form hydrogen bonds with free base. The diamines are an interesting series of compounds, exhibiting quite different relationships between hydrazine and the remaining members in acetonitrile and in water. These differences will be discussed elsewhere.[5]

2. Generally, the slopes of the *E vs.* log (C_b/C_s) plots in the early region, before complexation becomes significant, were within 1 or 2 mV from the theoretical value of 59 mV. However, in the case of di-n-butylamine (Fig. 1) the slope was considerably less (average of 4 series of measurements = 54 mV). The reason for this behaviour is unknown. In the case of aniline in picrate buffers (Fig. 4) there is marked curvature in the initial region of the plot. This is because of reversion of the salt to the weak parent acid and base:

$$BH^+ + Pi^- \rightleftharpoons B + HPi.$$

Titration curves

The complexation reactions of nitrogen bases in acetonitrile not only are interesting *per se*, but are also important in the interpretation of acid-base titration curves. Clearly, in the titration of an amine with perchloric acid the largest effect of complexation will occur in the early stages of the titration, and again just before the equivalence point, where either the base or the salt is in considerable excess over its conjugate species. It can be shown readily that complexation should result in a decrease of the buffer capacity of the solution and a reduction in the break at the equivalence point of a potentiometric titration. These generalisations were verified experimentally. For example, in a titration of 0·1*M* pyrrolidine in acetonitrile with 0·5*M* perchloric acid dissolved in methylene chloride the potential of the glass electrode deviated from the hypothetical values calculated from the dissociation constant of pyrrolidinium ion in acetonitrile[5] on the assumption that no complexation, no ion pair formation and no interference by methylene chloride occurs, by −12, −5, +6 and +10 mV at 10, 30, 70 and 90% titrated, respectively, where negative values indicate that the solution is more basic than the hypothetical value, and *vice versa*. The formation constants reported for pyrrolidine (Table II) account for the major part of this variation.

The influence of complexation on the titration curves of amines with *weak* acids is more striking. Fig. 5 gives the conductimetric titration curves of n-butylamine with salicylic acid. The pronounced curvature before the equivalence point is from the *BHB*$^+$ complex (*BH*$^+$*A*$^-$ ion pair formation is also important), and that after the equivalence point from the *AHA*$^-$ complex (studied in detail for similar systems by Kolthoff and Chantooni[8]). In a masking solvent, such as water, the two branches of the curve are virtually linear, and the section after the equivalence point is nearly horizontal. We will discuss elsewhere the conductimetric titration curves of a variety of amines with *ortho*-substituted benzoic acids.

CONCLUSIONS

It has been shown that many of the stronger amines, particularly aliphatic primary and cyclic secondary amines, form hydrogen-bonded complexes with their conjugate acids in acetonitrile as solvent. One may speculate that this behaviour is likely to be the norm, rather than the exception, in the majority of solvents which have very weak-base properties. A formation constant near 30, which is typical for a number of these bases in acetonitrile, corresponds to a free energy of formation given by

$$\Delta F = -10^{-3}\,RT \ln K = -10^{-3} \times 2{\cdot}0 \times 298 \times 2{\cdot}3 \times 1{\cdot}48 = -2{\cdot}0 \text{ kcal/mole.}$$

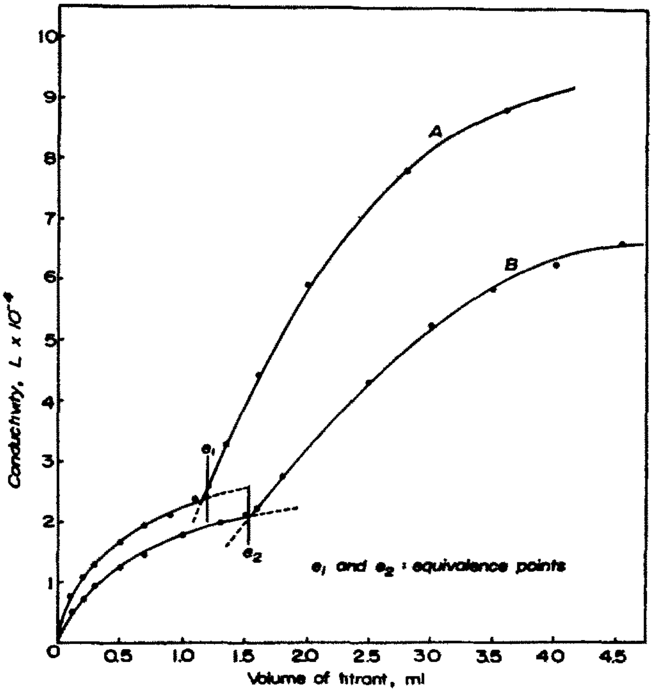


FIG. 5.—Conductimetric titration of n-butylamine with salicylic acid:
(*A*) 0·0287*M* base with 0 478*M* acid,
(*B*) 0·0191*M* base with 0 249*M* acid.

The corresponding complexes, AHA^-, formed between a number of Brönsted acids and their anions[3] are more stable, with formation constants ranging up to 10^3, corresponding to $\Delta F = -4$ kcal/mole. This difference reflects the fact that acetonitrile is more reluctant to solvate anions than cations, as compared to analogous solvation by water.

It is necessary to consider the possible formation of BHB^+ complexes in any exact determination of the relative strength of amines (with the proton as reference acid) in acetonitrile and similar solvents. If the potential of a hydrogen-ion indicator electrode at the "half-neutralisation" point in the titration of an amine with a relatively strong acid is regarded as an index of the strength of the base,[7] an error will be introduced if complexes higher than the 1:1 species are produced. We have determined the pK_a values of a series of nitrogen bases in acetonitrile by measurements similar to those described in this communication, but with provisions to maintain the absolute value of the net liquid junction potential constant for the entire series, and by making due allowance for complexation reactions. The results will be presented elsewhere.[5]

Acknowledgments—We thank the National Science Foundation for financial support under grant number NSF-G14502. We also wish to express our indebtedness to Professor Kolthoff, whose classical investigations of many facets of the chemistry of non-aqueous solutions have created widespread interest in this field.

Zusammenfassung—In Acetonitril als Lösungsmittel bilden stärkere Stickstoffbasen *B* mit einem oder mehreren Molekülen ihrer konjugierten Säuren BH^+ Wasserstoffbrückenkomplexe. Bildungskonstanten solcher Komplexe wurden durch Messungen mit Glaselektroden in Pufferlösungen aus konstanten Mengen des Perchlorats oder Pikrats der Base und variablen Mengen der freien Base bestimmt. Die Ergebnisse zeigen, daß der Komplexbildungsgrad mit steigender Basenstärke und steigender Anzahl von Wasserstoffatomen in der Ammoniumgruppe der konjugierten Säure wächst. Ferner sind erwartungsgemäß strenge sterische Bedingungen zu erfüllen. So ist die Komplexbildung am stärksten bei den niedrigen aliphatischen primären und den cyclischen sekundären Aminen wie Piperidin und bleibt bei nichtcyclischen tertiären Aminen außer Trimethylamin überhaupt aus. Die Bedeutung dieser Komplexbildungsreaktionen bei potentiometrischen und konduktometrischen Titrationen und bei Untersuchungen über die relative Stärke von Basen wird diskutiert.

Résumé—Dans l'acétonitrile, les bases fortes azotées, B, forme des complexes 1/1 et plus élevée par liaison hydrogène avec leurs acides conjugués BH^+. Les constantes de formation des ces complexes ont été déterminées par mesure au moyen d'électrode de verre en solution tamponnées constituées par un perchlorate ou un picrate de la base étudiée en concentration constante et en présence de concentrations variables de base libre. Les résultats montrent que le taux de complexation augmente avec l'accroissement de la force de la base et avec le nombre d'atomes d'hydrogène du groupement ammonium dans l'acide conjugué, et également que les impératifs stériques jouent un grand rôle, comme il faut s'y attendre. Ainsi, la formation de complexe est plus accentuée pour les amines aliphatiques primaires légères et les amines secondaires aliphatiques cycliques, comme la pipéridine, et n'apparaît pas avec les amines tertiaires non-cycliques, excepté la triméthylamine. Discussion de la signification de ces réactions de formation de complexes dans les dosages par potentiométrie et conductimétrie et dans les études relatives aux diverses forces de ces bases.

A.C. POLAROGRAPHIC STUDIES ON THE INFLUENCE OF TENSAMMETRIC WAVES ON REDUCTION PEAKS OF INORGANIC CATIONS AND *VICE VERSA*

S. L. GUPTA and S. K. SHARMA
(Department of Chemistry, Birla College, Pilani, Rajasthan, India)

(*Received* 19 *June* 1963 *Accepted* 10 *October* 1963)

Summary—This investigation deals with the studies on the effect of the nature and concentration of surface active substances (s.a.s) on the a c. reduction peaks of Cd^{2+} and Zn^{2+} ions and *vice-versa* by a.c. polarography. The magnitude of the reduction peak is not influenced up to a certain concentration of the s.a.s., but with concentrations higher than this, the magnitude of the reduction peak progressively decreases; a concentration of 1·3% of n-amyl alcohol completely removes the $10^{-3}M$ Cd^{2+} peak. Neither magnitude nor the peak potential of the tensammetric peak of n-amyl alcohol are influenced by the presence of Cd^{2+} ions. There is a linear relation between the concentration of the electroactive species and the optimum concentration of the s.a.s., and also the concentration of the s.a.s. just required to remove the reduction peak. These observations are further supported by the curve which gives the linear relation between the concentration of the electroactive species and the amount of the s.a.s. required to reduce the magnitude of the reduction peak to half its value. The amount of the surfactants required to remove the reduction peak completely is in the order n-amyl alcohol > Cerfak [sodium napthalene (2-dodecyl)3-sulphonate] > cetylpyridinium bromide. These results are discussed.

INTRODUCTION

SURFACE active substances usually employed to eliminate maxima on polarographic waves often cause undesirable effects such as suppression of a diffusion current, shift of a half-wave potential, splitting of a wave into two or more waves; in some cases the entire wave is obliterated, or a combination of these effects occurs. Breyer and Hacobian[1] studied the influence of tensammetric waves on a.c. and d.c. polarography. They showed, however, that in the presence of cyclohexanol the discharge of Cd^{2+} ions was rendered irreversible, as shown by the absence of an a.c. polarogram, only the tensammetric wave of cyclohexanol appearing. In contradistinction to Cd^{2+} the discharge of Mn^{2+} (−1·5v *vs.* S.C.E.) was completely unaffected by the presence of cyclohexanol.

The purpose of the present investigation was to study in detail the effect of the nature and concentration of surface active substances, *viz.*, n-amyl alcohol, Cerfak [sodium napthalene(2-dodecycl)3-sulphonate] and cetylpyridinium bromide, on the a.c. reduction peaks of Cd^{2+} and Zn^{2+} ions and *vice versa*. It is also to be seen if there is a possible correlation between the optimum concentration of the surface active substance and the amount of reducible species before any of the above undesirable effects are operative was also sought. This would be of great significance in removing polarographic maxima in d.c. polarography.

EXPERIMENTAL

Reagents

Cadmium sulphate and *zinc sulphate* used as reducible species were AnalaR quality (B.D.H.) *Normal amyl alcohol* of "Baker analysed reagent grade" was used as non-ionic surface active substance Pure samples of *Cerfak* and *cetylpyridinium bromide* were used as anionic and cationic agents respectively. All other chemicals used were of analytical quality, B.D.H.

Mercury used for the pool and the dropping electrode was passed through a Meyer's column[3] washed several times with distilled water, dried, passed through a sintered-glass filter and finally distilled under vacuum.

Apparatus

The apparatus employed in the present investigation is the same as that described before,[3,4] the only modification being as much reduction as possible of series resistance. This is done by applying to a dropping mercury electrode a 50-cycle a.c. ripple of 40 mV (r.m.s.) over the d.c. potentials and observing the alternating component of the resulting pulsating current. The d.c. potentials have been expressed with reference to the saturated calomel electrode. The constants of the d.m.e were as follows.

$$m = 3{\cdot}559 \text{ mg per sec.}$$

$$t = 2{\cdot}3 \text{ sec per drop in } 0{\cdot}1M \text{ KCl (open circuit).}$$

Potassium chloride solution (0·1*M*) was used as the supporting electrolyte, and was invariably shaken and kept in contact with mercury and mercurous chloride. In each case the measurements were taken with the indifferent electrolyte, and the effect has been expressed in terms of the per cent increase (with sign) of the alternating current. The d.m.e. was cathodic throughout the measurements. All the experiments were done at a pH of 3·3 and a temperature of 30 ± 0·5°.

RESULTS

Fig. 1 shows the effect of various concentrations of n-amyl alcohol on the Cd^{2+} ($10^{-3}M$) reduction peak. It is seen, in general, that the magnitude of the reduction peak is not influenced up to a certain concentration, known as the optimum concentration of the s.a.s., but with concentrations higher than this the magnitude of the reduction peak progressively decreases, so much so that a concentration of 1·3% of n-amyl alcohol completely removes the $10^{-3}M$ Cd^{2+} peak. The magnitude and the peak potential of the tensammetric peak of n-amyl alcohol shows the normal behaviour that would be expected without the presence of Cd^{2+} ions. These observations are further supported by Fig. 2, which gives the effect of various concentrations of Cerfak on the $10^{-3}M$ Cd^{2+} reduction peak. In this case, 0·066% of Cerfak is sufficient to remove the Cd^{2+} peak completely.

Fig. 3 shows the effect of various concentrations of Cd^{2+} ions on the tensammetric peak of 1·3% n-amyl alcohol. It is again confirmed that the $10^{-3}M$ Cd^{2+} peak is completely suppressed by 1·3% n-amyl alcohol, whereas, with higher concentrations of Cd^{2+}, the reduction peak reappears; its magnitude then increases with increase in the concentration of Cd^{2+} ion without affecting either the magnitude or the peak potential of the tensammetric peak of 1·3% n-amyl alcohol.

Fig. 4 gives the curve which relates the amounts of n-amyl alcohol required just to remove the Cd^{2+} peak completely using different concentrations of the electroactive species. It can be seen that the curve is linear within the concentration range $10^{-4}M$–$10^{-3}M$ of the electroactive species. From this curve one can see directly the amount of s.a.s. just required to remove completely the reduction peak of an electroactive species corresponding to any particular concentration. In other words, it gives the concentration of the s.a.s. which is sufficient to make the discharge process completely irreversible.

2. 1·3% n-amyl alcohol + $10^{-3}M$ Cd^{2+}
3. 1·3% n-amyl alcohol + 3 × $10^{-3}M$ Cd^{2+}
4. 1·3% n-amyl alcohol + 5 × $10^{-3}M$ Cd^{2+}

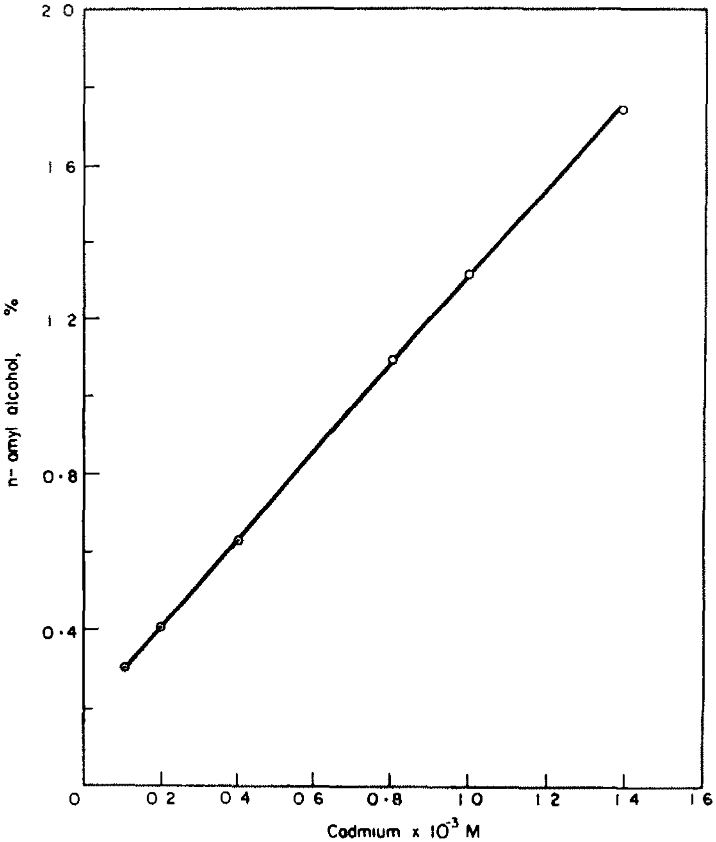

FIG. 4 —Relation between the amounts of n-amyl alcohol required to remove the Cd^{2+} peaks completely for various concentrations of Cd^{2+} ion.

Fig. 5 relates the optimum concentrations of n-amyl alcohol used for various concentrations of Cd^{2+} ion to produce the reduction peak. Here again it can be seen that the relation is linear in the concentration range $10^{-4}M$–$10^{-3}M$ of Cd^{2+}. This relation should be of particular interest in connection with d.c. polarography, where the optimum concentration of the s.a.s. is of significance in suppressing the polarographic maxima.

These observations are further substantiated by Fig. 6, which shows the linear relation between the concentration of the electroactive species and that of the surface active substance required to reduce the magnitude of the reduction peak to half its value. This linear relation holds good for the electroactive species between $10^{-4}M$ and $10^{-3}M$. The relation between the magnitude of the reduction peak and the molar concentration of the Cd^{2+} ion is linear within the above range.[5]

Fig. 7 shows the effect of various concentrations of n-amyl alcohol on the reduction peak of $10^{-3}M$ Zn^{2+} ions. Here, also, as in the case of Cd^{2+} ions, up to a certain concentration of n-amyl alcohol, the magnitude of the Zn^{2+} peak is not affected at all; but with concentrations greater than this optimum concentration, the magnitude of the peak decreases progressively till it is completely removed by 1 0% n-amyl alcohol. Further, the peak potential and the magnitude of the tensammetric peak of 1·0% n-amyl alcohol remain unaffected by the presence of $10^{-3}M$ Zn^{2+} ions.

These observations are further confirmed by Fig. 8 and Fig. 9, which show the effect of various concentrations of Cerfak and cetylpyridinium bromide on the reduction peaks of $10^{-3}M$ Zn^{2+} ion The concentrations of Cerfak and cetylpyridinium bromide required for completely removing the reduction peak are 0·056% and 0·008%, respectively. Therefore to remove completely the reduction peak of $10^{-3}M$ Zn^{2+}, the quantities of s.a.s. required are in the order n-amyl alcohol > Cerfak > cetylpyridinium bromide; this is supported by the effect of these s.a.s. on the reduction peak of Cd^{2+} ion.

DISCUSSION

Tensammetric peaks[1] are the outcome of the electrode processes which have their origin in adsorption/desorption processes occurring at the d.m.e. when a small sinusoidal a.c. voltage is superimposed upon the direct potential applied to a d.m.e. in the presence of s.a.s. and the resultant a.c. current is measured. They differ fundamentally from the a.c. reduction peaks of inorganic cations which are produced as a consequence of depolarisation processes occurring at the d.m.e., in the sense that in the former case no electron transfer takes place across the electrode boundary, whereas in the latter case it does.

In the absence of s.a.s. the reduction of inorganic cations takes place unhindered at the d.m.e. at the corresponding peak potential, and gives very high peaks which are reversible and diffusion-controlled. If s a.s is added, by virtue of the hydrophobic groups in the molecule it is preferentially adsorbed on the electrode surface, and hinders the electrode process either by film formation or by chemical interaction with the electroactive species in the immediate vicinity of the electrode surface. This adsorption is maximum at the electrocapillary zero (e.c.z), and diminishes on either side of the e.c.z. giving rise to tensammetric peaks arising from sudden desorption of the s.a.s. at higher cathodic or anodic potentials It is obvious, therefore, that the electrode processes whose reduction potentials lie within the adsorption range of the

2. 0 008% cetylpyridinium bromide
3. $10^{-3}M$ Zn^{2+} + 0 004% cetylpyridinium bromide
4. $10^{-3}M$ Zn^{2+} + 0 008% cetylpyridinium bromide.

s.a.s. will be affected by the presence of s.a.s., whereas outside this range there will be no significant influence on the electrode processes.

Because the peak potential and the magnitude of the tensammetric peak corresponding to any particular amount of s.a.s. remain constant with and without electroactive species, this suggests that the hindrance of the electrode process probably arises from film formation at the electrode surface and not from any chemical interaction between s.a s. and the electroactive speices. This is further supported by Fig. 3, in which both the peak potential and the amount of 1·3% n-amyl alcohol are unaffected by adding various amount of Cd^{2+} ions in the solution . It appears that with concentrations up to the optimum concentration of the s.a.s., the amount of s.a.s. is not sufficient to cover the electrode surface to a sufficient extent to hinder the electrode process, but concentrations greater than the optimum concentration progressively increase the extent of surface coverage within the life of the drop, and increase the degree of hindrance of the electrode process, thereby diminishing the magnitude of the reduction peak At higher concentrations of the s.a.s., corresponding to the removal of the reduction peak, it appears that most of the surface is covered with a unimolecular film; this hinders the rate of electron transfer from the electrode surface so much that it becomes slower than the diffusion rate, and hence the limiting current is no longer diffusion controlled. Thus a decrease in the rate of the electron transfer corresponds to an increase in irreversilibity of the electrode reaction, thereby producing no peak in a c. polarography.

With larger amounts of a particular reducible species, the quantity of the s.a.s. needed to make the rate of electron transfer slower than the rate of diffusion will be more than when smaller amounts of the same reducible species are present. Hence it is seen that the amount of n-amyl alcohol required for removing the reduction peak of Cd^{2+} using larger concentrations of Cd^{2+} ions are more than those for smaller amounts of Cd^{2+} ions. It may be mentioned that although the concentration of surfactants below the optimum concentration do not show any adverse effects on the kinetics of the electrode process, they are nevertheless capable of suppressing the polarographic maxima, probably because of preferential adsorption of the s.a s. at the neck of the mercury drop.[6]

The extent of inhibition on the kinetics of the electrode process depends, amongst other factors, on the structure of the adsorbed film, which in turn depends both on the nature of the s.a.s., especially its charge, and on the nature of the reducible species. On the cathodic side of the e.c.z., cationic surfactants will be adsorbed more strongly than anionic surfactants, and therefore the amount of cetylpyridinium bromide (which is cationic) required to remove Cd^{2+} and Zn^{2+} peaks is much less than the amount of Cerfak (which is anionic in nature.)

Zusammenfassung—Diese Arbeit befaßt sich mit dem Effekt von Art und Konzentration oberflächenaktiver Stoffe auf die Wechselstromreduktionsspitzen von Cd^{2+} und Zn^{2+} in der Wechselstrompolarograp hiesowie den umgekehrten Effekten. Die Größe der Reduktionsspitze wird bis zu einer gewissen Konzentration des oberflächenaktiven Stoffes nicht beeinflußt, daruber nimmt die Spitze ab; eine Konzentration von 1,3% n-Amylalkohol unterdruckt die Spitze bei 10 ^{3}m Cd^{2+} ganz Große und Potential der tensammetrischen Spitze von n-Amylalkohol werden durch Cd^{2+} nicht beeinflußt. Es besteht eine lineare Beziehung zwischen der Konzentration des reduzierbaren Ions und der Optimalkonzentration des oberflächenaktiven Stoffes und der Konzentration, die zur Unterdruckung der Spitze eben ausreicht Diese Beobachtungen werden weiter gestuzt durch die lineare Beziehung zwischen Konzentration des reduzierbaren Ions und der Menge des oberflächenaktiven Stoffes, die die Große der Spitze halbiert. Die zur volligen Unterdruckung der Reduktionsspitze notwendige Menge oberflachenaktiven Stoffes fällt von n-Amylalkohol uber Cerfak zu Cetylpyridiniumbromid Diese Ergebnisse werden in dieser Arbeit diskutiert.

Résumé—Cette recherche traite des études sur l'effet de la nature et de la concentration des substances tensioactives (s t.a) sur les pics de réduction en c.a des ions Cd^{2+} et Zn^{2+} et vice-versa par polarographie en c.a. On voit que l'amplitude du pic de réduction n'est pas influencée jusqu'à une certaine concentration en s t.a., mais à des concentrations supérieures à celle-ci, l'amplitude du pic de réduction décroît progressivement de sorte qu'une concentration de 1,3% en alcool n-amylique supprime complètement le pic 10^{-3}M Cd^{2+}. L'amplitude, ainsi que le potentiel de pic du pic tensammétrique de l'alcool n-amylique ne sont pas influencés par la présence d'ions Cd^{2+}. Il y a une relation linéaire entre la concentration de l'espèce électroactive d'une part, et la concentration optimale de la s.t.a., ou les concentrations de s t.a. juste nécessaires pour annuler le pic de réduction d'autre part. Ces observations sont en outre étayées par la courbe qui donne la relation linéaire entre la concentration de l'espèce électroactive et la quantité de s.t a nécessaire pour diminuer de moitié l'amplitude du pic de réduction La quantité de surfactant nécessaire pour supprimer totalement le pic de réduction se classe dans l'ordre. alcool n-amylique > cerfak > bromure de cétylpyridinium. Ces résultats sont discutés dans le mémoire

Summary—The expected effects of temperature on column efficiency are considered in detail for typical compounds of low, intermediate and high retention Situations involving various relative values of the resistances to mass transfer in the gas and liquid phases are analysed. One conclusion reached is that flow conditions cannot be chosen at any one temperature which will result in maximum efficiency for all solutes It would also be expected that column efficiency generally should increase with increasing temperature although under some conditions, of high mass transfer resistances in the liquid phase relative to that in the gas phase, a decrease or virtual independence of temperature may be found. The effect of variation of column temperature on pressure drop across the column is also examined briefly.

THE early work of Van Deemter *et al.*[1] immediately led to a greater understanding of the theory and practice of gas chromatography. Significant progress has been made with regard to theory since then by a number of persons of whom Jones,[2] Giddings[3] and Golay[4] might be mentioned. Much of the effort has been in relation to isothermal chromatography. It has been shown[5] that a knowledge of isothermal behaviour is important to an understanding of programmed temperature gas chromatography. In this paper some of the effects of temperature on isothermal gas chromatography, particularly with respect to column efficiency are examined. Because column efficiency is intimately related to the flow rate of the eluent gas and the distribution coefficients of the sample components, the effect of temperature on these two variables will first be briefly considered.

Flow rate and pressure drop

The effect of temperature on flow rate is primarily through its influence on gas viscosity which relates the flow rate to the pressure drop. There is a further strong effect from direct gas expansion if comparisons are made for conditions of constant mass flow rate.

The viscosity of most gases at ordinary pressures is approximately proportional to the temperature raised to a power somewhat less than one.[6] At high temperatures the limiting value of the slope shows a temperature dependence to the 0·63-power. At lower temperatures the coefficient is somewhat larger and no great error is incurred if the viscosities of gases of chromatographic interest are assumed to vary as the 0·7-power of the temperature.

It is noteworthy that the viscosity of hydrogen is about 0·84 × 10^{-4} g/sec cm at 0° and 1 atmos, whereas all other gases of chromatographic interest have viscosities which are about twice this value. Therefore, the absolute change in viscosity with temperature as well as the viscosity itself is least for hydrogen. Thus hydrogen is unquestionably the preferred eluent gas, both from the point of view of minimum pressure drop and of least change in pressure drop with temperature

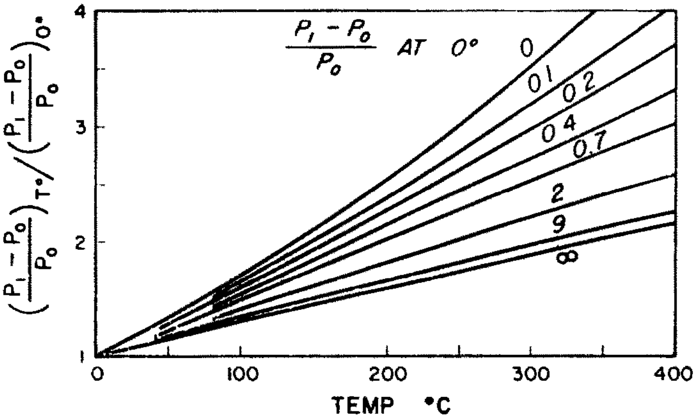

FIG. 1 -Change in relative pressure drop with temperature for columns with various pressure gradients (P_i is the inlet pressure, P_o is the outlet pressure and T is the temperature).

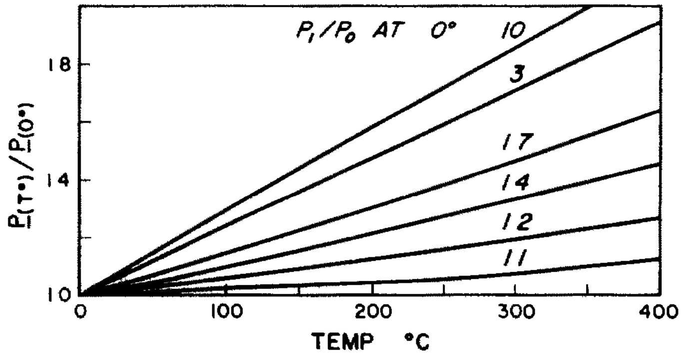

FIG. 2 --Change in inlet to outlet pressure ratio with temperature for columns with various pressure gradients

If one assumes that the flow rate, expressed at column outlet pressure and at a constant temperature of 0°, is maintained constant (constant mass flow rate) while the temperature of the column is changed, then some pressure drop relationships which can be calculated are shown in Figs. 1 and 2. Fig. 1 indicates that the relative change in pressure drop with increased temperature is greatest when the absolute pressure drop across the column is smallest. It can be deduced that when the pressure drop is small, *i.e.*, $P_o - 1$ approaches zero, then the temperature dependence of $\underline{P} - 1$ varies according to $(T/273)^{1·7}$, where $\underline{P}$ is the ratio of inlet to outlet pressure, P_i/P_o, and T is the column temperature. The power 1·7 arises from the 0·7 viscosity dependence and the 1·0 from thermal expansion. When the pressure drop is large $\underline{P} - 1$ varies according to $(T/273)^{0·85}$. In Fig. 2 the actual changes in the ratio of inlet to outlet pressure with temperature are illustrated. As expected, this ratio changes most when it is high initially. The principal significance of these changes for the present work are in connection with the James and Martin[7] compressibility correction to flow-rates, *i.e.*, $j = \frac{3}{2}\frac{(\underline{P}^2 - 1)}{(\underline{P}^3 - 1)}$.

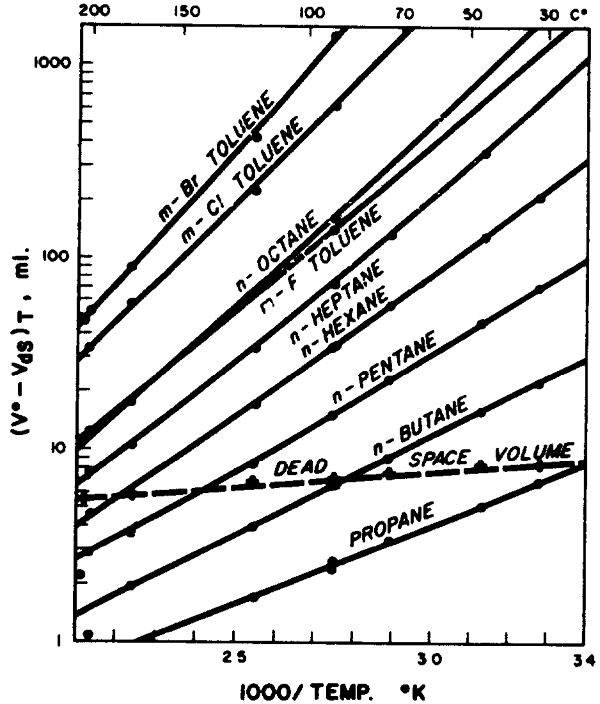

FIG. 3.—Dependence of net retention volume, ($V° - V_{ds}$), per g of column liquid, on temperature for a variety of solutes on Apiezon L on firebrick (2-m, 0·25-inch coiled copper column).

Distribution coefficient

The most important effect of temperatures is on the distribution coefficients of the sample components between the eluent gas and the stationary liquid and is reflected primarily in the retention volumes and secondarily in the relative peak broadenings. The variation in distribution coefficient with temperature is dependent principally upon the exponential change of vapour pressure with temperature and to a small extent on changes in activity coefficients.[8] This leads to the well-known linear relationship between the logarithm of the net retention volume and the reciprocal of the absolute temperature, such as shown in Fig. 3.

Column efficiency

Column efficiency, or the number of theoretical plates, is commonly expressed in terms of the theoretical plate height, *H*, as a function of eluent gas velocity for any particular system at constant temperature. The spreading of a chromatographic band in a column has been shown to be caused by a number of factors. These may be summarised in the following expression involving eluent gas velocity

$$H = A + B/u + C_{liq}\,uj + C_{gas}\,u \qquad (1)$$

A, B, C_{liq} and C_{gas} are constants at any given temperature, u is defined here as the eluent gas velocity at the outlet, and j is the compressibility correction.

The first and controversial term A in equation (1) is the contribution from eddy diffusion It is a term which is limited to packed columns and is ascribed to the multiple paths followed by the eluent gas. It is small and is considered negligible by some authors. If real, it should be independent of temperature and therefore need not concern us further.

The second term, B/u, which is most important at low flow velocities, describes the spreading because of diffusion in the flowing gas along the direction of flow. The constant B is $2\gamma D_g$, where D_g is the gas phase diffusion coefficient at column outlet conditions and γ is a tortuosity factor equal to somewhat less than 1 for a packed column To assess the importance of this term it is necessary to know the diffusion coefficients and their change with temperature. The equation of Chen and Othmer[9] appears to agree with experimental measurements better than any other general equation yet proposed and the constants involved are the readily accessible critical constants

$$D_{gas} = \frac{0{\cdot}43\left(\frac{T}{100}\right)^{1{\cdot}81}\left(\frac{1}{M_1}+\frac{1}{M_2}\right)^{0{\cdot}5}}{P\left(\frac{T_{C_1}\;T_{C_2}}{10{,}000}\right)^{0{\cdot}1405}\left[\left(\frac{V_{C_1}}{100}\right)^{0{\cdot}4}+\left(\frac{V_{C_2}}{100}\right)^{0{\cdot}4}\right]^2} \qquad (2)$$

D_{gas} is the diffusion coefficient in cm^2/sec, T is the absolute temperature, P is the pressure in atmospheres, M_1 and M_2 are the molecular weights of eluent gas and diffusing solute, and T_{C_1}, T_{C_2}, V_{C_1} and V_{C_2} are the critical temperatures and volumes. This equation indicates that the diffusion coefficient is inversely proportional to pressure and, important for our present purposes, proportional to the 1·81-power of temperature. Thus, the gaseous diffusion coefficient increases strongly with temperature and, for instance, could be expected to double in going from 25° to 160°. For conditions of constant mass flow rate, the actual velocity at the column outlet is proportional to temperature to the first power. Hence, for constant mass flow rate conditions the B/u term increases with temperature according to only the 0·81-power.

The third and fourth terms in equation (1) refer to band broadening, which results from the finite time taken for equilibrium to be reached across any column section between the gas and liquid phases. The third term, $C_{liq}\,uj$, describes the effects of resistance to mass transfer in the liquid phase. The C_{liq} coefficient of this term is generally agreed to have the form

$$C_{liq} = \frac{2}{3}\frac{k}{(1+k)^2}\frac{d_{liq}^2}{D_{liq}} \qquad (3)$$

where k is the ratio of moles of solute in the liquid to moles of solute in the gas, d_{liq} is the effective thickness of the liquid phase on the solid support and D_{liq} is the diffusion coefficient. In contrast to the second term, high diffusion coefficients minimise band broadening while high eluent gas velocities increase band broadening.

Experimental measurements of the diffusion coefficients of small solute molecules in high molecular weight viscous liquids are not very extensive, particularly over a range of temperatures. An estimate of the temperature dependence of diffusion coefficients may be made from viscosity measurements using the general relation that the diffusion coefficient is proportional to the absolute temperature divided by the viscosity. This quantity is plotted in Fig 4 for a variety of solvents.[10] Variations over many orders of magnitude are clearly indicated The temperature coefficient of viscosity, and hence of diffusion, appears to be particularly large for highly viscous liquids.

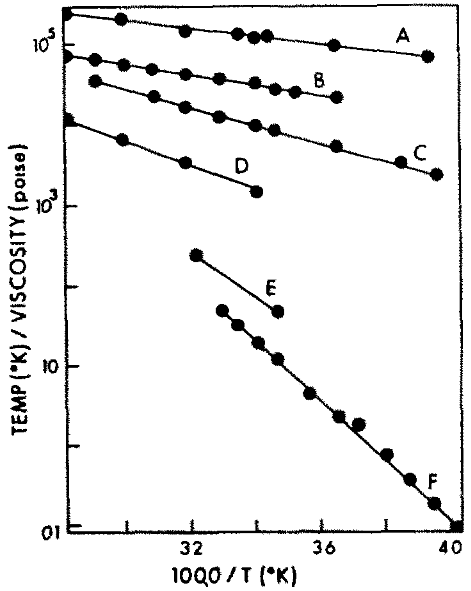

Fig 4 —Viscosity-temperature relations for various substances
A—ether, D—glycol,
B—carbon tetrachloride, E—heavy machine oil,
C—n-butyl alcohol, F—glycerol

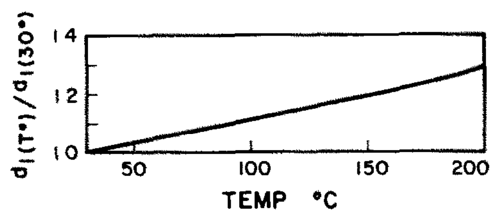

Fig. 5.—Relative thermal expansion of dinonylphthalate [$d_l(T°)$ is the effective thickness of liquid film at $T°$, $d_l(30°)$ is the effective thickness of film at 30°]

The absolute magnitude of the diffusion coefficient in liquids is very much smaller than in gases. Thus, Scott and Hazeldean[11] reported a value of $1{\cdot}1 \times 10^{-7}$ cm^2/sec for n-heptane in dinonylphthalate, which can be compared with a value of about 0·4 cm^2/sec for n-heptane in helium at a pressure of 1 atmos.

The remaining two factors contributing to C_{liq} [equation (3)] are also temperature dependent. The temperature dependence of the term d_{liq} is because of the thermal expansion of the liquid and Fig. 5 shows the relatively minor change in the relative value of d_{liq} as a function of temperature for dinonylphthalate.[12] Even though this factor is squared in equation (3) its temperature effect is still small.

Finally, the distribution ratio, k, as noted in the preceding section, varies exponentially with the reciprocal of the absolute temperature and hence will decrease strongly with increasing temperature. This is shown in Fig. 6 for three typical cases which are derived from the data of Fig. 3 and are chosen to represent cases of a substance with a very low retention volume, propane; one with an intermediate value, pentane; and one with a large retention volume, octane. The quantity $k/(1 + k)^2$ will have a maximum at k equal to 1 and thus starting from a high value of k at low temperature, $k/(1 + k)^2$ will first rise and then fall with temperature as shown in Fig. 7 for the same three examples. Normally k is somewhat greater than 1 for optimum chromatographic behaviour and, hence, the usual effect of increasing temperature will be to increase this factor.

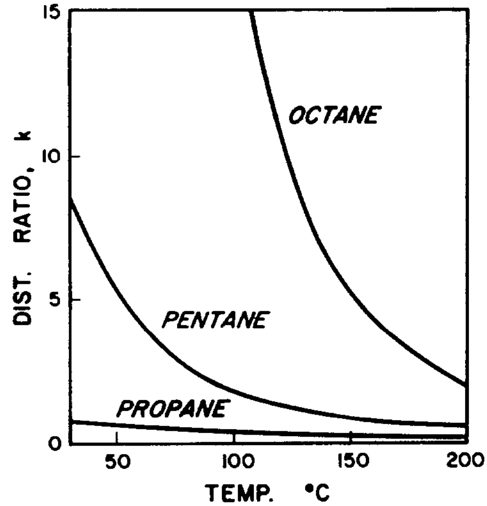

FIG. 6.—Distribution ratio, k, as a function of temperature for three hydrocarbons on an Apiezon L column using the data of Fig. 3.

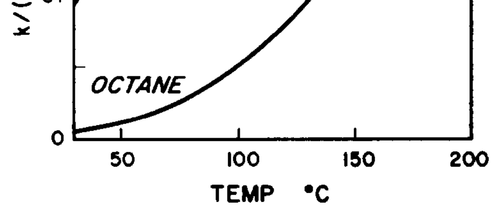

FIG. 7.—The factor $k/(1 + k)^2$ as a function of temperature for the three hydrocarbon systems.

When the temperature effects for all three factors of the third term are combined, the relative values of C_{liq} for the three hydrocarbon systems of Figs. 6 and 7 are obtained as functions of temperature (Fig. 8). In this figure it has been arbitrarily assumed that D_{liq} changes in the same way with temperature as does glycol, Fig. 4, and also that all three solutes have equal diffusivities. It can be seen that the highly volatile propane has a C_{liq} term decreasing strongly with temperature. For the more typical case of a strongly retained substance, such as octane, the factor is low and may even increase slightly with temperature. The contribution to plate height is equal to $C_{liq}\, uj$. For operation at constant mass flow rate u increases in proportion to temperature, while j decreases to an extent dependent upon the initial pressure drop across the column as explained in the first section. The product uj will increase with temperature and this effect must be considered along with the data of Fig. 8. The joint and competing effects of these various factors results in a complex temperature behaviour for the third term of equation (1).

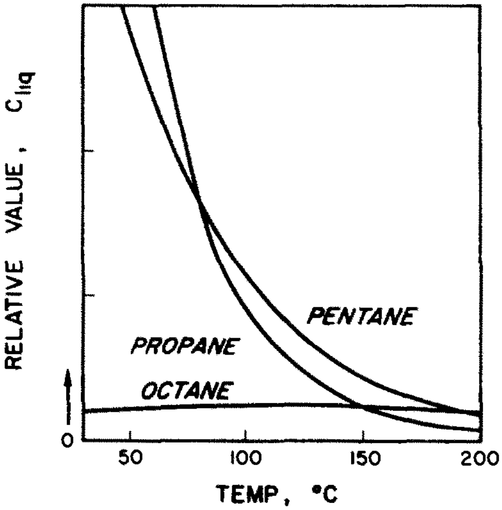

FIG. 8 —The relative value of the coefficient of resistance to mass transfer in the liquid phase, C_{liq}, as a function of temperautre.

Finally, the fourth term, $C_{gas}\, u$, refers to band broadening from resistance to mass transfer in the gas phase, where C_{gas} is a constant expressed in terms of the outlet conditions of the column. This term is probably the least well understood except for capillary columns.[3,13] As a general expression, Jones[2] has proposed that

$$C_{gas} = C_2 \frac{k^2}{(1+k)^2} \frac{d_{gas}}{D_{gas}} + C_3 \frac{d_p^{\,2}}{D_{gas}} + 2\rho(C_2C_3)^{\frac{1}{2}} \frac{k}{(1+k)} \frac{d_p\, d_{gas}}{D_{gas}} \tag{4}$$

where C_2 and C_3 are constants, d_{gas} is the average diffusion path length in the gas phase, d_p is the packing particle size and ρ is a factor between 0 and 1. These three factors refer to diffusion in the gas phase, mixing of streams of gas with different velocities and to interactions between these two effects. On the other hand, Giddings[14] has suggested that the major effect arises from the interactions of relatively high velocity portions of the gas stream in the large interparticle spaces with the relatively stagnant or low velocity portions, such as in intraparticle pores. Qualitatively, all of these contributions to the plate height show a decrease with increasing temperature, primarily because of the D_{gas} factor which increases according to the 1·81-power of the temperature [equation (2)] Factors involving k vary between 1 and 0, while d_{gas} would be expected to be essentially independent of temperature. To illustrate the magnitudes of the proposed effects Figs 9, 10 and 11 show relative values of the three gaseous resistance terms proposed by Jones for the widely variant situations represented by propane, pentane and octane cited before. It can be seen that the first and third factors decrease sharply with temperature, whereas the second decreases more slowly. The relative change in a factor, such as the one proposed by Giddings,[14] would be nearly identical with the curves for Jones' second factor. The over-all contribution of the fourth term, C_{gas} u, includes the contribution of the gas velocity. At constant mass flow rate it must be borne in mind that u increases in direct proportion to the temperature.

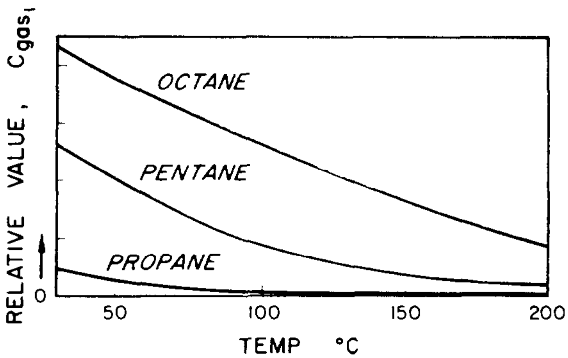

Fig 9.—The relative value of C_{gas_1}, the first term in equation (4), as a function of temperature

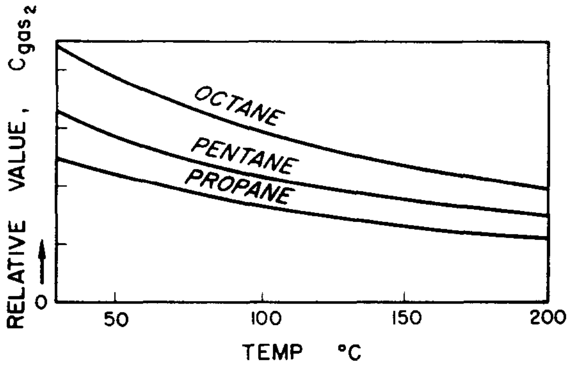

Fig. 10.—The relative value of C_{gas_2}, the second term in equation (4), as a function of temperature.

The contributions of the various terms of equation (1) to the final value of plate height for a particular column can vary independently over wide ranges. The data of the preceding figures and equations have been used to produce various sets of plate height—gas velocity curves (Fig. 12) for these same three hydrocarbon systems, propane, pentane and octane on Apiezon L, as representative of substances with low, intermediate and relatively high retention volumes. In order to combine the various terms of equation (1) the following conditions were specified:

1. The second term is 0·6 cm for propane at 30° and a value of u of 1 cm/sec. This is a reasonable value for a packed column at this low velocity.

2. The total contribution of the third and fourth terms is 0·1 cm for propane at the above conditions. This value for the mass transfer terms is arbitrary and would depend on the column packing.

3. The three contributions to C_{gas} in equation (4) apply in the ratio of 1·20·1. The proportions are arbitrary, but are influenced considerably by Giddings' conclusion.

4. Parts A, D and G of Fig. 12 are based on the term C_{liq} equal to the term C_{gas} for propane at 30°; parts B, E and H are based on C_{liq} equal to 10 C_{gas}; and parts C, F and J are based on C_{liq} equal to 100 C_{gas}, again for propane at 30°.

The results are further limited by the assumptions implied previously: helium carrier gas, outlet pressure of 1 atmos, negligible pressure drop, the term A equal to zero and a column liquid with the viscosity characteristics of glycol and the retention characteristics shown in Fig. 3. Following a usual convention the flow velocities shown are those measured at column temperature and at outlet pressure If the velocity is expressed at some standard temperature in order to make comparisons under conditions of constant mass flow rate, then the figures are qualitatively similar but with the high temperature curves compressed towards the vertical axis.

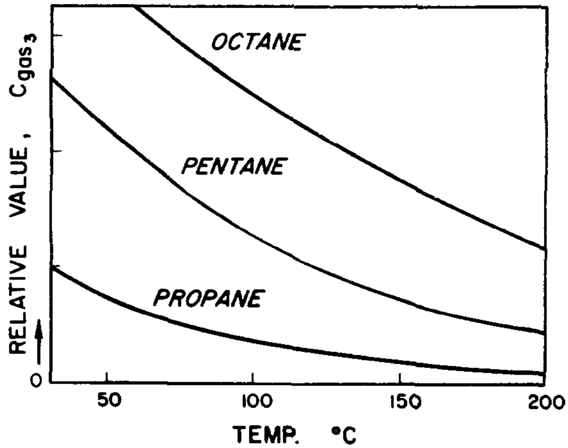

FIG. 11.—The relative value of C_{gas_3}, the third term in equation (4), as a function of temperature.

Fig. 12 illustrates most of the characteristics identifiable in experimentally observed curves. If one bears in mind that most chromatographic separations are based on k values in the range of 1 to 5, it can be seen from Fig. 6 that the three systems illustrated in Fig. 12 cover a much wider range of conditions than are usually employed in practice. Even at the lowest temperature of 30°, propane is still at the lower limit of useful retention while octane is only within this range in the upper 50° of the temperatures chosen.

At low velocities the predominant contribution to plate height arises from the term B, which decreases with decreasing temperature or increasing molecular weight of the sample component. The contribution of the term B becomes small at high velocities and for this reason will not be discussed in further detail.

At high velocities the mass transfer terms predominate. The general effect obvious from the various charts is a decrease in mass transfer resistance with increasing temperature although the curves in J are approaching the opposite behaviour.

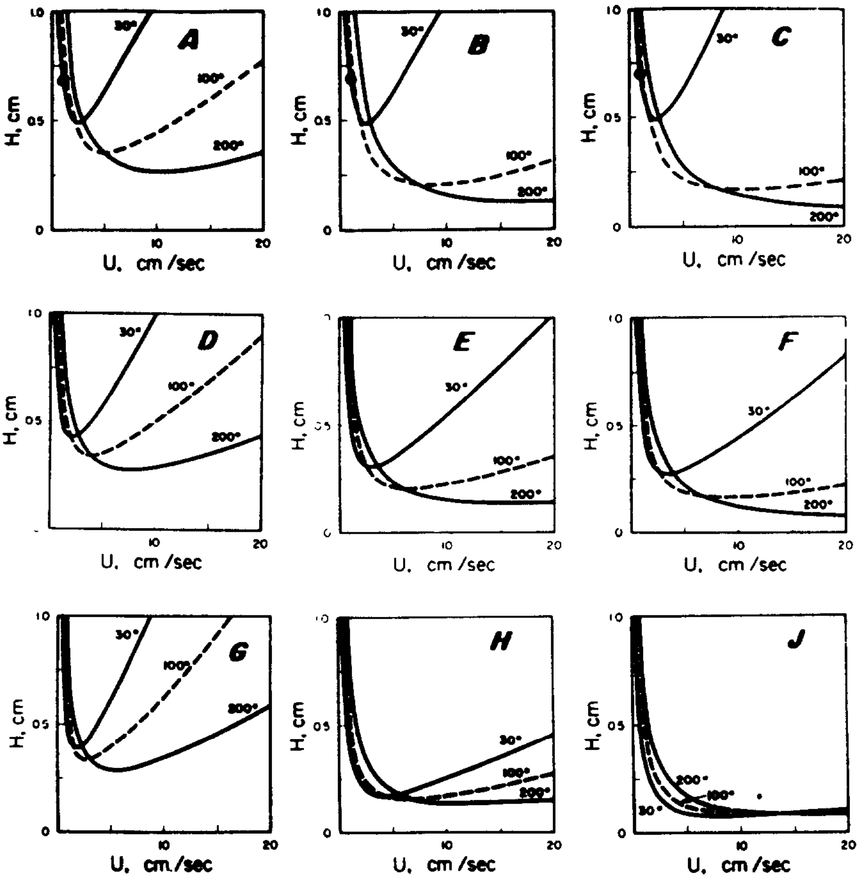

Fig. 12.—Calculated plate height—gas velocity curves for the same three systems of the previous figures at three temperatures and based on three arbitrary ratios of 1, 10 and 100 for C_{liq} to C_{gas} for propane at 30° [B/u of equation (1) taken as 0·6 cm and ($C_{liq}\,u + C_{gas}\,u$) taken as 0·1 cm for propane at 30° and u of 1 cm/sec]:

Temperature		30°		100°		200°	
Chart	Compound	C_{liq}	C_{gas}	C_{liq}	C_{gas}	C_{liq}	C_{gas}
A	propane	50	50	4·7	39	0·5	20
B	propane	91	9·1	8·6	7·1	0·8	3·7
C	propane	99	1·0	9·4	0·8	0·9	0·4
D	pentane	20	78	5·8	48	1·0	28
E	pentane	35	14	10	·87	1·8	5·1
F	pentane	38	1·6	12	0·9	2·0	0·5
G	octane	1·0	109	1·3	71	1·0	42
H	octane	1·9	20	2·4	13	1·8	7·6
J	octane	2·1	2·2	2·6	1·4	2·0	0·8

C_{liq} and C_{gas} given in sec × 10^3.

Charts A, D and G are based on equal contributions of the liquid- and gas-phase resistance to mass transfer for propane at 30°. The initial high temperature coefficient of C_{liq} for propane as well as the relative positions of the curves in Figs. 8 and 10 mean that the gas-phase contribution predominates at most temperatures and at all temperatures for the higher hydrocarbons. Thus, for instance, in A at 200° the contribution of liquid resistance to mass transfer is only about 2% of the gas-phase resistance. Charts A, D and G therefore illustrate the case of gas resistance being the major contribution to plate height. Under these conditions it is clearly advantageous to work at high temperatures. Furthermore, because of the relatively small effect of the distribution ratio on the value of C_{gas}, the curves for the different hydrocarbons are very similar to each other and high efficiencies may be attained at high temperatures for all components in an analysis. This type of operation is characteristic of most capillary columns which would therefore be expected to show a marked increase in efficiency with higher temperatures. This has been clearly demonstrated by Scott.[13]

At the other extreme in charts C, F and J, which are based on C_{liq} equal to 100 C_{gas} for propane at 30°, one sees curves in which liquid-phase resistance is generally predominant. At 200° both liquid and gas resistance to mass transfer are of the same order. Other generalisations are difficult because of the competing effects involved in the temperature coefficient of C_{liq}. With propane the decrease in $k/(1 + k)^2$ and of $1/D_{\mathrm{liq}}$ with temperature combine to show marked increases in efficiency with increasing temperature in the range 30° to 100°. With pentane the large change in the factor $1/D_{\mathrm{liq}}$ over-rides the increase in $k/(1 + k)^2$ in this same temperature interval and the curves are similar to those for propane. For octane the factors approximately compensate at all temperatures. Under these conditions the efficiencies may vary widely for the different components in a sample.

A case presumably similar to that in chart F has been described by Duffield and Rogers.[15] These authors have shown that liquid-phase viscosity affected plate height as would be expected for a column in which C_{liq} is controlling.

In a comparison of different ratios of liquid and gas resistances, such as shown in any horizontal row in Fig. 12, the effects to be expected will depend mostly on the type of temperature behaviour of the C_{liq} factor. Thus, for propane where C_{gas} and C_{liq} are qualitatively similar the temperature effects are not grossly different. For octane where the temperature coefficients of C_{gas} and C_{liq} are of the opposite sign over a wide temperature range, profound changes in the curves become evident in going from G to J.

It is not feasible to attempt to describe all of the possible extrapolations of the data shown in Fig. 12 to other possible conditions involving changes in gas and liquid properties. One case of possible interest would involve greater predominance of liquid-phase resistance, relatively high retention volume and possibly a lower temperature coefficient of liquid viscosity. A combination of these effects could lead to a marked decrease in column efficiency with increasing temperature, such as was almost reached in chart J. The curves shown in Fig. 13 may be an example of this sort. This figure shows the usual behaviour between 30° and 50°, but above 50° the efficiency appears to decrease with increasing temperature.

Further analysis of the relationships depicted in Fig. 12 may be made by considering the minimum plate height or maximum efficiency values and the corresponding velocities. The gas velocity at the minimum[16] in the plate height—velocity curves

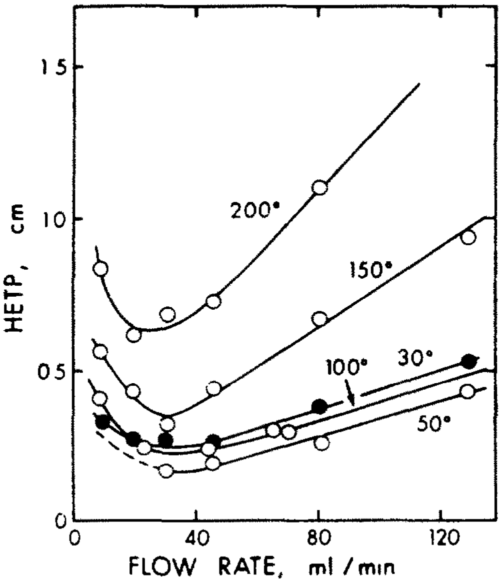

Fig 13.—Plate height—gas velocity curves for n-hexane at a series of temperatures on a 2-M Apiezon L column using hydrogen as the carrier gas

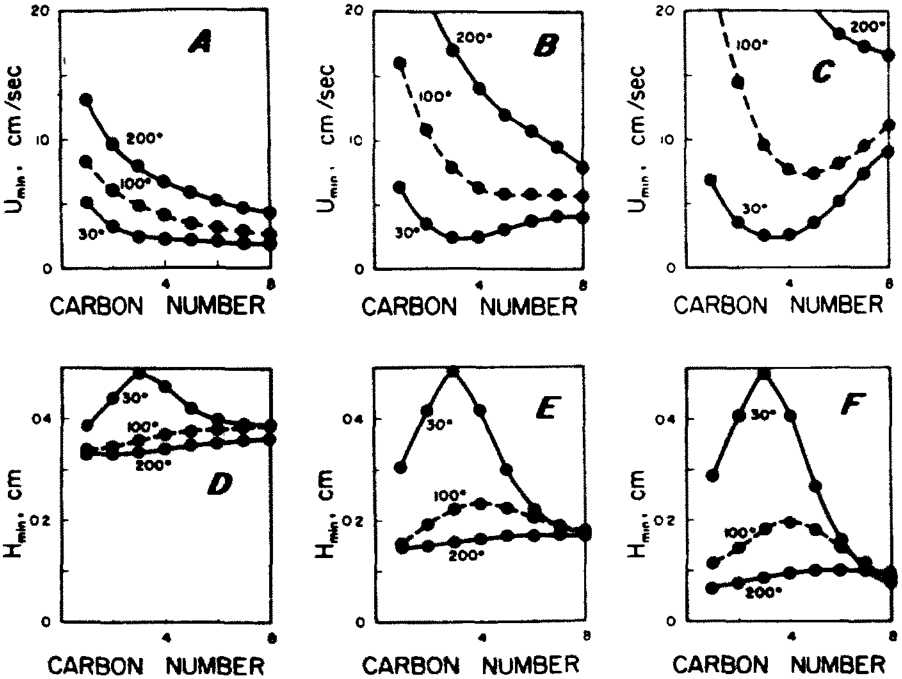

Fig 14 —Optimum velocity and minimum plate height as a function of carbon number and temperature for hydrocarbons under conditions specified in Fig 12·

A and D—Based on C_{liq} equal to C_{gas} for propane at 30°,
B and E—Based on C_{liq} equal to 10 C_{gas} for propane at 30°,
C and F—Based on C_{liq} equal to 100 C_{gas} for propane at 30°

at any one temperature is equal to $\sqrt{B/(C_{\text{liq}} + C_{\text{gas}})}$ and the value of the plate height at this minimum velocity is equal to $A - 2\sqrt{B(C_{\text{liq}} + C_{\text{gas}})}$. In Fig. 14 these two quantities are shown as a function of carbon number at three column temperatures and for the three $C_{\text{liq}}/C_{\text{gas}}$ conditions illustrated in Fig. 12. Reasonable estimates of the values of the retention characteristics of hydrocarbons not shown in Fig. 3 have been made. One may say generally that, for any one hydrocarbon, with increasing temperature the gas velocity at the minimum increases (charts A, B and C) and the H_{min} decreases (charts D, E and F). These effects are independent of the ratio of liquid- and gas-phase mass transfer resistances, although for octane in chart F a slight reverse trend in H_{min} is apparent. As indicated in the earlier discussion and possibly suggested in Fig. 13, this decrease in optimum efficiency with increasing temperature may occasionally be of some practical significance. At constant temperature the optimum velocity may decrease regularly with carbon number where gas phase resistances tend to predominate as in chart A; or it may show a more complex behaviour when liquid phase resistances become significant as in charts B and C. The H_{min} values are relatively independent of carbon number at higher temperatures but vary considerably through a maximum at lower temperatures. The variations in both U_{min} and H_{min} are greatest when liquid-phase resistances predominate.

It is obvious from Figs. 12 and 14 that flow conditions cannot be chosen at any one temperature which will result in maximum efficiencies for all solutes. This is recognised in chromatographic practice in that a gas velocity greater than the minimum is usually chosen.

It should be emphasised that while the conditions assumed for the construction of the curves in Figs 12 and 14 may exemplify actual chromatographic conditions there are innumerable alternatives. For example, the mass transfer terms may be larger or smaller compared to the longitudinal diffusion term, the gaseous mass transfer term may be more or less important, *etc*. Normally, one attempts by appropriate selection of design and operating variables to minimise both mass transfer contributions to plate height. Thus, changing the carrier gas to one with low diffusivity will decrease the longitudinal diffusion term but increase the term C_{gas} and leave the term C_{liq} unchanged. The relative values of C_{gas} and C_{liq} will also depend on column or particle dimensions and on the manner in which the liquid is distributed on the support. The effects of various combinations can be deduced from reasonable extensions of the data given by the curves shown in Fig. 12 For example, a ten-fold decrease of the terms C_{liq} and C_{gas} of A, D and G would produce three new figures all very similar to H.

Zusammenfassung—Der zu erwartende Temperatureinfluß auf die Wirksamkeit von Säulen wird im einzelnen fur typische Verbindungen niedriger, mittlerer und hoher Retention erörtert. Es werden Fälle mit verschieden großer Hemmung des Massenüberganges in Gas- und flüssiger Phase betrachtet. Es wird gefolgert, daß bei einer Temperatur keine für alle gelosten Stoffe optimal wirksamen Strömungsbedingungen zu finden sind. Es ist auch zu erwarten, daß die Wirksamkeit der Säule im allgemeinen mit steigender Temperatur zunehmen sollte, obwohl unter gewissen Bedingungen, nämlich starker Hemmung des Massenüberganges in der flüssigen Phase relativ zur Gasphase, ein Abfall oder scheinbare Unabhängigkeit von der Temperaturge funden werden kann. Außerdem wird kurz der Einfluß der Säulentemperatur auf den Druckabfall längs der Säule untersucht.

Résumé—On étudie en détail les effets de la température sur l'efficacité d'une colonne dans le cas de composés caractéristiques de haute, moyenne et basse rétention. On analyse des exemples comportant diverses valeurs relatives de la résistance au transfert de masse tant en phase liquide qu'en phase vapeur. On montre qu'on ne peut trouver des conditions de reflux à une température donnée, telles qu'on puisse obtenir l'efficacité maximale pour tous les solutés. On montre également que l'efficacité de colonne croit généralement avec la température. Cependant, dans certaines conditions, si le rapport des résistances au transfert de masse en phase liquide et en phase gazeuse est grand, on peut rencontrer une décroissance ou une pseudo-indépendance par rapport à la température. On examine également brièvement la variation de la température de la colonne sur la chute de pression le long de la colonne.

THERMOMETRIC TITRATIONS IN ACETONITRILE

EARL J. FORMAN and DAVID N. HUME
Department of Chemistry and Laboratory for Nuclear Science,
Massachusetts Institute of Technology, Cambridge 39, Mass., U.S.A.

(*Received* 19 *June* 1963 *Accepted* 5 *October* 1963)

Summary—The use of acetonitrile as a medium for thermometric acid-base titrations has been studied. Satisfactory titrations are obtainable for a wide variety of amines and organic acids, but the instability of the solvent in the presence of strong bases greatly limits its practical applicability. Data are given on the heats of neutralisation of various acids in acetonitrile, and the results for *m*- and *p*-substituted benzoic acids are shown to correlate well with their Hammett σ-values.

INTRODUCTION

THE advantages of performing acid-base titrations in non-aqueous systems are well known. The limitations of conventional methods of end-point detection have led to the exploration of alternatives. One of these, automatic thermometric titrations, introduced by Linde, Rogers and Hume,[1] is particularly well adapted to non-aqueous systems because of its independence of the chemical nature of the solvent and reactant. A general review has been given by Zenchelsky.[2] The applicability of thermometric titration to non-aqueous acid-base titrations in glacial acetic acid has been studied by Keily and Hume.[3] The present paper describes the investigation of acid-base titrations in acetonitrile.

Acetonitrile is a good solvent for a wide variety of organic acids and bases. Being very weakly basic and having negligible acidic properties, it permits titrations to be made over a very wide range of acidity as compared to water. Fritz,[4] carrying out potentiometric titrations with a glass-calomel electrode pair, showed that acetonitrile was a suitable solvent for differentiating titrations of strong and weak bases. Critchfield and Johnson[5] demonstrated acetonitrile to be a satisfactory solvent for differentiating potentiometric titrations of relatively strong acids. This lack of leveling action also shows in its range between the half-neutralisation potentials of strong acids and strong bases which Van der Heijde and Dahmen[6] observed to be one of the widest among the solvents which have been studied, being better in this respect than acetic acid, dimethylformamide, ethanol or amines. In practice, however, the range is limited somewhat by the effect of very strong bases, such as hydroxide ion or alkoxide, which catalyse the polymerisation of solvent.

EXPERIMENTAL

Apparatus

The instrumental set-up used was that designed, built and employed by Keily.[7] A constant-flow, motor-driven syringe burette delivers titrant into the sample, which is contained in a half-pint Dewar flask. The flask carries a Plexiglass cover insulated with cork, which holds the measuring thermistor, a glass-covered wire heater, and has holes for the burette tip and the shaft of a 600-rpm stirrer. The temperature of the titration mixture is measured continuously by a thermistor in a Wheatstone bridge circuit and recorded on a Speedomax G, 2-mV potentiometer-recorder. Pen displacement has been shown to be linear with temperature changes over a range of several tenths of a degree, and the instrument at the highest sensitivity responds to a change of 0 001 Titrations were performed by first adjusting the temperature of the sample to that of the titrant, then running in the titrant at constant speed with a continual recording of the temperature

Reagents

Acetonitrile Material obtained from Carbide and Carbon Chemicals Co was used throughout this work The water content of the material as received was of the order of 0 1% (by Karl Fischer titration) and, occasionally, small amounts of weakly acid impurities appeared in individual batches The presence of acidic impurity was tested for by the addition of 1 drop of thymol blue (salt form) to about 5 ml of solvent In satisfactory material the colour should be yellow (red indicates acidic impurity) and should change to blue upon the addition of not more than 1 drop of 0 1*M* sodium methoxide in methanol [7] Water and other impurities were removed in either of two ways One method consisted of predrying with anhydrous potassium carbonate, then distilling over phosphorus pentoxide This gave an excellent product at the expense of considerable time and effort. Another method which was employed throughout the bulk of this work involved drying the solvent by placing it in contact with Type 4A molecular sieves (Linde Air Products Co.) for at least 15 min before use The solvent treated in this way was found to contain less than 0·01% of water and the absorbant properties of these sieves were sufficient to remove small amounts of acid impurities.

Substances titrated Most of the bases titrated were subjected to some preliminary treatment or purification. They were of the best grades readily available, and all were Eastman White Label products unless otherwise noted Compounds used without further purification were *p*-toluidine, *p*-bromaniline, *m*-nitro-aniline, ethylamine (anhydrous), trimethylamine (anhydrous), isopropylamine and urea (Merck U S.P.).

Compounds distilled under vacuum were *o*-chloraniline, *N,N*-dimethylaniline, *N,N*-diethylaniline, *N*-methylaniline, aniline (Fisher Reagent), *p*-chloraniline (Eastman Practical), tri-n-butylamine (over sodium hydroxide) and tri-isobutylamine (Kahlbaum over sodium hydroxide).

Compounds subjected to simple distillation were isobutylamine (over calcium oxide), tert-butylamine (over calcium oxide), n-butylamine (over calcium oxide), 1-ethylpiperidine, pyridine (Mallinckrodt Reagent over sodium hydroxide), morpholine (Carbide and Carbon Co. over sodium hydroxide), n-propylamine (over sodium hydroxide), di-n-butylamine (over sodium hydroxide), diethylamine (Sharples Commercial over sodium hydroxide), triethylamine (Sharples Commercial over sodium hydroxide), sec-butylamine (Sharples over sodium hydroxide), di-sec-butylamine (Sharples over sodium hydroxide), and di-isopropylamine (Eastman Yellow Label over sodium hydroxide).

Ammonia (Matheson Co, Anhydrous) was passed through No. 4A Molecular Sieves (Linde Air Products Co.), then dissolved by passing it over a stirred volume of acetonitrile The *p*-nitroaniline and *p*-chloraniline were recrystallised from ethanol and air-dried, while *p*-anisidine was recrystallised once from water and once from 10% methanol-water solution and finally washed with iced water and air-dried

Compounds titrated as acids were prepared or purified in the following ways. No further purification was given to benzoic acid, *p*-toluic acid, *m*-nitrobenzoic acid, *p*-nitrobenzoic acid, *p*-chlorobenzoic acid, *m*-chlorobenzoic acid, *m*-bromobenzoic acid, glacial acetic acid (duPont 99 7%), formic acid (Baker and Adamson 98–100%) or sulphuric acid (duPont 98%).

Monochloracetic acid was dried over phosphorus pentoxide for 24 hr, then vacuum-sublimed at about 60°. Dichloracetic acid (Eastman technical grade) was vacuum-distilled and trichloracetic acid (Mallinckrodt Reagent) was dried for 1 week over magnesium perchlorate and vacuum-sublimed at about 60°. The water content of the compounds before solution in acetonitrile was determined by Karl Fischer titration and found to be 0 25%, 0 12% and 0·09% for the mono-, di- and trichloracetic acid, respectively.

Titrants Hydrogen bromide solutions in acetonitrile were used for the titration of organic bases The titrant was usually made up to a concentration of approximately 0·1*M*. Solutions were prepared by passing anhydrous hydrogen bromide (Matheson Co.) through a drying tower containing anhydrous magnesium perchlorate and silica gel and then over the surface of the acetonitrile, which was being stirred vigorously with a magnetic stirrer. The resulting solutions generally developed a yellow colour in a period of 1–2 hr, but appeared to be stable thereafter A similar colour developed when anhydrous solutions of hydrogen chloride were prepared, or when attempts were made to prepare anhydrous solutions of perchloric acid in acetonitrile. Hydrogen bromide appears to have a considerable vapour pressure over acetonitrile solutions: standard solutions were observed to decrease in strength by about 1% per day For this reason the titrants were standardised daily by diluting aliquots with water and titrating with standard sodium hydroxide using a potentiometric end-point.

Diphenylguanidine solutions were used to titrate acids. Eastman White Label 1,3-diphenylguanidine was recrystallised successively from toluene, ethanol and again from toluene before being dried at 110° over-night. The resulting product was found to be 99·7+% pure by titration with standard aqueous hydrochloric acid. Titrant solutions made with this product were colour-stable and did not change titre appreciably over a period of at least 1 month.

Procedure

The bases listed previously were all titrated with approximately 0·1*M* hydrogen bromide in acetonitrile. The solutions titrated were made up to about ten-fold more dilute than the titrant. In each instance, 15-ml portions were titrated. No corrections were made for density variations because all titrations were performed in an air-conditioned room with temperature fluctuations $> \pm 1^{\circ}$. In order to estimate the accuracy of the method, comparison was made between concentrations determined thermometrically and those determined by conventional methods. The concentration of aliphatic amines was determined by diluting aliquots about five-fold in water and titrating with standard aqueous hydrochloric acid, using either a glass-calomel potentiometric end-point or a methyl red-methylene blue mixed indicator. Aromatic amine concentrations were determined by dissolving aliquots in glacial acetic acid and titrating with perchloric acid in glacial acetic acid. The perchloric acid was standardised against potassium hydrogen phthalate using a glass-calomel electrode pair for potentiometric end-point determination.

RESULTS

Thermometric titration end-points consist of a change in slope of a temperature *vs.* volume curve. Typical curve shapes for the systems studied in this investigation are illustrated in Fig. 1. The ease of end-point estimation is evidently dependent upon the sharpness of the slope change. This, in turn, is related to two fundamental factors: the magnitude of the free-energy change of the reaction and the change in enthalpy which accompanies the reaction. Because it is the free-energy change which determines whether and how far a reaction will go towards completion, the magnitude of this term is of fundamental importance. Assuming a favourable free-energy change, the sharpness of the end-point break will be determined by the magnitude of the enthalpy change: the larger the change, the more acute the change in slope at the equivalence point. If the free-energy change in not favourable, there will be a rounded end-point because of the incompleteness of the reaction at the equivalence point, regardless of the magnitude of the enthalpy term. Because the temperature rise in thermometric titrations is nearly linear, rounded end-points may be estimated by extrapolation of the slopes before and after the highly curved portion of the plot. The general theory of the shape and characteristics of thermometric titration curves has been discussed by Keily and Hume.[9]

Titration of bases

Fig. 1 illustrates the general shapes of titration curves obtained for the titration of strong, weak and very weak bases with hydrogen bromide solution. It demonstrates the rough rule that sharpness of the end-point depends on the strength of the base titrated. This generalisation held in a qualitative sense for all of the bases titrated in this study. It is evident, however, from the data of Table I showing the precision and accuracy obtained in the titration of 17 non-aromatic amines that sharpness of the end-point is not the only factor which affects the precision and accuracy. The bases in Table I are listed in the general order of decreasing strength as determined by ionisation constant in water. It was noted that the precision for a number of the more volatile compounds was lower than that for the average, and this is probably a factor which contributes to the considerable range in standard deviations observed. The over-all percentage standard deviation from the pooled data of all of the titrations of bases is ±0·52%. This precision is poorer than the ±0·2% reported by Linde, Rogers and Hume for thermometric titrations in water[1] and by Keily and Hume for glacial acetic acid.[3] The observed precisions are similar to those reported by Fritz for potentiometric titrations.[4] It is of interest to note that the precision of titration of very weak bases was not significantly different from that of the over-all precision, even though the accuracy was lower. Table II shows results for aromatic and heterocyclic amines. With the exception of the values for *p*-bromaniline and *m*-chloraniline, the average accuracy is 99·2%. The latter compound defined the limits of practical titrability using the thermometric end-point in acetonitrile. All weaker bases, as measured by their pK_B values in water, gave thermometric curves which were so rounded that no significant change in slope could be seen to define the end-point. The weakest bases with discernible end-points have aqueous pK_B values in the range of 10–10·5. As is evident in the accuracy values for *p*-brom- and *m*-chloraniline, the tendency is for the observed end-point to err on the high side in the titration of very weak bases. A similar tendency is apparent in Keily's data for the titrations of the very weak bases, urea and acetanilide, in glacial acetic acid.[3]

TABLE I.—TITRATION OF NON-AROMATIC AMINES

Compound	No. of detns.	Present, *mmole*	Found *mmole*	Accuracy, %	Std. devn., %

p-Nitroaniline	6		too weak to titrate		
Urea	4		too weak to titrate		

The effect of precipitation of insoluble hydrobromides during the titration is seen in Fig. 2. The sudden appearance of the heat of precipitation distorts the curve but need not affect the accuracy of locating the end-point if the onset of precipitation is not too close to the end-point. The heat of neutralisation may, of course, be estimated independently of the precipitation by the use of the initial slope.

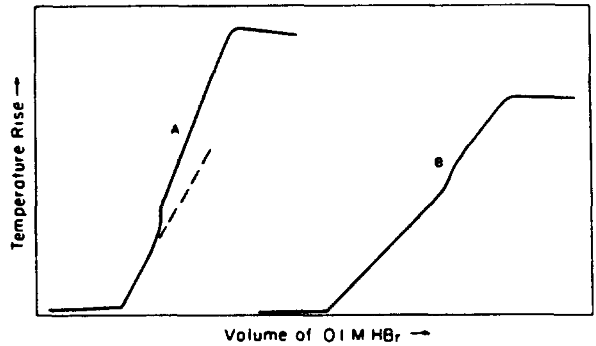

FIG. 2.—The effect of delayed precipitation during titration:
(A) aniline with hydrogen bromide,
(B) *p*-toluidine with hydrogen bromide

Differentiating titration of bases

The criteria for a good differentiating end-point are evident from a consideration of the factors affecting the thermometric end-point in general. For successful thermometric differentiation, not only must the free-energy change for each component in the mixture be great enough to assure completeness of reaction, and the free energies be sufficiently different that the reactions take place consecutively, rather than simultaneously, but the enthalpy change for each component must be sufficiently different that a significant change in slope can be recognised. It is difficult to say exactly how much of a difference in ΔH is essential to end-point discernment because in real titrations extraneous factors, such as heats of dilution, heat loss and changing heat capacity from addition of titrant, also act to obscure end-points. It appears that roughly a slope ratio of the order of 3 2 for the components is necessary in order that the break be clearly defined It has been shown that in acetonitrile there is a remarkably constant proportionality between ΔH and pK_B for amines of similar type [10] Because the slopes of thermometric titration curves are proportional to ΔH, this means that two bases which are sufficiently different in strength to be titrated consecutively are likely to have thermometric slope ratios favourable for differentiating titration in acetonitrile. As an illustration of the types of curves obtained, Fig. 3 shows the titration of mixtures of 1,3-diphenylguanidine (ΔH = 20·7 Kcal/mole) plus pyridine (ΔH = 14·4 Kcal/mole), and mixtures of *N*-butylamine (ΔH = 25·8 Kcal/mol) plus pyridine. The titration of the diphenylguanidine-pyridine mixture is illustrative of borderline conditions of titrability. The precisions of the two end-points (standard deviation) are 1·14 and 1·16%, respectively The titration curve for butylamine and pyridine is an example of an easily differentiated mixture Precisions of these end-points are 0 5% and 0·61%, respectively.

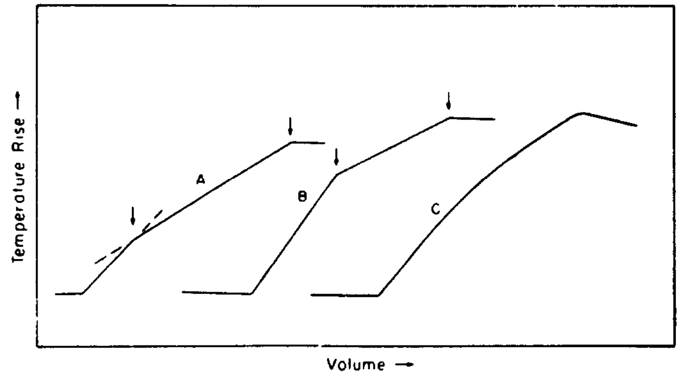

FIG 3 —Differentiating titrations·

(C) Sulfuric acid with 1,3-diphenylguanidine.

Titration of acids

The list of acids titrated with diphenylguanidine solution is given in Table III. The weakest acid that showed a distinct end-point was benzoic (pK_a in water 4·20). Acetic acid and *p*-toluic acids were too weak to be estimated thermometrically, in agreement with Kilpatrick,[8] who found that acetic acid could not be titrated in acetonitrile using indicators The reason for the limitation to relatively strong acids is related to the instability of the solvent in the presence of strong bases. Presumably, if one could titrate with bases stronger than diphenylguanidine or aliphatic amines, the range of titrability could be greatly extended. This is indicated by the work of Bruss and Wyld,[11] who claimed that acids as weak as the phenols could be titrated in acetonitrile if tetrabutylammonium hydroxide in isopropyl alcohol was used as titrant. Attempts to dissolve bases such as potassium hydroxide or sodium methoxide in acetonitrile resulted in the formation of a reddish-brown gelatinous residue, presumably polymeric in nature. The over-all pooled percentage standard deviation for the titration of acids was found to be 0·99%.

TABLE III.—TITRATION OF ACIDS WITH 1,3-DIPHENYLGUANIDINE

Acid	No. of detns	Present, *mmole*	Found, *mmole*	Accuracy, %	Std Devn, %

[a] Both protons

[b] Filtrate from barium perchlorate plus sulphuric acid reaction.

The titration of sulphuric acid with 1,3-diphenylguanidine is also shown in Fig. 3. Critchfield and Johnson showed that the two protons of sulphuric acid can be distinguished potentiometrically by titration with morpholine in acetonitrile solution. In the present instance, the free energy criterion appears to be fulfilled, but the difference in the heats of neutralisation of the two protons is not sufficiently great to allow a distinct evaluation of the first end-point.

Effect of water

Unfavourable effects from the presence of water in non-aqueous titration systems have been noticed by many authors. For the most part, interference from water is associated either with its acid-base properties or its high dielectric constant. Keily and Hume have also pointed out the problems from the heats of dilution and mixing that may result from the presence of even minute amounts of water.[3]

The situation is even more complex in acetonitrile where the possibility of acid- or base-catalysed hydrolysis of the solvent must also be considered. In the titration of solutions of hydrogen chloride with diphenylguanidine, there is little effect from the presence of 1–2% of water added immediately before the titration. If, however, as short a time as 1 hr elapses between the addition of water to the acid solution and the titration, as little as 0·5% of water can result in sufficient hydrolysis of the solvent to obscure the entire titration curve. On the other hand, there appears to be little perceptible effect of water on the titration of bases with hydrogen bromide.

In contrast with the behaviour of dry acetic acid systems, the presence of small amounts of water was found to have very little effect on the heat of dilution of the titrants. On running 0·1*M* hydrogen bromide into 50-ml portions of acetonitrile containing varying amounts of water, linear dilution curves of low slope were obtained. Even with 1% of water present, the temperature rise did not exceed 0·08°. Mixing studies with diphenylguanidine titrant and acetonitrile-water mixtures yielded similar results.

TABLE IV—HEATS OF REACTION OF ACIDS WITH 1,3-DIPHENYLGUANIDINE

DISCUSSION

Although satisfactory titrations may be obtained both for the titration of acids and of bases, the use of acetonitrile as a medium for acid-base titration with a thermometric end-point has no real advantage from a practical standpoint. The instability of the solvent in the presence of strong bases makes the determination of weak acids impractical, and the difficulty of preparing stable anhydrous acetonitrile solutions of strong acids is a drawback for the determination of bases. Attempts to prepare anhydrous acetonitrile solutions of perchloric acid by metathetical reactions were unsuccessful. For example, although barium sulphate is very insoluble in acetonitrile, a mixture of barium perchlorate and sulphuric acid continued to deposit a precipitate after equilibration for 6 months. Hydrogen bromide, in spite of its volatility, was the most satisfactory of the strong acids investigated. The utilisation of reagent solutions in solvents other than acetonitrile (*e.g.*, higher alcohols, ketones, dioxan) for titrations in an acetonitrile medium may generally be expected to give rise to heats of mixing and dilution which distort the titration curves and may not always be compensatable by differential temperature measurements.

The heats of reaction of carboxylic and mineral acids in acetonitrile with 1,3-diphenylguanidine are given in Table IV. It was of interest to see if the same sort of relationship existed between the heats of neutralisation of the carboxylic acids in acetonitrile and their acid strengths as was found to exist between the heats of neutralisation and basic strengths of amines in the same solvent.[10] The plot of $-\Delta H_{150}$ in acetonitrile *versus* the Hammet σ-value for benzoic acid and five *m*- or *p*-substituted benzoic acids (Fig. 4) shows that such a correlation does exist except for *m*-nitrobenzoic acid. The anomalously high value for the heat of neutralisation of this compound remains unexplained. The equation of the line in Fig. 4 is $-\Delta H_{150} = 1{\cdot}23\ \sigma + 12{\cdot}4 \pm 0{\cdot}1$ Kcal/mole. Data on the heats of neutralisation of 32 amines with hydrogen bromide in acetonitrile and their theoretical interpretation have been published elsewhere[10]

POLAROGRAPHY OF COPPER IN DIETHYLENE-TRIAMINEPENTA-ACETIC ACID SOLUTIONS

EINAR JACOBSEN and GUNNAR KALLAND
Chemical Institute A, University of Oslo, Blindern, Norway

(*Received* 19 *June* 1963 *Accepted* 6 *October* 1963)

Summary—The polarographic behaviour of copper in the presence of excess DTPA has been studied by means of the dropping mercury electrode In an acidic medium the $copper^{II}$ complex is reversibly reduced to the amalgam At pH values above 5 the wave is broken into two parts and a new irreversible wave appears at a more negative potential An increase in pH of the supporting electrolyte results in an increase of the second wave at the expense of the original one, the limiting current of the total wave remaining constant. The effect of temperature, pressure of mercury, pH and the concentration of DTPA on the limiting current and the half-wave potentials of the two waves have been investigated and the stability constant of the copper-DTPA complex has been redetermined. The double wave is assumed to be the result of an inhibited electrode reaction, the inhibition being caused by the deposition of the reduction product at the electrode surface When the applied potential is increased above −0·7 V *vs* S.C.E., the film is desorbed and the current rises to its original value

INTRODUCTION

DIETHYLENETRIAMINEPENTA-ACETIC acid (DTPA) forms stable complexes with $copper^{II}$ In the presence of excess DTPA three complexes with the formulae CuH_2DTPA, CuHDTPA and CuDTPA, respectively, are formed at various pH. The complexes have been investigated by spectrophotometric and potentiometric methods and the stability constants determined.[1–4]

The polarographic behaviour of the copper-DTPA chelates has not previously been investigated. Preliminary experiments with the dropping mercury electrode (D.M.E.) showed that copper in the presence of excess DTPA is reduced in two steps in an alkaline medium, and that the ratio of the two waves was highly dependent on the pH of the supporting electrolyte. The present work was carried out in order to study this effect of pH on the reduction of the copper-DTPA complexes.

EXPERIMENTAL

Reagents

Diethylenetriaminepenta-acetic acid Obtained from Geigy Chemical Corp., New York, U.S.A. The commercial DTPA was recrystallised twice from a minimum amount of hot water and dried in the air. The purity of the product was checked by infrared analysis. A $0{\cdot}05M$ stock solution was prepared by dissolving 19·7 g of DTPA and 6 g of sodium hydroxide in distilled water and diluting to 1 litre The solution was standardised against dipyridozincthiocyanate according to Buděšinsky [5]

Standard $copper^{II}$ solution: Prepared by dissolving an accurately weighed amount of electrolytic copper in nitric acid. Part of the excess acid was evaporated and the residue diluted to appropriate volume.

The remaining chemicals were of reagent grade quality and they were used without further purification.

Two-tenths molar acetate- phosphate- and ammonia-buffers were used as supporting electrolytes. The pH of the electrolytes was adjusted to the desired value by adding hydrochloric acid or potassium hydroxide to the solution and its pH measured with a pH meter. Triton X-100, obtained from Rohm and Haas Co., Philadelphia, U.S.A., was used as maximum supressor in some experiments

Apparatus

Polarograms were recorded with a Tast-Polarograph, Selector D (Atlas Werken, Bremen Germany). The conventional type of dropping mercury electrode and of electrolysis cell was used The capillary characteristics, measured in 0·1*M* potassium nitrate (open circuit) at a mercury height of 52 4 cm were. m = 2 998 mg/sec and t = 3 52 sec An external saturated calomel electrode (S C E), connected to the cell by means of an agar bridge, served as reference electrode Dissolved air was removed from the solutions by bubbling oxygen-free nitrogen through the cell for 10 min and passing it over the solution during the electrolysis All experiments were performed at 25 ± 0 1°

The reversibility of the electrode reactions was tested by determining the temperature coefficient of the half-wave potentials and the slopes of the curves of log $i/(i_d - i)$ *vs* potential Corrections were made for the residual current and IR-drop in the circuit Data for the logarithmic plots were taken by manual operation of the polarograph, measuring the applied potential with a Hartman and Braun (No. 10018) potentiometer. Half-wave potentials of the reversible waves were taken from the logarithmic plots and were reproducible to ±1 mV

RESULTS

Preliminary experiments

Current-voltage curves of DTPA in supporting electrolytes of different pH showed that the reagent is not reduced at the D.M.E. An anodic wave, however, probably from the oxidation of mercury to a mercury-DTPA complex, was observed on all polarograms. The wave was shifted to more negative values with an increasing pH of the supporting electrolyte and the height of the wave was found to be proportional to the concentration of DTPA.

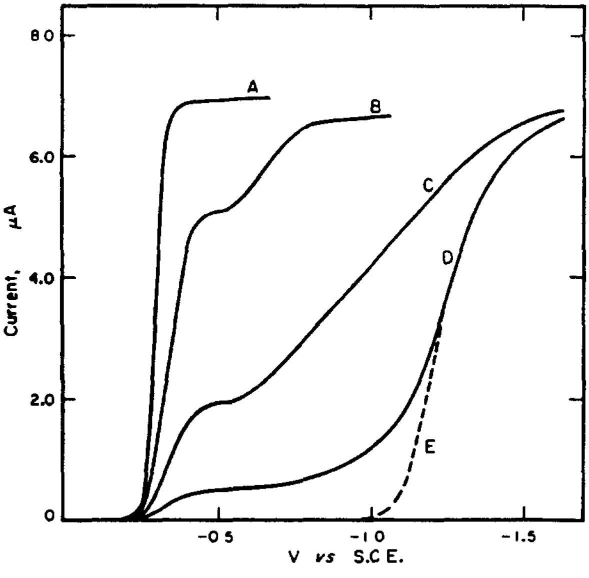

FIG. 1.—Polarograms of $10^{-3}M$ copper^{II} and $10^{-2}M$ DTPA in acetate buffer pH 4 60 with various amounts of Triton X-100 present. (a) 0%, (b) 0 002%, (c) 0 003%, (d) 0·006%, and (e) >0 01%.

Polarograms of copper in the presence of DTPA exhibited a maximum when recorded from solutions with low pH values. The maximum was easily suppressed by the addition of a minute amount of Triton X–100. Larger amounts of Triton had, however, a marked effect on the reduction wave, which was split into two waves and the limiting current was strongly decreased over a considerable potential range. A few polarograms recorded in the presence of various amounts of Triton X–100 are shown in Fig. 1. Experiments showed that the presence of 0·0005% of Triton was

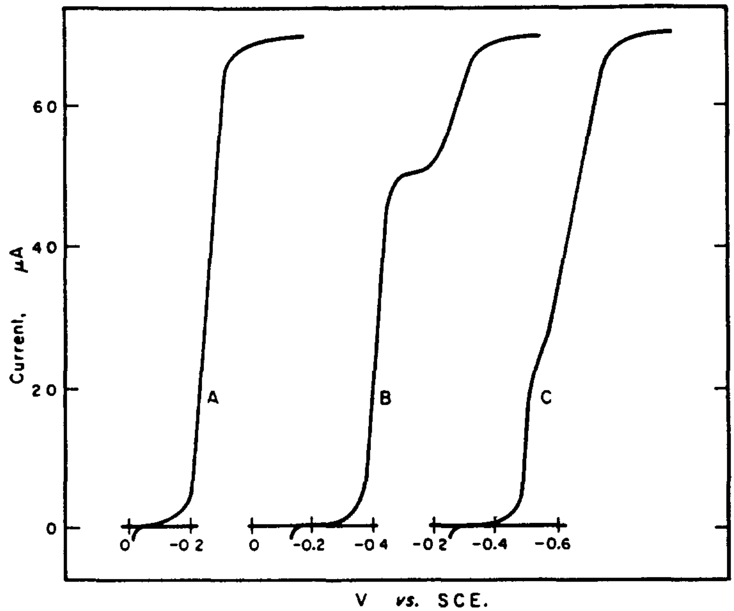

FIG. 2.—Polarograms of $10^{-3}M$ copper^{II} and $10^{-2}M$ DTPA: (A) acetate buffer pH 4·65, (B) phosphate buffer pH 6 80, and (C) phosphate buffer pH 9·60.

sufficient to suppress the maximum and this low concentration had no undesirable effect in an acidic medium. No maximum was observed on polarograms recorded from solutions with a pH greater than 4, and in the following experiments no surface active substances were added to the supporting electrolytes in the pH range 4–12.

Effect of pH

The effect of pH on the cathodic wave of copper^{II} in the presence of excess DTPA was investigated, using acetate and phosphate buffers as supporting electrolytes. Polarograms recorded from solutions with a pH less than 5 consisted of a single well-defined wave, whereas a second wave appeared on polarograms recorded at higher pH. An increase in pH of the supporting electrolyte resulted in an increase of the second wave at the expense of the first one, the total limiting current remaining constant. A few typical polarograms are shown in Fig. 2. The half-wave potential of the first wave was shifted to more negative values with increasing pH as indicated in Fig. 3. The half-wave potential of the second wave, however, remained practically constant ($E_{\frac{1}{2}} = -0{\cdot}68$ V *vs.* S.C.E.) in the entire pH range 5–12. The lower limit of pH in these measurements is restricted by the solubility of DTPA and the dissolution wave of mercury which interfered at pH values less than 3. The variation of the height of the first and second wave with the pH of the supporting electrolyte, is plotted in Fig. 4. The above results were perfectly reproducible. At a given pH identical polarograms were obtained, independent of the supporting electrolyte used (*i.e.*, acetate, phosphate or potassium nitrate/potassium hydroxide). The ratio between the first and second wave increased, however, in the presence of ammonia (Fig. 4). This is probably because of a mixed ligand complex and will be discussed below.

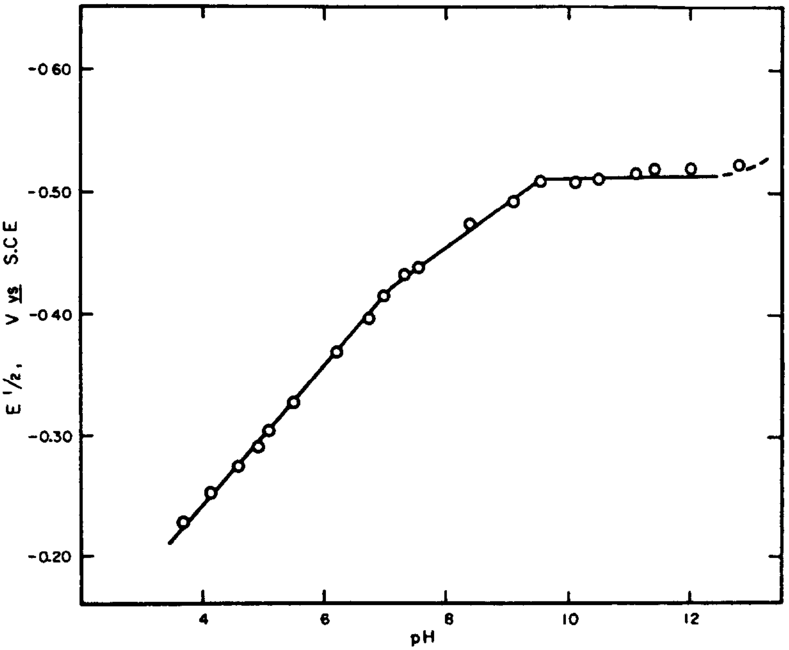

FIG 3.—Half-wave potentials of the first wave of $10^{-4}M$ copper^{II} and $10^{-2}M$ DTPA at various pH values

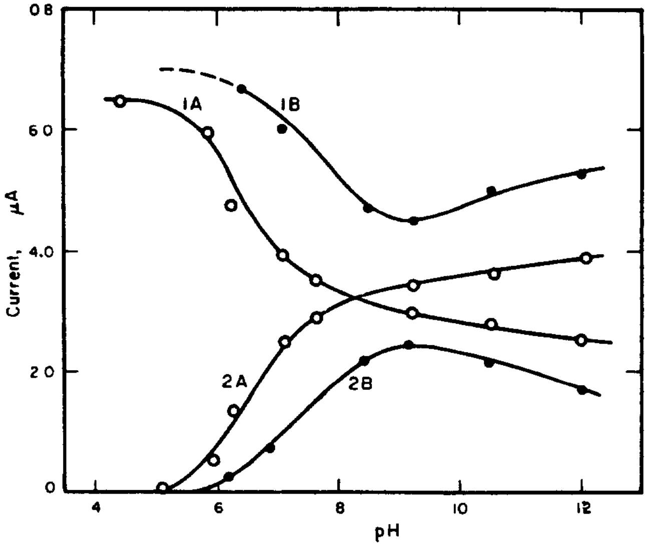

FIG. 4.—Limiting currents of the first (1) and second (2) wave of $10^{-3}M$ copper^{II} and $10^{-2}M$ DTPA at various pH values: (A) acetate and phosphate buffers, (B) ammonia buffers.

Reversibility of the electrode reactions

The reversibility of the electrode reactions was tested by plotting log $i/(i_d - i)$ *vs.* the potential. The plots yield straight lines at all pH for the first wave, and the slope of the lines indicated a reversible two-electron reduction of copper to the amalgam.

The half-wave potential of the first wave shifted to more negative values with an increasing concentration of DTPA, and the plot of the values of $E_{\frac{1}{2}}$ *vs.* the corresponding values of log C_x, resulted in straight lines. The slope of the lines indicated that only one group is co-ordinated in the complex. In the concentration range 5×10^{-4} to $10^{-2}M$ DTPA, the half-wave potential of the first wave may be expressed by the equation:

$$E_{\frac{1}{2}} = -0{\cdot}576 - 0{\cdot}029 \log C_x.$$

The concentration C_x of the free ligand available for complex formation was calculated using the dissociation constants of DTPA reported by Anderegg and coworkers.[2]

The second wave, which appeared on polarograms recorded from solutions with a pH greater than 5, showed an irreversible reduction. The plot of log $i/(i_d - i)$ *vs.* the potential yields curved lines at all pH from 5 to 12. The half-wave potential of this wave, taking $E_{\frac{1}{2}}$ as the point on the curve where $i = i_d/2$, was constant (—0·68 V *vs.* S.C.E.) and independent of the pH of the supporting electrolyte and the excess of DTPA present.

Effect of temperature

The effect of temperature on the cathodic waves of copper in the presence of excess DTPA was tested in acetate and phosphate buffers. In the region 20–45° the temperature dependence of both the half-wave potential and the height of the first wave was linear. The temperature coefficient of the half-wave potential, —0·3 mV/degree, is of the proper sign and magnitude for that of a reversible process.

TABLE 1 —EFFECT OF TEMPERATURE

Temp., °*C*	First wave		Second wave	
	$-E_{\frac{1}{2}}$, *V*	Current, μA	$-E_{\frac{1}{2}}$, *V*	Current, μA
20	0·396	0·53	0·68	0·16
25	0·397	0·56	0·68	0·16
30	0·399	0·60	0·68	0·16
35	0·400	0·64	0·68	0·16
40	0·402	0·68	0·68	0·15
50	0·403	0·73	0·68	0·15

$10^{-4}M$ copper^{II} and $10^{-3}M$ DTPA in phosphate buffer of pH 6·60.

The temperature coefficient of the diffusion current was 1·3% per degree, indicating a diffusion-controlled process. The data obtained from phosphate buffer pH 6·6 are reported in Table I. At this pH the two waves are very well separated and the temperature dependence of the second wave could also be measured. As seen from the table, the half-wave potential and the height of the second wave were found to be independent of the temperature within the experimental error.

Diffusion current constant

The diffusion current constant at different pH was determined by measuring the limiting current of 2×10^{-5} to $2 \times 10^{-3}M$ copper in the presence of $10^{-2}M$ DTPA. In the pH range 3–10, using acetate and phosphate buffers as supporting electrolytes, the limiting current of the *total wave* was independent of pH and it increased proportionally to the concentration of copper at all pH. The diffusion current constant in these media was found to be $I = 2{\cdot}42 \pm 0{\cdot}06$. In ammonia buffers of pH 10–12 the diffusion current constant was somewhat larger, $I = 2{\cdot}55 \pm 0{\cdot}05$. Comparison of these values with the diffusion current constant of the copper EDTA-complex determined by Pecsok,[6] $I = 2{\cdot}85$, indicates that the total wave is caused by a two-electron reduction of copper to copper amalgam.

Effect of drop time

The effect of drop time was investigated by recording polarograms of $10^{-4}M$ copper and $10^{-2}M$ DTPA in acetate and phosphate buffers at various heights of the mercury column. The height of the single wave obtained at pH <5 and the first wave obtained at higher pH values, increased with the height of the mercury, the value $i/\sqrt{h}$, where h is the height of the column after correction for the "back-pressure", was constant, indicating that the electrode reaction is diffusion controlled. The height of the second wave was found to increase proportionally to the height of the mercury column and indicates that this wave is from an adsorption on the electrode and that the current is controlled by the rate of penetration of the copper complex through an adsorbed film.[7] The data obtained at pH 6·65 are given in Table II.

TABLE II.—EFFECT OF PRESSURE OF MERCURY

h_{corr}, *cm*	First wave		Second wave	
	i_d, μA	$i_d/\sqrt{h}_{corr.}$	i, μA	i/h_{corr}
45·6	4·65	0·69	1·40	0·031
50·6	4·95	0·68	1·55	0·031
55·6	5·15	0·69	1·70	0·031
60·6	5·35	0·68	1·85	0·031

$10^{-3}M$ copper^{II} and $10^{-2}M$ DPTA in phosphate buffer of pH 6·65.

The drop time of the capillary was also measured as a function of the applied potential. The electrocapillary maximum was not shifted and the general shape of the curve did not change upon the addition of $10^{-3}M$ copper and $10^{-2}M$ DTPA to the supporting electrolyte, but a 2% decrease in drop time was observed over a considerable potential range.

DISCUSSION

It is evident from the experimental data that the first wave is from a reversible, diffusion-controlled, two-electron reduction of the copper-DTPA complex. The observed half-wave potentials are linear functions of the pH in the regions 4–7, 7–10 and 10–12·5 (Fig. 3). The slopes of the curves are −0·060, −0·035 and 0

V/pH unit, respectively, indicating that the following reactions take place at the electrode:

$$CuA^{3-} + 2H^+ + 2e^- \xrightarrow{pH\ 4-7} Cu(Hg) + H_2A^{3-}$$
$$CuA^{3-} + H^+ + 2e^- \xrightarrow{pH\ 7-10} Cu(Hg) + HA^{4-}$$
$$CuA^{3-} + 2e^- \xrightarrow{pH\ 10-12\cdot5} Cu(Hg) + A^{5-}$$

where H_5A represents DTPA.

At pH <4, the conditional constant[4] of $CuHA^{2-}$ is of the same order as that of CuA^{3-}, and the following reaction will probably take place in that pH region:

$$CuHA^{2-} + 2H^+ + 2e^- \xrightarrow{pH<4} Cu(Hg) + H_3A^{2-}.$$

The stability constants of the CuA^{3-} complex, calculated from the half-wave potentials of the first wave, was $pK_c = 20\cdot4$. Considering the great difference in ionic strength, this value compares favourably with the values 21·0, 21·5, 21·1 and 20·5 previously determined by potentiometric titration.[1-4]

The interpretation of the second wave is more difficult. The half-wave potential of this wave was constant, independent of excess reagent, pH and the kind of supporting electrolyte. Consequently, the double wave is not from the reduction of two copper complexes of different composition or mixed ligand complexes. The effect of temperature and the height of the mercury column on the second wave, indicates that the current is controlled neither by diffusion nor by kinetic reactions. At a given pH, the height of the second wave is proportional to the concentration of copper and to the height of the mercury column. The current did not, however, reach a limiting value with increasing concentration as in the case of catalytic and classical adsorption waves.

The double wave may, however, be the result of an inhibited electrode reaction.[8,9,10] The DTPA liberated at the electrode during the electrolysis is therefore assumed to be surface active and to accumulate on the electrode surface during the life of the drop. The effect will then be similar to the addition of Triton (Fig. 1), and the reaction will be partly inhibited until the desorption potential is reached. When the applied potential is increased above this value (about −0·7 V *vs.* S.C.E.), the film is desorbed and the current will rise to its original value.

Equipment for oscillographic current/time curves[8] was not available in this laboratory, but a detailed inspection of undamped polarograms indicated that an inhibition mechanism occurred at the electrode and the height of the second wave increased proportional to the height of the mercury column, as in the case of limiting penetration currents.[7]

At a given pH value the ratio of the two waves, and hence the degree of inhibition, was found to be independent of excess DTPA in the solution, indicating that only the DTPA species liberated at the electrode during the electrolysis is surface active. Hence, the electrode reaction cannot be completely inhibited as by the addition of a large amount of Triton X-100 (Fig. 1). The DTPA anions are desorbed at a less negative potential (−0·7 V) than the neutral Triton X-100 molecule (−1·3 V), indicating that the desorption potential depends on the charge and type of inhibitor present in the electrolyte.

It is of interest to note that the second wave does not appear on polarograms recorded from solutions of pH less than 5. In this pH range H_3A^{2-} is formed during the reduction and is probably less surface active and not so strongly adsorbed as the HA^{4-} and A^{5-} species liberated at higher pH values.

The co-ordination number of copper is six in the copper-EDTA complex and according to Kirson and Citron the complex exists as a polymer in solution.[11] By the addition of ammonia to the solution, the polymer is disrupted into single

$$[Cu(NH_3)_2EDTA]^{2-}$$

units.[12] A similar polymer with hexaco-ordinated copper is probably also formed in DTPA solutions, the six co-ordination being completed by weak intermolecular $C = O \cdots Cu$ linkages. When ammonia or ethylenediamine was added to the copper-DTPA chelate in phosphate buffer of pH 9–12, the blue colour of the complex increased in intensity. Polarograms of these solutions exhibited two waves as in phosphate buffers, but the height of the first wave increased at the expense of the second one upon addition of ammonia or polyamines to the supporting electrolyte, whereas the half-wave potentials remained practically constant. At a given pH and excess ammonia or ethylenediamine, the ratio of the two waves was constant and independent of other electrolytes present (Fig. 4). These experiments indicate that the DTPA species liberated at the electrode is less surface active and that a smaller amount is adsorbed in the presence of ammonia. It is possible that this effect is caused by a disruption of the polymer and the formation of a mixed ligand complex similar to that in EDTA solutions. No mixed ligand DTPA complexes have yet been reported in the literature, but the existence of a copper-ammonia–DTPA complex may probably be verified by infrared experiments as in the case of the EDTA complexes.[11,12]

Zusammenfassung—Das polarographische Verhalten von Kupfer in Gegenwart von überschüssiger DTPA wurde an der Quecksilbertropfelektrode untersucht. In saurem Medium wird der Kupfer (II)-Komplex reversibel zum Amalgam reduziert. Bei p_H-Werten über 5 spaltet die Welle in zwei auf und eine neue irreversible Welle erscheint bei negativerem Potential Ansteigen des p_H des Leitelektrolyten läßt die zweite Welle auf Kosten der ersten ansteigen, wobei der Gesamt-Grenzstrom konstant bleibt. Der Einfluß von Temperatur, Quecksilberdruck, p_H und DTPA-Konzentration auf Grenzstrom und Halbwellenpotential der beiden Wellen wurden untersucht und die Stabilitätskonstante des Cu-DTPA-Komplexes neu bestimmt. Die Doppelwelle wird als Folge einer gehemmten Elektrodenreaktion gedeutet, wobei die Hemmung in der Abscheidung des Reaktionsproduktes an der Elektrodenoberfläche besteht. Wenn die angelegte Spannung über −0,7V gegen die gesättigte Kalomelektrode gesteigert wird, wird der Film desorbiert, und der Strom steigt auf seinen ursprunglichen Wert an.

Résumé—Le comportement polarographique du cuivre en présence d'un excès de DTPA (acide diéthylène triamine pentaacétique) a été étudié au moyen de l'électrode à gouttes de mercure. En milieu acide le complexe du cuivre(II) est réduit réversiblement en amalgame. A un pH supérieur à 5 la vague se dédouble et une nouvelle vague irréversible apparaît à un potentiel plus négatif. A une augmentation de pH de l'électrolyte support correspond une augmentation de la hauteur de la deuxième vague aux dépens de la vague initiale, la somme des courants de diffusion restant constante. L'effet de la température, de la pression du mercure, du pH et de la concentration de DTPA sur le courant de

diffusion et sur les potentiels de demi-vague des deux vagues a été étudié et la constante de stabilité du complexe Cu-DTPA a été déterminée à nouveau. La double vague est supposée être le résultat d'une réaction à l'électrode inhibée, cette inhibition étant due au dépot du produit de réduction sur la surface de l'électrode Quand le potentiel appliqué devient plus négatif que $-0{,}7$ V/E C.S le film est désorbé et le courant reprend sa valeur initiale

GEOMETRY-RELATED ERRORS IN INSTRUMENTAL NEUTRON-ACTIVATION ANALYSIS

RALPH A. JOHNSON
Shell Development Company, Emeryville, California, U S A.

(*Received* 19 *June* 1963. *Accepted* 10 *October* 1963)

Summary—Geometry-related errors in instrumental neutron-activation analysis are defined and evaluated. Neutron-flux distributions, variations in counting geometry, and intra-sample neutron moderation and reflection are discussed in relation to these errors. Devices for error control are described.

NEUTRON ACTIVATION when combined with γ-ray spectrometry and decay-rate analysis offers a purely instrumental, non-destructive approach to elemental analysis. Because of the high penetrativeness of neutrons and of γ-rays, matrix effects are exceptionally small. In many cases, samples as large as 25–30 ml are analysed. Furthermore, in most cases, the results are relatively insensitive to differences in composition, sample volume or bulk density. With the introduction of accelerator systems for neutron production, this method, called instrumental neutron-activation analysis here, comes within the budgetary, space and manpower limitations of many laboratories, and shows promise of taking a place among the established instrumental analytical tools of the modern laboratory.

The physical concepts of the method, its instrumentation and some typical applications to routine analyses have been presented by Guinn and Wagner[1] for the system used in the Emeryville Research Center of Shell Development Company. Using this system, Guinn and Johnson[2] have found instrumental neutron activation to be a reliable and convenient tool for routine analysis and to be especially valuable in quickly solving new or unusual analytical problems which by other methods would require considerable research and development.

In seeking the greatest power and efficiency for this new method, it is the task of analytical research and development to explore its variables systematically and to relate them to such analytical characteristics as sensitivity, precision and selectivity. As a part of this exploration, the present study has to do with errors related to sample-source geometry and to sample-counter geometry. In the typical activation determination, results are calculated on the basis of a comparison of the respective count rates of a sample and a standard. Implicit in this comparison are the assumptions that sample and standard are exposed to the same neutron flux and are counted with the same counting efficiency. In practical activation sources, however, the neutron-flux distribution is non-uniform, and presents significant differences between and within sample spaces. Furthermore, for the detectors and samples used, the counting efficiency varies significantly over the sample space. Thus the assumptions of constant flux and constant counting efficiency are not simply and exactly met. In an evaluation of the analytical consequences of this situation, this study presents surveys of neutron distributions and of counting efficiencies, relates these variables to certain errors in activation analysis, and describes methods for control of these errors.

Although the results are specific for the actual source used, the principles evolved and the approach taken to control the geometry-related errors are expected to be generally applicable to other systems for instrumental neutron-activation analysis

EXPERIMENTAL

Apparatus

Neutron source The neutron source used is a modification of the source described by Guinn and Wagner[1] and illustrated in Fig. 1. Neutrons are generated by the action of bremsstrahlung, from a 3-MeV Van de Graaff electron accelerator with a gold target, on beryllium in a 6-inch cube of the metal. The moderator is Santowax, a radiation-resistant wax Neutron shielding is accomplished by a Boral cover and by boric acid around the side and bottom of the assembly

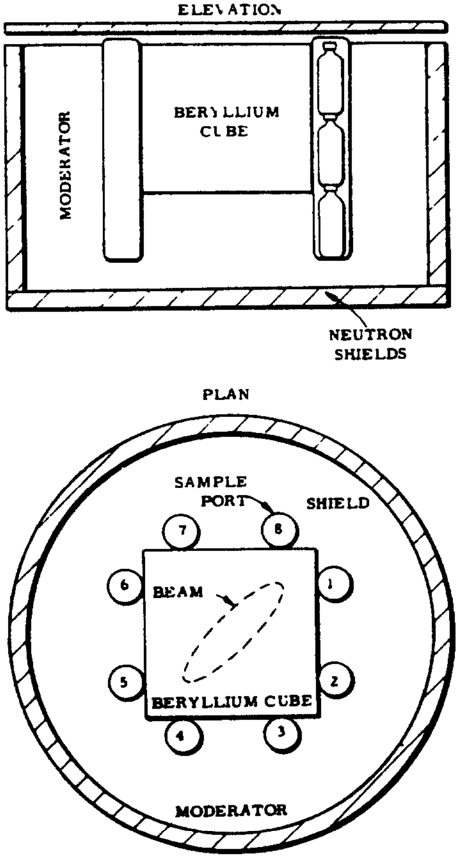

FIG. 1.—The photoneutron source.

Scintillation counter: Well-type NaI(Tl) crystal is used to yield maximum counting efficiency and to achieve the smallest variation in counting geometry with sample volume. The well accommodates commercially available 1-oz polyethylene bottles, as shown in Fig. 2. The over-all dimensions of the crystal, diameter × depth, is 3″ × 3″.

Procedure

Flux-distribution patterns are determined by activating and counting gold foils (usually about 20 mg of 0·5 mil gold sheet) supported in appropriate positions on pressure-sensitive cellophane tape.

The position of the X-ray beam relative to the beryllium block is determined photographically with the aid of X-ray sensitive polyvinyl chloride sheet.[2]

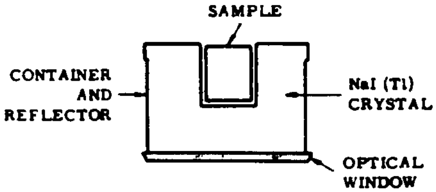

FIG. 2.—Cross-section of scintillation well detector with sample in well

The neutron-flux levels in different sample ports are determined by activating and counting a set of nearly identical standards, *e g* , gold foils, or suitable solutions, such as 0 1% manganous nitrate, at a given level in sample ports around the core.

Volume effects and height effects are determined in an analogous way using monitors irradiated and counted under the conditions being tested

RESULTS AND DISCUSSION

Positioning errors

Positioning errors are defined as errors attributable to differences in neutron flux at a given level from sample port to sample port. A typical positioning error pattern is given in Fig. 3. Also shown in this figure is the corresponding beam-to-core orientation, according to the photograph for this positioning run. A comparison of the pattern and the diagram illustrates the main dimensional and geometric effects on the pattern. In particular, positions 5–8 show a generally higher flux than positions 1–4, which correlates with the beam being located closer to the former positions than to the latter. Furthermore, a geometric correlation is observed in the similarity of the pattern for positions 1–4 to that for positions 4–8; thus the symmetry of the beam scan is reflected in the symmetry of the positioning pattern.

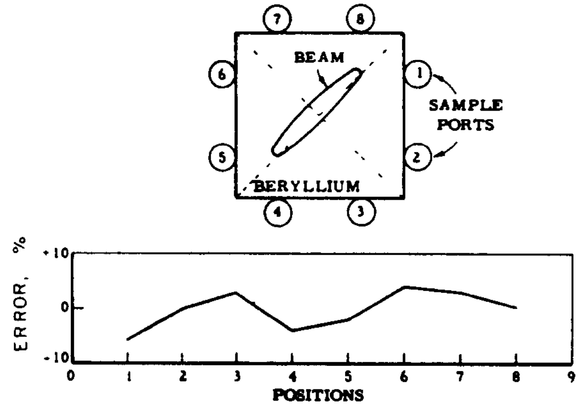

FIG. 3.—Positioning error with an uncentred beam

The correlations observed above are generally found throughout a series of positioning runs. However, the variability of the patterns from run to run is great enough to reduce the value of any single pattern as a calibration standard.

The position-to-position variation and the run-to-run variability are largely attributed to the strong dependence of the neutron flux on beam-to-sample distance. An illustration of this effect is given in Fig. 4, which presents the changes in neutron flux in the sample space with changes in the distance from the beam centre to the sample (see inset in Fig. 4). According to Fig. 4, the gradient for the centred beam, *i.e.*, at a beam-sample distance of 3·5 inches, is 16–20 relative % per inch. For a beam which is 0·25 inch off centre, this gradient corresponds to a difference of 8–10% between fluxes in ports on opposite sides of the core and, therefore, yields a positioning pattern like that of Fig. 3. In terms of precision, the above effects yield an error component of about 3% relative standard deviation.

Another view of the effect of flux distribution is given in Fig. 5, which shows how the flux varies with distance from the beam axis for a centred beam (see inset in Fig. 5).

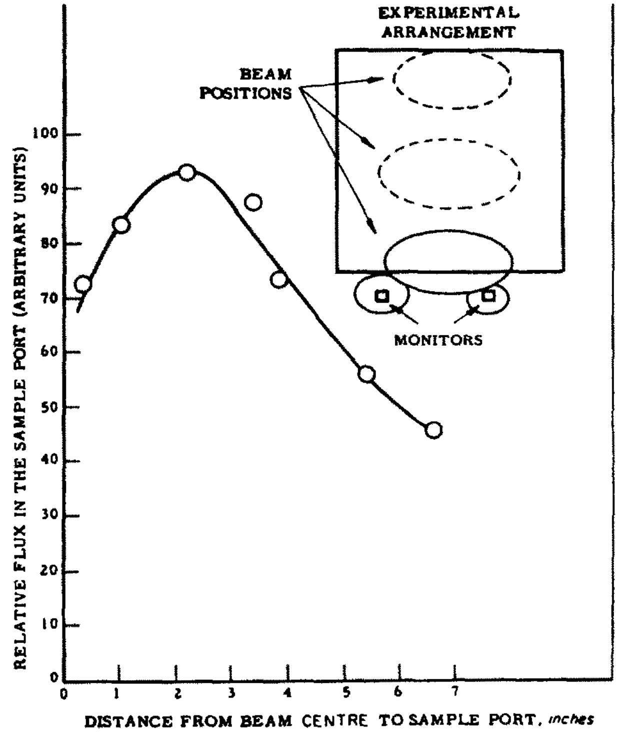

FIG. 4.—Effect of beam-to-port distance of flux in the sample port (beam position variable).

The sharp flux-distance gradient has the same implications as in the preceding discussion. A small maximum in the flux distribution is found in the reflector near its interface with the core. This maximum, signifying a local accumulation of neutrons in the reflector, is attributed to the fact that in comparison with the beryllium of the core the wax moderator has greater moderating power and a smaller neutron capture cross section.[4] The distribution of Fig. 5 is measured at the top of the source, *i.e.*, above the level of Sample C in Fig. 1. Experimental determination of distributions at lower levels are not feasible in this system, but results from other systems, to be described elsewhere, indicate that maxima at lower levels are less sharp. The development of the maximum near the interface has the effect of reducing the error from inhomogeneity within a cross-section of the sample.

Devices for controlling the positioning error

Foil monitors. Flux monitors of gold foil are attached to the tops of the containers of samples and standards, carried through the irradiation, and counted to yield a position-to-position flux calibration for the respective irradiation. Use of monitors is simple, but it contributes an additional counting error to the result.

"*Lazy susan*" *sample rotation.* If the sample ports and core are radially symmetrical with respect to an axis, rotation of samples about that axis eliminates errors from beam wandering and core-to-beam eccentricity. In practice, some variation is usually found from position-to-position because of dissymmetries in the rotating assembly, *i.e.*, in the interrelationship of ports, core, and axis of rotation. However, if the axis of rotation is accurately centred with respect to the ports, the pattern of flux variation from these dissymmetries is reproducible and, once determined, may be used as a calibration curve.

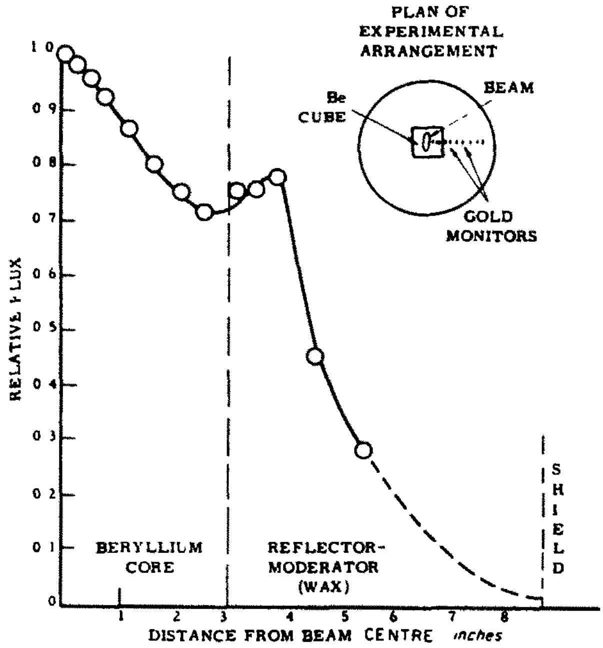

FIG. 5.—Effect of beam-to-monitor distance of flux distribution transverse to the beam (beam position fixed).

The off-centre beam position. If only one sample and one standard are to be irradiated, excellent flux uniformity can be achieved by scanning the beam parallel to and about 1 inch from one edge of the core, as shown by the beam position with the solid outline in Fig. 4. In this beam-to-core orientation, two effects compensate each other to form a maximum in the plot of flux available to the sample *vs.* beam-to-port distance as shown in Fig. 4. The compensating effects which result in the maximum are (1) a decrease in flux with increase in beam-to-port distance resulting from inverse square attenuation and neutron capture and (2) an increase in flux with increase in beam-to-port distance because of an increase in the fraction of bremsstrahlung beam falling within the beryllium core.

Volume errors

The volume errors in this discussion are those errors in activation analysis attributable to differences between the volumes of samples and the volumes of their respective comparison standards. In this investigation of these errors, the variables studied are: (1) differences in neutron flux at different levels within the ports, (2) enhancement of intra-sample neutron flux with increase of sample volume, and (3) differences in counting efficiency at different levels in the detector well.

The relationship between neutron flux and height within the sample port is shown in Fig. 6. The three sample positions indicated in Fig. 6 correspond with the sample levels shown in Fig. 1, the diagram of the neutron source assembly. It is evident from Fig. 6 that the neutron flux available to the sample depends strongly on the height at which it is situated in the sample port. It is also evident that both the sign and magnitude of the intra-sample flux-to-height gradient depend strongly on the choice of height at which the sample is irradiated. For example, for a sample in position A or position B of this source, the neutron flux increases with increasing height, *cf.*, Curve 1, Fig. 7; however, for a sample in position C, the neutron flux decreases with increasing height.

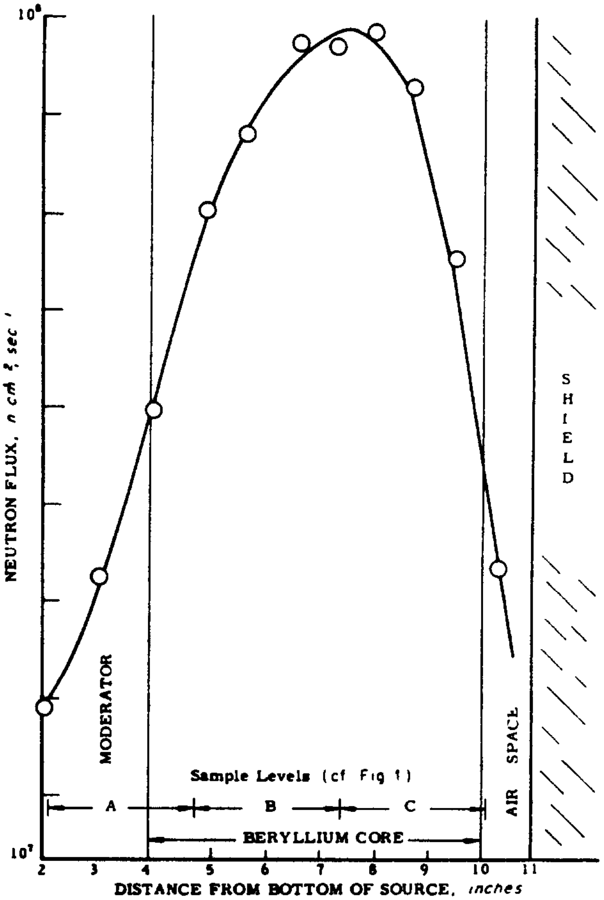

FIG. 6.—Flux distribution parallel to the beam axis (vertical distribution).

In instrumental neutron-activation analysis, the counterpart of the flux-to-height variation is the variation of counting efficiency with height in the detector. The latter relationship, shown in Curve 2 of Fig. 7, is largely determined by the sample-well geometry.

The count rate measured in a practical activation analysis, which is called the activation count rate here, is a function of the product of the neutron flux and the counting efficiency. Correspondingly, the variation of activation count rate with height in a given sample space varies with the product of the respective flux- and counting efficiency-height variations. This inter-relationship is illustrated in Fig. 7 for irradiation in the B position of the present source (Figs. 1 and 6). In this situation, the height-flux gradient (Curve 1, Fig. 7) is opposite in sign, but nearly equivalent in magnitude to the height-counting efficiency gradient (Curve 2, Fig. 7). Thus these two effects in an activation analysis may approximately cancel each other to yield a relatively small dependence of activation-induced count rate on height, as shown in Curve 3, Fig. 7. However, a quite different relationship may be found for irradiations carried out at a different height in the sample port. For example, samples irradiated in the C-position of the present source (Figs. 1 and 6) are exposed to a neutron flux which decreases with increasing height in the port. In this situation the flux-height gradient and the counting efficiency-height gradient enhance each other to yield a relatively strong dependence of activation count rate on sample height. It is clear, therefore, that the magnitude of errors possible from discrepancies between respective sample and standard volumes varies widely with differences in the height at which irradiations are carried out.

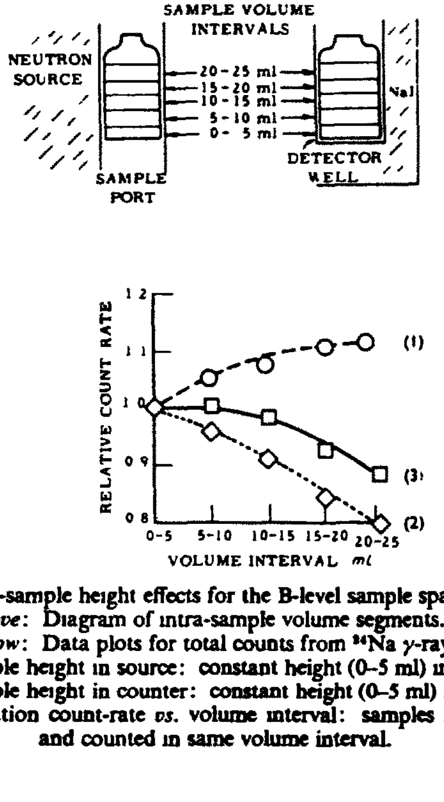

FIG. 7.—Intra-sample height effects for the B-level sample space of Fig. 6.
Above: Diagram of intra-sample volume segments.
Below: Data plots for total counts from ^{24}Na γ-rays.
○—Variable height in source: constant height (0–5 ml) in counter.
◇—Variable height in counter: constant height (0–5 ml) in source.
□—Activation count-rate *vs.* volume interval: samples irradiated and counted in same volume interval.

The preceding discussion deals with changes accompanying the displacement of a small volume segment along the vertical axis of the counter well and/or the sample port of the neutron source. On the basis of these effects, estimates may be made of the corresponding changes accompanying increases in sample volume. These estimates may be obtained by calculating the averages of the effects for the respective small volume displacements, *e.g.*, the counting efficiency of a 10-ml sample is approximately the average of the counting efficiencies of the 0–5 ml segment and the 5–10 ml segment in the crystal well. Thus the effect of increasing volume on activation count rate may be estimated as the averages of the activation count rates for the appropriate small volume segments. For the results given in Curve 3, Fig. 7, these averages are given in Column 2, Table I. For comparison, the experimentally-determined count rates for the indicated sample volumes are given in Column 3 of this Table The results in these two columns reveal that with increasing sample volume the experimental count rates exceed by progressively greater amounts the rates based on experiments with small volume segments. This difference is attributed to a third factor in the volume effect, namely, the effect of flux enhancement with increasing volume from intra-sample neutron moderation and reflection. This effect is more specifically demonstrated by the experiment and results shown in Fig. 8. Here it is shown that an increase in activation count rate is obtained in a sample segment without changing its radiation position or counting position if the sample segment is flanked by segments of water as a reflector. This enhancement, as indicated above, is attributed to neutron moderation and reflection within the sample. In general, the magnitude of this effect for samples ranging in volume from 2–25 ml is smaller than the flux-height and counting efficiency-height effects. Nevertheless, it is important enough to be considered in setting up the irradiation geometry for activation analysis of samples varying over a wide volume range such as this.

TABLE I —EFFECT OF SAMPLE VOLUME ON SPECIFIC COUNT RATE OF ^{24}Na γ-RAYS IN INSTRUMENTAL ACTIVATION ANALYSIS
Samples are irradiated in the position indicated as "B" in Fig. 1 and 6 and counted in a well-type scintillation detector

Sample volume, *ml*	Relative specific count rates	
	Averages of rates from corresponding 5-ml segments. Results of Curve 3, Fig. 7	Experimental rate for volume indicated
5	1·00	1·00
10	1·00	1·02
15	0·99	1·03
20	0·98	1·03
25	0·96	1·04

A similar effect observed in activation analysis in the ORNL graphite reactor is described by Reynolds and Mullins[6] as a neutron perturbation attributable to enhancement of the thermal flux by moderation of epithermal neutrons within the sample.

By using the above considerations as guide lines in choosing the irradiation positions in the present activation system, good uniformity of specific count rate over a relatively large volume range, 5–25 ml, has been obtained. This uniformity is evident in the results of Column 3, Table I. Although the examples given here are from one neutron source and one detector, the principles and general approach described have usually been successful in analyses with other neutron sources, *e.g.*, sources with beryllium cores of other shapes and sizes and fast neutron sources using the deuterium-tritium reaction to produce 14-MeV neutrons.

It should be noted that volume effects other than those which are geometry-related exist, and may cause large errors. These other effects are principally radiation absorption effects, *i.e.*, variations in self-shielding of neutrons and self-absorption of β rays and γ rays with variation in sample volume. These effects will be described elsewhere.

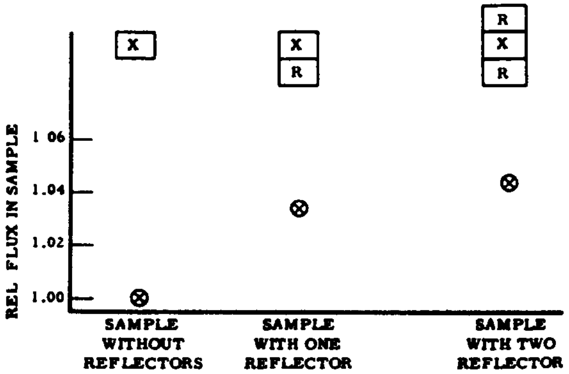

Fig. 8.—Effect of intra-sample neutron reflection.
Boxes show sample(X)-reflector(R) arrangements. For the samples irradiation position and counting geometry are held constant.

CONCLUSIONS

Geometry-related errors in instrumental neutron activation analysis are of two types, *viz.*, positioning errors and volume errors. Positioning errors are those which arise if samples and their comparison standards yield different specific count rates because of a variation in neutron flux from port-to-port around the source. In studies of this error, the port-to-port flux variations are found to correlate with small variations in beam-to-port distance. Furthermore, considerable variability among port-to-port flux patterns is found as small accidental changes in the beam-to-source geometry are made from run to run. These effects are attributed to the relatively large flux gradients shown to exist in neutron flux distributions normal to the beam axis. In the control of the positioning error, port-to-port flux patterns are usually too variable to permit the use of a single pattern as a calibration standard. However, satisfactory results have been obtained by (1) using gold foils attached to each container as flux monitors; (2) rotation of samples about the beam axis on a "lazy susan" to produce a uniform average flux to the samples; or (3) irradiation in an off-centre beam position chosen to yield excellent flux uniformity to a single sample-standard pair.

Volume errors are those which arise if the specific count rates of sample and standards are different because of differences in their volumes. The effects found to be the sources of geometry-related volume errors are the following:

(1) variation in counting efficiency with height in the detector well, which is found to be in general agreement with the variation predicted on the basis of solid geometry;

(2) variation in neutron flux with height in the port of the neutron source, which is characterised by a maximum flux near the midline of the core; and

(3) enhancement of neutron flux with increase in sample thickness, which is smaller than the preceding effects and is attributed to intra-sample neutron moderation and reflection.

From surveys of these effects on a particular system, an optimum irradiation position may be chosen in which respective height gradients compensate each other so as to yield a minimum variation of activation-induced count rate with changing volume.

This approach to control of the volume error is especially important in analysis in which large volume ranges are involved, *e.g.*, 2–25 ml. The principles and methods are expected to be applicable to instrumental activation analyses with other source-counter combinations

Zusammenfassung—Geometrisch bedingte Fehler bei der Neutronenaktivierungsanalyse werden definiert und berechnet. BIVALENT THALLIUM AND THE MECHANISM OF THE ELECTRODE REACTION $Tl^{3+} + 2e \rightleftharpoons Tl^{+}$*

H. A. CATHERINO and JOSEPH JORDAN
Department of Chemistry, Pennsylvania State University, University Park, Pa., U.S.A.

(*Received* 19 *June* 1963. *Accepted* 28 *September* 1963)

Summary—The thallium^{I}-thallium^{III} electrode reaction has been studied by hydrodynamic voltammetry at platinum anodes and cathodes. Conclusive evidence is presented that the electro-oxidation of the aquo ion Tl^{+} and the electroreduction of Tl^{3+} proceed via a bivalent thallium species. Thallium^{II} is a stronger oxidant than thallium^{III} ion. In 1*M* aqueous perchloric acid the rate of the disproportionation process

$$2Tl^{II} \rightarrow Tl^{+} + Tl^{3+}$$

is relatively fast compared to the electron transfer steps

$$Tl^{II} + e \rightarrow Tl^{+}$$
$$Tl^{3+} + e \rightarrow Tl^{II}.$$

THE investigation described below was devoted to the heterogeneous electron-transfer process

$$Tl^{3+} + 2e \leftrightarrows Tl^{+} \tag{1}$$

occurring at a platinum indicator electrode in a 1*M* aqueous perchloric acid supporting electrolyte, where the aquo-ions of univalent and tervalent thallium are the overwhelmingly predominating stable species. In view of this situation, equation (1) is of fundamental significance, as a possible example of a "single-stage two electron transfer" mechanism in an electrode reaction. In terms of a corresponding physical picture, this implies that the transfer of both electrons be completed during a single vibrational transition of the activated complex, *i.e.*, within a time interval of the order of 10^{-13} sec. For "purely chemical" electron-transfer processes occurring in homogeneous solution (*e.g.*, electron exchange between tagged and untagged ions involving two oxidation states of the same element; "cross reactions" involving two different couples, such as the oxidation of chromium^{II} by cobalt^{III}) this question has been the subject of a historic controversy. On the one hand, the Haber-Weiss school argued *a priori* that *all* electron transfer processes must necessarily be resolvable into ultimate "single electron transfer steps";[2,3] on the other hand, experimental evidence to the contrary was adduced.[4] As far as the thallium^{III}-thallium^{I} couple in perchloric acid is concerned, rate studies of the homogeneous electron-exchange process

$$Tl^{+} + \overset{\bullet}{Tl}{}^{3+} \xrightarrow{\text{aq. HClO}_4} Tl^{3+} + \overset{\bullet}{Tl}{}^{+} \tag{2}$$

---

* Based on a doctoral thesis by H. A. C. The senior author (J. J.) has had the benefit of the inspired guidance of Professor Kolthoff in an earlier study devoted to the voltammetry of thallium.[1] It is fitting that he contribute to this Honour Issue a paper on a related topic.

did not permit discrimination between the two alternatives.[5] However, kinetic data involving the oxidation of iron^{II} by tervalent thallium were interpreted[6] as being consistent with the formation of a bivalent thallium intermediate in accordance with the equations:

$$Fe^{2+} + Tl^{3+} \rightarrow Fe^{3+} + Tl^{II} \tag{3}$$

$$Tl^{II} + Fe^{2+} \rightarrow Fe^{3+} + Tl^{+} \tag{4}$$

The elucidation of the mechanism of the thallium^{I}-thallium^{III} electrode reaction is timely, because it has been suggested that similar transition states may be involved in electrode processes and in homogeneous electron-exchange reactions.[7] Vetter and Thiemke[8] have presented experimental evidence which is compatible with the assumption, that in 0·5–7·5 *M* aqueous sulphuric acid, reaction (1) proceeded *via* the two-step sequence.

$$Tl^{III} \overset{e}{\leftrightarrow} Tl^{II} \overset{e}{\leftrightarrow} Tl^{I} \tag{5}$$

In the investigation described in this paper, it has been shown *conclusively* that in 1*M* perchloric acid the thallium^{I}-thallium^{III} electron transfer at platinum electrodes occurred by the following mechanism.

Electroreduction of aquo-thallium^{III} ion.

$$2[Tl^{3+} + e \xrightarrow[\text{rate determining}]{k_{3,2}} Tl^{II}] \tag{6a}$$

$$2\,Tl^{II} \xrightarrow[\text{fast}]{k_{dispr}} Tl^{+} + Tl^{3+} \tag{7}$$

Electro-oxidation of aquo-thallium^{I} ion:

$$2[Tl^{+} \xrightarrow[\text{rate determining}]{k_{1,2}} Tl^{II} + e] \tag{6b}$$

$$2\,Tl^{II} \xrightarrow[\text{fast}]{k_{dispr}} Tl^{3+} + Tl^{+} \tag{7}$$

Implicit in equation (7) is direct evidence that the standard potential of the couple Tl^{II}/Tl^{+} must necessarily be more anodic than that of the Tl^{3+}/Tl^{+} couple. This accounts satisfactorily for the fact that bivalent thallium has never been prepared as a stable species in quantities amenable to chemical characterisation.

EXPERIMENTAL

The methodological approach employed for elucidating electrode kinetics was the technique of "hydrodynamic voltammetry", developed in these laboratories and previously described.[9–11] Current-voltage (c.v.) curves were recorded in a rotated electrolysis cell in which the electrolyte solution streamed past a stationary indicator electrode under judiciously controlled conditions of laminar flow.[11] The rates of the prevailing mass transport (between the bulk of the electrolyte solution and the indicator surface) corresponded within 1% to a forced convection model discussed in an earlier paper,[10] and characterised by the following equations:

$$I = \pm nFAm_i(a_i - a_i^0) \tag{8}$$

$$I_l = \pm nFAm_ia_i \tag{9}$$

$$m_i = \rho V^{1/2}D_i^{2/3}\nu^{-1/6}L^{-1/2} \tag{10}$$

which were verified in the present study. The symbols in equations (8)–(10) have the following meaning: I = net current (A), assigned a positive or negative sign to denote reduction or oxidation, respectively; nF = number of coulombs/mole involved in the over-all electrode reaction; I_l = limiting current (anodic or cathodic); A = effective area of indicator electrode (cm^2), m_i = mass transport coefficient (cm/sec) for the species identified by the subscript, a_i, a_i^0 = activity (moles/ml) of species i in the bulk of the solution and at the electrode surface, respectively; ρ = a dimensionless friction drag coefficient; v = linear velocity of solution (cm/sec) past the indicator electrode, D_i = a diffusion coefficient (cm^2/sec) defined in terms of activity gradients,[12] ν = kinematic viscosity (cm^2/sec), L = characteristic dimension (cm) of electrode, parallel to flow Concentrations of reactants and products at the indicator electrode interface (which are not accessible to direct experimental determination and are of critical importance in determining the values of the rate parameters in electrode reactions) were calculated on the basis of this mass transfer model Two indicator electrode geometries which yielded similar results were employed, viz, a conical micro electrode described previously[10] (L = the slant height of the cone) and a planar wedge electrode illustrated in Fig. 1.

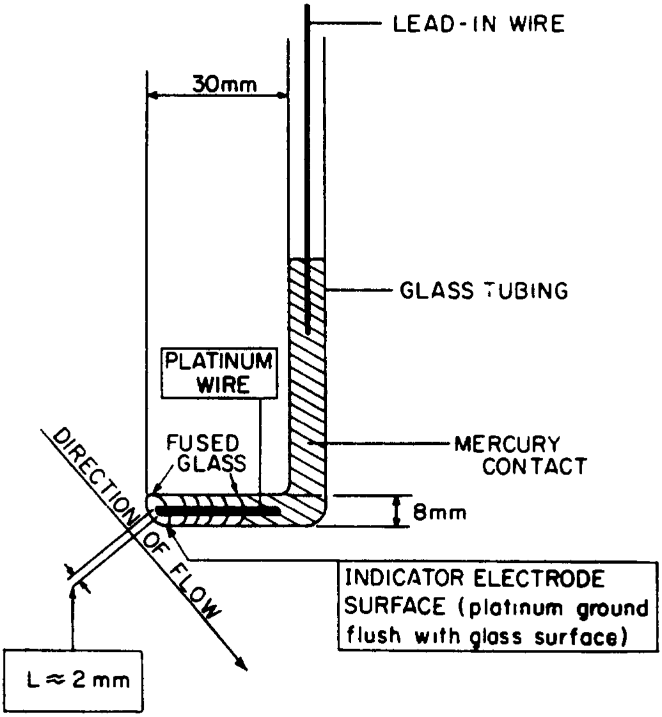

FIG. 1.—Planar wedge microelectrode
{L = characteristic dimension [see equation (10)]}

All c.v. curves were recorded in a range of potentials between 0 2 and 1 7 V versus the normal hydrogen electrode (NHE), where the platinum surface existed invariably in a reproducible "semi-oxidised" form, Pt(OH)$_n$, characterised by Feldberg.[13] As a working reference electrode, a saturated silver-silver chloride half cell (0·198 V *vs.* NHE), described by Lingane was used in conjunction with an agar gel salt bridge.[14] Appropriate precautions were taken to eliminate any consequential contamination of the electrolysis cell from the reference electrode. The electrolysis cell was constructed of polyethylene. It was ascertained, with the aid of *ad hoc* experiments carried out in all-glass apparatus, that the results obtained in this study were not affected by the polyethylene.

Voltammograms were recorded with conventional automatic polarographs, including a Sargent Model XXI instrument, and a Leeds and Northrup Electrochemograph, Model E. Potentials were scanned at rates customary in conventional polarography, *i.e.*, 1·24 to 3 33 mV/sec.

All experiments were carried out at 25·0°. Reagent-grade chemicals and triply distilled water were used. Current measurements were reproducible to within ±1%. Potential measurements were

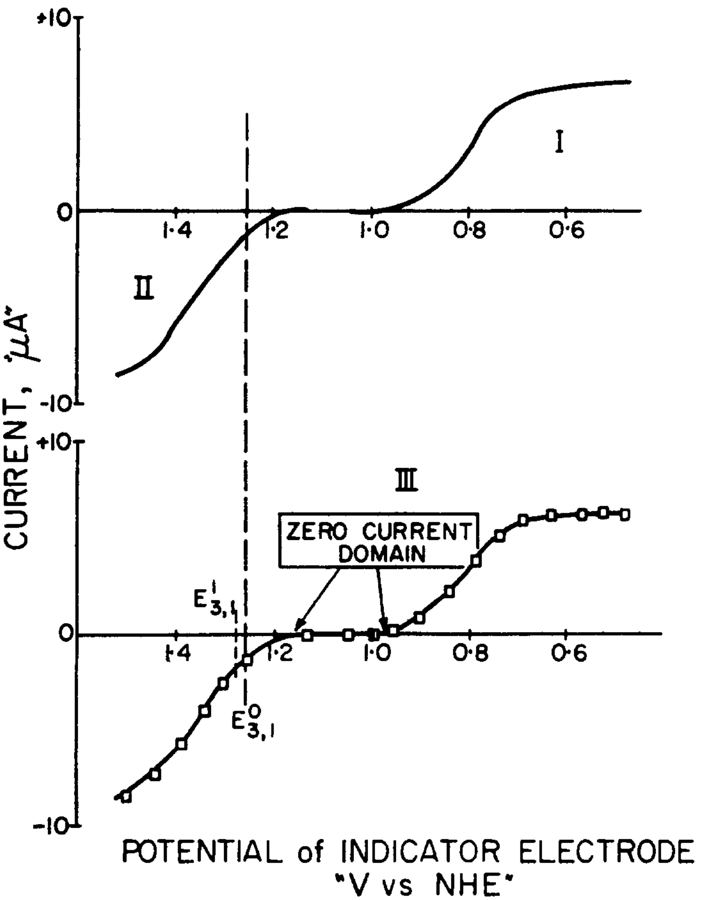

Fig. 2.—Examples of current-voltage curves obtained experimentally (flow velocity = 7·0 cm/sec): I—cathodic wave obtained in $10^{-3}M$ Tl^{3+}, in the absence of Tl^+;

precise and accurate to 0·005 V. Because the resistance of the electrolysis cell was 350 Ω and the maximum current measured was 50 μA, corrections for iR drops were not necessary. All potentials have been referred to the normal hydrogen electrode (NHE), using the Stockholm Sign Convention. All rate parameters reported in this paper have been consistently defined in terms of the activities of the reactants involved. This applies to the rate constants used to characterise electron transfer, as well as to mass transport coefficients [*m* in equations (8)–(10)] and diffusion coefficients. The choice of "activity rate constants", in preference to the more commonly used conventional "concentration rate constants", was predicated by considerations of fundamental consistency and general applicability (as well as convenience in correcting for electrical double layer effects, when applicable).[15]

Careful consideration was given to the magnitude of possible corrections from effects of the electric double layer.[16,17,18,19,20] At the high ionic strength used in this study ($\mu = 1$), corrections for "non-specific adsorption" proved unnecessary within the precision of the rate parameters determined (±30% for electron-transfer rate constants and ±10% for transfer coefficients). The experimental conditions were such that specific adsorption (as far as it can be assessed) was minimised.

All studies were carried out in a voltage domain which was more positive than the potential of zero charge on platinum ($\approx 0{\cdot}2$ V in $1M$ perchloric acid), where cations are generally not adsorbed.* The sole anion present in appreciable concentrations was perchlorate, the specific adsorption of which is known to be negligible in our working range of potentials.

RESULTS

Altogether, approximately 100 voltammograms were recorded at several concentrations and at 15 selected flow velocities in the ranges specified below:

(a) bulk concentrations of Tl^{3+}:

$5 \times 10^{-3} M$ to $5 \times 10^{-4} M$ [$3 \times 10^{-7} < a_{Tl^{3+}} < 3 \times 10^{-6}$ moles/ml]†

(b) bulk concentrations of Tl^+:

$5 \times 10^{-3} M$ to $5 \times 10^{-4} M$ [$3 \times 10^{-7} < a_{Tl^+} < 3 \times 10^{-6}$ moles/ml]†

(c) flow velocities:

5 to 90 cm/sec.

Values reported in this paper for rate parameters represent appropriately weighed averages of all of the relevant results, whose precision is indicated in terms of the standard deviation of the mean. The voltammograms illustrated in Fig. 2 are typical of the results obtained. As is evident from the figure, the cathodic wave was virtually unaffected by the presence of thallium^{I} ion and *vice versa*. Between the waves there exists a "zero current domain" (ZCD), in the potential range $1{\cdot}0 < E < 1{\cdot}2$‡. Such a situation is characteristic of "totally irreversible voltammograms",[22] indicating that at voltages corresponding to the cathodic wave, the rate of the over-all reaction

$$Tl^+ \rightarrow Tl^{3+} + 2e \tag{12}$$

was negligible compared to the rate of the converse process

$$Tl^{3+} + 2e \rightarrow Tl^+ \tag{13}$$

and *vice versa* for the anodic wave. The interesting effect of flow velocity on voltammograms is illustrated by a typical "family of curves" shown in Fig. 3.

DISCUSSION

In interpreting the experimental current voltage curves, three plausible mechanisms were considered for the electrode reaction (1);

(A) *A single stage two-electron transfer, viz.*

$$Tl^{3+} + 2e \xrightarrow{k_{s,1}} Tl^+ \tag{14}$$

---

* As a notable exception, Frumkin has recently reported[21] that thallium^{I} ion was adsorbed on black platinised anodes when present at a concentration of $1M$ in the bulk of the solution. The effect was appreciable at potentials between $0{\cdot}3$ and $0{\cdot}7$ V, but decreased abruptly when the voltage was made either more positive or more negative. The only potential domain where adsorption of thallium^{I} ions may have been of significance in the present study was $>1{\cdot}2$ V (*vide infra*). Extrapolation of Frumkin's data suggests that it would have been negligible in that voltage range, even under his own experimental conditions. However, in the present investigation the maximum concentration of Tl^+ was $5 \times 10^{-3}M$ (as compared to $1M$ in reference 21) and the electrodes we used were blank (rather than black) platinum. These factors can reasonably be expected to have reduced the adsorption of thallium^{I} ion (if any) to negligible proportions. Accordingly, it was ignored.

† Concentrations were converted into corresponding activities, with the aid of applicable molarity activity coefficients, *viz.*, $f_{Tl^{3+}} = 0{\cdot}65$, $f_{Tl^+} = 0{\cdot}54$.

‡ Actually, the ZCD is a region where c.v. curve III had a very small slope, which coincided with the zero current axis within the precision of the present investigation.

for the cathodic wave of thallium^{III} ion; and for the anodic wave of thallium^{I} ion:

$$Tl^{+} \xrightarrow{k_{1,a}} Tl^{3+} + 2e \qquad (15)$$

(B) *Two successive one-electron transfer steps, viz.**

$$Tl^{3+} \overset{e}{\longleftrightarrow} Tl^{II} \overset{e}{\longleftrightarrow} Tl^{+} \qquad (16)$$

(C) *A rate determining one-electron transfer followed by fast disproportionation of the intermediate* in accordance with equations (6)–(7).

These three schemes are examined critically below, with a view to ascertaining whether they can account for the results obtained in this study. The applicable assumption was made that under the experimental conditions a steady state prevailed at any given potential (*i.e.*, there was no transient variation of the measured currents), and rate laws characteristic of each particular mechanism were derived accordingly.[9,22,23]

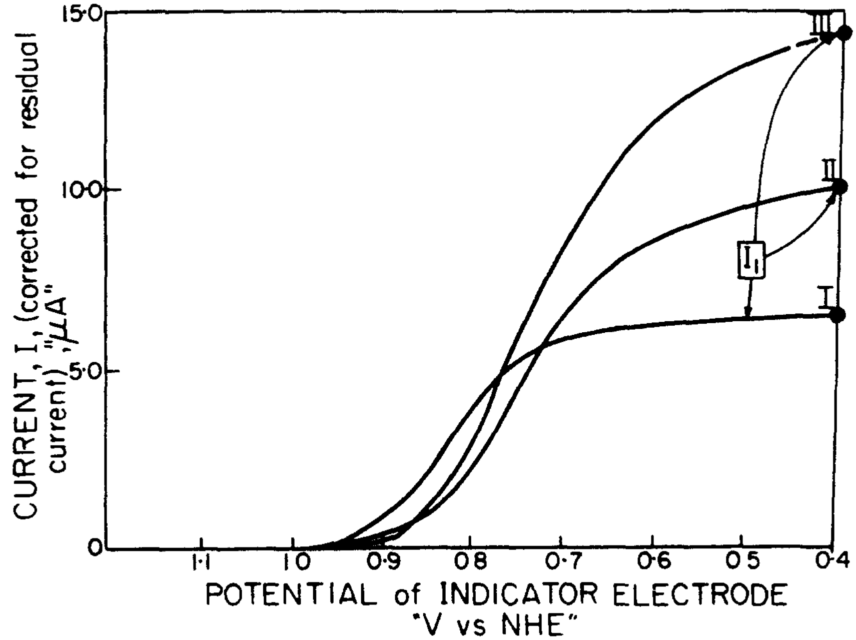

FIG. 3.—Typical "family of voltammograms" (of $10^{-3}M$ Tl^{3+} in $1M$ $HClO_4$), illustrating over-all effects of flow velocity: I—13·7 cm/sec; II—36·6 cm/sec; III—91·0 cm/sec (I_l = limiting current)

The following general observations, common to all current-voltage curves obtained, were taken into account:

(*a*) All cathodic and anodic voltammograms exhibited "shifts" as a function of flow velocity. The nature of these "shifts" is illustrated in the "normalised" voltammograms, shown in Fig. 4. These represent a replot of the data shown in Fig. 3 using as ordinate the quantity I/I_l instead of I.

---

* The symbol ⟷ is used to denote a "kinetically discrete" electron-transfer step, *i.e.*, one which proceeds in the forward (reduction) or reverse (oxidation) directions via the same activated complex.

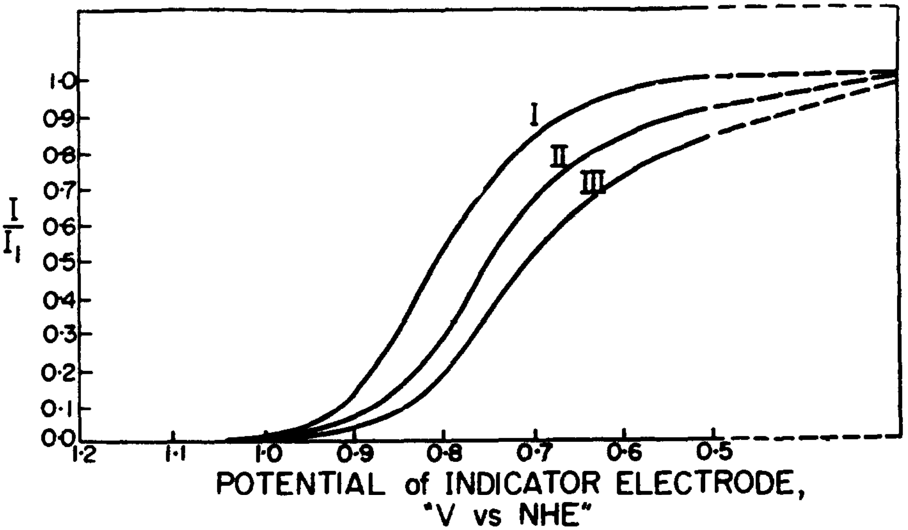

FIG 4.—Normalised voltammograms illustrating potential shifts as function of flow velocity. Replot of data shown in Fig. 3, using the dimensionless quantity $\left(\frac{I}{I_l}\right)$ as ordinate (I = current at a given potential; I_l = limiting current)

Shifts of the type illustrated in Fig. 4 are characteristic of situations where the ascending portion of c.v. waves is controlled concomitantly by rates of electron transfer and by mass transport. Consequently, only those mechanisms were considered, in which the rate of at least one electron-transfer step is a kinetically controlling factor of the over-all reaction.

(*b*) Without exception, in all of the voltammograms recorded in this investigation, the standard potential of the thallium^{III}-thallium^{I} couple was located on the ascending part of the anodic wave, rather than in the ZCD (see Fig. 2, Curve III), *i.e.*, the apparent "overvoltage" of the cathodic wave was considerably greater than that of the anodic wave. This remarkable feature proved an important clue in the elucidation of the electrode mechanism.

Mechanism A

From the viewpoint of formal "mathematical kinetics", this is a well-known case. With respect to electron transfer, the following equations apply:

$$I = I_+ + I_- \tag{17}$$

$$I_+ = 2\,F\,A\,k_{3,1}\,a_3{}^0 \tag{18}$$

$$I_- = -2\,F\,A\,k_{1,3}\,a_1{}^0 \tag{19}$$

$$k_{3,1} = k^0{}_{3,1}\exp\left[\alpha_{3,1}(E^0_{3,1} - E)\frac{2F}{RT}\right] \tag{20}$$

$$k_{1,3} = k^0_{3,1}\exp\left[(1 - \alpha_{3,1})(E - E^0_{3,1})\frac{2F}{RT}\right] \tag{21}$$

where I_+ and I_- denote the cathodic and anodic current components; $k_{3,1}$ and $k_{1,3}$ are electron-transfer rate constants (cm/sec) effective at the potential E, for reactions (14) and (15), respectively; subscripts $_3$ and $_1$ identify activities of the thallium^{III} and thallium^{I} ions, and $E^0_{3,1}$ denotes the standard potential of the thallium^{III}-thallium^{I} couple. A crucial consideration characterising Mechanism A is that the values of the specific rate constant, $k^0_{3,1}$, and of the transfer coefficient, $\alpha_{3,1}$, must be identical irrespective of whether they are calculated form cathodic currents [equations (14) and (20)] or anodic currents [equations (15) and (21)]. *The "sameness" of these two rate parametres represents an unambiguous test as to whether only one transition state is involved, which is mandatory whenever a genuine single-stage process prevails.*

The prevailing mass transfer model requires that the following equations hold:

$$\frac{I}{2FA} = m_3(a_3 - a_3{}^0) = m_1(a_1{}^0 - a_1) \tag{22}$$

$$I_{1,+} = 2\,F\,Am_3a_3 \tag{23}$$

$$I_{1,-} = -2\,F\,Am_1a_1 \tag{24}$$

where the subscripts + and − denote cathodic and anodic limiting currents, respectively. In accordance with the steady state assumption, the a's were eliminated between equations (17)–(19) and (22)–(24) yielding the following "general wave equation", which is applicable to voltammograms expected in the presence of either Tl^+ or Tl^{3+}, or both:

$$I = \frac{\dfrac{k_{3,1}}{m_3}\,I_{1,+} + \dfrac{k_{1,3}}{m_1}\,I_{1-}}{1 + \dfrac{k_{3,1}}{m_3} + \dfrac{k_{1,3}}{m_1}} \tag{25}$$

Theoretical c.v. curves, computed [from equations (20), (21) and (25)] for a solution which contains 10^{-3} M Tl^{3+} plus 10^{-3} M Tl^+, by assigning a variety of reasonable sets of values to the rate parameters $k^0_{3,1}$, α, m_3 and m_1, yielded the plots shown in Fig. 5. These represent a family of curves of a well-known type,[22] ranging in shape from

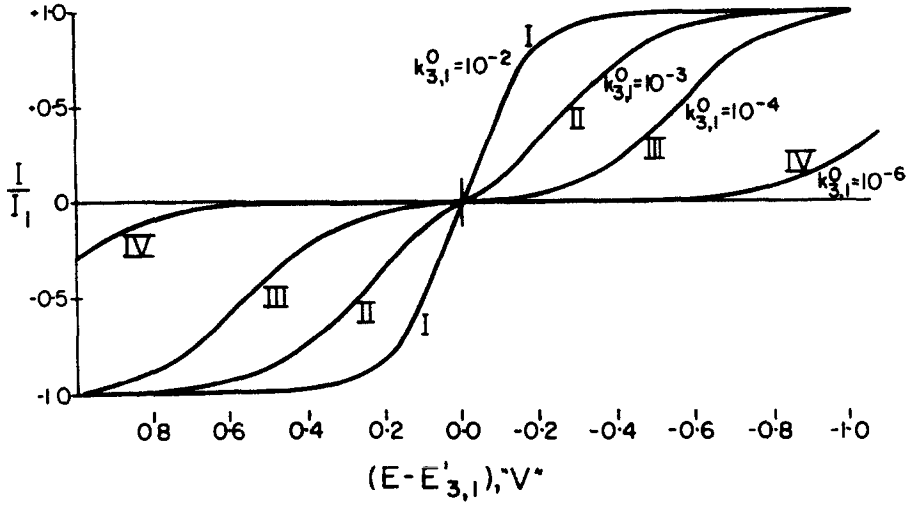

FIG. 5.—"Theoretical normalised voltammograms", calculated in accordance with Mechanism A, for a solution containing equimolar concentrations of Tl^+ plus Tl^{3+}. (E = potential of indicator electrode; $E_{3,1}{}'$ = same as in Fig. 2. Values assigned: $\alpha_{3,1} = 0{\cdot}50$; $m_3 = m_1 = 10^{-3}$ cm/sec; $k^0_{3,1}$–as shown on each curve)

a "reversible" composite wave (Curve I) via a "totally irreversible" split wave (Curve III), to Tafel plots (Curve IV). Comparisons of Fig. 5, on the one hand, with the corresponding experimental voltammogram (Fig. 2, Curve III) on the other, revealed irreconcilable differences: For instance, $E'_{3,1}$ in Fig. 5 is invariably in the ZCD, while in Fig. 2 it is located on the sigmoid section of the anodic wave. Quite generally, it was found that for all possible assignments of

$$0 < k^0_{3,1} < \infty$$

and

$$0 < \alpha^0_{3,1} < 1$$

calculations based on Mechanism A yielded c.v. curves which were significantly at variance with the experimental results.

The utter incompatibility of Mechanism A with our experimental data has been substantiated further, using the following argument. Assuming that Mechanism A did prevail, the rate parameters $k^0_{3,1}$ and $\alpha_{3,1}$ were evaluated separately from experimentally obtained cathodic and anodic c.v. waves. Using a procedure recommended in a classical paper by Laitinen *et al.*,[24] equations (18)–(21) were applied to the "foot" of the waves where concentration polarisation was negligible. This yielded two discrete sets of values, one obtained from cathodic voltammograms of Tl^{3+}, and the other from anodic voltammograms of Tl^+. The relevant data are listed in Table I. As can be seen in the table, the precision of the means *in each set* was better than ± 10% for $\alpha_{3,1}$ and better than ±30%, for $k^0_{3,1}$. However, the mean $k^0_{3,1}$ of the "cathodic set" differed by three orders of magnitude from that of the

TABLE I.—KINETIC PARAMETERS EVALUATED FROM THE EXPERIMENTAL DATA ON THE ASSUMPTION THAT MECHANISM A WAS OPERATIVE

Set of values obtained from cathodic waves of Tl^{3+} using equation (20)

13·7	0·60	$1{\cdot}14 \times 10^{-6}$
25·4	0·55	$1{\cdot}25 \times 10^{-6}$
36·6	0·55	$0{\cdot}45 \times 10^{-6}$
58·0	0·50	$1{\cdot}07 \times 10^{-6}$
70·8	0·59	$1{\cdot}00 \times 10^{-6}$
91·6	0·58	$0{\cdot}61 \times 10^{-6}$

Averages: $\alpha_{3,1} = 0{\cdot}28 \pm 0{\cdot}02$, $k^0_{3,1} = (0{\cdot}9 \pm 0{\cdot}2) \times 10^{-6}$

Set of values obtained from anodic waves of Tl^+ using equation (21)

Flow velocity, *cm/sec*	$2(1 - \alpha_{3,2})$	$k^0_{3,1}$, *cm/sec*
6·96	0·45	$4{\cdot}8 \times 10^{-4}$
13·0	0·60	$9{\cdot}0 \times 10^{-4}$
24·8	0·51	$5{\cdot}8 \times 10^{-4}$
35·5	0·60	$5{\cdot}8 \times 10^{-4}$
47·0	0·63	$5{\cdot}9 \times 10^{-4}$
48·9	0·59	$6{\cdot}3 \times 10^{-4}$
72·9	0·50	$7{\cdot}1 \times 10^{-4}$
85·4	0·51	$6{\cdot}3 \times 10^{-4}$
91·0	0·51	$9{\cdot}1 \times 10^{-4}$

Averages $\alpha_{3,1} = 0{\cdot}72 \pm 0{\cdot}03$; $k^0_{3,1} = (7 \pm 1) \times 10^{-4}$

"anodic set". The mean $\alpha_{3,1}$ values of the two sets were discrepant by a factor of three. All this indicated compellingly that more than one transition state was involved in Reaction 1.

Mechanism B

Current knowledge of the chemistry of thallium suggests strongly that the reversible standard potentials defined by equations (26) and (27) [where the subscript $_2$ identifies the bivalent thallium species in equation (16)]

$$E = E^0_{3,2} + \frac{RT}{F} \ln \frac{a_3}{a_2} \tag{26}$$

$$E = E^0_{2,1} + \frac{RT}{F} \ln \frac{a_2}{a^1} \tag{27}$$

do not differ too much (unless $E^0_{2,1} > E^0_{3,2}$, which requires a spontaneous disproportionation of bivalent thallium and leads to Mechanism C). If they did, it should have been easy to prepare bivalent thallium either by electro-oxidation of thallium^{I} ion or by the electroreduction of thallium^{III} ion. Furthermore, if

$$E^0_{2,1} \ll E^0_{3,2} \tag{28}$$

the anodic and cathodic waves shown in Fig. 2 should have each been split in two, corresponding to the appropriate discrete one-electron transfer steps. The precision and accuracy of the experiments was such that a corresponding resolution into a total of four one-electron transfer waves (in lieu of the two waves shown in Fig. 2, Curve III) would have been observed experimentally, whenever $(E^0_{3,2} - E^0_{2,1}) > 0{\cdot}05$ V.

The electron-transfer rate equations pertaining to Mechanism B are

$$I_+ = F A\, k_{3,2}\, a_3{}^0 + F A\, k_{2,1}\, a_2{}^0 \tag{29}$$

$$I_- = -F A\, k_{1,2}\, a_1{}^0 - F A\, k_{2,3}\, a_2{}^0 \tag{30}$$

Equation (31) holds concomitantly because a steady state exists

$$\frac{da_2}{dt} = 0 \rightarrow k_{3,2}\, a_3{}^0 + k_{1,2}\, a_1{}^0 = k_{2,3}\, a_2{}^0 + k_{2,1}\, a_2{}^0 \tag{31}$$

Relevant rate constants, transfer coefficients and potentials are correlated as follows:

$$k_{3,2} = k^0_{3,2} \exp\left[\alpha_{3,2}(E^0_{3,2} - E)\frac{F}{RT}\right] \tag{32}$$

$$k_{2,3} = k^0_{3,2} \exp\left[(1 - \alpha_{3,2})(E - E^0_{3,2})\frac{F}{RT}\right] \tag{33}$$

$$k_{2,1} = k^0_{2,1} \exp\left[\alpha_{2,1}(E^0_{2,1} - E)\frac{F}{RT}\right] \tag{34}$$

$$k_{1,2} = k^0_{2,1} \exp\left[(1 - \alpha_{2,1})(E - E^0_{2,1})\frac{F}{RT}\right] \tag{35}$$

$$E^0_{3,1} = \frac{E^0_{3,2} + E^0_{2,1}}{2} \tag{36}$$

Elimination of all activity terms between equations (22)–(24) and (29)–(31) yielded the "general wave equation":

$$I = \frac{\dfrac{k_{3,2}\,k_{2,1}}{m_3}\,I_{l,+} + \dfrac{k_{1,2}\,k_{2,3}}{m_1}\,I_{l,-}}{k_{2,3} + k_{2,1} + \dfrac{k_{3,2}\,k_{2,1}}{m_3} + \dfrac{k_{1,2}\,k_{2,3}}{m_1}} \tag{37}$$

Theoretical voltammograms corresponding to equations (32)–(35) and (37) were constructed with the aid of calculations similar to those employed in obtaining Fig. 5. Judicious comparison with experimental c.v. curves indicated unambiguously that Mechanism B could not account satisfactorily for the experimental observations, regardless of the values assigned to the rate parameters $k^0_{3,2}$, $k^0_{2,1}$, $\alpha_{3,2}$ and $\alpha_{2,1}$. That Mechanism B was indeed not operative is evident from the fact that in an equimolar solution of Tl^{3+} and Tl^{+}, where

$$\frac{a_3}{f_3} = \frac{a_1}{f_1} \tag{38}$$

equation (37) requires that

$$I = 0 \; at \; E = E'_{1,3} = E^0_{1,3} + \frac{RT}{2F} \ln \frac{f_3}{f_1} \tag{39}$$

Mathematical proof, that requirement (39) is mandatory for Mechanism B whenever Tl^{3+} plus Tl^{+} are present in equimolar bulk concentrations, is offered in the *Appendix*. It can be seen in Fig. 2, Curve III (which is a typical example of a voltammogram actually recorded in an equimolar solution of Tl^{3+} plus Tl^{+}) that the results obtained in this investigation were strikingly at variance with requirement (39). Consequently, Mechanism B has been ruled out.

Mechanism C

In accordance with equations (6)–(7) the following rate laws apply:

$$I_{+} = 2\,F A\,k_{3,2}\,a_3^0 \tag{40}$$

$$I_{-} = -2\,F A\,k_{1,2}\,a_1^0 \tag{41}$$

Concomitantly, rate and potential parameters must conform with equations (32)–(36), mass transport is governed by equations (22)–(24), and the following Steady State Requirement [based on equations (7), (40), (41)] must be met:

$$\frac{da_2^0}{dt} = 0;\; k_{3,2}\,a_3^0 + k_{1,2}\,a_1^0 = \delta k_{\text{dispr.}}\,(a_2^0)^2 \tag{42}$$

where δ denotes the thickness of the reaction layer at the electrode surface. The corresponding general wave equation (obtained by appropriate elimination of the activity terms) has the form:

$$I = \frac{\dfrac{k_{3,2}}{m_3}\,I_{l,+} + \dfrac{k_{1,2}}{m_1}\,I_{l,-}}{1 + \dfrac{k_{3,2}}{m_3} + \dfrac{k_{1,2}}{m_1}} \tag{43}$$

Theoretical voltammograms computed in accordance with equation (43) gave plots which proved, in all instances, identical with the corresponding experimental c.v.

curves. The excellent agreement is exemplified by the "calculated points", superimposed on Fig. 2, Curve III.

Numerical estimates of rate parameters, calculated from experimental voltammograms on the basis of equation (43) are listed in Table II

TABLE II—KINETIC PARAMETERS CALCULATED FROM THE EXPERIMENTAL DATA ON THE ASSUMPTION THAT MECHANISM C WAS OPERATIVE

Set of values obtained from cathodic waves of Tl^{3+} using equations (40) and (43)

Flow velocity. *cm/sec*	$\alpha_{3,2}$	$k_{3,2}$ (at 1·25 V)[a]
13·7	0·60	$1·14 \times 10^{-6}$
25·4	0·55	$1·25 \times 10^{-6}$
36·6	0·55	$0·45 \times 10^{-6}$
58·0	0·50	$1·07 \times 10^{-6}$
70·8	0·59	$1·00 \times 10^{-6}$
91·8	0·58	$0·61 \times 10^{-6}$

Average $\alpha_{3,2} = 0·56 \pm 0·03$; $k_{3,2} = (0·9 \pm 0·2) \times 10^{-6}$

Set of values obtained from anodic waves of Tl^{+} using equations (41) and (43)

Flow velocity *cm/sec*	$(1 - \alpha_{2,1})$	$k_{1,2}$ (at 1·25 V)[a]
6·97	0·45	$4·8 \times 10^{-4}$
13·0	0·60	$9·0 \times 10^{-4}$
24·8	0·51	$5·8 \times 10^{-4}$
35·5	0·60	$5·8 \times 10^{-4}$
47·0	0·63	$5·9 \times 10^{-4}$
48·9	0·59	$6·3 \times 10^{-4}$
72·9	0·50	$7·1 \times 10^{-4}$
85·4	0·51	$6·3 \times 10^{-4}$
91·0	0·51	$9·1 \times 10^{-4}$

Average: $\alpha_{2,1} = 0·45 \pm 0·05$; $k_{1,2} = (7 \pm 1) \times 10^{-4}$

[a] Because $E^0_{3,2}$ and $E^0_{2,1}$ are not known, values of $k_{3,2}$ and $k_{2,1}$ effective at $E^0_{2,1}$ (= 1·25 V) have been reported.

It is apparent that the values obtained at fifteen different flow velocities exhibited satisfactory "internal consistency" and the transfer coefficients $\alpha_{3,2}$ and $\alpha_{2,1}$ approximate 0·5 in agreement with reasonable *a priori* considerations. This confirms that under the experimental conditions prevailing in this investigation, the thallium^{I}-thallium^{III} electron transfer occurred via Mechanism C [equations (6)–(7)].

The finding, that in 1 *M* perchloric acid the thallium^{I}-thallium^{III} reaction involves a fast disproportionation of the bivalent intermediate, invites an interesting comparison with the report of Vetter and Thiemke.[8] In the presence of sulphuric acid in appreciable concentration, the same process was compatible with Mechanism B. It is noted in this context, that Vetter and Thiemke's experimental results are also compatible with Mechanism C. In other words, their data did not permit discrimination between Mechanisms B and C. The possibility, that the shape of d.c. voltammograms may be sometimes inconclusive for the purpose of identifying mechanisms of electrode processes, has been pointed out by Riddiford.[25] The experimental situation in the present investigation was fortunate in this respect. The genuine equilibrium potential of the thallium^{I}-thallium^{III} couple ($E'_{3,1}$ in the presence of equimolar concentrations of Tl^{+} plus Tl^{3+}) was invariably located *outside the ZCD* (see Fig. 2). This has permitted us to select *Mechanism C* as *uniquely applicable*, without ambiguity. However, we desire to emphasise that there is no necessary contradiction between Vetter and Thiemke's conclusions and ours. Quite possibly, the rates and mechanism of the thallium^{I}-thallium^{III} electrode reaction may be entirely different in perchloric and in sulphuric acids. Appreciable sulphato-complexation of thallium^{I} and thallium^{III} ion is known to occur in sulphate media.[8,26] Consequently, the electroreactive species are not necessarily the same in the presence of sulphate as in perchloric acid (where the aquo ions prevail). Furthermore, the presence of sulphate and/or perchlorate may quite radically change the rates and the mechanism if, for instance, a "bridged" transition state were involved. It should be noted, in this context, that Mechanism C may readily be converted into B if the rate of disproportionation [equation (7)] is slow compared to the rate of the electron-transfer steps (6a) and (6b). This is evident from the following scheme.

$$\text{PATH I: } \underbrace{Tl^{3+} \xleftrightarrow{\ e\ } \underbrace{Tl^{II}}_{} \xleftrightarrow{\ e\ } Tl^{+}}_{} \qquad (44)$$

PATH IIa PATH IIb
Oxidation of Tl^{II} Reduction of Tl^{II}

If the rate of reaction (7) is slow compared to the electron-transfer processes

$$Tl^{II} \xleftrightarrow{e} Tl^{+} \qquad (45)$$

$$Tl^{II} \xleftrightarrow{e} Tl^{3+} \qquad (46)$$

the over-all electrode reaction [equation (1)] must proceed via "PATH I" (as may have been the case in Vetter and Thiemke's work). Alternative PATH II would be operative (as was the case in the present investigation) in the following situations

$$r_7 \gg r_{45} \qquad (47)$$

$$r_7 \gg r_{46} \qquad (48)$$

where the symbol *r* denotes the rate of the reaction identified by the subscripts (which are identical with the serial numbers of the corresponding chemical equations listed earlier in this article).

The possibility of a mechanism where $r_7 \approx r_{45} \approx r_{46}$ was rejected, on the grounds that it would be characterised by a gradual changeover from Mechanism C to Mechanism B as a function of the concentration of the "primary reactants" Tl^{3+} and Tl^{+}: reaction (7) is second order with respect to Tl^{II}, while reactions (45) and (46) both have first order kinetics. Consequently, Mechanism B would be expected to predominate at low concentrations of Tl^{+} and Tl^{3+}, and Mechanism C at high concentrations. No such trend was evident in the present investigation.

In conclusion, it is apparent that the thallium^{III}-thallium^{I} electrode reaction proceeds via a bivalent intermediate which is a stronger oxidant than Tl^{3+}. In aqueous solution, and in the absence of complexing ligands, the relevant redox potentials [identified in expression (49)]

$$\underbrace{Tl^{3+} \xleftrightarrow{E^{0}_{3,2}} Tl^{II} \xleftrightarrow{E^{0}_{2,1}} Tl^{+}}_{E^{0}_{3,1}} \qquad (49)$$

are characterised by the following relative properties:

$$E^0_{2,1} > E^0_{3,1} \qquad (50)$$

$$2E^0_{3,1} = E^0_{3,2} + E^0_{2,1} \qquad (51)$$

Disproportionation of bivalent thallium into Tl^{3+} plus Tl^{+}, as required by relation (50), occurred in the presence of perchloric acid at a rate which was fast compared to reactions (45) and (46).

APPENDIX

Proof of requirement (39)

Because the denominator of equation (37) is finite, the necessary and sufficient condition for

$$I = 0 \qquad (A1)$$

is that the numerator be equal to zero, *viz.*:

$$\frac{k_{3,2} \, . \, k_{2,1}}{m_3} I_{1,+} + \frac{k_{1,2} \, . \, k_{2,3}}{m_1} I_{1,-} = 0 \qquad (A2)$$

Substituting for k the appropriate potential dependent expressions [equations (32)–(35)] and rearranging equation (A2), yielded

$$\exp\left\{[2E - (E^0_{3,2} + E^0_{2,1})] \frac{F}{RT}\right\} = -\frac{m_1 I_{1,+}}{m_3 I_{1,-}} \qquad (A3)$$

Expressing $(E^0_{3,2} + E^0_{2,1})$ and the quotient on the right side in terms of equivalent quantities via equations (36), (23) and (24), equation (A4) was obtained.

$$\exp\left\{(E - E^0_{3,1}) \frac{2F}{RT}\right\} = \frac{a_3}{a_1} \qquad (A4)$$

Applying equation (38) and taking logarithms, equation (39) was readily obtained:

$$(38) \rightarrow \frac{a_3}{a_1} = \frac{f_3}{f_1}; \qquad (A4) \rightarrow E_{I=0} \, E^0_{3,1} + \frac{RT}{nF} \ln \frac{f_3}{f_1}$$

Zusammenfassung—Die Thallium(I)- Thallium(III)- Elektrodenreaktion wurde mit Hilfe der hydrodynamischen Voltammetrie an Platinanoden und -kathoden untersucht. Es werden schlüssige Beweise dafür angegeben, dass die Elektrooxydation des hydratisierten Tl^{+} und die Elektroreduktion von Tl^{3+} über eine zweiwertige Thalliumstufe verlaufen Tl(II) ist ein stärkeres Oxydationsmittel als Tl(III). In 1m wässriger Überchlorsäure war die Geschwindigkeit der Disproportionierung

$$2\,Tl(II) \rightarrow Tl^{+} + Tl^{3+}$$

schnell im Vergleich den Elektronenübergängen

$$Tl(II) + e \rightarrow Tl^{+}$$

und

$$Tl^{3+} + e \rightarrow Tl(II).$$

---

* Preliminary assignments of values for two-electron transfer rate constants were made available to Dr. Marcus while the investigation described in this paper was still in progress. They have been incorporated for documentation purposes in a recent theoretical paper[7] and identified as "unpublished results". The values given in the present article are considered definitive assignment, superseding the preliminary data reported by Marcus.

This investigation was supported in part by Public Health Service Research Grant HE-02342 from the National Heart Institute

Résumé—La réaction Tl^{3+}/Tl^{+} aux électrodes a été étudiée par voltampérométrie hydrodynamique sur cathodes et anodes de platine. On montre que l'électrooxydation de l'ion Tl^{+} en milieu aqueux et l'électroréduction de Tl^{3+} font intervenir une forme divalente du thallium. Tl(II) est un oxydant plus fort que l'ion thallique. Dans l'acide perchlorique 1 M la vitesse de la réaction de dismutation

$$2\,Tl(II) \rightarrow Tl^{+} + Tl^{3+}$$

est relativement rapide comparée aux étapes du transfert électronique.

$$Tl(II) + e \rightarrow Tl^{+}$$

$$Tl^{3+} + e \rightarrow Tl(II)$$

POLAROGRAPHIC DETERMINATION OF CERTAIN MEDICINAL COMPOUNDS CONTAINING DICHLORACETAMIDO GROUPS*

CLARK A. KELLY†
Sterling-Winthrop Research Institute, Rensselaer, New York, U.S.A.

(*Received* 19 *June* 1963. *Accepted* 29 *September* 1963)

Summary—A polarographic study has been made of a variety of compounds containing dichloracetamido groups, including *N*-(2,4-dichlorobenzyl)-*N*-(2-hydroxyethyl)dichloracetamide (chlorbetamide), *N*-(4-methylsulphonylphenyl)-1,3-dihydroxy-2-propyldichloracetamide(raceophenidol), *N*,*N*′-bis-(2-ethoxyethyl)-*N*,*N*′-*p*-xylylene-bis-dichloracetamide (teclozan), *N*,*N*′-octamethylene-bis-dichloracetamide and their corresponding analogues. Analytical results are discussed from a quantitative and qualitative point of view with special emphasis on the stability of the compounds at various pH and the effect of various elements or groups in the molecule on the half-wave potentials of the two resulting cathodic waves.

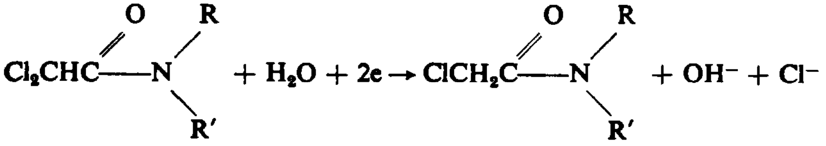
INTRODUCTION

In the past, little attention has been given polarographically to the dichloracetamido group in medicinal compounds. Chloramphenicol, D(−)-threo-2,2-dichloro-*N*-[β-hydroxy-α-(hydroxymethyl)-*p*-nitrophenethyl]-acetamide, has been studied polarographically by Hess[1], Varela,[2] and Knobloch and Svatek[3] The emphasis was, however, on the reduction characteristics of the nitro group rather than the dichloracetamido group. Elving and Ching-Siang Tang[4,5,6] have shown the polarographic characteristics of mono-, di- and trichloracetic acid as well as esters of these acids. In many respects the compounds described in the present paper are like the esters of dichloracetic acid in that as long as they remain intact two cathodic waves result when polarographed.

If the compounds are split by hydrolysis, only one cathodic wave develops, showing all of the polarographic characteristics of dichloracetic acid. These compounds, being amides, are not as susceptible to hydrolysis as are the esters of dichloracetic acid.

The mechanism for these polarographic reductions, representing the successive removal of chlorine from the dichloracetyl portion of the molecule, would be the same as Elving has stated and for the same reasons:—

First Cathodic Wave:

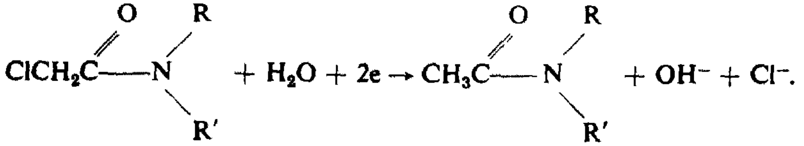


---

* Paper presented before the Division of Analytical Chemistry 144th Meeting, American Chemical Society, Los Angeles, California, April, 1963.

† Fellow of the American Foundation for Pharmaceutical Education.

Second Cathodic Wave



$$\mathrm{ClCH_2C(=O)NRR'} + H_2O + 2e \rightarrow \mathrm{CH_3C(=O)NRR'} + OH^- + Cl^-.$$

It is the purpose of this communication to show the polarographic characteristics of a variety of compounds containing the dichloracetamido group. The compounds have been divided into four major groups (Table I).

EXPERIMENTAL

Reagents

All chemicals and organic solvents were reagent grade. Nitrogen was Edison's dry high-purity nitrogen. Distilled water was used throughout as a solvent as well as in rinsing the polarographic cell.

The buffers were constant ionic strength (1*M*) McIlvaine pH 3, 4, 5, 6, 7 and 8 buffers[7] and a 2·5*M* constant ionic strength aqueous ammonia–ammonium chloride buffer pH 8·2. Unless otherwise stated, the ionic strength of the polarographic media was 0·5*M*. The buffers were adjusted to the stated pH ± 0·1. On addition of these buffers to the polarographic medium the pH of the resulting medium was changed:

in 10% methanol the pH was 0·2–0·3 unit higher;
in 50% methanol the pH was nearly 1 unit higher;
in 70% methanol–10% *N,N*-dimethylformamide (DMF) the pH was 0·5–0·6 unit lower.

Because the polarographic waves resulting from the dichloracetamido groups are independent of pH in the pH range studied, the pH mentioned in the text will refer to that of the aqueous buffer.

Sample solutions: Stock solutions of Group I, II and IV compounds (0·005, 0·005 and 0·0025*M*, respectively) were prepared in 50 ml of methanol. Because of their poor solubility in methanol, 0·0025*M* solutions of the compounds of Group III were prepared in 50 ml of DMF.

Apparatus

A Sargent Recording Polarograph Model XXI with a conventional dropping mercury electrode (DME) and an aqueous saturated calomel electrode (SCE) were used throughout these studies at a sensitivity setting of 0·06 μA/mm of scale. The damping switch was set at number one. The polarographic cell was a Lingane and Laitinen H-type cell with an agar potassium chloride salt bridge. Unless otherwise stated, all polarograms were recorded in a Sargent constant temperature bath set at 25·0 ± 0·1°. The capillary used in these studies had the following characteristics in 0·5*M* pH 8 McIlvaine buffer in 50% methanol (open circuit): $m = 1{\cdot}861$ mg/sec and $t = 4{\cdot}28$ sec for $h = 50$ cm.

All polarograms were recorded with the mercury height (h) at 50 cm. All diffusion currents were corrected for residual current, which never exceeded 0·2 μA for any potential at which the diffusion current was measured. Maxima were occasionally observed with the second wave but never the first. No maximum suppressors, which might distort the resulting waves, were added to any of the solutions. The half-wave potentials reported are not corrected for iR drop (cell resistance). A Beckman pH meter, Model G, was used to measure pH of the various buffers and solutions.

General procedure for recording the current-voltage curves

Five ml (by pipette) of the appropriate stock solution were added to a 50-ml volumetric flask containing the desired buffer and methanol concentration. For Groups I, II and IV the medium consisted of 25 ml of the 1*M* buffer and 20 ml of methanol. For Group III the medium consisted of 10 ml of 2·5*M* aqueous ammonia–ammonium chloride buffer pH 8·2 and 35 ml of methanol. In each case the solvent mixture was allowed to cool to room temperature before addition of the sample. After the sample addition, the solution was diluted to volume with water and mixed. About 20 ml of this buffered solution was then polarographed within 15 min and the remaining portion after standing 3 days at room temperature. Nitrogen was first passed through a wash bottle containing the same solvent and buffer as the sample, then through the polarographic cell containing the sample for 5 min to deaerate the medium. During the recording of the polarogram (0·0 to −2·0 V) nitrogen was passed over the surface of the solution but without disturbing it. From the resulting polarograms, the half-wave potentials were determined by the intersecting point method[8] and the diffusion current was determined by subtracting the extrapolated residual current from the extrapolated limiting

TABLE I

Group	Structure and chemical name of representative medicinal compound	Generic name	Major medicinal activity
I	 *N*-(2,4-dichlorobenzyl)-*N*-(2-hydroxyethyl) dichloracetamide	Chlorbetamide	Amebicidal
II	 *N*-(4-methylsulphonylphenyl)-1,3-dihydroxy-2-propyldichloracetamide	Raceophenidol	Antibacterial
III	 *N*,*N*′-bis(2-ethoxyethyl)-*N*,*N*′-*p*-xylylene-bis-dichloracetamide	Teclozan	Amebicidal
IV	 $Cl_2CHOC\text{-}N(H)(CH_2)_8N(H)\text{-}COCHCl_2$ *N*,*N*′-octamethylene-bis-dichloracetamide	None	Antispermatogenic

current at the half-wave potential of the first wave. The diffusion current of the second wave was determined by subtracting the extrapolated limiting current of the first wave from the extrapolated limiting current of the second wave Using this approach a satisfactory method was applicable. on a comparative basis, to all of the waves obtained. The diffusion current constant (I) was calculated from data obtained from these polarograms: $I = i_d/Cm^{2/3}t^{1/6}$ where i_d is expressed in μA, C in mmoles (of the given compound)/litre, m in mg (of mercury)/sec and t in sec (length of time for 1 drop of mercury at the stated potential at which the diffusion current was measured).

RESULTS AND DISCUSSION

General

The polarographic waves of these dichloracetamido compounds are well-defined irreversible waves, in that they do not comply with the accepted criteria for reversibility. The change in slope for both waves is gradual and usually over a 0·3-V span. The half-wave potentials vary with concentration (become more negative with increasing concentration). The average diffusion current constant (I) values are in good agreement, as shown in Table II. The I values for the bisdichloracetamido compounds (Groups III and IV) are about twice the values of the mono-dichloracetamido compounds (Groups I and II). This is added evidence that the resulting polarographic waves are from the amount of the dichloracetamido in the given compound. Even though the second wave is not as well-defined as the first, its average I value is in close agreement with that of the first wave. This again is evidence for the reduction of the chlorines individually, from the dichloracetamido group

TABLE II

$$I^* = \frac{i_d}{Cm^{2/3}t^{1/6}}$$

Group	Average I-Value for first wave	Average I-Value for second wave
I	1 55	1 72
II	1 49	1 42
III	2 92	3 32
IV	2·90	3 01

* I is the diffusion current constant where i_d is expressed in μA, C in mmoles/litre, m in mg/sec and t in sec.

The temperature coefficient for these dichloracetamido compounds is 1·5 to 2·0% between 20° and 40°. On changing the mercury column height from 30 to 90 cm, the ratio of $i/h^{1/2}$ was found to be constant. The current resulting from the reduction of these chlorine atoms is diffusion controlled current (i_d) according to the existing criteria.

With none of the compounds did pH (in the pH 3–8 range) affect the wave-height or the half-wave potential of the freshly prepared solution of a given compound.

The ionic strength of the media was varied from 0·1 to 0·5*M* without affecting any of the polarographic wave characteristics of the compounds The methanol content in the polarographic media was varied from 10 to 80%. With most of the compounds, the current decreases about 20% when the methanol content is increased from 10 to 50%. The half-wave potentials usually become more negative (of the order of 0·03 to 0·3 V) as the methanol content increased from 10 to 50%.

With the Group I and II compounds, the diffusion current (corrected for residual current) for the first wave is proportional to concentration from 0·0002 to 0·001*M* (the highest concentration tested). For the bis-dichloracetamido compounds (Groups III and IV) the range is 0·0001 to 0·001*M*.

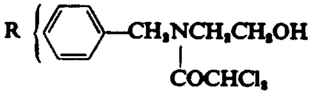
When related compounds were available, containing the several amido groupings (acetyl, mono-, di- or trichloracetyl), it was found that the polarographic waves are very closely related. With the trichloracetamido group, three polarographic waves result. The first appearing to be nearly reversible with a half-wave potential between 0·1 and 0·2 V. The second wave has the same half-wave potential as the first wave of the dichloracetamido group. The third wave has the same half-wave potential as the second wave of the dichloracetamido group and the same as the single wave of the monochloracetamido group. The simple acetamido group results in no wave other than that of the residual current. With the various waves the diffusion current constants are quite similar.

When polarographed, all of the compounds containing the dichloracetamido group resulted in two cathodic waves which are well suited for both the qualitative and quantitative analysis of the intact compounds as well as the main hydrolysis product, the dichloracetate ion. It is from this approach that the compounds will be discussed under their respective groupings.

Group I

Effect of ring substituents. The positioning of the halogen atoms on the benzyl nucleus (Table III) alters the half-wave potential of the first reduction wave of this group of compounds. The 3,4-dichloro analogue's half-wave potential is nearly 0·2 V more positive (thus making the first chlorine of the dichloraceto group easier to reduce) than the 2,6-dichloro analogue. Between these extremes the half-wave potentials of the other halogen compounds are found.

TABLE III.—POLAROGRAPHIC REDUCTION OF GROUP I COMPOUNDS IN BUFFERED 50% METHANOL



R	First wave		Second wave		Hydrolysed after 3 days at pH 8, %
	$-E_{1/2}$	I	$-E_{1/2}$	I

9 3,4-CH_2O_2—	0·55	1·34	1·20	1·50	89

The presence of various alkoxy groups on the benzyl nucleus (Table III) does not appreciably change the polarographic characteristics of the dichloracetamido group.

Effect of substituents on the amide nitrogen. The changes in half-wave potentials of the dichloracetamido group resulting from the various groups on the tertiary amide are not extreme, as shown in Table IV.

From the values (Hydrolysis, %) in the last column of Tables III and IV, the effect of the adjacent substituents on the hydrolysis of the dichloracetamido group is

* This is the same compound as number 4 in Table III.

quite apparent. Only the compounds which contain the 2-hydroxyethyl group (numbers 1–9) or the 2-acyloxyethyl group (numbers 15 and 16) attached to the amide nitrogen show any tendency towards hydrolysis of the dichloracetamido group in the 50% methanol pH 8 medium at room temperature. This hydrolysis of the dichloracetamido group may be followed polarographically through the reduction waves of the chlorine on the dichloracetyl group. As long as the dichloracetyl group is still attached to the nitrogen, the two resulting waves are those characteristic of the individual chlorines from the dichloracetamido group being reduced. When about 10% of the dichloracetamido group is hydrolysed, a third wave is detected in the polarogram. The wave height of this third wave increases as the hydrolysis of the dichloracetamido group proceeds to completion. When the dichloracetamido group is 100% hydrolysed, only one reduction wave remains which has all of the polarographic characteristics of dichloracetic acid in this same medium

With the various compounds containing the 2-hydroxyethyl group there is no apparent correlation between the rate of hydrolysis of the dichloracetamido group and the ease of reduction polarographically of the first chlorine of the dichloracetamido group. It is noted, however, that the amount of hydrolysis taking place in this pH 8 medium at room temperature in 3 days depends on the R-substituent of the molecule. The alkalinity of the medium also plays an important role on the rate of hydrolysis of the dichloracetamido group: if the pH 8 buffer is replaced with 0·1*M* tetramethylammonium hydroxide, the dichloracetamido group of chlorbetamide is 100% hydrolysed within 15 min at room temperature, whereas in the pH 8 buffer only 64% is hydrolysed after 3 days at room temperature. In an acidic medium (pH 3) none of these compounds which hydrolyse at pH 8 showed any polarographic signs of hydrolysis of the dichloracetamido group.

It is of particular interest to note the polarograms of *N*-(4-nitrobenzyl)-*N*-(2-hydroxyethyl)dichloracetamide in that both the nitro group and the two chlorines of the dichloracetamido group are reduced polarographically in 50% methanol at pH 8 (Fig. 1). The freshly prepared solution of this compound results in three waves polarographically (Curve A in Fig. 1). The first is the reduction wave of the nitro group. The second and third waves result from the reduction of the individual chlorines of the dichloracetamido group. Curve B in Fig. 1 represents, polarographically, the same solution only after it had been set aside for 3 days at room temperature. Only two waves are present in this polarogram, the first being identical with the reduction wave of the nitro group in the fresh solution. The second wave does not have the polarographic characteristics of either the reduction wave of the chlorines of the dichloracetamido group but does have the same polarographic characteristics of dichloracetic acid in this medium.

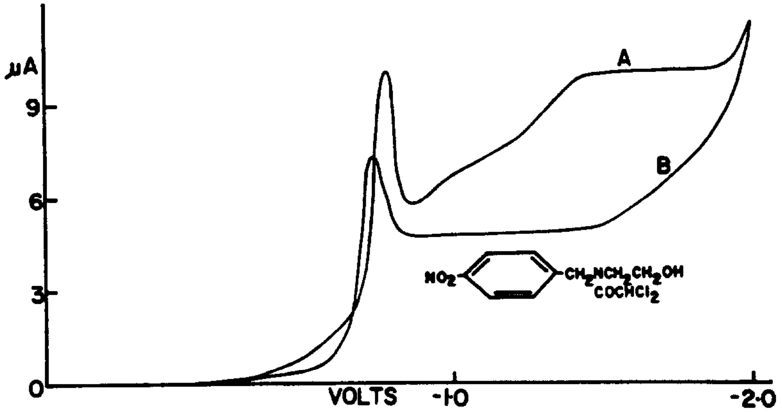

FIG. 1.—Polarograms of 0·0005*M* solutions in 50% methanol and pH 8 buffer:
A—fresh solution,
B—3-day old solution.

This is unequivocal evidence that the dichloracetamido group in the presence of a nitro group does contribute to the resulting polarogram of a freshly prepared solution in 50% methanol and pH 8, and that upon hydrolysis of the compound at room temperature that the dichloracetate ion contributes to the resulting polarogram along with the reduction wave of the nitro group.

With chloramphenicol {D(—)-threo-2,2-dichloro-*N*-[β-hydroxy-α-(hydroxymethyl)-*p*-nitrophenethyl]-acetamide}, in the same polarographic medium as above, three reduction waves result which are similar to those in Curve A in Fig. 1. After 3 days in this medium, the resulting polarogram is identical with the polarogram of the freshly prepared solution. This emphasises the stability of both the nitro and dichloracetamido groups in a compound not having a 2-hydroxyethyl group present on the amide nitrogen to initiate the hydrolysis of the dichloracetamido group at pH 8.

Group II

With the compounds in Group II only the aliphatic group attached to the sulphone or sulphide is varied. With the sulphone homologues, increasing the aliphatic chain from methyl to butyl results in a decrease in half-wave potentials (Table V), while with the sulphide homologues (Table V) an increase in half-wave potentials results.

Comparison of the sulphide, sulphoxide and sulphone analogues (numbers 28, 27, 22 in Table V) shows an increase of half-wave potential with an increase of oxygen content.

With certain isomeric compounds, polarography has shown a difference between the isomers. With the three available isomers of raceophenidol (dl, Dd, and Ll) there is no apparent difference in their polarograms at pH 3 or 8.

Group III

Compounds from the three other groups discussed in this communication dissolve readily in methanol while the compounds in Group III not only dissolve with difficulty but crystallise out of the buffered 50% methanol media within a short period of time at room temperature. This series did dissolve readily in *N,N*-dimethylformamide (DMF), but on mixing with the constant ionic strength buffers, the buffer constituents precipitated in the presence of 50% DMF. With less DMF the compound crystallises out of the media. On using a medium consisting of 70% methanol, 10% DMF and 20% water (containing the buffer) clear solutions with these Group III compounds result for at least 3 days at room temperature. Because of these solubility problems, polarograms were run only at pH 8·2. For a given compound of Group III, the half-wave potentials and the wave heights from the resulting polarograms are the same whether the medium is 70% methanol-10% DMF or the 50% methanol medium (before crystallisation of the compound occurs).

The half-wave potentials decrease about 0·3 V when the structure of the compound is changed from a secondary to a tertiary amide (Table VI).

With the tertiary amide series of compounds, the various substituents did not appreciably affect the polarographic characteristics of the given series of compounds when n = 1 or 0 (Table VI). If the benzene nucleus is replaced with cyclohexane, the polarographic characteristics are not altered appreciably.

Compounds in Group III which possess the 2-hydroxyethyl group attached to the amide nitrogen, as was the case with chlorbetamide and related compounds in Group I, result in hydrolysis of the dichloracetamido groups. The 2-hydroxyethyl

compound (number 37 in Table VI) shows 77% hydrolysis after 3 days at room temperature and pH 8·2. The 2-acetoxyethyl analogue (number 39 in Table VI) shows only 15% hydrolysis under the same conditions. This emphasises again the necessity of the free 2-hydroxyethyl group to initiate the hydrolysis of the dichloracetamido group

Replacement of the benzene nucleus with naphthalene (Table VII) does not change appreciably the general polarographic characteristics. The 2-hydroxyethyl compound (number 46 in Table VII), however, results in 60% hydrolysis of the dichloracetamido groups after 3 days at room temperature and pH 8·2.

Replacement of the benzene nucleus with stilbene results in a series of compounds (Table VII) which are all the same polarographically, even though the aliphatic substituents attached to the amide nitrogen are different.

Group IV

This series of *N*,*N*′-bis-(dichloracetyl)-polymethylenediamines presented the opportunity to study polarographically two homologous series, one with the secondary amide linkage and the other with the tertiary amide linkage of the dichloracetyl group.

With the secondary amide homologous series (Table VIII) the effect of increasing the distance between the two dichloracetamido groups by increasing the methylene groups from 2 to 9 is readily apparent. The half-wave potentials decrease (not linearly though) with the increasing number of methylene groups. The decamethylene homologue is not listed in this table because its first wave is entirely different from any other members of this series (or for that matter from any of the compounds studied). The half-wave potential of the first wave is −0·79 V and has the appearance of a reversible wave (very steep slope). The slope of the second wave (−1·24 V) is similar to the other members of the series (gradual change in slope).

With the tertiary amide homologous series (Table IX) the presence of the ethyl group appears to nullify any appreciable change in the half-wave potentials of these methylene homologues (n = 4 to 12). The trend, however, is the opposite of the striking effect shown by the secondary amide series in that the half-wave potentials increase rather than decrease with the increasing number of methylene groups. It should be noted that with the tertiary amide series the half-wave potentials are 0·1 to 0·3 V lower than the corresponding secondary amide.

With the hexamethylene compounds (Table X) the various substitutions on the nitrogen result in very little change in the half-wave potentials of the two waves of the dichloracetamido groups. Only two of these compounds show, polarographically, hydrolysis of the dichloracetamido groups. Number 70 in Table X which contains the 2-hydroxyethyl group attached to the amide nitrogen and number 73 which contains a potentially available 2-hydroxyethyl group (2-acetoxyethyl analogue of number 70). Both of these compounds are hydrolysed 100% after 3 days at room temperature and pH 8, as determined polarographically by the presence of only the dichloracetate ion reduction wave.

Possible correlation between polarographic findings and biological effectiveness

Groups I, II and III. With the available data there is no clear-cut relationship between the biological activity of these compounds and their polarographic characteristics.[9,10,11,12]

* This is the same compound as number 55 in Table VIII.

† This is the same compound as number 61 in Table IX.

Group IV. With the homologous series of the secondary amide compounds (Table VIII), when n = 2, 3, 4, 5, 6, 7, 9 or 10 the compounds possess amebicidal activity. This amebicidal activity is found to increase with the increase in the number of methylene groups between the two dichloracetamido groups.[13] Polarographically, the half-wave potentials of the first reduction wave of the dichloracetamido group decrease, though not linearly with the increase in the number of methylene groups. When n is 8, however, the amebicidal activity is very low. On the other hand, this homologue (number 57 in Table VIII) has proved to possess the most effective antispermatogenic activity of all of the compounds yet tested in either Group III or IV.[12,13,14] Why the octamethylene homologue has such a singular potency as a spermatocide remains unanswered because the homologues (n = 7 or 9) have little such activity. Polarographically, one does note a uniqueness with the octamethylene compound in that it shows a sharply defined prewave (at 0·71 V) before the first reduction wave. None of the other homologues shows this polarographic characteristic.

With the tertiary amide series (Table IX), even though there is no consistent relationship between the length of the methylene chain and amebicidal activity, they possess (as a group) the greater amebicidal activity on comparing with the secondary amide compounds.[13] Polarographically, the half-wave potentials resulting from the reduction of the first chlorine of the dichloracetamido group in the tertiary amide series are 0·1 to 0·3 V lower than those from the secondary amide compounds.

With the various analogues of the hexamethylene series (Table X) there is little change in amebicidal activity.[13] These different R-groups had little effect on the polarographic characteristics of these analogues.

CONCLUSION

Because the first reduction wave of the chlorine from the dichloracetamido group is so well-defined, its wave height may be utilised in measuring quantitatively the amount of intact dichloracetamido compound in various pharmaceutical formulations (chiefly tablets, injections and feed premixes). The values obtained were within ±2% of label claim. The resulting polarograms, during a stability testing programme, of 1 year, were especially helpful in proving conclusively that the dichloracetamido group is stable in the pharmaceutical preparation as shown by the absence of the dichloracetate reduction wave.

Zusammenfassung—An verschiedenen Verbindungen, die die Dichloracetamidogruppe enthalten, wie N-(2,4-dichlorbenzyl-)N-(2-hydroxyäthyl-) dichloracetamid (Chlorbetamid), N-(4-methylsulfonylphenyl-) 1,3-dihydroxy-2-propyl-dichloracetamid (Raceophenidol), N,N′-bis-(2-äthoxyäthyl-)N,N′-p-xylylen-bisdichloracetamid (Teclozan), N,N′-octamethylen-bisdichloracetamid und analogen Verbindungen, wurden polarographische Untersuchungen angestellt. Die analytischen Ergebnisse werden vom quantitativen und qualitativen Gesichtspunkt aus diskutiert, mit besonderem Nachdruck auf der Stabilität der Verbindungen bei verschiedenen p_H-Werten und auf dem Einfluß verschiedener Elemente oder Gruppen im Molekül auf die Halbwellenpotentiale der beiden kathodischen Wellen

Résumé—L'auteur a étudié par polarographie une série de composés contenant des groupes dichloroacétamide comprenant N-(2,4-dichlorobenzyl)-N-(2-hydroxyéthyl)dichloroacétamide (chlorbetamide), N-(4-méthylsulfonylphényl)-1,3-dihydroxy-2-propyl-dichloroacétamide (raceophenidol), N,N′-bis-(2-éthoxyéthyl)-N,N′-p-xylylène-bis-dichloroacétamide (teclozan), N,N′-octaméthylène-bis-dichloroacétamide et leurs analogues. Les résultats analytiques sont discutés du point de vue qualitatif et quantitatif en insistant particulièrement sur la stabilité de ces composés à différents pH et sur l'influence des éléments ou des groupes variés situés dans la molécule sur les potentiels de demi-vague des deux vagues de réduction

SCHIFF BASE COMPLEXES

A NUMERICAL STUDY OF THE NICKEL^{II}—PYRUVATE—GLYCINATE SYSTEM USING A HIGH SPEED COMPUTER*

D. L. LEUSSING
McPherson Chemical Laboratory, Ohio State University, Columbus, Ohio, U.S.A.

(*Received* 19 *June* 1963. *Accepted* 25 *September* 1963)

Summary—A numerical study of the nickel^{II}-pyruvate-glycinate system is undertaken and a computer method of solving the pertinent equations is developed. Theoretical titration curves using trial constants are calculated for conditions corresponding to those used experimentally. The observed inter-relationships between the values of the constants, the concentrations of the reactants and the resulting titration curves yield valuable information regarding the importance of the various mixed complexes under the differing conditions. The "best" set of constants which fits the experimental data according to the minimum value of the sum of the squares of the residuals, $pH_{calc}\, i - pH_{obs}\, i$, is obtained. The results of the study lead to a procedure which should be applicable to determining the constants for mixed complex systems in general.

SCHIFF base complexes partake in many interesting reactions. Pfeiffer and coworkers[1] have demonstrated that enhanced rates of ester exchange and hydrolysis and oxidative de-amination can occur in these systems. The paramagnetic and diamagnetic properties of the nickel^{II} complexes have recently come under intensive study.[2,3] The investigations of Krumholz,[4a] Figgins and Busch[4b,c] and Blight and Curtis[4d] have resulted in interesting compounds having unusual properties. Of special importance is the role these complexes play in non-enzymatic transamination.[5,6,7,8,9] In order to understand more completely the behaviour of Schiff base co-ordination compounds it is desirable to extend our knowledge of the compositions and stabilities of the complexes formed in solution. Such information is a prerequisite to the complete understanding of any equilibrium or kinetic properties of these systems.

One difficulty in the study of equilibria involving Schiff base complexes is the dissociation of the Schiff base itself,[10] *i.e.*, in addition to the Schiff base-metal ion equilibria, there is superimposed the equilibrium between the Schiff base and its component amine and carbonyl compounds. In one approach to the problem a recent communication[11] points out the value of treating these species as "mixed complexes" and using the Bjerrum titration method[12] to obtain the data. In this earlier paper, which concerns the nickel^{II}-pyruvate-glycinate system, Watters' method[13] of obtaining the concentrations of combined and uncombined glycinate was used. This method was feasible because a large difference exists in the basicities of the pyruvate and glycinate ions, and the nickel^{II} "mixed complexes" form predominantly under conditions of pH where pyruvic acid is almost completely dissociated and uncombined glycine is ionized to only a very slight extent. An iterative procedure was used to obtain the formation constants of the species NiPG, $NiPG_2^-$ and $NiP_2G_2^{2-}$ (P^- = pyruvate, G^- = glycinate).

In those systems where the "mixed complexes" are formed under conditions

---

* Presented in part before the 145th National ACS Meeting, New York, 1963.

where appreciable concentrations of undissociated pyruvic acid are present, Watters' method does not apply. This was found to cause minor difficulties even in the present study and produces a more severe interference when the complexes of copper^{II} are under investigation. Also, in systems of considerable interest, such as those involving pyridoxal or salicylaldehyde and its derivatives, the acidities of the carbonyl compounds approach those of the amino acids, completely obviating Watters' method.

In the present study employing an IBM 7090 computer a numerical investigation of the inter-relationships between the experimental parameters, the concentrations of metal, pyruvate and glycinate ions, the values of the complex formation constants and the shapes of the titration curves, was undertaken. The results led to a general method of obtaining the "best" constants according to a least-squares fit for such systems, and also rendered valuable insight into their equilibrium properties. While the method described below concerns one particular system it can be applied directly to other metal ion-ketoacid-amino acid systems and, with only slight modifications, should even be applicable to those more complicated situations where pyridoxal is involved.

OUTLINE OF COMPUTATIONAL METHOD

In the experiments, solutions containing complexing metal ions, pyruvic acid, sodium pyruvate and inert electrolyte in known concentrations were titrated with a sodium glycinate solution and the equilibrium values of pH were measured after each addition of titrant. A series of titration curves was obtained using solutions with different initial concentrations. The formation constants of the simple complexes, the acid dissociation constants of the ligands and their Schiff base formation constant were determined from the results of similar, separate experiments.

In the computation all of these data, including observed points (pH *vs.* ml) from the experimental titration curves, and the initial concentrations of reactants are first read into and stored in the computer. A predetermined network of trial values of the formation constants of the mixed complexes is then systematically scanned. For each set of constants a theoretical titration curve is calculated pertaining to each of the initial conditions. The residual, $pH_{calc}-pH_{obs}$, is obtained for each of the observed points and the quantity U, which is the sum of the squares of the residuals over all of the points, is computed.

Residuals in pH were minimised because values of pH are measured directly while in mixed complex systems the derived quantity $\bar{n}$, which is more commonly used in calculating equilibrium constants, is not single-valued with regard to the experimental variables, volume and pH. Furthermore, weighting procedures, which may be somewhat involved when $\bar{n}$ values are used,[14] are simplified because each point can be given unit weight. The error is assumed to lie entirely in the measured value of pH and the volume is assumed to be accurately known.

If a sufficiently broad network of constants has been used the region where the minimum value of U lies can be located and passing finer and finer networks through this region the constants which best fit the data can be obtained to the appropriate degree of accuracy. When the calculated N + 1 dimensional surface (N is the number of equilibrium constants being evaluated) is sufficiently wrinkled it is possible for the compution to converge on a "false minimum". One of the purposes of the present approach was to determine if such false minima are apt to interfere with obtaining the "best fit" for these systems.

Considering the bidentate character of pyruvate and glycinate, the tridentate character of their Schiff base and the predominant hexadentate character of the transition metal ions of the first series, the mixed complexes MPG, MP_2G^-, MPG_2^- and MP_2G^{2-} are expected. Considering also the simple species, mass-conservation leads to the following set of equations:

$$M_t = (M^{2+}) + (MP^+) + (MP_2^0) + (MG^+) + (MG_2^0) + (MG_3^-) + (MPG) \\ + (MP_2G^-) + (MPG_2^-) + (MP_2G_2^{2-}) \qquad (1)$$

$$P_t = (HP) + (P^-) + (MP^+) + 2(MP_2^0) + (MPG) + 2(MP_2G^-) + (MPG_2^-) \\ + 2(MP_2G_2^{2-}) + (PG^{2-}) \qquad (2)$$

$$G_t = (H_2G^+) + (HG^\pm) + (G^-) + (MG^+) + 2(MG_2^0) + 3(MG_3^-) + (MPG) \\ + (MP_2G^-) + 2(MPG_2^-) + 2(MP_2G_2^{2-}) + (PG^{2-}) \qquad (3)$$

$$H_t = 2(H_2G^+) + (HG^\pm) + (HP) + (H^+) - (OH^-) \qquad (4)$$

where the quantities on the left-hand side are the known concentrations of complexing metal ions, pyruvate, glycinate and replaceable hydrogen ions and those on the right-hand side are the concentrations of the various species.

Defining the over-all formation constant of the complex MP_pG_g as

$$Q_{pg} = \frac{(MP_pG_g)}{(M)(P^-)^p(G^-)^g}$$

and the formation constant of the Schiff base PG^{2-} as Q_{SB}, substitution into equations (1)–(4) gives:

$$M_t = (M^{2+})[1 + Q_{10}(P^-) + Q_{20}(P^-)^2 + Q_{01}(G^-) + Q_{02}(G^-)^2 + Q_{03}(G^-)^3 \\ + Q_{11}(P^-)(G^-) + Q_{21}(P^-)^2(G^-) + Q_{12}(P^-)(G^-)^2 + Q_{22}(P^-)^2(G^-)^2] \qquad (5)$$

$$P_t = \left[\frac{a_H}{\mathrm{Kap}} + 1\right](P^-) + Q_{10}(M^{2+})(P^-) + 2Q_{20}(M^{2+})(P^-)^2 + Q_{11}(M^{2+})(P^-)(G^-) \\ + 2Q_{21}(M^{2+})(P^-)^2(G^-) + Q_{12}(M^{2+})(P^-)(G^-)^2 + 2Q_{22}(M^{2+})(P^-)^2(G^-)^2 \\ + Q_{SB}(P^-)(G^-) \qquad (6)$$

$$G_t = \left[\frac{a_H^{\,2}}{K_{1aG}K_{2aG}} + \frac{a_H}{K_{2aG}} + 1\right](G^-) + Q_{01}(M^{2+})(G^-) + Q_{02}(M^{2+})(G^-)^2 \\ + Q_{03}(M^{2+})(G^-)^3 + Q_{11}(M^{2+})(P^-)(G^-) + Q_{21}(M^{2+})(P^-)^2(G^-) \\ + 2Q_{12}(M^{2+})(P^-)(G^-)^2 + 2Q_{22}(M^{2+})(P^-)^2(G^-)^2 + Q_{SB}(P^-)(G^-) \qquad (7)$$

$$H_t = \frac{a_H(P^-)}{K_{ap}} + \left[\frac{2a_H^{\,2}}{K_{1aG}K_{2aG}} + \frac{a_H}{K_{2aG}}\right](G^-) + (H^+) - (OH^-) \qquad (8)$$

In equation (8) a_H refers to the hydrogen ion activity whereas (H^+) is the concentration. From blank titrations of the inert electrolyte with hydrochloric acid solutions it was found that $(H^+) = a^{0.96}$ and this relationship was used to make the correction iteratively for free (H^+).

In the experiments, the values of M_t, P_t and H_t are known at each point on the titration curve from the initial concentration and the dilution factor. The value of G_t is also known from the concentration of NaG in the titrant and the volume added.

However, in computing the theoretical curves, because of the higher order equations involved, it is simpler to begin with a value of (G^-) and from this to calculate the corresponding values of pH and G_t than it is to calculate the values of pH and G^- using G_t. Accordingly, the above equations are rearranged in terms of (G^-) and the unknowns (P^-) and a_H.

Solving equation (5) for (M^{2+}) and substituting into equation (6) gives, on rearrangement,

$$F(P^-) = C_3(P^-)^3 + C_2(P^-)^2 + C_1(P^-) - S_0P_t \tag{9}$$

where

$$\begin{aligned}
C_3 &= C_0S_2\\
C_2 &= C_0S_1 + (2M_t - P_t)S_2\\
C_1 &= C_0S_0 + (M_t - P_t)S_1\\
C_0 &= a_H/K_{ap} + Q_{SB}(G^-) + 1\\
S_1 &= Q_{10} + Q_{11}(G^-) + Q_{12}(G^-)^2\\
S_2 &= Q_{20} + Q_{21}(G^-) + Q_{22}(G^-)^2\\
S_0 &= 1 + Q_{01}(G^-) + Q_{02}(G^-)^2 + Q_{03}(G^-)^3
\end{aligned}$$

and the quantities S_i are polynomials depending only on (G^-) and the formation constants.

The correct solution for a given value of G^- is that positive value of (P^-) (and a_H) which causes $F(P^-)$ to become equal to zero.

The value of a_H can be obtained in terms of (G^-) and (P^-) using the quadratic equation

$$a_H = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \tag{10}$$

where, from equation (8),

$$\begin{aligned}
a &= 2(G^-)/K_{1aG}K_{2aG},\\
b &= (G^-)/K_{2aG} + (P^-)/K_{ap},\\
c &= a^{0.96} - H_t.
\end{aligned}$$

The positive root is used because the quantity a_H must be positive.

Once the value of (G^-) is chosen, equation (9) and (10) become two non-linear equations in two unknowns. The equations are solved as follows. First (P^-) is set equal to zero and the corresponding value of a_H is calculated from equation (10) [iteratively when the term resulting from free (H^+) is appreciable with regard to H_t]; these values of a_H and (P^-) are inserted into equation (9) to give a value of $F(P^-)$; (P^-) is incremented by some predetermined amount (usually of the order 0·1 to 0·2 P_t) and a new value of $F(P^-)$ is similarly obtained. A test is made to determine if $F(P^-)$ has changed sign. This process is repeated until a sign change in $F(P^-)$ indicates that a root of equation (9) has been reached. The values of (P^-) and a_H are then refined iteratively using the Newton-Raphson[15] method until any change in (P^-) is less than 0·2% of its value at that time. A test is made to verify that a_H is positive. A negative value signifies an incorrect root and (P^-) is again successively incremented until $F(P^-)$ once more changes sign. In practice it has been observed that the correct root lies at the first sign change. The reason for this can be seen in the data of Table I where $F(P^-)$ and a_H have been computed for various conditions. Only one root appears to exist in the range $0 \leq P^- \leq P_t$. In the region of interest $F(P^-)$ is a smooth curve for which the first, second and third derivatives are all positive. The last appears to be about constant. No troublesome convolutions nor inflections exist in the region F(P⁻) = 0. Also, it can be seen that any error in pH caused by a 0·2% uncertainty in (P⁻) has negligible proportions as far as the present purposes are concerned.

Using the chosen value of (G⁻) and those obtained for (P⁻) and a_H, (M^{2+}) is evaluated from equation (5) and using these results in equation (7), G_{tcalc} is calculated. The volume of titrant necessary to give this value of G_{tcalc} is obtained from the experimentally known concentration of the titrant and the initial volume. The values of M_t, P_t and H_t are corrected for dilution and the last is also corrected for the effect of any excess sodium hydroxide in the titrant. The entire calculation is repeated iteratively until changes in H_t amount to less that 0·2% of its value. In this way one theoretical point on the titration curve (pH *vs.* ml) is obtained. To obtain another point, the value of $-\log(G^-)$ is increased. The final titration curve results when the desired range of (G⁻) values has been covered. The time taken to compute one point is of the order of 25 msec with the IBM 7090 computer.

Only by rare coincidence does an observed and computed volume of titrant agree. Therefore, to obtain the residual for each observed volume it is necessary to interpolate. A second order LaGrange interpolation[16] is performed. Three calculated points bracketing each observed point are used in the interpolation. In the region of interest where the mixed complexes are formed, the buffer capacity of the solutions is large and a higher order equation is not necessary for the interpolation.[17]

The computed points are printed out and the next set of experimental conditions is taken. When the computation for the final experiment has been performed the value of U is also printed out. A new set of constants is then taken. With the IBM 7090 computer the time required to compute a theoretical curve of 16 points, interpolate and obtain the sum of the squares of the residuals is less than 0.6 sec.

In the first version of the programme the constants were varied from initial to final values in fixed steps. To save computer time all of the titration curves were not computed for a given combination of constants if it was found that at any point the absolute value of a residual was greater that 0·15 pH unit. The programme was designed to cease calculations at this point and go on to the next set of constants. Furthermore, because the constants were varied from low to high values, shifting the computed curves to more acid values as the computation progressed, a particular region was considered to be out of range of interest and was no longer investigated if a point on a calculated curve was found to become more acid by 0·15 pH unit than the corresponding experimental point.

DATA AND RESULTS FOR THE NICKEL^{II} PYRUVATE-GLYCINATE SYSTEM

The data from which the $\bar{n}_G$ and log (G⁻) values reported in reference 11 were calculated was taken. In these experiments solutions which contained either 0·0500*M* NiCl$_2$, 0·0500*M* pyruvic acid, (I); 0·0500*M* NiCl$_2$, 0·0500*M* pyruvic acid, 0·0550*M* sodium pyruvate, (II); 0·0500*M* NiCl$_2$, 0·0500*M* pyruvic acid, 0·100*M* sodium pyruvate, (III); 0·0220*M* NiCl$_2$, 0·0500*M* pyruvic acid and 0·100*M* sodium pyruvate, (IV) were prepared. These solutions also contained sufficient potassium chloride to bring the ionic strength to 0·70. Twenty-five ml aliquots were titrated at 25·0° with 0·800*M* sodium glycinate. The pH measurements were made with a Radiometer pHM22 pH meter with a scale expander. Readings were made to the nearest 0·005 pH

unit. National Bureau of Standards buffers were used to standardise the glass and calomel electrodes. In the titration curves only those points in the buffer regions where the mixed complexes form, were used in the calculations. As the concentration of pyruvate increases a pronounced break in the titration curve appears where the $Ni^{II}:(G^-)$ ratio is 1:2. This break is informative as far as the stoichiometry is concerned but the points close to the end-point have only slight value as far as determining the constants is concerned.

The constants for the formation of the simple nickel^{II}-glycinate complexes were found to be $4{\cdot}6 \times 10^5$, $3{\cdot}2 \times 10^{10}$ and $9{\cdot}0 \times 10^{13}$ for Q_{01}, Q_{02} and Q_{03}, respectively. For the nickel^{II}-pyruvate system Q_{10} was found to be 14. No evidence for the existence of NiP_2 was observed. The Schiff base formation constant was found to have a value of 2·2–2·3 from the results of a potentiometric titration of glycine in the presence of pyruvate with a solution of sodium hydroxide. This value compares favourably with 2·47 obtained polarographically by Zuman.[18] The value found for the acid dissociation constant of pyruvic acid, K_{aP}, is $4{\cdot}07 \times 10^{-3}$ while K_{1aG} and K_{2aG} for glycine were found to be $3{\cdot}4 \times 10^{-3}$ and $2{\cdot}0 \times 10^{-10}$.

In the previous communication[11] the values reported for Q_{11}, Q_{12} and Q_{22} are $1{\cdot}15 \times 10^8$, $2{\cdot}5 \times 10^{13}$ and $1{\cdot}6 \times 10^{15}$. Ordinarily these results would not be available in which case it is desirable, but not necessary, to make quick preliminary desk calculations to obtain the likely approximate values of the mixed complex formation constants. It is convenient to initiate the computations with the high speed computer using a network of constants with points spaced from about one-third to one-half the preliminary values. In the present series, Q_{11} was first varied from 0 to $3{\cdot}0 \times 10^8$ in steps of $0{\cdot}5 \times 10^8$, Q_{12} was varied from 0 to $4{\cdot}9 \times 10^{13}$ in steps of $0{\cdot}7 \times 10^{13}$ and Q_{22} was varied from 0 to $4{\cdot}5 \times 10^{15}$ in steps of $0{\cdot}5 \times 10^{15}$. Because Q_{20} was found to have a negligibly small value, it seemed reasonable that the same is also likely for Q_{21}. Therefore, in the first series of calculations Q_{21} was set equal to zero.

Complete sets of computed titration curves and values of U were obtained for only a relatively small region of the vector space of trial constants scanned because points for most of the computed curves fell outside the 0·15 pH unit limit. The results are shown in Table IIA. A finer network was then used to obtain the results given in Table IIB.

A final run was made using initial values $Q_{11} = 1{\cdot}15 \times 10^8$, $Q_{12} = 0{\cdot}8 \times 10^{13}$ and $Q_{22} = 1{\cdot}8 \times 10^{15}$, with increments $dQ_{11} = 0{\cdot}10 \times 10^8$, $dQ_{12} = 0{\cdot}20 \times 10^{13}$ and $dQ_{22} = 0{\cdot}20 \times 10^{15}$. The minimum value of U was found to be 0·0229 (43 points)[19] lying at $Q_{11} = 1{\cdot}25 \times 10^8$, $Q_{12} = 1{\cdot}0 \times 10^{13}$ and $Q_{22} = 2{\cdot}0 \times 10^{15}$. A plot of the points obtained for this last set of constants is given in Fig. 1 along with the observed values.

At this stage attempts were made to improve the fit by scanning a four dimensional array of constants using relatively small values of Q_{21} of the order of 10^9. These attempts resulted only in increased U values so it is concluded that as far as the present experimental conditions are concerned any effect of NiP_2G^- is negligible.

It is important to establish whether or not the values found above are meaningful or merely reflect the uncertainties in the pH measurements. Sillén[20] has described methods for obtaining the standard deviations of the constants and the observed points in cases such as the present, where the sum square surface has been obtained. After Sillén[20] a generalised four dimensional paraboloid was fitted to the displacements

TABLE II.—VALUES OF THE SUM-SQUARE AS A FUNCTION OF THE TRIAL CONSTANTS

[a] Values of the sum-square were printed out for only those sets of data for which the condition $-0{\cdot}15 \leq \mathrm{pH}_{\mathrm{calc}} - \mathrm{pH}_{\mathrm{obs}} \leq 0{\cdot}15$ is satisfied for all points on the computed titration curves. A total of 41 points was used in this series of calculations.

[b] $Q_{11} \times 10^{-6}$.

[c] $Q_{12} \times 10^{-18}$.

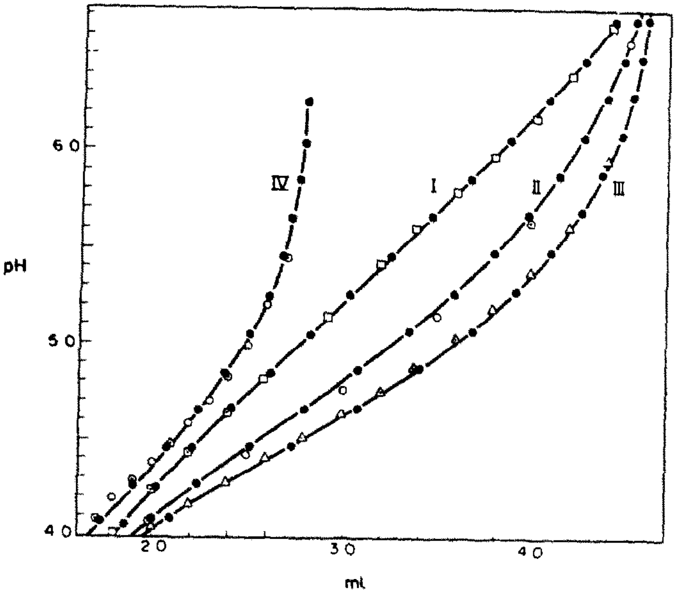

FIG 1.—Computed and Observed Titration Curves.
The roman numerals refer to the experiment number given in the text. The open points are observed and the solid points are computed. The values used in the computation are $Q_{11} = 1{\cdot}25 \times 10^{+8}$, $Q_{12} = 1{\cdot}0 \times 10^{+13}$ and $Q_{13} = 2{\cdot}0 \times 10^{+15}$

in U and in the constants for the last set of calculations taking the observed minimum where $U = 0{\cdot}0229$ as the origin. This gave the equation

$$U = 0{\cdot}0299 + 0{\cdot}0205 \times 10^{-8}x_1 + 0{\cdot}825 \times 10^{-16}x_1^2 - 0{\cdot}0035 \times 10^{-13}x_2 + 0{\cdot}155 \times 10^{-26}x_2^2 + 0{\cdot}0075 \times 10^{-15}x_3 + 0{\cdot}345 \times 10^{-30}x_3^2 - 0{\cdot}445 \times 10^{-21}x_1x_2 - 0{\cdot}625 \times 10^{-23}x_1x_3 + 0{\cdot}280 \times 10^{-28}x_2x_3$$

where $x_1 = Q_{11} - 1{\cdot}25 \times 10^{+8}$, $x_2 = Q_{12} - 1{\cdot}0 \times 10^{+13}$ and $x_3 = Q_{22} - 2{\cdot}0 \times 10^{+15}$. The surface defined by this equation is calculated to have a minimum, $U_{\min}$, equal to 0·0225. Because the values of three constants have been obtained losing three degrees of freedom the standard deviation of the points is calculated to be $\pm 0{\cdot}0225/(43-3) = \pm 0{\cdot}024$. This deviation is only slightly larger than the expected 0·01 – 0·02 unit uncertainty in the measured pH values. From the matrix of the coefficients of the displacements, the constants at the minimum and their standard deviations are calculated to be $Q_{11} = 1{\cdot}23 \pm 0{\cdot}04 \times 10^{+8}$, $Q_{12} = 1{\cdot}01 \pm 0{\cdot}08 \times 10^{+13}$ and $Q_{22} = 1{\cdot}97 \pm 0{\cdot}05 \times 10^{+15}$. The standard deviations are well below the values of the constants.

It is also worthwhile to make plots of various computed curves. In this way visual evidence may be obtained regarding the effects which given species have on the measured parameters under different conditions This information is valuable in the design of experiments. In Fig. 2 are plotted the curves which were obtained using several values of Q_{11}, Q_{12} and Q_{22} for conditions pertaining to experiments I and II. Here it is seen that curve I is sensitive to the values of Q_{11} and Q_{12}, but the variation in Q_{22} has a negligible effect. On the other hand, curve III shows only a slight dependence on the value of Q_{12} but is shown to depend primarily on Q_{11} and Q_{22}. Thus, under the conditions of experiment (I) NiPG and $NiPG_2^-$ are indicated to be important, whereas in experiment (III) $NiP_2G_2^{2-}$ replaces the latter species. For more quantitative

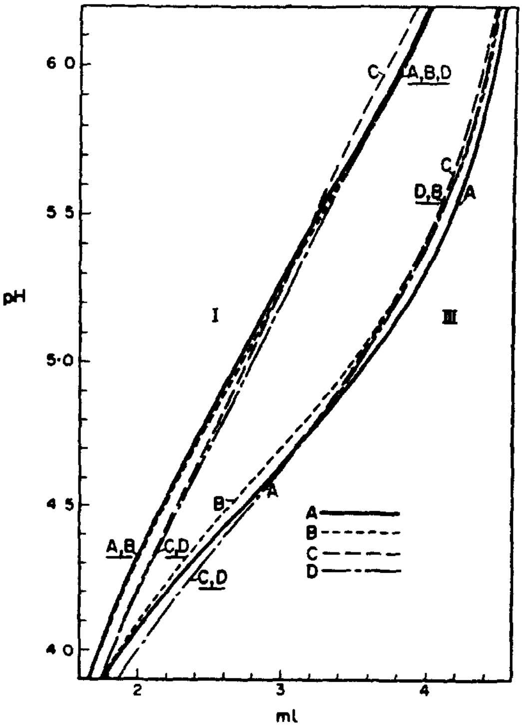

FIG. 2.—The Effect of Variations in Q_{11}, Q_{12} and Q_{22} on the Computed Curves. The roman numerals refer to the experiment number given in the text. The values used in the computation are:

Curve	Q_{11}	Q_{12}	Q_{22}
A	$1·0 \times 10^{+8}$	$0·70 \times 10^{+13}$	$2·0 \times 10^{+15}$
B	$1·0 \times 10^{+8}$	$0·70 \times 10^{+13}$	$1·5 \times 10^{+15}$
C	$1·5 \times 10^{+8}$	$0·70 \times 10^{+13}$	$2·0 \times 10^{+15}$
D	$1·5 \times 10^{+8}$	$1·4 \times 10^{+13}$	$2·0 \times 10^{+15}$

information it is desirable to compute the fractions of each of the species. This can be easily done because (M), (P^-) and (G^-) are known at each point.

The method of obtaining the constants in the present work has the advantages over the iterative procedure used previously[11] in that all of the pertinent data are treated simultaneously and the "best" constants in a "least squares" sense result (see reference 20). Furthermore, by noting the relationships between the experimental conditions and the sensitivities of the curve shapes to the values of the constants, useful information regarding the actual existences of proposed complexes and the proper conditions for studying their properties may be obtained.

SEARCH FOR THE CONSTANTS: A MODIFIED PROGRAMME

The procedure described above is inefficient if all that is desired is the constants for a particular system. The above results indicate that certain modifications in the search procedure can be made to find the minimum more rapidly. The surface $U = F(Q_{11}, Q_{12}, Q_{22})$ is relatively smooth and shows only one important minimum in the region where positive concentrations obtain. Furthermore, in Tables IIA and IIB it is seen that the minimum value of U in each column lies approximately along a downward sloping line which can be drawn across the table. The slope of the line depends on the magnitudes of the increments and the sensitivity of the sum-square to the values of the constants.

To obtain a faster search for the "best" constants the programme has been modified so primarily only those trial sets lying along the valleys shown in Table II are considered. After the preliminary phase where the constants are narrowed down to those giving titration curves falling within some prescribed range, the mapping of the sum-square surface[20] is begun. The value of Q_{11}, at constant Q_{12} and Q_{22}, is incremented until a minimum in U has been reached. This process is then repeated with the next value of Q_{12} but because the valleys slope downward it is not necessary to return Q_{11} to its initial value before starting the new column, but only to reduce it by the value of one increment. As long as the minimum value of U in each new column is found to be smaller than in the preceding column the search at constant Q_{22} continues. Once the lowest value has been reached, ascertained by the simple test that a minimum in a column is larger than that of the preceding column, Q_{22} is increased and Q_{11} and Q_{12} are decreased slightly so as to remain in the vicinity of the minimum.

The search continues in the same manner until the Q_{22} plane having the smallest U has been uncovered. The constants can then be refined either by automatically rescanning the region of minimum U employing smaller and smaller increments until the desired accuracy has been obtained, or by employing procedures based on those described by Hugus[14] or, as illustrated above, Sillén.[20]

Acknowledgement—The author wishes to extend his thanks to the staff of the OSU Numerical Computation Laboratory for their kind assistance and the generous use of their facilities in carrying out this study.

Zusammenfassung—Das Nickel (II)-Pyruvat-Glycinat-System wurde numerisch untersucht. Ein Rechenprogramm zur Lösung der zugehörigen Gleichungen wurde entworfen. Für Bedingungen, die den experimentellen entsprechen, wurden mittels angenommener Konstanten theoretische Titrationskurven berechnet. Die beobachteten Beziehungen zwischen den Werten der Konstanten, den Konzentrantionen der Reaktanten und den sich ergebenden Titrationskurven ergaben wertvolle Informationen über die Bedeutung der verschiedenen gemischten Komplexe unter den verschiedenen Bedingungen. Der "beste" Satz von Konstanten, der gegenüber den experimentellen Daten die kleinste Summe der quadratischen p_H-Abweichungen gibt, wurde erhalten. Die Ergebnisse führen zu einem Verfahren, das auf die Ermittlung der Konstanten in gemischten Komplexsystemen allgemein anwendbar wäre.

Résumé—Une étude quantitative du système Ni(II)-pyruvate-glycinate a été entreprise. On a développé une méthode de résolution des équations correspondantes au moyen d'un calculateur. Les courbes de titrage théoriques correspondant aux conditions expérimentales ont été calculées en utilisant des constantes expérimentales. Les relations observées entre les valeurs des constantes, les concentrations des réactifs, et les courbes de titrage qui en résultent fournissent des renseignements valables concernant l'importance des différents complexes mixtes dans des conditions variées. La "meilleure" série de constantes qui soit en accord avec les données expérimentales est choisie comme étant celle qui donne le minimum pour la somme des carrés des résidus $pH_{calc\,i} - pH_{obs\,i}$. On déduit de ces résultats une méthode qui serait applicable à la détermination des constantes de systèmes de complexes mixtes en général.

[19] Inadvertently, the two most acid points shown for curve IV in Fig. 1 had been omitted in the first series of computations. These points were included in the last series. As a matter of interest, exclusion of these points yields a minimum U equal to 0·0175 for which the values of the constants are unchanged.

POTENTIOSTATIC DETERMINATION OF KINETIC PARAMETERS OF ELECTRODE REACTIONS WITH GENERATION OF A REACTANT *IN SITU*

Y. OKINAKA*, S. TOSHIMA and H. OKANIWA
Department of Applied Chemistry, Faculty of Engineering,
Tohoku University, Sendai, Japan

(*Received* 19 *June* 1963. *Accepted* 25 *September* 1963)

Summary—It is shown that kinetic parameters of simple, fast electrode reactions of the type $O + ne = R$, where R is soluble in the solution or in the mercury electrode, can be determined by the potentiostatic method with a solution initially containing only the substance O, the substance R being generated *in situ* during electrolysis, provided that the electrode reaction involves only a single rate-determining step. Current-time curves are recorded with a fast response, electronic potentiostat and an oscilloscope upon applying a potential step from the zero-current potential to various potentials on the ascending part of the current-potential curve The forward rate constant k_f at a given potential is calculated from the current at zero time found by extrapolation of the linear portion of the plot of current against square root of time, while the backward rate constant k_b is calculated indirectly from the slope of the same straight line. Plotting log k_f and log k_b against potential allows a simultaneous determination of the formal standard rate constant k_s, both cathodic and anodic transfer coefficients, the number of electrons involved in the rate-determining step and the formal standard potential of the system being studied. This method is considerably simpler than the well-known Gerischer-Vielstich method, and it should be particularly advantageous when R is highly reactive or forms an amalgam which is unstable in air. The upper limit of k_s that can be determined by this method is the same as that determinable by the Gerischer-Vielstich method. The kinetic parameters found by the present method for the electrode reactions zinc ion-zinc amalgam in $1M$ potassium nitrate, copper^{II} ion-copper amalgam in $1M$ potassium nitrate and cadmium ion-cadmium amalgam in $0{\cdot}5M$ sodium sulphate were in fair agreement with the values reported in the literature.

INTRODUCTION

THE potentiostatic method developed by Gerischer and Vielstich[1,2] is a well-established method for the determination of kinetic parameters of fast electrode reactions. In their method, current-time curves are recorded upon applying a potential step from the equilibrium potential of a given system containing initially both oxidised and reduced species at known concentrations, and the exchange current is calculated from the slope at the equilibrium potential of the plot of current at zero time against potential. The standard rate constant and the transfer coefficient are normally

---

* Present address: Bell Telephone Laboratories, Whippany, New Jersey, U.S A.

evaluated by determining the variation of exchange current with the concentration of either oxidised or reduced species. Thus, the Gerischer-Vielstich method suffers experimental complications when the reduced species in solution or in amalgam is highly reactive and subject to air oxidation.

In the method described in this paper, kinetic parameters are evaluated by analysing current-time curves obtained at only one concentration of the oxidised species, the reduced species being absent before electrolysis. Metal ion-amalgam systems can thus be studied by the present method without using an amalgam electrode of accurately known concentration. As expected from theoretical considerations, errors involved in the determination of the backward rate constant are somewhat greater than those involved in the determination of the forward rate constant, particularly at potentials away from the standard potential. Nevertheless, the method should be of practical value, as is evidenced by the fact that the kinetic parameters determined by the proposed method for the few systems are in satisfactory agreement with the values reported in the literature.

CURRENT-TIME RELATIONSHIP

Consider the reduction of a substance O to another substance R in an electrode process involving n electrons at a stationary mercury electrode under the following conditions:

(1) The reduction product R is soluble either in solution or in mercury.
(2) The solution contains the substance O at a known concentration and the concentration of R is negligible before electrolysis.
(3) Because the electrolysis time is very short and the thickness of the diffusion layer is very small in the present potentiostatic method, semi-infinite linear diffusion is the sole mode of mass transfer.
(4) The electrode process involves only a single rate-determining step.
(5) The electrode potential is maintained constant during electrolysis.

The general equation for current-time curves obtained under these conditions is well-known and takes the form[3]

$$i = nFAk_fC_0 \exp(\xi^2)\mathrm{erfc}(\xi) \tag{1}$$

where

$$\xi = st^{1/2} \tag{2}$$

$$s = k_fD_R^{-1/2} + k_bD_R^{-1/2} \tag{3}$$

and i is the current in A, F the Faraday, A the surface area of the electrode in cm^2, k_f and k_b the rate constants for the forward and backward reactions in cm . sec^{-1}, C_0 the concentration of substance O in the bulk of the solution in moles . cm^{-3}, t the time in sec, and D_0 and D_R the diffusion coefficients of 0 and R in cm^2 . sec^{-1}.

For values of ξ smaller than 1, one can write

$$\exp(\xi^2) = 1 + \xi^2 + \frac{\xi^4}{2!} + \dots$$

and for any values of ξ

$$\mathrm{erfc}(\xi) = 1 - \frac{2}{\sqrt{\pi}}\left(\xi - \frac{\xi^3}{3\cdot 1!} + \dots\right).$$

When ξ is so small that the higher terms in the above expansion can be neglected, equation (1) can be written in the following form:

$$i = nFAk_fC_0\left(1 - \frac{2s}{\sqrt{\pi}}t^{1/2}\right) \tag{4}$$

This equation predicts that plotting current against $t^{1/2}$ yields a straight line at sufficiently short times at potentials where the condition $st^{1/2} \ll 1$ is fulfilled. The current at $t = 0$ found by extrapolation of this straight line is directly proportional to k_f, while k_b can be calculated from the slope of this line, provided that the diffusion coefficients are known.

On the other hand, k_f and k_b are related to the standard rate constant k_s and potential E by

$$k_f = k_s \exp\left[-\frac{\alpha n_a F}{RT}(E - E^\circ)\right] \tag{5}$$

$$k_b = k_s \exp\left[\frac{\beta n_a F}{RT}(E - E^\circ)\right] \tag{6}$$

where α and β are the cathodic and anodic transfer coefficients and $\alpha + \beta = 1$, n_a is the number of electrons involved in the rate-determining step, and E° is the formal standard potential. Thus, it is anticipated that plotting $\log k_f$ and $\log k_b$ against E should yield two straight lines, and that it should be possible to find k_s and E° from the intersection of these straight lines. From the slopes of these lines, it should be possible to evaluate separately α, β and n_a.

EXPERIMENTAL

Reagents

All chemicals used were of the highest purity available commercially, and they were used without further purification. De-aeration was carried out by passing highly pure tank nitrogen. Solutions of zinc, copper^{II} and cadmium ions were prepared by dissolution of zinc nitrate, copper^{II} nitrate and cadmium sulphate, respectively. The concentrations were determined polarographically in suitable supporting electrolyte solutions.

Apparatus

Electrodes: A dropping mercury electrode with a drop time of about 10 sec was used as the working electrode, and current-time curves were recorded upon closing the circuit at a certain time (8 to 9 sec) after the beginning of the drop formation. The time when the circuit was closed was measured with a stop-watch, and the switch for closing the circuit was operated manually. Current-time curves were perfectly reproducible, indicating that the error resulting from the manual operation of the switch was quite negligible as compared to that associated with the oscilloscopic recording. Because current-time curves were needed only up to 10 msec after the circuit was closed, the variation of surface area of the mercury drop during the recording was also negligible.

A saturated calomel electrode served as the reference electrode, and it was connected with the dropping electrode through a Luggin capillary.

The counter electrode was a platinum foil, which was placed in the compartment separated by a sintered glass disk.

Potentiostat: The potentiostat used in the present study was an electronic potentiostat constructed by the authors according to the circuit designed and described by Shimodaira, Matsuo, Sugawara and Ebiko[4] of this University. The voltage source for 200 V d.c. described in their paper was found to be unsuitable for this type of work and it was replaced by batteries to minimise disturbances resulting from incomplete rectification. The rise time of the potentiostat was about 6 × 10^{-5} sec, which is one order of magnitude longer than that (2·5 × 10^{-6} sec) of the potentiostat constructed by Electronische Werkstätte of Germany. For the systems studied in this work, however, this was not critical. A micro relay switch was used in the early stages of this investigation. Because this switch generated transients in 0 8 msec, it was later replaced by a sealed-in mercury switch, which was found to give excellent results. The preset potential was read exactly with a potentiometer.

Current-time curves were recorded with a Synchroscope Model SS5151 combined with a high gain differential preamplifier Model SP02-DFH-A, both manufactured by Iwasaki Communication Apparatus Co. Ltd. The calibrated resistances used had a value of 10 to 50 Ω, and the sensitivity of the oscilloscope was always set at the maximum sensitivity of 1 mV. cm^{-1}

All experiments were carried out in a thermostat maintained at 25°.

RESULTS AND DISCUSSION

Experiments were carried out for reductions of zinc ion in 1*M* potassium nitrate, copper^{II} ion in 1*M* potassium nitrate and cadmium ion in 0·5*M* sodium sulphate. Examples of $i - t^{1/2}$ plots are reproduced in Fig. 1. Good straight lines were obtained in all cases at sufficiently short times. The upper limit of t before which a linear $i - t^{1/2}$ is obtained greatly depends on k_s of the system and also on potential. For example, in the vicinity of the standard potential and for the case of $D_0 = D_R(=D)$, we have $s \approx k_s D^{-1/2}$ [*cf.* equations (3), (5) and (6)]. If one prescribes the condition $st^{1/2} \leq 0{\cdot}2$ for a linear $i - t^{1/2}$ plot to be obtained, then one finds $t \leq 10^{-2}$ sec for a reaction with $k_s = 10^{-3}$ cm.sec^{-1} and $t \leq 10^{-3}$ sec for a reaction with $k_s = 10^{-2}$ cm.sec^{-1}. For faster reactions, current-time curves must be recorded at shorter times. At very short times ($<10^{-4}$ sec), however, correction for the capacity current becomes excessive and limits the maximum measurable value of k_s. The discussion given by

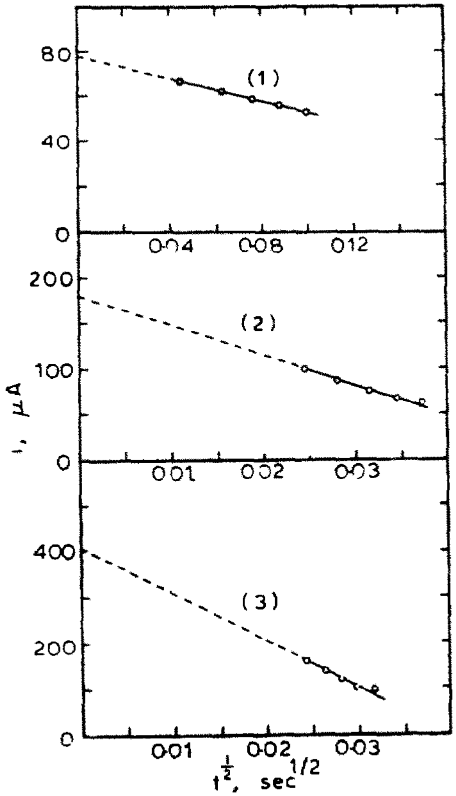

FIG. 1.—Plots of $i - t^{1/2}$: (1) 5 mM Zn^{2+} in 1*M* KNO_3 at −0·986 V; (2) 2 mM Cu^{2+} in 1*M* KNO_3 at +0·034 V; (3) 2 mM Cd^{2+} in 0·5*M* Na_2SO_4 at −0·581 V.

Delahay[5] on this point for the Gerischer-Vielstich method applies directly to the present case, and it can easily be shown that in both methods k_s much greater than 0·2 cm.sec^{-1} cannot be measured. In the experimental examples given in this paper, it was not necessary to measure current at times shorter than 6×10^{-4} sec and the capacity current was quite negligible.

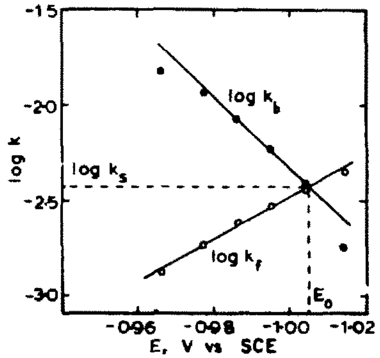

FIG. 2.—Plot of log k − E obtained with 5 mM Zn^{2+} in 1M KNO_3.

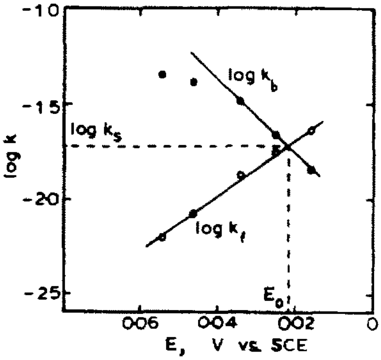

FIG. 3.—Plot of log k − E obtained with 2 mM Cu^{2+} in 1M KNO_3

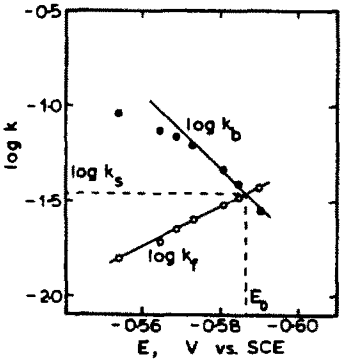

FIG. 4.—Plot of log k − E obtained with 2 mM Cd^{2+} in 0·5M Na_2SO_4.

As is obvious from the theory, a knowledge of diffusion coefficients of both the oxidised and reduced species is required in order to calculate k_b. The values of diffusion coefficients used in the calculation were as follows ($D \times 10^5$ cm^2.sec^{-1}): Zn^{2+} in 1M KNO_3, 0·666; Zn in mercury, 1·57[6]; Cu^{2+} in 1M KNO_3, 0·713[7]; Cu in mercury, 1·06[8]; Cd^{2+} in 0·5M Na_2SO_4, 0·720; Cd in mercury, 2·07[6]. The values for which no literature reference is given were calculated from the average polarographic diffusion current by using the original Ilkovic equation. It is generally recognised that diffusion coefficients calculated in this manner are often in considerable error. For example, the D value of zinc ion calculated by using a modified Ilkovic equation (the numerical constant in the second, correction term being taken equal to 34) was equal to $0·562 \times 10^{-5}$ cm^2.sec^{-1} instead of $0·666 \times 10^{-5}$ cm^2.sec^{-1} found by using the original Ilkovic equation. This difference, however, resulted in only a minor difference in kinetic parameters. For example, the values of k_s for the zinc system calculated with the above two D values were $3{\cdot}6 \times 10^{-3}$ and $3{\cdot}8 \times 10^{-3}$ cm sec^{-1}, respectively.

Plots of log k_f and log k_b against potential for the three systems studied are shown in Figs. 2, 3 and 4. The kinetic parameters found from these plots are summarised and compared in Table I with the values reported in the literature. In general, the agreement between the values found by the present method and the literature values was satisfactory, except that the k_s value for the copper system was somewhat lower than the value found by other methods.

TABLE I —KINETIC PARAMETERS AND FORMAL STANDARD POTENTIALS OF SOME METAL ION–AMALGAM SYSTEMS

System	Temp., °C	$E^{\circ\prime}$, V vs SCE	k_s, cm sec^{-1}	n_a	α	β	Method
Zn^{2+}/Zn(Hg) In 1M KNO_3	25	−1·005	$3{\cdot}8 \times 10^{-3}$	2	0·35	0·56	This study
	25		$3{\cdot}5 \times 10^{-3}$				A C. polarography[9]
Cu^{2+}/Cu(Hg) in 1M KNO_3	25	+0·022	$1{\cdot}9 \times 10^{-2}$	2	0·43	0·53	This study
	25		$4{\cdot}5 \times 10^{-2}$				A.C. polarography[9]
	20		$4{\cdot}5 \times 10^{-2}$				Faradaic impedance[10]
Cd^{2+}/Cd(Hg) in 0·5M Na_2SO_4	25	−0·587	$3{\cdot}6 \times 10^{-2}$	2	0·29	0·62	This study
	25				0·38		A.C. polarography[11]
	25		$2{\cdot}5 \times 10^{-2}$				A.C polarography[12]
	20		$2{\cdot}6 \times 10^{-2}$		0·25		Voltage-step[13]
	20		$4{\cdot}2 \times 10^{-2}$		0·17		Faradaic impedance[14]
	20		$4{\cdot}5 \times 10^{-2}$		0·22		Current-step[15]

In Figs. 2–4, it is noted that the points for log k_b obtained at less negative potentials tended to deviate in the same direction in all three cases. The reason for this deviation is not obvious. At any rate, it is clear from equation (3) that errors involved in the determination of k_b should be minimum at potentials near the standard potential where k_f and k_b are of the same order of magnitude. It should also be noted that as the potential is made more negative, the current-potential characteristics become steeper and this trend is more marked with faster reactions. At such potentials the precision and stability of potential control of the potentiostat become critical. Also, because current becomes larger at more negative potentials, the effect of iR drop between the working electrode and the tip of the Luggin capillary becomes more serious at more negative potentials. For these reasons, satisfactory k_b values could not be obtained at potentials much more negative than the standard potential. While the present method is simpler than the Gerischer-Vielstich method from the experimental viewpoint, it is the disadvantage of this method that the accuracy in the determination of k_b is less than that in the determination of k_f.

If it is desired that k_b be determined with the same degree of accuracy as k_f in a wider potential range and if the reduced species is sufficiently stable, k_b should be calculated from the anodic current at $t = 0$ measured with a system containing the reduced species alone, the oxidised species being generated *in situ* in this case. It also would be of interest to apply the principle of this method to totally irreversible reactions.

Zusammenfassung—Es wird gezeigt, daß kinetische Parameter einfacher schneller Elektrodenreaktionen vom Typ O + *ne* = R, wo R in der Lösung oder in der quecksilbernen Elektrode löslich ist, mit der potentiostatischen Methode bestimmt werden können. Die Lösung enthält dabei zuerst nur O, R wird *in situ* bei der Elektrolyse erzeugt, vorausgesetzt, daß die Elektrodenreaktion nur einen geschwindigkeitsbestimmenden Schritt enthält. Strom-Zeit-Kurven werden mit einem schnell ansprechenden elektronischen Potentiostaten und einem Oszillographen registriert, wobei das Potential sprunghaft vom Potential, bei dem kein Strom fließt, auf ein Potential im ansteigenden Teil der Stromspannungskurve geändert wird. Die Konstante der Hinreaktion k_f bei einem bestimmten Potential wird aus dem Strom zur Zeit Null berechnet, den man durch Extrapolation des linearen Anstiegs des Stromes gegen die Quadratwurzel der Zeit findet. Die Konstante der Rückreaktion k_b wird indirekt aus der Steigung derselben Geraden berechnet. Trägt man log k_f und log k_b gegen das Potential auf, so erhält man gleichzeitig die formale Standard-Geschwindigkeitskonstante k_s, kathodische und anodische Durchtrittsfaktoren, die am geschwindigkeitsbestimmenden Schritt beteiligte Anzahl von Elektronen und das formale Standardpotential des untersuchten Systems. Diese Methode ist beträchtlich einfacher als die bekannte Gerischer-Vielstich-Methode und sollte besondere Vorteile bieten, wenn R sehr reaktionsfähig ist oder ein nicht luftbeständiges Amalgam bildet. Das größte bestimmbare k_s ist hier gleich wie bei der Gerischer-Vielstich-Methode. Die nach der neuen Methode gefundenen kinetischen Parameter für die Reaktionen Zinkion-Zinkamalgam in 1m KNO_3, Kupfer(II)-Ion-Kupferamalgam in 1m KNO_3 und Cadmiumion-Cadmiumamalgam in 0,5m Na_2SO_4 stimmten mit den in der Literatur angegebenen Werten befriedigend überein.

Résumé—On montre que les paramètres cinétiques des réactions aux électrodes, simples, rapides et du type O + *ne* ⇌ R, où R est soluble dans la solution ou dans l'électrode, peuvent être déterminés par une méthode potentiostatique sur une solution qui ne contient initialement que O, la substance R étant fabriquée in situ pendant l'électrolyse. Cette méthode implique qu'une seule réaction détermine la vitesse de la réaction à l'électrode. Les courbes courant-temps sont enregistrées à l'aide d'un potentiostat électronique à réponse rapide et d'un oscilloscope, en appliquant un saut de potentiel allant du potentiel à courant nul jusqu'à divers potentiels de la partie ascendante de la courbe intensité-potentiel. La constante de vitesse directe k_f à un potentiel donné est calculée à partir du courant au [illegible], déterminé par extrapolation de la partie linéaire de la courbe courant-racine carrée du temps, tandis que la constante de vitesse inverse k_b est calculée indirectement à partir de la pente de la même droite. Si l'on trace log k_f et log k_b en fonction du potentiel, on peut déterminer en même temps la constante de vitesse globale k_s, les deux coefficients de transferts cathodique et anodique, le nombre d'électrons mis en jeu au cours de la réaction qui détermine la vitesse, et le potentiel normal du système. Cette méthode est beaucoup plus simple que la méthode bien connue de Gerischer-Vielstich, et devrait être particulièrement avantageuse dans le cas où R est très réactif ou forme un amalgame instable à l'air. La plus forte valeur de k_s que l'on puisse déterminer par cette méthode est la même que celle que l'on détermine par la méthode de Gerischer-Vielstich. Les paramètres cinétiques trouvés par cette méthode pour les réactions à l'électrode: ion zinc-amalgame de zinc dans du nitrate de potassium 1 M, ion cuivre(II)-amalgame de cuivre dans du nitrate de potassium 1 M et ion cadmium-amalgame de cadmium dans du sulfate de sodium 0,5 M sont en bon accord avec les valeurs indiquées dans la littérature.

THE BORON-CARBON-HYDROGEN SYSTEM

I. SHAPIRO
Universal Chemical Systems, Inc, Culver City, California, U.S.A

(*Received* 19 *June* 1963 *Accepted* 5 *October* 1963)

Summary—Identification of many newly-discovered compounds composed only of the three elements, B, C and H, has been accomplished by use of mass, infrared and nuclear magnetic resonance spectroscopy in conjunction with the isotopic substitution technique. These compounds can be classified into two general categories: (1) the organo derivatives of boron hydrides, and (2) the carboranes (and their organo derivatives) Examples of compounds identified by purely spectroscopic means are given.

THE state of the art of the B-C-H system as of 1942 has been summarised by Schlesinger and Burg.[1] Actually, in addition to the trialkyl boranes, only the alkyldiboranes were prepared and some of their physical properties given. Very little progress in this area was made until 1952, when the present author introduced the isotopic boron technique with spectroscopy as a routine analytical tool for identification of boron-containing compounds. Since that time the organo-substitution compounds of the higher boron hydrides, as well as new boron-carbon systems, have been prepared and identified. It is the purpose of this paper to discuss the various ramifications of these analyses with respect to the identification of the new organoboron compounds.

ANALYTICAL TECHNIQUES

Mass spectrometry

In boron chemistry the mass spectrometer is a particularly useful tool because of the readiness with which compounds of varying isotopic boron composition may be prepared. Isotopically-normal and ^{10}B-enriched organoboranes of the same chemical composition can be prepared by the reaction of unsaturated organic compounds or alkyl halides with corresponding isotopically-normal or ^{10}B-enriched boron hydrides. The exact number of boron atoms in the organoboranes can then be calculated from the shift in peak heights of their mass spectra. The number of carbon and hydrogen atoms can be obtained from the difference of the molecular weight (corresponding to the highest m/e value) and the accountable mass of the boron atoms. No shift in corresponding mass spectra distinguishes pure organic compounds from those containing boron. As an extension of this technique, deuterated compounds can be used to verify the number of hydrogen atoms attached to the carbon and/or boron atoms.

As a matter of historical importance, the discovery (1953) of the carborane series of compounds was a direct application of this isotopic boron technique coupled with mass spectroscopy. Fig. 1 shows the comparison of the mass spectra of products formed by the reaction of acetylene with ^{10}B-enriched and isotopically-normal diboranes. In this case, no fractionation of products was made; consequently, the mass spectra represent a composite spectra of all components in the mixture A high peak at m/e 78 in both spectra must belong to a pure organic compound, subsequent purification and analysis indicated that this pronounced peak at m/e 78 is produced by benzene. The general contour of the three distinct groups of peaks in the high mass range indicates polyboron-containing compounds. This "boron shape" is a function of the number of boron atoms and the isotopic composition[2] For example, the high peak at m/e 95 in the ^{10}B-spectrum shifts to m/e 100 in the normal spectrum, the shift of 5 units indicates a B_5-compound. Similarly, the shift from m/e 109 to m/e 114 also indicates a B_5-compound, and the shift from m/e 114 to m/e 122 signifies a B_8-compound. All of these compounds were later isolated and identified as belonging to the carborane series.

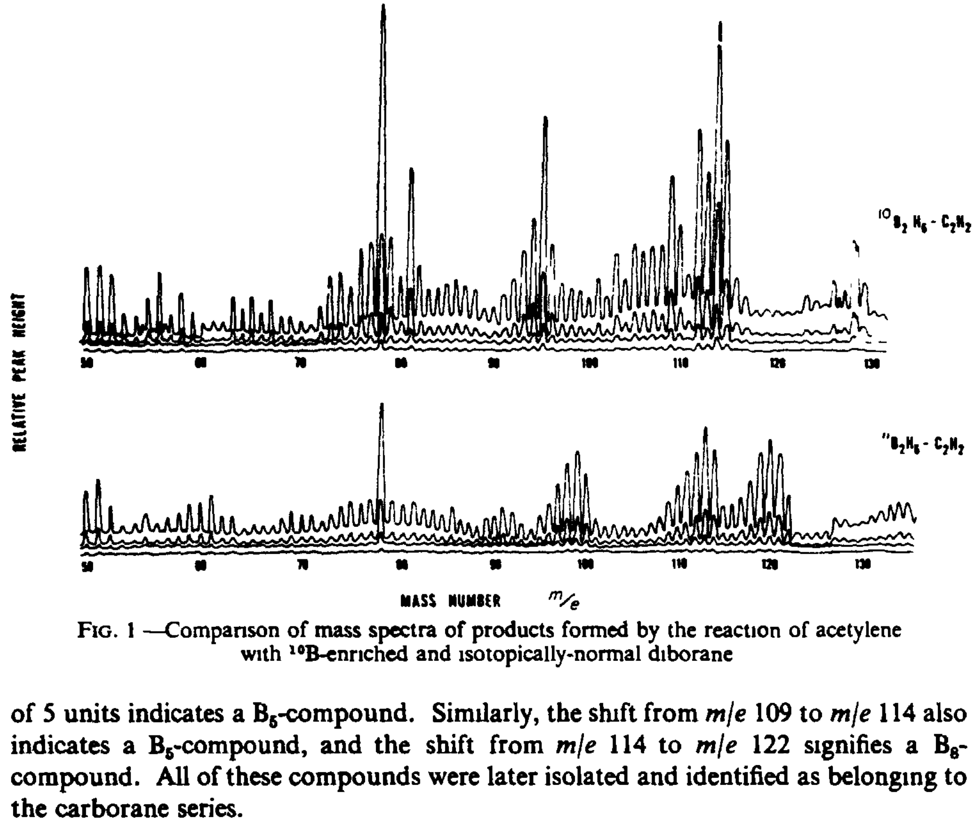

FIG. 1 —Comparison of mass spectra of products formed by the reaction of acetylene with ^{10}B-enriched and isotopically-normal diborane

Infrared spectroscopy

Infrared spectral analysis gives an insight into group arrangements of boron, carbon and hydrogen in the compounds. It is possible, for example, to distinguish between terminal borons (B_t-H) and bridge borons (B-H-B), such as those illustrated in Fig. 2, which shows the absorption peaks for the alkyl diboranes.[3] The bridge-boron absorption frequency is in the 1600 cm^{-1} range; and the terminal boron frequency in the 2500 cm^{-1} range. Further, it is possible to distinguish the number of hydrogen atoms attached to the terminal boron—a single peak indicates one hydrogen and a double peak indicates two hydrogens.

The shift in absorption frequency upon partial deuteration of the organoboron compound can be used to locate the position of the hydrogen (deuterium), *i.e.*, whether it is attached to the boron atom or to the carbon atom.

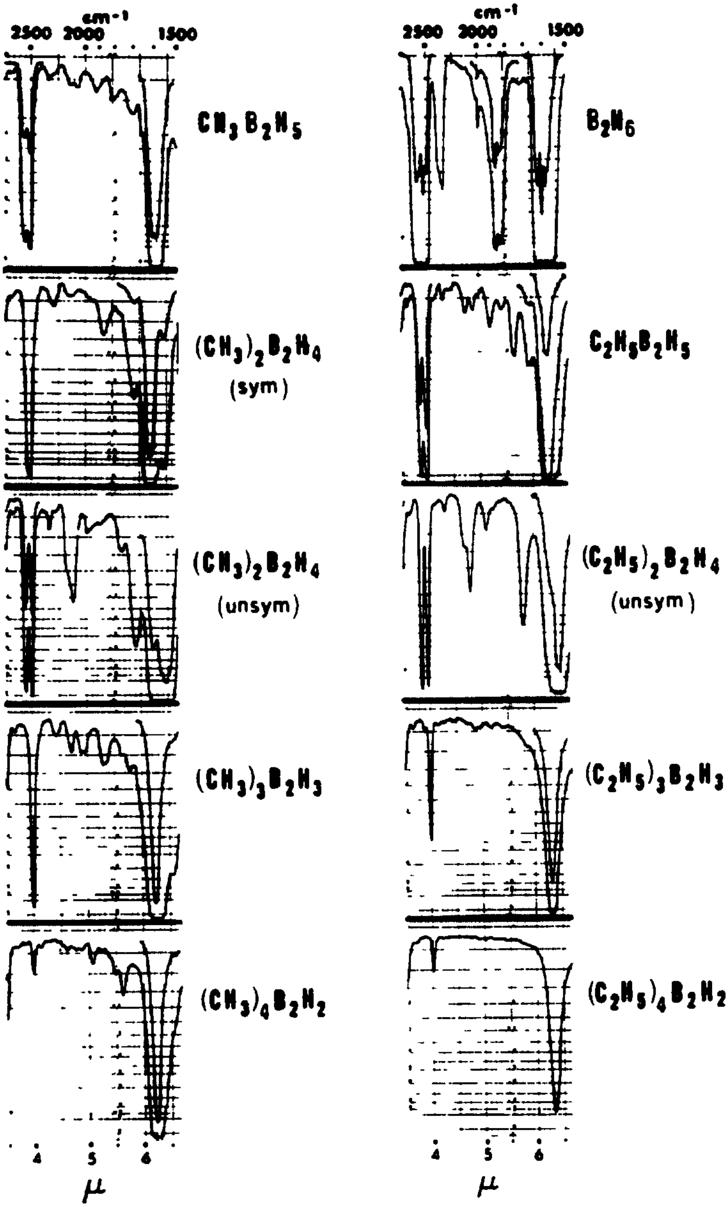

FIG 2.—Infrared region 1500–2850 cm^{-1} showing terminal hydrogen and bridge hydrogen absorptions in alkyldiboranes.

Nuclear magnetic resonance spectroscopy

For complete analysis of organoboron compounds, one should be able to derive the structure of the compound so that one can locate the actual position of, say, an alkyl group, substituted for a hydrogen atom. For example, for a monoalkyl pentaborane, one would like to know whether the alkyl group is located at an apex boron position or on a base boron position. Such information is not readily available from either mass or infrared spectral analyses. By n.m.r. spectroscopy, one can easily distinguish between such positions.

The ^{11}B n.m.r. spectrum yields information of the environment of the boron nucleus. The interaction of a single proton with boron results in a doublet, whereas a BH_2 unit will be represented by a triplet. On the other hand, a boron atom without hydrogen attached will be represented by a singlet. Bridge hydrogens are not observed. Replacement of deuterium for hydrogen collapses the doublet or triplet to a singlet. Because of chemical shift, borons in different positions also can be distinguished. The n.m.r. spectra of the various boron hydrides have been summarised, both by splitting and chemical shift.[4] Alkyl substitution on boron hydrides will manifest itself both by changes in number of peaks and/or relative position in the spectra. Examples of such changes will be given later.

In the proton n.m.r. spectrum, the interaction of the ^{11}B nuclear spin of 3/2 with a proton results in a quartet of (equal size) peaks. On the other hand, the C-H interaction is a single peak. Bridge hydrogens (B-H-B) are manifested by a broad unresolved peak. Because the proton spectrum is the sum of all component peaks, the proton spectrum may at first appear complicated; however, in most instances the spectrum can be reconciled with the structure of the compound, and thus serve as a verification of structure.

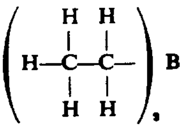
ORGANOBORON COMPOUNDS—COMPOSITION AND STRUCTURE

The organoboron compounds (containing only B, C and H) fall into two general categories (1) Derivatives of boron hydrides, and (2) carboranes. In the first category, the organic component (alkyl, aryl, *etc.*) usually is appended to a boron hydride, whereas the term "carborane" was coined to signify that the carbon atom had become an integral part of the boron skeleton. Organo derivatives of carboranes also have been synthesised. In this instance the organic component is appended either to a boron or carbon atom in the carborane. Thus, the number of possible organoboron compounds is large, and new compounds are constantly being discovered. It is apparent that simple elemental analysis no longer suffices in identifying these compounds.

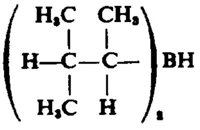
Derivatives of boron hydrides

1. *Monoborane:* The trialkylboranes (BR_3) are well known, and can be prepared by the Grignard reaction or by the addition of diborane to alkenes. If the alkene is a low molecular weight compound, *e.g.*, ethylene, the product will be triethylborane; or in the case of excess diborane, the various ethyl diboranes.

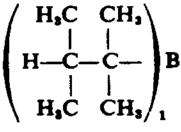
Interestingly, it is not possible to form BHR_2 or BH_2R in the simple compounds because of the great tendency of the boron to be tetrahedrally bonded, thus resulting in dimerisation. However, if the alkene is complex so as to present a large steric hindrance, the monoborane containing one or two hydrogens can be formed,[5] *viz.*,



$(H{-}CH_2{-}CH_2{-})_3B$



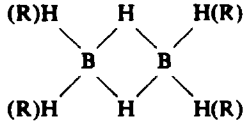
$(H{-}C(CH_3)_2{-}CH(CH_3){-})_2BH$



$(H{-}C(CH_3)_2{-}C(CH_3)_2{-})_1BH_2$

The alkenylboranes, alicyclic boranes and triarylboranes also are known.[6]

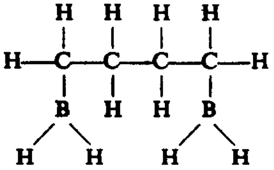
2. *Diborane:* The alkyl diboranes have the same basic boron structure as diborane, *viz.*, two boron atoms held together by two bridge hydrogens with substitution occurring at any of the four terminal hydrogens:

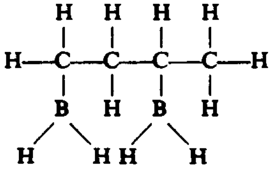


The five possible substituted simple alkyldiboranes had been prepared as early as 1935;[7] however, the purity of some of these compounds may be questionable because of the equilibrium which exists between the various alkyldiboranes. It was not until the advent of spectroscopy that the purity of these compounds could be monitored with any degree of accuracy.[8]

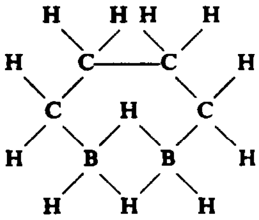
That the molecule contains two boron atoms can be recognised by mass spectral analysis of isotopic variants of the compounds.[9] Infrared analyses[3,8] reveal the presence of B-H-B bridge bonds. The R groups attached to the borons are restricted to low molecular weights; with large sterically hindered groups the molecule dissociates to BH_2R or BHR_2, as mentioned previously.

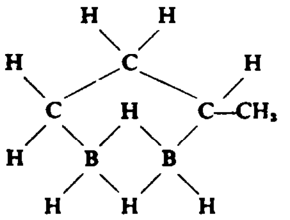
The addition of diborane to alkenes has been studied extensively by H. C. Brown and his school. In the case of the addition of diborane to 1,3-butadiene, Brown[10] reports two possible structures to yield polymeric products:





The reaction of diborane with 1,3-butadiene under different experimental conditions also was carried out in the present author's laboratory.[11] In addition to polymeric products, the product contained an appreciable amount of the 1:1 butadiene diborane addition product. Spectroscopic analyses (mass, infrared and n.m.r.) clearly show two cyclic compounds as follows:

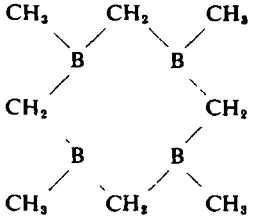




Apparently the presence of two BH_2 groups in the same compound results in tetrahedral boron bond formation. The equivalence of the four hydridic hydrogens (attached to boron) was shown by complete exchange of these hydrogens with deuterium of deuteriodiborane. Such exchanges occur freely in diborane. Interestingly, deuterium in B_2D_6 does not exchange with hydrogen attached to carbon, thus this exchange technique is useful in determining the number of hydrogens attached to boron.[11]

3. *Tetraborane:* To date, there is only one organotetraborane known. This compound formed by the reaction of ethylene with tetraborane has been identified as 2,4-dimethylenetetraborane.[12,13] That the ethylene molecule adds across the 2,4 boron sites is evident in the infrared spectrum by the change of the doublet (BH_2) to a singlet (BH) for the B-H terminal stretching absorption peak. The ^{11}B n.m.r spectrum confirms this conclusion in that the low field triplet (BH_2) of tetraborane changes to a doublet (B-H), whereas the high field doublet remains unchanged (boron sites 1,3) (see Fig. 3).

In the thermal decomposition of trimethylborane, Goubeau[14] reports the formation of a compound containing four boron atoms $[(BCH_2)_4(CH_3)_4]$; however, this compound is visualised as four boron atoms and four CH_2 groups connected alternatively in a ring with a methyl group attached to each boron atom, *viz.*,



Although this compound contains four boron atoms, this compound obviously does not qualify as a tetraborane, but rather as a monoborane.

4. *Pentaborane* Alkyl pentaboranes have been formed in our laboratory by a number of methods, *viz.*, reaction of pentaborane with ethylene or with alkyl halides and aluminum chloride, or by the Grignard reaction. Identification of the various alkylated pentaboranes was made by mass spectral analysis.

Extensive studies on the alkylated pentaboranes also have been carried out at the Explosives Research and Development Establishment in England.[15,16] The various alkylated pentaboranes were separated by gas chromatography and identified by n.m.r. spectroscopy. Up to five ethyl groups have been substituted on pentaborane. Because pentaborane consists of four equivalent boron atoms in a base and one atom in the apex of a tetragonal pyramid, the substitution of alkyl groups gives rise to isomers, and such isomers can be identified by n m.r. spectra. For monoethylpentaborane the ethyl group can be apex or base substituted and its location can be determined by whether the apex doublet or base doublet of pentaborane collapses to a singlet. Diethylpentaborane and tetraethylpentaborane also can have only two isomers, but triethylpentaborane has three possible isomers. All of the possible isomers of the ethylated pentaboranes have been observed [16]

5. *Decaborane* Alkyldecaboranes can be formed by analogous reactions of the alkylpentaboranes. The mass spectrum of monoethyldecaborane already has been given.[17] The various isomers of the alkyldecaboranes can be identified by the changes in the n.m.r. spectrum of decaborane.[18]

The following methyldecaboranes have been prepared and analysed:[19–21] 2-, 5- and 6-methyl-; 1,2-, 2,4-, 5,6- and 6,9-dimethyl-; 1,2,3- and 1,2,4-trimethyl-; 1,2,3,4- and 1,2,3,5-tetramethyldecaborane. For the ethyldecaboranes the following derivatives have been prepared [16,20,22] 1-, 2-, 5- and 6-ethyl-; 1,2- and 2,4-diethyl; at least three isomers of triethyl-, and at least three isomers of tetra-ethyldecaboranes. Benzyldecaborane also has been reported.[23]

6. *Other boron hydrides:* Although not yet reported, organoderivatives of other boron hydrides, such as hexaborane, octaborane, nonaborane, and higher boron hydrides, are anticipated.

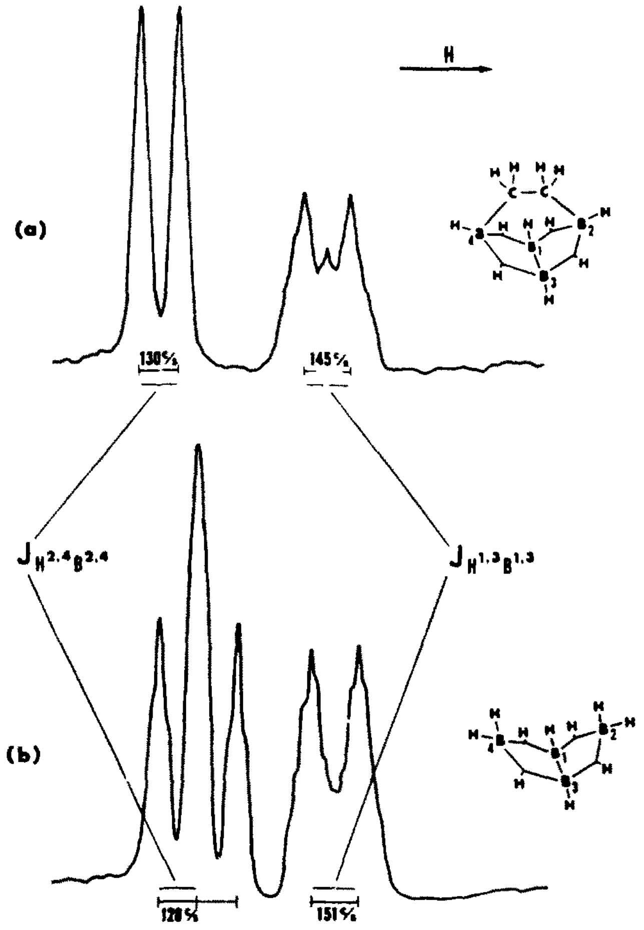


FIG. 3—Comparison of ^{11}B n m r spectra of tetraborane and 2,4-dimethylenetetraborane.

Carboranes

As mentioned previously under the section on *Mass spectrometry*, the study of the reactions of acetylene with various boron hydrides led to the discovery of a new class of organoboron compounds. From spectroscopic identification and characterisation of these compounds, it was shown that they differed from other known boron-carbon compounds. These new compounds have no bridge hydrogens and the carbon atoms are incorporated into the structure of the boron network; consequently, these compounds were named "carboranes". The generic formula for this series of compounds is $B_nC_2H_{n+2}$.[24] Although the entire series of carboranes can be formed by the low pressure flashing reaction of diborane and acetylene, better yields can be obtained by use of the higher boron hydrides as discussed below.

1. *Carborane*-3 ($B_3C_2H_5$): This compound was one of a series of carboranes prepared by the reaction of pentaborane and acetylene in the silent discharge apparatus.[24] Identification was made by comparison of the mass spectra of isotopic variants of the compound, *viz.*, $^{10}B_3C_2H_5$, $B_3C_2H_5$, $B_3C_2H_3D_2$, $B_3C_2D_3H_2$ and $B_3C_2D_5$. From infrared and n.m.r. spectra, the structure of the compound is regarded as a trigonal bipyramid with the three boron atoms in one plane and one carbon above and below the boron plane. The hydrogens attached to the boron and carbon atoms are the same as originally present in the parent compound. The deuterium in deuteriodiborane will exchange with the hydrogens attached to the boron atoms, but not with the hydrogens attached to the carbons. This selectivity of hydrogen-deuterium exchange is common to the boron hydrides and is the basis of a method for determining the location of hydrogen, *i.e.*, whether attached to boron or carbon atoms.

2. *Carborane*-4 ($B_4C_2H_6$): Two isomers of carborane-4 have been identified.[25] The symmetrical isomer is analogous to $B_3C_2H_5$, except that there are four borons in one plane; in the unsymmetrical form, one carbon and one boron atom have interchanged positions. Because of similarities in the vapour pressures of carborane-4 and pentaborane (parent compound), it is not possible to separate the two compounds by direct fractional distillation. However, such separation can be effected by first complexing the pentaborane with triethylamine to change the degree of volatility. The excess triethylamine can be complexed with diborane.

3. *Carborane*-5 ($B_5C_2H_7$): This compound has been identified by comparison of the mass spectra of the ^{10}B-enriched and isotopically-normal variants of the compound.[26] One characteristic feature of the carboranes is the low degree of skeletal breakdown observed in their fragmentation patterns.

4. *Carborane*-8 ($B_8C_2H_{10}$): This compound also has been identified by application of the isotopic boron technique and mass spectrometry.[26] In addition to use of pentaborane as a parent compound, carborane-8 is a product when acetylene is reacted with tetraborane or decaborane.

5. *Carborane*-10 ($B_{10}C_2H_{12}$): Carborane-10 can be prepared conveniently by the reaction of acetylene with decaborane.[26] The n.m.r. spectra of carborane-10 is consistent with the concept that the two carbon atoms replace the four bridge hydrogens of decaborane,[18] thus completing the icosahedron structure.[*] This compound is quite stable.

6. *Alkyl derivatives of carboranes:* In the preparation of the carboranes from acetylene, it has been observed that various alkylated derivatives of the different carboranes are also formed. The alkylated derivatives of the carboranes are also formed by reaction of boron hydrides with alkylated acetylenes, *e.g.*, methylacetylene. The derivatives observed in the mass spectra are as follows: $B_3C_3H_7$, $B_3C_4H_9$, $B_4C_3H_8$, $B_4C_4H_{10}$, $B_5C_3H_9$, $B_5C_4H_{11}$, $B_5C_5H_{13}$, $B_5C_6H_{15}$, $B_8C_3H_{12}$ and $B_8C_4H_{14}$. Numerous derivatives of $B_{10}C_2H_{12}$ also have been formed; these compounds will be the subject of a separate paper.

---

[*] The introduction of the two boron atoms of diborane into the decaborane structure results in the unstable $B_{12}H_{12}$ molecule;[27] however, the $B_{12}H_{12}^{-2}$ ion is reported to be stable with an icosahedral arrangement.[28]

Dihydrocarborane

When pentaborane and acetylene react at low pressures, carborane-4 is formed; however, when these same reactants are confined under pressure at elevated temperatures, the product is another organoboron compound whose composition is $B_4C_2H_8$.

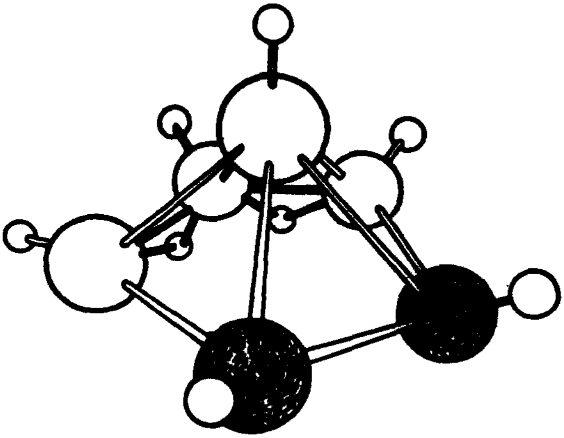

FIG. 4.—Structure of dihydrocarborane-4 ($B_4C_2H_8$).

Before being analysed by n.m.r. spectroscopy, this compound was believed to be "ethenyltetraborane";[29] however, subsequent studies in our laboratory indicate that the compound is structurally similar to hexaborane-10 in which the two carbon atoms have replaced two boron atoms and two bridge hydrogens in the base of the pentagonal pyramid (Fig. 4). Consequently, this compound is named "dihydrocarborane-4". Recently,[30] some alkyl derivatives of $B_4C_2H_8$ have been reported.* It is very probable that other dihydrocarboranes will be prepared in the future.

Now that pure organoboron compounds can be synthesised and identified, methods for elemental analysis of boron and carbon are being developed.[31,32]

Zusammenfassung—Die Identifizierung vieler neuentdeckter Verbindungen, die nur die Elemente B, C und H enthalten, gelang mittels Massen-, Infrarot- und Kernresonanzspektroskopie in Verbindung mit Isotopensubstitution. Die Verbindungen können in zwei Klassen aufgeteilt werden: 1) organische Derivate der Borhydride und 2) Carborane (und ihre organischen Derivate). Beispiele von Verbindungen, die mit ausschließlich spektroskopischen Mitteln identifiziert wurden, werden angegeben.

Résumé—L'identification de nombreux composés nouvellement découverts, constitués seulement par les trois éléments B, C et H, a été réalisée par l'emploi des spectroscopies de masse, infrarouge, et de résonance magnétique nucléaire, en liaison avec la technique de substitution isotopique. Ces composés peuvent être classés en deux catégories générales: (1) les organo-dérivés des borohydrures et (2) les "carboranes" (et leurs dérivés organiques). On donne des exemples de composés identifiés par des méthodes purement spectroscopiques.

---

* Attention is called to the fact that the structure of $B_4C_2H_8$ cited recently[30] was taken from the work of I. Shapiro and H G. Weiss without permission or acknowledgment of the senior investigator.

POLAROGRAPHIC REDUCTION OF MANGANESE^{III} IN AN ALKALINE TARTRATE SOLUTION

NOBUYUKI TANAKA, YASUKO KIKUCHI and YUICHI SATO
Department of Chemistry, Faculty of Science, Tohoku University, Sendai, Japan

(*Received* 19 *June* 1963. *Accepted* 8 *October* 1963)

Summary—The formation of manganese^{III} complexes by the air oxidation of manganese^{II} in alkaline tartrate solution is confirmed by measurement of the direct current and the Kalousek polarograms. A distinct minimum is observed on the polarogram in the pH range from 10 to 13. The effects of pH, the concentration of sodium tartrate and surface-active substances on the polarogram are investigated, and the electrode processes of manganese^{III} in an alkaline tartrate solution are discussed

THE polarographic reduction of manganese^{II} has been extensively studied, but that of manganese^{III} has not received full investigation. Kolthoff and Watters[1] studied the reduction of the pyrophosphate complex of manganese^{III}, which was prepared by the preliminary oxidation of manganese^{II} in a pyrophosphate solution with excess lead dioxide. Novák, Kůta and Říha[2] studied the polarographic behaviour of manganese^{III} in a solution containing sodium chloride, sodium hydroxide and triethanolamine. Svátek, Roubal and Přibil[3] found a reversible wave for the manganese^{III} complex with pyrocatechol-3,5-disulphonate in an ammoniacal buffer and in sodium hydroxide solution. Verdier[4] reported the polarographic reduction of hexacyanomanganate$^{(III)}$, which was prepared by air oxidation of manganese^{II} in potassium cyanide solution. He[4] found, however, that in 2*M* potassium hydroxide solution containing sodium tartrate, manganese^{II} was oxidised to manganese^{IV} by atmospheric oxygen.

The present paper is concerned with a polarographic study of the manganese^{III} complex produced by the air oxidation of manganese^{II} in an alkaline tartrate solution. The oxidation state of the complex is discussed on the basis of the direct current and the Kalousek polarograms obtained. The minimum on the current-voltage curve is explained from the standpoint of the charges of the complex and the electrode. The deceleration and the acceleration of the electron-transfer process by the addition of surface-active ions are demonstrated.

EXPERIMENTAL

The manganese^{III} was prepared by air oxidation of manganese^{II} in an alkaline tartrate solution. The formation of manganese^{III} was confirmed by the polarographic method described later A 0 1*M* manganese^{II} solution was prepared by dissolving a known amount of manganese^{II} chloride tetrahydrate.

Direct current (d c.) polarograms were recorded by a Yanagimoto PB-4 pen-recording polarograph and a Yanagimoto Galvarecorder GR-103 with an automatic potential scanner. A Yanagimoto Galvarecorder Y-GR 2 with an automatic potential scanner was used to record alternating current (a.c.) polarograms. Kalousek polarograms[5] were obtained with the same circuit as previously described.[6,7] Current-time (i-t) curves were recorded using a Rikadenki ER-J 1 recorder with an RLDC-201 preamplifier. An electrolysis cell of a simple beaker type was used in all measurements. The dropping mercury electrode (DME) used had an m value of 2·16 mg/sec and a drop time t_d of 4 59 sec, being measured in 0 1*M* potassium chloride solution containing 0 005% of gelatin at 25°

and −0·5 V *vs* SCE at a 40 cm height of the mercury reservoir The potential of the DME was measured against a saturated calomel electrode (SCE), which was connected to the electrolytic solution through a Hume and Harris type salt bridge When a.c polarograms were measured, a platinum wire electrode of a large surface area was inserted in the electrolytic solution as the third electrode, which was terminated at the SCE through a 100-μF capacitor A Hitachi Model EHP-1 pH meter was used for measurement of the pH of the solution

All measurements were carried out in a thermostat of 25° ± 0·1°, and the dissolved oxygen in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution Precautions were taken against oxygen and light for manganese^{II} and manganese^{III}* solutions, respectively The d c and Kalousek polarograms given in this paper are corrected for the residual current.

RESULTS AND DISCUSSION

Manganese species in an alkaline tartrate solution

Polarograms of 1·2 mM of manganese obtained before and after the air oxidation in the solutions of pH 11·8 containing Britton-Robinson buffer, 0·25*M* sodium tartrate and 0·005% of gelatin are reproduced in Fig. 1. The polarogram of manganese^{II} (curve 1) is the same as that reported by Er-Kong and Vlček.[8] They consider that manganese^{II} exists in various forms of mono- and binuclear hydroxotartratomanganate$^{(II)}$, of which only the mononuclear complexes are reducible at the dropping mercury electrode. The polarogram obtained after the air oxidation (curve 2) shows a remarkable minimum, and does not coincide with the polarogram obtained by Verdier[4] in 2*M* potassium hydroxide solution containing sodium tartrate. The limiting currents of curve 2 measured at −1·55 V and −1·90 V were both proportional

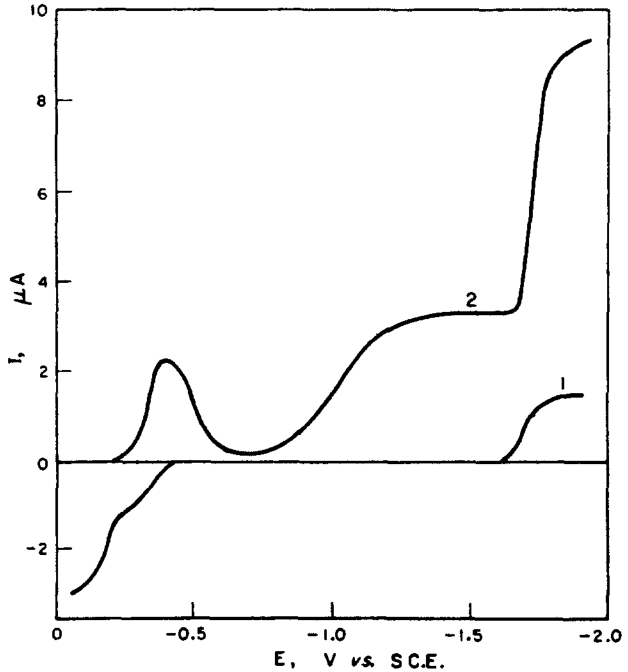

FIG 1 —Polarograms of 1·2 mM of manganese in the solutions of pH 11·8 containing Britton-Robinson buffer, 0·25*M* sodium tartrate and 0·005% of gelatin, obtained before (curve 1) and after (curve 2) the air oxidation.

---

* Photochemical reduction of manganese^{III} in an alkaline tartrate solution is reported elsewhere.

to the concentration of manganese^{II} added, and the ratio of the latter to the former was found to be 2·96 after correction for the drop time. This means that the limiting current at −1·55 V is from the one-electron reduction of manganese^{III} to manganese^{II} because the second wave starting approximately at −1·6 V is a reduction wave of manganese^{II} to manganese^{0}.

The formation of manganese^{III} was also confirmed by the Kalousek polarograms recorded before and after the air oxidation. Curves 1 and 2 in Fig. 2 are the Kalousek polarograms which were recorded with an alkaline tartrate solution of manganese^{II} at —0·10 V and —0·30 V of E_2 potential.[6,7] The cathodic part of the polarograms is essentially the same as the polarogram obtained after the air oxidation. The Kalousek polarograms recorded after the air oxidation (curves 3 and 4 in Fig. 2) give anodic waves, which are similar to those observed with the alkaline tartrate solution of manganese^{II}. These observations suggest that the product obtained by the air oxidation is the same as that obtained by electro-oxidation. In addition, the Kalousek polarograms of the alkaline tartrate solution of manganese^{III} recorded at —0·42 V and —1·55 V of E_2 potential show that the reduction products are the same at both potentials and that the potential of the anodic wave agrees with that of the mononuclear manganese^{II} tartrate complexes.[8] This suggests that the manganese^{III}-tartrate complex obtained by the air oxidation is of a mononuclear type.

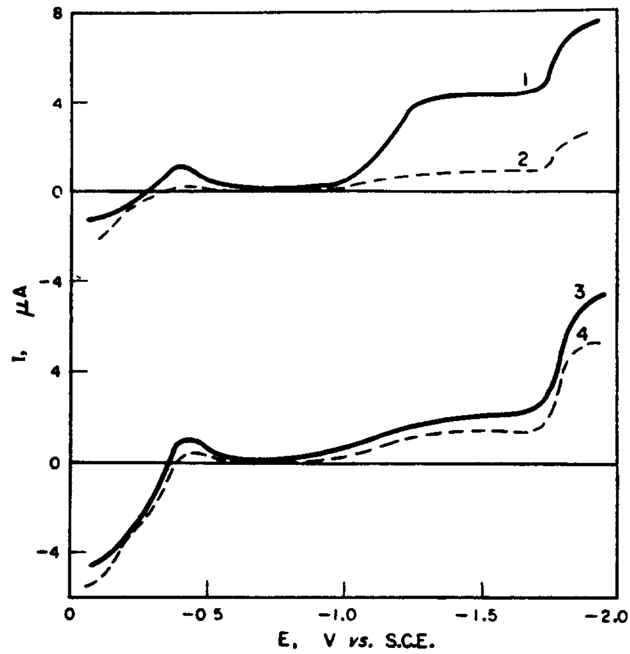

Fig. 2.—Kalousek polarograms of 1·2 mM of manganese^{II} (curves 1 and 2) and manganese^{III} (curves 3 and 4) in the solutions of pH 11·8 containing Britton-Robinson buffer, 0·25*M* sodium tartrate and gelatin (0 005% for 1 and 2 and 0·001% for 3 and 4). E_2 potentials are:

(1) —0 10 V; (2) —0·30 V; (3) —0 42 V; (4) —1·55 V *vs.* SCE.

Effect of pH, tartrate concentration and potassium nitrate

A synoptical denotation of the wave is given in Fig. 3. The first round-shape wave is called the i_1' wave and the second drawn-out one the i_1 wave, because both are considered as being caused by the reduction of manganese^{III} to manganese^{II}. The average currents of both waves are represented with $\bar{i}_1'$ and $\bar{i}_1$, respectively.

The effect of pH on the polarogram of manganese^{III} in a tartrate solution is shown in Fig. 4. Because manganese^{II} was not readily oxidised by air at a pH less than 11, the pH of the solution was adjusted with perchloric acid after manganese^{II} is oxidised to manganese^{III} at pH 11·8. With decreasing pH, the minimum becomes less pronounced, the i_1' wave shifts to less negative potentials and $(\bar{i}_1')_l$ increases to reach the limiting value that is the same as $(\bar{i}_1)_l$, where $(\bar{i}_1')_l$ and $(\bar{i}_1)_l$ represent the limiting currents of the corresponding waves. At pH 9·1 a polarogram with no minimum is obtained (see curve 1), while in 0·1M sodium hydroxide the i_1' wave almost vanishes

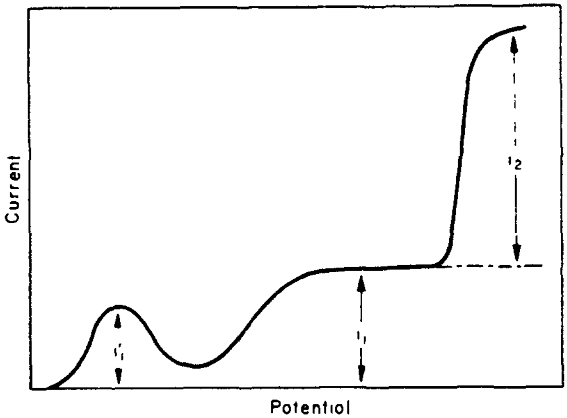

FIG. 3.—Synoptical denotation of the manganese^{III} wave in alkaline tartrate solution.

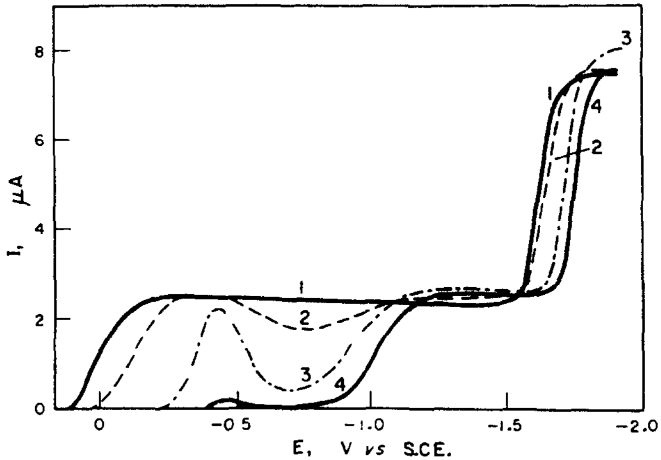

FIG. 4.—Polarograms of 1·0 mM of manganese^{III} at various pH in the solutions containing 0·25M sodium tartrate, 0·001% of gelatin and Britton-Robinson buffer (curves 1, 2 and 3) or 0·1M sodium hydroxide (curve 4)

(1) pH 9·1; (2) pH 10·5; (3) pH 11·8.

(curve 4). The decreasing pH also shifts the i_2 wave to less negative potentials. The shifts of the i_1' and the i_2 waves to more negative potentials with increasing pH indicate that hydrogen ions are taken up when the manganese^{III} and the manganese^{II} complexes are reduced to the corresponding lower oxidation states.

The effect of tartrate ion on the reduction wave was investigated by recording the polarograms in the presence of varied concentrations of sodium tartrate. With increasing concentrations of tartrate, the i_1' wave started at more negative potentials and the $\bar{i}_1'$ current decreased; the $\bar{i}_l/10$-potentials, which mean the potentials at $\bar{i} = \bar{i}_l/10$, were found to be $-0{\cdot}24$ V at $0{\cdot}10M$ and $-0{\cdot}35$ V at $0{\cdot}70M$ of tartrate, respectively. This suggests that tartrate ions are liberated when the manganese^{III} complex is reduced to the bivalent state. As for the i_1 wave, the potentials were not appreciably affected with the increase of tartrate concentration, but the limiting current was depressed to a great extent. The value of $(\bar{i}_1)_l/C$ measured at $-1{\cdot}55$ V *vs.* SCE varied from $2{\cdot}7_7$ μA/mM to $2{\cdot}2_5$ μA/mM, when the tartrate concentration was changed from $0{\cdot}25M$ to $0{\cdot}63M$. This decrease may be attributed to the increasing number of tartrate ions co-ordinating.

In Fig. 5 are given the polarograms which were obtained at various concentrations of tartrate but at a constant ionic strength, being adjusted with potassium nitrate The same decrease in the limiting current of the i_1 wave with increasing tartrate concentrations was observed. These polarograms in Fig. 5 present, however, not only the affect of tartrate but also the affect of potassium nitrate on the reduction wave. A separate experiment indicated that upon the addition of potassium nitrate, the i_1' wave was suppressed and the i_1 wave was shifted to less negative potentials The former seems to be from the presence of nitrate ions and the latter from potassium ions.

Effect of surface-active substances

By the addition of gelatin both the i_1' and the i_1 wave are depressed (Fig. 6). This agrees with the fact that gelatin adsorbs on the mercury surface in the wide range of potentials. On the other hand, the addition of thiocyanate ions, which adsorb mainly at the positive branch of the electrocapillary curve, depressed only the i_1' wave (Fig. 7). A most interesting effect of a surface-active substance was found when trimethyloctadecylammonium chloride, $(CH_3)_3(C_{18}H_{37})N^+Cl^-$, (denoted as TMOAC) was added to the solution. Fig. 8 presents the polarograms obtained at various concentrations of TMOAC. The addition of a small concentration of TMOAC depresses both the i_1' and the i_1 wave. At higher concentrations of TMOAC, however, the electron transfer at the i_1' wave is further decelerated but that at the i_1 wave is considerably accelerated. The dual (deceleration and acceleration) effect of surface active substance has been reported by Frumkin and coworkers,[9] who found that tetrapentylammonium ion, at its lower concentration, accelerates the reduction of tetrachloroplatinate$^{(II)}$ but, at its higher concentration, decelerates the reduction The dual effect of TMOAC on the reduction of manganese^{III} in an alkaline tartrate solution is seen also from the current-time curves during the life of a mercury drop measured at $-0{\cdot}82$ V *vs.* SCE (Fig. 9).

Electrode process of manganese^{III} in an alkaline tartrate solution

As mentioned above, the results obtained with the Kalousek polarograms suggest that the manganese^{III} species produced by the air oxidation in an alkaline tartrate

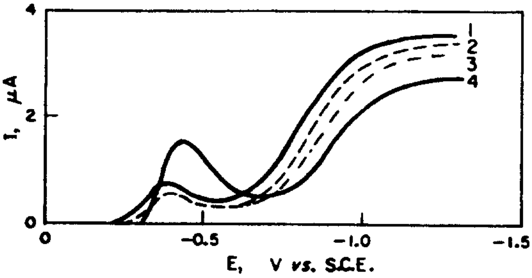

FIG. 5.—Polarograms of 1·2 mM of manganese^{III} in the solutions of pH 11·8 and ionic strength 2·0 (adjusted with potassium nitrate) containing Britton-Robinson Buffer, various concentrations of sodium tartrate and 0·001% of gelatin. Concentrations of sodium tartrate: (1) 0 125*M*; (2) 0·250*M*; (3) 0 375*M*; (4) 0 625*M*.

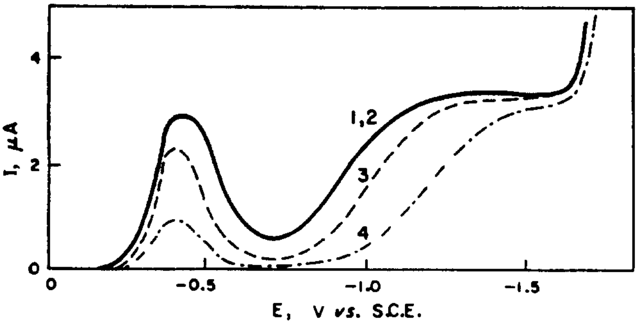

FIG. 6.—Effect of gelatin on the polarograms of 1·2 mM of manganese^{III} in the solutions of pH 11·8 containing Britton-Robinson buffer, 0 25*M* sodium tartrate. Concentrations of gelatin: (1) 0; (2) 0·001%; (3) 0 005%; (4) 0 01%.

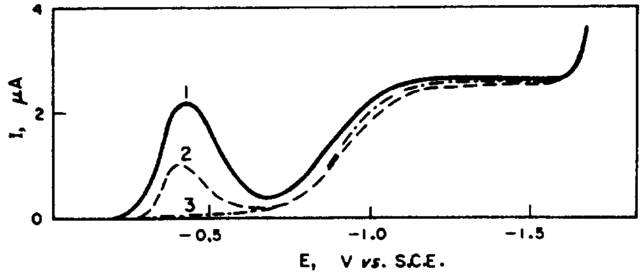

FIG. 7.—Effect of thiocyanate ions on the polarograms of 1·0 mM of manganese^{III} in the solutions of pH 11·8 containing Britton-Robinson buffer, 0·25*M* sodium tartrate and 0·001% of gelatin. Concentrations of thiocyanate: (1) 0; (2) 0·010*M*; (3) 0·030*M*.

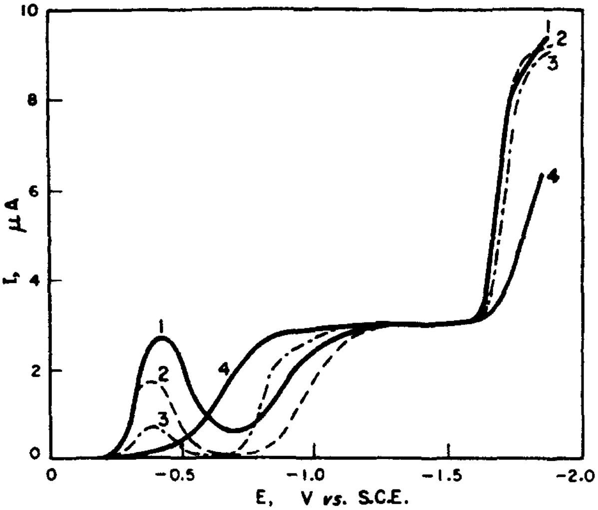

FIG. 8.—Polarograms of 1·2 mM of manganese^{III} in the solution of pH 11·8 containing Britton-Robinson buffer, 0 25*M* sodium tartrate in the absence (curve 1) and in the presence of 0 13 mM (2), 0 25 mM (3) and 1·2 mM (4) of trimethyloctadecylammonium chloride.

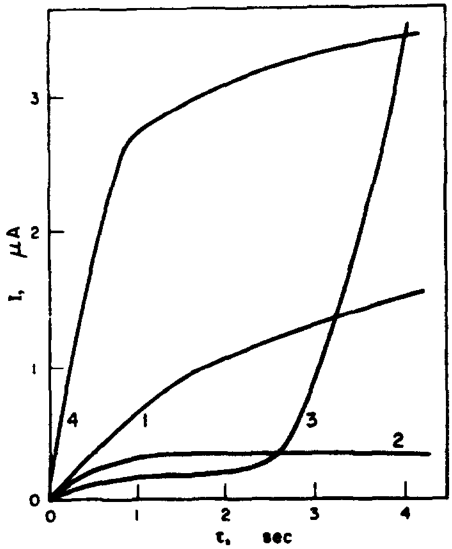

FIG. 9.—Current-time curves at −0·82 V vs. SCE obtained with the same solutions as given in Fig. 8.

solution is hydroxotartratomanganate(III) complex, $Mn(OH)_p(tar)_q^{\gamma-}$ (tar = tartrate), which is considered to be negatively charged in an alkaline solution.

The plot of log $\bar{i}/(\bar{i}_d - \bar{i})$ against E for the i_1' wave gives a straight line with a slope of approximately 80 mV, which is somewhat greater than expected for the reversible one-electron reduction. The i_1 wave, on the other hand, is drawn-out and of an irreversible type. The measurement of a.c. polarograms confirmed the degree of irreversibility of both i_1' and i_1 waves. The value of $i_p/n\bar{i}_d\sqrt{t_d}$[10] of the i_1' wave, where i_p means a peak current of a.c. polarogram, $\bar{i}_d$ the diffusion current of d c. polarogram, n the number of electrons involved in the electrode process and t_d the drop time, was calculated to be 25·4 $\mho A^{-1}$ $sec^{-1/2}$, which is about half of that for the reduction of zinc^{II} in 1*M* potassium nitrate solution, but approximately 4 times greater than that for the reduction of nickel^{II} in 0·1*M* potassium chloride solution. The i_1 wave, on the other hand, shows no peak on the a.c. polarograms.

The hydroxotartratomanganate(III) complex is reduced to the corresponding manganese^{II} complex. Because the complex is negatively charged, it can readily approach to the positively charged electrode surface and, consequently, the electrode process takes place with lower activation energy. The rate of electron transfer is of the magnitude of the quasi-reversible type, being estimated from the value of $i_p/n\bar{i}_d\sqrt{t_d}$ and the shape of the Kalousek polarogram. This electrode process is, however, easily hindered by the addition of a small amount of surface active substance that is specifically adsorbed in the positive branch of electrocapillary curve, such as thiocyanate ions, because the complex is not specially surface active, as was confirmed by the measurement of the electrocapillary curve.

This electrode process is decelerated by the decrease in positive charge and the increase in negative charge of the electrode. This causes a minimum on the current-potential curve as has been reported in the case of the reduction of many anions.[11] The minimum is not observed at lower pH, because of the decrease in negative charge of the manganese^{III} complex species.

In the negative branch of the electrocapillary curve, the electroreduction of the complex with higher activation energy takes place. This seems partly because of the electrostatic repulsion between the complex and the negatively charged electrode. The addition of cations that adsorb on the electrode surface neutralises the negative charge of the electrode or those cations act as bridging ions so that the activation energy is lessened and the electron transfer is accelerated.

Zusammenfassung—Die Bildung von Mangan(III)-Komplexen durch Luftoxydation von Mangan(II) in alkalischer Tartratlösung wurde durch Messung der Gleichstrom- und der Kalousek-Polarogramme bestätigt Ein deutliches Minimum erschien im pH-Bereich von 10 bis 13 auf dem Polarogramm Der Einfluß des pH, der Konzentration von Natriumtartrat und von oberflächenaktiven Stoffen auf das Polarogramm wurden untersucht und die Elektrodenprozesse von Mangan(III) in alkalischer Tartratlösung diskutiert

Résumé—La formation de complexes du manganèse(III) par oxydation à l'air du manganèse(II) en solution tartrique alcaline a été confirmee par la mesure du courant continu et les polarogrammes de Kalousek On a observé un minimum net sur le polarogramme, dans l'intervalle de pH 10–13 On a étudié les effets, sur le polarogramme, du pH, de la concentration du tartrate de sodium, et des substances tensioactives, on discute des processus à l'électrode du manganèse(III) en solution tartrique alcaline.

A MODIFICATION OF THE EXPONENTIAL EXCHANGE LAW IN HETEROGENEOUS SYSTEMS

B. VAN'T RIET and L. J. PARCELL*
Cobb Chemical Laboratory, University of Virginia, Charlottesville, Virginia, U.S.A.

(*Received* 19 *June* 1963. *Accepted* 27 *September* 1963)

Summary—The exponential exchange law for heterogeneous systems can be applied to isotope exchange between solid salts and their saturated solutions after allowance is made for the initial rapid exchange between the solution and the crystal surface. For a variety of salts it is possible to get information on the dynamic equilibrium between the surface and the interior of the crystals. Experimental results are presented for the chromates of silver, barium and lead. Silver chromate exchanges rapidly with silver ion, without showing significant exchange with chromate ion. Recrystallisation effects are evident in the chromates of barium and lead.

INTRODUCTION

THE exchange between fresh precipitates and saturated solutions has been the subject of study by Kolthoff and his associates since 1933.[1] The incorporation of radioisotope in the solid was attributed to recrystallisation of the solid, thus exposing continuously new surface. Most of this work preceded the formulation of the "exponential exchange law" by McKay in 1938.[2]

This law, as applied to heterogeneous systems, states that

$$Rt = -\frac{A \cdot B}{A + B} \ln (1 - F) \tag{1}$$

where R = moles of tagged material crossing the interface per time unit,
t = time,
A = moles of solid,
B = moles of tagged solute in solution,
F = fraction of exchange, which can be expressed in count rates of aliquots of the solution.

If the solution contains all the radioactivity initially,

$$F = \frac{S_0 - S_t}{S_0 - S_\infty}$$

in which S_0 = cpm at $t = 0$; S_t = cpm at $t = t$, and S_∞ = cpm at isotopic equilibrium throughout the system.

Experimental results show clearly that the exponential exchange law is not valid in exchange between an initially inactive solid and its saturated radioactive solution.

---

* From Ph.D. dissertation, submitted by L. J. Parcell to the Graduate School of Arts, and Sciences, University of Virginia, June, 1963.

An example of the results of such an experiment is shown in Fig. 1, curve I A rapid initial increase, followed by a slower, but linear increase of $-\log(1-F)$ with time is shown.

Because the initial rapid exchange is caused by exchange with the surface, there is a simple method of separating the fast and slow exchanges mathematically. We studied the slow exchange process by application of a modification of the exponential exchange law. Apparent deviations from this law, as caused by the initial rapid surface exchange, are eliminated by this modification.

DISCUSSION

One essential requirement for conformity with the exponential exchange law of heterogeneous systems is a relatively rapid isotopic equilibrium in each phase compared to the rate-determining step in exchange at the interface. Generally the surface of crystals is considered to be part of the solid phase. However, in isotopic exchange it is necessary to treat the crystal surface and the solution as one single phase, and the interior of the crystals as the second phase. This approach is made because the rate-determining step in the slow exchange process is either between the surface and the interior of the crystals, or in the interior of the crystals, but certainly not between solution and surface.

The initial condition for the slow exchange process is ideally a solution in isotopic equilibrium with the surface, without any activity being present in the interior of the crystals. An approximation to this condition is obtained by extrapolation of the linear part of curve I in Fig. 1 to $t = 0$; the F value obtained by this extrapolation pertains to surface exchange only.

The slow exchange process starts with an initial activity in solution reduced by surface exchange from S_0 to $S_0{}^*$. The value of $S_0{}^*$ is obtained from $S_0{}^* = \dfrac{B}{M_s + B}$, in which B is the number of moles of tagged species in solution, and M_s is the number of moles of the same chemical species in the surface of the crystals. This modification of S_0 to $S_0{}^*$ is not dependent upon the mechanism of the secondary slow exchange process. The newly defined $S_0{}^*$ can be used to check the validity of the exponential exchange law for the slow secondary exchange. It is determined from the F value obtained by extrapolation of $-\log(1-F)$ to $t = 0$.

The exponential exchange law needs modification when it is applied to the slow exchange process after isotopic equilibrium is established between the solution and the surface. It takes the form

$$Rt = -\frac{(A - M_s)(B + M_s)}{A + B} \ln(1 - F^*) \qquad (2)$$

where A, B, R and t are as in equation (1), M_s = number of moles in the surface, and

$$F^* = \frac{S_0{}^* - S_t}{S_0{}^* - S_\infty}.$$

A plot of $-\log(1 - F^*)$ versus time is given in Fig. 1, curve II. For this example of exchange between solid silver chromate and its saturated solution containing tagged silver nitrate, a linear relationship is obtained. A small positive deviation from the origin on the time abscissa would be expected, because the slow exchange process cannot become significant until some exchange has occurred between the solution and the surface. However, the linear relationship is an indication of a rate-determining step in exchange between the surface and the interior of the crystals.

More indication of the validity of this form of the exchange law is obtained by changing variables which should not affect the chemical composition at the interfaces. The weights of identical crystals taken for an experiment can be varied. R should be directly proportional to the interfacial area, or to the weight of solid used. It is convenient to define K by $R = K \, . \, A$, because K is independent of the weight of solid used, and K is expressed in reciprocal time units. Because M_s is generally small compared with A, the following expression is obtained:

$$\mathrm{d}\frac{[-\ln(1 - F^*)]}{\mathrm{d}t} = K\frac{A + B}{B + M_s}. \tag{3}$$

The two criteria, a linear relationship between log $(1 - F^*)$ and time, and a value of K independent of the amount of solid used, can be applied to a variety of systems. Results of our studies show that the exchange between silver ion in solution and solid silver chromate conforms to equations (2) and (3) in all cases.

Deviations from this exchange law are evident in exchange between either solid lead chromate or barium chromate, and tagged chromate in their saturated solutions, because a linear relationship is not obtained The deviations do not necessarily show that there is no rate-determining step in exchange somewhere between the surface and the interior of the crystals. The requirements for conforming with equations (2) and (3) include:

(*a*) a relatively rapid equilibrium of isotopes in each of the two parts in which the system is separated;

(*b*) a constant interfacial area during the experiment. Recrystallisation generally decreases this area, and solutions should be used in which recrystallisation is kept to a minimum. Shaking may rupture crystals, causing increase of the surface area.

(*c*) no unidirectional recrystallisation. Some freshly prepared crystals (*e.g.*, lead chromate) may change to a more stable crystal lattice, or they may undergo a chemical change. A temporary heterogeneous isotopic distribution may result from such transitions.

Generally the number of moles of tagged species in solution is much smaller than the number of moles of solid, because the most accurate determinations of M_s are obtained when $B \cong M_s$. The value of S_∞ is much smaller than that of either S_0 or $S_0{}^*$ in our determinations. If S_∞ is ignored in calculation of F and of F^*, the following approximate values are obtained:

$$-\ln(1 - F) \cong -\ln\frac{S_t}{S_0} \quad \text{and} \quad -\ln(1 - F^*) \cong -\ln\frac{S_t}{S_0{}^*}.$$

The variable with time is S_t in both cases, and identical slopes are obtained for the linear part of curve I and curve II in Fig. 1. The modification of the exchange law causes a change in the relationship between the slope and K, without changing the slope significantly.

In any experiment with systems conforming to the modified exchange law, a value of the rate constant K can be found, giving the number of moles of tagged species crossing the interface per time unit per mole of solid present. More information on the actual mechanism can be obtained by determination of K at various temperatures, at different compositions of the saturated solution, and for changes of size and shape of crystals. The effect of some of these variables on the exchange between silver ion and silver chromate is shown under *Experimental.*

EXPERIMENTAL

Reagents

Radioactive silver 0·546 g of Analysed Reagent grade silver foil was irradiated in the 1-Mw reactor at the University of Virginia to give about 1 mcurie of ^{110m}Ag. The silver was dissolved in dilute nitric acid, and suitable portions of the solution were used for exchange studies. Excess of nitric acid was removed by evaporation under infrared radiation followed by heating at 110° for 1 hr. The residue was dissolved in distilled water

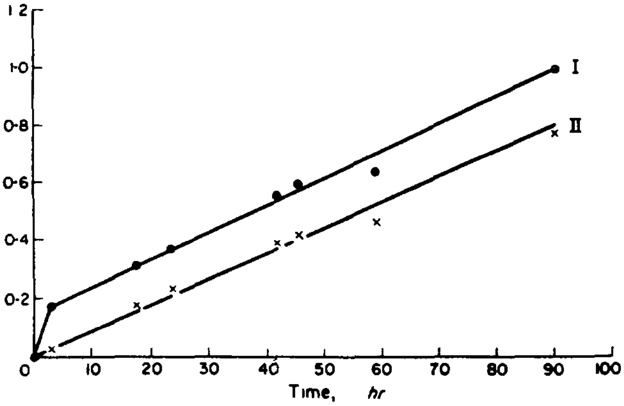

FIG. 1.—A typical exchange between solid silver chromate and tagged silver ion in 50% ethanol.

I. Ordinate is $-\log(1 - F)$
II: Ordinate is $-\log(1 - F^*)$

Radioactive chromium. ^{51}Cr in the form of chromate was obtained from Squibb in 50-μ curie amounts. Also 10 mcuries of $^{51}CrCl_3$ in HCl (Oak Ridge National Laboratories) was used. Chloride, which was present in the solutions from both sources, must be removed, because it would cause precipitates of silver chloride in silver ion-silver chromate exchange. This removal was done by addition of excess of 6N nitric acid and sufficient inactive potassium chromate to make a final solution of about $10^{-6}M$ chromate. Evaporation removes chloride as NOCl, and reduces chromate to chromic ion. Oxidation back to chromate was done by excess of hydrogen peroxide after adjustment of the pH to 10 with potassium hydroxide. After evapcration of this solution to remove hydrogen peroxide, the residue was dissolved in distilled water, and the pH was adjusted to 7·0 with 0·001M perchloric acid.

s-Diphenyl carbazide reagent for chromate contained 0·25 g of Eastman reagent (Cat 618) and 4 g of phthalic anhydride (Matheson Coleman and Bell, Cat 2619) in 100 ml of 95% ethanol.

Silver nitrate and potassium nitrate: 0·100M stock solutions were prepared from Baker and Adamson AR-grade chemicals, and distilled water.

Barium chloride Baker and Adamson purified $BaCl_2 \cdot 2H_2O$ was used to prepare a 0·1M solution in distilled water.

Lead perchlorate. Baker's N.F. PbO was added slowly to 70% Baker and Adamson reagent-grade perchloric acid. The solution was filtered to remove traces of PbO_2, and was diluted to 2M. The pH was adjusted to 2·5 with dilute perchloric acid.

Acetate buffer 160 g of sodium acetate and 6·0 g of glacial acetic acid, both AR-grade were dissolved in 2 litres of distilled water.

Ethanol: Either Pharmco or USI ethanol was used in the experiments.

PLATE I.—Photomicrographs A B C D

Preparations of precipitates

In general, stock solutions of reagents were filtered through fine glass filters before use in precipitations Supersaturated mixtures were prepared by rapid mixing of equivalent solutions in a 400-ml polyethylene beaker A Sargent Cone-Drive Stirrer, with a glass impeller having two blades of 2-cm length each, was used at 300 rpm for mixing. After about 3 min most of the precipitate had formed, and the suspension was poured into 200-ml wide-mouth bottles, and was centrifuged for 5 min at 2000 rpm After decantation, the precipitate was washed twice with distilled water, then with inactive solution of the same composition as the exchange solution

Precipitates of silver chromate were prepared by rapid mixing of 200 ml of solutions of silver nitrate and of potassium chromate to give initial concentrations of silver chromate of 8 75 × $10^{-4}M$, and of 5·00 × $10^{-3}M$. The chromate solution contained 10 ml of acetate buffer.

Solid barium chromate was formed by mixing 0·005*M* solutions of barium chloride and of potassium chromate Lead chromate was formed in mixtures of 0·010*M* lead perchlorate and of 0 010*M* potassium chromate The pH of both solutions was adjusted to 1 8 before mixing

Exchange experiments

The precipitates were left in the 200-ml centrifuge bottles after the last washing The appropriate tagged solution was added (generally 100 ml), and the resulting suspension was kept agitated using a Burrell wrist-action shaker. The bottles were kept in a water bath at 25 ± 0 1°. At intervals the liquid and the solid phase were separated by centrifugation. Aliquots of 0·500 ml were taken from the solution for activity measurements. At the end of the experiment the crystals were filtered into fine sintered-glass crucibles, and their weight was determined after drying at 110° The chromate concentration in solutions containing silver nitrate was determined by the diphenylcarbazide method The absorbance at 540 mμ was compared with the absorbance of standard solutions of chromate The presence of silver ion did not affect the absorbance.

The counting of the aliquots was done in a scintillation well counter (Baird Atomic, Model 810) connected to a single channel analyser, which counted in the photopeak of the isotope The counting of ^{51}Cr samples was done at approximately the same time for each experiment in order to avoid decay corrections.

Because the surface area was poorly reproduced in duplicate experiments the values of *K* determined from the count rates were divided by the percentage of surface found by exchange *K* is expected to be proportional to the specific surface if the crystals are of identical shape, but of different size *K*/% surface gives a measure of the exchange per unit area of the surface.

RESULTS

Electron micrographs were made of carbon replicas of silver chromate crystals formed from stirred supersaturated solutions at various initial concentrations Typical results are presented for precipitates from 8·75 × $10^{-4}M$ Ag_2CrO_4 (micrograph A, Plate I), and from 5·00 × 10^{-3} *M* Ag_2CrO_4 (micrograph B, Plate I) The pyramid faces formed on crystals at the lower concentration are not visible on crystals from the higher concentration. Agglomeration is evident in the second micrograph.

Aging for three days in $10^{-4}M$ $AgNO_3$ in 50% ethanol gives an indication of surface changes on the large crystals, without causing change in the appearance of the agglomerates of small crystals. Micrograph C, Plate I, shows the effect of aging on crystals from 8·75 × $10^{-4}M$ Ag_2CrO_4, and micrograph D, Plate I, indicates little change of the agglomerates formed from 5·00 × $10^{-3}M$ Ag_2CrO_4.

Table I shows results obtained using precipitates formed under identical conditions. Nevertheless, surface exchange varied from 2·79% to 2·02%, and *K* from 2·14 × 10^{-3} to 1·52 × 10^{-3}/hr. However, *K*/% surface remains fairly constant, indicating little, if any, effect of the three-fold increase of the silver ion concentration in solution on the rate of exchange.

Table II shows the effect of increase of supersaturation in precipitate formation on exchange. The exchange surface and the exchange rate constant are smaller than

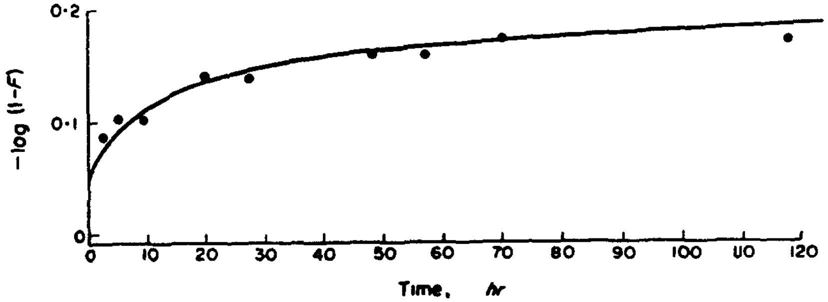

FIG. 3.—Exchange between solid $PbCrO_4$ and 1·00 × $10^{-4}M$ $K_2{}^{51}CrO_4$ in 50% ethanol. $A = 7{\cdot}44 \times 10^{-4}$ moles.

those found under the conditions in Table I. A two-fold increase of the silver ion concentration does not change the value of $K/\%$ surface.

Table III shows the results of exchange between portions of the same batch of precipitate of silver chromate and either $^{51}CrO_4^-$, or ^{110m}Ag ion in 50% ethanol. Surface exchange is only 0·85 mole%, and $K = 4{\cdot}7 \times 10^{-5}$/hr for chromate exchange in a saturated solution of silver chromate in $10^{-4}M$ silver nitrate. The exchange with silver ion gives 3·4 mole% of surface, and $K = 3{\cdot}3 \times 10^{-3}$/hr. Fig. 2 shows the difference in exchange rate, and it includes exchange in 1·00 × $10^{-4}M$ $K_2{}^{51}CrO_4$ (curve I). The unfavourable ratio of B/A prevents determination of K from the slope of curve I.

Our results indicate a ratio of eight readily exchangeable silver ions to one exchangeable chromate at the surface. Preliminary experiments with other precipitates gave a similar ratio.

Chromate exchange between solid lead chromate or barium chromate, and solutions tagged with chromate is illustrated in Figs. 3 and 4. The slopes of the curves change continuously, and therefore the modified exchange law cannot be applied to this exchange.

CONCLUSIONS

The modified exponential exchange law can be applied to exchange between solid silver chromate and solutions containing either tagged silver ion, or tagged chromate. The difference in the rate constant, *K*, between the exchange with silver ion and that with chromate is appreciable. Recrystallisation alone cannot account for the exchange mechanism. Moreover, recrystallisation would change the area of the interface, causing deviation from the exchange law. This process of recrystallisation may account mainly for the results obtained in exchange between $^{51}CrO_4^{2-}$ and solid lead or barium chromate.

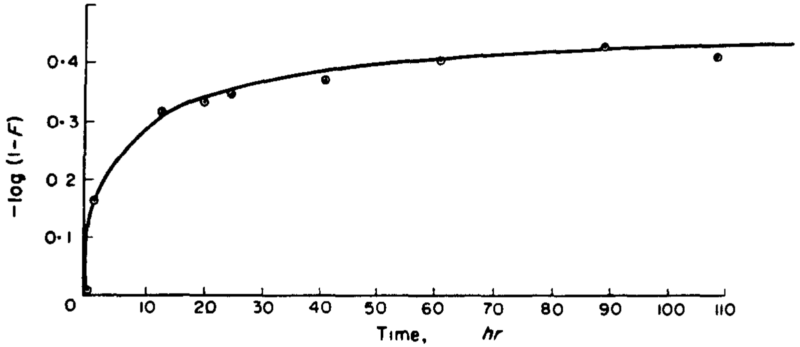

Fig. 4.—Exchange between solid $BaCrO_4$ and 1 00 × $10^{-4}M$ $K_2{}^{51}CrO_4$ in 50% ethanol A = 12 2 × 10^{-4} moles.

The difference between the exchange surface found in chromate and silver ion exchange with silver chromate cannot be explained before more extensive studies are completed. Possible causes include adsorbed silver salt during the preparation of the precipitate, and more surface layers with readily exchangeable silver than layers containing similar chromate ions.

Calculating *K*/% surface, in evaluation of the properties of precipitates, gives interesting results. According to the results in Tables I and II, the exchange rate per unit area is much smaller for the agglomerates of small particles than for the relatively large crystals. Rapid aging during the precipitation, causing agglomeration, could decrease the areas of faces on which exchange mainly takes place, possibly the pyramidal faces shown in electron micrograph A.

This study was supported by the U.S. Atomic Energy Commission under Contract AT-(40-1)-2683.

Zusammenfassung—Das exponentielle Austauschgesetz für heterogene systeme kann auf den Isotopenaustausch zwischen festen Salzen und ihren gesättigten Lösungen angewandt werden, wenn man den anfänglichen schnellen Austausch zwischen Lösung und Kristalloberfläche berücksichtigt. Bei verschiedenen Salzen ist es möglich, Aufschluß über das dynamische Gleichgewicht zwischen Oberfläche und Innerem der Kristalle zu erhalten. Experimentelle Ergebnisse an den Chromaten von Silber, Barium und Blei werden angegeben. Silberchromat tauscht mit Silberionen rasch aus, mit Chromat nicht merklich. Bei Barium- und Bleichromat sind deutlich Rekristallisationseffekte zu beobachten.

Résumé—On peut appliquer la loi exponentielle d'échange des systèmes hétérogènes aux échanges isotopiques entre les sels solides et leurs solutions saturées, apres avoir apporte une correction pour l'échange initial rapide entre la solution et la surface du cristal. Pour des sels divers, il est possible d'obtenir des renseignements sur l'équilibre dynamique entre la surface et l'intérieur des cristaux. On présente des données expérimentales pour les chromates d'argent, de baryum et de plomb Le chromate d'argent montre un échange rapide avec l'ion argent, sans échange important avec l'ion chromate Les effets de la recristallisation sont evidents pour les chromates de baryum et de plomb

REACTION OF IRON^{III} WITH HYDROXYAMINOACIDS

N,*N*-DIHYDROXYETHYLGLYCINEIRON^{III}

Summary—The stoichiometry and equilibrium for the reaction of iron^{III} with *N*,*N*-dihydroxyethylglycine in aqueous medium has been investigated. Iron^{III} is shown to form only a 1:1 complex with the ligand; previous reports of a 2.3 complex are demonstrated to be erroneous and probably resulted from non-equilibrium titration measurements. Using a modified Bjerrum titration procedure, the equilibrium constant for the formation of the 1:1 complex at 25° has been determined to be $3 \cdot 8 \times 10^{-2}$ moles^2/litre^2. Attempts to differentiate between alternative structures for the complex are inconsequential, because the complex exists only in aqueous medium, where the ligand hydroxyl groups exchange rapidly with solvent water.

Previous studies in our laboratories[1,2] have investigated the use of *N*,*N*-dihydroxyethylglycine (DHEG) as a complexing agent to control the mechanism for hydrolysis of iron^{III} and permit the precipitation from aqueous solution of crystalline iron^{III} oxide as β-FeOOH. Because the role of the tetradentate DHEG ligand appears to be unique in facilitating the precipitation of the crystalline oxide, the stoichiometry and equilibrium for the reaction of DHEG with iron^{III} have been investigated in order to provide further information concerning the reactions involved.

In an aqueous solution of pH 2–4, iron^{III} reacts with DHEG to form the complex (I)

$$\mathrm{Fe^{+3} + HG + 2H_2O \rightarrow \underset{(I)}{Fe(OH)_2G} + 3H^+}. \qquad (1)$$

In this reaction DHEG is assumed to behave as a monoprotic acid HG, which coordinates in four positions about the iron^{III} ion. Formula (I) is identical with that proposed by Toren and Kolthoff[3] from polarographic studies of the reaction of iron^{II} and iron^{III} with DHEG. It conflicts with the earlier work by Martell and co-workers[4,5] who assumed DHEG to react as a triprotic acid H_3A, according to equation (2):

$$\mathrm{Fe^{+3} + H_3A + 2H_2O \rightarrow \underset{(II)}{Fe(H_2O)_2A} + 3H^+}, \qquad (2)$$

[†] Present address: Nuclear Defense Laboratory, Nuclear Chemistry Division, Edgewood Arsenal, Md, U.S.A.

where water fills the two co-ordination positions allotted to the hydroxyl ions in equation (1). Formulae (I) and (II) differ in that Martell *et al.* assumed the two hydroxyl groups in the co-ordinated ligand to be more acidic than water, whereas the conventional interpretation assumes the co-ordinated water to be the more acidic Because the iron^{III} complex is stable only in aqueous solution, where the ligand hydroxyl groups should exchange rapidly with the solvent, differentiation between the two structures would be trivial if Martell *et al.* had not reported the formation, above pH 8, of a second binuclear complex, $Fe_2A_3^{-3}$, which was not observed in the other studies [2,3]

The present work is a reinvestigation of the stoichiometry for the reaction between iron^{III} and DHEG, and the equilibrium constant for equation (1) has been determined The previous evidence[4] for the formation of the $Fe_2A_3^{-3}$ complex is demonstrated to be erroneous, and probably resulted from non-equilibrium titration measurements

EXPERIMENTAL

DHEG was purified by recrystallising twice from ethanol. Standard iron^{III} solutions were prepared by dissolving iron wire in hydrochloric acid and diluting to volume

Oxidation of aliquots of the iron solution was effected by treating with hydrogen peroxide and decomposing the excess hydrogen peroxide by boiling. The stability constant of the iron^{III}-DHEG complex was determined by titration at 25° (*vide infra*). Before titration, the acidity of the iron^{III} solution was reduced to pH 2·0 ± 0·05 by neutralisation with gaseous ammonia to prevent the excess acid from consuming an appreciable portion of the added base. The DHEG complexing agent was then added, and the solution was diluted to volume and titrated with standard sodium hydroxide solution Details have been described elsewhere [5]

NMR spectra were recorded using a Varian A-60 spectrometer.

RESULTS

Acidic solutions containing 0·001M iron^{III} and 0·0011M to 0·02M DHEG were titrated with standard base. The titration curves exhibit two end-point inflections. The first of these occurs when the ratio m, the number of moles of base added per mole of iron^{III} in solution, equals three. This end-point corresponds to the titration of the three equivalents of hydrogen ion liberated according to equation (1) or (2). Using a modified Bjerrum-type procedure, the equilibrium constant, K, for equation (1) may be calculated from the titration results, where

$$K = \frac{[Fe(OH)_2G][H^+]^3}{[Fe^{III}][HG]}. \qquad (3)$$

If n is the number of moles of complex formed per mole of total iron^{III}, for $n = 0·5$,

$$[Fe^{III}] = [Fe(OH)_2G],$$

and

$$K = [H]^{+3}/[HG]. \qquad (4)$$

In acid solution the concentrations of $[OH^-]$ and $(G^-]$ are negligibly small, and HG may be readily calculated as

$$[HG] = \frac{\{(3 - a)C_G - [H^+]\}K_1}{4[H^+] + 3K_1}, \qquad (5)$$

where a is the number of moles of base added per mole of total DHEG, K_1 is the first acid dissociation constant[3,4] of the protonated amino acid, H_2G^+, and C_G is the total concentration of DHEG in solution. Knowing [HG] as a function of the pH during the titration, n is given by

$$n = \frac{C_G - [HG]\{[H^+]/K_1 + 1\}}{C_{Fe}} \tag{6}$$

where C_{Fe} is the concentration of total iron^{III} in solution. Plotting $[H^+]$ and [HG] as a function of n, values corresponding to $n = 0·5$ permit the calculation of K in equation (4). Using this procedure, the pH of the solutions in the vicinity of $n \simeq 0·5$ remains sufficiently acidic (pH < 3·6) to prevent interference from the incipient precipitation of $Fe(OH)_3$.

TABLE I—DETERMINATION OF EQUILIBRIUM CONSTANT FOR $Fe(OH)_2G$.
(Ionic strength = 0·01 T = 25° $C_{Fe} = 1·00\ 10^{-3}M$)

C_G/C_{Fe}	$(pH)_{n=0·5}$	$10^3\ [HG]_{n=0·5}$	$10^8\ K$
1·1	3·55	0·490	4·58
1·1	3·60	0·492	3·21
2·0	3·54	1·26	1·90
2·0	3·55	1·17	1·91
5·0	3·34	3·61	2·64
5·0	3·36	3·74	2·23
10·0	3·10	8·43	5·82
10·0	3·10	6·21	8·21
			avg. = (3·8 ± 1·8)
			$pK = 7·4$

Table I indicates typical values for K calculated from titration results for various ratios of C_G/C_{Fe}. Our value of $pK = 7·4$ is in reasonable agreement with the equally precise value of 6·1 calculated from the polarographic data of Toren and Kolthoff[3] Their K_{III} is related to our K by

$$K = K_{III}K_w{}^2K_2,$$

in which K_w is the autoprotolysis constant for water and K_2 is the second ionisation constant for DHEG.[3,4]

The position of the second end-point inflection in the titration curves depends upon the concentration of excess DHEG in solution. For C_G/C_{Fe} ratios of 2, 5, 10 and 20, the end-point occurs when m equals 5, 8, 13 and 23, respectively. If three moles of base are required to titrate the acid liberated by the formation of the iron^{III}-DHEG complex according to equation (1) or (2), the remainder $(m - 3)$ represents the amount of base required to precipitate $Fe(OH)_3$ from the complex and to neutralise the excess DHEG in solution. These latter reactions may be represented by the general equation:

$$Fe(OH)_2G + (m - 4)HG + (m - 3)OH^- \rightarrow Fe(OH)_3 + (m - 3)G^- + (m - 4)H_2O. \tag{6}$$

As written, this reaction requires all of the iron^{III} in solution to be precipitated upon addition of $(m - 3)$ moles of base.

The amount of $Fe(OH)_3$ precipitated during the titrations was analysed gravimetrically by ignition to Fe_2O_3 and also by dissolving the hydrous oxide in acid and titrating with standard cerium^{IV} solution. Because the aggregation and precipitation of the colloidal iron^{III} hydroxide is very slow under these conditions, if solutions to which *m* moles of base had been added were allowed to settle for 1-3 days, quantitative precipitation of the iron was achieved in every case The ability to precipitate the iron under such conditions has been the basis for the procedure for the quantitative precipitation of crystalline iron^{III} oxide as β-FeOOH.[1]

DISCUSSION

The present studies have confirmed the stoichiometry of reaction (1) [or (2)] in which iron^{III} forms only a 1:1 complex with DHEG in acid medium They contrast sharply with those of Martell *et al.* (*loc. cit.*), who reported an unspecified partial precipitation of iron which led them to suggest a second binuclear complex $Fe_2A_3^{-3}$*. We conclude that the latter complex is not formed, for it is not thermodynamically stable, and iron^{III} is quantitatively precipitated under the experimental conditions

The propriety of formula (I) or (II) in solution cannot be determined. Intuitively, structure (I) is preferred, because the ligand hydroxyl groups should have approximately the same acidity as in ethanol, and should be considerably less acidic than water (K_3 and K_4 for DHEG are too small to be measured in aqueous medium) However, the relative acidities of $HOCH_2CH_2$— and H_2O when co-ordinated by iron^{III} have not been determined On the basis of polarisability and ligand-field strength, it is predicted that H_2O will dissociate to a considerably greater degree than will CH_3CH_2OH when co-ordinated by iron^{III}; and hydrolysed species such as $Fe(OH)^{-2}$ and $Fe(OH)_2^+$ are well known NMR spectra of solutions of DHEG in 99·5% D_2O show, in addition to the HOD singlet, two triplets and one singlet, each of relative area 2, which are characteristic of the three methylene groups in the ligand molecule The absence of a more detailed spectrum, including a triplet of relative area 1 at the proper chemical shift for the ethanolic —OH group, indicates that the ligand hydroxyl groups do exchange rapidly with the solvent water. Because the exchange is rapid, differentiation between structures (I) and (II) is inconsequential.

Zusammenfassung—Stochiometrie und Gleichgewicht der Reaktion von Eisen(III) mit N,N-dihydroxyathylglycin in wassrigem Medium wurden untersucht Es wird gezeigt dass Eisen(III) nur einen 1.1-Komplex bildet; fruhere Angaben uber einen 2 3-Komplex sind falsch und basierten wahrscheinlich auf Messungen ausserhalb des Gleichgewichts Mit einer modifizierten Titrationsmethode nach Bjerrum wurde eine Gleichgewichtskonstante von 3,8 10^{-8} mol^2/l^2 für die Bildung des 1 1-Komplexes bei 25°C erhalten. Strukturangaben für den Komplex sind nocht sinnvoll, da er nur in wassrigem Medium existiert, wo die als Liganden auftretenden Hydroxylgruppen rasch mit dem Lösungsmittel ausgetauscht werden

Résumé—La stoechiométrie et l'équilibre de la reaction du fer(III) avec l'acide N,N' dihydroxyéthyl amino-acétique en milieu aqueux ont été études Il est établi que le fer(III) forme seulement un complexe 1 1 avec le complexant; il est démontré que le complexe 2 3 décrit précédemment n'existe pas et résultait probablement de mesures faites avant que l'équilibre soit réalisé En utilisant une méthode de Bjerrum modifiée, la constante d'équilibre de formation du complexe 1 1 déterminée à 25°C est 3,80 . 10^{-8} $moles^2/l^2$. Les structures du

POTENTIOMETRIC STUDY OF THE COMPLEXES OF MERCURY^{I} WITH PYROPHOSPHATE, TRIPHOSPHATE AND TETRAPHOSPHATE

JAMES I. WATTERS and RICHARD A. SIMONAITIS*
Macpherson Chemical Laboratory, Department of Chemistry
The Ohio State University, Columbus 10, Ohio, U.S.A.

(*Received* 19 *August* 1963. *Accepted* 3 *October* 1963)

Summary—The dimer of mercury^{I} forms stable complexes with polyphosphates The stabilities of these complexes decrease slightly as the chain length increases Because of the strong tendency of mercury^{I} to associate with hydroxide ions, the mixed complex species containing both polyphosphate and hydroxide ions were found to be the predominant species in slightly alkaline solutions. In polyphosphate solutions, polarographic waves of Hg^{I} and Hg^{II} are obtained at similar potentials, because the Hg^{II} reacts chemically with the mercury of the drop to form Hg^{I} complexes before the electrode reaction occurs Similar anodic waves are obtained in the presence or absence of mercury ions in solution because of the formation of mercury^{I} complexes. The tetraphosphate complexes which have not been studied before, and their over-all complexity constants in the presence of 1*M* KNO_3 and 0 15*M* guanidinium ion at 25°, are:

$Hg_2(P_4O_{13})^{4-}$, $10^{7.32}$, $Hg_2(P_4O_{13})_2^{10-}$, $10^{9\ 88}$,
$Hg_2(P_4O_{13})(OH)^{5-}$, $10^{15\ 26}$, $Hg_2(P_4O_{13})(OH)_2^{6-}$, $10^{22\ 45}$

INTRODUCTION

THE nature and stability of the various species formed by mercury are of considerable importance because of the unique application of mercury in polarography. The reversibility of a large number of mercury electrode reactions, and the possibility of forming either mercury^{I} or mercury^{II} species, enhance the importance of these studies.

Relatively few stable complexes of mercury^{I} have been prepared. In the presence of strong complexing agents, such as ethylenediamine[1] and ethylenediaminotetraacetate,[2] the mercury^{I} disproportionates to form the stable soluble mercury^{II} complex and free mercury as a black colloid. However, Yamane and Davidson[3] have shown that mercury^{I} forms stable complexes with pyrophosphate, triphosphate, oxalate, dimethylmalonate and succinate, and have determined their stability constants by means of potentiometric measurements using the mercury pool electrode. In the present study, a similar behaviour was established in tetraphosphate solutions, and the existence of mercury^{I} complexes in pyro- and triphosphate solutions was confirmed. By maintaining constant conditions, it was possible to establish trends in stability with increasing phosphate chain length.

Preliminary experiments were performed with the dropping mercury electrode, and electrode reversibility was established by the continuity of these waves across the

---

* Abstracted from the thesis of R. A. Simonaitis submitted in partial fulfillment of the requirements for the Ph.D. degree, 1962, The Ohio State University.

zero-current axis. However, because of the requirement of very dilute mercury solutions to avoid precipitation in acidic solutions, the quiet mercury pool was used in the final potential measurements.

Previous studies of tetraphosphate and its acidic properties are described in an earlier paper.[4] Details of the theoretical approach to the interpretation of the potential values in the presence of several complexing species by Leden's method have also been described[5-7] The existence of the mixed hydroxide complexes and values for their complexity constants were obtained both by determinants and graphically by slope intercept plots.

Consider the equilibrium between a metal ion and several ligands involving only molecular complexes:

$$\mathrm{M + iA + jB + kC \rightleftarrows MA_iB_jC_k}$$

for which one can write the over-all complexity constant

$$\beta_{ijk} = [\mathrm{MA_iB_jC_k}]/[\mathrm{M}][\mathrm{A}]^i[\mathrm{B}]^j[\mathrm{C}]^k.$$

The corresponding equation and equilibrium constant for the stepwise addition of any one ligand, for example, C, are

$$\mathrm{MA_iB_jC_k + C \rightleftarrows MA_iB_jC_{k+1}}$$

$$K^{ijk}_{ijk+1} = [\mathrm{MA_iB_jC_{k+1}}]/[\mathrm{MA_iB_jC_k}][\mathrm{C}].$$

In this series of studies, A indicates H^+; B, the polyphosphate ion; and C, the hydroxide ion while i, j and k are small integers or zero. Ionic charges are omitted in general expressions. Brackets indicate concentrations, and parentheses indicate activities. For example, the over-all complexity constant for $Hg_2(P_4O_{13})(OH)^{5-}$ is indicated as follows

$$\beta_{011} = [\mathrm{Hg_2(P_4O_{13})(OH)^{5-}}]/[\mathrm{Hg_2}^{2+}][\mathrm{P_4O_{13}}^{6-}](\mathrm{OH})^-.$$

The stepwise constant for the addition of another OH^- ion to this species is

$$\mathrm{K}^{011}_{012} = [\mathrm{Hg_2(P_4O_{13})(OH)_2}^{6-}]/[\mathrm{Hg_2(P_4O_{13})(OH)^{5-}}](\mathrm{OH})^-.$$

As previously discussed, the simultaneous association of H^+ with the complexed polyphosphate and OH^- with the metal ion, if this should occur, cannot be detected, because this is equivalent to the addition of a molecule of water. Only the addition of one in excess causes a potential shift.

Mixed complexes containing hydroxide ions were found to be present throughout most of the pH range in which the mercury$^{\mathrm{I}}$ complexes were stable. As a result, the association of hydrogen ions with the complexed polyphosphate, which played an important role in the copper-polyphosphate systems, was generally not observed.

Leden's first function, F_0, has the general form

$$\mathrm{F_0} = \mathrm{antilog}\,\frac{E_{\mathrm{aq}} - E_{\mathrm{c}}}{S} = \sum_{i=O}^{i=N} \; \sum_{j=O}^{j=N'} \; \sum_{k=O}^{k=N''} \beta_{ijk}[\mathrm{A}]^i[\mathrm{B}]^j[\mathrm{C}]^k.$$

In this equation, E_{aq} is the spontaneous reversible electrode or half-wave potential of a particular concentration of aquo metal ion in a solution containing no complexing agent, while E_c is the corresponding potential of the same total concentration of a metal ion in the presence of a fixed excess concentration of ligands and at the same temperature. In order to maintain a constant ionic strength, both solutions should contain the same concentration of supporting electrolyte in large excess. The symbol

S indicates 2·303 RT/nF of the Nernst equation, and has the value 0·02958 for Hg_2^{2+} at 25°.

EXPERIMENTAL

The experimental procedure and methods for preparing the polyphosphates have already been described.[4,5,6] However, the experiments were all performed in the presence of 1M alkali metal ions In the tetraphosphate experiments, guanidinium ions were also present, because the ligand was purified by crystallisation in the form of the guanidinium salts Because alkali metal ions are known to form complexes with polyphosphates,[8,9] we have adopted the expedient followed by Yamane and Davidson of calculating the free ligand concentration on the basis of the experimentally determined apparent acidity constants after correcting for the concentration of ligand bound in the mercury complex. This is equivalent to ignoring the association of alkali metal ions with the free or complexed ligand, and is justified if the activity of the alkali metal ions and, consequently, the apparent acidity constants, are kept essentially constant. This phenomena is discussed in some detail at the end of the paper on copper triphosphate complexes [6] The last two acidity constants are indicated by the symbols K_N and K_{N-1}. For tetraphosphate, they have the form

$$K_6 = (H^+)[P_4O_{13}^{6-}]/[HP_4O_{13}^{5-}],$$

$$K_5 = (H^+)[HP_4O_{13}^{5-}]/[H_2P_4O_{13}^{4-}].$$

Following the procedure of Pugh,[10] a stock solution of mercury$^{\rm I}$ nitrate was prepared by shaking red mercury$^{\rm II}$ oxide, mercury and nitric acid until, after the addition of sodium chloride to precipitate mercury$^{\rm I}$, a filtered aliquot gave no test for mercury$^{\rm II}$ ion with H_2S. The stock solution was then standardised by titrating with a standard sodium chloride solution using 0·04% bromophenol blue as the indicator. In this paper, the concentration of mercury$^{\rm I}$ will be indicated in terms of the molar concentration of Hg_2^{2+} which is one-half that of the mercury$^{\rm I}$ atoms

Mercury$^{\rm II}$ nitrate was prepared by dissolving metallic mercury with freshly boiled concentrated nitric acid and diluting. The mercury$^{\rm II}$ nitrate solution was standardised against standard thiocyanate using ferric alum as the indicator, according to the method of Kolthoff and Sandell [11]

The most extensive preliminary polarographic experiments were performed in the presence and absence of pyrophosphates Just as was observed by Kolthoff and Miller,[12] the spontaneous potentials of similar concentrations of aquo mercury$^{\rm I}$ and aquo mercury$^{\rm II}$, namely 1 22 mM, were identical, but the diffusion coefficient of the latter was somewhat smaller. In the presence of $5 \times 10^{-2}M$ $Na_4P_2O_7$, 1M $NaNO_3$ and 0 0005% methyl red, the waves coincided even in the diffusion-current region Both waves were continuous across the zero-current axis, which proved that the electrode reaction was reversible The absence of any black colloidal mercury in the mercury$^{\rm I}$ solution indicated that a stable mercury$^{\rm I}$ complex was present Furthermore, a mercurous chloride precipitate was obtained upon the addition of excess chloride ion. A similar test of the mercury$^{\rm II}$ pyrophosphate solutions was negative After removing oxygen of the air by flushing with nitrogen, both solutions were shaken in the presence of an excess of free mercury The quantitative conversion of the mercury$^{\rm II}$ pyrophosphate complex to mercury$^{\rm I}$ complex, upon contact with free mercury, was shown by the previously described titration with standard NaCl

These experiments confirm the observation of Yamane and Davidson that both mercury$^{\rm I}$ and mercury$^{\rm II}$ form stable complexes However just as Kolthoff and Miller[12] observed for the aquo system, the mercury$^{\rm II}$ complex is chemically reduced to the mercury$^{\rm I}$ complex upon diffusing to the drop surface, so that, in both cases, it is the mercury$^{\rm I}$ complex which determines the electrode potential The diffusion currents for similar concentrations of the Hg^{2+} and Hg_2^{2+} coincide, so that their diffusion coefficients are similar. This probably results from the relatively large contribution of the complexed polyphosphate to the size of ions

The remainder of the study was made with mercury$^{\rm I}$ solutions. When the solution was made more acidic, the waves decreased in height and a precipitate was observed By reducing the concentration of mercury to the order of $10^{-5}M$, this complication was eliminated. The accuracy of measuring the spontaneous potential of the dropping electrode was greatly decreased because of the relatively large magnitude of the residual current, so that it was found expedient to replace the dropping mercury electrode with a quiet mercury pool Typical potential values for the mercury$^{\rm I}$ pyro-, tri- and tetraphosphate systems are given in Tables I, II and III, respectively. The absence of mercury$^{\rm II}$ in these solutions was established by the previously discussed qualitative tests.

The acidic limit was indicated by the failure of the electrode to undergo further change in potential. The alkaline limit, which was manifested by unsteady potentials, was ascribed by Yamane and Davidson to the formation of solid HgO The pH was varied without altering the total mercury$^{\rm I}$ and ligand concentrations, by mixing various portions of a solution which was acid-free with a similar solution which contained nitric acid. The experiments were performed as rapidly as possible after acidifying the solution, to minimise hydrolysis of the polyphosphates to lower phosphates. Fresh solutions were prepared after a few measurements. The extent of hydrolysis was readily shown by the phosphomolybdate test for orthophosphates.

TABLE I.—POTENTIAL VALUES FOR PYROPHOSPHATE-MERCURY[1] SYSTEM

Part A: $[Hg_2^{2+}]_t = 1{\cdot}22 \times 10^{-5}M$,

RESULTS AND DISCUSSION

Using the symbol Pp to indicate the polyphosphate ion and omitting the complex ion charge for simplicity, the predominant species necessary to account for the potential shift as a function of pH and polyphosphate concentration were Hg_2Pp, Hg_2Pp_2, HgPpOH and $HgPp(OH)_2$. The corresponding Leden function F_0 is:

$$F_0 = \text{antilog}\,(E_{aq} - E_c)/S = 1 + \beta_{010}[Pp] + \beta_{020}[Pp]^2 + \beta_{011}[Pp](OH^-) + \beta_{012}[Pp](OH^-)^2$$

Subtracting unity, and dividing through by [Pp], yields the Leden function, F_1, thus

$$F_1 = (F_0 - 1)/[Pp] = \beta_{010} + \beta_{020}[Pp] + \beta_{011}(OH^-) + \beta_{012}(OH^-)^2.$$

The limiting constant value of F_1 at low values of [Pp] and (OH^-) or the F_1 intercept of a graph of F_1 versus [Pp] at low or constant values of (OH^-) is equal to β_{010}. In the

sodium pyrophosphate study, as shown in Table IA and summarised in the last line of Table IA, the limiting constant value of F_1 in the pH range 4·56–5·29 was $10^{8·83}$, corresponding to the complexity constant for the association of one pyrophosphate with Hg_2^{2+}. Thus:

$$Hg_2^{2+} + P_2O_7^{4-} \rightleftharpoons Hg_2(P_2O_7)^{2-},$$
$$\beta_{010} = [Hg_2(P_2O_7)^{2-}]/[Hg_2^{2+}][P_2O_7^{4-}] = 10^{8·83}.$$

In the presence of 1*M* potassium ions, a constant value was not obtained until the additional species $Hg(HP_2O_7^-)$ was assumed to be present. Solving simultaneous equations, assuming these two species to be present, yielded

$$\beta_{1\overset{*}{1}0} = [Hg_2HP_2O_7^-]/[Hg^{2+}][HP_2O_7^{3-}] = 10^{5·94}.$$

Because of the uncertainty of the values available for the more acidic solutions, these constants for species containing associated hydrogen ion cannot be regarded as reliable, so will not be reported,

The next Leden function obtained by subtracting β_{010} from F_1 and dividing by $[P_2O^4{}_7^-]$ was used to calculate β_{020}, thus:

$$F_2 = (F_1 - \beta_{010})/[P_2O_7^{4-}] = \beta_{020} + \beta_{011}(OH^-)/[P_2O_7^{4-}] + \beta_{012}(OH^-)^2/[P_2O_7^{4-}].$$

6·85	0·1983	1·94	8·64	10·56	15·67	22·60
6·68	0·1877	2·05	8·39	10·40	15·52	22·48
6·52	0·1790	2·16	8·21	10·31	15·43	22·41
6·30	0·1678	2·34	8·01	10·23	15·37	22·41
6·15	0·1600	2·48	7·89	10·23	15·35	22·46

From Table I, it is evident that, in the sodium pyrophosphate solution, F_2 has the constant value of $10^{11·72}$ from a pH of 8·32 to 5·73.

Thus

$$\beta_{020} = [Hg_2(P_2O_7)_2^{6-}]/[Hg_2^{2+}][P_2O_7^{4-}]^2 = 10^{11·72}.$$

Conclusive graphic evidence for the mixed hydroxide species was obtained by a graphic solution of the following Leden function:

$$F_{2a} = (F_2 - \beta_{020})[P_2O_7^{4-}]/(OH^-) = \beta_{011} + \beta_{012}(OH^-).$$

The limiting constant value of F_{2a} or the F_{2a} intercept of a graph in which F_{2a} is plotted versus (OH^-) is equal to β_{011} while the slope is equal to β_{012}. The following Leden functions constant value can be used to confirm β_{012}·

$$F_{3a} = (F_{2a} - \beta_{011})/(OH^-) = \beta_{012}$$

In all of the systems, pyro-, tri- and tetraphosphate, a region was found in which the plot of F_{2a} versus (OH^-) was linear and its intercept value agreed well with the constant value obtained for F_{3a} The F_{2a} graph was linear above a hydroxide concentration of $5 \times 10^{-6}M$ in pyrophosphate solutions. It was linear above a hydroxide concentration of $4 \times 10^{-5}M$ in the triphosphate solutions and it was linear above a hydroxide concentration of $2 \times 10^{-7}M$ in tetraphosphate solutions. These results constitute conclusive evidence for the existence of the mixed complexes of the type $Hg_2(Pp)(OH)$ and $Hg_2Pp(OH)_2$. For the pyrophosphate system in $1M$ $NaNO_3$:

$$\beta_{011} = [Hg_2(P_2O_7)(OH)^{3-}]/[Hg_2^{2+}][P_2O_7^{4-}](OH^-) = 10^{15\,07}$$

$$\beta_{012} = [Hg_2(P_2O_7)(OH)_2^{4-}]/[Hg_2^{2+}][P_2O_7^{4-}](OH^-)^2 = 10^{20\cdot40}.$$

* Results by Yamane and Davidson

A summary of the values obtained for all of the constants, both in the form of over-all constants and stepwise constants, is given in Table IV. These are the mean of all of the values obtained both by determinants considering all species and by slope intercept methods. The corresponding values obtained by Yamane and Davidson are also included. Our results confirm their important discovery of mercury^{I} polyphosphate complexes. The present study indicates the existence of additional species such as Hg(Pp) and the mixed hydroxide complex $HgPp(OH)_2$. Bringing this difference and the difference in experimental conditions into consideration, the quantitative agreement of the two studies is satisfactory. The difference in the values of our constants results in part from the difference in our experimentally determined acidity constants, pK_N and pK_{N-1}, shown in Table IV. Their experimental conditions of 27·4° and $0{\cdot}75M$ Na^+ are fairly similar to the 25° and $1{\cdot}0M$ Na^+ used in one phase of our study. In addition, the present study includes the Hg_2^{2+} tetraphosphate system.

Several interesting generalisations can be made. Just as was the case in the copper polyphosphate systems but not in the alkali polyphosphate systems, the stepwise constant for the addition of the first polyphosphate, as manifested by the value of K^{000}_{010}, decreases with increasing polyphosphate chain length, but the difference decreases from tri- to tetraphosphate. Of particular significance is the strong tendency of the polyphosphate complex to associate with additional hydroxide ions, as manifested by the magnitudes of K^{010}_{011} and K^{011}_{012}. As might be expected from the above observation, these constants increase in magnitude with increasing polyphosphate chain length. This observation is consistent with the observation by Bennett,[13] as well as Sillén and his coworkers,[14,15] who obtained values of the order of 10^9–10^{10} for the association of one hydroxide with the aquo Hg_2^{2+} ion. These can be compared to our values of $10^{7.94}$ and $10^{8.93}$ for the addition of one hydroxide to $Hg_2P_4O_{13}^{4-}$ in the presence of 1*M* KNO_3 and 1*M* $NaNO_3$, respectively.

Zusammenfassung—Das Dimere von Quecksilber(I) bildet stabile Komplexe mit Polyphosphaten Die Stabilität dieser Komplexe nimmt mit steigender Kettenlange schwach ab. Wegen der starken Tendenz von Quecksilber(I) zur Assoziation mit Hydroxylionen wurden in schwach alkalischen Losungen vorwiegend gemischte Komplexe mit Polyphosphat-und Hydroxylionen gefunden. In Polyphosphatlosungen findet man die polarographischen Wellen von Hg(I) und Hg(II) beim gleichen Potential, da Hg(II) mit dem Quecksilber des Tropfens vor der Elektrodenreaktion chemisch zu Hg(I)-Komplexen reagiert Ähnliche anodische Wellen findet man mit oder ohne Quecksilberionen in der Losung wegen der Bildung von Quecksilber(I)-Komplexen. Es wurden folgende bisher nicht untersuchte Tetraphosphatkomplexe mit ihren Gesamt-Komplexbildungskonstanten in Gegenwart von 1m KNO_3 und 0,15m Guanidiniumion bei 25°C gefunden· $Hg_2(P_4O_{13})^{4-}$ $10^{7,32}$, $Hg_2(P_4O_{13})_2^{10-}$: $10^{9,88}$; $Hg_2(P_4O_{13})(OH)^{5-}$ $10^{15,26}$, $Hg_2(P_4O_{13})(OH)_2^{6-}$ $10^{22,45}$

Résumé—Le dimère du mercure(I) forme des complexes stables avec les polyphosphates La stabilité de ces complexes décroît légèrement lorsque croît la longueur de la chaîne. Par suite de la forte tendance du mercure(I) à s'associer aux ions hydroxyle, on a trouvé que les types de complexes mixtes, contenant à la fois les ions polyphosphate et hydroxyle, sont ceux qui prédominent dans les solutions légèrement alcalines En solutions polyphosphoriques, les vagues polarographiques de Hg(I) et Hg(II) s'obtiennent à des potentiels similaires, parce que Hg(II) reagit chimiquement avec le mercure de la goutte en formant des complexes de Hg(I) avant que ne se produise la réaction à l'électrode On obtient des vagues anodiques semblables en présence ou en l'absence d'ions mercure dans la solution, par suite de la formation de complexes de mercure(I) Pour les complexes tétraphosphoriques qui n'ont pas été étudiés auparavant, les constantes globales de complexité en présence de KNO_3 1 M et d'ion guanidinium 0,15 M à 25° sont $Hg_2(P_4O_{13})^{4-}$, $10^{7,32}$; $Hg_2(P_4O_{13})_2^{10-}$, $10^{9,88}$; $Hg_2(P_4O_{13})(OH)^{5-}$, $10^{15,26}$, $Hg_2(P_4O_{13})(OH)_2^{6-}$, $10^{22,45}$.

ANALYTICAL APPLICATIONS OF RADIOACTIVE VITAMIN B_{12}

CHARLES ROSENBLUM
Merck Sharp and Dohme Research Laboratories, Division of Merck and Co, Inc
Rahway, New Jersey, U S A

(*Received* 19 *June* 1963 *Accepted* 6 *October* 1963)

Summary—Radioactive vitamin B_{12} has been employed as an analytical tool, a biochemical tracer and as a diagnostic agent. Of the several labelled modifications reported, only those labelled with cobalt isotopes are useful at physiological dose levels. Because of the high specific activities of (1–200) $\mu c/\mu g$, detection sensitivities in the picagram region are realised with cobalt-labelled vitamin B_{12} Clinical applications including diagnostic tests for pernicious anaemia in humans, are in a sense analytical procedures, involving as they do measurements of vitamin B_{12} transport. Of more direct analytical character is the application of the isotope dilution method to pharmaceutical preparations, feed concentrates, sewage and fermentation products and crystalline cobalamins The stability of hydroxocobalamin in pH 4 2 stabilised aqueous solution has been demonstrated by this method The reverse isotope dilution method also has been very helpful in facilitating stability and degradation studies. The quantitative recovery of unchanged cyanocobalamin from cereals and from capsules containing biological concentrates has been demonstrated by this method. By contrast, the conversion of cyanocobalamin to hydroxocobalamin has been found to occur in the liver of dogs receiving labelled vitamin An extensive study of protective agents to stabilise vitamin B_{12} in solutions containing ascorbic acid has been performed by this reverse dilution procedure The sensitivity of the isotope dilution method has been greatly extended to physiological levels by the application of "saturation analysis," an extension of the binding power measurement applied to intrinsic factor concentrates and to animal tissues including serum or plasma

RADIOACTIVE vitamin B_{12}, in its several forms, has found wide use[1,2] as an analytical tool, as a diagnostic agent and as a biochemical tracer. Even the biological uses have been essentially analytical in nature, because they have involved quantitative determinations of the extent of vitamin adsorption by serum proteins or tissue, absorption or excretion by animals, including man, or stability and degree of conversion to related degradation products.

Vitamin B_{12} is one of a family[3,4] of related, highly coloured, corrinoid compounds called cobalamins or, by a more recent convention, cobamides. The cobalamins are corrin complexes of tervalent cobalt, *i.e.*, porphyrin-like with one bridge carbon atom missing. The best known of the cobalamins is the cyanide complex, cyanocobalamin, the structure of which is shown in Fig. 1, and which is customarily referred to as vitamin B_{12}. It is a neutral, undissociated, relatively stable molecule which can be converted to non-cyano cobalamins photochemically or by catalytic reduction. The major non-cyano analogue, hydroxocobalamin, is a weak base which is converted in the presence of acids into a positive aquocobalamin ion and the respective anion. All non-cyano forms are converted to cyanocobalamin by the addition of cyanide.

LABELLING

Vitamin B_{12} is produced microbiologically by a number of micro organisms incubated in appropriate nutrient media containing sufficient inorganic cobalt for maximal growth. This requires[5] about 2 ppm of cobalt. To produce radioactive cyanocobalamin, the fermentation is usually carried out in the presence of suitable radioactive precursors and, after a rather complicated isolation procedure, the pure crystalline radioactive vitamin is isolated. Radioisotopes which have been successfully incorporated in the cobalamin molecule in this manner are phosphorus-32, carbon-14 and the four long-lived cobalt isotopes. Carbon-14 is also readily introduced[6] as $C^{14}N$ to yield usable specific activities. This modification is, unfortunately, limited by the ease of exchange[7] of the cyanide group, which is in striking contrast to the exchange stability of the central cobalt atom.[8] Cyanocobalamin containing radioactive hydrogen has been prepared by prolonged contact with several curies of tritium gas. Cyanocobalamin containing radioactive cobalt is produced by fermentation in a nutrient medium containing a low concentration of $\lessdot$ 0·1 ppm of radioactive cobalt[9] to maintain a high specific activity of final product. Only radioactive cobalt yields labelled vitamin adequate for studies at physiological levels.

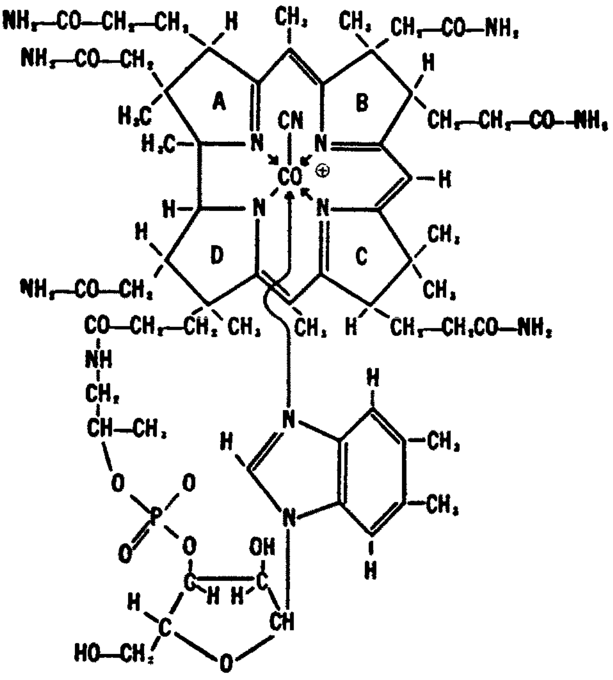

FIG. 1.—Structural formula of vitamin B_{12}.

Cobalt radioisotopes are by far the most useful nuclides with which to label cyanocobalamin. Their radiation properties are tabulated in Table I which lists the type (*i.e.*, beta ray, positron, gamma ray or K-capture X-ray), energy in MeV and frequency of emission of each radiation. Here, 100% signifies that a given ray or particle is emitted with each radioactive disintegration. Relative detection sensitivities will depend on the type of detection devices employed. Detectors, such as

TABLE I—EMISSION BY RADIOACTIVE COBALT ISOTOPES[a]

				3.25	12.3
				2.02	11.0

[a] Minor components omitted

Geiger-Muller and proportional counters, ionisation chambers and liquid scintillation devices, which measure particulate radiation efficiently are excellent for cobalt-56, -58 and -60 but least effective for cobalt-57. This order is reversed when gamma radiation is measured in solid scintillation counters. Thus, cobalt-57 is measured with greatest efficiency in a sodium iodide crystal and cobalt-58 least efficiently. In general, gamma scintillation counting is the most convenient means of determining these radioisotopes.

The characteristics of cyanocobalamin labelled with cobalt isotopes are tabulated in Table II, which shows first the cobalt content of the carrier-free (*i.e.*, 100% isotope) modifications of the vitamin, including the normal, non-radioactive form cobalt-59. This is followed by the maximum specific activities of such carrier-free forms of radioisotopic cobalt (mc/μg) and of the carrier-free labelled cyanocobalamin (in μc/μg) derived therefrom. The next two columns list the specific activities reported or readily available, and the ratios of radioactive cobalt atoms to total cobalt atoms in these preparations. Actually, cyanocobalamin-^{58}Co with specific activities up to 200 μc/μg may be obtained.[10] The last column lists estimated detection sensitivities (in picagrams) computed for a well-type scintillation counter, assuming a detection limit of ±3 cpm. Quantities of the order of picagrams of vitamin can be detected with the radioactive modifications listed, an order of magnitude not readily achieved by other analytical methods.

Vitamin B_{12}-^{57}Co would seem to be the isotopic modification of choice for biological and chemical purposes because of its many desirable properties which may be enumerated as follows:

1. Conveniently long half-life, with attendant flexibility in scheduling the biosynthesis of the radioactive vitamin, and greater shelf-life of the finished product.

2. Less intense gamma radiation, hence greater safety in handling, manufacture and storage of the vitamin.
3. Absence of particulate radiation, with resultant lower radiation exposure of tissue and greater safety for use of the labelled vitamin in humans and animals.
4. Lower self-irradiation exposures, therefore, greater stability of the radioactive vitamin.
5. High detection sensitivity in sodium iodide gamma scintillation phosphors.

TABLE II CHARACTERISTICS OF CYANOCOBALAMIN CONTAINING RADIOACTIVE COBALT ISOTOPES

[a] Stable cobalt.

For *in vitro* work, as is involved in conventional analytical procedures, cyanocobalamin-^{60}Co is perfectly satisfactory, even preferable, provided subdivision and concentration are such as to assure radiation stability. It has been shown that cyanocobalamin-^{60}Co with a specific activity of ≃1 μc/μg will deteriorate at a rate of ≃2% year because of self-irradiation when stored in the cold in concentrations of ≃1 μg/ml.[11,12] Even greater self-irradiation stability is exhibited by vitamin labelled with cobalt-57 and cobalt-58.[12]

CLINICAL APPLICATION

The earliest application of cobalt-labelled vitamin B_{12} led, fittingly, to simple and direct methods of diagnosis of pernicious anaemia, a disease for which vitamin B_{12} is a specific and life-saving treatment. Pernicious anaemia results essentially from the failure of the human stomach to secrete a substance called intrinsic factor. This factor is necessary for the oral absorption of vitamin B_{12}, which is of microbial origin and which is present in ingested food. Haematological diagnosis is a difficult and time-consuming procedure, depending as it does upon observations of the effect of doses of vitamin B_{12} on the blood picture and on changes therein. Radioactive vitamin B_{12}, however, permits a direct measurement of cyanocobalamin absorption[2] from observation of the (1) extent of faecal excretion, (2) extent of urinary excretion, (3) measurements of blood radioactivity, (4) external body scintillation counting over the liver area, and (5) by whole body counting. By these methods, the degree of oral absorption of vitamin B_{12}, and the effect of potent intrinsic factor preparations on oral absorption, are readily ascertained, and a judgement made as to whether absorption is normal or defective. By similar procedures the potency of intrinsic factor preparations employed for the treatment of pernicious anaemia can be evaluated, and the relative absorbability and retention of the several vitamin B_{12} analogues by animals and by man compared. These applications are based on measurements of the extent of vitamin transport from the gastro-intestinal tract, across the intestinal wall, into the blood stream and other tissue. The radioactive properties of the labelled vitamin make it possible to distinguish ingested vitamin in a medium which contains comparatively larger amounts of endogenous vitamin B_{12}.

Innumerable animal studies have revealed the pattern of distribution and excretion of vitamin B_{12} in animals and demonstrated the target organs and storage sites of the vitamin. A major storage site for the vitamin ingested by animals is the liver. The chief site of absorption from the gut appears to be the ileum, and the operation of an enterohepatic mechanism has been discovered. Turnover studies reveal the existence of several compartments or excretion forms of the vitamin.

ISOTOPE DILUTION ASSAYS

Radioactive vitamin B_{12} has been employed as an isotope dilution indicator to police the plant production of cyanocobalamin.[13] Assays[14,15,16] have been performed similarly of fermentation broths, sludge products, pharmaceutical preparations, oral grade solids and tissues, and crystalline vitamin B_{12}. In fact, the isotope dilution or "Radioisotope Tracer" method has been included in the U.S. Pharmacopoeia XV and the National Formulary XI as a standard cobalamin assay.[17]

The principle of the method and the conditions which must be satisfied for the proper application have been discussed elsewhere.[11] To a sample containing X μg of cyanocobalamin, one adds an amount Y μg of radioactive cyanocobalamin with a specific activity $S_0 = \dfrac{\text{A cpm}}{\text{Y}\ \mu\text{g}}$. Here, A cpm is the radioactivity of the tracer added in counts per minute on a suitable detection device. After treatment to ensure mixing of labelled and unlabelled vitamin, and isolation of a portion of the pure, or uniquely determined vitamin, one measures the radioactivity (B cpm) and quantity (Z μg) of a portion of the isolate. The specific activity of the isolate is obviously $S_f = \dfrac{B}{Z}$. The expressions by which X can be computed are

$$X = Y\left[\frac{S_0}{S_f} - 1\right] = Y\frac{S_0}{S_f} - Y = Z\frac{A}{B} - Y. \tag{1}$$

The ratio $\dfrac{A}{B}$ is the factor which corrects the quantity Z for inefficiency of isolation, and the term Y is subtracted from the total cyanocobalamin to correct for the quantity of radioactive indicator added initially. Specific activities of labelled vitamin are usually so high that the amount Y required for accurate radioactivity measurements is negligible compared to X. The above equations reduce accordingly to

$$X = Y\frac{S_0}{S_f} = Z\frac{A}{B}. \tag{2}$$

In the case of vitamin B_{12}, homogenisation of tracer with complex media, such as tissue, in which the vitamin may be retained within cellular matter and bound by biological components as proteins, is assured by treatment with acid nitrite, enzymes, and/or heat. Isolation is rather complicated, involving a variety of separation and purification procedures. A typical sequence of these steps applicable to the determination of total cobalamins in dog liver is enumerated below. Many modifications are permissible depending on the complexity of the matrix and the initial cobalamin content.

Isolation procedure for liver total cobalamins

1. Homogenise 200 g of tissue with $\simeq$350 ml of water, add radioactive vitamin B_{12} and mix[*], add $NaNO_2$ ($\simeq$5 mg/ml) and KCN ($\simeq$2 mg/ml)[†].
2. Adjust to pH 4 with glacial acetic acid; boil 1 hr with stirring (caution: in hood).
3. Zinc defaecation. Cool and add 40 g of $ZnSO_4$ and sufficient 20% NaOH to yield a pH of 7·8–8·0. Filter.
4. Extract with 10 ml of cresol CCl_4 (1·1), wash twice with 10 ml of H_2O
5. Dilute the cresol CCl_4 extract with 3 volumes of butanol CCl_4 (1·4); extract into 10 ml of water
6. Re-extract the aqueous phase with 5 ml of cresol:CCl_4 (1 1)
7. Repeat steps 5 and 6
8. Wash the cresol.CCl_4 extract four times with 10 ml of 5*N* H_2SO_4 and twice with 20 ml of pH 9 phosphate buffer (40 g of Na_2HPO_4/1.) containing a trace of cyanide (0·001*N*)
9. Repeat steps 5 and 6
10. Repeat step 5 extraction into 2 ml of H_2O.
11. Charge to chromatographic column (1 cm in diameter) containing (top to bottom) 2 g of alumina, 5 g of wet IRA 400 (OH cycle) and 5 g of wet IR120 (H cycle). Elute with water
12. Collect the aqueous eluate when a pink colour appears Total volume will be 5 ml Determine the cyanocobalamin content (Z) spectrophotometrically at 361 mμ and its associated radioactivity (B cpm)

This treatment is capable of eliminating "red pigments" resembling cobalamins in structure but devoid of comparable biological and clinical activity.[16]

Because the amount of cobalamin in the isolate is determined spectrophotometrically from absorbancies at 361 mμ, $\left(A_{1\,\mathrm{cm}}^{1\%} = 207\right)$ and the efficiency of isolation $\frac{B}{A}$ is 30–50%, one needs a bare minimum of 50 μg/sample to give a reasonably accurate absorbancy in the final 3–5 ml of resin column eluate usually recovered. Because so large a sample is required, other tissues, which contained $\leqslant$0·5 μg/g, have not been assayed by the isotope dilution method. Blood plasma or serum, for example, contains the order of 0·3 mμg of cobalamin/ml, which is completely out of reach of this procedure. Fortunately, another approach to be discussed below makes it possible to analyse even this tissue concentration by the radioactive indicator method.

Results of the isotope dilution assay of a feed concentrate are shown in Table III Two 100-g samples were analysed by a procedure modified from that described above for liver, by omission of the nitrate treatment and the initial introduction of an alcohol or water extraction procedure. The radioactive cyanocobalamin employed had a specific activity of $\simeq$ 60 μc/mg and the amount added was $\simeq$ 26 μg, which is not a negligible quantity, so that a correction for added tracer (Y) had to be applied. The average concentration was 2·6 μg/g or 1·2 mg/lb of concentrate which agreed

with other, less convenient, biological assays, such as the chick growth assay employed at the time.

Crystalline cyanocobalamin and hydroxocobalamin preparations are also most reliably assayed by the dilution procedure which is specific for cobalamins. For cyanocobalamin and total cobalamin, a reproducibility of ±3% has been estimated. Hydroxocobalamin preparations can be analysed as a difference between total cobalamin content (cyanide addition in step 1) and cyanocobalamin content (no cyanide addition). Typical results of total cobalamin assays for a series of pharmaceutical preparations, fermentation products and crystalline cobalamins are listed in Table IV. Isotope dilution analyses of the two pharmaceutical products are not influenced by the addition of inert coloured materials which do, however, increase the

L. leichmannii assay results. The analyses of vitamin B_{12} concentrates (*i.e.*, "animal protein factor") of fermentation origin emphasise the non specificity of microbial and spectrophotometric procedures as compared to the isotope dilution method, which is usually in good agreement with the chick-growth assay procedure. Agreement is also excellent for the crystalline cobalamin samples which contain 10–20% of volatiles.

The direct isotope dilution method has also been employed to demonstrate the thermal stability of hydroxocobalamin* in stabilised aqueous solution, buffered with acetate buffer and sodium chloride to pH 4·2 and containing $\simeq 1$ mg of hydroxocobalamin/ml. Extrapolation to room temperature of accelerated test data gathered at 40°, 75° and 121° indicated a half-life of 15–20 years, corresponding to a loss of $\not< 4\%$ of hydroxocobalamin/year.

REVERSE ISOTOPE DILUTION

The biochemist studying the mechanism of action or the degradation of a compound into metabolites frequently administers an isotopic modification and fractionates tissue or excreta into labelled components, the nature and quantity of which he seeks to ascertain. The chemist can apply the same technique to stability studies; and to facilitate recovery and assure identity at very low concentrations, he can add an excess of unlabelled modification as carrier before isolation. This is the reverse isotope dilution procedure; and in contrast to isotope dilution, it is not limited by the sensitivity of a spectrophotometric measurement but only by the detection sensitivity of the labelled cobalamin which, for cyanocobalamin containing radioactive cobalt, is in the picagram range. In the reverse isotope dilution assay method one adds the desired amount of the radioactive vitamin $B_{12}\left(X_0\,\mu g;\ A\text{ cpm};\ S_0 = \frac{A}{X_0}\right)$ to the matrix in question. This matrix might be simply an aqueous solution if thermal or radiochemical stability[11] of solutions is concerned or, as has been already reported, cereals or capsules containing biological concentrates.[11,18] Degradation studies in animals receiving labelled vitamin are also cases in point.

At any subsequent time of interest, a large excess (Y mg) of carrier cobalamin is added, and isolation undertaken with recovery of an isolate containing Z mg of cobalamin and B cpm $\left(i.e.,\ S_f = \frac{B}{Z}\right)$. The value of Z is again measured spectrophotometrically. If the actual amount of residual vitamin B_{12} is X μg, then one may say

$$X = Y\left[\frac{1}{\frac{S_0}{S_f} - 1}\right] \text{ or } X = Y\frac{S_f}{S_0} \text{ because } S_0 \gg S_f.$$

Accordingly, the percentage of cohalamin left is

$$\frac{X}{X_0} \times 100 = \left[\frac{Y}{Z} \times B\right] \times \frac{100}{A} \tag{3}$$

Here, $\frac{Y}{Z}$ is the spectrophotometric factor correcting for incomplete recovery of

---

B cpm, $\left[\frac{Y}{Z} \times B\right]$ is the actual radioactivity in cpm recovered with the X μg of cobalamin, and $\frac{X}{X_0} \times 100$ is the percentage of initial radioactivity (A) still recoverable as cobalamin. This method is independent of the presence of endogenous cobalamins.

An obvious use of this approach is for the establishment of the radiochemical purity and authenticity of a labelled compound. This is part of the armoury of methods which the radiochemist employs to prove the suitability of labelled materials. An application of more general analytical relevance is illustrated by the measurement of the radiochemical[11] stability of vitamin B_{12} in aqueous solution employing ^{60}Co-labelled vitamin. Thermal stability has also been investigated. A stabilisation study* of cyanocobalamin in the presence of ascorbic acid is reported in Table V.

* Experiments performed by Messrs. H. T. Meriwether and P. E. Gethard of these Laboratories.

numerous reports of enhanced oral absorption of the vitamin ingested simultaneously with certain of these materials. Because clear solutions were involved, it was not necessary to apply that part of the isolation procedure designed to eliminate tissue components. Estimates based on spectral changes are uncertain because of the lack of knowledge of degradation products and their spectra. The dilution procedure is unequivocal in that pure cobalamin is isolated. It is also performed more expeditiously than a microbiological assay. Given the rapid degradation of vitamin B_{12} in the presence of ascorbic acid, it is seen from Table V that the vitamin is indeed much stabilised by several of the intrinsic factor preparations. Neither sorbitol nor the proteins were effective.

The fate of administered cyanocobalamin retained in animal tissue has also been studied by the reverse isotope dilution method. Thus, practically all of the radioactivity resident in the liver of dogs receiving 3·6 or 14·3 μg of vitamin B_{12}-^{60}Co by the intravenous route and examined 5–71 days after dosing, were found to be recoverable as a cobalamin.[19] The isolation procedure described above was applied to these liver specimens. This being the case, the resident cobalt-60 radioactivity could be assumed to represent vitamin B_{12}-^{60}Co, which could thus serve as a resident indicator for determining the vitamin B_{12} content of the liver specimens by the direct isotope dilution method. This was confirmed by direct isolation (without addition of carrier) of total cobalamin from 100 to 200-g samples of tissue and measuring its activity (B cpm) and quantity (Z) in the isolate. The value of the initial radioactivity (A cpm) was obtained by direct measurement of the tissue radioactivity. The cobalamin content of dog livers could then be calculated from equation (2). These values were confirmed simultaneously by the addition of high specific activity vitamin B_{12}-^{57}Co tracer prior to isolation. The actual isotope dilution analysis thus constituted a "double labelling" tracer experiment in which cobalt-60 and cobalt-57 were determined simultaneously in a gamma-ray scintillation spectrometer. Results are reported in Table VI which show that resident cobalt-60 radioactivity is recoverable quantitatively as a cobalamin, and the cobalamin could serve as an indigenous tracer for vitamin B_{12} because it yielded essentially the same values for the vitamin B_{12} content of dog liver as did exogenous vitamin B_{12}-^{57}Co.

Although retained as an intact cobalamin, the administered cyanocobalamin does

undergo considerable conversion to the hydroxo analogue. This was shown by the reverse isotope dilution method employing the proteolytic enzyme papain instead of nitrous acid to liberate bound vitamin B_{12} from protein and other tissue components, and by using both cyanocobalamin and hydroxocobalamin as carriers. In this study,[20] 2·4 μg of oral vitamin B_{12}-^{57}Co and $\simeq 14$ μg of intravenous vitamin B_{12}-^{60}Co were administered in divided doses, and tissues examined 4 weeks after the last dose. It appears from Table VII that, regardless of the mode of administration,

most of the radioactivity was recoverable as hydroxocobalamin, and that only 7–25% was retained as intact cyanocobalamin. This is consistent with the observation that hydroxocobalamin predominates among the natural sources of vitamin B_{12} activity.

SATURATION ANALYSIS

The interaction between vitamin B_{12} and micro organisms, blood serum, intrinsic factor and other substances of biological importance has received intensive study because of the possible diagnostic significance and to gain an insight into the mechanism of action of the vitamin. This "binding power" for vitamin B_{12} has been employed, among other uses, as a qualitative indication of the potency of intrinsic factor (IF) preparations, and to guide the concentration and isolation of this biological material from animal intestinal sources.[21] The binding power (BP) is measured most easily if a radioactive vitamin is employed. In principle, one only needs to incubate suitable amounts of intrinsic factor concentrate (IFC) with an excess of labelled cyanocobalamin and, after a predetermined time, remove free vitamin by dialysis,[22] adsorption, chromatography or by electrophoresis. If the intrinsic factor is recovered quantitatively, as in the dialysis procedure where it remains in the dialysis sac employed, its radioactivity as measured by scintillation counting indicates the weight of vitamin B_{12} retained by the IF present, and the weight of vitamin/unit weight of binder (*i.e.*, BP) follows. Alternatively, the excess radioactive vitamin B_{12} removed by the inert adsorbent could be measured and the bound vitamin deduced by difference. A typical set of data[23] is illustrated in Table VIII, which shows the amount (mg) of a given intrinsic factor preparation added to 15 ml of solution containing a total of 624 mμg of cyanocobalamin-^{60}Co before dialysis, the percentage of vitamin retained by the intrinsic factor concentrate after incubation at room temperature for 1 hr and dialysis in Nojax casing against running tap water for 22 hr, and the ratio of the retained vitamin (mμg) to the weight (mg) of binder. Up to 0·928 mg of intrinsic factor concentrate, a constant average binding power of 675 mμg/mg is obtained because the binding capacity of the IFC is saturated. Beyond this point, which just corresponds to the retention of 100% of the labelled vitamin, the vitamin excess is exhausted and progressively lower B_{12}/IF ratios are obtained.

TABLE VIII—BINDING OF VITAMIN B_{12} BY INTRINSIC FACTOR CONCENTRATE (VITAMIN ADDED: 624 mμg)

Wt. IF, *mg*	B_{12} bound, %	BP, *mμg/mg*	Wt. IF, *mg*	B_{12} bound, %	BP, *mμg/mg*
0·055	5·7	650	0·764	84·0	686

0·710	79·5	699	2·18	97	280

At higher concentrations of vitamin, the percentage of total vitamin bound/given weight of IF would be lower because its binding power is fixed and its capacity already saturated. Clearly, therefore, the addition of extraneous vitamin B_{12} to the system represented in Table VIII would lower the percentage of vitamin B_{12} bound, and the radioactivity retained would be less than the figures shown in Table VIII. This, in effect, would constitute an isotope dilution assay without separation of the isotopic mixture for measurement. This would be valid if no extraneous components in the medium interfere with the binding of vitamin B_{12}; then the IF serves both to isolate pure or uniquely distinguished radioactive vitamin and to permit facile measurement of final specific activity. This approach to the measurement of small amounts of vitamin B_{12} was proposed[24] for the assay of urine and applied[25] to the measurement of the capacity of gastric juice to bind the vitamin. The adsorbent there was resting *L. leichmannii*[24] cells; the proposal was never actively pursued, presumably because of the difficulty of cultivating a cellular mass of uniform and reproducible binding capacity.

This principle* has since been applied to the micro estimation of fluoride[26] and, under the designation of "saturation analysis", to the analysis of biological media for insulin,[27] thyroxine[28] and recently, again vitamin B_{12}.[29,30,31] The vitamin B_{12} adsorbents utilised are, however, not micro organisms but hog intrinsic factor concentrate,[30]

---

* A similar principle was employed[32] to determine the solubility of lead sulphate in aqueous solutions containing large excesses of sodium sulphate and in alcohol-water mixtures. The indicator utilised was the lead isotope ThB(^{212}Pb) and the adsorbent was lead sulphate of predetermined specific surface.

which is a proteinaceous material, or other binding protein as is supplied in a "standard" serum[31] or plasma[29] specimen. In all of these proposals, a specimen of urine, plasma or serum of unknown vitamin B_{12} content is heated to liberate its vitamin B_{12} burden, and incubated with a fixed amount of radioactive vitamin B_{12}-(^{57}Co or -^{60}Co) and a standardised vitamin B_{12} binder. After incubation for a suitable period, the sequestered radioactivity is determined either (1) by dialysis[29] to remove excess ("free") vitamin and measurement of residual ("bound") radioactivity, (2) by removal of free vitamin by adsorption on charcoal[31] and measurement of same, or (3) by removal of bound vitamin by precipitation of the IF-vitamin B_{12} complex by the Somogyi method,[30] and measurement of the free vitamin left in the filtrate. Because the quantity of the initial radioactive vitamin employed is known, one can always deduce the relative amounts of free and bound vitamin, and the ratios of these quantities, and from this measurement deduce the vitamin B_{12} content of the urine or plasma sample.

It has been customary among investigators to construct a calibration curve relating exogenous crystalline vitamin B_{12} concentration (1) with free radioactive vitamin,[31] or (2) with the ratio of free to bound[29] radioactive vitamin or the inverse ratio,[30] and reading the vitamin B_{12} concentration of an unknown from such a calibration curve. A plot of Free/Bound radioactive vitamin *vs.* vitamin B_{12} concentration is perhaps most convenient because it is linear. The identification of saturation analysis as an isotope dilution procedure, where the adsorbent serves the dual function of isolation and facilitating the determination of final specific activity, was recognised by one group of investigators[29] whose expression for vitamin B_{12} concentration of an unknown is: $B_{12}\ \text{m}\mu\text{g/ml} = \frac{C_a}{V}\left[\frac{B}{C_r} - \frac{1}{S}\right]$, where V = sample volume; C_a = cpm added; C_r = cpm in aliquot dialysed; B = mμg of vitamin B_{12} interpolated from the linear calibration curve; and S = specific activity of the radioactive vitamin B_{12} in cpm/mμg. Rewriting with the notation employed above in an earlier section, we have $V \times B_{12} = X$; $C_a = A$ cpm, $S = S_0$; $B = Z$; and $C_r = B$ cpm, so that the preceding expression becomes $X = \frac{A}{B} Z - Y$, a standard isotope dilution equation.

This "saturation" variant of the isotope dilution method for vitamin B_{12} yields results in excellent agreement with those of microbiological assays for urine and serum, and has the advantages of being much more rapid and probably more reproducible. A comparison of both methods, and of the radiometric method as applied by its several protagonists, is shown in Table IX. This version of the isotope dilution method is significant as an extension of the vitamin B_{12} assay to physiological concentrations. Hitherto, one had been limited by the detection sensitivity of the spectrophotometric method to levels above approximately 50 μg/sample. This quantity is far beyond that which is readily available in samples of tissue and body fluids. The greatly increased detection sensitivity for vitamin B_{12} attainable with the adsorption method permits the analysis of extremely low levels of vitamin present in natural media, and opens up a whole area of applicability for the isotope dilution method.

Zusammenfassung—Radioaktives Vitamin B_{12} wurde als analytisches Hilfsmittel, als biochemischer Tracer und als diagnostisches Agens eingesetzt. Von den verschiedenen beschriebenen markierten Verbindungen sind nur die mit isotopem Kobalt markierten in physiologischen Dosierungen von Nutzen. Wegen der hohen spezifischen Aktivitäten von 1-200 μc/μg lassen sich Nachweisgrenzen im Picogrammbereich mit kobaltmarkiertem Vitamin B_{12} realisieren Klinische Anwendungen, wie diagnostische Tests auf perniciose Anamie beim Menschen, sind gewissermaßen analytische Vorgänge, die Messungen des Vitamin B_{12}-Transports erfordern. Von deutlicher analytischem Charakter ist die Anwendung der Isotopenverdunnungsmethode auf pharmazeutische Präparate, Nahrungskonzentrate, Abfall- und Gärungsprodukte und kristalline Cobalamine. Die Beständigkeit von Hydroxocobalamin in stabilisierter wäßriger Lösung bei p_H 4,2 wurde auf diese Weise gezeigt. Die umgekehrte Isotopenverdünnungsmethode war bei der Erleichterung von Stabilitäts- und Abbauuntersuchungen ebenfalls sehr nützlich. Auf diese Weise wurde die quantitative Gewinnung unveränderten Cyanocobalamins aus Getreide und aus biologische Konzentrate enthaltenden Kapseln gezeigt. Umgekehrt wurde Umwandlung von Cyanocobalamin zu Hydroxocobalamin in der Leber von mit markiertem Vitamin gefütterten Hunden gefunden. Eine umfangreiche Untersuchung uber Agentien zur Stabilisierung von Vitamin B_{12} in ascorbinsäurehaltigen Lösungen wurde mit Hilfe des umgekehrten Isotopenverdünnungsverfahrens durchgeführt. Die Empfindlichkeit der Isotopenverdunnungsmethode wurde in Richtung auf physiologische Mengen stark ausgedehnt durch Anwendung der "Sättigungsanalyse", eine Erweiterung der Messung der Bindungskraft, die auf "intrinsic factor-"Konzentrate und auf tierische Gewebe einschließlich Serum oder Plasma angewandt wurde.

Résumé—La vitamine B_{12} radioactive a été employee dans un but analytique, comme traceur biologique et comme agent de diagnostic Des différentes molécules marquées, seules celles marquées avec des isotopes du cobalt sont utiles au niveau des doses physiologiques A cause des hautes activités spécifiques de (1–200) μc/μg, la sensibilité de la détection dans la région du picagramme utilise de la vitamine B_{12} marquée au cobalt. Des applications cliniques, y compris les diagnostics de l'anémie pernicieuse chez l'homme, sont, en un sens, des moyens analytiques comprenant des mesures du transport de la vitamine B_{12} D'un caractère analytique plus direct est l'application

de la méthode de dilution isotopique aux préparations pharmaceutiques, concentrés alimentaires, produits de dégradation et de fermentation et aux cobaltamines cristallisées. On a montré par cette méthode la stabilité de l'hydroxocobaltamine en solution aqueuse tamponnée (pH = 4,2). La méthode de dilution isotopique en retour est aussi très utile pour faciliter les études de stabilité et de dégradation. On a montré par cette méthode que, dans les céréales et dans des capsules contenant des concentrés biologiques, on retrouvait la même quantité de cyanocobaltamine n'ayant subi aucune transformation. Au contraire, la cyanocobaltamine se transforme en hydroxocobaltamine dans le foie des chiens recevant de la vitamine marquée. Toujours par cette méthode on a peu effectuer une étude complète des agents protecteurs pour stabiliser la vitamine B_{12} dans des solutions contenant de l'acide ascorbique. La sensibilité de la dilution isotopique a été grandement accrue vers les niveaux physiologiques par l'application de "l'analyse de saturation", une extension de la mesure du pouvoir de liaison appliquée au facteur intrinsèque des concentrés et aux tissus animaux contenant du sérum ou du plasma.

SOME PHYSICAL PROPERTIES OF HIGHLY PURIFIED BROMINE

M. S. CHAO and V. A. STENGER
Special Services Laboratory, The Dow Chemical Company, Midland
Michigan, U.S.A.

(*Received* 19 *June* 1963. *Accepted* 7 *October* 1963)

Summary—The electrical conductivity of very pure bromine is lower than that given in most of the earlier literature, and the surface tension is slightly higher. In the liquid range, these properties can be expressed by the equations $\log k = -11{\cdot}372 + 0{\cdot}0128t$ and $\gamma = 45{\cdot}5 - 0{\cdot}182t$, where k is in ohm^{-1} cm^{-1}, γ in dyne . cm^{-1} and t in °C. Data on the thermal conductivity of the liquid are given for the first time.

INTRODUCTION

AMONG the continuing interests of this laboratory is one involving the properties and applications of bromine and its compounds. Through the years, elemental bromine has become available commercially with ever-increasing purity, until the 99·98–99·99% products on the market today rival the especially purified materials used for properties measurements some generations ago. Much of the improvement in the commercial product derives from better methods of fractionation and other treatments to remove organic substances and chlorine, recognition of the need for eliminating moisture and acidity to minimise corrosion problems, and the development of improved analytical methods for detecting impurities. Infrared analysis, for example, can reveal the presence of a few ppm of moisture as well as of chloroform and other partially halogenated hydrocarbons. Wagner[19] has recently pointed out that pure bromine is transparent throughout the normal infrared region, a fact which had been known in the industry for quite a few years. The difficulty of removing the last traces of organic substances by permanganate or chromic acid oxidation had not been realised originally. Thermal oxidation processes have been found in this laboratory to be more effective. One such process has been described by Codell and Norwitz.[4]

With high-purity bromine available as a starting material, it appeared desirable to make new determinations of some of the physical properties of this element. The present paper deals with measurements of the electrical conductivity of liquid and solid bromine, and of the thermal conductivity and surface tension of liquid bromine.

I—ELECTRICAL CONDUCTIVITY

Previous determinations of the specific conductance of bromine have given results as shown in Table I (*cf.* Sharpe[18]).

The data are concordant in that they all indicate a very high resistance of bromine, but discrepancies are evident. It should be noted that Exner's value, reported in 1882, was necessarily obtained with equipment inferior to that available later, and that Moessen and Kraus in their work were concerned primarliy with bromine solutions rather than with a fundamental value for pure bromine. The conductivity of solid bromine has been reported by Rabinowitsch[14] as 8×10^{-12} at $-18\cdot5°$ and $4\cdot5 \times 10^{-11}$ at $-9°$.

TABLE I.—ELECTRICAL CONDUCTIVITY OF LIQUID BROMINE

Temp., °*C*	Spec. cond. (K), *mhos. cm*$^{-1}$	Reported by
-9*	$5\cdot14 \times 10^{-10}$	Rabinowitsch[14]
-6	$5\cdot50 \times 10^{-10}$	Rabinowitsch[14]
$-5\cdot5$	$7\cdot94 \times 10^{-14}$	Exner[5]
0	$8\cdot63 \times 10^{-14}$	Exner[5]
0	$9\cdot6 \times 10^{-10}$	Anderson[2]
0	$6\cdot32 \times 10^{-10}$	Rabinowitsch[14]
15·5	$8\cdot95 \times 10^{-10}$	Rabinowitsch[14]
17·2	$1\cdot21 \times 10^{-13}$	Exner[5]

EXPERIMENTAL

Purification of bromine

A procedure combining that of Codell and Norwitz[4] with that of Hildenbrand, Kramer, MacDonald and Stull[8] was employed. High-purity commercial bromine was vapourised and passed with oxygen through a quartz tube at 900°. The condensed bromine was allowed to stand overnight with about 10% of its weight of previously fused caesium bromide (to remove chlorine), then was distilled. Traces of hydrochloric acid, hydrobromic acid, carbon dioxide and water were removed by repeated vacuum distillations back and forth through drying tubes containing alternate layers of ignited magnesium oxide and barium oxide, in a closed system. The product was finally distilled under its own vapour pressure into the evacuated and cooled conductivity cell. Although no freezing-point data were obtained, the purity should be slightly better than that of Hildenbrand *et al.* Their data had indicated an impurity content of less than 0·001 mole per cent, but the presence of 10–15 ppm of chloroform was subsequently found by infrared analysis.

Apparatus

The conductivity cell consisted of a Pyrex chamber of about 150-ml capacity, having near the centre two parallel square tungsten electrodes 2·6 cm on a side and a little less than 0·5 mm apart. Electrical leads were also of tungsten, brought in from opposite sides through Pyrex tubes. The cell constant as determined at audio frequency with 0·01*M* potassium chloride solution was $5\cdot92 \times 10^{-3}$.

Resistance was measured with a megohmmeter of a type similar to one described by Prinz,[13] loaned by V. J. Caldecourt. This had a feedback circuit yielding a linear current output proportional to the unknown resistance. The current was recorded by a Sargent MR recorder. The system was calibrated against a nominal 100*M*Ω resistor, which in turn had been standardised in a Wheatstone bridge circuit against precision resistors of smaller magnitude.

Temperatures above 10° were regulated to within 0·01° in a bath of the usual type. For lower temperatures it was necessary to add dry ice periodically for cooling, and the constancy during reading intervals was only to about 0·1°. Transformer oil was used as a bath liquid with suitable insulating properties.

Procedure

The leads from the electrodes were kept short-circuited except for the 0·5-min periods of measurement. After each recording the polarity of the leads was reversed to lessen polarisation effects. The period between recordings was at least 5 min. In each run the applied d.c. voltage was small, about 5 V. Because the resistance of the system was found to increase with time, indicating polarisation, an extrapolation to zero time was made and taken as the true value of the resistance. A typical run is illustrated in Fig. 1, showing the extrapolation. At least four runs were made at each temperature.

The conductivity of solid bromine was obtained in the same equipment after lowering the loaded cell into a dry ice-trichlorethylene bath at a rate of 5 mm/hr. The measurement and extrapolation were made in the same way as for the liquid.

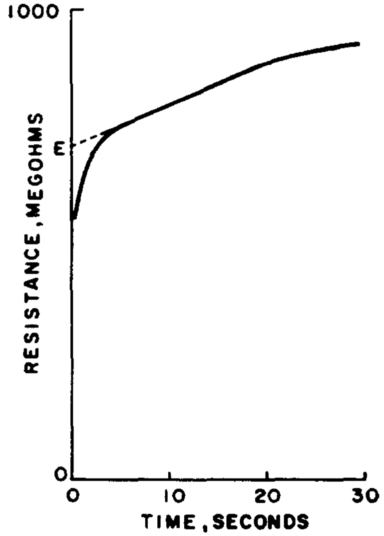

FIG. 1 —Change of resistance with time

RESULTS

Averaged values of the data obtained are presented in Table II. Generally, the individual runs at a given temperature yielded values agreeing within 3–5%. The conductances are estimated to be precise to 5% for the liquid and to 10% for the solid. The data are shown in a semi-log plot in Fig. 2. Over the linear range (liquid), the conductance can be represented by the equation:

$$\log k = -11{\cdot}372 + 0{\cdot}0128t$$

where k is in ohm^{-1}.cm^{-1}. and t is in °C.

TABLE II.—ELECTRICAL CONDUCTIVITY OF SOLID AND LIQUID BROMINE

Temp., °C	Resistance in cell, $M\Omega$	Spec. cond. (K), *mhos. cm*$^{-1}$
−20·0 (solid)	21,250	$2{\cdot}8 \times 10^{-13}$
−15·0	16,350	$3{\cdot}6 \times 10^{-13}$
−10·0	11,050	$5{\cdot}35 \times 10^{-13}$
−7·3	7,320	$8{\cdot}1 \times 10^{-13}$
−7·0 (liquid)	1,800	$3{\cdot}3 \times 10^{-12}$
−5·0	1,610	$3{\cdot}7 \times 10^{-12}$
0·0	1,390	$4{\cdot}25 \times 10^{-12}$
5·0	1,210	$4{\cdot}90 \times 10^{-12}$
10·0	992	$5{\cdot}97 \times 10^{-12}$
15·0	888	$6{\cdot}67 \times 10^{-12}$
20·0	753	$7{\cdot}86 \times 10^{-12}$
25·0	651	$9{\cdot}10 \times 10^{-12}$
30·0	586	$1{\cdot}01 \times 10^{-11}$
35·0	497	$1{\cdot}19 \times 10^{-11}$
40·0	439	$1{\cdot}35 \times 10^{-11}$
45·0	369	$1{\cdot}60 \times 10^{-11}$
50·0	321	$1{\cdot}84 \times 10^{-11}$

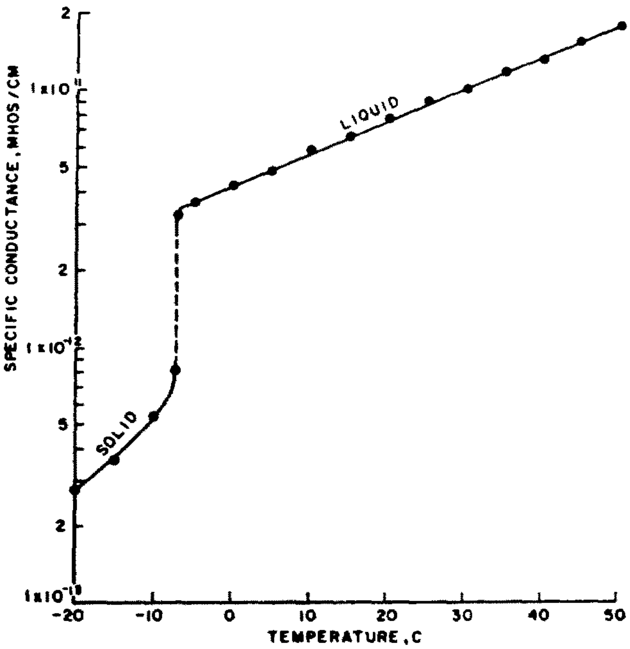

Fig. 2.—Electrical conductivity of bromine

DISCUSSION

Tungsten rather than platinum was chosen for the electrodes because of the observation that on prolonged contact with bromine, platinum became coated with a thin layer of a brownish-yellow substance which upon solution in water would yield a spot test for platinum.[2,6] Tungsten remained unchanged throughout the experiments, though considerably later after standing in moist air, the electrodes were found to have acquired an olive-green coating. The inertness of tungsten towards bromine was also evidenced by potentiometric measurements in a bromine-bromide system. A tungsten electrode exhibited a stable and reproducible potential, positive to that of a silver or magnesium electrode but identical with that of a tantalum electrode in the same system.

Ideally, the conductivity should be measured at audio frequency. However, with a resistance of about 1000 $M\Omega$ any small capacitance would short-circuit the input, making a.c. measurement exceedingly difficult. Therefore d.c. measurements were used here as well as in most of the work previously cited. Moessen and Kraus[12] used an a.c. method.

While polarisation still existed in our experiments, it was minimised by the use of a low d.c. voltage, brief recording time and short-circuiting between recordings. The reproducibility of the extrapolated values and their independence of the polarity of the electrodes indicate that polarisation had not caused any permanent changes in the system.

It is of interest to note the course of polarisation over longer recording periods, similar to what was found by Anderson.[2] Curve I of Fig. 3 was obtained after the electrodes had been shorted for a long time. The resistance slowly rose to a maximum, then tapered off. Curve II was obtained immediately after I and with the polarity changed. The resistance rapidly rose to a maximum A, dropped to a minimum B and finally rose again to a nearly level maximum C. Additional recordings after immediate changes of polarity were similar in shape to curve II, except that the resistances were shifted to lower values. Anderson's curves also showed a minimum in resistance (or rather a maximum in current in her paper), which was taken as the correct value. Separate similar experiments here showed that if our minimum had been considered the correct value according to Anderson, it would be within 10 to 20% of the extrapolated value E of Fig. 1. The extrapolated value was more reproducible, however, and hence was chosen as the one to be reported.

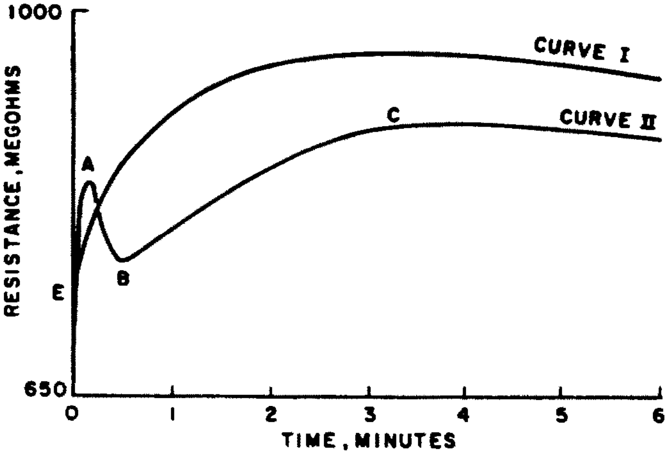

FIG 3.—Effect of polarisation Curve I—Resistance after prolonged shorting, Curve II—Resistance after passage of current and change of polarity.

Compared with the findings of other workers, except Exner, the present values are about two orders of magnitude smaller in specific conductance. This is attributed mainly to more complete removal of impurities, especially moisture, because a value more comparable with those of other workers ($1{\cdot}8 \times 10^{-10}$ at 25°) was observed in using high-quality commercial bromine without additional purification. Furthermore, the conductance of a purified sample continued to decrease with more passes through the purifying columns until about the tenth passage. On the other hand, Exner's values were about one order of magnitude smaller than ours. This may be fortuitous, in view of the fact that he used bromine without stated exclusion of moisture, in a cell of rather large cell constant (electrodes each 1·36 cm^2, 2 mm apart), which called for fairly large applied voltage. It is also of interest that Addenbrooke[1] in discussing Anderson's work, mentioned that he had earlier obtained a specific resistance of 10^{11} *megohms* for bromine. Clearly *ohms* was intended, judging from his data. Although he accepted Anderson's values, his own lies closer to ours (assuming it to be expressed in ohms).

The resistance curves of solid bromine during short recording periods with intermediate short-circuiting were similar in shape to those of the liquid. For longer recording time and intermediate switching of polarity the shapes of the curves were always like that of curve I in Fig. 3, showing that the effect of previous polarisation was negligible.

II—THERMAL CONDUCTIVITY

No previous data on the thermal conductivity of liquid bromine were located. It was decided to employ a hot wire method, the principle of which has been adequately discussed by Hutchinson.[9] Thanks are expressed to W. E. Hatton for assistance in applying this method.

EXPERIMENTAL

Apparatus

The cell was made up of a Pyrex tube, 2·79 mm o.d. and 1·57 mm i.d., housing a coil 5·5 cm in length and 0·092 mm in diameter made from tungsten wire 0·012 mm in diameter. Separate leads for current and potential measurement were connected at each end of the tungsten coil. The resistance of the coil in air was 146·809 Ω at 20°.

In the electrical circuit the following elements were connected in series, in a closed loop a bank of Edison cells with a total e.m.f. of 8 V, decade resistors ranging from 100 to 10,000 Ω to adjust the current level, a calibrated 100-Ω precision resistor with negligible temperature coefficient and the conductivity cell. A precision Rubicon potentiometer with a sensitive galvanometer was used to determine the potential across the cell to within 0·01 mV.

For temperature control a 4-litre beaker with a stirrer was placed in an ordinary constant temperature bath with an insulating cover. The temperature of water in the beaker could be kept constant to about 0·002°, as indicated by a Princo thermometer with divisions in 0·01°. For the measurement at 10°, ice-water was circulated through a coil in the outer bath. The conductivity cell was placed inside the beaker.

Reagents

Reagent-grade toluene and carbon tetrachloride were doubly distilled. By gas chromatography the toluene showed impurities totalling 0·46 area per cent. These consisted of two major impurities, probably paraffin hydrocarbons boiling near toluene, and three traces one of which was most likely benzene. This product should be similar to the analytical-reagent grade used by Challoner and Powell[8]

Procedure

The cell was dried by evacuation and was loaded in the same manner as the electrical cell, to avoid contact of bromine with the air. At each bath temperature a constant current was applied to the tungsten coil for 1 hr or longer. Potentials through the standard resistor and through the cell were measured at the end of the period. From these values the resistance of the tungsten coil at a definite power level could be calculated. The current was then changed and the determinations repeated. A plot of resistance against power resulted in a straight line, which also served as a check for internal consistency. With a series of bath temperatures, a series of such straight plots was obtained.

For each plot the extrapolated value of resistance at zero power level was the resistance of the coil at the bath temperature. When this resistance was plotted against the bath temperatures, the slope of the resulting straight line plot was equal to the temperature coefficient, α, of the coil.

Choosing a suitable value of power w from a resistance-power plot, its corresponding Δt_1 was obtained by reading ΔR from the plot and multiplying it by α. Δt_1 denoted the temperature difference between the wire and the bath. When a correction term Δt_2, representing the temperature drop across the Pyrex wall, was subtracted from Δt_1, the difference was Δt, the temperature drop across the thin shell of the sample liquid. The value of Δt_2 could be calculated from the dimensions of the cell by means of known formulae.[17]

The values of w and Δt are related by the equation:

$$w = kC\Delta t \tag{1}$$

where k is the thermal conductivity of the sample and C is the cell constant. The latter was determined by calibration experiments with toluene and carbon tetrachloride. For this purpose the data of Challoner and Powell[8] were used because of their apparently high precision (see below) and suitable spacing of temperatures.

RESULTS

Calibration data are listed in Table III and the averaged results obtained with pure bromine are shown in Table IV. The determinations on bromine presented no difficulty in the range from 20 to 50°, with results reproducible to 1 or 2%. Over-all accuracy is estimated at ±5%. The measurement at 10° showed larger scattering and its accuracy is estimated at ±10%. The data are plotted in Fig. 4.

TABLE III.—CALIBRATION OF THERMAL CONDUCTIVITY CELL

Standard	Temp., *°C*	Thermal conductivity[a]	Power (W), *watt*	Δt, *°C*	Cell constant, *cm*

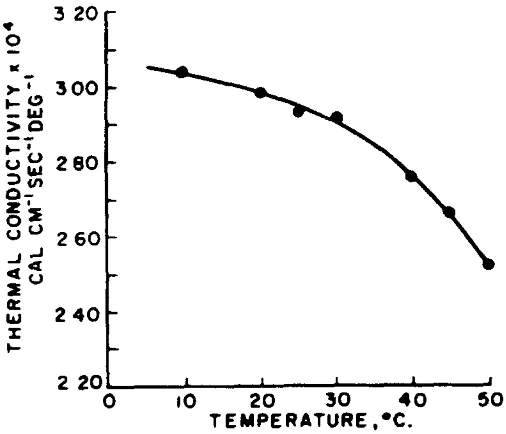

FIG. 4.—Thermal conductivity of bromine.

DISCUSSION

For work with bromine, it is a particular advantage of the hot wire method that the cell can be constructed of materials resistant to corrosion. However, the accuracy of the method is dependent upon calibration against a substance of known thermal conductivity. The thermal conductivity of toluene has been studied by many investigators, whose results have recently been examined statistically by Ziebland.[20] According to his conclusions, the values of Challoner and Powell are about 1·8% too high. If this is the case, our data for bromine are also too high. We have chosen to retain the higher values, particularly because a change would give poorer agreement for the cell constant as found with carbon tetrachloride.

The thermal conductivity of bromine around room temperature lies between those of toluene and carbon tetrachloride. The temperature coefficient is negative, as is also observed with many non-polar liquids, but it is not constant. The drop in thermal conductivity above 30° shown in Fig. 4 is not likely a result of experimental error. While the explanation is uncertain, it must be remembered that bromine is a liquid whose heat capacity, heat of vaporisation and boiling point are all quite low.

Over the range from 0 to 50°, the thermal conductivity of liquid bromine may be approximated by the expression $k = 3{\cdot}04 - 0{\cdot}004\,(t - 10) - 2{\cdot}0 \times 10^{-4}(t - 10)^2$.

III—SURFACE TENSION

A brief literature search failed to reveal any recent determinations of the surface tension of bromine. International Critical Tables[10] lists values which appear to have come almost entirely from unpublished work of W. D. Harkins and G. L. Clark, because the results in cited earlier references are either discordant or difficult to interpret. Mellor[11] gives an equation, based upon data by Ramsay and Aston,[15] which yields surface tension figures about 6% lower than those in International Critical Tables. In no case is there an indication that the bromine used was carefully purified. Both capillary rise and drop weight methods had been employed for the earlier measurements, the former was chosen for use in the present study.

EXPERIMENTAL

Apparatus

A cell was made from two sections of Pyrex tubing 9 inches long, the inside diameters being 2 inches in one case and 1·2 inches in the other. Two precision capillaries were positioned inside the narrower tube, affixed by glass rods to the tube walls. The larger tubes were connected side-by-side through very short sections of 3/8-inch glass tubing at each end, and the ends were sealed and flattened so that the cell would stand upright. An arm at the top of the smaller tube made a connection with the bromine purification train. The cell was placed in a constant temperature bath controllable within 0·01°.

Readings of the bromine levels were made with a Gaertner cathetometer, the vernier of which could be read to within 0·005 cm.

Reagents

Doubly-distilled reagent-grade benzene was used for calibration of the capillaries. Deionised water distilled from alkaline permanganate was employed for the same purpose.

Procedure

The cell was cleaned with a hot mixture of nitric and perchloric acids, rinsed with the above distilled water and thoroughly dried before calibration or connection with the bromine train. After filling and temperature adjustment, readings were taken of the liquid levels in both capillaries and in the wider arm of the cell. The cell was illuminated strongly from behind and no difficulty was encountered in reading the bottom of the bromine meniscus in the capillaries. In the wider tube, the meniscus was read at the lowest point through which transmitted light could be recognised. This was about 0·06 cm below the upper point of contact of liquid bromine with the cell wall.

Although readings were made on both capillaries, only those from one capillary were used in calculating the results. These were from the one which showed closest agreement between calibrations against benzene and water. The other capillary served as a check against any abnormality, such as the presence of a bubble

Density values used were extrapolated and rounded off from a set obtained on the purified bromine of Hildenbrand *et al.* by O L. Daniels of this laboratory. His data covered the range 15–30°, falling on a straight line. The gravitational constant was calculated as 980 5 by Helmert's equation. Surface tension data of Richards and Coombs[14] were used in calibrating the capillaries.

RESULTS

The radius of the capillary used for the calculations was taken as 0·005158 cm, this being the mean of the values from calibration against benzene and water. The value from benzene was only 0·1% larger than that from water.

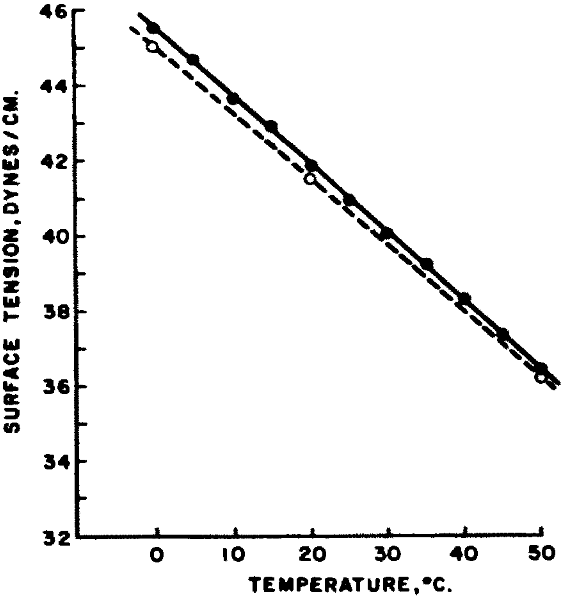

FIG. 5.—Surface tension of bromine: ●—present values, ○—I.C.T. data.

TABLE V—SURFACE TENSION OF LIQUID BROMINE

Temp., °C	Capillary rise, *cm*	Density, $g.ml^{-1}$	Surface tension, $dyne.cm^{-1}$
0	5 640	3 191	45·5
5	5 570	3 174	44·7
10	5·470	3·156	43·6
15	5·400	3 140	42·9
20	5 300	3·122	41·8
25	5·210	3·106	40·9
30	5·120	3·088	40·0
35	5·055	3·070	39·2
40	4·960	3·053	38·3
45	4·860	3 036	37·3
50	4 770	3·019	36·4

The surface tension data obtained with bromine are listed in Table V and plotted in Fig 5 along with those from the International Critical Tables. The equation representing the upper line is:

$$\gamma = 45{\cdot}5 - 0{\cdot}182t$$

where γ is in dyne.cm^{-1} and t is in °C.

DISCUSSION

The maximum error of the present results, based on possible errors in calibration, observed capillary rise and temperature, should not exceed 1·4% or 0·5 dyne.cm^{-1}. This compares favourably with the $\pm 0{\cdot}7$ dyne.cm^{-1} estimate given in the International Critical Tables, and the two sets of data are not separated by more than 0·5 dyne cm^{-1}. Actually, however, the consistency of each set suggests that the difference between the curves is a real one independent of small random measurement errors. This would point to the purity of the bromine as a possible major item in the discrepancy If such is the case, the difference in purity probably amounts to several tenths of 1 per cent. One experiment with high purity commercial bromine (impurity less than 0 05%) at 27·0° yielded a surface tension only 0·1 dyne.cm^{-1} below the upper curve Naturally this is within our experimental error. Nevertheless, it is apparent that the surface tension of bromine is not highly sensitive to the presence of trace impurities

Zusammenfassung—Die elektrische Leitfähigkeit von sehr reinem Brom ist niedriger als meist in der fruheren Literatur angegeben, und die Oberflachenspannung etwas hoher. Im flussigen Bereich konnen diese Eigenschaften beschrieben werden durch die Gleichungen $\log k = -11{,}372 + 0{,}0128t$ und $\gamma = 45{,}5 - 0{,}182t$, wo k in Ohm^{-1}.cm^{-1}, γ in dyn/cm und t in °C angegeben sind. Erstmals werden Angaben uber die Wärmeleitfahigkeit von flüssigem Brom gemacht

Résumé—La conductivité électrique du brome très pur est inférieure à celle donnée le plus souvant dans la littérature antérieure, et la tension superficielle est légèrement plus élevée Dans le domaine liquide, ces propriétés peuvent être exprimées par les équations $\log k = -11{,}372 + 0{,}0128t$ et $\alpha = 45{,}5 - 0{,}182t$, où k est exprimé en ohm^{-1} cm^{-1}, α en dyne cm^{-1} et t en °C. Pour la première fois, on fournit des données sur la conductivité thermique du liquide

D_2O EFFECT ON $\Delta H\ddagger$ AND $\Delta S\ddagger$ IN THE IRON^{II}-IRON^{III} ELECTRON-EXCHANGE REACTION

SHOUZOW FUKUSHIMA§ and WARREN L. REYNOLDS¶
Chemistry Department, University of Minnesota, Minneapolis 14
Minnesota, U S.A

(*Received* 19 *June* 1963. *Accepted* 29 *September* 1963)

Summary—The equilibrium constant of the reaction $Fe^{3+} + D_2O \rightarrow FeOD^{2+} + D^+$ has been measured at 0·500 ionic strength at 5°, 15° and 25°. The ΔH and ΔS of this reaction are 9·32 ± 0.56 kcal mole^{-1} and 17·7 ± 2·0 cal. deg.$^{-1}$ mole^{-1}, respectively. The rates of the electron-exchange reactions $Fe^{2+} + {}^*Fe^{3+} \rightarrow Fe^{3+} + {}^*Fe^{2+}$ and $Fe^{2+} + {}^*FeOD^{2+} \rightarrow FeOD^{2+} + {}^*Fe^{2+}$ have been measured at 0·500 ionic strength at 5°, 15° and 25°. The enthalpy and entropy of the latter reaction are 11·5 ± 0·5 kcal mole^{-1} and −4·0 ± 1·8 cal. deg.$^{-1}$ mole^{-1}, respectively.

THE electron exchange-reactions (1) and (2) were studied by Silverman and

$$Fe^{2+} + {}^*Fe^{3+} \xrightarrow{k_0} Fe^{3-} + {}^*Fe^{2+} \quad (1)$$

$$Fe^{2+} + {}^*FeOH^{2+} \xrightarrow{k_H} FeOH^{2+} + {}^*Fe^{2+} \quad (2)$$

Dodson[1] in $H_2O + HClO_4 + NaClO_4$ media with the aid of ^{55}Fe tracer and an end-window Geiger tube to determine the radioactivity of the hydrous iron oxide precipitates obtained at various times throughout the course of the reaction. The energies and entropies of activation reported were 9·9 kcal.mole^{-1} and −25 cal. deg.$^{-1}$ mole^{-1} for reaction (1) and 7·4 kcal.mole^{-1} and −18 cal. deg.$^{-1}$ mole^{-1} for reaction (2).

Reactions (1) and (3) were studied by Hudis and Dodson[2] in

$$Fe^{2+} + {}^*FeOD^{2+} \xrightarrow{k_D} FeOD^{2+} + {}^*Fe^{2+} \quad (3)$$

~90% $D_2O + DClO_4 + NaClO_4$ media using essentially the same techniques. It was found that the rate constants in D_2O media were less than the rate constants of the corresponding reactions in H_2O media. At 7·1° the ratio of the rate constants of reaction (1) in H_2O and D_2O was approximately equal to 2 as was the ratio of the rate constants of reactions (2) and (3). It was not determined whether the substitution of D_2O for H_2O affected the enthalpy or entropy of activation or both The present-day availability of the isotopic tracer ^{59}Fe and of well-type scintillation counters allows more precise determinations of the rates of these reactions to be made. Hence, it was decided to determine the rates more precisely and to investigate the effect of D_2O on the enthalpies and entropies of activation.

The rate of the iron^{II}-iron^{III} exchange reaction in perchlorate media is given by[1,2]

$$R = \left\{\frac{k_{0,H} + k_H K_H/[H^+]}{1 + K_H/[H^+]}\right\} . [Fe^{II}][Fe^{III}] \quad (4)$$

$$= k_{ob} . [Fe^{II}][Fe^{III}] \quad (5)$$

---

§ On leave from Osaka University, Osaka, Japan.

¶ Present address: 1898 Eustis Street, St. Paul, 13, Minnesota, U.S.A.

in which $k_{0,D}$, k_D, K_D and $[D^+]$ should be substituted for $k_{0,H}$, k_H, K_H and $[H^+]$, respectively, when the exchange occurs in D_2O media, K_H is the equilibrium constant of reaction (6) and K_D the corresponding equilibrium constant in

$$Fe^{3+} + H_2O \rightarrow FeOH^{2+} + H^+ \qquad (6)$$

D_2O. Hudis and Dodson[2] reported a determination of K_D at 21·6° and assumed that the enthalpy change for reaction (6) was approximately the same in D_2O as in H_2O but this was insufficient for our purpose. Hence, determinations of K_D at several temperatures are reported here.

EXPERIMENTAL

Reagents

D_2O (>99 8%). Obtained from Nichem Inc, Bethesda, U.S.A., and purified by distillation in an all-glass apparatus. D_2O used in an experiment was reclaimed and purified by vacuum distillation for further use. Anhydrous sodium carbonate and potassium permanganate were used, when necessary, to destroy acids and organic impurities before distillation. The D_2O content of the solvent was determined by measuring the specific gravity at 25°.[3] All D_2O solvent used had a D_2O content greater than 98 5%.

$DClO_4$· Prepared by passing a solution of $NaClO_4$ through a column of deuterated Dowex 50W-X-8 (50–100 mesh) cation-exchange resin. The deuterated form of the cation-exchange resin was obtained as follows Resin in the sodium form was dehydrated in vacuum at room temperature to eliminate most of the H_2O present, washed with a large amount of D_2O, placed in a 50-ml burette and converted to the deuterated form with a D_2SO_4 solution followed by pure D_2O. D_2SO_4 was prepared beforehand by dissolving anhydrous SO_3 in D_2O The $DClO_4$ solution obtained from ion exchange was distilled under reduced pressure several times to free it from small amounts of sulphate ion and organic impurities, the final distillate was found to be free from SO_4^{2-}. The concentration of acid in the final solution was determined by titration with a standard NaOH solution.

Crystalline $Fe(ClO_4)_3$ $6H_2O$ *and* $Fe(ClO_4)_2 \cdot 6H_2O$: Obtained from G. F. Smith Chemical Co, U.S.A., and dissolved in dilute $DClO_4$ solutions in D_2O in order to prepare the iron^{III} and iron^{II} perchlorate stock solutions used in the rate experiments, the amount of ordinary water introduced by the crystalline salts was negligible. The methods of standardising the iron concentrations and of preparing the iron^{III} perchlorate solution tagged with ^{59}Fe were entirely similar to those described in a previous paper[4] Care was taken to oxidise any trace of iron^{II} impurity to iron^{III} in preparing the iron^{III} perchlorate stock solution in D_2O to be used in the spectrophotometric determination of the hydrolysis constant of iron^{III} in D_2O by treating the salt with hot fuming $DClO_4$.[5] The total acid concentration, *i e.*, the sum $[DClO_4] + 3[Fe^{III}]$, was determined by potentiometric titration with a *standard NaOH solution. The concentration of iron^{III} was then determined spectrophotometrically*[6] and the $DClO_4$ concentration calculated It was established by adding known quantities of iron^{III} to known quantities of $HClO_4$ that each mole of iron^{III} added required three equivalents of base in the determination of the total acid concentration

Anhydrous $NaClO_4$, used to maintain a constant ionic strength, was prepared from $NaCO_3$ and $HClO_4$, recrystallising and drying at 130°.

Measurement of the acid dissociation constant of iron^{III} in D_2O

The methods used to determine the acid dissociation constant of iron^{III} in D_2O were essentially similar to those used by Siddall and Vosburgh.[7] A stock solution containing $5{\cdot}64 \times 10^{-4}M$ iron^{III} and $1\ 29 \times 10^{-1}M$ $DClO_4$ was diluted five-fold in making a set of sample solutions containing a constant concentration of iron^{III} and varying $DClO_4$ concentrations. All solutions were left to stand for a period of 2 weeks before spectrophotometric measurements were made. This was in excess of the necessary length of time[7] The aging period gives any polynuclear iron^{III} species, which may be present in the more concentrated stock solution, time to dissociate.

Transmittance measurements were made at 340 mμ by means of a Beckman DU spectrophotometer equipped with an insulated cell compartment thermostated on all six sides so as to control the temperature within ±0·1° A set of 10-cm corex cells with carefully measured cell characteristics was used and all absorbance values were corrected to correspond to hypothetical 10·00-cm cells with zero blank corrections

Measurement of isotope-exchange rate

The main modifications made on the method of Silverman and Dodson[1] for separation of the valence states and for determination of radioactivity in the iron^{II} portion have been described elsewhere.[4] However, further modifications were found to be necessary in the present study to reduce zero-time exchange. At a time t approximately 1 ml of reaction mixture was withdrawn and delivered by means of a pipette thermostatted at the temperature of the reaction into an ice-cold quenching solution stirred by a magnetic stirrer. An alcoholic solution of α,α'-dipyridyl was used as quenching solution to increase the solubility of tris-(α,α'-dipyridyl) iron^{II} perchlorate or precipitation of this salt gave incorrect results. Ice-cold Al^{3+}-carrier, ammonium acetate buffer and ammonium nitrate-aqueous ammonia buffer solutions were added successively at controlled intervals. Small fluctuations in the volume of sample withdrawn and in the drainage of the pipette resulted in small fluctuations of the iron^{II} concentration of the samples taken for radioactivity determination. To correct this source of error the absorbance of each radioactive iron^{II} solution at 520 mμ was compared with a standard iron^{II} solution and the radioactivity multiplied by an appropriate factor to take into account the change of iron^{II} concentration.

The reaction mixture was thermostatted to ±0·02° by means of an outer insulated bath controlled to ±1° and an inner bath controlled to ±0·02° by means of opposing heating and cooling devices

RESULTS

Determination of K_D *in* D_2O

If it is assumed that $[D^+] = [DClO_4] \gg [FeOD^{2+}]$ and that a wavelength can be found where $FeOD^{2+}$ is the main light absorbing species, then equation (7) is readily derived[7] for constant total $[Fe^{III}]$ and varying $[D^+]$.

$$\frac{1}{A} = a + b[D^+] \tag{7}$$

in which A = measured absorbance $\simeq \varepsilon_2 l[FeOD^{2+}]$, $a = 1/\varepsilon_2 l[Fe^{III}]$, $b = 1/K_D\, \varepsilon_2 l[Fe^{III}]$, ε_2 = molar extinction coefficient of $FeOD^{2+}$ and l = length of absorption cell. When A^{-1} was plotted versus $[D^+]$ an approximate value of K_D was obtained from the relation $K_D = a/b$. With this value of K_D, approximate values of $[Fe^{3+}]$, $[FeOD^{2+}]$, $[D^+] = [DClO_4] + [FeOD^{2+}]$ and the absorbance $\varepsilon_3 l[Fe^{3+}]$ from Fe^{3+} were calculated. Corrected absorbance values for $FeOD^{2-}$ and corrected $[D^+]$ values were now plotted to give new values of a and b in equation (7). Successive approximations were continued until the value of K_D remained constant; usually one or two cycles yielded constant K_D values. The corrected A and $[D^+]$ values used to obtain K_D are given in Table I and plotted in Fig. 1.

TABLE I.—DETERMINATION OF K_D IN $D_2O + DClO_4 + NaClO_4$ MEDIA

Temp., °C	$10^2[D^+]M$	A
25·2 ± 0·1	2·612	0·385

	12·67	0·0362

{$[Fe^{III}] = 1{\cdot}128 \times 10^{-4}M$; $\mu = 0{\cdot}500$}

A weighted least squares[8] calculation of a and b in equation (7) was made; the results are given in Table II. The relative weight given to each point (x_i, y_i), where $x_i = [D^+]_i$ and $y_i = A_i^{-1}$, was taken to be equal to $(\Delta y_i)^{-2}$. The error, Δy_i, in the value of y_i was considerably larger than the corresponding error in x_i for most data points.

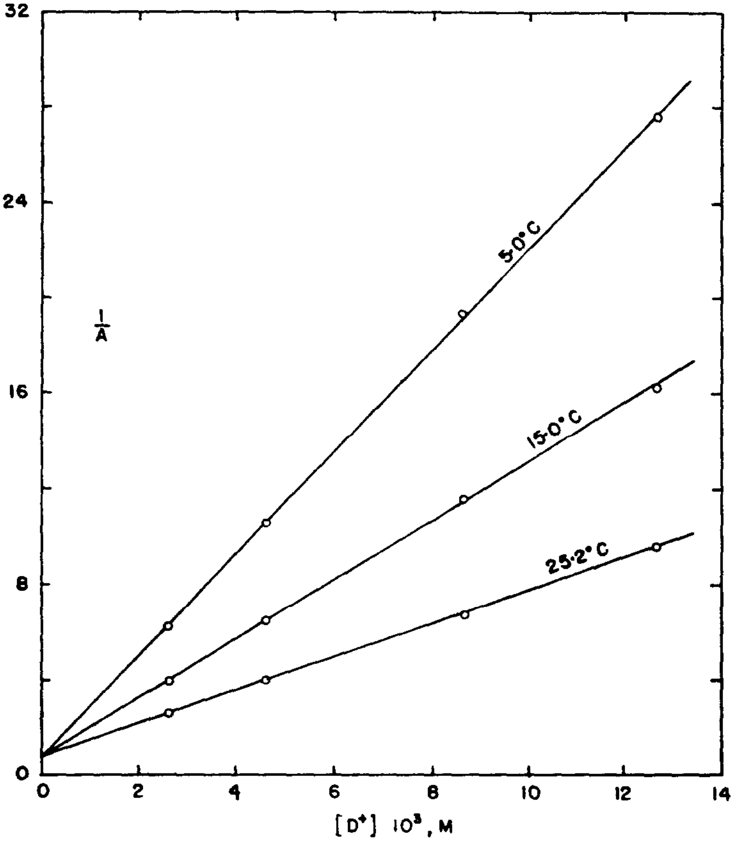

FIG 1—The inverse of the corrected absorbance for $FeOD^{2+}$ versus the deuterium ion concentration, $[D^+]$.

The error Δy_i was calculated from the relations

$$\Delta y_i = \Delta(A_i^{-1}) = \frac{d}{dT}\left(\frac{1}{A_i}\right)(\Delta T)$$

$$= \frac{1}{2{\cdot}303 A_i^2 T_i}(\Delta T) \qquad (8)$$

in which T_i is the percentage transmittance and ΔT is the error made in reading the percentage transmittance. ΔT was assumed to be constant over the scale used. A plot of log K_D versus $1/T$, shown in Fig. 4, gave the least squares values of ΔH and ΔS for reaction (6) in D_2O as 9·32 ± 0·56 kcal.mole^{-1} and 17·7 ± 2·0 cal. deg.$^{-1}$ mole^{-1}, respectively.

The values of ε_2 at 25°, 15° and 5° were 1130, 1140 and 1150 cm^{-1} M^{-1}, respectively. The corresponding extinction coefficient in H_2O[6] at 25° is 925 cm^{-1} M^{-1}.

Exchange rate in H_2O

Because $\Delta H\ddagger$ and $\Delta S\ddagger$ have to be known rather precisely in order to determine the D_2O effect on each it was necessary to re-determine the rates of reactions (1) and (2) in H_2O. The results are given in Table III. The product D . k_{ob}, in which k_{ob} is defined by equations (4) and (5) and $D = 1 + K_H/[H^+]$, the denominator in the expression for k_{ob}, has been plotted versus $1/[H^+]$ in Fig. 2. Excellent precision was obtained. Milburn's semi-empirical expression,[9] equation (9), was used to calculate values of

TABLE III—RATE OF IRON^{II}–IRON^{III} EXCHANGE IN $H_2O + HClO_4 + NaClO_4$ MEDIA.[a]

	0·250	0·442	5·1	26·0
	0·167	0·316	5·1	37·3
	0·125	0·253	5·1	47·5

[a] $\mu = 0·500$.

[b] The errors given in the temperatures are ranges; the standard deviation probably does not exceed ±0·01°.

$$\log K_H = \log K_H{}^{\circ} - \frac{4A\sqrt{\mu}}{1 + 2{\cdot}4\sqrt{\mu}} \qquad (9)$$

$\log K_H$ at $\mu = 0{\cdot}500$ and at each one of the temperatures 18°, 25° and 32°. A regression line, obtained from these values of $\log K_H$, is given in equation (10) and was used to obtain K_H at $\mu = 0{\cdot}500$ and at 5°, 15° and 25°.

$$\log K_H = 4{\cdot}531 - 2{\cdot}165 \times 10^3/T \qquad (10)$$

The errors of calculating $\log K_H$ by equation (10) were estimated[10] from equation (11), in which $Y = \log K_H$ calculated by equation (10), $X = 10^3/T$

$$\sigma(Y) = \sigma\left\{\frac{1}{n} + \frac{(X_i - \bar{X})^2}{\Sigma(X_i - \bar{X})^2}\right\}^{1/2} \qquad (11)$$

$X = \Sigma X_i/n$, n the number of (X_i, Y_i) sets used to obtain equation (10) and σ the standard error of $y_i = \log K_{H_i}$ calculated by equation (9) σ was estimated as the variance of Milburn's experimental values about expression (9).

A least squares treatment of the data shown in Fig. 2, together with the values of K_H calculated from equation (10) and the standard deviations of K_H calculated from equation (11), gave the rate constants and standard deviations listed in Table IV.

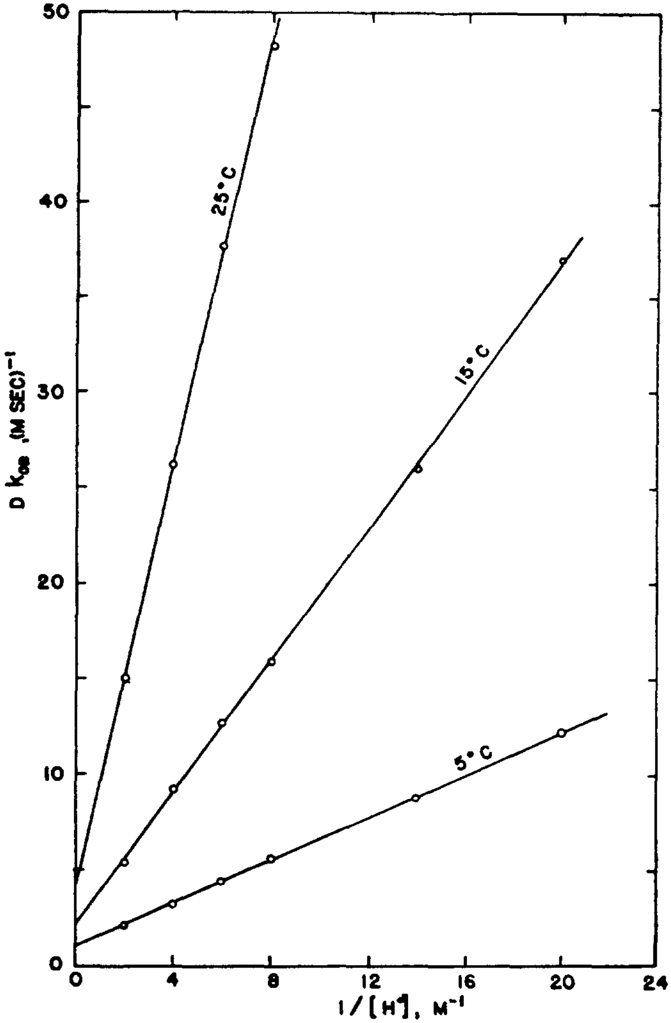

FIG. 2.—Dependence of observed rate constant on acid concentration in H_2O media.

A least squares plot of each log k versus 1/T gave $\Delta H_0^\ddagger = 10{\cdot}5 \pm 0{\cdot}85$ kcal. mole^{-1}, $\Delta S_0^\ddagger = -20{\cdot}6 \pm 3{\cdot}0$ cal. deg^{-1}. mole^{-1} for reaction (1) and $\Delta H_H^\ddagger = 8{\cdot}44 \pm 0{\cdot}47$ kcal.mole^{-1}, $\Delta S_H^\ddagger = -14{\cdot}4 \pm 1{\cdot}6$ cal. deg.$^{-1}$ mole^{-1} for reaction (2). The plot of log k_H versus 1/T is shown in Fig. 4. The values given by Silverman and Dodson[1] for these four quantities are in agreement with the values given here within the error of their measurements. The errors in $\Delta H_0^\ddagger$ and $\Delta S_0^\ddagger$ are still considerable because the steep slope of the D . k_{ob} versus $1/[H^+]$ plots at the higher temperatures gives rise to standard deviations of 8 to 10% in $k_{0,H}$ as may be seen in Table IV.

Exchange rate in D_2O

Exchange rate measurements made at three temperatures are given in Table V. Plots of D . k_{ob} are shown in Fig. 3. The intercepts, $k_{0,D}$, and slopes, $k_D . K_D$, of the straight lines in Fig. 3 are given in Table VI. The errors reported are least squares standard deviations. The values of k_D were obtained by dividing the slopes by the values of K_D obtained from regression equation (12). The standard deviation of each k_D was obtained from equation (13)

$$\left[\frac{\sigma(k_D)}{k_D}\right]^2 = \left[\frac{\sigma(K_D)}{K_D}\right]^2 + \left[\frac{\sigma(k_D K_D)}{k_D K_D}\right]^2 \tag{13}$$

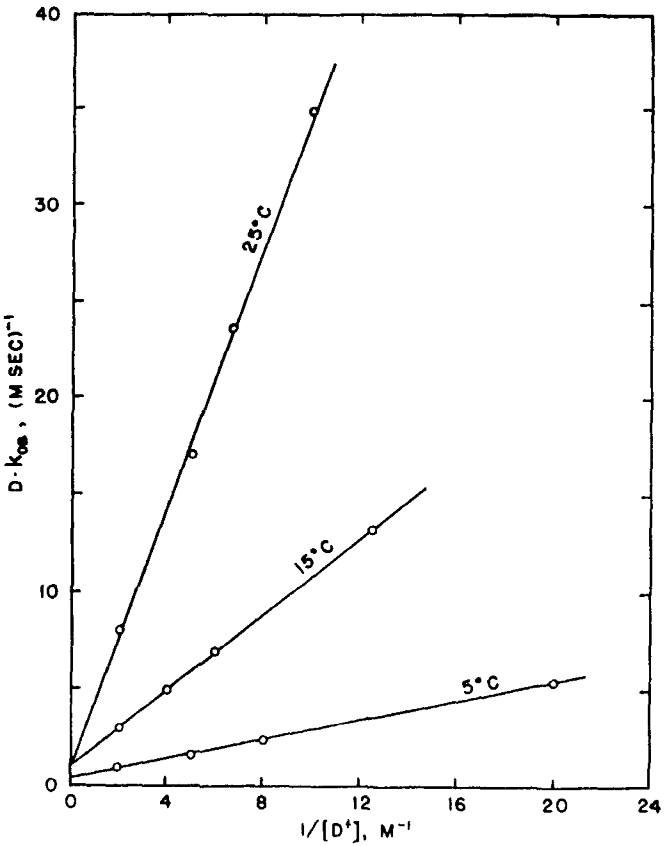

FIG. 3—Dependence of observed rate constant on acid concentration in D_2O media.

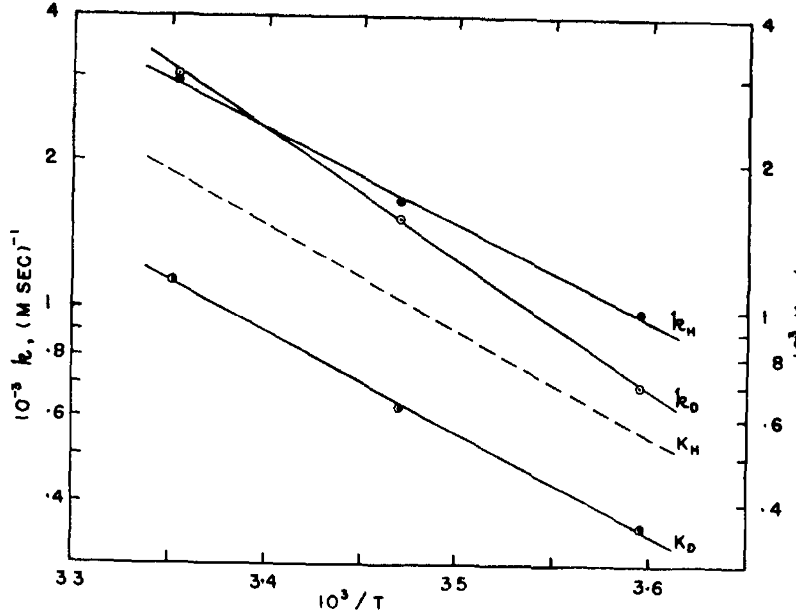

FIG 4—Equilibrium and rate constants plotted versus $(10^3/T)$. ⊙—k_D in D_2O, ●—k_H in H_2O, ◑—K_D in D_2O. The dashed line gives the calculated values of K_H in H_2O.

A least squares plot of log k_D versus 1/T shown in Fig. 4 gave the values $\Delta H_D^{\ddagger} = 11{\cdot}5 \pm 0{\cdot}5$ kcal.mole^{-1} and $\Delta S_D^{\ddagger} = -4{\cdot}0 \pm 1{\cdot}8$ cal. deg.$^{-1}$ mole^{-1} for reaction (3). The errors in $k_{0,D}$ do not make a similar plot for this rate constant worthwhile. Qualitatively it can be seen that the D_2O effect on reaction (1) is in agreement with the effect found by Hudis and Dodson [2]

DISCUSSION

The first acid dissociation constant of $Fe(H_2O)_6^{3+}$ was less in D_2O than in H_2O at the three temperatures and ionic strengths employed in this investigation. Thus at 21·6°, in particular, it was found that K_H/K_D is approximately equal to 1·7 instead of unity as reported by Hudis and Dodson.[2] Despite the fact that $K_H > K_D$, the enthalpy change in H_2O seems to be somewhat larger than in D_2O. However, the difference is small so that it is uncertain.

The differences between $\Delta H_H^{\ddagger}$ and $\Delta H_D^{\ddagger}$ and between $\Delta S_H^{\ddagger}$ and $\Delta S_D^{\ddagger}$ were much larger and seem to be outside of experimental error. The D_2O effect on $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ is much larger than that predicted by Marcus' equations[11] for an outer-sphere activated complex in which the inner co-ordination shells of the reactant complexes are not shared and in which the inner shell solvent is dielectrically saturated, whereas the solvent outside of the inner shell is dielectrically unsaturated. However, this result was to be expected in view of the small difference between the dielectric constants of H_2O and D_2O and the considerable effect of D_2O on the rate constants as has already been noted.[11] What is more important is the fact that D_2O seems to increase $\Delta H^{\ddagger}$ of the OH^--catalysed reaction more than it increases the $\Delta H^{\ddagger}$ of the Cl^--catalysed reaction[5] given in equation (14). The activation energy of the latter reaction in D_2O[5] was found to

$$Fe^{2+} + {}^*FeCl^{2+} \rightarrow FeCl^{2+} + {}^*Fe^{2+} \qquad (14)$$

be approximately 1·7 kcal. mole^{-1} greater than the activation energy in H_2O. However, the experimental error was sufficiently large so that this difference was not regarded as significant.[5] If the mechanism of the OH^--catalysed reaction is H-atom transfer as compared to either Cl-atom transfer or outer-sphere activated complex mechanisms for reaction (14), then it would be expected that the former reaction would show the larger increase in activation energy in D_2O.

Johnston and Rapp[12] have investigated the tunnelling effect in hydrogen atom transfer reactions of methyl radical with hydrocarbons and concluded that the tunnelling contribution was significant. The end groups in the activated complex $R_1 \cdots H \cdots R_2$ were considered to be so heavy that their contribution to tunnelling was negligible. These authors found that the ratio k_H/k_D increased with decreasing temperature more than the ratio would have increased if the ratio had been dominated only by the difference in the R—H and R—D bond energies in the reactants. Furthermore, a lower limit of 1·5 for the ratio k_H/k_D is given in the high temperature limit. In the present work it was found that the ratio k_H/k_D could be as small as unity. If hydrogen atom transfer, with its accompanying contribution from tunnelling, in the activated complex $[(H_2O)_5Fe^{II}(OH). \, .. \, H \, ... \, (OH)Fe^{III}(H_2O)_5]^{4+}$ is the most important mechanism for reactions (2) and (3), then it is apparent that isotope effects other than those considered by Johnston and Rapp must be contributing. Furthermore, if the dominant effect on the apparent $\Delta S^{\ddagger}$ in the D-for-H substitution comes from the mass effect on the tunnelling coefficient and if the tunnelling coefficient is assumed to be independent of temperature over the small temperature range used, then it is to be expected that the apparent $\Delta S^{\ddagger}$ would be larger for H_2O for D_2O. The opposite effect has been observed.

A possible explanation of the $\Delta S^{\ddagger}$ increase in D_2O is that water molecules are partially or wholly freed from some or all of the hydration shells when the activated complex is formed from the separated reactants This results in a positive contribution to $\Delta S^{\ddagger}$ even though the total $\Delta S^{\ddagger}$ for the activation reaction is negative. Because the entropy of 1 molecule of liquid water is approximately 1·5 cal. $deg.^{-1}$ $mole^{-1}$ greater for $D_2O(l)$ than for $H_2O(l)$,[13] each 1 mole of water wholly or partially freed in the activation reaction contributes towards a larger $\Delta S^{\ddagger}$ in D_2O than in H_2O. If an OH^--bridged activated complex is formed, at least one inner shell water molecule must be displaced from the hydrated $iron^{II}$ ion and perhaps other iron-ligand water distances appreciably lengthened in order to accommodate the penetration of $FeOH^{2+}$ with its attached water molecules into the first co-ordination shell of $iron^{II}$ However, the low activation energy of this electron-transfer reaction rather seriously limits the number of inner-shell water molecules which can be wholly or partially displaced. On the other hand, a hydrogen atom transfer does not require any of the inner-ligand water molecules to be wholly displaced.

Qualitatively, the increase of $\Delta H^{\ddagger}$ in D_2O is readily explained. If one assumes with Bigeleisen[14] that the 3 degrees of vibrational freedom of a water molecule essentially retain their identity in a ligand water molecule, then a hydrated metal ion such as $M(H_2O)_6^{+z}$ has 33 vibrational degrees of freedom associated with liberation and with vibration of the water molecules as rigid groups and 18 internal degrees of vibrational freedom inside the 6 ligand water molecules Each of these liberational and vibrational degrees of freedom has a smaller zero-point energy in $M(D_2O)_6^{+z}$ than in $M(H_2O)_6^{7+}$. If only a minor fraction[14] of this zero-point energy difference had to be absorbed in forming the activated complex the increase of 3 $kcal.mole^{-1}$ would be readily accounted for.

The D_2O effects reported in this paper, and which seem to be outside of experimental error, point up an obvious danger in measuring the D_2O effect on the rate constant alone without an accompanying investigation of the effect on $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ The ratio k_H/k_D at room temperatures is very close to unity and had this ratio been measured at this temperature alone it would have been assumed that a D_2O effect was absent

Acknowledgments—The authors wish to thank Professor A. C. Wahl for interesting and informative discussions and also Professor Z. Z. Hugus, Jr., for helpful advice. This research was carried out with funds supplied by A.E C. Contract No AT-(11-1)-622.

Zusammenfassung—Die Gleichgewichtskonstante der Reaktion $Fe^{3+} + D_2O \rightarrow FeOD^{2+} + D^+$ wurde bei der Ionenstärke 0,500 bei 5°, 15° und 25°C gemessen. Ferner wurden $\Delta H = 9{,}32 \pm 0{,}56$ kcal/mol und $\Delta S = 17{,}7 \pm 2{,}0$ cal/grad.mol gefunden. Die Geschwindigkeiten der Elektronenaustauschreaktionen $Fe^{2+} + {}^*Fe^{3+} \rightarrow Fe^{3+} + {}^*Fe^{2+}$ und $Fe^{2+} + {}^*FeOD^{2+} \rightarrow {}^*Fe^{2+} + FeOD^{2+}$ wurden bei der Ionenstarke 0,500 bei 5°, 15° und 25°C gemessen Aktivierungsenthalpie und -entropie der letzten Reaktion wurden zu $11{,}5 \pm 0{,}5$ kcal/mol und $-4{,}0 \pm 1{,}8$ cal/grad.mol gefunden.

Résumé—La constante d'équilibre de la réaction $Fe^{3+} + D_2O \rightleftharpoons FeOD^{+2} + D^+$ a éte mesurée à force ionique 0,500 et aux températures 5°, 15° et 25°C Les valeurs ΔH et ΔS de cette réaction sont respectivement 9,32 ± 0,56 kcal . mole^{-1} et 17,7 ± 2,0 cal . deg $^{-1}$ mole^{-1}. Les vitesses d'échange de l'électron dans les réactions $Fe^{2+} + {}^*Fe^{3+} \rightleftharpoons Fe^{3+} + {}^*Fe^{2+}$ et $Fe^{2+} + {}^*FeOD^{2+} \rightleftharpoons FeOD^{2+} + {}^*Fe^{2+}$ ont été mesurees à force ionique 0,500 et aux températures 5°, 15° et 25°C. L'enthalpie et l'entropie d'activation de cette dernière réaction sont respectivement 11,5 ± 0,5 kcal mole^{-1} et −4,0 ± 1,8 cal deg.$^{-1}$ mole^{-1}.

LEAD-DITHIZONE EQUILIBRIA IN WATER-CARBON TETRACHLORIDE SYSTEMS*

OWEN B. MATHRE† and E. B. SANDELL
School of Chemistry, University of Minnesota, Minneapolis, Minn., U.S.A.

(*Received* 19 *June* 1963. *Accepted* 7 *October* 1963)

Summary—Equilibrium of the principal reactions involved in the extraction of lead dithizonate from aqueous solution with carbon tetrachloride (0) have been determined at $\mu = 0{\cdot}1$:

$$K_{ex} = \frac{[Pb(HDz)_2]_0(aH^+)^2}{[Pb^{2+}][H_2Dz]_0^2} = 5{\cdot}6 \pm 0{\cdot}3 \qquad (5{\cdot}8 \pm 0{\cdot}6 \text{ at } \mu = 0{\cdot}3)$$

$$P = \frac{[Pb(HDz)_2]_0}{[Pb(HDz)_2]} = \frac{\text{soly. in } CCl_4}{\text{soly in } H_2O} = \frac{6 \times 10^{-6}}{3 \times 10^{-9}} = 2 \times 10^3$$

$$K_{diss} = \frac{[Pb^{2+}][HDz^-]^2}{[Pb(HDz)_2]} = 7 \times 10^{-16}$$

$$K_{sp} = [Pb^{2+}][HDz^-]^2 = 2 \times 10^{-24} \qquad \frac{[HPbO_2^-](aH^+)^3}{[Pb^{2+}]} = 7 \times 10^{-29}$$

$$\frac{[PbCit^-]}{[Pb^{2+}][Cit^{3-}]} = 5{\cdot}4 \times 10^5 \qquad \frac{[PbNO_3^-]}{[Pb^{2+}][NO_3^-]} = 0{\cdot}11$$

The pH range for extraction of >99% of lead under analytical conditions (citrate and cyanide present, low equilibrium concentration of dithizone) is 7·5–11·5 Cyanide in the concentrations likely to be used does not significantly decrease the extraction of lead. Above pH 10·85, >99% of the excess dithizone is extracted from the carbon tetrachloride phase into an equal volume of aqueous phase A pH of 10·8–10·9 is recommended for determination of lead with a carbon tetrachloride solution of dithizone A variation of *ca.* ~0·2 pH unit from this value causes little error

DITHIZONE is a valuable reagent both for the separation of lead and its spectrophotometric determination. Although dithizone extraction methods for lead with carbon tetrachloride or chloroform as solvent have now been worked out quite satisfactorily, they rest on an empirical basis. Therefore, it seemed desirable to study a little more closely than heretofore the equilibria existing in the system dithizone-water-carbon tetrachloride, with special reference to the factors bearing on the determination of lead.

EXPERIMENTAL

Reagents

Water. Conductivity water was run through a 20 × 500-mm column of Amberlite IR-120 ion-exchange resin. The content of heavy metals reacting with dithizone at pH 8, as determined spectrophotometrically, at 520 mμ was equivalent to 0·001 ppm of lead. No coloured substances were extracted by carbon tetrachloride. Water thus purified was lower in dithizone-reacting metals than water redistilled in Pyrex apparatus (0·014 ppm of lead)

Hydrochloric acid. A 7*M* solution obtained by isothermal distillation at room temperature (polyethylene beaker) contained heavy metals equivalent to 0·001 ppm of lead.

---

* From the Ph.D. thesis of O. B. Mathre, University of Minnesota, 1956.

† Present address: E. I. du Pont de Nemours and Co, Memphis, Tennessee, U S A.

Nitric acid A reagent-quality product contained 0·008 ppm of lead and was used without further purification after boiling out oxides of nitrogen.

Perchloric acid The 70% acid (reagent grade) available contained only *ca.* 0·001 ppm of lead. Because perchloric acid sometimes contains substances oxidising dithizone, the concentrated acid was diluted with water to 1*M* and shaken for 1 week with a saturated carbon tetrachloride solution of dithizone. The trace of dithizone was removed by extraction with carbon tetrachloride.

Aqueous ammonia A 9*M* solution obtained by isothermal distillation contained 0·001 ppm of lead. A 12*M* solution prepared by absorbing tank ammonia in water contained 0·0012 ppm of lead.

Sodium hydroxide Carbonate-free *ca* 0·15*M* sodium hydroxide solution was prepared by passing purified sodium perchlorate solution through a column of Amberlite IRA-410 resin in the hydroxide form and collecting under nitrogen. The heavy metal content of the solution was equivalent to 0·0008 ppm of lead.

Potassium cyanide A product free from sulphide and containing 0·008 ppm of heavy metals as lead was used without purification. (Some reagent-quality potassium cyanide contained so much sulphide that it could not be used in the dithizone determination of lead.)

Sodium perchlorate A slight excess of perchloric acid was added to sodium carbonate so as to give a solution *ca* 0·001*M* in acid. This was shaken for 2 days with dithizone in carbon tetrachloride to remove substances oxidising dithizone. The pH was adjusted to 8 and heavy metals were extracted with dithizone. A 6*M* sodium perchlorate solution contained 0·0045 ppm of heavy metals as lead.

Sodium citrate. After dithizone extraction at pH 8, a 0·5*M* solution contained 0·003 ppm of lead. *Sodium sulphite* (10%) and *sodium nitrate* (3*M*) solutions purified in like manner contained 0·0015 and 0·002 ppm of metals equivalent to lead.

Lead nitrate The salt was recrystallised several times from 0·01*M* nitric acid and vacuum-dried over potassium hydroxide after grinding to a powder. Determination of lead gravimetrically gave the theoretical value.

Dithizone Two g of Eastman dithizone were dissolved in 150 ml of reagent-quality chloroform, insoluble material was filtered off, and the filtrate was shaken with four 50-ml portions of dilute purified aqueous ammonia. A small amount of sulphur dioxide was passed into the combined aqueous extracts and an extraction was made with 25 ml of chloroform, which was discarded. Sulphur dioxide was passed into the aqueous solution until acidic and dithizone was extracted with four 30-ml portions of chloroform which had been washed with 1:100 aqueous ammonia just before use. The chloroform solution was filtered through a pledget of glass wool into a flask. An equal volume of carbon tetrachloride was added and nitrogen was bubbled through the solution at 40°. When the volume had been reduced to 50 ml, the liquid was cooled in ice and filtered through sintered glass. The solid dithizone as washed with a little carbon tetrachloride and vacuum-dried over potassium hydroxide for 2 weeks.

The dithizone content of the product was determined by photometric titration with silver. Ten-ml portions of *ca* $5 \times 10^{-5}M$ dithizone in carbon tetrachloride were shaken with 10-ml portions of 0·1*N* sulphuric acid containing varying amounts of silver (less than required for the stoichiometric ratio). A plot of the absorbance of the carbon tetrachloride at 620 mμ against the amount of silver gave a straight line whose intersection with the silver axis indicated the equivalence point. Two batches of dithizone gave the following replicate values (%) for active reagent:

99·9	100·1
99·8	99·8
100·2	99·8
99·8	100·2
100·1	

The molar absorptivities of dithizone in carbon tetrachloride (solutions prepared by weighing out solid dithizone) at 25°, based on an average of 8 absorbance measurements of $0{\cdot}25-1{\cdot}26 \times 10^{-4}M$ solutions (standard deviations *ca* 1%), were found to be

$$1{\cdot}90 \times 10^4 \text{ at } 450 \text{ m}\mu$$
$$4{\cdot}69 \times 10^4 \text{ at } 510 \text{ m}\mu$$
$$3{\cdot}17 \times 10^4 \text{ at } 620 \text{ m}\mu$$

and $\varepsilon_{620}/\varepsilon_{450} = 1{\cdot}67$. A Beckman DU spectrophotometer was used for these measurements. Weber and Vouk[1] report $\varepsilon_{450} = 2{\cdot}14 \times 10^4$, $\varepsilon_{620} = 3{\cdot}64 \times 10^4$ and $\varepsilon_{620}/\varepsilon_{450} = 1{\cdot}70$.

Lead dithizonate. The solid was prepared in two ways:

(1) A 0·01% solution of dithizone in chloroform was shaken with an ammoniacal cyanide solution containing 95% of the theoretical amount of lead required to react with the dithizone. The filtered chloroform phase was evaporated to small volume at 40° in the dark with a stream of purified

nitrogen. The suspension of lead dithizonate was cooled in ice and the microcrystalline lead dithizonate was collected on a sintered-glass filter. The product was vacuum dried over potassium hydroxide.

(2) Lead nitrate in 0·001*M* perchloric acid was added slowly to an aqueous ammonia-potassium cyanide-ammonium sulphide mixture of pH 10·5 which was $10^{-4}M$ in dithizone. The precipitated lead dithizonate was filtered off, washed with dilute aqueous ammonia, water, alcohol and chloroform, then vacuum-dried over potassium hydroxide.

Lead was determined in the products by precipitation as the chromate after destroying dithizone with perchloric acid. Dithizonate radical was determined spectrophotometrically after reverting a weighed amount of the solid by shaking the carbon tetrachloride solution with 0·1*M* hydrochloric acid. As a check on the gravimetric lead determination, a portion of the acid was analysed for lead spectrophotometrically with dithizone. The analytical figures shown in Table I were obtained.

TABLE I

	Pb, %	Dithizonate radical, %	Pb - dithizonate, %	% Dithizonate / % Pb
Preparation (1)	28·9 (grav.) 28·9 (grav.) 28·7	70·7	99·5	2·444
Preparation (2)	28·5 (grav.) 28·3 28·6	69·9 70·2	98·55	2·458
Theoretical	28·87	71·13	100·0	2·464

The solid lead dithizonate seems to be approximately 99% pure. If the remainder is water (which is not certain), its amount is not large enough to correspond to a hydrate.

The molar absorptivity of lead dithizonate in carbon tetrachloride at 520 mμ, the wavelength of maximum absorption, was determined by three methods, each average being based on 20 absorbance measurements (Table II). The standard deviation is a little less than 1%. The concentration of lead dithizonate ranged from 5×10^{-6} to $1·6 \times 10^{-5}M$; ε was independent of the concentration.

TABLE II.—MOLAR ABSORPTIVITY OF LEAD DITHIZONATE IN CARBON TETRACHLORIDE AT 520 mμ

Method	ϵ_{520}
(1) Known amounts of lead extracted with 0·005% dithizone from aqueous ammonia-cyanide-sulphite buffer of pH 10·8 into CCl_4	66,200 ± 500
(2) Solid lead dithizonate [Preparation (1)] dissolved in CCl_4 and absorbance measured. Lead dithizonate dissociated by shaking with dilute HCl and lead determined spectrophotometrically by mono colour dithizone method. These values were checked by determination of dithizone in original CCl_4 solution	66,300 ± 600
(3) Absorbance of CCl_4 solutions of solid lead dithizonate measured and lead determined by spectrophotometric titration with standard $AgNO_3$ solution	66,600 ± 500

The molar absorptivity-wavelength curve of lead dithizonate in carbon tetrachloride is reproduced in Fig. 1. Weber and Vouk[1] report $\epsilon_{620} = 7·29 \times 10^4$ and $\epsilon_{620} = 3·9 \times 10^3$ for lead dithizonate in carbon tetrachloride.

Carbon tetrachloride. The reagent-grade product was treated with a few drops of bromine, allowed to stand 2 weeks, shaken with 10% sodium hydroxide, refluxed for 4 hr with the same solution, washed free from alkali, refluxed with 10% aqueous hydroxylamine hydrochloride solution for 0·5 hr, washed with water, dried with Drierite and finally distilled from calcium oxide. The purified product was stored in a refrigerator.

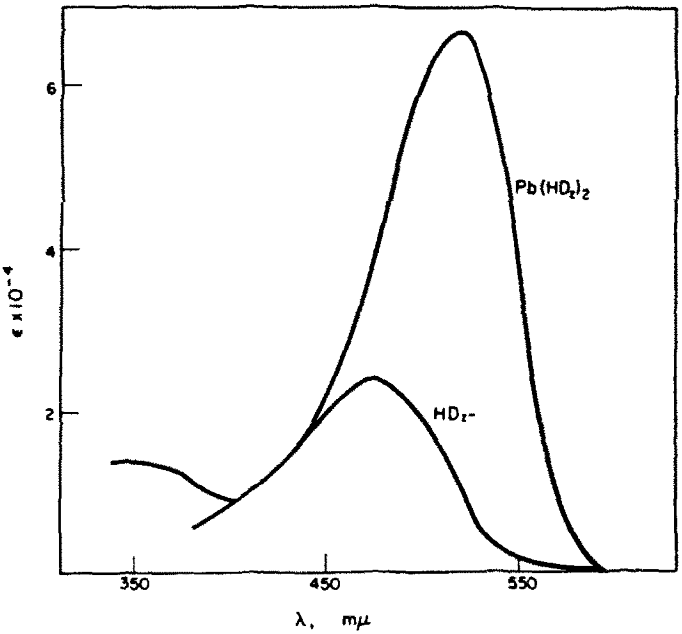

FIG. 1 —Molar absorptivity curves of lead dithizonate, $Pb(HDz)_2$, in carbon tetrachloride, and primary dithizonate ion, HDz^-, in 0·01M sodium hydroxide.

Dilute dithizone solutions prepared from carbon tetrachloride purified in this way show little decomposition in 1 week. For example, a $1{\cdot}29 \times 10^{-5}M$ dithizone solution kept in the dark at 23 ± 3° decreased in strength by about 1·5% after 1 week, as shown by the decrease in absorbance at 620 mμ (Table III).

TABLE III

Time, *days*	A_{450}	A_{510}	A_{620}
0	0·256	0·066	0·422
1	0·256	0·065	0·419
3	0·258	0·066	0·423
7	0·259	0·067	0·416

Used carbon tetrachloride was reclaimed by shaking with concentrated sulphuric acid, in portions one-tenth the volume of the carbon tetrachloride, until the acid remained colourless; washing with water and 1% sodium hydroxide; drying with Drierite and distilling from calcium oxide. Carbon tetrachloride reclaimed five times was used to prepare a $1{\cdot}99 \times 10^{-5}M$ dithizone solution, which after 10 days at room temperature in the dark gave a decrease of only *ca.* 1% in absorbance at 620 mμ.

Analytical-grade carbon tetrachloride which was not purified gives unstable dithizone solutions. "Analysed" carbon tetrachloride from two U.S. manufacturers gave *ca.* $5 \times 10^{-5}M$ dithizone solutions whose absorbance at 620 mμ decreased 14 and 41%, respectively after 10 days at room temperature in the dark.

EQUILIBRIA IN THE LEAD-DITHIZONE-WATER-CARBON TETRACHLORIDE SYSTEM

The equilibrium constant for the extraction reaction

$$Pb^{2+} + \underset{o}{2H_2Dz} \rightleftharpoons \underset{o}{Pb(HDz)_2} + 2H^+$$

(o = organic, *i.e.*, carbon tetrachloride, phase) is the *extraction constant* (at a specified ionic strength)

$$K_{ex} = \frac{[Pb(HDz)_2]_o(aH^+)^2}{[Pb^{2+}][H_2Dz]_o^2} \tag{1}$$

If the only lead species in the system are Pb^{2+} and $[Pb(HDz)_2]_o$, the *extraction coefficient*, the ratio of concentrations of lead in the organic and aqueous phases, is given by

$$E = \frac{[Pb(HDz)_2]_o}{[Pb^{2+}]} = K_{ex}\frac{[H_2Dz]_o^2}{(aH^+)^2} \tag{2}$$

In practice, other lead species will be present in the aqueous phase, so that

$$E = \frac{[Pb(HDz)_2]_o}{\Sigma[Pb]} \tag{3}$$

The equilibrium constants involving these species, relating their concentrations to $[Pb^{2+}]$, must then be known before E can be calculated as a function of $[H_2Dz]_o$ and aH^+. The possible presence of the following in the aqueous phase must be considered·

1. Hydroxo-lead species [$PbOH^+$, $Pb(OH)_2$, *etc.*],
2. Dithizone-lead species [$PbHDz^+$, $Pb(HDz)_2$],
3. Lead complexes with anions (cyanide, citrate, *etc.*).

The equilibrium constants for these species will be symbolised and defined as follows:

$$k_1 = \frac{[PbOH^+](aH^+)}{[Pb^{2+}]} \tag{4a}$$

$$k_2 = \frac{[Pb(OH)_2](aH^+)^2}{[Pb^{2+}]} \tag{4b}$$

$$k_3 = \frac{[HPbO_2^-](aH^+)}{[Pb^{2+}]} \tag{4c}$$

$$k_{d1} = \frac{[PbHDz^+]}{[Pb^{2+}][HDz^-]} \tag{4d}$$

$$k_{d2} = \frac{[Pb(HDz)_2]}{[Pb^{2+}][HDz^-]^2} \tag{4e}$$

$$k_{x1} = \frac{[PbX^+]}{[Pb^{2+}][X^-]} \tag{4f}$$

$$k_{x2} = \frac{[PbX_2]}{[Pb^{2+}][X^-]^2}, \text{ etc.} \tag{4g}$$

X represents a singly (or doubly) charged complexing anion. The values of the constants hold for a specified ionic strength.

The total concentration of lead in the aqueous phase is

$$\Sigma[\mathrm{Pb}] = [\mathrm{Pb}^{2+}] + [\mathrm{PbOH}^+] + \dots [\mathrm{PbHDz}^-] + \dots + [\mathrm{PbX}^+] + \dots$$

$$= [\mathrm{Pb}^{2+}] \times \left(1 + \frac{k_1}{aH^+} + \dots\ k_{d1}[\mathrm{HDz}^-] + \dots k_{x1}[\mathrm{X}^-] + \dots\right) \qquad (5)$$

and

$$[\mathrm{Pb}^{2+}] = \frac{\Sigma[\mathrm{Pb}]}{\left(1 + \frac{k_1}{aH^+} + \dots k_{d1}[\mathrm{HDz}^-] + \dots k_{x1}[\mathrm{X}^-] + \dots\right)} \qquad (6)$$

Substitution of (6) into (1) and rearrangement give

$$E = \frac{K_{ex}[\mathrm{H_2Dz}]_0^2}{(aH^+)^2\left\{1 + \frac{k_1}{aH^+} + \dots k_{d1}[\mathrm{HDz}^-] + \dots k_{x1}[\mathrm{X}^-] + \dots\right\}} \qquad (7)$$

or

$$E = \frac{K_{ex}[\mathrm{H_2Dz}]_0^2}{(aH^+)^2 + k_1(aH^+) + k_2 + \frac{k_3}{(aH^+)} + k_{d1}(aH^+)^2[\mathrm{HDz}^-] + \dots k_{x1}(aH^+)^2[\mathrm{X}^-] + \dots}$$

If O = original concentration of H_2Dz in carbon tetrachloride and phase volumes are equal: $[\mathrm{H_2Dz}]_0 = \frac{7 \times 10^8(aH^+)O}{1 + 7 \times 10^8(aH^+)}$. E should be independent of the lead concentration. It has been assumed that there is no polymerisation of any lead or dithizone species in either phase. Moreover, it has been assumed that no secondary lead dithizonate, PbDz, is formed. There is no experimental evidence to the contrary.

Except when otherwise noted, the constants reported in this paper refer to an ionic strength of 0·1*M* and a temperature of 25 ± 1°. The following values for the hydrolysis constants of lead ion, calculated to $\mu = 0{\cdot}1$, have been used:

$$k_1 = 3 \times 10^{-7}, \qquad k_2 = 3 \times 10^{-18}, \qquad k_3 = 7 \times 10^{-29}.$$

The values of k_1 and k_2 are based on the constants reported by Garrett *et al.*[2] and that of k_3 is derived from the dithizone extractability of lead in alkaline solutions as discussed later. The following activity coefficients have been used for $\mu = 0{\cdot}1$:

$$\gamma_{\mathrm{Pb}^{2+}} = 0{\cdot}37, \qquad \gamma_{\mathrm{PbOH}^+} = 0{\cdot}79, \qquad \gamma_{\mathrm{HPbO_2}^-} = 0{\cdot}80.$$

Solubility of lead dithizonate in carbon tetrachloride

As usually obtained, solid lead dithizonate has such a small particle size that it shows greater than normal solubility in carbon tetrachloride and even after shaking for 1 day its solubility is slightly greater than the true value. The recrystallisation of the small crystals of lead dithizonate proceeds more rapidly in the presence of an aqueous phase. Therefore, most of the solubility determinations were made by shaking solid lead dithizonate with deoxygenated carbon tetrachloride and an acidic or basic aqueous phase. As originally precipitated in most of these experiments, the lead dithizonate consisted of crystals 2–5 μ in length which grew to larger dimensions (crystal length up to 30 μ) on continued shaking. The rate of attainment of solubility

TABLE IV.—SOLUBILITY OF LEAD DITHIZONATE IN CARBON TETRACHLORIDE AT 25°

Expt. No.	Method	Shaking time, *min*	Solubility, $M \times 10^6$

[a] The first value, $6{\cdot}03 \times 10^{-6}$, has been omitted.

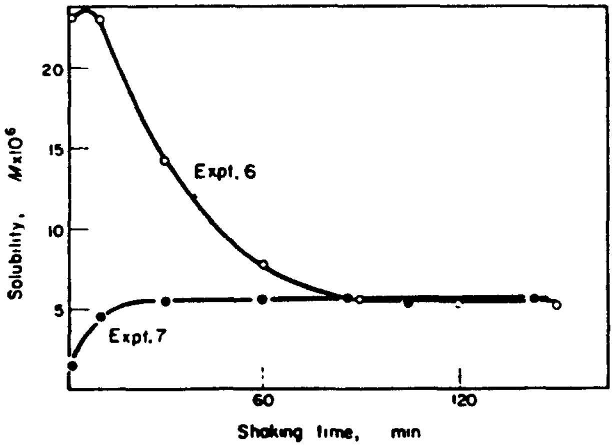

FIG 2.—Solubility of lead dithizonate in carbon tetrachloride (expts. No. 6 and 7, Table IV) at 25°.

equilibrium from supersaturation increases as the pH decreases. Within experimental error, the same solubilities were obtained by approaching equilibrium from supersaturation and undersaturation (Table IV). Fig. 2 illustrates the rate of attainment of equilibrium. Lead was determined spectrophotometrically as dithizonate at pH 10·8 after suitable dilution of the saturated solution.

Extraction constant of lead dithizonate

K_{ex} can be obtained from distribution determinations with aqueous solutions having a pH less than 4 so that the concentration of $PbOH^+$ can be neglected ($[PbOH^+]/[Pb^{2+}] < 0·01$ at $aH^+ = 10^{-4}$). The concentration of $Pb(HDz)_2$ in the aqueous phase can be disregarded under these conditions, and there is no indication that $PbHDz^-$ need be taken into account.

Carbon tetrachloride solutions of dithizone were shaken mechanically for 15 min with perchloric acid-sodium perchlorate solutions of lead at 25 ± 1°. The phases were separated by centrifugation. Dithizone was determined spectrophotometrically in the carbon tetrachloride phase by absorbance measurement at 620 mμ, corrected for $Pb(HDz)_2$. Lead was usually determined in both phases with dithizone at pH 10·8 in the presence of nitrate and cyanide according to the procedure described later. When E was <0·02, lead in the aqueous phase was obtained by difference. The pH of the aqueous phase was determined with a glass electrode (Beckman model G pH meter).

The average of 17 values of K_{ex}, over the pH range 1·5–4·0, is 5·6 ± 0·3 (*ca.* 5% relative standard deviation) (Table V). Least squares treatment of the data gives the same value (Fig. 3). Five determinations of K_{ex} at $\mu = 0·3$ yielded an average of 5·8 ± 0·6. The largest source of error in the measurements is probably the pH determination. A deviation of 0·01 in the pH leads to a deviation of about 5% in K_{ex}. Calculations from the lead-dithizone-carbon tetrachloride data of Babko and Pilipenko[3] give a K_{ex} of 8·9; the ionic strength and composition of their buffer solutions are not specified. Koroleff[4] found K_{ex} = 2·4 at pH 4·1–5·6 in acetate-containing solutions.

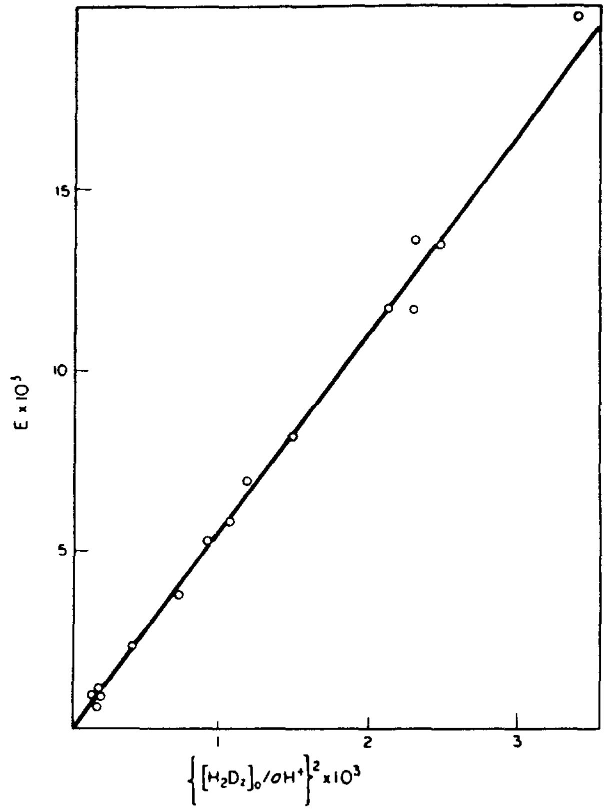

FIG 3.—Extraction coefficient of lead as a function of $\{[H_2Dz]_0/aH^+\}^2$ ($pK_{ex} = -0{\cdot}75$, $K_{ex} = 5{\cdot}6$).

Partition coefficient and water solubility of lead dithizonate

The partition coefficient $\frac{[Pb(HDz)_2]_0}{[Pb(HDz)_2]} = P$, was determined by obtaining the extraction coefficient of lead at pH 3·68–4·86 with the carbon tetrachloride phase saturated with dithizone and lead dithizonate.

Twenty-five ml portions of carbon tetrachloride saturated with dithizone (solid present) were shaken in a nitrogen atmosphere for 3 hr at 25 ± 1° with 200 ml of sodium perchlorate—perchloric acid solutions containing 0·65 ppm of lead ($\mu = 0{\cdot}1$). Lead was determined spectrophotometrically in both phases ($5{\cdot}7 \pm 0{\cdot}2 \times 10^{-6}M$ in carbon tetrachloride). A 10-cm absorption cell was used in determining the lead in the aqueous phase.

The lead species that must be considered in the aqueous phase are Pb^{2+}, $PbHDz^-$ and $Pb(HDz)_2$. From equation (7):

$$\frac{1}{E} = \frac{(aH^+)^2}{K_{ex}[H_2Gz]_0^2}(1 + k_{d1}[HDz^-]) + \frac{1}{P}$$

$\left(\text{because } k_{d2}(aH^+)^2[HDz^-]^2/K_{ex}[H_2Dz]_0^2 = \frac{1}{P}\right)$. If the term $\frac{(aH^+)^2k_{d1}[HDz^-]}{K_{ex}[H_2Dz]_0^2}$ can be neglected, a plot of $\frac{1}{E}$ against $\frac{(aH^+)^2}{[H_2Dz]_0^2}$ should give a straight line of slope K_{ex}. The data obtained seem to fulfill this condition (Fig. 4). The course of 10 of the 11 points can be represented quite well by a line which has a slope of 5·9 (theoretical 5·6). The intercept of the line is $\frac{1}{P} = 5{\cdot}0 \times 10^{-4}$, or $P = 2 \times 10^{3}$.

The value of k_{d1} has not been determined, but it is not likely to exceed 1×10^{7}. With this value of k_{d1} the slope of the plot of $\frac{1}{E}$ against $\frac{(aH^{-})^{2}}{[H_2Dz]_0^{2}}$ would be 4·85, which

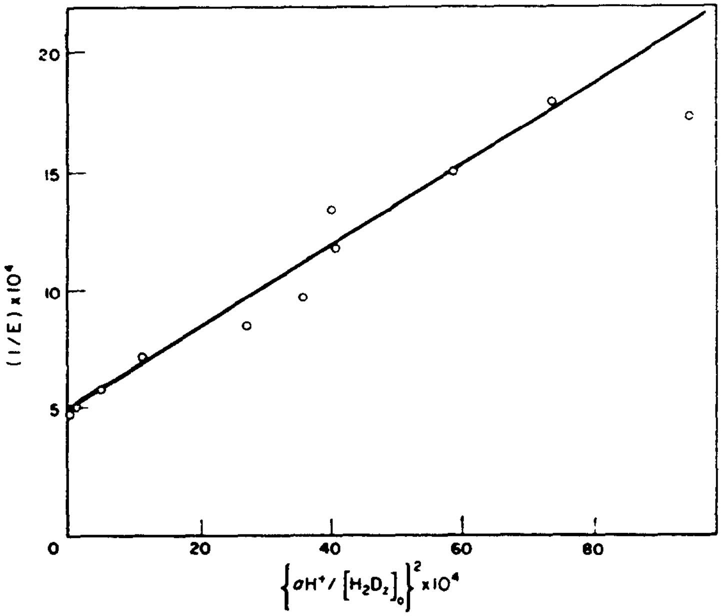

FIG. 4.—Reciprocal of extraction coefficient of lead dithizonate when carbon tetrachloride and aqueous phases are saturated with dithizone and lead dithizonate ($\mu = 0{\cdot}1$, 25°).

differs sufficiently from the slope of the experimental line to make the value implausible. But even if $k_{d1} = 1 \times 10^{7}$, an aqueous solution at pH 4·85 saturated with lead dithizonate and dithizone will be only *ca.* $1 \times 10^{-10}M$ in $PbHDz^{-}$ (and *ca.* $5 \times 10^{-11}M$ in lead ion) compared to *ca.* $3 \times 10^{-9}M$ in lead dithizonate. Thus P would be in error by about 5%, its true value then being $2{\cdot}1 \times 10^{3}$ instead of $2{\cdot}0 \times 10^{3}$ as based on the assumption that all other lead species than $Pb(HDz)_2$ are present in negligible concentrations in this solution. Because of the very low lead concentration in the aqueous phase, the spectrophotometric error in its determination is large, and P may be in error by *ca.* 25%.

From the solubility of lead dithizonate in carbon tetrachloride ($6 \times 10^{-6}M$), the calculated solubility in water (saturated with carbon tetrachloride) is $3 \times 10^{-9}M$.

The dissociation constant of lead dithizonate in water is given by the expression[5]

$$\frac{[Pb^{2+}][HDz^{-}]^{2}}{[Pb(HDz)_2]} = \frac{P_{Pb(HDz)_2}}{K_{ex}}\left(\frac{K_d}{P_d}\right)^{2} = \frac{2 \times 10^{3}}{5{\cdot}6} \times (1{\cdot}4 \times 10^{-9})^{2} = 7 \times 10^{-16}.$$

K_d and P_d are the primary ionisation constant and partition coefficient of dithizone. Because the solubility of lead dithizonate in water (saturated with carbon tetrachloride) is 3×10^{-9}, the solubility product constant of lead dithizonate in water is

$$[Pb^{2+}][HDz^-]^2 = 3 \times 10^{-9} \times 7 \times 10^{-16} = 2 = 10^{-24}.$$

Apparently the only other metal dithizonate whose dissociation constant and solubility product have been determined is primary copper^{II} dithizonate ($K_{diss} = 2 \times 10^{-23}$, $K_{sp} = 2 \times 10^{-31}$).[5] The great difference between the values of K_{ex} for lead and copper (10^{+10}) arises, as would be expected, from the much smaller dissociation constant of copper dithizonate. It may be noted that the solubility product constants of lead and copper dithizonates are much larger than those of the sulphides ($K_{sp\ PbS} = 10^{-27}$, $K_{sp\ CuS} = 10^{-41}$).

Extraction of lead from alkaline solutions

From weakly acidic and weakly basic aqueous solutions the extraction of lead is so complete with even a slight excess of dithizone that the distribution is hardly worth studying. Over a considerable pH range the extraction coefficient of lead is essentially equal to the partition coefficient of molecular lead dithizonate. If a $4 \times 10^{-5}M$ (0·001% w/v) dithizone solution in carbon tetrachloride is shaken with an equal volume of lead solution of such low concentration that the dithizone concentration is not significantly decreased by reaction with lead, the extraction coefficients may be calculated from equation (7), taking P as $2{\cdot}0 \times 10^3$ (Table VI).

TABLE VI

pH	E
6	$1{\cdot}4 \times 10^3$
7	$1{\cdot}9 \times 10^3$
8	$2{\cdot}0 \times 10^3$
9	$2{\cdot}0 \times 10^3$
10	$2{\cdot}0 \times 10^3$
11	$1{\cdot}7 \times 10^3$

From pH 7 to 10, E is essentially the same as P. Above pH 11, the extraction coefficient decreases rapidly because of the formation of biplumbite ion. Determination of the extraction coefficient in an alkaline solution allows the determination of the constant $[HPbO_2^-](aH^+)^3/[Pb^{2+}]$ and a check of equation (7) above pH ~11.

If lead species other than $HPbO_2^-$ can be neglected in the aqueous phase, the extraction coefficient of lead becomes

$$E = \frac{[Pb(HDz)_2]_0}{[HPbO_2^-]} = \frac{K_{ex}[H_2Dz]_0^2(aH^+)}{k_3}$$

$$= \frac{5{\cdot}6 \times (7 \times 10^8)^2[HDz^-]^2(aH^+)^3}{k_3} \text{ (because } [H_2Dz]_0 = 7 \times 10^8(aH^+)[HDz^-])$$

A plot of log E against log $\{(aH^+)^3[HDz^-]^2\}$ should give a straight line having the intercept log $\dfrac{2{\cdot}7 \times 10^{18}}{k_3}$.

Carbon tetrachloride solutions containing dithizone and lead dithizonate ($1{\cdot}5 \times 10^{-5}M$) were shaken under nitrogen with sodium hydroxide—sodium perchlorate solutions (from 0·01 to 0·009M sodium hydroxide, $\mu = 0{\cdot}1$) at 25 ± 1° for 5 min. The phases were separated by centrifugation and the concentration of HDz^- in the aqueous phase was determined by absorbance measurements at 475 mμ ($\varepsilon_{475} = 2{\cdot}40 \pm 0{\cdot}02 \times 10^4$). Lead was determined in the carbon tetrachloride phase by shaking with an aqueous ammonia-cyanide-sulphite mixture of pH 10·8 ($[HDz^-] = 10^{-4}M$) and measuring the absorbance at 520 mμ; it was determined similarly in an aliquot of the aqueous phase after acidifying to 0·16M with hydrochloric acid The pH was determined with an alkaline-range electrode. The values of aH^+ thus obtained agreed within 0·02 with the values calculated from the sodium hydroxide concentration and the activity coefficient $\gamma_{OH} = 0{\cdot}76$

From Table VII and Fig. 4, it is seen that the assumption of the presence of $HPbO_2^-$ as the only significant lead species in the pH range 11·9–12·8 is justified

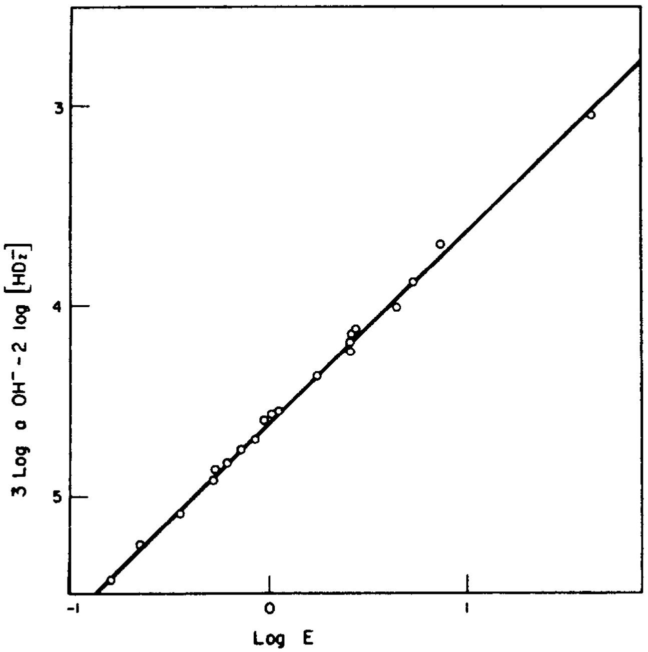

FIG. 5.—Extraction of lead dithizonate from basic solution (E as a function of aOH⁻ and [HDz⁻]).

TABLE VII.—EXTRACTION OF LEAD DITHIZONATE FROM ALKALINE SOLUTION

2	12·73	0·56 – 0·75	4·2
4	12·83	0·17 – 0·89	4·3 ± 0·1
Avg.		(0·17 – 44·5)	4·2 ± 0·3

The value of

$$k_3 = \frac{[\mathrm{HPbO_2^-}](\mathrm{aH^+})^3}{[\mathrm{Pb^{2+}}]}$$

derived from these distribution determinations is 7×10^{-29}. Because the factor 7×10^8 may be in error by *ca.* 7% (1:15), there may be an error of *ca.* 15% in k_3 from this source. The calculated value of $(\mathrm{aHPbO_2^-})(\mathrm{aH^+})^3/(\mathrm{aPb^{2+}})$ is $1{\cdot}5 \times 10^{-28}$, which agrees quite well with the value $1{\cdot}1 \times 10^{-28}$ of Garrett and coworkers.[2]

Extraction of lead dithizonate in the presence of cyanide and citrate

From equation (7), using the complex constant

$$\frac{[\mathrm{Pb(CN)_4^{2-}}]}{[\mathrm{Pb^{2+}}][\mathrm{CN^-}]^4} = 2 \times 10^{10}$$ (Kolthoff and Lingane[6])[*],

we calculate the following approximate values for the extraction coefficient of lead for systems in which the original carbon tetrachloride concentration of dithizone is 0·001% ($4 \times 10^{-5}M$) and 0·0001% ($4 \times 10^{-6}M$) and the phases are equal in volume, in the presence of cyanide (0·1M) and its absence (Table VIII).

TABLE VIII

pH	E			
	$4 \times 10^{-5}M$ $\mathrm{H_2Dz}$		$4 \times 10^{-6}M$ $\mathrm{H_2Dz}$	
	No $\mathrm{CN^-}$	0·1M $\mathrm{CN^-}$	No $\mathrm{CN^-}$	0·1M $\mathrm{CN^-}$
10	2×10^5	$1{\cdot}2 \times 10^5$	$1{\cdot}7 \times 10^3$	29
11	$1{\cdot}9 \times 10^5$	$1{\cdot}0 \times 10^5$	$2{\cdot}9 \times 10^3$	20
12	57	56	0·60	0·58

It has been assumed that the amount of lead present is so small that the dithizone concentration is not altered by reaction. Even at the relatively high concentration of 0·1M, cyanide should hardly affect the extractability of lead if the original dithizone concentration in the carbon tetrachloride is $4 \times 10^{-5}M$ and the phase volumes are the same or nearly so. However, if the original dithizone concentration is reduced ten-fold to $4 \times 10^{-6}M$ (equivalent to reaction of 90% of the dithizone in a $4 \times 10^{-5}M$ dithizone solution with lead), the effect of cyanide becomes marked.

The negligible effect of *ca.* 0·1M cyanide on the extraction of lead at pH 12 was verified experimentally. The distribution of lead between aqueous solutions, which were 0·01M in sodium hydroxide and 0·09M in potassium cyanide, and carbon tetrachloride-dithizone solutions (10^{-5}–$10^{-4}M$) was determined as described under the extraction of lead from alkaline solutions. The distribution was unaffected by the

---

[*] The value of the constant, derived from the half-wave potential of lead in 1M potassium cyanide is approximate and tentative because of the question of the reversibility of the electro-reduction. It seems likely that the constant does not exceed 1×10^{11} (at $\mu = 0{\cdot}1$), for then, contrary to the experimental finding, cyanide would affect the extraction of lead at pH 12.

cyanide. Calculation of

$$\frac{K_{ex} \times (7 \times 10^8)^2}{k_3}\left(= \frac{[Pb(HDz)_2]_0}{[HPbO_2^-][HDz^-]^2(aH^+)^3}\right) \text{ gave the value } 4{\cdot}2 \times 10^{46},$$

the same as the average obtained in the absence of cyanide (Table VII). This agreement also indicates the absence of significant amounts of sulphide in the cyanide used.

The effect of citrate on the extraction of lead dithizonate up to a pH of approximately 8 is in accord with the formation of the complex ion PbCit.$^-$. Kety[7] has already shown that this ion forms in approximately neutral solution (pH 6·95–7·45) and his potentiometric data (corrected for incomplete dissociation of lead nitrate in his reference solution) give the value 1·7 × 10^{-6} for the constant $\{[Pb^{2+}][Cit^{3-}]\}/]PbCit^-]$. Below a pH of 7·5 the formation of this complex impedes the extraction of lead dithizonate (*cf.* Figs. 6 and 7) even when the concentration of dithizone is fairly high (0·001%) and the complex constant can thus be easily determined. Forty extraction coefficients determined in the pH range 4 to 6·8 lead to the value 1·85 × 10^{-6} for the dissociation constant (or 5·4 × 10^5 for $[PbCit^-]/\{[Pb^{2+}][Cit^{3-}]\}$) at $\mu = 0{\cdot}1$. The extractability of lead as a function of the citrate concentration was not studied systematically above pH 7·5, but it was observed that under analytical conditions the extraction of lead is as complete in the presence of citrate (0·01*M*) as in its absence (Figs. 6 and 7). There is considerable disagreement concerning the composition of the lead citrate complexes. According to Tikhonov,[10] $Pb(C_6H_5O_7)_2^{4-}$ is formed at pH 6–8 and $PbOH(C_6H_5O_7)^{2-}$ at pH 9–13. The formation of $Pb(C_6H_5O_7)_2^{4-}$ in approximately neutral solutions is not supported by the lead extraction data.

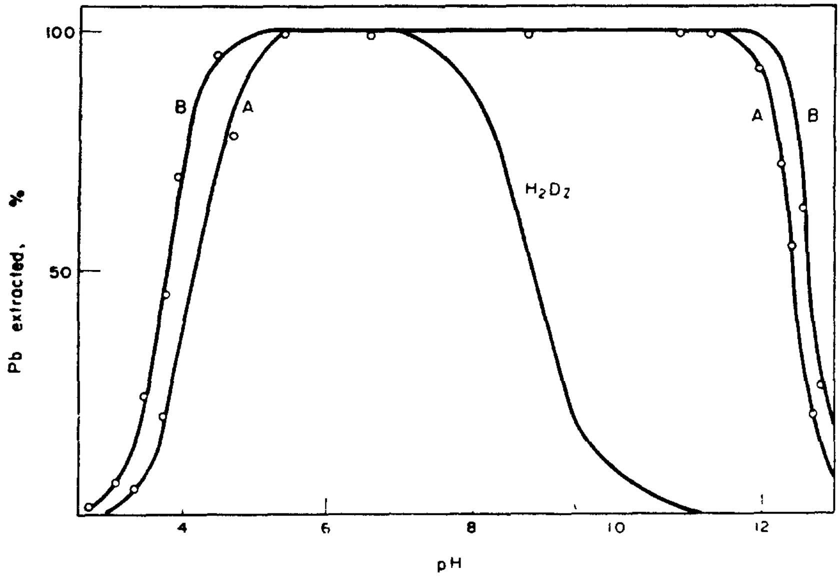

FIG 6 —Extraction of lead dithizonate and dithizone from sodium perchlorate solution The solid curves are the calculated curves for the extraction of lead (0 0625 mg in 25 ml aqueous solution, μ = 0 1) with 25 ml of 0 001% (w/v) dithizone in carbon tetrachloride (A), and with 25 ml of 0·002% (w/v) dithizone (B) The circles represent experimental values The extraction curve for dithizone ($_2$Dz) is calculated

Vouk and Weber[11] studied the extraction of lead dithizonate at pH 5–11 in the presence of citrate and cyanide with more dilute dithizone solutions than used in the present work. Decreasing extraction of lead from *ca.* 0·1*M* citrate solution was noted above a pH of about 8. (These authors obtained low and inconstant values for K_{ex} because they did not take into account the concentration of the lead citrate and cyanide complexes in the aqueous phase when formulating the expression for K_{ex}.)

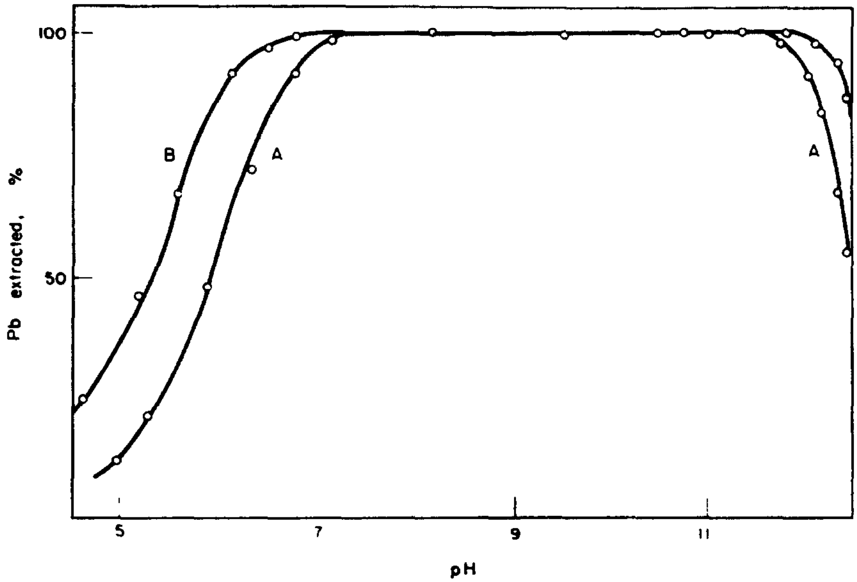

FIG. 7.—Extraction of lead dithizonate from sodium citrate-potassium cyanide solutions The solid curves are those calculated for the extraction of lead (0·0625 mg in 25 ml of aqueous solution, 0·01*M* in sodium citrate and 0·02*M* in potassium cyanide, $\mu = 0{\cdot}1$) with 25 ml of 0·001% (w/v) dithizone in carbon tetrachloride (A), and with 25 ml of 0·002% (w/v) dithizone (B). The circles represent experimental values

A few runs were made in the present work to test the effect of nitrate on the lead extraction. From 4 determinations of the extraction coefficient of lead at pH 3·0–3·5, with $[NO_3^-] = 0{\cdot}08$ and $\mu = 0{\cdot}1$, the average value 0·11 was obtained for $[Pb^{2+}] \times [NO_3^-]/[PbNO_3^+]$. Under analytical conditions the effect of nitrate is negligible.

ANALYTICAL CONSIDERATIONS

The spectrophotometric determination of trace amounts of lead usually involves two steps: first, the isolation and separation of lead by dithizone extraction from a basic citrate-cyanide solution, followed by the transfer of the lead to aqueous solution by shaking the carbon tetrachloride (or chloroform) phase with dilute acid; second, the determination proper, in which the aqueous phase is brought to a fixed, appropriate pH and lead is extracted with a standard dithizone solution and the absorbance of the organic phase is measured at a suitable wavelength. The final extraction is also made from a citrate-cyanide medium so that any small amounts of metals escaping separation in the first step will be inactivated. Sometimes sulphite is added to the aqueous solution to provide a reducing environment and lessen the possibility of oxidation of dithizone. Detailed directions for the procedure are available[12] and will not be repeated here We shall examine the effect of some factors in the procedure on the basis of the equilibria which have been discussed in a general way, beginning with the determination of lead after separation.

Determination of lead

The use of a carbon tetrachloride solution of dithizone allows spectrophotometric determination of lead by a mono colour method at a pH of approximately 11. At and near this pH, lead is virtually completely extracted into the carbon tetrachloride phase with a relatively slight excess of dithizone, whereas the latter is almost completely transferred to the aqueous phase. Other factors being the same, such a method for lead will be preferred to one in which some of the excess dithizone remains in the immiscible organic solvent, because the latter method will require a closer control of the pH and the concentration of the standard dithizone solution.

The theoretical extraction curves of lead—which are also the actual extraction curves—as a function of the pH are shown in Figs. 6 and 7, the former for a perchlorate solution, the latter for a citrate-cyanide solution. With equal volumes of aqueous and carbon tetrachloride phases initially containing, respectively, 2·5 ppm of lead ($1{\cdot}2 \times 10^{-5}M$) and 10 ppm (w/v) dithizone ($4 \times 10^{-5}M$), the calculated pH range for virtually complete (*ca.* 99%) lead extraction from $0{\cdot}01M$ sodium citrate —$0{\cdot}02M$ potassium cyanide is 7·5–11·5. The experimental and calculated values agree very well. The minimum pH for removal of 99% of the excess dithizone from the carbon tetrachloride phase is, from the relation

$$\frac{[\mathrm{HDz}^-]}{[\mathrm{H_2Dz}]_0} = \frac{1{\cdot}4 \times 10^{-9}}{\mathrm{aH}^+},$$

equal to 10·85. The pH range for a mono colour method with carbon tetrachloride as solvent is accordingly approximately 10·8–11·5. In practice one may aim for a pH of 10·8–10·9 to keep safely away from the sharp drop in extractability occurring above pH 11·5. The molar absorptivity of dithizone in carbon tetrachloride is only about 0·07 of that of lead dithizonate at 520 mμ, so that if a few per cent of the excess dithizone remains in the carbon tetrachloride little error results. The error incurred by a 0·2 unit departure from pH 10·8 can almost always be disregarded. Even if the standard curve is established at pH 10·6 and the determination is made at pH 11·0 with 0·001% dithizone, the error would be difficult to detect *ca.* 1% for 5 μg of lead and less for larger amounts of lead.

Because of the limited solubility of lead dithizonate in carbon tetrachloride, the amount of lead in the sample solution should preferably be such that the concentration of lead does not exceed 1·2 μg/ml in the carbon tetrachloride phase. Supersaturated solutions of twice, or even thrice, this concentration are, however, sufficiently stable to allow their use in the spectrophotometric lead determination. Because a carbon tetrachloride solution of lead dithizonate corresponding to 1 μg of lead/ml shows an absorbance of 0·32 at 520 mμ in a 1-cm cell, the concentration limit imposed by solubility does not limit the precision.

The accuracy attainable in the spectrophotometric determination of lead according to the recommended procedure[12] outlined is illustrated in Fig. 8. The accuracy of the reversion method (Irving and Butler[13]) is also represented. The two methods appear to be of comparable accuracy. By the use of a 10-cm cell (25 ml of carbon tetrachloride phase), 1 μg of lead can usually be determined to within 2%. With 5 μg of lead in 10 ml of carbon tetrachloride, the same accuracy is attainable in a 1-cm cell. By reducing the dithizone volume to 5 ml, similar accuracy should be attainable with 2–3 μg of lead

Carbon tetrachloride is superior to chloroform as a solvent in a mono colour method for lead, because the pH required to transfer 99% of the dithizone from chloroform into an equal volume of aqueous phase is *ca.* 12·5, which is in the range where biplumbite is formed to a considerable extent and *ca.* 10% of the lead is unextracted when a 0·001% dithizone solution is used.

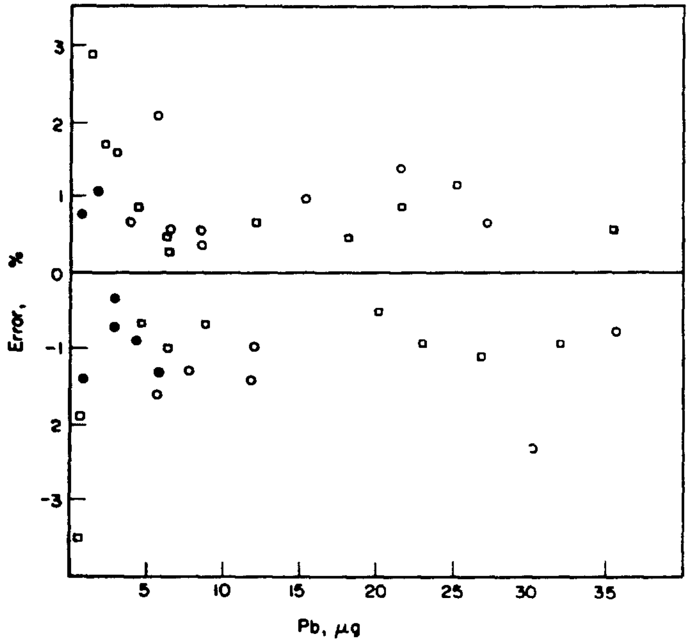

FIG. 8.—Accuracy of determination of lead by mono-colour dithizone method:
○—10 ml of aqueous phase, pH 10·8; 10 ml of 0·001 % dithizone in CCl_4; 1-cm cell, 520 mμ;
●—10 ml of aqueous phase, pH 10·8, 25 ml of 0·001 % dithizone in CCl_4; 10-cm cell, 520 mμ;
□—Reversion method: 10 of ml aqueous phase, pH 10·8; 25 ml of 0·001 % dithizone; reverted with 10 ml of 0·16*M* HNO_3; 1-cm cell (10-cm cell below 8 μg of Pb), 620 mμ.

Separation of lead

The separatory extraction with dithizone in carbon tetrachloride is usually carried out at pH 9–9·5 from an aqueous solution approximately 0·5*M* in citrate and 0·2*M* in cyanide. For a rough calculation of the lead extraction coefficient under these conditions we will use the equilibrium constants valid for an ionic strength of 0·1 and assume that $PbCit^-$ is the principal lead citrate species at pH 9. If the phases are equal in volume and the original concentration of dithizone in the carbon tetrachloride is 0·005% ($2 \times 10^{-4} M$), the extraction coefficient is

$$E = \frac{3{\cdot}8 \times 10^{-6}}{\underset{Pb^{2+}}{10^{-18}} + \underset{PbOH^{+}}{3 \times 10^{-16}} + \underset{Pb(OH)_2}{3 \times 10^{-18}} + \underset{HPbO_2^{-}}{7 \times 10^{-20}} + \underset{Pb(HDz)_2}{1{\cdot}9 \times 10^{-11}} + \underset{(PbCit^{-})}{3 \times 10^{-13}} + \underset{(PbCN)_4^{2-}}{8 \times 10^{-13}}}$$

$$= 1{\cdot}9 \quad 10^{3}$$

(The amount of lead present is taken to be so small that the concentration of dithizone is not significantly decreased.) The greater part of the lead in the aqueous phase is present as $Pb(HDz)_2$, so that the extraction coefficient is almost the same as the partition coefficient of lead dithizonate. Even when, as in practice, the volume of the carbon tetrachloride phase is 1/5–1/10 that of the aqueous phase, the recovery of lead should be satisfactory. Besides, a second extraction with a fresh portion of dithizone is always made so that there seems to be little likelihood of significant lead loss in the separation step, barring the formation of precipitates, such as calcium phosphate, which can carry down lead. A similar calculation for pH 10 gives $E = 1{\cdot}0 \times 10^{3}$, the lower value being from a smaller fraction of the cyanide being present as HCN at this pH. Because the dithizone extraction constants and the cyanide complex constants of a considerable number of metals are known, the extent of extraction of foreign metals from a cyanide medium can be calculated approximately when required.

The effect of sulphide, which appears to be a not uncommon impurity in alkali cyanides, on the extraction of lead cannot be precisely predicted because of incomplete knowledge of the Pb^{2+}—HS^{-}—S^{2-} system. However, on the assumption that Pb^{2+} is removed only as PbS, it can be demonstrated that very low concentrations of sulphide can have a serious effect on the dithizone extraction of lead. Taking K_{sp} of PbS as 10^{-27}, we obtain the following expression for the concentration of lead dithizonate in the carbon tetrachloride phase at pH 9 when solid lead sulphide is formed

$$[Pb(HDz)_2]_0 = \frac{(\Sigma[Pb] - \Sigma[S]) \pm \{(\Sigma[Pb]^{-} - \Sigma[S])^{2} + 4 \times 5{\cdot}6 \times 10^{-5}[H_2Dz]_0^{2}\}^{1/2}}{2}.$$

where $\Sigma[Pb] = [Pb(HDz)_2]_0 + ,q_{PbS}$ the latter term being the quantity of lead sulphide in moles obtained from 1 litre of aqueous lead solution, lead species in the aqueous phase being considered negligible in concentration compared to lead in the carbon tetrachloride phase; and $\Sigma[S] = [HS^{-}] + q_{PbS}$ (at pH 9, $[S^{=}] = 10^{-4}[HS^{-}]$). $\Sigma[Pb]$ and $\Sigma[S]$ are thus the initial molar concentrations of lead and sulphide (including HS^{-}) in the aqueous phase. The two phases are assumed to have the same volume. For example, if the initial dithizone concentration in carbon tetrachloride is $2{\cdot}0 \times 10^{-4} M$, $\Sigma[Pb] = 1{\cdot}0 \times 10^{-6} M$ and $\Sigma[S] = 6 \times 10^{-7}$ (corresponding to 19 μg ΣS per litre), $[Pb(HDz)_2]_0$ at pH 9 is calculated to be $8{\cdot}4 \times 10^{-7} M$ instead of $1{\cdot}0 \times 10^{-6}$ in the absence of sulphide. This illustration is given merely to show the possibility of serious interference by small amounts of sulphide. As long as the concentration of Pb^{2+} in the aqueous phase, in equilibrium with lead dithizonate in the carbon tetrachloride phase, is not great enough to cause the solubility product of lead sulphide to be exceeded, sulphide should have no effect on the extraction, provided other lead-sulphide species do not exist in the aqueous phase. But to assume that this is true would be naive.

THE ANODIC AMPEROMETRIC TITRATION OF LOW CONCENTRATIONS OF NITRITE WITH SULPHAMIC ACID OR CERIUM^{IV} ION*

JOHN T. STOCK and R. G BJORK
Department of Chemistry, University of Connecticut, Storrs, Connecticut, U.S.A.

(*Received* 19 *June* 1963. *Accepted* 4 *October* 1963)

Summary—Nitrite at a concentration of approximately $6 \times 10^{-4}M$ in $0{\cdot}05M$ sulphuric acid can be titrated amperometrically at a rotating platinum micro-anode with sulphamic acid or cerium^{IV} ion Results with sulphamic acid are free from bias and have a standard deviation of about 1%. Titration with cerium^{IV} is less precise, giving results that are high or low according to the method used for end-point location, but is applicable to lower nitrite concentrations than is titration with sulphamic acid.

STOCK and BJORK[1] found that low concentrations of nitrite in acid media can be titrated amperometrically with potassium permanganate solution at a rotating platinum micro-anode. This titrant is not electroactive at potentials from $+1{\cdot}05$ to $+1{\cdot}10$ V with reference to a saturated calomel electrode (S.C.E.), but nitrite under these conditions yields an oxidation limiting current that is proportional to the concentration of nitrite.[2] A titration curve of "L" type is therefore obtained. The present work concerns the application of sulphamic acid and cerium^{IV} ion as alternatives to permanganate in the titration of nitrite by this method.

Hirozawa and Brasted[3] have demonstrated that amperometric titration with sodium nitrite solution at a dropping mercury cathode permits the determination of sulphamic acid in concentrations from 4×10^{-4} to $5 \times 10^{-3}M$. These workers used a hydrochloric acid-potassium chloride supporting solution that contained a low concentration of uranyl ion. In the presence of this ion, nitrite gives a well-defined reduction wave; the limiting current measured at a potential of $-1{\cdot}2$ V *vs.* S.C.E. is proportional to the concentration of nitrite. Sulphamic acid is not reduced under these conditions, so that the titration curve is of "reversed-L" form.

Kolthoff, Harris, and Matsuyama[4] discovered that the simultaneous reduction of uranyl ion catalyses the reduction of nitrate ion at a dropping mercury electrode. Keilin and Otvos[5] found that nitrite in acid solution yields the same reduction wave as nitrate in the presence of uranyl ion. Any appreciable concentration of nitrate that is introduced into the supporting solution used for the amperometric titration of sulphamic acid by Hirozawa and Brasted's method therefore gives a high background current and hence poor end-point discrimination. Hirozawa and Brasted found that the presence of nitrate in the titrant solution gives a positive slope to the pre-equivalence portion of the titration curve and causes low results. The error is tolerable only if the nitrate : nitrite molar ratio does not exceed 2 : 100. Interference is, of course, caused by phosphate and other substances that precipitate uranyl

* Taken largely from the thesis submitted by Robert Gesler Bjork in partial fulfilment of the requirements for the M.S. degree.

ion. Because the presence of uranyl ion is not required when changes in the concentration of nitrite are measured in terms of its *oxidation* limiting current, it should be possible to perform nitrite-sulphamic acid titrations at a rotating platinum anode without interference by nitrate or phosphate.

EXPERIMENTAL

Apparatus

Amperometric titration assembly Titrations were performed in a 100-ml tall-form beaker. This was closed with a cover that carried the nitrogen dispersal tube and the junction tube that accommodated the salt bridge of a large saturated calomel electrode. Holes in the cover were provided for the insertion of the rotating platinum electrode and the jet of the Gilmont 1-ml microburette; these holes were large enough to allow free escape of nitrogen. Except when current readings were taken, the solution in the beaker was stirred at a steady rate of about 200 rpm by means of a small glass-covered magnetic stirrer bar.

Rotated at 600 rpm by a Sargent Synchronous Rotator, the platinum wire micro electrode gave an average current of 14·8 μA in $2 \times 10^{-4}M$ nitrite in deoxygenated 0·05M sulphuric acid, when maintained at a potential of +1·05 V *vs.* S.C.E. The actual sensitivity was poorly reproducible and sensitive to electrode pretreatment However, changes in sensitivity that occurred from run to run did not affect the linearity of the current-to-nitrite concentration relationship within a given run The electrical equipment was similar to that used previously,[6] a shunt-equipped Cambridge Spot galvanometer of maximum sensitivity 170 mm per μA was used to measure the current.

Reagents

Sodium nitrite solution: Prepare an approximately 0·1M solution and standardise against permanganate solution by thiosulphate titration of iodine liberated by the excess of permanganate.[7] This method was used to permit the direct comparison of the results of the present work with those obtained in the amperometric titration of nitrite with permanganate.[1]

Standard (approximately 0·1M*) sulphamic acid solution:* Prepare by the direct weighing of the recrystallised and dried analytical-grade reagent.[8]

Cerium^{IV} *ammonium sulphate solution*· Prepare an approximately 0·1M solution in 3% (v/v) sulphuric acid and standardise against arsenious oxide [8]

Osmium catalyst solution Prepare approximately 0·01M osmium tetroxide in 0·05M sulphuric acid.

Anodic voltammetry of sulphamic acid

The current-voltage curve of $1 \times 10^{-3}M$ sulphamic acid in 0·05M sulphuric acid at a rotating platinum anode was found to be essentially the same as that of 0·05M sulphuric acid alone.

Pretreatment of the platinum electrode

Store the platinum electrode in approximately 10M nitric acid. Before use, rotate in deoxygenated 0·1M perchloric acid and maintain at zero potential (*i.e.*, short-circuit to the S.C.E.) until the current becomes very small [9] Rinse well and prepolarise for 10 min at the chosen potential in a solution of composition similar to that to be titrated

Titration of nitrite with sulphamic acid

Place 50 ml of 0·05M sulphuric acid in the titration apparatus and deoxygenate with a stream of nitrogen, this step improves the precision of the titration. Stop the gas stream and introduce the nitrite solution from a microburette until the concentration is about $5 \times 10^{-4}M$. Titrate immediately with small increments of 0·1M sulphamic acid at a potential of +1·05 V *vs.* S.C.E. (or at +1·10 V if the nitrite concentration is greater than about $6 \times 10^{-4}M$). Take current readings 15–20 sec after each titrant addition Temporarily increase the interval to about 40 sec when near the end-point

Titration of nitrite with cerium^{IV} *ion*

Proceed as described for the titration with sulphamic acid, but add 3 drops of osmium catalyst before titrating with 0·1M cerium^{IV} solution

RESULTS AND DISCUSSION

Titration with sulphamic acid

Well-defined linear L-shaped titration curves were obtained at nitrite concentrations that were not less than $6 \times 10^{-4}M$. The descending arm of the curve became very slightly bowed when the nitrite concentration was lowered to 4 × $10^{-4}M$. This malformation increased as the initial nitrite concentration was lowered further, and became excessive when the titration of 1 × $10^{-4}M$ of nitrite was attempted. Results for sets of six replicate titrations of nitrite are given in Table I. In the concentration range 6 × 10^{-4} to 1 × $10^{-3}M$ of nitrite, the standard deviations are a little larger than those obtained with permanganate as the titrant.[1] Permanganate, but not sulphamic acid, can be used to titrate nitrite at a concentration as small as 5 × $10^{-5}M$. These effects are almost certainly caused by differing speeds of reaction; the titration of a given concentration of nitrite can be performed considerably more rapidly with permanganate than with sulphamic acid.

TABLE I.—TITRATION WITH 0·0995*M* SULPHAMIC ACID

Nitrite in 50 ml of 0·05*M* sulphuric acid Six titrations at each concentration of nitrite.

Nitrite concn., × 10^4M	Potential, *V*	Average error, %	Standard deviation, %
10·00	+1·10	0·0	0·9
8·00	+1·10	0·0	1·0
6·00	+1·05	0·0	0·9
4·00	+1·05	−2·5	2·4

Low results, obtained when permanganate is the titrant and attributed to the instability of nitrite in acid solution,[1] were generally absent in titrations with sulphamic acid. The absence of bias in most of the results given in Table I probably arises from the fortunate compensation of the negative error through loss of nitrous acid by positive errors arising from the non-stoichiometry of the reaction

$$HNO_2 + H_2NSO_3H \rightarrow H_2SO_4 + N_2 + H_2O$$

and the effects of the oxides of nitrogen that are produced in side reactions.[10]

The titration of 1 × $10^{-3}M$ nitrite in 0·05*M* sulphuric acid-0·1*M* potassium nitrate or 0·05*M* sulphuric acid-0·1*M* phosphoric acid gave results that were within one standard deviation of those given in Table I. There is thus no evidence of interference by massive amounts of nitrate or phosphate ion.

Titration with cerium^{IV} ion

The titrations were all performed at a potential of +1·05 V *vs.* S.C.E. The results exhibited somewhat larger standard deviations than those obtained in the titration of nitrite with permanganate or sulphamic acid. As indicated in Fig. 1, the excess titrant line (which is horizontal in titrations with permanganate or sulphamic acid) has a definite negative slope. An inspection of the current-voltage curves at a rotating platinum electrode of the cerium^{IV}–cerium^{III} couple in sulphuric acid medium[11] suggests this type of behaviour. Positive errors were obtained when the end-point was located by the usual extrapolation of the linear portions of the branches of the titration curve (construction A). An alternative method of location (construction B) shown in Fig. 1 is to produce the descending branch of the titration curve to cut the residual current line (*i.e.*, the horizontal line drawn through the current reading

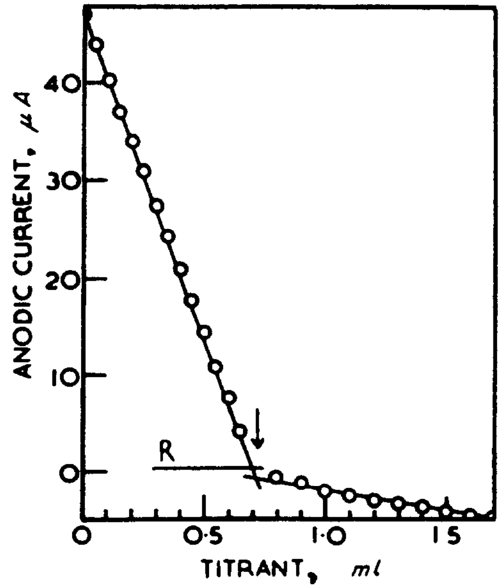

FIG 1 —Titration of 50 ml of 6 00 × $10^{-4}M$ nitrite with 0 0820M cerium^{IV}
The arrow indicates the stoichiometric end-point
R is the residual current line

TABLE II —TITRATION WITH 0·820M CERIUM^{IV}

Nitrite in 50 ml of 0 05M sulphuric acid Applied potential, +1 05 V *vs* S C.E. Six titrations at each concentration of nitrite

Nitrite concn, × 10^5M	Construction A		Construction B	
	Average error, %	Standard deviation, %	Average error, %	Standard deviation, %
60 0	−1 4	1 4	−1 9	2 4
40 0	−0 2	0 8	−2 6	3·1
20 0	+2 9	2 6	−2 5	3·0
10 00	−0 8	5 2	−3 3	2·4
8·00	−2 6	2 5	−0 9	1·9
6 00	−5 5	2 4	−0 4	2·7
4 00	−5 7	5 0	−5 2	4 1

obtained in the absence of both nitrite and titrant). The two constructions give results that are comparable in over-all precision and accuracy (Table II). However, neither set of results is free from bias; the over-all average errors for 42 titrations of nitrite in the concentration range 4 × 10^{-5} to 6 × $10^{-4}M$ were +2·7 and −2·4% for constructions A and B, respectively.

From the practical point of view, the negative bias of the results obtained by use of construction B is in line with the known instability of nitrite in acid solution. Readings beyond the end-point are not utilised, so that the determination is expedited. However, the residual current must be frequently checked.

Acknowledgement—This work was carried out with the partial support of the U.S Atomic Energy Commission

Zusammenfassung—Nitrit kann in einer Konzentration um 6 10^{-4} m in 0,05 m Schwefelsäure amperometrisch an einer rotierenden Platinmikroanode mit Amidosulfonsaure oder Cer(IV) titriert werden. Die Ergebnisse mit Amidosulfonsaure sind frei von systematischen Abweichungen und haben eine Standardabweichung von etwa 1% Die Titration mit Cer(IV) ist weniger genau, gibt je nach der Endpunktsbestimmung zu hohe oder zu niedrige Ergebnisse, aber sie ist bei niedrigeren Nitritkonzentrationen anwendbar als die Titration mit Amidosulfonsaure.

Résumé—On peut titrer ampérométriquement les nitrites, à une concentration d'environ 6 × 10^{-4} M, en acide sulfurique 0,05 M, avec l'acide sulfamique ou l'ion cérium (IV), au moyen d'une microanode rotative en platine. Les résultats obtenus avec l'acide sulfamique sont exempts de divergences, et présentent un écart type d'environ 1%. Le dosage au cérium (IV) est moins précis, et donne des résultats trop élevés ou trop faibles selon la méthode employée pour déterminer le point final, mais il est applicable à des concentrations en nitrite inférieures à celles qu'autorise le dosage à l'acide sulfamique

Summary—The effect of contamination of a mercury surface by camphor and thymol on the standard rate constant of the titanium^{IV}–titanium^{III} half reaction in 1*M* tartaric acid has been determined by means of voltage-step and impedance methods. Complications arising from specific adsorption of the electronegative species proved more disturbing to the impedance method than to the voltage-step method. A linear decrease of rate constant with surface coverage is indicated.

IT has long been known that adsorption of many surface active substances can affect an electrochemical reaction. The various important features of this problem have already been reviewed by several authors.[1-4] In this work the effect of camphor and thymol, substances of different surface active characteristics, on the Ti^{IV}/Ti^{III} redox reaction has been investigated by measuring the standard rate constants of the reaction in the presence of these surfactants. It was desired to compare the voltage-step method with the impedance method to obtain the rate constant of the reaction.

The electroactive species employed were chosen so that the redox potential of the couple was located as close to the electro-capillary maximum (e.c.m.) potential as possible. No surface-active anion was included in the supporting electrolyte. In such circumstances perturbation of the double layer charge can be neglected. The potential of maximum adsorption can generally be expected to be located close to the e.c.m. potential of the system. However, such a condition has not been fully satisfied by the systems employed. Hence, the electrode coverage was calculated from differential and integral capacity and used for the interpretation of the observations.

EXPERIMENTAL

Apparatus

Cell· The cell was essentially a 100-ml lipless beaker with a rubber stopper which had been bored with a variety of holes to admit a dropping mercury electrode, a stirring rod, a gas disperser, a porous Vycor tube and a glass-frit tube. The cell solution was electrically connected to the S.C.E through an agar bridge inserted into a glass-frit tube.

Dropping mercury electrode (*d.m.e.*): Because it was essential for the voltage-step method to keep the total resistance of the cell circuit as low as possible, a low resistance d.m.e. was employed A piece of glass tubing was sealed to 0·04-mm i.d. marine barometer tubing, then drawn out and cut to give a fine tip at one end. Contact was made through a platinum wire sealed into a portion of large bore. The electrical resistance of this type of electrode was in the range of 1·0 to 1 5 Ω.

A sufficiently long life of each mercury drop and small "m" value as well as a fine tipped capillary[5]

---

* Present address: Department of Physics and Chemistry, Gakushuin University, Toshima-ku, Tokyo, Japan.

† Present address. Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo, Japan.

were required to allow the impedance measurements to be carried out satisfactorily A capillary tube with a pointed tip to meet these requirements was made by stretching under heat an ordinary commercial polarographic capillary and cutting so as to provide a sharp end The "m" value was $1{\cdot}880 \times 10^{-4}$ g/sec at the mercury head of 70 cm, and the drop life was long enough for the experimental use.

Voltage-step apparatus: The electrical circuit and apparatus were quite similar to those of Laitinen and Roe.[6,7] A voltage divider, a three-way mercury relay switch and an oscilloscopic recording divider were essential parts of the whole assembly

Impedance Bridge: The assembly used for the a.c. impedance-bridge method consisted of an oscillator, a variable resistance and capacitance, a potentiometer, a mechanical drop-detacher controlled by a timing device, a cathode-ray oscilloscope and a cell containing the solution in question. The entire setup of the assembly, except the cell, has been exhaustively described [8]

Solutions

All aqueous stock solutions were prepared by dissolving reagent-grade materials, with or without further purification, in distilled water.

H_2SO_4 (1 00*M*) *and* NaOH (2 00*M*). Slightly more concentrated solutions were prepared by dissolving reagent-grade materials in water. These solutions were diluted with water until they gave the required values of concentration in the titration with standard alkali and acid solutions, respectively.

Titanium^{IV} (0·0500*M*): A weighed amount of titanium dioxide was converted into soluble sulphate by fusion with $KHSO_4$, and was dissolved in dilute H_2SO_4. Titanium was precipitated with NaOH, and then redissolved in dilute H_2SO_4. The procedure was repeated, and the final precipitate was dissolved in 1·00*M* H_2SO_4 to make up the required volume.

Tartaric Acid (2*M*). *d*-Tartaric acid was purified by repeated recrystallisation from water A weighed amount was dissolved in water.

Camphor (0·1*M*): *d*-Camphor was dissolved nearly to saturation in methanol and crystallised out by adding an equal volume of water. The procedure was repeated. Camphor thus treated was submitted to further purification by sublimation under reduced pressure

A weighed amount of purified camphor was dissolved in methanol and then water was added dropwise from a burette until the volume of water added was equal to that of methanol The solution was made up to volume with a 1:1 mixture of methanol and water.

Thymol (0·1*M*): A weighed amount of thymol, which had been purified by two-fold distillation under reduced pressure, was dissolved in a mixture of methanol and water (1 · 1), and the solution was left standing overnight until it became clear.

Mercury: Mercury was purified by distillation under reduced pressure

Ti^{IV}–Ti^{III} *mixed solution* An equimolar mixture of Ti^{IV} and Ti^{III}, 10 mM in total concentration, was extensively used for the rate determinations. A solution 10 mM in Ti^{IV}, 1*M* in *d*-tartaric acid and 0·2*M* in sodium sulphate was prepared by mixing the stock solutions. A mixture of Ti^{IV} and Ti^{III} was made just before use by electrolysing the Ti^{IV} solution, with constant stirring, at a constant current of about 10 mA between a mercury-pool cathode and a platinum-wire anode inserted into a porous Vycor tube. The solution had been completely deaerated by passing nitrogen, and a thick nitrogen blanket was maintained over the solution during the electrolysis. Under such conditions electrolysis proceeded without an appreciable amount of evolution of hydrogen gas. The concentration ratio of Ti^{IV} to Ti^{III} was determined polarographically. Characteristics of the Ti^{IV} solution were as follows: pH = $1{\cdot}6_5$, $E_{1/2} = -0{\cdot}64$ V *vs.* saturated calomel electrode (S.C E), and the diffusion current constant,

$$I = \frac{i_d}{Cm^{2/3}t^{1/6}} = 1{\cdot}34.$$

Blank solution: A solution 1*M* in *d*-tartaric acid and 0·2*M* in sodium sulphate was prepared from stock solutions for the differential capacity measurement. The pH of the solution was $1{\cdot}5_8$.

Special care was taken in introducing thymol and camphor into the cell solution because of their low solubility and high volatility. Injection of a 0 1*M* 50% methanol solution of surfactant with a microlitre syringe pipette was satisfactorily used for this purpose.

Measurement procedure

A. *Voltage-Step Method:* Each time 60 ml of the Ti^{IV}–Ti^{III} solution were used It was important to keep a thick nitrogen blanket over the solution in the course of the measurement [5] A voltage step, usually about 5·5 mV, was applied between the mercury pool and the d.m e. through a three-way mercury relay switch. Because the faradaic current to be determined was quite low, a Tektronix 532 oscilloscope, equipped with an E-type high gain a.c. differential preamplifier, was used for obtaining the current-time relation The trace photographed on Polaroid-3000 film was reproducible. Sweep rates of 20–50 μsec. cm^{-1} were chosen because the current of interest was expected to be displayed for less than 500 μsec The faradaic current was obtained by simply subtracting the charging current from the observed current, the former being given by the equation $i_{ch} = V/R_T \times \exp(-t/R_TC_{dl})$, where V, R_T and C_{dl} are the voltage, the total resistance and the double layer capacity, respectively. The total resistance thus obtained was not as reproducible as other quantities, especially in the presence of high concentration of a surfactant, because of the rather large rise time of the preamplifier. Therefore R_T and C_{dl} were determined by means of an a.c. impedance bridge at 1,000 cycles. The resistance was varied from 53 to 56 Ω, corresponding to the change of distance between the electrodes, 2 5 to 5 5 mm. The time between the instant at which the preceding droplet fell from the capillary and the instant at which the voltage step was applied was measured with a 1/100-second electric stop-clock. It was usually 8–10 sec. The area of a drop was calculated assuming its sphericity. There was no perceptible difference in the rate constant between 8 and 10 sec. The equations (2) and (7) of Vielstich and Delahay[11] were used to determine the kinetic parameters of the reaction from the faradaic current at zero time, $i_{t=0}$. Although the maximum of the faradaic current was taken as $i_{t=0}$ instead of estimating an "effective zero time,"[6,7] no appreciable error could be introduced by this procedure, because the slope of the i *vs.* $t^{1/2}$ plot was very small, as expected.

B. *Impedance method. Blank solution.* All the electronic instruments were warmed up for more than 20 min before use A single frequency of 1,000 cps was employed for the measurement of differential capacity throughout the range of polarisation potential from +0 2 to −1·4 V (*vs.* S.C E), while frequencies 200–500 cps. were employed at the certain potentials which corresponded to the equilibrium potential of the titanium couple Because the detailed description of the operation has been provided by Sherman[9] a brief comment will suffice here

As differential capacity data are needed after exactly 8 0 sec of the growth of a mercury drop, the timing device was so adjusted that the mechanical drop-detacher was operated at exactly 9 0-sec intervals. At the same time, the horizontal stretch of the image on the oscilloscopic screen was extended to 9·0 divisions. This resulted in a scanning rate of 1·0 division per sec on the screen. When the impedance of the electrode was balanced at 8 0 sec of drop-life, the vertical amplitude of the image on the screen was reduced to a point only at the eighth division line.

Reactants. An identical procedure was employed in determining the impedance of the electrode as was previously described for the blank solution. However, in the presence of the redox couple the dropping mercury cathode was maintained at a constant potential by means of a polarisation unit[8–10] Only the results obtained at the lower frequencies were analysed because of their better reliability.

RESULTS AND DISCUSSION

Determination of surface coverage

It is first necessary to consider the evaluation of differential double-layer capacity measurements in terms of the surface concentration of adsorbate. If the potential of the redox couple, the electrocapillary maximum, and the potential of maximum adsorption of surfactant were all coincident, the fractional coverage could be calculated from the equation

$$\theta = (C_1 - C)/(C_1 - C_2)$$

where C, C_2 and C_1 are, respectively, the corresponding differential capacities of the partially covered surface, the fully covered surface and the bare surface. From Figs. 1 and 2 the potentials of maximum adsorption of camphor and thymol have been estimated as −0·70 V and −0·55 V, respectively, whereas the redox potential of the Ti couple, at which the coverage has to be estimated, is located at −0·63 V *vs.* S.C.E. It should be better in such circumstances to make use of the integral capacity or the charge density instead of the differential capacity for the calculation of θ. Recently, Breiter and Delahay[12] reported that Frumkin's expression[13] for θ in terms of the charge density gave a good agreement with the thermodynamic surface excess over the entire range of potential including the potential of desorption. Thus, the two kinds of covered fraction were calculated, one from the integral capacity, denoted by θ, and the other from the differential capacity θ'; these are illustrated in Figs. 3a and 3b, and are tabulated in Table I. Integration of the differential capacity was

performed graphically between the redox potential and the e.c.m. potential of the blank solution. The latter was estimated as —0·52 V from the potential dependence of the drop time. The differential capacity at 1,000 cycles was used for the integration because the frequency dispersion of the capacity at —0·64 V over the range 200–5,000 cycles was less than 3% with all of the concentrations of the surfactant solution. In Fig. 4, the differential capacity has been plotted against the coverage calculated from the integral capacity. It can be seen that the error caused by using differential capacity calculations is not much in the case of thymol, as expected.

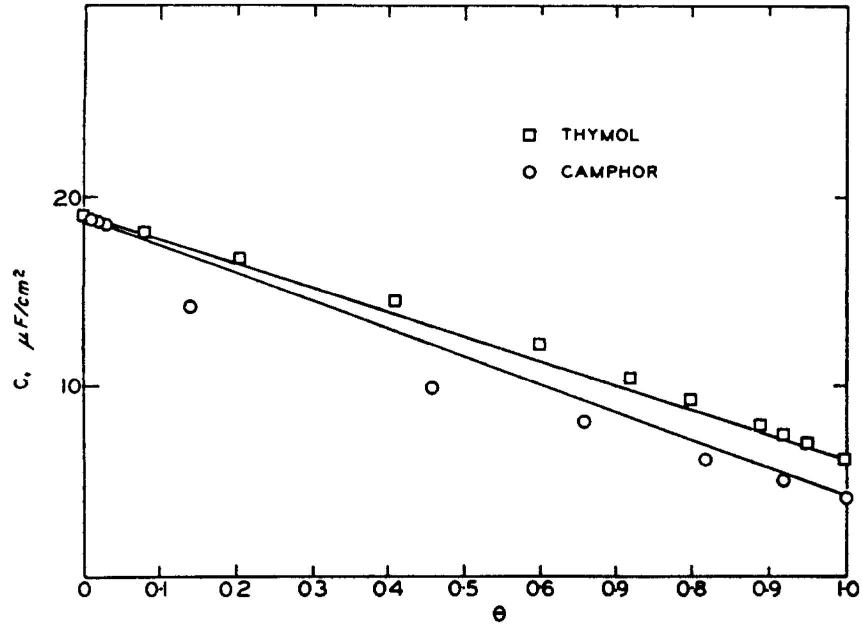

Fig. 4.—Differential capacity *vs.* coverage calculated from integral capacity.

At camphor concentrations less than 0·35 mM, the measured double layer capacity per unit of electrode area decreased slightly during drop growth. The maximum rate of decrease at —0·64 V was observed at a concentration of 0·25 mM, where the value decreased from 16·0 μF. cm^{-2} at 2-sec drop age to 14·0 μF. cm^{-2} at 8-sec drop age. This indicates that adsorption equilibrium had not quite been attained during growth.

Determination of rate constants by voltage-step method

In the absence of surfactant, the Ti^{IV}/Ti^{III} couple had the following kinetic parameters: the standard rate constant $k = 1{\cdot}7_2 \pm 0{\cdot}05 \times 10^{-3}$ cm. sec^{-1} at $0{\cdot}63_5$ V *vs.* S.C.E. and the cathodic transfer coefficient $\alpha = 0{\cdot}48$. The number of electrons transferred at the rate-determining step has been assumed as unity. In Figs. 3, 5 and 6, the rate constant and the differential double-layer capacity at the redox potential have been plotted against the concentration of the surfactant. The effect of the adsorption on the rate constant appears quite similar to that on the capacity.

Figs 7 and 8 show a relationship between the rate constant and the coverage θ. A few points plotted against θ are also included in these figures for comparison.

Taking various complications and difficulties associated with those determinations

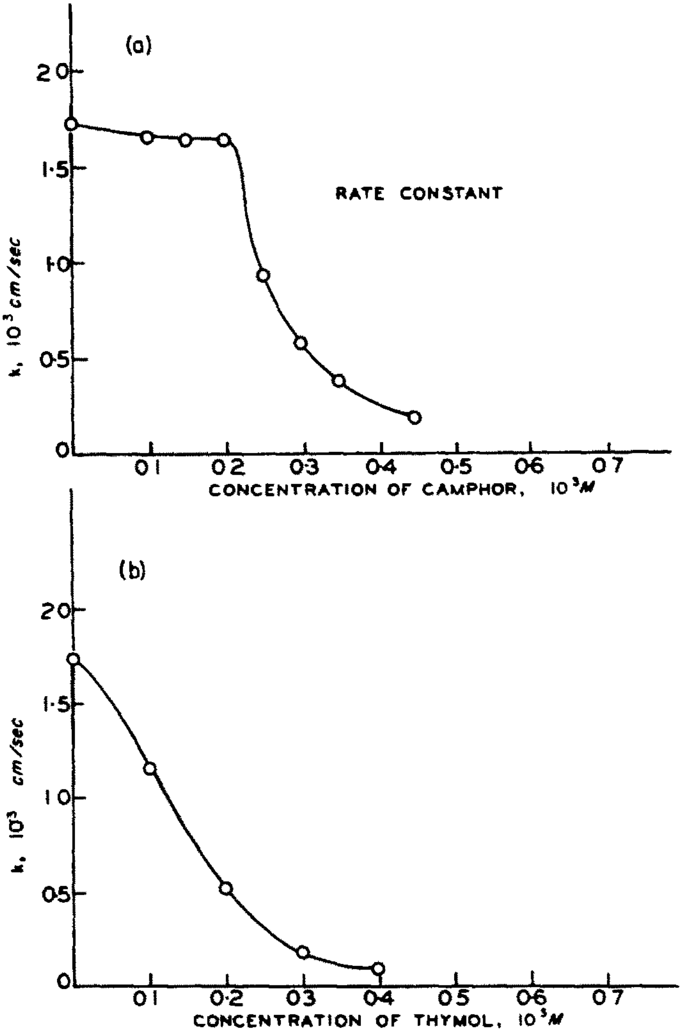

FIG 5a —Differential capacity *vs.* concentration of surfactant (camphor) at 0 64 V.
FIG 5b.—Rate constant *vs.* concentration of surfactant (camphor).

into account, the change of the rate constant can be considered as linear with respect to θ in both cases. Thus, $k = k_1(1 - \theta) + k_2\theta$, where k_1 and k_2 are the rate constants of bare and of fully covered surface, respectively, the latter being estimated with thymol as less than 10^{-9} cm. sec^{-1} from d.c. current measurements.

Determination of rate constants by impedance method

The faradaic impedance at an electrode-solution interface of an electrochemical reaction can be represented by a series combination of a capacitance, C_F, and a resistance, R. In the case where the concentration of the oxidised form is equalised to that of the reduced form, the two components of the impedance are expressed by the equations[14-17]

$$R_F = \frac{RT}{n^2F^2AC}\left[\frac{1}{k_s} + \left(\frac{2}{\omega D}\right)^{1/2}\right] \quad (1)$$

and

$$\frac{1}{\omega C_F} = \frac{RT}{n^2F^2AC}\left(\frac{2}{\omega D}\right)^{1/2} \tag{2}$$

where k_s is the heterogeneous rate constant of the reaction, ω is the angular frequency of a.c. employed, C and D are the concentration and the diffusion coefficient, respectively, of the ion, and A is the area of the electrode surface. R, T, F and n have the usual significance.

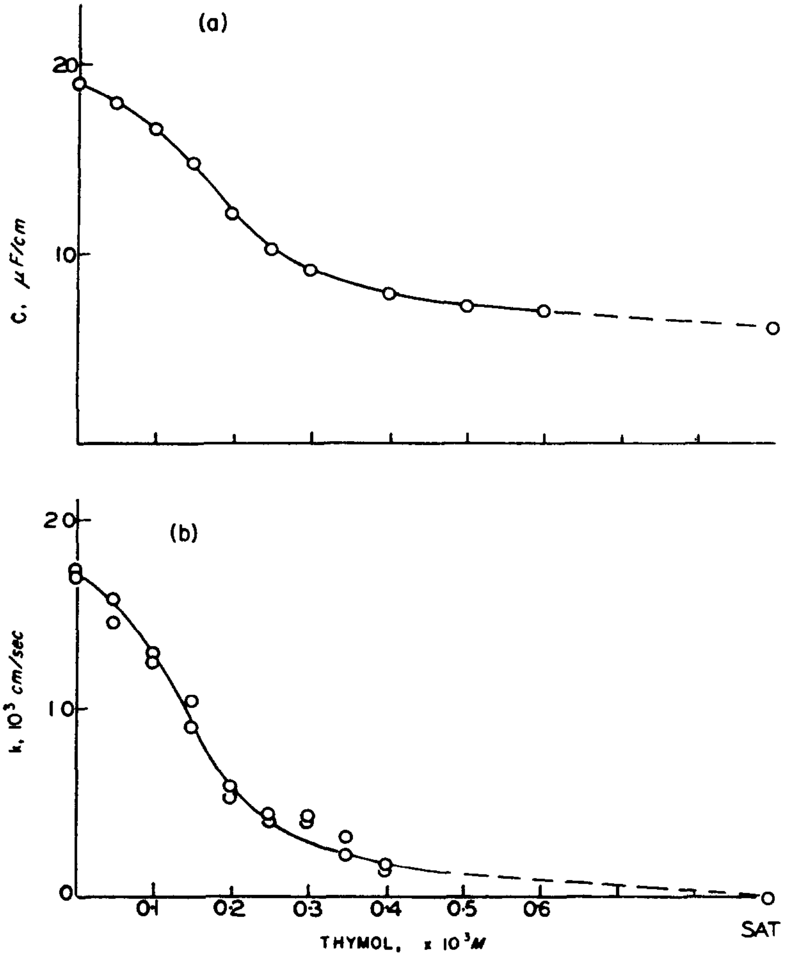

FIG. 6a.—Differential capacity at 0·64 V *vs.* concentration of surfactant (thymol).
FIG. 6b.—Rate constant *vs.* concentration of surfactant (thymol)

Observation of equations (1) and (2) shows that a plot of the faradaic reactance, $1/\omega C_F$ against $\omega^{-1/2}$ should lie on a straight line which extrapolates to the origin; and that a corresponding plot of the faradaic resistance, R_F, should lie on another straight line which is parallel to the reactance line. The rate constant, k_s, can be calculated from the vertical distance between the two lines.

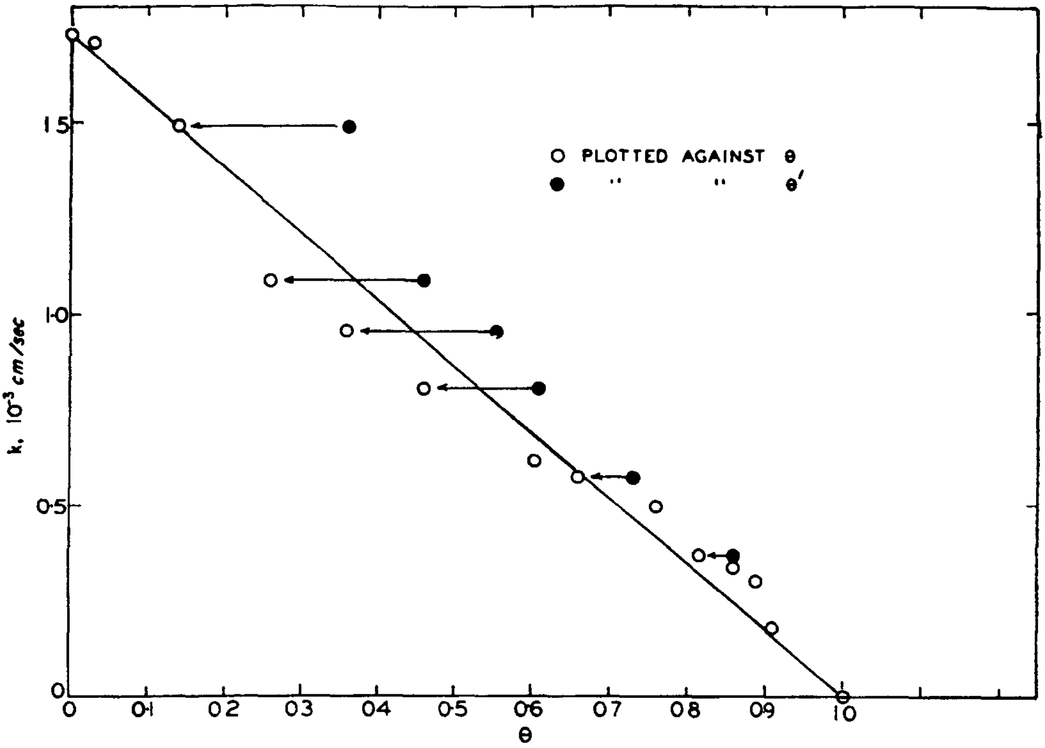

FIG 7.—Rate constant *vs.* surface coverage (camphor)

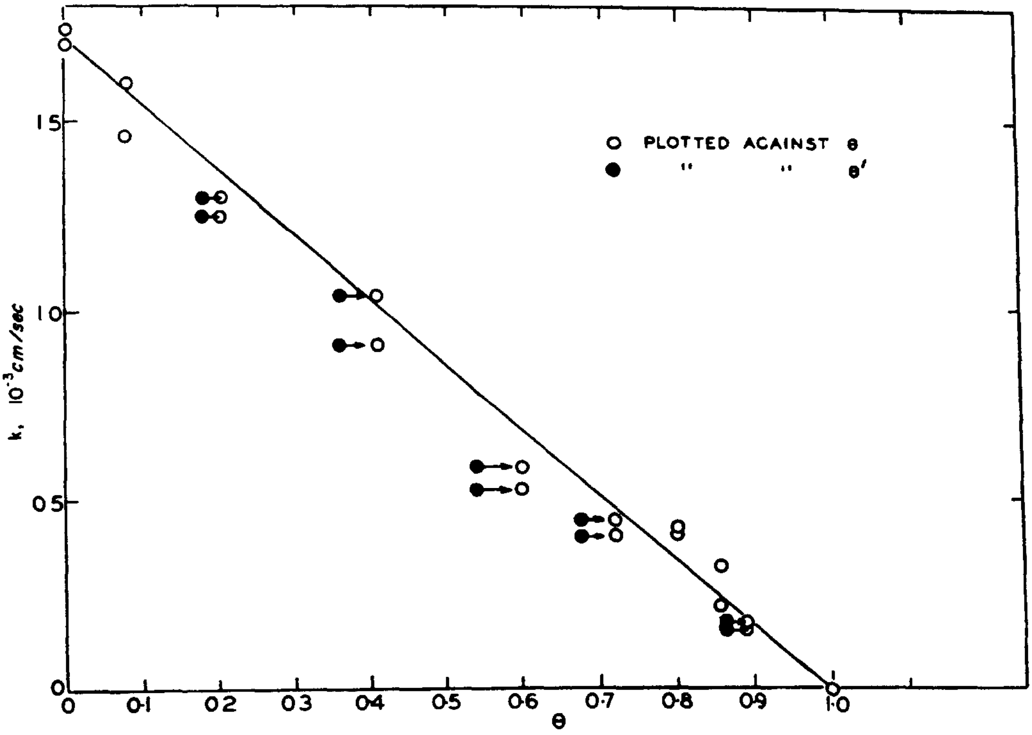

FIG 8.—Rate constant *vs.* surface coverage (thymol).

First, the over-all impedance across the solution and the solution-mercury interface, in the presence of the titanium couple, was assumed to be represented by the equivalent circuit as shown in Fig 9.[5 14–18] Calculation for the faradaic resistance and reactance can be performed by either the numerical[18] or vector diagram[14] method

Values of R_s, the ohmic resistance of solution, and C_{dl}, the capacity of double layer, were supplied by the experiment for differential capacity, which had been determined with a.c. of 1,000 cps applied to the blank solution.

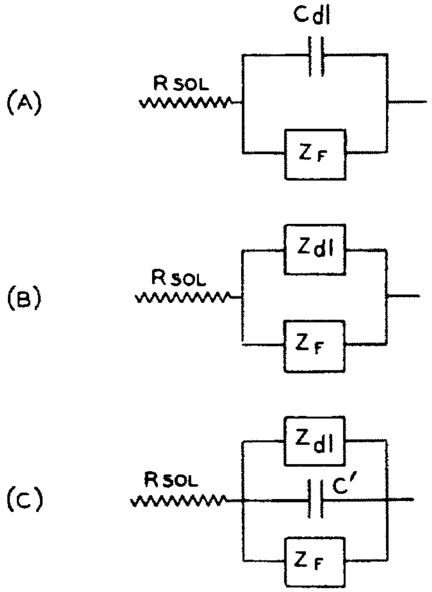

FIG 9.—Equivalent circuits of electrode impedance

The calculated values of the faradaic resistance, R_F, and the faradaic reactance, $1/\omega C_F$, were plotted against $\omega^{-1/2}$. The plots never lay on two parallel straight lines as postulated by equations (1) and (2). Instead two curved lines were obtained, and the vertical distance between these lines decreased with an increase of frequency. This was a trend common to all the results.

The blank solution was carefully re-examined to determine whether the equivalent circuit shown in Fig. 9A is consistent with the actual case. The results obtained by employing various frequencies revealed that the matched values of resistance increased at lower frequencies, especially in the higher concentration range of surfactants, while the values of capacitance remained almost constant regardless of frequency. The observed values of resistance in the blank solution were extrapolated to infinite frequency to obtain the resistance of the solution, R_{sol}. Then each resistance subtracted by R_{sol} can be considered as the resistance of the double layer. When the surfactants were either absent or in small concentrations, the resistance of the double layer was so small that it could reasonably be ignored in the calculations. But when the concentration of the surfactants were relatively large, the contribution of the resistance reached at most 2% of the corresponding reactance in magnitude and was no longer negligible.

A. *Double layer as a complex impedence* To represent the double layer in the presence of adsorbed material Grahame[5] proposed an equivalent circuit consisting of a capacitance in series with a parallel combination of capacitance and resistance. The experimental values of capacitance, C_s, and resistance, R_s, represented as a series combination, are given for several concentrations of thymol in Table II. The resistance represents the excess over the solution resistance (330 Ω) extrapolated to infinite frequency, the same value being observed in the absence or presence of surfactant Because the capacitance, C_s, remains almost constant with frequency while the excess resistance, R_s, is strongly dependent on frequency, it is qualitatively apparent that the Grahame equivalent circuit must consist of a relatively small capacitance, C_T, in series with a parallel combination of a relatively large capacitance C_3, and a large resistance, R_3. By trial and error, the components C_T, C_3 and R_3 were chosen to give the representation of R_s and C_s, as shown in Table II. The effect of increasing thymol concentration is to decrease C_T, the "pure" capacitance, more rapidly than C_3, the frequency-dependent capacitance. The parallel resistance R_3 goes through a minimum at an intermediate thymol concentration (0·4 × $10^{-3}M$), corresponding to a maximum in the observed series resistance R_s. The reason for this behaviour is not clear, but it leads to complications in subtracting the double-layer admittance in calculating the rate constant of the electrode process.

		1000	18	10	0·085	0·084

Faradaic resistance and reactance were calculated by the vector-diagram method, using the complex admittance, in place of mere capacitive admittance of the double layer. The calculated values, however, gave only small increases to the plots for both components. Hence, the resulting curves were not remarkably improved.

B. *Introducing an additional capacitance*: Assuming that the double layer capacity might change its magnitude between the blank solution and the solution containing titanium, an equivalent circuit was considered which included an additional capacity parallel to the impedance of double layer (C in Fig. 9).

The magnitude of the capacitance was empirically chosen so that the resistive and the reactive components of the faradaic impedance were as close to those postulated by equations (1) and (2) as possible. The vector-diagram method was adopted for the calculation.

By choosing a suitable capacitance, both the resistance and the reactance lines became almost straight and parallel to each other, and the latter lines could be extrapolated to the origin. The values of the additional capacitance are tabulated in Tables III and IV, where they are also compared with the differential capacity measured at 1,000 cps. The improvement is marked by thus introducing an additional capacitance.

TABLE III—EFFECT OF CAMPHOR

Concentration of camphor, $10^{-3}M$	C', Capacity subtracted		Slope, $10^{2}\ \Omega\ sec^{-1/2}$	D(apparent), $10^{-6}\ cm^{2}\ sec^{-1}$	k_s, $10^{-3}\ cm\ sec^{-1}$
	$\mu F/cm.^2$	% to C_{dl} at 1000 cps			
0	2·50	13·1	7	1	1·7$_3$
0·10	1·88	9·9	10	0·5	1·6$_6$

0·20	1·63	8·7	12	0·3	1·6$_5$
0·25	0	0	15	0·2	0·9$_4$
0·30	0·29	2·9	48	0·02	0·5$_9$
0·35	0·43	5·3	70	0·01	0·3$_9$
0·45	0·29	4·6	125	0·003	0·2$_0$

TABLE IV—EFFECT OF THYMOL

Concentration of thymol, $10^{-3}M$	C', Capacity subtracted		Slope, $10^{2}\ \Omega\ sec^{-1/2}$	D(apparent), $10^{-6}\ cm^{2}\ sec^{-1}$	k_s, $10^{-3}\ cm.\ sec^{-1}$
	$\mu F/cm^2$	% to C^{dl} at 1000 cps			
0	2·47	12·9	8	0·5	1·7$_4$
0·10	3·26	19·6	12	0·2	1·1$_6$
0·20	2·47	20·1	38	0·02	0·5$_2$
0·30	1·68	16·8	100	0·002	0·1$_8$
0·40	1·13	13·6	650	(8×10^{-5})	0·0$_9$

The effect of this additional admittance may be interpreted as a rapid electron exchange between the adsorbed reactants and the electrode, such as that postulated by Laitinen and Randles[18] for a cobalt^{III}/cobalt^{II} system.

C. *Reaction rate*: Estimated values of R_F and $1/\omega C_F$ for various concentrations of the surfactants, camphor and thymol, were plotted against $\omega^{-1/2}$. Fig. 10, which is an example of the plots, illustrates the variation of both R_F and $1/\omega C_F$ with the increasing concentration of camphor.

Rough estimation of the apparent diffusion coefficient of the titanium ion is possible from the slopes of each pair of corresponding lines. Values of slopes and, hence, the diffusion coefficient are shown in Tables III and IV in the presence of camphor and thymol, respectively. The large decrease of apparent diffusion coefficient observed at high surface coverages cannot be attributed to a change of diffusion rate in solution because the polarographic diffusion current is not appreciably affected even by high concentrations of camphor or thymol. It might be regarded, however, as evidence for a slow penetration step of a nearly saturated surface layer. Further experimental work on this point is desirable.

Vertical distances between corresponding resistance and reactance lines permit

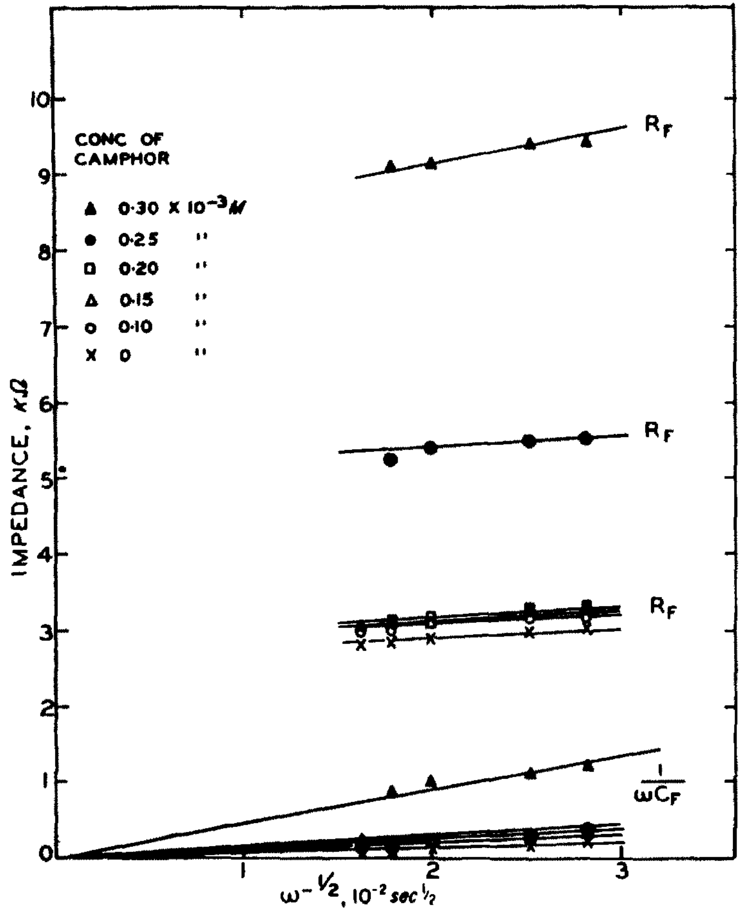

FIG. 10a.—Faradaic resistance, R_F and reactance, $1/\omega C_F$, in the presence of camphor.

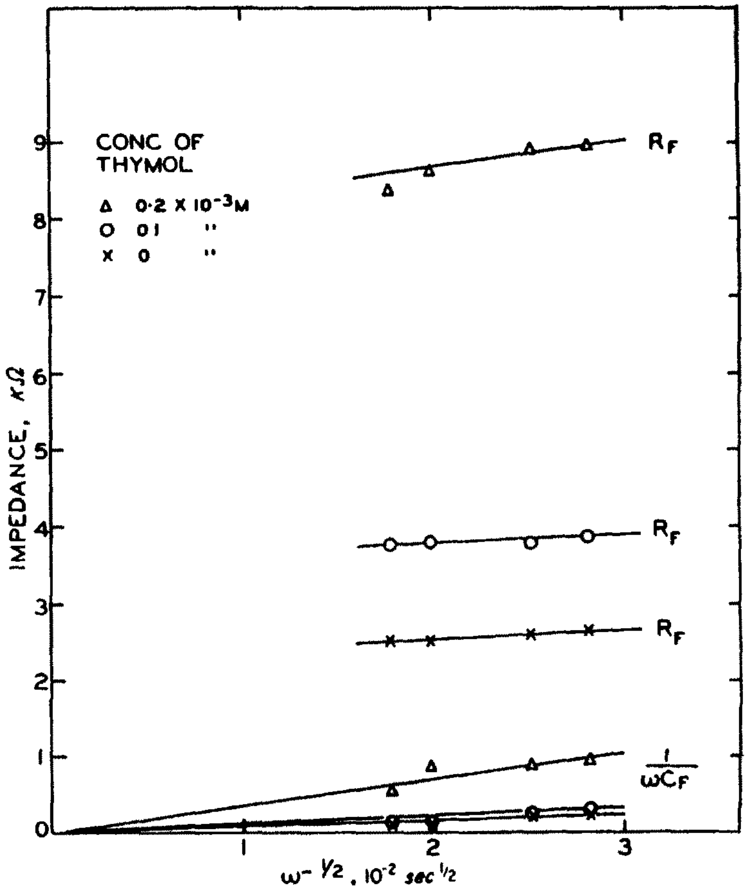

FIG 10b.—Faradaic resistance, R_F and reactance, $1/\omega C_F$, in the presence of thymol.

the reaction rate constants to be calculated, the values also being tabulated Experiments had been extended to the saturating concentrations of camphor and thymol, but the extremely small values of capacitance gave rise to intolerable errors in calculation; therefore, these results have been neglected here

The observed value of the rate constant, 1·7 × 10^{-3} cm sec^{-1}, in the absence of surfactants is in good agreement with that obtained by the voltage-step method This is smaller than either 9 × 10^{-3} by Randles and Somerton[20] or 5 or 3·5 × 10^{-3} by Delahay and Trachtenberg[21] obtained by the impedance method. Because the experimental condition of the former was not described and the latter was obtained in a solution containing sodium chloride, an exact comparison is difficult to make.

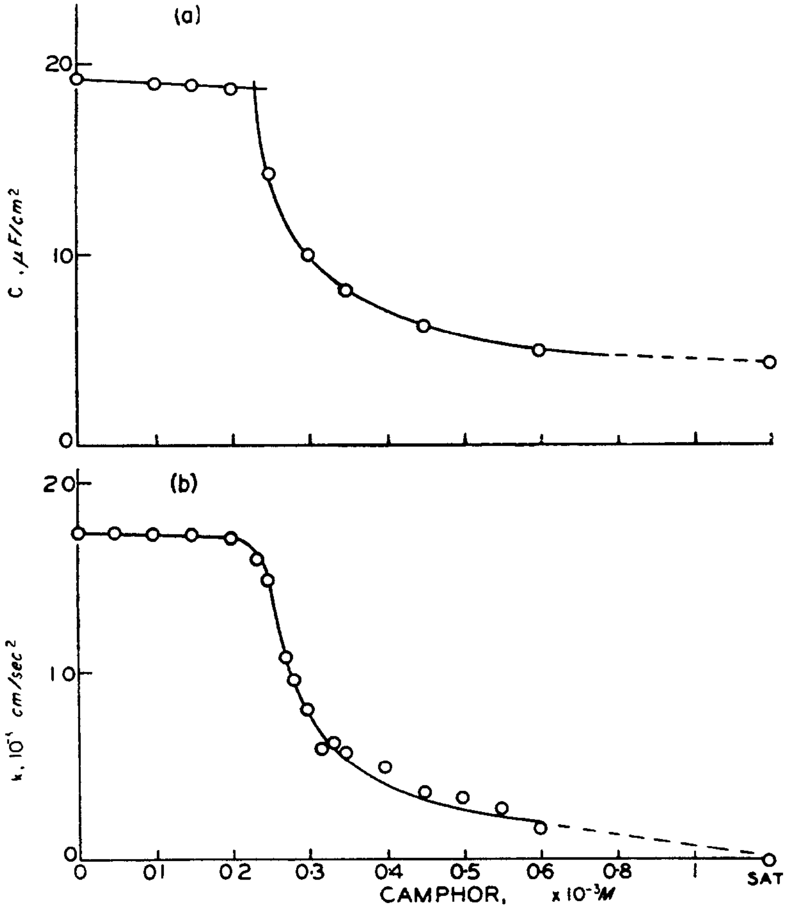

FIG. 11a — Effect of camphor on electrode reaction of Ti
FIG 11b — Effect of thymol on electrode reaction of Ti

The rate constant decreases rapidly in the presence of thymol, and is reduced to one-tenth of the original value at the concentration of thymol 0·3 × $10^{-3}M$. On the other hand, camphor exerts almost no inhibiting effect up to 0·2 × $10^{-3}M$, then exerts a serious effect, the rate constant being about one-tenth of the original value at 0·45 × $10^{-3}M$. These effects on the rate constant are shown in Fig. 11.

Comparison of voltage-step and impedance methods

For a simple electrode reaction, the voltage-step and impedance methods may be said to be equivalent, but for the determination of rate constants greater than 10^{-2} cm. sec^{-1} the impedance method is usually more accurate.[22]

In the present case, however, the voltage-step method has advantages which led to more reliable values for rate constants in the presence of adsorbed organic materials. The essential difficulty in interpreting impedance results arises from complications in subtracting out the admittance of the blank. First, the frequency dependence of resistance and capacitance observed in the presence of an adsorbed layer means that the double layer can no longer be represented as a simple capacitance but a capacitance shunted by a resistance, as has previously been shown by Grahame.[5] In the present investigation, it has been shown that this is a relatively minor complication, but undoubtedly it leads to additional scatter in the calculated rate constants. Second, the abnormally great Warburg impedance observed in the presence of adsorbed materials especially at high surface coverages needs further study. The uncertainty from this correction appears to be more serious, and would probably be encountered whenever adsorbed phases are present. Third, a specific effect encountered in the present problem is that of adsorption of electroactive species. Although this effect may not always be observed, it has led in the present case to further uncertainties in the rate constant calculated from impedance values.

In the voltage-step method, the total period of time during which a current was recorded was usually less than 300 μsec. Thus, all observations in this study would correspond to bridge measurements at high frequencies (several kilocycles per sec). The frequency dispersion of double-layer capacity becomes unimportant at high frequencies. Moreover, the abnormal Warburg admittance becomes relatively less important at high frequencies because it approaches zero at infinite frequency. Finally, the effect of adsorbed electroactive species appears as an abnormally large double-layer capacitance, which is subtracted out automatically in the extrapolation procedure. This latter statement is true only if the adsorbed species undergo sufficiently rapid electron exchange that their effect can be represented by a pure capacitance. A slow electron exchange of adsorbed species would give rise to a capacitance in series with a resistance, which would result in an increased time constant for the reduction process as compared with the charging process.

CONCLUSIONS

The adsorption of camphor and thymol on a dropping mercury electrode was determined from capacitance measurements. A comparison was made of the electrode coverage as calculated from differential and integral double-layer capacity, and the magnitude of the error caused by using differential capacity calculations was estimated.

The standard rate constant for the titanium^{IV}-titanium^{III} couple in 1*M* tartaric acid, 0·2*M* sodium sulphate was determined in the absence of surfactant. The voltage-step method gave a value of $1{\cdot}72 \times 10^{-3}$ cm. sec^{-1}, and the impedance method gave 1·73 and $1{\cdot}74 \times 10^{-3}$ cm. sec^{-1}.

The voltage-step method proved simpler than the impedance method in the presence of surfactant. To interpret the impedance method, it was necessary to introduce an empirical correction in the form of an additional capacitative admittance in parallel with the usual Warburg admittance. This correction arises from specific adsorption of electroactive species.

The rate constants calculated from voltage-step measurements were more reliable than those from impedance values, and showed approximately linear dependance on surface coverage, for both thymol and camphor.

CHRONOPOTENTIOMETRIC STUDY OF THALLIUM[1] ION IN GLACIAL ACETIC ACID†

S. BRUCKENSTEIN, T. O. ROUSE‡ and STEPHEN PRAGER
Department of Chemistry, University of Minnesota, Minneapolis, Minn , U.S.A

(*Received* 12 *August* 1963 *Accepted* 10 *October* 1963)

Summary—The thallous ion-thallium amalgam system has been studied chronopotentiometrically in glacial acetic acid (HAc) as a solvent, using 0·25*M* ammonium acetate as supporting electrolyte The transition time relationships between the cathodic transition time and the first anodic transition time on current reversal were verified. Analogous studies were carried out at the thallium amalgam electrode, determining the anodic transition time and the cathodic transition time on current reversal. The predicted potential-time relationships for the above-mentioned chronopotentiometric processes were verified, and it was established that the thallous acetate-thallium amalgam couple is reversible with the formal potential of 0 347 ± 0·005 V *vs.* the saturated aqueous calomel electrode. The diffusion coefficients of thallous ion and thallium in mercury were found to be identical, 4 3 × 10^{-6} cm^2. sec^{-1}.

INTRODUCTION

VARIOUS investigators[1–17] have obtained solutions for a number of simple and complex problems arising in chronopotentiometry. The present work is concerned with the verification of the predicted relationships between concentration and transition time, and between potential and time, for the thallous acetate—thallium amalgam couple, using 0·25*M* ammonium acetate supporting electrolyte in acetic acid (HAc) as solvent. Studies reported below include the reduction of thallous acetate into a mercury pool or thallium amalgam, followed by current reversal at the first cathodic transition time; and oxidation of thallium from thallium amalgam followed by current reversal at the first anodic transition time.

Table I summarises the surface concentrations of thallous ion, C_O^s, and thallium amalgam, C_R^s, which will result at time, t, after the start of reduction before the first cathodic transition time, τ_c, and between the first cathodic transition time and the subsequent anodic transition time, τ_a', on current reversal at $t = \tau_c$,[12]

where $$\tau_c = \frac{n\mathscr{F}(\pi D_O)^{\frac{1}{2}}}{2i_0} C_O^{\circ},$$

D_O and C_O° represent the diffusion coefficients and bulk concentrations of the oxidised species, respectively, i_0 is the absolute value of constant current density, and τ_a' is the time lapse between the cathodic transition time and the anodic transition time. Analogous relations are given for the case where the initial process is an oxidation, resulting first in an anodic transition time, τ_a,

where $$\tau_a = \frac{n\mathscr{F}(\pi D_R)^{\frac{1}{2}}}{2i_0} C_R^{\circ},$$

followed by cathodic transition time, τ_c', on current reversal at $t = \tau_a$.[12]

TABLE I —SURFACE CONCENTRATIONS DURING CONSTANT CURRENT ELECTROLYSIS FOLLOWED BY CURRENT REVERSAL AT FIRST TRANSITION TIME†[12]

Initial Process	Before first transition time		Between first and second transition times	
	C_O^s	C_R^s	C_O^s	C_R^s
Reduction	$k_O\{\tau_c^{1/2} - t^{1/2}\}$ $(t \le \tau_c)$	$k_R\{\tau_a^{1/2} + t^{1/2}\}$ $(t \le \tau_c)$	$k_O\{\tau_c^{1/2} + 2(t - \tau_c)^{1/2} - t^{1/2}\}$ $(\tau_c < t \le \tau_c + \tau_a')$	$k_R\{\tau_a^{1/2} - 2(t - \tau_c)^{1/2} - t^{1/2}\}$ $(\tau_c < t \le \tau_c + \tau_a')$
Oxidation	$k_O\{\tau_c^{1/2} + t^{1/2}\}$ $(t \le \tau_a)$	$k_R\{\tau_a^{1/2} - t^{1/2}\}$ $(t \le \tau_a)$	$k_O\{\tau_c^{1/2} - 2(t - \tau_a)^{1/2} + t^{1/2}\}$ $(\tau_a < t \le \tau_a + \tau_c')$	$k_R\{\tau_a^{1/2} + 2(t - \tau_a)^{1/2} - t^{1/2}\}$ $(\tau_a < t \le \tau_a + \tau_c')$

† For the reduction (or oxidation) of one soluble species to another where

$$k_O = \frac{2i_0}{n\mathscr{F}(\pi D_O)^{1/2}}$$

$$k_R = \frac{2i_0}{n\mathscr{F}(\pi D_R)^{1/2}} \text{ and } i_0 = \text{absolute value of current density}$$

If the first electrode process is a reduction, the relationship between the first cathodic transition and the anodic transition time occurring on current reversal is

$$[\tau_c + \tau_a']^{1/2} + \tau_a^{1/2} = 2[\tau_a']^{1/2}, \tag{1}$$

while if the initial process is an oxidation, the analogous relation is

$$[\tau_a + \tau_c']^{1/2} + \tau_c^{1/2} = 2[\tau_c']^{1/2}. \tag{2}$$

The potential-time curves for the reversible electrode process are obtained by substituting the surface concentrations given in Table I into equation (3a)

$$E = E^* + \frac{RT}{n\mathscr{F}} \ln \frac{C_O^s D_O^{1/2}}{C_R^s D_R^{1/2}}, \tag{3a}$$

where E^* is the observed potential when $C_O^s D_O^{1/2} = C_R^s D_O^{1/2}$. In the case under consideration, E^* is identical with the polarographic half-wave potential and the chronopotentiometric quarter-wave potential, *i.e.*,

$$E^* = E^\circ + \frac{RT}{n\mathscr{F}} \ln \frac{f_O D_R^{1/2}}{f_R D_O^{1/2}}, \tag{3b}$$

where E° is the standard potential for Ox. + $n\varepsilon$ = Red. and f represents the activity coefficient of the species indicated in the subscript. We call E^* the "characteristic potential". This characteristic potential occurs at a time, t^*, the "characteristic time". Relationships for the various cases are given in Table II. If the first electrode process

TABLE II —CHARACTERISTIC TIMES, t^*

Initial process	Before first transition time	Between first and second transition times
Reduction	$0.5(\tau_c^{1/2} - \tau_a^{1/2}) = t^{*1/2}$ observed only if $\tau_c > \tau_a$	$4(t^* - \tau_c)^{1/2} - 2(t^*)^{1/2} = \tau_a^{1/2} - \tau_c^{1/2}$ always observed
Oxidation	$0.5(\tau_a^{1/2} - \tau_c^{1/2}) = t^{*1/2}$ observed only if $\tau_a > \tau_c$	$4(t^* - \tau_a)^{1/2} - 2(t^*)^{1/2} = \tau_c^{1/2} - \tau_a^{1/2}$ always observed

is a reduction and $C_R'' = 0$, then $\tau_a = 0$ and the first current reversal relationship given in Table II reduces to a result previously obtained by Berzins and Delahay.[3]

EXPERIMENTAL

Apparatus

The constant current source high impedance amplifier and recorders used in this study are described elsewhere.[12] The chronopotentiometric cell used was similar to that used by Delahay[13] with the following differences. (1) The plug was machined from Teflon instead of from Lucite. (2) The entire cell body was jacketed with water and maintained at 25 ± 0·2 by circulating water from a thermostat. (3) The Lugen capillary was sealed through the side of the cell to fix the position of the tip of the salt bridge with respect to the mercury pool. The diameter of the hole in the Teflon plug was 1·630 cm. and exactly the same volume of mercury was delivered to the plug in all the experiments to ensure a constant distance between the tip of the salt bridge and the mercury surface. The effective electrode area was determined by a procedure which will be reported elsewhere.

Reagents

Reagent-grade chemicals were used in all cases.

Glacial acetic acid was purified by boiling with anhydrous chromic oxide, followed by azeotropic distillation with excess benzene to remove water, in turn followed by careful fractionation.

0·25*M Ammonium acetate*. Reagent-grade ammonium acetate was dissolved in the purified HAc. The water content of the supporting electrolyte used was found to be 0·1% by Karl Fischer titration.

Thallium amalgams were prepared *in situ* in the chronopotentiometric cell by constant-current electrolysis at the mercury cathode of stirred, deaerated solutions of thallous acetate in 0·25*M* ammonium acetate in HAc. The current densities chosen were such that the potential of the mercury cathode insured 100% current efficiency for the reduction of thallous ion. The concentration of the amalgams was calculated from the number of coulombs used in the electrolysis and the known volume of the mercury cathode.

Thallium acetate. A standard thallium acetate solution was prepared by solution of an appropriate amount of thallium formate in water followed by precipitation with sodium carbonate. The resulting carbonate was recrystallised several times from water, washed and dried. A weighed amount of this carbonate was dissolved in the ammonium acetate supporting electrolyte. The amount of water formed in this process is negligible compared with the total amount of water in the electrolyte.

All potentials were measured against the saturated aqueous calomel electrode. An intermediate salt bridge containing the acetic acid supporting electrolyte present in the chronopotentiometric cell was placed between aqueous calomel electrode and the Lugen capillary.

RESULTS AND DISCUSSION

The reaction

$$\mathrm{Tl^{(I)}} + \varepsilon + \mathrm{Hg} \rightleftharpoons \mathrm{Tl(Hg)} \tag{4}$$

was studied in 0·25*M* ammonium acetate in HAc in order to verify the relations given in Tables I and II. In such a mixture of reduced and oxidised forms, two transition time constants, J_O and J_R, may be defined in terms of relationships given in Table I. The transition time constant for the oxidised form is given by

$$J_O = \frac{i_0\tau_c^{\frac{1}{2}}}{C_O^{\circ}} = \frac{-i_0[(\tau_a + \tau_c')^{\frac{1}{2}} - 2(\tau_c')^{\frac{1}{2}}]}{C_O^{\circ}} = \frac{n\mathscr{F}(\pi D_O)^{\frac{1}{2}}}{2} \tag{5a}$$

in the case where the first electrochemical process is a reduction.

If the current is reversed at the first transition time, the transition time constant for the reduced form is given by

$$J_R = \frac{i_0\tau_a^{\frac{1}{2}}}{C_R^{\circ}} = \frac{-i_0[\tau_c + \tau_a')^{\frac{1}{2}} - 2(\tau_a')^{\frac{1}{2}}]}{C_R^{\circ}} = \frac{n\mathscr{F}(\pi D_R)^{\frac{1}{2}}}{2} \tag{5b}$$

when the initial process is an oxidation and the current is reversed at the first transition time.

TABLE III —CHRONOPOTENTIOMETRY OF THALLOUS ION–THALLIUM AMALGAM IN HAc

Initial process	$C^{0(b)}_{Tl^+}$ mM	$C^{0(b)}_{Tl(Hg)}$, mM	$J'^{(a)}_{Tl^+}$ $\frac{\mu A\ sec^{\frac{1}{2}}}{cm^2 mM}$	$J^{(a)}_{Tl(Hg)}$ $\frac{\mu A\ sec^{\frac{1}{2}}}{cm^2 mM}$	Exptl value of $2·303 \frac{RT}{n\mathcal{F}}$ Before first transition time v	Exptl value of $2·303 \frac{RT}{n\mathcal{F}}$ After current reversal, v	E^*, v	Number of determinations

(a) See equations (5a) and (5b) for definition.

(b) C^0 = bulk concentration.

The results obtained with several HAc solutions containing thallous acetate at mercury and at thallium-amalgam electrodes are summarized in Table III. The values of J_{Tl^+} for the initial cathodic experiments at an amalgam electrode are omitted, because the concentration of the HAc solution, after preparation of the amalgam, was determined from the cathodic transition times and the value of J_{Tl^+} found for experiments at a mercury electrode. Current densities varied from 154 μA. cm^{-2} to 2050 μA. cm^{-2}. As is seen in Table III, the agreement between the various J values is good, and verifies the relationships between the different transition times. Also summarised in Table III are the slopes of E *vs.* log $\dfrac{C^s_{\mathrm{Tl}^+}}{C^s_{\mathrm{Tl(Hg)}}}$ where the appropriate surface concentrations given in Table I have been substituted. The slopes indicate that reaction (4) occurs reversibly in a supporting electrolyte of 0·25M ammonium acetate in HAc

The characteristic potentials listed in Table III are corrected for the ohmic potential drop contribution which cannot be avoided in this high-resistance supporting electrolyte. The observed characteristic potential, $(E^*)_{\mathrm{obs}}$, is related to the actual characteristic potential by

$$(E^*)_{\mathrm{obs}} = E^* - iR \tag{6}$$

where R is the effective resistance between the tip of the Lugen capillary and the mercury pool. The actual characteristic potentials listed in Table III were obtained by plotting the observed characteristic potential *vs.* the current used in the particular electrolysis and extrapolating to zero current. The agreement found between the characteristic potentials is excellent, and verifies the validity of the theoretical relationship pertaining to these different situations.

In addition, potentiometric measurements (at zero current) indicate that the value of formal potential for reaction (4) is $-0{\cdot}353$ v. Because ion-pair formation must be extensive, this potential value merely represents the e.m.f. at which the ratio of the analytical concentration of thallous acetate to the thallium amalgam concentration is 1. We also find that the diffusion coefficient of thallous ion in HAc solutions of 0 25M ammonium acetate (4 3 $\times$ 10^{-6} cm^2. sec^{-1}) equals that of thallium amalgam, therefore the observed formal potential should correspond exactly to E^*. Within the experimental error this result is found, further supporting the above conclusions

RADIOCHEMICAL DETERMINATION OF STRONTIUM-89 AND -90 IN URANIUM MINERALS AND SALTS

P. K. KURODA and HIROFUMI ARINO
Department of Chemistry, University of Arkansas, Fayetteville, Arkansas, U.S A

(*Received* 19 *June* 1963 *Accepted* 31 *October* 1963)

Summary—A combination of low-level counting technique and large-scale analytical operation has been employed to determine extremely small quantities of strontium-89 and -90 in uranium ores and salts Strontium carrier is added to a kilogram quantity of the samples of non-irradiated uranium ore and salt, exhaustively purified, and counted The levels of radiostrontium found are of the order of 10^{-4} disintegrations $sec^{-1}.g^{-1}$ of uranium in the sample. These strontium isotopes are formed in non-irradiated uranium salts and ores predominantly by the spontaneous fission of uranium, but neutron-induced fission of uranium-235 also appears to occur in the latter

INTRODUCTION

THE existence of extremely small activities of natural fission-produced strontium-89 and -90 in pitchblende was first reported by Kuroda and Edwards[1] about a decade ago. Determination of these strontium isotopes in uranium ore is tedious and requires a large-scale chemical operation, which looks somewhat like a miniature version of Mme. Curie's experiment of the isolation of radium from pitchblende.

In connection with a study on the process of natural fission, currently being carried out in this laboratory, it was necessary to measure the levels of strontium-90 in pitchblende and in various uranium-bearing materials. The purpose of the experiment was to see if the amount of strontium-90 found in pitchblende agrees with the calculated amount from the known spontaneous fission half-life ($8 \cdot 0 \times 10^{15}$ years) of uranium-238, or if there is an excess of strontium-90 from the contribution by neutron-induced fission of uranium-235. The contribution from the latter process would imply that a nuclear chain reaction occurs in nature, *i.e.*, some of the neutrons produced by the uranium-238 spontaneous fission are absorbed by the uranium-235 atoms and produce additional fission neutrons.

The existence of such a nuclear chain-reacting system in nature has been demonstrated mass-spectrometrically.[2,3] The mass-spectrometric measurements deal, however, with the stable isotopes of krypton and xenon, and hence reveal the cumulative effects of the nuclear chain reaction throughout the life-time of the uranium ores.

Measurements of the levels of strontium-90 in pitchblende would tell us something about the extent to which the nuclear chain reaction is occurring "today" in the uranium ore Knowing this, one may be able to compute the total number of uranium atoms which have participated in the nuclear chain reaction during the entire history of the earth.

The recent discovery that the earth's atmosphere appears to contain an excess of "fission-produced" xenon isotopes relative to the xenon extracted from meteorites can be explained from either (*a*) the contribution from the extinct transuranium element, such as plutonium-244 (half life· 7·6 × 10^7 years),[4,5] or (*b*) the natural uranium chain reaction which occurred during the geological history of the earth.[6–9]

No attempt will be made in this paper to discuss fully the nuclear and geo-cosmochemical aspects of the process of natural fission However, mention will be made here that pitchblende and other uranium ores are expected to contain similar activities of natural fission-produced technetium and promethium isotopes. These so-called "missing" elements can be also isolated from uranium ores by a large-scale chemical operation Measurements of the levels of technetium and promethium activities in pitchblende are currently being continued in this laboratory [10–15]

The present paper describes some of the analytical and radiochemical problems encountered in the separation and determination of the extremely small quantities of strontium-89 and -90 in kilogram-quantities of uranium ores. It has been our experience that the strontium fraction of pitchblende can be very easily lost during the chemical operation, even when a fairly large quantity of strontium carrier is added to the pitchblende sample. A failure in the recovery of the strontium fraction meant a loss of kilogram quantity of pitchblende, as well as a loss of "face" to the investigators involved in the operation. In fact, the experiment of Kuroda and Edwards[1] has never been successfully repeated in this laboratory and elsewhere until the new analytical scheme described in this paper was developed

EXPERIMENTAL

Materials

A large quantity of African pitchblende and a sample of depleted uranium with the isotopic composition of 99 98 % ^{238}U and 0·011 % ^{235}U were made available to us for this study by Dr H M Roth of the Research and Development Division, U.S. Atomic Energy Commission, Oak Ridge, Tennessee, U S.A.

All reagents used in this work were of the highest purity obtainable, usually Reagent ACS purity

Counting equipment

A CE14 Tracerlab Low-Background Beta Counter was used to count the strontium fractions isolated from pitchblende and depleted uranium.

Chemical procedure

A flow sheet of the chemical operations is shown in Fig. 1. The final adoption of the analytical scheme shown in Fig 1 was based on the knowledge gained from the preliminary experiments on the behaviour of strontium as described in the latter part of this report.

In the case of the determination of radiostrontium in depleted uranium salt, the sample was converted to $UO_2(NO_3)_2$ $6H_2O$, 200 mg of strontium carrier were added, and this was first treated with 80% nitric acid The strontium nitrate found in the precipitate was then exhaustively purified and counted.

RESULTS AND DISCUSSION

The final strontium carbonate precipitate recovered from 2·6 kg of pitchblende weighed 124 mg and showed an activity of about 300 cpm. This activity was found to be mostly from the decay products of radium. The sample was dissolved in dilute nitric acid and was repurified, starting with the ion-exchange separation step of the flow sheet shown in Fig. 1.

The purified strontium carbonate precipitate weighed 114 mg and had a weak beta activity shown as Curve I in Fig 2. The growth-decay curve observed indicated the presence of 50-day ^{89}Sr and the growth of 64·5-hour ^{90}Y from 28-year ^{90}Sr.

To calculate the radiostrontium content of the pitchblende, the chemical yield has

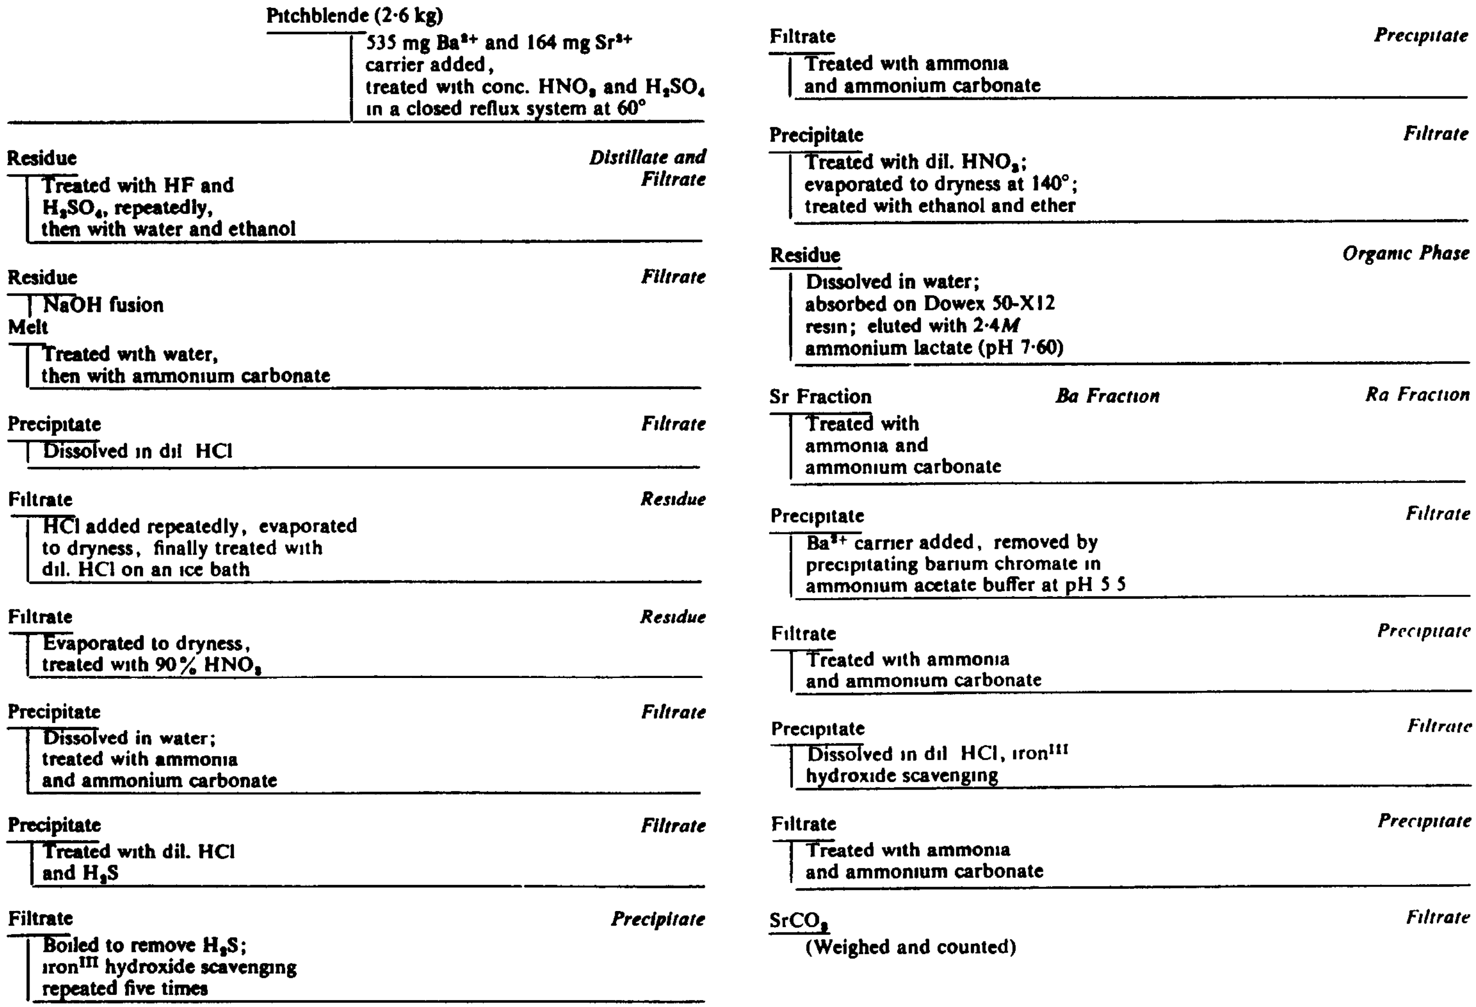

FIG. 1.—Flow diagram for the determination of strontium-90 in pitchblende.

to be accurately known. If *a* mg of strontium carrier were added and *b* mg were recovered, the chemical yield, *y*, is

$$y = \frac{b}{a - x} \; 100\% \qquad (1)$$

where x is the amount of strontium originally present in the sample

Attempts to determine x in the African pitchblende have all failed and we are currently of the opinion that $x \ll a$ Thus, if one neglects x, the chemical yield in this case is calculated to be 42%, which is the highest chemical yield so far attained

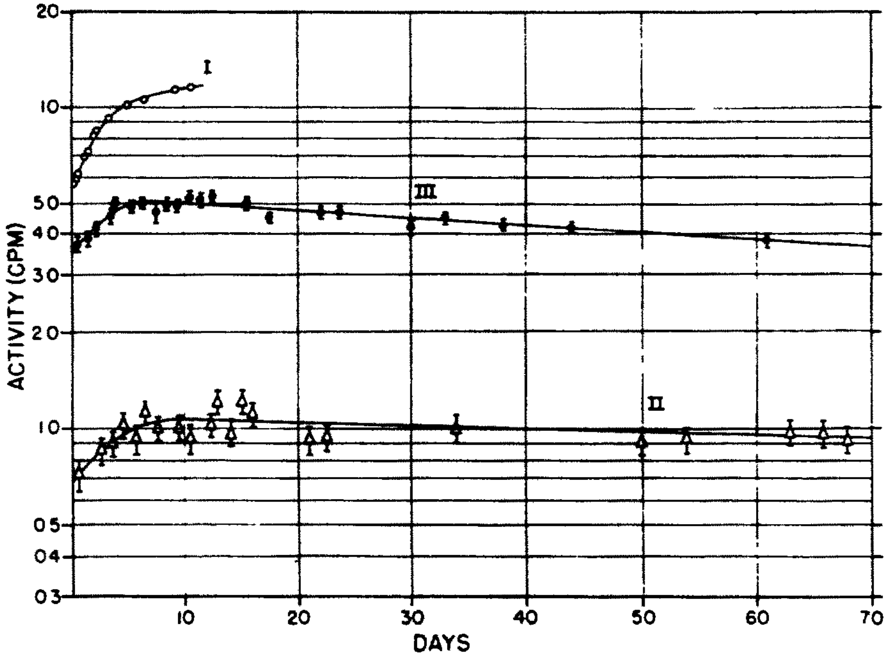

FIG 2.—Radioactivity of the strontium fractions isolated from pitchblende and depleted uranium.

I—2,600 g of pitchblende; chemical yield: 42%.
II—3,750 g of pitchblende; chemical yield 5%,
III—2,052 g of ^{238}UO$_3$; chemical yield 39%.

Numerous attempts made to recover strontium from acid-soluble fractions of the African pitchblende have all failed. The chemical yields were generally 5% or less in all such analytical schemes.

For example, strontium carrier (141 mg) was added to 3,750 g of the pitchblende, the whole being dissolved in dilute nitric acid; and, after the nitric acid was distilled off, the bulk of uranium was extracted with ether. The strontium carrier was recovered from the residue, after a lengthy chemical operation, with a chemical yield of only 5%. The counting data for the strontium fraction obtained in this experiment are shown in Fig. 2 as Curve II.

An attempt to separate the strontium fraction from 200 g of the pitchblende together with 150 mg of added barium carrier gave a chemical yield of only 3·7%. A chemical yield of 0% was obtained in many similar experiments.

All of these results suggest that the strontium is probably precipitated as the sulphate in the initial stage of the sample treatment, and hence it is almost impossible to recover the strontium fraction without the process of fusion.

The recovery of the strontium fraction from uranium salt is somewhat easier, in that the fusion step is not required. $^{238}UO_3$(2,052 g) was converted to

$$UO_2(NO_3)_2.6H_2O(2{,}945\ g)$$

and was treated with 40 litres of 80% nitric acid, after the addition of 200 mg of strontium carrier. The precipitate, which contained calcium, strontium, barium and radium, was converted to the carbonates. The carbonate precipitate was dissolved in dilute hydrochloric acid, and the iron^{III} hydroxide scavenging process was repeated three times. The purified carbonate precipitate was treated with nitric acid and evaporated to dryness. The strontium fraction was further purified according to an analytical scheme similar to that given in Fig. 1. The strontium was finally precipitated as the carbonate, filtered, dried and weighed. The chemical yield was 39%. The counting data are shown in Fig. 2 as Curve III.

TABLE I—RADIOSTRONTIUM CONTENTS OF THE AFRICAN PITCHBLENDE AND DEPLETED URANIUM

Sample	Chemical yield, %	10^{-4} × Disintegrations. sec^{-1}. g^{-1} of uranium in the sample[b]	
		^{89}Sr	^{90}Sr
I. African pitchblende (2,600 g)[c]	42	3·5 ± 0·3	5·8 ± 0·5
II. African pitchblende (3,750 g)[d]	5·0	——[a]	3 ± 2
III Depleted uranium (2,052 g) as $^{238}UO_3$[d]	39	2·8 ± 0·2	1·1 ± 0·1

[a] Measurement was impossible because about 200 days have elapsed since the initial separation of strontium from pitchblende.

[b] The errors reported here originate from uncertainty in analyzing the decay-growth curves.

[c] Sample I treated by fusion procedure.

[d] Samples II and III treated by acid-extraction procedure.

Precise determinations of the low-level activities of strontium-89 and -90 require at least a few months of careful counting, and hence only preliminary results can be reported here. Table I summarises the results obtained so far.

The results indicate that the strontium-89 and -90 are formed predominantly by the spontaneous fission of uranium-238. The equilibrium activity of the spontaneous fission-produced strontium-90 in uranium-bearing materials is calculated to be

$$\begin{aligned} N^{90}\lambda_{90} &= N^{238}\lambda_{238f} \,.\, Y^{90} \\ &= \frac{6{\cdot}02 \times 10^{23}}{238} \cdot \frac{\ln 2}{(8{\cdot}0 \times 10^{15})(3{\cdot}16 \times 10^{7})} \cdot (0{\cdot}05) \qquad (2) \\ &= 3{\cdot}5 \times 10^{-4} \text{ (disintegrations. sec}^{-1}\text{. g}^{-1}\text{ of uranium),} \end{aligned}$$

where N^{90} and N^{238} are the number of atoms of strontium-90 and uranium-238, respectively, λ_{90} is the decay constant of strontium-90, λ_{238f} is the spontaneous fission decay constant of uranium-238, and Y^{90} is the yield of mass 90 chain (tentatively assumed to be 5% in the above calculation).

The amount of strontium-90 in pitchblende appears to be considerably higher than the value calculated above, probably because of the contribution from the neutron-induced fission of uranium-235.

On the other hand, the level of strontium-90 in non-irradiated depleted uranium is much lower than that in uranium ore. This is most likely because the half-life of strontium-90 is greater than the "age" or the time elapsed since the preparation of the uranium salt. The results thus indicate that the secular equilibrium between strontium-90 and uranium is not yet established in the uranium salt. The following relationship should hold between the strontium-90/uranium-238 ratio and the "age" of the uranium salt:

$$N^{90}\lambda_{90} = N^{238}\lambda_{238f} \, . \, Y^{90} \, . \, (1 - e^{-\lambda_{90}t}) \tag{3}$$

where t is the "age" of the uranium salt. Thus it appears that the uranium salts can be dated from the observed strontium-90/uranium-238 ratios.

It is interesting to compare the activities of strontium-90 and radium in pitchblende. Because radium is expected to be also in secular equilibrium with uranium in pitchblende,

$$\frac{\text{Strontium-90 activity}}{\text{Radium-226 activity}} = \frac{\lambda_{238f}}{\lambda_{238\alpha}} \, . \, Y^{90}, \tag{4}$$

where $\lambda_{238\alpha}$ is the alpha-decay constant of uranium-238.

Equation (4) yields a value of 28 mμc of strontium-90 per g of radium in pitchblende. This calculation shows that Mme. Curie must have handled quite a considerable activity of strontium-90 (in fact, roughly 60,000 disintegrations per min of strontium-90 per g of radium isolated from pitchblende!) during her experiments. This activity would have been well within the limit of detection of the electroscope used in those days. It is perhaps fortunate, though, that man did not discover the process of nuclear fission almost a half century earlier!

Acknowledgments—One of the authors (P.K.K.) would like to take this opportunity to thank his great teacher, Professor Kolthoff, not only for invaluable guidance, encouragement, advice and inspiration, but also for (i) allowing him to marry one of the pupils (Miss Loes Morren from the Hague, Netherlands), (ii) promptly giving a warm overcoat to the chemist just immigrated from Japan, who was shivering in the cold winter of Minnesota, and (iii) allowing him to consume a quite considerable quantity of his teacher's blood for the purely scientific purpose of developing a better method for the amperometric determination of -SH and -SS groups in biological samples, in connection with the cancer research project at the University of Minnesota.

This investigation was supported by the U S Atomic Energy Commission. We are grateful to Mr J. C. Kizziar for his assistance.

Zusammenfassung—Durch Zählen bei niedrigen Zählraten und analytische Verarbeitung großer Mengen wurden extrem geringe Mengen von Strontium-89 und -90 in Uranerzen und -salzen bestimmt. Strontiumträger wurde zu Kilogramm-Mengen nicht bestrahlten Uranerzes bzw. -salzes gegeben, erschopfend gereinigt und gezählt. Der Anteil von Radiostrontium lag in der Größenordnung von 10^{-4} Zerfällen pro Sekunde und Gramm U in der Probe. Diese Strontiumisotope werden in nicht bestrahlten Uransalzen und -erzen vorwiegend durch spontane Spaltung von Uran gebildet, in den Erzen scheint aber auch neutroneninduzierte Spaltung von Uran-235 vorzukommen.

Résumé—Une technique de comptage à bas niveau a été combinée à une opération analytique à grande échelle pour déterminer des quantités extrêmement faibles de strontium-89 et -90 contenues dans les minerais et les sels d'uranium. On a ajouté du strontium comme porteur à un échantillon d'un kilogramme de minerai et de sel d'uranium non irradié, parfaitement purifié et compté Les niveaux du strontium radioactif étaient de l'ordre de 10^{-4} désintégration par seconde et par gramme d'uranium dans l'échantillon Ces isotopes du strontium dans les sels et les minerais d'uranium non irradiés proviennent principalement de la fission naturelle de l'uranium, mais la fission induite par les neutrons de l'uranium-235 semble aussi se produire

148. The sensibility of indicator dyes at temperatures higher than ordinary temperatures. *Rec. Trav. chim.*, 1921, **40**, 775–85.
149. Titration of moderately strong, in the presence of very weak, acids or bases. *Pharm. Weekblad*, 1922, **59**, 129–42.
150. Colorimetric determination of hydrogen-ion concentration without buffer. *Ibid.*, 1922, **59**, 104–18.
151. The use of the iodine electrode in potentiometric titrations. *Rec. Trav. chim.*, 1922, **41**, 172–91.
152. The hydrolysis of antipyrine salicylate. *Ibid.*, 1922, **41**, 135–44.
153. Application of conductometric titrations in analysis. *Chem. Weekblad*, 1920, **17**, 694–701.
154. Application of conductometric methods to precipitation analysis. *Z. analyt. Chem.*, 1922, **61**, 171–80.
155. The use of conductivity titrations in precipitation analysis. *Ibid.*, 1922, **61**, 229–40.
156. Conductivity titrations in precipitation analysis. *Ibid.*, 1922, **61**, 332–43.
157. The application of conductivity titrations in precipitation analysis. *Ibid.*, 1922, **61**, 369–77.
158. The use of potassium ferrocyanide in potentiometric titrations. *Rec. Trav. chim.*, 1922, **41**, 425–37.
159. Potentiometric titrations of potassium ferrocyanide and potentiometric titrations by means of ferrocyanide. *Ibid.*, 1922, **41**, 343–52.
160. Active carbonic acid and the hydrogen-ion concentration in water investigations. *Z. Nahr. Genussm.*, 1922, **43**, 184–92.
161. Qualitative reaction for arsenic. *Pharm. Weekblad*, 1922, **59**, 334–50.
162. Iodometric determination of arsenic acid. *Z. analyt. Chem.*, 1923, **62**, 137–8.
163. The use of conductivity titrations in precipitation analyses. *Ibid.*, 1922, **61**, 433–8.
164. Conductivity titration in precipitation analysis. *Ibid.*, 1923, **62**, 1–7.
165–168. The application of conductivity titrations in precipitation analysis. VIII. *Ibid.*, 1923, **62**, 161–78. IX. *Ibid.*, 209–14. X. *Ibid.*, 214–5. XI. *Ibid.*, 216–7.
169. Iodine determination in ferrous iodide pills. *Pharm. Weekblad*, 1922, **59**, 1100–3.
170. Detection of methanol in liquids containing ethyl alcohol. *Ibid.*, 1922, **59**, 1268–74.
171. Determination of chloral hydrate. *Ibid.*, 1923, **60**, 2–8.
172. Iodometric titration of sublimate. *Ibid.*, 1923, **60**, 18–20.
173. The determination of traces of invert sugar in sucrose. *Arch. Suikerind.*, 1922, **30**, 867–70.

174. The calculation of the salt content of drinking water from the electric conductivity. *Chem. Weekblad*, 1922, **19**, 407–9.
175. The successive titration of boric acid and phosphoric acid. *Ibid.*, 1922, **19**, 449–50.
176. Iodometric determination of antipyrine. *Pharm. Weekblad*, 1923, **60**, 194–9.
177. Colorimetric determinations of the water content of absolute alcohol. *Ibid*, 1923, **60**, 227–31.
178. Titration of calcium hypochlorite. *Ibid.*, 1923, **60**, 241–8; *Rec. Trav. chim.*, 1922, **41**, 740–50.
179. The degree of acidity of milk. *Handel Genootsch. Melkk.*, 1920, **120**, Pt. 2, 5–16.
180. Acidimetric titration of magnesium in its salts. *Rec. Trav. chim.*, 1922, **41**, 787–94.
181. Iodometric determination of aldose. *Pharm. Weekblad*, 1923, **60**, 362–75.
182. The reaction between hypochlorite and potassium iodide. *Rec. Trav. chim.*, 1922, **41**, 615–26.
183. Adaptation of the iodometric aldose determination to the analysis of mixtures containing carbohydrate. *Pharm. Weekblad*, 1923, **60**, 394–402.
184. Compounds between sugars and salts. *Arch. Suikerind.*, 1923, **31**, 261–9.
185. Compounds between sugars and salts: II. *Ibid.*, 1923, **31**, 799–802.
186. Titration of iodides according to Winkler. *Pharm. Weekblad*, 1923, **60**, 841–5.
187. The influence of alcohol on the sensitiveness of dye indicators. *Rec. Trav. chim.*, 1923, **42**, 251–75.
188. The use of the quinhydrone electrode in place of the hydrogen electrode in potentiometric acidity determination. *Ibid.*, 1923, **42**, 186–98.
189. Colorimetric determination of hydrogen-ion concentration by the method of Michaelis with one-colour indicators, with inorganic solutions for colour comparison. *Pharm. Weekblad*, 1923, **60**, 949–66.
190. Estimation of the alkali metals as sulphates (With N. Schoorl). *Chem. Weekblad*, 1920, **17**, 425–7.
191. A new qualitative test for sodium. *Pharm. Weekblad*, 1923, **60**, 1251–5.
192. The detection and colorimetric determination of cyanide as thiocyanate. *Z. analyt. Chem.*, 1924, **63**, 188–90.
193. Influence of salts on the potential of the silver–silver bromide electrode. *Z. anorg. Chem.*, 1923, **132**, 117–24.
194. The adaptation of potassium permanganate to oxidimetry. *Pharm. Weekblad*, 1924, **61**, 133–7.
195. The dissociation constant of lithium hydroxide. The second dissociation constant of salicylic acid. *Rec. Trav. chim.*, 1923, **42**, 969–72.
196. The dissociation constants of the alkaline earth hydroxides. *Ibid*, 1923, **42**, 973–9.
197. The salt error of nitramine (picrylmethylnitramine). *Ibid.*, 1923, **42**, 964–8.
198. The colorimetric determination of the hydrogen exponent of the soil. *Chem. Weekblad*, 1923, **20**, 675–7.
199. Spontaneous decomposition of permanganate under various conditions. *Pharm. Weekblad*, 1924, **61**, 337–43.
200. The use of diphenylcarbazide as a qualitative reagent on metals. *Chem. Weekblad*, 1924, **21**, 20–2.

201. The use of benzidine as reagent and also as indicator for a definite oxidation potential. *Ibid.*, 1924, **21**, 2–4.
202. The titration of oxalic acid with permanganate. *Pharm. Weekblad*, 1924, **61**, 377–90, 417–29.
203. The titration of oxalic acid with permanganate. *Z. analyt. Chem.*, 1924, **64**, 185–211.
204. The influence of some colloids on the titration of chlorine by the Volhard method. *Chem. Weekblad*, 1924, **21**, 188–9.
205. The use of mercury electrodes in potentiometric titrations. The determination of halogens, cyanides, sulphides and thiosulphate (With E. J. A. H. Verzijl). *Rec. Trav. chim.*, 1923, **42**, 1111.
206. Standardisation of permanganate with Mohr's salt. *Pharm. Weekblad*, 1924, **61**, 561–6.
207. The colorimetric determination of the hydrogen-ion concentration by the wedge method and the dissociation constants of various indicators. *Rec. Trav. chim.*, 1924, **43**, 144–52.
208. The second dissociation constant of sulphuric acid. *Rec. Trav. chim.*, 1924, **43**, 207–15.
209. The strength of the acid function of the sulphur-oxygen acids. *Ibid.*, 1924, **43**, 216–20.
210. Standardisation of permanganate with different reagents. *Pharm. Weekblad*, 1924, **61**, 786–9.
211. The titration of arsenious acid with permanganate. *Ibid.*, 1924, **61**, 738–42.
212. Volumetric analysis of hydrazine by the iodine, bromate, iodate and permanganate methods. *J. Amer. Chem. Soc.*, 1924, **46**, 2009–16.
213. Determination of sulphurous acid, thiosulphate and sulphide with potassium permanganate. *Pharm. Weekblad*, 1924, **61**, 841–6.
214. Oxidation of nitrous acid, hydrazine, ammonia and hypophosphite by permanganate. *Ibid.*, 1924, **61**, 954–60.
215. A double salt of ferricyanide of caesium and zinc (With E. J. A. H. Verzijl). *Rec. Trav. chim.*, 1924, **43**, 394–6.
216. The practical utility of the potentiometric titration of zinc with ferrocyanide (With E. J. A. H. Verzijl). *Ibid.*, 1924, **43**, 380–8.
217. The titration of zinc by means of different metallic ferrocyanides (With E. J. A. H. Verzijl). *Ibid.*, 1924, **43**, 389–93.
218. The standardisation of permanganate with various standard substances. *Z. analyt. Chem.*, 1924, **64**, 255–62.
219. The hydrostrychnine reagent for nitrites and nitrates. *Chem. Weekblad*, 1924, **21**, 423–4.
220. The titration of manganous salts with permanganate. *Pharm. Weekblad*, 1924, **61**, 1141–9.
221. The titration of ferrous salts with permanganate (With Nel Smit). *Ibid.*, 1924, **61**, 1082–95.
222. Determination of ammonium salts by acidimetric titration with formaldehyde. *Arch. Suikerind.*, 1924, **32**, 665–6.
223. The state of the silver in protargol and collargol. *Pharm. Weekblad*, 1924, **61**, 1280–5.

224. The application of titanous chloride to potentiometric titrations: I. *Rec. Trav. chim.*, 1924, **43**, 768–74.
225. The application of titanous chloride to potentiometric titrations: II (With O. Tomiček) *Ibid.*, 1924, **43**, 775–83.
226. The titration of ferric and cupric salts separately and in the presence of one another, also in the presence of antimony, by means of titanous chloride. *Rec. Trav. chim.*, 1924, **43**, 816–22.
227. A colour reaction for glycerol. *Pharm. Weekblad*, 1924, **61**, 1497–8.
228. Evaluation of morphine in opial. *Ibid.*, 1925, **62**, 106–8.
229. Evaluation of opial. *Ibid.*, 1925, **62**, 190–2.
230. A new set of buffer mixtures that can be prepared without the use of standardized acid or base. *J. Biol. Chem.*, 1925, **63**, 135–41.
231. The state of methyl red in the interval of its colour change. *Rec. Trav. chim.*, 1925, **44**, 75–81.
232. The state of methyl orange in the interval of its colour change. *Ibid.*, 1925, **44**, 68–74.
233. The adsorption of electrolytes on charcoal. *Proc. Acad. Sci. Amsterdam*, 1924, **27**, 742–9.
234. The use of bromophenol blue in the determination of alkaloids in galenical preparations and drugs. *Pharm. Weekblad*, 1925, **62**, 478–85.
235. The salt error of indicators in solutions poor in electrolytes. *Rec. Trav. chim.*, 1925, **44**, 275–8.
236. Detection and determination of *p*-saccharin in saccharin and crystallose. *Pharm. Weekblad*, 1925, **62**, 548–53.
237. The sensitive adaptation of the iodoform reaction and the detection of acetone in spirit. *Ibid.*, 1925, **62**, 652–5.
238. The reliability of the quinhydrone electrode for the measurement of hydrogen-ion concentration in various solutions. *Z. Physiol. Chem.*, 1925, **144**, 259–71.
239. The standard values for calculation of pH from measurements with hydrogen or quinhydrone electrode. *Chem. Weekblad*, 1925, **22**, 332–9.
240. Reactions in ionisation and catalysis. *Ibid.*, 1925, **22**, 356–7.
241. The titration of iodide with iodate. *Pharm. Weekblad*, 1925, **62**, 878–82.
242. Adaptation of the cyanogen iodide method to the titration of iodide and ferrous iron in syrup of ferrous iodide. *Ibid.*, 1925, **62**, 910–14.
243. The acid character of saccharin and related acids. The detection and determination of *p*-sulphamylbenzoic acid in saccharin and crystallose. *Rec. Trav. chim.*, 1925, **44**, 629–37.
244. Argentometric titration of iodide. *Pharm. Weekblad*, 1925, **62**, 1309–12.
245. The state of silver in protargol (argenti proteinatum) and collargol (colloid silver argentum crede). *J. Amer. Pharm. Assoc.*, 1925, **14**, 183–9.
246. The chemical state of protein solutions. *Chem. Weekblad*, 1925, **22**, 489–94.
247. The significance of pH in bacteriology. *Tijdschr. vergel. Geneeskunde*, 1925, **11**, 268–77.
248. Electrometric titration of alkaloids and the reaction of alkaloid salts. *Pharm. Weekblad*, 1925, **62**, 1287–93.
249. The reaction of neutral water and of distilled water. *Chem. Weekblad*, 1925, **22**, 590–4.

250. The interpretation of the neutralisation curves of mixtures of boric acid and polyhydric alcohols. *Rec. Trav. chim.*, 1925, **44**, 975–82
251. The reaction of neutral and distilled water. *Biochem. Z.*, 1926, **168**, 110–21
252. Standardisation of hydrochloric acid against potassium iodate compared with results obtained against soda and borax. *Pharm. Weekblad*, 1926, **63**, 37–48.
253. A simple method for determination of nitrobenzene *Chem. Weekblad*, 1925, **22**, 558–9.
254. Standardisation of hydrochloric acid with potassium iodate as compared with borax and sodium carbonate as standard substances *J. Amer. Chem. Soc*, 1926, **48**, 1447–54.
255. A modification of Schoorl's titration of sugars *Chem. Weekblad*, 1926, **23**, 61–2.
256. Clarification of urine containing sugar with charcoal. *Biochem. Z.*, 1926, **168**, 122–7.
257. The reaction between cupric copper and iodide and between cuprous iodide and iodine. *Rec. Trav. chim.*, 1926, **45**, 152–61.
258. The iodometric determination of cuprous oxide in sugar titrations. *Arch. Suikerind.*, 1926, **34**, 123–30.
259. Note on the significance of the reaction in refinery operation. *Ibid.*, 1926, **34**, 130–4.
260. The dissociation constants, solubility product and titration of alkaloids. *Biochem. Z.*, 1925, **162**, 289–353.
261. Detection and determination of free chlorine in drinking water. *Chem. Weekblad*, 1926, **23**, 203–4.
262. The hydration of dissolved sucrose and the expression of the concentration by measuring the activity of the ions. *Verslag. Akad. Wetenschappen Amsterdam*, 1926, **35**, 281–95.
263. The methyl orange error in the colorimetric pH determination by comparison with Clark's buffer mixtures. *Rec. Trav. chim.*, 1926, **45**, 433–5.
264. The influence of boric acid on the electrolytic dissociation of electrolytes. *Ibid.*, 1926, **45**, 394–9.
265. The change of the dissociation constant of boric acid with the concentration of this acid. *Ibid.*, 1926, **45**, 501–7.
266. The expression of the reaction of aqueous solutions. *Biochem. Z.*, 1926, **169**, 490–3.
267. The carbon-dioxide content of distilled water and its determination. *Chem. Weekblad*, 1926, **23**, 381–4.
268. The microtitration of iodides with iodate and the determination of the iodide and ferrous iron content in syrup of ferrous iodide. *J. Amer. Pharm. Assoc.*, 1926, **15**, 164–6.
269. The titration of hypophosphorous acid and hypophosphites with permanganate. *Z. analyt. Chem.*, 1926, **69**, 36–8.
270. Hydration of dissolved sucrose and the expression of the concentration in measuring the activity of ions. *Proc. Acad. Sci. Amsterdam*, 1926, **29**, 885–98.
271. The Denigès reaction for citric acid. *Pharm. Weekblad*, 1926, **63**, 1322–3.
272. Influence of chlorides on the Denigès reaction for citric acid. *Ibid.*, 1926, **63**, 1453–5.

273. The carbon dioxide content of distilled water and its exact determination. *Biochem. Z.*, 1926, **176**, 101–9.
274. Reduction-oxidation potentials. A comment on the paper by P. Hirsch and R. Rüter. *Z. analyt. Chem.*, 1926, **69**, 374–7.
275. Iodometric titration of acids. *Chem. Weekblad*, 1926, **23**, 260–1.
276. Micro-titration of iodide. *Mikrochemie*, 1925, **3**, 75–9.
277. Complex-dissociation constants of compounds of boric acid with salts of some organic hydroxyacids. *Rec. Trav. chim.*, 1926, **45**, 607–19.
278. The volatility of borax. *Nature*, 1927, **119**, 425–6.
279. The argentometric determination of iodide in the presence of chloride with adsorption indicators as recommended by Fajans. *Z. analyt. Chem.*, 1927, **70**, 395–7.
280. A specific reagent for sodium ions. *Ibid.*, 1927, **70**, 397–400.
281. The titration of hydroquinone with iodine or dichromate according to the ordinary and the potentiometric method. *Rec. Trav. chim.*, 1926, **43**, 743–52.
282. The use of methoxytriphenylcarbinols as one-color indicators. *J. Amer. Chem. Soc.*, 1927, **49**, 1218–21.
283. The direct titration of zinc with potassium ferrocyanide with diphenylamine or diphenylbenzidine as indicators. *Chem. Weekblad*, 1927, **24**, 203–4.
284. The argentometric titration of chloride and iodide with adsorption indicators. *Z. analyt. Chem.*, 1927, **71**, 235–43.
285. A new specific colour test and a colorimetric method for determining traces of magnesium. *Chem. Weekblad*, 1927, **24**, 254–5.
286. A new specific colour reaction of magnesium and a simple colorimetric method for the determination of traces of this element. *Biochem. Z.*, 1927, **185**, 344–8.
287. The dissociation constant of hypophosphorous acid, phosphorous acid and phosphoric acid. *Rec. Trav. chim.*, 1927, **46**, 350–8.
288. A determination of the basic constant of morphine and its application in the titration of morphine. *Pharm. J.*, 1927, **118**, 126–7.
289. The use of potassium bi-iodate as a standard substance in alkalimetric and iodometric titrations (With L. H. Van Berk). *J. Amer. Chem. Soc.*, 1926, **48**, 2799–801.
290. The accuracy of halide and thiocyanate titration according to Fajans and according to the usual methods compared to the results of potentiometric determinations (With L. H. Van Berk). *Z. analyt. Chem.*, 1927, **70**, 369–94.
291. The use of yellow mercuric oxide and of metallic mercury as standards in volumetric analysis (With L. H. Van Berk). *Ibid.*, 1927, **71**, 339–49.
292. The application of the quinhydrone electrode to solutions with a low buffer capacity (With Wouter Bosch). *Chem. Weekblad*, 1927, **24**, 78–80.
293. A correction for the new citrate buffers (With J. J. Vleeschhouwer). *Ibid.*, 1927, **24**, 78.
294. The abnormal change in pH in boric acid-sodium hydroxide mixtures at different concentrations and temperatures (With Wouter Bosch). *Rec. Trav. chim.*, 1927, **46**, 180–8.
295. The use of the quinhydrone electrode for measuring the hydrogen-ion concentration in solutions of low buffer capacity (With Wouter Bosch). *Biochem. Z.*, **183**, 434–43.

296. The influence of neutral salts on acid-salt equilibria: I. (With Wouter Bosch). *Rec. Trav. chim.*, 1927, **46**, 430–8.
297. The potentiometric determination of the hydrogen ion concentration at higher temperatures (With F. Tekelenburg). *Proc. Acad. Sci. Amsterdam*, 1926, **29**, 766–75.
298. The change of the pH in buffer mixtures at varying temperatures (With F. Tekelenburg). *Rec. Trav. chim.*, 1927, **46**, 33–41.
299. The potentiometric determination of ferrous and ferrocyanide ions with potassium bromate (With J. J. Vleeschhouwer). *Ibid.*, 1926, **45**, 923–7.
300. A new set of buffer mixtures of pH 2·2 to 6·0 (With J. J. Vleeschhouwer). *Chem. Weekblad*, 1926, **23**, 510.
301. A new series of buffer solutions of a pH range between 2·2 and 6·0 (With J. J. Vleeschhouwer). *Biochem. Z.*, 1926, **179**, 410–3.
302. A correction to the new buffer solution series (With J. J. Vleeschhouwer). *Ibid.*, 1927, **183**, 444–5.
303. Displacement of chemical equilibria at an interface. *Kolloid-Z.*, 1927, **43**, 51.
304. A sensitive reaction of aluminium: the colorimetric determination of this element. *Chem. Weekblad*, 1927, **24**, 447–8.
305. Adsorption of electrolytes on pure ash-free carbon. *Rec. Trav. chim.*, 1927, **46**, 549–73.
306. The adsorption of strong electrolytes on pure ash-free charcoal. *Z. Elektrochem. angew. physik. Chem.*, 1927, **23**, 497–501.
307. The use of mixed indicators in acidimetry or alkalimetry. *Biochem Z.*, 1927, **189**, 26–32.
308. The detection and determination of metals by means of 8-hydroxyquinoline (oxine). *Chem. Weekblad*, 1927, **24**, 606–10.
309. The detection of traces of beryllium and the colorimetric determinations of this element. *J. Amer. Chem. Soc.*, 1928, **50**, 393–5.
310. The exact determination of the equivalence point in potentiometric titrations. *Rec. Trav. chim.*, 1928, **47**, 397–400.
311. Colloidal silver preparation. *Pharm. Weekblad*, 1928, **65**, 362–5.
312. The use of quinaldine red for hydrogen-ion concentration determinations in acid medium. *Biochem. Z.*, 1928, **194**, 78–82.
313. The use of pinachrome as a one-color indicator. *J. Amer. Chem. Soc.*, 1928, **50**, 1604–8.
314. The determination and colorimetric determination of traces of aluminum. *J. Amer. Pharm. Assoc.*, 1928, **17**, 360–1.
315. Rapid method for the separation of aluminum and beryllium (With Ernest B. Sandell). *J. Amer. Chem. Soc.*, 1928, **50**, 1900–4.
316. The dissociation constant of naphthylaminesulphonic acid. *Chem. Weekblad*, 1928, **25**, 234.
317. Effect of dilution on the pH of buffer mixtures. *Biochem. Z.*, 1928, **195**, 239–47.
318–320. The influence of neutral salts on acid-salt equilibria (With Wouter Bosch). II. *Rec. Trav. chim.*, 1928, **47**, 558–75. III. *Ibid.*, 819–25. IV. *Ibid.*, 826–33.
321. Volumetric determination of ammonia with hypobromite according to the usual method and by the potentiometric method (With A. Laur). *Z. analyt. Chem.*, 1928, **73**, 196–200.

322. Gravimetric determination of copper as thiocyanate (With G. H. P. v. d. Meene). *Ibid.*, 1927, **72**, 337-45
323. The completion of the series of buffer mixtures for the alkaline range (With J J. Vleeschhouwer). *Biochem. Z.*, 1927, **189**, 191-3.
324. Addition to the series of buffer solutions in the alkaline range (With J. J. Vleeschhouwer). *Chem. Weekblad*, 1927, **24**, 526.
325. A specific reagent for the rapid gravimetric determination of sodium (With H. H. Barber). *J. Amer. Chem. Soc.*, 1928, **50**, 1625-31
326. The salt error of indicators in the colorimetric determination of pH. *J. Phys. Chem.*, 1928, **32**, 1820-33
327. Directions for the preparation of a "universal indicator" for estimating pH over a wide range. *Pharm. Weekblad*, 1929, **66**, 67-70.
328. Influence of sucrose on the dissociation constant of weak acids in aqueous solution. *Rec. Trav. chim* , 1929, **48**, 220-6.
329. The decomposition of aqueous bromide and of bromic acid solution by charcoal *Ibid.*, 1929, **48**, 291-7
330. The influence of charcoal upon the velocity of the reaction between iodide-iodate and hydrogen ions, the decomposition of thiosulphuric acid and the reaction between phenol and bromine. *Ibid.*, 1929, **48**, 298-309.
331. Zinc uranyl acetate as a reagent for sodium. *Chem. Weekblad*, 1929, **26**, 294-8.
332. Titration of potassium ferrocyanide with diphenylamine as internal indicator *Ibid.*, 1929, **26**, 298-301
333. The "water correction" in the measurement of the electrical conductivity of very dilute aqueous solutions of electrolytes. *Rec. Trav. chim.*, 1929, **48**, 664-80.
334-336. The influence of neutral salts on acid-base equilibria (With W. Bosch) V. *Rec. Trav. chim* , 1928, **47**, 861-72. VI. *Ibid.*, 872-82. VII. *Ibid.*, 1929, **48**, 1929, 37-48.
337. The adsorption of hydroxybenzenes and other aromatic compounds and their displacement of each other at the interface water-charcoal (With Els van der Goot) *Rec. Trav. chim.*, 1929, **48**, 265-87.
338. Measurement of the hydrogen-ion concentration in unbuffered solutions. I (With Tohru Kameda) *J. Amer. Chem. Soc.*, 1929, **51**, 2888-2900.
339. Volumetric determination of manganese as dioxide with special reference to the application of potassium bromate as oxidizing agent (With Ernest B. Sandell). *Ind. Eng. Chem., Analyt.*, 1929, **1**, 181-5.
340. Lecture demonstrations in analytical chemistry. *J. Chem. Educ.* 1929, **6**, 1910-5.
341. Confusion in the expression of the so-called "hydrogen-ion concentration" of a solution and a review of Brønsted's conception of acidity and basicity. *Rec. Trav. chim.*, 1930, **49**, 401-14.
342. Two delicate tests for the detection of copper with some remarks on the rhodanine test of Feigl for silver. *J. Amer. Chem. Soc.*, 1930, **52**, 2222-6.
343. Conductometric titration. *Ind. Eng. Chem., Analyt.*, 1930, **2**, 225-30.
344. Indicator constants. *J. Phys. Chem.*, 1930, **34**, 1466-83.
345. The cobalt thiocyanate reaction for the detection of cobalt and thiocyanate. *Microchemie* (*N.S.*), 1930, **2**, 176-81.

346 Ionic activity products and ionic activity constants. *Chem. Weekblad*, 1930, **27**, 250–61.

347. Use of dichlorofluorescein as an adsorption indicator for the argentometric titration of chlorides (With W. M. Lauer and C. J. Sunde) *J. Amer. Chem. Soc.*, 1929, **51**, 3273–7.

348 Determination of chromium and vanadium after oxidation with potassium bromate. Separate titration of chromate and vanadate in the same solution and application of the method to steel analysis (With Ernest B. Sandell). *Ind. Eng. Chem., Analyt.*, 1930, **2**, 140–5.

349. Properties of diphenylamine and diphenylbenzidine as reduction-oxidation indicators (With L. A. Sarver). *Z. Elektrochem.*, 1930, **36**, 139–41.

350. Gravimetric determination of sodium by the uranyl zinc acetate method II (With H. H. Barber). *J. Amer. Chem. Soc.*, 1929, **51**, 3233–7.

351. The "drop method" apparatus of Todt for the colorimetric determination of pH values. *Chem. Weekblad*, 1931, **28**, 78–9.

352. The "drop method" apparatus of Todt for the colorimetric determination of pH *Ibid.*, 1931, **28**, 262.

353. Acid-base-catalysis according to J. N. Brønsted. *Ibid.*, 1930, **28**, 110–21.

354. Color reactions for magnesium. *Mikrochem., Emich Festschr.*, 1930, 180–90.

355. The dissociation of acid-base indicators in ethyl alcohol with a discussion of the medium effect upon the indicator properties. *J. Phys. Chem.*, 1931, **35**, 2732–48.

356. The sensitivity of chemical precipitations. *Z. analyt. Chem.*, 1931, **86**, 34–40.

357. Lanthanum alkali oxalates (With Ruth Elmquist). *J. Amer. Chem. Soc.*, 1931, **53**, 1232–6.

358. The solubilities of lanthanum oxalate and of lanthanum hydroxide in water. The mobility of the lanthanum ion at 25° (With Ruth Elmquist). *Ibid.*, 1931, **53**, 1217–25.

359. The quantitative determination of lanthanum by precipitation as oxalate or as hydroxide and the higher oxide formation of lanthanum (With Ruth Elmquist). *Ibid.*, 1931, **53**, 1225–32.

360. The measurement of the hydrogen-ion concentration in unbuffered solutions: II (With Tohru Kameda). *Ibid.*, 1931, **53**, 821–4.

361. Conductometric titration of sulfate and barium (With Tohru Kameda). *Ind. Eng. Chem., Analyt.*, 1931, **3**, 129–33.

362. The hydrolysis of zinc sulfate solutions, solubility product of hydrous zinc oxide and the composition of the latter precipitated from zinc sulfate solutions (With Tohru Kameda). *J. Amer. Chem. Soc.*, 1931, **53**, 832–42.

363. Stability of potassium ferrocyanide solutions (With E. A. Pearson). *Ind. Eng. Chem., Analyt.*, 1931, **3**, 381–2.

364. Direct and reverse titration of sulfuric acid with barium hydroxide (With E. B. Sandell). *Ibid.*, 1931, **3**, 115–7.

365. Properties of diphenylamine and diphenylbenzidine as oxidation-reduction indicators (With L. A. Sarver). *J. Amer. Chem. Soc.*, 1930, **52**, 4179–91.

366. The reaction between nitrite and iodide and its application to the iodimetric titration of these anions (With Carlos A. Abeledo). *Ibid.*, 1931, **53**, 2893–7.

367. Diphenylaminesulfonic acid as a new oxidation-reduction indicator (With L. A. Sarver). *Ibid.*, 1931, **53**, 2902–5.

368. Indicator corrections for diphenylamine, diphenylbenzidine and diphenylaminesulfonic acid (With L. A. Sarver). *Ibid.*, 1931, **53**, 2906–9
369. Solubilities and solubility products of metallic sulfides in water. *J. Phys. Chem.*, 1931, **35**, 2711–21.
370. The theory of coprecipitation-formation and properties of crystalline precipitates. *Ibid.*, 1932, **36**, 860–81.
371–374. Formation and properties of precipitates Theory of coprecipitation: IV. *Chem. Weekblad.*, 1932, **29**, 346–8. V. *Ibid.*, 362–3. VI. *Ibid.*, 378–80. VII. *Ibid.*, 395–400.
375. Formation and properties of precipitates, theory of coprecipitation. *Ibid.*, 1932, **29**, 442–8.
376. The activity coefficient of benzoic acid in solutions of neutral salts and of sodium benzoate (With Wouter Bosch). *J. Phys. Chem.*, 1932, **36**, 1685–94.
377. The ionization constant of benzoic acid and the activity coefficient of benzoate ion in presence of neutral salts (With Wouter Bosch). *Ibid.*, 1932, **36**, 1695–1701.
378. The mean and individual ion activity coefficients of silver benzoate in salt solutions (With Wouter Bosch). *Ibid*, 1932, **36**, 1702–11.
379. Titration of zinc with potassium ferrocyanide. Use of diphenylamine or diphenylbenzidine as internal indicators (With E. A. Pearson). *Ind. Eng. Chem., Analyt.*, 1932, **4**, 147–50.
380. Composition of precipitated copper sulfide (With E. A. Pearson). *J. Phys. Chem.*, 1932, **36**, 642–5.
381. The promoting action of copper sulfide on the speed of precipitation of zinc sulfide. The so-called coprecipitation of zinc with copper sulfide (With E. A. Pearson). *Ibid.*, 1932, **36**, 549–66.
382. The adsorption of cations from ammoniacal solution of silica gel (With V. A. Stenger). *Ibid.*, **36**, 2113–26.
383. The analytical adaptation of bromine substitution in phenols. *Pharm. Weekblad*, 1932, **69**, 1147–58.
384 Bromine substitution in salicylic acid *Ibid.*, 1932, **69**, 1159–61.
385. Properties of active charcoal reactivated in oxygen at 400°. *J. Amer. Chem. Soc.*, 1932, **54**, 4473–80.
386. Volumetric determination of uranium with potassium dichromate as reagent and the application of the method to the indirect titration of minute quantities of sodium (With J. J. Lingane). *Ibid.*, 1933, **55**, 1871–6.
387. Diphenylaminesulfonic acid as a reagent for the colorimetric determination of nitrates. (With G. E. Noponen). *Ibid.*, 1933, **55**, 1448–53.
388. Specific surface and the adsorbent properties of lead sulfate (With Charles Rosenblum). *Ibid.*, 1933, **55**, 851.
389. The adsorbent properties and the specific surface of lead sulfate (With Charles Rosenblum). *Ibid.*, 1933, **55**, 2656–64.
390. The adsorption of Ponceau 4R (New Coccine) and methylene blue by lead sulfate and the effect of adsorbed Ponceau on the speed of kinetic exchange (With Charles Rosenblum). *J. Amer. Chem. Soc.*, 1933, **55**, 2664–72.
391. Exchange adsorption and its influence upon the solubility of precipitates with ionic lattices in electrolytic solutions (With E. B. Sandell). *Ibid.*, 1933, **55**, 2170–1.

392–394. Coprecipitation (With E. B. Sandell): IV. *J. Phys. Chem.*, 1933, **37**, 443–58. V. *Ibid.*, 459–73. VI. *Ibid.*, 723–33.

395. Nephelometric determination of chloride (With Henry Yutzy). *J. Amer. Chem. Soc.*, 1933, **55**, 1915–22.

396. Studies in coprecipitation: III (With E. B. Sandell). *J. Phys. Chem.*, 1933, **37**, 153–70.

397. The formation and properties of precipitates. Theory of coprecipitation. *Chem. Weekblad*, 1934, **31**, 102–3.

398–399. Theory of coprecipitation: IIA. *Ibid.*, 1934, **31**, 230–7. IIB. *Ibid.*, 244–51.

400. Gravimetric and volumetric determination of antipyrine in the presence of amidopyrine. *J. Amer. Pharm. Assoc.*, 1933, **22**, 947–50.

401. Exchange adsorption and adsorption indicators. *Kolloid-Z.*, 1934, **68**, 190–200.

402. Titration of chloride and bromide with mercurous nitrate using bromophenol blue as adsorption indicator (With W. D. Larson). *J. Amer. Chem. Soc.*, 1934, **56**, 1881–4.

403 The gravimetric and volumetric determination of brucine and strychnine as dichromate (With J. J. Lingane). *J. Amer. Pharm. Assoc.*, 1934, **23**, 404–8.

404. The free mobility of lead ions in amicronic crystals of lead sulfate (With Charles Rosenblum). *Phys. Rev.*, 1934, **45**, 341.

405–406. Structural changes taking place during the aging of freshly formed precipitates (With Charles Rosenblum): I. *J. Amer. Chem. Soc.*, 1934, **56**, 1264–9. II. *Ibid.*, 1658–61.

407. Detection and estimation of small amounts of fluorine. Application of the zirconium-purpurin test (With Maurice E. Stansby). *Ind. Eng. Chem., Analyt.* 1934, **6**, 118–21.

408–409. Adsorption from ammoniacal solution (With V. A. Stenger): II. *J. Phys. Chem.*, 1934, **38**, 249–58. III. *Ibid.*, 475–86.

410. The solubilities of calcium hydroxide, calcium iodate and ammonium perchlorate in dilute ammoniacal solutions (With V. A. Stenger). *J. Phys. Chem.*, 1934, **38**, 639–43.

411. The benzoate method. A new procedure for the separation of iron, aluminum and chromium from the other ions of the third group and the alkaline earth ions (With V. A. Stenger and B. Moskovitz). *J. Amer. Chem. Soc.*, 1934, **56**, 812–15.

412. The adsorption of wool violet (4BN) by lead sulfate and the effect of the adsorbed dye on the speed of kinetic exchange (With W. von Fischer and Charles Rosenblum). *Ibid.*, 1934, **56**, 832–6..

413. The dissociation of some inorganic acids, bases and salts in glacial acetic acid as solvent (With A. Willman). *Ibid.*, 1934, **56**, 1007–13.

414. The acid strength of inorganic cations and the basic strength of inorganic acetates in acetic acid: II (With A. Willman). *Ibid.*, 1934, **56**, 1014–16.

415. Chronometric catalytic method for the determination of micro quantities of iodine (With E. B. Sandell). *Ibid.*, 1934, **56**, 1426.

416. Reply to N. A. Brunt. *Chem. Weekblad*, 1935, **32**, 448–9.

417. Coprecipitation and postprecipitation. Aging of precipitates. *Z. analyt. Chem.*, 1936, **104**, 321–33.

418. Indicators. *Ind. Eng. Chem., Analyt.*, 1936, **8**, 237–9.

419. The adsorption of electrolytes on crystal surfaces. Reply to L de Brouckers *Chem. Weekblad*, 1936, **33**, 321–4.
420. The adsorbant properties of barium sulphate. *Bull Soc. chim. belges*, 1936, **45**, 270–8.
421. Potassium thiocyanate as a primary standard substance (With J. J. Lingane). *J. Amer. Chem. Soc.*, 1935, **57**, 2126–31.
422. Accuracy of the titration of thiocyanate with mercuric mercury (With J. J. Lingane). *Ibid.*, 1935, **57**, 2377–9
423. The accuracy of the potentiometric iodide-silver titration (With J. J Lingane). *Ibid.*, 1936, **58**, 1524–8.
424. Absorption of silver and iodide ions by freshly precipitated silver iodide-isoelectric point of the fresh precipitate (With J J. Lingane). *Ibid.*, 1936, **58**, 1528–33.
425–426. Structural changes taking place during aging of precipitates (With W. M. MacNevin): IX. *J. Amer. Chem Soc*, 1936, 58, 499–504 X. *Ibid.*, 725–8.
427. Adsorption of barium salts on barium sulfate from solutions in 50% ethanol (With Wm. M. MacNevin). *Ibid.*, 1936, **58**, 1543–6.
428. Induced precipitations and properties of metal sulfides (With D. R. Moltzau). *Chem. Rev.*, 1935, **17**, 293–325.
429. Postprecipitation of zinc sulfide with mercuric sulfide (With D. R. Moltzau). *J. Phys. Chem.*, 1936, **40**, 779–98
430. The constitution of β-iron oxide monohydrate (With B. Moskovitz). *J. Amer. Chem. Soc.*, 1936, **58**, 777–9.
431–434. Structural changes taking place upon aging of freshly prepared crystalline precipitates (With Charles Rosenblum) V. *Ibid*, 1935, **57**, 2573–7. VI. *Ibid.*, 2577–9. VII. *Ibid.*, 1936, **58**, 116–20. VIII. *Ibid.*, 121–2.
435. The fourth ionization constant of ferrocyanic acid (With Wm. J Tomsicek). *J. Phys. Chem.*, 1935, **39**, 955–8.
436. The oxidation potential of the system potassium ferrocyanide/potassium ferricyanide at various ionic strengths (With Wm. J. Tomsicek). *Ibid.*, 1935, **39**, 945–54.
437. Oxidation potential of the system potassium molybdocyanide/potassium molybdicyanide, and the effect of neutral salts on the potential (With Wm. J. Tomsicek). *Ibid.*, 1936, **40**, 247–55.
438. Mixed crystal formation of zinc sulfide postprecipitated with mercuric sulfide. The aging of mercuric sulfide and of zinc sulfide (With R. Moltzau). *Ibid.*, 1936, **40**, 637–43.
439. Modified persulfate-arsenite method for manganese with special reference to steel analysis (With E. B. Sandell and J. J. Lingane). *Ind. Eng. Chem., Analyt.*, 1935, **7**, 256–8.
440. Detection and colorimetric estimation of microquantities of bromide (With V. A. Stenger). *J. Amer. Chem. Soc.*, 1935, **57**, 831–3.
441. "Absurdly" low concentration and the law of mass action. The ion theory. *Chem. Weekblad.* 1935, **32**, 246–9.
442 Acidimetric titration of *p*-hydroxybenzoic acid alone and in the presence of acetic acid. *J. Amer. Chem. Soc.*, 1935, **57**, 973–4.

443. Determination of strychnine and brucine as hydroferrocyanides and their separation by means of ferrocyanide (With J. J. Lingane). *J. Amer. Pharm. Assoc.*, 1934, **23**, 302–8.
444. Catalytic and induced reactions in microchemistry (With R. S. Livingston). *Ind. Eng. Chem., Analyt.*, 1935, **7**, 209–13.
445–446. Structural changes taking place during the aging of freshly formed precipitates (With Charles Rosenblum): III. *J. Amer. Chem. Soc.*, 1935, **57**, 597–600. IV. *Ibid.*, 607–11.

486. Determination of potassium with hexanitrodiphenylamine (dipicrylamine) reagent (With Gordon H. Bendix). *Ibid.*, 1939, **11**, 94–8.

487. Adsorption experiments on a sample of barium sulphate submitted by Mlle. de Brouckere (With A. A. Bushey): *Bull. Soc. chim. belges*, 1938, **47**, 689–701.

488–491. Studies in aging and coprecipitation: XXVI. (With R. T. Eggertsen). *J. Amer. Chem. Soc.*, 1939, **61**, 1036–40. XXVII. (With Roy A. Halversen). *J. Phys. Chem.*, 1939, **43**, 605–11. XXVIII. (With L. G. Overholser). *Ibid.*, 767–80. XXIX. (With L. G. Overholser). *Ibid.*, 909–22.

492. Studies on aging and formation of precipitates: XXIX (With A. S. O'Brien). *J. Chem. Phys.*, 1939, **7**, 401–4.

493 Ionization constants of acid-base indicators in methanol (With L. S. Guss). *J. Amer. Chem. Soc.*, 1938, **60**, 2516–22.

494–495. Acid-base indicators in methanol (With L. S. Guss): II. *Ibid.*, 1939, **61**, 16–19. III. *Ibid.*, 330–3.

496. Standardization of strong oxidizing agents with potassium iodide by the acetone method (With H. A. Laitinen). *Ibid.*, 1939, **61**, 1690–1.

497. The fundamental principles and applications of electrolysis with the dropping-mercury electrode and Heyrovský's polarographic method of chemical analysis (With J. J. Lingane). *Chem. Rev.*, 1939, **24**, 1–94.

498. The relation between equilibrium constants in water and in other solvents (With J. J. Lingane and W. D. Larson). *J. Amer. Chem. Soc.*, 1938, **60**, 2512–15.

499–500. Aging of precipitates (With Wm. von Fischer): XXIV. *Ibid.*, 1939, **61**, 191–4. XXV. *Ibid.*, 195–7.

501. Amperometric titrations *Trans. Electrochem. Soc.*, 1940, **78**, 16 pp. (Preprint)

502. Cerimetric determination of small amounts of arsenic after reduction with hypophosphite reagent (With Elias Amdur). *Ind. Eng. Chem., Analyt.*, 1940, **12**, 177–9.

503. Aging and coprecipitation: XXXII (With Frank T. Eggertsen). *J. Amer. Chem. Soc.*, 1940, **62**, 2125–31.

504. Voltammetric determination of oxygen (With H. A. Laitinen). *Science*. 1940, **92**, 152–4.

505. Amperometric titrations · II (With A. Langer). *J. Amer. Chem. Soc.*, 1940, **62**, 211–18.

506. Aging and coprecipitation: XXXIII (With W. M. MacNevin). *J. Phys. Chem.*, 1940, **44**, 921–35.

507. Mixed potentials at the dropping-mercury electrode (With C. S. Miller). *J. Amer. Chem Soc.*, 1940, **62**, 2171–4.

508–509. Aging and formation of precipitates (With A. S. O'Brien): XXX. *Ibid.*, 1939, **61**, 3409–14. XXXI. *Ibid.*, 3414–19.

510. Amperometric (polarometric) titrations: I (With Yu-Djai Pan). *Ibid.*, 1939, **61**, 3402–9.

511. Ionization constants of acid-base indicators in ethanol (With L. S. Guss). *Ibid.*, 1940, **62**, 249–51.

512. The distribution of protons between water and other solvents (With L. S. Guss). *Ibid.*, 1940, **62**, 1494–6.

513. Study of diffusion processes by electrolysis with microelectrodes (With H. A. Laitinen). *Nature*, 1939, **144**, 549–50.

514. A study of the diffusion processes by electrolysis with microelectrodes (With H. A. Laitinen). *J. Amer. Chem. Soc.*, 1939, **61**, 3344–9.

515. Polarographic study of the reduction of chromate ion at the dropping-mercury electrode (With J. J. Lingane). *Ibid.*, 1940, **62**, 852–8.

516. The silicon carbide electrode (With D. N. Hume). *Ibid.*, 1941, **63**, 2805–6.

517. Photovoltaic behavior of pure silver bromide (With Herbert L. Sanders). *J. Phys. Chem.*, 1940, **44**, 936–43.

518. Chemistry of vitamin E: XXIX (With Lee Irvin Smith, Stanley Wawzonek and P. M. Ruoff) *J. Amer. Chem. Soc.*, 1941, **63**, 1018–24.

519. The anodic reaction and waves of cysteine at the dropping-mercury electrode and at the platinum micro wire electrode (With Cyrus Barnum). *Ibid.*, 1940, **62**, 3061–5.

520. The reduction of cystine at the dropping-mercury electrode (With Cyrus Barnum) *Ibid.*, 1941, 520–6.

521. Studies on aging and coprecipitation: XXXIV (With F. T. Eggertsen). *Ibid.*, 1941, **63**, 1412–18.

522–524. Amperometric titrations: III. (With H. A. Laitinen). *Rec. Trav chim.*, 1940, **59**, 922–8. V. (With A. Langer). *J. Amer. Chem. Soc.*, 1940, **62**, 3172–5 (1940). VI. (With Yu-Djai Pan). *Ibid.*, 332–5.

525. The reduction of oxygen at the dropping-mercury electrode (With C. S. Miller). *Ibid.*, 1941, **63**, 1013–17.

526. Anodic waves involving electro-oxidation of mercury at the dropping-mercury electrode (With C. S. Miller). *Ibid.*, 1941, **63**, 1405–11.
527. Current voltage curves of mercurous and mercuric salts at the dropping-mercury electrode (With C. S. Miller). *Ibid.*, 1941, **63**, 2732–4.
528. The reduction of sulfurous acid (sulfur dioxide) at the dropping-mercury electrode (With C. S. Miller). *Ibid.*, 1941, **63**, 2818–21.
529. The use of the dropping-mercury electrode as an indicator electrode in poorly poised systems (With E. F. Orlemann). *Ibid.*, 1941, **63**, 664–7.
530. An application of the Ilkovič equation to the analysis of mixtures of reducible substances with the dropping-mercury electrode (With E. F. Orlemann). *Ibid.*, 1941, **63**, 2085–8.
531. A quantitative expression for the extractability of metals in the form of dithizonates from aqueous solutions. The equilibrium constant of zinc dithizonate. Preliminary paper (With E. B. Sandell). *Ibid.*, 1941, **63**, 1906–8.
532. Factors to be considered in quantitative polarography. *Ind. Eng. Chem., Analyt* 1942, **14**, 195–200.
533. Amperometric titrations. Amperometric determination of phosphate with uranyl acetate (With Gunter Cohn). *Ibid.*, 1942, **14**, 412–18.
534–535. Aging and coprecipitation (With F. T. Eggertsen)· XXXV. *J. Phys. Chem.*, 1942, **46**, 458–63. XXXVI. *Ibid.*, 616–20.
536. Elimination of the water wave in polarographic work at relatively high indifferent electrolyte concentrations (With E. F. Orlemann). *Ind. Eng. Chem , Analyt.*, 1942, **16**, 321–3.
537. The solubility of lead sulfate and of lead oxalate in various media (With R W Perlich and D. Weiblen). *J. Phys. Chem.*, 1942, **46**, 561–70.
538. Voltammetric determinations and amperometric titrations with a rotating microelectrode of platinum wire (With H. A. Laitinen). *Ibid.*, 1941, **45**, 1079–93.
539. Voltammetry with stationary microelectrodes of platinum wire (With H. A. Laitinen). *Ibid.*, 1941, **45**, 1061–79.
540. Potassium iodide for use as a primary standard (With J. J. Lingane). *Inorganic Syntheses*, 1939, **1**, 163–5.
541. The anomalous electroreduction of water at the dropping-mercury electrode in relatively concentrated salt solutions (With E. F. Orlemann). *J. Amer. Chem. Soc.*, 1942, **64**, 833–8.
542. The reaction of iodate and bromate in acid medium at the dropping-mercury electrode (With E. F. Orlemann). *Ibid.*, 1942, **64**, 1044–52.
543. The reduction of iodate and bromate at the dropping-mercury electrode in neutral and basic media and the effects of salts on the current-voltage curves (With E. F. Orlemann). *Ibid.*, 1942, **64**, 1970–7.
544–545. Chemistry of vitamin E (With Lee Irvin Smith and Leo J. Spillane): XXXVI. *Ibid.*, 1942, **64**, 644–5. XXXVII. *Ibid.*, 646–8.
546. Chemistry of vitamin E: XXXV (With Lee Irvin Smith and Leo J. Spillane). *Ibid.*, 1942, **64**, 447–51.
547. The validity of the Ilkovič equation in the polarographic analysis of alkali metals and the characteristics of the alkali waves in various media (With Ignace Zlotowski). *Ibid.*, 1942, **64**, 1297–1301.

548. Polarographic determination of potassium, sodium and lithium (With Ignace Zlotowski) *Ind Eng Chem*, *Analyt*, 1942, **14**, 473–7.
549. Polarographic determination of potassium, sodium and lithium (With Ignace Zlotowski) *Ibid*, 1942, **14**, 473–7
550. Determination of pyrophosphate by precipitation with cadmium and polarographic measurement of cadmium in the precipitate (With Gunther Cohn). *Ibid.*, 1942, **14**, 886–90.
551. Determination of calcium by precipitation with picrolonic acid and polarographic measurement of the residual picrolonic acid (With Gunther Cohn). *J. Biol. Chem*, 1943, **147**, 705–9
552. Amperometric titration of picrolonic acid and indirect volumetric determination of calcium by precipitation as picrolonate and back titration of the excess of picrolonic acid with methylene blue (With Gunther Cohn). *Ibid.*, 1943, **148**, 711–18.
553. Aging and coprecipitation XXXVII (With C. W Carr). *J. Phys. Chem.*, 1943, **47**, 148–52.
554 Determination of iodate in the presence of bromate and chlorate (With David N. Hume). *Ind. Eng. Chem.*, *Analyt.*, 1943, **15**, 174–5.
555. The attachment and detachment of dropping mercury under various conditions (With G. J. Kahan). *J. Amer. Chem. Soc.*, 1942, **64**, 2553–7.
556. Polarographic determination of manganese as tri-dihydrogen pyrophosphatomanganate (With J. I. Watters). *Ind. Eng. Chem.*, *Analyt.*, 1943, **15**, 8–13.
557. The Lewis and the Bronsted-Lowry definitions of acids and bases. *J. Phys. Chem.*, 1944, **48**, 51–7.
558. A new method for the polarographic determination of nitrate (With W. E. Harris and G. Matsuyama) *J. Amer. Chem. Soc.*, 1944, **66**, 1782–6.
559. The behavior of SO_2 as an acid in MeOH (With L. S. Guss). *Ibid.*, 1944, **66**, 1484–8.
560. A revision of the oxidation potentials of the *o*-phenanthroline- and bipyridyl-ferrous complexes (With David N. Hume). *Ibid.*, 1943, **65**, 1895–7.
561. The oxidation potential of the chromocyanide-chromicyanide couple and the polarography of the chromium cyanide complexes (With David N. Hume). *Ibid.*, 1943, **65**, 1897–1901.
562. Iodometric determination of iodates, bromates or permanganates in the presence of copper (With David N. Hume). *Ind Eng Chem*, *Analyt.*, 1944, **16**, 103–4.
563. Polarographic studies of sulfonamides: I (With Nathan I. Levitan, Wm. G. Clark and Daniel J. Tenenberg). *J. Amer. Chem. Soc.*, 1943, **65**, 2265–8.
564. Determination of manganese after oxidation to tri-dihydrogen pyrophosphatomanganate (With J. I. Watters). *Ind. Eng. Chem.*, *Analyt.*, 1944, **16**, 187–9.
565. Polarographic behavior of alkaline earth metals: I (With I. Zlotowski). *J. Amer. Chem. Soc.*, 1944, **66**, 1431–5.
566. The polarography of uranium: I (With W. E. Harris). *Ibid.*, 1945, **67**, 1484–90.
567. The mechanism of emulsion polymerizations· I (With W. J. Dale). *Ibid.*, 1945, **67**, 1672–4.
568. Aging of crystalline precipitates. *Suomen Kem.*, 1943, **16A**, 89–96.
569. Amperometric titration of mercaptans with silver nitrate using the rotating platinum electrode (With W. E. Harris). *Ind. Eng. Chem.*, *Analyt.*, 1946, **18**, 161–2.

570. The polarography of uranium II (With W. E. Harris). *J. Amer Chem. Soc.*, 1946, **68**, 1175–9.

571. Solubilization of *p*-dimethylaminoazobenzene in soap solutions (With W F Johnson) *J. Phys. Chem*, 1946, **50**, 440–2.

572. Assay of hydroquinone (With Thomas S Lee). *Ind. Eng. Chem., Analyt*, 1946, **18**, 452.

573. Polarographic analysis of aluminum alloys (for iron, copper, lead, nickel and zinc) (With Geo. Matsuyama). *Ibid.*, 1945, **17**, 615–20.

574. Amperometric microtitration of very dilute chromate solutions using the rotating platinum electrode (With D. R. May). *Ind. Eng. Chem., Analyt*, 1946, **18**, 208–9.

575. Determination of alkyl disulfides in the absence and presence of mercaptans (With D. R. May, Perry Morgan, H. A. Laitinen and A. S. O'Brien). *Ibid*, 1946, **18**, 442–4.

576. Polarographic behavior of alkaline earth metals. II (With I Zlotowski) *J. Phys. Chem.*, 1945, **49**, 386–405.

577. Determination of polystyrene in GR-S rubber (With T. S. Lee and C. W Carr) *J. Polymer Sci.*, 1946, **1**, 429–33.

578 Determination of persulfate in emulsion polymerization latexes (With L. S. Guss, D. R. May and A. I. Medalia). *Ibid.*, 1946, **1**, 340–52.

579. Aging of precipitates and coprecipitation: XXXIX (With I. Shapiro). *J Chem Phys.*, 1947, **15**, 41–6.

580. The electrokinetic potentials of precipitates (With L. H. Reyerson and Keith Coad). *J. Phys Colloid Chem.*, 1947, **51**, 321–32.

581. The mechanism of emulsion polymerizations: II (With W. J. Dale). *J. Amer Chem. Soc.*, 1947, **69**, 441–6.

582. The polarography of uranium· III (With W. E. Harris). *Ibid.*, 1947, **69**, 446–51.

583. The aging of precipitates and coprecipitation· XXXVIII (With I. Shapiro) *J. Phys. Colloid Chem.*, 1947, **51**, 483–93.

584–587. Thiols as promoters and modifiers in emulsion copolymerization of butadiene and styrene using potassium persulfate as catalyst (With W E. Harris): I. *J. Polymer Sci.*, 1947, **2**, 41–8. II. *Ibid.*, 49–71. III. *Ibid.*, 72–81. IV. *Ibid.*, 82–9.

588–590. Use of perbenzoic acid in analysis of unsaturated compounds: I. (With Thomas S. Lee and Mary Anne Mairs). *Ibid.*, 1947, **2**, 199–205. II. (With Thomas S. Lee). *Ibid.*, 206–19. III. (With Thomas S. Lee and Mary Anne Mairs). *Ibid.*, 220–8

591. The use of membrane electrodes in the study of soap solutions (With C. W. Carr and W. F. Johnson). *J. Phys. Colloid Chem.*, 1947, **51**, 636–44.

592. Amperometric titration of styrene with potassium bromate using the rotating platinum electrode (With F. A. Bovey). *Analyt. Chem.*, 1947, **19**, 498–500.

593. The mechanism of emulsion polymerization: III. Oxygen as a comonomer in the emulsion polymerization of styrene (With F. A. Bovey). *J. Amer. Chem. Soc.*, 1947, **69**, 2143.

594. Ethanol-toluene-water as solvent mixture for extraction of nonpolymer from R-SG (With C. W Carr and Betty J. Carr). *J. Polymer Sci.*, 1947, **2**, 637.

595. Laurate-ion activity in solutions of potassium laurate in the absence and presence of neutral salts (With Warren F Johnson). *J. Phys Colloid Chem.*, 1948, **52**, 22.
596. Determination of unsaturation of synthetic and natural rubbers by means of iodine monochloride (With T. S. Lee and Mary Anne Mairs). *J. Polymer Sci.*, 1948, **3**, 66.
597. Studies of retarders and inhibitors in the emulsion polymerization of styrene: I. Retarders (With F. A. Bovey). *J. Amer. Chem. Soc.*, 1948, **70**, 791.
598. Combination of potassium ferricyanide, diazothio-ether and mercaptan as "catalyst" for emulsion polymerizations of butadiene and styrene (With W. J. Dale). *J. Polymer Sci.*, 1948, **3**, 400.
599. Polarographic behavior of phenolphthalein (With D. J. Lehmicke). *J. Amer. Chem. Soc.*, 1948, **70**, 1879.
600 Polarographic behavior of nitrosophenylhydroxylamine (With A. Liberti). *Ibid.*, 1948, **70**, 1885.
601 Studies on the aging of precipitates and coprecipitation· XL. The solubility of lead chromate as a function of the particle size (With D. R. May). *J. Phys. Colloid Chem.*, 1948, **52**, 836.
602. Solubilization of dimethylaminoazobenzene in solutions of detergents: I. The effect of temperature on the solubilization and upon the critical concentration (With W. Stricks). *Ibid.*, 1948, **52**, 915.
603. Studies on aging of precipitates and coprecipitation. XLI. The bulkiness and porosity of silica powder (With I. Shapiro). *Ibid.*, 1948, **52**, 1020.
604. Inhibition and retardation of vinyl polymerization (With F. A. Bovey). *Chem. Rev.*, 1948, **42**, 491.
605. Reaction of ferrous and ferric iron with 1,10-phenanthroline: I. Dissociation constants of ferrous and ferric phenanthroline (With T. S. Lee and D. L. Leussing). *J. Amer. Chem. Soc.*, 1948, **70**, 2348.
606. Potentiometric investigation of tripyrophosphatomanganic(III) acid (With James I. Watters). *Ibid.*, 1948, **70**, 2455.
607. Accumulation of traces of arsenate by coprecipitation with magnesium ammonium phosphate (With C. W. Carr). *Analyt. Chem.*, 1948, **20**, 728.
608. Reaction of ferrous and ferric iron with 1,10-phenanthroline: II. Kinetics of formation and dissociation of phenanthroline (With T. S. Lee and D. L. Leussing). *J. Amer. Chem. Soc.*, 1948, **70**, 3596.
609. Studies on aging of precipitates and coprecipitation: XLII. Aging of silver bromide in the dry state (With I. Shapiro). *J. Phys. Colloid Chem.*, 1948, **52**, 1319.
610. Polarographic and amperometric determination of barium (With H. P. Gregor). *Analyt. Chem.*, 1948, **20**, 541.
611. Thermal aging of silica. *Festskr. J. Arvid Hedvall* (With Gunther Cohn). 1948, 97.
612. Beginning course in quantitative analysis. *J. Chem. Educ.*, 1948, **25**, 597.
613. Amperometric titrations. *Analyt. Chim. Acta*, 1948, **2**, 606–621.
614. Equilibrium and kinetic studies on the formation and dissociation of ferroïn and ferriïn (With T. S. Lee and D. L. Leussing). *Analyt. Chem.*, 1948, **20**, 985.
615. Indicators. *Ibid.*, 1949, **21**, 101

616. Polarographic determination of the molecular weight of serum albumin by its effect on the diffusion current of methyl orange (With W. Stricks). *J Amer Chem Soc.*, 1949, **71**, 1519
617. Solubilization of dimethylaminoazobenzene in solutions of detergents· II. Effect of electrolytes on the critical concentration and the solubilization of dimethylaminoazobenzene, orange OT, and transazobenzene in detergent solutions (With W. Stricks) *J. Phys Colloid Chem*, 1949, **53**, 424–454.
618. A polarographic study of cobalt cyanide complexes (With David N. Hume) *J. Amer. Chem. Soc.*, 1949, **71**, 867.
619. Physicochemical principles in analytical research. *Chem. Eng. News*. 1949, **27**, 835. (*a*) Translation of the above published in *Information de Quimicá Analiticá*. Vol. III, No. 6. pp. 183-192 (Nov. Dec., 1949).
620 Polarographic determination of pentavalent antimony in the presence of pentavalent arsenic (With R. L Probst). *Analyt. Chem.*, 1949, **21**, 753.
621 Amperometric determination of primary and tertiary mercaptans in their mixtures (With W E Harris). *Ibid*, 1949, **21**, 963.
622. Polarographic procedure for determination of cobalt as cobalt(III) ammine (With J I Watters) *Ibid*, 1949. **21**, 1466
623. The reaction between ferrous iron and peroxides. I. Reaction with hydrogen peroxide in the absence of oxygen (With A. I. Medalia). *J. Amer. Chem. Soc*, 1949, **71**, 3777
624 The reaction between ferrous iron and peroxides. II. Reaction with hydrogen peroxide in the presence of oxygen (With A. I. Medalia). *Ibid.*, 1949, **71**, 3784.
625. The reaction between ferrous iron and peroxides: III. Reaction with cumene hydroperoxide in aqueous solution (With A I Medalia). *Ibid.*, 1949, **71**, 3789
626. Redox Recipes· I. Reaction between ferrous iron and peroxides. General consideration (With A. I Medalia). *J. Polymer Sci.*, 1949, **4**, 377–398.
627. Determination of disappearance of bis-isopropyl Xanthogen (Dixie) in synthetic rubber latex during polymerization (With D. R. May). *J. Polymer Sci.*, 1949, **4**, 735–743
628 Indicators. *Analyt Chem*. 1950, **22**, 65.
629. The polarography of chloroform and carbon tetrachloride (With T. S. Lee, D. Stocescova, and E. P. Parry). *Ibid.*, 1950, **22**, 521.
630. Determination of unsaturation of butyl rubbers and certain branched olefins. Iodine monochloride method (With T. S. Lee and Ethel Johnson). *Ibid.*, 1950, **22**, 995.
631. Determination of free carbon in cured rubber stocks (With R. G. Gutmacher). *Ibid*, 1950, **22**, 1002
632. Polarographic determination of cobalt as trioxalatocobaltate(III) (With J. I. Watters). *Ibid*. 1950, **22**, 1422
633. Analytical chemistry as a technique and as a science. *Chem. Eng. News*, 1950, **28**, 2882
634 Studies on aging of precipitates and coprecipitation: XLIII. Thermal aging of precipitated silica (silica gel) (With I. Shapiro) *J. Amer. Chem. Soc.*, 1950, **72**, 776.
635 Argentometric amperometric titration of cysteine and cystine (With W. Stricks). *Ibid.*, 1950, **72**, 1952.

636. Reaction of ferrous and ferric iron with 1,10-phenanthroline. III. The ferrous monophenanthroline complex and the colorimetric determination of phenanthroline (With D. L. Leussing and T. S. Lee). *Ibid.*, 1950, **72**, 2173.
637. The locus of the initiation in an emulsion polymerization recipe containing ferrous iron and benzoyl peroxide (With Madolyn Youse). *Ibid.*, 1950, **72**, 3431.
638. The polarography of nickel cyanide complexes and the solubilities and constitution of nickel cyanide (With D. N. Hume) *Ibid.*, 1950, **72**, 4423.
639. Mikro-Drahtelektroden in Der Polarographie and Bei Amperometrischen Titrationen. (Micro-wire electrodes in polarography and amperometric titrations) (With D. L. Leussing and Gustav F. Hüttig). *Z. Anorg. Chem.*, 1950, **262**, 160.
640. The sorption of GR-S type rubber by carbon black: I. Sorption from benzene solution by Graphon (With A. Kahn). *J. Phys. Colloid Chem.*, 1950, **54**, 251.
641. Studies on the rate of the emulsion polymerization of butadiene-styrene (75:25) as a function of the amount and kind of emulsifier used: I. Polymerizations with commercial and pure soaps (With C. W. Carr, E. J. Meehan, and R. J. Stenberg). *J. Polymer Sci.*, 1950, **5**, 101.
642. Studies on the rate of the emulsion polymerization of butadiene-styrene (75:25) as a function of the amount and kind of emulsifier used: II. Polymerization with fatty acid soaps, rosin soaps and various synthetic emulsifiers (With C. W. Carr, E. J. Meehan and D. E. Williams). *Ibid.*, 1950, **5**, 201.
643. The potassium ferricyanide-diazothio-ether-mercaptan recipe for emulsion polymerization of butadiene and styrene: II. Effect of some chemical variables (With W. J. Dale). *Ibid.*, 1950, **5**, 301.
644. Redox recipes: II. Redox recipes in alkaline medium initiated by the system cumene hydroperoxide-iron-sugar at 30° (With A. I. Medalia). *Ibid.*, 1950, **5**, 391.
645. The mechanism of emulsion polymerization: IV. Kinetics of polymerization of styrene in water and detergent solutions (With F. A. Bovey). *Ibid.*, 1950, **5**, 487.
646. Studies of retarders and inhibitors in the emulsion polymerization of styrene: II. Inhibitors (With F. A. Bovey). *Ibid.*, 1950, **5**, 569.
647. The potassium ferricyanide-diazothioether-mercaptan recipe for emulsion polymerization of butadiene and styrene: III. Determination of *p*-methoxyphenyl diazothio-(2-naphthyl) ether (With W. J. Dale and I. K. Miller). *Ibid.*, 1950, **5**, 667.
648. Polarographic investigations of reactions in aqueous solutions containing copper and cysteine (With W. Stricks). *Analyt. Chem.*, 1951, **23**, 763.
649. Argentometric amperometric titration of traces of chloride with the rotated platinum electrode as indicator electrode (With P. K. Kuroda). *Ibid.*, 1951, **23**, 1306.
650. Determination of traces of chloride by potentiometric titration to the apparent equivalence potential (With P. K. Kuroda). *Ibid.*, 1951, **23**, 1304.
651. Polarographic determination of cobalt as trioxalatocobaltate (III) (With J. I. Watters). *Ibid.*, 1950, **22**, 1422.
652. Analysis of mixtures based on rates of reaction (With T. S. Lee). *Ann. Sci.*, 1951, **53**, 1093.

653. The chemistry of persulfate: II. The reaction of persulfate with mercaptans solubilized in solutions of saturated fatty acid soaps (With I. K. Miller). *J. Amer. Chem. Soc.*, 1951, **73**, 5118.
654. Catalytic polarographic waves of hydrogen peroxides: II. Kinetic waves for the peroxy compounds of molybdenum^{VI}, tungsten^{VI} and vanadium^{V} (With E. P. Parry). *Ibid.*, 1951, **73**, 5315.
655 Catalytic polarographic waves of hydrogen peroxide: I. The kinetic wave for the ferric iron-hydrogen peroxide system (With E. P. Parry). *Ibid.*, 1951, **73**, 3718.
656. The reaction between ferrous iron and peroxides: IV. Reaction with potassium persulfate. *Ibid.*, 1951, **73**, 1733.
657. The chemistry of persulfate: I. The kinetics and mechanism of the decomposition of the persulfate ion in aqueous medium (With I. K. Miller). *Ibid.*, 1951, **73**, 3055.
658. Determination of the degree of dissociation of micelles of 1-n-dodecanesulfonic acid by use of the acid catalyzed reaction between iodine and acetone (With W. F. Johnson). *Ibid.*, 1951, **73**, 4563.
659. Equilibrium constants of the reaction of sulfite with cystine and with dithiodiglycolic acid (With W. Stricks). *Ibid.*, 1951, **73**, 4569.
660. Ferric iron with 1,10-phenanthroline: IV. Application to investigation of zinc phenanthroline complexes (With D. L. Leussing and T. Lee). *Ibid.*, 1951, **73**, 390.
661. Polarographic investigations of reactions in aqueous solution containing copper and cysteine: I. Cuprous copper and cysteine in ammoniacal medium (With W. Stricks). *Ibid.*, 1951, **73**, 1723.
662. Polarographic investigations of reactions in aqueous solutions containing copper and cysteine: II. Reaction in ammoniacal medium in the presence and absence of sulfite (With W. Stricks). *Ibid.*, 1951, **73**, 1728.
663. Amperometric titration of Sn^{IV} and Hg^{II} with tetraphenylarsonium chloride (With B. A. Johnson). *J. Electrochem. Soc.*, 1951, **98**, 231.
664. Amperometric titrations with s-nitrophenylarsonic acid (With B. A. Johnson). *Ibid.*, 1951, **93**, 138.
665. Cosolubilization in solutions of potassium laurate. Effect of co-solubilized alcohol and hydrocarbons on the solubilization of several aromatic compounds in potassium laurate solutions. *J. Phys. Colloid Chem.*, 1951, **55**, 699.
666. Sorption of GR-S type rubber black: II. Effect of variables on the sorption of Craphan (With A. G. Gutmacher and A. Kahn). *Ibid.*, 1951, **55**, 1240.
667. Redox recipes: IV. Dihydroxyacetone recipes at 0°C (With A. I. Medalia). *J. Polymer Sci*, 1951, **6**, 189.
668. Redox recipes: III. Use of various sugars at 0°C and 30°C in a cumene hydroperoxide-iron sugar recipe (With A. I. Medalia). *Ibid.*, 1951, **6**, 93.
669. Redox recipes: V. Redox system, ferrous sulfide-cumene hydroperoxide (With A. I. Medalia). *Ibid.*, 1951, **6**, 209.
670. Studies on rate of emulsion polymerization of butadiene styrene 75:25 as a function of amount and kind of emulsifier used: III. Effect of amount of soap on rate of polymerization (With E. J. Meehan and E. M. Carr). *Ibid.*, 1951, **6**, 73.

671. Determination of nicrogel in GR-S rubber (With A. I. Medalia). *Ibid.*, 1951, **6**, 433.
672. Studies on the rate of emulsion polymerization of butadiene-styrene (75:25) as a function of the amount and kind of emulsifier used with persulfate as activator. IV. Addition of emulsifier during reaction. Seeding effects (With E. J. Meehan and E. M. Carr). *Ibid.*, 1951, **6**, 577.
673. Electrolytic initiation of polymerization (With L. Ferstanding). *Ibid.*, 1951, **6**, 963.
674. Polarography of tin^{IV} in presence of traces of tetraphenylarsonium chloride (With R. A. Johnson). *Analyt. Chem.*, 1951, **23**, 574.
675. Determination of organic peroxides by reaction with ferrous iron (With A. I. Medalia). *Ibid.*, 1951, **23**, 595.
676. Solubilization of dodecylammonium thiosulfate in dodecylammonium bromide solution at 50° (With W. F. Johnson). *J. Amer. Chem. Soc.*, 1952, **74**, 20
677. A study of the reaction between dodecylbromide and thiosulfate ion solutions of dodecylammonium bromide (With W. F. Johnson). *Ibid.*, 1952, **74**, 22.
678. Anodic and cathodic voltammetry of thallium at the rotated platinum wire electrode (With J. Jordan). *Ibid.*, 1952, **74**, 382.
679. Studies on the system iron-ethylenediaminetetra-acetate (With Clemens Auerbach). *Ibid.*, 1952, **74**, 1452.
680. Oxygen induced electroreduction of hydrogen peroxide at rotating platinum electrode (With J. Jordan). *Ibid.*, 1952, **74**, 570.
681. Amperometric titrations. *Jubilaire*, 1897–1947, pp. 127–144 (Belgrade, Yugoslavia).
682. Kinetic (catalytic) currents for systems containing hydrogen peroxide (With E. P. Parry). *International Polarographic Congress* (*Prague*), 1951, **1**, 145–154
683. Formation of bound rubber of GR-S type polymers with carbon black. (With J. Duke and W. K. Taft) *Ind. Eng. Chem.*, 1951, **43**, 2885.
684. Polarographic protein tests with milk (With W. Stricks). *International Polarographic Congress* (*Prague*), 1951, **1**, 386.
685. Das polarographische Verhalten von Ti(III) and Ti(IV) in Athylendiamintetraazetat (With M. Blumer). *Experientia*, 1952, VIII/4 138.
686. Exaltation of the limiting current of oxygen by hydrogen peroxide at the rotated gold electrode as a means for amperometric determination of traces of oxygen (With J. Jordan). *Analyt. Chem.*, 1952, **24**, 1071.
687. The reduction of carbon disulfide at the dropping mercury electrode (With P. E. Toren and R. W. Ramette). *Ibid.*, 1952, **24**, 1037.
688. Sorption of GR-S type of polymer on carbon black: III. Sorption by commercial blacks (With R. G. Gutmacher). *J. Phys. Chem.*, 1952, **56**, 570.
689. Chemistry of persulfate. III. Reaction of persulfate with mercaptan solubilized in sodium laurate solution in the presence of unsaturated compounds (With E. J. Meehan). *J. Amer. Chem. Soc.*, 1952, **74**, 4419.
690. Polarography of glutathione (With W. Stricks). *Ibid.*, 1952, **74**, 4646.
691. Redox recipes: VI. Redox systems containing potassium chromate as oxidizing constituent (With E. J. Meehan). *J. Polymer Sci.*, 1952, **9**, 327–342.
692. Redox recipes: VII. A recipe with ferric versenate, hydrazine and hydroperoxide as activating system (veroxazine recipe) (With E. J. Meehan). *Ibid.*, 1952, **9**, 343

693. Redox recipes: VIII A recipe with ferric versenate, sodium sulfide and hydroperoxide as activating system (veroxasulfide recipe) (With E J. Meehan). *Ibid.*, 1952, **9**, 433–52.
694. Oxygen induced electroreduction of hydrogen peroxide and reduction of oxygen at the rotated gold wire electrode (With J. Jordan). *J. Amer. Chem. Soc.*, 1952, **74**, 4801.
695. Aging of crystalline precipitates. *Analyst*, 1952, **77**, 1000–1011.
696 Determination of osmium (With E. P. Parry). *Analyt. Chem.*, 1953, **25**, 188.
697. Volumetric determination of persulfate in the presence of organic substances (With E M. Carr). *Ibid.*, 1953, **25**, 298.
698. Mechanism of initiation of emulsion polymerization by persulfate (With E. J. Meehan and E. M. Carr). *J. Amer. Chem. Soc.*, 1953, **75**, 1439.
699. Acid strength of iodine monochloride, antimony trichloride and picric acid with reference to the bases pyridine and aniline in nitrobenzene (With D. Stocesova and T. S. Lee). *J. Amer. Chem. Soc.*, 1953, **75**, 1834.
700. Voltammetry of iodine and iodide at rotated platinum wire electrodes (With J. Jordan). *Ibid.*, 1953, **75**, 1571–5.
701. Polarography of nitroprusside. Equilibrium constant of the reaction between nitroprusside and hydroxyl ions (With P. E. Toren). *Ibid.*, 1953, **75**, 1197–1201.
702. Voltammetric determination of lead as lead dioxide at the rotated platinum wire electrode (With J. Jordan and A. Heyndrickx). *Analyt. Chem.*, 1953, **25**, 884–87.
703. Redox recipes. IX. Alkaline nitroprusside-hydroperoxide recipes (With E. J. Meehan). *J. Polymer Sci*, 1953, **9**, 71–82.
704. Solubility product of ferrous hydroxide and the ionization of the aquo-ferrous ion (With D. L. Leussing). *J. Amer. Chem. Soc.*, 1953, **75**, 2476–77.
705. Polarography of thioglycolic acid (With D. L. Leussing). *J. Electrochem. Soc.*, 1953, **100**, 334–8.
706 Amperometric titration of oxidized glutathione in presence of cystine (With W. Stricks). *Analyt. Chem.*, 1953, **25**, 1050–57.
707. Experimental study of the polarographic cancer test and of the sulfhydryl titration for the differentiation between normal, cancerous and other pathological sera (With W. Stricks, D. G. Bush, and P. K. Kuroda). *Lancet*, 1953, **73**, 328–35.
708. Iron-thioglycolate complexes (With D. L. Leussing). *J. Amer. Chem. Soc.*, 1953, 75, 3904–11
709. The amperometric titration of traces of ammonia with hypobromite at the rotated platinum wire electrode (With W. Stricks and L. Morren). *Analyst*, 1953, **78**, 405–414.
710. Electrodes with convection controlled limiting currents (convection electrodes) (With J Jordan). *J. Amer. Chem. Soc.*, 1953, **75**, 4869.
711. The polarographic serum reaction and the amperometric sulphydryl titration for the detection of cancer. The sulphydryl content of normal and of cancerous blood serum. *Pharm. Weekblad*, 1953, **88**, 733–44.
712. Reactions between mercuric mercury and cysteine and glutathione. Apparent dissociation constants, heats and entropies of formation of various forms of mercuric mercapto-cysteine and -glutathione (With W. Stricks). *J. Amer. Chem Soc.*, 1953, **75**, 5673–81.

713. Amperometric titration and voltammetric determination of iodide with rotated platinum wire indicator electrode (With J. Jordan). *Analyt. Chem.*, 1953, **25**, 1833–7.
714. Effect of detergent on the polymerization of allyl acetate (With E. J. Meehan, E. M. Carr). *J. Polymer Sci.*, 1954, **13**, 113–21.
715. Polarographic and amperometric mercurometric determination of disulfide groups in cystine, oxidized glutathione, and proteins (With W. Stricks and N. Tanaka). *Analyt. Chem.*, 1954, **26**, 299.
716. Amperometric mercurimetric titration of sulfhydryl groups in biologically important substances at the rotated platinum wire electrode as indicator electrode (With W. Stricks and L. Morren). *Ibid.*, 1954, **26**, 366.
717. Studies on aging and coprecipitation: XLIV. Aging of silver bromide in the colloidal state (With R. C. Bowers). *J. Amer. Chem. Soc.*, 1954, **76**, 1503–9.
718. Formation and properties of various mercuric mercapto thioglycolates formed in reactions between mercuric mercury and thioglycolic acid (With W. Stricks and A. Heyndrickx). *Ibid.*, 1954, **76**, 1515–19.
719. Studies on aging and coprecipitation: XLV. The irreversible flocculation of colloidal silver bromide and the aging in the flocculated state (With R. C. Bowers). *Ibid.*, 1954, **76**, 1510–15.
720. Rotated and stationary platinum wire electrodes. Residual current-voltage curves and dissolution patterns in supporting electrolytes (With Nobuyuki Tanaka). *Analyt. Chem.*, 1954, **26**, 632–636.
721. Nitrogen, sulfhydryl, and disulfide contents in normal and cancer sera and in their albumin and globulin fractions. Action sulfite on disulfide groups in normal and cancer sera (With W. Stricks, Loes Morren, and A. Heyndrickx). *J. Natl. Cancer Inst.*, 1954, **14**, 1233–45.
722. Convection controlled limiting currents (convection currents): I. The platinum wire convection electrode (With J. Jordan). *J. Amer. Chem. Soc.*, 1954, **76**, 3843–45.
723. Convection controlled limiting currents (convection currents: II. The convection mercury electrode (With J. Jordan and S. Prager). *Ibid.*, 1954, **76**, 5221–25.
724. Relations between voltammetry and potentiometric and amperometric titrations. *Analyt. Chem.*, 1954, **26**, 1685–91.
725. Anodic polarographic wave of vanadium^{IV} aged in alkaline solution (With P. T. Toren). *Ibid.*, 1954, **26**, 1361.
726. Mechanism of emulsion polymerization of styrene with persulfate as activator in the absence and presence of mercaptan and a retarder (With P. R. O'Connor and J. L. Hansen). *J. Polymer Sci.*, 1955, **15**, 459–73.
727. The use of rotating and stationary electrodes for fast reactions (With W. L. Reynolds). *Faraday Soc. Discussion*, 1954, **17**, 167–73.
728. Apparent transfer constants of mercaptans in emulsion polymerization: I. Role of diffusion and distribution coefficients (With E. J. Meehan and P. R. Sinha). *J. Polymer Sci.*, 1955, **18**, 471–82.
729. Iron-cysteinate complexes (With N. Tanaka and W. Stricks). *J. Amer. Chem. Soc.*, 1955, **77**, 1996–2004.
730. Oxidation of ferrous cysteinate complex by cystine. Oxidation potential of the cystine-cysteine system (With N. Tanaka and W. Stricks). *Ibid.*, 1955, **77**, 2004–2006.

731. Equilibrium constants of the reaction between sulfite and oxidized glutathione (With W. Stricks and R. C. Kapoor). *Ibid.*, 1955, **77**, 2057–2061.
732. *N,N'*-Dihydroxyethylglycine and its complexes with iron (With P. E. Toren). *Ibid.*, 1955, **77**, 2061–2064.
733. Halide films at the convection mercury electrode (With J. Jordan). *Ibid.*, 1955, **77**, 3215–16.
734. Equilibrium constants of exchange reactions of cystine with glutathione and with thioglycolic acid both in the oxidized and reduced state (With W. Stricks and R. C. Kapoor). *Ibid.*, 1955, **77**, 4733–39.
735. The polarographic prewaves of cystine (RSSR) and dithiodiglycolic acid (TSST) and the oxidation potentials of the systems RSSR-RSH and TSST-TSH (With W. Stricks and Noboyuki Tanaka). *Ibid.*, 1955, **77**, 4739–42.
736. Polarographic reduction of cystine and of dithiodiglycolic acid in the presence of iron (With W. Stricks and Nobuyuki Tanaka). *Ibid.*, 1955, **77**, 5215–18.
737. The anodic waves of cysteine at the convection and dropping mercury electrodes (With W. Stricks and Nobuyuki Tanaka). *Ibid.*, 1955, **77**, 5211–15.
738. Voltammetry of silver halide suspensions and amperometric titration of halides (With J. T. Stock). *Analyst*, 1955, **80**, 860–870.
739. Acid-base equilibria in glacial acetic acid: I. Spectrophotometric determination of acid and base strengths and of some dissociation constants (With S. Bruckenstein). *J. Amer. Chem. Soc.*, 1956, **78**, 10.
740. Acid-base equilibria in glacial acetic acid: II. Spectrophotometric determination of the ionization and dissociation constants of p,p'-dimethylaminoazobenzene and pyridine. The abnormal effect of water on indicator bases (With S. Bruckenstein). *J. Amer. Chem. Soc.*, 1956, **78**, 109.
741. Instrumental methods in analytical curricula. *J. Chem. Educ.*, 1956, **33**, 423–4.
742. Acid-base equilibria in glacial acetic acid: III. Acidity scale. Potentiometric determination of dissociation constants of acids, bases and salts (With S. Bruckenstein). *J. Amer. Chem. Soc.*, 1956, **78**, 2974.
743. The reaction between aquo ferrous iron and cumene hydroperoxide (With W. L. Reynolds). *J. Phys. Chem.*, 1956, **60**, 969.
744. The reactions of ferrous versenate and ferrous pyrophosphate with cumene hydroperoxide (W. L. Reynolds). *Ibid.*, 1956, **60**, 996.
745. Amperometric titrations. *J. Assoc, Offic. Agric. Chemists*, 1956, **39**, 47–9.
746. A redox system utilizing *N*-nitroso-acetanilide for the emulsion polymerization of styrene and of butadiene-styrene (With D. S. Brackman and E. J. Meehan). *J. Polymer Sci.*, 1956, **21**, 519–34.
747. Interpretation of acid-base titrations in glacial acetic acid, *Experientia*, supplementum V/3 1956, 33–45. Birhäuser Verlag, Basel.
748. Reduction of hexavalent chromium at the rotated platinum electrode. Permeability of the film formed (With A. M. Shams El Din). *J. Phys. Chem.*, 1956, **60**, 1564–8.
749. Acid-base equilibria in glacial acetic acid: IV. Quantitative interpretation of acid-base titrations in glacial acetic acid (With S. Bruckenstein). *J. Amer. Chem. Soc.*, 1957, **79**, 1–7.
750. Kinetics of the reaction between chromate and arsenic trioxide in alkaline medium. Induced reduction of oxygen by this couple (With M. A. Fineman). *J. Phys. Chem.*, 1956, **60**, 1383–88.

751. Polarography in acetonitrile: I. Metal ions which have comparable polarographic properties in acetonitrile and in water (With J. F. Coetzee). *J. Amer. Chem. Soc.*, 1957, **79**, 870–74.
752. Polarography in acetonitrile: II. Metal ions which have significantly different polarographic properties in acetonitrile and in water. Anodic waves. Voltammetry at rotated platinum electrode (With J. F. Coetzee). *Ibid.*, 1957, **79**, 1852–58.
753. Mechanism of retardation in emulsion polymerization of styrene (With E. J. Meehan, Nora Tamberg and C. L. Segal). *J. Polymer Sci.*, 1957, **26**, 215–32.
754. Voltammetry and amperometric titration at the rotated platinum electrode of manganese (II), (III), and (VII) in pyrophosphate medium (With Einar Jacobsen). *Microchem. J.*, 1957, **1**, 3–16.
755. A stable equimolar copper(II)-albumin complex (With B. R. Willeford, Jr). *J. Amer. Chem. Soc.*, 1957, **79**, 2656–57.
756. Equations for the limiting current at the rotated dropping mercury electrode (With Y. Okinaka). *Ibid.*, 1957, **79**, 3326–39.
757. The composition and formation of cobalt complexes with 1-nitroso-2-naphthol (With Einar Jacobsen). *Ibid.*, 1957, **79**, 3677–81.
758. The use of cacotheline as an oxidation-reduction indicator for the volumetric oxidation of iron (With D. N. Hume). *Analyt. Chim. Acta*, 1957, **16**, 415–18.
759. Voltammetric behavior of the iron(II)-(III) and cerium(III)-(IV) couples in potentiometric titrations at constant current and amperometric titrations with two indicator electrodes (With E. R. Nightingale, Jr.). *Ibid.*, 1957, **17**, 329–38.
760. The amperometric titration of bovine serum albumin with copper^{II} (With Bennett R. Willeford). *J. Amer. Chem. Soc.*, 1957, **79**, 2656.
761. Reactivity of sulfhydryl and disulfide upon denaturation of proteins (With Ada Anastasi, B. H. Tan and G. S. Deshmukh). *J. Amer. Chem. Soc.*, 1957, 79, 5102.
762. Polarography in acetonitrile: III (With J. F. Coetzee). *Ibid.*, 1957, **79**, 6110.
763. Acid base equilibria in glacial acetic acid: V. The effect of water on potentiometric and indicator end-points in acid-base titrations in acetic acid (With S. Bruckenstein). *Ibid.*, 1957, **79**, 5915.
764. Application of the rotated dropping mercury electrode to the analysis of mixtures of electroactive substances (With Y. Okinaka and T. Fujinaga). *Analyt. Chim. Acta*, 1958, **18**, 295.
765. Factors to be considered in quantitative polarography with the rotated dropping mercury electrode (With Y. Okinaka). *Ibid.*, 1958, **18**, 83.
766. Mechanism of retardation in emulsion polymerization of styrene (With E. J. Meehan, Nora Tamberg and C. L. Segal). *J. Polymer Sci.*, 1957, **24**, 215–32.
767. Voltammetric behavior of the iron (II)-(III) and cerium (III)-(IV) couples in potentiometric titrations at constant current and amperometric titrations with two indicator electrodes (With E. R. Nightingale, Jr.). *Analyt. Chim. Acta.*, 1957, **17**, 329–38.
768. Reactivity of sulfhydryl and disulfide in proteins, II. Reactive disulfide as related to viscosity and potical rotation in denatured bovine serum albumin (With Ada Anastasi and B. H. Tan). *J. Amer. Chem. Soc.*, 1958, **80**, 3235–40.

769. Reactivity of sulfhydryl and disulfide in proteins: III. Oxidation with ferricyanide of sulfhydryl in native and denatured bovine serum albumin (With Ada Anastasi). *Ibid.*, 1958, **80**, 4248–50.
770. Controlled current polarography at the dropping-mercury electrode (With Y. Okinaka). *Ibid.*, 1958, **80**, 4452–58.
771. Utilization of radioactive isotopes in the study of aging of crystalline precipitates. *Trudy Kom. analit. Khim., Akad. Nauk. U.S.S.R. Inst. Geokhim. i, Anal. Khim.*, 1958, **9**, 98–114.
772. Polarography of sodium hydrosulfate and sodium formaldehyde sulfoxylate at the dropping mercury electrode (With N. Tamberg). *J. Polarog. Soc.*, 1958, **3**, 54–63.
773. Potentiometric titrations with an attackable electrode. The bimetallic electrode pair platinum-tungsten (With E. R. Nightingale, Jr). *Analyt. Chim. Acta*, 1958, **19**, 593–600.
774. Amperometric determination of fluoride at a rotated aluminum electrode (With C. J. Sambucetti). *J. Amer. Chem. Soc.*, 1959, **81**, 1516–17.
775. Reactivity of sulfhydryl and disulfide in proteins: IV. Reaction between disulfide and sulfite in bovine serum albumin denatured in guanidine hydrochloride and urea solutions (With Ada Anastasi and B. H. Tan). *Ibid.*, 1959, **81**, 2047–52.
776. The induced reduction at the dropping mercury electrode of colloidal silver bromide by dicyano argentate (I) ion (With R. C. Bowers). *Ibid.*, 1959, **81**, 1836–40.
777. Effect of surface-active substances on polarographic waves of copper^{II} ions (With Y. Okanaka). *Ibid.*, 1959, **81**, 2296–2302.
778. Voltammetric, potentiometric, and amperometric studies with a rotated aluminum wire electrode: I. Voltammetric behavior of the rotated aluminum electrode (With C. J. Sambucetti). *Analyt. Chim. Acta*, 1959, **21**, 17–24.
779. II. The rotated aluminum electrode as indicator electrode in potentiometric and amperometric acid-base titrations. *Ibid.*, 1959, **21**, 155–65.
780. Formation and aging of precipitates: XLVI. Precipitation of lead sulfate at room temperatures (With B. van't Riek). *J. Phys. Chem.*, 1959, **63**, 817–23.
781. Voltammetric, potentiometric and amperometric studies with a rotated aluminum wire electrode: III. Amperometric determination of fluoride with the rotated aluminum electrode (With C. J. Sambucetti). *Analyt. Chim. Acta*, 1959, **21**, 233–45.
782. Amperometric titration of albumin in blood serum by copper^{II} (With B. R. Willeford, Jr. and D. Singh). *Ibid.*, 1960, **22**, 92–5.
783. Redox recipes: X. Recipe with ferric versenate, sodium dithionite, and hydroperoxide as activating system. (Veroxathionite recipe) (With E. J. Meehan.) *J. Appl. Polymer Sci.*, 1959, **1**, 200–11.
784. Mechanism of oxidation of hydrazine by ferric ethylenediaminetetra-acetate (FeY^-) (With H. Minato, E. J. Meehan and C. Auerbach). *J. Amer. Chem. Soc.*, 1959, **81**, 6168–73.
785. Determination of traces of hydroperoxide by reaction with arsenic (III). Application to determination in polymer latex. (With E. J. Meehan, S. Bruckenstein and H. Minato) *Microchem. J.*, 1960, **4**, 33–41.

786. Characteristics of irreversible waves and kinetic currents at the rotated dropping mercury electrode (With Y. Okinaka). *J. Amer. Chem. Soc.*, 1960, **82,** 324–9.

787–788. Voltammetric, potentiometric and amperometric studies with a rotated aluminum wire electrode: IV. A comparison of the Baker and Morrison cell with a rotated aluminum electrode (With C. J. Sambucetti). *Analyt. Chim. Acta.*, 1960, **22,** 253–60.
V. Amperometric titration of fluoride with aluminum (With E. J. Meehan and C. J. Sambucetti). *Ibid.*, 351–63.

789. The interaction of copper^{II} with bovine serum albumin (With B. R. Willeford, Jr.). *J. Amer. Chem. Soc.*, 1960, **80,** 5673–8.

790. Polarography of copper^{II} thiocyanate solutions (With Y. Okinaka). *Rec. Trav. chim.*, 1960, **79,** 551–6.

791. Post adsorption wave of cuprous thiocyanate in polarograms of dilute thiocyanate solutions containing copper^{II} (With Y. Okinaka). *J. Amer. Chem. Soc.*, 1960, **82,** 3528–33.

792. Reactivity of sulfhydryl and disulfide in proteins: V. Reversal of denaturation of bovine serum albumin in 4*M* guanidine hydrochloride of 8*M* urea and of splitting of disulfide groups in 4*M* guanidine hydrochloride (With Ada Anastasi and B. H. Tan). *J. Amer. Chem. Soc.*, 1960, **82,** 4147–51.

793. Formation and aging of precipitates: XLVII. Maxima in particle size of lead sulfate formed under various conditions (With B. Van't Riet). *J. Phys. Chem.*, 1960, **64,** 1045–7.

794. Amperometric cerimetric titration of iron^{II} with ferroïn as indicator (With B. B. Bhayie). *Microchem. J.*, 1960, **4,** 451–7.

795. Amperometric argentimetric and mercurimetric titration of sulfhydryl (groups): I. Argentimetric titration (With J. Eisenstadter). *Analyt. Chim. Acta*, 1961, **24,** 80–83.

796. Effects on polarographic waves of the formation of insoluble films on dropping mercury (With Y. Okinaka). *J. Amer. Chem. Soc.*, 1961, **83,** 47–53.

THE DETERMINATION OF THE OXIDATION STATES OF TRACER URANIUM, NEPTUNIUM AND PLUTONIUM IN AQUEOUS MEDIA

S. C. Foti and E. C. Freiling
U.S. Naval Radiological Defense Laboratory, Chemical Technology
Division, San Francisco, Calfornia, U.S.A.

(*Received* 8 *January* 1962. *Revised* 23 *July* 1963. *Accepted* 10 *August* 1963)

Summary—This report describes the development, testing and application of a chemical procedure for determining the distributions of uranium, neptunium and plutonium among their respective oxidation states in various aqueous media at tracer concentrations. The separations achieved are of the order of 95% clean. Results are presented which show the per cent extraction of uranium, neptunium and plutonium oxidation states by $0{\cdot}4M$ 2-thenoyltrifluoracetone at various values of pH, and per cent carried by lanthanum fluoride from distilled water and sea water under various conditions. Radiochemical analysis of the separated fractions can then be used to determine the required oxidation state distributions.

INTRODUCTION

Uranium, neptunium and plutonium oxidation state determinations become increasingly important as the utilisation of nuclear power expands, the study of radioactive fallout progresses, and plans are made to test peaceful applications of nuclear explosions. Published material provides much useful information, but some of this is conflicting, and additional data are required to permit reliable measurements of oxidation state distributions. This report describes the development and testing of a method for determining the distribution of tracer concentrations of uranium, neptunium and plutonium among their respective oxidation states in aqueous media. Some areas of application are as follows.

The contribution of uranium-237 and neptunium-239 to the gross activity after a nuclear detonation may be appreciable for a period of ten half lives for each radionuclide.[1] Nuclear detonations in sea water will cause significant quantities of these radionuclides to be present in the aqueous phase of the debris.[2] Nuclear reactor accidents at sea or in the air above are more recent potential sources of sea water contamination by these nuclides as well as by plutonium-239. The biological fate of such contaminants would be expected to depend upon their oxidation states.

The chemical behaviour of uranium, neptunium and plutonium in the process of concentrating, isolating and purifying these elements from aqueous solutions will depend upon their oxidation states. It is therefore important to have means of verifying predicted species.

The development of an oxidation state separation scheme at the tracer level is beset with certain inherent difficulties. The only observable properties of a tracer which give evidence of the oxidation state arise from its chemical behaviour, which in most instances closely resembles the chemical behaviour of the element at macro concentrations. However, the importance of such effects as radiocolloid formation, adsorption on container walls, and oxidation state perturbation by small amounts of impurities becomes greatly magnified at tracer levels, and modifies the properties observed. Two other peculiarities of tracer behaviour are particularly appropriate. The first involves the kinetics of homogeneous bimolecular reactions when both reactants are present at tracer concentrations. Such reactions include the disproportionation of tracer uranium^{V}, neptunium^{V}, plutonium^{IV}, and the corresponding reproportionation reactions. In the absence of surface catalysis, such reactions will be exceedingly slow. The second is concerned with the solubility and carrying of neptunium^{V}. According to Katz and Seaborg[3] macroscopic neptunium^{V} fluoride is soluble, but according to Hyde[4] the tracer is carried on lanthanum fluoride precipitates. As a result of situations like these the investigator must be continually on guard against begging the question.

The recognised oxidation states of uranium, neptunium and plutonium in aqueous solution are summarised in Table I.

Table I.—Oxidation states of uranium, neptunium, plutonium in aqueous solution

Oxidation state	Uranium	Neptunium	Plutonium
III	Oxidised by water to uranium^{IV}	Rapidly oxidised by dissolved oxygen	Stable
IV	Stable	Stable	Stable
V	Disproportionates to uranium^{IV} and uranium^{VI}	Stable	Thermodynamically unstable
VI	Stable	Stable	Stable

It is well known that 2-thenoyltrifluoracetone (TTA) in benzene is a good extracting agent for actinide elements in the +4 oxidation state at low pH values[3,5] and that lanthanum fluoride carries all oxidation states of the actinides except the +6 state.[4] It was therefore decided to use a combination of these methods as the basis for a determination scheme. Although at low concentrations plutonium^{V} is fairly stable in the pH range 2 to 7,[6] its behaviour during extraction has not been previously determined. Marklen and McKay[7] have assumed that it is not extracted by TTA and Connick[8] has concluded that it is carried on a lanthanum fluoride precipitate.

EXPERIMENTAL

Tracers

Uranium-237 was produced by irradiating enriched uranium-236 oxide with thermal neutrons in the MTR at Arco, Idaho.

Neptunium-239 was produced by irradiating depleted uranium-238 metal with thermal neutrons.

Plutonium-237 was produced by bombarding enriched uranium-235 with 30 MeV alpha particles in the University of California 60-inch cyclotron.

In each case the target material was dissolved in hydrochloric acid and purified by ion exchange.[9,10] The radiochemical purity was established by gamma-ray spectrometry and by decay measurements during the course of experimental work.

Reagents

2-*Thenoyltrifluoracetone*, obtained from the Peninsular Chemical Research, Inc., Gainesville, Florida was used without further purification. Otherwise, natural sea water and reagent-grade chemicals were used throughout.

Preparation of stock solutions

Uranium^{IV} was prepared by passing uranium-237 tracer solution containing 2 mg of normal uranium in 4M hydrochloric acid through a 0·4-cm × 10-cm lead reductor column.[11]

Uranium^{VI}, *neptunium*^{VI} and *plutonium*^{VI} were all prepared by evaporating the tracer to dryness with nitric acid and taking up the residue with 0·05M perchloric acid and 0·005N potassium dichromate.

Neptunium^{IV} tracer was prepared by evaporating the neptunium tracer solution to dryness and dissolving with a warm solution of 0·5M hydrochloric acid, 0·1M potassium iodide and 0·1M hydrazine hydrochloride. Attempts to prepare neptunium^{IV} quantitatively with potassium iodide or hydroxylamine or both, and by back-extraction from 2-thenoyltrifluoracetone with 8M hydrochloric acid did not produce solutions with the expected properties.

Plutonium^{III} was prepared by evaporating the tracer to dryness and dissolving the residue in 0·6M hydrochloric acid and hydroxylamine solution.

Plutonium^{IV} tracer was prepared by evaporating the solution to dryness with hydroxylamine and dissolving the residue in a dilute nitric acid and sodium nitrite solution.

Extraction procedure

A 10-ml portion of the aqueous solution was adjusted to the appropriate pH with hydrochloric acid or ammonium acetate and "spiked" with a μlitre portion of tracer solution in a given oxidation state. An equal volume of 0·4M 2-thenoyltrifluoroacetone in benzene was added and the total solution was shaken for approximately 10 min. The phases were separated and a 4-ml aliquot of each phase was pipetted into a glass tube and counted in a well crystal scintillation counter.

Precipitation procedure

A 25-ml portion of solution was "spiked" with a μlitre portion of tracer solution in a given oxidation state, followed by the addition of 2·5 mg of lanthanum carrier and 1 ml of hydrofluoric acid. The solution was stirred for 2 min and centrifuged. The supernatant solution was decanted and the precipitate dissolved, without washing, in a mixture of 1 ml of saturated boric and 1 ml of concentrated hydrochloric acid. The volume was adjusted to equal that of the supernatant solution and gamma-ray assay was performed on both portions.

RESULTS

The results in Table II show that the extraction of uranium^{VI} increases with an increase in the pH from 0·4 to 4·2. Uranium^{IV} is extracted. The extraction of the hexavalent form could be the result of the increase in the effective ligand concentration with the increase in pH on the addition of dilute aqueous ammonia

TABLE II.—PER CENT EXTRACTION OF U^{IV} AND U^{VI} BY 0·4M TTA *vs.* pH IN THE ABSENCE OF ACETATE IONS

pH	U^{IV}	U^{VI}
0·4	94·5	1·1
1·7	—	73·6
2·3	—	96·9
3·1	—	99·3
4·2	98·5	99·5

Table III shows the effect of acetate concentration upon the extraction of uranium^{IV} and uranium^{VI} at pH 4·2. The extraction of uranium^{VI} decreases with an increase in the molarity of the ammonium acetate whereas uranium^{IV} is extracted at all molarities. It would take approximately 11M ammonium acetate to complex almost all of the hexavalent state in order to prevent its extraction by TTA.

The per cent extraction of the oxidation states of uranium, neptunium and plutonium from distilled water and sea water at various values of pH are given in Table IV. The results are averages of at least duplicate determinations. It is seen that pH 0·3–0·4 is favourable for separating the 4-oxidation states from the remaining oxidation states by the extraction procedure.

Table III.—Per cent extraction of U^{IV} and U^{VI} by 0·4*M* TTA *vs.* acetate concentrations at pH 4·2

Ammonium acetate, *M*	U^{IV}	U^{VI}
0·55	96·5	96·4
2·20	95·6	35·9
4·40	97·3	22·5
8·80	96·8	9·7
11·00	97·8	4·4

In the case of uranium^{IV}, repeated separations performed 2 hr apart on different aliquots showed increasing activity in the raffinate from the extraction and in the supernatant solution from the precipitation. Because this indicates gradual atmospheric oxidation of uranium^{IV}, the earliest recorded results have been taken as the most indicative of uranium^{IV} behaviour.

At pH 4·2 plutonium^{III}, plutonium^{IV}, uranium^{IV} and neptunium^{IV} are extracted.

Table IV.—Per cent extraction of uranium, neptunium and plutonium oxidation states by 0·4*M* TTA from distilled water and sea water at various values of pH

State	pH	Distilled water	Sea water
U^{IV}	0·3	93·3	94·3
	1·5	97·5	98·4
	4·3*	98·8	98·7
U^{VI}	0·4	3·4	1·7
	4·3*	4·4	3·6
Np^{IV}	−0·3	87·7	80·1
	0·3	98·7	98·8
	4·3*	100·0	92·0
Np^{VI}	0·3	0·1	0·1
	4·1	0·2	5·0
Pu^{III}	0·0	3·5	1·2
	0·3	4·6	2·8
	1·1	10·5	7·5
	2·0	—	79·4
	4·3*	99·0	100·0
Pu^{IV}	0·3	95·1	96·5
	4·2*	98·2	99·5
Pu^{VI}	0·0	0·1	5·2
	0·3	0·5	9·2
	4·2*	2·9	3·5

* Ammonium acetate is $>10M$.

The per cent of each oxidation state carried by lanthanum fluoride precipitation in the presence and absence of uranyl ion holdback or hydrochloric acid is given in Table V.

TABLE V.—PER CENT CARRYING OF URANIUM, NEPTUNIUM AND PLUTONIUM OXIDATION STATES ON LANTHANUM FLUORIDE FROM DISTILLED WATER AND SEA WATER UNDER VARIOUS CONDITIONS

State	Distilled water			
	Without UO_2^{2+} carrier		With UO_2^{2+} carrier	
	No HCl	1 ml of HCl	No HCl	1 ml of HCl
U^{IV}	—	—	97·3	98·2
U^{VI}	—	20·0	—	3·8
Np^{IV}	95·9	96·2	96·2	97·4
Np^{VI}	18·2	13·4	4·6	3·8
Pu^{III}	94·5	93·5	94·4	95·6
Pu^{IV}	—	—	—	99·0
Pu^{VI}	18·0	10·2	3·0	3·8
	Sea water			
U^{IV}	—	91·5	98·9	96·9
U^{VI}	40·1	3·4	34·6	2·6
Np^{IV}	94·6	97·6	96·2	99·1
Np^{VI}	39·7	1·6	27·9	1·3
Pu^{III}	96·4	97·8	97·4	97·5
Pu^{IV}	99·0	—	99·0	98·0
Pu^{VI}	14·0	3·6	12·5	5·0

Here again, the uranium results, as well as those for neptunium and plutonium, are averages of at least duplicate determinations. No design experiments were run to determine the optimum amounts of uranium and lanthanum carriers. It was noted, however, that less than 2·5 mg of lanthanum carrier was insufficient to carry all of the uranium^{IV}. With the exception that hydrofluoric acid was the last reagent added, no preferred order of reagent addition was noted. Without uranyl ion holdback carrier, as is seen in Table V, uranium^{VI} tends to coprecipitate with lanthanum fluoride from distilled water. The best results were achieved using both 2 mg of uranyl ion and 1 ml of hydrochloric acid.

The results for neptunium and plutonium in Table IV are in general agreement with those of Lai, *et al.*[12] which are presented in Table VI.

We did not obtain any results for neptunium^{V} in distilled water or sea water. Because little difference in the behaviour of the other actinide oxidation states between distilled water, salt water and sea water has been noted, and because the +5-state should be least affected by complex ion formation, the results with sodium chloride solutions have been taken as being applicable to the other two media.

It is seen from Tables IV and V that near-optimum conditions for neptunium oxidation state separation correspond closely to those used for uranium, namely, a pH of 0·4 for extraction and the use of uranyl ion holdback carrier and hydrochloric acid for precipitation. In the case of uranium, either the extraction at low pH or the precipitation method could be used to distinguish between uranium^{IV} and uranium^{VI}.

TABLE VI.—PER CENT EXTRACTION AND CARRYING OF NEPTUNIUM AND PLUTONIUM OXIDATION STATES FROM SODIUM CHLORIDE SOLUTION

State	TTA Extraction, pH 0·4	TTA Extraction, pH 4·2	LaF_3 precipitation, 2 mg of UO_2^{2+}
Np^{IV}	—	97–100	96
Np^{V}	—	0–5	95–100
Np^{VI}	—	2[b]	2
Pu^{III}	4	98–100	96
Pu^{IV}	97–100	97–100	96
Pu^{V}[b]	not extracted	not extracted	carried
Pu^{VI}	4	5–12[a]	4

[a] See section on Results.

[b] Predicted behaviour.

Lai prepared neptunium^{V} by fusing the tracer in sodium chloride for 1 hr at 850°–875°, cooling and dissolving the residue in dilute hydrochloric acid.

In the case of neptunium, because of the additional oxidation state, both methods must be used. The results are then interpreted as

$$\begin{aligned}
\mathrm{Np(TTA)} &= \mathrm{Np^{IV}}\\
\mathrm{Np(Raf.)} &= \mathrm{Np^{V}} + \mathrm{Np^{VI}}\\
\mathrm{Np(LaF_3)} &= \mathrm{Np^{IV}} + \mathrm{Np^{V}}\\
\mathrm{Np(Sup.)} &= \mathrm{Np^{VI}}\\
\mathrm{Np(Total)} &= \mathrm{Np^{IV}} + \mathrm{Np^{V}} + \mathrm{Np^{VI}}
\end{aligned}$$

where, for simplicity, separations are written as being quantitative. This overdetermined system of five equations in three unknowns can then be solved by the method reported by Wilson[13] in order to obtain the most consistent distribution.

It is seen that near optimum conditions for extracting plutonium^{IV} or holding plutonium^{VI} in solution during lanthanum fluoride precipitation correspond closely to those found for uranium. In the case of plutonium, because of its additional oxidation state, two extractions and a lanthanum fluoride precipitation must be carried out. The first extraction is done from pH 0·4 solution. The aqueous phase may then be adjusted to 4·2.

The behaviour of plutonium^{VI} towards extraction did not agree with that expected from the results of Heisig and Hicks[14] because of the acetate concentration. It appears that the plutonium^{VI} is complexed during the extraction.

As in the case of neptunium, the lanthanum fluoride precipitation should then be carried out on a separate aliquot. The results are then interpreted as

$$\begin{aligned}
\mathrm{Pu(TTA,\ pH\ 0{\cdot}4)} &= \mathrm{Pu^{IV}}\\
\mathrm{Pu(TTA,\ pH\ 4{\cdot}2)} &= \mathrm{Pu^{III}}\\
\mathrm{Pu(Raf.,\ pH\ 4{\cdot}2)} &= \mathrm{Pu^{V}} + \mathrm{Pu^{VI}}\\
\mathrm{Pu(LaF_3)} &= \mathrm{Pu^{III}} + \mathrm{Pu^{IV}} + \mathrm{Pu^{V}}\\
\mathrm{Pu(Sup.)} &= \mathrm{Pu^{VI}}\\
\mathrm{Pu(Total)} &= \mathrm{Pu^{III}} + \mathrm{Pu^{IV}} + \mathrm{Pu^{V}} + \mathrm{Pu^{VI}}.
\end{aligned}$$

Here again, separations have been written as being quantitative, and again, the unknowns are overdetermined.

DISCUSSION

Ideally, in order to demonstrate that two oxidation states of the same tracer element can be separated from each other by a given procedure, is should be shown that:

(1) tracer solutions have been prepared for each state, and that in each solution the given state is quantitatively maintained;

(2) the states are not altered by the separation process, and the results of the separation process are not affected by the substances introduced with the tracer (*e.g.*, oxidising or reducing agents);

(3) the separation is quantitative.

In practice, the second requirement may be modified with regard to oxidation state perturbation. Provided that sequential separation procedures are not utilised, it is only necessary that the final states be separable, and that the separated quantities correspond to the original distribution. For example, consider the LaF_3 method in separating the two oxidation states neptunium^{IV} and neptunium^{VI}. The neptunium^{VI} remains in the supernate and the neptunium^{IV} is coprecipitated. Now, if the procedure changes the oxidation state of neptunium^{IV} to neptunium^{V}, and neptunium^{V} coprecipitates when present, no error is incurred by overlooking the change, provided the supernate is not subjected to any further separations. The investigator must consider each case on individual merit and decide whether likely redox effects are or are not going to lead to bias in his results.

The above ideal has been approached in varying degrees by the methods described. What has been achieved is a self-consistent interpretation of a series of preparation and separation procedures, which is also consistent with published procedures for, and properties of, the various oxidation states, the procedures being "nearly quantitative." This interpretation is summarised in Table VII.

TABLE VII.—SUMMARY OF OXIDATION STATE BEHAVIOUR OF URANIUM, NEPTUNIUM AND PLUTONIUM AT TRACER CONCENTRATIONS

Precipitation by LaF_3		Extraction by TTA	
		pH 0·4	pH 4·3
M^{3+}	Carried	Not extracted	Extracted
M^{4+}	Carried	Extracted	Extracted
MO_2^+	Carried	Not extracted	Not extracted
MO_2^{2+}	Not carried	Not extracted	Extracted, unless complexed

Without further information, it is uncertain whether lack of quantitativeness in the separations results from the behaviour of the oxidation state, the presence of small fractions of other oxidation states in the stock solutions, or partial changes of oxidation state by the procedure. In some instances, this could be determined by re-extraction or reprecipitation. If the same distribution ratio were obtained for successive performances of the same separation, it could then be argued that the species was originally present in pure form. The use of inert carriers in the extraction procedures might serve to sharpen separations and should also be tried.

In practice[15] for a solution containing all three elements, the following separation scheme is adhered to. First a 25-ml portion of the solution is made 0·5M with respect to hydrochloric acid and the uranium^{IV}, neptunium^{IV} and plutonium^{IV} are extracted with an equal volume of $0{\cdot}4M$ 2-thenoyltrifluoracetone for 10–15 min. The pH of the raffinate is then raised to 4·3 with $11M$ ammonium acetate, and plutonium^{III} is extracted with a second portion of 2-thenoyltrifluoracetone. The lanthanum fluoride carrying step is then performed on a separate 25-ml portion of the solution being analysed. In rapid succession, 2 mg of natural uranium holdback carrier, 2·5 mg of lanthanum carrier, 1 ml of hydrochloric acid and 1 ml of hydrofluoric acid are added. Uranium^{VI}, neptunium^{VI} and plutonium^{VI} remain in the supernatant solution. Radiochemical analysis of each fraction is then carried out using Wish's method.[10] The results may then be interpreted using the equations described above, or more general equations may be used to incorporate the distribution ratios present.

Zusammenfassung—Der vorliegende Bericht beschreibt die Entwicklung, Erprobung und Anwendung chemischer Methoden zur Ermittelung der Verteilung von Uran, Neptunium und Plutonium in ihren verschiedenen Wertigkeitsstufen in wässrigem Medium und bei Anwesenheit in Tracermengen. Die erzielten Trennungen sind in der Grössenordnung von 95%. Die mitgeteilten Daten zeigen die perzentuelle Extraktion der drei Metalle in ihren verschiedenen Oxydationsstufen durch 0,4 m 2 Thenoyltrifluoroazeton bei verschiedenen pH-Werten. Radiochemische Analyse wurde auf die Bestimmungen in den Fraktionen angewandt.

Résumé—Ce rapport décrit le développement, l'essai et l'application d'un procèdé chimique pour déterminer les répartitions des différents degrès d'oxydation de l'uranium, du neptunium et du plutonium dans divers milieux aqueux à l'état de traces. Les séparations effectuées donnent une pureté de l'ordre de 95%. Les résultats indiquent le pourcentage d'extraction par la 2 thénoyltrifluoracétone 0,4 M des degrès d'oxydation de l'uranium, du neptunium et du plutonium à différentes valeurs de pH et le pourcentage donné par le fluorure de lanthane à partir de l'eau distillée et de l'eau de mer dans diverses conditions. L'analyse radiochimique des parties fractionnées peut alors être utilisée pour déterminer les séparations demandées des degrès d'oxydation.

SOME OBSERVATIONS ON THE ZERO-CURRENT BEHAVIOUR OF ANTIMONY INDICATOR ELECTRODES

E. Bishop and G. D. Short*
Washington Singer Laboratories, The University, Exeter, Devon, England

(*Received* 21 *June* 1963. *Accepted* 14 *August* 1963)

Summary—Methods are described for the preparation and handling of antimony electrodes of precise area and good reproducibility, and for the determination of potential-pH and potential-log P_{O_2} relationships under controlled conditions. Conditions affecting the response characteristics are defined and critically examined: they include the purity of the antimony, the history of the electrode, the temperature, agitation, poising, ionic strength and composition of the solution, the working pH range, the condition of the electrode surface and the oxygen content of the solution. The marked influence of the presence of buffering materials, of the condition of the electrode surface and of the oxygen content of the solution are emphasised. Phosphates cause changes of the electrode surface. The current situation is reviewed in the context of the present work, and electrode mechanisms are discussed.

During the course of fundamental investigations of the differential electrolytic potentiometry of acid-base reactions[1] and of the polarisation of antimony electrodes,[2] the necessity arose for a close enquiry into the zero-current behaviour of antimony electrodes.[3] Despite the general superiority of the glass electrode, antimony, the best of the metal-metal oxide electrodes, has advantages of cheapness, simplicity, robustness, ease of fabrication, cleaning and activation, comparative insensitivity to poisoning, low impedance, a reasonable exchange current and fast response speed, and claims continuing interest in many situations, such as in non-aqueous titrimetry,[4] and in polarisation methods.[1] The literature, however, contains much confusion and contradiction, and not until comparatively recently has this been recognised[5,6] as probably arising from a lack of standardisation of conditions of preparation, handling and use of the electrodes, in turn the result of a lack of appreciation of influential factors. This derogates much of the virtue of earlier work on the subject. The present investigation was undertaken in the hope of resolving some of the points of contention, and it has been thought worth offering a summary of the current situation. To avoid repetition, the present work is intermingled as comment with the review.

EXPERIMENTAL

Preparation of electrodes

Spectrographically pure antimony (Johnson Matthey Ltd.) is melted in a quartz crucible in air. A short length (the bottom) of Pyrex tubing of appropriate diameter sealed to a 5-inch length (the top)

---

* Present address: Chemistry Department, Massachusetts Institute of Technology, Cambridge 39, Mass., U.S.A.

of 10-11-mm tubing is clamped vertically with the lower end just above the molten antimony. The tube is preheated by flaming and lowered to dip into the molten antimony, and the liquid metal is drawn into the tube to about 1 cm above the seal by suction applied from a rubber bulb attached to the top. A tight metal-glass junction results on cooling, and electrical contact is effected by pouring molten solder into the upper tube and sealing into this a length of tinned copper wire. The connecting lead is fixed at the top with wax, and a fresh surface of antimony is exposed at the bottom by cutting off a slice of the assembly at 90° to the tube axis with a diamond wheel. A plane surface of area equal to the internal cross-section of the tube is obtained. Many sets of electrodes were made of areas ranging from 0·126 cm^2 to 0·00102 cm^2, mean diameters being determined by a vernier microscope. Matched pairs of micro electrodes are made by drawing out a thick-walled capillary, cutting in the middle and sucking antimony into the two sections. Larger, cylindrical electrodes are made by cutting back the glass sheath to expose a rod of metal.

Electrodes are usable immediately after sawing, or may be aged (oxidised) by storage in water. No pre-treatment other than wiping with tissue before use has been found necessary—a process now meeting with general acceptance.[7] Electrodes are never allowed to dry out.

Reagents

Water, of chloride, nitrogen and silica content less than $10^{-11}M$, prepared in a quartz still,[8] is boiled out in borosilicate glass, handled under nitrogen in polythene, and protected from carbon dioxide as previously described.[1] This water, never stored for more than 36 hr, is used throughout the experimental work and for the preparation of all solutions.

Carbon dioxide-free perchloric acid solutions are prepared as required by dilution of standardised $0{\cdot}1M$ solutions prepared from the 72% AnalaR acid.

Barium hydroxide solutions are prepared as before.[1]

The background electrolytes, usually potassium chloride, occasionally sodium sulphate, of AnalaR grade, are selected for neutral reaction. Buffer and other materials are of AnalaR grade. Calibrated glassware is used throughout.

Procedure

(*a*) *Potential-pH measurements:* A 400-ml beaker is charged with 200 ml of water and 0·5 g of potassium chloride ($\equiv 0{\cdot}03M$) and fitted with a cover carrying a mounted set of three (or more) antimony electrodes, a calibrated E.I.L. GHS23 lithium-barium glass electrode, the salt bridge, terminated with a low leakage rate ceramic plug, a high-capacity saturated calomel cell of area 30 cm^2, a burette and a gas inlet which so dips into the solution that gas bubbles do not break on the electrode surfaces. Coating the beaker with hard paraffin wax to obviate attack of the glass and dissolution of alkali was found to make no difference to the results. The solution is magnetically stirred just at cavitation speed with a PTFE-coated paddle of a length just less than the diameter of the beaker. The potentials of the electrodes with respect to the reference electrode are read on an E.I.L. model 23A pH meter, from which a Cambridge DE 2-sec recorder is driven. By means of helipots, the recorder scale can be expanded and backed off to provide more sensitive discrimination and to observe potential drift. Scale expansion to incipient noise level can also be used to overcome recorder dead space in establishing the attainment of equilibrium and in examining low drift rates. Electrode circuits are selected by a Doran high impedance switching unit. An interval of at least 30 min is allowed for potential equilibration at each pH value, and the pH is changed by addition of increments of $0{\cdot}001M$ perchloric acid or $0{\cdot}0005M$ barium hydroxide from the burette. More concentrated solutions are used outside the pH range 4–10. Supplementary results are provided from numerous perchloric acid—barium hydroxide titrations.[1] A vigorous stream through the solution of the appropriate gas at constant pressure is maintained throughout.

(*b*) *Variation of partial pressure of oxygen:* As in (*a*), with the addition that pure oxygen and "oxygen-free" (white spot) nitrogen are passed through separate banks of calibrated rotameters of sizes such that a nominal variation from 0·1% to 100% of oxygen in the gas stream bubbling through the solution can be effected. The gas flow from the cylinder reducing valves is further regulated by calibrated needle valves. The attainment of potential equilibrium is observed on the recorder trace, and a series of measurements is started with the lowest required oxygen partial pressure because equilibration is much more rapid in the direction of increasing oxygen concentration.

Each series of experiments was replicated many times, both with the same and with fresh electrodes and/or solutions, and each run was carried out with at least three electrodes. Replicability is discussed below. Sets of results are illustrated graphically in Figs. 1 and 2. The laboratory was thermostatted at 20°. The pH values indicated by the glass electrode agreed with those calculated from solution composition.

REVIEW, RESULTS AND DISCUSSION

Factors recognised[9] as affecting the performance of antimony electrodes in aqueous media are:

(*a*) the purity of the antimony and the history of the electrode;
(*b*) temperature and agitation of the solution;
(*c*) the poising, ionic strength and composition of the solution;
(*d*) the working pH range;
and (*e*) the oxygen content of the solution or partial pressure of oxygen in the atmosphere in contact with the solution.

It is therefore necessary to describe meticulously the preparation, handling and conditions of use of the electrodes if the results are to be of significance and their validity is to be appraised. The factors will be discussed as grouped above.

Potential-governing equilibria of metal–metal oxide electrodes

Imprimis, as a metal–metal oxide electrode, it is tacitly assumed that the following equilibria are applicable:

$$Sb_2O_3 + 3H_2O \rightleftharpoons 2Sb(OH)_3 \qquad (1)$$

$$Sb(OH)_3 \rightleftharpoons Sb^{3+} + 3OH^- \qquad (2)$$

whence the solubility product $S_{Sb_2O_3}$ is

$$S_{Sb_2O_3} = [Sb^{3+}][OH^-]^3 = [Sb^{3+}]\frac{K_w{}^3}{[H^+]^3} \qquad (3)$$

and that the electrode responds to antimony^{III} ions by the Nernst relationship

$$E = E_{0_{Sb/Sb^{3+}}} + \frac{RT}{3F}\log_e [Sb^{3+}] \qquad (4)$$

From (3) and (4)

$$E = E_{0_{Sb/Sb^{3+}}} + \frac{RT}{3F}\log_e S_{Sb_2O_3}\frac{[H^+]^3}{K_w{}^3} \qquad (5)$$

$$= E_{0_{Sb/Sb^{3+}}} + \frac{RT}{3F}\log_e \frac{S_{Sb_2O_3}}{K_w{}^3} + \frac{RT}{3F}\log_e [H^+]^3 \qquad (6)$$

The first two terms on the right hand side of (6) are assumed to be constant, and may be combined as the single term E_0', so that

$$E = E_0' + \frac{RT}{F}\log_e [H^+] = E_0' - \frac{2{\cdot}303RT}{F}\,\text{pH} \qquad (7)$$

DISCUSSION

Equilibria (1) and (2) can be strongly challenged. The hydration process is undoubtedly complex, and strongly dependent on conditions; it may be represented by

$$aSb_2O_3 + (3a - 2b)H_2O \rightleftharpoons 2Sb_aO_b(OH)_{(3a-2b)} \qquad (8)$$

and it is unlikely that Sb^{3+} ions will be formed, of a concentration adequate to control electrode potentials, the over-all ionisation being either

$$Sb_aO_b(OH)_{(3a-2b)} \rightleftharpoons Sb_aO_b{}^{(3a-2b)+} + (3a - 2b)OH^- \qquad (9)$$

or

$$Sb_aO_b(OH)_{(3a-2b)} \rightleftharpoons Sb_aO_{(3a-2b)}{}^{(3a-2b)-} + (3a - 2b)H^+ \qquad (10)$$

with an isoelectric region of overlap of the two modes of ionisation, which are themselves complex equilibria. This does not affect the pH dependence, because the relevant term in either case resolves to

$$\frac{RT}{(3a - 2b)F} \log_e [\mathrm{H}^+]^{(3a-2b)} = \frac{RT}{F} \log_e [\mathrm{H}^+] \tag{11}$$

but the constancy of the term E_0' is no longer assured, and the second term in (6) may well vary with conditions. This possibility has not received sufficient attention in the past, but suspicion has recently been turned upon the constancy of normal electrode potentials.[7]

(*a*) *Purity and history of the electrode*

After early confusion, Perley's careful work established the detrimental effects of traces of copper, which are now confirmed; but otherwise antimony is comparatively insensitive to impurity,[6] notably to arsenic and sulphur.[10] Many methods of preparation have been examined.[6,11] Electrodeposition gives variable quality[6] because of deficiency of oxygen in the metal lattice, inclusion of electrolyte (*cf.* "explosive" antimony[12]) and variable surface activity. Casting in air is found to give the most satisfactory electrodes. Compression of mixtures of powdered metal and oxide[11] has been advocated for ensuring uniform distribution of oxide.

Pretreatment to secure a clean reproducible surface by electrolysis,[13] chemical activation,[13] abrasion[14] and scraping[15] has been advocated; simple wiping with tissue has been found perfectly satisfactory. Electrodes after drying out, or prolonged storage in aerated water, behave erratically when returned to use because of too thick an oxide film on the surface. Activity is quickly restored by the differentiating current in DEP,[1] so that cathodic polarisation at $\sim 10\ \mu\text{A cm}^{-2}$ is effective; but normal practice is to saw a thin slice off the end of the electrode to expose a fresh surface. The electrode is then used immediately, or after ageing for 24–48 hr in aerated water. Electrodes are not exposed to solutions outside the pH range 2–10, otherwise marked hysteresis occurs. Electrodes prepared and handled as described show good reproducibility (± 5 mv). No specific area effects[16] have been observed.

(*b*) *Temperature and agitation of the solution*

The scant work on temperature effects[17] indicates far from theoretical behaviour at temperatures above 30°, and no consistent theory has been advanced to account for the deviations. The present work has been confined to a temperature of 20°, but polarisation measurements up to 50° have been analysed.[2a]

Stirring affects the electrode potentials.[9,14,18] The effect has been reviewed,[6] and Gatty and Spooner have plausibly applied the local action theory of corrosion.[9] The electrode surface consists of anodic (bare metal) and cathodic (oxide layer) sites, and the advent of dissolved oxygen increases the proportion of cathodic sites, causing a positive potential drift. Stirring either increases the rate of diffusion of oxygen to the bare metal, to increase the proportion of cathodic sites causing a positive deviation, or enhances anodic dissolution to expose more bare metal, causing a negative drift; both effects have been observed under appropriate conditions.[9] The versatility of the theory makes it difficult to prove or disprove the interpretation of a given observation.

(*c*) *Poising, ionic strength and composition of the solution*

Poising: Perley[14] alone appears to have observed that the potential at a fixed pH differs in the presence or absence of buffering substances. That good linear plots of near theoretical slope result from calibration of the electrode in a series of buffer solutions is no guarantee that the behaviour will be similar in unpoised solutions, or in solutions of low buffer concentration or low ionic strength. For example, at pH 7 and 20° in a pure oxygen atmosphere, the antimony electrode potential with respect to the SCE was -320 mv in unpoised solution. Addition of ammonium acetate (pH 6·98) lowered the potential to -356 mv. In ordinary nitrogen ($\sim$1 % oxygen) these potentials became -405 ± 5 and -411 ± 2 mv, respectively. Change of atmosphere may cause a change in electrode reaction,[9,20] or removal of oxygen overvoltage;[20] but the negative shift on addition of buffer is unlikely to be caused by reduction of the solubility of oxygen on the addition of electrolyte[6] because the high supporting electrolyte concentration ensures that the ionic strength is hardly altered. The concentration of ammonium acetate is not critical; variation from 0·005*M* to 0·03*M* made no significant difference to the potentials.

Ionic strength: Effects claimed to result from changes in ionic strength[14,21,22] can more probably be ascribed to adventitious addition of impurities with the electrolytes, to change in hydrogen ion activity, or to change in oxygen solubility,[6] or, at low ionic strengths, to activation overpotential.

Composition of solution: Oxidising, reducing or complexing (particularly oxygen-ligand) substances will naturally affect the potential of the antimony electrode by upsetting the equilibria on which it depends. For example, buffers containing tartrate or citrate must be avoided.[23] Silver[24] and copper ions, and, presumably, other metal ions, such as mercury, displaceable by antimony, produce abnormal potentials. The effect of phosphate ion is discussed below.

(*d*) *Working pH range. Potential-pH relationships and* E_0' *values*

Linearity, slope and range of response: The reasonably linear pH response has repeatedly been affirmed, but it is generally recognised that the useful range is limited to pH 1–12, and that excursions to these limits give rise to hysteresis, so that the electrode functions best in the range pH 3 to 10. Most results refer to calibration in aerated buffer solutions. Perley, however, has shown[14] that different slopes for the emf-pH plot result, depending on whether the solution pH is greater or less than 8: a break occurs in the region around neutrality. Others have noted this phenomenon.[15] The emf-pH plots of Fig. 1 show that for unbuffered, oxygenated solutions, the antimony electrode yields a line of slope 58 mv/pH unit over the range pH 3–6 in agreement with Perley's results; but the plot becomes non-linear at higher pH values,[25] and shows a flat portion over the range pH 6·5–7·5, somewhat resembling that observed by Kolthoff and Hartong.[15] Under ordinary ($\sim$1 % of oxygen) nitrogen, the slope in the region pH 8–11 is 52 mv/pH unit, again in agreement with Perley's results. The effect of oxygen is greatest in unpoised neutral or weakly alkaline media, and addition of buffer causes an immediate negative shift of potential towards the value in nitrogen. The change in slope could well indicate a change in active ion from hydrogen to hydroxyl, *i.e.*, a change in electrode order, as happens with silver-halide systems,[16] or of electrode reaction [*cf.* refs. (9) and (10)].

Formal potential, E_0': Assuming that equation (7) is valid, extrapolation of the emf-pH plot should give values for E_0', but in practice the extrapolation extends over 2–8 orders of concentration, casting doubt on its reliability. Moreover, slopes vary between 50 and 60 mv/pH unit; potentials at a given pH value may vary by 100 mv according to the conditions of measurement; and temperature coefficients are uncertain. The diversity of reported E_0' values[6] is not surprising, and any attempt to draw conclusions from such evaluations must be approached with caution. Pourbaix *et al.*[26] give the theoretical value of E_0' on the hydrogen scale as 0·167 v: most quoted values are about 0·1 v higher.[6] Values from Fig. 1 are 0·274 v in a pure oxygen atmosphere, and 0·245 v in ordinary nitrogen. Mehta and Jatkar,[27] surveying a large number of reported values, discern a tendency towards the formation of two distinct groups, one around 0·275 v, the other around 0·25 v. It is tempting to ascribe the higher value to determinations in aerated or oxygenated solutions, and the lower to de-aerated solutions; but the correlation is vitiated by certain exceptions and by lack of definition of experimental conditions.

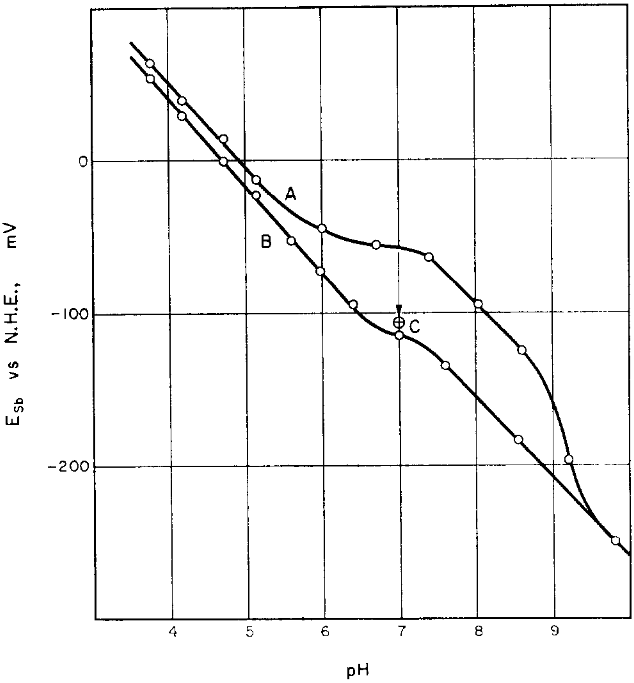

FIG. 1.—Emf—pH relationships of antimony electrodes.
Curve A: In an atmosphere of pure oxygen. Point C illustrates the effect of the addition of a buffering material to the solution.
Curve B: In an atmosphere of nitrogen containing a trace (about 1 %) of oxygen. Potentials have been converted to the hydrogen scale using the value 0·245 v for the SCE.

Under customary conditions, the electrode does not accord with the simple concept (7), but does approach theoretical behaviour under strictly anaerobic conditions[17,28] for which E_0' values of 0·16 v have been reported, and deoxygenation shifts the potentials towards the theoretical values. The electrode reaction must therefore be complex rather than simple, *e.g.*, (8), and may be a mixed process. For instance,

$$2Sb + 3H_2O \rightleftharpoons Sb_2O_3 + 6H^+ + 6\varepsilon \tag{12}$$

gives a potential linearly dependent on pH, and an E_0' value of 0·16 v, while

$$O_2 + 4H^+ + 4\varepsilon \rightleftharpoons 2H_2O \tag{13}$$

gives the same pH dependence and an E_0 value of 1·23 v, but the potential is also dependent on log P_{O_2}. At a constant partial pressure of oxygen, the electrode should show a linear pH response, with an E_0 between 0·16 and 1·23 v, depending on the partial pressure of oxygen and the state of the electrode surface. Several theories attempt a more detailed mechanistic explanation,[9,20] probably the most successful being the local action theory of corrosion; but none has yet been completely vindicated. Clearly, however, the buffering and oxygen content of the solution are intimately involved in the response of the electrode, and the E_0' value is a function of conditions of use.

(*e*) *Oxygen response of antimony electrodes*

Most reports refer to aerated solutions, one or two to pure oxygen or pure nitrogen atmospheres. Tourky and Moussa[20] examined the response in carefully de-aerated solutions of electrodes prepared in an atmosphere of hydrogen, and found a step-like emf-pH plot with alternating high and low slopes showing five breaks which they attempted to interpret in terms of neutralisation of hydroxyl and hydrogen groupings on antimony oxide. No investigation of the effect of variation of oxygen content appears to have been reported other than those of Holmqvist[29] and of Kauko and Knappsberg.[13] From equation (13) the plot of emf against $\log_{10} P_{O_2}$ at constant pH should have a slope of $2{\cdot}3\ RT/4F$, which Kauko and Knappsberg claim for polished antimony electrodes at pH 5·9, 7 and 9 in phosphate and borate buffers over the partial pressure range of 3–100% of oxygen. Holmqvist found an S-shaped plot with the potential of the antimony electrode changing rapidly at about 10% of oxygen and reaching constancy at high and low levels.

Results

Effect of buffers: The present work was done at pH 7 in 0·03*M* potassium chloride, with or without the addition of ammonium acetate or a phosphate buffer, and subjected to manyfold replication. Typical results are shown in Fig. 2 and support Holmqvist. Notable is the effect of buffers in shifting the potentials to more negative values and in diminishing the potential swing for a given change in oxygen pressure. The concentration of buffering substance in the solution is not critical, provided that it exceeds a minimum value of about 0·005*M*: determinations have been made in concentrations up to 0·3*M* without revealing any concentration-dependent effect. The reproducibility of the slopes is not good, but the slope $\partial E/\partial \log_{10} P_{O_2}$ in buffered solutions tends to be less than in unpoised solution. Freshly cut electrodes give lower slopes and more negative potentials than oxidized electrodes.

Equilibration time: Kauko and Knappsberg attribute Holmqvist's results to failure to attain equilibrium; and certainly equilibration is sluggish, especially at oxygen partial pressures below 10%. Accordingly, two oxygen levels falling on the straight portion between 0·5% and 10% oxygen of the emf–$\log_{10} P_{O_2}$ plot were selected, and the potential at each pressure was recorded for 6 hr repeatedly. After the initial rapid drift for 10 min, and a slow drift for a further 20 min, the potentials varied by no more than 0·25 mv. The slopes calculated from these measurements in ammonium acetate, assuming linearity of the plot, were 30 mv for freshly sawn electrodes and 57 mv for oxidised electrodes, each of these being means of three separate determinations showing a maximum scatter of 3 mv.

Discussion

The approach to constant potential at low oxygen levels can be explained by postulating either that this represents the residual partial pressure of oxygen in "white spot" nitrogen, probably about 0·1%; or that this level represents the "failure point" of the electrode response,[16,30] *i.e.*, the concentration below which no further change in potential occurs with change in concentration of the reactive species. Constancy of potential at high oxygen levels is not so easily explained. Possibly in this region the antimony surface is fully populated with oxygen doublets, so that further increase in oxygen partial pressure does not change the potential,[31] a view in accord with the postulate of Tourky *et al.*[17,20] that antimony electrode behaviour is governed by a layer of chemisorbed oxygen on the metal surface.

The disaccord of Kauko and Knappsberg's results may be resolved on the basis of the presence of phosphate in their solutions. Electrode surfaces, even if initially dull and thickly coated with oxide, become bright and shiny after immersion in solutions containing phosphate ion. Phosphate ion evidently reacts with antimony oxide species, probably to form a phosphate antimonate-III ion, though no report of such a reaction has been traced in the literature. The measurements in phosphate media provide emf–$\log_{10}P_{O_2}$ slopes closest to the theoretical value claimed by Kauko and Knappsberg, and indicate participation of the bare metal surface in reaction (13).

The slopes of the emf–$\log_{10}P_{O_2}$ plots vary from 20 to 60 mv depending on whether electrodes are fresh or aged, and whether or not buffering substances or phosphate ion are present, forcing the conclusion that the precise involvement of oxygen in the electrode reaction is condition-dependent. Processes involving one, two or four [reaction (13)] electrons per oxygen molecule can be written:

$$2H^+ + 2Sb + 2O_2 + 2\varepsilon \rightleftharpoons Sb_2O_3 + H_2O \tag{14}$$

with a slope of

$$\frac{\partial E}{\partial(\log_{10}P_{O_2})_{T,\mathrm{pH}}} = \frac{2{\cdot}3RT}{F};$$

$$6H^+ + 2Sb + 3O_2 + 6\varepsilon \rightleftharpoons Sb_2O_3 + 3H_2O \tag{15}$$

with a slope of

$$\frac{\partial E}{\partial(\log_{10}P_{O_2})_{T,\mathrm{pH}}} = \frac{2{\cdot}3RT}{2F};$$

but reactions involving three electrons are less plausibly formulated:

$$18H^+ + 2Sb + 6O_2 + 18\varepsilon \rightleftharpoons Sb_2O_3 + 9H_2O$$

with a slope of

$$\frac{\partial E}{\partial(\log_{10}P_{O_2})_{T,\mathrm{pH}}} = \frac{2{\cdot}3RT}{3F}.$$

Values of the oxygen response slopes can be accounted for on a basis of such a reaction series, one or other reaction preponderating as conditions change.

CONCLUSIONS

When used merely as an indicator electrode for locating titrimetric end-points, the antimony electrode performs satisfactorily, provided that it is not exposed to solutions outside the pH range 2–10, or solutions containing ligands that will combine with, or metal ions displaceable by, antimony; but reproducible results will be accessible only if all conditions are rigorously standardised.

The formal potential E_0', and electrode slope, are dependent on the oxygen content of the solution, the presence or absence of buffering material and the condition of the electrode surface. The oxygen response also depends on the same factors, and is markedly affected by the presence of phosphate. For the determination of pH, the response is so much dependent on conditions that the electrodes should be calibrated and used under as nearly identical conditions as possible.

The method of preparation and handling which has been described gives electrodes of excellent reproducibility independent of electrode area; but the simple mechanism of metal-metal oxide electrodes is inadequate to describe their behaviour. It seems likely that equilibrium (12) combined with (13), (14) and (15), in the presence of oxygen, is responsible for the mixed behaviour of antimony electrodes, but the marked influence of buffering materials is difficult to explain.

S.) is indebted to Electronic Instruments Ltd. and to the Company of Scientific Instrument Makers for maintanence grants during his tenure of the E.I.L. Fellowship.

Zusammenfassung—Herstellung und Handhabung von gut reproduzierbaren Antimonelektroden genau definierter Fläche und Bestimmung der Potential-p_H-und Potential-log p_{O_2}-Beziehungen unter definierten Bedingungen werden beschrieben. Die das Ansprechen beeinflussenden Parameter werden definiert und kritisch untersucht: Reinheit, Vorgeschichte der Elektrode, Temperatur, Rührung, Ionenstärke und Zusammensetzung der Lösung, p_H, Oberflächenzustand der Elektrode und Sauerstoffgehalt der Lösung. Nachdruck wird gelegt auf den starken Einfluß von Puffern, des Oberflächenzustandes der Elektrode und des Sauerstoffgehalts der Lösung. Phosphate verändern die Oberfläche der Elektrode. Eine Ubersicht über das Verhalten bei Stromfluß wird gegeben und Elektrodenmechanismen diskutiert.

Résumé—On décrit des méthodes de préparation et de manipulation des électrodes d'antimoine, de surface précise et de bonne reproductibilité, et des méthodes de mesures potentiométriques du pH et des relations potentiel-log P_{O_2} dans des conditions controles. Les facteurs susceptibles d'affecter les caractéristiques de la réponse ont été définis et étudiés: ils comprennent la pureté de l'antimoine, les antécédents de l'électrode, la température, l'agitation, l'équilibration, la force ionique et la composition de la solution, le domaine de pH utilisé, les conditions de surface de l'électrode et la teneur en oxygéne de la solution. L'influence déterminante qu'ont les facteurs suivants: présence de tampons, conditions de surface de l'électrode et teneur en oxygéne de la solution, a été mise en lumiére. Les phosphates perturbent la surface de l'électrode. Les théories actuelles et le mécanisme des électrodes sont résumés dans le contexte de cet article.

THERMOGRAVIMETRIC AND DIFFERENTIAL THERMAL ANALYSIS OF EUROPIUM^{III} OXALATE AND SOME EUROPIUM^{II} SALTS*

A. GLASNER, E. LEVY, M. STEINBERG and W. BODENHEIMER
Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Israel

(*Received* 24 *June* 1963. *Accepted* 26 *September* 1963).

Summary—The differential thermal analysis curves of $Eu_2(C_2O_4)_3$, EuC_2O_4 and $EuCO_3$ exhibit prominent exothermic peaks in the region of 420° because of the oxidation of europium^{II} to europium^{III}. The first step in the decomposition of $Eu_2(C_2O_4)_3$, after completion of dehydration, is $Eu_2(C_2O_4)_3 \rightarrow 2EuC_2O_4 + 2CO_2$. The reasons for some conflicting differential thermal analysis curves of the rare earth oxalates obtained by various authors are explained. The europium^{II} oxalate, $EuC_2O_4 \cdot 1.7H_2O$, is prepared.

INTRODUCTION

THE oxalates of the rare earths are of special importance for the separation and quantitative analysis of this group of elements. There is also a wide interest in other aspects of the rare earth oxalates, as evidenced by the numerous investigations on their thermal behaviour published during the last decade. Mostly thermogravimetric (TG)[1] and differential thermal analytical (DTA)[2] methods have been employed, but the thermal curves obtained were complicated and their interpretation was often dubious.

In a series of studies carried out in this laboratory[3] the mechanism and stepwise decomposition of many of the rare earth oxalates has been elucidated by analysing the solid residues and the gaseous products formed in vacuum or in various atmospheres.[4] It was found that $Eu_2(C_2O_4)_3$[4] and $Yb_2(C_2O_4)_3$[4] were internally reduced to the bivalent cation in the first step of their decomposition, at about 300° and 340°, respectively. In the presence of oxygen the cations were soon re-oxidised to the tervalent state. In vacuum or in an inert atmosphere, bivalent carbonates (or oxycarbonates) were found to be stable well above 400°. In the light of these results a re-examination of the TG and DTA curves of $Eu_2(C_2O_4)_3$ was thought to be desirable. A few bivalent europium salts, such as EuC_2O_4, $EuCO_3$ and $EuSO_4$, were also prepared and their thermal curves were compared to that of the tervalent europium salts. Disregarding minor fluctuations, the recorded thermal curves were found to be consistent with the previously proposed mechanisms of decomposition.

EXPERIMENTAL

Reagents

Eu_2O_3 (Lindsay, code 1013, 99·9% purity) served as the starting material for all of the preparations examined in this work.

$Eu_2Ox_3 \cdot 5.8H_2O$ (or 10 H_2O): Prepared in the usual manner by precipitation with oxalic acid from a nitric acid solution[4] and kept in an evacuated desiccator over phosphorus pentoxide.

---

* This paper contains part of the Ph.D. thesis submitted to the Senate of the Hebrew University by E. L.

$EuSO_4$ and $EuCO_3$: Prepared as described by Cooly and Yost;[5] the solution from the Jones' reductor was allowed to pass directly into a 4*M* sulphuric acid solution and the precipitated $EuSO_4$ was filtered, washed and dried.

A batch of $EuSO_4$ was further digested in a 10% sodium hydroxide plus sodium carbonate mixture to yield the greenish-yellow $EuCO_3$, which, after drying, was found by analysis to conform to the formula $EuCO_3 \cdot 0.21H_2O$. The infrared absorption spectrum of this preparation, by the potassium bromide disc method, is shown in Fig. 1.

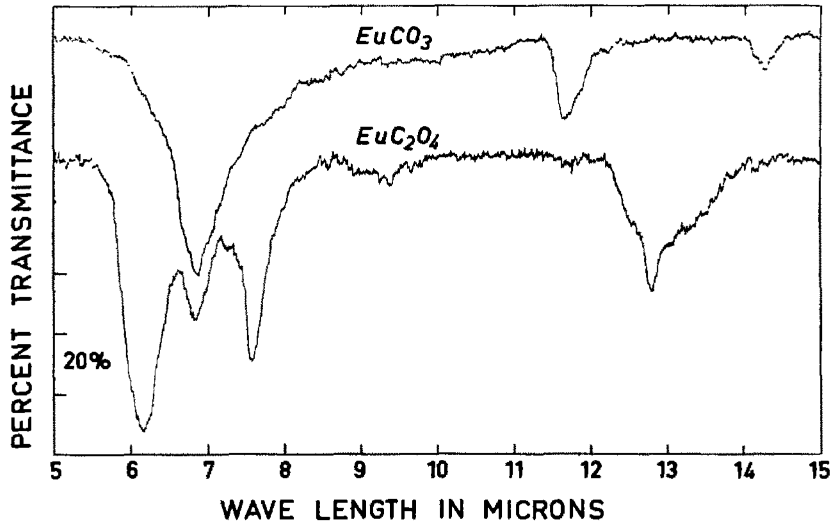

Fig. 1.—Infrared spectra of EuC_2O_4 and $EuCO_3$ showing absorption bands characteristic for the anions.

EuC_2O_4: Its preparation has not yet been described in the literature. Various procedures were investigated. On either adding the reduced solution from the Jones' reductor to a saturated solution of oxalic acid (previously boiled to expel oxygen) or dissolving $EuCO_3$ in 1*M* hydrochloric acid and adding the oxalic acid to this solution, a beige coloured precipitate was obtained. An elementary analysis* of the last preparation gave:

	Found	Theoretical		
		EuC_2O_4	$EuC_2O_4 \cdot 0 \cdot 5H_2C_2O_4$	$Eu_2(C_2O_4)_3$
C, %	13·08	10·0	12·64	12·68
H, %	0·18	0·0	0·315	0·00

and its composition is evidently undefined.

Pouring a saturated oxalic acid solution onto the solid $EuCO_3$ proved more successful. Evolution of carbon dioxide, but no dissolution of the solid (which turned from yellow to a rusty red) was observed. At this stage two volumes of distilled ethyl alcohol were added, and the red crystals were filtered and dried at 90°. If no alcohol is added, the red crystals change slowly to the beige modification, but no similar change occurs when the dry material is contacted with water. The elementary analysis of the red preparation gave 8·86% of carbon and 1·28% of hydrogen. Assuming that all hydrogen is from absorbed water or from water of crystallisation, the formula for the preparation should be $EuC_2O_4 \cdot 1 \cdot 72H_2O$, in excellent agreement with the 8·86% of carbon found. This formula was

further confirmed by igniting a weighed portion of the preparation in air at 1000°:

	H, %	C, %	Wt. loss at 1000°, %
Theoretical for			
$EuC_2O_4 \cdot 1{\cdot}7H_2O$	(1·28)	8·86	35·0 (Eu_2O_3)
Found	1·28	8·86	34·5

The infrared absorption spectrum of this preparation, obtained by the potassium bromide disc method, is shown in Fig. 1.

$Eu_2(SO_4)_3 \cdot nH_2O$: Crystallised from a sulphuric acid solution of Eu_2O_3 by evaporation. It was collected on a fritted glass crucible and washed with a small amount of water and dry acetone. This product was not analysed, and it is therefore possible only to estimate its water content or surplus sulphuric acid, from the thermogravimetric curve.

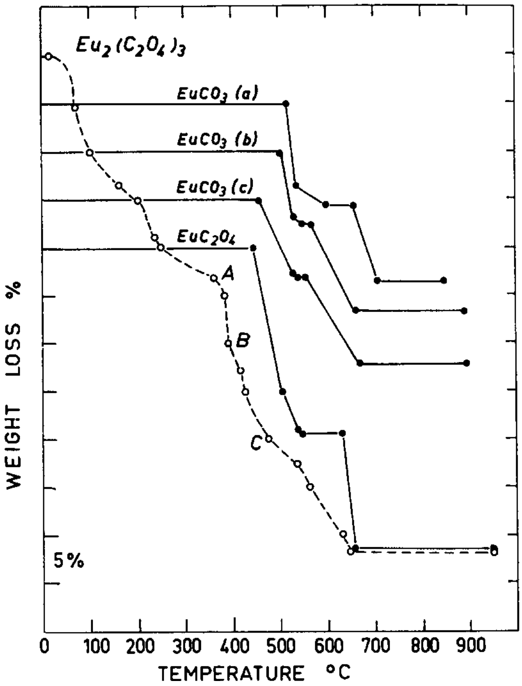

FIG. 2.—Thermogravimetric curves of $Eu_2(C_2O_4)_3 \cdot 10H_2O$, $EuC_2O_4 \cdot 1{\cdot}7H_2O$, two samples of $EuCO_3$ (a and b), and $EuCO_3$ mixed with alumina (c).

Apparatus

For the thermogravimetric measurements a Stanton decimilligram model thermobalance was used. The heating rate was maintained at 6°/min and the furnace temperature control is generally correct within ±2°. Samples weighing 100 mg each were taken for all of the experiments, so that weight losses can be directly read on the recorded thermograms in percentages.

For the DTA measurements a Gallenkamp tube furnace, provided with a ceramic heating block and ceramic twin crucibles, was employed. One of the crucibles contained the sample, mostly weighing 500 mg, mixed with an equal weight of α-alumina (previously ignited at 1000°), and the other crucible 1 g of the pure inert reference material. The rate of heating was maintained at 10°/min. Temperatures were measured with chromel-alumel thermocouples. The temperature of the alumina was taken as reference and recorded on a Kent multilec instrument, whilst the temperature difference between the two crucibles was recorded on a Kent microvolt instrument.

RESULTS

Fig. 2 shows the percentage weight loss (TG curves) obtained on heating $Eu_2(C_2O_4)_3$, EuC_2O_4 and $EuCO_3$ and Figs. 3, 4 and 5 the thermal spectra (DTA curves) of the same materials.

Europium^{III} *oxalate.* There are no distinct plateaux on the thermogram of the tervalent hydrated oxalate (Fig. 2), but one may attribute definite compositions to the decomposing sample at most points of inflection. Thus the percentage loss at *A* (350°) corresponds to the anhydrous salt $Eu(C_2O_4)_3$, the decomposition of which has been retarded by the presence of the last traces of water. The steep slope to *B* (390°) corresponds approximately to the formation of EuC_2O_4, although a partial re-oxidation of the europium by air may have taken place. Re-oxidation and decomposition of the oxalate to carbonate is completed at *C* (475°), where the weight loss indicates the composition: $(EuCO_3)_2O$. The decomposition to the sesquioxide is completed at about 650°.

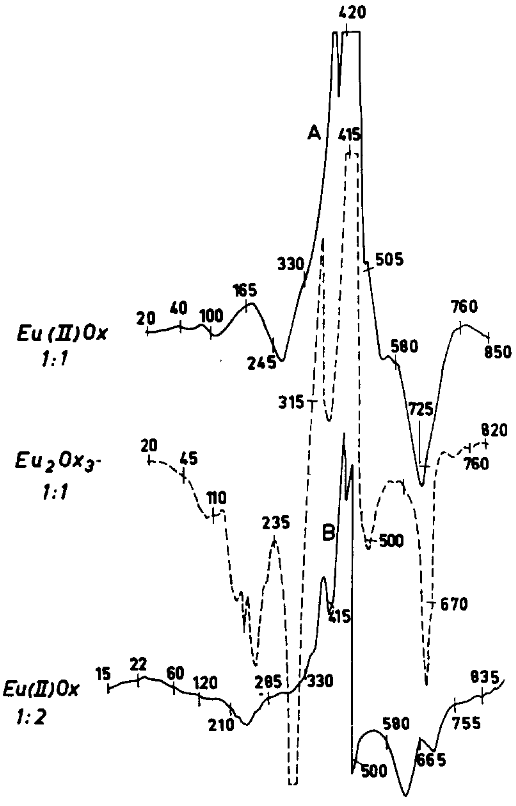

FIG. 3.—DTA curves of $Eu_2(C_2O_4)_3{\cdot}5{\cdot}8H_2O$ and $EuC_2O_4{\cdot}1{\cdot}7H_2O$. Weight ratio of oxalate to alumina for curve B was 1 : 2. Numbers on curves indicate temperatures (°C).

The most prominent feature of the DTA curves in Figs. 3 and 4 (inclusive of the $EuCO_3$ curves) is a broad and high exothermic peak at 410°–420°. For the sake of comparison, the thermal spectrum of $La_2(C_2O_4)_3{\cdot}10H_2O$ is also shown in Fig. 5, with

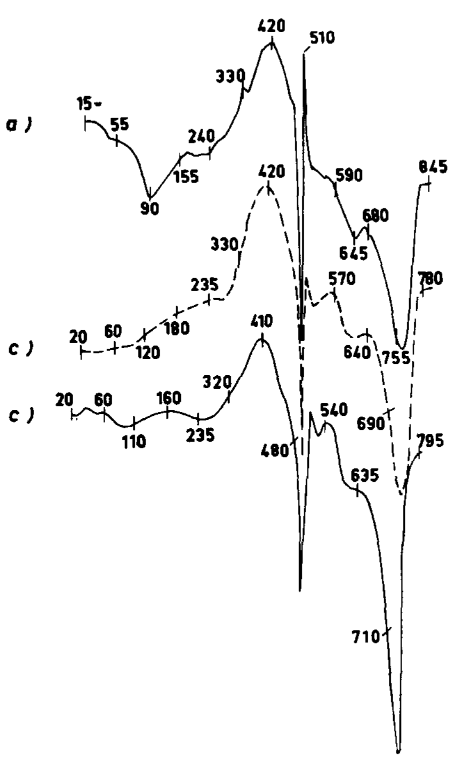

FIG. 4.—DTA curves of $EuCO_3 \cdot 0{\cdot}2H_2O$ (a), and $EuCO_3 \cdot 0{\cdot}04H_2O$ (c).

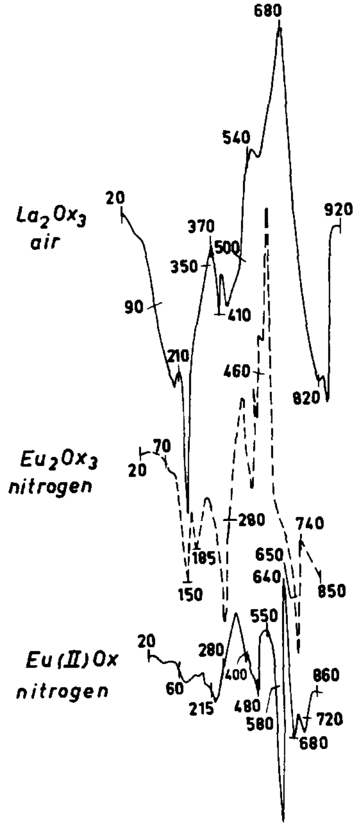

FIG. 5.—DTA curves of $La_2(C_2O_4)_3 \cdot 10H_2O$ in air, and of europium^{II} and europium^{III} oxalates in an atmosphere of nitrogen.

endothermic reactions in this range of temperatures and a prominent exothermic peak at 680°, in good agreement with the measurements of Wendlandt *et al.*[2] Hence the exothermic peaks at 420°, common to the bivalent and tervalent europium salts, are most probably from the air-oxidation of the europium, and imply a previous reduction of the tervalent europium according to the equation

$$Eu_2(C_2O_4)_3 \rightarrow 2\,EuC_2O_4 + 2\,CO_2 \tag{1}$$

This reduction took place at a lower temperature, as indicated by the endothermic peak at ~300°.

The complete interpretation of the DTA curve of $Eu_2(C_2O_4)_3 \cdot 5{\cdot}8\ H_2O$ is therefore as follows. The endothermic peaks below 235° are from partial dehydration. The peak at about 300° is a combined effect of the final dehydration and decomposition (reduction) according to equation (1). The latter endothermic peak terminates in a narrow pointed exothermic peak because of some re-oxidation of the europium, and is soon followed by the main exothermic peak at 415° (the pointed head of this peak came beyond the limits of the paper), which hides most of the endothermic effect from the conversion of the oxalate to a carbonate

$$2EuC_2O_4 + 0{\cdot}5O_2 \rightarrow (EuCO_3)_2O + 2CO \tag{2}$$

Reaction (2) terminates in a small endothermic peak at 490° in good agreement with the point *C* on the TG curve. The last endothermic peak at about 660° also corresponds to the formation of the oxide Eu_2O_3 indicated by the TG measurement. Some of the more prominent thermal data obtained from the TG and DTA curves are recorded in Table I for the sake of ease of comparison. The heading of each column shows the composition of the residue formed at the temperature indicated.

TABLE I.—TEMPERATURES OF FORMATION

Sample	System	$Eu_2(C_2O_4)_3$	EuC_2O_4	$Eu(CO_3)_2O$	$(EuO)_2CO_3$	Eu_2O_3

	DTA	—	—	—	500°	750°
	Vacuum[a]	—	—	—	400°	620°

[a] After heating at constant temperature for 24 hr.

Europium^{II} *oxalate.* The similarity between the DTA curves of the two europium oxalates (Fig. 3) above 310° is most striking, precluding any doubts with respect to the assumed reduction of $Eu_2(C_2O_4)_3$ to EuC_2O_4 [reaction (1)] at a temperature below 310°. The endothermic peak on the EuC_2O_4 curve at ~270° is from dehydration ($1{\cdot}7$ MH_2O per formula weight), but we have no explanation for the small exothermic peak at ~180°.

Fig. 3, curve *B*, shows another DTA run with EuC_2O_4 and α-alumina mixed in the weight ratio of 1:2. As expected, the thermal effects are less pronounced, but better resolved in this case; three exothermic peaks are followed by three endothermic peaks, all at temperatures corresponding to those which may also be observed on curve *A* with the 1:1 mixture.

Two more DTA curves, one of EuC_2O_4 and one of $Eu_2(C_2O_4)_3$, obtained on passing a current of nitrogen through the cylinder which contained the double crucible, are shown in Fig. 5. The exothermic peaks were not eliminated in these experiments, but they were shifted to considerably higher temperatures. In other aspects the two thermal spectra are similar to the two corresponding curves obtained in air (Fig. 3). Hence it may be inferred that under conditions of limited access of oxygen, the exothermic oxidation of europium^{II} to europium^{III} is completed at 560° and at 640°, when the initial salts were $Eu_2(C_2O_4)_3{\cdot}5{\cdot}8H_2O$ and $EuC_2O_4{\cdot}1{\cdot}7H_2O$, respectively.

On the thermogram of EuC_2O_4 (Fig. 2), no change of weight corresponding to the DTA peaks up to 420° was observed. (Apparently the alumina admixed with the sample in the DTA experiments assists dehydration and consequently promotes the whole sequence of the decomposition reactions.) Decomposition starts at 450°, with a steep loss of weight ($19{\cdot}5$%). The plateau between 550° and 630° indicates the stability of the intermediate oxycarbonate $(EuCO_3)_2O$, which again decomposes in one step to the oxide Eu_2O_3. The agreement between the latter half of the TG and the DTA curves is good.

Europium^{II} *carbonate.* Three thermograms of the decomposition of $EuCO_3$ are shown (Fig. 2): (a) the analysed sample which contained $0{\cdot}21$ M H_2O per formula weight, (b) another preparation which contained only about $0{\cdot}04$ M H_2O, and (c) a sample of the latter preparation admixed with an equal weight of alumina, as in the DTA experiments. In all three cases decomposition occurred in two steps, as shown in detail in Table II.

TABLE II.—COMPILED DATA OF TG RUNS ON $EuCO_3$

	Temp. range of 1st step, °C	Wt. loss for $(EuO)_2CO_3$, %		Temp. range of 2nd step, °C	Wt. loss for Eu_2O_3, %	
		Calc.	Found		Calc.	Found
a	520–605	8·3	10·5	665–715	18·5	18·4
b	505–550	6·9	7·5	570–665	17·1	16·6
c	455–540	6·9	8·0	555–675	17·1	17·0

The final weight loss indicates in all three runs the formation of Eu_2O_3 at about 700°. On the other hand, the loss at the intermediate stage is always larger than that calculated for $(EuO)_2CO_3$. This difference suggests that the bivalent europium has been only partially oxidised to the tervalent state (complete oxidation gives a *gain* in weight of 3·7%).

It is of interest to note the lowering of the temperature of the initial decomposition in sample *b*, containing less water, and again in run *c*, where the admixed alumina assists dehydration.

On the DTA curve (Fig. 4) of sample *a* one can actually observe the endothermic dehydration peak at 95°, which is absent on the two parallel runs of sample *c*. The parallel runs exemplify the excellent reproducibility of these analyses. The prominent exothermic peaks at 410°–420°, which testify to the oxidation of the europium, occur at the very same temperature as those on the DTA curves of the oxalates. The absence of parallel changes of weight on the TG curve (Fig. 2, curve *a*) are understandable if it is assumed that alumina assists dehydration and that the dehydrated carbonate is more prone to oxidation. (In the thermogravimetric runs there may also be a partial cancellation of the loss of weight from dehydration and the weight gained by oxidation).

A pointed narrow endothermic peak at 500° shows evidence of another reaction, namely the decomposition to the oxycarbonate, proceeding simultaneously with the oxidation of the europium. The oxidation reaction is indeed completed only at 510°, as indicated by a second pointed exothermic peak. The final decomposition to the oxide was shifted to higher temperatures (750°) in the DTA experiments as compared with the TG experiments (see Table I).

It should be emphasised that on heating $EuCO_3$ at temperatures above 400°, the evolving carbon dioxide may oxidise the europium to the tervalent state, even in the absence of air. This is illustrated in Table III, which shows the composition of

TABLE III.—COMPOSITION OF GASES EVOLVED FROM $EuCO_3$ ON HEATING

Temp., °C	Wt. of sample, *mg*	Expected total pressure, μ	Partial pressures			
			μ (CO_2)	μ (CO)	CO_2, %	CO, %
400	3·47	62·8	15	12	23·9	19·1
620	5·33	96·5	54	41	55·9	42·5

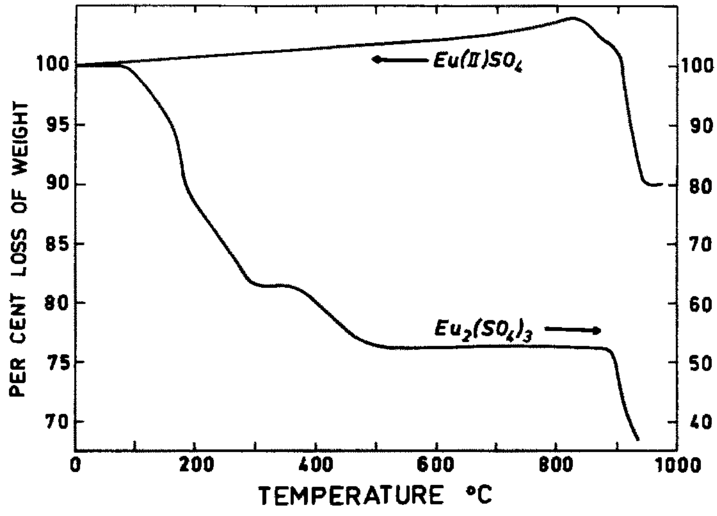

FIG. 6.—Thermogravimetric curves of europium^{II} and europium^{III} sulphates. Arrows indicate ordinate scale to be used.

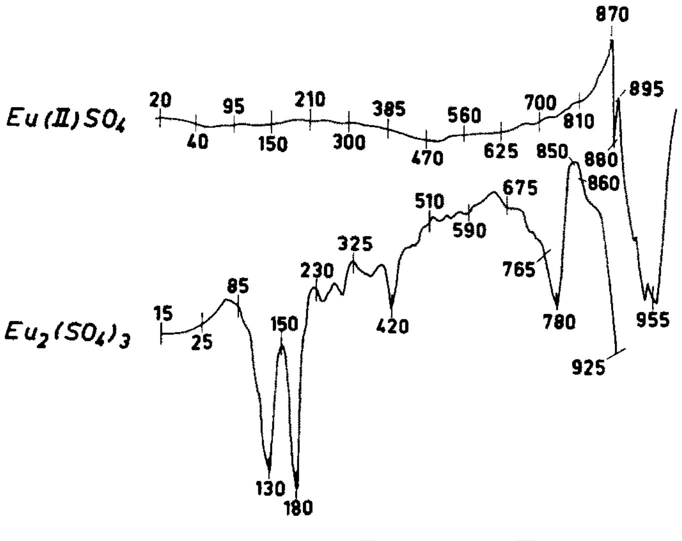

FIG. 7.—DTA curves of europium^{II} and europium^{III} sulphates.

the gases accumulated in the vacuum apparatus after heating for 24 hr at the indicated temperatures.

At 400° the residue approximates to the composition of the oxycarbonate $(EuO)_2CO_3$, while at 620° the decarbonisation is complete, but the oxidation of the europium seems to be 100% only at higher temperatures.

The TG and DTA curves of the europium sulphates are shown in Figs. 6 and 7. On the thermogravimetric curve of $EuSO_4$ the oxidation of the europium is indicated by a slow continuous increase in weight up to 830°. At this point decomposition of $(EuSO_4)_2O$ sets in, proceeding at an increased rate from 910° upwards, to form the oxysulphate $(EuO)_2SO_4$ at 950°. The oxidation peak at 870° and the endothermic peaks at 940°–960° on the DTA curve are in good agreement with this interpretation.

The thermal decomposition of $Eu_2(SO_4)_3$, among other rare earth sulphates, has been recently studied by Nathans and Wendlandt.[6] The starting points for the decomposition of the anhydrous salt indicated by our curves are: 880° (870°, TG) and 855° (810°, DTA) (the results of Nathans and Wendlandt are given in the brackets).

The dehydration of our hydrated sample proceeded in three steps, indicated by three endothermic peaks at 130°, 180° and 420°, and by the corresponding changes in the slope of the weight-loss curve.

An additional endothermic peak at 780° is inexplicable, considering the level plateau between 500° and 880° on the TG curve.

There is an intermediate plateau on the TG curve, between 300° and 360° at about 37% weight loss, which suggests the intermediate composition $Eu_2(SO_4)_3{\cdot}H_2SO_4{\cdot}H_2O$ and the formula $Eu_2(SO_4)_3{\cdot}H_2SO_4{\cdot}24H_2O$ for the initial sample.

DISCUSSION

The DTA curves of Wendlandt *et al.* for the rare earth oxalates[2] show, as a rule, endothermic peaks in the temperature range 350°–600°, with the exception of $Eu_2(C_2O_4)_3$ which exhibits a prominent exothermic peak at 390°. In contrast, Blum and Maguire[7] obtained with the oxalates of yttrium, lanthanum, neodymium, samarium and gadolinium a series of exothermic peaks in the same range of temperatures, and stated that "the curves could be re-run with extremely good reproducibility".

Claudel, in a thesis[8] on the thermal decomposition of thorium oxalate, investigated the occasional appearance of an exothermic peak in the region of 400°, observed by Padmanabhan *et al.*,[9] but absent on the curve of Wendlandt *et al.* Claudel attributes the exothermic reaction to the air oxidation of carbon monoxide evolving from the decomposing oxalate (catalysed by thorium dioxide). He demonstrates that the oxidation is promoted by a metallic container and the use of alumina (absorbed oxygen) as the inert diluent, while in an atmosphere of nitrogen only an endothermic peak was obtained under any condition. Hence, it seems plausible that Blum and Maguire's experiments were carried out under exceptionally good oxidising conditions.

A comparison of the $La_2(C_2O_4)_3$ curves shows that our experimental conditions were very much the same as those of Wendlandt *et al.*, the exothermic peak from the oxidation of carbon monoxide or deposited carbon, appearing at 680° (Fig. 5). The same curve is reproduced on flushing the apparatus with nitrogen, and it is supposed that the oxygen adsorbed on the alumina serves as oxidant in this case.

It is interesting to note that, particularly in the case of $La_2(C_2O_4)_3$, there is no exothermic, but a broad shallow endothermic peak in the region of 700° on Blum and Maguire's DTA curve. Evidently, all carbon monoxide and carbon has been burned away below 600°.

Attribution of the prominent exothermic peaks at 420° on the thermograms of the salts of europium to the oxidation of europium^{II} to europium^{III} is, therefore, the only straightforward conclusion to the above considerations. In the case of $Eu_2(C_2O_4)_3$, reaction (1) obviously precedes all other reactions in the consecutive steps of decomposition,[4] and hence the great similarity between the thermograms of the europium^{II} and europium^{III} oxalates above 400°.

By flushing the DTA chamber with nitrogen, the oxidation of europium^{II} to europium^{III} could not be prevented, but it proceeded at a slower rate and was shifted to higher temperatures. The probable source of oxygen in this case was the gas adsorbed by the bulky alumina powder, yet the infiltration of some air with the stream of nitrogen cannot be excluded. The oxidation of europium^{II} in $EuSO_4$ is rather slow, and the exothermic peak on the DTA curve appears only at 870°. On the TG curve, on the other hand, the continuous gain in weight is clearly discernable. Hence, the proneness of the europium^{II} salts to oxidation appears to be in the following increasing order: $EuSO_4 < EuC_2O_4 < EuCO_3 < EuO$.

In conclusion, it should be remarked that DTA curves may supply useful information only in conjunction with data from other methods of investigation. Unexpected complications that might arise are well exemplified in the case of the oxalates. In a well aerated apparatus the evolving carbon monoxide may be oxidised at a comparatively low temperature ($\sim$400°),[4] but the sample will overheat only if the oxidation takes place in the bulk of the material. With a limited supply of oxygen disproportionation occurs and the exothermic peak is shifted to a temperature above 600°, when the deposited carbon burns away. The exothermic peak from the oxidation of europium^{II}, on the other hand, is not subject to such irregularities.

Zusammenfassung—Die DTA-Kurven von $Eu_2(C_2O_4)_3$, EuC_2O_4 und $EuCO_3$ zeigen um 420° deutliche exotherme maxima, die auf Oxydation von Europium^{II} zu Europium^{III} beruhen. Die erste Stufe der Zersetzung von $Eu_2(C_2O_4)_3$ nach beendeter Entwässerung wird durch die Gleichung $Eu_2(C_2O_4)_3 \rightarrow 2EuC_2O_4 + 2CO_2$ beschrieben. Gründe für nicht übereinstimmende DTA-Kurven der Oxalate seltener Erden von verschiedenen Autoren werden angegeben. Ein Europium^{II}-oxalat mit $1 \cdot 7H_2O$ wurde dargestellt.

Résumé—Les courbes DTA des systèmes $[Eu^{(III)}]_2Ox_3$, $[Eu^{(II)}]Ox$ et $[Eu^{(II)}]CO_3$ présentent des pics exathermiques importants dans la région des 420°C, dûs à l'oxydation de l'ion europeux en ion europique. La première étape de la décomposition de Eu_2Ox_3 après deshydration complète est donnée par l'équation

$$Eu_2Ox_3 \rightarrow 2EuOx + 2CO_2.$$

Les raisons de discordance de quelques courbes DTA d'oxalates de terres rares obtenues par différents auteurs sont éclaircies. Le préparation d'un oxalate, $[Eu^{(II)}]Ox \,.\, 1 \cdot 7H_2O$ est décrivé.

AN INVESTIGATION OF 2-AMINO-4-CHLOROBENZENETHIOL HYDROCHLORIDE AS A SPECTROPHOTOMETRIC REAGENT FOR THE DETERMINATION OF MOLYBDENUM

GORDON F. KIRKBRIGHT and JOHN H. YOE
Pratt Trace Analysis Laboratory, Department of Chemistry, University of Virginia
Charlottesville, Virginia, U.S.A.

(*Received* 20 *June* 1963. *Accepted* 4 *August* 1963)

Summary—2-Amino-4-chlorobenzenethiol hydrochloride forms a green precipitate with molybdenum^{VI} at pH 2. The precipitate can be extracted into chloroform and has an absorbance maximum at 720 mμ. The sensitivity of the reaction is 0·0054 μg of molybdenum per cm^2 for log $I_0/I = 0{\cdot}001$. Development of the spectrophotometric method for the determination of molybdenum included a study of the effect of pH, reagent concentration, rate of complex formation and extraction, temperature and conformity to Beer's law. The method has been applied to the determination of molybdenum in steel and cast iron.

A SYSTEMATIC qualitative investigation of the reactivity of a number of aromatic mercapto compounds with 78 inorganic ions was undertaken utilising the spot-test procedure of Yoe.[1] It was found that 2-amino-4-chlorobenzenethiol hydrochloride reacts with molybdate ions in aqueous solution over a wide range of pH to form an insoluble green complex. The precipitate can be extracted into chloroform and other non-polar and polar solvents. The variables governing formation and extraction of the complex have been studied, and a method for the spectrophotometric determination of traces of molybdenum has been developed and applied to the analysis of steel and cast iron.

PRELIMINARY QUALITATIVE STUDIES

2-Amino-4-chlorobenzenethiol hydrochloride hydrolyses in water to the free base, which is insoluble in water. The hydrochloride is quite soluble in ethanol, however, and a 1% solution in 95% ethanol was used to investigate the reactivity of the compound with metal ions.

The reagent forms colours or precipitates with a number of metal ions. Between pH 2 and 10 it forms precipitates with molybdenum (green), palladium (orange), bismuth (orange), lead (yellow), nickel (pale green), cobalt (brown), copper (pale green), tungsten (white), cadmium (white) and zinc (white). The reagent also precipitates slowly when the alcoholic solution is added to the aqueous metal ion solution. No reaction was observed between molybdenum and the reagent between pH 1 and 4 in the presence of a large amount (greater than 1000-fold excess over the molybdenum present) of EDTA, citrate, tartrate, oxalate and fluoride, although the presence of excess potassium cyanide did not affect the reaction.

The molybdenum complex can be extracted into chloroform, carbon tetrachloride, benzene, isoamyl alcohol, isopropyl ether and petroleum ether between pH 1 and 4. When freshly precipitated from aqueous solution it can also be dissolved by the addition of ethanol, methanol, acetone, isopropyl alcohol, pyridine, dioxan or dimethylformamide. The solvents used to dissolve the precipitate all produce a clear solution whose green colour fades rapidly. Of the solvents used to extract the complex, only chloroform, carbon tetrachloride and benzene produce a green organic phase whose colour is sufficiently stable for spectrophotometric measurement. Under standardised conditions for the colour formation and extraction, the absorbance spectra of the complex dissolved in these three non-polar solvents are virtually identical with respect to both the wavelength and intensity of the absorption maximum. Chloroform was chosen as the extractant, because it was preferred to use a solvent of density greater than water. The free reagent also extracts into chloroform and produces an organic phase which is yellow in colour. The intensity of the yellow colour is dependent upon the extraction pH.

The palladium and bismuth complexes of the reagent can also be extracted into chloroform, but the precipitates formed with the other metal ions mentioned previously are either insoluble in chloroform or only slightly soluble and produce a colourless organic phase.

EXPERIMENTAL

Apparatus

Spectrophotometers: Beckman Spectrophotometers, Models DU and DK-2, with matched 1-cm Corex cells.

pH meter: Beckman Model G, with general-purpose glass electrode.

Reagents

2-Amino-4-chlorobenzenethiol hydrochloride: Obtained from Eastman Kodak (No. 3279) in the form of pale yellow crystals. It is only slightly soluble in water, and was used as a 4% solution in 95% ethanol. The pale yellow solution becomes deep yellow over a period of several days and appears to undergo slow decomposition. The reagent solution was therefore prepared fresh every 2 days.

Standard molybdenum solution: 1·840 g of dry ammonium molybdate, $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, ('Baker Analyzed' A.C.S.) was dissolved in distilled water and diluted to 1 litre. The solution was standardised by precipiting the molybdenum with α-benzoinoxime, igniting the precipitate and weighing as the oxide.[8] The 1000 ppm of molybdenum^{VI} standard stock solution was diluted as required.

Buffer solutions: Clark and Lubs buffers were used throughout.

Na_2H_2EDTA (*disodium salt of ethylenediaminetetra-acetic acid*): 3% aqueous solution.

Solutions of diverse ions: Reagent-grade salts were used to prepare solutions of various ions. The solutions were made to contain 1 g of the ion per litre of solution.

All other reagents were analytical reagent grade.

Preparation of calibration curves

(*a*) *Pure solution:* Transfer 0, 1·0, 2·0, 3·0, 4·0 and 5·0 ml of standard molybdenum solution (10 μg of Mo per ml) to 50-ml separating funnels. Add 3 ml of pH 2·2 buffer solution and dilute each solution to 10 ml with distilled water. Add 0·25 ml of 4% 2-amino-4-chlorobenzenethiol hydrochloride reagent solution, mix, and allow to stand for 15 min. Add 10·0 ml of chloroform and shake vigorously for 1 min. When the phases have separated, measure the absorbances at 720 mμ using a chloroform blank.

(*b*) *Steel analysis:* Transfer 0, 1·0, 2·0, 3·0, 4·0 and 5·0 ml of the standard molybdenum solution (10 μg of molybdenum per ml) to 50-ml separating funnels. Add to each funnel a volume of ferric chloride solution (10 mg/ml) which contains approximately the equivalent amount of iron to that present in the steel or cast iron sample. Add just sufficient 3% Na_2H_2EDTA solution to complex the ferric iron added, and add 5 ml of pH 2·4 buffer. Dilute each solution to the same volume with distilled water. Add 0·25 ml of 4% 2-amino-4-chlorobenzenethiol hydrochloride solution, mix, and allow to stand for 15 min. Add 10·0 ml of chloroform and shake vigorously for 1 min. Measure the absorbances of the chloroform phases at 720 mμ against a reagent blank.

Preparation of samples for analysis

Dissolve the sample (0·2–0·5 g) in a mixture of 10 ml of hydrochloric acid and 3 ml of nitric acid. Evaporate the solution to small volume, dilute with 10 ml of water and boil. Dilute the solution to 40–50 ml with distilled water, adjust the pH of the solution to 1·5–2·0 with dilute aqueous ammonia solution, transfer the solution to a 100-ml volumetric flask, and dilute to volume. Take a 1-ml aliquot of the solution for analysis, and, assuming the sample to contain 100% ferric iron, add the required volume of 3% Na_2H_2EDTA solution (0·45–1·2 ml) to complex the iron present. After the addition of the buffer and reagent, determine the molybdenum content as described for calibration curve (*b*).

The conditions, the volume of the solution, pH and time of shaking, *etc.*, should be carefully controlled in order to obtain good reproducibility.

DETERMINATION OF OPTIMUM CONDITIONS

Spectral characteristics

The absorbance spectra for 2-amino-4-chlorobenzenethiol and its molybdenum complex in chloroform are shown in Fig. 1. The molybdenum complex has a well-defined absorption maximum at 720 mμ. The reagent exhibits no absorbance at 720 mμ, and only begins to absorb appreciably at wavelengths less than 450 mμ. The 720 mμ absorbance maximum is suitable for spectrophotometric absorbance measurements and no reagent blank is required.

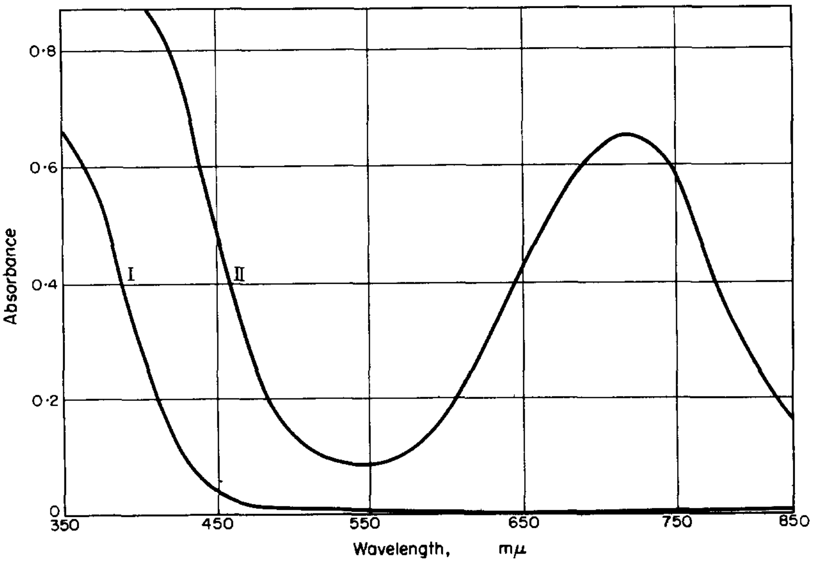

FIG. 1.—Absorbance spectra for (I) reagent and (II) molybdenum complex against chloroform at pH 2 (20 μg of Mo).

Effect of pH

(*a*) *Complex formation.* Curve (I) in Fig. 2 shows the effect of pH on the formation of the molybdenum complex in aqueous solution. A constant large excess of reagent solution was added to buffered solutions containing 20 μg of molybdenum^{VI}, and the mixture was allowed to stand for 15 min. The solutions were then brought to pH 1 by the dropwise addition of dilute hydrochloric acid, and extracted with 10 ml of chloroform for 1 min. The absorbances of the chloroform extracts were measured at 720 mμ using a chloroform blank. The optimum pH for complex formation is at 1·9–3·3.

(*b*) *Solvent extraction.* Curve II in Fig. 2 shows the effect of pH on the extraction of the molybdenum complex into chloroform. The precipitate of the complex was formed at pH 2·8 and allowed to stand for 15 min. The pH of the solutions was adjusted to between 1 and 5 by the addition of a large excess of the required buffer, and the solutions were shaken immediately with 10 ml of chloroform for 1 min. The absorbance of the chloroform extracts was measured at 720 mμ against a chloroform blank. For solvent extraction the pH of the solution should be adjusted to between 1 and 2·3. The complex can also be extracted at pH < 1, in dilute hydrochloric acid medium, and there is no significant variation in the absorbance with acid concentration when the medium is 0·1–0·3M with respect to hydrochloric acid. All pH values are uncorrected for ionic concentration.

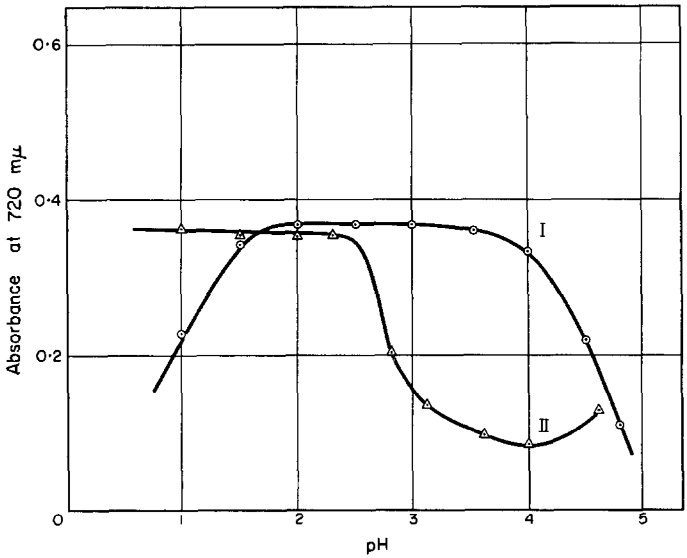

FIG. 2.—Effect of pH on absorbance at 720 mμ: (I) complex formation and (II) solvent extraction.

Order of addition of reactants

The ethanolic solution of 2-amino-4-chlorobenzenethiol must be added to the buffered molybdenum^{VI} solution. Because of the precipitation of the reagent in aqueous solution, sufficient excess of reagent does not remain in solution to give a rapid quantitative reaction if the molybdenum solution is added to the buffered reagent solution.

Effect of reagent concentration and time of shaking

It was found satisfactory to use 1 ml of a 1% reagent solution in ethanol. When the effect of the time of shaking on the absorbance at 720 mμ was studied using this reagent concentration, however, it was found that the absorbance decreased considerably when the shaking time was extended above 1 min. Further investigation revealed that the decrease was related to the volume of ethanol present, and that the rate of decrease was considerably less when a smaller volume of a more concentrated reagent solution was used. As shown in Fig. 3, when 0·25 ml of a 4% reagent solution in ethanol was used no change in absorbance was produced when the mixture was extracted between 30 and 60 sec.

Time required for complex formation

At least 5 min are required for the formation of the extractable molybdenum complex in order to obtain constant absorbance after extraction. The mixture may be allowed to stand for as long as 1 hr before extraction without change in the absorbance of the chloroform extract at 720 mμ. A 15-min standing time was adopted for convenience.

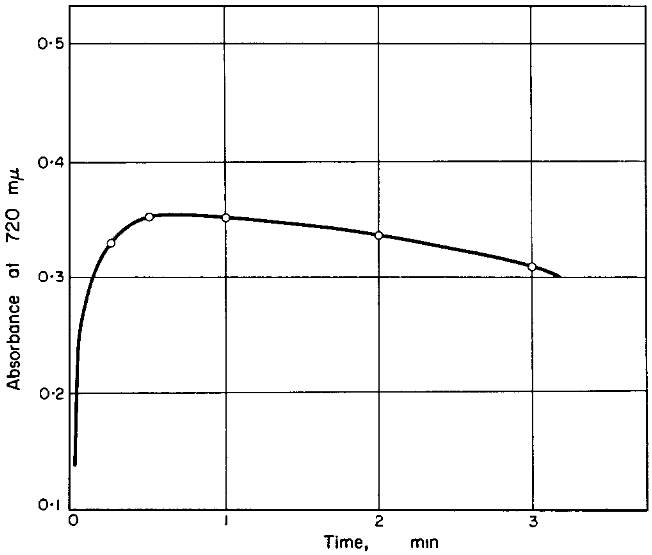

FIG. 3.—Effect of extraction time on absorbance.

Effect of temperature

The complex formation was conducted at temperatures between 10° and 40° in a water bath. No significant variation in the absorbance of the chloroform extract was observed.

Beer's law and sensitivity

The calibration curve follows Beer's law in the range 5–45 μg of molybdenum in 10 ml of chloroform. The optimum range for absorbance measurements on the spectrophotometer is 0·2–0·7 unit. With the recommended procedure these values correspond to 10–35 μg of molybdenum in 10 ml of chloroform.

According to Sandell's expression of sensitivity,[3] *i.e.*, μg of Mo per cm^2 for log $I_0/I = 0{\cdot}001$, the sensitivity was found to be 0·0054 μg of Mo per cm^2. A more practical sensitivity, however, based on an absorbance reading of 0·005 unit, is 0·027 μg of Mo per cm^2.

Stability

The absorbance of the chloroform solution of the molybdenum complex was found to decrease by 6% after standing for 4 hr and 9% after 6 hr. The absorbance should be measured at 720 mμ within 30 min after the extraction.

Precision

To obtain the precision of the method in pure molybdenum solutions, the same amount of molybdenum was determined 12 times. The average absorbance was 0·351 and the standard deviation 0·004 or 1·1%. This precision, however, is not obtained when complex mixtures are analysed. The values for the precision of three such analyses are given in Table I.

TABLE I.—ANALYSIS OF NBS SAMPLES

NBS Sample	Mo, %		Difference, %
	NBS	Found[a]

[a] Each value represents the average of three aliquots in good agreement.

Interference studies

The preliminary qualitative investigation revealed that the most serious interfering ions in the determination of molybdenum were the transition metal ions. These ions consume the reagent and form non-extractable precipitates. Other interferences result from metal ions which are precipitated as their hydrated oxides at the recommended pH, and from certain complexing anions which interfere with the formation of the molybdenum complex.

Solutions were prepared containing 20 μg of molybdenum and varying concentrations of each ion to be tested. The molybdenum was then determined by the recommended procedure. The limiting value of the concentration of foreign ion was taken as that which caused an error of 3% in the absorbance. This corresponds to an error of 0·01 absorbance unit.

The presence of a 100-fold excess (2 mg) of the following ions caused no interference: Al^{3+}, Ba^{2+}, Ca^{2+}, Cr^{3+}, Fe^{2+}, K^+, Mg^{2+}, Mn^{2+}, NH_4^+, Na^+, Sr^{2+}, VO_2^{2+}, VO_3^-, Br^-, I^-, SO_4^{2+}, HSO_3^- and $B_4O_7^{2-}$. A 100-fold excess of the following caused the negative error given in parentheses: F^- (31%), CO_3^{2-} (12·5%), CNS^- (6·5%), acetate (7·5%), citrate (15%), oxalate (22%), phosphate (7%), silicate (15%), tartrate (13%), ascorbic acid (7%). A 100-fold excess of EDTA produced less than 3% error in the absorbance.

The following ions caused not greater than 3% error in the absorbance produced by 20 μg of molybdenum when present in the number of fold excess given in parentheses: Au^{3+} (5), As^{3+}(50), Bi^{3+} (20), Ce^{4+} (40), Co^{2+} (0·5), Cr^{6+} (2), Cu^{2+} (1), Fe^{3+} (50), Ga^{3+} (20), Ge^{2+} (35), Hg^{2+} (4), Ni^{2+} (3), Pb^{2+} (25), Pd^{2+} (2), Pt^{2+} (25), Th^{4+} (50), W^{6+} (0·5), Zn^{2+} (10).

Ag^+ is precipitated as its chloride. Se^{4+} and Te^{4+} give a yellow precipitate with the reagent which is extracted into chloroform. Ti^{4+} and Zr^{4+} are precipitated and cause negative errors.

Nature of complex

The complex was isolated as a green precipitate by the addition of a slight excess of the reagent solution to 100 ml of $10^{-2}M$ molybdate solution at pH 2. The precipitate was filtered off, washed with a mixture of 2 volumes of ethanol and 1 volume of water, and dried to constant weight at 50°. The molybdenum content was then determined by igniting a weighed portion to molybdenum trioxide at 500°. The results of the duplicate analyses were 15·9% and 16·0% of Mo. A 3:1 complex of reagent to molybdenum requires 15·8% Mo, *e.g.*, $MoO(OH).[C_6H_5NSCl]_3$.

A study was made to determine the empirical formula of the molybdenum complex in solution. The mole ratio method of Yoe and Jones[4] gave indication of a 3:1 complex of reagent to molydbenum, and the subsequent formation of a higher complex. The complex appears to be appreciably dissociated, because no sharp breaks were observed. The continuous variations method of Job,[5] as modified by Vosburgh and Cooper,[6] gave results in agreement with those obtained from the mole ratios studies and the determination of the molybdenum content of the solid complex. It seems that a 3:1 complex of reagent to molybdenum is formed and there is some indication of the existence of a higher complex.

ANALYSIS OF COMPLEX MIXTURES

The principal interferences, from a practical viewpoint, are iron^{III}, copper, cobalt, nickel and tungsten. The permissible concentrations of these ions, with the exception of iron^{III}, are high enough to allow the determination of molybdenum in a range of steel and cast iron samples. Although an appreciable excess (1 mg) of iron^{III} can be tolerated, this value is too low to permit the analysis of these samples without masking or prior separation of the iron.

An attempt was made to separate the iron by precipitation as ferric hydroxide. Coprecipitation errors, even after repeated precipitation by the method recommended by Lundell and Hoffman,[7] prevented complete recovery of the molybdate. The interference from iron^{III} was successfully overcome by the addition of EDTA to the sample solution. An appreciable excess of EDTA (2 mg) can be tolerated, but it was preferred to add only the required amount, calculated assuming the steel and cast iron samples contained 100% of iron. Under these conditions, high results were obtained when the sample absorbance is compared with a calibration curve obtained using pure molybdenum solutions. A calibration curve was produced from standard molybdenum solutions containing a large excess of iron^{III} and the equivalent amount of Na_2H_2 EDTA. Comparison of absorbance values against this calibration curve gave better accuracy, although slightly lower precision, than when the calibration curve obtained from pure solution was used.

To test the efficiency of the method, three National Bureau of Standards samples were analysed for molybdenum. The results are shown in Table I.

Zusammenfassung—2-Amino-4-chlorthiophenolhydrochlorid bildet bei pH 2 mit Molybdän(VI)-Ionen einen grünen Niederschlag. Dieser kann mit Chloroform extrahiert werden und hat ein Absorptionsmaximum bei 720 mμ. Die Empfindlichkeit der Reaktion beträgt 0,0054 μg Mo pro cm^2 für log $I_0/I = 0,001$. Die Entwicklung der spektralphotometrischen Mo-Bestimmung schloß eine Untersuchung über p_H-Einflüß, Konzentration des Reagenses, Komplexbildungs- und Extraktionsgrads, Temperaturabhängigkeit und Gültigkeit des Beerschen Gesetzes ein. Die Methode wurde auf die Molybdänbestimmung in Stahl und Gußeisen angewandt.

Résumé—Le chlorhydrate de l'amino-2-chloro-4-benzènethiol fournit un précipité vert avec les ions molybdène(VI) à pH 2. Le précipité peut être extrait au chloroforme et présente une absorption maximum à 720 mμ. La sensibilité de la réaction est de 0,0054 μg de molybdène par cm^2 pour log $I_0/I = 0,001$. Le développement de la méthode spectrophotométrique de dosage du molybdène comprend une étude sur l'influence du pH, la concentration des réactifs, le taux de formation du complexe et de son extraction, la température et la conformité à la loi de Beer. Cette méthode a été appliquée au dosage du molybdéne dans l'acier et la fonte.

PHOTOMETRIC TITRATIONS—VII*

THE CONSECUTIVE TITRATION OF CADMIUM AND ZINC

H. FLASCHKA and F. B. CARLEY
School of Chemistry, Georgia Institute of Technology, Atlanta, Ga., U.S.A.

(*Received* 16 *July* 1963. *Accepted* 31 *July* 1963)

Summary—Zinc and cadmium can be determined in one solution in the following manner. The sample is adjusted to pH 10 with an ammonia-ammonium chloride buffer so that the total ammonia concentration is 0·02–0·03*M*. Murexide is added so that its amount is in at least 5-fold excess over the amount of zinc present. The titration is performed photometrically at about 450 mμ with ethyleneglycol bis(β-amino-ethylether)-*N*,*N*,*N'*,*N'*-tetra-acetic acid (EGTA) as the titrant. The titration curve obtained shows two breaks which are related to the consecutive titration of cadmium and zinc. The influence of calcium impurities in the reagents used has been studied and a method of pretitration is proposed. For this purpose a small amount of zinc is pretitrated and then the sample solution is added. Thus the calcium blank is established for each titration.

In a previous paper of this series,[1] it was shown that calcium and magnesium can both be determined from a single photometric titration curve. This is achieved by the addition of Calmagite[2] in an amount greater than equivalent to the sum of the two metals, or at least to the magnesium. In that titration, Calmagite does not function in the usual manner as a "step indicator" but, in combination with the magnesium, gives a self-indicating system. Because calcium forms a stronger complex with the titrant (EDTA) than does magnesium, the self-indicating Mg-Calmagite system serves as a "slope indicator" for calcium. Thus a titration curve with two breaks is obtained, the first and second slope changes marking the end-points for calcium and magnesium, respectively.

In the EDTA titration of zinc in ammoniacal solution with Erio T as indicator, the amount of pH 10 buffer added has little influence on the colour change at the end-point. With cadmium, however, increasing amounts of buffer pH 10 cause a decrease in the sharpness of the end-point. Experiments have shown that the addition of large amounts of ammonia pH 10 buffer to a solution containing cadmium and Erio T progressively diminishes the red colour of the cadmium-indicator complex until the pure blue of the free indicator is essentially restored. Under the same conditions, the red colour of the Zn-Erio-T complex is little affected. As expected, Calmagite behaves in exactly the same manner as Erio T but is preferable because it is stable in solution.

From these considerations, it would seem that a Cd-Zn determination analogous to that used for Ca-Mg is feasible. EDTA, however, is not the appropriate titrant in this case because the stabilities of its zinc and cadmium complexes are almost identical. Ethyleneglycol bis(β-amino-ethylether)-*N*,*N*,*N'*,*N'*-tetra-acetic acid (EGTA) is a more favourable titrant because its cadmium complex is stronger than its zinc

---

* Part VI—see ref. 1.

complex, the constants being log $K_{Cd} = 16{\cdot}7$ and log $K_{Zn} = 14{\cdot}5$.[3] Of course, the apparent stability constants must be compared, and these are obtained from a knowledge of the stability constants of the metal-ammonia and metal-dye complexes. At the high ammonia concentrations necessary to decompose the Cd-Calmagite complex, the value of the β_{NH_3}-factor (pH = 10) for zinc is close to 100 times that for cadmium. Because the Zn-Calmagite complex is not decomposed, the Zn-Calmagite β-factor is significant, and thus the logs of the β-factors for cadmium and zinc will differ by more than two units. This indicates that the apparent stabilities of the Cd-EGTA and Zn-EGTA differ by a factor somewhat greater than 10^4, so that a selective titration should be possible. Unfortunately, however, the Zn-EGTA complex is not sufficiently more stable than the Zn-Calmagite complex, so that even a photometric end-point is unsatisfactory. Moreover, galvanometer drift after titrant addition indicated that the reaction ZnY + CdI → ZnI + CdY is quite slow. Changing the titration conditions did not improve the situation, so it was necessary to find a more suitable dye.

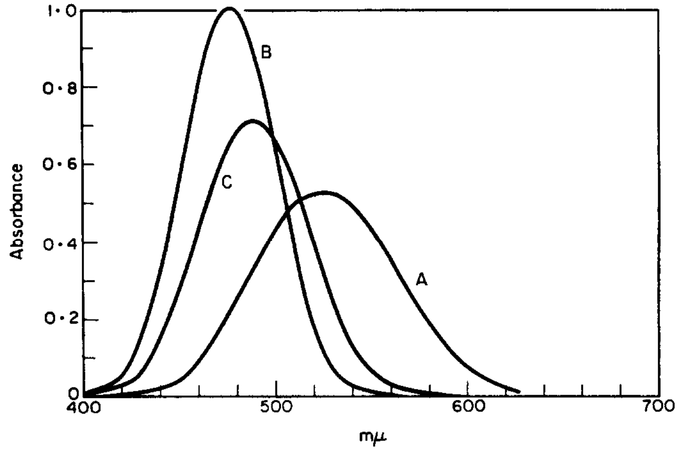

FIG. 1.—Absorbance curves for free Murexide (A), Zn-Murexide (B) and Cd-Murexide (C) at pH 10 (ammonia-ammonium chloride buffer).

Many common metallochromic indicators were investigated and eventually Murexide was found to meet the necessary requirements. Murexide has already been used as indicator in the titration of zinc at pH 8–8·5 in ammonia-free solutions.[4] It was found that the yellow Zn-Murexide complex also persists in solutions buffered to pH 10 with ammonia provided that the ammonia concentration does not exceed certain limits. Also, at some ammonia concentrations where the Zn-Murexide complex is still formed to a considerable degree, the Cd-Murexide complex is largely decomposed. These qualitative findings were substantiated by later quantitative investigations. The spectral curves of free Murexide (A), its zinc (B) and its cadmium (C) complexes at pH 10 are represented in Fig. 1. These curves were obtained with the same total concentration of Murexide and with excess metal ions present to assure complete complex formation. Fig. 2 shows a plot of the difference curve, Zn-Murexide minus Murexide (B-A from Fig. 1), to aid in the selection of an appropriate wavelength. The maximum difference is at 470 mμ and for highest sensitivity this wavelength should be chosen. In practice, however, a somewhat shorter wavelength is more convenient for two reasons. Under the conditions of the titration an excess of Murexide is required, which would provide a considerable background absorbance at 470 mμ. In itself, this is no detriment, although instrument settings are simplified when it is avoided. A second more serious consideration is the instability of the free Murexide in solution. Thus, when considerable amounts of free Murexide are present, and no measures are taken to inhibit its decomposition, a drift of the galvanometer occurs. The decomposition is partly caused by oxidation of the dye, because it is inhibited by deaeration of the solution with nitrogen or by the addition of ascorbic acid. Part of the decomposition is caused by hydrolysis of the dye. At a wavelength of about 450 mμ, the difference is still sufficiently high but the absorptivity of free Murexide is so low that the influence of the decomposition of free Murexide on the optical behaviour of the system is negligible. It may be mentioned in this connection that, as is the case for many other unstable complexing agents, complexed Murexide is stabilised against decomposition. The yellow colour of a solution of Zn-Murexide persists long after the red-violet colour of a solution containing an equal amount of Murexide alone has disappeared.

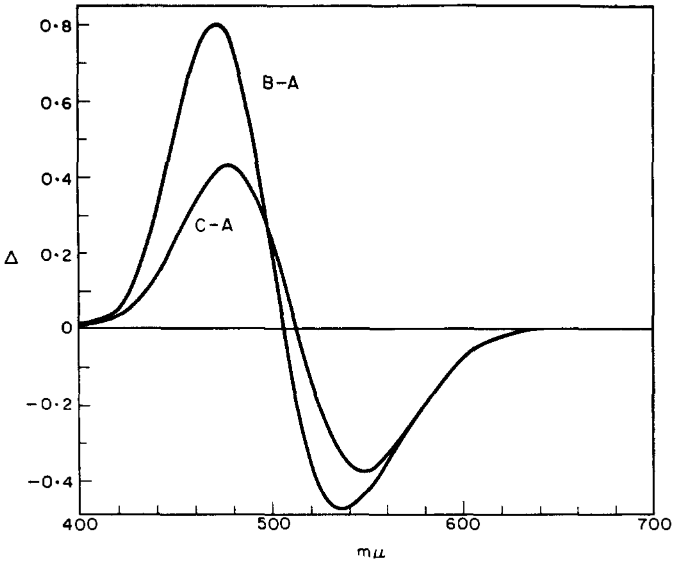

FIG. 2.—Difference curves obtained from Fig. 1.

The difference curve, Cd-Murexide minus Murexide (C-A from Fig. 1), is also shown in Fig. 2. Unless cadmium can be masked completely against the reaction with Murexide, the absorbance of the Cd-Murexide complex must also be considered. (See later.)

The conditions for a working, self-indicating system, zinc-Murexide-EGTA at pH 10, were established as follows. Titrations were performed using $10^{-5}M$ zinc and $10^{-2}M$ EGTA solutions in a 1-cm cell with a 456-mμ interference filter. At first the amount of pH 10 buffer was held constant, and the amount of Murexide was varied. In order to obtain a straight titration curve before the equivalence point, at least a 5-fold Murexide excess over the zinc was necessary; larger excesses did no harm. Next the Murexide concentration was held constant at a sufficient excess and the buffer concentration was varied. Up to approximately 0·01M in total ammonia ($[NH_3] + [NH_4^+]$), identical titration curves were obtained. Upon addition of more buffer, the slopes of the titration curves decreased, as was to be expected. A buffer concentration of 0·01M is not always sufficient to prevent the precipitation of zinc hydroxide; however, the excess Murexide keeps the metal in solution. This fact makes it necessary to add the Murexide to the titration solution before the sample, when the buffer concentration is low.

Titrations of solutions containing both cadmium and zinc were attempted next.

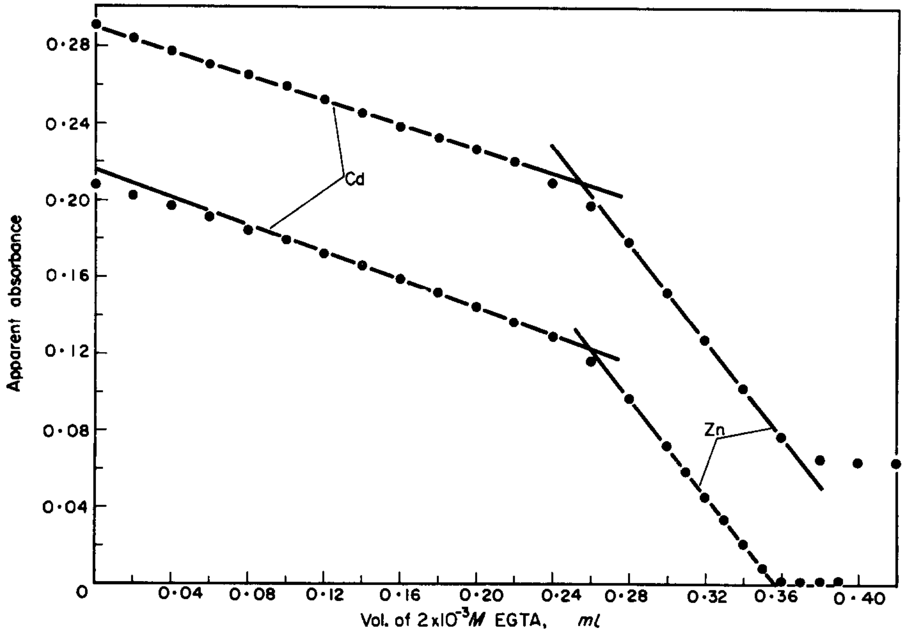

FIG. 3.—Typical curves obtained by titration of a sample containing cadmium and zinc with EGTA.

As expected, cadmium reacts with the titrant before zinc. At low ammonia concentrations (0·01M and below), the cadmium segment of the titration curve shows an appreciable slope. With increasing buffer concentration, however, the cadmium segment approaches the horizontal as predicted. The effect of buffer concentration on the zinc segment is less pronounced. Thus a concentration of 0·02–0·03M in total ammonia gives the best possible angle at the cadmium end-point without seriously affecting the zinc segment of the curve. The cadmium segment, of course, becomes steeper when the concentration of Murexide is increased. The amount of Murexide necessary is governed only by the amount of zinc present. When the excess of Murexide is not sufficient to complex all the cadmium, the titration curve is nearly horizontal at the beginning and then bends down to the usual cadmium slope. This, however, does not affect the determination because, for the location of the cadmium end-point, only the straight line portion immediately before the abrupt slope change is necessary for the extrapolation.

Typical titration curves with sufficient excess of Murexide showing all three straight portions in nearly perfect fashion are presented in Fig. 3.

It is generally expected that with a very weak complex a curvature should be produced in a titration curve. Thus it is rather unexpected that, with the deliberately weakened Cd-Murexide complex, such a perfect straight line is obtained. Similar reasoning holds as for the analogous conditions of the calcium segment of the Ca-Mg-titration described in a previous paper of this series.[1] The full mathematical treatment of this situation is reserved for another publication, and here only a simplified derivation will be given.

Consider a metal ion, M, reacting with a dye, I, according to

$$\mathrm{M} + \mathrm{I} \rightleftarrows \mathrm{MI}.$$

(Charges are omitted because they are irrelevant to the point in question.) Only MI is assumed to absorb at the wavelength selected. Hence

$$A = \varepsilon b \times [\mathrm{MI}].$$

The stability constant of the complex MI is given by

$$K = \frac{[\mathrm{MI}]}{[\mathrm{M}] . [\mathrm{I}]} \tag{1}$$

The following two equations must hold:

$$C_{\mathrm{M}} = [\mathrm{MI}] + [\mathrm{M}] \tag{2}$$

$$C_{\mathrm{I}} = [\mathrm{MI}] + [\mathrm{I}] \tag{3}$$

When the dye is in considerable excess the condition $C_{\mathrm{I}} \gg C_{\mathrm{M}}$ is given and consequently also

$$C_{\mathrm{I}} \gg [\mathrm{MI}].$$

Using this and substituting (2) and (3) in the expression for the equilibrium constant (1), one obtains

$$K = \frac{[\mathrm{MI}]}{(C_{\mathrm{M}} - [\mathrm{MI}])C_{\mathrm{I}}} \tag{4}$$

Solving for [MI] results in

$$[\mathrm{MI}] = \frac{KC_{\mathrm{I}}}{KC_{\mathrm{I}} + 1} . C_{\mathrm{M}} = \text{const.} \times C_{\mathrm{M}} \tag{5}$$

and finally,

$$A = \varepsilon b. \text{ const.} \times C_{\mathrm{M}} = \text{const.}' \times C_{\mathrm{M}} \tag{6}$$

Thus the absorbance is directly proportional to the total metal ion concentration regardless of how weak the complex may be. If these findings are applied to a titration the following reasoning holds: assume that the metal is titrated with a complexing agent, Y, and that the titration complex, MY, is of so high a stability that its dissociation can be neglected to a first approximation. Then C_{M} in equation (6) is the concentration of metal ion not complexed by the titrant, and consequently a straight-line titration curve is obtained even with a very weak metal-dye complex.

It is of interest to speculate in this connection as follows. Many photometric determinations (not titrations!) employ rather weak complexes and the procedure requires "addition of a considerable excess of chromogenic agent in order to shift the equilibrium to virtual completion, so that a straight calibration curve is obtained". It is entirely possible that there is no shift to completion at all, but rather that the straight calibration curve is a consequence of the situation discussed above.

Because many other metal ions (of notable interest are lead, copper, nickel and cobalt) also give yellow Murexide complexes, the selectivity of the proposed titration is not expected to be high. Selective masking and demasking may improve the situation but no investigations in this direction were undertaken. Separation of Cd + Zn is possible by several methods (ion exchange, paper chromatography, solvent extraction) so that the method described may be applied after such a separation is effected. Only the influences of magnesium and calcium were investigated, because these two metals, present as impurities in the reagents used, or introduced by dust, may affect the results seriously, especially when small amounts of zinc and cadmium are to be determined.

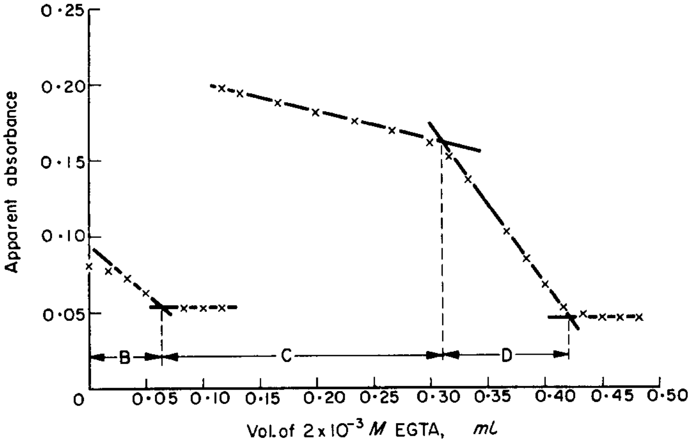

FIG. 4.—Calculation of an analysis of a Cd-Zn mixture using the pretitration method. Let A stand for the EGTA (ml) equivalent to the known amount, P, of zinc added for the pretitration.

Then: pretitrated impurity of Ca $\hat{=}$ B − A ml
Cd $\hat{=}$ C + A ml
Zn $\hat{=}$ D − A ml.

Magnesium was found not to interfere at all, as was to be expected from the low stability constant of its EGTA complex (log K = 5·4) and the fact that it shows only very little tendency to complex with Murexide. Calcium is titrated after cadmium and before zinc. The slope of the calcium segment is virtually identical to that of the cadmium segment so that the sum Cd + Ca is obtained at the "cadmium end-point". Thus cadmium may be corrected for any calcium blank established. Unfortunately the calcium blank is not constant over a long period of time. Water and reagent solutions prepared in the way described in the experimental part are at the beginning virtually free from calcium. But on the repeated opening of the plastic bottles dust enters the solution and the blank becomes noticeable and increases with time. It is, therefore, most convenient to establish the blank for each titration *via* a pretitration. For this purpose the buffer solution containing the Murexide is placed in the titration cell and diluted to the desired volume. Then a small, accurately known amount of zinc is introduced and titrated. After this pretitration the sample solution is introduced and the titration is performed as usual. The amounts of titrant required for the cadmium and zinc in the sample are obtained from the titration curve as shown in Fig. 4. This method, of course, corrects for only those impurities (calcium or any other metals with similar interference mechanisms) present in the reagents, but any calcium in the sample solution is still cotitrated with the cadmium.

Zinc or cadmium alone may also be titrated using the pretitration technique and in this case the amount of zinc added initially need not be accurately known. The amount of metal present in the sample is obtained simply from the difference of two zinc end-points.

The accuracy and precision of the method are satisfactory. Table I shows a selection of results for titrating zinc alone and cadmium alone, as well as zinc and cadmium together, using the pretitration technique.

EXPERIMENTAL

Apparatus

The phototitrator described in Part II of this series was used.[5] An improvement was found to be necessary. At the wavelength selected, strong deviations from Beer's law were observed initially. These were eventually traced to insufficient monochromacy. The filter used not only passed light of the nominal wavelength but showed also a transmittance peak in the near infrared. Hence a heat ray absorbing filter was permanently positioned in the light beam behind the interference filter. Some titrations were initially performed in the micro cell assembly described in Part VI of this series.[1] It was then possible to titrate as little as a few μg of cadmium and zinc. In this case a Beckman Spinco ultra-microburette was employed. Again, however, serious dust problems were encountered under the prevailing conditions. Therefore a macro cell of 35-ml capacity and a light path of 2 cm were used, and the titrant was delivered from a 1-ml micro burette. An interference filter of 456 mμ and in some cases of 444 mμ nominal wavelength has employed.

Reagents

All reagents were of highest purity. The water used was deionised water, redistilled using a condenser tube of polyethylene. All solutions were stored in polyethylene bottles. The buffer solution was prepared by mixing ammonia and hydrochloric acid solutions which had been purified by isothermal distillation. The distillations were accomplished by placing a beaker containing the concentrated commercial reagent along with a polyethylene beaker containing redistilled water in a desiccator (without desiccant) for a day or two. The total concentration of ammonia in the buffer was $2M$.

Stock solutions of zinc and cadmium (about $0{\cdot}1M$) were prepared by dissolving appropriate amounts of highest purity metal in HNO_3 followed by dilution with redistilled water.

Stock solutions of chelons (of about $0{\cdot}1M$) were prepared by dissolution of the reagent in redistilled water (a few pellets of NaOH were added, if necessary, to effect solution).

The stock solutions were standardised by well established complexometric methods.

More dilute solutions were prepared by quantitative dilution of these stock solutions.

Procedure

Place about 25 ml of water in the absorption cell. Add 0·2 ml of buffer and about 0·5–1 mg of Murexide.* Adjust the light to give a galvanometer reading of about 90 S.D. (or 180 S.D. with zero suppressed to −100). Add 0·2–0·5 ml (exactly measured) of a $5 \times 10^{-4}M$ zinc solution and titrate with $2 \times 10^{-3}M$ EGTA until the curve shows 2–3 points of the horizontal after the zinc end-point (see Fig. 4). Add the unknown sample and titrate again.† Plot the results and evaluate the curve as shown in Fig. 4.

* It is not necessary to weigh the Murexide accurately. One may dilute Murexide by grinding it with sodium chloride and add a certain amount with a spoon of appropriate size. However, it is much simpler to add Murexide (diluted or undiluted) to the solution containing buffer until a predetermined galvonometer reading is obtained. The amount of Murexide is not at all critical as long as there is a sufficient excess over the zinc.

† For samples with very high metal contents it may be necessary to operate with a "sectioned titration curve". See Part VI in this series for details.[1]

Zusammenfassung—Zink und Cadmium können in einer Lösung wie folgt bestimmt werden. Die Probe wird mit Ammoniak-Ammoniumchlorid-Puffer auf pH 10 gebracht, sodass die totale Ammoniak-Konzentration 0.02–0.03 m beträgt. Sodann wird Murexid in mindestens fünffachem molaren Überschuss (auf Zink bezogen) eingetragen. Es wird photometrisch bei 450 mμ titriert. Die erhaltene Titrationskurve zeigt zwei Knicke, deren erster dem Cadmium- und deren zweiter dem Zink-Endpunkt entspricht. Der Einfluss von Calciumverunreinigungen in den Reagenzien wurde studiert und eine Vortitration wird vorgeschlagen. Hierbei wird erst eine kleine, genau bekannte Menge an Zink vortitriert und dann die Probe zugesetzt. So lässt sich der Cacliunblindwert der Reagenzlösung für jede Titration in Rechnung stellen.

Résumé—Le zinc et le cadmium peuvent être dosés dans une solution unique de la manière suivante. L'échantillon est amené à pH 10 par addition d'une solution tamponnée ammoniaque-chlorure d'ammonium et composée de telle sorte que la concentration totale en ammoniaque soit de 0,02–0,03 M. On ajoute du murexide en quantité telle su'elle représente un excès d'au moins cinq fois sur la quantité de zinc présente. Ce dosage est effectué par photométrie à environ 450 mμ et en présence d'EDTA comme agent titrant. La courbe de dosage obtenue montre deux cassures correspondant aux neutralisations successives du cadmium et du zinc. L'influence des impuretés calciques dans les réactifs utilisés a été étudiée et une méthode de prédosage proposée. Dans ce but, une petite quantité connue de zinc est prédosée et l'on ajoute la solution à analyser. Ainsi le taux de calcium dans l'essai témoin est établi pour chaque dosage.

Analytical Laboratory, Jilská 16, Prague 1
Czechoslovakia

(*Received* 20 *June* 1963. *Accepted* 20 *August* 1963)

Summary—Sorption of $Co(Phen)_3^{2+}$ on silica is not affected by EDTA or citric acid in appropriate conditions of acidity. This fact has been used for the selective determination of microgram amounts of cobalt. Desorption of $Co(Phen)_3^{2+}$ is carried out from an alkaline aqueous-methanolic solution of ammonium formate, and cobalt is determined indirectly, colorimetrically, *via* ferroïn. Special attention has been paid to the determination of trace amounts of cobalt in the presence of iron.

As previously mentioned,[1] the complex of Co^{II} with 1,10-phenanthroline (Phen), $[Co(Phen)_3^{2+}$ (pK = 20·1)], can be sorbed on silica quantitatively over a large pH range even in the presence of EDTA and citric acid. Anionic complexes of metals with EDTA and citric acid are not sorbed on silica, and therefore it is possible to use these reagents to increase the selectivity of the sorption of $Co(Phen)_3^{2+}$, and thus also to permit the determination of cobalt. The formation of ion association complexes $[Co(Phen)_3^{2+}, 2X^-]$ which increases at high concentrations of X^- has been similarly used for the desorption of $Co(Phen)_3^{2+}$, sorbed on silica, as well as for the desorption of ferroïn.[2,3] Complexes of this type, where X^- indicates anions of some monobasic acids, *e.g.*, formic, acetic, trichloro- and monochloroacetic, are, to a certain degree soluble in water, and are very soluble in a mixture of methanol and water.

After elution of the $Co(Phen)_3^{2+}$, cobalt is determined in the solution colorimetrically;[4] the cobalt bound in the phenanthroline complex is oxidised with $iron^{III}$, and the concentration of the resulting ferroïn is determined colorimetrically.

This paper describes a number of influences on the sorption of $Co(Phen)_3^{2+}$ on silica, and on its use for the selective determination of trace amounts of cobalt. Special attention has been paid to the determination of cobalt in the presence of $iron^{III}$ which results in the oxidation of $cobalt^{II}$ to $cobalt^{III}$ with an excess of Phen, and the formation of an equivalent amount of ferroïn.

EXPERIMENTAL

Reagents

Silica: Silica of pore size 85 Å and particle size 0·15–0·20 mm, activated at 120° was used (if not stated otherwise) for the sorption, which was carried out on a column of 16 mm internal diameter and 50 mm in height. The "silica pH" was adjusted to the required value by washing with a suitable buffer solution.

1,10-Phenanthroline solution: 0·1*M*: Prepared by dissolving 18 g of reagent-grade 1,10-phenanthroline in hot water, acidifying with 5 drops of acetic acid and diluting to 1 litre.

Cobalt chloride solution: $10^{-4}M$: Prepared by dissolving $CoCO_3$ (Kahlbaum, Ni-free) in a minimum amount of HCl and diluting it with water.

Salt solutions: 1*M* solutions of ammonium formate, acetate, tri- and monochloroacetate were prepared by the solution of the appropriate salts or acids in redistilled water, and adjusting the pH to 9·5 with aqueous ammonia.

EDTA solution: 1M: Prepared by dissolving 372 g of reagent-grade EDTA in warm water, making alkaline with aqueous ammonia (1 : 1) and diluting to 1 litre. The pH of the resulting solution should be 8.

Buffer solutions: Prepared by potentiometric neutralisation of suitable acids (trichloro-, monochloroacetic, acetic or boric acid (with aqueous ammonia) to give a final concentration of *ca.* 1*M*.

Other solutions prepared from reagent-grade chemicals, and standardised by recommended procedures.

Apparatus

Optical densities were measured with a Pulfrich photometer (Zeiss, Jena, East Germany) equipped with an arrangement for objective measuring—Elpho II. pH values were measured with a glass electrode and pH meter Multoscop V (Labor. potřeby, Prague, Czechoslovakia).

Sorption of $Co(Phen)_3^{2+}$ *on silica*

In most cases the influence of factors on the sorption of $Co(Phen)_3^{2+}$ on silica was followed by a kinetic method, which was also used for analytical purposes. As already mentioned, the changes in the concentration of the Co^{II} complex with phenanthroline were followed by indirect colorimetric measurements, *via* ferroïn. The reaction used occurs quantitatively even in an aqueous-methanolic medium, under identical conditions. The procedure, except in cases mentioned explicitly, was as follows.

Procedure: To a measured amount of 10^{-4} or $10^{-3}M$ $CoCl_2$ was added a known amount of 1*M* EDTA solution or 1*M* citric acid; alternatively the pH was adjusted by addition of 5 ml of 1*M* buffer solution. To this solution, 1 ml of 0·1*M* phenanthroline was added, and after a further adjustment of the pH, the volume of the solution was adjusted to ~25 ml. The sorption on the silica column was carried out, after adjusting the pH of the silica, at a flow rate of about 2 ml/min. The washing of the column after the sorption was carried out with 25 ml of a 0·1*M* buffer solution with a pH of the same value as during the sorption, and, finally, with 10 ml of water. The desorption of the sorbed $Co(Phen)_3^{2+}$ was carried out with 15 ml of *ca.* 1*M* solution of ammonium formate of pH 9·5, containing, in every 100 ml, 1 ml of 0·1*M* phenanthroline* and 15 ml of methanol. The desorption can be carried out reliably at the same rate as the sorption. The washing of the column was carried out with 10 ml of water. The pH of the solution, containing $Co(Phen)_3^{2+}$, was adjusted with HCl (1 : 1) to ~3. One ml of 0·1*M* phenanthroline was added, and 2 ml of *ca.* $10^{-3}M$ $FeCl_3$ (containing no Fe^{II}). The volume was adjusted to 50 ml, and the extinction of the ferroïn was measured after 15 min, in 2-cm cells at 510 mμ, against a blank at pH 3, containing, in the same volume, the same amount as the sample of $FeCl_3$ and Phen. The evaluation was read from a calibration curve, obtained by adding to 2–15 ml of $10^{-4}M$ $CoCl_2$, 1 ml of 0·1*M* Phen, 1 ml of $10^{-3}M$ $FeCl_3$ and 5 ml of buffer solution of pH *ca.* 3, and diluting to 50 ml as in the case of the sample solution.

RESULTS AND DISCUSSION

Influence of pH, EDTA and citric acid

The influence of pH, EDTA and citric acid was studied on the sorption of 29·5 μg of cobalt. The curves in Fig. 1 show that the sorption of cobalt is complete in the pH range 2–7·5 (curve 1), even in the presence of citric acid (curve 2). In the solution of 0·1*M* EDTA the sorption of $Co(Phen)_3^{2+}$ is not influenced in the pH range 6·5–8·5. At lower pH values, however, EDTA interferes by forming chelates. At higher pH values, the presence of EDTA reduces the hydrolysis of Co^{II} (curve 3). These examples show the dependence of the apparent stability constants of $Co(Phen)_3^{2+}$ and of the Co–EDTA complex on pH.

Influence of rate of sorption, dilution and ionic strength

Under given conditions, the sorption of 29·5 μg of cobalt in 25 ml of solution is quantitative, even at a flow rate of 6 ml/min, which was, in our case, the maximum possible rate.

---

* Phenanthroline must be present in the solution, otherwise there will be a partial hydrolysis of $Co(Phen)_3^{2+}$, and its desorption is then not quantitative.

The influence of the ionic strength was tested by sorption of $Co(Phen)_3^{2+}$ from saturated solutions of some salts of alkali metals (*e.g.*, 29·5 μg of Co were sorbed with an error of −4·2% from a saturated solution of NaCl.

Capacity of silica

It was found by using a kinetic method that a silica column (50 mm high and 16 mm in diameter) at pH 3·5 and a flow rate of 2 ml/min sorbs quantitatively as much as 1·16 mg of Co as $Co(Phen)_3^{2+}$.

Using a static method the capacity of the silica was determined in the following way: 1 g of silica was shaken intensively for 5 hr on a shaking machine with a solution of 5 ml of 5×10^{-2} *M* $CoCl_2$, 5 ml of 1*M* buffer solution of pH 3·5, 10 ml of 10^{-1} *M* Phen, the volume being adjusted to 25 ml. The change of the concentration of Co $(Phen)_3^{2+}$ was determined colorimetrically by measuring the intensity of the yellow coloration of the complex at 410 mμ (pH *ca.* 3.)[5] It was found that at pH *ca.* 3·5 6·35 mg of cobalt is sorbed on 1 g of silica. During the study of the mechanism of the sorption,[6] it was found that the capacity of silica for $Co(Phen)_3^{2+}$ is effectively unaltered in the pH range 1·5–9·5.

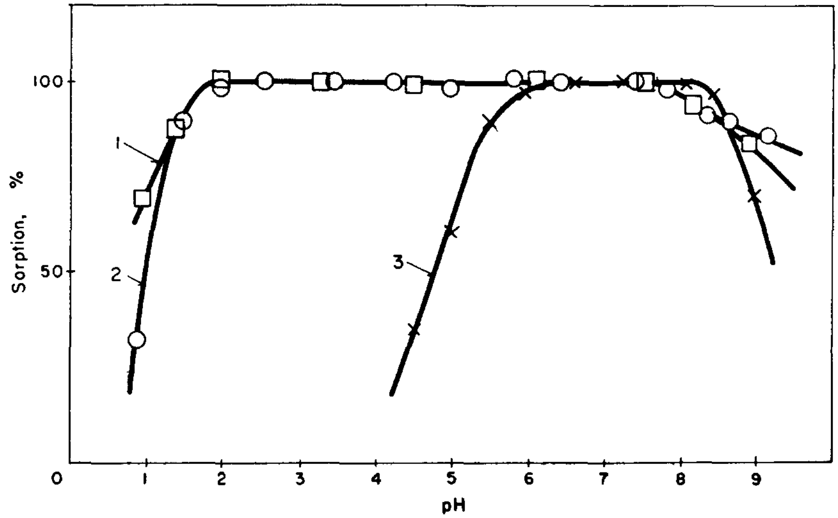

FIG. 1.—Influence of pH on sorption of $Co(Phen)_3^{2+}$ on silica

1—in 0·1*M* buffer solutions.
2—in 0·1*M* citric acid.
3—in 0·1*M* EDTA.

The capacity of silica is influenced by the size of grain and of pores in the same way as in the sorption of ferroïn.[2] These results apply to the commonly used silica (pore size 85 Å, grain size 0·15–0·20 mm). With decreasing grain size of silica the capacity rises abruptly. Because of the resistance of a column of finer silica, the application to sorption under kinetic conditions is rather problematical. For the determination of trace amounts of Co— which is the aim of the work described in this paper—silica with a higher capacity is not necessary. The pore size in a given range does not influence appreciably the sorption of $Co(Phen)_3^{2+}$(32·65 and 85 Å); larger pore silica (150 Å), however, has a very small capacity.

Reagents for desorption

Alkaline solutions (pH 9·5–10) of ammonium salts of some acids may be used in the same way as for the desorption of ferroïn sorbed on silica. Instead of the more usual ammonium formate, it is possible to use, under the same conditions, ammonium salts of trichloroacetic, monochloroacetic and acetic acids. To prevent the hydrolysis of $Co(Phen)_3{}^{2+}$, the presence of phenanthroline is necessary just as when formic acid is used. The minimum volume necessary for the desorption under the same conditions was obtained when ammonium formate and trichloroacetate were used. Methanol lowers still further the volume of the minimum amount of elution mixture.

Analytical application

It is advantageous for the analytical application that the sorption of $Co(Phen)_3{}^{2+}$ on silica is quantitative, even from solutions of high ionic strength. Very dilute solutions can be concentrated by sorption from a large volume and desorption by a minimum volume. It is possible to use the masking properties of EDTA and citric acid to increase the selectivity of the determination of cobalt. For a rapid determination of cobalt it is important that the sorption of $Co(Phen)_3{}^{2+}$ on silica can be carried out reliably at a comparatively high flow rate and that the final colorimetric determination does not need a special treatment of the solution of $Co(Phen)_3{}^{2+}$, and is rapid.

Also, the fact that the sorption is carried out on an inexpensive type of silica, needing no special treatment, is an advantage in the analytical application. The procedure for the analytical utilisation of the sorption of $Co(Phen)_3{}^{2+}$ on silica is practically identical with the procedure for the sorption. In the sequel, only results will be given, and any digressions from the given working procedure.

Reliability of determination

With the above procedure, at pH 7, a number of determinations of 29·5 μg–1·16 mg of cobalt were carried out, taking care to maintain the excess of phenanthroline during the sorption at least to ten-fold (molar). In the case of larger concentrations of cobalt, the solution containing $Co(Phen)_3{}^{2+}$ was adjusted to a volume suitable for a sensitive determination of cobalt *via* ferroïn. The results obtained show that, in the given concentration range, cobalt is determined with an average relative error of $\pm 3·7\%$.

Selectivity of determination

The influence of interfering ions on the formation and sorption of $Co(Phen)_3{}^{2+}$ (pK = 20·1) on silica is identical to that in the case of $Fe(Phen)_3{}^{2+}$ (pK = 21). The formation of complexes of cobalt^{II} is affected especially by those ions which also form with Phen stable soluble complexes or less soluble ion associates (*e.g.*, Ni, Cu, Zn, Cd, Hg, Ag, W, Mo). The course of the sorption on silica is also affected by other metal ions which hydrolyse at optimal conditions, forming hydroxo complexes (which are also sorbed on silica), giving in water partly soluble hydroxides which inhibit the smooth course of the reaction (*e.g.*, Bi, Ti, Cr, Al, Sn, Sb, *etc.*)

To avoid the separation of cobalt from these interfering ions, their influence can be prevented, in most cases, by utilising the complex-forming properties of EDTA and citric acid, complexes of these reagents not being sorbed on silica, because of their anionic character.

Masking with EDTA

In the pH range 6·5–8·5 it is possible, with EDTA, to mask those metals which, under given conditions with this reagent, form complexes which are stable enough to prevent a reaction with phenanthroline or a hydrolysis.

Working procedure: To a solution of 29·5 μg Co and of the interfering metal, an amount of 1*M* solution of EDTA is added, sufficient to bind the metal quantitatively. The pH of the solution is adjusted to *ca.* 7, the volume to *ca.* 25 ml, and 1 ml of 0·1*M* Phen is added. The sorption of $Co(Phen)_3^{2+}$ and its determination is carried out according to the procedure used during the sorption. Metals which hydrolyse easily and do not form very stable complexes with Phen can be masked with EDTA to allow the determination of trace amounts of cobalt in their presence.

In this way 29·5 μg of cobalt were determined in the presence of *ca.* 100 mg of Pb, Mn, Be, Zr, Sc, In, La, Al, Cr or Bi with an error not exceeding ±4% rel. It is probable that the determination of cobalt is possible in the presence of an even larger excess of these metals. In the case of Al and Cr it is necessary to boil the solution after adding EDTA—both ions react slowly with EDTA at normal temperature. During the sorption of $Co(Phen)_3^{2+}$ in the presence of higher concentrations of Cr bound with EDTA, a sorption of hydroxo complexes of chromium occurs (a violet layer on the column); these are not desorbed in alkaline medium by formate, and do not influence the determination. The elution can be carried out with dilute acid.

Only limited concentrations of metals which form stable complexes with Phen and which have stability constants nearly equal to, or higher than, the complexes of EDTA (Cu, Ni, Cd, Zn, Fe) can be screened. In this way 29·5 μg of Co were determined with an error not exceeding ±5% rel., in the presence of 23·6 mg of Ni, 15·5 mg of Cu, 225 mg of Cd and 130 mg of Zn. In the case of Cd and Zn it is necessary to boil and cool the solution after adjustment of pH and addition of Phen, otherwise the Co^{II} complex forms, and the results are low.

Masking with citric acid

Citric acid does not affect the sorption of $Co(Phen)_3^{2+}$ on silica, even at high concentrations. For a number of metals, pH 3·5–4 is optimal, as in the masking of metals which affect the formation and sorption of ferroïn. Most multivalent metals, *e.g.*, Sn, Sb, Bi, Tl and Zr, can be screened by citric acid when hydrolysis is to be prevented; the same applies to metals which form with Phen practically insoluble associates (W, Mo). An excess of sodium citrate must be used in most cases to prevent hydrolysis, and therefore the formation of complexes with Phen.

Procedure: For example for the determination of 29·5 μg of cobalt in the presence of 47 mg of Mo (as molybdate). About 10 ml of 1*M* sodium citrate are added to the solution, the pH is adjusted to 3·5–4, and 1 ml of 0·1*M* Phen is added. The sorption, desorption and determination of cobalt *via* ferroïn is carried out in the same way as before.

With the method described, the same amount of cobalt was determined even in the presence of 75 mg of W and 82 mg of Bi. The relative error of the determination did not exceed ±3·5%.

Determination of cobalt in the presence of iron

Special attention was paid to this case because Fe^{III} and Fe^{II} form with Phen very stable complexes, and because of the redox reaction[8] which occurs over a large pH range in the presence of cobalt, bound as $Co(Phen)_3^{2+}$:

$$Fe_2(OH)_2(Phen)_4^{4+} + 2Co(Phen)_3^{2+} + 2HPhen^+ \leftrightharpoons 2\,Fe(Phen)_3^{2+} + 2Co(Phen)_3^{3+} + 2H_2O \quad (2)$$

which is the reaction used for the final indirect colorimetric determination of cobalt.

For the determination with milligram amounts of Fe^{III}, the amount of ferroïn formed corresponds to the concentration of cobalt, which permits the determination of this metal[4]. Reaction (2) can be applied even for the concentration or separation of ferroïn from a mixture.

With a molar ratio Fe:Phen = 1:1, reaction (2) proceeds quantitatively, but all the excess of Fe^{III} bound as $Fe_2(OH)_2(Phen)_4^{4+}$ (which is of cationic nature) is sorbed along with ferroïn, and is desorbed by ammonium formate. This phenomenon causes a positive error in the determination, because the yellow-orange coloration of the $Fe_2(OH)_2(Phen)_4^{4+}$ complex is measured together with the coloration of ferroïn. The formation of $Fe_2(OH)_2(Phen)_4^{4+}$ can be considerably reduced by the presence of EDTA, according to the following equation:

$$Fe_2(OH)_2(Phen)_4^{4+} + 2H_2Y^- + 2H^+ \rightleftarrows 2FeY^- + 2H_2O + 2OH^- + 4HPhen^+, \quad (3)$$

which is strongly influenced by the pH. At higher pH values weaker complexes of Fe^{III}-EDTA than FeY^- can be formed (*e.g.*, $FeOHY^{2-}$), shifting the equilibrium to the left and raising the concentration of the hydro complex Fe^{III}-Phen in equivalent conditions.

When the absolute concentration of Fe^{III} is small, and the excess of EDTA is large, the formation and sorption of $Co(Phen)_3^{2+}$ occurs in the solution at pH 6·5–8·5 in the presence of Phen, and the course of the determination of cobalt does not differ from that already described. At concentrations higher than a few mg of Fe^{III}, the redox reaction (2) occurs even in the presence of EDTA, because the absolute equilibrium concentration of the complex $Fe_2(OH)_2(Phen)_4^{4+}$ is sufficient. It is, however, necessary to carry out the sorption at pH 4–5, and at higher concentrations of iron a blank sorption experiment must be made.

Working procedure: (*a*) To a solution containing 5–100 μg of cobalt and a maximum of 25 mg of Fe sufficient EDTA is added to complex all iron, and then 50% excess. The pH of the solution is adjusted to 4·5, and 1 ml of 0·1*M* Phen is added. After 15 min, the sorption of ferroïn, after the oxidation of cobalt, is carried out, and the ferroïn is desorbed in the same way as described for the sorption of $Co(Phen)_3^{2+}$. The extinction of the ferroïn is measured against water, and the result is evaluated against a calibration curve in the same way as described above. The error in the determination of 29·5 μg of Co in the presence of 25 mg of Fe^{II} does not exceed ±5% rel.

(*b*) In the presence of more than 26 mg of iron a blank has to be carried out with a solution of the same concentration as the sample, in order to eliminate the influence of the coloration of $Fe_2(OH)_2(Phen)_4^{4+}$ which is sorbed and desorbed as ferroïn. The procedure is analogous to that with the sample. After elution the pH is adjusted to the same value, and the resulting solution serves as a comparison in the colorimetry of ferroïn. It is also possible to measure the absorption (at 510 mμ) against water, and subtract the resulting value from the value of the extinction of the sample at the same wavelength. This procedure is suitable for routine determinations of cobalt with similar amounts of Fe (one blank is sufficient). It may be presumed that the above principle and procedure can be used for the determination of small amounts of cobalt in special steels.

Zusammenfassung—Es wurde die Sorption von $Co(phen)_3^{2+}$ an Silicagel studiert, welche bei geeigneten Aciditätsbedingungen weder durch EDTA noch durch Zitronensäure gestört wird, was zur selektiven Bestimmung von μg-Mengen Co ausgenützt wurde. Die Desorption des $Co(phen)_3^{2+}$ wurde mit einer alkalischen, wässrig-methanolischen Ammoniumformiatlösung durchgeführt. Die eigentliche Kobaltbestimmung erfolgte kolorimetrisch auf indirektem Wege über Ferroin. Besondere Aufmerksamkeit wurde der Bestimmung von Spuren Co neben Fe gewidmet.

Résumé—La sorption de $Co(Phen)_3^{2+}$ sur silice n'est pas perturbée par l'addition d'EDTA ou d'acide citrique dans des conditions d'acidité convenables. Ce fait a été utilisé pour le dosage sélectif de quantités de cobalt de l'ordre du μg. La désorption de $Co(Phen)_3^{2+}$ s'effectue au moyen d'une solution alcaline composée de formiate d'ammonum en solution dans le méthanol aqueux, et le cobalt dosé indirectement, par colorimétrie, par l'intermédiaire de la ferroïne. Considérations spéciales sur le dosage des traces de Co en présence de Fe.

Zusammenfassung—Es wird der Verlauf der Entmischung der Lösungsmittel als Wirkung des Trägers (Cellulose, Silicagel) untersucht. Durch Studium der Verhältnisse bei Gemischen von Alkohol, Wasser und Säure konnte bewiesen werden, daß es bei der Verteilungschromatographie zur Entmischung des Fließmittels kommt und daß der Verlauf dieser Entmischung von der Konzentration der Komponenten im ursprünglichen Gemisch abhängt. Es wird die Hypothese ausgesprochen, daß sich an der Grenze zwischen Träger und Lösungsmittelsystem eine Zwischenschicht bildet, an deren Aufbau alle Komponenten des Lösungsmittelsystems beteiligt sind.

NACH der heute allgemein anerkannten Hypothese von Hanes und Isherwood[1] beruht der Trennvorgang bei der Papierchromatographie in erster Linie auf der Einstellung eines Verteilungsgleichgewichts zwischen einem Cellulose-Wasser-Komplex als stationäre Phase und dem Fließmittel als mobile Phase. Dabei ist allerdings zu berücksichtigen, daß die Zusammensetzung des Lösungsmittelgemischs während des Trennvorganges nicht konstant bleibt.

Horner, Emrich und Kirschner[2] verfolgten die Veränderung der Fließmittelzusammensetzung durch das Papier auf die Weise, daß sie in einem geschlossenen Raum ein Lösungsmittelgemisch über das Papier laufen liessen und die abtropfende Flüssigkeit dann refraktometrisch untersuchten. Sie bewiesen dabei, daß beim Durchfluß eine Entmischung des Lösungsmittelsystems eintritt, welche durch die Bindung von Wasser an die Cellulose hervorgerufen wird. Andererseits fanden sie aber bei Gemischen von Phenol mit Wasser eine bevorzugte Sorption der organischen Komponente durch die Cellulose. Sie schlossen daraus, daß die Verhältnisse beim Aufbau der stationären Phase nicht so einfach sind und sprachen die Vermutung aus, daß ein ternärer Komplex aus Cellulose, Wasser und organischem Lösungsmittel entsteht.

Martin[3] benutzte in seiner Arbeit die von Krulla[4] vorgeschlagene Methode und kam damit zum Schluß, daß das Papier Wasser aus dem Lösungsmittelgemisch bis zur Bildung eines bestimmten Gleichgewichtes adsorbiert und daß dabei die Cellulosefasern stark aufquellen.

Da einerseits die bisher erschienenen Arbeiten der einzelnen Autoren recht wenig sichere Ergebnisse enthalten, andererseits aber die Ursache für die Veränderung der Zusammensetzung des Fließmittels für den Trennvorgang und seine theoretische Behandlung von großer Bedeutung ist, erschien uns eine weitere Bearbeitung dieses

Fragenkomplexes wünschenswert. Dabei war zu erwarten, daß mit Hilfe der erhaltenen Ergebnisse auch gleichzeitig die Entstehung der 2. Front bei der papierchromatographischen Trennung aufgeklärt werden kann.

WAHL DER UNTERSUCHUNGSMETHODE

Für die Versuche benutzten wir zunächst die von Martin[3] beschriebene Methode. Sie besteht darin, daß das Fließmittel an einem bei 110°C getrockneten Papierstreifen im geschlossenen, lösungsmitteldampf-gesättigten Raum in üblicher Weise aufsteigt. Nachdem die Flüssigkeitsfront eine bestimmte Höhe erreicht hat, wird der Versuch abgebrochen und das Chromatogramm schnell in vorher markierte Streifen von 2 × 5 cm zerschnitten. Diese werden sofort in getrocknete, austarierte Wägegläser gegeben und gewogen. Durch Subtraktion der Masse des bei 110°C getrockneten Papierstreifens bestimmt man die Flüssigkeitsmenge auf dem Papier in den einzelnen Chromatogrammteilen. Durch Auswaschen mit Wasser und Titration mit 0,05 N Natriumhydroxidlösung beim Studium des Gemisches Alkohol-Wasser-Säure und durch Extraktion mit Alkohol und anschließende Titration mit Karl-Fischer-Reagens beim Studium des Gemisches Alkohol-Wasser wurden die Konzentrationsänderungen im Verhältnis zur Menge des Gemisches in den einzelnen Streifen untersucht.

Abb. 1 zeigt typische Kurven, welche wir dadurch erhielten, daß wir die Masse des Fließmittels (Äthanol 3M an Salzsäure) und die Konzentration der Säure im Verhältnis zu den Rf-Werten des Lösungsmittels verfolgten.

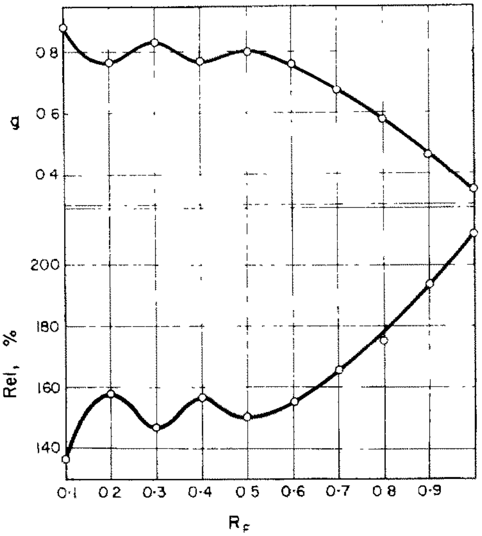

ABB. 1.—Masseänderung des Lösungsmittels (in g) und Änderung der Chlorwasserstoffsäurekonzentration (bezogen auf den Säuregehalt der Ausgangslösung)

Aus den Kurven geht hervor, daß mit der absoluten Masse-Abnahme des Lösungsmittels auf dem Papier der Gehalt an Salzsäure zunimmt. Da sich jedoch diese Abhängigkeit nicht nur im Gesamtbild der Kurve zeigt, sondern auch an den Stellen, an denen es bei der Durchführung der Versuche zu Unregelmäßigkeiten gekommen war, entstand der Verdacht, daß während der Bearbeitung der einzelnen Chromatogrammteile eine selektive Verdampfung auftritt. Es liegt nahe, daß dieser Effekt dann die Form der Kurven maßgeblich bestimmt. Das bedeutet aber, daß das Studium der Entmischung der Fließmittel mit Hilfe des gewählten Untersuchungsverfahrens zu fehlerhaften Ergebnissen führen muß.

Um diese Vermutung zu stützen, haben wir das angewandte Arbeitsverfahren noch etwas näher überprüft.

Für die folgenden Versuche benutzten wir als Fließmittel Methanol, Äthanol, Isopropanol und Butanol mit einem Wassergehalt von 5 Mol/l bei einem Chlorwasserstoff-Gehalt von 3 Mol/l.

Papierstreifen (Whatman Nr. 1, 2 × 7 cm), auf welchen mit Bleistift bei 1 und 6 cm Marken angebracht waren, tauchten wir mit dem unteren Ende in das zu untersuchende Fließmittel und ließen die Front genau bis zur oberen Marke aufsteigen. Danach haben wir die Papierstreifen aus dem Entwicklungsgefäß genommen, den Teil zwischen 1 und 6 cm schnell abgeschnitten und in ein vorher tariertes Wägeglas gebracht, gewogen und anschließend den Gehalt an Wasser bzw. Säure durch Titration bestimmt.

Diesen Vorgang wiederholten wir mit dem Unterschied, daß wir nach Entnahme des Papiers aus der Entwicklungskammer die Streifen 1, 2, 3, 4 und 5 min an der Luft hängen ließen und sie erst dann wie beschrieben behandelten.

Als Beispiel für weitere völlig gleichartig ausgefallene Versuche zeigt Abb. 2 das Verhalten des Gemisches Butanol-Wasser.

Aus Abb. 2a erkennt man, daß erwartungsgemäß mit steigender Lagerzeit an der Luft eine beträchtliche Gewichtsabnahme festgestellt werden kann. Bezieht man, wie Abb. 2b zeigt, die bei der Titration gefundene Wassermenge auf die nach Abb. 2a vorhandene Gesamtflüssigkeit, so ist gegenüber der Ausgangslösung eine erhebliche Zunahme des Wassergehaltes festzustellen, d. h. aber, daß aus dem Fließmittel während der Verarbeitung selektiv der Alkohol verdampft.

Aus diesen Versuchen geht eindeutig hervor, daß mit Hilfe der von Martin[3] beschriebenen Methode keine exakten Aussagen über die Veränderung der Fließmittelzusammensetzung auf dem Papier gemacht werden können.

Wir haben uns deshalb für die Methode der Säulen-Chromatographie entschieden, in welcher wir das zu untersuchende Flüssigkeitssystem über eine Säule aus Cellulosepulver fließen ließen. Es mußte zuvor noch geklärt werden, ob die Verhältnisse auf der Säule mit denen auf dem Papierblatt verglichen werden können.

Zu diesem Zweck untersuchten wir die Trennung von Nickel, Kobalt und Kupfer mit einem Gemisch Aceton-Wasser-Salzäure (8,7 + 0,5 + 0,8) sowohl auf Whatman-Papier wie auch auf der Cellulosesäule. In beiden Fällen arbeiteten wir nach der aufsteigenden Methode. Das Austauscherrohr wurde dazu der Länge nach in 2 Teile zerschnitten und mittels Klebestreifen zusammengehalten.[5] Nach Beendigung der Entwicklung und Öffnen der Säule wurden beide Chromatogramme mit 5%iger Natriumsulfidlösung behandelt. Wie Abb. 3 zeigt, wirken tatsächlich beide Verfahren ähnlich, so daß wir für die weiteren Versuche ohne Bedenken zur Prüfung der Entmischung von Fließmittelsystemen Cellulosesäulen verwenden konnten.

ENTMISCHUNG DER FLIESSMITTEL AN DER CELLULOSESÄULE

Zum Studium des Entmischungsvorganges verwendeten wir Gemische aus Alkohol, Wasser und Chlorwasserstoffsäure. An Alkoholen setzten wir Methanol, Äthanol, n-Propanol, n-Butanol und Benzylalkohol ein.

Durchführung

Über eine an der Luft getrocknete Cellulosesäule (Durchmesser 2,5 cm, Höhe 40 cm, 35 g Cellulosepulver Whatman Standard Grade) floß die zu untersuchende Mischung mit einer Geschwindigkeit von 2 ml pro Minute. Das Eluat wurde in Meßzylindern aufgefangen, aus welchen wir Portionen von 2 ml entnahmen und nach Verdünnung mit dest. Wasser mit 0,05 N Natronlauge gegen Methylrot titrierten.

Alle Alkohol-Säure-Gemische stellten wir so her, daß, 2 ml konz. Salzsäure in einem 100 ml Meßkolben mit reinem, mehrfach destilliertem Alkohol bis zur Marke aufgefüllt wurden.

ABB. 2.—Veränderung der Zusammensetzung des Fließmittels durch Verdampfen der Alkoholkomponente.

(1) Butanol mit 8% Wasser
(2) Butanol mit 4% Wasser
(3) Butanol mit 2% Wasser

(a): Abnahme der absoluten Lösungsmittelmasse (g Wasser/Mol Cellulose) mit der Zeit
(b): Zunahme des Wassergehaltes mit der Zeit

Abb. 4 zeigt die bei der Untersuchung verschiedener Alkohol-Säure-Gemische erhaltenen Meßergebnisse.

Aus dem Diagramm geht hervor, daß in allen Fällen das Filtrat zu Anfang des Versuches einen wesentlich geringeren Säuregehalt aufweist als die Ausgangslösung. Außerdem kann man erkennen, daß die Menge der von der Säule zurückgehaltenen Salzsäure von der Art des Alkohols bestimmt wird und mit dessen Molekulargewicht wächst. Die Veränderung in der Zusammensetzung des Fließmittels wird

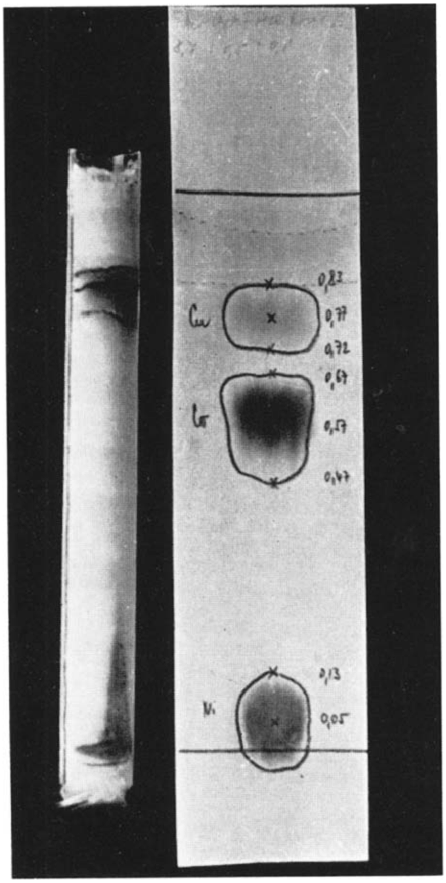

Abb. 3.—Trennung von Nickel, Kobalt und Kupfer mit Aceton-Wasser-Salzsäure. Säulenchromatogramm und Papierchromatogramm

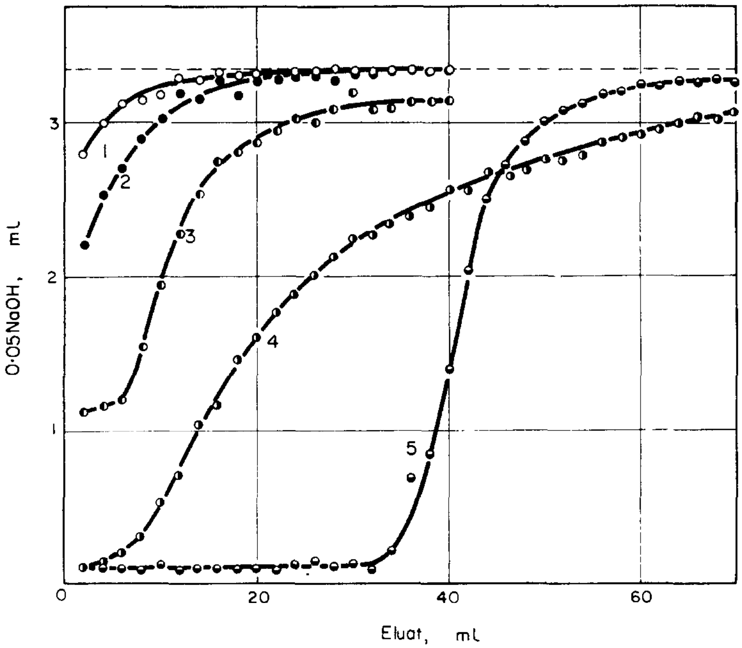

Abb. 4.—Konzentrationsänderung der Chlorwasserstoffsäure im Filtrat. Cellulosesäule, lufttrocken

(1) Methanol-Salzsäure
(2) Äthanol-Salzsäure
(3) n-Propanol-Salzsäure
(4) n-Butanol-Salzsäure
(5) Benzylalkohol-Salzsäure

augenscheinlich dadurch hervorgerufen, daß die Cellulose selektiv Komponenten des Gemisches bindet und erst nach Sättigung das Lösungsmittel die Säule in seiner ursprünglichen Zusammensetzung durchläuft.

Um zu prüfen, ob die beobachteten Effekte auf den unterschiedlichen Wassergehalt der verwendeten Alkohole zurückzuführen sind, bestimmten wir diesen.

Durchführung

3 ml des verwendeten Alkohols werden mit Karl-Fischer-Lösung nach der Dead-stop-Methode titriert. Das Reagens bereiteten wir auf folgendem Wege. 252 g sublimiertes Jod werden in 400 ml reinem Pyridin gelöst und so lange Schwefeldioxid eingeleitet, bis die Gewichtszunahme 131 g beträgt. Nach Abkühlung wird mit reinstem Methanol auf 2000 ml aufgefüllt. Man läßt 24 Stunden stehen und bestimmt dann den Wirkungswert der Lösung durch Titration einer bekannten Wassermenge. Die Bestimmung erfolgte unter Luftabachluß.

Bei den benutzten Alkoholen fanden wir die folgenden Wassergehalte:

Methanol	4,80%
Äthanol	8,02%
n-Propanol	8,64%
n-Butanol	4,20%
Benzylalkohol	4,03%

Wie man erkennt, ist der Wassergehalt der Alkohole etwas unterschiedlich. Aus dem Vergleich des Verhaltens von Methanol, n-Butanol und Benzylalkohol, die annähernd den gleichen Prozentsatz Wasser enthalten, muß man schließen, daß die

Form der Kurven in Abb. 4 in erster Linie durch die Art des Alkohols bestimmt wird. Äthanol und n-Propanol lassen sich zwanglos in das Bild einorden, obwohl sie etwas mehr Wasser enthalten.*

Unter ähnlichen Bedingungen untersuchten wir auch die Mischung von Aceton bzw. Methyläthylketon mit Salzsäure (2 ml konz. Salzäure mit Keton auf 100 ml aufgefüllt).

Abb. 5 zeigt, daß es auch bei diesen Systemen zu einer Entmischung kommt und daß der Effekt sogar noch deutlicher als bei den Alkoholen auftritt.

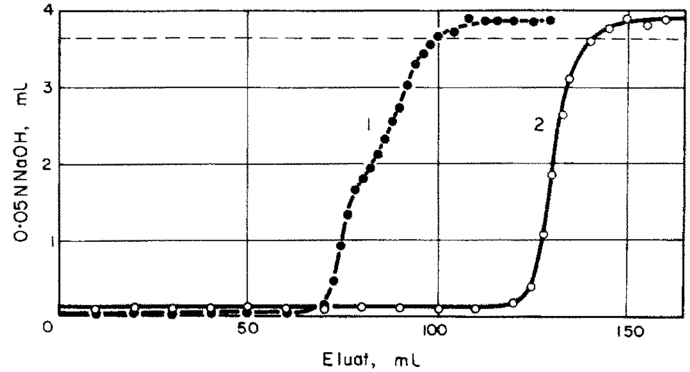

ABB. 5.—Konzentrationsänderung der Chlorwasserstoffsäure im Filtrat. Cellulosesäule, lufttrocken
(1) Aceton-Salzsäure (2) Methyläthylketon-Salzsäure

Um zu klären, ob die Entmischung der Lösungsmittel nur durch Cellulose hervorgerufen wird, prüften wir Gemische von Benzylalkohol mit Chlorwasserstoffsäure und Aceton mit Chlorwasserstoffsäure auch auf einer Silicagelsäule.

Durchführung

Über eine Säule (Durchmesser 2,5 cm, Höhe 40 cm) mit 55 g getrocknetem Silicagel (Korngröße 0,3 bis 0,6 mm) floß die zu untersuchende Mischung mit einer Geschwindigkeit von 2 ml/min. Das Filtrat wurde in gleicher Weise wie bei den vorangegangenen Versuchen geprüft.

Die Kurven der Abb. 6 zeigen, daß die Entmischung des Fließmittels an der Silicagelsäule mit dem Verhalten an Cellulose vergleichbar ist.

Die Befunde beweisen, daß in der Verteilungschromatographie die Entmischung des Lösungsmittels durch den Träger hervorgerufen wird. Die bei den Alkoholen und Ketonen festgestellte Abhängigkeit deutet darauf hin, daß der Zustand an der Grenze zwischen fester und flüssiger Phase nicht so einfach ist wie es im allgemeinen bisher angenommen wurde. Besser charakterisiert werden die Verhältnisse wahrscheinlich durch die Vermutung welche von Horner und Mitarbeitern[2] ausgesprochen worden ist, daß sich nämlich an der Cellulose ein ternärer Komplex Cellulose-Wasser-organisches Lösungsmittel ausbildet.

Die angeführten Versuchsergebnisse sprechen für diese Erklärung, wenn sie auch diese Hypothese noch nicht exakt beweisen. Nehmen wir die Bindung aller Komponenten des Lösungsmittelsystems an der Oberfläche der festen Phase an, so können wir die Verschiebung der Konzentrationskurven bei einer Reihe von Alkoholen und

---

* Über die genauerer Wirkung des Wassergehaltes bei den einzelnen Alkoholen wird später berichtet.

Ketonen durch Änderung des Mengenverhältnisses der Komponenten an der festen Phase erklären.

Über weitere Untersuchungen zu diesem Fragenkomplex soll später berichtet werden.

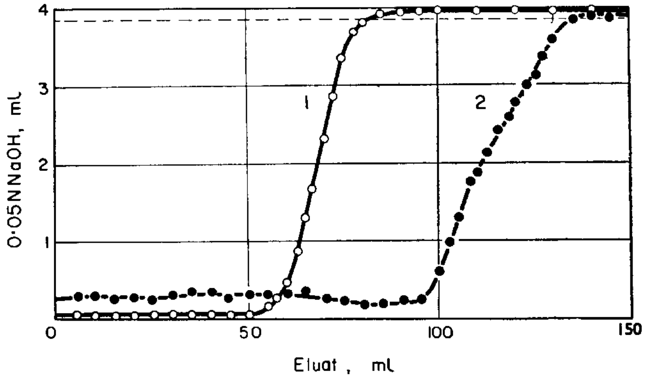

Abb. 6.—Konzentrationsänderung der Salzsäure im Filtrat. Silicagelsäule, getrocknet
(1) Benzylalkohol-Salzsäure (2) Acteon-Salzsäure

ENTSTEHUNG DER ZWEITEN FRONT BEI DER PAPIERCHROMATOGRAPHISCHEN TRENNUNG

Bei den Gemischen von Benzylalkohol mit Chlorwasserstoffsäure und noch deutlicher bei Methyläthylketon-Chlorwasserstoffsäure ist die Abnahme der Säurekonzentration in den ersten Teilen des Filtrates so bedeutend, daß dieser Teil praktisch säurefrei ist. Erst in einiger Entfernung nach dieser praktisch neutral reagierenden Front folgt dann die Säurefront.

Die Bildung zweier Fronten in der Papierchromatographie wird häufig beobachtet. Da sie mit der Entmischung des Fließmittels in unmittelbarer Beziehung stehen muß, widmeten wir auch dieser Erscheinung unsere Aufmerksamkeit. Weil eine selektive Verdampfung des Lösungsmittels hier keine wesentliche Rolle spielen kann, haben wir uns entschlossen, zum Studium der zweiten Front wieder die Methode der Papierchromatographie zu benutzen.

Durchführung

Chromatographiert wurde nach der aufsteigenden Methode auf Streifen von Whatman Papier Nr. 1 (2 × 30 cm). Die Chromatogramme besprühten wir sofort nach Entnahme aus der Entwicklungskammer mit einer 0,05% igen Thymolblaulösung. Der saure Teil des Chromatogramms bis zur zweiten Front erschien dabei rot gefärbt, die Zone darüber gelb.

Um zu zeigen, daß der Einfluß der selektiven Verdampfung bei diesen Versuchen tatsächlich vernachlässigt werden kann, haben wir die Lage der zweiten Front auf der Cellulosesäule (Abb. 4, Kurve 5) mit der auf dem Papier beim Gemisch Benzylalkohol-Chlorwasserstoffsäure verglichen. Für die Säule konnte ein formaler Rf-Wert von 0,81 errechnet werden. Auf dem Papier erhielten wir Rf-Werte von 0,76, 0,78 und 0,76.

Wenn auch die Eigenschaften des Trägers maßgebend für den Verlauf der Entmischung sind und die große Ähnlichkeit der Meßwerte zufällig sein kann, so beweist sie dennoch die Möglichkeit des Einsatzes der Papierchromatographie bei der Untersuchung des gegebenen Problems.

Nach der o. a. Methode prüften wir systematisch Gemische aus Aceton, Wasser und Salzsäure. Um gleichzeitig den Einfluß der Papierqualität mit zu erfassen, führten wir die Versuche parallel auf Whatman Papier Nr. 1 und Nr. 3 MM durch.

Wie Abb. 7 zeigt, verschiebt sich die 2. Front in Richtung höherer Rf-Werte, wenn man bei konstanter Salzsäurekonzentration den Wassergehalt auf Kosten des Acetons erhöht.

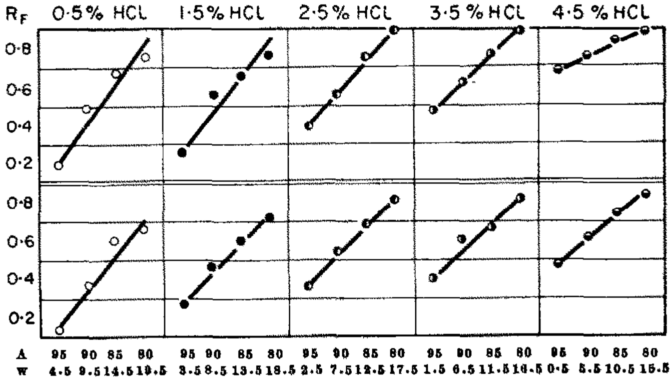

ABB. 7.—Abhängigkeit der Rf-Werte der 2. Front vom Verhältnis Wasser:Aceton bei konstantem Salzsäuregehalt

Hält man den Acetongehalt konstant, dann verschiebt sich die 2. Front zu höheren Rf-Werten mit steigendem Säuregehalt. Die Ergebnisse dieser Versuche sind in Abb. 8 dargestellt.

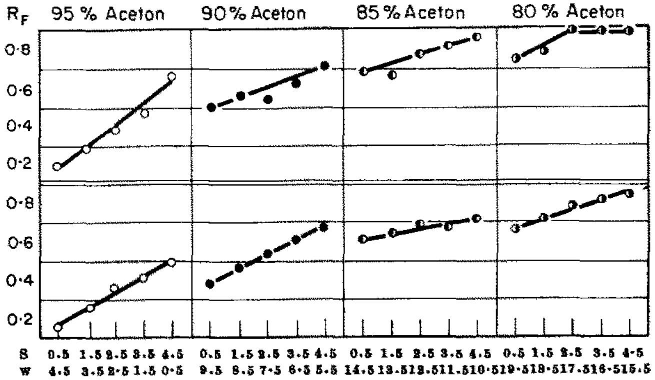

ABB. 8.—Abhängigkeit der Rf-Werte der 2. Front vom Verhältnis Wasser:Salzsäure bei konstantem Acetongehalt.

Aus den Abb. 7 und 8 geht hervor, daß sich die Verhältnisse prinzipiell bei beiden Papiersorten gleichen, daß aber auf der Sorte 3 MM (untere Reihe) die Rf-Werte der 2. Front niedriger liegen.

Diese Versuchsreihe beweist ebenfalls, daß das Fließmittel bei der papierchromatographischen Trennung entmischt wird. Aus den gefundenen Abhängigkeiten geht weiter hervor, daß, wie bei der Säule, die Verhältnisse an der Grenze zwischen mobiler und stationärer Phase nicht durch Bildung einfacher Wasser-Cellulose-Komplexe erklärt werden können. Auch bei der Trennung auf dem Papierbogen nehmen sicher alle Komponenten des Fließmittels am Aufbau der stationären Phase teil.

Es wird Gegenstand weiterer Untersuchungen sein diese Hypothese zu beweisen und die dabei entstehenden Gleichgewichte an der Grenzfläche zwischen Träger und Lösungsmittel zu untersuchen.

Summary—The course of separation of the components of a solvent mixture by the carrier (cellulose or silica gel) has been investigated. By a study of alcohol-water-acid mixtures it has been shown that in partition chromatography the components of the eluting solvent are partially separated, and that the course of the separation depends on the composition of the original solvent mixture. The hypothesis is proposed that at the boundary between the carrier and the solvent system an intermediate layer forms, in which all the compounds of the solvent are present.

Résumé—On a examiné la marche de la séparation des constituants du solvant par le support (cellulose ou gel de silice). Par l'étude de mélanges alcool-eau-acide, on a montré qu'en chromatographie de partage les constituants du solvant d'élution sont partiellement séparés, et que la marche de cette séparation dépend de la composition du mélange solvant initial. On propose l'hypothèse selon laquelle, à la séparation entre le support et le système solvant, il se forme une couche intermédiaire, dans laquelle sont présents tous les constituants du solvant.

SELEKTIVE SORPTION DER MISCHUNGEN ALKOHOL–WASSER UND ALKOHOL–WASSER–SÄURE AN DER CELLULOSESÄULE

JAN MICHAL und GERHARD ACKERMANN
Institut für Erzforschung Praha, ČSSR und Institut für anorganische und analytische Chemie der Bergakademie Freiberg (Sachsen), DDR

(*Eingegangen am* 17. *Juli* 1963. *Angenommen am* 18. *September* 1963)

Zusammenfassung—Bei der Untersuchung von Gemischen aus Alkohol und Wasser bzw. Alkohol, Wasser und Säure wird festgestellt, daß der Charakter der selektiven Sorption sich in der Reihe der Alkohole und mit steigendem Wassergehalt ändert. Bei Gemischen mit sehr geringem Wasseranteil kommt es in einigen Fällen zu bevorzugter Sorption des Alkohols. Mit steigendem Wassergehalt ändert sich der Charakter der Entmischung und es kann bevorzugte Wasseraufnahme festgestellt werden. Bei den Mischungen Alkohol–Wasser–Säure wurde bewiesen, daß an der Bildung der Zwischenschicht auf der Cellulose auch die Säure beteiligt sein muß. Im Falle des Verhaltens der Mischungen auf lufttrockener Cellulose konnte ein weiteres Argument dafür erhalten werden, daß sich offenbar am Aufbau der Grenzschicht zwischen fester und flüssiger Phase alle Komponenten des Lösungsmittelsystems beteiligen.

IN der 1. Mitteilung[1] haben wir gezeigt, daß aus einem Lösungsmittelgemisch einzelne Komponenten an der Cellulosesäule selektiv festgehalten werden. Auf Grund unserer Meßergebnisse gelangten wir zur Ansicht, daß sich am Aufbau der Grenzschicht zwischen Träger und Fließmittelsystem wahrscheinlich alle Komponenten des Lösungsmittels beteiligen. Es muß vermutet werden, daß dabei Gleichgewichtssysteme entstehen, deren Zusammensetzung von Art und Mischungsverhältnis des Fließmittels bestimmt wird.

Im folgenden soll dieser Entmischungsvorgang an Gemischen aus Alkohol–Wasser bzw. Alkohol–Wasser–Salzsäure näher betrachtet werden. Aus experimentellen Gründen wird dabei zunächst die Aufnahme von Wasser und von Säure in die stationäre Phase untersucht werden.

VERSUCHSANORDNUNG

Es wurden wieder Säulen mit einem Durchmesser von 2,5 cm und einer Höhe von 40 cm verwendet, die stets 35 g Cellulose enthielten. Das Cellulosepulver (Whatman Standard Grade) wurde in der unten beschriebenen Weise vorbehandelt, wobei wir auf genaue Einhaltung der Versuchsbedingungen besonderen Wert legten.

Die benutzten Alkohole reinigten wir durch mehrfache Destillation und bewahrten sie in Flaschen mit Schliffstopfen auf. Den Wassergehalt der Alkohole bestimmten wir wieder durch Titration mit Karl-Fischer-Lösung. Die vorbehandelte Cellulose füllten wir in die Säule bis zur Marke, welche einer Cellulosemenge von 35 g entsprach, ein. Das zu untersuchende Gemisch lief dann wieder mit einer Geschwindigkeit von 1–2 ml/min über die Säule. Das Eluat wurde in Meßzylindern aufgefangen aus denen wir jeweils 2 ml Lösung für die Wasserbestimmung entnahmen.

---

* I. Mitteilung: Literatur Punkt 1.

SYSTEM ALKOHOL–WASSER

Die einfachsten Systeme, welche zum Studium des Entmischungsvorganges der Fließmittel in der chromatographischen Analyse benutzt werden können, sind Gemische der niederen Alkohole mit Wasser. Diese Alkohole sind infolge ihrer Affinität zur Cellulose und der Größe ihrer Dielektrizitätskonstanten aus der großen Reihe der organischen Lösungsmittel, die man in der Verteilungschromatographie benutzt, dem Wasser am nächsten. Sie geben uns durch ihre unbegrenzte Mischbarkeit mit Wasser die Möglichkeit Änderungen an der Grenze zwischen fester und flüssiger Phase unter verschiedenen Bedingungen zu verfolgen.

Das verwendete Cellulosepulver wurde wie folgt vorbehandelt:

(1) 12 Std. bei 110°C im Trockenschrank getrocknet
(2) 12 Std. bei 110°C im Trockenschrank getrocknet und anschließend 12 Std. in wasserdampfgesättigter Atmosphäre aufbewahrt.
(3) 12 Std. bei 110°C im Trockenschrank getrocknet und anschließend 12 Std. dem Dampf des verwendeten Alkohols ausgesetzt.

Methanol-Wasser

Die Mischung wurde mit mehrmals destilliertem reinem Methanol hergestellt. Der Wassergehalt betrug 4,5 mg/ml Methanol.

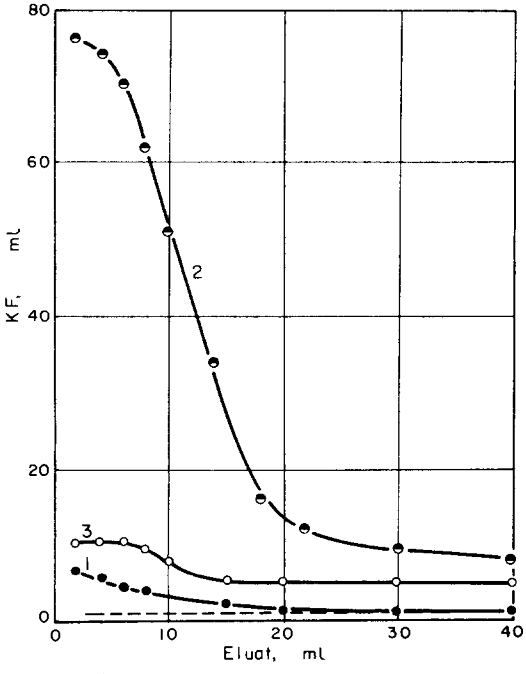

ABB. 1.—Änderung der Wasserkonzentration im Filtrat. Methanol–Wasser
(1) Cellulose bei 110°C getrocknet.
(2) Cellulose bei 110°C getrocknet und mit Wasserdampf gesättigt.
(3) Cellulose bei 110°C getrocknet und mit Methanoldampf gesättigt.

In Abb. 1 ist die Änderung des Wassergehaltes im Eluat in Abhängigkeit von dessen Gesamtvolumen dargestellt.

Aus der Figur muß man die erstaunliche Tatsache ableiten, daß es bei allen 3 Versuchsreihen zu einer bevorzugten Alkoholaufnahme aus dem Gemisch Methanol-Wasser kommt. Nach dem Durchfluß durch die mit getrockneter Cellulose gefüllte Säule sind die ersten Fraktionen des Eluats reicher an Wasser als die ursprüngliche Mischung. Eine ähnliche Erscheinung war auch an der mit Alkoholdämpfen gesättigten Säule zu beobachten. Der gleiche Effekt trat bei der mit Wasserdampf gesättigten Säule auf, wobei hier der Wassergehalt des Eluats besonders hoch lag. Auf Grund dieser Versuchsreihe ist es allerdings noch nicht möglich zu erklären, ob bei diesen Versuchen das an die Cellulose gebundene oder nur das "freie" Wasser an das Filtrat abgegeben wird.

Äthanol-Wasser

Die Mischung wurde mit mehrmals destilliertem reinem Äthanol hergestellt. Der Wassergehalt betrug 40,2 mg/ml Äthanol.

In Abb. 2 ist wieder die Änderung des Wassergehaltes im Eluat in Abhängigkeit von dessen Gesamtvolumen dargestellt.

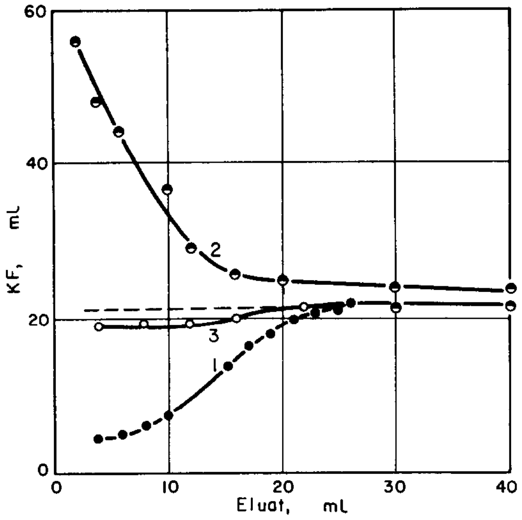

Abb. 2.—Änderung der Wasserkonzentration im Filtrat.
Äthanol-Wasser
(1) Cellulose bei 110°C getrocknet.
(2) Cellulose bei 110°C getrocknet und mit Wasserdampf gesättigt.
(3) Cellulose bei 110°C getrocknet und mit Äthanoldampf gesättigt.

Die an der trockenen und mit Alkoholdampf gesättigten Säule erhaltenen Meßwerte sprechen für die bisher gültigen Vorstellungen vom Aufbau eines Cellulose-Wasser-Komplexes, denn die ersten Anteile des Eluats sind wasserärmer als die Ausgangslösung. Bei der mit Wasserdampf gesättigten Säule ist allerdings das Filtrat wie beim Methanol zu Anfang wasserreicher als die Ausgangslösung.

n-Propanol-Wasser

Die Mischung wurde mit reinem mehrfach destilliertem n-Propanol hergestellt. Der Wassergehalt betrug 3,8 mg/ml n-Propanol.

In Abb. 3 ist wieder die Änderung des Wassergehaltes im Eluat in Abhängigkeit von dessen Gesamtvolumen dargestellt.

Der Charakter des Entmischungsvorganges entspricht merkwürdigerweise sowohl auf der trockenen wie auf der mit Wasserdampf gesättigten Säule wieder dem Befund beim Gemisch Methanol–Wasser.

Da diese Unregelmäßigkeit in der Reihe der Alkohole auffallend war, schenkten wir den Bedingungen, unter welchen diese Resultate erhalten worden waren besondere Aufmerksamkeit. Es ist auffallend, daß Methanol und n-Propanol bedeutend wasserärmer sind als das verwendete Äthanol. Es mußte daher kontrolliert werden, ob die Wassermenge in der Ausgangslösung auf den Charakter der bevorzugten Sorption Einfluß hat.

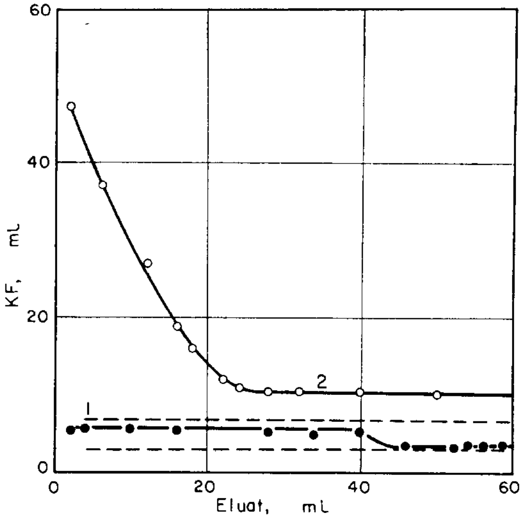

ABB. 3.—Änderung der Wasserkonzentration in Filtrat. n-Propanol–Wasser
(1) Cellulose bei 110°C getrocknet.
(2) Cellulose bei 110°C getrocknet und mit Wasserdampf gesättigt.

Wir wiederholten deshalb zunächst diese Versuche an der getrockneten Cellulosesäule mit n-Propanol–Wasser–Mischungen, die 3,8 mg bzw. 11,5 mg bzw. 26,5 mg Wasser/ml n-Propanol enthielten. Die Resultate dieser Versuchsreihe sind in Abb. 4 wiedergegeben.

Es muß angenommen werden, daß sich die für das Propanol gefundenen Verhältnisse im Prinzip auch auf die anderen Alkohole übertragen lassen. Weitere Versuche, über die später noch berichtet wird, bestätigen diese Vermutung.

Man kann also feststellen, daß die Zusammensetzung des Fließmittels von bestimmenden Einfluß auf den Charakter der selektiven Sorption der Lösungsmittel für die Cellulose ist. Während es bei Gemischen mit geringem Gehalt an Wasser zur bevorzugten Aufnahme des Alkohols kommt, ändert sich mit steigendem Wasseranteil der Charakter der Kurven und es kommt zur bevorzugten Sorption des Wassers.

SYSTEM ALKOHOL–WASSER–SÄURE

Um die Verhältnisse auch bei komplizierteren Mischungen zu klären, haben wir die ternären Systeme Alkohol–Wasser–Säure studiert. Wir wählten wieder Methanol, Äthanol, Isopropanol (und Benzylalkohol) und—in allen Fällen—Chlorwasserstoffsäure. Die Mischungen waren etwa 0,05 M an Salzsäure und enthielten 50–100 mg Wasser/ml Lösung.

Das verwendete Cellulosepulver wurde wie folgt vorbehandelt:

(1) 12 Std. bei 110°C im Trockenschrank getrocknet

(2) An der Luft bei Zimmertemperatur getrocknet

(3) Lufttrockenes Pulver 12 Std. dem Dampf des verwendeten Alkohols ausgesetzt

(4) Lufttrockenes Pulver 12 Std. dem Dampf des verwendeten Fließmittels ausgesetzt

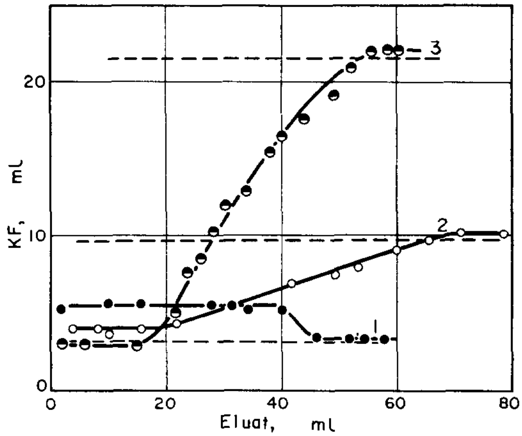

Abb. 4.—Änderung der Wasserkonzentration im Filtrat. n-Propanol–Wasser

(1) Wassergehalt 3,8 mg/ml.

(2) Wassergehalt 11,5 mg/ml.

(3) Wassergehalt 26,5 mg/ml.

In allen Fällen sind wir prinzipiell so vorgegangen, wie wir es beim Studium der Mischungen Alkohol–Wasser beschrieben haben. Das Eluat verwendeten wir abwechselnd einmal zur Wasserbestimmung mit Karl-Fischer-Reagens und zum anderen zur Bestimmung des Säuregehaltes durch Titration mit 0,05 N Natronlauge.

Methanol–Wasser–Chlorwasserstoffsäure

Die Abb. 5 und 6 zeigen die Abhängigkeit des Wasser- bzw. des Säuregehaltes vom Gesamtvolumen des Eluats. Die Diagramme enthalten auch gleichzeitig als gestrichelte Linie Angaben über den Wasser- bzw. Säuregehalt der Ausgangslösung.

Äthanol–Wasser–Chlorwasserstoffsäure

Die Abb. 7 und 8 zeigen die Abhängigkeit des Wasser- bzw. Säuregehaltes vom Gesamtvolumen des Eluats. Die Diagramme enthalten auch gleichzeitig als gestrichelte Linie Angaben über den Wasser- bzw. Säuregehalt der Ausgangslösung.

Isopropanol–Wasser–Chlorwasserstoffsäure

Die Abb. 9 und 10 zeigen die Abhängigkeit des Wasser- bzw. Säuregehaltes vom Gesamtvolumen des Eluats. Die Diagramme enthalten auch gleichzeitig als gestrichelte Linie Angaben über den Wasser- bzw. Säuregehalt der Ausgangslösung.

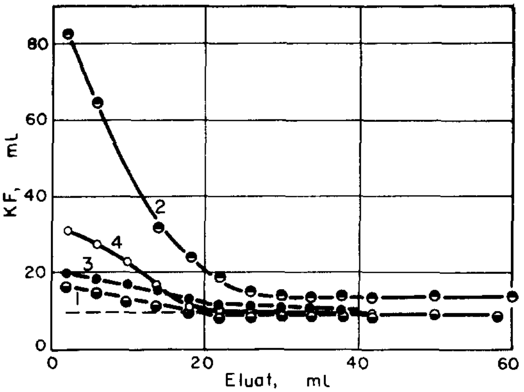

ABB. 5.—Abhängigkeit des Wassergehaltes im Filtrat von dessen Gesamtmenge. Methanol–Wasser–Salzsäure

(1) Cellulose, bei 110°C getrocknet. (3) Cellulose, lufttrocken, mit Methanoldampf gesättigt.
(2) Cellulose, lufttrocken. (4) Cellulose, lufttrocken, mit Fließmitteldampf gesättigt.

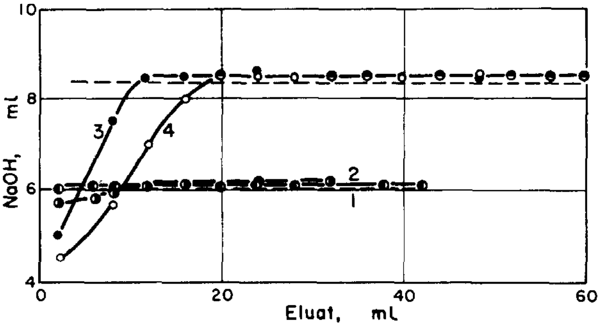

ABB. 6.—Abhängigkeit der Salzsäurekonzentration im Filtrat von dessen Gesamtmenge. Methanol–Wasser–Salzsäure

(1) Cellulose, bei 110°C getrocknet. (3) Cellulose lufttrocken, mit Methanoldampf gesättigt.
(2) Cellulose, lufttrocken. (4) Cellulose, lufttrocken, mit Fließmitteldampf gesättigt.

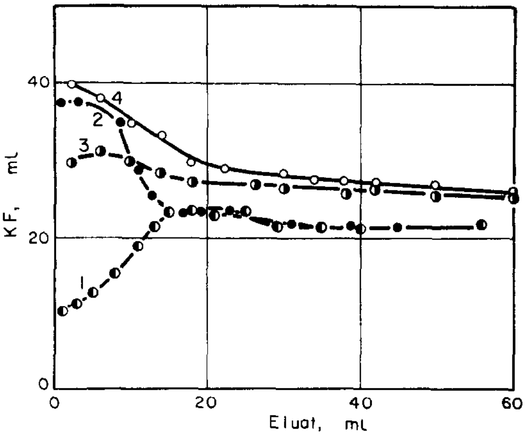

ABB. 7.—Abhängigkeit des Wassergehaltes im Filtrat von dessen Gesamtmenge. Äthanol–Wasser–Salzsäure

(1) Cellulose, bei 110°C getrocknet. (3) Cellulose, lufttrocken, mit Äthanoldampf gesättigt.
(2) Cellulose, lufttrocken. (4) Cellulose, lufttrocken, mit Fließmitteldampf gesättigt.

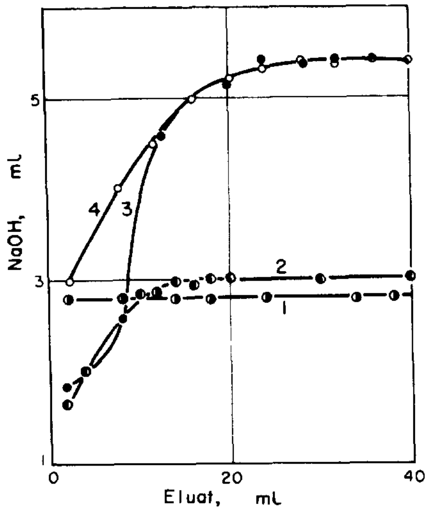

ABB. 8.—Abhängigkeit der Salzsäurekonzentration im Filtrat von dessen Gesamtmenge.
Äthanol–Wasser–Salzsäure
(1) Cellulose, bei 110°C getrocknet.
(2) Cellulose, lufttrocken.
(3) Cellulose, lufttrocken, mit Äthanoldampf gesättigt.
(4) Cellulose, lufttrocken, mit Fließmitteldampf gesättigt.

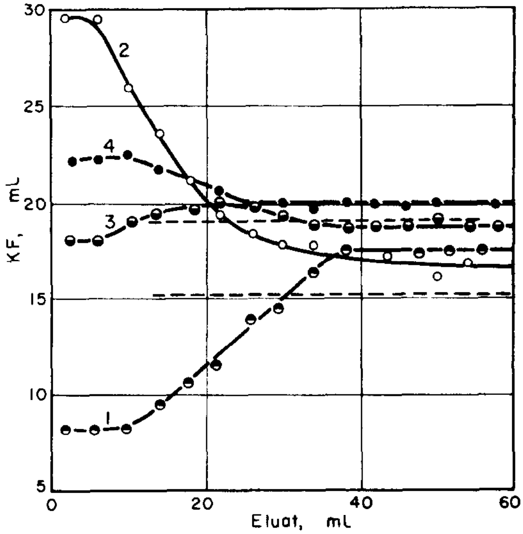

ABB. 9.—Abhängigkeit des Wassergehaltes im Filtrat von dessen Gesamtmenge.
i-Propanol–Wasser–Salzsäure
(1) Cellulose, bei 110°C getrocknet.
(2) Cellulose, lufttrocken.
(3) Cellulose, lufttrocken, mit i-Propanoldampf gesättigt.
(4) Cellulose, lufttrocken, mit Fließmitteldampf gesättigt.

Auch bei den untersuchten 3-Komponenten-Systemen können wir beobachten, daß es beim Durchlauf der Lösungsmittelgemische durch die Cellulosesäulen zu einer Veränderung in deren Zusammensetzung kommt. Mit wechselndem Alkohol ändert sich der Charakter der Kurven nicht prinzipiell. Allerdings sind bei den einzelnen Versuchen in den ersten Teilen des Eluats recht unterschiedliche Mengen an Wasser und an Chlorwasserstoffsäure enthalten. Vergleicht man die beiden Serien von Meßreihen miteinander, so kann man erkennen, daß die Veränderung der Salzsäure- und der Wasserkonzentration im Eluat im entgegengesetzten Sinn verlaufen. Eine Ausnahme bildet die bei 110°C getrocknete Cellulose, wo die Salzsäurekonzentration im Eluat konstant bleibt und praktisch der Säurekonzentration in der ursprünglichen Mischung gleicht. In allen anderen Fällen wird Säure von der Säule aufgenommen.

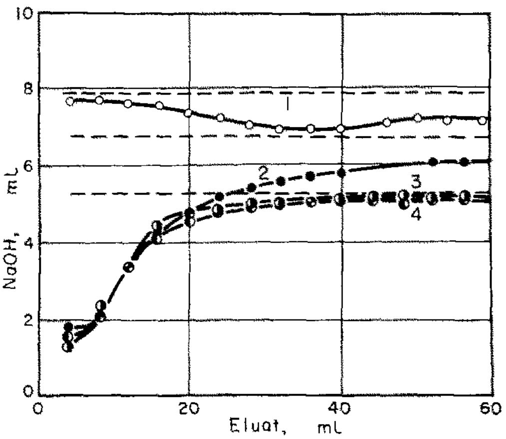

ABB. 10.—Abhängigkeit der Salzsäurekonzentration im Filtrat von dessen Gesamtmenge.

i-Propanol–Wasser–Salzsäure

(1) Cellulose, bei 110°C getrocknet.
(2) Cellulose, lufttrocken.
(3) Cellulose, lufttrocken, mit i-Propanoldampf gesättigt.
(4) Cellulose, lufttrocken, mit Fließmitteldampf gesättigt.

Zu einem interessanten Ergebnis kommen wir noch, wenn wir uns den Wassergehalt der Eluate bei den verschiedenen Alkoholen [Abb. 5, 7 und 9, Kurve (2)] in den Lösungen ansehen, die die bei 110°C getrockneten Säulen passiert haben. Die entsprechenden Kurven sind nochmals in Abb. 11 zusammengefaßt.

Obwohl der Wassergehalt in den untersuchten Gemischen nicht exakt gleich ist, geht aus dem Bild hervor, daß die verschiedenen Alkohole aus der Celluslose unterschiedliche Wassermengen verdrängen. Methanol steht wieder an der Spitze, während aus Benzylalkohol im Gegenteil von der Säule noch Wasser aufgenommen wird.

Da bei allen Versuchen die Cellulose in gleicher Weise präpariert und aufbewahrt wurde, können wir aus den erhaltenen Elutionskurven wieder den Schluß ziehen, daß offensichtlich alle Komponenten des Lösungsmittelsystems an der Oberfläche der Cellulose gebunden werden. Das Verhältnis ist aber nicht nur durch die Konzentrationsverhältnisse der Komponenten in der Ausgangsmischung, sondern auch durch die Eigenschaften der organischen Lösungsmittel bedingt. Bei diesen Versuchen wird das Methanol am stärksten gebunden. Mit ansteigenden Gliedern aus der Reihe der Alkohole fällt dann der Gehalt des an der Oberfläche der Cellulose gebundenen Alkohols.

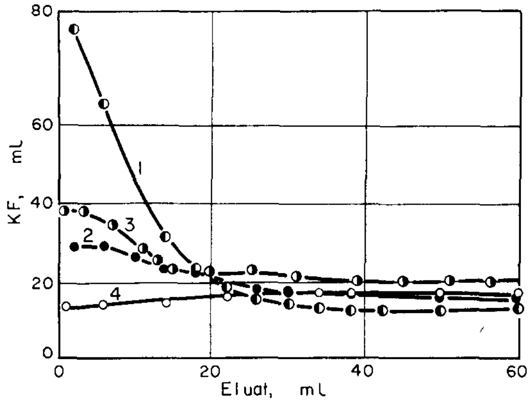

Abb. 11.—Abhängigkeit der Wasserkonzentration im Filtrat bei verschiedenen Alkoholen. Cellulose lufttrocken

(1) Methanol–Wasser–Salzsäure.
(2) Äthanol–Wasser–Salzsäure.
(3) i-Propanol–Wasser–Salzsäure.
(4) Benzylalkohol–Wasser–Salzsäure.

Es muß Gegenstand weiterer Untersuchungen sein diese Abhängigkeit quantitativ zu erfassen und die exakten Verhältnisse an der Grenze zwischen Träger und Lösungsmittel zu untersuchen.

Summary—The character of the selective sorption of alcohol–water and alcohol–water–acid mixtures has been shown to alter on ascending the alcohol series, and with increasing water content. From some mixtures with very low content the alcohol is preferentially sorbed. As the concentration of water increases preferential sorption of water can be shown to occur. For alcohol–water–acid mixtures the acid also participates in the formation of the boundary layer on the cellulose. In the case of air-dried cellulose, it further appears that all the components of the solvent system participate in the formation of the boundary layer between the solid and liquid phases.

Résumé—On a montré que le caractère de sorption sélective de mélanges alcool-eau et alcool-eau-acide est modifié lorsqu'on s'élève dans la série des alcools, et lorsque croît la teneur en eau. A partir de quelques mélanges à très faible teneur en eau, l'alcool est sorbé préférentiellement. Lorsque croît la concentration en eau, on peut montrer qu'il apparaît une sorption préférentielle de l'eau. Pour des mélanges alcool-eau-acide, on a établi que l'acide doit aussi participer à la formation de la couche de jonction sur la cellulose. Dans le cas de la cellulose séchée à l'air, on a acquis un argument supplémentaire quant au fait que tous les constituants du système solvant participent à la formation de la couche de jonction entre les phases solide et liquide.

(*Received* 17 *July* 1963. *Accepted* 21 *October* 1963)

Summary—Elemental sulphur can be titrated directly in a benzene-acetone medium with potassium cyanide dissolved in isopropyl alcohol. A potentiometric or visual indicator (bromothymol blue) end-point can be used. Elemental selenium can be determined by dissolving it in an excess of a standard solution of potassium cyanide in isopropyl alcohol and back-titrating the excess with a standard solution of sulphur in benzene-acetone. Selenium and sulphur can also be determined simultaneously. With these titrants, salts of quaternary ammonium bases, dissolved in a mixture of isopropyl alcohol and acetone, can be titrated.

OUR cyanometric titrations in a non-aqueous medium may be divided into three groups: the determination of elemental sulphur, the determination of elemental selenium and the determination of heterocyclic quaternary ammonium salts.

For the determination of elemental sulphur many methods are known. Most methods suggest a preliminary dissolution in acetone or some other solvent for the purpose of separation or enrichment. For the determination of the sulphur content of this extract, gravimetric as well as titrimetric methods are known. A direct titrimetric method in non-aqueous solution has been reported by Skoog and Bartlett.[1] They used acetone as solvent and were able to prepare a $0{\cdot}01F$ solution of sulphur. The titration was carried out with a standard solution of potassium cyanide in isopropyl alcohol. For the determination of substances of higher elemental sulphur content this method could only be used with satisfactory accuracy if a solvent could be found in which sulphur is more soluble than in acetone. For that special purpose we wanted to improve this method and to extend its field of application.

We found that by using benzene and acetone mixed in a ratio of 4 to 1, sulphur solutions may be prepared of $0{\cdot}1F$ concentration. Experience has shown that the sulphur content of sulphur solutions prepared in benzene-acetone mixtures is stable. Consequently, such solutions may be used as standard solutions for the titration of cyanide and indirectly for the determination of elemental selenium.

The titration is based on the fact that cyanide ion, which is a strong Lewis base, is converted to the less basic thiocyanate or selenocyanide ion in the presence of sulphur or selenium; when an excess of cyanide is added there is a sudden increase in the basicity of the solution. On the other hand, when titrating cyanide with standard sulphur solution, the basicity of the solution suddenly decreases at the equivalence point.

In accordance with Skoog and Bartlett,[1] we confirm that bromothymol blue indicates precisely the equivalence point. In order to follow the reaction occurring

---

* Presented at XIXth International Congress of Pure and Applied Chemistry, London, England, 17th July, 1963.

during the titration, we first carried out potentiometric titrations. A 0·1*F* stock solution of sulphur in benzene-acetone, prepared from sulphur recrystallised several times from carbon disulphide and dried at 60°, was titrated with a 0·1*F* standard solution of potassium cyanide in isopropyl alcohol.

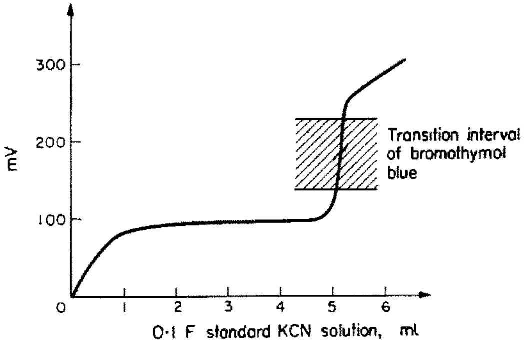

Fig. 1.—Potentiometric titration of a benzene-acetone solution of sulphur with a standard solution of potassium cyanide in isopropyl alcohol.

For the potentiometric titrations a glass indicator electrode and a calomel reference electrode were used, without a salt bridge. This was possible because the small water content of the isopropyl alcohol solution is sufficient for dissolution of the potassium cyanide and at the same time it does not decompose the benzene-containing solution. Twenty-five ml of the sulphur stock solution were titrated with potassium cyanide at 50–60° with magnetic stirring and nitrogen bubbling through the solution. A Metrohm potentiometer was used as the measuring instrument.

Table I.—Titration of a solution of sulphur in benzene-acetone with a standard solution of potassium cyanide in isopropyl alcohol using bromothymol blue as indicator.

KCN consumed, *ml*		Sulphur found, *mg*	Sulphur taken, *mg*	Deviation, %
4·99	0·1*F*	16·00	16·03	−0·18
5·00		16·03	16·03	−0·00
9·92		31·80	32·06	−0·81
9·97		31·99	32·06	−0·22
19·87		63·74	64·13	−0·60
19·95		63·99	64·13	−0·22
9·90	0·01*F*	3·171	3·206	−1·03
9·86		3·161	3·206	−1·40

In order to ascertain the transition interval of bromothymol blue the potentiometric titrations were also carried out in the presence of this indicator. Fig. 1 shows the titration curve thus obtained. Bromothymol blue is seen to change colour at the potential change which corresponds with the equivalence point. Consequently, the titration can also be carried out with visual end-point indication. The results of some titrations with the visual indicator, performed in the same way as the potentiometric titration, are shown in Table I. The deviation from the true value is seen to vary between 0·0 and −0·8% with 0·1*F* potassium cyanide solution, and between −1 and −1·4% with a 0·01*F* solution.

The method was next applied to various technical materials. Thus, to determine the elemental sulphur content of sulphur recovered from gases, after appropriate pretreatment of a weighed sample it was washed with benzene into a volumetric flask. The flask was shaken until dissolution of the sulphur, then diluted to the mark with acetone. Two–three drops of a 0·1% isopropyl alcohol solution of bromothymol blue indicator were added to an aliquot of this stock solution. After warming to 50–60°, it was titrated with potassium cyanide standard solution until the appearance of a blue coloration. In the neighbourhood of the end-point it is advisable to titrate slowly, because the reaction becomes slow and part of the sulphur may remain untitrated. Some results are summarised in Table II.

TABLE II.—DETERMINATION OF THE ELEMENTAL SULPHUR CONTENT OF SULPHURS RECOVERED FROM GASES

0·1*F* KCN consumed, *ml*	Sulphur found, *mg*	Substance taken, *mg*	Sulphur content of substance, %
I (purified sample)			
10·34	33·15	33·17	99·9
11·97	38·38	38·30	100·2
9·25	29·68	29·71	99·9
II (impure sample)			
8·71	27·93	30·25	92·4
9·55	30·63	33·21	92·2
10·49	33·65	36·23	92·8

TABLE III.—DETERMINATION OF THE ELEMENTAL SULPHUR CONTENT OF PLANT PROTECTIVES

Substance	0·05*F* KCN consumed /10 ml, *ml*	Substance taken, *mg*	Sulphur found, *mg*	Sulphur found, %	Sulphur present, %
"Sulfex"	3·62	178·6	58·03	32·49	30–33
	5·55	269·7	88·98	32·99	
	7·71	385·8	123·61	32·04	
"Sulfarol"	2·29	55·6	41·61	74·98	74–75
	14·00	301·2	224·78	74·53	
	16·24	350·0	260·40	74·40	
"Netzschwefel-Pahlberg"	8·21	217·8	131·74	60·49	60–63
	3·94	103·1	63·30	61·40	
	7·91	206·2	126·91	61·55	

We have also determined the elemental sulphur content of various plant protectives, as did Bartlett and Skoog.[1] The sulphur content of the sample may be extracted either by shaking the test sample with benzene in a volumetric flask or by means of an extractor. The latter procedure must be used if a volume correction should be applied because of a large amount of accompanying material. Aliquots of the resulting stock solution were titrated both potentiometrically and with visual end-point indication (bromothymol blue), the results of these titrations being given in Table III.

The data of this table prove that the method is well suited to the determination of the elemental sulphur content of sulphur-containing plant protectives. The method is rapid and the difference between parallel titrations does not exceed ±1 %.

TABLE IV.—DETERMINATION OF ELEMENTAL SULPHUR IN SULPHUR-CONTAINING MEDICINAL CARBON (NEOCARBOLAX)

Elemental sulphur present, *mg/pill*	Sulphur found, *mg*	
	Visual end-point	Potentiometric indication
50	50·10	50·11
50	49·75	49·94
50	49·95	49·99
50	50·02	49·98
50	49·98	50·09

The titration with potassium cyanide was also applied to the determination of the elemental sulphur content of sulphur-containing medicinal carbon (Neocarbolax). Because of the high carbon content the titration must be carried out potentiometrically. Visual end-point indication can only be used after filtration. Table IV shows the results of some titrations. The determination is of sufficient accuracy, the greatest observable error being about ±0·2 %.

An attempt was made to apply the sulphur titration to the determination of cyanide. A 0·1*F* isopropyl alcohol solution of cyanide was titrated with a 0·1*F* standard sulphur solution in acetone-benzene using both potentiometric and visual end-point indication. The curve of our potentiometric titration carried out by using a glass and a saturated calomel electrode in the presence of bromothymol blue or titan yellow can be seen in Fig. 2 and the results of the titrations carried out in the presence of titan yellow are to be seen in Table V. The standard deviation calculated on the basis of 20 parallel titrations, in which 65 mg of potassium cyanide were taken as test, was ±0·014 ml of 0·1*F* sulphur solution.

TABLE V.—TITRATION OF A 0·1*F* SOLUTION OF POTASSIUM CYANIDE IN ISOPROPYL ALCOHOL WITH A 0·1*F* STANDARD BENZENE-ACETONE SOLUTION OF SULPHUR IN THE PRESENCE OF TITAN YELLOW

0·1*F* Sulphur solution consumed, *ml*	KCN found, *mg*	KCN taken, *mg*	Deviation, %

9·98	64·98	65·12	−0·21
9·95	64·79	65·12	−0·50
Deviation from true value			−0·49

The possibility of titrating potassium cyanide in a non-aqueous solution with a standard solution of elemental sulphur led us to try and extend the method to the determination of selenium. Elemental selenium was found to dissolve easily in an excess of an isopropyl alcohol solution of potassium cyanide to form selenocyanide. The excess cyanide can be titrated with a 0·1*F* standard solution of elemental sulphur to titan yellow or potentiometrically. Some results of the determination of purified selenium are shown in Table VI.

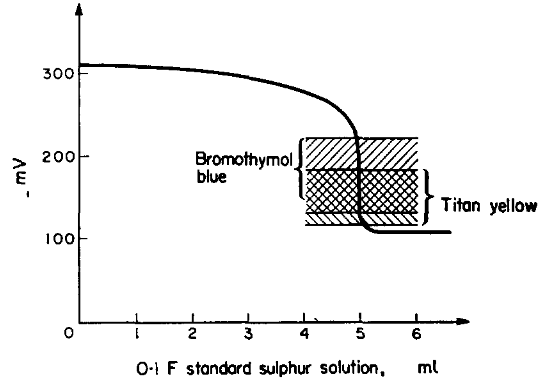

FIG. 2.—Potentiometric titration of a solution of potassium cyanide in isopropyl alcohol with a standard solution of sulphur in benzene-acetone.

TABLE VI.—INDIRECT TITRATION OF PURIFIED SELENIUM WITH A STANDARD SOLUTION OF SULPHUR IN BENZENE-ACETONE

0·1*F* KCN soln. used, *ml*	0·1*F* Sulphur soln. consumed, *ml*	Selenium found, *mg*	Selenium taken, *mg*	Deviation, %
10·00	5·47	35·82	35·60	+0·62
10·00	5·79	33·24	33·10	+0·45
10·00	6·39	28·58	28·39	+0·99
10·00	6·16	30·34	30·65	+1·01
10·00	6·13	30·60	30·45	+0·59

Elemental sulphur and selenium can be determined in the presence of each other, because elemental sulphur dissolves in benzene whereas selenium does not. The dissolved sulphur can be titrated directly with a standard solution of potassium cyanide in isopropyl alcohol. After the whole of the sulphur has been converted to thiocyanate, which may be indicated either visually or potentiometrically, the solid selenium is dissolved in an excess of standard potassium cyanide solution. The excess cyanide solution is then back-titrated with a standard solution of sulphur in benzene-acetone. Fig. 3 shows a potentiometric titration curve obtained with glass and saturated calomel electrodes in the presence of tital yellow. One can observe definite potential changes at the end-point of both reactions. Table VII shows some results of the titration carried out in the presence of titan yellow as indicator. The greatest deviation from the theoretical value is 1·3% for sulphur and +1·0% for selenium.

In a previous method[2] elementary sulphur or selenium was determined by treatment with an excess of potassium cyanide solution, the excess of which was determined by adding excess nickel solution and titrating the uncomplexed nickel with EDTA. It was not possible to determine sulphur and selenium in admixture as in the present method. Furthermore, the present method enables sulphur to be extracted from a sample containing ions which would interfere in a complexometric titration.

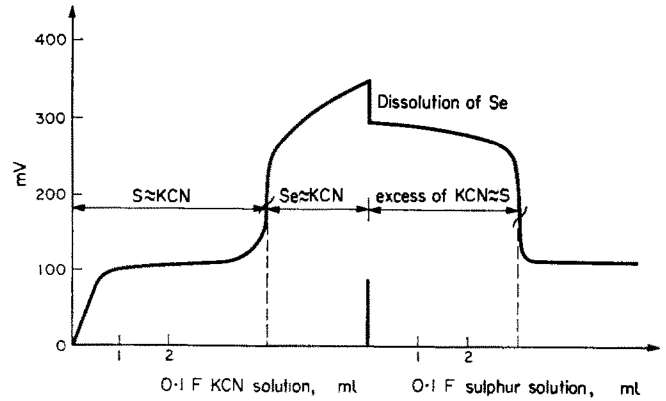

FIG. 3.—Potentiometric titration of elemental sulphur and selenium in the presence of each other.

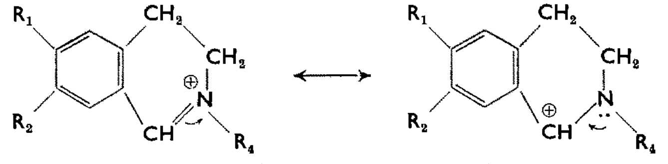
TABLE VII.—TITRATION OF SULPHUR AND SELENIUM IN THE PRESENCE OF EACH OTHER

Sulphur found, *mg*	Sulphur taken, *mg*	Selenium found, *mg*	Selenium taken, *mg*	Deviation from true value	
				Sulphur, %	Selenium, %
17·86	17·98	28·40	28·34	−0·66	+0·21
17·90	17·98	25·28	25·20	−0·44	+0·35
17·74	17·98	30·30	30·20	−1·33	+0·33
17·85	17·98	29·30	29·00	−0·72	+1·02

It has also been found possible to titrate the salts of heterocyclic quaternary ammonium bases with a standard solution of potassium cyanide in isopropyl alcohol. These salts react quite easily with cyanide ion, the carbon atom next to the quaternary nitrogen atom binding it with a covalent bond. The stability of the resulting cyanide compound depends upon the polarity of the solvent. Heterocyclic quaternary ammonium salts have two mesomeric forms:



quaternary ammonium ion carbonium ion

In polar solvents the quaternary ammonium is the stable form, whereas the non-polar solvents favour the formation of the carbonium ion. The strongly nucleophilic cyanide ion attacks the carbonium ion with the formation of a covalent bond. Because the reaction takes place rapidly and quantitatively, it is well suited for quantitative determinations.

After the heterocyclic quaternary ammonium salt is consumed, the cyanide ion will be in excess and behave in a non-aqueous medium as a strong base. Consequently, the end-point of the titration can be indicated either with acid-base indicators or potentiometrically.

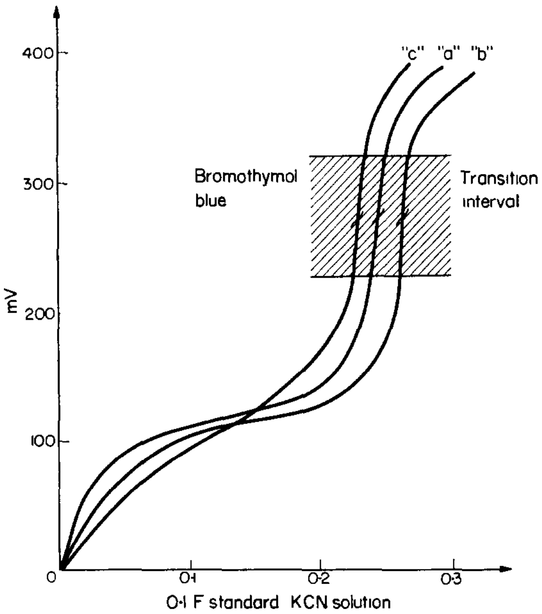


FIG. 4.—Potentiometric titration of heterocyclic quaternary ammonium salts with a standard solution of potassium cyanide in isopropyl alcohol:
(a) cotarnine chloride,
(b) *p*-chlorophenylnorcotarninium chloride,
(c) 2,4-dinitrophenyl-6,7-dimethoxyisoquinolinium chloride.

The method was tested by using the following three heterocyclic quaternary ammonium salts:

(a) cotarnine chloride ($R_1 + R_2 = CH_2O_2$, $R_3 = CH_3O$—, $R_4 = CH_3$-),
(b) *p*-chlorophenylnorcotarninium chloride

($R_1 + R_2 = CH_2O_2$, $R_3 = CH_3O$—, $R_4 =$ C— ),

(c) 2,4-dinitrophenyl-6,7-dimethoxyisoquinolinium chloride

($R_1 = R_2 = CH_3O$—, $R_3 =$  , $R_4 =$ ).

The substance to be analysed or an aliquot of a previously prepared stock solution was transferred to a titration vessel and the volume adjusted to about 20 ml with a mixture of acetone and isopropyl alcohol (1 : 1). Potentiometric titrations were carried out with a glass and saturated calomel electrode using a 0·1*F* standard solution of potassium cyanide in isopropyl alcohol. Fig. 4 shows the titration curves obtained.

The potentiometric titrations were repeated in the presence of bromothymol blue as indicator. As can be seen, the titration can be carried out with visual end-point indication, because the inflection point of the potentiometric curve coincides with the colour transition of bromothymol blue.

TABLE VIII.—TITRATION OF HETEROCYCLIC QUATERNARY AMMONIUM SALTS WITH A STANDARD SOLUTION OF POTASSIUM CYANIDE IN ISOPROPYL ALCOHOL

Substance	Concentration of standard soln., *F*	Standard soln. consumed, *ml*	Substance found, *mg*	Substance taken, *mg*	Deviation, %
Cotarnine chloride	0·05	0·58	7·4	7·5	−1·3
		0·57	7·3	7·5	−2·6
		1·19	15·2	15·4	−1·3
	0·01	3·13	80·0	80·2	−0·3
p-Chlorophenyl-norcotarninium chloride	0·01	0·95	3·05	3·12	−2·2
		1·91	6·14	6·24	−1·6
	0·05	0·85	15·44	15·60	−1·0
2,4-dinitrophenyl-6,7-dimethoxy-isoquinolinium chloride	0·01	0·78	3·07	3·16	−2·8
		5·41	21·2	21·0	+0·9
	0·01	3·19	62·6	63·0	−0·6
		4·20	82·3	82·4	−0·1

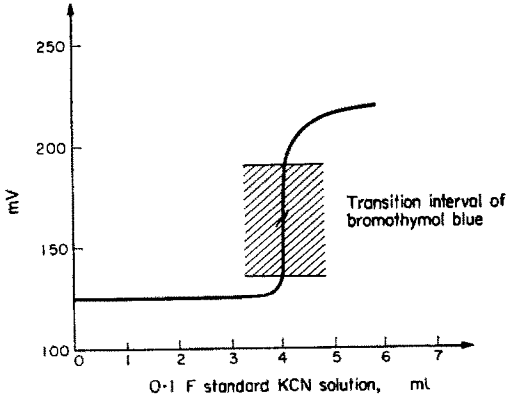

FIG. 5.—Potentiometric titration of cotarnine chloride in the presence of free cotarnine base.

The results of some titrations carried out in the presence of bromothymol blue are summarised in Table VIII. The data show that for titrations performed on the micro scale (10 mg of substance taken and 0·01*F* standard solution used), the error was about 0–3 %, whereas by taking greater amounts of sample, the deviation is only 0·1 %. The standard deviation of the method using 30 mg of substance is ±0·05 ml of 0·05*F* potassium cyanide solution.

It was later found that heterocyclic quaternary ammonium bases in non-aqueous solution do not react with an isopropyl alcohol solution of potassium cyanide. This made it possible to determine quaternary ammonium salts in the presence of their free bases. Fig. 5 shows the curve of the potentiometric titration of cotarnine chloride in the presence of free cotarnine. It is seen from the curve that the medium has a buffer effect and the potential changes only just before the equivalence point giving a definite and well perceptible jump.

In conclusion, a standard solution of potassium cyanide in isopropyl alcohol is seen to be well suited to the titration of many substances. We have succeeded in extending the field of its application for the titration of elemental sulphur. Furthermore, new methods have been developed for the determination of elemental selenium and heterocyclic quaternary ammonium salts. By the last method it is also possible to follow the formation of quaternary salts from the corresponding free bases.

Zusammenfassung—Elementarer Schwefel kann in einer Benzol-Aceton-Lösung mit in Isopropanol gelöstem Kaliumcyanid direkt titriert werden. Es kann potentiometrische oder visuelle (Bromthymolblau) Endpunktsanzeige verwendet werden. Elementares Selen kann bestimmt werden durch Lösen in einem Überschuß eingestellter Kaliumcyanidlösung in Isopropanol und Rücktitration mit einer eingestellten Schwefellösung in Benzol-Aceton. Selen und Schwefel können auch nebeneinander bestimmt werden. Mit diesen Titranten können auch Salze heterocyclischer quartärer Ammoniumbasen, gelöst in Isopropanol-Acton, titriert werden.

Résumé—On peut doser directement le soufre élémentaire en milieu benzène-acétone au moyen de cyanure de potassium en solution dans l'isopropanol. Le point final peut être déterminé potentiométriquement ou au moyen d'un indicateur visuel (bleu de bromothymol). Le sélénium élémentaire peut être dosé par dissolution dans un excès d'une solution titrée de cyanure de potassium en isopropanol, et dosage en retour de l'excès par une solution titrée de soufre dans un mélange acétone-benzène. On peut aussi doser simultanément le sélénium et le soufre. Au moyen de ces solutions titrées, on peut doser des sels de bases hétérocycliques à fonction ammonium quaternaire, dissous dans un mélange isopropanol-acétone.

INVESTIGATION OF REAGENTS FOR THE COLORIMETRIC DETERMINATION OF SMALL AMOUNTS OF CYANIDE—I

L. S. BARK and H. G. HIGSON
Department of Chemistry and Applied Chemistry, Royal College of Advanced Technology, Salford 5, Lancashire, England

(*Received* 26 *July* 1963. *Accepted* 13 *September* 1963)

Summary—The König synthesis of pyridine dyestuffs by reaction of cyanogen bromide and suitable aromatic amines with pyridine, used as the basis of standard British and American colorimetric methods for the determination of small amounts of cyanide, is reinvestigated. After consideration of the carcinogenic properties of amines capable of being used in a method for cyanide, *p*-phenylenediamine is selected for further examination.

A REVIEW[1] of methods available for the determination of small amounts of cyanide indicates that the colorimetric determination is far superior to others, including titrimetric, polarographic and chromatographic methods. The standard methods for trade wastes and effluents[2,3,4,5] and for waters[4,6] are based either on the colorimetric procedure developed by Aldridge[7,8] or on that of Epstein,[9] which themselves are based on the König reaction[10,11] for the synthesis of pyridine dyestuffs. The latter are formed by reaction of cyanogen bromide or chloride with pyridine and an aromatic amine. Aldridge's method utilises a pyridine/benzidine mixture reacting with cyanogen bromide; Epstein uses cyanogen chloride reacting with pyridine/1-phenyl-3-methyl-5-pyrazolone and a small amount of bis-(1-phenyl-3-methyl-5-pyrazolone). Other workers[12] have used a variation of the Aldridge procedure employing barbituric acid in place of benzidine.

The pyridine/pyrazolone colour development requires the preparation of a relatively unstable reagent, whilst the benzidine method has the distinct disadvantage that the aromatic amine is a well known active carcinogen and the developed colour only obeys Beer's law up to concentrations of the order of 1–2 μg/ml so that it cannot be used for effluents containing more than 2 ppm of cyanide in the measured sample. The barbituric acid method requires a relatively large sample (25 ml) and a relatively long period of heat treatment (40 min at 40°); furthermore, the reagent becomes discoloured on standing for short periods of time.

In view of these criticisms it was decided to reinvestigate the König synthesis as the basis of a method for the determination of cyanide, examining aromatic amines in addition to those considered by König for colour production, and heterocyclic amines other than pyridine as the parent reagent for dyestuff formation.

Examination of heterocyclic amines other then pyridine in the König synthesis

Replacement of pyridine by other heterocyclic amines and their reaction with benzidine and cyanogen bromide (produced from 1 μg of cyanide) produced the results shown in Table 1.

TABLE I

Amine	Colour obtained
Pyridine	Red
Piperidine	None
Morpholine	None
Piperazine	None
Quinoline	None
Isoquinoline	None
2,6-Lutidine	None
α-Picoline	Golden yellow

Apart from pyridine, only α-picoline produced a colour and in this case a much lower maximum absorbance was obtained. Pyridine is, therefore, the best common heterocyclic amine to use.

Examination of aromatic amines other than benzidine in the König synthesis

König synthesised dyes from a number of aromatic amines using pyridine and relatively large quantities of cyanogen bromide. Goris and Larsonneau[13] utilised this reaction for the characterisation of small amounts of pyridine, using aniline as the aromatic amine. One drop of pyridine, 1 drop of aniline and 50–100 mg of cyanogen bromide in 1–20 ml of water, when mixed, yield an intense red colour and a crystalline precipitate; but with traces of pyridine a yellow colour is first produced, which changes after 30–40 min to an orange colour. Přibyl[14] used benzidine instead of aniline for the determination of small amounts of pyridine in aromatic hydrocarbons, measuring the extinction of the solutions at 518 mμ. With only traces of cyanogen bromide, some amines produce different colours from those of the dyes originally synthesised by König. Accordingly, a number of amines were substituted for benzidine in the Aldridge procedure, and the colours produced by reaction with 1 μg of cyanide (as cyanogen bromide) were compared to the corresponding colours of the dyes reported by König (see Table II).

TABLE II

a. *Benzene derivatives*

Number	Amine	Colour of dye	
		As reported by König	Aldridge procedure
1	Aniline	Orange	Yellow, changing to orange (20 to 30 min)
2	*p*-Toluidine	Orange	Yellow, changing to orange (20 to 30 min)
3	*p*-Chloraniline	Orange	Yellow changing to orange (20 to 30 min)
4	*p*-Nitro-aniline	Orange	None detected

TABLE II (*continued*)

b. *Naphthalene derivatives*

Number	Amine	Colour of dye	
		As reported by König	Aldridge procedure
5	*o*-Anisidine	Salmon-pink, with yellowish-red fluorescence	Orange
6	*p*-Phenetidine	Rose-red	Orange, changing to pink
7	*o*-Aminophenol	Rose-red	None detected
8	*p*-Aminophenol	Rose-red	Yellow, changing to orange (20 to 30 min)
9	Anthranilic acid	Bright red, with yellowish-red fluorescence	Yellow, changing to pink (20 to 30 min); fading always occurs
10	Sulphanilic acid	Orange, with greenish fluorescence	Yellow
11	*p*-Aminobenzoic acid	Red	Yellow
12	*o*-Phenylenediamine	Red	Orange (detectable only by spectrophotometer)
13	*m*-Phenylenediamine	Red	None detected (reagent too strongly coloured; evidence of reaction when diluted 125 times)
14	*p*-Phenylenediamine	Red	Cherry-red
15	*p*-Bromo-aniline	—	Yellow
16	α-Naphthylamine	Rose-red	Yellow
17	β-Naphthylamine	Rose-red	Yellow, changing to orange

c. *Amino-azo-compounds*

18	Amino-azobenzene	Heliotrope	None detected

d. *Benzidine derivatives*

19	Benzidine	Lilac	Red
20	*o*-Dianisidine	Blue-violet	Red

TABLE II (*continued*)

e. *Miscellaneous amines not used by König*

Number	Amine	Aldridge procedure colour
21	*p*-Aminodiphenylamine	Cherry-red
22	*p*-Amino-*N*,*N*-dimethylaniline	Red
23	*p*-Acetamido-aniline	Yellow (fades during 10 to 20 min)
24	*p*-Amino-acetophenone	Yellow (fades during 20 to 20 min)
25	4,4'-Diaminodiphenylene oxide	Yellow (fades)
26	*N*-Benzyl-*p*-phenylenediamine	Yellow (fades)
27	*N*-(4-Aminophenyl)piperidine	Yellow[a]
28	*N*-(2-Aminophenyl)piperidine	Yellow[a]
29	*N*-(4-Aminophenyl)pyrrolidine	None detected (red solutions)
30	*N*-(2-Aminophenyl)pyrrolidine	Yellow[a]
31	*N*-(4-Aminophenyl)morpholine	Red
32	*N*-(2-Aminophenyl)morpholine	Yellow (fades rapidly)[a]
33	*N*-(4-Aminophenyl)piperazine	Orange
34	*N*-(2-Aminophenyl)piperazine	None detected (green solutions)
35	Diphenylamine	None detected
36	*p*-Cyclohexylaniline	Yellow, changing to pink (fades)
37	3-Amino-4-cyclohexylaniline	Yellow, changing to orange (fades)
38	4-Aminophenazone	Yellow (fades)
39	Rosaniline	Impossible to detect[b]
40	*N*-(1-Naphthyl)ethylenediamine	None detected
41	Benzylamine	None detected
42	2-Piperidino-3-aminopyridine	None detected
43	2-Pyrrolidino-3-aminopyridine	None detected
44	2-Morpholino-3-aminopyridine	None detected
45	3-Amino-4-morpholinopyridine	None detected
46	2-Aminopyridine	None detected

[a] Certain amines (Nos. 27, 28, 30, 32) only show evidence of reaction with 50 and 100 μg of cyanide (as cyanogen bromide).

[b] With a strongly coloured amine (No. 39), the initial solution is intensely coloured and reaction with 100 μg of cyanide is impossible to detect even at great dilution of the amine solution.

In every case where a yellow colour is produced initially, fading always occurs. Where an orange or red colour is obtained, fading is not so apparent. Therefore, from the amines investigated only *o*-anisidine, *p*-phenetidine, *p*-phenylenediamine, benzidine, *o*-dianisidine, *p*-aminodiphenylamine, *p*-amino-*N*,*N'*-dimethylaniline, *N*-(4-aminophenyl)morpholine and *N*-(4-aminophenyl) piperazine are worth further consideration. For comparison purposes 3-amino-4-cyclohexylaniline was also examined.

By dilution with cyanide-free water of a suitable stock solution, previously standardised with silver nitrate by potentiometric titration and by titration using *p*-dimethylaminobenzylidenerhodanine as indicator, the following 6 cyanide solutions were prepared for each of the 10 amines: (i) 0·0 μg, (ii) 0·1 μg, (iii) 0·2 μg, (iv) 0·5 μg, (v) 1·0 μg, and (vi) 2·0 μg of CN^-. These were examined using a method similar to the Aldridge procedure, the alkaline solutions of cyanide being acidified with 0·6 ml of glacial acetic acid, treated with 0·2 ml of saturated bromine water, mixed thoroughly, excess bromine in the solution removed with 0·2 ml of arsenious acid (2% w/v in water, refluxed until solution is complete) and bromine vapour in the tube removed by air. Before addition of mixed amine/pyridine reagent, the volume of solution was adjusted to 50·0 ml and a 5·0 ml-aliquot taken for the rest of the procedure.

Cyanide solution (v) was examined first in every case. A freshly prepared mixture of 3·0 ml of pyridine reagent (1 litre of 60% w/w aqueous pyridine plus 100 ml of concentrated hydrochloric acid) and 1·0 ml of amine reagent (0·1 g of amine dissolved in 50 ml of 0·5*M* hydrochloric acid; where difficulty was experienced in effecting solution, the mixture was heated to boiling point, cooled and filtered) was added and the absorbance of the solution measured between 450 and 550 mμ at different time intervals using a recording spectrophotometer to ascertain a suitable wavelength to use for each amine reagent. The other test solutions were then treated with the relevant mixed pyridine/amine solutions and the absorbances measured at the appropriate wavelength for each amine reagent, after 20 and 30 min, using a manual spectrophotometer. In most cases the wavelength chosen was that wavelength at which the spectral curve after 30 min crossed the spectral curve after 20 min (isosbestic point). The relatively low concentration of the amine reagent (0.2%) was chosen to enable some amines which were themselves highly coloured in more concentrated solution, to be included in any comparison tests. The same concentration was also used for the benzidine reagent.

Further tests were made altering the conditions simultaneously as follows:

1. The concentration of the amine reagent was increased to 1·0% for amines Nos. 1, 5, 6, 7 and 10.
2. The solutions containing cyanide were arranged so that a volume of 1·0 ml contained the cyanogen bromide before addition of mixed pyridine/amine reagent.

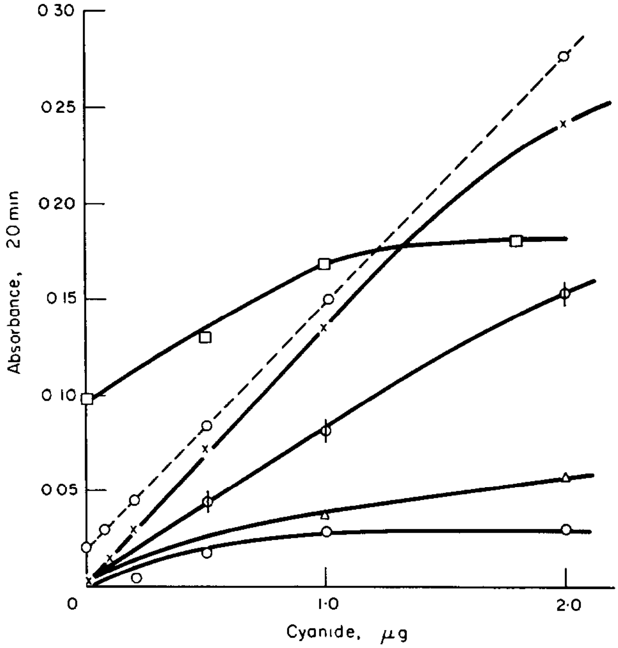

Fig. 1—Calibration curves using 0·2% amine reagents:

——×—— benzidine,
——○—— *o*-anisidine,
——△—— *o*-dianisidine,
——□—— *p*-amino-*N*,*N*-dimethylaniline,
——⏀—— *p*-phenetidine,
- - -○- - - *p*-phenylenediamine.

The results obtained with the 0·2 and 1·0% amine reagents are given in Tables III and IV, respectively, and the corresponding calibration curves in Figs. 1–3.

It appears that a number of amines would be satisfactory for the determination of concentrations of cyanide between 0·1 and 1·0 μg. For more concentrated cyanide solutions, however, the number of amines is restricted. The best amines are benzidine, *p*-phenylenediamine and *p*-aminodiphenylamine. Using the stated conditions and a concentration of 0·2% amine in 0·5*M* hydrochloric acid, *p*-phenylenediamine is the best of the three. At a higher amine concentration (1·0%), benzidine produces the most intense colour and has an absolute absorbance of 0·636 (2·0 μg of cyanide/1·0 ml test solution), whereas *p*-phenylenediamine has an absolute absorbance of only 0·540 but gives a better calibration curve than does benzidine (see Fig. 3). It was necessary at this junction to consider the carcinogenic properties of the amines.

Carcinogenic hazards of aromatic amines

The carcinogenic properties of benzidine are well known. Related compounds, such as 3,3′-dihydroxybenzidine, tetramethylbenzidine and dichlorobenzidine, and other binuclear compounds like 4-aminodiphenyl, 2,3-dimethyl-4-aminodiphenyl and

[b] Volume of final mixture of reagents: 5·0 ml.

naphthalene derivatives, such as 1-amino-2-naphthol, 2-amino-1-naphthol, α-naphylamine and β-naphthylamine, have been reported as being highly active.[15] Dianisidine and the tolidines are suspected of being carcinogenic.

Because there is no published evidence that amines with only a single ring are active, it was decided to confine further investigations to *p*-phenylenediamine.

Zusammenfassung—Die Farbstoffsynthese nach König, die Reaktion von Bromcyan nit geeigneten Aminen, die britischen und US-Standardmethoden zugrundeliegt, wird an 46 Aminen unter geeigneten Bedingungen nachgeprüft. Nach Erörterung der carcinogenen Eigenschaften von Aminen, die zur analytischen Bestimmung kleiner Cyanidmengen geeignet sind, wurde *p*-Phenylendiamin zur weiteren Untersuchung gewählt.

Résumé—Les auteurs ont repris l'étude de la synthèse de König des colorants dérivés de la pyridine, par action du bromure de cyanogène et d'amines aromatiques appropriées sur la pyridine, sur laquelle sont fondées les méthodes colorimétriques étalons britannique et américaine de détermination de petites quantités de cyanure. Tenant compte des propriétés cancérigènes des amines susceptibles d'être utilisées dans une telle méthode, ils ont choisi a p-phenylènediamine pour une étude plus poussée.

CHELATING RADIOMETRIC TITRATIONS BY ION EXCHANGE FOR DETERMINATION OF TRACES OF METALS

JIŘÍ STARÝ, JAROMÍR RŮŽIČKA and ADOLF ZEMAN
Department of Nuclear Chemistry, Faculty of Technical and Nuclear Physics
Praha 1, Břehová 7, Czechoslovakia

(*Received* 29 *July* 1963. *Accepted* 13 *October* 1963)

Summary—A new type of radiometric titration has been developed. Using EDTA solutions, the negatively charged or neutral metal chelates are formed, and these can easily be separated from the excess of unreacted metal ions using a cation exchanger. Titration curves are constructed from the activities of the eluates. The method has been used for the determination of microgram amounts of indium using ^{114m}In as an isotopic tracer, and for the determination of submicrogram traces of cobalt using the same indicator as a non-isotopic tracer.

IN radiometric titrations the radiotracer is involved in the chemical reaction which is the basis of the determination. The compound formed during the titration must be easily separated from the excess of the unreacted ions and the end-point is determined from the change in the activity of the residual solution or of the other phase. Two types of radiometric titration have previously been described. In precipitation titrations the second phase is a precipitate, and the end-point can be determined by the appearance of the activity in the aqueous phase, or by its disappearance from the aqueous phase, according to circumstances.[1] Precipitation titrations are difficult to apply, because of the necessity for handling precipitates, to less than milligram amounts and impossible at the submicrogram level.

Extractive titrations[2,3] are based on the formation of metal chelates which can be separated from the unreacted metal ions by solvent extraction. The end-point is determined similarly from the change in activity either of the aqueous phase or of the organic phase. This type of titration is far more sensitive, but has been applied only to a limited number of determinations.

In the present paper a new type of radiometric titration using EDTA is proposed and its utility is verified.

RADIOMETRIC TITRATIONS USING EDTA

EDTA titrations are widely used for determination of many metals, but their sensitivity is limited by the sensitivity of the determination of the end-point. However, using radiometric indication the determination of submicrogram amounts of metals can be carried out without difficulty.

Radiometric titrations using EDTA are based on the formation of negatively charged or neutral chelates which can easily be separated from the excess of the unreacted metal ions on a cation exchanger. The end-point is determined from the activities of the eluates obtained. As in other radiometric titrations, isotopic or non-isotopic tracers can be used. In the first case the radioactive indicator is a radioisotope of the element being determined. In the second case the titration of the element to be assayed is followed by means of an element which is chelated after all the metal being determined is bonded in the EDTA complex (*i.e.* the stability constant of the complex of the radioactive tracer with EDTA is much lower than that of the metal to be determined).

The optimum pH for the titration can be calculated from the basic theory given in our paper on isotope dilution by ion exchange.[4] From this theory it follows that the determination of metals forming very stable chelates (*e.g.*, Co^{III}, Zr^{IV}, Fe^{III}, In^{III}, Th^{IV}, *etc.*[5]) can be carried out at pH 2–3 using 10^{-6}–10^{-7} M EDTA solutions. The pH for the determination of metals having lower stability constants must, however, be much higher.

This method has been applied to the determination of microgram amounts of indium by means of an isotopic tracer, and to the determination of traces of cobalt using a non-isotopic tracer.

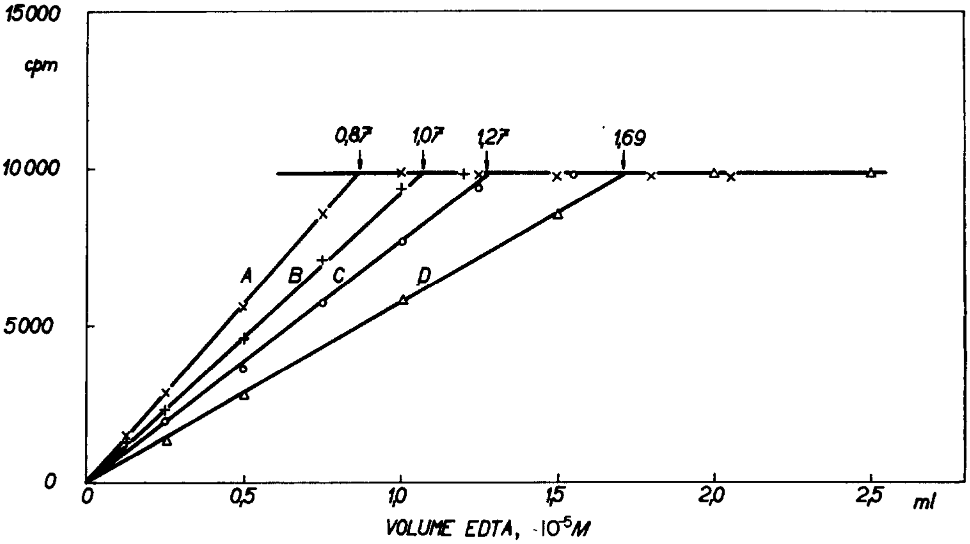

FIG. 1.—Radiometric titration of indium using ^{114}In tracer with $10^{-5}M$ EDTA solution: A—1·00 ml of radio-indium standard solution; B, C, D—1·00, 2·00, 4·00 ml of inactive indium solution mixed with 1·00 ml of radio-indium standard solution.

DETERMINATION OF TRACES OF INDIUM USING ISOTOPIC TRACER

Procedure

The pH of a series of equal, known volumes of analysed solution of indium (2·0 ml containing about 1 μg/ml), labelled with a known amount of radio-indium (^{114m}In, $t_{\frac{1}{2}} = 50$ days), is adjusted approximately to a value of 2–3. Any $iron^{III}$ present, which can interfere, is reduced to $iron^{II}$ by adding 2 drops of 10% ascorbic acid. The solutions thus prepared are carefully mixed with known, increasing amounts of titrating solution ($10^{-5}M$ EDTA) and are simultaneously passed through a series of cation-exchanger columns. The eluate from each column is made up to 10 ml and the activity of 4-ml aliquots are measured by a well-type scintillation counter. Each value of activity measured represents a point on the titration curve (Fig. 1).

The results obtained are also summarised in Table I. The amount of the indium in the non-active sample being analysed can be determined from the difference between the end-point of the standard curve, A (solution containing only standard labelled indium), and the end-points of the corresponding curves, B, C, D (solutions prepared by mixing the standard labelled samples with the sample to be analysed).

TABLE I.—DETERMINATION OF INDIUM

Curve	Indium added, μg	Radio-indium added, μg	Total indium present, μg	Total indium found, μg

D	0·88	1·02	1·90	1·94

DETERMINATION OF TRACES OF COBALT USING NON-ISOTOPIC TRACER

Because of much higher stability with EDTA of the cobalt^{III} complex than of the indium complex it is possible to use radio-indium as non-isotopic tracer for the determination of traces of cobalt.

Procedure

To the series of solutions containing equal, known volumes of the analysed solution (slightly acid), known, increasing amounts of EDTA ($10^{-5}M$) are added. Each of these solutions is carefully mixed in a polyethylene flask with 0·5 ml of 0·01M aqueous ammonia containing 1·5% hydrogen peroxide. The pH of the solutions thus prepared should be 6–8. The solutions are heated on a boiling water bath for 5 min (formation of Co^{III}-EDTA complex). After cooling to room temperature the pH of all the solutions is readjusted to approximately 2–3, and the radio-indium tracer is added. The remainder of the procedure is carried out as before.

The results obtained are given in Fig. 2 and Table II.

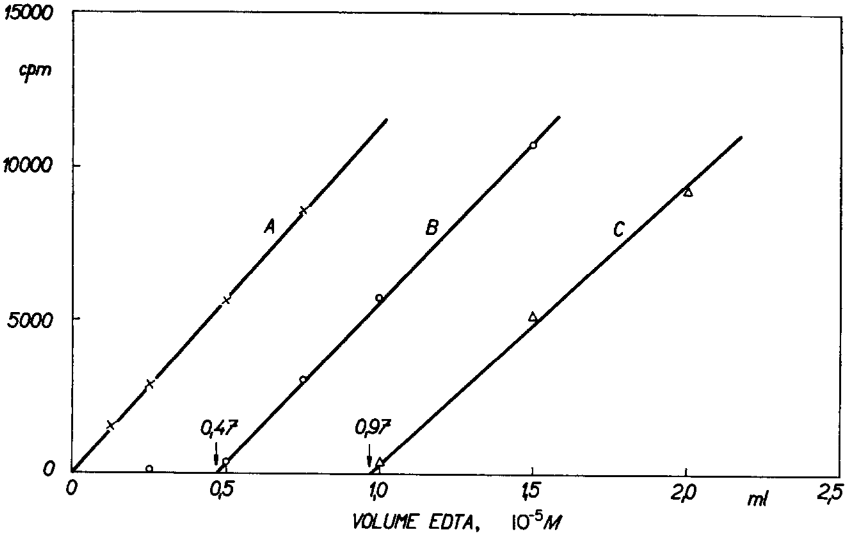

FIG. 2.—Radiometric titration of cobalt using ^{114}In tracer with $10^{-5}M$ EDTA solution: A—1·00 ml of radio-indium standard solution; B, C—1·00, 2·00 ml of inactive cobalt solution.

Curve	Cobalt added, μg	Cobalt found, μg
A	0·00	0·00
B	0·29	0·27
C	0·58	0·56

DISCUSSION

Radiometric titrations such as those described above can in general be used for the same determinations as common complexometric titrations, but their sensitivity is much higher. They have the advantage that the selectivity can be easily predicted from the stability data of EDTA-complexes, which are well known. Thus, for example, in the determination of traces of indium uni- and bivalent metal cations will not interfere, because of their lower stability constants. This has been verified in the present work. However, titrations using isotopic tracers are limited to instances where suitable radioisotopes are available. This restriction does not hold for determinations using non-isotopic tracers. The non-isotopic tracer most suitable for achieving the highest selectivity can also be chosen using the stability constants of the EDTA complexes. The stability constant of the EDTA complex of the tracer must be lower than that of the metal to be determined, but higher than the stability constants of interfering metals which might be present.

Compared with extractive titrations, radiometric titrations using EDTA have the advantage of high stability of the titrant even in very dilute solutions.

Acknowledgement—The authors thank Professor V. Majer, D. Sc. for his interest in this work and to Professor C. L. Wilson for his critical discussion.

Zusammenfassung—Eine neue Art radiometrischer Titration wurde entwickelt. Mit EDTA-Lösungen werden negative oder neutrale Metallchelate gebildet, die leicht mittels Kationenaustauscher von den nicht gebundenen Metallionen abgetrennt werden können. Die Titrationskurven werden aus der Aktivität der Eluate konstruiert. Die Methode wurde an der Bestimmung von Mikrogramm-Mengen Indium mit ^{114m}In als isotopem Tracer und an der Bestimmung von Submikrogramm-Mengen Kobalt mit ^{114m}In als nichtisotopem Tracer verifiziert.

Résumé—On a mis au point un nouveau type de titrage radiométrique. Par l'emploi de solutions d'EDTA, on forme les chélates du métal chargé négativement ou du métal neutre, et ceux-ci peuvent être. aisément séparés des ions en excès qui n'ont pas réagi au moyen d'un échangeur cationique. On trace des courbes de titrage à partir des activités des éluats. On a utilisé la méthode pour doser des quantités d'indium de l'ordre du microgramme par l'emploi de ^{114m}In comme traceur isotopique, ainsi que pour doser des traces de cobalt en quantités inférieures au microgramme au moyen du même indicateur, utilisé comme traceur non isotopique.

SOME SULPHUR-CONTAINING ORGANIC COMPOUNDS AS REAGENTS FOR THE PHOTOMETRIC DETERMINATION OF SELENIUM

A. I. BUSEV
Department of Chemistry, M. V. Lomonosov State University
Moscow, U.S.S.R.

(*Received* 29 *July* 1963. *Accepted* 11 *September* 1963)

Summary—The reactions of diethylphosphorodithioate, 2-mercaptobenzimidazole, *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine with selenous acid have been studied. Diethylphosphorodithioate and 2-mercaptobenzimidazole react with selenous acid in a 4:1 molar ratio, and with *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacelyl-*p*-toluidine in a 2:1 ratio. New extraction-photometric methods for the determination of small amounts of selenium in various materials not containing tellurium, have been developed, using 2-mercaptobenzimidazole, *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine as reagents.

THE photometric determination of selenium is carried out mainly in the form of a colloidal solution of elementary selenium or in the form of the piazselenol formed by the reaction of selenous acid with 3,3′-diaminobenzidine.[1,2] No other reagents have found practical application.[3]

Of sulphur-containing reagents it has been reported that selenous acid can react with diethyl phosphorodithioate[4] and with 2-thiopyrogallol,[5] giving yellow compounds which can be extracted with organic solvents. More recent experiments have shown[6,7,8] that many reagents containing sulphydryl groups react with selenous acid, forming yellow compounds which possess sufficient stability to be used for the determination of small amounts of selenium. Some of these reagents possess high sensitivity and selectivity.

In the present work the results are given of a study of the reaction of selenous acid with diethyl phosphorodithioate, 2-mercaptobenzimidazole, and some products of the condensation of thioglycollic acid with primary aromatic amines, together with the photometric methods developed for determining small amounts of selenium in various materials.

Diethyl phosphorodithioate, $(C_2H_5O)_2PSSH$

When an aqueous solution of nickel or potassium diethyl phosphorodithioate, $[(C_2H_5O)_2PSS]_2Ni$ or $(C_2H_5O)_2PSSK$, is added to an aqueous solution of selenous acid at an acidity of between about pH 3 and not greater than 2*M* in hydrochloric acid, a yellowish precipitate is formed. Under these conditions, selenium is quantitatively precipitated by an excess of the reagent. The compound formed consists of needle-shaped, bright yellow crystals with a melting point of 81–82°.[6] Chemical analysis (Se: 17·4%; P:13·6%; S:30·9%) shows that the compound corresponds to the formula $[(C_2H_5O)_2PSS]_2Se$. Therefore selenous acid appears to react with nickel diethyl phosphorodithioate according to the equation:

$$2[(C_2H_5O)_2PSS]_2Ni + H_2SeO_3 + 4HCl \rightarrow [(C_2H_5O)_2PSS]_2Se + [(C_2H_5O)_2PSS]_2 + 2NiCl_2 + 3H_2O.$$

The diethyl phosphorodithioate salt of bivalent selenium is completely stable. In the dry state it can be kept in diffuse daylight for not less than 4 months without visible changes. Its solutions in chloroform have been kept without change for 1 year. Unfortunately, nickel diethyl phosphorodithioate cannot be used to determine selenium either by the gravimetric method (the precipitation takes place slowly) or by the photometric method {the disulphide $[(C_2H_5O)_2PSS]_2$ formed strongly interferes with the photometric determination of the selenium (Fig. 1)}, although the reagent is quite sensitive: the molar absorption coefficient of extracts of the diethyl phosphorodithioate salt of bivalent selenium is 1900.

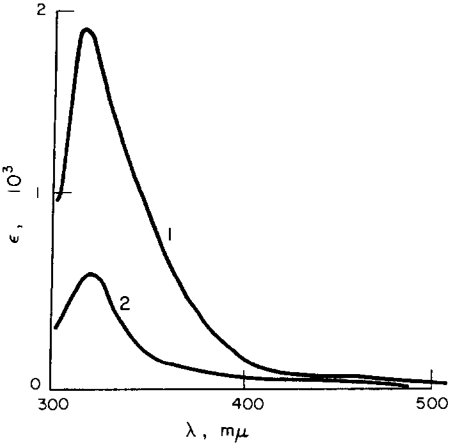

FIG. 1—Absorption curves of the diethyl phosphorodithioate salt of bivalent selenium (1) and the disulphide $[(C_2H_5O)_2PSS]_2$ (2).

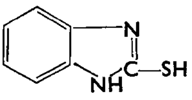
2-Mercaptobenzimidazole,



2-Mercaptobenzimidazole has been used for the gravimetric determination of bismuth, copper, cadmium, lead, mercury and gold.[9] Experiments have now shown that 2-mercaptobenzimidazole permits the photometric determination of small amounts of selenium. When a 1 % ethanolic solution of 2-mercaptobenzimidazole is added to an acid solution [the optimum optical density is found at an acidity of from 1 to 3*M* hydrochloric acid (Fig. 2)] of selenous acid, it gives a yellow coloration or a bright yellow crystalline precipitate, depending on its concentration. The compound formed is not extracted by benzene, toluene or ether, is poorly extracted by isoamyl and isobutyl alcohols, is somewhat better extracted by dichloroethane and chloroform, and is well extracted by a 1:5 mixture of butyl alcohol and chloroform, the coloration being very stable. It does not change during several months. The extraction takes place practically completely in a single treatment.

It has not been possible to isolate in the pure state and analyse the compound formed by the reaction of selenous acid with 2-mercaptobenzimidazole, because when it is filtered on paper it decomposes after some minutes with the liberation of red elementary selenium.

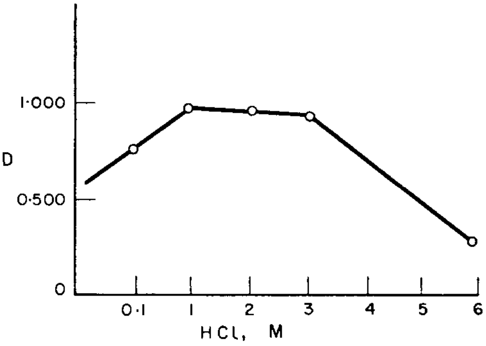


FIG. 2.—Absorption at 335 mμ of the compound of selenium with 2-mercaptobenzimidazole as a function of the acidity of the solution.

The extracts of the compound of 2-mercaptobenzimidazole with selenous acid in a 1:5 mixture of butyl alcohol and chloroform have a maximum light absorption at 330 mμ. The optical density was measured relative to the pure extractant (Fig. 3). If the optical density is measured relative to an extract of the reagent with a mixture of butyl alcohol and chloroform, the maximum light absorption is found at 335 mμ.

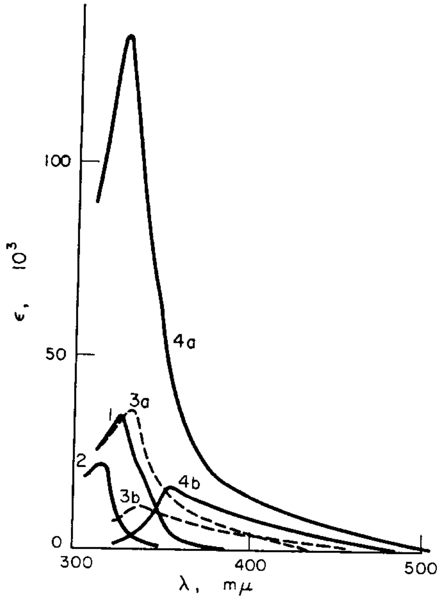

FIG. 3.—Absorption curves of 2-mercaptobenzimidazole (1), $(C_7H_5N_2S)_2$ (2), and the compounds of 2-mercaptobenzimidazole with selenium (3a, 3b) and with tellurium (4a, 4b) relative to the pure extractant (3a, 4a) and relative to an extract of the reagent (3b, 4b).

Under the experimental conditions, the reagent is itself extracted to a large extent and it absorbs light intensely; its maximum absorption is at 325 mμ (Fig. 3). The molar absorption coefficient of extracts of the compound of selenium with 2-mercaptobenzimidazole was found to be 10,500.

The method of isomolar series has shown that selenous acid reacts with 2- mercaptobenzimidazole in a molar ratio of 1:4. This suggests that the reaction between selenous acid and 2-mercaptobenzimidazole takes place according to the equation:

$$4C_7H_6N_2S + H_2SeO_3 \rightarrow (C_7H_5N_2S)_2Se + (C_7H_5N_2S)_2 + 3H_2O.$$

Extracts of the compound of selenium with 2-mercaptobenzimidazole obey Beer's law within the range of concentrations from 1 to 10 μg/ml at 360–380 mμ and 1–40 μg/ml at 420 mμ (Fig. 4). Satisfactory results for the determination of selenium are obtained by measuring the optical density of extracts of its compound with 2-mercaptobenzimidazole in the region of wavelengths greater than 360 mμ or, best, at 420 mμ. At wavelengths less than 360 mμ, the reagent itself absorbs light and thereby prevents satisfactory results being obtained.

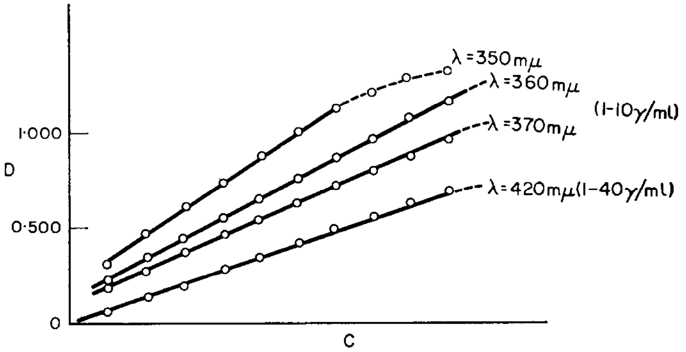

Fig. 4.—Obedience to Beer's law of the compound of selenium with 2-mercaptobenzimidazole at various wavelengths.

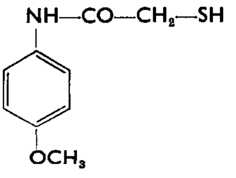
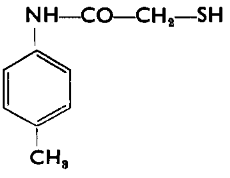
Derivatives of thioglycollic acid

A series of derivatives of thioglycollic acid, RNH-CO-CH_2-SH, (where R is -$C_6H_4OCH_3$-*p*, -$C_6H_4CH_3$-*p*, -C_6H_4Cl-*m*, -$C_6H_4NO_2$-*m*, *etc.*) has been used for the detection and gravimetric and photometric determination of silver, lead, mercury^{I}, mercury^{II}, copper, cadmium, bismuth, tin, zinc, cobalt, nickel and molybdenum.[10,11] Experiments have now shown that some of these derivatives can be used for the photometric determination of small amounts of selenium. As examples, the results are given of a study of two derivatives of thioglycollic acid obtained by the condensation of the latter with *p*-anisidine and *p*-toluidine, respectively:



N-mercaptoacetyl-*p*-anisidine



N-mercaptoacetyl-*p*-toluidine

When a solution of selenous acid is added to an acid solution of either of these reagents [the optimum optical density is found at an acidity of 0·05–1M hydrochloric acid in the case of *N*-mercaptoacetyl-*p*-anisidine and 0·05–0·5M hydrochloric acid in the case of *N*-mercaptoacetyl-*p*-toluidine (Fig. 5)], a yellow coloration or pale yellow turbidity or precipitate is immediately formed which can be extracted with many organic solvents: benzene, chloroform, *etc.* The extracts are yellow and are very stable. The extraction of selenium in the form of the coloured compounds takes place practically completely in a single extraction with a 1:5 mixture of butyl alcohol and chloroform.

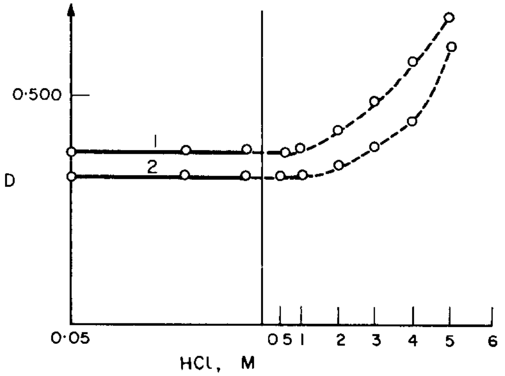


Fig. 5.—Absorption of the compounds of selenium with *N*-mercaptoacetyl-*p*-anisidine (1) and *N*-mercaptoacetyl-*p*-toluidine (2) as a function of the acidity of the solution.

The absorption curves of the extracts of the compound of selenium with *N*-mercaptoacetyl-*p*-anisidine have a maximum at 310 mμ relative to the pure extractant and at 315 mμ relative to an extract of the reagent (Fig. 6). The extract of the reagent itself under the experimental conditions also absorbs light intensely; its absorption curve has a maximum at 306 mμ (Fig. 6).

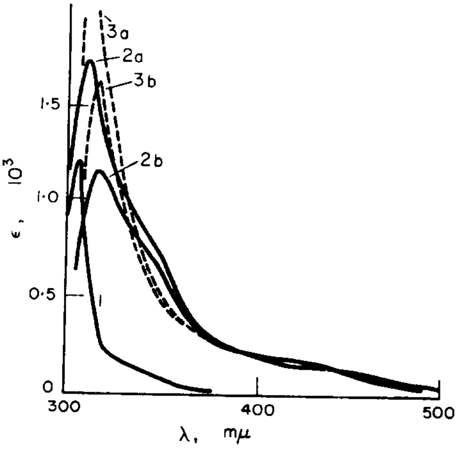

Fig. 6.—Absorption curves of *N*-mercaptoacetyl-*p*-anisidine (1) and its compounds with selenium (2a, 2b) and with tellurium (3a, 3b) relative to the pure extractant (2a, 3a) and to an extract of the reagent (2b, 3b).

N-Mercaptoacetyl-*p*-toluidine is also extracted well under the experimental conditions, but its extract absorbs light very feebly and therefore all the absorption curves of extracts of the compound of selenium with *N*-mercaptoacetyl-*p*-toluidine relative to the pure extractant and relative to an extract of the reagent have maxima in the same position at 318 mμ (Fig. 7). The molar absorption coefficients of the compounds of selenium with *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine are similar at 1200.

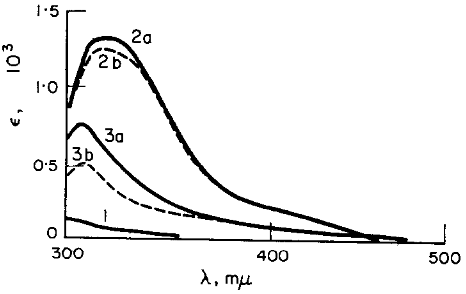

FIG. 7.—Absorption curves of *N*-mercaptoacetyl-*p*-toluidine (1) and its compounds with selenium (2a, 2b) and with tellurium (3a, 3b) relative to the pure extractant (2a, 3a) and to an extractant of the reagent (2b, 3b,).

The molar ratio in which selenous acid reacts with these reagents was found to be 1:2 (Fig. 8). Thus selenous acid probably reacts according to the following equations:

$$2C_9H_{11}O_2NS + H_2SeO_3 \rightarrow (C_9H_{10}O_2NS)_2SeO + 2H_2O$$

$$2C_9H_{11}ONS + H_2SeO_3 \rightarrow (C_9H_{10}ONS)_2SeO + 2H_2O.$$

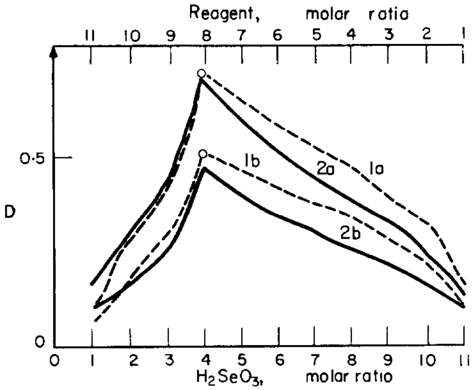

FIG. 8.—Determination of the molar ratios in the reaction of selenous acid with *N*-mercaptoacetyl-*p*-anisidine (1a, 1b) and *N*-mercaptoacetyl-*p*-toluidine (2a, 2b) at 340 mμ (1a, 2a) and 360 mμ (1b, 2b).

It has not been possible to isolate in the pure state and analyse the selenium compounds formed because they are unstable. After they have been filtered, red selenium appears on the filter after a few minutes.

Extracts of the compounds of selenium with *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine obey Beer's law within the range of concentrations from 8 to 70 μg/ml at wavelengths from 340 mμ to 380 mμ. At wavelengths greater than

380 mμ, the extracts still follow Beer's law, but the sensitivity is considerably less. At wavelengths less than 340 mμ, *N*-mercaptoacetyl-*p*-anisidine itself absorbs light and thereby prevents satisfactory results being obtained. In the case of *N*-mercaptoacetyl-*p*-toluidine, the lower limit of obedience of the extracts to Beer's law can be reduced to concentrations below 7 μg/ml, but it is then necessary to work with a hydrogen lamp.

It must be mentioned that 2-mercaptobenzimidazole, *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine permit the determination of selenium only in the absence of tellurium. Tellurous acid, as can be seen from Figs. 3, 6 and 7, behaves completely analogously to selenous acid under the experimental conditions. It reacts with the reagents mentioned, likewise forming either a yellow coloration or a precipitate. The tellurium compounds formed are also extracted by organic solvents. The light-absorption maxima of the extracts of the tellurium compounds and the corresponding selenium compounds are very close to one another (Table I). Consequently, in order to determine selenium in materials containing tellurium, the latter must previously be removed.

TABLE I.—ABSORPTION MAXIMA OF COMPOUNDS OF SELENIUM AND TELLURIUM WITH VARIOUS REAGENTS

Reagent	λ_m(Se)	λ_m(Te)
2-Mercaptobenzimidazole	335	350
N-Mercaptoacetyl-*p*-anisidine	315	325
N-Mercaptoacetyl-*p*-toluidine	318	308

Bismuth and copper interfere with the determination of selenium by the proposed reagents, with which they form either greyish-yellow or pale yellow precipitates which are partially extractable with organic solvents, giving yellow extracts. Moderate amounts of mercury, silver, gold, cadmium and lead cause practically no interference. Bromate and iodate interfere with the determination of selenium with 2-mercaptobenzimidazole, and molybdate interferes with its determination by means of *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine.

Determination of selenium in various materials not containing tellurium

A 0·1 to 0·5-g sample of the material to be analysed is dissolved by means of a mixture of nitric, hydrochloric and sulphuric acids.[12] Any excess of nitrous acid is removed by the addition of urea.[13] The resulting solution is diluted with twice its volume of distilled water and any insoluble residue is filtered off through a loose filter. The filtrate is diluted in volumetric flasks with appropriate volumes of water to give concentrations of selenium in the resulting solution within the range 50 to 200 μg/ml.

One-five ml of the solution to be analysed is added by means of a pipette to an acid solution of the reagents namely 3 ml 1% ethanolic solution of 2-mercaptobenzimidazole, or 3 ml 0·2% ethanolic solution of *N*-mercaptoacetyl-*p*-anisidide or *N*-mercaptoacetyl-*p*-toluidine (final concentration 2*M* hydrochloric acid in the case of 2-mercaptobenzimidazole and 0·5*M* hydrochloric acid in the case of *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine) in a separating funnel and the mixture is well shaken, then extracted with 5 ml of a 1:5 mixture of butyl alcohol and chloroform. It is left to stand for 1 hr for complete separation of the aqueous and organic phases. The extracts are filtered through a dry filter paper into 10·00-mm cells and the optical density measured on a spectrophotometer Beckman DU at the appropriate wavelength (420 mμ for 2-mercaptobenzimidazole and 360 mμ for *N*-mercaptoacetyl-*p*-anisidine and *N*-mercaptoacetyl-*p*-toluidine). The selenium content is found from a calibration curve.

Calibration curves are obtained as above, using different amounts of a standardised solution of selenous acid. The completion of a single selenium determination requires 4 hr.

Some results for the determination of selenium are given in Tables II, III and IV.

Zusammenfassung—Die Reaktion von Diäthylphosphorodithioat, 2-Mercaptobenzimidazol, N-Mercaptoacetyl-*p*-anisidin und N-Mercaptoacetyl-p-toluidin mit seleniger Säure wurden untersucht. Die ersten zwei Verbindungen reagieren mit seleniger Säure im Verhältnis 4:1, die andern beiden im Verhältnis 2:1. Neue extraktionsphotometrische Methoden zur Bestimmung kleiner Selenmengen in verschiedenen nicht tellurhaltigen Materialien wurden entwickelt mit 2-Mercaptobenzimidazol, N-Mercaptoacetyl-p-anisidin und N-Mercaptoacetyl-p-toluidin als Reagentien.

Résumé—On a étudié des réactions du diéthylphosphorodithioate, de la mercapt-2-benzimidazole, de la N-mercaptoacétyl-p-anisidine et de la N-mercaptoacétyl-p-toluidine, avec l'acide sélénieux. Le diéthylphosphorodithioate et la mercapto-2-benzimodazole réagissent avec l'acide sélénieux dans le rapport moléculaire de 4/1. La N-mercaptoacétyl-p-anisidine et la N-mercapto-p-toluidine réagissent dans le rapport 2/1. Etude de nouvelles méthodes photométriques d'extraction pour le dosage de petites quantités de sélénium dans des produits variés et ne contenant pas de tellure; on utilise la mercapto-2-benzimidazole, la N-mercaptoacétyl-p-anisidine et la N-mercaptoacétyl-p-toluidine comme réactifs.

ANION-EXCHANGE BEHAVIOUR OF SCANDIUM IN CHLORIDE-THIOCYANATE MEDIA

HIROSHI HAMAGUCHI, NAOKI ONUMA, MASANORI KISHI and ROKURO KURODA
Department of Chemistry, Tokyo Kyoiku University, Koishikawa, Tokyo, Japan

(*Received* 29 *July* 1963. *Accepted* 22 *October* 1963)

Summary—A method is described for the separation of scandium from rare earths and thorium by anion exchange. The method utilises the adsorption of a negatively-charged thiocyanato complex of scandium on the strongly-basic anion exchanger Dowex 1-X8 from a $2M$ solution of ammonium thiocyanate in $0{\cdot}5M$ hydrochloric acid. Rare earth elements are not retained on the column, while scandium and thorium show moderate adsorptions and can be separated chromatographically by elution with $3M$ hydrochloric acid. The distribution coefficient data for elements in this medium suggest many possible analytical separations of scandium.

MOST ion-exchange separations of scandium have been based on the use of cation exchangers with eluents containing an organic complexing agent. Thus, elution with citric acid,[1] nitrilotriacetic acid,[2] ethylenediaminetetra-acetic acid,[2] hydrazine diacetic acid[3] and ammonium acetate-ammonium oxalate solution[4] seem to provide an excellent cation-exchange separation of scandium from rare earth elements. There has been little published information about the effective anion-exchange separation of scandium from rare earths and thorium. Vickery[5] has demonstrated that scandium in citrate or oxalate solution is adsorbed on an anion-exchange resin. Scandium is also weakly adsorbed from $13{\cdot}3M$ hydrochloric acid, which affords the basis of a simple separation from rare earths,[6] but thorium also behaves like scandium. Walter[7] has effected the separation of scandium, titanium and vanadium by anion exchange from oxalic-hydrochloric acid mixtures and Schindewolf and Irvine[8] worked out the separation of traces of scandium from the same elements by anion exchange from 0·5 to $15M$ hydrofluoric acid solution. The adsorption of several metals, including scandium, on Dowex-1 from potassium thiocyanate solution has been reported by Turner, Philp and Day,[9] the separation of scandium and chromium having been accomplished. In a recently published study Fritz and Pietrzyk[10] have reported distribution coefficients for dysprosium, lanthanum and scandium in mixtures of hydrochloric acid and several alcohols. Yttrium and scandium were separated from lanthanum in hydrochloric acid-ethanol mixtures by Wilkins and Smith,[11] while Faris and Warton[12] worked out an extensive spectrographic determination of distribution coefficients for scandium, yttrium and rare earths in nitric acid-methanol mixtures, giving a promising separation factor for scandium from rare earths.

A study of the anion-exchange behaviour of scandium in an ammonium thiocyanate-hydrochloric acid system was, therefore, undertaken to provide information which would give a method for the sharp separation of scandium from the whole of the lanthanide elements and thorium as well as from several common metals.

EXPERIMENTAL

Ion-exchange resin

Dowex 1-X8, 100–200 mesh, was used in the thiocyanate form. Before use the resin was placed in a large column and back-washed with distilled water to remove fine particles. It was then washed with 3*M* hydrochloric acid, followed by a sufficient amount of 3*M* ammonium thiocyanate solution to convert it to the thiocyanate form. After washing with distilled water the resin was dried at 50° for 1 hr, then placed in a large desiccator containing saturated potassium bromide solution.

Resin column

Ten g of dried resin were slurried with distilled water and poured into a conventional ion-exchange column, 1·1 cm in diameter, packed at the bottom with glass wool. The column bed usually had a height of approximately 18 cm. Eluent was added dropwise from a conventional separatory funnel attached to the top of the column through a rubber stopper.

Reagents and tracer

Scandium^{III} solution (0·600 mg of scandium/ml) was made by dissolving *ca.* 100 mg of 99·9% purity Sc_2O_3 in 3*M* hydrochloric acid, evaporating to dryness and diluting to 100 ml with 0·5*M* hydrochloric acid. Lanthanum and lutetium chloride solutions (2·85 mg of lanthanum/ml; 1.83 mg of lutetium/ml) were prepared by dissolving the appropriate amount of the respective oxide (99·9% purity) in 3*M* hydrochloric acid, evaporating to dryness and diluting to a definite volume with 0·5*M* hydrochloric acid. Thorium chloride solution (4·85 mg of thorium/ml) was made by simply dissolving *ca.* 820 mg of thorium chloride in 100 ml of 0·5*M* hydrochloric acid.

The strengths of the above solutions were determined by titration with 0·001*M* EDTA solution previously standardised against primary-standard zinc metal. All other reagents used were of analytical-reagent quality.

^{46}Sc (half-life 85 day) and ^{160}Tb (73 day) tracers were produced by irradiating 40 mg of the appropriate oxide in the Japan Research Reactor JRR-1 for 15 hr at a power level of 50 kW and a neutron flux of 3×10^{11} neutron.cm^{-2}.sec^{-1}. After cooling for a sufficient period of time each oxide was dissolved in hydrochloric acid, evaporated to dryness and the residue taken up in 0·5*M* hydrochloric acid to give a final volume of 100 ml. An aliquot, usually 0·5 ml for scandium and 1 ml for terbium, was used for elution work. A 0·5*M* hydrochloric acid solution of carrier-free ^{152}Eu (13 year) was obtained commercially. An aliquot was taken, evaporated and diluted to 100 ml of 0·5*M* hydrochloric acid, to give a suitable level of activity. Each tracer was carefully checked for radiochemical purity before use by gamma spectrometry.

Column separation of scandium

A sample solution containing scandium and rare earth or thorium is evaporated and taken up in a minimum amount of 2*M* ammonium thiocyanate in 0·5*M* hydrochloric acid. The resin bed should be previously equilibrated with the same solution. Load the sample solution onto the top of the column. When the liquid level in the column has almost reached the top of the resin bed, elution is started with 3*M* hydrochloric acid at room temperature. The rate of flow of eluent through the column is adjusted to be approximately 0·17 ml/min and the effluent is collected in 5- or 10-ml fractions. These fractions are transferred to a beaker, diluted with water and titrated with 0·001*M* EDTA using Xylenol Orange as indicator. In the cases of separation of europium or terbium from scandium a quantitative measure of their concentration in the effluent fractions is obtained by counting the respective total gamma activity using a standard well-type scintillation counter.

RESULTS AND DISCUSSION

Like hydrochloric acid, thiocyanic acid (a pseudohalogenic acid), forms stable thiocyanato complexes with a number of metals and it has been put to analytical use in connection with solvent extraction using diethyl ether. Some attention[9,13,14,15,16] has been paid to the use of thiocyanate with or without hydrochloric acid in ion-exchange separations. Korkisch and Hecht[16] devised a separation of gallium, iron and aluminium, by the use of a thiocyanate elution system. In a weakly acid solution gallium and iron form negatively-charged thiocyanato complexes which are adsorbed on an anion-exchange column, while aluminium passes through the column with no sign of adsorption. Gallium and iron are then chromatographically desorbed by elution with hydrochloric acid which decreases the stability of the respective thiocyanato complexes.

It is of interest to note here that the elution system enhances the tendency of scandium and thorium to behave as anionic species; from a hydrochloric acid medium both elements do not show any marked adsorption on an anion-exchange resin.

Fig. 1 illustrates the quantitative elution profile curves when scandium and rare

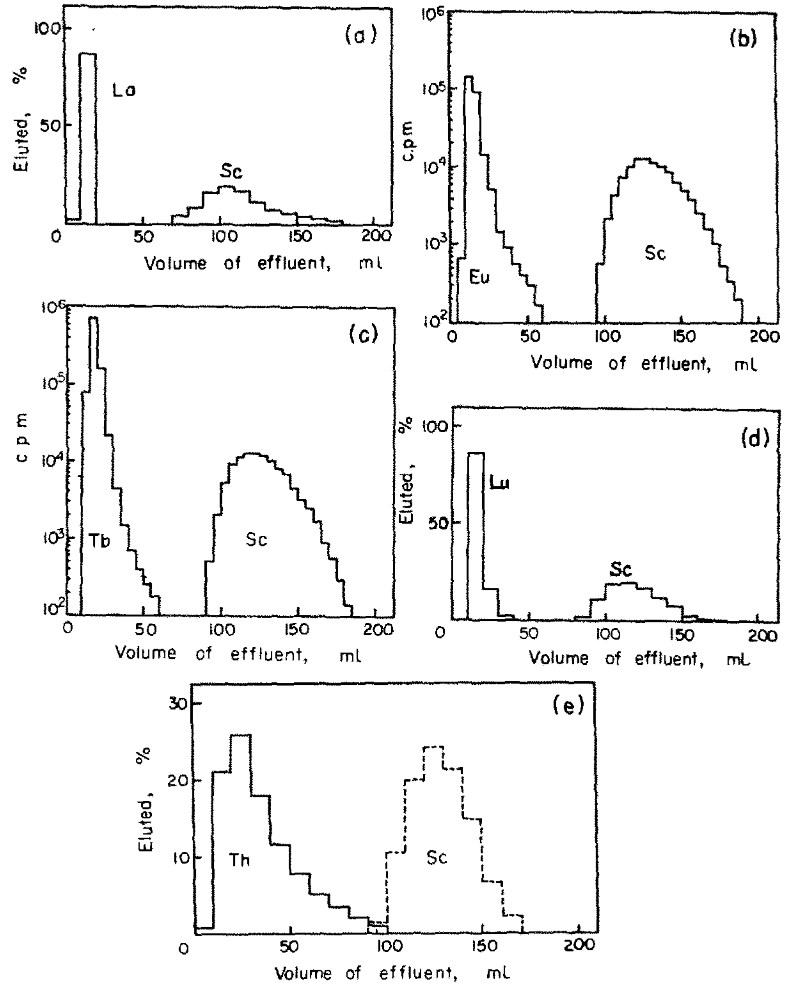

FIG. 1.—Elution profile curves

(*a*) The elution with 3*M* HCl of La and Sc from an 18 × 1·1 cm column of Dowex 1 X8, 100–200 mesh, previously treated with 2*M* NH_4SCN in 0·5*M* HCl. La 2·9 mg, Sc 0·6 mg present with recovery of 98% for La and 99% for Sc.

(*b*) The elution with 3*M* HCl of ^{152}Eu and ^{46}Sc from the same column as in (*a*). Eu carrier-free, Sc 130 μg present with recovery of 87% for Eu and 98% for Sc.

(*c*) The elution with 3*M* HCl of ^{160}Tb and ^{46}Sc from the same column as in (*a*). Tb 350 μg, Sc 130 μg present with recovery of 99% for Tb and 99% for Sc.

(*d*) The elution with 3*M* HCl of Lu and Sc from the same column as in (*a*). Lu 1·8 mg, Sc 0·6 mg present with recovery of 100% for Lu and 98% for Sc.

(*e*) The elution with 3*M* HCl of Th and Sc from the same column as in (*a*). Th 4·9 mg, Sc 0·6 mg present.

TABLE I.—DISTRIBUTION COEFFICIENT OF SOME ELEMENTS IN NH_4SCN-HCl MEDIUM ON DOWEX 1-X8

Element	Concentration of NH_4SCN in 0·5*M* HCl, *M*				
	0·2	0·4	0·6	0·8	1·0
Sc	56	250	905	5040	2818
La	<1	<1	<1	<1	<1

Cu	$>10^4$	$>10^4$	$>10^4$	$>10^4$	$>10^4$
Zn	$>10^4$	$>10^4$	$>10^4$	$>10^4$	$>10^4$
Cd	$>10^4$	$>10^4$	$>10^4$	$>10^4$	$>10^4$
In	579	646	734	580	706
Hg	$>10^4$	$>10^4$	$>10^4$	$>10^4$	$>10^4$

Kd value of Sc in 2*M* NH_4SCN—0·5*M* HCl is $>10^4$.

TABLE II.—SEPARATION OF SCANDIUM FROM OTHER ELEMENTS IN NH_4SCN-HCl MEDIUM

Scandium µg		Foreign ions used, *mg*		Foreign ions		Remark
Taken	Found			Break-through	Elution complete	
600	598	Al	3·4	0	60	Al eluted first, then Sc with 3*M* HCl.
600	599	Ca	2·0	0	60	Ca eluted first, then Sc with 3*M* HCl.
600	601	Fe	1·0	—	—	Sc eluted first with 3*M* HCl; Fe strongly adsorbed on resin.
600	592	Zn	1·3	210	300	Sc eluted first with 3*M* HCl, then Zn with H_2O.
600	588	Cd	1·1	210	300	Sc eluted first with 3*M* HCl, then Cd with H_2O.
600	594	In	1·8	210	270	Sc eluted first with 3*M* HCl, then In with 0·005*M* HCl.
600	592	La	2·9	0	20	La eluted first, then Sc with 3*M* HCl.
600	588	Lu	1·8	10	40	Lu eluted first, then Sc with 3*M* HCl.

earth or thorium are eluted by 3*M* hydrochloric acid. It can be seen that scandium can be separated successfully from lanthanum, europium, terbium and lutetium. Scandium tends to give slightly asymmetrically-shaped elution bands. This would result either from rather slow approach to exchange equilibrium or from non-linearity of the adsorption isotherm. According to an equilibrium study by a batch method it takes more than 20 hr for scandium to attain exchange equilibrium in the anion exchanger-thiocyanic acid system at room temperature.

In cation-exchange chromatography with elution by hydrochloric acid-ammonium thiocyanate, heavy rare earth elements ranging from europium to lutetium can be separated from scandium with difficulty.[14] Extreme difficulty has been encountered in separating scandium from heavier rare earths, even in lactate, citrate and EDTA eluent systems coupled with a cation exchanger. Scandium is eluted between thulium and erbium in close proximity to thulium in the form of a complex with EDTA by anion-exchange chromatography.[17] The anion-exchange separation of scandium presented here is likely to offer a simple, rapid and convenient way to separate scandium successfully with a rather shorter column.

The separation of thorium is not very satisfactory, but it may be achieved by the use of a slightly longer column or, more effectively, by the proper choice of eluent system, say 0·2*M* ammonium thiocyanate in 0·5*M* hydrochloric acid. In this case it is preferable to desorb scandium with hydrochloric acid after elution of the thorium fraction in order to minimise the tailing of scandium elution.

In Table I the weight distribution coefficient values, Kd, are given for several elements.

Increasing the concentration of thiocyanate resulted in an increased adsorption of scandium and thorium. The adsorption of scandium was found to be almost independent of the concentration of hydrochloric acid over the range 0·25*M* to 2·0*M*. The feasibility of the separation of scandium from common metal ions was investigated briefly. In Table II several of the results obtained are recorded. Scandium is completely eluted by a 130 ml-fraction of 3*M* hydrochloric acid, while the breakthrough of aluminium and calcium occurred in the effluent from the sample solution. Because iron, copper, indium and mercury are not desorbed with 3*M* hydrochloric acid, the separation of scandium from most metal ions which form strong thiocyanato complexes should be feasible.

Zusammenfassung—Eine Methode zur Trennung von Scandium von seltenen Erden und Thorium durch Anionenaustausch wird beschrieben. Dabei wird der negativ geladene Rhodanokomplex von Scandium am stark basischen Anionenaustauscher Dowex 1-X8 aus einer Lösung mit 2m NH_4SCN und 0,5m HCl adsorbiert. Seltene Erden werden auf der Säule nicht zurückgehalten, Scandium und Thorium werden mäßig stark adsorbiert und können chromatographisch durch Elution mit 3m HCl getrennt werden. Die Verteilungskoeffizienten für verschiedene Elemente in diesem Medium weisen auf viele mögliche analytische Abtrennungsverfahren für Scandium hin.

Résumé—On décrit une méthode de séparation du scandium des terres rares et du thorium par échange d'anions. La méthode utilise l'adsorption, sur l'échangeur anionique fortement basique Dowex 1-X8, d'un complexe sulfocyané du scandium chargé négativement, à partir d'une solution 2*M* de sulfocyanure d'ammonium en acide chlorhydrique 0,5*M*. Les éléments des terres rares ne sont pas retenus sur la colonne, cependant que le scandium et le thorium sont moyennement adsorbés et peuvent être séparés chromatographiquement par élution à l'acide chlorhydrique 3M. Les données sur les coefficients de distribution des éléments dans ce milieu suggèrent de nombreuses séparations analytiques possibles du scandium.

(*Eingegangen am* 29 *Juli* 1963. *Angenommen am* 13 *September* 1963)

Zusammenfassung—Anhand einer Möglichkeit, die vorher grundsätzlich aufgeklärt war, wurde eine photometrische Methode zur Bestimmung geringer Goldmengen mit *N,N'*-Tetramethyl-*o*-tolydin (Tetron) entwickelt. Das Gold wurde von den Begleitelementen zunächst durch Mitfällung mit Tellur, ferner durch Extraktion mit Äther aus Bromwasserstoffsäurem Medium getrennt und schliesslich mit Tetronlösung behandelt. Es entstand eine orangegelbe Färbung, die in etwa 4 Minuten zur vollen Intensität gelangte. Man verdünnte und photometrierte bei Blaulichtfilter. Die Färbung blieb 20 bis 25 Minuten bestehen, verblasste dann allmählich. Das Verfahren wurde zur Bestimmung von Gold in Kupfer-, Blei- und gemischten Konzentraten sowie im Anodenkupfer verwendet. Die Aussagen wurden statistisch ausgewertet.

BEKANNT sind zahlreiche Farbreaktionen für Gold(III)-ionen mit verschiedenen organischen Reagentien.[2–18] Den meisten von ihnen liegen photometrische Methoden zur Bestimmung geringer Goldmengen zugrunde. Eine kritische Bewertung derselben ergibt,[19] dass am empfindlichsten diejenige ist, bei der das o-Tolydin als Reagens verwendet wird.

Unsere Untersuchungen zeigten,[1] dass *N,N'*-Tetramethyl-o-tolydin (Tetron) etwa zweimal so empfindliche Reaktionen bewirkt als das o-Tolydin; auch ist hierbei die Färbung seiner Oxydationsform tiefer und nachhaltiger. Der Extinktionskoeffizient der unter der Einwirkung von Gold(III)-ionen entstandenen Oxydationsform des Tetrons beträgt 50,000 bei Blaulichtfilter des ФЭК–М. Die Geschwindigkeit des Redoxprozesses hängt von der Acidität des Mediums ab. In schwefelsaurem Medium (1 :20) kommt die Färbung zur vollen Entwicklung in 3 bis 4 Min., bleibt 20 bis 25 Min. unverändert und verblasst dann allmählich. Direktes Sonnenlicht beschleunigt die Entfärbung, daher sind die Lösungen davor zu schützen.

Dass hierbei Fe(III), Cu, Mn(II), Pb, As, Sb, Sn, Ni, Co, Zn, Ag, Hg, Se, Te und Tl nicht störend wirken, wohl aber Ce(IV), Mn(IV), Ir(IV), Chromat- und Nitritionen, ergibt sich eindeutig aus dem Vergleich des Redoxpotentials des Tetrons mit dem zahlreicher anderer Stoffe, die das Gold in Gesteinen, Konzentraten oder Halbprodukten begleiten können.

Wir nahmen uns vor, dieses Verhalten des Tetrons zu verwerten, um eine empfindlichere, selektivere und zugleich weniger anspruchsvolle Methode zur Bestimmung von geringen Goldmengen zu schaffen.

EXPERIMENTELLER TEIL

Reagentien

Goldstandartlösung: 0,0250 g Gold wird in etlichen ml Königswasser aufgelöst, mittels IR-Glühlampe zur Trockne eingedampft, der Rückstand mit 1 ml Konz. Salzsäure versetzt, wieder zur Trockne eingedampft und in einem Messkolben auf 250 ml mit 1M Salzsäure verdünnt. Dieser Lösung, die 100 μg Au(III)/ml enthält, entnimmt man 10 ml, verdünnt sie mit frisch destilliertem Wasser auf 100 ml und erhält eine Lösung von 10 μg Au(III)/ml.

0,1 %*ige Tetronlösung:* 0,1 g Tetron, aufgelöst in 100 ml verd. Schwefelsäure (1:20).

0,1 %*ige Lösung von Kaliumtellurit:* 0,1 g K_2TeO_3 werden in etlichen ml 2,5M Salzsäure aufgelöst und mit Wasser auf 100 ml verdünnt.

10%*ige Zinn*(II)*-chloridlösung:* Frisch bereitete Auflösung von 10 g $SnCl_2$ in 2,5M Salzsäure unter Erhitzen.

3M Bromwasserstoffsäure

Äthyläther: p.a.

2,5M Salzäure

konz. Salzsäure; konz. Salpetersäure.

ERGEBNISSE

Eine der wesentlichsten Schwierigkeiten, auf die man bei der Bestimmung geringer Mengen von Gold stösst, ist seine Trennung. Dazu benutzt man: die Mitfällung des Goldes durch ein geeignetes Fällungsmittel (Tellur,[14] Bleisulfid,[21,22] ein Gemisch von Quecksilber-(II)-chlorid und Magnesium[20] u.a.); ferner die Extraktion des Goldes mit Äthyläther,[23,24] Isopropyläther[25] oder Äthylacetat[23] aus Chlor- bzw. Bromwasserstoff-säurem Medium und schliesslich Ionenaustausch[26] oder Adsorption über Kohle, Zellulose u.a.

Unsere Versuche zeigten, dass es bei der Aufarbeitung zusammengesetzter Proben wie Gesteine, Erze und Konzentrate am zweckmässigsten ist, das Gold zunächst durch Mitfällung mit Tellur von den Begleitelementen abzutrennen und anschliessend die Gold(III)-ionen mit Äther aus einem Medium von 3M Bromwasserstoffsäure zu extrahieren.

Bestimmung des Goldes in Kupfer-Eisen- und gemischeten Konzentraten

Analysegang: 0,5 bis 2,0 g der fein verriebenen Probe werden im Gemisch von Lunge aufgelöst. Man dampft die Lösung auf Sandbad zur Trockne ein. Einwirkenlassen von 3 bis 4 ml konz. Salzsäure auf den Rückstand mit nochmaligem Eindampfen zur Trockne. Nach Zugabe von 60 bis 70 ml der 2,5M Salzsäure und 2 ml Kaliumtelluritlösung erwärmt man fast bis zum Sieden und reduziert mit 15–20 ml Zinn(II)-chloridlösung.* Es entsteht eine dunkelbraune kolloidale Lösung von Elementartellur, die beim Liegenlassen flockig wird wobei sich das Tellur auf den Boden setzt. Der Niederschlag wird nach einer Stunde abfiltriert (Weissbandfilter) und mit 0,2M Salzsäure ausgewaschen. Das Filter wird samt Niederschlag im Porzellantiegel bei 800–900° verbrannt und geglüht. Unter diesen Bedingungen entweicht das Tellur als Oxyd, und im Tiegel verbleibt das Gold, gelegentlich mit einigen Platinmetallen, geringen Mengen von Siliciumsäure, Kupfer, Blei und Eisen vermischt. In das Becherglas, in dem die Mitfällung erfolgt war, bringt man 2 bis 3 ml Königswasser, deckt mit dem Uhrglas zu und erhitzt auf dem Sandband 15–20 Min. lang. Das Säurengemisch wird in den Tiegel eingegossen, mit Uhrglas bedeckt und 15–20 Min. erwärmt. Nach Abnahme des Uhrglases dampft man die Lösung mittels IR-Glühlampe zur Trockne ein.† Dem Trockenrückstand werden 10 ml 3M Bromwasserstoffsäure zugesetzt; nach heftigem Umrühren mit Glasstab wird die Lösung samt dem Niederschlag der Siliciumsäure in den Scheidetrichter gebracht und darin 3 Min. lang mit 10 ml Äthyläther extrahiert. Praktisch geht das Gold schon bei der ersten Extraktion in die organische Phase über. Um grössere Gewissheit zu erlangen führt man am besten eine zweite Extraktion durch.‡ Die vereinten ätherische Auszüge werden in einem 25 ml-Becherglas mit Hilfe der IR-Glühlampe langsam zur Trockne eingedampft. Auf den Rückstand lässt man 10–15 Tropfen Königswasser einwirken, dann erhitzt man 15 Min. mit aufgesetztem Uhrglas und dampft vorsichtig zur Trockne ein. Nach Versetzen mit 1 ml 0,1 % iger Tetronlösung entsteht orangegelbe Färbung, die allmählich

---

* Die Menge an Zinn(II)-chlorid muss dazu ausreichen, nicht nur das Tellur, sondern auch die vorhandenen Eisen(III)- und Kupfer(II)-ionen reduzieren zu können.

† Die Temperatur darf 70–80° nicht übersteigen, sonst könnte sich das Gold(III)-chlorid zersetzen. Die Luft darf nicht verstaubt noch verqualmt sein (kein Tabakrauch!), da Reduktion des Gold(III)-chlorids zu Elementargold eintreten könnte.

‡ Geringe Mengen an Siliciumsäure bleiben dispergiert in der Wasserphase zurück und halten an den Trichterwänden. Damit sie nicht vom Äther mitgerissen werden, giesst man diesen durch die obere Öffnung des Scheidetrichters ab.

intensiver wird. Nach 3 bis 4 Min. verdünnt man mit frisch destilliertem Wasser* auf ein angemessenes Volumen (10-, 20- oder 50 ml) und photometriert bei Blaulichtfilter.

Goldbestimmung in Bleikonzentraten

Analysengang: 0,5 bis 2,0 g der Probe werden mit 10 bis 15 ml konz. Salzsäure übergossen und bis zum Aufhören der Entwicklung von Schwefelwasserstoff erhitzt. Dann gibt man 5 bis 10 ml konz. Salpetersäure hinzu und lässt die Lösung auf dem Sandbad zur Trockne verdunsten. Der weitere Gang der Analyse ist derselbe wie bei der Analyse von Kupferkonzentraten.

Bleibt bei der Verdünnung, die der Mitfällung des Goldes mit Tellur vorausgeht, noch ungelöstes Bleichlorid zurück, so wird es nach Abfiltrierung dadurch entfernt, dass man den gesamten Niederschlag mit 15–20 ml heissem Wasser auswäscht.

Goldbestimmung im Anodenkupfer

Bei der Aufarbeitung von Proben mit einfacher Zusammensetzung, z.B. von Anodenkupfer, kann die Abrennung des Goldes mit Hilfe eines Ionenaustauschers vorgenommen werden.

Bekanntlich haftet $[AuCl_4]^-$-an-Anionit in einem ziemlich weiten pH-Intervall: von 0,1 bis 12 n HCl.[27] Auf dieser Eigenschaft beruht das von S. Hirano, A. Mizuike und Y. Yida[26] angewandte Verfahren zur Bestimmung geringer Goldmengen im Kupfer.

Bei unseren Versuchen bedienten wir uns des Ionenaustauschers Dowex II 310 mesh in Cl^--Form. Die Säule stellte ein mit Hülse versehenes Filtrierröhrchen dar,[28] das bis zur Höhe von 10 mm mit dem Ionenaustauscher gefüllt war. Durch Aufsaugen mittels Wasserstrahlpumpe wird die Ausströmungsgeschwindigkeit auf etwa 1 ml/min eingestellt.

Analysengang: 0,1 bis 0,5 g Anodenkupfer werden in 6 ml salpetersäure (1:1) aufgelöst; der Lösung setzt man 2 ml konz. Salzsäure hinzu und verdünnt mit Wasser auf etwa 20 ml. Man lässt die Lösung durch die Säule fliessen. Diese wäscht man dann mit etwa 10 ml Salzsäure (1:10) durch. Die Filtrierpapierhülse wird mit dem Glasstab aus der Säule in einen Porzellantiegel geschoben, verbrannt und auf 800° geglüht. Den kaum merklichen Rückstand versetzt man mit ein paar Tropfen Königswasser, dampft mit Salzsäure ein, setzt 1 ml Tetronlösung hinzu, verdünnt und photometriert.

Aufnahme der Standardgeraden

Die Goldkonzentration in der zu untersuchenden Probe kann nach einer vorher aufgenommenen Standardgeraden ermittelt werden. Zur Vermeidung gelegentlicher methodischer Fehler müssen die Punkte, mit deren Hilfe die Gerade aufgenommen werden soll, das Resultat der Goldbestimmung in Lösungen sein, die bestimmte Goldkonzentration aufweisen und an denen der entsprechende Analysengang angewendet worden ist.

Da Zufallsfehler während der Bestimmung unterlaufen können, wird man die wahrscheinlichste Gerade nur erhalten, wenn jeder Punkt das arithmetische Mittel aus mehreren Berechnungsaussagen ist.

In den Konzentraten schwankt der Goldgehalt meist zwischen 0,5 und 50 g/t. Aus diesem Grunde ist es zweckmässig, zwei Standdardgeraden aufzunehmen: eine für Konzentrationen von 1 bis 7 g/t und die andere für solche von 5 bis 30 g/t. Bei der ersten werden die zu photometrierenden Lösungen auf 10 ml verdünnt, bei der zweiten auf 25 ml. Benutzt wird eine Küvette von 2 cm-Stärke des absorbierenden Mediums.

BEURTEILUNG DER ERGEBNISSE

Bewertung der Genauigkeit der Methode

Im Laufe der Analyse kommen methodische Fehler vor, deren Betrag von dem gewählten analytischen Arbeitsgang abhängig ist. Das Vorliegen solcher Fehler stellten wir bei der Aufnahme der Standardgeraden unter verschiedenen Bedingungen fest: eine bei der direkten Bestimmung von Gold(III)-chlorid mit Tetron (s. Abb. 1, Gerade I), die zweite nach vorausgegangenem Haftenbleiben des Goldes am Anionit (Gerade II) und die dritte nach der Mitfällung des Goldes mit Tellur und anschliessender Extraktion des komplex an Goldbromids mit Äther (Gerade III). Der Betrag jedes den Goldmengen 2, 4, 6, 8 μg entsprechenden Punktes stellt das arithmetische

---

* Ist das Wasser nicht frisch destilliert, enthält es Mikro-organismen, durch deren reduzierende Wirkung die Entfärbung der Lösung beschleunigt wird.

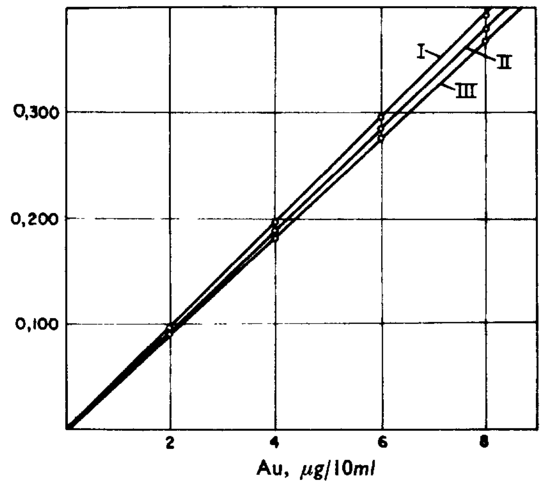

ABB. 1

Mittel aus zehn Bestimmungen dar. Die Abweichung der Geraden II and III von der Geraden I um entsprechend 2,5 oder 5,6% besagt, dass im Gange der Analyse infolge der Unvollständigkeit der Mitfällung, der Extraktion oder des Ionenaustausches Gold teilweise verloren geht. Es leuchtet daher ein, dass es zweckmässig ist, die Aufnahme der Standardgeraden auf den jeweiligen Analysengang abzustimmen, um methodische Fehler dieser Art zu vermeiden. Ist diese Anforderung erfüllt, dann wird die Reproduzierbarkeit bzw. Genauigkeit der Methode von den unbestimmten Fehlern abhängig sein. Da diese meist aus Variationen der bestimmten Fehler herrühren, müssen sie selbst variabel sein, wie dies aus Tab. I hervorgeht.

Demnach liegt der Relativfehler innerhalb der Grenzen ±7,5 bis ±4,5%, wenn Gold einmalig in Kupfer-, Blei- oder gemischten Konzentraten mit Goldgehalt 2 bis 8 g/t bei 95% statistischer Sicherheit bestimmt wird. Handelt es sich um Bestimmung des Goldes im Anodenkupfer, so wird sich der Relativefehler unter denselben Bedingungen auf ±3,6 bis ±4,5% belaufen.

Anwendungsgebeit der Methode

Das Verfahren wurde bei industriellen Objekten angewendet: Gold-, Kupfer-, Blei- und gemischten Konzentraten.

Tabelle II veranschaulicht die gute Reproduzierbarkeit der Ergebnisse, die mit denen der Kupelationsmethode in Einklang stehen.

Bestimmt wurde auch der Goldgehalt im Anodenkupfer. Zur Trennung des Goldes wurden die beiden Varianten eingesetzt: einmal durch Ionenaustauscher und zum andern durch Mitfällung mit Tellur und anschliessende Extraktion.

Die erste Variation ergab bei $N = 10$; $\bar{C} = 59{,}3$ g/t; $\varsigma = 0{,}89$; $\frac{\varsigma}{\bar{C}} \cdot 100 = 1{,}5\%$.

Nach der zweiten Variante bei $N = 10$; $\bar{C} = 58{,}5$ g/t; $\frac{\varsigma}{\phi} = 1{,}25$; $\frac{\varsigma}{\bar{C}} \cdot 100 = 2{,}1\%$.

Summary—A photometric method can be used for the determination of small amounts of gold with *N,N'*-tetramethyl-*o*-tolidine (Tetron). The gold is separated by precipitation with tellurium and extraction by ether from an HBr medium, and is then treated with Tetron solution. An orange-yellow colour develops and reaches its full intensity in about 4 min. The solution is diluted, and the colour is measured using a blue filter. The colour is stable for 20–25 min, and then fades gradually. The procedure may be applied to the determination of gold in copper-, lead- and mixed-concentrates or in anode-copper. The results have been evaluated statistically.

Résumé—En vertu d'une possibilité préalablement éclaircise est proposée une méthode de determination de petites quantités d'or a l'aide de la *N,N'*-tetramethyl-*o*-tolydine (tètrone). L'or est coprécipite avec le tellure, puis extrait par l'ether en milicu bromhydrique et á la fin traité par une solution de la *N,N*-tetramethyl-*o*-tolydine. On obtient une coloration jaune orangée, qui se develloppe 4 minutes. On amene a un volume convenable et effectue la photometue en utilisant un filtre bleu, la coloration est stable 20–25 minutes, après quoi elle commence a s'affaiblir. La méthode est appliquèe a l'analyse de l'or dans des concentrés différens et dans le cuivre anodique. Les résultats sont interprétés par le calcul statistique.

PHASE TITRATIONS—III*

NEW APPLICATIONS AND THE PHASE TITRATION OF BINARY SOLUTIONS OF CHEMICALLY SIMILAR COMPONENTS

D. W. ROGERS, A. ÖZSOĞOMONYAN and A. SÜMER
Department of Chemistry, Robert Kolej, Bebek, Istanbul, Turkey

(*Received* 29 *July* 1963. *Accepted* 20 *August* 1963)

Summary—Results are given for the phase titration of 27 new binary solutions of the water-immiscible components dichloromethane, cyclohexane, allyl bromide, benzene, toluene and xylene in combination with the water-miscible components methanol, ethanol, isopropanol, dioxan, acetone and acetic acid. A new method for the phase titration of binary solutions of liquids which are chemically similar is described. Results are given for the phase titration of binary solutions of the chemically similar liquids methyl aniline–aniline, nitrobenzene–aniline, carbon tetrachloride–chloroform, n-butyl bromide–n-butyl acetate and cyclohexane–benzene. Sampling procedures and sources of error are discussed.

MOST of the titrations of binary solutions reported in this series depend on great differences in solubility of the components. For example, solutions of carbon tetrachloride, which is completely immiscible with water, and methanol, which is completely miscible, can be analysed using water as a titrant. Part of this work has been devoted to extending the original technique to 27 new systems of this kind.

Bogin[1] showed that it is possible to take advantage of differences in solubility even when the components of a binary solution are chemically similar. Thus he was able to titrate solutions of butanol in propanol because of the partial immiscibility of butanol with water.

We will describe a method for the analysis, by phase titration, of binary solutions made up of components which are not only chemically similar but also have almost identical solubilities in water. The method is so sensitive to slight differences in solubility characteristics that it is possible to analyse solutions of chloroform in carbon tetrachloride and solutions of cyclohexane in benzene.

The new technique, like the old one, is capable of extremely wide application.

THEORY

Consider, as an illustrative binary solution, carbon tetrachloride and chloroform (solubilities: 0·077 and 0·822 g/100 ml of water respectively[2]). The phase titration of each in combination with water-miscible organic liquids has been reported.[3,4] Although they are both regarded as being completely immiscible with water, the solubility curve of the carbon tetrachloride-ethanol-water phase diagram is slightly higher than the solubility curve of the chloroform-ethanol-water phase diagram[5] as shown in Fig. 1.†

It has been shown[3] that a higher solubility curve gives a lower phase-titration calibration curve and *vice versa*. This is shown in Fig. 2. In the discussion that

---

* Part II, *Talanta*, 1963, **10**, 633.

† In the actual experiment described, acetic acid was used instead of ethanol but the principle is the same. Ethanol is referred to in this discussion because the phase diagrams are readily available.

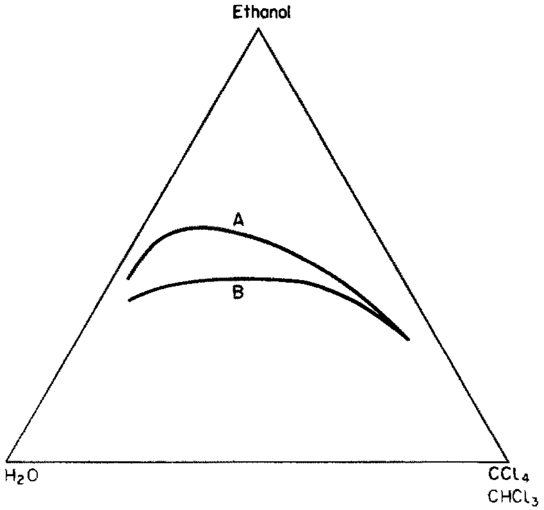

FIG. 1.—Ternary phase diagrams at 0°

B: chloroform–ethanol,
titrated with water.
The vertical line segment represents a constant composition with respect to ethanol.

follows, phase-titration calibration curves of the kind shown in Fig. 2 will be referred to as Type A solubility curves.

If, instead of titrating binary solutions of ethanol and immiscible component with water, one titrates ternary solutions of carbon tetrachloride, chloroform and ethanol with water, the titres will fall in the area between the Type A solubility curves shown in Fig. 2. The locus of the number of ml of water necessary to cause turbidity, as a function of the composition of the three component system titrated, is the three-dimensional surface shown in Fig. 3. The Type A solubility curves are the XZ plane and the outer edge of the solubility surface which is parallel to it. Notice that the concentration of water necessary to cause turbidity as a function of three other composition variables is not a surface in four dimensions because, of the four composition variables, only three are independent.

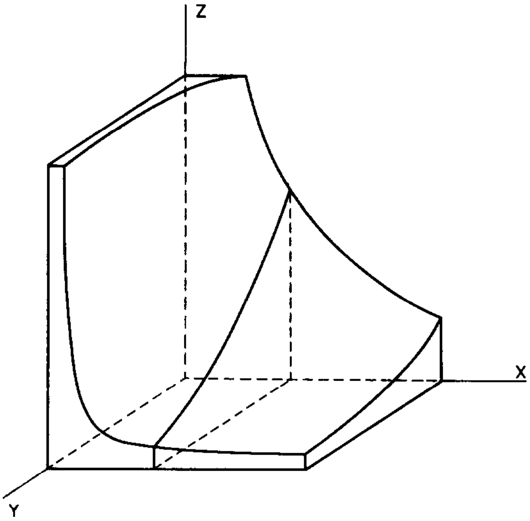

Fig. 3.—The solubility surface for the ternary system carbon tetrachloride–chloroform–ethanol titrated with water.

The axes are: X, 100 − % ethanol; Y (ml of carbon tetrachloride/ml of carbon tetrachloride + ml of chloroform), 100, *i.e.*, % carbon tetrachloride before the addition of any ethanol or water; and Z, ml of water necessary to cause turbidity.

The vertical plane parallel to the YZ plane shown in the diagram indicates constant ethanol composition.

Now simplify the problem by holding the amount of ethanol constant and allowing variation in the ratio of carbon tetrachloride to chloroform. Let the constant composition of ethanol be represented by the vertical line in Fig. 2. This line and an intersecting line perpendicular to the plane of the page define a plane. The plane so defined intersects the solubility surface as shown in Fig. 3. Its projection on the YZ plane is Fig. 4, the number of ml of water necessary to cause turbidity as a function of carbon tetrachloride percentage at constant amount of ethanol. Fig. 4 will be referred to as a Type B solubility curve. Its use as a calibration curve for the phase titration of binary solutions of carbon tetrachloride and chloroform is described in detail in the Experimental section.

The projection of the Type B solubility curve on its vertical axis gives the vertical line segment between the two Type A solubility curves in Fig. 2. The intersection of

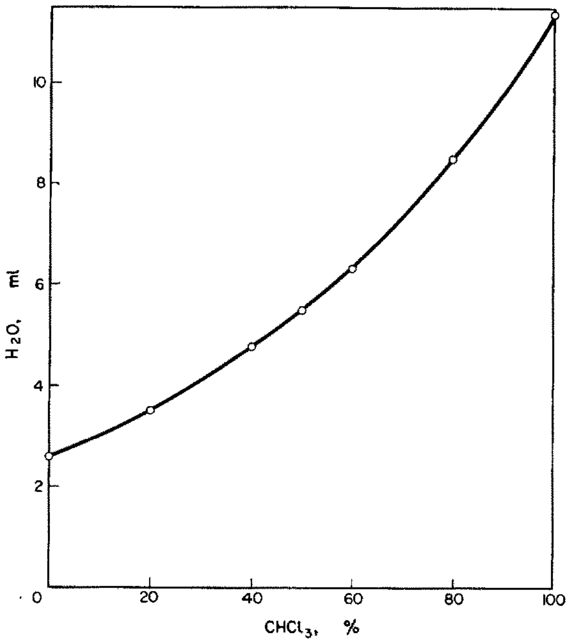

FIG. 4.—Type B solubility curve for the system carbon tetrachloride–chloroform. The horizontal axis represents the % chloroform before addition of ethanol.

the vertical line segment with the Type A solubility curves gives the upper and lower limits of the Type B solubility curve, *i.e.*, 0% and 100%. The greater the separation of the Type A solubility curves, the greater will be the slope of the Type B solubility curve and the greater will be the accuracy of any determination which depends on it.

The separation of the Type A solubility curves depends on the following factors:

The nature of the immiscible component is of prime importance.

The amount of miscible component added determines the position of the vertical line in Fig. 2. Sometimes advantage can be taken of flat portions and bulges in the Type A solubility curves to achieve a wider separation. Generally, the Type A solubility curves converge as they approach the horizontal axis, so that a wider separation is achieved at higher proportions of the miscible component. On the other hand, the end-point is usually sharper at lower proportions of the miscible component. There is an optimum proportion of miscible component which best satisfies both of these conditions.

Shifting the position of the vertical line in Fig. 2 also determines the size of the titre. It is generally best placed so that the limits of the Type B solubility curve are about 1 and 12 ml.

Doubling the sample size doubles each titre and doubles the separation of the Type A curves. Thus, advantage can be taken, by appropriate increase in the sample size, of subtle differences in the solubility characteristics of the substances titrated.

There are exceptions to this rule, but inspection of over one hundred Type A solubility curves showed that the miscible component has little effect on the separation of the curves. Factors of availability and price were most important in determining the choice of the miscible component, and we expect that a change in the miscible component in the systems reported in Table II would have little effect on the results.

Bogin[1] has suggested, but not carried out, the application of this principle to analogous systems in which the ratio of two completely water-miscible components can be determined by phase titration with water in the presence of a constant amount of a water-immiscible or slightly water-miscible component. He suggests that ethanol–propanol mixtures can be titrated with water in the presence of a constant amount of butanol. Bogin has also devised a method for the titration of chemically similar components using as the titrant, not water, but binary and even ternary solutions in which one of the components is water. Such a method involves titration surfaces like the one shown in Fig. 3, but is less easily visualised because the addition of titrant causes a variation in two or even three of the composition variables. The selection of the composition of the mixed solvent titrant was empirical. The disadvantages involved in the use of a mixed-solvent titrant, which must be exactly the same in composition from one titration to the next, as contrasted to water, which never need be standardised, are discussed by Bogin.

EXPERIMENTAL

Reagents

Reagent-grade carbon tetrachloride and benzene were obtained from E. Merck A. G., Darmstadt. Reagent-grade aniline and xylene were obtained from Mallinckrodt Chemical Works, New York and reagent-grade nitrobenzene from Fischer Scientific Co., Fair Lawn, N.J. Technical methyl aniline was obtained from Amend Drug and Chemical Co., New York, and practical-grade cyclohexane from Eastman Organic Chemicals, Rochester, N.Y.

TABLE I.—RESULTS FOR THE TITRATION OF 27 HOMOGENEOUS BINARY SYSTEMS WITH WATER,
The end-point was indicated by the appearance of a distinct permanent turbidity.

Sample	Optimum range, %	Number of titrations	Average error, *absolute* %
Dichloromethane-methanol	13–50	9	0·21
Dichloromethane-ethanol	15–50	12	0·19
Dichloromethane-isopropanol	17–38	6	0·23
Dichloromethane-dioxan	7–22	12	0·19
Dichloromethane-acetone	6–20	10	0·22
Dichloromethane-acetic acid	15–50	14	0·23
Cyclohexane-methanol	1–10	12	0·10
Cyclohexane-ethanol	1–20	12	0·06
Cyclohexane-isopropanol	5–45	12	0·04
Cyclohexane-dioxan	1–15	12	0·13
Cyclohexane–acetone	1–25	12	0·03
Cyclohexane–acetic acid	1–7	12	0·05
Allyl bromide-methanol	4–35	12	0·01
Allyl bromide-ethanol	5–40	15	0·05
Allyl bromide-isopropanol	10–45	12	0·08
Allyl bromide-dioxan	4–25	12	0·07
Allyl bromide-acetone	3–20	12	0·09
Allyl bromide-acetic acid	5–30	12	0·22
Benzene-dioxan	3–20	12	0·05
Benzene-acetone	4–25	12	0·05
Benzene-acetic acid	5–30	12	0·06
Toluene-dioxan	2–20	12	0·04
Toluene-acetone	3–23	12	0·16
Toluene-acetic acid	2–25	12	0·06
Xylene-dioxan	1–20	6	0·09
Xylene-acetone	2–25	12	0·04
Xylene-acetic acid	2–20	12	0·11

Chemicals of unspecified grade were toluene and dichloromethane (density 1·322–1·324) from E. Merck; and allyl bromide (3-bromopropene, b.p. 70–71°, lot no. 370220) from Matheson Coleman and Bell, New Jersey. All other reagents have been described elsewhere, and their sources given.[6]

Sampling procedure

Aliquot portion method: An appropriate volume of the water-insoluble or least water-soluble component was pipetted into a 50-ml volumetric flask and diluted to the mark with the water-soluble or most water-soluble component. For example, in Table I, cyclohexane was diluted to the mark with methanol; and in Table II carbon tetrachloride was diluted to the mark with chloroform. Aliquot portions (10 ml unless otherwise noted) were withdrawn for titration with water. The first was arbitrarily taken as a point on the calibration curve and the remaining three were taken as synthetic unknowns.

TABLE II.—RESULTS FOR THE TITRATION OF 5 HOMOGENEOUS BINARY SYSTEMS WITH WATER
A soluble component was added to each before titration

Sample	Soluble component added	Sample taken, *ml*	Soluble component added, *ml*	No. of titrations	Average error, *absolute* %
Methylaniline–aniline	Ethanol	10	10	12	0·16
Carbon tetrachloride–chloroform	Acetic acid	10	25	10	0·65
n-Butyl bromide–n-butyl acetate	Ethanol	10	15	10	1·0
n-Butyl bromide–n-butyl acetate	Ethanol	10	15	9	0·32
Nitrobenzene-aniline	Ethanol	10	10	12	0·43
Cyclohexane-benzene	90% ethanol 10% water	3	25	15	1·1
Cyclohexane-benzene	Ethanol	5	25	15	0·59

Individual portion method: An appropriate volume of each component was measured into a titration vessel. The volume percentage of the least soluble component was calculated, disregarding volume changes caused by mixing. Alternatively, weight percentages could have been used. After constructing the calibration curve, synthetic unknowns were prepared by the same method and determined by comparison. Compositions of the synthetic unknowns were, in most cases, different from the solutions used to construct the calibration curve.

Titration procedure

The results in Table I were obtained as described in the first paper of this series.[3]

The data in Table II were obtained by placing 3–10 ml of the unknown binary solution in a beaker and diluting with 10–25 ml of a liquid miscible with water and both components of the solution to be analysed. The amount of each liquid used, and the miscible component chosen are given in Table II. The criteria for the choice of the miscible component are maximum separation of the Type A solubility curves and a sharp end-point. The criteria for choosing the amount of miscible component are similar: maximum separation of the solubility curves consistent with a good end-point and a convenient titre. The criteria for good end-points have been discussed elsewhere.[4]

The ternary solution so obtained is then titrated with water. The behaviour of the solution during titration and the end-point is in all respects similar to the phase titration of binary solutions with water. A Type B solubility curve is constructed from known samples, and synthetic unknowns are determined by comparison.

Calculations

The calculations are straightforward, except that in the single sample method, if the final volume of all the samples is not the same, they must be normalised to one another. Thus, if one sample is made up by adding 2 ml of one component to 10 ml of the other, and if the second sample is made up by adding 3 ml to 10 ml. the titres could be normalised by multiplying the second by 12/13.

RESULTS AND DISCUSSION

Table I shows the results of the titration of 27 binary systems containing one water-miscible component. All end-points are fair to good except cyclohexane-acetic acid and allyl bromide-acetone. Even those titrations with fair or poor end-points gave small errors because the calibration curves are steep in the optimum titration range.

Table II shows the results for 5 binary systems both components of which are insoluble in water. The maximum titre was 10–15 ml, and the separation of the 0% and 100% titres was about 10 ml. The two series of determinations on the system n-butyl bromide–n-butyl acetate only differed in that the first was by the single sample method and the second by the aliquot portion method. A mixed solvent was added to the first of the cyclohexane-benzene systems to bring the titre into a more convenient range. All end-points were good to excellent with the exception of the first cyclohexane-benzene system, which was fair to poor. All systems in Table II showed a gradual opalescence followed by a sharp turbidity. This effect has been discussed before[6] but was much more noticeable in the systems given in Table II than in any other systems we have studied. The end-point is similar to, but not identical with, the end-point of a 100% sample of the less soluble of the two components. All calibration curves increased in slope with increasing titre, as shown in Fig. 3.

Errors

Of the systems given in Table I, those in which dichloromethane is one of the components were done by the single sample method, and the others were done by the aliquot portion method. The error reported for the latter may be called titration error, and largely results from uncertainty in the end-point. The error reported for the dichloromethane systems is the sum of the titration error, the errors arising from sample mixing and measurement and the errors resulting from interpolation between points on the calibration curve. In principle, these sources of error can be reduced to any desired level by more sophisticated measuring techniques and more points on the calibration curve. The two systems containing n-butyl bromide in Table II have the same relationship as that described above.

If many points are to be taken on the calibration curve, it may become tedious to construct a new curve each time there is an appreciable temperature change. The use of a constant-temperature room has the advantage in convenience over the use of a thermostatted bath. Even though heat of mixing causes temperature fluctuations, these effects will cancel between the unknown and the calibration curve (all other factors being constant). Sensitivity to temperature change varies considerably from one system to another.

The last two series in Table II show the effect of curve separation and end-point quality on accuracy.

In the penultimate determination, the difference in titres was about 11 ml, but in order to achieve that separation the composition line intersected the Type A solubility curves where they were very steep. We have seen[4] that most systems have the best end-point on the flat of their Type A solubility curves.

The final entry in Table II shows the same determination at a lower relative ethanol concentration. The difference between maximum and minimum titres has been reduced to 9·5 ml but the end-point has been improved and the error considerably reduced.

Acknowledgment—The authors gratefully acknowledge a grant by the Society of Sigma Xi in support of this research. We thank Tuğrul Yasar for help with the calculations.

Zusammenfassung—Ergebnisse der Phasentitration 27 neuer binärer Lösungen mit den wasserunlöslichen Komponenten Dichlormethan, Cyclohexan, Allylbromid, Benzol, Toluol und Xylol und den wasserlöslichen Komponenten Methanol, Äthanol, Isopropanol, Dioxan, Aceton und Essigsäure werden angegeben. Eine neue Methode für die Phasentitration binärer Lösungen chemisch ähnlicher Flüssigkeiten wird beschrieben. Ergebnisse werden für die Phasentitration binärer Lösungen der chemisch ähnlichen Flüssigkeitspaare Methylanilin-Anilin, Nitrobenzol-Anilin, Tetrachlorkohlenstoff-Chloroform, n-Butylbromid-n-Butylacetat und Cyclohexan-Benzol angegeben. Verfahren zur Probenahme und Fehlerquellen werden diskutiert.

Résumé—On donne les résultats de la détermination de la composition des phases de 27 nouveaux mélanges binaires de liquides non miscibles à l'eau: dichlorométhane, cyclohexane, bromure d'allyle, benzène, toluène et xylène combinés à des liquides miscibles à l'eau: méthanol éthanol, isopropanol, dioxanne, acétone et acide acétique. Une nouvelle méthode pour la détermination de la composition des phases de mélanges binaires de liquides qui sont chimiquement analogues est décrite. On donne les résultats de la détermination de la composition des phases de mélanges binaires de liquides chimiquement analogues: méthylaniline-aniline, nitrobenzène-aniline, tétrachlorure de carbone-chloroforme, bromure de n-butyle-acétate de n-butyle et cyclohexane-benzène. Les méthodes d'échantillonnage et les causes d'erreur sont discutées.

LE TITRAGE ENTHALPIMETRIQUE DE QUELQUES REACTIFS ORGANIQUES SOUFRES UTILISES EN CHIMIE ANALYTIQUE

E. POPPER, L. ROMAN et P. MARCU
Département de Chimie Analytique de la Faculté de Pharmacie Cluj, Rumania

(*Reçu le* 29 *Juillet* 1963. *Accepté le* 7 *Septembre* 1963)

Résumé—Dans le présent travail on a appliqué la méthode de titrage enthalpimétrique de deux réactifs organiques soufres, le 2-mercapto-5-anilino-1,3,4-thiodiazol et l'allylmonoamide de l'acide hydrazin-*N,N'*-bisthiocarbonique, qui ont un caractère très faiblement acide. On a appliqué une technique manuelle discontinue, et dans le cas de l'allyl-monoamide de l'acide hydrazin-*N,N'*-bisthiocarbonique on a procédé à une transformation des coordonnées droites en coordonnées obliques, afin d'écarter l'influence des processus secondaires sur l'effet thermique de la réaction de neutralisation. A partir des données expérimentales on a calculé aussi les chaleurs de neutralisation de ces réactifs par l'hydroxyde de sodium.

PRINCIPE DE LA MÉTHODE

TOUTE réaction chimique est accompagnée d'une variation de l'enthalpie du système, ainsi que l'attestent les effects thermiques qui ont lieu pendant la réaction. De ce fait, des renseignements précieux peuvent être obtenus sur une réaction chimique par la connaisance des échanges thermiques au cours de la réaction.

La méthode de titrage enthalpimétrique a été l'objet de modifications, tant en ce qui concerne la dénomination que la technique de travail. A l'origine, cette méthode était nommée "titrage thermique" ou "titrage thermométrique" et la quantité de chaleur dégagée était déterminée calorimétriquement.[1]

La détermination calorimétrique de la quantité de chaleur dégagée au cours d'une réaction chimique implique certaines difficultés. Dutoit et Grobet[2] ont remplacé la détermination calorimétrique de la quantité de chaleur par la mesure des variations de température. Par ailleurs, par la différence de titrage potentiométrique, on évalue l'énergie libre au moyen de la réaction:

$$\Delta F = -\varepsilon z Fy$$

(ε = f.e.m. de la pile, z = nombre d'équivalents qui participent au transport du courant électrique, Fy = constante de Faraday).[3]

Les titrages enthalpimétriques mettent en évidence d'une part l'énergie libre et d'autre part l'entropie du système, en vertu de la relation:

$$\Delta H = \Delta F + T\Delta S$$

(ΔH = variation de l'enthalpie, respectivement du contenu calorique, ΔF =variation de l'énergie libre, ΔS = variation de l'entropie, T = température absolue).

Il en résulte avec évidence pourquoi la notion de "titrage thermique" ou de "titrage thérmométrique" a été remplacée par celle de "titrage enthalpimétrique". En outre, cette notion rend mieux compte de la méthode.

TECHNIQUE DE TRAVAIL

Ainsi que nous le signalions, la technique de travail a subi elle aussi des modifications au long des années. C'est ainsi que de la détermination calorimétrique de la quantité de chaleur on est passé à la détermination de la variation de température. Cela est réalisable soit à l'aide d'un thermomètre différentiel Beckmann, soit d'un thermistor.

Il importe que ces titrages soient effectués dans des vases thermiquement isolés—Dewar—, avec des dispositifs de titrage également isolés, que l'on ajoute des quantités égales de réactif à des intervalles de temps égaux et que l'on mesure la température avec toute la précision possible. On représente graphiquement la variation de température, en fonction des ml. de réactif additionnés, tandis que la courbe obtenue représente le titrage enthalpimétrique, dans le processus donné.

Dans les installations modernes, réalisées par certains chercheurs,[4,5] on effectue les titrages enthalpimétriques à l'aide de burettes à écoulement constant, tandis que la variation de la température est enregistrée par un thermistor et la courbe de titrage se trace avec un enregistreur potentiométrique.

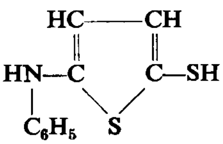
La technique utilisée par nous a été la suivante: un vase Dewar, isolé lui aussi par précaution, une burette Schelbach de grande précision introduite dans un manchon de verre, afin de réaliser l'isolation thermique par la couche d'air formée de la sorte, un thermomètre Beckmann, et pour l'agitation continue et constante un agitateur électromagnétique du type I.O.R. (R.P.R.). Pour la lecture des millièmes de degré nous avons utilisé une loupe. Avant la détermination on vérifie les températures des solutions contenues dans la burette et le vase Dewar à l'aide d'un thermomètre décimal. La différence entre les températures de la solution à titrer et la solution titrante ne doit pas être plus grande que 0,3°C. La pointe de la burette doit être effilée et isolée, et elle s'introduit dans le vase Dewar par un bouchon en liège, tout comme le thermomètre Beckmann.

Les déterminations doivent être faites dans une pièce où les variations de température soient minimales; les solutions y sont abandonnées pendant une heure environ pour permettre l'équilibre de la température avec celle du milieu ambiant.

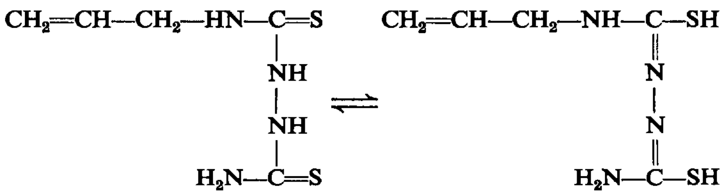
APPLICATION DE LA MÉTHODE

Cette méthode physico-chimique peut être appliquée à l'étude de beaucoup de réactions chimiques, parmi lesquelles nous signalons: la neutralisation des acides polybasiques, le déplacement des acides faibles de leurs sels avec des bases fortes, la précipitation des hydroxydes métalliques, la formation des hydroxydes amphotères, la formation des sels basiques, diverses précipitations analytiques, la formation de complexes, réactions d'oxydation-réduction, sulfonations, titrages[6] ainsi le titrage de certains alcaloides.[7] Contrairement aux méthodes de volumétrie physico-chimique, conductivités électriques et sauts de potentiel, comme indicateurs, cette méthode n'est pas assez précise pour un dosage analytique.

Dans le présent travail, nous rapportons une étude enthalpimétrique de la réaction de neutralisation de quelques réactifs organiques soufrés, à savoir le 2-mercapto-5-anilino-1,3,4,-thiodiazol (I) et l'allyl-monoamide de l'acide hydrazin-*N*,*N'*-bisthiocarbonique (II), par de l'hydroxyde de sodium:



(I)



(II)

la forme cétonique la forme énolique

Cette étude vient compléter celles effectuées avec ces réactifs en vue d'élaborer de nouvelles méthodes gravimétriques rapides, colorimétriques, etc.,[8] pour le dosage des divers cations, ainsi que les recherches tendant a remplacer l'hydrogène sulfuré comme réactif analytique.

Compte tenu du fait que ces réactifs ont un caractère faiblement acide, en raison de l'influence que l'atome de soufre exerce sur l'hydrogène qui lui est lié ou qui est voisin, nous avons cru utile de proceder au titrage enthalpimétrique, afin de déceler le comportement de ces réactifs dans certaines réactions. Cela est d'autant plus utile qu'il est bien connu que l'on titre difficilement les acides très faibles par la titrimétrie habituelle. Dans le cas des acides bibasiques très faibles, le second palier de dissociation ne peut pas même être mis en évidence. Or, on verra que, par cette méthode, dans le cas de L'allyl–amide on peut mettre en évidence le deuxieme palier de dissociation. On a calculé aussi la chaleur de neutralisation dans le cas des deux réactifs.

RÉSULTATS DES EXPERIENCES

A. *Détermination de la constante enthalpimétrique de la cellule*

Avant d'effectuer un titrage enthalpimétrique, il importe de déterminer expérimentalement la constante enthalpimétrique de la cellule où l'on fait le titrage, en utilisant la relation:

$$Q = Nm \frac{\Delta H}{\Delta T_Q}$$

où:

Q = la constante enthalpimétrique de la cellule,
Nm = nombre de mols du produit formé,
$\Delta H = \Delta H^\circ = 13{\cdot}4$ kcal/mol,

ΔT_Q = la variation totale de température, à la neutralisation de 250 ml de HCl. 0·01*M* par une solution d'hydroxyde de sodium 1*M*. Pratiquement, on place dans la cellule 250 ml de HCl 0·01*M* et on titré par de l'hydroxyde de sodium 0·1*M* en ajoutant un ml. de minute en minute. Cicontre (fig. 1) est représentée la courbe de titrage enthalpimétrique de l'acide chlorhydrique par de l'hydroxyde de sodium, qui permet de déterminer la constante enthalpimétrique de la cellule de titrage.

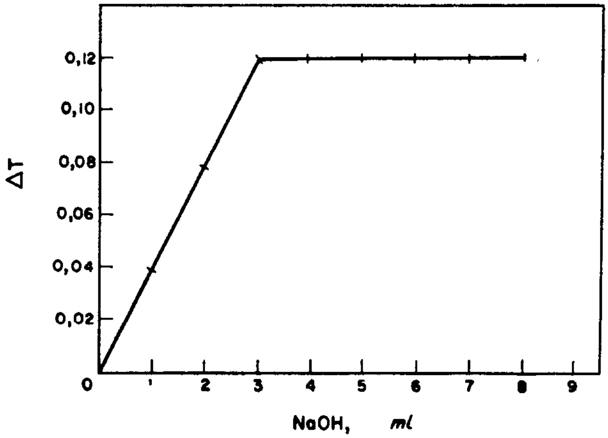


FIG. 1

Si $\Delta H = \Delta H^\circ = 13{\cdot}4$ kcal/mol, $\Delta T_Q = 0{\cdot}12$°C et $Nm = 0{\cdot}003063$, la constante enthalpimétrique a la valeur:

$$Q = Nm \frac{\Delta H}{\Delta T_Q} = 0{\cdot}003063 \frac{13{\cdot}4}{0{\cdot}12} = 0{\cdot}34205 \text{ kcal/°C.}$$

B. *Titrage enthalpimétrique du 2-mercapto-5-anilino-*1,3,4,*-thiodiazol*

Ce réactif a une fonction mercapto dont l'atome d'hydrogène peut être remplacé par des métaux. Comme nous venons de le dire, ce réactif a été employé pour le dosage pour divers cations (Ag^+, Pb^{2+}, Cu^{2+}, Hg^{2+}, Cd^{2+}, Bi^{3+}).

Ce réactif a été titré en solution *M*/334·4 par une solution 0·1*M* d'hydroxyde de sodium, en ajoutant à 300 ml de réactif, 2,5 ml d'hydroxyde de sodium par minute. Le réactif étant insoluble dans l'eau on a préparé aussi bien le réactif que l'hydroxyde en solutions alcooliques (50% alcool). Ce fait est particulièrement important parce que, lorsqu'on travaille avec une solution alcoolique de réactif et une solution aqueuse d'hydroxyde, l'effet thermique de la dilution de l'alcool est beaucoup plus grand que celui de la réaction. La courbe de titrage pour ce cas est représentée dans la fig. 2, où est consignée la variation de température ΔT, en fonction du volume de réactif ajouté. Il ressort du graphique, comme prenu que dans l'intervalle A-B la température varie de manière linéaire. Au point B, qui normalement devrait correspondre au point d'équivalence, la température demeure constante, et l'on obtient un palier horizontal parallèle à l'axe des abscisses.

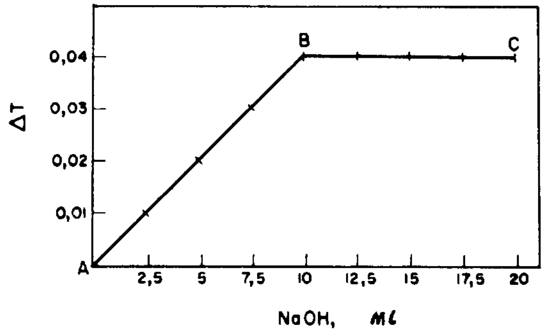

FIG. 2

Nous avons essayé d'appliquer la méthode à des dosages, mais pour de petits volumes d'hydroxide (0·5–1 ml) la variation de témperature est très petite, surtout autour du point d'équivalence, parce que ce réactif est un acide très faible.

Puisque dans ce cas ΔT = 0·04°C, Q = 0·34205 et Nm = 0·00099135, dans cette réaction la chaleur de neutralisation est:

$$\Delta H = \frac{Q}{Nm} \cdot \Delta T = \frac{0{\cdot}34205}{0{\cdot}00099135} \cdot 0{\cdot}04 = -13{\cdot}801 \text{ kcal/mol.}$$

C. *Titrage enthalpimétrique de l'allyl-monamide de l'acide hydrazin N,N'-bisthiocarbonique*

Avec ce réactif, le titrage enthalpimétrique est plus utile et plus intéressant parce que, ayant deux fonctions mercapto d'un caractère acide plus faible ($K_1 = 1{\cdot}437 \,.\, 10^{-11}$), la méthode offre la possibilité de mettre en évidence le second palier de dissociation.

Dans ce cas aussi nous avons travaillé avec des solutions alcooliques (50% alcool) de réactif et d'hydroxyde en plaçant dans la cellule 200 ml de réactif *M*/29·996, et ajoutant de minute en minute 2 ml NaOH env. 1*M*.

La courbe de titrage est consignée dans la fig. 3, où on a representé graphiquement les variations de température au cours du titrage (ΔT) en fonction du volume d'hydroxyde de sodium ajouté. Il ressort du graphique que la température varie de manière

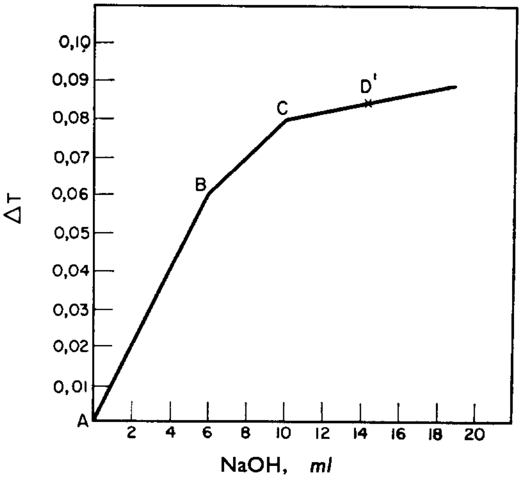

Fig. 3

linéaire dans l'intervalle A-B. Cette portion de la courbe correspond à la neutralisation du premier atome d'hydrogène. A partir du point B, la pente de la courbe se modifie brusquement, la température variant également de manière linéaire sur la portion B-C, qui correspond en réalité au titrage du deuxième atome d'hydrogène. A partir du point C, la pente de la courbe se modifie de nouveau, la température variant de manière linéaire lorsqu'on ajoute l'excès d'hydroxyde.

Afin d'écatrer l'effet thermique qui résulte du mélange de deux liquides à des température relativement différentes, un système de coordonnées obliques, *ayant les niveaux en* ordonnée inclinés avec la pente a été adojté:

$$p = \frac{\Delta T}{\Delta n}.$$

La courbe de titrage transposée sur les nouvelles coordonnées est représentée fig. 4. On remarque que cette représentation met en évidence seulement la variation de température déterminée par le procès de neutralisation, en éliminant l'influence des

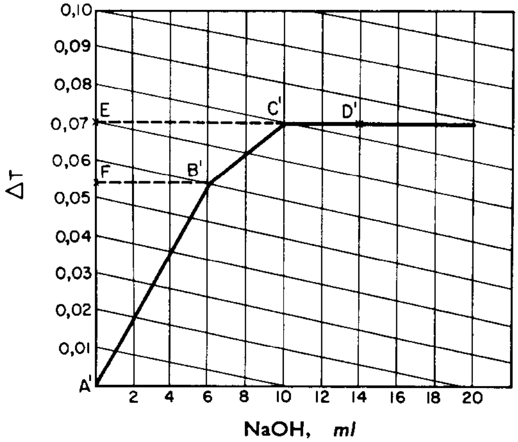

Fig. 4

phénomènes secondaires. Ce fait ressort avec évidence lorsqu'on prolonge le segment C'D' et que l'on trace une parallèle à l'abscisse par B', ce qui détermine sur l'ordonnée les points E et F correspondant à la variation de température due uniquement au processus de neutralisation.

On passe aux coordonnées obliques à l'aide des équations de transformation suivantes:

$$Y = y - px$$

$$X = x\sqrt{1 + p^2}$$

où:

X et Y sont les coordonnées du nouveau système de représentation, x et y les coordonnées de l'ancien système, et p la pente de la dernière portion de la courbe.

Les coordonnées des points B et C dans le système de coordonnées droites sont $x_B = 6$, $y_B = 0{\cdot}06$, la pente du segment CD, $p = \frac{\Delta T}{\Delta n} = \frac{0{\cdot}04}{4} = 0{\cdot}01$, et après la transformation en coordonnées obliques, les coordonnées des points B' et C' sont:

$$X_B' = 6\sqrt{1 + 0{\cdot}0001} = 6\varepsilon$$

$$Y_B' = 0{\cdot}060 - 0{\cdot}006 = 0{\cdot}054$$

$$X_C' = 10\sqrt{1 + 0{\cdot}0001} = 10\varepsilon$$

$$Y_C' = 0{\cdot}08 - 0{\cdot}01 = 0{\cdot}07.$$

Etant donné que l'accroissement ε a de X_B, et X_C, par la transposition en coordonnées obliques est très petit on le néglige, de sorte que ces coordonnées restent pratiquement les mêmes; en revanche, la diminution de Y_B, et Y_C, est sensible.

En ce qui concerne la chaleur de neutralisation, on la calcule comme dans le cas du titrage du 2-mercapto-5-anilino-1,3,4-thiodiazol au moyen de la relation:

$$\Delta H = \frac{Q}{Nm} . \Delta T .$$

Compte tenu du fait que la valeur de la constante enthalpimétrique de la cellule est $Q = 0{\cdot}34205$, $\Delta T_1 = 0{\cdot}054$, $\Delta T_2 = T - T_1 = 0{\cdot}07 - 0{\cdot}054 = 0{\cdot}016$ et que $Nm_1 = Nm_2 = 0{\cdot}00337$, les valeurs des chaleurs de neutralisation pour les deux paliers de la réaction sont:

$$\Delta H_1 = -5{\cdot}5403 \text{ kcal/mol}$$

$$\Delta H_2 = -1{\cdot}6417 \text{ kcal/mol}$$

CONCLUSIONS

1. Le titrage enthalpimétrique du 2-mercapto-5-anilino-1,3,4-thiodiazol et de l'allyl-monoamide de l'acide hydrazin-*N*,*N'*-bisthiocarbonique par de l'hydroxyde de sodium démontre l'allure des réactions de neutralisation, et dans le cas du dernier réactif permet de mettre en évidence le second palier de dissociation (par la transposition de la courbe en coordonnées obliques).

2. La méthode permet de calculer les chaleurs de neutralisation dans le cas des deux réactifs, après la détermination préalable de la constante enthalpimétrique de la cellule.

3. En dépit des essais que nous avons faits, la méthode n'a pas pu être utilisée pour des déterminations quantitatives; Nous pensons néanmoins y parvenir en modifiant la technique de travail.

4. Ce travail constitue le commencement d'une étude physico-chimique de ces réactifs qui ont été étudies et utilisés à des fins analytique. Nous aurons en vue, par suite, d'etudier le problème de la structure des combinations que ces réactifs forment avec les cations lourds.

5. En ce qui concerne l'établissement des équations de transformation en coordonnées obliques, les auteurs ont joui de l'aide précieuse que leur a accordée l'Institut de calcul de L'Académie de la R.P.R. Cluj, auquel ils adressent par cette voie leurs plus vifs remerciements.

Summary—Enthalpimetric titration has been applied to two organic sulphur compounds, 2-mercapto-5-anilino-1,3,4-thiodiazol and hydrazine-*N*,*N*′-bisthiocarbonic acid allyl-monoamide, which are weakly acidic. A discontinuous manual technique has been used, and in the case of the allyl-monoamide a transformation from rectangular to oblique co-ordinates allows for the influence of secondary processes on the thermal effect of the process of neutralisation. From the experimental results the heats of neutralisation of the compounds with sodium hydroxide have also been calculated.

Zusammenfassung—Die enthalpimetrische Titration wurde auf zwei schwach saure organische Schwefelverbindungen, 2-Mercapto-5-anilino-1,3,4-thiodiazol und Hydrazin-*N*,*N*′-bisthiocarbonsäure-allyl monoamid, angewandt. Es wurde mit diskontinuierlichem Handbetrieb gearbeitet. Im Falle des Allylmonoamids wird dem Einfluß von Sekundärprozessen auf den thermischen Effekt der Neutralisation durch Übergang von rechtwinkligen auf schiefwinklige Koordinaten Rechnung getragen. Aus den Versuchsergebnissen wurden auch die Neutralisationswärmen der Verbindungen mit Natriumhydroxyd berechnet.

ANION-EXCHANGE BEHAVIOUR OF URANIUM AND OTHER ELEMENTS IN THE PRESENCE OF ALIPHATIC DI- AND TRICARBOXYLIC ACIDS

METHOD FOR THE SEPARATION OF URANIUM FROM THORIUM AND RARE EARTHS

J. Korkisch and I. Hazan
Analytical Institute of University of Vienna, IX Währingerstrasse 38, Austria

(*Received* 1 *August* 1963. *Accepted* 10 *October* 1963)

Summary—The exchange behaviour of uranium, thorium, the rare earths and some other elements towards the strongly basic anion exchanger Dowex 1 in aqueous and methanolic systems containing di- or tricarboxylic acids is described. Based on the measurement of the distribution coefficients in such media a method for the separation of uranium from thorium and the rare earths in an aqueous solution containing malonic acid has been developed.

INTRODUCTION

Investigations carried out by Zaki and Shakir[1] have shown that uranium can be separated from other elements on an anion exchanger by using buffered solutions of oxalic, succinic or adipic acid. Uranium, thorium and zirconium, as well as other elements, form with these acids negatively charged complexes which are strongly retained by the exchange resin.[1-3] Several other authors have also reported on the adsorption behaviour of uranium and various other elements from solutions containing organic acids, such as acetic[4-6] and ascorbic acid.[7-9]

Previous research work dealing with the anion-exchange behaviour of uranium and other elements in organic acid-organic solvent mixtures[10] showed that in such media many separation possibilities for uranium could be uncovered. For this reason we have now investigated the behaviour of some elements in the presence of polyfunctional organic acids, especially the homologous dicarboxylic acids of the aliphatic series.

EXPERIMENTAL

Reagents

Ion-exchange resin. The strongly basic anion exchanger Dowex 1, ×8 (100–200 mesh, chloride form) was used. For the equilibrium and separation experiments in the various media the corresponding organic acid forms of this resin were employed. The preparation of these forms was performed according to the directions previously given for the monocarboxylic acid forms.[10]

Standard solutions of uranium and other elements. Hydrochloric or nitric acid solutions of the chlorides or nitrates of precisely known element content were employed. For each experiment an aliquot corresponding to the desired amount of the element to be investigated was evaporated to dryness on a water bath. To the residue thus obtained, first the solid organic acid and then the solvent was added.

Organic acids and solvent. The following reagent-grade acids were employed: oxalic, malonic, succinic, glutaric, *d,l*-tartaric and citric. The methanol employed was also of reagent-grade purity.

Apparatus

The column operations were carried out in columns of the same type and dimensions as described earlier.[7] For the fluorimetric determination of uranium a Galvanek Morrison Mark V fluorimeter and for the spectrophotometric determination of the other elements a Beckman Model B spectrophotometer was employed.

Quantitative determination of elements investigated

The determination of uranium was performed fluorimetrically,[11] and that of thorium and the rare earths spectrophotometrically by employing the azo dye Solochromate Fast Red.[12,13] The other elements were determined quantitatively using photometric methods recommended by Sandell.[14]

Determination of distribution coefficients

The distribution coefficients of all elements were determined in the same manner as has earlier been described for the equilibrium experiments in mineral acid-organic solvent[15] and organic acid-organic solvent[10] mixtures. Twenty ml of solvent, containing a certain amount of the acid and 5 mg of the element in question, were equilibrated with 1 g of the resin. The results of the experiments shown in Figs. 1 and 2 were obtained by using varying amounts of acid whereas those recorded in Fig. 3 and in Table I were always performed in the presence of 1 g of acid.

Column operations

All separation experiments on resin columns were performed by employing the following working procedure.

Pretreatment of resin bed. In order to transform the chloride form of the resin into the malonate form the resin bed was treated with a 10% aqueous malonic acid solution which had been buffered to a pH of approximately 5 to 6 with aqueous ammonia. As soon as the effluent was free from chloride ions (which was usually the case after the passage of less than 50 ml of this solution), the resin was washed with 50 ml of a solution (washing solution) containing 50 g of malonic acid/1,000 ml of distilled water.

Adsorption of uranium. The sorption solution was prepared by dissolving the residue obtained by evaporation of certain amounts of the standard solutions of the elements in question, first by adding 5 g of malonic acid to the dry residue, followed by 100 ml of distilled water. This solution was passed through the column at a flow rate of 0·5–0·75 ml/min. During this operation uranium was strongly adsorbed whereas the other elements, *i.e.*, thorium, cerium and gadolinium, passed into the effluent.

Washing process. In order to remove the last traces of the other elements the resin bed was washed with 50 ml of the washing solution.

Elution. The uranium was eluted with 100 ml of 1*M* hydrochloric acid.

Further treatment of eluate and effluent. After evaporation of the eluate to dryness (water bath) the uranium was determined as previously described.[16] During this process as well as when evaporating the effluent, malonic acid was decarboxylated, whereby acetic acid was formed, so that very little organic matter was present in the residue. In the residues obtained after evaporation of the effluents, thorium and the rare earths were determined by previously described procedures.[12,13]

The results of a series of such column separations are recorded in Table II.

RESULTS

Effect of acid concentration on distribution coefficients of uranium and thorium

In Figs. 1 and 2 the results of the experiments performed in aqueous and methanolic solutions containing varying amounts of the organic acids are recorded.

Although the adsorption of uranium from oxalic acid solutions is higher than from all mixtures containing other acids, it did not seem practical to use this acid for further investigations because its solubility in water is rather low; furthermore, it forms insoluble precipitates with thorium, the rare earths and other elements in aqueous as well as in methanolic media. In malonic acid mixtures, however, both these adverse effects are not observed so that this acid was employed for the separation of uranium, thorium and rare earths on ion-exchange columns.

By comparing Fig. 1 with Fig. 2 it can clearly be seen that the difference existing between the adsorption of uranium in aqueous and methanolic solutions is rather large (especially at a higher acid concentration) in comparison with that of thorium, which shows in both solvents a practically identical adsorption behaviour. Besides,

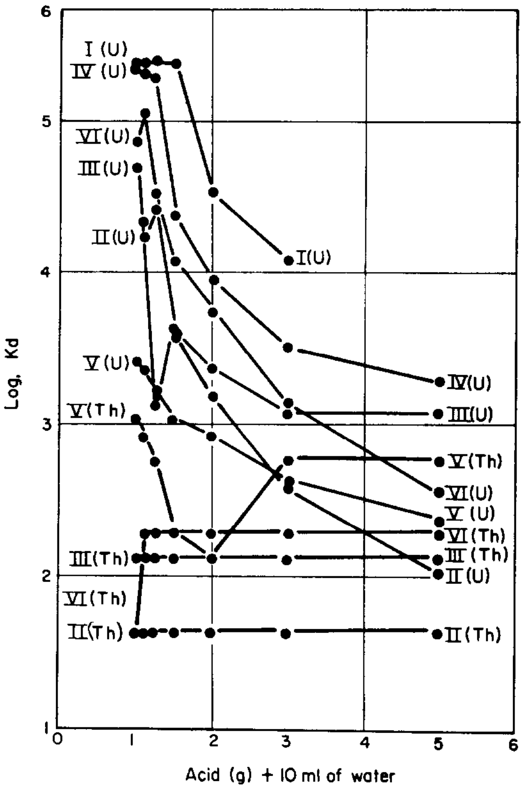

FIG. 1.—Adsorption of uranium and thorium from aqueous solutions containing di- and tricarboxylic acids:

I—oxalic acid, IV—glutaric acid,
II—malonic acid, V—tartaric acid,
III—succinic acid, VI—citric acid.

its solubility in methanolic solutions is rather limited. That is why in Fig. 2 only two curves for thorium could be established. Several experiments in other solvents, *e.g.*, ethanol, n-propanol, acetone, *etc.*, with some of the acids have shown that the adsorption of uranium from tartaric and citric acid media did not deviate appreciably from the results obtained in methanolic solutions, whereas in the presence of the other acids a decrease of uranium adsorption with increasing chain length of the alcohols could be observed[15] in the case of oxalic acid. Because of the low solubility of the acids, however, no systematic investigations as to the adsorption of uranium or other elements were conducted in solvents other than water and methanol.

Effect of water-methanol concentration

In Fig. 3 the variation of the distribution coefficients of uranium at different water to methanol ratios is shown. From the results it is seen that the Kd of uranium in the dicarboxylic acid-methanol-water mixtures does not vary as much with increasing percentage of methanol as in tartaric and citric acid media, where a sharp decline of the Kd occurs when increasing the methanol content of the mixtures from 80 to 100%. This is because the hydrophilic hydroxyl groups of these acids gradually lose their complex-forming tendencies by a decrease in the water content of the mixtures. In

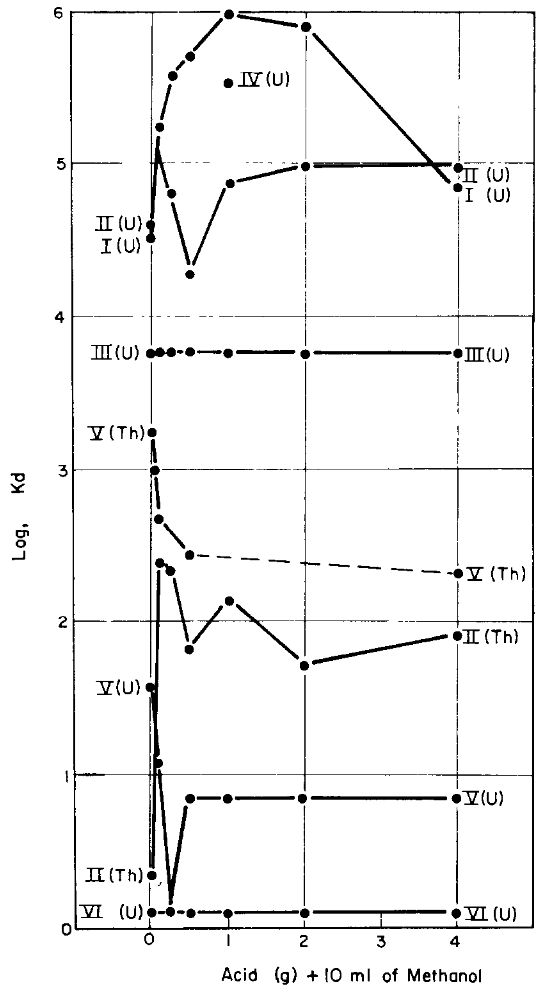

Fig. 2.—Adsorption of uranium and thorium from methanolic solutions containing di- and tricarboxylic acids:

I—oxalic acid,	IV—glutamic acid,
II—malonic acid,	V—tartaric acid,
III—succinic acid,	VI—citric acid,

- - - - region of insolubility.

the case of the dicarboxylic acids without hydroxyl groups, however, the adsorption of uranium in 100% aqueous solutions of the acids is less than in 100% methanol solutions of the acids, so that in the presence of these acids an increase of the methanol concentration increases the uranium adsorption.

Adsorption behaviour of other elements

In Table I the distribution coefficients of a series of other elements in aqueous and methanolic media containing malonic, succinic, glutaric, tartaric and citric acid are recorded.

For comparison purposes the distribution coefficients of uranium and thorium in the various media have also been included in this table.

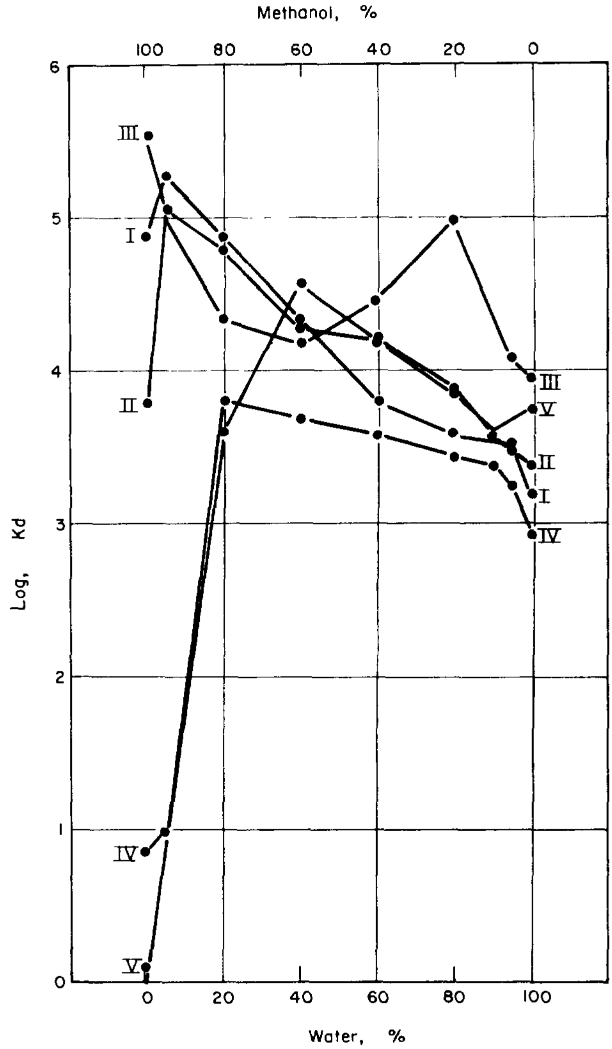

Fig. 3.—Effect of water-methanol concentration on uranium adsorption:
I—malonic acid, III—glutaric acid,
II—succinic acid, IV—tartaric acid,
V—citric acid.

From the results it is seen that malonic acid in methanol is superior to the other di- and tricarboxylic acids in-so-far as it shows the greatest solubility and sufficient acid strength to keep most of the investigated elements in solution without forming precipitates or causing hydrolysis. In aqueous solutions, however, all of the acids can be employed for the adsorption of uranium with nearly equal effect, irrespective of their chemical constitution. For the purpose of separating uranium from thorium and other elements (with the exception of iron, which could easily be separated from uranium in a water-succinic acid medium), the use of malonic acid seemed to be advantageous because most of the elements, except for iron and yttrium, show rather low distribution coefficients in aqueous malonic acid solutions.

× In these media completely or partially insoluble.

In methanolic solutions of this acid, on the other hand, the possibility of co-adsorbing uranium together with thorium, the rare earths and other elements exists, so that malonic acid can be regarded as a more versatile complexing agent than the other acids, the element salts of which are also poorly soluble in methanol.

Separation procedure

Based on the results presented in Figs. 1 and 2 and in Table I a method of separating uranium from thorium, cerium and gadolinium (as representatives of the rare earth elements) in an aqueous medium was developed. The experimental steps involved in this ion-exchange procedure have been described above under *Column operations*.

In Table II the results of these resin column separations are recorded. It is seen that all separations of uranium from the other elements were practically quantitative. For this reason and because the break-through capacity for uranium under these conditions (2g of resin in column 15 cm high and 0·5 cm diameter) was found to be

* Each result is the average of 3 separations performed under the same experimental conditions.

60 mg of uranium, this procedure could be employed effectively for the removal of fission products like the rare earths, strontium, *etc.*, from uranium.

By this anion-exchange method not only the separation of these elements from uranium can be accomplished but also from a series of other elements (those having sufficiently low distribution coefficients, *viz.* <50). It is, therefore, of broad applicability, unlike the method described by Zaki and Shakir[1] which has only limited use for analytical purposes.

Acknowledgements—This research was sponsored by the International Atomic Energy Agency and the United States Atomic Energy Commission under Contract No. 67/US (AT(30-1)-2623). The generous support from these agencies is gratefully acknowledged.

Zusammenfassung—Es wurde das Ionenaustauschverhalten von Uran, Thorium, der seltenen Erden und einiger anderer Elemente gegenüber dem stark basischen Anionenaustauscher Dowex 1 in wäßrigen und methanolischen Systemen die Di- oder Tricarboxylsäuren enthalten untersucht. Auf Grund von Messungen der Verteilungskoeffizienten in derartigen Medien konnte eine Methode zur Trennung des Urans von Thorium und den seltenen Erden in malonsaurer wäßriger Lösung entwickelt werden.

Résumé—On décrit l'échange de l'uranium, du thorium, des éléments de terres rares et de quelques autres éléments en présence de l'échangeur d'anions fortement basique Dowex 1 dans des systémes aqueux ou méthanoliques contenant des acides di- ou tricarboxyliques. Dével-oppement d'une méthode basée sur la mesure des coefficients de distribution dans de tels milieux, pour séparer l'uranium du thorium et des éléments des terres rares en solution aqueuse contenant de l'acide malonique.

(*Received* 8 *August* 1963. *Accepted* 11 *October* 1963)

Summary—A study of the coprecipitation of thallium with As_2S_3, SnS_2, MoS_3, Re_2S_7, PtS_2, PdS, Ru_2S_3, Rh_2S_3, Ir_2S_3 and In_2S_3, and of indium with CuS and Ag_2S by physicochemical analysis has shown that the process results from formation of the following compounds: $TlAsS_2$, $TlSnS_2$, $TlMoS_2$, $TlReS_4$, $TlPtS_3$, $TlPd_2S_3$, $TlRu_2S_6$, $TlRh_2S_4$, Tl_3Ir_3S, $TlIn_2S_3$, $CuInS_2$ and $AgInS_2$. A type of coprecipitation diagram characteristic for the case of the formation of chemical compounds has been established and the fields on it, corresponding to phases of definite composition, have been delimited. The formation in the coprecipitation of microdisperse systems of "colloidal" solid solutions of one sulphide in another has been shown.

VARIOUS views have been put forward to explain the reasons for the coprecipitation of cations with sulphides.[1,2] A number of authors consider that the entrainment of cations by sulphides results from formation of chemical compounds. Feigl explains the coprecipitation by the formation of heteropolymers or mixed sulphides of the type: $Me^{I}S\text{–}SMe^{II}$.[3–5] Okač also indicates the formation of heteropolysulphides $(MeS)_x$ $(Me'S)_y$.[6] He states that x and y may in special cases correspond to the stoichiometric figures for hypothetical complex compounds of the general formula $[Me(SMe')_x]S$. According to Hawley's results, in the simultaneous precipitation of Tl_2S and SnS_2 and also of Tl_2S and As_2S_5, compounds of the composition Tl_4SnS_4 and Tl_3AsS_4 are formed.[7,8] Bruner and Zawadzki mention the compound $Tl_2S{\cdot}4CuS$, which, in their opinion, is obtained in the coprecipitation of thallium with CuS.[9] Malfatti considers that the precipitation of FeS in the presence of the alkali and the alkaline-earth metals gives thiosalts of the composition $MeFeS_2$ and $Me(FeS_2)_2$, where Me is a uni- or bivalent cation.[10] The compounds $PbS{\cdot}Tl_2S$ and $GaS{\cdot}ZnS$, formed in the coprecipitation of thallium with PbS and of gallium with ZnS, respectively, are referred to by Nanobashvili *et al.*[11,12] In the precipitation of sulphides of copper and germanium, Davydov and Diyev obtained a precipitate with a composition close to that for the compound $CuS{\cdot}GeS_2$.[13]

In the papers discussed, only individual facts indicating the formation of chemical compounds under certain conditions are given. In the majority of them, however, only hypotheses, not confirmed by direct experiments, are put forward about their formation. No investigations exist with a general approach to the solution of the question of the possibility of the formation of chemical compounds in coprecipitation.

In an investigation of the coprecipitation of thallium and indium with sulphides of the second analytical group of the classical hydrogen sulphide scheme, we found that the phenomenon was clearly expressed where the sulphides in the system possessed opposite—basic and acidic—properties. This fact gave grounds for assuming the formation of chemical compounds. Consequently, we considered it desirable to carry out investigations of the coprecipitation of cations with sulphides starting from the positions of the elements in the Periodic Table. This study of the phenomenon was carried out on the basis of physicochemical analysis.

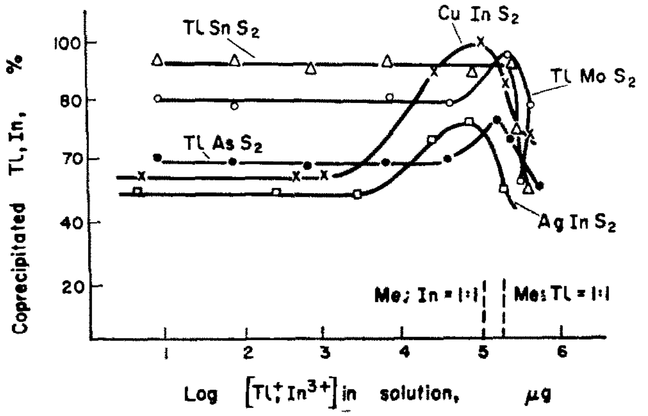

FIG. 1.—Coprecipitation diagrams of Tl with As_2S_3, SnS_2 and MoS_3, and of In with Ag_2S and CuS.

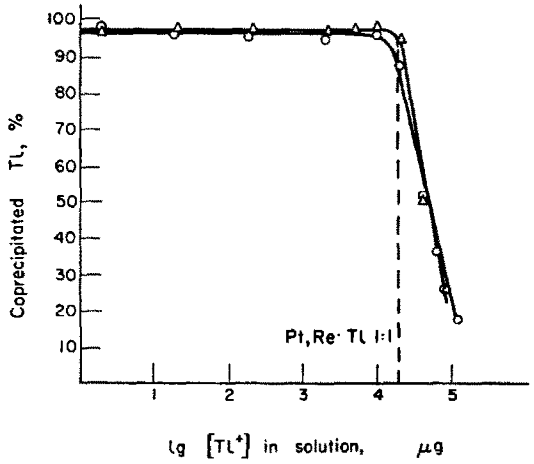

FIG. 2.—Coprecipitation diagrams of Tl with Re_2S_7 and PtS_2.

Physicochemical analysis with a constant concentration of one component and a variable concentration of the other was used. Construction of the coprecipitation diagrams was carried out by plotting as ordinates the amount of coprecipitation in per cent and as abscissae the logarithm of the concentration of the thallium or indium in the solution. The amount of coprecipitation was determined by a radioactive tracer method using the radioisotopes ^{204}Tl and ^{114}In.

EXPERIMENTAL

I. *Application of physicochemical analysis to the coprecipitation of thallium and indium with sulphide*

Below we give data on the coprecipitation in a series of systems for sulphides of the metals mentioned.

The systems Tl^+, H^+/AsO_3^{3-}, S^{2-}; Tl^+, H^+, Sn^{4+}/S^{2-}; Tl^+, H^+/MoO_4^{2-}, S^{2-}; and Tl^+, H^+/ReO_4^-, S^{2-}. From the breaks in the coprecipitation diagrams given in Figs. 1 and 2 may be deduced the formation of compounds having ratios of As, Sn, Mo and Re to Tl of 1:1.

The constancy of the distribution coefficient of thallium in the case of the coprecipitation of small concentrations of thallium is striking.*

Analysis of the compounds isolated showed that they had the following compositions: $TlSnS_2$, $TlAsS_2$, $TlMoS_3$ and $TlReS_4$.

An X-ray examination of Tl_2S, As_2S_3, SnS_2, MoS_3 and Re_2S_7, and also of $TlSnS_2$, $TlAsS_2$, $TlMoS_3$ and $TlReS_4$, gave amorphous pictures.

The systems Cu^{2+}, In^{3+}, H^+/S^{2-}; Ag^+, In^{3+}, H^+/S^{2-}. As follows from the coprecipitation diagrams given (Fig. 1), chemical compounds are also formed in these systems. The breaks in the diagrams correspond to a ratio in the precipitates of Cu or Ag to In of 1:1.

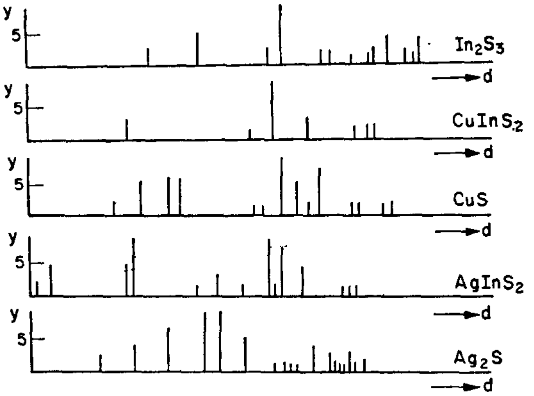

FIG. 3.—Results of calculation of the X-ray diagrams for CuS, In_2S_3, $CuInS_2$, Ag_2S and $AgInS_2$.

The behaviour of low concentrations of indium is analogous to the cases of the coprecipitation of thallium already considered.

From the results of analysis, the compositions of these compounds are as follows: $CuInS_2$ and $AgInS_2$.

X-ray investigation showed diffraction pictures for $CuInS_2$ and $AgInS_2$ different from those for the starting materials CuS, Ag_2S and In_2S_3, which is characteristic for the formation of chemical compounds (Fig. 3).

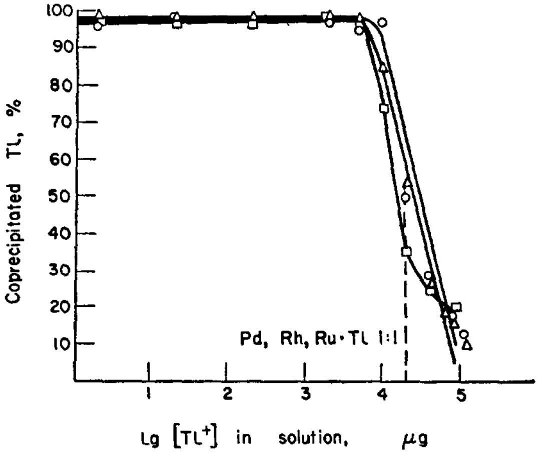

FIG. 4.—Coprecipitation diagrams of Tl with Rh_2S_3, Ru_2S_3 and PdS.

---

* The distribution coefficient may be calculated from the formula $K = \frac{C_{\text{solid phase}}}{C_{\text{solution}}}$

The systems Tl^+, H^+ / Pt^{IV}, S^{2-}; Tl^+, H^+/Pd^{II}, S^{2-}; Tl^+, $H^+/Ru,^{III}$ S^{2-}; *and* Tl^+, H^+/Rh^{II}, S^{2-} Analogous results were also obtained in the coprecipitation of thallium with sulphides of the platinum metals. As can be seen from the diagrams given (Fig. 4), in contrast to those obtained previously the breaks in the curves correspond to a ratio of Pd, Ru and Rh to Tl of 2:1. In the case of the coprecipitation of Tl with PtS_2, the ratio of Tl and Pt in the compound formed is 1:1 (Fig. 2).

Analysis of the compounds obtained showed that they had the compositions: $TlPtS_3$, $TlPd_2S_3$, $TlRu_2S_6$ and $TlRh_2S_4$. The results of calculation of the X-ray diagrams for $TlPtS_3$, $TlPd_2S_3$, $TlRu_2S_6$ and $TlRh_2S_4$ are given in Fig. 5. For PtS_2, PdS, Ru_2S_3 and Rh_2S_3, amorphous X-ray pictures were obtained.

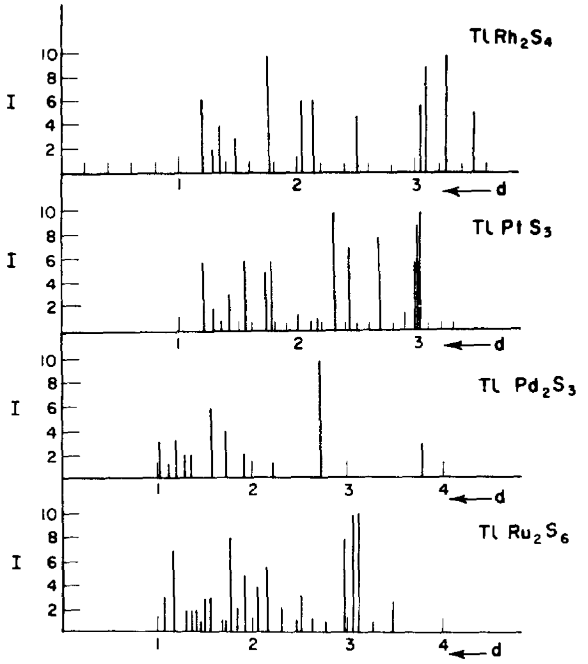

FIG. 5.—Results of the calculation of the X-ray diagrams for $TlRh_2S_4$, $TlPtS_3$, $TlPd_2S_3$ and $TlRu_2S_6$.

The systems Tl^+, H^+/Ir^{III}, S^{2-}; In^{3+}, Tl^+, H^+/S^{2-}. In a study of the coprecipitation of thallium with Ir_2S_3, a diagram somewhat different from those given above was obtained (Fig. 6). From the break in the curve, as in the diagrams given in Figs. 1, 2 and 4, it may be concluded that a compound with a Tl:Ir ratio of 1:1 is formed.

Analysis of the compound formed showed that it had the composition Tl_3Ir_3S, the unusual nature of which is striking.

The most interesting field in the diagram obtained is C, characterising a proportionality between the concentration of the cation in the solution and in the solid phase, which shows the formation of solid solutions (the distribution coefficient may be calculated from the formula $K = \frac{C_{\text{solid phase}}}{C_{\text{solution}}}$

The X-ray diagrams of Tl_3Ir_3S and Ir_2S_3 are given in Fig. 7. The difference in the position and intensity of the lines of the Tl_3Ir_3S X-ray diagram as compared with that for Ir_2S_3 confirms the formation of a chemical compound.

It follows from the results of our study of coprecipitation in the systems given above that the formation of chemical compounds is found in those cases where one of the sulphides of the given system possesses basic properties and the other acidic properties. The elements giving these compounds are located in different groups of the Periodic Table. The rule mentioned has been confirmed in many cases of the coprecipitation of thallium with sulphides of an acidic character and of indium with sulphides of a basic character. It is quite natural to assume that the coprecipitation of thallium with In_2S_3 will also lead to the formation of a chemical compound. The results obtained are given in Fig. 8. The break in the diagram corresponds to an In:Tl ratio in the precipitate of 1:0·5.

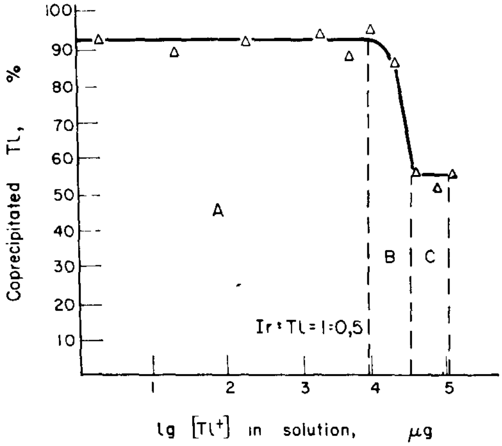

FIG. 6.—Coprecipitation diagram of Tl with Ir_2S_3.

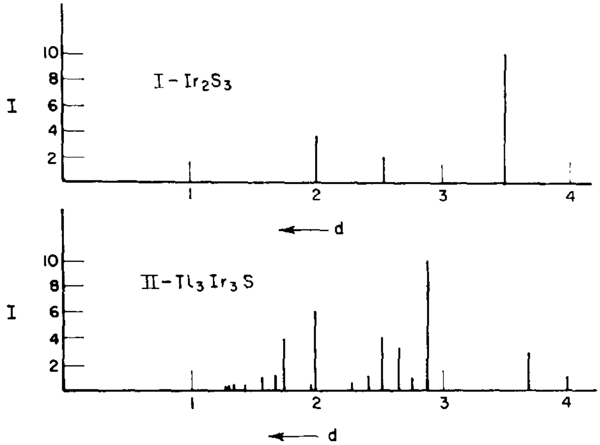

FIG. 7.—Results of the calculation of the X-ray diagrams for Tl_3Ir_3S and Ir_2S_3.

Of particular interest is the shape of the curve for ratios of In to Tl in the solution of 1:10, 1:12, 1:14 and 1:16, where there is a constant degree of coprecipitation of thallium with In_2S_3. On the diagram, this corresponds to the parallel course of the coprecipitation curve. The constancy of the distribution of thallium between the solution and the solid phase shows the formation of a solid solution of this composition with an excess of Tl_2S (field D).

Analysis of the precipitate showed that the compound obtained had the composition $TlIn_2S_3$. The X-ray diagrams of $TlIn_2S_3$ and In_2S_3 are given in Fig. 9. The difference in the position and intensity of the lines of the X-ray diagrams of $TlIn_2S_3$ and In_2S_3 is characteristic for a chemical compound.

Thus, in spite of the presence of indium and thallium in a single Sub-Group of the Periodic Table, in consequence of which the acidic—basic properties of In_2S_3 and Tl_2S differ less than for the sulphides of the elements mentioned above, the formation of a chemical compound also takes place in this case.

II. *X-ray investigation of the solid phases obtained in coprecipitation when a chemical compound is formed*

A more complete idea of the reactions in the solid phases for the investigated concentrations of the coprecipitating cation can be obtained by the use of X-ray analysis.

In the majority of the systems which we studied, the sulphides were amorphous to X-rays, which limited their application. The system Cu^{2+}, In^{3+}, H^+/S^{2-} proved to be suitable, because CuS, In_2S_3 and $CuInS_2$ give sharp X-ray diagrams.

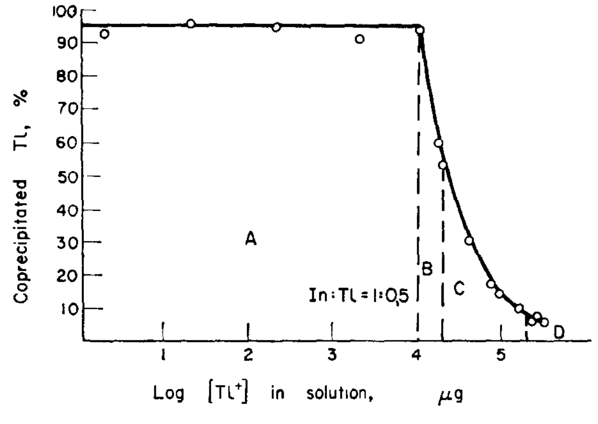

FIG. 8.—Coprecipitation diagram for Tl with In_2S_3.

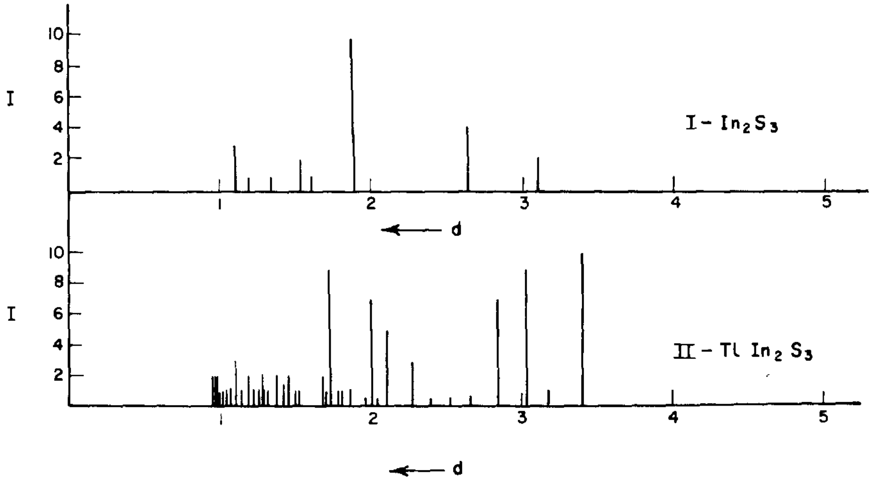

FIG. 9.—Results of the calculation of the X-ray diagrams of In_2S_3 and $TlIn_2S_3$.

The diagrams of coprecipitation of indium with CuS are given in Fig. 10.

The changes in the composition of the phases formed in the coprecipitation of various concentrations of In^{3+} with CuS are shown schematically in Fig. 11 on the basis of the results of the X-ray analysis.

In this diagram (Fig. 11) there are three regions: a single-phase region A′ (the pure CuS component), a two-phase region A (CuS + $CuInS_2$ in various proportions) and a single-phase region ($CuInS_2$).

Field A, where there is a constant distribution of indium between the solution and the solid phase, indicates the formation of solid solutions. However, it follows from the X-ray diagrams that this is a two-phase region. This contradiction can be resolved by assuming in our case the formation of a microdisperse system where the dispersion medium is CuS and the dispersed substance is $CuInS_2$. The structure, the particle size and the features of its formation are such that the uniform distribution of one phase in the other is possible. As can be seen from Fig. 11, from a certain ratio between CuS and $CuInS_2$ onwards, the latter will be the dispersion medium and the CuS will be the dispersoid.

The following facts favour this hypothesis. In the case of the coprecipitation of In^{3+} with CuS, because its molecules are being formed at the moment when the CuS produced passes through the colloidal stage, a uniform distribution of the compound formed, $CuInS_2$, throughout the volume of the CuS gel is quite natural. Entrainment of indium after the separation of the CuS in the form of a solid phase must also give a uniform distribution of $CuInS_2$ by virtue of the extremely high porosity of CuS and the possibility of the interaction of the In^{3+} ion practically throughout the mass of CuS, The exceptionally large specific surface of sulphide precipitates (600 m^2) follows from its determination

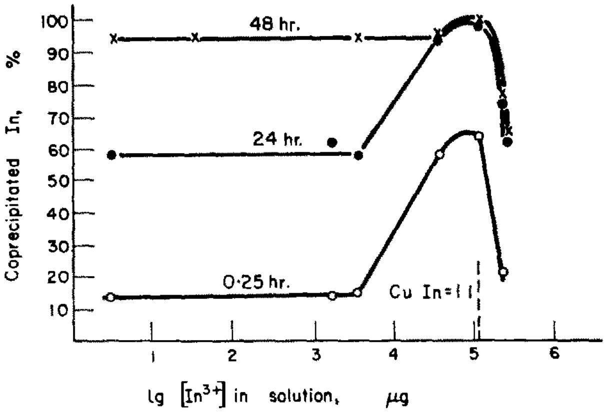

FIG. 10.—Coprecipitation diagram of In with CuS.

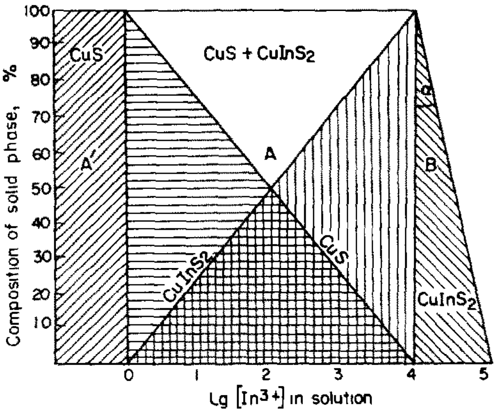

FIG. 11.—Change in the composition of the phases obtained in the coprecipitation of various concentrations of In^{3+} with CuS.

by the sorption of surface-active dyes[14] and by isotopic exchange between ions in the solution and the solid sulphide phase,[15] and also from electron-microscope pictures.[14,16]

The X-ray diagrams of the precipitates recorded were used to determine the particle dimensions of the phases of interest to us. Calculations of the mean effective grain size were carried out by Selyakov's formula.[17]

As the results showed, the mean effective grain size for CuS and $CuInS_2$ was *ca.* 3×10^{-6} cm. Consequently, the particles of $CuInS_2$, with a degree of dispersion of 3×10^{-6} cm, are distributed in a precipitate of CuS with a particle size of the same order.

According to the hypothesis being discussed, the constancy of the distribution coefficient is connected with the formation of solid solutions with a molecular degree of dispersion of the components. The results we obtained indicate the possibility of the compatibility of the constancy of the distribution of the coprecipitated cation and the absence of a molecularly dispersed distribution of one component in the other. In the present case, we encounter new facts requiring a revision of the hypotheses that have become established.

III. *Conditions of formation and properties of the compounds*

The compounds concerned are obtained as the result of coprecipitation, *i.e.*, under somewhat unusual conditions. Consequently, it was of interest to study these conditions and also the properties of the compounds arising. It is possible in this way to obtain a more profound insight into the coprecipitation process.

In view of the fact that the sulphide precipitates have an enormous surface with HS^- and S^{2-} ions present on it and giving to it a negative charge, it was essential to elucidate the role of adsorption in the formation of the compounds we were studying.

It was possible to elucidate the dependence of the coprecipitation on adsorption by studying the influence on the degree of coprecipitation of the conditions existing when the coprecipitating cation was added to a precipitate of previously separated sulphide and also when foreign ions were present in the solution.

The results obtained are given in Tables I and II.

TABLE I—COPRECIPITATION OF THALLIUM WITH Re_2S_7, PtS_2, PdS, Ru_2S_3 AND Ir_2S_3 UNDER VARIOUS CONDITIONS

	Coprecipitation of thallium, %			
		Addition to previously formed precipitate		
Metal sulphide	At the moment of formation of the precipitate	Unwashed	Washed with H_2O	Washed with H_2O, but on the addition of Tl H_2S–H_2O was introduced
Re_2S_7	51·7	40·7	6·5	15·8
PtS_2	49·9	21·6	2·6	10·1
PdS	49·6	37·9	7·9	16·4
Ru_2S_3	49·5	50·9	6·1	25·5
Ir_2S_3	56·7	24·2	1·6	—

TABLE II—INFLUENCE OF FOREIGN IONS ON THE COPRECIPITATION OF THALLIUM WITH Re_2S_7, PtS_2, PdS AND Ru_2S_3

	Coprecipitation of thallium, %			
Foreign electrolyte	For a Re:Tl ratio in the solution of 1:2	For a Pd:Tl ratio in the solution of 1:1	For a Ru:Tl ratio in the solution of 1:1	For a Pt:Tl ratio in the solution of 1:2
$MgSO_4$(4·9 mg of Mg)	54·2	51·1	50·1	52·8
$Al_2(SO_4)_3$(5·4 mg of Al)	52·4	48·8	50·9	49·1
$ZnSO_4$(6·5 mg of Zn)	50·1	50·0	51·2	51·9
In the absence of foreign electrolyte	51·7	49·6	49·5	49·9

As the results given show, the coprecipitation of thallium at the moment of formation of Ru_2S_3 is identical with that produced by a previously formed precipitate of this sulphide. In the case of Re_2S_7, PtS_2, PdS and Ir_2S_3, thallium is coprecipitated in considerably greater amount than when it is added to preformed precipitates of these sulphides. Precipitates of sulphides first washed free from H_2S with water entrain thallium to only a slight extent. However, if a washed sulphide is added to a sulphuric acid solution containing H_2S, then marked coprecipitation of the thallium is again found.

The presence of large amounts of foreign cations—Mg^{2+}, Al^{3+}, Zn^{2+}—does not affect the degree of coprecipitation of the thallium with Re_2S_7, PtS_2, Ru_2S_3 and PdS. It follows from this that the formation of these compounds is not associated with an ordinary adsorption process. In order to obtain a more detailed explanation of the role of hydrogen sulphide in the process under study, the sorption by PdS of H_2S in solution in different concentrations was determined. Experiments were carried out at the same time with Ag_2S. The latter coprecipitates the cations from all sulphides to the smallest extent. Consequently, we desired to establish whether there was a relationship between the amounts of sorbed H_2S and the degree of coprecipitation of thallium.

The experiments showed that PdS and Ag_2S sorb approximately the same amounts of H_2S. Nevertheless, thallium is not coprecipitated with Ag_2S, or else this phenomenon is not exhibited to an appreciable extent.

The precipitates previously washed free from H_2S with water also entrain thallium to an inconsiderable extent.

Consequently, we may conclude that the presence of H_2S on the surface of the sulphides is a necessary, but not sufficient, condition for coprecipitation of the cations.

The chemistry of the phenomenon is also confirmed by the maintenance of stoichiometric ratios between the elements in the precipitate on the partial separation of the main component.

The results obtained are given in Table III.

TABLE III—COPRECIPITATION OF THALLIUM WITH PARTIAL SEPARATION OF Re_2S_7

Re precipitated, %	Tl coprecipitated, %	Ratio of Re to Tl in the precipitate
100	52·4	1:1·04
75·0	37·0	1:0·96
50·0	24·2	1:0·97
25·0	10·0	1:0·80

As follows from the results given, the amount of thallium is equivalent to the Re_2S_7 which separated, which is characteristic for the formation of chemical compounds.

It was also of interest to determine the solubility of the compounds obtained. These compounds were obtained by coprecipitation, *i.e.*, by a somewhat unusual method. Nevertheless, a determination of their solubilities was important from the point of view of using these compounds for analytical purposes.

Solubility figures determined from the contents in aqueous solutions of the given compounds of the ions Tl, Ag and Cu, respectively, are given in Table IV.

TABLE IV—SOLUBILITY OF THE COMPOUNDS OBTAINED IN WATER AT $t° = 25 \pm 0·5$

Compound	Solubility, *mole/litre*
$TlReS_4$	$7·3 \times 10^{-5}$
$TlPd_2S_3$	$2·0 \times 10^{-5}$
$TlRu_2S_6$	$3·4 \times 10^{-5}$
$TlPtS_3$	$4·4 \times 10^{-5}$
Tl_3Ir_3S	$4·9 \times 10^{-5}$
$TlRh_2S_4$	$0·49 \times 10^{-5}$
$TlAsS_2$	$4·5 \times 10^{-6}$
$TlMoS_2$	$2·5 \times 10^{-5}$
$TlSnS_2$	$2·2 \times 10^{-5}$
$AgInS_2$	$4·7 \times 10^{-9}$
$CuInS_2$	$6·3 \times 10^{-8}$

The figures in Table IV clearly show that the magnitude of the solubility is not characteristic for the sulphides. Moreover, magnitudes of the same order are obtained for all of the compounds.

The experiments on the addition of thallium to a previously separated precipitate of Ru_2S_3 proved to be extremely fundamental. Under these conditions, thallium is entrained in the same amounts as at the moment of separation of the Ru_2S_3. Consequently, it was necessary to determine whether the compound $TlRu_2S_6$ is formed by the reaction of the Tl^+ ion with Ru_2S_3 or whether the thallium is present on the surface of the Ru_2S_3 in the form of Tl_2S. The identical X-ray diagrams for these compounds show that the first hypothesis is correct.

DISCUSSION

The experimental results presented show that chemical compounds are very important in the sulphide coprecipitation process. For the formation of chemical compounds to take place in the coprecipitation process, the presence in the sulphides of opposing properties—acidic and basic—is necessary. This condition is connected with the position of the elements forming the sulphides in the Periodic Table. Consequently, knowing the components of a given system, it is possible to predict the formation of chemical compounds and, consequently, the degree of coprecipitation, its course and the properties of the solid phase formed.

In the case of the formation of chemical compounds, the coprecipitation diagrams obtained are of a single type; the difference between them consists only in the position of the breaks corresponding to the ratio of the components in the solid phase.

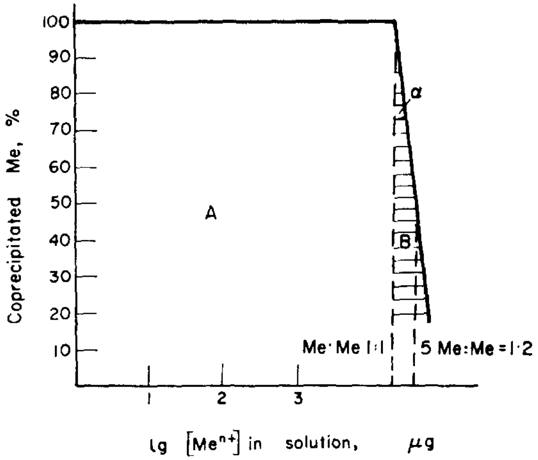

FIG. 12.—Theoretical coprecipitation diagram caused by formation of a chemical compound.

In the case of the coprecipitation of thallium with MoS_3, As_2S_3, SnS_2, Re_2S_7, PtS_2 and Ir_2S_3, and of In with CuS and Ag_2S, the ratio of Tl or In to Me is 1 : 1.

The coprecipitation of thallium with In_2S_3, PdS, Ru_2S_3 and Rh_2S_3 is characterised by curves with breaks at a Tl : Me ratio of 1 : 2.

It is important to note that at a ratio in the solution of Tl to Re, Pt or Ir of 1 : 1, the ratios in the solid phase are, respectively, 1 : 0·85, 1 : 0·95 and 1 : 0·87, and at ratios of Tl to Pd, Ru or Rh in the solutions of 1 : 2 these ratios are 1 : 0·42, 1 : 0·48 and 1 : 0·39, respectively.

We obtained an analogous picture for the coprecipitation of Tl with As_2S_3, SnS_2 and MoS_3, and also for In with CuS and Ag_2S.

Thus, the coprecipitation reaction, for example for the Tl^+ ion with Re_2S_7, takes place to the extent of only 85·4% by the equation

$$2Tl^+ + Re_2S_7 \cdot nH_2S \rightleftharpoons 2TlReS_4 \cdot (n-1)H_2S + 2H^+.$$

In order that the coprecipitation reactions mentioned should take place quantitatively, a two-fold excess of Tl^+ ion in the solution is necessary. The investigation of coprecipitation in the systems mentioned which has been carried out permits the theoretical coprecipitation diagram characteristic for the formation of chemical compounds to be given (Fig. 12). All of the systems that we have studied correspond to this type of diagram, in which coprecipitation is connected with the formation of chemical compounds.

In the case of the coprecipitation of Tl with As_2S_3, SnS_2 and MoS_3, and of In with CuS and Ag_2S, the coprecipitation diagrams should have a similar form. The displacement of part of the curve with respect to the abscissae apparently resulted from the fact that for low concentrations of Tl^+ and In^{3+} the equilibrium state was not attained (Fig. 10.).

In the diagrams of this type, field A (Fig. 12) is characterised by parallel coprecipitation curves indicating proportionality between the amount of coprecipitated cation and its concentration in the solution. As is well known, such a situation is characteristic for solid solutions.

As the results of X-ray analysis have shown, in the range of concentrations of the second component corresponding to field A, the formation of a microdisperse system—a "colloidal" solid solution—takes place.

When the concentration of the cation in the solution is increased, a new field B appears on the diagram (Fig. 11). For the case of the formation of chemical compounds, the break in the curve is found at multiple ratios between their components. The formation of chemical compounds for the range of concentrations corresponding to field B was confirmed by analysis of the precipitates and by their X-ray diagrams. The composition of the solid phase as the concentration of the second component is increased within the range AB remains constant. Graphically, this is determined by the angle of inclination α of the coprecipitation curve.

As the experiments show, with an excess of thallium in the solution (Me:Tl = 1 : 4 — 1 : 16) its content in the solid phase exceeds the stoichiometric amount. This is particularly clearly expressed in the case of the coprecipitation of thallium with In_2S_3 and Ir_2S_3.

The phenomenon observed is obviously connected with the general property of chemical compounds of giving solid solutions with an excess of their components. A confirmation of the hypothesis expressed is the invariability of the distribution constant of the second component between the solution and the solid phase formed under these conditions. The capacity of chemical compounds for giving solid solutions with an excess of the second component explains the appearance on the diagram for the coprecipitation of thallium with Ir_2S_3 (Fig. 6) of a new field C, and with In_2S_3 of field D (Fig. 8).

It follows from the results given that the coprecipitation diagram in association with X-ray analysis of the solid phases obtained permits a fairly complete picture of the phenomenon to be obtained.

In conclusion, we should like to mention that the experimental material presented shows the importance of chemical compounds in the coprecipitation of cations with sulphides. Construction of the coprecipitation diagram makes it possible to obtain a complete picture of this process.

Acknowledgment—The authors express their thanks to Corresponding Member of the U.S.S.R. Academy of Sciences, I. P. Alimarin, for valuable advice on the investigation.

Zusammenfassung—Eine Untersuchung der Mitfällung von Thallium mit As_2S_3, SnS_2, MoS_3, Re_2S_7, PtS_2, PdS, Ru_2S_3, Rh_2S_3, Ir_2S_3 und In_2S_3 und von Indium mit CuS und Ag_2S mit physikochemischen Methoden zeigte, daß die Mitfällung auf der Bildung folgender

Verbindungen beruht: $TlAsS_2$, $TlSnS_2$, $TlMoS_2$, $TlReS_4$, $TlPtS_3$, $TlPd_2S_3$, $TlRu_2S_6$, $TlRh_2S_4$, Tl_3Ir_3S, $TlIn_2S_3$, $CuInS_2$ und $AgInS_2$. Eine für die Bildung von Verbindungen charakteristische Art von Mitfällungsdiagramm wurde aufgestellt und darauf die Phasen bestimmter Zusammensetzung entsprechenden Bereiche abgegrenzt. Es wurde gezeigt, daß sich bei der Mitfällung mikrodisperser Systeme "kolloide" feste Lösungen eines Sulfids im andern bilden.

Résumé—Une étude de la coprécipitation du thallium avec As_2S_3, SnS_2, MoS_3, Re_2S_7, PtS_2, PdS, Ru_2S_3, Rh_2S_3, Ir_2S_3 et In_2S_3, et de l'indium avec CuS et Ag_2S au moyen de l'analyse physico-chimique a montré que le phénomène est dû à la formation des composés suivants: $TlAsS_2$, $TlSnS_2$, $TlMoS_2$, $TlReS_4$, $TlPtS_3$, $TlPd_2S_3$, $TlRu_2S_6$, $TlRh_2S_4$, Tl_3Ir_3S, $TlIn_2S_3$, $CuInS_2$ et $AgInS_2$. On a établi un type de diagramme de coprécipitation caractéristique, pour le cas où il y a formation de composés chimiques, et on y a délimité les domaines correspondant aux phases de composition définie. On a montré qu'il se forme, lors de la coprécipitation, des systèmes microdispersés de solutions solides "colloïdales" d'un sulfure dans l'autre.

A THERMOGRAVIMETRIC STUDY OF ALUMINIUM OXINATE

C. J. KEATTCH
John Laing Research and Development Ltd., Manor Way, Boreham Wood
Hertfordshire, England

(*Received* 8 *August* 1963. *Accepted* 27 *September* 1963)

Summary—A thermogravimetric study of aluminium oxinate obtained by three different procedures has confirmed the view generally held that 150° is a suitable drying temperature. It has also been shown that this temperature is satisfactory, irrespective of the original moisture content of the precipitate. That a temperature of 700° is sufficient to obtain aluminium oxide is also confirmed. On the other hand, the statement by some workers that aluminium oxinate can be dried at 375° has not been substantiated.

INTRODUCTION

THERE is some confusion in the literature regarding the drying and decomposition temperatures of aluminium oxinate. Dupuis and Duval[1] studied this complex thermogravimetrically and found that it achieved constant weight between 102 and 220°, thus concluding that the drying temperature of 110° recommended by many workers is correct but too restrictive. In addition, they found that total destruction of organic matter and conversion to the oxide was only complete above 1000°.

However, Borrel and Paris,[2] also from thermogravimetric data, found that anhydrous aluminium oxinate is not obtained until 135° and that 110° is too low a drying temperature to obtain the anhydrous material. They further claimed that the complex is stable up to 375°, but beyond this temperature there is gradual decomposition until 700° when the oxide is formed, with an unexplained and anomalous weight change at 520°. Unlike Dupuis and Duval, they consider it unnecessary to raise the temperature to 1000° in order to destroy organic matter and suggest that Dupuis and Duval used too rapid a heating rate to obtain complete decomposition at 700°.

In his authoritative text-book on oxine and its derivatives, Hollingshead[3] comments on the above divergence of opinion as to the drying temperature of aluminium oxinate that "in view of the fact that many other workers have obtained satisfactory gravimetric determinations by drying in this range (100–135°) it would appear that further substantive evidence is necessary before the lower drying temperatures are discarded".

It was in an attempt to clarify the situation that this present work was initiated.

EXPERIMENTAL

In thermogravimetric measurements, many parameters can influence the final shape of the thermogram[4] and in the present context, it was considered that the following factors merited investigation:

(1) *Heating Rate*

It is reasonable to assume that the heating rate employed by Dupuis and Duval of approximately 6°/min was too fast to obtain good resolution of a thermogram. Borrel and Paris used a heating rate

12

of 3°/min, which is considered to be a reasonable increment in order to achieve good resolution of a thermolysis curve. In the present work a heating rate of 3°/min was employed.

(2) *Moisture Content of Precipitate*

It has been demonstrated[5] that the moisture content of a precipitate can considerably alter the position of the thermogram plateau. Dupuis and Duval give no details as to the moisture content of their samples, although the published thermogram indicates that it is considerable. On the other hand, Borrel and Paris dried their precipitates on the filter crucible by drawing air at room temperature through the precipitate for 24–48 hr. In view of these two widely differing procedures and their possible influence on the shape of the thermolysis curve, undried and air-dried precipitates were studied in the current investigation.

(3) *Mode of Precipitation*

It is well known that different methods of forming precipitates influence the shape of the thermogram[6] and it appears feasible that this observation could apply in the present context. Dupuis and Duval precipitated aluminium oxinate by Berg's method[7] whereas Borrel and Paris, although saying that the oxinate was precipitated by the usual method, used a procedure which differed in detail from Berg's technique. It would not, of course, be practicable to study aluminium oxinate precipitated by all of the numerous published methods, but in addition to the two procedures mentioned above, it was considered worthwhile including the technique currently in use in the author's laboratory[8] because, again, this differs in detail.

In order that a comparison can be made, the essential details of the precipitation methods used in the current investigations are given below.

Method of Berg[7]

To an aluminium solution containing less than 100 mg of aluminium/ml were added 3–5 g of sodium acetate followed by a slight excess of oxine solution (3 g of oxine dissolved in 3 ml of glacial acetic acid, diluted to 100 ml with water and neutralised with aqueous ammonia). The mixture was stirred vigorously, warmed to 60–70° and the precipitated complex filtered, then washed with water until the washings were colourless.

Method of Borrel and Paris[4]

To 100 ml of 0·0333*M* aluminium solution was added sufficient oxine solution (0·1*M* in 0·2*M* hydrochloric acid) to give a 10% excess and the mixture warmed to 70–80°. The solution was neutralised with 0·5*M* sodium carbonate, then buffered to about pH 7 with 15% w/v ammonium acetate solution. The mixture was boiled gently for 2–3 min, then maintained at 80° for 0·5 hr. The oxinate was filtered, washed twice by decantation with hot water, transferred to the filter crucible and washed further with hot water to remove the excess oxine.

Method of the British Ceramic Research Association[8]

To approximately 100 ml of neutralised aluminium solution, containing 15–35 mg of aluminium, were added 4 ml of 50% w/v hydroxylamine hydrochloride followed by 5 ml of freshly prepared 1% w/v *o*-phenanthroline [1g dissolved in 100 ml of acetic acid (1 + 1)]. The solution was heated to 40–50°, 20 ml of 5% w/v oxine solution added (5 g of oxine dissolved in 12 ml of glacial acetic acid and diluted to 100 ml with water) followed by 40 ml of 40% w/v ammonium acetate solution, added slowly and with stirring. The solution was heated to 70° with stirring and maintained at this temperature for 10 min, stirring periodically. After cooling for 30 min, the precipitate was filtered and washed thoroughly with warm water (40–50°).

Portions of the oxinate obtained by these three different procedures were removed from the filter crucible immediately after washing was complete and stored in well-stoppered containers. The remainder of the precipitate in each case was dried by drawing air through the filter crucible for 48 hr.

A sample of each preparation, weighing between 250 and 350 mg, was transferred to a prefired recrystallised alumina crucible and heated in air on a Stanton thermobalance, Model HT-SM, which was programmed for a linear temperature rise from room temperature to 1400° over 8 hr (3°/min nominal) and a chart speed of 6 in./hr. The thermograms obtained are given in Fig. 1.

DISCUSSION

From the thermograms, it is apparent that all of the samples have achieved constant weight at 160°. Thus it can be concluded that the drying temperature of 150° recommended by many workers is satisfactory, irrespective of the original

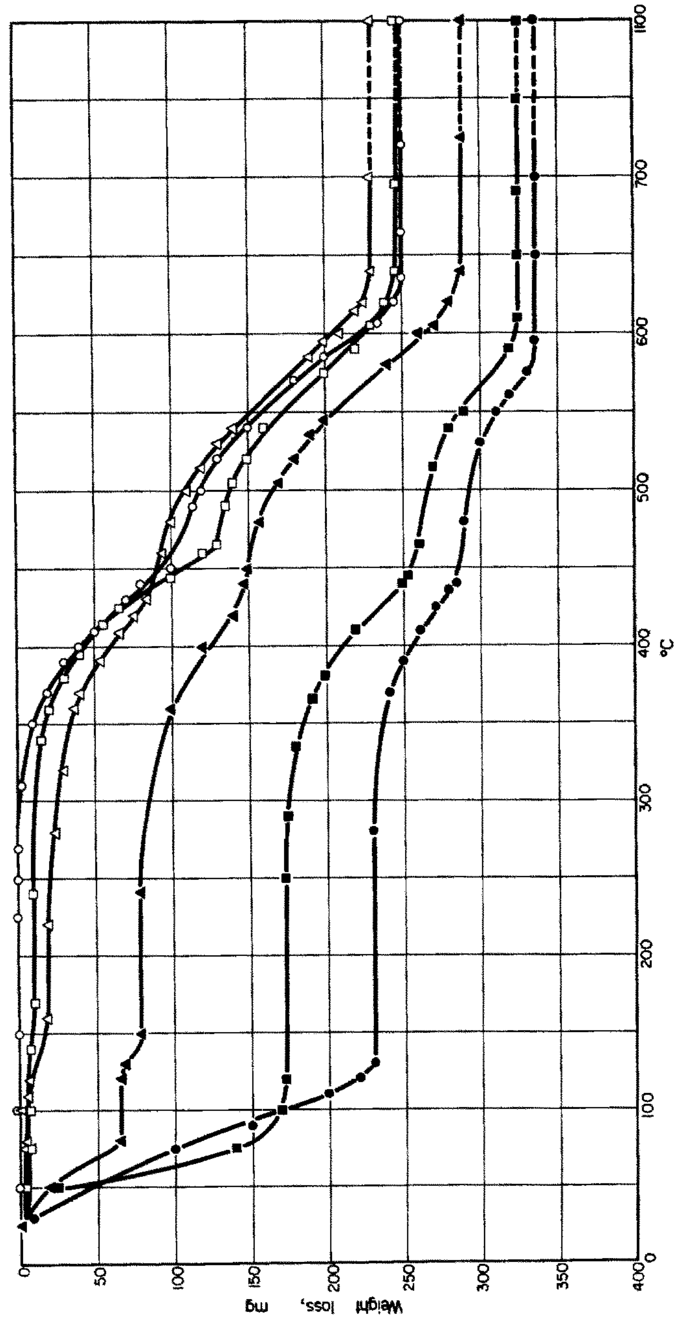

Fig. 1.—Thermograms of aluminium oxinate obtained by different precipitation procedures:

■—Berg, undried.

moisture content of the precipitate. Although only three different methods of precipitation have been investigated, it is reasonable to assume that 150° is a suitable drying temperature for aluminium oxinate precipitated by any published method.

The results also confirm the conclusion of Dupuis and Duval that a drying temperature of 110° is satisfactory, but too restrictive. However, contrary to the findings of Borrel and Paris, the thermograms of all of the samples demonstrate, quite conclusively, that the precipitate is not stable at 375° and independent attempts to dry aluminium oxinate at this temperature resulted in complete failure. On another point, the thermograms indicate that aluminium oxide is formed at approximately 600°. There is little doubt that, as Borrel and Paris remark, 700° is a sufficiently high temperature to obtain the oxide and that Dupuis and Duval used too high a heating rate to obtain complete decomposition at this temperature.

The anomalous weight change at 520° described by Borrel and Paris is manifest in the present work by a change in slope occurring at about 460°, which suggests the formation of an intermediate compound. It is doubtful whether it would be possible to isolate this intermediate, because it has been shown[9] that the decomposition of metal oxinates is a complicated process and the exact mechanism of decomposition is not known.

CONCLUSIONS

Using three different procedures for precipitating aluminium oxinate, it has been confirmed that a satisfactory drying temperature for the complex is 150°. It has been shown that this temperature can be used irrespective of the original moisture content. Contrary to the findings of Borrel and Paris, spurious results were obtained on drying the complex at 375°. Aluminium oxide is formed at temperatures above 600° and failure to obtain complete decomposition at temperatures much in excess of this value strongly indicates too high a heating rate.

Aluminium oxinate, prepared by precipitation from homogeneous solution (PFHS), has also been studied. The procedure used was according to Marec, Salesin and Gordon[10] except that the 8-acetoxyquinoline was purchased. (B. Newton Maine Ltd., Silsoe, Bedfordshire, England.)

As was to be expected, the thermolysis curves of both undried and air-dried samples were very similar to those depicted in Fig. 1. They confirm that 150° is a suitable drying temperature for aluminium oxinate precipitated by this technique but that drying at 375° results in decomposition.

The major difference in the thermolysis curves of aluminum oxinate prepared by PFHS is that aluminium oxide is not formed until a little over 700°. This is to be expected as PFHS results in denser crystals.

Acknowledgment—The author thanks the Directors of John Laing Research and Development Ltd., for permission to publish this paper.

Zusammenfassung—Eine thermogravimetrische Untersuchung an auf drei verschiedene Arten erhaltenem Aluminiumoxinat bestätigte die allgemeine Ansicht, daß 150° eine geeingete Trocknungstemperatur ist. Es wurde auch gezeigt, daß diese Temperatur unabhängig vom ursprünglichen Feuchtigkeitsgehalt des Niederschlags ausreicht. Es wurde auch bestätigt, daß 700° zur Bildung von Aluminiumoxyd ausreichen. Andererseits ließ sich nicht bestätigen, daß Aluminiumoxinat bei 375° getrocknet werden kann.

Résumé—Une étude thermogravimétrique de l'oxinate d'aluminium obtenu par trois procédés différents a confirmé l'opinion généralement admise que 150°C constitue une bonne température désséchante. Il a pu être montré que cette température est satisfaisante pour l'humidité du précipité. Le fait que 700°C soient suffisants pour obtenir l'oxyde d'aluminium a été également confirmé. D'autre part, les conclusions de certains chercheurs qui indiquent 375° comme température de dissociation de l'oxinate d'aluminium n'ont pu être confirmés.

NEW STUDIES ON CALCIUM OXALATE MONOHYDRATE

A GUIDE TO THE INTERPRETATION OF THERMOGRAVIMETRIC MEASUREMENTS

E. L. SIMONS and A. E. NEWKIRK
Research Laboratory, General Electric Company, Schenectady, New York, U.S.A.

(*Received* 21 *August* 1963. *Accepted* 20 *October* 1963)

Summary—The pyrolysis of calcium oxalate monohydrate in air occupies a unique place in the literature of thermogravimetry. Not only was a thermogram for this reaction the first pyrolysis curve published by Duval and his collaborators, but Duval and others have suggested that it can be used as a reference substance for judging the performance of a thermobalance. However, the pyrolysis of calcium oxalate monohydrate under a variety of conditions gives rise to considerable differences in its thermograms. The effects of sample size, heating rate, atmosphere and container geometry are presented in a series of paired thermograms, and the differences are accounted for with the aid of additional evidence from differential thermal analysis and from combustion train experiments. Variations in atmosphere are particularly important, and the atmospheres studied are dry nitrogen, humidified nitrogen, dry air, humidified air, dry oxygen, dry carbon dioxide and dry carbon monoxide. Even subtle variations in the shape of a thermogram obtained on a reliable balance may reflect the complexity of the reactions that produce the more noticeable over-all weight changes. Results presented in this report thus delineate conditions for the use of calcium oxalate monohydrate as a thermogravimetric reference substance, and show that its behaviour under controlled conditions in a thermobalance can provide an unusually versatile guide to the interpretation of thermogravimetric measurements.

INTRODUCTION

THE pyrolysis of calcium oxalate monohydrate in air occupies a unique place in the literature of dynamic thermogravimetry. A thermogram for this reaction (Fig. 1) was the first pyrolysis curve published by Duval and his collaborators[42] in their comprehensive study of the thermogravimetric behaviour of analytical precipitates, and was

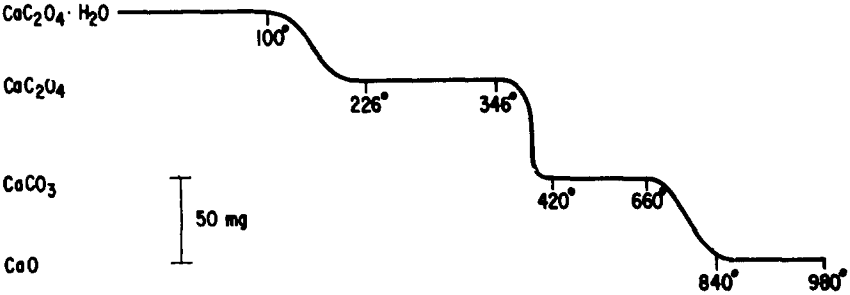

FIG. 1.—Pyrolysis curve of calcium oxalate monohydrate as published by Peltier and Duval.[42]

singled out by Duval for special mention in his book.[13] Because the thermogram's unusual sequence of consecutive reactions was characterised by four parallel, horizontal plateaux, corresponding successively to calcium oxalate monohydrate, calcium oxalate, calcium carbonate and calcium oxide, the material was used by Duval[12] "to adjust the thermobalances after they have been set up, cleaned, or repaired." He further claimed that the thermogravimetric measurements on this material with a photographic recording Chevenard thermobalance were accurate and reproducible enough to permit students to obtain reliable values for the atomic weight of carbon from the dimensions of thermograms obtained as an instructional exercise.[13] Subsequently, Barcia Goyanes[2] and Wilson[57] suggested that the extremities of the plateaux in this thermogram be used as temperature calibration points for a thermobalance, as if they were characteristic transition temperatures.

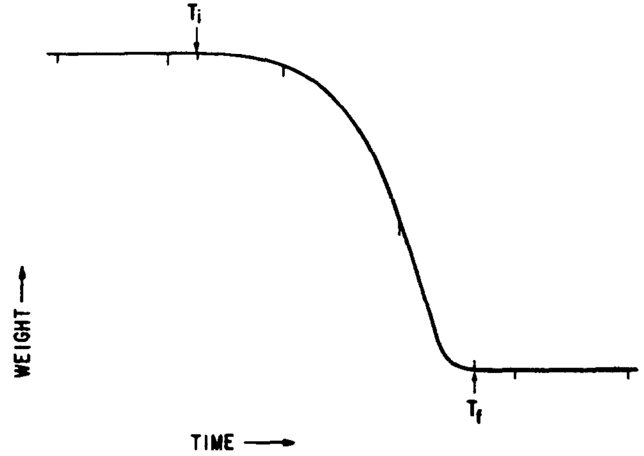

Fig. 2.—Schematic thermogram for general single-stage reaction: $A_{(solid)} = B_{(solid)} + C_{(gas)}$.

Previous work in this Laboratory has demonstrated that the accuracy and precision of measurements with a Chevenard pen-recording thermobalance (which has the same suspension and sensitivity as the photographic recording balance) are below the level required for atomic weight work[48] and that the temperature limits of a plateau are not a property of the sample alone.[36] This report presents thermograms for calcium oxalate monohydrate pyrolysed under a variety of conditions and attempts to provide a consistent explanation for all of the observed differences, using additional data from differential thermal analysis measurements and from combustion train experiments. The results of these studies show that if calcium oxalate monohydrate is pyrolysed under carefully controlled conditions in a thermobalance, it can serve as a yardstick for judging the performance of the instrument and can provide an unusually versatile guide to the interpretation of thermogravimetric measurements.

CHARACTERISTICS OF SINGLE-STAGE REACTIONS

The thermogram of Fig. 2 has been drawn to represent the general reaction

$$A_{(solid)} = B_{(solid)} + C_{(gas)}.$$

Two temperatures may be selected as characteristic of any single-stage non-isothermal reaction: T_i (initial temperature) is the temperature at which the cumulative weight-change reaches a magnitude that the thermobalance can detect, and T_f (final temperature) is the temperature at which the cumulative weight-change first reaches its maximum value, corresponding to complete reaction. Although T_i may be the lowest temperature at which the onset of a weight-change can be observed in a given experiment, it is neither a transition temperature in the phase rule sense,[35] nor is it a true decomposition temperature below which the reaction rate suddenly becomes zero.[20,21,24,25] Because the value of T_i depends upon the interaction of many variables, it shall be called the *procedural decomposition temperature*,[36] a term introduced by Doyle[10] in reporting his thermogravimetric studies of the pyrolysis of polymers. At a linear heating rate, T_f must be greater than T_i, and the difference $(T_f - T_i)$ will be called the *reaction interval.* For an endothermic decomposition, T_i and T_f both increase with increasing heating rate, the effect being greater for T_f than for T_i, as has been clearly shown by Richer[45] and others.[8,34,36]

SIGNIFICANCE OF TEMPERATURE IN DYNAMIC THERMOGRAVIMETRY

At this point it is advisible to comment upon the significance of temperature as a variable in dynamic thermogravimetry. The fundamental datum produced by a recording thermobalance is a record that shows the variation with time of some quantity whose changes may be related in magnitude to changes in the weight of the sample. The foundations of modern dynamic thermogravimetry were laid in the early 1920's by Guichard,[22,23] who proposed that the method of continuous weighing be applied to "the study of all reactions that cause the weight of any solid to vary in one way or another . . . in a selected atmosphere, while the temperature is raised at a rate nearly proportional to the time, and slowly enough." Although Guichard did not explicitly specify the temperature to be measured, it is apparent from his work and that of his students that he referred to the temperature of the furnace atmosphere and not to that of the sample.[11,53,54]

Guichard had insisted, since the beginning of his studies, "on the necessity of realising a very regular rise of temperature." He pointed out that "there is a risk that every irregularity in this increase may appear on the curve of weight *vs.* time and complicate its interpretation." Such regularity in heating rate can be achieved in the furnace atmosphere but not in the sample, whose rate of temperature rise changes with the onset of each exothermic or endothermic phase transition or chemical change. These internally generated changes in the rate of sample temperature rise, of course, provide the basis for the widely used method of differential thermal analysis. Both differential thermal analysis and dynamic thermogravimetric analysis require a linear furnace heating rate. In differential thermal analysis one detects the onset of reactions or transitions in a sample by observing the perturbations in what would otherwise be a regular rate of increase in sample temperature. In thermogravimetry one detects and measures those transformations that produce a change in the weight of a sample. The only independent temperature variable in either technique is the heating rate of the furnace. The changes in sample weight and temperature are both consequences of the chemical and physical changes produced in a sample when it is brought into contact with a given atmosphere whose temperature is changing at a predetermined rate.

In this investigation an independent record was kept of the furnace temperature as a function of time, which record also served to verify the linear heating rate that had been set on the furnace controller. The temperature markings on the thermograms were established by coupling the temperature and weight recorders so that a pip was automatically introduced into the pyrolysis curve at each integral 100-degree reading of the furnace temperature. The pips could also have been introduced after the run by juxtaposition of the weight-time curve with the separate record of furnace temperature as a function of time. Values of T_i and T_f were interpolated between 100-degree markings.

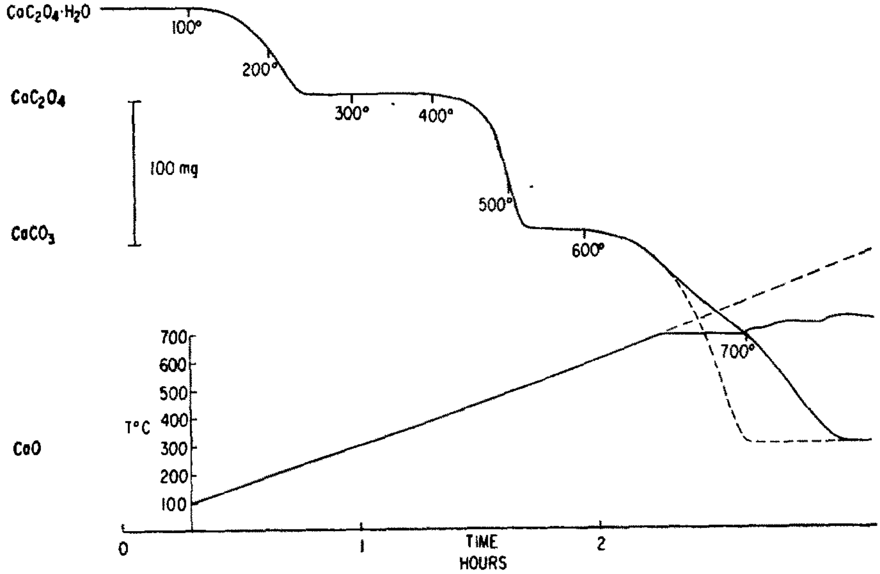

FIG. 3.—Effect of perturbation in rate of heating upon thermogram for calcium oxalate monohydrate (500 mg, platinum dish, flowing dry nitrogen):
- - - unperturbed rate of heating.

It is particularly risky to try to record a thermogram directly by feeding the weight and temperature signals to the two inputs of an X-Y recorder. Unexpected disturbances that sometimes occur in the heating rate or thermocouple response can produce artificial perturbations in the weight-temperature record. Only a separate temperature-time record can disclose these adventitious effects and permit effects caused solely by changes in sample weight to be distinguished from them.[27] Fig. 3 shows the thermobalance record of a pyrolysis of calcium oxalate monohydrate during which the temperature controller became stuck at 695°, for a period of time, after which it produced an irregular temperature rise up to about 750°. The dashed curve shows the course that the thermogram would have taken had the linear heating rate of 300 degree/hr been maintained above 695°. The perturbation in the recorded curve can be properly understood only in the light of the independent record of temperature as a function of time. Had an X-Y recorder been used for this run, the period of constant temperature would have been represented by a vertical line at 695°. Although such an abrupt change in the slope of the curve would probably have been suspect, more subtle, but nonetheless significant changes in heating rate could pass completely unnoticed in a direct recording of weight *vs.* temperature.

CHARACTERISTICS OF MULTI-STAGE REACTIONS

Successive, non-overlapping reactions

Under certain conditions, the thermogram for a sequence of successive decompositions, such as occurs during the pyrolysis of calcium oxalate monohydrate

$$CaC_2O_4{\cdot}H_2O = CaC_2O_4 + H_2O$$

$$A_{(s)} = B_{(s)} + \text{gas} \qquad (1)$$

$$CaC_2O_4 = CaCO_3 + CO$$

$$B_{(s)} = C_{(s)} + \text{gas} \qquad (2)$$

$$CaCO_3 = CaO + CO_2$$

$$C_{(s)} = D_{(s)} + \text{gas} \qquad (3)$$

can be considered as the composite of the thermograms for the individual stages. This is shown in Fig. 4, in which are superimposed the thermograms that were obtained on separate days by heating in air, at 300 degree/hr, 500 mg of calcium oxalate monohydrate and equivalent quantities of the anhydrous oxalate and of calcium carbonate, each in a porcelain crucible. The initial stages of the latter two curves are indicated by broken lines. Thermograms 4(B) and 4(C) are identical with 4(A) at temperatures above their intersections.

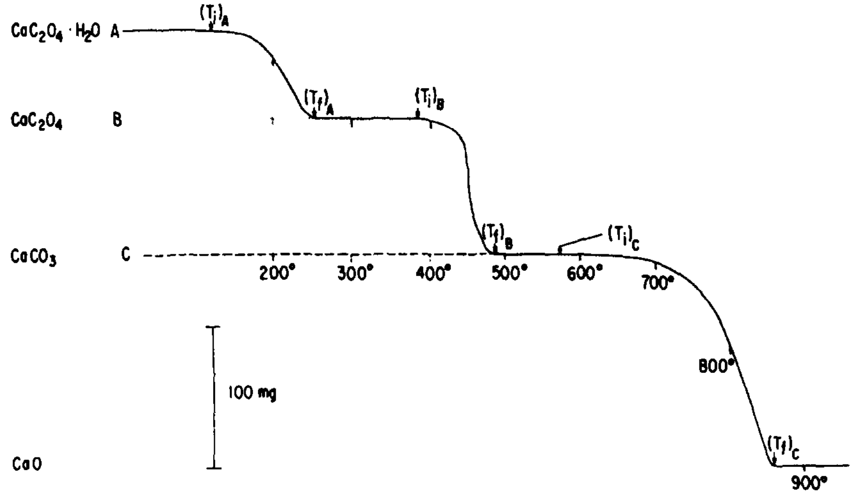

FIG. 4.—Thermograms for successive non-overlapping reactions (porcelain crucible, ambient air, 300 degree/hr):
——— 500 mg of calcium oxalate monohydrate,
...... 438 mg of calcium oxalate,
– – – – 343 mg of calcium carbonate.

It is not evident from this reproduction that the true value of $(T_i)_B$ is about 390°. The position of $(T_i)_B$ shown in this figure was chosen for illustrative purposes only.

Although temperature $(T_f)_A$ marks the beginning of the plateau for calcium oxalate, its value is determined by the interaction between the heating rate, the sample size and the rate of dehydration of calcium oxalate monohydrate; it cannot be interpreted as setting a lower limit to the thermal stability of the anhydrous salt. Temperature $(T_f)_A$ lies on the calcium oxalate plateau only because, under the conditions of the experiment, the dehydration reaction was complete before the temperature reached the value of $(T_i)_B$, the procedural decomposition temperature of the anhydrous salt. When calcium oxalate, previously dehydrated at 175°, was the starting material, the thermogram, beginning at level B, showed no perturbation as it passed through $(T_f)_A$. The calcium carbonate plateau, of course, bears the same relationship to its precursor as the calcium oxalate plateau bears to the monohydrate.

The exact superposition of the independently determined thermograms of Fig. 4 could have been achieved only if the reactions being studied were indeed successive and non-overlapping, and only if the characteristics of the thermobalance remained constant over the period of days covered by the experiments.

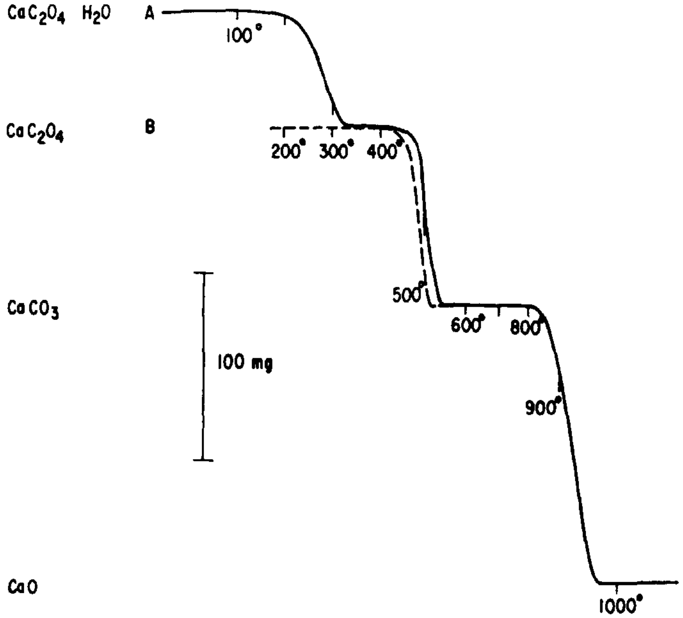

Fig. 5.—Thermograms for successive, partially overlapping reactions (porcelain crucible, ambient air, 600 degree/hr):
——— 500 mg of calcium oxalate monohydrate,
– – – – 438 mg of calcium oxalate.

Successive, partially overlapping reactions

The exact superposition of Fig. 4 is not characteristic of the pyrolysis of calcium oxalate monohydrate under all conditions. As noted earlier, both T_i and T_f for a given reaction rise as the heating rate is increased, the effect being more pronounced for T_f. The consequences of this are shown in Fig. 5, in which are superimposed the thermograms that were obtained by repeating two of the pyrolyses of Fig. 4, but at a heating rate of 600 degree/hr. The intermediate plateau for calcium carbonate is still clearly defined, but it begins at a higher temperature.[36] On the other hand, the formation of anhydrous calcium oxalate as an intermediate in the pyrolysis of the monohydrate is no longer marked by a true plateau, but simply by a change in the slope of the thermogram. At the higher heating rate the dehydration reaction on curve 5(A) was not complete by the time the furnace temperature had reached about 350°, which is the procedural decomposition temperature indicated for the anhydrous salt on curve 5(B). During the latter part of pyrolysis 5(A), therefore, water and carbon monoxide were being evolved simultaneously,[43] and at the point where the cumulative weight loss reached level B the sample crucible contained anhydrous calcium oxalate and a small amount of both the monohydrate and calcium carbonate.

A careful examination of the original thermograms discloses that curve 5(A) lies above curve 5(B) even in the region between 300° and 400°, and does not become coincident with it until the calcium carbonate plateau is reached. By increasing the heating rate from 300 to 600 degree/hr the initial sequence of two successive decompositions has been transformed to a sequence of two partially overlapping or simultaneous decompositions, the thermogram for which is not an exact composite of the individual stages.

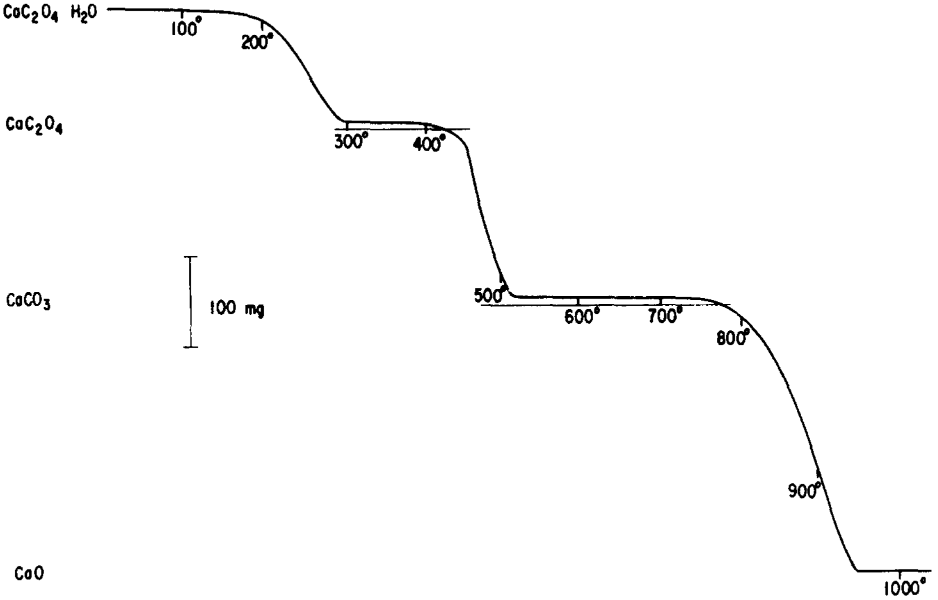

FIG. 6.—Thermogram for calcium oxalate monohydrate (1·019 g, porcelain crucible, ambient air, 300 degree/hr).

The transformation of a true plateau for anhydrous calcium oxalate into a curve like that of Fig. 5(A) was also produced by keeping the heating rate at 300 degree/hr, but increasing the sample weight from 0·5 g to approximately 1 g (Fig. 6). With more water in the initial sample, complete dehydration was not achieved before the procedural decomposition temperature for the anhydrous salt was reached, even at 300 degree/hr. This parallelism between the effects of heating rate and sample weight will be examined more closely in a subsequent section of this report.

At this point the following general conclusions may be drawn from the foregoing experiments on the multi-stage pyrolysis of calcium oxalate monohydrate:

1. *The appearance of a plateau for a compound on a dynamic thermogram does not necessarily imply that the compound is isothermally stable, either in a thermodynamic or practical sense, at all or any temperatures that lie on that plateau.* The temperature limits between which it extends apply only to the particular conditions of that pyrolysis.[5,20,44]

Certainly, none of the curves in Figs. 4, 5 or 6 can be used to set an upper limit to the isothermal stability of calcium carbonate in air. Similarly, anhydrous calcium oxalate undergoes slow isothermal decomposition in air at 300°, even though this temperature lies on the true plateau observed for that compound in Fig. 4.[43]

2. *If the thermogram obtained for a multi-stage reaction has no intermediate portion in which the sample weight remains constant with time over a range of temperature, one can make the reasonable inference that the reactions leading to the formation and to the subsequent decomposition of the intermediate are not independently sequential, but at least partly overlap.* The weight level at which a bend or change of slope occurs in the thermogram for such a pair of successive but overlapping reactions depends upon the relative amount of product B that has been formed by the time its procedural decomposition temperature has been reached and upon the relative rates of decomposition of A and B.

3. *In the absence of a true plateau, which can appear only if* $(T_f)_A \leqslant (T_i)_B$, *one cannot determine from a thermogram for successive reactions exact values for either* $(T_f)_A$, $(T_i)_B$, *or the stoichiometric weight level of B,*[4] *although a reasonable inference as to the latter can often be made.* There is little doubt, for example, that the gently sloping portion of Fig. 5 indicates the formation of anhydrous calcium oxalate.

CHARACTERISTICS OF INDIVIDUAL REACTIONS OF $CaC_2O_4 \cdot H_2O$

Among the factors that affect the thermogravimetric behaviour of calcium oxalate monohydrate are the reversibility of each stage of the pyrolysis and the enthalpy change that accompanies each of the individual reactions. The pertinent data are summarised in Table I.

TABLE I

Reaction	Heat of reaction ($\Delta H^\circ_{298^\circ K}$ kcal/mole)[47]	Reversibility
(1) $CaC_2O_4 \cdot H_2O = CaC_2O_4 + H_2O$	13·3*	Reversible[43]
(2) $CaC_2O_4 = CaCO_3 + CO$	15·5*	Irreversible[48,58]
(3) $CaCO_3 = CaO + CO_2$	42·5	Reversible

* Heat of formation of CaC_2O_4 estimated from tabulated values for the di- and monohydrates.

Reactions (1) *and* (3)

Both of these reactions are endothermic and reversible. In their thermogravimetric work, Peters and Wiedemann[43] showed that calcium oxalate monohydrate, after dehydration at about 280°, could be regenerated by allowing the anhydrous salt to cool to room temperature in humidified air. The effect of carbon dioxide in markedly raising the procedural decomposition temperature and decreasing the reaction interval for calcium carbonate has been clearly demonstrated by these workers and by Richer and Vallet.[44,45] For any given atmosphere containing carbon dioxide, the procedural decomposition temperature must be equal to or greater than the temperature at which the dissociation pressure of calcium carbonate reaches the partial pressure of carbon dioxide in that atmosphere.[28]

Reaction (2)

Thermal measurements by several investigators[14,41,49,56] have shown that the decomposition of anhydrous calcium oxalate is endothermic in an inert atmosphere, but becomes strongly exothermic in an oxidising atmosphere. These results have been confirmed in a Chevenard thermobalance. With the balance mechanism locked and a Pt-Pt, 10% Rh thermocouple inserted into the powdered sample, the difference between the sample temperature and the furnace temperature was recorded as a function of the furnace temperature, and the tracings shown in Fig. 7 were obtained from experiments made in flowing dry nitrogen and oxygen.

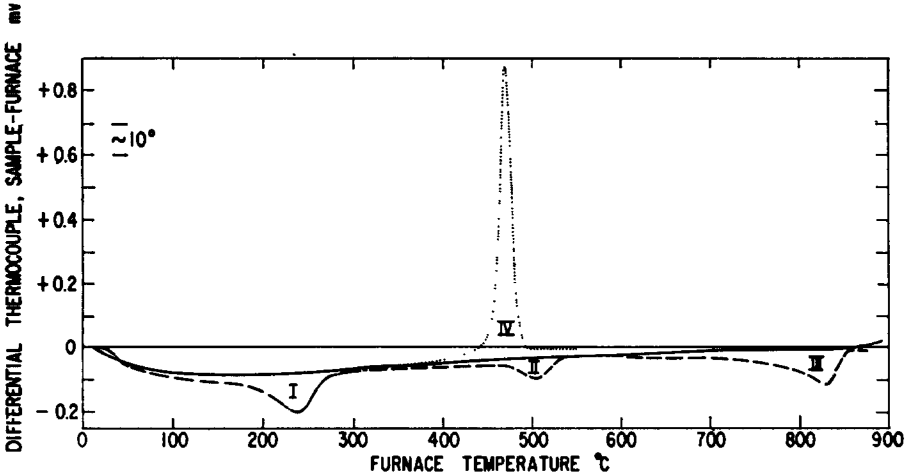

FIG. 7.—Differential thermal measurements on calcium oxalate monohydrate (500 mg):
——— inert sample (ignited calcium oxide),
– – – – calcium oxalate monohydrate in dry nitrogen,
...... calcium oxalate monohydrate in dry oxygen.

The exothermic peak observed in oxygen (and, with a more complex shape, in air) has been attributed by the investigators previously cited to the formation of carbon dioxide by oxidation of the carbon monoxide produced in the decomposition of the oxalate. The heat evolved/mole of carbon monoxide oxidised in the reaction

$$CO + 0{\cdot}5O_2 = CO_2 \qquad (4)$$

is 67·7 kcal at 700°K,[7] which is about four times larger than the heat absorbed by reaction (2). Reaction (4) has also been postulated to explain the exothermic effects noted when thorium oxalate was decomposed under oxidising conditions.[6,38]

The evidence to support the hypothesis that reaction (4) can also occur during the pyrolysis of calcium oxalate is presented in the following section.

DECOMPOSITION OF ANHYDROUS CALCIUM OXALATE

A weighed sample of calcium oxalate monohydrate in a platinum boat was loaded into a combustion tube and heated overnight at 125° in a stream of dry nitrogen to effect complete dehydration. Then, as in the method used by D'Eye and Sellman[9] for studying the thermal decomposition of thorium oxalate, the modified combustion train shown in Fig. 8 was assembled, and isothermal decompositions of the anhydrous salt were carried out for 3 hr at 420° with a stream of suitable carrier gas passing over the sample at a rate of 20 ml/min.

The gas, after leaving the pyrolysis chamber, passed through a series of tubes filled, successively, with Ascarite, hot copper oxide at 700° and Ascarite. Any carbon dioxide in the exit gas stream was trapped in the first Ascarite tube; any carbon monoxide in the exit gas stream was oxidised by the hot copper oxide and subsequently absorbed as carbon dioxide in the last absorption tube.

The results obtained with dry air and dry nitrogen as the carrier gases are given in Table II, to which the following comments are pertinent:

1. The dehydration of the samples was complete at 125°.

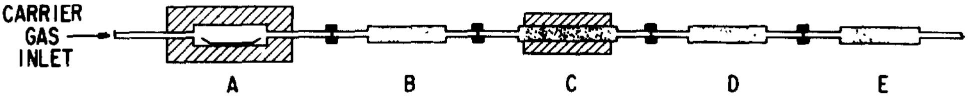

FIG. 8.—Schematic illustration of modified combustion train for experiments with dry nitrogen and dry oxygen:

A—furnace with combustion tube and platinum boat,
B—Ascarite absorption tube,
C—furnace with tube of copper oxide,
D—Ascarite absorption tube,
E—Ascarite tare tube.

2. The amount of calcium oxalate that decomposed in 3 hr at 420° was significantly greater in dry air than in dry nitrogen.

3. In dry air (run 1), the primary gaseous product of the decomposition of anhydrous calcium oxalate at 420° was carbon monoxide. Virtually all of this product had been oxidised to carbon dioxide by the time the gas stream reached the first Ascarite tube, and the total moles of carbon dioxide trapped by both Ascarite tubes is in excellent agreement with the weight loss of the sample, calculated as moles of carbon monoxide.

4. In dry nitrogen (run 2) most of the carbon monoxide produced during the decomposition of the anhydrous calcium oxalate left the reaction zone unchanged and appeared as carbon dioxide only after passing through the hot copper oxide tube. However, a significant amount of carbon dioxide was absorbed in the first Ascarite tube, between the pyrolysis furnace and the copper oxide furnace. In a nitrogen atmosphere, this carbon dioxide could not have been produced by oxidation of carbon monoxide, but must have arisen from the disproportionation reaction

$$CO = 0{\cdot}5CO_2 + 0{\cdot}5C \qquad \Delta H_{700^\circ K} = -20{\cdot}7 \text{ kcal}^{7} \qquad (5)$$

On this basis, the following material balance can be made:

CO (mmole) undergoing disproportionation = 2(0·36)	= 0·72
CO (mmole) undergoing oxidation by CuO	= 2·30
Total	= 3·02
CO (mmole) calculated from weight loss	= 2·90

Thus, in dry nitrogen as in dry air, the primary gaseous product of the decomposition of anhydrous calcium oxalate at 420° was carbon monoxide.

The disproportionation reaction has been observed by Glasner and Steinberg[17–19] in their studies of the thermal decomposition of rare earth oxalates in vacuum. Qualitative evidence for its role in the vacuum decomposition of sodium oxalate and of alkaline earth oxalates has been reported by Günther and Rehaag[26] and by Wöhler and Schuff,[58] and it has been observed by D'Eye and Sellman[9] when thorium oxalate was decomposed in a stream of nitrogen.

Further evidence for disproportionation in these experiments was the grey discoloration observed in the sample that had been partially decomposed in a stream of nitrogen; the residue from the air run was pure white. The intensity of the discoloration could be reduced by passing air over the hot residue. A greyish-brown discoloration was also observed in the residues from thermogravimetric runs made in dry nitrogen.

To confirm the reported irreversibility of the decomposition of anhydrous calcium oxalate,[43,58] runs were made at 420° in a stream of dry carbon monoxide; this

TABLE II.—PYROLYSIS OF $CaC_2O_4{\cdot}H_2O$ IN MODIFIED COMBUSTION TRAIN

Run no.	1	2	3(a)	3(b)

Total CO_2 absorbed, *mg*	141·7 (≡ 3·22 mmole CO_2)	116·9 (≡ 2·66 mmole CO_2)	129·4 (≡ 2·94 mmole CO_2)	77·8 (≡ 1·77 mmole CO_2)
Wt. H_2O absorbed in Anhydrone tube, *mg*			12·8 (≡ 0·71 mmole H_2O)	0·7 (≡ 0·04 mmole H_2O)

atmosphere neither prevented the decomposition of the pure salt nor reversed the decomposition of a partially decomposed sample. This observation means, of course, only that if the reaction is reversible, its equilibrium pressure of carbon monoxide at 420° is greater than 1 atmos.

The following conclusions may be drawn from the foregoing combustion train experiments and from the thermal measurements described in the preceding section:

1. In both oxidising and inert atmospheres the primary endothermic formation of carbon monoxide from anhydrous calcium oxalate is accompanied, to varying degrees, by one or more secondary exothermic reactions that produce carbon dioxide from carbon monoxide.
2. The direct oxidation of carbon monoxide by oxygen occurs more readily than the disproportionation reaction.
3. The heat evolved during direct oxidation of carbon monoxide by oxygen raises the temperature of the remaining sample and solid product at a rate greater than the heating rate of the furnace, and, as a result, the decomposition is more rapid in dry air than in dry nitrogen.

EFFECT OF VARIABLES UPON A DYNAMIC THERMOGRAM

The characteristics of the separate stages in a multi-stage pyrolysis have an important bearing on the interpretation of thermogravimetric data. In particular, the pyrolysis of calcium oxalate monohydrate, with its sequence of alternating reversible and irreversible reactions, coupled with secondary reactions between components of the atmosphere and a primary decomposition product, provides an ideal vehicle for demonstrating the effects of many variables upon the shape of a dynamic thermogram. In the remainder of this report, a series of comparison thermograms is presented to show these effects.

Geometry of sample container

Several investigators have recommended that for thermogravimetric measurements the sample should be loosely packed in a shallow dish in order to facilitate gaseous exchange between the sample and the atmosphere that surrounds it.[3,8,16,37,41] Indeed, Garn and Kessler[16] have declared, "That the traditional crucibles are useless in thermogravimetry is essentially true. In a few cases crucibles are acceptable... In controlled atmosphere work, where the atmosphere is solely the gas involved in the reaction, the geometry of the container is immaterial."

As can now be shown with calcium oxalate, the geometry of the container is also immaterial if no interaction is possible between the solid phase and the gaseous atmosphere or products. The pyrolysis of 500 mg of calcium oxalate monohydrate was conducted in flowing dry carbon dioxide using both a porcelain crucible and a quartz dish as sample holders. The thermograms in Fig. 9 are identical above about 275°, which marks the completion of the dehydration reaction in the crucible. As expected, the loss of water occurred more readily from the shallow dish than from the crucible. On the other hand, the shape of the container had no effect upon the decomposition of anhydrous calcium oxalate because this reaction is not reversible, and in a carbon dioxide atmosphere no important diffusion-controlled secondary reactions can occur. The shape of the container also had no effect upon the dissociation of calcium carbonate because this reaction is reversible, and the atmosphere used was

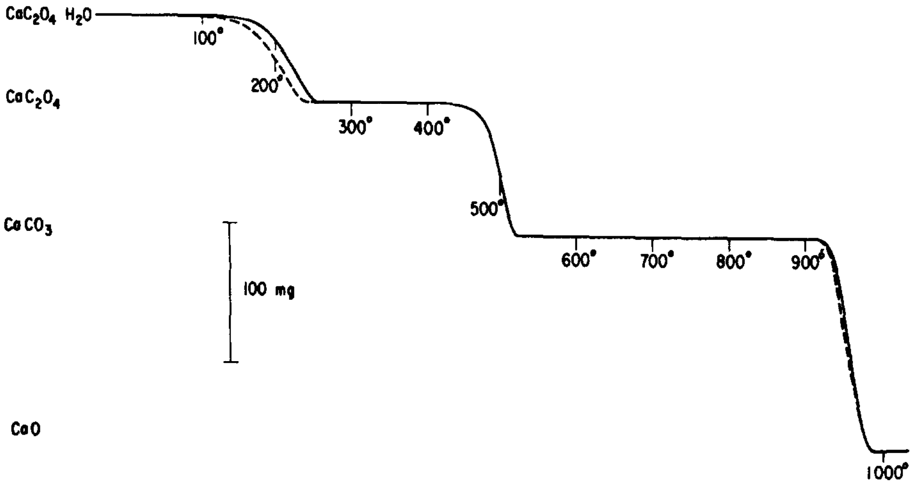

FIG. 9.—Effect of sample container upon thermogram for calcium oxalate monohydrate in flowing dry carbon dioxide (500 mg, 300 degree/hr):
- - - - quartz dish,
——— porcelain crucible.

solely the gas involved in the reaction. When the reversible pyrolysis of calcium carbonate was performed in a given container, the higher the pressure of carbon dioxide in the atmosphere, the higher the value of the procedural decomposition temperature and therefore, the smaller the reaction interval, ($T_f - T_i$). (Compare Fig. 9 with Figs. 5, 4, 6, and 10.)

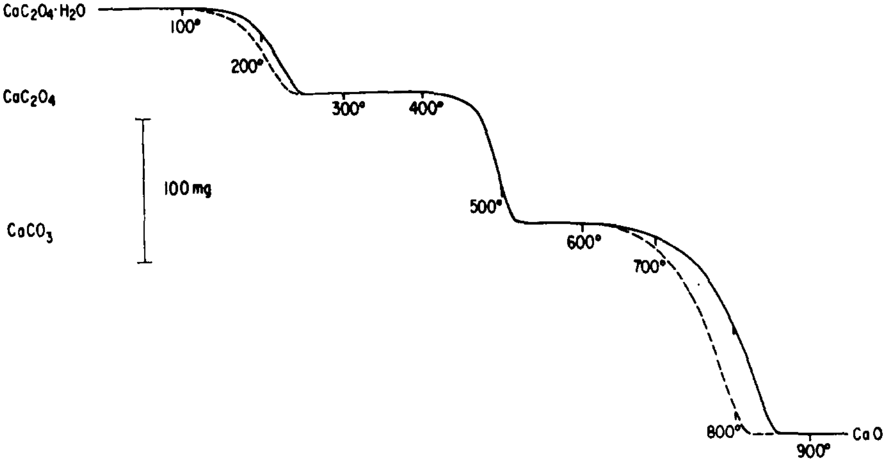

FIG. 10.—Effect of sample container upon thermogram for calcium oxalate monohydrate in flowing dry nitrogen (500 mg, 300 degree/hr):
- - - - quartz dish,
——— porcelain crucible.

When the pyrolysis was carried out in a flowing stream of dry nitrogen (Fig. 10), both the loss of water and the loss of carbon dioxide were affected by the shape of the container; the loss of carbon monoxide was unaffected. There is a thermodynamic possibility that the loss of carbon dioxide, illustrated by the dashed curve of Fig. 10, was caused by reaction between the calcium carbonate and the quartz dish. However, Longuet[59] has shown that this reaction becomes significant below 900° only if both the silica and the calcium carbonate are finely divided and intimately mixed. We have repeated the pyrolysis of Fig. 10 using a platinum-lined quartz dish, and the results were the same as those obtained with the unlined dish. Both curves shown in Fig. 10, therefore, represent only the thermal dissociation of calcium carbonate.

The marked effect of container shape that is illustrated in Figs. 9 and 10 provides evidence that a significant pressure of water vapour and carbon dioxide must have existed in the interior of the crucible during dissociation, even when the atmosphere that flowed over the crucible entered the thermobalance free from either water or carbon dioxide or both.

In the study of reversible reactions or of reactions in which a component of the atmosphere can react either with the original sample or with a solid or gaseous decomposition product, one must recognise the possible existence of such partial pressure gradients throughout a mass of powdered sample. These gradients can effect both the shape of thermogravimetric curves[31,51,52] and the magnitude of thermal effects that accompany the reactions.[30] They can be reduced by packing the powder loosely in a shallow dish,[16] by using crucibles with micro-porous[15,29] or macro-porous[1] walls, or by passing a controlled atmosphere through the bed of powdered sample. The effectiveness of the latter technique for differential thermal analysis has been vividly demonstrated by Stone,[50] who has also announced the development of thermogravimetric equipment to provide dynamic gas flow through the specimen under study.[46] Papailhau[39,40] has designed a crucible, for use with a null-type balance, that permits an externally generated atmosphere to be passed through the entire bed of powdered sample.

Except for the experiments of Figs. 9 and 10 that were made with a quartz dish, all differential thermal and thermogravimetric measurements described in this report were made with Coors high form-000 porcelain crucibles, in which both thermal gradients and partial pressure gradients undoubtedly existed. Reproducible results were obtained by careful control of experimental conditions, but, as illustrated by Fig. 10, these results would have been different with more efficient interaction between solid sample and gaseous atmosphere. The interpretation of the experiments has been made with this restriction in mind.

Comparison of dry nitrogen and dry oxygen

Thermograms that were obtained by heating calcium oxalate monohydrate in flowing atmospheres of dry nitrogen and of dry oxygen are shown in Fig. 11. The dehydration step is unaffected by the change in atmosphere, and the two curves are nearly identical in this region because both gases are equally effective in sweeping evolved water vapour away from the sample surface. On the other hand, the thermograms diverge at the intermediate stage because in oxygen or air the secondary oxidation of carbon monoxide raises the temperature of the unreacted solid at a rate greater than the heating rate of the furnace, producing a marked acceleration in the decomposition rate. The decomposition of calcium oxalate occurs more rapidly and is completed at a lower furnace temperature in an atmosphere of dry oxygen (or air) than in an atmosphere of dry nitrogen.

Although the product of this decomposition in either atmosphere is calcium carbonate, the procedural decomposition temperature for the subsequent loss of carbon dioxide was higher in the run made in an oxygen atmosphere than for that made in a nitrogen atmosphere (Fig. 11). This small difference is not an artifact of the instrument. Indeed, thermograms that we obtained by heating separate portions of the same sample of *calcium carbonate* in nitrogen and in air were identical in the region of weight loss because nitrogen and air were equally effective in sweeping away the evolved carbon dioxide. However, the calcium carbonate produced by the decomposition of a given sample of calcium oxalate in an oxygen atmosphere is *not* identical with that produced by decomposition of the same material in a nitrogen atmosphere.

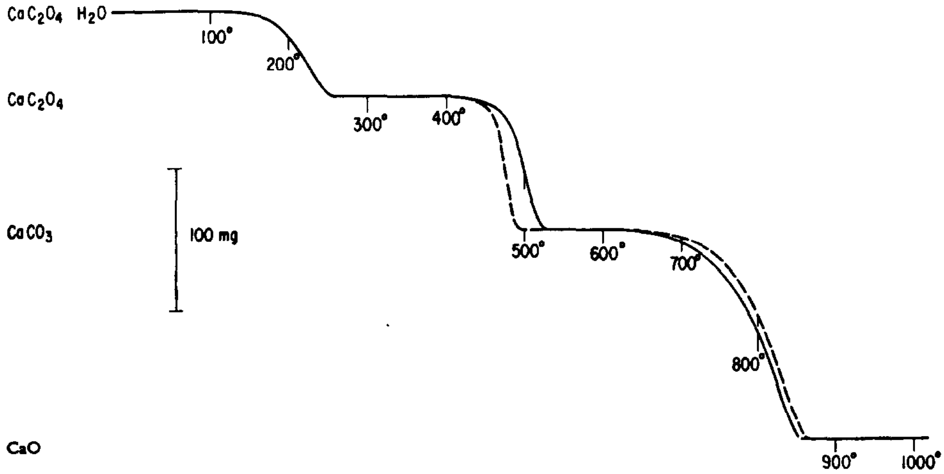

FIG. 11.—Effect of atmosphere upon thermogram for calcium oxalate monohydrate (500 mg, porcelain crucible, 300 degree/hr):

- - - - dry oxygen,
——— dry nitrogen.

The dry oxygen run shown in Fig. 11 was repeated, but at a temperature of about 450° the furnace was turned off and the flowing oxygen was replaced by flowing nitrogen. After the temperature had dropped to about 140°; the heating rate of 300 degree/hr was resumed. The resulting thermogram, although obtained in a nitrogen atmosphere, was identical above 500° with the dashed oxygen curve of Fig. 11. The thermogravimetric behaviour of the calcium carbonate in these experiments was determined by the atmosphere in which it had been formed and not by the atmosphere in which it was decomposed. Thermogravimetry cannot disclose whether this difference in pyrolytic behaviour is a reflection of differences in particle size, surface area, lattice imperfections, or some other characteristics, but these experiments and those shown in Fig. 10 do illustrate the usefulness of thermogravimetric measurements, made on a reliable balance, for quickly surveying a variety of experimental conditions and thus disclosing those areas in which more detailed studies should be made, possibly with other supplementary techniques. As will be shown later, the shape of even a single thermogram can indicate complexities in the reaction under study.

Sample weight

In the earlier discussion of successive, partially overlapping reactions, certain similarities were noted between the effects of heating rate and sample weight upon the shape of a dynamic thermogram. This parallelism cannot be carried too far. Unlike heating rate, sample weight is not a completely independent variable in thermogravimetry. For a given sample container a change in the weight of a powdered solid sample simultaneously changes the thickness of the sample bed, its total heat capacity, and its area of contact with the walls of the container, through which much of the heat transfer with the furnace atmosphere occurs.

Some of these factors can change during a pyrolysis, as illustrated by Fig. 12, in which are superimposed the thermograms obtained in ambient air with approximately 1 g of calcium oxalate monohydrate (Fig. 6) and those obtained with equivalent quantities of the anhydrous salt and calcium carbonate. The relationship between curve 12B and the second weight-loss section of curve 12A is the same as shown in Fig. 5 and arises from the overlap of the dehydration reaction and the loss of carbon monoxide. However, even though this second stage, the loss of carbon monoxide, was complete before the procedural decomposition temperature of calcium carbonate was reached (and therefore a true plateau was observed for this compound), the value of T_i for the loss of carbon dioxide is markedly lower for curve 12C than for curves 12A and B. Examination of the crucibles at the end of each pyrolysis showed that the residues of calcium oxide from runs 12A and B were more loosely packed than that from run 12C, and were separated by an air gap from the wall of the sample crucible. Although the final weight of calcium oxide was the same in each run, its volume represented a larger shrinkage from the initial sample volume in runs A and B than in run C. The gaps produced by this shrinkage undoubtedly reduced the flow of heat

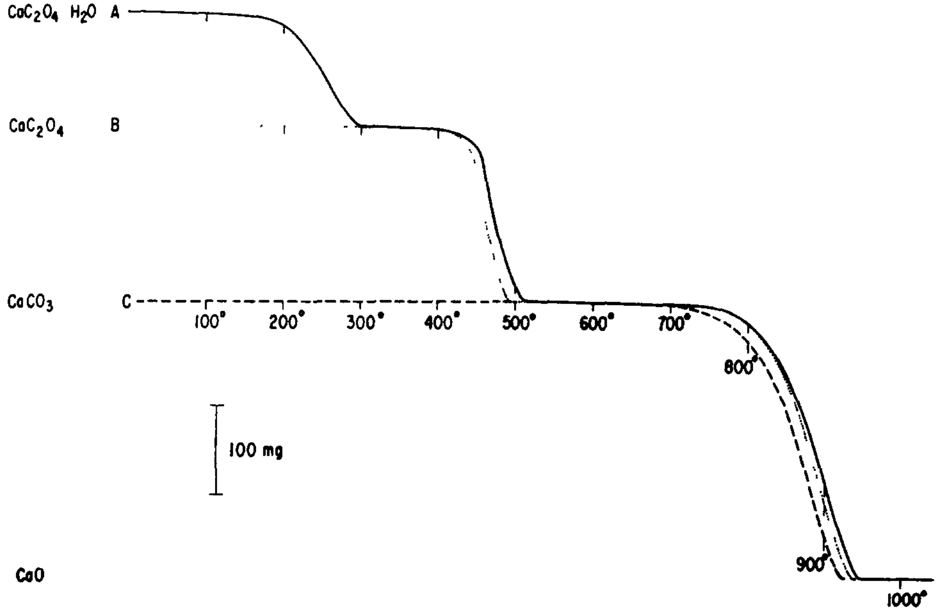

FIG. 12.—Thermogram for successive partially overlapping reactions (porcelain crucible, ambient air, 300 degree/hr; curve A as for Fig. 6):

——— 1·019 g of calcium oxalate monohydrate,
...... 0·893 g of calcium oxalate,
– – – – 0·699 g of calcium carbonate.

between the sample and furnace and thus contributed, at least in part, to the higher value of T_i in runs A and B.

Undoubtedly the effect of sample shrinkage observed with the 1-g (and equivalent) samples of Fig. 12 was also present during the runs made with 0·5-g (and equivalent) samples of Fig. 4, but because the sample was smaller the magnitude was much less.

Thus, although the thermograms of Fig. 4, demonstrate that under certain conditions the curve for a multi-stage pyrolysis can be considered as the exact summation of the curves for the individual stages, those of Figs. 11 and 12 emphasise that under other conditions the thermogravimetric behaviour of a given substance may depend upon whether it is the material initially loaded into the sample container or whether it is formed in the container by decomposition of a percursor.

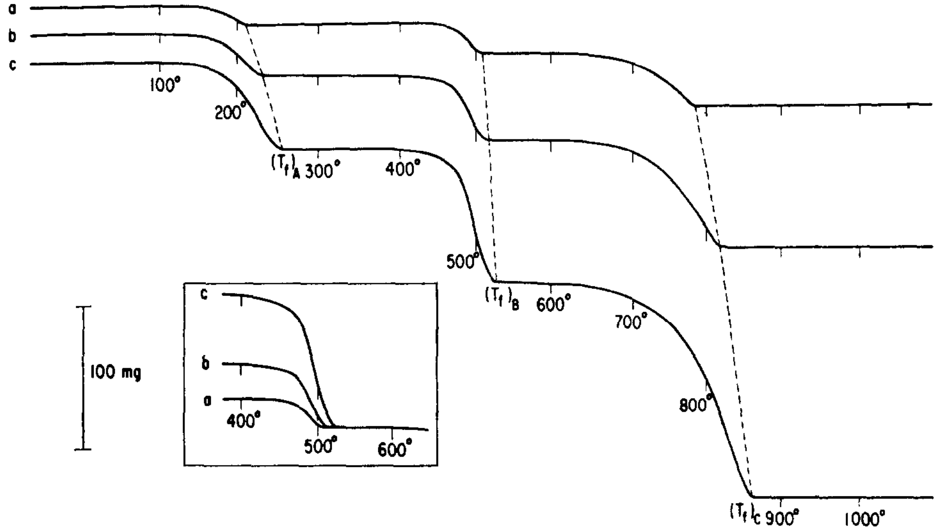

FIG. 13.—Effect of sample weight upon thermogram for calcium oxalate monohydrate in flowing dry nitrogen (porcelain crucible, 300 degree/hr):

a—126 mg of calcium oxalate monohydrate,
b—250 mg of calcium oxalate monohydrate,
c—500 mg of calcium oxalate monohydrate.

Insert shows three curves superimposed at calcium carbonate level to emphasise effect of sample weight on loss of carbon monoxide.

From the foregoing results it appears that no generalisations can be made about the effect of sample weight upon the procedural decomposition temperature, particularly for intermediate products. Even with powdered calcium carbonate as a starting material, Richer and Vallett^{44,45} found that T_i was virtually independent of sample weight in the range 0·25 to 1 g, both in nitrogen and carbon dioxide. At 100 degree/hr, T_i was 517° in nitrogen and 914° in carbon dioxide. On the other hand, once the decomposition of a powdered solid has begun, it generally does not occur uniformly in every particle throughout the entire mass of sample.^{31,51,52,55} Measurable temperature gradients exist even across relatively thin beds of powder.$^{32-34}$ Under such non-homogeneous conditions one would expect that the time required for complete decomposition of a powdered solid would increase with increase of sample weight. Because the furnace heating rate is linear there would be a resultant increase in the observed value of T_f. This expected increase was observed by Richer and

Vallet[44,45] for the pyrolysis of calcium carbonate and in this work for each stage in the pyrolysis of calcium oxalate monohydrate in nitrogen at 300 degree/hr (Fig. 13).

A perturbation in this generalisation can occur if the reaction is exothermic. The sample temperature then increases more rapidly than does the measured furnace temperature, and the resultant acceleration in specific reaction rate may compensate, at least in part, for the increase in sample weight. It has already been noted that in air the endothermic decomposition of calcium oxalate is accompanied by the highly exothermic oxidation of carbon monoxide, with a consequent acceleration of the reaction rate. As a result, as shown in Fig. 14, T_f for the decomposition of calcium oxalate in air is less than in nitrogen and is virtually independent of the starting weight of monohydrate, at least in the range 125 to 500 mg. A comparison between Figs. 14 and 6 shows the normally expected increase in T_f between 500 mg and 1 g and the pronounced increase in T_i for calcium carbonate that was noted in the discussion of Fig. 12.

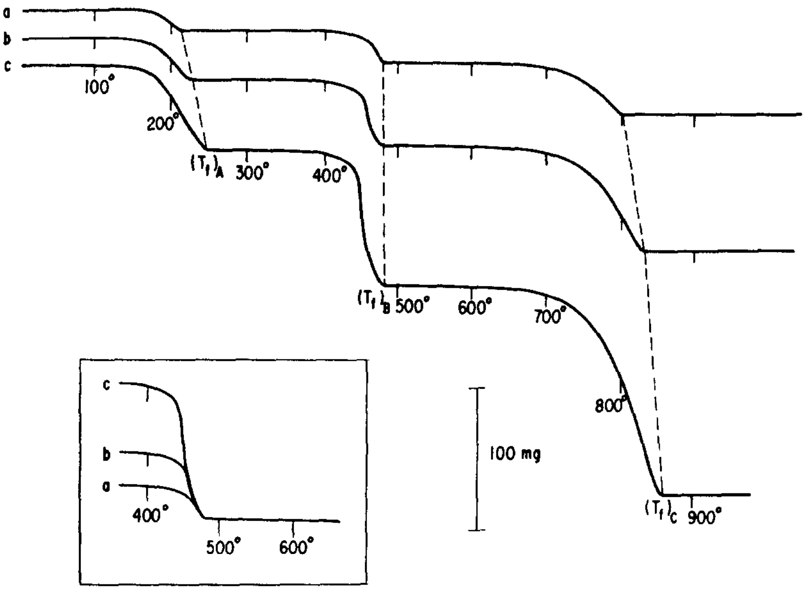

FIG. 14.—Effect of sample weight upon thermogram for calcium oxalate monohydrate in ambient air (porcelain crucible, 300 degree/hr):

a—126 mg of calcium oxalate monohydrate
b—250 mg of calcium oxalate monohydrate,
c—500 mg of calcium oxalate monohydrate.

Insert shows three curves superimposed at calcium carbonate level to emphasise that T_f for loss of carbon monoxide is independent of sample weight.

Water vapour

The value of a dynamic thermogram in the preliminary study of chemical reactions lies not just in its gross characteristics, such as plateaux or clearly marked changes of slope, from which one can draw inferences about the stoichiometry of the reaction, but also in the more subtle variations of shape that may reflect the complexity of the reactions that produce the more noticeable, over-all weight changes. This is illustrated by a re-examination of Fig. 4 for the pyrolysis of calcium oxalate monohydrate in ambient air. The over-all stoichiometry of the three distant stages is clearly defined by each of the plateaux. However, there is a significant qualitative difference between the shape of the curve that marks the loss of carbon monoxide and the shapes of the curves for the loss of water and of carbon dioxide. The latter curves are smooth and continuous between the two plateaux, but the loss of carbon monoxide is characterised by three rather abrupt changes in slope that have no apparent stoichiometric significance. This shape is reproducible and is not an artifact of the instrument, although it can be modified by using a platinum instead of a porcelain crucible. Clearly, the thermogram suggests that further investigation of this stage of the reaction is warranted.

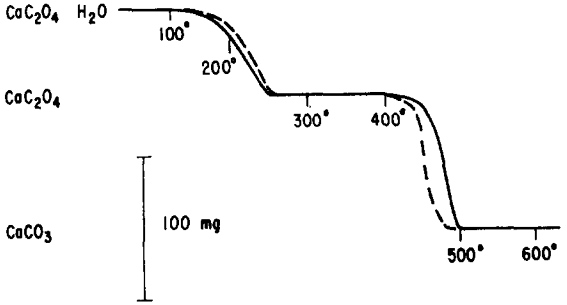

FIG. 15.—Effect of water vapour upon thermogram for calcium oxalate monohydrate in oxidising atmosphere (500 mg, porcelain crucible, 300 degree/hr):

——— dry air,

– – – – humid air.

In the region of carbon monoxide loss the curve obtained in ambient air (curve A of Fig. 4 and curve *c* of Fig. 14) is identical to the dashed curve in humid air.

Additional experiments were performed, which showed (Fig. 15) that the unusual shape, originally observed in ambient air, could be reproduced exactly in a flowing atmosphere of humidified air, but that in dry air the loss of carbon monoxide was characterised by the same smooth continuous shape noted in Fig. 11 for dry nitrogen and oxygen. Furthermore, the accelerating effect of water vapour upon the decomposition of CaC_2O_4 is clearly evident from the curves of Fig. 15. Finally, a comparison between thermograms obtained in dry air, dry nitrogen, and humid nitrogen (Fig. 16) shows that the loss of carbon monoxide begins more abruptly and at a lower furnace

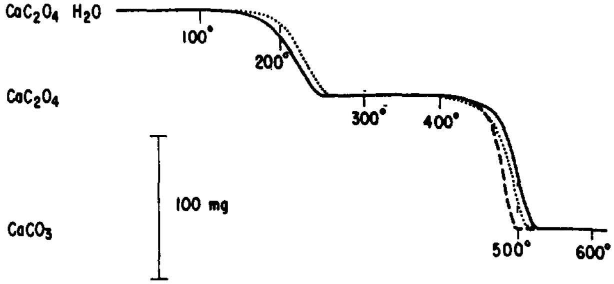

FIG. 16.—Effect of water vapour upon thermogram for calcium oxalate monohydrate in inert atmosphere (500 mg, porcelain crucible, 300 degree/hr):

——— dry nitrogen,

...... humid nitrogen,

– – – – dry air.

temperature in humid nitrogen than in dry air, although the total loss is completed at a lower furnace temperature in the latter gas.

That water vapour has a marked effect upon the decomposition of anhydrous calcium oxalate was confirmed by repeating the thermal experiments illustrated in Fig. 7 with humidified gases. The exotherm noted previously in dry oxygen was still present, but it had been shifted about 40° to a lower temperature. In humidified nitrogen, however, the magnitude of the endotherm for the oxalate decomposition was significantly reduced. The combustion train experiment was also repeated as a two-part experiment. During the first 3-hr period the carrier gas was humidified nitrogen; during the second 3-hr period it was dry oxygen. For the period in humidified nitrogen the combustion train was modified by inserting a large capacity water absorption tube at the exit end of the pyrolysis tube to ensure that no water vapour was present in the gas that entered the first Ascarite tube. In addition, an Anhydrone absorption tube was inserted in the train immediately after the copper oxide furnace. Any hydrogen in the gas stream leaving the reaction zone would be oxidised by the hot copper oxide and be absorbed as water in the Anhydrone tube.

The results are listed as runs 3(a) and 3(b) in Table II. The following comments are pertinent to the data:

1. The amount of calcium oxalate that decomposed during the first 3 hr at 420° was significantly greater in humid nitrogen than in dry nitrogen.

2. Unlike run 2 made in dry nitrogen, less than one-third of the total carbon dioxide that was absorbed by the Ascarite appeared in the tube that was mounted at the exit end of the copper oxide furnace, indicating that less than one-third of the evolved carbon monoxide left the reaction zone unchanged.

3. Part of the carbon monoxide evolved in the humidified nitrogen atmosphere was oxidised by the water vapour to carbon dioxide:

$$CO + H_2O = CO_2 + H_2 \qquad \Delta H_{700^\circ K} = -9{\cdot}1 \text{ kcal}^7 \qquad (6)$$

The hydrogen that was simultaneously produced appeared as water after it had passed through the copper oxide furnace.

4. Not all of the evolved carbon monoxide ended up as carbon dioxide. Unlike runs made in dry air and dry nitrogen, the total mole of carbon dioxide absorbed during run 3(a) was significantly less than the weight loss of the sample, calculated as mole of carbon monoxide. During this run in humid nitrogen a yellow deposit appeared at the cool exit end of the combustion tube. Preliminary pyrolysis experiments in humid nitrogen with both calcium and magnesium oxalates had produced similar deposits, which were soluble in benzene and whose infrared spectra showed them to contain aliphatic C-H bonds. In addition to hydrogen, various hydrocarbon species are thermodynamically possible products of the reaction between carbon monoxide and water vapour. Depending upon their volatility, such species can condense out of the gas stream at various points in the train before the copper oxide furnace and therefore would not appear ultimately as carbon dioxide and water. More volatile hydrocarbons might reach the hot copper oxide tube but be incompletely oxidised in passing through it. Experience in this Laboratory has shown that at the recommended temperature of 700° for operation of the copper oxide furnace, even the oxidation of methane may be slow enough to permit small amounts of the gas to pass

through the reaction zone unchanged. For the foregoing reasons a reliable material balance was not possible in this experiment.

5. To confirm the reliable operation of the train itself, run 3(b) was made by passing dry oxygen over the residue remaining from 3(a). As seen from the results in Table II, all of the evolved carbon monoxide was oxidised in the reaction zone and was absorbed as carbon dioxide in the first Ascarite tube.

No further work has been performed to explore and understand the effect of water vapour upon this reaction, and certainly thermogravimetry alone will not provide the answers. Thermogravimetry has provided, however, as few other techniques could, simple and graphic evidence for the existence of an effect that might warrant further investigation.

CONCLUSION

Calcium oxalate monohydrate is ideally suited for demonstrating many of the factors that affect the quality of thermogravimetric measurements. It is particularly useful for showing the great variety of effects that may be produced by three common atmospheric constituents, carbon dioxide, oxygen and water vapour, as well as three common experimental variables, heating rate, shape of sample container and size of sample. These variables and the interaction between them will determine whether the thermogravimetric curve for the pyrolysis of calcium oxalate monohydrate will appear as a succession of independent reactions or as a sequence of partially overlapping and non-independent reactions. Calcium oxalate monohydrate can be used as a standard for judging the performance of a thermobalance only if it is pyrolysed under carefully controlled conditions.

Acknowledgments—The authors acknowledge the skilful assistance of Adrian Breitenstein, Harley W. Middleton and Mrs. Renette Vincelette, in performing some of the measurements described in this report. They are also indebted to Dr. Paul D. Garn, University of Akron, for suggesting both the interpretation of the calcium carbonate portion of Fig. 11 and the revised experiments described in the text.

Zusammenfassung—Die Pyrolyse von Calciumoxalat-Monohydrat an Luft nimmt in der Literatur über Thermogravimetrie einen hervorragenden Platz ein. Ein Thermogramm dieser Reaktion war die erste von Duval und Mitarbeitern publizierte Pyrolysenkurve und Duval und andere schlugen diese Substanz als Bezugssubstanz zur Beurteilung der Anzeige einer Thermowaage vor. Die Pyrolyse von Calciumoxalat-Monohydrat gibt aber unter verschiedenen Bedingungen beträchtliche Unterschiede in den Thermogrammen. Die Einflüsse von Probengröße, Aufheizgeschwindigkeit, Atmosphäre und Gefäßgeometrie werden in einer Reihe von Thermogrammpaaren vorgelegt und die Unterschiede mit zusätzlichen Informationen aus Differential thermoanalyse und Versuchen im Verbrennungs-schiffchen erklärt. Besonders wichtig sind Änderungen der Atmosphäre: untersucht wurden trockener und feuchter Stickstoff, trockene und feuchte Luft, trockener Sauerstoff, Kohlendioxyd und Kohlenmonoxyd. Selbst geringfügige Änderungen der Form eines Thermogramms von einer verläßlichen Waage können die Kompliziertheit der Reaktionen widerspiegeln, die die leichter bemerkbaren Gewichtsänderungen insgesamt hervorrufen. Die hier vorgelegten Ergebnisse grenzen auf diese Weise die Arbeitsbedingungen ab, unter denen Calciumoxzlat-Monohydrat als thermogravimetrische Bezugssubstanz verwendet werden kann, und sie zeigen, daß sein Verhalten in einer Thermowaage unter kontrollierten Bedingungen eine ungewöhnlich vielseitige Anleitun zur Interpretation thermogravimetrischer Messungen bieten kann.

Résumé—La pyrolyse dans l'air de l'oxalate de calcium monohydraté occupe une place unique dans la littérature de la thermogravimétrie. Non seulement la première courbe de pyrolyse publiée par Duval et ses collaborateurs a été un thermogramme de cette réaction, mais Duval et d'autres auteurs ont proposé ce composé comme substance de référence pour juger des possibilités d'une thermobalance. Toutefois, la pyrolyse de l'oxalate de calcium monohydraté dans des conditions variées conduit à des différences considérables dans les thermogrammes. Les influences de la taille de la prise d'essai, de la vitesse de chauffage, de l'atmosphère, et de la forme du récipient, sont présentées dans une série de thermogrammes comparatifs, et les différences sont confirmées au moyen de preuves supplementaires apportées par l'analyse thermique différentielle et des expériences de combustion en série. Des variations dans l'atmosphère sont particulièrement importantes, et les atmosphères étudiées sont l'azote sec, l'azote humide, l'air sec, l'air humide, l'oxygène sec, le gaz carbonique sec et l'oxyde de carbone sec. Même de très faibles variations dans la forme d'un thermogramme obtenu avec une balance fidèle peuvent refléter la complexité des réactions qui produisent les changements de poids globaux les plus remarquables. Les résultats présentés dans ce mémoire délimitent ainsi les conditions d'emploi de l'oxalate de calcium monohydraté comme substance de référence thermogravimétrique, et montrent que son comportement dans une thermobalance, dans des conditions contrôlées, peut constituer un exemple particulièrement souple pour l'interprétation des mesures thermogravimétriques.

COLORIMETRIC DETERMINATION OF NICKEL WITH 2-MERCAPTOBENZOTHIAZOLE

E. G. Walliczek
Rhoanglo Mine Services Limited
Research and Development Division
P.O. Box 172, Kitwe, N. Rhodesia

(*Received* 1 *September* 1963. *Accepted* 24 *October* 1963)

Summary—A colorimetric method has been developed for determining nickel with 2-mercaptobenzothiazole. At pH 7·7–8·1 in an ammoniacal medium nickel forms a yellow-brown complex, insoluble in water but soluble in chloroform. It is suitable for determining nickel in the concentration range 0·4–16 ppm with an average error of 0·5–2%. Cobalt, copper and iron interfere and have to be removed by an anion-exchange method before analysis. Bismuth and lead, if present, are removed with hydrogen sulphide, and complex formation of 2-mercaptobenzothiazole with alkali metals is prevented by fluoridation. No other metals were found to interfere.

This paper describes an investigation of 2-mercaptobenzothiazole as a colorimetric reagent in chloroform for the determination of nickel. In procedures involving the use of dimethylglyoxime,[1] manganese interferes and has to be removed before the colorimetric determination can be applied. A literature survey revealed that 2-mercaptobenzothiazole has not been reported previously for the colorimetric determination of nickel.

2-Mercaptobenzothiazole is not specific for nickel, but the reagent allows the determination of nickel in the presence of many other metal ions. It has already found use as a reagent for the gravimetric determination of a variety of metals too numerous to be listed here. Majumdar and Chakrabartty[2] have also investigated this reagent for the colorimetric determination of palladium.

EXPERIMENTAL

Reagents

2-Mercaptobenzothiazole. 1% w/v in chloroform; for purification of the commercial material see *Appendix.*

Standard nickel solution. A stock solution prepared from *Specpure* nickel sponge was suitably diluted, so that 1 ml contained 0·1 mg of nickel.

Hydrochloric acid. 0·5*M* solution prepared from A.R. reagent (Merck).

Aqueous ammonia. 0·5*M* solution prepared from A.R. reagent.

Hydrofluoric acid. Conc. (A.R.) and (1 + 20) solution prepared from A.R. reagent.

Chloroform. A.R.

Apparatus

Spekker absorptiometer (mercury vapour lamp), 2-cm and 4-cm cells and Hilger No. 1 violet-blue filters.

Procedure

Transfer 1·0, 2·0, 3·0 and 8·0-ml portions of the standard nickel solution from a micro burette into a series of beakers containing 10 ml of distilled water. Using a pH meter, adjust the pH of the solutions to 7·7–8·1 with 0·5*M* aqueous ammonia or 0·5*M* hydrochloric acid. Transfer the solutions quantitatively into 100-ml separating funnels and extract the nickel with 2 × 10 and 1 × 5 ml of

1% 2-mercaptobenzothiazole in chloroform. Shake gently for 2 min for each extraction and filter the organic phase into a 50-ml volumetric flask by means of a small funnel fitted with a cotton wool plug. After filtration, wash the cotton plug through with fresh chloroform and make the extracts up to the mark with chloroform. Measure the optical density of the yellow-brown solutions against a blank in chloroform using 2-cm cells. Plot a graph relating the optical density to the quantity of nickel present; it should be linear and pass through the origin.

Calibrations containing from 0·01–0·10 mg of nickel should be carried out in the same way but using 25-ml volumetric flasks and 4-cm cells. Extraction of nickel is established with 10 ml and 5 ml of 1% 2-mercaptobenzothiazole in chloroform.

DISCUSSION

The nickel-2-mercaptobenzothiazole complex in chloroform is yellow-brown whereas the reagent solution itself is almost colourless. The absorption spectrum for the coloured complex shows a maximum near 750 mμ.

FIG. 1.—Complex formation as a function of pH.

The complex formation is dependant on the pH of the aqueous solution and Fig. 1 indicates that a pH of 7·7–8·1 is critical for the quantitative formation of nickel-2-mercaptobenzothiazole. The optical density of the complex in chloroform showed no change after 24 hr.

Job's method of continuous variations[3] shows that every atom of nickel in the complex is bound to two molecules of 2-mercaptobenzothiazole and that a single complex species is formed in solution.

Various metal ions have been tested, after fluoridation, by the method described and their colour reactions are as follows:

Bi: yellow; Co: green; Cu: yellow; Fe: brown;
Ni: yellow-brown; Pb: yellow; Pd not tested.

Al, Ag, Au, Ba, Be, Ca, Cd, Ce, Cr, Hg, K, Li, Mg,
Mo, Mn, Na, Re, Se, Sr, Sn, Te, Ti, U, Zr, Zn:
no colour reaction

The interference from cobalt, copper, bismuth and iron is entirely removed by an anion exchange method* on a large column with a resin bed of 350-ml volume,† rejecting the first 100 ml of eluate, after which 500 ml are collected for the analysis of nickel in 8*M* hydrochloric acid as described by Liberman.[4] Lead, if present, passes

---

* Permutit "De-Acidite" FF(SRA 65) anion-exchange resin, chloride form, 14–52 mesh.

† At the discretion of the analyst the size of the column may, of course, be adjusted in accordance with the size of the sample.

through the column but is removed by gassing with hydrogen sulphide for a period of 5 min at pH 1 either before or after the anion-exchange separation.

After removal of all interfering metal ions the hydrochloric acid eluate is evaporated and made up to a convenient volume. An aliquot which should contain 0·02–0·8 mg of nickel is pipetted into a platinum crucible and 2 drops of sulphuric acid added, followed by 1 ml of perchloric acid. The sample is evaporated to dryness preferably on a sand bath. After cooling, 0·5 ml of hydrofluoric is added and the sample is again evaporated to dryness. The sample residue in the platinum crucible is dissolved by the addition of 3·0 ml of (1 + 20) hydrofluoric acid whilst heating. The sample solution is transferred into a beaker and the pH adjusted to 7·7–8·1, then quantitatively transferred into a 100-ml separating funnel and analysed as described. The concentration of nickel in the sample is read from the calibration curve.

RESULTS

To verify the method, tests were carried out in which known amounts of nickel were added to synthetic solutions of various metal ions. The results obtained are shown in Tables I–V.

TABLE I.—SOLUTIONS ALL EVENTUALLY MADE TO 50 ml IN CHLOROFORM. ERROR IS THE DIFFERENCE BETWEEN THE 'EXPECTED' AND 'OBSERVED' NICKEL CONCENTRATIONS EXPRESSED AS A PERCENTAGE.

(A) A 50-ml aliquot was separated on the column. After evaporation of the hydrochloric acid eluate the volume was adjusted to 100 ml and 5-ml portions were taken for each analysis.

Absorbance	Ni found, *mg*	Error
0·448	0·498	−0·5
0·450	0·500	0·0

	0·140	0·028
	0·140	0·028

[a] Dimethylglyoxime method after removal of Mn = 0·010% Ni. Mn 0·10; Bi 0·02; Cu 1·0; Co 0·4; Fe 17% (Al, Ca, Mg, Si rest).

[b] Dimethylglyoxime method after removal of Mn = 0·007% Ni. Mn 0·10; Bi 0·02; Cu 1·0; Co 0·3; Fe 16% (Al, Ca, Mg, Si rest).

TABLE V.—DETERMINATION OF NICKEL IN COBALT METAL IN THE PRESENCE OF MANGANESE (SAMPLES MADE UP TO VOLUME OF 100 ml AND EVENTUALLY MADE TO 50 ml IN CHLOROFORM)

Wt. of sample, *g*	Aliquot, *ml*	Absorbance	Ni found, *mg*
4·1717[a]	5	0·438	0·488
0·9290[a]	20	0·365	0·410
0·6230	20	0·250	0·280

[a] Because of the high cobalt load the eluate was evaporated and re-introduced on a fresh column for the removal of cobalt.

APPENDIX

Purification of 2-mercaptobenzothiazole

2-Mercaptobenzothiazole, when pure, is a creamy-white crystalline powder with a melting point of 182·2°. The reagent is available commercially but further purification is necessary.

Dissolve 20 g of commercial 2-mercaptobenzothiazole in 100 ml of 5% sodium hydroxide solution. Add 20 g of activated charcoal powder and shake for 5 min. Filter the solution under vacuum through a Buchner funnel using Whatman No. 42 filter paper. To the filtrate add 50 ml of 1% magnesium chloride (A.R.) solution and dilute to an approximate volume of 2 litres. Precipitate sodium 2-mercaptobenzothiazole whilst stirring with an excess of a dilute hydrochloric acid solution. Filter the precipitate under vacuum. Repeat the above operation without the use of charcoal or magnesium chloride. Filter and wash the precipitate freely with distilled water. Dissolve the partially dry filter cake in 200–300 ml of A.R. acetone. Filter the acetone solution, under vacuum, through a column approximately (0·5 inch in diameter) which contains 10 inches of Whatman cellulose powder. On top of the cellulose powder is placed a 3 to 4-inch layer of activated charcoal powder. The column packing is changed when half of the acetone solution has passed through it. Receive the filtrate into a 1-litre Buchner flask which contains 500 ml of distilled water. Filter the purified crystalline 2-mercaptobenzothiazole through a clean No. 3 Gooch crucible and dry the powder under vacuum over sulphuric acid.

Zusammenfassung—Eine quantitative Farbenmethode wurde für die Bestimmung von Nickel mit 2-Mercaptobenzothiazole im Bereich von 0·4–16 p.p.m. und einer Genauigkeit von 0·5–2 percent ausgearbeitet. Der Nickel 2-Mercaptobenzothiazole Komplex wird mit Chloroform in einem ammoniakalischem medium extrahiert und ist kritisch im pH Bereich 7·7–8·1. Kobalt, Kupfer und Eisen stören in der Bestimmung und werden mit einem Anionvertauscher in 8N Salzsäure festgehalten. Wismuth und Blei stören auch und müssen durch ausgasen mit Schwefelwasserstoff bei pH 1 zuvor oder nach der Anionvertauschtrennung beseitigt werden. Keine anderen Metalle stören.

Résumé—On a développé une méthode quantitative colorimetrique pour le dosage de nickel avec 2-mercaptobenzothiazole dans la portée de 0·4–16 p.p.m. avec une precision de 0·5–2 pourcent. Le complexe coloré du nickel 2-mercaptobenzothiazole est extrait avec du chloroforme dans un agent ammoniacal et est critique á pH 7·7–8·1 On élimine l'intervention du cobalt, du cuivre, et du fer par une methode d'échange dans du 8N acide chlorhydrique. Le bismuth et le plomb interférent aussi mais on les enléve par le moyen de passage au gaz avec du hydrogéne sulphuré á pH 1 on avant on aprés la séparation par l'échange du anion. On constata qu'aucun autre métal n'interféra.

(*Received* 10 *September* 1963. *Accepted* 25 *October* 1963)

Summary—An improved gas extraction, collection, pressure measurement and calculation apparatus is described for use in the vacuum fusion method. It is designed for routine analysis and versatility in research investigations. The time required for gas collection is 1–2 min, including 15–60 sec for gas extraction. The total time required for a complete analysis is 7–9 min. The operating blank is 0·01–0·03 ml/30 min at 1850°. Analysis of 20 or more samples can be made in 8 hr, including loading, outgassing and gas analysis. A description is given of a newly designed gas extraction recording system for studying the optimum conditions for determination of gases in metals of current interest.

INTRODUCTION

In recent years there has been an increasing demand for simple and rapid analytical methods that may be used under plant conditions for the determination of gases in metals and many such techniques have been successfully developed.[1–4] Particularly in the steel industry, more rapid and simple procedures have been required, and for the newer metals, such as titanium, uranium, hafnium, tantalum, *etc.*, more exacting demands are imposed on the analytical method.[5–8]

In this paper an improved vacuum fusion apparatus is described. The apparatus provides the following features:

1. A rapid gas extraction system.
2. A furnace assembly which is available for various kinds of sample and a wide range of sample weights.
3. A system in which the state of gas extraction can be simply and rapidly observed.
4. A simple and automatic pressure measurement system and minimisation of the use of mercury.
5. An automatic computer geared to the gas analysis system.

EXPERIMENTAL

Apparatus

The general appearance of the apparatus and the arrangement of the components are shown in Fig. 1. This apparatus differs from others which have been described in the fast gas extraction system, gas extraction recording system, gas collecting system and pressure measurement system. Some general considerations on these matters precede the detailed description of the various parts of the apparatus.

Gas extraction system

It is important that the gases evolved from a sample are removed from the furnace tube as rapidly as possible to minimise losses from chemisorption and reactions with evaporating metal vapours or evaporated metal films. This requirement has been met by connecting a newly designed, fast mercury diffusion pump[9] to the furnace tube by a wide-bore spherical joint (50-mm dia.) as shown in Fig. 4.

C_1, C_3, C_4—stopcocks.

This transfer pump should have a reasonably high critical backing pressure because the pressure in the intermediate collecting volume (3 in Fig. 1) may occasionally build up to 0·1–0·3 mm of mercury. The pump used has, in fact, a speed of 70 litre/sec at 10^{-5}–10^{-2} mm of mercury and a critical backing pressure of 0·7 mm of mercury.

The spherical joint is sealed in place with synthetic rubber packing[10] as shown in Fig. 4, in place of grease, so that any blank caused by grease is reduced.

Gas extraction recording system

Pressure changes in the vacuum furnace chamber measured with an ionisation gauge attached directly to the high pressure side of the extraction pump do not follow accurately a pressure change at the beginning of gas evolution as shown in Fig. 2. Therefore pressure changes were measured indirectly with a Pirani gauge (4 in Fig. 1) attached to the intermediate collecting volume (about 400 ml) between the extraction pump and the collection pump. Pressure changes are recorded with an automatic self-balancing recorder to make gas extraction curves similar to the one illustrated in the right hand portion of Fig. 2. By partly closing the stopcock C_3 (Fig. 1), these curves can be run with greater sensitivity. Valuable information on gas extraction phenomena can be obtained from these recordings.

Stopcock C_3 is used to isolate the furnace system while the gas analysis is carried out. If gas extraction is incomplete, the residual gas evolved from the last sample can be collected during the following blank run in the intermediate collecting volume, and a check made to determine whether the gas extraction is complete or not.

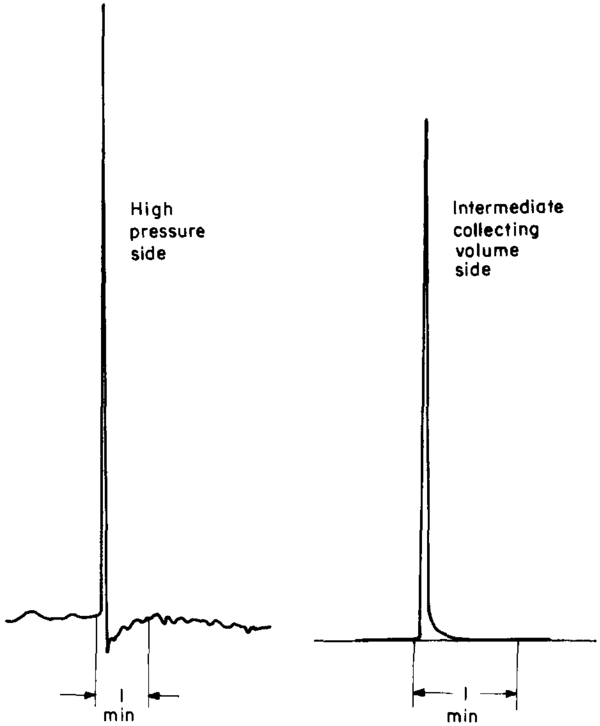

FIG. 2.—Comparison of pressure change between high vacuum side of extraction pump and intermediate collecting volume side.

Collection and circulation pump

The gas extracted is collected into a small collecting volume through the intermediate collecting volume with a newly designed vacuum pump. It is a two-stage mercury ejector pump (6 in Fig. 1),[9] capable of working against a high backing pressure. When the stopcock C_3 is closed, this pump can also be used to circulate the gas in the analysis system. Because the maximum backing pressure of this pump is 9 mm of mercury, the collecting volume can be made small, so that the pressure in it can be so high as to be easily measured.

The effective collecting volume is 75 ml, and the pressure in the collecting volume usually builds up to 3–5 mm of mercury. The speed of the pump is 5 litre/sec at 10^{-3}–1 mm of mercury.

Pressure measurement

Quantitative pressure measurements are made accurately, easily, continuously and rapidly by a newly designed oil manometer, as shown in Fig. 3, because the pressure in the collecting volume is comparatively high.

The oil used is No. 703 or 704 of Dow Corning Silicone. After redistilling and degassing, the oil is poured into the oil pool of the manometer. The manometer is attached to the collecting volume and turned upside down. Once more the oil is degassed by heating the oil pool with a weak flame. For the purpose of avoiding defects, such as absorption and release of gas, the volume of oil used should be a minimum and the contact area between oil and gas should also be a minimum.

An expansion volume of 400 ml (11 in Fig. 1) can be connected by opening a tap if the range of the oil manometer is exceeded by an unexpectedly large evolution of gas.

The volume in which the gases are collected is calibrated by means of a gas burette, and it can be determined with a precision of ±1 %. The temperature of the collecting volume should be held to within ±2° if a high precision measurement is desired. The electric current of the heater of the collection pump and the temperature of the cooling water should be controlled at the same condition as during calibration. The sensitivity (mg/mm of oil) for each gas is calculated, namely, 0·000670 for hydrogen, 0·00532 for oxygen and 0·00931 for nitrogen.

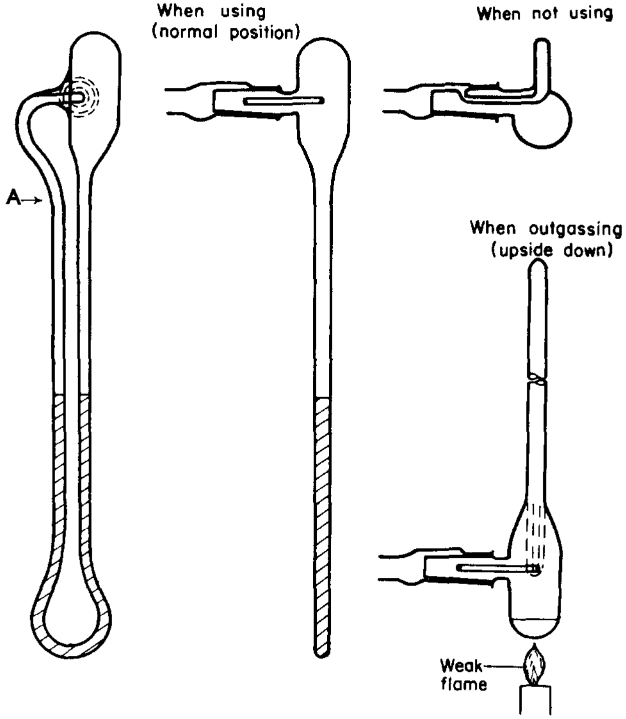

FIG. 3.—Oil manometer.
Below A the tubing is capillary.

The manometer reading is made automatically with photoelectric attachments and recorded on an automatic self-balancing recorder.

Induction heater

An induction heater of 3 kW nominal output at 400 kc/s is used. With the right combination of coil and crucible, a lower power, such as 0·6 kVA (plate voltage × plate current), is dissipated in the graphite to produce a temperature of 2300°. The 16-turn coil is 110 mm high with an internal diameter of 82 mm. The induction heater is provided with a control unit that gives a continuous change of temperature from about 800° to 2300°.

Furnace assembly

The furnace assembly developed by Guldner and Beach[11] has been modified. For the purpose of rapid gas extraction and collection, the dimensions of all parts of the assembly are changed as shown in Fig. 4. This section is an air-cooled Pyrex shell. A joint at the bottom is sealed in place with Dekhotinsky cement and acts as a support for a quartz thimble, which is positioned more uniformly and easily than when suspended by platinum wires from glass hooks. The thimble contains a graphite crucible surrounded by 200–250 mesh graphite powder.

The crucible with a renewable insert is of simple form. The insert, which makes a sliding fit with the crucible, is 75 mm high, 65 mm deep by 26 mm external diameter with a wall thickness of 3 mm, and has a working capacity of 50 g.

A large crucible assembly has the advantages of being able to treat a much greater total weight of metal per run, being more available for a wider range of sample weights, and having a lower rate of increase of bath viscosity, because of the reduction in the ratio of crucible-bath interface area to bath material. The disadvantage of having a somewhat larger blank than for a smaller crucible was a matter for consideration, but in practice the blank is usually as low as 0·01–0·03 ml/30 min at N.T.P.

Gas analysis system

Low-pressure methods of gas analysis are rapid and accurate, and they have been used almost exclusively in the present work. Carbon monoxide and hydrogen are oxidised to carbon dioxide and water, respectively, by circulating the gas mixture over heated copper^{II} oxide. Water is absorbed with phosphorus pentoxide and carbon dioxide is frozen out in a liquid nitrogen trap. By measuring the pressure drop, each gas is determined. The residual gas is assumed to be nitrogen.

General vacuum system

The system is evacuated by a newly designed all-glass, two-stage mercury diffusion-ejector pump.[9] The speed is 30 to 50 litre/sec at 10^{-5}–10^{-3} mm of mercury, and the critical backing pressure is as high as 5 to 6 mm of mercury. By using this pump it is possible to shorten the outgassing time of the graphite crucible and also to simplify the apparatus on the low pressure side.

Calculation system

Analytical data can be automatically calculated and printed out with a digital electric computer[12] designed newly for chemical analysis. Briefly, if two resistances correspond with the sample weight and the sensitivity of the manometer, respectively, and a third resistance follows the response of the pressure change in the analytical system, and if these are used as three arms in the bridge circuit of the computer, the analytical data can be calculated by automatically matching the resistance of the fourth arm of the bridge circuit.

Safety devices

The most troublesome breakdowns in this apparatus were caused by failure of the cooling water, by breakage of glass parts or by the increase of leaks. The electric power to each part is automatically switched off by safety devices assembled with a pressure gauge or water level meter and meter relay. By these devices, any accident of interruption of the water supply or vacuum break can be avoided. Occasionally at the beginning of heating, a sudden rush of graphite powder used as a heat shield has been experienced. As a symptom of such a sudden rush, the vacuum becomes poorer. At this time a safety device switches off the induction heater automatically and then the sudden rush can be prevented.

Procedure

Sample preparation

A sample weight of 0·1–10 g, but below 10 mm in maximum dimension, is suitable for analysis. Samples are cut by a lathe or shaper without using cutting oil and should be stored in the side arm of the furnace chamber. Twenty or more samples can be placed in the side arm and released in turn by means of magnetic plungers.

Outgassing

Before a new crucible is placed in the apparatus, it is preheated to 400–500° in a stream of argon for about 1 hr. This reduces the time necessary for outgassing and also the crucible blank.

After evacuation of the system, the temperature of the crucible is raised to 2200–2300° and held at this temperature for 1·5–5 hr. The crucible assembly should not be outgassed at a higher temperature, otherwise the rate of evaporation of graphite becomes excessive.

When the outgassing of the graphite crucible is complete, the crucible is allowed to cool to below the extraction temperature. It is then desirable to outgas the bath material little by little because of the reduction of the time necessary for outgassing.

Blanks

The 'blank' gas is collected for 30 min and analysed. The composition normally consists of 30 to 100% of carbon monoxide, 0–70% of hydrogen and is free from nitrogen. The average value of the blank rate at 1850° is equivalent to 0·01–0·03 ml/30 min at N.T.P. This normally is only a small percentage of the gas collected from a sample during a collection time of 1 to 2 min.

The blank is always measured for the 3 min immediately following the collection of gas from a sample. Carbon monoxide and hydrogen blanks do not increase with the number of droppings of the sample but the nitrogen blank tends to increase gradually for some kinds of sample.

Dropping the sample

To obtain a rapid reduction of the oxide, it is generally desirable to introduce the sample into a molten metal bath containing dissolved graphite, except light metal samples. Even if the reaction between bath and sample is violent and a part of the sample or bath material is ejected from the crucible, or if the gas comes off in a rush from the crucible, our experience has shown that lower results are not obtained. It has been observed with the gas extraction curve that ejection of a sample does not happen before gas evolution but at the same time. The crucible lid has been provided but we have not used it, except when outgassing a crucible assembly. By this means, a prolonged stay of gas inside the crucible is avoided. Generally, it seems that high pressure causes incomplete extraction of the gas.

Gas extraction temperature

A gas extraction curve for every kind of sample is determined while the crucible temperature is increased from 800° to 2100°. The selected extraction temperature is 50°–100° higher than the temperature at which gas evolution stops.

Collection time

The observed gas extraction curves show that only 15–60 sec is required for the rate of evolution to become equal to that of the original blank rate. In this apparatus, the gas is usually collected for

1–2 min. If residual gas is found in the intermediate collecting volume during the following blank run, the gas is measured again and analysed.

Gas analysis

The analysis of the gas, the evacuation of the nitrogen and the transfer of the following blank gas into the system, can be completed in 5–7 min. It is undesirable to use anhydrous magnesium perchlorate as an absorber of water vapour in place of phosphorus pentoxide, possibly because of the higher water vapour pressure of the former.

Time required for analysis

The time required for determination of gases in a metal is as follows:

1. Setting furnace assembly, including crucible assembly and sample introduction	30 min
2. Pumping out furnace	5 min
3. Outgassing of crucible at 2200°–2300°	90–300 min
4. Cooling to extraction temperature	5–7 min
5. Blank run	3 min
6. Dropping of sample	0·05–0·2 min
7. Gas collection time	1–2 min
8. Gas analysis (for three elements)	7 min
(for oxygen only)	5 min
9. Calculation by automatic computer	0·1 min
10. Recording with digital printer	0·05 min
11. Evacuation of gas analysis system	0·5–1 min

The total time required for carrying out a complete extraction up to printed results is 7–9 min. If the time required for gas analysis is shortened, the total time may be reduced even more. Analysis of 20 or more samples can be made in 8 hr, including loading, outgassing and gas analysis.

APPLICATION OF GAS EXTRACTION CURVE

Much valuable information about gas extraction phenomena can be obtained from the gas extraction curves measured with a Pirani gauge (4 in Fig. 1).

Gas extraction curve at extraction temperature

From a curve recorded at the extraction temperature, information can be obtained on the following items: state of gas evolution, gas extraction time and gas collection time, successful dropping of sample, state of melting of sample and bath condition.

If dropping, melting and gas extraction are carried out under good conditions, the normal gas extraction curve has a shape similar to curve A in Fig. 5. In such a case, the gas extraction may be completed in as short a time as 15–60 sec.

A gas extraction curve also provides information on whether the results are reasonable or not. For example, when analysing hafnium metal samples, various shapes of gas extraction curve, as shown in Fig. 6, were obtained. The normal gas extraction curve shown in Fig. 6 (A) gives accurate results. Low results are obtained for extraction curves of the type shown in Fig. 6 (B).

When pieces of sample or bath material are dropped one by one into a new crucible, the shape of the gas extraction curve changes gradually and approaches the shape of a normal gas extraction curve as shown in Fig. 7. By this means the state of melting of a metal sample can be observed.

When unexpectedly large amounts of gas evolve from a sample, the curve obtained is similar to B in Fig. 5. In such a case, the tap of the expansion volume should be opened as soon as possible. If a sample is occasionally caught on an upper position of the crucible and does not drop directly into the bath, the curve obtained is as shown in Fig. 5 (C) or (D). Sometimes a similar curve is observed when the bath becomes viscous and a dropped sample floats on the bath.

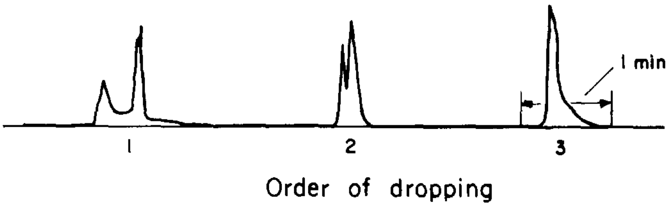

FIG. 7.—Change of gas extraction curve with order of dropping (sample: nickel; temperature: 1850°).

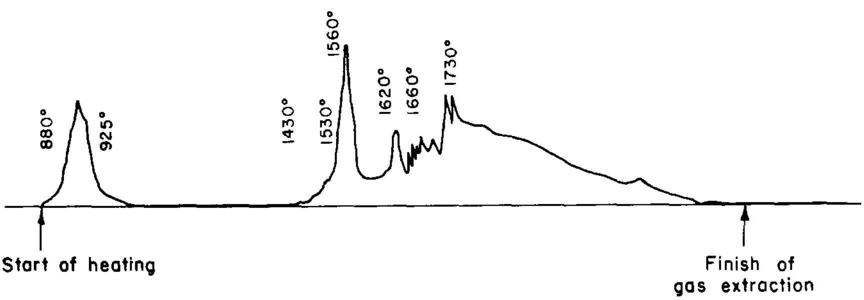

FIG. 8.—Extraction curve of gases in hafnium with increasing temperature.

Gas extraction curve with increasing temperature

From a curve recorded with increasing temperature, information can be obtained on the following items: gas extraction temperature, form of oxides or nitrides, *etc.*

It is very important to decide on a reasonable gas extraction temperature. That is, its temperature should be high enough to complete the extraction but conversely it should be as low as possible in order to avoid the evaporation of sample and bath material. A reasonable temperature can be decided by a gas extraction curve. For example, by this means, the extraction temperature of a sample of hafnium metal in a nickel bath could be decided easily and reasonably. Its extraction curve is shown in Fig. 8.

The total oxygen and nitrogen in a sample can only be obtained by the usual vacuum fusion method. If some information on the form in which the oxygen or nitrogen exists can be obtained, this will be very useful, particularly in the steel industry. By measuring a gas extraction curve with increasing temperature, some information on the form of the oxides or nitrides can be obtained. For example, gas extraction curves of some kinds of steel are shown in Fig. 9. The shape of the curves varies with the kind of sample and it seems that there is a possibility of inference of the form of oxide or nitride.

APPLICATION

Iron and steel

Samples of various kinds and various ranges of oxygen content from 10 ppm up to 650 ppm have been examined. The determinations were made at 1850° without employing a bath material, using sample weights up to 2 g and collecting the gas for 1 min. More reproducible results were obtained than with other types of apparatus and in spite of a very short collection time the analytical results coincided with those found by other investigators, as shown in Table I. The effect of manganese[14] on the determination of oxygen in steel was also studied. As shown in Table II, if a platinum or tin bath is used, the effect of manganese was negligible, but without such a bath more than about 1 % of manganese had a bad effect.

A number of difficulties in the determination of nitrogen by the vacuum fusion method have been reported.[13] Nitrogen results obtained with the old type of apparatus at our laboratory were 20–50 % lower than with the Kjeldahl method. By using the new apparatus the recovery of nitrogen increased, and the nitrogen values were lower by 0–15 % than those obtained by the Kjeldahl method. We think this is caused by the very fast gas extraction. If the same collection time as with oxygen is applied, the extraction of nitrogen is incomplete and the nitrogen content in a blank run gradually increases. Therefore, the amount of nitrogen in the following 26-min blank run was added to the nitrogen value of the last sample. Consequently, the reproducibility was relatively improved as shown in Fig. 10. Yet these results were a little lower than the Kjeldahl values. By using a platinum bath, however, the difference became smaller and in addition, if the collection time was reduced to only 3 min, the recovery of nitrogen was almost complete. Moreover, the effect of manganese on the determination of nitrogen almost disappeared. These results are shown in Table III.

Acknowledgement—The investigators were assisted by helpful discussions with Drs. H. Ishii and A. Ito and the staff of Industrial Analytical Chemistry, Faculty of Engineering, University of Tokyo.

Zusammenfassung—Eine verbesserte Anordnung für die Freisetzung und Sammlung von Gasen sowie für Messung und Berechnung des Druckes zum Gebrauch beim Vakuumschmelzverfahren wird beschrieben. Es ist für Routineanalyse und für Forschungsaufgaben mit vielseitigen Ansprüchen ausgelegt. Die Sammlung des Gases braucht 1–2 Minuten, einschließlich 15–60 Sekunden zur Freisetzung des Gases. Der gesamte Zeitaufwand für eine fertige Analyse beträgt 7–9 Minuten. Der Blindwert ist 0,01–0,03 ml in 30 Minuten bei 1850°. In 8 Stunden können 20 oder mehr Proben analysiert werden, Aufgeben der Probe, Entgasen und Gasanalyse inbegriffin. Ein neu entworfenes Registriersystem zur Gasextraktion wird beschrieben, mit dem man die günstigsten Bedingungen zur Bestimmung von Gasen in den gebräuchlichsten Metallen aufsuchen kann.

Résumé—On décrit un appareil amélioré pour extraire les gaz, les recueillir, effectuer les mesures de pression et les calculus, pour emploi dans la méthode de fusion sous vide. Il est conçu pour les analyses courantes et les recherches de caractère général. Le temps nécessaire pour recueillir les gaz est de 1–2 mm, y compris 15–60 sec. pour l'extraction des gaz. Le temps total nécessité pour une analyse complète est de 7–9 mn. L'essai à blanc est de 0,01–0,03 ml/30 mn à 1850°. On peut effectuer, en 8 h, l'analyse de 20 échantillons, ou davantage, en comprenant la charge, le dégazage et l'analyse des gaz. On décrit un système enregistreur d'extraction de gaz nouvellement conçu, pour étudier les conditions optimales de dosage des gaz dans les métaux d'intérêt courant.

PIONIERE DER ELEKTROANALYSE

F. SZABADVÁRY
Institut für Allgemeine Chemie, Technische Universität, Budapest, Ungarn

(*Eingegangen am* 3 *September* 1963. *Angenommen* 16 *September* 1963)

Zusammenfassung—Es werden die Erfinder und die bedeutendsten Forscher der verschiedenen Zweige der Elektroanalyse, und zwar der Elektrogravimetrie, pH-Messung, potentiometrischern und konduktometrischern Titration, Coulombmetrie, Polarographie, Amperometrie und der verschiedenen üblichsten Elektroden besprochen. Von der Mehrzahl der erwähnten Persönlichkeiten werden auch die wichtigsten biographischen Daten gegeben.

IM Jahr 1800 begann das Zeitalter der Elektrizität, als Volta seine berühmte "Säule" erfand und damit der elektrische Strom "erfunden" war. Noch im selben Jahr hatten damit Carlisle und Nicholson das Wasser zersetzt,[1] und Cruikshanks beobachtete, dass wenn die Elektrizität der Voltaischen Säule durch eine Metallsalzlösung geleitet wird, daraus Metalle am negativen Pol abscheiden.[2] Das waren die Anfänge einer neuen Wissenschaft, der Elektrochemie, die dann besonders durch die Arbeit von Ritter, Davy und Faraday einen raschen Aufschwung nahm.

Merkwürdiger Weise liess aber die analytische Anwendung des elektrischen Stromes noch ziemlich lange auf sich warten, obzwar man annehmen würde, dass nach Cruikshanks Beobachtung die Elektrogravimetrie sich schnell entwickeln hätte müssen. Tatsächlich liest man aber in den folgenden Jahrzehnten höchstens über einzelne qualitative Nachweise mit Hilfe des elektrischen Stroms. Fischer wies 1812 das Arsen elektrolytisch nach,[3] Cozzi und Gaultier de Claubry empfahlen elektrischen Strom zum Nachweis von Metallen bei toxikologischen Analysen[4,5] während Despretz Blei und Kupfer nebeneinander elektrolytisch nachwies, indem das eine an der Anode, das andere an der Kathode abgeschieden wurde.[6]

DIE ELEKTROGRAVIMETRIE

Die Elektrogravimetrie wurde endlich im Jahr 1864 geboren, also mehr als ein halbes Jahrhundert später als die erste elektrische Batterie. Ihr Erfinder war Wolcott Gibbs. Er bestimmte Kupfer and Nickel in Platintiegeln mit Hilfe der Bunsenschen Batterie. Die Tiegelwand selbst diente als Kathode, während die Anode ein in den Tiegel reichender Platindraht war.[7]

Luckow veröffentlichte 1865 eine ähnliche Methode und behauptet darin sie seit 1860 schon benützt zu haben.[8]

Nun folgten rasch nacheinander Vorschriften zur elektrogravimetrischen Bestimmung weiterer Metalle.

Bedeutend war die Tätigkeit Classens, der zuerst die Rolle der Stromstärke untersuchte und Galvanometer in den Stromkreis schaltete. Er elektrolysierte zuerst unter Erwärmen der Lösung, wodurch die Abscheidung beschleunigt wurde. Ebenfalls Classen ist die erste Monographie über Elektrogravimetrie zu verdanken.[9] Lange Zeit diente der Platintiegel als Kathode, Paweck konstruierte die erste Netzelektrode.[10] Die Quecksilberkathode stammt von Gibbs selbst.[11]

Verwandt zur Elektrogravimetrie, weshalb hier zu erwähnen ist die sogenannte coulombmetrische Analyse, wo unmittelbar Faradays Gesetze zur Bestimmung verwertet werden. Diese verhältnismässig junge Methode wurde 1938 von Szebellédy und Somogyi in die Analyse eingeführt.[12]

ELEKTROMETRISCHE pH-MESSUNG UND ELEKTRODEN

Wie bekannt, gab Nernst die erste quantitative Beziehung für die elektromorische Kraft der galvanischen Ketten.[13] Die elektromotorische Kraft steht danach in Verhältnis mit der Konzentration der Elekrolytlösung. Somit war prinzipiell eine Möglichkeit gegeben zur elektrometrischen Konzentrationsbestimmung. Es fehlte aber die geeignete Elektrode um die Wasserstoffionenkonzentration, der nach der Arrheniusschen Dissoziationstheorie eine bevorzugte Rolle zukam, zu bestimmen. Le Blanc machte 1893 die Beobachtung, dass eine mit Wasserstoff von bekanntem Druck gefüllte Platinelektrode sich gegen Säurelösungen ebenso verhält wie eine Metallelektrode gegen eine entsprechende Metallsalzlösung.[14] Mit Hilfe von Konzentrationsketten unter Anwendung von Wasserstoffelektroden bestimmte dann Salessky die Wasserstoffionenkonzentration von solchen Säure- bzw. Basenlösungen in welchen verschiedene Indikatoren eben Übergangsfarbe zeigten.[15] Soerensen mass den pH-Wert seiner Pufferlösungen schon mit Hilfe von Wasserstoff und Kalomelelektroden.[16] (Kalomelelektrode soll aber Kohlrausch zu physikalischen Zwecken schon im vorigen Jahrhundert verwendet haben.) Cremer beobachtete 1906 bei seinen biologischen Versuchen,[17] dass eine Potentialdifferenz zwischen zwei durch Glasmembran getrennten Lösungen von verschiedenen Wasserstoffionenkonzentrationen auftritt, und stellte auch fest, dass dafür die Membran verantwortlich ist. Haber und Klemensiewicz untersuchten dann diese Frage weiter und fanden dass eine mit neutraler Salzlösung gefüllte dünnwandige Glaskugel ihr Potential ebenso in Funktion der Wasserstoffionenkonzentration ändert wie eine Wasserstoffelektrode. Sie konstruierten 1909 dann die erste Glaselektrode.[18] Obzwar Sie ihrer Elektrode in der Ersetzung der Platinwasserstoffelektroden grosse Zukunft voraussagten, liess diese ziemlich lange auf sich warten. Der grosse innere Widerstand der Elektrode verhinderte nämlich ihren Gebrauch bei der üblichen Kompensationsmethode, man konnte sie nur benützen, wenn mit Quadrantenelektrometer gemessen wurde, das jedoch wegen der Umbequemlichkeit nicht sehr beliebt war. Das richtige Zeitalter der Glaselektroden kam erst mit den Röhrevoltmetern in den dreissiger Jahren unseres Jahrhunderts.

Die Chinhydronelektrode entdeckte Biilmann 1920,[19] die Antimonelektrode Uhl und Kestranek 1923.[20]

POTENTIOMETRISCHE TITRATION

Die erste potentiometrische Titration unternahm Behrend 1893.[21] Er titrierte Quecksilber (I)nitrat mit Kaliumchloridlösung in einer Hg-n/10 $HgNO_3$-n/10 $HgNO_3$-Hg Kette: “Setzt man nun zu einer der Lösungen Chlorkalium, so fällt Quecksilberchlorür aus, der osmotische Druck der Quecksilberionen wird auf dieser Seite geringer und man erhält eine Potentialdifferenz in dem Sinne, dass das Quecksilber unter der mit Chlorkalium versetzten Lösung negativ wird gegen das unter der unveränderten Nitratlösung. Bei weiterem Zusatz von Chlorkalium wird die Potentialdifferenz grösser und zwar bei gleichen Zusätzen zuerst langsam dann immer schneller... Den stärksten Einfluss auf die Änderung der Potentialdifferenz übt der

Zusatz von Chlorkalium in dem Augenblick, in welchem der letzte Rest des Merkuronitrats ausgefällt wird... Weiterer Zusatz von Chlorkalium bewirkt alsdann ein verhältnismäasig langsames Steigen der Potentialdifferenz..." schrieb Behrend, woraus zu sehen ist, dass er den Vorgang auch theoretisch gut zu erklären vermochte.

Vier Jahre folgte dann nichts auf diesem Gebiet, bis dann 1897 Böttger zuerst eine Säure-Basetitration potentiometrisch unter Anwendung einer mit Palladium überzogenen Goldelektrode und der Kompensationsmethode unternahm.[22] Die Redoxtitration war die letzte, die potentiometrisch ausgeführt wurde. Crotogino titrierte 1900 Halogene mit Kaliumpermanganat unter Anwendung einer glatten Platinelektrode.[23]

Zur Messung diente im allgemeinen die Kompensationsmethode. Doch wurden bald auch andere Methoden geschaffen. Wenn man z.B. einen Artikel von Salomon aus 1897[24] aufmerksam durchliest, so findet man, dass dort eigentlich schon ganz genau die sogenannte "dead-stop" Methode beschrieben wurde, die allerdings dann 1926 neu entdeckt wurde.[25]

Unter Anwendung einer polarisierten Elektrode titrierten zuerst 1911 Dutoit und Weisse, die Titration auf Nullpotential wurde gleichzeitig von Pinkhof und Treadwell und Weiss entdeckt,[27] die Differenztitration stammt von Cox.[28]

KONDUKTOMETRISCHE TITRATION

Leitfähigheitsmessungen an Flüssigkeiten wurden für physikalische Zwecke seit Mitte des vorigen Jahrhunderts oft unternommen, sie trugen in hohem Mass zur Ausbildung der physikalischen Chemie bei. Die durch die Neutralisation oder Fällung verursachte Leitfähigkeitsverminderung einer Lösung nützten zu analytischen Zwecken jedoch erst im Jahr 1903 Küster und Grüters aus, die die erste konduktometrische Titration ausführten.[29] In ihrer sehr kurzen Mitteilung berichteten sie aber nichts näheres über die angewandte Einrichtung.

Die moderne Hochfrequenztitration beruht ebenfalls auf der Leitfähigkeitsänderrung der Lösung, sie wurde 1946 unabhängig voneinander von englischen und amerikanischen Forschern entdeckt.[30]

POLAROGRAPHIE

Heyrovský beobachtete 1922 dass das gleichmässig tropfende Quecksilber eine sehr geeignete Elektrode zum Studium von Elektrolysevorgängen bietet. An der sich ständig erneuernden Oberfläche besteht eine grosse Überspannung, man kann sie vollständig polarisieren. Er fand ferner, dass man aus den Potentialkurven die depolarisierenden Komponenten der Lösung qualitativ und quantitativ ermitteln kann.[31] Zur praktischen Vereinfachung dieses Prinzips konstruierten dann 1924 Heyrovský und Shikata den ersten Polarographen.[32] Die Weiterentwicklung der Polarographie, die Oscillopolarographie ist ebenfalls Heyrovský zu verdanken,[33] ebenso wie die sogenannte polarometrische (amperometrische) Titration (1927).[34]

BIOGRAPHISCHE DATEN

Behrend, Robert (1856–1926)

Schüler Ostwalds in Leipzig, von 1897 Professor der organischen Chemie an der Technischen Hochschule Hannover.

Biilmann, Einar (1873–1946)

Professor der Chemie an der Universität Koppenhagen.

Böttger, Wilhelm (1871–1949)

Schüler Ostwalds, von 1910 bis 1938 Professor der analytischen Chemie an der Universität Leipzig.

Carlisle, Anthony (1768–1840)

Arzt im Westminster Hospital, London.

Classen, Alexander (1843–1934)

Von 1883 Professor der analytischen Chemie an der Technischen Hochschule, Aachen.

Cozzi, Andrea (+1852)

Professor der Chemie an der Universität Florenz.

Cruikshanks, William (1745–1800)

Arzt, Professor der Anatomie in London und Chemiker der Artillerie.

Davy, Humphry (1778–1829)

Professor an der Royal Institution, einer der berühmtesten Chemiker, Entdecker der Alkalimetalle, des Bogenlichsts usw.

Despretz, César (1792–1863)

Professor der Physik an der Universität Paris.

Dutoit, Paul (1873–1944)

Von 1898 Professor der physikalischen, von 1918 der analytischen Chemie an der Universität Lausanne.

Faraday, Michael (1791–1867)

Laborant, später Mitarbeiter Davys, endlich Direktor der Royal Institution. Machte bedeutende Entdeckungen sowohl in der Physik (Indukton) wie in der Chemie (Gesetze der Elektrolyse, Benzol usw.)

Foulk, Charles William

Geboren 1869, von 1898 bis 1939 Professor der analytischen Chemie an der Ohio State University.

Gaultier de Claubry, Francois (1792–1878)

Professor der Chemie, später der Toxicologie an der École Supérieure de Pharmacie, Paris.

Gibbs, Wolcott (1822–1908)

Arzt. studierte in Europa neben Rose, Liebig und Dumas, dann Professor im

College of the New York City, später Professor der Chemie an der Harward University, U.S.A.

Haber, Fritz (1868–1934)

Professor der Chemie an der Technischen Hochschule Karlsruhe, von 1912 Direktor des Kaiser Wilhelm Institute für Chemie. Berühmt wegen seiner Arbeit hinsichtlich der Ammoniak-Synthese. Nobelpreisträger für Chemie 1916.

Heyrovský, Jaroslav

Geboren 1890, von 1926 Professor der physikalischen Chemie an der Karls Universität, Prag, seit 1950 Leiter des Polarographischen Instituts der Tschechoslowakischen Akademie. Nobelpreisträger für Chemie 1959.

Klemensiewicz, Zygmunt

Geboren 1886, bis 1939 Professor der Physik an der Technischen Hochschule Lemberg.

Kohlrausch, Friedrich (1840–1910)

Professor der Physik der Reihe nach an der Technischen Universität Zürich, an der Universität Würzburg, Strassburg und endlich Berlin.

Küster, Friedrich Wilhelm (1861–1917)

Schüler von Nernst, wurde 1899 Professor der Chemie an der Bergakademie Clausthal, zog sich 1904 zurück und lebte privatisierend weiter.

Le Blanc, Max (1865–1943)

Zuerst Professor der physikalischen Chemie an der Technischen Hochschule Karlsruhe, dann von 1906 bis 1934 an der Universität Leipzig.

Nernst, Walther (1864–1941)

Schüler Ostwalds, von 1894 bis 1904 Professor der physikalischen Chemie an der Universität Göttingen, von 1904 an der Universität Berlin. Von 1922 Direktor der Physikalisch-Technischen Reichsanstalt. Nobelpreisträger für Chemie 1920.

Nicholson, William (1753–1815)

Beamter des Ostindischen Gesellschaft, dann Schuldirektor in London, dann Privatingenieur, endlich Herausgeber einer wissenschaftlichen Zeitschrift.

Paweck, Heinrich (1870–1941)

Von 1907 Professor der Elektrochemie an der Technischen Hochschule, Wien.

Ritter, Johann Wilhelm (1776–1810)

Praktisierender Arzt in Jena und Gotha, von 1810 in München lebend als Mitglied der Bayrischen Akademie der Wissenschaften.

Shikata, Mazuro

1895 geboren, arbeitete 1923 in Prag, wurde 1924 Professor an der Universität Kyoto, nach 1953 Professor an der Universität Nagoya.

Soerensen, Soeren Paul Lauritz (1868–1939)

Direktor des Carlsberg Laboratoriums in Koppenhagen, Einführer der pH-Bezeichnung.

Somogyi, Zoltán

Assistent an der Universität Budapest. Gestorben durch Kriegsereignisse 1945.

Szebellédy, László (1901–1944)

Von 1938 Professor der anorganischen und analytischen Chemie an der Universität, Budapest.

Treadwell, William Dupré (1885–1959)

Bis 1955 Professor der analytischen Chemie an der Technischen Universität Zürich.

Uhl, Alfred

Geboren 1889, tätig in dem Oesterreichischen Forschungsinstitut für die Landwirtschaft, von 1942 bis 1947 Direktor ebendort.

Volta, Alessandro (1745–1827)

Von 1780 bis 1819 Professor der Physik an der Universität Pavia, Erfinder der ersten elektrischen Batterie (Voltaische Säule, 1800).

Über die im Artikel erwähnten Forscher die im biographischen Teil nicht aufgezählt sind, konnte ich leider überhaupt keine biographischen Daten erfahren.

Summary—The pioneers and the most outstanding research workers in the different branches of electro-analysis—electrodeposition, pH measurement, potentiometric and conductometric titration, coulometry, polarography and amperometry, and the inventors of the commoner types of electrodes are discussed. Brief biographies are given for most of the individuals mentioned.

Résumé—On donne des récapitulations des fondateurs et des chercheurs remarquables dans les différentes branches de l'électroanalyse, la galvanoplastie, la mesure de pH, dosages potentiométrique et conductimétrique, coulométrie, polarographie et ampérométrie, ainsi que des inventeurs des différents types d'électrodes. Brèves biographies sont données pour la plupart des chercheurs.

LIQUID-LIQUID EXTRACTION OF TUNGSTEN^{VI} WITH TRIBUTYL PHOSPHATE

ANIL K. DE and M. SYEDUR RAHAMAN
Department of Chemistry, Jadapur University, Calcutta, 32, India

(*Received* 12 *September* 1963. *Accepted* 12 *November* 1963)

Summary—A new method has been developed for the rapid extraction of tungsten^{VI} with tributyl phosphate (TBP). Quantitative extraction occurs from 8–10*M* hydrochloric acid using 100% TBP. Tungsten is finally determined spectrophotometrically as thiocyanate. The extractable species is probably $WO_2Cl_2.2TBP$. There are very few interferences. The method is shown to be applicable to an alloy steel.

IN this laboratory tributyl phosphate (TBP) has been used for the extraction of iron^{III} and vanadium^{V}.[1] The extraction studies with TBP have now been extended to tungsten^{VI}. The latter can be extracted from hydrochloric acid solution with TBP. It can then be stripped with water and treated with tin^{II} chloride plus thiocyanate to give a coloured product for spectrophotometric determination. This forms the basis of the method outlined in this paper for extraction and determination of tungsten^{VI} at the milligram level. The method has been successfully applied to an alloy steel.

The thiocyanate method for extraction of tungsten after reduction with tin^{II} chloride or any other suitable reducing agent is well known.[2] Dithiol[3] has been reported to be a good extractant for tungsten. Thenoyltrifluoroacetone[4] in n-butyl alcohol-acetophenone mixture in a strong hydrochloric acid medium has also been used to extract tungsten^{VI}. Other extractants for tungsten are α-benzoinoxime[5] and cupferron.[6]

Pfeifer[12] has previously reported the extraction of tungsten as thiocyanate complex by TBP from 3–6*M* hydrochloric acid. However, his method involves a time-consuming procedure of wet ashing after extraction for subsequent determination of tungsten by the hydroquinone method. The present technique is simple and more rapid.

EXPERIMENTAL

Apparatus

Spectrophotometric measurements were carried out with a Unicam SP600 spectrophotometer using matched 1-cm glass cells.

Reagents

Tributyl phosphate: The reagent (Matheson, Coleman and Bell, Cincinnati, Ohio, U.S.A.), b.p. 143–145° at 5 mm, was employed as extractant after purification according to the method of Peppard *et al.*,[13] *viz.*, washing first with 8*M* hydrochloric acid, then with 5% sodium carbonate and finally with water.

Stock solution of sodium tungstate: Prepared by dissolving about 9 g of sodium tungstate (Riedel De Haenag Seelze-Hanover, Germany) in 1 litre of water containing 4g of sodium hydroxide and 8 g of tartaric acid. The solution, standardised by the oxinate method, contained 4·42 mg of tungsten^{VI}/ml. Test solutions for extraction purposes were prepared by dilution of the stock solution so as to contain 188 μg of tungsten^{VI}/ml.

50% *Potassium thiocyanate solution*: Prepared from E. Merck reagent.

7% *Tin*^{II} *chloride solution:* Prepared from E. Merck reagent in 10*M* hydrochloric acid.

General procedure

A 2-ml aliquot of sodium tungstate solution containing 188 μg of tungsten^{VI}/ml was mixed in a 250-ml separatory funnel with the requisite volume of hydrochloric acid to give an acid concentration of 9*M*. In the experiments involving salting-out agents and diverse ions, the appropriate salting-out agents and foreign ions were added before the acid. The resultant aqueous solution was extracted with an equal volume of 100% TBP for 10 min. Where the effect of TBP concentration was studied, benzene was the diluent. At the end of the extraction, the two layers were allowed to separate. The aqueous phase was retained for measurement of acidity and also for determination of any residual tungsten. Tungsten was then stripped from the TBP layer by consecutive shaking for 10 min with 10 and 5 ml, respectively, of water. To remove any TBP dissolved in the aqueous layer, the back-extract was washed with 5 ml of benzene in a separatory funnel and transferred to a 25-ml volumetric flask. To this 1·5 ml of 50% potassium thiocyanate were added, mixed well and diluted to the mark with 7% tin^{II} chloride in 10*M* hydrochloric acid. The absorbance of the yellow coloured solution was measured at 420 mμ against water within 4 hr.

The optimum period of extraction is 10 min.

RESULTS AND DISCUSSION

Effect of acidity

The solvent extraction behaviour of tungsten^{VI} with respect to TBP was investigated at varying concentrations of hydrochloric acid from 2 to 11*M*. In moderately concentrated acid ($< 6M$), the precipitation of tungstic acid was prevented by the presence of tartaric acid. The distribution ratio (D) was computed from the ratio of the concentrations in the organic and aqueous phases (Table I, Fig. 1). The tungsten in the organic phase was determined as above and in the aqueous phase by the thiocyanate method.[2]

Table I shows that extraction with 100 % TBP (3·66*M*) starts from 2*M* hydrochloric acid and becomes quantitative ($>$ 99%) from 7*M* acid onwards, the aqueous phase after extraction being practically free from tungsten. In Fig. 1, a steep rise in

the extraction is observed at lower acidities. This is followed by a further rise at higher acidities. The effect is probably caused by salting-out from the aqueous phase by the chloride ion. For quantitative extraction the optimum acid concentration is 8–10*M*

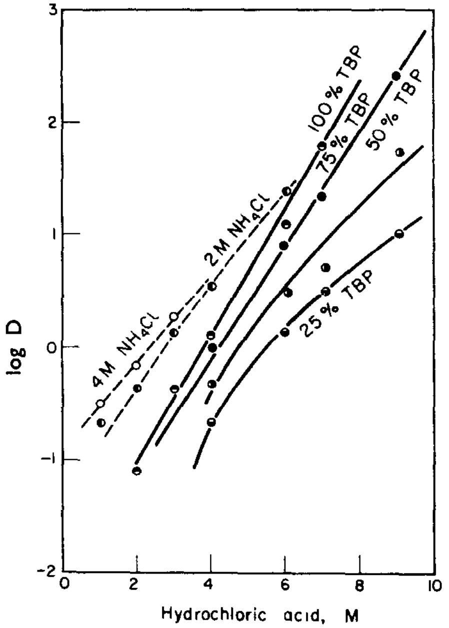

FIG. 1.—Extraction of tungsten^{VI} with TBP as a function of hydrochloric acid concentration in the aqueous phase.

hydrochloric acid (equilibrium acidity 6–7*M*). More concentrated acid is not recommended because of trouble in manipulation, although the extraction is quantitative.

TBP concentration

The concentration of TBP was varied from 25% (0·914*M*) to 100% (3·66*M*) with benzene as diluent. The effect on the extraction was noted at different acid concentrations (Table I). Dilution of the TBP lowers the extraction (Fig. 1). An attempt was made to determine the composition of the extractable tungsten-TBP species by means of a log D *vs.* log C_{TBP} plot.[7] For the plot at 9*M* hydrochloric acid (to obtain four points in all) an extra measurement was taken at a lower concentration of TBP, *i.e.*, 10% TBP (D = 1·3). Below a TBP concentration of 10% the extraction is very poor and the accuracy of measurement unsatisfactory; no further experiments were therefore attempted. The best lines through the points at 6 and 9*M* hydrochloric acid (Fig. 2) give slopes of 1·77 and 2·33, respectively, showing that the extractable species is most probably $WO_2Cl_2 \cdot 2TBP$. This is analogous to other solvated species, *e.g.*, $H[FeCl_4.(TBP)_2]$,[1] $ZrCl_4.2TBP$,[8] $Th(NO_3)_4.2TBP$[9] and $VOCl_3.2TBP$,[1] at high acidity. The optimum reagent concentration is 100% (3·66*M*).

A study of the extraction with 100% TBP from 9*M* hydrochloric acid as a function of tungsten concentration shows that the optimum analytical range is from 50 to

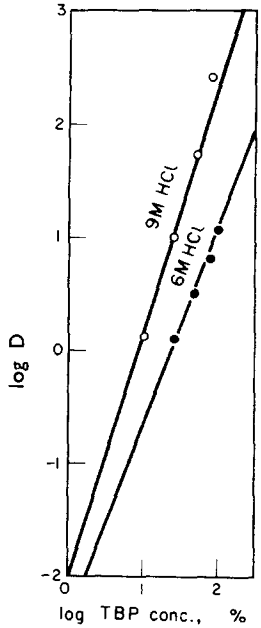

FIG. 2.—Distribution ratio as a function of TBP concentration.

TABLE II.—EFFECT OF AMMONIUM CHLORIDE AND MAGNESIUM CHLORIDE AS SALTING-OUT AGENTS

	3	1·17

470 μg of tungsten. For higher concentrations the relationship between percentage extraction and tungsten concentrations is not linear.

Salting-out agent

The presence of ammonium chloride in the aqueous phase serves to exert a salting-out effect leading to an increased extraction of tungsten^{VI} (Table II). Magnesium chloride in the aqueous phase increases the extraction to the same extent as ammonium chloride. The partition coefficients at lower acidity are found to increase by several orders of magnitude. Under this condition TBP is less combined with acid and so is more available for extraction. This occurs in conjunction with the salting-out function of chloride ion from the added salt. The extractant used was 100% TBP (3·66*M*).

Diverse ions

Nineteen representative ions were carried through the procedure and examined for interference. The tolerance limit for each, recorded in Table III, represents that concentration of the foreign ion in the presence of which tungsten^{VI} can be extracted and determined spectrophotometrically within ± 2%. It is interesting to note that chromium^{III} and nickel^{II} (10 mg) are not extracted; iron^{III} (10 mg) is co-extracted with tungsten^{VI} but does not interfere in the spectrophotometric determination; zirconium^{IV}, manganese^{II}, phosphate, borate, fluoride, EDTA (10 mg) and citrate, acetate, tartrate (1 g) do not interfere; thorium (1 mg) and uranium^{VI} (0·5 mg) can be tolerated; copper^{II}, molybdenum^{VI}, cobalt^{II}, titanium^{IV} and vanadium^{V} are co-extracted with tungsten and interfere but this can be eliminated by either their preliminary removal or by using suitable masking agents.

TABLE III.—EFFECT OF DIVERSE IONS
[376 μg of tungsten^{VI}; 100% TBP]

[a] Masked with hydrogen peroxide.
[b] In presence of tartaric acid.
[c] Foreign ion removed first.

Copper^{II} and cobalt^{II} are first removed by extracting with 0·15*M* TTA in benzene[10,11] at pH 4·5 and 6, respectively. The aqueous phase, after evaporation to small volume, is extracted from 9*M* hydrochloric acid as usual for tungsten.

Molybdenum^{VI} is extracted with 0·15*M* TTA in acetophenone from 0·5*M* hydrochloric acid.[4] Tungsten^{VI} remains in the aqueous phase which is then extracted with TBP.

It has already been shown[1] that tartaric acid reduces vanadium^{V} to vanadium^{IV}

and prevents its extraction with TBP. In order to remove the interference from vanadium^{V} 1 g of tartaric acid was used in the aqueous phase (vanadium$^{(V)}$ = 0·4 mg) during the extraction. Titanium^{IV} in 9*M* hydrochloric acid was masked with hydrogen peroxide (5 ml) and tungsten extracted with TBP.

APPLICATION TO AN ALLOY STEEL

A known weight (0·1 g) of alloy steel (No. 64a, Bureau of Analysed Samples, Ltd., Newham Hall, Yorks., U.K.) was dissolved in 9 ml of concentrated sulphuric acid and 50 ml of water. After the initial reaction was over, the solution was heated, oxidised carefully with 5 ml of nitric acid and evaporated to fumes. Finally, it was diluted with 80 ml of water, boiled to dissolve the salts, filtered to remove silica and washed with 1% sulphuric acid. The filtrate was evaporated to about 25 ml, then diluted to 100 ml in a 100-ml volumetric flask with water. A 4-ml aliquot of this solution was taken in a 250-ml separatory funnel, 0·5 g of tartaric acid added to remove interference from vanadium, followed by 10 ml of 9*M* hydrochloric acid. The solution was extracted twice with 12-ml portions of 100% TBP. Molybdenum^{VI}, tungsten^{VI} and iron^{III} were extracted. From the combined extracts, iron, molybdenum and tungsten were stripped with three 10-ml portions of water. The aqueous phase was evaporated to a small volume (about 2 ml) and transferred to a separatory funnel together with 10 ml of 0·5*M* hydrochloric acid plus 10 ml of 0·15*M* TTA in acetophenone[4] and extracted for 10 min. Molybdenum and some iron were extracted. The aqueous phase containing tungsten^{VI} and iron^{III} was transferred to a 25-ml volumetric flask and tungsten was determined as outlined before.

The results from triplicate analysis of this alloy steel were 5·55, 5·60 and 5·54% of tungsten (reported present: 5·66% of tungsten, 4·11% of molybdenum).

Zusammenfassung—Eine neue Methode zur schnellen Extraktion von Wolfram^{VI} mit Tributylphosphat (TBP) wurde entwickelt. Aus 8–10m Salzsäure ist die Extraktion mit 100% TBP quantitativ. Wolfram wird zuletzt als Rhodanid spektralphotometrisch bestimmt. Die extrahierte Spezies ist höchstwahrscheinlich WO_2Cl_2.2TBP. Es gibt nur wenige Störungen. Die Methode läßt sich auf legierte Stähle anwenden.

Résumé—Description d'une méthode d'extraction rapide du tungstène VI par le tributylphosphate-TBP. L'extraction quantitative est effectuée par l'acide chlorhydrique 8 à 10M, en utilisant 100% de TBP. Le tungstène est finalement dosé spectrophotométriquement sous forme de thiocyanate. Le produit extractible est probablement formé en grande partie de WO_2Cl_2.2TBP. Il y a très peu d'interférences. Application de la méthode aux alliages d'acier.

INDIRECT DETERMINATION OF TRACES OF URANIUM USING 1-(2-PYRIDYLAZO-)2-NAPHTHOL

M. R. HAYES and J. S. WRIGHT
United Kingdom Atomic Energy Authority, Springfields Works
Salwick, Preston, Lancashire, England

(*Received* 28 *August* 1963. *Accepted* 2 *October* 1963)

Summary—In the determination of traces of uranium using 1-(2-pyridylazo)-2-naphthol (PAN), solvent extraction of the complex is replaced by the separation of the insoluble complex from homogeneous solution. This is followed by hydrolysis to give free PAN equivalent to the uranium present. An increase in sensitivity of almost 50% results, and the conditions for complex formation require less stringent control. A general method for the determination of uranium in impure liquors is described. Reversed-phase partition chromatography is used for the initial separation of uranium, followed by the use of complexing agents to prevent interference from any residual ions. The method is simple and rapid, and the precision compares favourably with other methods using PAN.

INTRODUCTION

THE use of 1-(2-pyridylazo)-2-naphthol (PAN) as a reagent for the determination of traces of uranium has been described by Cheng,[1] and this work has been extended by Shibata.[2] Cheng reports that the complex with uranium, formed under conditions of controlled pH in the presence of EDTA and cyanide ion to complex other cations, can be selectively extracted into *o*- or *m*-dichlorobenzene or bromobenzene and the absorption measured at 570 mμ. He gives the molar absorptivity as 23,000. Shibata's extension of the procedure permits the use of other solvents, such as chloroform and carbon tetrachloride, which Cheng had found unsuitable under the conditions of his work.

In attempting to adapt the procedure to the analysis of impure uranyl liquors some difficulty was experienced in achieving consistent behaviour. The reagent is largely precipitated in the aqueous medium prescribed, and it was considered possible that the heterogeneous reaction of uranyl ion and solid reagent in suspension could be a factor contributing to the difficulty.

The reagent PAN is readily soluble in a mixture of equal volumes of water and acetone and at approximately pH 9 the presence of a few μg of uranium results in the formation of an insoluble red compound. This precipitate can be separated quantitatively by filtration on asbestos fibre and washed free from excess PAN. If precipitation of the uranium complex is reproducible and a suitable solvent is available to dissolve the complex from the filter, an alternative procedure emerges. This avoids heterogeneous reaction conditions and enables the optical density of the solution of the uranium complex to be measured without interference from the excess PAN.

The non-specific nature of PAN as a reagent leads to interference in the determination of uranium by other metal ions. This effect can be overcome by the use of complexing agents, but where gross amounts of impurity are present a separation of the uranium is essential. A combination of a selective separation procedure, such as reversed-phase partition chromatography (RPPC)[3] with the use of complexing agents, can then be employed to obtain complete freedom from interference.

EXPERIMENTAL

Reagents[6]

All reagents are of analytical-grade quality unless otherwise stated.

1-(2-pyridylazo)-2-naphthol: Supplied by L. Light & Co., Ltd., England; 0·1% w/v solution in acetone.

Asbestos fibre: Powminco Grade A long fibre supplied by Hopkins and Williams Ltd., England.

Kel-F powder: Grade Kel-F 300 low density, supplied by the Minnesota Mining & Manufacturing Co., Ltd., England. Grind to powder with Drikold and liquid nitrogen. Retain the fraction B.S.S.44 to B.S.S.120 for use in preparing the column.

Tributyl phosphate (TBP): Purify the commercial product by refluxing with 0·5% w/v aqueous sodium hydroxide solution. Wash with cold 5% w/v aqueous sodium hydroxide solution until free from di- or monobutyl phosphate. To test this, neutralise a portion of the wash liquid to litmus with nitric acid and add a neutral solution of thorium nitrate. The formation of a precipitate indicates that di- and/or monobutyl phosphate is present and washing must be continued.

Ammonium acetate-aqueous ammonia buffer solution: Dissolve 60 g of ammonium acetate in 450 ml of cold water. Add aqueous ammonia solution to raise the pH to 9·5. Adjust the volume to 500 ml with cold water.

EDTA-ammonium tartrate complexing solution: Dissolve 7·5 g of tartaric acid in 200 ml of cold water. Neutralise to pH 9·0 with aqueous ammonia solution. Dissolve 18·75 g of EDTA (disodium salt) in 250 ml of water and mix with the tartrate solution. Adjust the volume to 500 ml with cold water.

Apparatus[6]

Preparation of asbestos fibre filter. The filter tube is shown in Fig. 1. Hold the perforated porcelain button in position and add a small quantity of a thin aqueous slurry of asbestos fibre to the tube. Apply gentle suction and press lightly with the flattened end of a glass rod to form a uniform pad about 3 mm deep. On removing the suction, water should pass through the filter at 1–2 ml/min; filters with faster rates should be rejected. Wash the pad with 10 ml of hydrochloric acid and finally with water until free from acid.

Shortly before use, wash twice with 5-ml portions of water-acetone solution (1 + 1). The pad may be used repeatedly if it is tamped lightly with the flattened end of a glass rod before re-use.

Preparation of the Kel-F column. The column tube is shown in Fig. 2. Fill the tube with water and press a small piece of cotton wool lightly into the junction with the side tube. Make a slurry of 5 g of Kel-F powder with 5 ml of TBP, set aside for 5 min, then add sufficient water to make a loose slurry. Transfer a small portion of this to the column tube and agitate with a glass rod to remove adherent air bubbles. Allow the Kel-F to settle under gravity while passing a constant stream of cold water through the tube. Repeat the addition of Kel-F several times until the tube is filled to within 1 cm of the reservoir. Insert a cotton wool plug to give a depth of about 1 cm. The rate of elution from the column should be 1·5–2 ml/min and visual inspection should reveal no voids.

Shortly before use, condition the column by passing 25 ml of nitric acid solution (7 + 13) through it. When not required further, wash the column with water until free from nitric acid, then close the outlet tube. Half fill the reservoir with cold water and cover with a watch glass to restrict evaporation.

The life of the column is about 15–20 separations before repacking is required.

Spectrophotometer. All absorption spectra and optical densities were measured using a Unicam S.P.600 spectrophotometer.

Dissolution of PAN-uranium complex following separation on an asbestos filter

Precipitates of the PAN-uranium complex, containing 40 μg of uranium, were formed in a water-acetone (1 + 1) medium buffered to approximately pH 9. The precipitates were separated by filtration on asbestos-fibre filters and washed with water-acetone solution (1 + 1) to remove excess PAN. The residues were extracted by washing with a variety of organic solvents. When solvents immiscible in water were used, the filter and precipitate was first washed with methanol. Methanol, distilled methylated spirit and carbon tetrachloride had no apparent effect. Acetone, chloroform, dichlorobenzene and trichlorethylene all dissolved the complex in varying degrees, giving red solutions, but

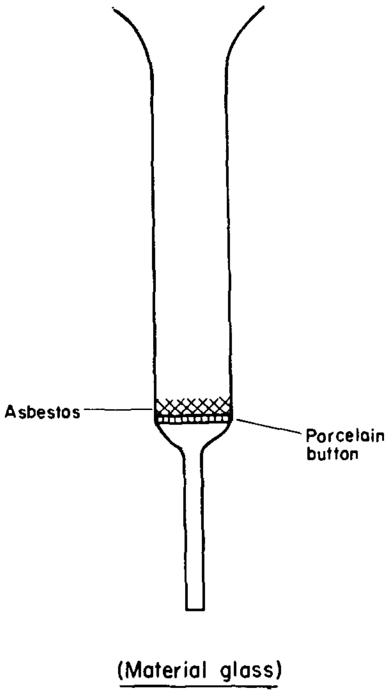

FIG. 1.—Tube for asbestos fibre filter. (Half scale)

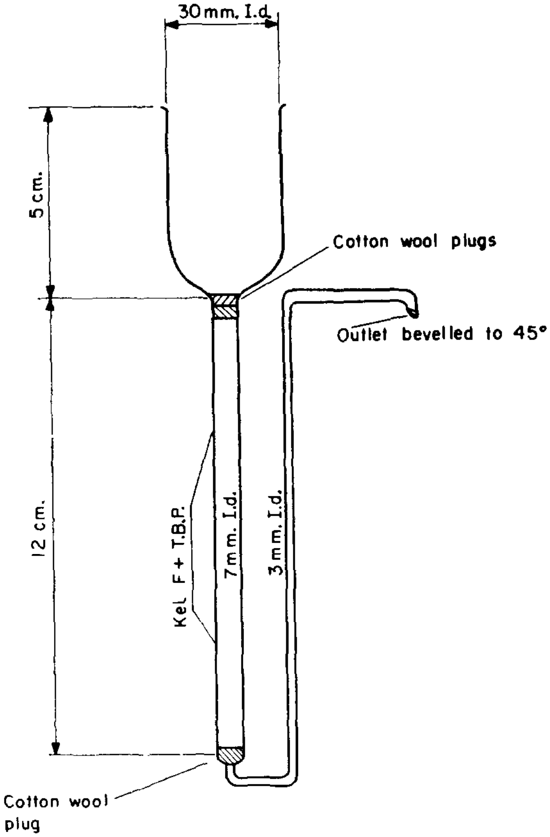

FIG. 2.—Chromatography column tube.

in each case an insoluble pink residue remained on the filter. Tetrahydroxysylvan gave a yellow-brown extract with a dark residual colour on the filter, which on drying showed a pink hue. Similar results were obtained when the complex was formed in a water-methanol medium.

Strong hydrochloric acid dissolved the PAN-uranium precipitates quickly and completely to give a yellow solution. This colour was considered to be that of free PAN resulting from the hydrolysis of the PAN-uranium complex, the optical density of which was found to be proportional to the uranium content of the precipitate. The stability of the PAN colour in hydrochloric acid solution appeared to be adequate and warranted further study of this method for determining the amount of PAN-uranium complex formed.

Absorptiometry

Visible absorption spectra. The visible absorption spectra of solutions of PAN and of PAN-uranium complex in 20% v/v hydrochloric acid solution were identical, both having an absorption maximum at 440 mμ (Fig. 3). Dissolution of the PAN-uranium complex in 20% v/v hydrochloric acid therefore results in complete hydrolysis to the free reagent.

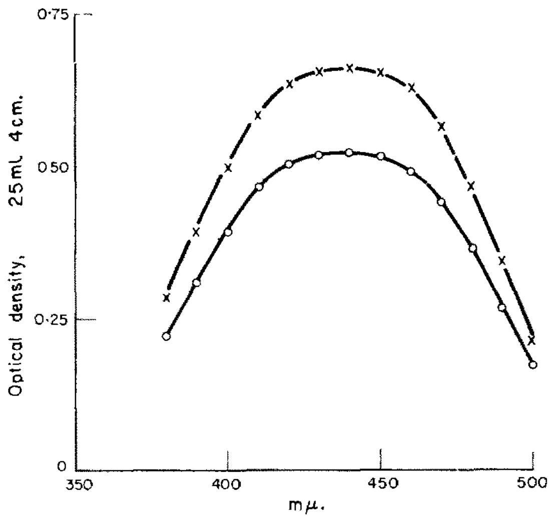

FIG. 3.—Visible absorption spectra of solutions of PAN-uranium complex and of PAN reagent in hydrochloric acid (1 + 4):
○—25 μg of uranium as hydrolysed PAN-uranium complex,
×—60 μg of PAN.

Effect of hydrochloric acid concentration. Aliquots of a solution of PAN-uranium complex in hydrochloric acid solution were diluted to standard volume with hydrochloric acid solutions of differing concentrations and the optical densities measured at 440 mμ. The optical densities were identical within experimental error over a range of concentrations of hydrochloric acid of 5–40%,v/v. At higher concentrations, acid fumes make measurements in the spectrophotometer difficult. In succeeding work, all optical densities were measured in 20% v/v hydrochloric acid solution unless otherwise stated.

Stability of the colour. To test the stability of the solution resulting from dissolution of the PAN-uranium complex in hydrochloric acid, precipitates were formed from varying known quantities of uranium, separated by filtration on asbestos fibre and dissolved in strong hydrochloric acid. The solutions were diluted to standard volume with water, and the optical densities measured at 440 mμ at timed intervals after this dilution. The results are shown in Table I.

The decrease in optical density with time is slow and less than a 1% error results if measurements are made within 1 hr of the dissolution of the precipitate.

Formation of PAN-uranium complex

Solution conditions. PAN-uranium precipitates were formed, using 50 μg of uranium in water-acetone solution (1 + 1) containing ammonium acetate, by adding dilute ammonia solution until a desired pH value was obtained. The precipitates were separated by filtration on asbestos fibre,

TABLE I—STABILITY OF THE COLOUR RESULTING FROM THE HYDROLYSIS OF THE PAN-URANIUM COMPLEX

Time, *hr*	Optical density			
	0 μg U	10 μg U	25 μg U	40 μg U
0	0·013	0·203	0·592	1·005
1	0·013	0·202	0·587	0·990

6	0·010	0·196	0·565	0·955
72	0·005	0·155	0·425	0·717

dissolved in hydrochloric acid and the optical densities measured at 440 mμ. The results are shown in Table II.

It is necessary to adjust the solution to at least pH 8 in order to achieve maximum precipitation of the PAN-uranium complex. Over the range pH 8 to pH 10 there is no further effect. Cheng[1] states that in an aqueous medium containing EDTA no significant complex between uranium and the dye is formed below pH 5 and above pH 12. His conditions give maximum complex formation at pH 10 and this is critical, the extent of complex formation falling rapidly above and below this value. The use of an acetone-water medium therefore results in a shift to higher pH for complex formation, but requires much less stringent control. An ammonium acetate-aqueous ammonia buffer adjusted to pH 9·5 was found to give adequate control.

Time required for complex formation. The time taken to complete the reaction between uranium and PAN at room temperature, was measured. The reagents were added to a series of solutions which were then set aside for various time intervals before separation of the complex by filtration. No significant difference in optical density of the final solutions was observed for reaction times in the range 5 to 20 min. The experiment was duplicated at both 40- and 100-μg levels of uranium.

Effect of other ions and limiting of interferences

Cheng and Bray[4] reported that a number of metal ions form coloured chelates and that some of these may be extracted into organic solvents. They also state that EDTA prevents all of the metal ions tested, from reacting with PAN.

A series of experiments was carried out taking 40 μg of uranium, an equal amount of each of 12 other metal ions, and a lower PAN concentration (1 mg), the object of the diminished PAN concentration being to emphasise any interference effects.

These experiments showed that:—

(a) Magnesium and molybdenum are virtually without effect.

(b) Iron, in the bivalent and tervalent states, and nickel form insoluble complexes with PAN and therefore interfere in the determination of uranium.

(c) Copper, lead, chromium, zirconium, thorium, manganese and vanadium capture PAN to the exclusion of uranium, or otherwise affect the precipitation of the PAN-uranium complex forming complexes which are soluble in the buffered acetone-water medium.

Further experiments, using EDTA at the maximum concentration which could be tolerated without affecting the determination of 40 μg of uranium (in the absence of other metal ions), showed that EDTA was not entirely effective in preventing interference from manganese, vanadium, copper, chromium and zirconium. Tartaric acid used together with EDTA eliminated these interferences to a large extent. In conjunction with the full concentration of PAN contemplated (10 mg), up to 190 mg of EDTA or 60 mg of tartaric acid could be tolerated without reducing the recovery of 40 μg of uranium. In admixture the maximum concentrations tolerable were 93 mg of EDTA and 37 mg of tartaric acid. These were reduced to 75 mg and 30 mg, respectively, to allow a margin of safety.

Calibration procedure for the spectrophotometer[6]

Evaporate to dryness aliquots of a standard uranium nitrate solution (1 ml ≡ 40 μg of uranium) covering the range 0–200 μg of uranium. Dissolve each residue in 3 ml of hydrochloric acid solution (1 + 49). Add, with stirring, 2 ml of EDTA-tartrate solution followed by 10 ml of PAN solution and 5 ml of buffer solution in that order. Set aside for 20–25 min at room temperature, then separate the precipitate by filtration on an asbestos fibre filter. Wash the beaker five times with 5-ml portions of water-acetone solution (1 + 1), using each wash to rinse down the tube supporting the filter and allowing each portion to drain through the filter before adding the next. Wash the outside of the filter tube stem to remove crystallised reagent. Finally, wash the beaker and filter with two 5-ml portions of water and allow to drain completely. Dissolve the precipitate from the filter by adding 10 ml of hydrochloric acid (sp. gr. 1·18) in portions, followed by small portions of water, using about 15 ml in all. Collect the eluate in a graduated cylinder containing about 20 ml of water and finally adjust the volume to 50 ml. Measure the optical density of each solution using a 2-cm cell at 440 mμ and correct for the reagent blank value.

Fig. 4 shows a typical calibration curve over a range of 20–175 μg of uranium.

The calibration curve was studied in more detail below 20 μg of uranium, employing standard conditions, but a reduced final volume and increased light path to enhance the sensitivity of the measurements. The results are shown in Fig. 5.

The non-linear behaviour below 18 μg of uranium may result either from a kinetic effect or a solubility effect. The latter is unlikely because the normal calibration curve from 20 μg of uranium upwards passes through the origin.

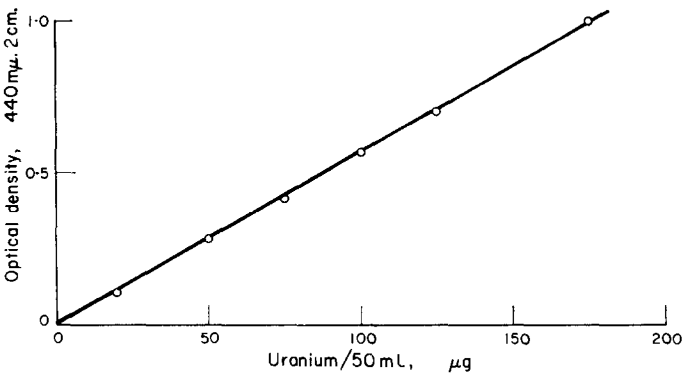

FIG. 4.—Calibration of Unicam SP 600 spectrophotometer for the determination of uranium.

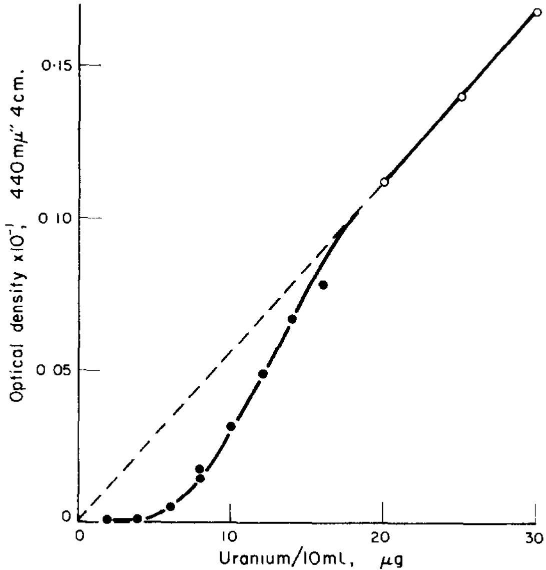

FIG. 5.—Calibration for 0–20 μg of uranium (10-ml volume; 4-cm cell; 440 mμ):

○—○—Calibration between 20 and 175 μg of uranium (see Fig. 4);

●—●—Calibration for 0–16 μg of uranium using stated conditions.

The deviation from linearity confines the lower limit of the method to 20 μg of uranium for normal operation and will cause some error in reagent blank determinations when these fall in the range 4–16 μg of uranium. Because a reagent blank was, however, subtracted from the optical density values used in constructing Fig. 4 and this curve passes through the origin, the effect is apparently not significant. Several more calibrations failed to reveal any effect.

Application of procedure to impure liquors[6]

Procedure. Evaporate a suitable volume of the sample to dryness with a mixture of 1 ml each of nitric and perchloric acids. Dissolve the residue in 5 ml of nitric acid solution (7 + 13) and transfer this solution to a prepared Kel-F tributyl phosphate column. Elute at not more than 2 ml/min. Wash the beaker with four 5-ml portions of nitric acid solution (7 + 13), adding each portion to the column and allowing it to elute at the specified rate before adding the next. Reject the eluate.

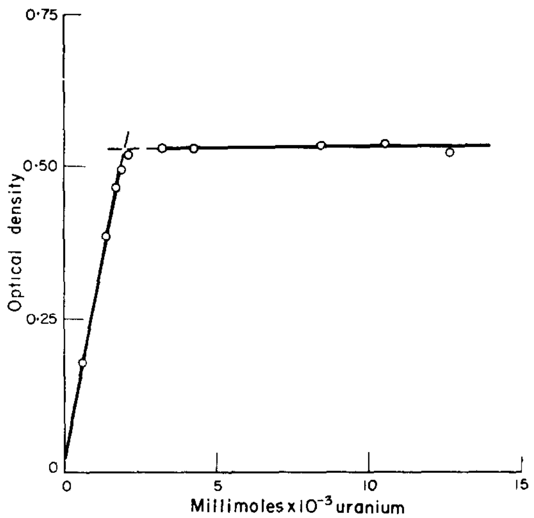

FIG. 6.—Mole ratio of uranium to PAN (separation of uranium using 4·00 × 10^{-3} mmole of PAN).

10	2	$\frac{3}{4}$	46	—		

Wash the column with 20 ml of cold water added in two equal portions. Collect the eluate in a 50-ml beaker. Aliquoting may be undertaken at this stage. Evaporate to dryness and continue as described in the procedure for calibration. Carry out a reagent blank determination as above, omitting the sample.

Results on impure sample liquors. The above procedure was applied to a representative selection of samples of impure uranic liquors in which the uranium had been determined by alternative methods. The results are shown in Table V in which the aliquoting of samples after the RPPC separation is indicated

In sample No. 10 a clear yellow band formed at the top of the Kel-F column and was ultimately eluted in the water wash with the uranium. The colour was found to be from cerium^{IV} ion. Because the tolerance of cerium in the PAN determination is not more than 100 μg, 100 mg of sodium nitrite were added to the nitric acid solution of the sample before transferring to the Kel-F column. This served to reduce the cerium to the tervalent state in which it was no longer retained on the column.

Precision test

A number of equal volumes of two samples of impure liquor containing 65–75 μg of uranium were analysed by the procedure given. The results of 19 determinations gave a standard deviation of $\pm 0{\cdot}96$ μg of uranium.

Mole ratio of uranium to PAN in complex and the sensitivity of procedure

The mole ratio of uranium to PAN was determined by making a series of precipitations of the complex from a constant concentration of PAN with varying quantities of uranyl ion. The precipitated complex was then treated as described in the calibration procedure. The results, shown in Fig. 6, indicate a mole ratio of uranium: PAN of 1·0:2·0.

The calibration data shown in Fig. 4 give a molar extinction coefficient of 33,000.

DISCUSSION

In the procedures of Cheng and Shibata the PAN reagent is virtually insoluble in the test solution. This leads to heterogeneous reaction conditions during the formation of the PAN-uranium complex in which the concentration of reagent in solution is very low. Possibly as a result of this, these procedures are extremely sensitive to pH change.

Working in a mixed aqueous/organic solvent, homogeneous reaction conditions apply, and it was found that the PAN-uranium complex forms over a wide pH range, the complex being insoluble. This leads to the possibility of either solvent extraction of the complex or separation followed by dissolution, before colour measurement. Our experience with the PAN-uranium complex has shown that its solution properties in the usual solvents recommended are rather unpredictable. For this reason, separation of the insoluble PAN-uranium complex, followed by hydrolysis to give free PAN equivalent to the uranium, has been used. This gives a molar extinction coefficient of 33,000, an increase in sensitivity of almost 50% over procedures based on solvent extraction of the complex (23,000 and 21,000 by the procedures described by Cheng and Shibata, respectively).

Using the homogeneous reaction conditions a PAN-uranium complex in the molar ratio 2:1 is formed; this is the same as reported by Cheng. The complex is very insoluble, although a possible solubility effect can be detected at concentrations below $4 \times 10^{-6}M$ uranium. This is, however, insufficient to give rise to any significant effect over the normal working range of the method (20–180 μg of uranium). Complexing agents can be tolerated in moderate amounts during the PAN-uranium complex formation but, as with other methods using this reagent, there is some competition for the uranium and a fairly high concentration of reagent must be employed to offset this effect.

In applying the procedure as a general method for the determination of uranium, reversed phase partition chormatography (RPPC) has been used to effect an initial separation of the uranium from other metal ions. An EDTA-tartrate complexing medium is then used to eliminate any possible interference from traces of impurity which pass the initial separation stage. Under the conditions used for the RPPC, thorium, cerium^{IV} and zirconium will be eluted from the column together with the uranium. The amount of these which can be tolerated in the sample solution is therefore limited to that which is effectively complexed, namely, 1000, 100 and 150 μg, respectively. Interference from cerium^{IV} is readily removed by reduction to cerium^{III} with nitrite before RPPC.

Omitting the RPPC stage it was found that 100 mg of sulphate, 1 mg of fluoride and 100 μg of phosphate could be tolerated in the determination of 100 μg of uranium.

The method is applicable to a wide range of impure sample liquors, and is easy and relatively economical to operate. Although the sensitivity is 50% higher than other methods using this reagent, the precision, measured on impure samples, compares very favourably. No evidence of bias has been obtained over the normal working range of the method.

Zusammenfassung—Bei der Bestimmung von Uranspuren mit 1-(2-Pyridylazo)-2-naphthol (PAN) wird die Extraktion des Komplexes durch Abtrennung des unlöslichen Komplexes aus homogener Lösung ersetzt. Die anschließende Hydrolyse liefert eine der anwesenden Uranmenge äquivalente Menge PAN. Die Empfindlichkeit steigt um fast 50% und die Bedingungen für die Komplexbildung erfordern nicht mehr die selbe genaue Kontrolle. Eine allgemein anwendbare Methode zur Bestimmung von Uran in verunreinigten Flüssigkeiten wird beschrieben. Die erste Abtrennung von Uran erfolgt durch Verteilungschromatographie mit umgekehrten Phasen, anschließend werden Komplexbildner zugesetzt, um Störungen durch andere Ionen zu vermeiden. Die Methode ist einfach, geht schnell, und ihre Genauigkeit ist mit anderen Methoden vergleichbar, die PAN verwerden.

Résumé—Dans le dosage des traces d'uranium au moyen du (pyridil-2-azo)-1-naphtol-2 (P.A.N.), le solvant d'extraction du complexe est remplacé par la séparation du complexe insoluble dans la solution homogène. La séparation est suivie d'une hydrolyse redonnant le P.A.N. équivalent à l'uranium présent. Une augmentation dans la sensibilité de presque 50% des résultats et les conditions de formation du complexe nécessitent un controle moins rigoureux. Description d'une méthode générale pour le dosage de l'uranium dans les solutions non pures; une chromatographie de partage par inversion de phase est utilisé pour une première séparation de l'uranium; on traite par un agent complexant pour éviter les interférences dues aux ions résiduels. Cette méthode est simple, rapide et la précision est comparable à celle que l'on obtient avec les autres méthodes utilisant le P.A.N.

Summary—Cationic-sensitive glass electrodes are used to study the weak complex formed by sodium ion and malic acid in aqueous media. The best value of 1·1 ± 0·3 for the calculated formation constant agrees well with literature values. Methods of measurements and calculation are described and evaluated.

INTRODUCTION

SINCE the recent commercial introduction of cationic-sensitive glass electrodes, a number of useful applications of these electrodes to analytical problems have been reported.[1] Palaty[2] has suggested that such electrodes might also be valuable in the study of complex equilibria, and particularly in the evaluation of formation constants for the alkali metal chelates. Attempts to extend this technique to the study of weak complexes of the alkali metal cations in aqueous solution are reported here.

The sodium-malate system was chosen for consideration because it has recently been studied by neutralisation[3] and nuclear magnetic resonance methods.[4] A value of 2·0 ± 0·3 for the formation constant of the 1:1 sodium-malate complex was reported. Because of certain assumptions concerning the effect of ionic strength and the dissociation of malic acid, however, the absolute value of this constant is probably meaningful only for the specific solution conditions for which the formation of the complex was studied. The principal attractiveness of the cationic-sensitive glass electrode is, in fact, that such restrictive assumptions might be avoided by direct measurements of alkali metal activities.

EXPERIMENTAL

All potentiometric measurements were made using a Beckman Model 76 pH meter on the expanded scale. The Beckman 78137V cationic-sensitive glass electrode and the 39170 fibre-junction calomel reference electrode were employed. In a few cases, a salt bridge containing a portion of the test solution was used, to eliminate the minute leakage of potassium chloride from the reference electrode. During the potentiometric measurements, the temperature was maintained at 30·0° ± 0·1° in the sample vessel by means of a circulating thermostat. Solutions were prepared from reagent-grade chemicals without further purification.

Because the cationic-sensitive glass electrode responds to hydrogen ion, and to ensure complete dissociation of the malic acid, it was desirable to work in alkaline media. Below pH 5, the potential developed by the electrode has been found to be a function of both hydrogen ion concentration and the concentrations of other univalent cations.[1] As a general rule, the hydrogen ion concentration should be 10^3 times less than the concentration of univalent cation under investigation. Tris-(hydroxymethyl)aminomethane was found to be an excellent reagent for pH control. When necessary, ionic strength was controlled with tetramethylammonium chloride.

Preconditioning of the glass electrode is essential if reproducible potentials are to be obtained. The electrodes employed here were soaked for a minimum of 48 hr in neutral 0·1M sodium chloride solutions. To avoid transfer of interfering species to the sample, the electrode may be rinsed with portions of the test solution before measurement, but wiping or drying of the electrode leads to erratic potentials.

RESULTS AND DISCUSSION

General considerations

A serious limitation to the determination of formation constants by a direct potentiometric measurement arises at once out of the logarithmic relationship between potential and concentration. Because of the nature of this relationship, an error of only 2 mv corresponds to an apparent relative concentration error of about 8·5%. This is particularly serious in the study of weak complexes where the formation of a 1:1 complex with $K = 2$ results only in a 14% decrease in metal ion concentration if the total concentrations of metal ion and ligand are both 0·1M initially. Unfortunately, errors of 1 or 2 mv are still to be expected when working with these electrodes. In principle, at least, this problem could be minimised by working with high concentrations of the complexing species, but, apart from solubility considerations, changes in ionic strength and activity coefficient more than nullify any gain in relative measuring accuracy. Table I shows the pronounced effect of ionic strength on the measured potential in sodium chloride solutions.

TABLE I.—EFFECT OF IONIC STRENGTH ON POTENTIAL

Solution	Ionic strength (Adjusted with Mg SO_4)	Potential *vs.* S.C.E., *mv*
0·1M NaCl	0·1	152·0
	0·3	149·2
	0·5	147·9
	2·1	146·2
0·01M NaCl	0·05	92·3
	0·21	89·2

Methods of attack

All potentiometric methods of determining stability constants are based on the Nernst equation and the mass action laws, but three specific procedures have been employed here:

(1) *Titration method:* A plot of glass electrode potential *vs.* log sodium ion concentration is prepared as a calibration curve in the absence of complexing ligand. A known initial concentration of sodium chloride is then titrated with a standard solution of the ligand, and a plot of potential *vs.* log apparent concentration is prepared. With appropriate correction for dilution effects, the complex formation constant may then be calculated from the original metal ion concentration, the amount of complexing agent added, and the apparent decrease in metal ion concentration at each point along the titration curve. This method of calculating formation constants gives acceptable internal agreement for values calculated at different points along the titration curve, but yields considerable variation in values calculated from separate sets of experiments, probably because of "drifting" of the glass electrode potentials and changes in the slope of the calibration curve which accompany ageing of the electrode.

(2) *Single-point-calibration method:* The apparent formal potential is calculated *via* the Nernst equation from measurements performed on standard solutions of metal ion in the absence of complexing agent. Using this apparent formal potential and the appropriate Nernst slope, the metal ion concentrations in the presence of complexing agent are then calculated directly from the Nernst equation. This method has the advantage over the titration technique of permitting rapid successive measurements on pairs of solutions—one containing a known concentration of metal ion and the other containing metal ion plus ligand in known initial concentrations. The time-dependent effects noted in the titration method can thus be largely eliminated. The necessity of assuming or calculating an appropriate Nernst slope still remains as a significant source of error, however, unless measurements are made on pairs of solutions nearly identical in effective metal ion concentration.

(3) *Emf-difference method:* If it is assumed that in a series of solutions differing only slightly in total metal ion concentration but identical with regard to ligand concentration, pH, *etc.*, the numerical values for the various terms of the Nernst equation remain unchanged, apart from the term in metal ion concentration, then we can write for any such pair of solutions:

$$\mathrm{E}_1 - \mathrm{E}_2 = (\text{slope}) \log \frac{C_{\mathrm{M}_1^+}}{C_{\mathrm{M}_2^+}} \tag{1}$$

Combining equation (1) with the mass action expression for a 1:1 complex, one can derive:

$$\mathrm{E}_1 - \mathrm{E}_2 = (\text{slope}) \log \\ \times \frac{C^0_{\mathrm{M}^+1} - \left[C^0_{\mathrm{M}^+1} + C^0_{\mathrm{A}^{-n}1} + \frac{1}{K}\right] - \sqrt{\left[C^0_{\mathrm{M}^+1} + C^0_{\mathrm{A}^{-n}1} + \frac{1}{K}\right]^2 - 4C^0_{\mathrm{M}^+1}\,C^0_{\mathrm{A}^{-n}1}}}{C^0_{\mathrm{M}^+2} - \left[C^0_{\mathrm{M}^+2} + C^0_{\mathrm{A}^{-n}2} + \frac{1}{K}\right] - \sqrt{\left[C^0_{\mathrm{M}^+2} + C^0_{\mathrm{A}^{-n}2} + \frac{1}{K}\right]^2 - 4C^0_{\mathrm{M}^+2}\,C^0_{\mathrm{A}^{-n}2}}} \tag{2}$$

where K is the formation constant of the complex and $C^0_{\mathrm{M}^+}$ and $C^0_{\mathrm{A}^{-n}}$ denote initial concentrations of metal ion and ligand, respectively. Because all initial concentrations are known, equation (2) can be solved for K using the difference of the potentials determined in rapid succession on two similar solutions. This method has the advantage of not requiring a knowledge of the formal potentials involved, and circumvents the difficulties resulting from changes in activity coefficients with drastic alteration in solution composition. The major disadvantage of the method is its relative insensitivity to small changes in K.

A summary of the results obtained using the single-point-calibration and emf-difference methods is given in Table II.

It is immediately apparent that the emf-difference method yields values most nearly corresponding to the formation constants previously reported,[3,4] while the results obtained by the single-point-calibration method are difficult to interpret because of experimental variations. The relatively large variation in calculated values is not surprising, however, when one considers that an emf change of only 0·6 mv will change the calculated formation constant from 0·8 to 1·0 in a typical experiment. That pick-up of carbon dioxide from the atmosphere by the alkaline test solution cannot be of significance here is seen from the similarity of results obtained in runs

TABLE II.—FORMATION CONSTANTS OF SODIUM-MALATE SYSTEM

System	pH	Emf, *mv*	Nernst slope	Formation constant	Method

				Mean = 5·5	

using either sodium chloride and sodium carbonate as sources of metal ion. Variations in pH of the test solutions from 7 to 9·8 also produced no significant trends in calculated formation constants. Most of the observed uncertainties must, therefore, be attributed to limitations of the measuring techniques; work is currently in progress to improve these measurements by the use of null-balance potentiometry and will be described in a future report.

Zusammenfassung—Kationenempfindliche Glaselektroden werden zur Untersuchung des schwachen Komplexes aus Na^+ und Äpfelsäure in wäßrigen Medien verwendet. Der Bestwert von 1,1 ± 0,3 für die berechnete Bildungskonstante stimmt gut mit den Literaturwerten überein. Meß- und Berechnungsmethoden werden beschrieben und bewertet.

Résumé—Les électrodes de verre sensibles aux cations sont utilisées pour étudier les complexes peu stables formés par l'ion sodium et l'acide malique en milieu aqueux. La valeur la meilleure de la constante de formation (1,1 ± 0,3) déterminée par le calcul est en bon accord avec les valeurs indiquées dans la littérature. Des méthodes de mesure et de calcul sont décrites et leur précision évaluée.

INVESTIGATION OF REAGENTS FOR THE COLORIMETRIC DETERMINATION OF SMALL AMOUNTS OF CYANIDE—II*

A PROPOSED METHOD FOR TRACE CYANIDE IN WATERS

L. S. BARK and H. G. HIGSON
Department of Chemistry and Applied Chemistry, Royal College of Advanced Technology, Salford 5, Lancashire, England

(*Received* 30 *September* 1963. *Accepted* 7 *November* 1963)

Summary—*p*-Phenylenediamine is used in a König-type reaction for the determination of trace amounts of cyanide in waters. With slight variation in procedure, the method is applicable over the range 0·005–100 ppm.

THE present main methods for the determination of trace amounts of cyanide ion are based on the formation of a dyestuff by the reaction of cyanogen bromide[1] or chloride[2] with an aromatic amine in the presence of pyridine hydrochloride. The fundamental reaction involved is that of the König synthesis[3] of pyridine dyestuffs. A critical consideration of the amines capable of giving dyestuffs suitable for use in the colorimetric determination of cyanide,[4] revealed that only three amines, *p*-aminodiphenylamine, benzidine and *p*-phenylenediamine, formed coloured compounds of any significance. Although benzidine is in use in the United Kingdom standard method (Aldridge method), the range of concentrations that may be determined on the *raw* sample is very limited; furthermore, benzidine itself is a well known and active carcinogen and its use is deprecated by many authorities. It is possible to extend the range of the Aldridge method by suitable modifications,[5] but it is not possible to alter the physiological activity of benzidine.

Of the two other amines, *p*-aminodiphenylamine and *p*-phenylenediamine, the latter compound is more suitable as the dyestuff precursor for the following reasons:

1. It is easily soluble in dilute hydrochloric acid (0·5*M*), whereas *p*-aminodiphenylamine is fairly insoluble. (Prolonged boiling, cooling and filtering is required to produce even a 0·2% solution of *p*-aminodiphenylamine.).
2. When stored in a dark bottle, a 0·2% solution of *p*-phenylenediamine in 0·5*M* hydrochloric acid is stable for at least 6 weeks without noticeable discoloration; *p*-aminodiphenylamine turns blue-purple in less than 1 day.
3. The colour intensity of the pyridine dyestuff with *p*-phenylenediamine is much greater than that with *p*-aminodiphenylamine.[4]
4. With regard to the physiological properties of the two amines, whilst neither has been reported as causing cancer of any type, *p*-phenylenediamine, being a simple mononuclear compound, is more likely to be non-carcinogenic than is *p*-aminodiphenylamine.

---

* Part I: see reference 4.

Factors which may affect the formation of a coloured compound of the pyridine dyestuff type, the intensity of its absorbance and the optimum wavelength to be used in any determination, are:

(i) The treatment of the *raw* sample before colour development;
(ii) The concentration of the reagents used;
(iii) The time allowed for colour development;
(iv) The treatment of the solution after colour development;
(v) The presence of interfering substances in the *raw* sample;

A factor which is of great practical importance is the stability of the reagent.

Treatment of Raw Sample and Colour Development

The initial treatment involves acidification to liberate hydrocyanic acid; this then reacts with added bromine to give cyanogen bromide which is the active species in the König reaction. The acid used in all recommended procedures is glacial acetic acid. A standard volume of glacial acetic acid was used throughout our previous work,[4] and the possible effect of varying the amount of acid used was now investigated.

Reagents

p-Phenylenediamine solution. Dissolve 0·1 g of solid in 50 ml of 0·5M hydrochloric acid.

Bromine water. Saturate cyanide-free water with liquid bromine.

Arsenious acid solution. Reflux 2 g of arsenious oxide with 100 ml of cyanide-free water until solution is complete.

Pyridine reagent. Add 3 ml of concentrated hydrochloric acid to a mixture of 18 ml of freshly distilled pyridine and 12 ml of cyanide-free water.

Standard cyanide solutions. Prepared by suitable dilution, with cyanide-free water, of a standardised stock solution.[4]

Procedure

To 4·0 ml of standard cyanide solution, 0·2 ml of bromine water and either 0·1, 0·2 or 0·6 ml of glacial acetic acid were added. The differences in volume were adjusted with cyanide-free water. To each solution 0·2 ml of arsenious acid solution was added; after mixing, the excess bromine vapour in the tube was removed by aeration. To this mixture were added 4 ml of freshly mixed pyridine reagent/*p*-phenylenediamine solution (3·0 ml of pyridine reagent + 1·0 ml of *p*-phenylenediamine solution). The two amines are mixed immediately before use. They must not be added singly because erratic and erroneous results are then obtained.

After thorough mixing the spectra of these solutions were examined using a recording spectrophotometer to establish the best wavelength (isosbestic point) for measurement of the developed colour. This wavelength (515 mμ) was then used to measure the absorbances of the solution compared to water,* with a manually-operated instrument (see Table I).

The effect of varying the amount of acetic acid used is very large. In our previous work regarding the König synthesis[4] the effect of glacial acetic acid was minimised by dilution of the standard cyanogen bromide solutions and the use of an aliquot therefrom, *i.e.*, 0·6 ml of glacial acetic acid was used for acidification of the slightly alkaline cyanide solutions before the formation of cyanogen bromide; then after arsenious acid solution addition, the volumes of the resultant solutions were adjusted to 50 ml. Aliquots of 1·0 or 5·0 ml of these solutions were used, *i.e.*, the equivalent amount of glacial acetic acid used was 0·06 ml in a 5-ml aliquot.

---

* Because we have been particularly concerned with the stability of the aromatic amine reagent employed, we have always preferred to measure absorbances against water of both samples and blanks. With *p*-phenylenediamine the absorbance of a sample may be measured directly against a blank, especially if the amine reagent is reasonably fresh. In the case of a large number of samples, however, the absorbance of the blank may change significantly by the time the final sample is measured against it. Under these conditions measurement of both samples and blank against water is recommended.

[a] All measurements at 515 mμ.

Because the amount of acetic acid used altered the absorbance of the colour developed, it was decided to investigate the effect of other acids. The acids chosen were concentrated hydrochloric acid, phosphoric acid and the acidity from the addition of saturated bromine water alone. The results were compared with those obtained using acetic acid. Because slight variations in absorbances with time were noted in the work with glacial acetic acid, the absorbances were measured at various fixed time intervals under standard conditions.

The procedure followed was as before, except that to the standard cyanide solution (4·0 ml) and bromine water (0·2 ml) one of the following was added:

(a) 0·2 ml of glacial acetic acid,
(b) 0·2 ml of cyanide-free water (acidity from bromine water alone),
(c) 0·2 ml of concentrated hydrochloric acid (sp. gr. 1·18),
(d) 0·2 ml of concentrated phosphoric acid (sp. gr. 1·75).

Calibration curves obtained from these results (Table II) are shown in Fig. 1.

The colour developed in the presence of all of the acids investigated obeys Beer's Law. Hydrochloric acid does not alter the absorbance of the solution from that when acidified only with bromine water, but both acetic acid and phosphoric acid greatly decrease the absorbance at all times.

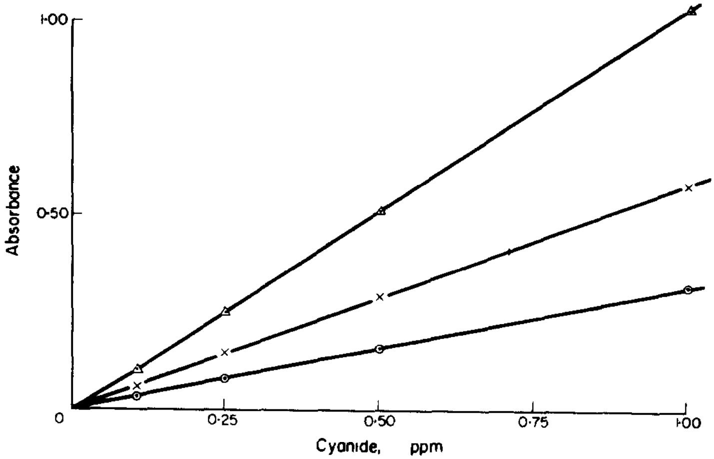

FIG. 1.—Absorbance with various acids (after 25 min; 515 mμ):
—△— water or concentrated hydrochloric acid,
—×— phosphoric acid,
—○— glacial acetic acid.

In order to show the effectiveness of *p*-phenylenediamine compared to benzidine, which is at present accepted as the standard reagent for determination of cyanide, the two were compared under conditions employed with the standard reagent (Aldridge procedure), except that the sample solution was acidified with bromine water alone, with bromine water plus concentrated hydrochloric acid or with bromine water plus glacial acetic acid.

The results are presented in Table III; the curves obtained from (a) and (d) are shown in Fig. 2. On the same scale, the curves from (a), (b), (c) and (f) are coincident for much of the range. Thus, neither glacial acetic acid nor hydrochloric acid has any appreciable effect on the absorbances produced when using benzidine. In the presence of acetic acid, the absorbances developed with *p*-phenylenediamine and benzidine are similar. When using conditions where no decrease in absorbance of the *p*-phenylenediamine colour occurs, this reagent gives a much greater absorbance than does the same concentration of benzidine.

Because the type of acid used has a significant effect, the possible effects of varying amounts of reagents were investigated for both *p*-phenylenediamine and benzidine. Increasing the amount of bromine water from 0·2 ml to 2·0 ml had no effect.

Using a 10-ml or a 5-ml *raw* sample and equal amounts of the other reagents had

[a] 515 mμ for *p*-phenylenediamine, and at 522 mμ for benzidine;[5] 0·2% solutions of the two amines in 0·5*M* hydrochloric acid were used.

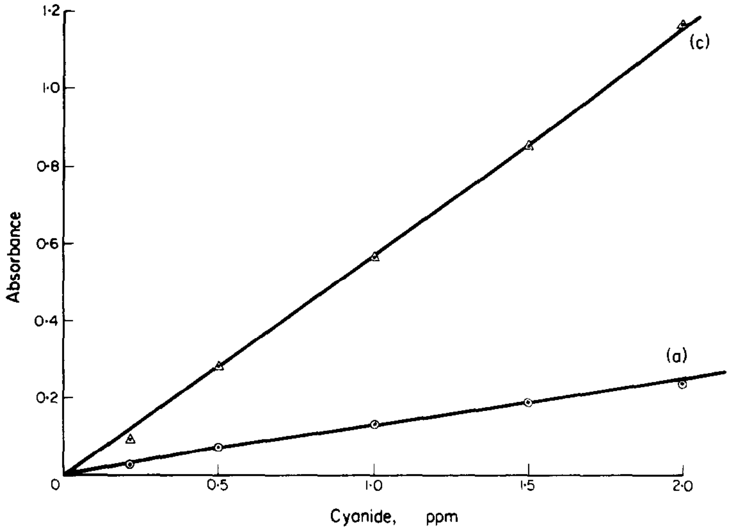

FIG. 2.—Absorbance obtained with 0·2% w/v solutions of:
(a) benzidine (522 mμ),
(c) *p*-phenylenediamine (515 mμ).

no significant effect. Less than a 0·4% difference in the absorbances of the two solutions was noted over a range of concentrations of cyanide.

Treatment of Solution After Colour Development

For samples containing cyanide at concentrations greater than 2·0 ppm, the procedure must be altered because the absorbance becomes so great as to make measurement by normal methods impracticable. In earlier work[5] we have shown that the upper range of the Aldridge method using benzidine could be extended by a modification of the method of Baker *et al.*,[6] using aqueous alcohol to dilute the developed colour. The present method was investigated using a similar dilution technique.

To 2·0-ml samples containing 0·0, 0·5, 1·0, 4·0, 5·0 and 10·0 ppm of cyanide in 25-ml volumetric flasks, 2·0 ml of bromine water and 0·1 ml of concentrated hydrochloric acid were added. After 5 min, 0·4 ml of arsenious acid solution was added and 4·0 ml of freshly mixed pyridine/*p*-phenylenediamine. After 1 min, 5 ml of ethyl alcohol were added and cyanide-free water to make each volume 25 ml. The best wavelength for measurement was ascertained, then the absorbance of the solutions was measured in 1-cm cells, compared to water, at this wavelength, using a manually operated spectrophotometer.

The results are shown in Tables IV(a) and IV(b). The isobestic point for solutions processed by the above dilution technique was at 520 mμ. This shift of wavelength from 515 mμ (isosbestic point for 2·0-, 4·0- or 5·0-ml sample is 515 mμ and for 10·0-ml sample 512 mμ, both using the non-dilution technique) must be caused by a concentration effect.

Table IV(a).—Absorbance of reagent blank solution

Time after mixing, *min*	Absorbance compared with water
20	0·018
30	0·017
40	0·018
50	0·020
60	0·020

Table IV(b).—Absorbance of solutions containing cyanide

Time after mixing, *min*	Absorbance (Corrected for blank)				
	Cyanide, *ppm*				
	0·5	1·0	4·0	5·0	10·0
20	0·035	0·078	0·366	0·486	1·010
30	0·034	0·077	0·365	0·485	1·005
40	0·033	0·076	0·367	0·487	1·006
50	0·033	0·075	0·363	0·482	0·999
60	0·033	0·074	0·362	0·477	0·995

The dilution procedure is fairly satisfactory when using *p*-phenylenediamine solution as reagent but offers no advantage over dilution of the *raw* sample before the addition of bromine and amine.

For samples containing trace amounts of cyanide and using benzidine as the dye precursor, Nusbaum and Skupeko[7] extended the lower range of the Aldridge method by extracting the pyridine dyestuff into n-butanol. The procedure of Nusbaum and Skupeko was followed, except that *p*-phenylenediamine solution (0·2% w/v) was used in place of benzidine. The developed colour was extracted using 10 ml of n-butanol. The absorption spectrum shows a maximum at 480 mμ. Some typical results are included in Table V.

Small bubbles occasionally form in the butanolic extract in the optical cell. These are water bubbles forming from a slightly supersaturated water/butanol solution; they may be removed by using a 5% solution of disodium phosphate to break any emulsion formed and centrifuging the butanol extract for 2–3 min. The phosphate does not have any appreciable effect on the actual absorbances. However, the extraction procedure involves one or two more steps in the over-all procedure and this is

TABLE V

Cyanide, *ppm*	Absorbances (corrected for blank) Solvent extraction (480 mμ)	Without extraction (515 mμ)
0·01	0·018	0·009
0·02	0·032	0·021
0·05	0·065	0·049
0·10	0·167	0·101
0·20	0·323	0·201
0·30	0·496	0·298
0·50	0·838	0·509

an obvious disadvantage. Although there is a 50% increase in the absorbance, at the lower end of the range the reproducibility using solvent extraction is not as good as without extraction. With a very low concentration of cyanide, more than one extraction is necessary and the resultant volume errors tend to remove the advantage of increased colour absorbance. The method is not recommended.

Thus, the procedure as so far envisaged is:

Using a 4·0-ml *raw* sample, add 0·2-ml of bromine water and 0·1 ml of concentrated hydrochloric acid. Mix well, add 0·2 ml of arsenious acid solution followed by 4·0 ml of freshly mixed pyridine/*p*-phenylenediamine. The absorbance is measured against water in 1-cm cells, at 515 mμ, after 30 min.

The results are as described (Fig. 1). It is possible to use the method down to 0·005 ppm with an accuracy of 1–2%, the main source of error being the measurement of the small volumes of reagents.* However, because industrial samples of cyanide (effluents, *etc.*) are relatively unlimited, these sources of error can be minimised by using a larger sample size. To ensure an adequate excess of bromine in the sample, the amount of this reagent used must, of course, be increased. The following procedure was adopted for samples of "unlimited" size:

Treat 40 ml of the *raw* sample in a 50-ml volumetric flask with 2·0 ml of saturated bromine water and 0·1 ml of concentrated hydrochloric acid, then thoroughly mix. After 5 min, 0·4 ml of arsenious acid solution is added and the total volume adjusted to 50 ml with cyanide-free water. A 5·0-ml aliquot of this mixture is treated with 4·0 ml of freshly mixed pyridine/*p*-phenylenediamine. The solutions are thoroughly mixed and the absorbance of the resulting solution is compared to that of water at 515 mμ, at various times after mixing.

The results obtained showed that the colour obeys Beer's Law. To extend the upper range of the method, dilution of the sample before addition of reagents enables the method to be used from 0·001–100 ppm. Some typical results using this procedure are given in Table VI.

The absorbances after 30 min obtained from 5·0-ml of the treated mixture are shown graphically on Fig. 3.

For small concentrations of cyanide this procedure has no advantage over the original procedure other than that of increasing the accuracy by decreasing the relative volume errors in the sample size. For relatively large concentrations of cyanide (10 ppm or greater), however, the use of a 1·0-ml sample and dilution to 40·0 ml reduces the concentration of other material present by a factor of 10. This may reduce interferences (see later) to a tolerable level in some instances.

---

* For 4-ml samples a 4-ml grade A pipette was used, and for volumes of reagents of less than 1-ml a 1-ml pipette (graduated into 0·01 ml) was used.

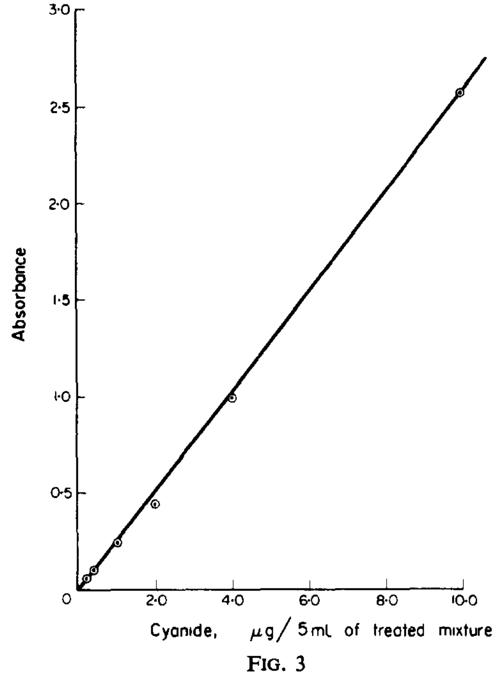

FIG. 3

Interferences

Interfering substances may be divided into:

(i) Those which react with bromine and form cyanogen bromide under the conditions of the reaction; these substances give high values for the cyanide present.

(ii) Those which prevent the cyanide ion from forming cyanogen bromide and hence give low results.

In the first class of substances, the most important is the thiocyanate ion, which reacts with bromine to produce cyanogen bromide. Both methods developed, employing *p*-phenylenediamine, may be used to determine the amount of thiocyanate present. The difference in reaction weights of the cyanide and thiocyanate ions is reflected in the absorbances produced, *viz.*

0·2 ppm of cyanide gives, on reaction, an absorbance of 0·200,

0·2 ppm of thiocyanate gives, on reaction, an absorbance of 0·100.

It is possible to determine the two ions in admixture, using the following procedure based on the non-volatility of thiocyanic acid. The total cyanogen bromide-producing substances in one aliquot of the sample are determined in the proposed manner. A second aliquot of the sample is acidified with either trichloracetic acid or boric acid, heated to 90–100° and aerated by a slow stream of air bubbles for 10–15 min. The evolved hydrocyanic acid is collected in 0·1*M* sodium hydroxide solution and the cyanide content of the resulting solution determined as previously described. The residual thiocyanate in the acidified solution may also be determined (like hydrochloric acid, trichloracetic acid and boric acid have no effect on the absorbance produced by bromine water alone).

Cyanates, hexacyanoferrate (II) and hexacyanoferrate (III) are without effect. Cyano-complexes of zinc and copper, however, yield cyanogen bromide when treated with bromine water, and it is necessary to remove free (uncomplexed) cyanide ion by the aeration procedure described.

Iron^{II}, nickel^{II} and copper^{II}, in quantities of 100 ppm, produce a ten-fold, three-fold and two-fold decrease in the concentration of cyanide found, respectively.

Of the other metal ions probable in effluents, manganese, lead, zinc, mercury^{II} and silver do not interfere in amounts up to at least 100 ppm in the solution as tested.

Reducing and/or oxidising agents present do not interfere except by consuming the bromine water or arsenious oxide solution, respectively.

Free chlorine which is often present in trade effluents, does not interfere; the cyanogen chloride formed has the same effect as cyanogen bromide.

Non-oxidising or non-reducing ions present, such as borate, bromide, carbonate, chloride, nitrate, phosphate and sulphate, do not interfere in amounts up to at least 100 ppm.

It is to be noted that using the dilution technique a ten-fold decrease of any interfering substances is obtained (on a 1·0-ml sample), and it is thus possible that relatively high concentrations of ions in a *raw* sample may be tolerated without any noticeable loss in accuracy.

Procedures for the decomposition of complex cyanides to give hydrogen cyanide for determination have been previously reviewed[8,9] and any of the recommended methods are applicable to the determination of cyanide by *p*-phenylenediamine.

Stability of the Reagent

The stability of the reagent was investigated using standard solutions of cyanide (4-ml samples) and a 0·2% w/v solution of *p*-phenylenediamine in 0·5*M* hydrochloric acid:

(1) freshly prepared (less than 1 hr)

(2) solution kept in a 'dark' bottle for 6 weeks.

TABLE VII(a).—ABSORBANCE OF REAGENT BLANK SOLUTION

Time after mixing, *min*	15	25	30
Absorbance (fresh solution)	0·019	0·020	0·022
Absorbance (6-weeks old solution)	0·021	0·020	0·023

TABLE VII(b).—ABSORBANCE OF SOLUTIONS CONTAINING CYANIDE

Cyanide, *ppm*	Time after mixing, *min*	Absorbance (corrected for blank)	
		Aged reagent	Fresh reagent
0·2	15	0·200	0·196
	25	0·203	0·201
	30	0·203	0·201
0·4	15	0·398	0·396
	25	0·406	0·404
	30	0·406	0·404
2·0	15	2·01	2·01
	25	2·01	2·02
	30	2·02	2·03

From the results in Tables VII(a) and VII(b), the reagent solution is stable for at least 6 weeks when stored in a dark bottle, and the reproducibility of the results at 30 min after mixing is $\pm 1\%$.

CONCLUSION

The procedure to be used depends on the expected concentration of cyanide to be determined, the size of the sample available and the contaminants. The following procedures are recommended.

Unlimited sample ($\nless$ 40 ml)

For a concentration of cyanide between 0·005 and 0·25 ppm, the sample is obtained free from interferences (if necessary) by distillation, aeration, *etc.* Forty ml of the sample are then treated with 2·0 ml of saturated bromine water and 0·1 ml of concentrated hydrochloric acid and the solutions thoroughly mixed. After 5 min, 0·4 ml of arsenious acid solution is added and the total volume adjusted to 50·0 ml. A 5·0-ml aliquot of the mixture is then treated with 4·0 ml of freshly mixed pyridine/*p*-phenylenediamine (3·0 ml of pyridine reagent + 1·0 ml of *p*-phenylenediamine solution). After thorough mixing and standing for 30 min at room temperature, the absorbance of the resulting solution is compared to that of water at 515 mμ.

The absorbance of a blank solution should be determined under the same conditions and the absolute absorbance used to calculate the concentration of cyanide present, from a previously determined calibration curve.

For samples containing 0·25—100 ppm of cyanide, a suitable aliquot should first be diluted to 40·0 ml with cyanide-free water, then processed as above.

Limited Sample

If the sample size is limited and dilution to 40·0 ml would decrease the concentration below 0·005 ppm, then 4·0 ml of the sample are mixed well with 0·2 ml of saturated bromine water and 0·1 ml of concentrated hydrochloric acid. After 5 min, 0·2 ml of arsenious acid solution is added, followed by 4·0 ml of freshly mixed pyridine/*p*-phenylenediamine. After 30 min at room temperature, the absorbance is measured at 515 mμ.

A separate calibration curve should be determined. If necessary, the sample may be obtained free from interferences as above.

Zusammenfassung—Zur Bestimmung von Cyanidspuren in Wässern wird p-Phenylendiamin in einer Reaktion vom Typ der König-Reaktion verwendet. Mit geringfügigen methodischen Änderungen läßt sich die Methode im Bereich von 0,005 bis 100 ppm anwenden.

Résumé—Pour doser le cyanure à l'état de traces dans les eaux, on utilise la p-phénylènediamine, dans une réaction du type König. Avec une légère modification de technique, la méthode est applicable dans l'intervalle de 0,005 à 100 p.p.m.

WET OXIDATION OF ORGANIC COMPOSITIONS

MIXED NITRIC AND HYDROCHLORIC ACIDS WITH AMMONIUM PERCHLORATE AS OXYGEN DONORS

G. Frederick Smith
Noyes Chemical Laboratories, University of Illinois, Urbana, Illinois, U.S.A.

(*Received* 14 *October* 1963. *Accepted* 23 *October* 1963)

Summary—The wet oxidation of organic compositions as introductory manipulation in the determination of micro- and macrogram metallic and non-metallic elements is described. The principal oxygen donor in this procedure is perchloric acid generated *in situ*. Mixed nitric and hydrochloric acids are employed to convert ammonium perchlorate to perchloric acid. The three mixed acids then serve as superior solvent for the organic matter to be oxidised. Conditions are particularly suited for the oxidation of large samples. Reaction rates are repressively controlled to give assurance against violent oxidation. Applications include organic compositions, essentially of cellulose, sugars and polyhydric alcohols, or proteins. Conditions prevail in the leisurely application of reaction time to provide maximum effects from nitric acid. This provision is the key to slowly advancing oxidation potential. The final high potential provided by perchloric acid over the temperature range 150° to 203°, stepwise increasing, completes oxidations with no accompanying menacing carbonisations. Reaction times involve 50 to 60-min digestions.

INTRODUCTION

THE oxidation of organic compositions by dry ignition has been shown[1] to be frequently accompanied by a serious loss of residual elements from high temperature volatilisation. By exhaustive test, wet oxidations employing perchloric, sulphuric and nitric acids involve no loss under easily adjusted reaction conditions. There appears to be general acceptance that the use of perchloric acid as oxygen donor in wet oxidation of organic compositions provides the most valuable reaction medium.

Wet oxidation digestions in the elimination of organic matter, with retention of metallic and non-metallic accompanying elements, fall into five general categories according to the reagents involved:

(1) Nitric plus perchloric acids: "The Liquid Fire Reaction."[2]

(2) Perchloric acid alone. This procedure applies static oxidation potential magnitudes of predetermined values.[3]

(3) Perchloric and sulphuric acid mixtures. This application applies high redox potentials.[4]

(4) Sulphuric acid at 350° followed by a perchloric acid finishing reaction at 190–195°.[5] Used with fuel oils and samples rich in fat.

(5) Periodic acid and perchloric acid: "The Periodic Acid Liquid Fire Reaction."[6]

The last listed method provides general oxidation at the lowest possible temperatures and shortest reaction times.

Employing one or more of these five reaction procedures, a wide range of organic compositions may be expeditiously oxidised. Samples include fuels (such as coal or oils), carbon (such as gas-mask canister materials), fats, synthetic fabrics (such as nylon, orlon or dacron), foods and feeds, leather and wool, syrups, conserves, fruits and cellulose-rich products. Method (5) has been applied to the determination of amino nitrogen.[7] Many published works involving one or more of the five procedures have been documented, but these are too numerous to cite in the interests of brevity.

EXPERIMENTAL

Reagents

Concentrated (67–68 %) *nitric and* (37–38 %) *hydrochloric acids*

Ammonium perchlorate (99·5 %). As produced in multiple tonnage for use in the solid rocket fuel programme. Recrystallisation purification is recommended.

Apparatus

The Bethge apparatus[8] is requisite. By its use reaction conditions are best controlled. Heat is provided using a ring burner and modified nichrome wire gauze. A modified Rogers ring burner with micro control of gas-fuel intake[9] is preferred. An electric hot plate or a glass fabric heating mantle with voltage control may be substituted. Rate of energy input should be of such magnitude as to bring the reaction temperature to no more than 100° during the first 5 min. The Bethge apparatus assembled is shown in Fig. 1. Adjustment of the thermometer insert is provided by a teflon adapter as shown.

RESULTS AND DISCUSSION

Reaction characteristics

The reactions involved fall under three stages:

(A) Initial conversion of ammonium perchlorate to perchloric acid. The reaction with mixed hydrochloric and nitric acid converts the ammonium ion to nitrous oxide and water. An amount of water approximately equal to the combined mixed acid volumes is added to the sampling mixture. Reaction time is 10 min at a maximum of 110°. Heat is applied at such magnitude to attain 90° to 100° in not less than 5 min. Reaction conditions involve a mildly exothermic condition and the reaction is conducted under reflux of the condensed vapour phase. In general, the organic compositions being oxidised are dissolved by the three mixed acids present during stage (A).

(B) Adjustment is provided to retain condensate during the remainder of the digestion. The hydrochloric acid has been consumed. The dilute solution of mixed nitric and perchloric acids gradually concentrates over the temperature range 110° to 150°. The reaction is exothermic to a greater or less extent depending upon the nature of the organic matter being oxidised. During this stage the nitric acid undergoes gradual uniform increase in concentration. The oxidation potential of the nitric acid increases gradually to its maximum value at 150°. All organic matter capable of destruction by nitric acid has been reacted upon and excess nitric acid has been collected in the condensate. Little reactivity from perchloric acid has, as yet, been applied. Stage (B) requires from 30 to 40 min at the same application of heat applied throughout the three stages (A), (B) and (C). Variation in time during stage (B) is governed by the exothermic reaction provided by nitric acid oxidation.

(C) The final stage completes the oxidation following the limited destruction of organic matter provided by nitric acid and elimination of its excess at 140° to 150°. At 150° the first influence of perchloric acid as oxygen donor becomes effective. As the temperature advances because of concentration increase, the oxidation potential steadily and uniformly increases from approximately 0·8 to 2·0 V. The perchloric acid concentration increases from 50 % at 150° to 72·5 % at 203°. The reaction over this range becomes increasingly exothermic. At 203° the distillate and residual acid

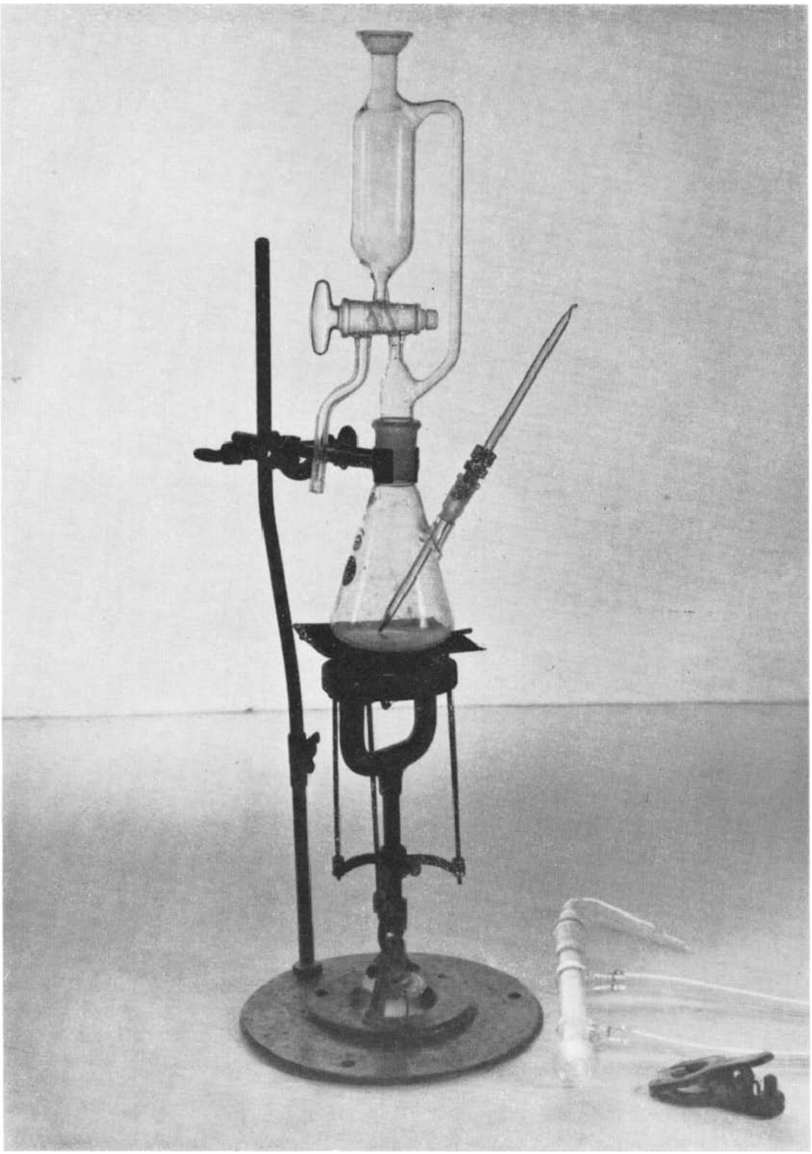

FIG. 1.—Bethge apparatus (water condenser disengaged) and modified Rogers ring burner.

in the reaction flask is at the water-perchloric acid azeotropic composition. The extent of the exothermic reaction depends upon the nature of the organic material being oxidised. Stage (C) requires 10 min, in general. Total reaction time, over-all, is approximately 60 min.

Reaction advantages

Previously described wet oxidation procedures[2-6] have one common objective, that of controlled oxidation at minimum time intervals. All types of organic compositions may be oxidised by one to three of the various applicable procedures. In general, the products oxidised involve little or no carbonisation. Degradation products, as well as the original compositions, are usually all in homogeneous solution throughout the entire digestion. Such reactions, if accompanied by the formation of dark brown or black reaction products, are still reaction rate controlled. However, in general, sample weights are limited to the 1 to 2 g magnitude.

The present work involves no reactions resulting in dark or black reaction media. Samples of 5 g are applicable. Conditions are adjusted to require longer reaction periods. Accordingly, the full possible effect of nitric acid as oxygen donor is provided. The oxidation of organic matter is thus as complete as possible before the perchloric acid oxidation begins. By following the reaction temperature during stage (b), the mildly exothermic nitric acid oxidation indicates the extent to which the removal of organic matter is progressing. Adjustment in the volume of nitric acid employed may then be made. Perchloric acid reaction in stage (c) may thus be favourably minimised.

The entire new procedure requires little operator attention. The apparatus involved is readily assembled and dismantled. It does not require a fume hood. The use of the new procedure encourages those reluctant to apply perchloric acid in wet oxidations, in fear of uncontrolled reaction intensities, to adopt the procedure in routine operations. In the present studies, no protective reaction screen was employed in any test oxidation.

Graphical representation of data

Three distinct types of organic compositions for wet oxidation include those which are predominantly cellulose, sugars or proteins. The time-temperature recording of the progress of the oxidation is the most informative technique serving to characterise each type of reaction. Employing the Bethge apparatus (Fig. 1), the oxidation of 2 g of tuna fish is characterised in Fig. 2. Because of the small weight of sample the reaction flask employed is 250 ml in volume. The oxidation is, for this reason, complete in 26 min. Stage (A) in Fig. 2 is complete in 6 min, and from 4 to 6 min no temperature rise indicates the conversion of ammonium perchlorate to perchloric acid. The sample during this period has been completely dissolved. At this point the return of reflux to the reaction flask is discontinued. For the following 16 min the stage (B) reaction of nitric acid is operative. Over the period 6 to 14 min the temperature elevation is slow and uniform indicating no appreciable exothermic nitric acid oxidation. Over the reaction period 15 to 22 min the oxidation is progressing at an increased tempo, as shown by the materially increased slope of the time-temperature plot. At 22 min the temperature has advanced to 150°. All excess nitric acid has now left the reaction flask to be collected in the condenser system. The effective oxidation period, 22 to 26 min, involves the reaction of perchloric acid as oxygen donor, stage (C). At 150° the perchloric acid concentration is approximately 50%. Here there comes into play a gradual increase in oxidation potential accompanied by a material exothermic reaction complete in 4 min. The completion of oxidation (as indicated by the oxidation of the chromium indicator,* Cr^{III} to Cr^{VI}, at 202°) indicates a perchloric acid concentration of 72·5%. During the entire reaction [stages (A), (B) and (C)] no alteration of heat applied has been made. Stage (C) owes its temperature rise almost entirely to its exothermic properties.

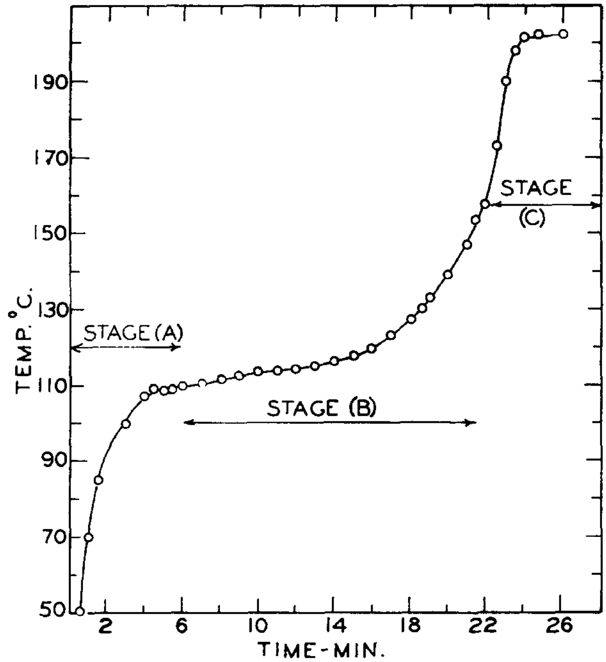

FIG. 2.—Oxidation of tuna fish [2 g of sample; 250-ml reaction flask; 10 ml of HCl; 17·6 ml of HNO_3; 21·5 g of NH_4ClO_4; 26 ml of H_2O; chromium indicator; 43 ml of distillate; 21·75 g (13 ml) of residue in $HClO_4$ flask].

At the completion of the oxidation the condensate may be removed, the air and water-cooled condenser rinsed and the distillation continued with elevation of temperature input. By this means excess perchloric acid can be removed from the reaction flask. Any silica originally present in the sample is now dehydrated and insoluble. The reaction flask can now be diluted with water, filtered and made ready for determination of metallic and non-metallic minor or major components originally present in the organic compositions of the sample. The flask contents, after completion of the oxidation covered by the results of Fig. 2, weighed 21·75 g or approximately 13 ml of perchloric acid. The distillate was 43 ml.

Non-condensed volatile products may be conducted from the top of the water-cooled condenser by flexible tubing into the sink drain, thus avoiding, by the use of the Bethge apparatus, the need for a fume hood in which to perform the oxidation.

---

* 1–2 mg of potassium dichromate are included in the reaction mixture. As long as any organic matter is present, the chromium is held in the green tervalent state. When all traces of organic matter are oxidised, the chromium is immediately oxidised to the orange hexavalent state.

Oxidation of 5-g samples of organic compositions

The oxidation of 5 g of dried beef is characterised in Fig. 3. A 1000-ml Bethge apparatus was employed. As well as using a 5-g sample, the reactants were augmented and a resultant 60-min reaction time was required. As could be predicted, the general profile of the graphical recording of data duplicates that of Fig. 2 for the reason that both organic compositions oxidised are proteins (distillate: 67 ml; perchloric acid remaining in the reaction flask: 33·6 g or 20 ml).

The oxidation of 5 g of vegetable tanned leather is graphically recorded in Fig. 4. The reaction time is shown as 41 min under the same conditions as for an equal sample of dried beef. In the case of leather it is observed that the oxidation is less in

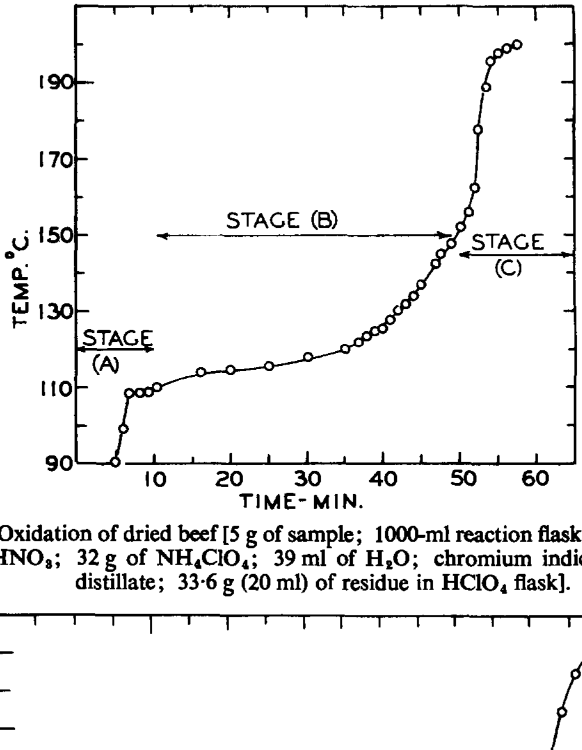

FIG. 3.—Oxidation of dried beef [5 g of sample; 1000-ml reaction flask; 15 ml of HCl; 26·5 ml HNO_3; 32 g of NH_4ClO_4; 39 ml of H_2O; chromium indicator; 67 ml of distillate; 33·6 g (20 ml) of residue in $HClO_4$ flask].

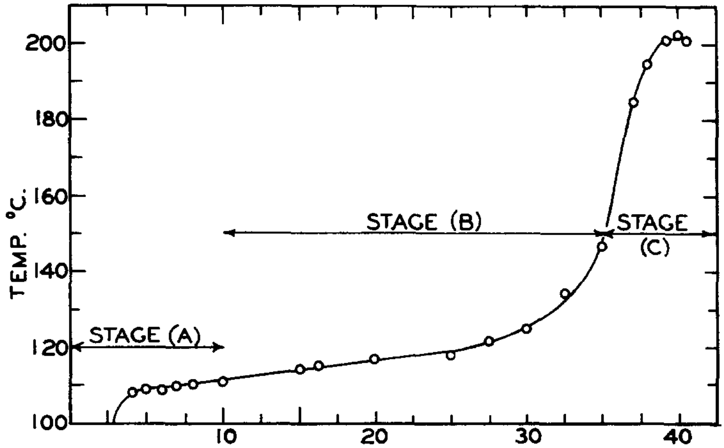

FIG. 4.—Oxidation of leather [5 g of sample; 500 or 1000-ml reaction flask; 15 ml of HCl; 35 ml of HNO_3; 32 g of NH_4ClO_4; 39 ml H_2O; chromium indicator; 71 ml of distillate; 29 g (17·4 ml) of residue in $HClO_4$ flask].

the nitric acid stage (B) and the burden of reactivity is placed upon the perchloric acid stage (C). With the same sample weight, the distillate was 71 ml and the perchloric acid in the reaction flask 29 g or 17·4 ml. The same amounts of mixed reactants were employed in the reactions shown in Figs. 3 and 4. An additional 2·6 ml of perchloric acid were consumed.

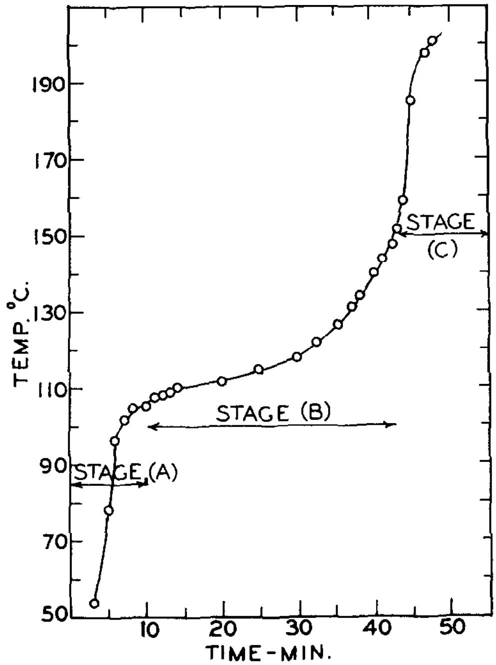

FIG. 5.—Oxidation of sugar [5 g of sample; 1000-ml reaction flask; 15 ml of HCl; 35 ml of HNO_3; 32 g of NH_4ClO_4; 39 ml of H_2O; chromium indicator; 70 ml of distillate; 35·3 g (21·1 ml) of residue in $HClO_4$ flask].

The oxidation of 5 g of cane sugar is shown in the graph of results in Fig. 5. The results indicate that the oxygen donor contribution of both nitric acid and perchloric acid are approximately equal.

The oxidation of 5 g of raffia and 5 g of cinnamon bark (principally both cellulose) is depicted in Figs. 6 and 7. As would be predicted, the results indicate almost duplicate reaction characteristics. Subsequent to the reaction with nitric acid in stage (B), the exothermic nature of the perchloric acid oxidation is more pronounced than that of either the oxidation of samples essentially sugar or protein in composition.

Reaction commentary

Nitrous oxide formed in reaction stage (A), being soluble in water and many organic compositions, especially in the case of cellulose-laden materials, promotes foam formation. Such foams are very light and can be counteracted by increasing the flask volume of the Bethge apparatus.

The oxidations described in Figs. 2 to 7 may be well conditioned by employing modified amounts of reactants to suit any particular type of routine plant control oxidation samples. By trial, for example, the volume of nitric acid may be reduced to such favourable volume, provided there results no dark brown or black degradation reaction products. The time required may thus be favourably reduced for a given application.

Sufficient perchloric acid should be obtained to prevent dry spots from forming on the inside bottom of the reaction flask. By withdrawing distillate from the apparatus condenser system, and rinsing with distilled water at the completion of oxidations, one may collect by further distillation the bulk of the perchloric acid formed previously.

Organic compositions containing siliceous materials, in boiling 72·5% perchloric acid, precipitate insoluble SiO_2 quantitatively. In general, perchloric acid is a preferred medium for final determination of metallic and non-metallic residual isolated

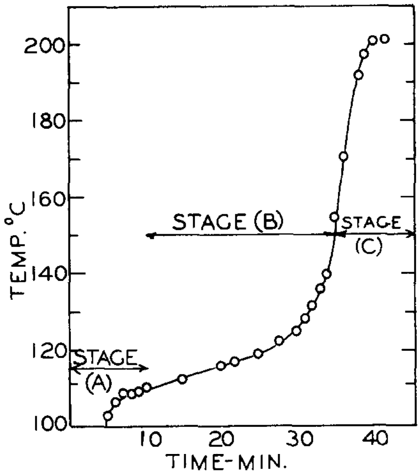

Fig. 6.—Oxidation of raffia [5 g of sample; 1000-ml reaction flask; 15 ml of HCl; 35 ml of HNO_3; 32 g of NH_4ClO_4; 39 ml of H_2O; chromium indicator; 71 ml of distillate; 29 g (17·4 ml) of residue in $HClO_4$ flask].

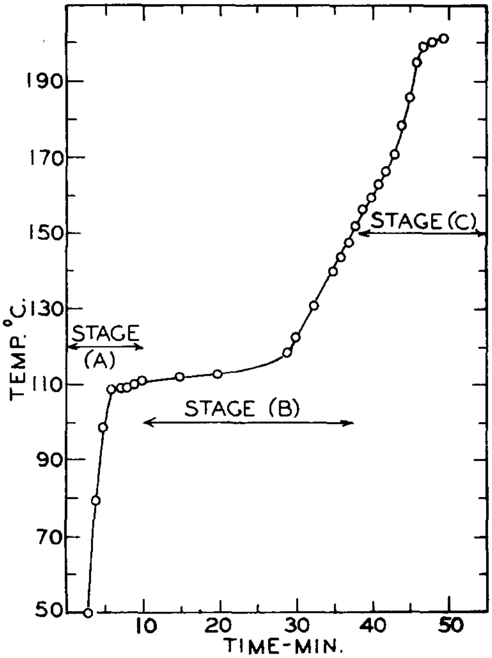

Fig. 7.—Oxidation of cinnamon bark [5 g of sample; 1000-ml reaction flask; 15 ml of HCl; 35 ml of HNO_3; 32 g of NH_4ClO_4; 39 ml of H_2O; chromium indicator; 73 ml of distillate].

and retained elements. If for any reason a sulphuric acid solution is preferred, it may be added to the perchloric acid solution and the latter displaced by volatilisation upon fuming at 180–190°.

Forty test oxidations of a wide variety of organic compositions have been carried out. Analysts, formerly apprehensive of methods 2 to 6, may well make "assurance doubly sure" through the use of the present disclosures.

Zusammenfassung—Die nasse Oxydation organischer Mischungen als erste Operation bei der Bestimmung von Mikro- und Makromengen metallischer und nicht-metallischer Elemente wird beschrieben. Bei diesem Vorgang dient in situ erzeugte Überchlorsäure in erster Linie als Sauerstoffquelle. Mit Salpetersäure-Salzsäure-Gemisch wird Ammoniumperchlorat zu Überchlorsäure umgesetzt. Das Dreisäurengemisch dient dann als ausgezeichnetes Lösungsmittel für das zu oxydierende organische Material. Die Bedingungen sind besonders zur Oxydation großer Proben geeignet. Die Reaktionsgeschwindigkeit wird zum Schutz gegen zu heftige Oxydation unter Kontrolle gehalten. Die Anwendungen schließen hauptsächlich Mischungen von Cellulose, Zuckern, mehrwertigen Alkoholen oder Proteinen ein. Hauptsächlich kommt es darauf an, daß man der Reaktion Zeit läßt, damit die Salpetersäure optimal ausgenutzt wird. So kann man das Oxydationspotential langsam steigern. Das zum Schluß von Überchlorsäure bei stufenweise ansteigender Temperatur von 150° bis 203° gelieferte hohe Potential beendet, die Reaktion, ohne daß Verkohlung droht. Der Aufschluß dauert 50–60 Minuten.

Résumé—On décrit l'oxydation humide de mélanges organiques, en tant que manipulation initiale dans le dosage d'éléments métalliques et non métalliques aux échelles du microgramme et du macrogramme. Le principe donneur d'oxygène est, dans cette technique, l'acide perchlorique généré "in situ". On utilise un mélange d'acides nitrique et chlorhydrique pour convertir le perchlorate d'ammonium en acide perchlorique. Le mélange des trois acides sert alors de solvant principal pour la matière organique à oxyder. Les conditions sont particulièrement appropriées à l'oxydation de grosses prises d'essai. Les vitesses de réaction sont très étroitement controlées, afin que l'on soit assuré d'éviter une oxydation violente. Les applications comprennent des mélanges organiques constitués essentiellement de cellulose, de sucres et polyols, ou de protéines. Les conditions reposent essentiellement sur un temps de réaction suffisamment long pour obtenir les effets maximaux de l'acide nitrique. Cette précaution est la clef qui autorise un potentiel d'oxydation lentement progressif. Le haut potentiel final apporté par l'acide perchlorique, pour les températures s'échelonnant de 150° à 203°, et croissant graduellement, complète les oxydations sans que celles-ci soient accompagnées d'une menace de carbonisation. Les temps de réaction comprennent des digestions de 50–60 minutes.

5-(8-HYDROXY-5-QUINOLYLMETHYL)-8-HYDROXY-1-METHYLQUINOLINIUM SALTS AS SOLVATOCHROMIC CHELATING AGENTS

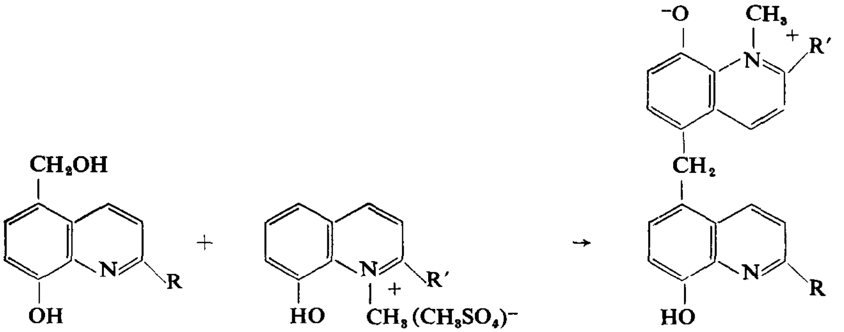
J. W. Faller and J. P. Phillips
Department of Chemistry, University of Louisville, Louisville 8, Kentucky, U.S.A.

(*Received* 25 *October* 1963. *Accepted* 29 *November* 1963)

Summary—The title compounds and related substances were prepared, characterised and tested as solvatochromic chelating agents. These reagents show large color changes with solvent, and the chelates, though insoluble in most common solvents, are also solvatochromic. Reagents with a 2-methyl group adjacent to the chelating centre do not precipitate aluminium, and this effect can be used as a colour test for aluminium.

In continuation of studies of chelating agents that undergo large colour changes with solvent polarity (solvatochromism),[1] we have prepared four reagents of general formula I (R and R′ are H or CH_3). In these compounds the solvatochromism is conferred by the betaine function in one quinoline ring, and this is isolated by a methylene bridge from an 8-quinolinol (or 8-hydroxyquinaldine) moiety that can form chelates with metal ions. The chelates as well as the reagents can thus be solvatochromic, and it was anticipated that the two functions should be independent.

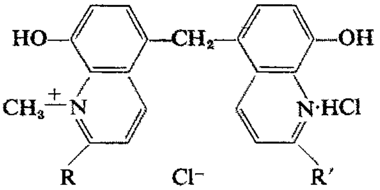
It was not possible to obtain the compounds by direct methylation of available bis(8-hydroxy-5-quinolyl)methanes[2,3] because dimethyl sulphate methylated both nitrogen atoms (see *Experimental*); though these products are solvatochromic they obviously are not chelating agents. The desired monomethylated compounds were obtained by rather tedious condensation reactions of 5-hydroxymethyl-8-quinolinol[4] or 5-hydroxymethyl-8-hydroxyquinaldine[5] with either 1-methyl-8-hydroxyquinolinium methosulphate or its 2-methyl derivative as shown in the following equation:



I
(R = R′ = H)
(II–IV; R or R′ is H or Me)

A similar condensation of 1-methyl-5-hydroxymethyl-8-hydroxyquinolinium methosulphate with 8-quinolinol also gave I, identical in m.p. and ultraviolet-visible spectra with a sample of the same compound prepared by the above reaction. All four of the compounds were isolated as the dark red inner salt represented by formula I and were also converted to the dihydrochlorides, yellow solids of high decomposition point. It is noteworthy (Table I) that all products were hydrated, a demonstration of the affinity of these substances for solvent molecules.

Table I.—5-(8-hydroxy-5-quinolylmethyl)-8-hydroxy-1-methylquinolinium salts



Substituents in formula						Nitrogen	
No.	R	R′	Formula	M.P.,[a] °C	Yield, %	Calcd., %	Found, %
I	H	H	$C_{20}H_{18}Cl_2N_2O_2{\cdot}H_2O$	c320	—	6·87	6·81

IV	CH_3	H	$C_{21}H_{20}Cl_2N_2O_2{\cdot}H_2O$	207–209	—	6·65	6·50
IVB[b]			$C_{21}H_{18}N_2O_2{\cdot}H_2O$	155	61	8·04	8·42

[a] All compounds melt with decomposition.

[b] B = Betaine, which refers to the neutral molecule formed by the loss of two HCl molecules from the salt (see equation).

Spectra of basic I in a variety of solvents showed a considerable negative solvatochromism in the visible (Table II), with a change in the wavelength of principal maximum by over 100 mμ from water to chloroform as solvent. [For comparative purposes maxima for the inner salt (V) of *N*-methyl-8-hydroxyquinaldinium hydroxide are listed too.] The spectrophotometric determination of ionisation constants of these compounds gave the results of Table III, with the three ionisation constants representing transitions, respectively, from diprotonated to neutral (zwitter-ionic) to anion forms as the pH increases. Thus, the first pKa is for the N-H$^+$ dissociation and the second and third for the phenolic hydrogen atoms. Comparative figures for some related compounds are also listed.

Infrared spectra of potassium bromide pellets of the compounds were also obtained.

Because all four reagents have a pK$_2$ of about 6·7 they would be expected to exist primarily in the cationic form at pH values of 5 or less, and chelates formed at pH 5 or less should not be solvatochromic. All reagents gave yellow solutions at pH 5 with copper, nickel, zinc and aluminium ions and a green solution with iron^{III} ion. In concentrated solutions precipitates of these chelates, presumably as salts with anions in the solution, could be obtained, but lack of knowledge of the anions incorporated prevented successful analysis.

At pH 9 orange to red precipitates from aqueous solution were obtained with copper, cobalt, nickel, zinc, magnesium and iron^{III} ions using reagents I–IV and with aluminium using reagents I and IV. The reagents are soluble in chloroform, but the chelates

TABLE II.—ABSORPTION MAXIMA IN THE VISIBLE SPECTRA OF I AND V

Solvent[a]	Dielectric constant[b] (and Z values[c])	Maximum, $m\mu$ (log ε)	
		I	I
Water	80·4 (94·6)	458 (3·30)	428 (3.18)
90% MeOH	37·9 (85·8)	496 (3·26)	456 (3·06)
90% 1-Propanol	29·8	504 (3·25)	465 (3·13)
90% 2-Propanol	23·5 (83·20)	507 (3·24)	470 (3·09)
90% Acetone	25·9 (77·7)	516 (3·24)	479 (3·09)
Benzyl alcohol	13·1	495 (3·29)	462 (3·18)
Chloroform	4·8 (63·2)	575 (3·39)	529 (3·09)

[a] Visible maxima only.

[b] An additional maximum is present near 355 mμ; this maximum appears to be caused by the chelating function.

are not. This lack of solubility of the chelates extended to most organic solvents, though aqueous pyridine mixtures did dissolve them well enough to allow solvatochromism to be observed, the chelates ranging from orange to violet with increasing pyridine content. In water the chelates were somewhat more soluble than is suitable for quantitative precipitations.

It would appear that the solvatochromism of the reagent determines in large part the colour of the chelates. Chelates prepared in alcohols and other non-aqueous solvents showed colours generally close to that of the reagent in each solvent, but upon filtration and loss of solvent the chelates changed to the red colour usually observed in the samples prepared from water solutions.

Any utility of these reagents must rest on the colours produced by extraction of the reagent. A novel colour test for aluminium, for example, is afforded by adding III to an aqueous solution containing metal ions to chelate all except aluminium; after addition of base, chloroform then extracts any excess III. Addition of a drop of dilute I to the aqueous phase and extraction again with chloroform will give a blue-violet chloroform layer if no aluminium is present but will leave the chloroform colourless if aluminium is present, because the aluminium chelate of I is not soluble in chloroform. There is no chelate of III with aluminium.

EXPERIMENTAL

Preparation of Compounds

1-Methyl-8-hydroxyquinolinium methosulphate was obtained by heating 0·1 mole of 8-quinolinol until liquid, then adding 0·1 mole of dimethyl sulphate and heating the mixture with stirring in a steam bath for 10 min. The solid product was washed with ether, dissolved in 2-propanol and precipitated with ether, and finally recrystallised from 2-propanol as yellow needles of m.p. 156° (52% yield). (Literature[6] gives m.p. 145–6°.)

1-Methyl-8-hydroxyquinaldinium methosulphate (m.p. 169–70°) was prepared similarly in 53% yield from 8-hydroxyquinaldine. (*Analysis.* Calcd. for $C_{12}H_{15}NO_5S$: C, 50·51; H, 53·0; N, 4·91. Found: C, 50·56; H; 4·89; N, 4·78.)

An aqueous solution of the methosulphate was converted to the chloride by passage through Dowex 2X-8 in the chloride form, evaporation of the effluent and recrystallization from 90% 2-propanol in the form of yellow needles melting at 231°. (*Analysis.* Calcd. for $C_{11}H_{12}ClNO{\cdot}2H_2O$: N, 5·48. Found: N, 5·48.)

1-Methyl-5-hydroxymethyl-8-hydroxyquinolinium methosulphate was similarly obtained from 5-hydroxymethyl-8-quinolinol[4] and dimethylsulphate in 73% yield by heating a nitrobenzene solution of the reactants for 1 hr on the steam bath. After three recrystallisations from 90% 2-propanol the product melted at 128°. (*Analysis.* Calcd. for $C_{12}H_{15}NO_6S{\cdot}H_2O$: N, 4·39. Found: N, 4·35.) In 0·1*M* hydrochloric acid the compound had λ_{max} 376 mμ; in 0·1*M* potassium hydroxide, 470 mμ (log ε 2·8).

5,5′-Methylenebis(8-hydroxy-1-methylquinolinium) dimethosulphate, decomposing 211–215°, was prepared in 47% yield by heating bis(8-hydroxy-5-quinolyl)-methane in excess dimethyl sulphate for 1 hr on the steam bath, precipitating the product by addition of 1:1 acetone-ether and recrystallising from 2-propanol. (*Analysis.* Calcd. for $C_{23}H_{26}N_2O_{10}S_2$: C, 49·81; H, 4·73; N, 5·05. Found: C, 49·78; H, 4·98; N, 5·02.)

This compound was converted to the dichloride, decomposing at 300°, by extracting an ammoniacal solution (pH 10) with amyl alcohol, adding ether and extracting the resulting solution with 0·1*M* hydrochloric acid. Evaporation of the aqueous extract and recrystallisation from ethanol gave the dichloride. (*Analysis.* Calcd. for $C_{21}H_{20}Cl_2N_2O_2{\cdot}2H_2O$: N, 6·38. Found: N, 6·31.)

In a similar way bis(8-hydroxy-5-quinaldyl)methane[3] was converted to the dimethylated derivative, isolated only as the chloride (m.p. 250°), because the methosulphate was hygroscopic. (*Analysis.* Calcd. for $C_{23}H_{24}Cl_2N_2O_2$: N, 6·46. Found: N, 6·43.)

5-(8-*Hydroxy*-5-*quinolylmethyl*)-8-*hydroxy*-1-*methylquinolinium salts*

Either 0·01 mole of 5-hydroxymethyl-8-quinolinol (1·75 g) or 5-hydroxymethyl-8-quinaldinol (1·89 g) or 5-hydroxymethyl-8-quinaldinol (1·89 g) and 0·02 mole of 1-methyl-8-hydroxy-quinolinium methosulphate (5·43 g) or 1-methyl-8-hydroxyquinaldinium methosulphate (5·71 g) were dissolved in 20 ml of glacial acetic acid. After the dropwise addition of 6 ml of concentrated sulphuric acid, the reaction mixture was allowed to stand for 2 days at room temperature, then was heated to 60° for an additional 2 hr. The mixture was poured over ice and diluted to approximately 200 ml. An aqueous solution of 2·5 g of $CuSO_4{\cdot}5H_2O$ was added and the solution neutralised with 20% sodium hydroxide solution until the formation of the olive copper chelate began. The pH of the solution was then adjusted to 9 by the addition of dilute ammonia solution. Warming the solution on a steam bath for 1 hr coagulated the precipitate, which was filtered and washed with dilute aqueous ammonia and water.

The chelate was dissolved in approximately 250 ml of $2M$ hydrochloric acid and the copper removed by precipitation with hydrogen sulphide. After coagulation of the copper^{II} sulphide by warming the solution, the sulphide was separated by filtration. The filtrate was neutralised with 20% aqueous sodium hydroxide, then saturated with carbon dioxide. After standing several hr, the precipitate was collected, washed with water and dried. The crude product was taken up in methanol and recovered by evaporation or alternatively, by precipitation with ether. The pure hydrated betaines were obtained as small dark red needles after two recrystallisations from 90% ethanol. Upon drying the betaines turned to a dark purple.

The chloride-hydrochloride is obtained by saturation of a methanolic solution of the betaine with hydrogen chloride, precipitation of the salt with a 1:1 acetone-ether mixture, and recrystallisation from 90% ethanol, to which several drops of hydrochloric acid had been added to prevent dissociation.

5-(8-*Hydroxy*-5-*quinolylmethyl*)-8-*hydroxy*-1-*methylquinolinium chloride* (*I in Table I*)
(*alternate method*)

A solution of 0·005 mole of 5-hydroxymethyl-8-hydroxy-1-methyl-quinolinium methosulphate (1·5 g) (XIV) and 0·01 mole of 8-quinolinol (1·5 g) in 10 ml of glacial acetic acid was prepared and 6 ml of concentrated sulphuric acid added dropwise. The mixture was allowed to stand at room temperature for 2 days, then heated at 60° for 2 hr. The mixture was poured over ice and neutralised with 20% sodium hydroxide and steam distilled. The pH of the remaining aqueous solution was adjusted to approximately 8·5 and the solution extracted with benzyl or amyl alcohol. An equal volume of ether is added to the combined alcoholic extracts and the resulting solution extracted with $0{\cdot}1M$ hydrochloric acid. This acidic extract was treated with ether to remove the remaining alcohol and evaporated to yield 0·3 g (15%) of I, melting at 319–322° (dec.).

Determination of Spectra and Ionisation Constants

Ultraviolet and visible spectra were recorded with a Beckman DK-2 Spectrophotometer using 1·004-cm matched silica cells for most measurements and 10-cm cells for very dilute solutions. Visible spectra as a function of pH for a large number of equimolar solutions of I were recorded in order to calculate the ionisation constants by standard procedures.[7]

Distribution coefficients for I between an aqueous buffer and chloroform or benzyl alcohol were estimated by recording the spectrum of the buffered solution (pH 8) before and after extraction of a known volume of solution with a known volume of the solvent. The ratio of absorbance at a given wavelength is the fraction of reagent remaining in the aqueous phase. These measurements were only approximate, but indicated coefficients of 2 and 46 for I extracted into chloroform and benzyl alcohol, respectively.

Infrared spectra were recorded on potassium bromide pellets using a Baird AB-2 spectrophotometer. Spectra of I-IV were very similar showing broad absorption in the 3-μ region for the bonded hydroxyl as well as broad absorption from about 3·2 to 5 μ indicative of quaternary nitrogen. The presence of the methyl group on the carbon adjacent to methylated nitrogen in II and IV apparently gave a double maximum at 6·17 and 6·23 μ, while the other two compounds (I and III) had only a single peak at 6·20 μ. Other bands were not assigned.

Formation of Chelates

Qualitative tests at pH 5 and 9 were run in accordance with previous procedures.[2] Results are described before *Experimental.*

A number of chelates of I with metals were precipitated at pH 9, filtered, washed, dried and weighed. Analysis of these for metal content by ashing to the corresponding metal oxide gave the following results:

Cu^{II}—Calcd. for $Cu(C_{20}H_{15}N_2O_2)_2{\cdot}2H_2O$: Cu, 8·7; found: Cu, 8·7.
Fe^{III}—Calcd. for $Fe(C_{20}H_{15}N_2O_2)_3$: Fe, 5·6; found: Fe, 5·7.
Zn^{II}—Calcd. for $Zn(C_{20}H_{15}N_2O_2)_2$: Zn, 9·4; found: Zn, 9·4.
Al^{III}—Calcd. for $Al(C_{20}H_{15}N_2O_2)_3$: Al, 2·8; found: Al, 3·1.

Zusammenfassung—Die in der Überschrift genannten Verbindungen sowie verwandte Substanzen wurden dargestellt, charakterisiert und als solvatochrome chelatbildende Reagentien geprüft. Diese Reagentien zeigen große Farbänderungen je nach Lösungsmittel und die Chelate sind ebenfalls solvatochrom, obwohl sie in den meisten gebräuchlichen Lösungsmitteln unlöslich sind. Reagentien mit einer 2-Methylgruppe neben dem chelatbildenden Zentrum fällen kein Aluminium; dieser Effekt kann als Farbreaktion auf Aluminium verwendet werden.

Résumé—On a préparé, caractérisé, et essayé les composés du titre et des substances apparentées comme agents chélatants donnant des solvats colorés. Ces réactifs présentent d'importantes variations de couleur en fonction du solvant, et les chélates, quoique insolubles dans les solvants les plus usuels, sont également "solvatochromes." Les réactifs qui ont un groupement 2-méthyl adjacent au centre chélatant ne précipitent pas l'aluminium, et ce fait peut être mis à profit pour un essai coloré de l'aluminium.

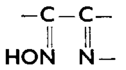
SHORT COMMUNICATIONS

Bisbiacetylmonoxime-ethylenedi-imine and bisbiacetylmonoxime-*o*-phenylenedi-imine as new gravimetric reagents for nickel and palladium

(*Received* 14 *March* 1963. *Accepted* 19 *November* 1963)

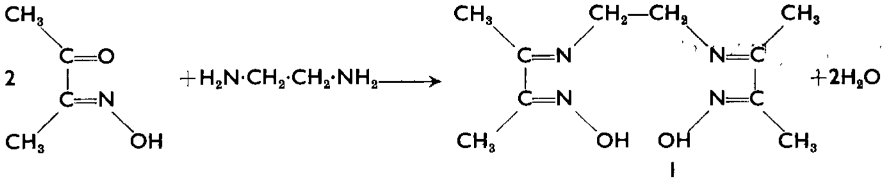
Vicinal diketone dioximes are among the most important organic reagents used in inorganic analysis. Dimethylglyoxime was the first dioxime to be used, as a reagent for nickel and palladium by Tschugaeff,[1] and since then a large number of dioximes have been prepared and tested as analytical reagents.[2-7]

It has been well established that the tautomeric form of the oximes (nitrone form) is responsible for the formation of metal complexes[8] and that the metal involved forms four nitrogen-metal bonds in the dioxime complex. Pfeiffer[8] has shown that if one of the oxime groups is replaced by the imino or methyl-imino group, complex formation occurs in the same fashion. Certain other reagents giving rise to a five-membered chelate ring with the nickel ion and having two co-ordinating nitrogen atoms have a highly selective action towards nickel, the group responsible for the formation of such complexes being

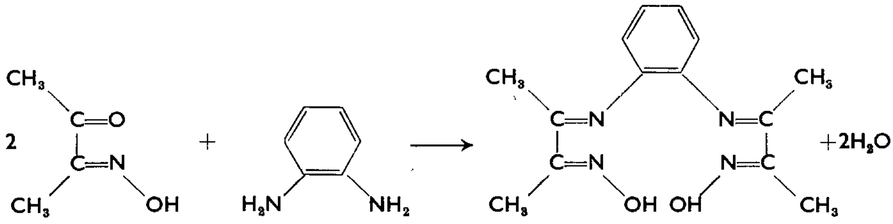


$$\begin{array}{c}-\mathrm{C}-\mathrm{C}-\\ \|\qquad\| \\ \mathrm{HON}\quad\mathrm{N}-\end{array}$$

A possibility exists of condensing diketone monoximes, such as biacetylmonoxime, with certain diamines, such as ethylenediamine and *o*-phenylenediamine, giving rise to the corresponding di-imines.



I



II

These compounds should have two salt-forming and two co-ordinating nitrogen atoms and give rise to tetradentate ligands.

The above possibility has now been verified experimentally and the new reagents, bisbiacetylmonoxime-ethylenedi-imine(I) and bisbiacetylmonoxime-*o*-phenylenedi-imine(II), form precipitates with nickel and palladium ions in which the metal and the reagent are present in the ratio of 1:1. As with other dioximes, such precipitates can be used for the gravimetric determination of these metal ions.

EXPERIMENTAL

Synthesis of the reagents

Ten g of biacetylmonoxime[9] were dissolved in 100 ml of water, 3·5 g of ethylenediamine or 5 g of *o*-phenylenediamine were added and the mixture was refluxed for about 1 hr. On cooling in ice, colourless crystals separated in the former case and pale yellow crystals in the latter case. Both compounds were recrystallised from ethanol:—

Compound I: m.p. 242° (with decomposition); 23·8% of N found, $C_{10}H_{18}O_2N_4$ requires 24·8% of N.

Compound II: m.p. 179°; 20·0% of N found, $C_{14}H_{18}O_2N_4$ requires 20·4% of N.

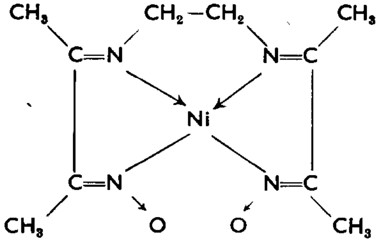
Gravimetric determination of nickel and palladium with the proposed reagents

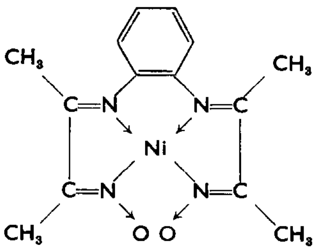
Reagents. One percent solutions of the reagents (I and II) were prepared in aqueous ethanol. A nickel solution was prepared by dissolving 19·735 g of AnalaR ammonium nickel sulphate in 1 litre of water, and a palladium solution by dissolving 1 g of palladium chloride in 500 ml of water. The strengths of the nickel and palladium solutions were checked gravimetrically using dimethylglyoxime.[2]

Procedures. To an aliquot of the nickel solution containing hydrochloric acid an excess of the reagent (I or II) was added, followed by aqueous ammonia till the solution became slightly ammoniacal. The red precipitate of the nickel complex obtained with both reagents was filtered using sintered glass crucibles and dried at 110° for 1 hour.

In the case of palladium a yellow precipitate was formed with both reagents in the presence of hydrochloric acid and it was determined in a similar way to that with the usual dioximes.[2]

By analogy with the dioxime complexes of nickel and palladium, the following structures have been assigned to the complexes with I and II:





Some typical results of determinations with the new reagents are given in Table I. Compound II has a more favourable conversion factor than dimethylglyoxime.

TABLE I

Determination of Nickel

	Ppt., *mg*	Ni, *mg* Found	Ni, *mg* Taken	Error, %
Compound I	211·7	43·95	43·87	0·18
	175·5	36·43	36·35	0·22
Compound II	177·4	31·49	31·42	0·23
	185·5	32·92	32·90	0·10

Determination of Palladium

	Ppt., *mg*	Pd, *mg* Found	Pd, *mg* Taken	Error, %
Compound I	205·8	76·26	76·18	0·10
	185·9	59·99	60·12	0·21
Compound II	223·0	62·84	62·95	0·18
	212·5	59·87	59·75	0·20

TABLE II

Metal ion	Mole ratio of Ni:other metal	Masking agent	Remarks
Fe^{II}	1:1	Acetate	Any Fe^{III} first reduced
Fe^{III}	1:1	Tartrate	Any Fe^{II} first oxidised
Co^{II}	1:1	Cyanide	—
Cu^{II}	1:1	Acetate	—
Ca^{II}, Mg^{II}	1:2	—	—
Zn^{II}	1:2	Acetate	—
Bi^{III}	1:0·5	Unsatisfactory	Prior separation necessary

Effect of foreign ions. Although the proposed reagents are highly selective for nickel, some metals interfere in its quantitative determination. These should either be removed by a prior separation or masked by suitable agents (see Table II). Because the precipitation of palladium takes place in an acidic medium, most of the common metals do not interfere.

Summary—The condensation products of diketone monoximes with diamines have been shown to form precipitates with nickel which contain metal and reagent in the ratio 1:1, and can be used for the gravimetric determination of nickel.

Zusammenfassussung—Es ist gezeignet worden, dass die aus Diketonmonoximen und Diaminen entstehenden Kondensationsprodukte mit Nickel Niederschläge bilden, welche Metall und Reagens in Verhältnis 1:1 enthalten. Diese können zur gravimetrische Nickelbestimmung dienen.

Résumé—Les monoximes de dicétones réagissent avec les diamines en produisant des composées qui donnent avec le nickel des complexes dont la composition metal:nickel égal est à 1:1. Ces complexes peuvent être utilisées pour le dosage du nickel.

Amperometric determination of lanthanum as molybdate

(*Received* 19 *April* 1963. *Accepted* 25 *November* 1963)

IN an earlier publication[1] the authors studied the reaction of lanthanum nitrate with sodium molybdate and some of its analytical applications by e.m.f. measurements. The present investigation was undertaken with a view to substantiating the earlier results and to studying the possibility of developing the reaction as an analytical method for the determination of lanthanum.

TABLE II

Metal ion	Mole ratio of Ni: other metal	Masking agent	Remarks
Fe^{II}	1:1	Acetate	Any Fe^{III} first reduced
Fe^{III}	1:1	Tartrate	Any Fe^{II} first oxidised
Co^{II}	1:1	Cyanide	—
Cu^{II}	1:1	Acetate	—
Ca^{II}, Mg^{II}	1:2	—	—
Zn^{II}	1:2	Acetate	—
Bi^{III}	1:0·5	Unsatisfactory	Prior separation necessary

Effect of foreign ions. Although the proposed reagents are highly selective for nickel, some metals interfere in its quantitative determination. These should either be removed by a prior separation or masked by suitable agents (see Table II). Because the precipitation of palladium takes place in an acidic medium, most of the common metals do not interfere.

Summary—The condensation products of diketone monoximes with diamines have been shown to form precipitates with nickel which contain metal and reagent in the ratio 1:1, and can be used for the gravimetric determination of nickel.

Zusammenfassussung—Es ist gezeignet worden, dass die aus Diketonmonoximen und Diaminen entstehenden Kondensationsprodukte mit Nickel Niederschläge bilden, welche Metall und Reagens in Verhältnis 1:1 enthalten. Diese können zur gravimetrische Nickelbestimmung dienen.

Résumé—Les monoximes de dicétones réagissent avec les diamines en produisant des composées qui donnent avec le nickel des complexes dont la composition metal: nickel égal est à 1:1. Ces complexes peuvent être utilisées pour le dosage du nickel.

Amperometric determination of lanthanum as molybdate

(*Received* 19 *April* 1963. *Accepted* 25 *November* 1963)

IN an earlier publication[1] the authors studied the reaction of lanthanum nitrate with sodium molybdate and some of its analytical applications by e.m.f. measurements. The present investigation was undertaken with a view to substantiating the earlier results and to studying the possibility of developing the reaction as an analytical method for the determination of lanthanum.

EXPERIMENTAL

Reagents

Merck's guaranteed extra pure lanthanum nitrate and sodium molybdate were used and their solutions prepared in air-free conductivity water. The lanthanum solution was standardised potentiometrically as oxalate[2] and the molybdate solution as the 8-hydroxyquinoline complex.[3] The pH of the lanthanum and molybdate solutions, measured by means of a glass electrode, was 5·3 and 7·4, respectively.

Apparatus

A manual polarograph with scalamp galvanometer as a current recorder was used for the amperometric titrations; the dropping mercury cathode was used in conjunction with a saturated calomel electrode connected to the electrolysis cell by a low resistance salt bridge. The drop time in general was 3–3·5 sec. Both direct and reverse amperometric titrations were carried out at an applied potential of $-1·5$ V (*vs.* S.C.E.). At this potential the lanthanum ion yields a diffusion current proportional to its concentration, while the molybdate ion does not produce any wave in neutral or alkaline medium except the residual current of the sodium ion. Twenty ml of either lanthanum or molybdate solution containing 0·01% of gelatine were taken in the electrolysis cell and the dissolved oxygen removed by bubbling nitrogen through the solution for 10–15 min. After each addition of the titrant, the galvanometer deflection was read and the corresponding current calculated (corrected for the dilution effect[4]), then plotted against the volume of titrant added (Figs. 1 and 2). The titrations were also performed in the presence of ethanol. The presence of an indifferent electrolyte was not found necessary because the sodium nitrate formed during the reaction was quite sufficient to eliminate the effect of migration current. The end-point was obtained graphically making allowance for the volume change during the titration. The results are recorded in Table I.

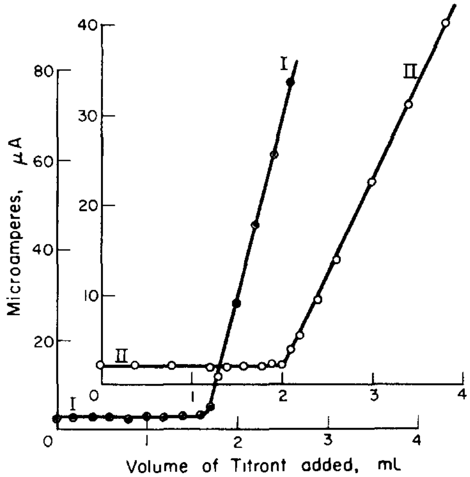

FIG. 1.—Direct amperometric titrations at an applied potential of $-1·5$ V (*vs.* S.C.E.):
I—0·1000M $La(NO_3)_3$ added to 20·0 ml of 0·0125M Na_2MoO_4,
II—0·0333M $La(NO_3)_3$ added to 20·0 ml of 0·0050M Na_2MoO_4.

TABLE I.—AMPEROMETRIC DETERMINATION OF LANTHANUM BY DIRECT AND REVERSE METHODS AT AN APPLIED POTENTIAL OF $-1·5$ V (*vs.* S.C.E.)

Direct titration			Reverse titration		
Lanthanum			Lanthanum		
Present, *g/litre*	Found, *g/litre*	Error, %	Present, *g/litre*	Found, *g/litre*	Error, %
13·900	13·900	0	0·695	0·695	0
4·633	4·5766	1·22	0·278	0·2795	0·54
3·089	3·0482	1·33	0·1853	0·1824	1·56

DISCUSSION

Figs. 1 and 2 represent direct and reverse amperometric titrations between lanthanum nitrate and sodium molybdate in an aqueous medium in the absence of any supporting electrolyte. In the direct titrations (Fig. 1) when lanthanum nitrate is the 'titrant,' at an applied potential of $-1{\cdot}5$ V molybdate ions do not produce any measurable diffusion current and hence no change in the value of current is observed on the addition of the lanthanum salt till the stoichiometric end-point, where a molecular ratio for $La^{3+}:MoO_4^{2-}$ of 2:3 is reached, after which the diffusion current from the lanthanum ions increases with the addition of the latter.

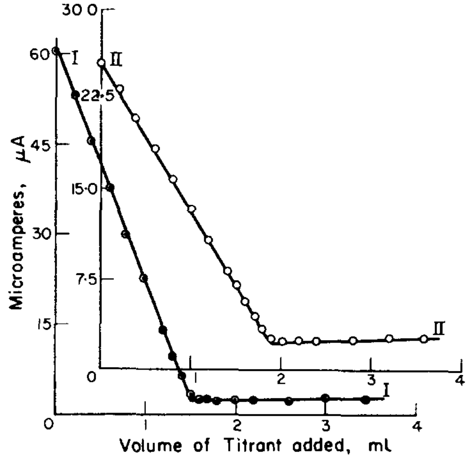

FIG. 2.—Reverse amperometric titrations at an applied potential of $-1{\cdot}5$ V (*vs.* S.C.E.):
I—0·1000*M* Na_2MoO_4 added to 20·0 ml of 0·0050*M* $La(NO_3)_3$,
II—0·0333*M* Na_2MoO_4 added to 20·0 ml of 0·0020*M* $La(NO_3)_3$.

In the reverse titrations (Fig. 2), addition of the molybdate solution causes a decrease in diffusion current which is proportional to the decrease in the concentration of lanthanum ions. Beyond the end-point when the lanthanum ion concentration becomes zero, the current almost remains constant. The amperometric titration curves indicate a sharp break at the point where the molecular ratio of $La^{3+}:MoO_4^{2-}$ is 2:3, corresponding to the formation and precipitation of normal lanthanum molybdate, $La_2O_3{\cdot}3MoO_3$, at pH 5–6 (this pH results from the reactants themselves—see *Experimental*). The accuracy and reproducibility of the titrations has been found to be excellent, even at low concentrations of lanthanum salt ($1 \times 10^{-3}M$). The presence of ethanol improves the end-point slightly because it reduces the solubility of the precipitated compound.

The quantitative precipitation of lanthanum as molybdate at pH 5–6 can be used for the amperometric determination of this metal at an applied potential of $-1{\cdot}5$ V (*vs.* S.C.E.). The method is simple, rapid, accurate and permits the determination of small quantities of lanthanum. Cations which form precipitates with alkali molybdate, *e.g.*, silver, cadmium, $cerium^{III}$, $thorium^{IV}$, $mercury^{I}$ and $mercury^{II}$, and anions which react with lanthanum, *e.g.*, vanadate, tungstate and chromate, interfere and must be absent. The formation of normal lanthanum molybdate as obtained from electrometric results[1] has now been confirmed by amperometric titrations.

Summary—The reaction between lanthanum and molybdate ions has been followed by means of direct and reverse amperometric titration in aqueous and aqueous-alcoholic media at an applied potential of $-1{\cdot}5$ V (*vs.* S.C.E.). The amperometric end-point obtained from the sharp break in the titration curves occurs when the molecular ratio of $La^{3+}:MoO_4^{2-}$ is 2:3 and corresponds to the formation and precipitation of normal lanthanum molybdate, $La_2O_3.3MoO_3$, at pH 5–6. Amperometric titrations yield very accurate and reproducible results and offer a simple and rapid method for the determination of lanthanum as molybdate even at low concentrations ($1 \times 10^{-3}M$ lanthanum nitrate).

Zusammenfassung—Die Reaktion zwischen Lanthan und Molybdat wurde mittels direkter und umgekehrter amperometrischer Titration in wäßrigen und wäßrig-alkoholischen Medien verfolgt. Ein Potential von −1,5 V gegen die gesättigte Kalomelelektrode wurde angelegt. Der als scharfer Knick in der Titrationskurve sichtbare amperometrische Endpunkt liegt beim Molverhältnis $La^{3+}:MoO_4^{2-} = 2:3$, entsprechend der Bildung und Ausfällung von normalem Lanthanmolybdat $La_2O_3.3MoO_3$ bei pH 5–6. Die apperometrische Titration liefert sehr genaue und reproduzierbare Ergebnisse und bietet eine einfache und schnelle Methode zur Bestimmung von Lanthan als Molybdat selbst bei niedrigen Konzentrationen ($1 \cdot 10^{-3}$ M Lanthannitrat).

Résumé—On a suivi la réaction entre les ions lanthane et molybdate au moyen de dosages ampérométriques direct et inverse en milieux aqueux et hydroalcoolique, à u potentiel appliqué de −1.5 V (par rapport à une électrode de référence). Le point équivalent ampérométrique, obtenu à partir de la brisure nette des courbes de dosage, apparaît lorsque le rapport moléculaire $La^{3+}:MoO_4^{2-}$ est 2:3 et correspond à la formation et à la précipitation du molybdate de lanthane normal, La_2O_3, $3MoO_3$, à pH 5–6. Les titrages ampérométriques donnent des résultats très précis et reproductibles et offrent une méthode simple et rapide de dosage du lanthane à l'état de molybdate, même à de faibles concentrations (1×10^{-3} M de nitrate de lanthane).

Phase titrations—IV:* New applications including the assay of water in pyridine

(*Received* 7 *May* 1963. *Accepted* 19 *June* 1963)

Recently Barreto and Barreto have described a convenient spectrophotometric method for the assay of water in organic solvents.[1] It is based on the development of a purple colour when an organic solvent containing a small amount of water is added to a solution of chloranilic acid in absolute ethanol.

The authors point out that the new method cannot be used for the assay of water in nitrogen-containing solvents, such as pyridine, because they react with chloranilic acid. We therefore suggest the use of phase titrations to supplement the chloranilic acid method, because these are applicable to problems to which the latter method is not. The assay of water in pyridine is given below as an example of the application of phase titration to nitrogen-containing solvents.

The theory, optimum titration conditions and pertinent references are given in the previous papers in this series,[2,3]

Results for 18 new binary solutions of organic solvents which have been analysed by phase titration with water are also included.

EXPERIMENTAL

Reagents

Reagent-grade *methanol*, *acetic acid* (96%) and *acetone*, were obtained from E. Merck A.G., Darmstadt. Reagent-grade *dioxan* and 1,2-*dibromoethane* were obtained from Fischer, Fair Lawn, New Jersey, U.S.A. *Bromobenzene* was a Fischer purified laboratory chemical. *Chloroform puriss.*, was obtained from Hoechst, Frankfurt (M.). Chemically pure *pyridine* and *isopropanol* of unspecified grade were obtained from Riedel De Haën A.G., Seelze-Hannover. *Ethanol* (96·6%) was obtained from Tekel Idaresi, Istanbul. *Distilled water* was used throughout.

Procedure

Six known binary solutions of pyridine and water were titrated with chloroform to obtain a calibration curve of the titre as a function of the volume per cent of the water in pyridine. Synthetic unknown solutions were analysed by comparison with it. Details of the procedure are given in the first paper of this series.[3]

RESULTS AND DISCUSSION

Preliminary tests were made on a number of solvents to determine which would be the best titrant. Chloroform was selected and proved to be excellent although benzene, nitrobenzene and dichloroethane were also promising; bromobenzene, carbon tetrachloride, acetophenone and cyclohexane were not.

A typical end-point (20% water–80% pyridine) was investigated with a Zeiss PMQ II spectrophotometer. Plotting absorbancy, *i.e.*, turbidity, as a function of ml of titrant gave the curve shown in Fig. 1. The earliest phase separation is not easy to observe and takes place before the solution becomes definitely turbid. Hence all solutions were titrated beyond the point of first phase separation to a point at which the increase in turbidity is greater and correspondingly more reproducible.

Eighteen samples, containing 10–40% of water in pyridine were titrated with chloroform. The average error was 0·07 absolute %; the maximum error was 0·2 absolute %. The end-point was good to excellent throughout the optimum titration range of 8–45% water in pyridine.

The accuracy is considerably better than with the chloranilic acid method (relative mean deviation 1·5%, maximum deviation 2·5%) but the present method suffers from the drawback that a suitable titrant must be found for each new system. A less suitable titrant would have given a less distinct end-point and a corresponding reduction in accuracy. The criteria for suitable titrants have been discussed.[3]

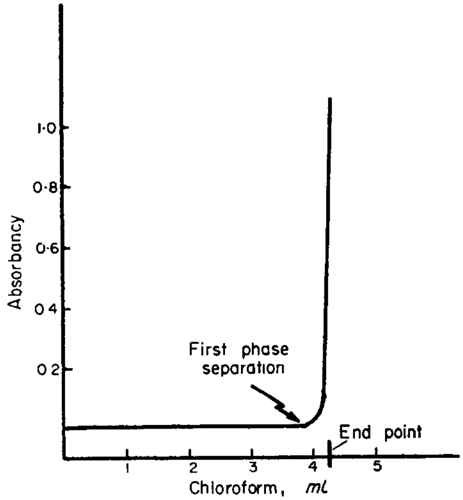

Fig. 1.—Absorbancy at 500 mμ, resulting from turbidity, of a solution of water in pyridine titrated with chloroform.

The assay of water in solvents by phase titration is based on the same principle as the well known cloud-point method.[4,5] In the cloud-point method, a standard amount of an insoluble component is added to a binary mixture of water and some solvent. The temperature at which opalescence appears is then compared with a calibration curve of the temperature of opalescence as a function of composition. We believe that phase titration has the advantage over the cloud-point technique in simplicity and speed because it is easier to carry out a titration than to control and adjust the temperature of a system.

If only a few samples are to be analysed, however, the cloud-point technique has the advantage that the calibration curve need not be made anew, provided that the chemical composition of the insoluble component can be reproduced exactly.[5] Reported results for the cloud-point technique show greater accuracy (0·01–0·02% error) than those for phase titration.

TABLE I.—RESULTS FOR THE TITRATION OF 18 HOMOGENEOUS BINARY SYSTEMS WITH WATER

Sample	Optimum range, %	Number of titrations	Average absolute error, %
Bromobenzene-methanol	2–25	12	0·09
Bromobenzene-ethanol	3–33	12	0·04
Bromobenzene-isopropanol	7–45	12	0·12
Bromobenzene-dioxan	2–20	12	0·07
Bromobenzene-acetone	2–25	12	0·05
Bromobenzene-acetic acid	2–23	10	0·10
Chloroform-methanol	8–60	15	0·13
Chloroform-ethanol	11–50	12	0·12
Chloroform-isopropanol	12–40	12	0·06
Chloroform-dioxan	4–20	9	0·16
Chloroform-acetone	4–30	12	0·09
Chloroform-acetic acid	10–50	11	0·13
1,2-Dibromoethane-methanol	2–25	12	0·06
1,2-Dibromoethane-ethanol	2–20	12	0·07
1,2-Dibromoethane-isopropanol	5–25	12	0·09
1,2-Dibromoethane-dioxan	2–15	12	0·06
1,2-Dibromoethane-acetone	3–20	12	0·04
1,2-Dibromoethane-acetic acid	3–25	12	0·13

The end-point was indicated by the appearance of a distinct permanent turbidity. Titrations and determination of the calibration curve were carried out on the same day.

Table I shows the results for the phase titration of 18 new binary solutions of organic solvents using water as the titrant. The optimum titration range varies slightly with ambient temperature. Binary solutions in which dibromoethane was one component showed good end-points; those with bromobenzene showed excellent end-points; those with chloroform were good in the middle but fair to poor at the extreme ends of the optimum titration range. The end-point appears somewhat more slowly (0·5-min pause) in isopropanol solutions, probably because of the relatively high viscosity of isopropanol.

Acknowledgement—The authors gratefully acknowledge the assistance of the Society of Sigma Xi through a grant in aid of research.

Summary—The assay of water in organic solvents by means of phase titration has been discussed in relation to the chloranilic acid method of Barreto and Barreto (*Analyt. Chim. Acta*, 1962, **26**, 494) and the older cloud-point technique. Results are given for the titration of water-pyridine solutions with chloroform, as representative of the phase titration of a nitrogen-containing compound to which the chloranilic acid method is inapplicable. In addition, results are given for the phase titration of 18 new binary solutions using water as the titrant. They are bromobenzene, chloroform and 1,2-dibromoethane, each in binary solution with methanol, ethanol, isopropanol, dioxan, acetone and acetic acid.

Zusammenfassung—Die Bestimmung von Wasser in organischen Lösungsnitteln durch Phasentitration wird im Vergleich zur Chloranilsäure-methode von Baretto und Baretto und der älteren Trübungsmethode diskutiert. Daten werden angegeben für die Titration von Wasser-Pyridin-Mischungen mit Chloroform als Beispiel für die Phasentitration einer stickstoffhaltigen Verbindung, auf die die Chloranilsäuremethode nicht anwendbar ist. Ferner werden Ergebnisse von Phasentitrationen mit Wasser als Titrant an 18 neuen binären Mischungen angegeben. Es handelt sich um Brombenzol, Chloroform und 1,2-Dibromäthan in Mischungen mit Methanol, Äthanol, Isopropanol, Dioxan, Aceton und Essigsäure.

Résumé—La détermination de l'eau dans les solvants organiques au moyen du dosage de phase a été discutée en relation avec la méthode à l'acide chloranilique de Baretto et Baretto et la méthode ancienne du point de trouble. Les résultats ont été donnés pour des solutions eau-pyridine avec le chloroforme comme exemple de dosage de phase des composés contenant de l'azote, et pour lesquels la méthode à l'acide chloranilique est inaplicable. De plus, les résultats concernant le dosage de phase de 18 nouvelles solutions binaires utilisant l'eau comme agent titrant sont données; ce sont: le bromobenzène, le chloroforme, le dibromo-1,2-éthane en binaire respectivement avec le méthanol, l'éthanol, l'isopropanol, le dioxane, l'acétone et l'acide acétique.

A simple method for the determination of carbon in uranium and plutonium carbides

(*Received* 8 *October* 1963. *Accepted* 7 *November* 1963)

INTRODUCTION

On account of their high thermal conductivity, metal density and melting point, and temperature stability, carbides of uranium and plutonium have been considered as potential fuels for nuclear reactors. It is often necessary to find the carbon content of these carbides; this may be present as both combined carbon and free carbon. The total carbon is determined by combustion at a high temperature in a stream of oxygen, and the carbon dioxide thus evolved is measured either manometrically,[1–3] gravimetrically by absorption in soda asbestos,[4] conductometrically[5,6] or titrimetrically by absorption in standard barium hydroxide solution.[7,8] The free carbon is separated from the sample by dissolving it in hydrochloric acid; the insoluble part, being free carbon, is determined in a similar way.[4,8]

---

* Present address: Chemistry Department, Long Island University, Brooklyn 1, New York, U.S.A.

The present paper describes a simple method in which both combined and free carbon are determined in the same sample by taking advantage of their combustion at different temperatures.

PREPARATION OF THE CARBIDES

Well-powdered mixtures of U_3O_8 and graphite were heated in an atmosphere of argon in a high-current graphite-resistor furnace to 1600° for the formation of mainly uranium monocarbide, and to 2400° for the formation of mainly uranium dicarbide. Carbides of plutonium were likewise prepared by heating, at 2400°, a well-powdered mixture of PuO_2 and graphite. The carbide pellets were powdered in an argon atmosphere, and were stored dry in ground-glass stoppered tubes filled with argon.

THERMOGRAVIMETRIC ANALYSIS

Ten mg of the carbide under investigation were loaded on to the pan of a silica spring thermobalance,[9] and the weight changes in air were observed as a function of temperature; the rate of heating of the furnace being 5°/min. Uranium carbides started to decompose at 250°; for plutonium carbides the temperature was 300° (Fig. 1). The weight of the sample increased, showing the formation of oxide from the carbide. There was no change in weight for either carbide between 500 and 600°, which showed that the carbides are oxidised below 500°. Above 600° there was a loss of weight from the oxidation of free carbon; and at 800° there was complete combustion of carbon, leaving the metal oxides. This behaviour clearly showed the possibility of determining combined carbon in a combustion tube heated at 500°, and free carbon by heating the same sample above 800°, in each case determining the carbon dioxide evolved.

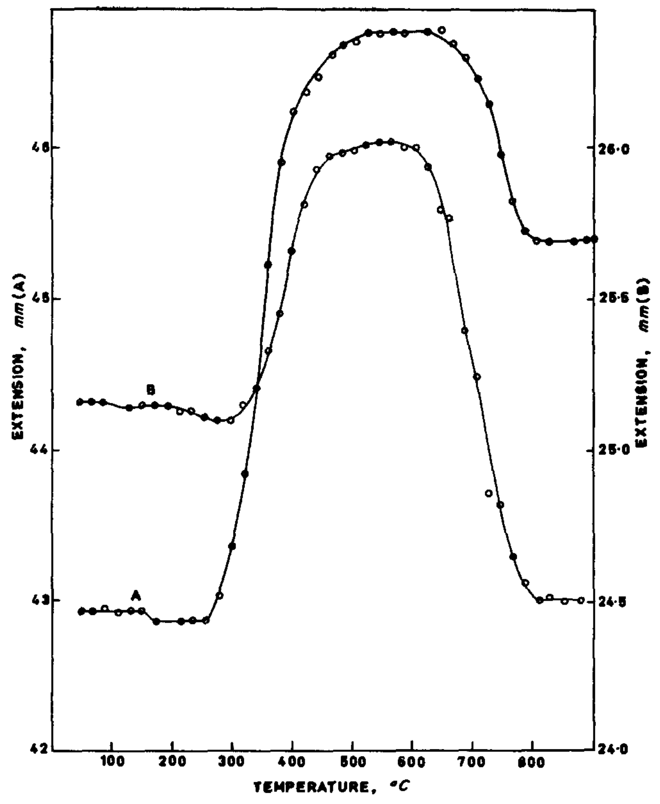

FIG. 1

DETERMINATION OF CARBON

The carbide sample (2–10 mg), weighed in a platinum microcombustion boat, was placed in a quartz combustion tube and heated at 500° for 45 min, passing a current of oxygen, purified by a

U-tube packed with "Carbosorb" (soda asbestos) and Anhydrone, through the combustion tube at the rate of a few bubbles per sec as counted by a sulphuric acid bubbler. The liberated carbon dioxide was absorbed in two conical flasks, each containing 10 ml of ~0·05*N* barium hydroxide solution. The carbon dioxide was determined by titrating the excess barium hydroxide against standard hydrochloric acid solution from an Agla microsyringe, using phenolphthalein as indicator. The same sample was thereafter heated at 900° for 45 min, and the liberated carbon dioxide was again determined. All titrations were performed in a nitrogen atmosphere to prevent absorption of any atmospheric carbon dioxide. The results are given in Tables I and II.

7·420			9·12

* Based on the total weight of sample.

COMPARISON WITH CONVENTIONAL METHOD

To test the reliability of this method, samples of uranium and plutonium carbides were analysed by the new and the conventional methods, and the results were compared. In the conventional method, the weighed sample was heated with 5*M* hydrochloric acid for 2 hr to decompose the carbide. The free carbon, which remains unaffected, was centrifuged, washed thoroughly with water, alcohol, acetone and ether to remove the solid and liquid hydrocarbons, and determined as described earlier. The results are given in Tables III and IV.

3·760	9·00	8·04	
2·25			8·27
2·05			8·20

* Based on the total weight of the sample.

CONCLUSION

The conventional method for the determination of combined carbon and free carbon requires two samples, and the value for combined carbon is obtained by taking the difference between the total carbon present and the free carbon determined separately. The error in this method is, therefore, likely to be greater. In the present method, both combined and free carbon are determined separately in the same sample, thus saving time and reducing the error.

Summary—A simple method for the determination of combined and free carbon in the carbides of uranium and plutonium is based on the examination of the oxidation of carbide and free carbon thermogravimetrically. The combined carbon (carbide) oxidises to carbon dioxide in air below 500° while the free carbon oxidises above 600°. This allows the determination of both combined and free carbon in a single sample, using a furnace tube and a conventional method for carbon dioxide.

Zusammenfassung—Eine einfache Methode zur Bestimmung von gebundenem und freiem Kohlenstoff in den Carbiden von Uran und Plutonium wird beschrieben, die auf der thermogravimetrischen Untersuchung der Oxydation von Carbid und Kohlenstoff beruht. In Carbiden gebundener Kohlenstoff verbrennt an der Luft unter 500°C zu Kohlendioxyd, der freie Kohlenstoff erst über 600°C. Dies erlaubt die Bestimmung von gebundenem und freiem Kohlenstoff in einer Probe in einem Röhrenofen mit einer gebräuchlichen Bestimmungsmethode für Kohlendioxyd.

Résumé—On décrit une méthode simple pour le dosage du carbone combiné et libre dans les carbures d'uranium et de plutonium, basée sur l'observation de l'oxydation du carbure et du carbone libre au moyen de la méthode thermogravimétrique. Le carbone combiné (carbures) est oxydé à l'air en gaz carbonique en dessous de 500°C cependant que le carbone libre s'oxyde au-dessus de 600°C. Ceci rend possible les dosages du carbone combiné et du carbone libre dans un seul échantillon, par l'emploi d'un four tubulaire et d'une méthode usuelle de dosage du gaz carbonique.

Possibility of automation of potentiometric EDTA titrations

(*Received* 23 *October* 1963. *Accepted* 4 *December* 1963)

In many laboratories automatic and semi-automatic apparatus is in use for the simpler types of titration, *e.g.*, of acids, bases and halides. Because there are also many examples of metal titrations which have to be carried out daily, it was considered worthwhile to investigate the possibilities of automation in this field. Very little has been reported on this subject, so far. Haslam *et al.*[1] described an automatic titration of the hardness of water using an amalgamated silver rod as the indicator electrode. Lacy[2] recently published a photometric titration for the semi-automatic determination of hardness in water.

We have investigated the possibility of automation of the complexometric titration of some 20—mostly common—metals for which well-established titration curves were available from earlier work on manual titrations. These examples include direct and back-titrations—the latter with a copper solution as the titrant—in three different pH ranges that are easy to establish. The work is certainly not exhaustive in the sense that many other possibilities undoubtedly exist.

EXPERIMENTAL

Apparatus

Experiments have been carried out with the aid of the well-known Beckman model K titrator, which could be used without modification. An amalgamated gold wire served as indicator electrode, and a saturated potassium chloride calomel electrode as reference. The amalgamated gold wire was prepared by immersing 3 cm of the top part of a pure gold wire (24 carat, length 10 cm, diameter 1·5 mm) for some min in pure mercury. The electrode had to be cleaned frequently with fine emery paper and re-covered. The calomel electrode was connected with the solution by means of a potassium nitrate/agar bridge. pH values were checked by means of a pH meter, but a good grade of pH paper would have been satisfactory in most cases.

The model K titrator is equipped with an "anticipation circuit" which smooths the approach to the end-point of a titration. The number of titration increments is regulated by a dial, the correct setting of which has to be determined for each kind of titration. This is especially important for electrochemical reactions at the mercury electrode which do not proceed instantaneously.[3]

Reagents

The titrants for direct and back-titrations were 0·01*M* standard solutions of EDTA and of copper nitrate, respectively. The buffers were (a) 10 g of sodium hydroxide with 28 ml of glacial acetic acid diluted to 500 ml with water (acetate buffer), and (b) 8 g of ammonium nitrate with 55 ml of 25% aqueous ammonia diluted to 1 litre with water (ammonium buffer). Nitric acid and potassium hydroxide were used to adjust the pH when necessary. A 0·005*M* solution of mercury-EDTA was prepared by mixing a 0·01*M* solution of mercury$^{\mathrm{II}}$ nitrate with an equal amount of 0·01*M* EDTA and then adjusting to pH 4. All reagents were analytical grade.

Procedure

Titrations were carried out in 250-ml beakers in which 20 ml of an approximately 0·01*M* metal solution† were diluted with water to 100 ml. Four drops of 0·005*M* mercury-EDTA solution were

† Chlorides and sulphates must be absent because they interfere with potentiometric determinations using the mercury electrode.

added and the pH established at the values given in Table I. For the lower pH range this was effected with nitric acid, for the pH range 4 to 6 with 10 to 15 ml of acetate buffer and for the higher range with 10 to 15 ml of the ammonium buffer. The correct end-point was derived from curves obtained by manual potentiometric titrations using the same electrochemical system; the values are given in Table I. The "anticipation" used is also given in the table. In the case of back-titrations (*B* in Table I), an excess of 0·01*M* EDTA was added to the beaker before titration with copper nitrate solution.

RESULTS AND DISCUSSIONS

Table I contains data on the accuracy of the 18 automatic titrations that were investigated. The standard deviations are calculated from seven-fold titrations in pure single metal-ion solutions. The accuracy has been determined at optimum and carefully controlled pH values.

TABLE I.—ACCURACY OF AUTOMATIC EDTA TITRATIONS WITH THE BECKMAN MODEL K TITRATOR

Table II compares the accuracies of automatic titrations with those of manual titrations found in earlier work. In the case of zinc there is only a negligible difference in accuracy; for magnesium the difference is a little larger. The automatic procedure might have been expected to be less accurate,

TABLE II

Metal	Standard deviation, *ml*	
	Automatic	Manual
Zn	0·03	0·02
Mg	0·13	0·035

but the difference actually found is surprisingly small and proves the feasibility of the automatic method. Even in the case of magnesium the relative error is less than 1% when 20 to 25 ml are titrated.

In general it can be said—and this is illustrated by the figures in Table 1—that if the titration curve shows a slight jump, the automatic titration is least accurate. Such curves occur, for instance, when the apparent stability of the metal-EDTA complex to be formed is lower than, say 10^9. At the pH applied this is the case for barium ($K^* = 10^7$), magnesium ($K^* = 10^8$) and strontium ($K^* = 10^8$). Also a curve with a flat top part (*e.g.*, that for thorium) is unfavourable for automatic indication of the end-point. Finally, back-titrations will tend to be somewhat less accurate, because two measurements of volume are necessary.

For work of a routine character, *e.g.*, plant control, it is important to know how far variations in the prescribed titration conditions (dial settings, pH, salt concentration) will affect the accuracy. It has been found that the end-point potential must be set precisely because even small deviations may cause the titration result to be very inaccurate. This is caused by the steep fall or rise of the curves in the region of the equivalence point and their sometimes peculiar shape. This effect can, to a certain extent, be compensated by a high "anticipation", but then titrations become very slow. A low setting of the "anticipation" may lead to overshooting of the end-point and it sometimes renders titration impossible because the apparatus does not stop at all.

It is evident that a lower pH value than prescribed will cause errors because this leads to a lowering of the apparent stability of the metal-EDTA complex concerned, which degrades the titration curves. It has been found that for the medium pH range errors will in the majority of cases not exceed ±0·2 ml of titrant when the pH is maintained between 4·0 and 6·0. Especially for the alkaline range, however, large errors must be expected when the pH deviates only a few tenths from the prescribed value.

The quantity of neutral salt in the titration solution was found not to be very critical. A high concentration leads to a slight shift of the titration curves because of a change in activity coefficients. Titration errors were serious only in the case of the poorest curves. In titrating 100 ml of a 0·002*M* solution of calcium ions to which 5 g of potassium nitrate had been added the result was 6% low (1·21 ml of 0·01*M* EDTA). For many other metals the difference was less than 0·2 ml.

The possibility of applying the automatic technique to samples that contain more than one metal will have to be studied for each individual case. An example is the determination of the hardness of water which essentially is the titration of the sum of calcium and magnesium. In a four-fold automatic titration of the hardness of tap water we found: 15·59, 15·56, 15·68 and 15·52°G.H., respectively. The extreme values differ by only 1%, which is very reasonable.

Summary—Experiments are described which show that many metals can be determined in a simple way with the aid of the Beckman model K automatic titrator. As regards accuracy, the method is in many cases practically on a par with manual titrations.

Zusammenfassung—Es wird experimentell nachgewiesen, dass sich viele Metalle mit Hilfe eines automatischen Titrationsapparates (Beckmann, Modell K) einfach bestimmen lassen. In vielen Fällen ist die erzielte Genauigkeit der bei manuellen Titrationen erreichten praktisch gleich.

Résumé—Des expériences démontrent que nombre de métaux peuvent être dosés d'une manière simple à l'aide de l'appareil de titration automatique Beckman, modèle K. La précision atteinte est en beaucoup de cas équivalente à celle obtenue dans les titrations manuelles

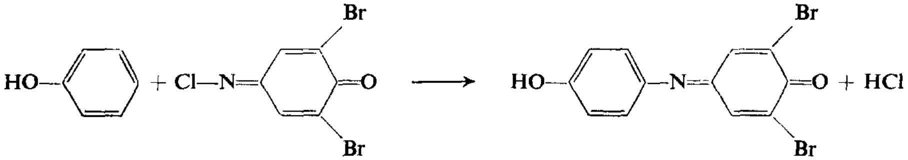
Zur Kenntnis der Gibbs'schen Farbreaktion auf Phenole

(*Eingegangen am* 13 *November* 1963. *Angenommen am* 18 *November* 1963)

DER von Gibbs[1] entdeckte Nachweis von Phenol mit 2,6-Dibrom-*p*-benzochinon-4-chlorimin beruht auf der Kondensation:



wobei durch gleichzeitige oder nachträgliche Alkalisierung (Natronlauge, Natriumcarbonat, Natriumbicarbonat, Ammoniak, Borax oder Pufferlösungen) ein tiefblaues Produkt entsteht. Gemäß obiger Umsetzung sollte die Farbreaktion mit allen Derivaten des Phenols eintreten, die eine freie *p*-Stellung besitzen. Daß dies jedoch nicht ausnahmslos der Fall ist, hat zuerst Bohdanecký[2] bei der Salicylsäure festgestellt, die nicht reagiert. Da auch bei einigen anderen *o*-substituierten Phenolen mit freier *p*-Stellung die Farbreaktion ausbleibt und somit kein allgemeiner Phenolnachweis möglich ist, mußte die Anwendung des Gibbs'schen Reagens in der Tüpfelanalyse auf bestimmte Fälle beschränkt bleiben. In Betracht kommt der Nachweis von bei Erwärmung flüchtigem Phenol, *o*-Kresol, Thymol, Brenzkatechin, Resorcin und Oxin.[3] Des weiteren ermöglicht der empfindliche Nachweis von Phenoldämpfen den tüpfelanalytischen Nachweis solcher Verbindungen, die bei trockener Erhitzung oder durch den Eintritt in chemische Umsetzungen Phenol abspalten.[4] Schließlich ist noch der Nachweis von Vitamin B_6 (Adermin) mittels des Gibbs'schen Reagens zu erwähnen.[5]

Es wurde festgestellt, daß im Gegensatz zur Salicylsäure das Salicylamid die Gibbs'sche Phenolreaktion zeigt. Dieses verschiedene Verhalten ließ es wünschenswert erscheinen, den Einfluß von *o*- und *m*-ständigen Substituenten auf den Eintritt der Gibbs'schen Phenolreaktion zu ermitteln. Diesbezügliche Versuche wurden mit 2%igen Lösungen hierhergehöriger Verbindungen nach folgenden Arbeitsvorschriften durchgeführt:

Test 1: Auf Filtrierpapier wurde je ein Tropfen der Probelösung, enthaltend 1 mg Probe, und ein Tropfen der benzolischen Lösung von 2,6-Dibrom-*p*-benzochinon-4-chlorimin bzw. des entrsprechenden 2,6-Dichlorderivates so aufgebracht, daß die beiden Tropfen sich auf dem Papier überschneiden. Dann wurde das Papier über Ammoniak geräuchert, wobei bei positiven Ausfall die spindelförmige Überlappung der durch die zwei Tropfen auf dem Filtrierpapier entstandenen Kreise gefärbt wurde. Ein Blindversuch wurde mit dem Reagens und dem Lösungsmittel der Probe angestellt.

Test 2: Wie oben, nur wurde nicht über Ammoniak geräuchert, sondern mit Sodalösung angetüpfelt.

Die Überprüfung von neun *m*-substituierten Phenolen mit freier *p*-Stellung (in Tabelle I) hat

TABELLE I

ergeben, daß diese ausnahmslos die Gibbs'sche Farbreaktion zeigen. Abweichungen scheinen demnach lediglich bei *o*-Derivaten zu bestehen, wie folgende Gegenüberstellung in Tabelle II zeigt.

Aus Tabelle I und II geht hervor, daß die Gibbs'sche Farbreaktion bei solchen o-substituierten Phenolen ausbleibt, die im Substituenten ein am C-Atom bzw. N-Atom doppelt gebundenes Sauerstoffatom enthalten. Diese Konstitution ermöglicht eine Chelatisierung des Wasserstoffs der phenolischen Hydroxylgruppe zwischen zwei Sauerstoffatomen, und dies dürfte die Ursache für das Ausbleiben der Reaktion sein, da in diesen Fällen gar keine phenolische Hydroxylgruppe mehr vorliegt:

TABELLE II

Phenole	mit positiver Rk.	mit negativer Rk.
Phenol	blau	Salicylsäure
o-Kresol	blau	Salicylsäuremethylester
Thymol	blau	Salicylsäureisoamylester
o-Phenylphenol	blau	Salicylsäurehydrazid
Brenzkatechin	blau	*o*-Nitrophenol

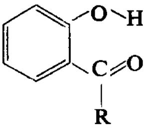
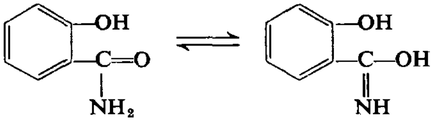
Salicylsäureamid	blau	
Orthoeugenol	blau	
Salicylalanilin	blau	



Der Eintritt der Gibbs'schen Farbreaktion bei Salicylamid und Salicylanilid ist offenbar dadurch su erklären, daß in diesen Fällen der Substituent auch in einer tautomeren Imidform vorliegt, die keinen am Kohlenstoff doppelt gebundenen Sauerstoff enthält:



Die Tatsache, daß Salicylsäurehydrazid die Gibbs'sche Reaktion nicht zeigt, deutet darauf hin, daß bei dieser Verbindung eine dem Salicylamid analoge Tautomerie nicht vorliegt, zumindest nicht in dem für die Kondensation erforderlichem Ausmaß.

Daß doppelt gebundener Stickstoff die phenolische OH-Gruppe gegenüber der Gibbs'schen Reaktion nicht maskiert, zeigt die Reaktionsfähigkeit von Salicylaldoxim, Salicylalhydrazon und 8-Hydroxychinolin. Im Einklang damit kann die Reaktionsunfähigkeit von Salicylaldehyd durch Einwirkung von Ammoniakdampf aufgehoben werden, weil hierbei Salicylaldimin entsteht, das kein zur Chelatisierung erforderliches Sauerstoffatom besitzt.

Die Tatsache, daß bei Phenolen mit zur Chelatbildung befähigten Substituenten in *o*-Stellung die Gibbs'sche Farbreaktion ausbleibt, ist zur Charakterisierung von Phenolen von Bedeutung. Der positive Ausfall der Farbreaktion beweist das Vorliegen von Phenolen mit freier *p*-Stellung ohne o-ständige —CHO,COOH oder —COOR Gruppen. Die Anwesenheit solcher Gruppen ist demnach erwiesen, wenn bei positiven Ausfall anderer Nachweisreaktionen auf Phenole mit freier *p*-Stellung die Gibbs'sche Farbreaktion ausbleibt. Von Interesse ist auch die Anwendung der Gibbs'schen

Reaktion zur Unterscheidung von gewissen isomeren Derivaten des Phenols. Von Phenolcarbonsäuren und deren Estern sowie von Hydroxybenzaldehyd gibt es jeweils drei Isomere, von denen lediglich das *m*-Isomere die Gibbs'sche Reaktion zeigt.

Zusammenfassung—Es wurde der Einfluss von Substituenten auf die Reaktionsfähigkeit von Phenolen gegenüber 2,6-Dibromchinon-4-chlorimin bzw. dessen Chloranalogem untersucht. Es zeigte sich, dass Substituenten in *m*-Stellung wenig Einfluss haben, hingegen in Orthostellung Substituenten mit einer C=O bzw. N=O Gruppe den Eintritt der Reaktion verhindern.

Summary—The influence of substituents on the reactivity of phenols towards 2,6-dibromoquinone-4-chlorimine and its chloro analogue has been investigated. It has been shown that substituents in the *m*-position have little influence, whereas *o*-substituents with a C=O or N=O group prevent the reaction taking place.

Résumé—On a étudie l'influence des substituants sur la réactivité des phénols vis-à-vis de la 2,6-dibromoquinone-4-chlorimine et de son analogue chloré. On a montré que les substituants en méta ont peu d'influence, mais que les substituants en ortho, avec un groupe C = O ou N = O empêchent la réaction.

Use of "dead-stop" indication of the end-point in chelometric titrations

SIR,

For indicating the end-point of the titration of iron^{III} salt with EDTA, we have used the change of current in a system of two stationary Pt-microelectrodes at a constant applied potential (dead-stop indication).* During the titration of iron^{III} in acidic unbuffered medium at pH 1–1·5, the current changes were found to be maximum 0·1 (μA) at an applied potential of 1–1·4v. The nature of the corresponding titration curves depends on the value of the applied potential, as will be discussed later.

Because indication of the end-point in the titration of iron^{III} with EDTA is possible even in a medium of 0·2*M* HCl, the determination is quite selective. Also, the stabilisation of the current after each addition of the titrant is very rapid, in comparison with the same titration carried out under potentiometric control.[1] This titration with two Pt electrodes can be used for the indirect determination of a series of metals by the back-titration of the excess of EDTA with iron^{III} solution. Preliminary results have shown also the possibility of a direct titration of Cu^{II}, Tl^{III} or U^{IV} with EDTA; and in the presence of small amounts of Fe^{III} with some traces of Fe^{II} it is possible to use dead-stop indication for the direct titrimetric determination of metals forming very stable complexes with EDTA (Th, Zr, *etc.*)

Details of this indication, and methods for the determination of some metals will be published in this Journal at a later date.

Rapid chemical analysis of silicate rocks

SIR:

IN recent years, numerous schemes for the rapid chemical analysis of silicate rocks and minerals have been proposed, and some of these are in widespread use throughout the world.

One of the greatest problems in devising such rapid schemes is that of obtaining a clear homogenous solution of the sample from which aliquot portions may be measured for the various determinations. In particular, the preparation of a solution for the colorimetric determination of silica is somewhat troublesome.

It has been found that a clear aqueous solution of most silicate samples may be quickly and conveniently prepared by the following simple procedure. No element likely to cause serious interference in any of the common determinations is added, and it should be possible to adapt existing methods for use with this method of solution. The procedure is as follows:

Weigh 0·1000 g of the 200-mesh sample into a 55-ml flat-bottom platinum dish, and add 0·50 g of anhydrous lithium metaborate ($LiBO_2$). Mix, and heat over a Meker burner (in an oxidising flame) for 5–10 min.

Rapid chemical analysis of silicate rocks

SIR:

IN recent years, numerous schemes for the rapid chemical analysis of silicate rocks and minerals have been proposed, and some of these are in widespread use throughout the world.

One of the greatest problems in devising such rapid schemes is that of obtaining a clear homogenous solution of the sample from which aliquot portions may be measured for the various determinations. In particular, the preparation of a solution for the colorimetric determination of silica is somewhat troublesome.

It has been found that a clear aqueous solution of most silicate samples may be quickly and conveniently prepared by the following simple procedure. No element likely to cause serious interference in any of the common determinations is added, and it should be possible to adapt existing methods for use with this method of solution. The procedure is as follows:

Weigh 0·1000 g of the 200-mesh sample into a 55-ml flat-bottom platinum dish, and add 0·50 g of anhydrous lithium metaborate ($LiBO_2$). Mix, and heat over a Meker burner (in an oxidising flame) for 5–10 min.

After fusion is complete, remove the dish from the flame, and drop it (preferably while still red hot) into 125 ml of 2% v/v nitric acid in a 250-ml beaker. Pour 2% nitric acid into the dish until the latter sinks to the bottom of the beaker, and immediately add a Teflon covered stirring bar. Stir at moderate speed (without heating) until solution is complete. This will take about 10 min.

Transfer to a 200-ml flask, dilute to the mark with water and mix. The solution is now ready for use. Aliquot portions may be removed for the determination of silica, alumina, iron, titania, magnesia and the alkaline earths. Because lithium does not interfere seriously with the flame photometry of sodium and potassium, the alkali metals may also be determined.

The solution may also be used for spectrochemical analysis using spark-solution techniques. If this is intended, internal standard may conveniently be added to the dilute nitric acid before the sample fusion.

Lithium metaborate is an extremely active flux, and readily dissolves most of the minor refractory minerals (chromite, ilmenite, *etc.*) commonly found in silicate rocks. The suggested solution procedure is thus not only very much faster than those using hydrofluoric acid, but much more efficient as well. Hydrofluoric acid mixtures do not adequately attack all of the mineral constituents of rocks. The suggestion that the sample be ground to pass a 200-mesh screen is made because of sampling considerations, and not because the fine grinding is necessary for attack by the flux.

Detailed procedures for rapid silicate analysis based on this and other solution methods are at present being developed in this laboratory.

PRECIPITATION FROM MIXED SOLVENTS—V*

URANIUM 8-HYDROXYQUINOLATE

LESTER C. HOWICK® and TONY RIHS
Department of Chemistry, University of Arkansas, Fayetteville, Arkansas, U.S.A.

(*Received* 21 *June* 1963. *Accepted* 16 *January* 1964)

Summary—The technique of precipitation from homogeneous solutions of mixed solvents has been applied to the case of uranium 8-hydroxyquinolate. Precipitation from a water-acetone solution results in the formation of well-defined crystals of high purity. The separation of uranium from magnesium is easily accomplished and separations from thorium and lead may be achieved in the presence of EDTA.

THE use of 8-hydroxyquinoline as a gravimetric precipitant for uranium offers the advantages of forming a highly insoluble material and yielding a very favourable gravimetric factor. However, the direct addition of the reagent to a solution of uranyl ion results in the formation of a very finely divided material that is difficult to filter and wash. Bordner, Salesin and Gordon[1] have reported the use of 8-acetoxyquinoline as a reagent for the *in situ* generation of the precipitant as a means of improving the physical properties of the crystals. It has been reported earlier that the 8-hydroxyquinolates of aluminium, nickel, magnesium and copper are precipitated as well-defined, highly pure crystals by the volatilisation of the organic component of a water-organic solvent mixture.[2–6] A similar method has now been developed for the precipitation of uranium and excellent results are obtained.

EXPERIMENTAL

Reagents

Uranium: A uranium solution was prepared from reagent-grade $UO_2(CH_3COO)_2 \cdot 2H_2O$ (J. T. Baker Chemical Company, Phillipsburg, New Jersey, U.S.A.) containing approximately 10 mg of uranium per 10 ml of solution. This solution was standardised by evaporating an aliquot sample in a porcelain crucible under an infrared lamp, igniting the dry residue at 700–800° for 5 hr, and weighing the product as U_3O_8. The results of the analysis of twelve 25-ml aliquots resulted in an average value of 24·94 mg of uranium, with a standard deviation of 0·19. The rather large standard deviation, and reported discrepencies in the stoichiometry of the final product,[7] prompted the verification of this value by an alternative method. For this purpose an aliquot of the uranyl solution was reduced by metallic lead, treated with excess iron^{III} alum, and the iron^{II} ions produced were titrated with a standard cerium^{IV} solution. The results thus obtained were in agreement with those reported above and no increase in precision was obtained.

Magnesium: Reagent-grade $Mg(NO_3)_2 \cdot 6H_2O$ (J. T. Baker Chemical Company, Phillipsburg, New Jersey, U.S.A.) was used to prepare a solution which contained 5·0 mg of magnesium per ml of solution.

Lead: Reagent-grade $Pb(NO_3)_2$ (Mallinckrodt Chemical Works, St. Louis, Missouri, U.S.A.) was used to prepare a solution containing 5·0 mg of lead per ml of solution.

Thorium: Reagent-grade $Th(NO_3)_4 \cdot 4H_2O$ (J. T. Baker Chemical Company, Phillipsburg, New Jersey, U.S.A.) was used to prepare a solution containing 5·0 mg of thorium per ml of solution.

8-*Hydroxyquinoline:* A 1% acetonic solution of 8-hydroxyquinoline (reagent-grade, J. T. Baker Chemical Company, Phillipsburg, New Jersey, U.S.A., or Fisher Scientific Company, Fair Lawn,

---

* Part IV: See reference 6.

New Jersey, U.S.A.) was prepared by dissolving 1·0 g of the reagent in 100 ml of reagent-grade acetone. A fresh solution was prepared at least once a week.

EDTA solution: A 0·01*M* solution of disodium ethylenediaminetetra-acetate (reagent-grade, Fisher Scientific Company, Fair Lawn, New Jersey, U.S.A.) was prepared by dissolving 3·72 g of the reagent in 1 litre of distilled water.

Acetone: Reagent-grade acetone was distilled through a 30-cm Vigreaux column using all-glass apparatus. This precaution was necessary to remove an unidentified, water-insoluble material.

All other chemicals used were reagent-grade.

Apparatus

A Beckman Model G pH meter equipped with glass and calomel electrodes was used for all pH measurements.

Procedure

Preliminary experiments involving adjustments in the experimental parameters of pH, evaporation, temperature and acetone-water ratio led to the following recommended procedure:

A sample of about 25 mg of uranium is prepared in approximately 75 ml of nearly neutral solution. To this are added 50 ml of acetone, 10 ml of 1% 8-hydroxyquinoline solution and 10 ml of 0·5*M* ammonium acetate. The reaction mixture is placed on a water-bath at 70–75° and left uncovered for 2·5 to 3 hr. Visible precipitation occurs within the first hour of heating. At the end of the evaporation period, the samples are cooled to room temperature and filtered through medium-porosity sintered-glass crucibles. The precipitates are washed 4 times with 10 ml of distilled water and dried at 135° for at least 4 hr or overnight. The red product is weighed as $UO_2(C_9H_6ON)_2{\cdot}C_9H_7ON$. The gravimetric conversion factor is 0·33840. In all cases the filtrate pH was found to be between 5·8 and 6·0.

Coprecipitation

The studies in the presence of magnesium were performed by the above procedure, the magnesium being introduced into the original uranium solution. In the case of the lead and thorium coprecipitation studies it was found desirable to alter the order of the addition of the reagents. For these studies a three-fold excess of EDTA over that required to form a 1:1 complex with the diverse ion was added to the buffered solution containing the uranium and diverse ion. The acetone and reagent solution were then added and the analysis completed as above.

RESULTS AND DISCUSSION

Following the above procedure a well-formed, crystalline precipitate was obtained which was easily filtered and displayed no tendency to creep. The analysis of fifteen 25-ml aliquots yielded an average value of 24·84 mg of uranium with a standard deviation of 0·05. These figures may be compared to the value of 24·94, with a standard deviation of 0·19, that was obtained by the evaporation and ignition to U_3O_8. Particularly striking is the four-fold increase in precision.

During the preliminary experiments it was noted that precipitations at a pH of 5 or in the presence of increased amounts of ammonium acetate resulted in low values. However, in all cases the reported composition appeared to be the only one obtained and agreed with that generally found.[8] No evidence for the precipitation of excess reagent was noted, though this may arise from the fact that at the drying temperature of 135° any excess reagent would be decomposed.[9,10]

Table I reports the results of the coprecipitation studies. The ability of this technique to increase the separation from magnesium is obvious from the results in this table. In the case of lead and thorium the proposed method still fails to yield good separation; however, the addition of EDTA to the reaction mixture results in practically complete separation from these two important uranium decay products.

CONCLUSIONS

The precipitation of uranium 8-hydroxyquinolate from homogeneous mixtures of water and acetone is a convenient and practical method of achieving the formation

TABLE I.—EFFECT OF DIVERSE IONS UPON THE PRECIPITATION OF 24·96 MG OF URANIUM[e]

		Classical method	Present method	
Diverse ion added	Weight of diverse ions, *mg*	Apparent weight of uranium, *mg*	Apparent weight of uranium, *mg*	Difference, *mg*
—		24·82 ± 0·06[d]		−0·12
Mg	25·0		24·82 ± 0·08[b]	−0·12

of this precipitate. The product is produced in a highly pure form and the method is particularly advantageous for use in the presence of large amounts of magnesium, or of at least equal weights of lead or thorium when excess EDTA is present.

Acknowledgement—The authors wish to acknowledge the support given to this work by the U.S. Atomic Energy Commission under research contract AT(40-1) 2954.

Zusammenfassung—Die Methode der Fällung aus homogener Lösung eines Lösungsmittelgemisches wurde nun auf Uranoxinat angewandt. Gut ausgebildete Kristalle von hoher Reinheit werden erhalten bei der Fällung des Oxinats aus einer Wasser-Acetonlösung. Die Abtrennung des Urans von Magnesium ist leicht durchführbar, und eine Trennung von Blei and Thorium kann durch Zusatz von ADTE erreicht werden.

Résumé—Les auteurs décrivent une méthode pour le dosage de l'uranium, en précipitant l'oxinate en solution homogène, contenant un mélange d'eau et d'acétone comme solvants. En appliquant cette technique, les cristaux précipités sont bien formés, et très purs. Le magnésium est séparé aisément de l'uranium; de même, la séparation du thorium et du plomb est possible en présence d'EDTA.

AMPEROMETRISCHE BESTIMMUNG DER METALLE UNTER DER ANWENDUNG VON THIOACETAMID—V*

UNTERSUCHUNGEN ÜBER PbS-BILDUNGSGESCHWINDIGKEIT IN AMMONIAKALISCHEN Pb^{2+}-IONENLÖSUNGEN MITTELS THIOACETAMID

MARIA PRYSZCZEWSKA
Institut für Allgemeine Chemie, Technische Hochschule
Szczecin, Polen.

(*Eingegangen am* 3 *September* 1963. *Angenommen am* 30 *September* 1963)

Zusammenfassung—Auf Grund der polarographisch durchgeführten Untersuchungen über PbS-Fällungsgeschwindigkeit mittels Thioacetamid (TAA) wurden folgende Gleichungen für Reaktionsgeschwindigkeit zwischen Pb^{2+}-Ionen und TAA in ammoniakalischen Lösungen abgeleitet:

$$-\frac{d[Pb^{II}]}{dt} = k_1 . \frac{[Pb^{II}][CH_3CSNH_2][NH_3H_2O]}{[H^+]^{\frac{1}{2}}} . \frac{f_{Pb^{2+}}}{f_{H^+}{}^{\frac{1}{2}}} \qquad (1)$$

$$-\frac{d[Pb^{II}]}{dt} = k_2 . \frac{[Pb^{II}][CH_3CSNH_2][NH_3H_2O]}{[H^+]^{1/3}} . \frac{f_{Pb^{2+}}}{f_{H^+}{}^{\frac{1}{3}}} \qquad (2)$$

Der Wert der Geschwindigkeitskonstante k_1 beträgt für Temp. 25°C: $3{,}67 \cdot 10^{-4} \pm 0{,}65 \cdot 10^{-4}$ $Mol^{-\frac{3}{2}} . L^{\frac{3}{2}} . Min^{-1}$. Der Wert der Konstante. k_2 für dieselbe Temperatur beträgt: $2{,}00 \cdot 10^{-2} \pm 0{,}30 \cdot 10^{-2}$ $Mol^{-5/3} . L^{5/3}$ Min^{-1}. Die Geltung der Gleichung (1) wurde für NH_3H_2O-Konzentrationsgebiet vom 1,12 Mol/L bis 2,25 Mol/L im c_H-Intervall: $2{,}09 \cdot 10^{-12} \leqslant c_H \leqslant 4{,}17 \cdot 10^{-11}$ überprüft. Die Überprüfung der Gleichung (2) wurde im NH_3H_2O-Konzentrationsgebiet vom 2,25 Mol/L bis 4,5 Mol/L im c_H-Intervall: $1{,}26 \cdot 10^{-12} \leqslant c_H \leqslant 8{,}31 \cdot 10^{-11}$ durchgeführt.

EINLEITUNG

UNTERSUCHUNGEN über die Geschwindigkeit der Reaktion zwischen dem Thioacetamid und Metallionen bilden den Grund für die Arbeit über das eigentliche Problem der Anwendbarkeit des TAA zu der elektrometrischen Bestimmung der Metalle der H_2S- und $(NH_4)_2S$-Gruppe.

Die Untersuchüng über die Geschwindigkeit der Reaktion zwischen TAA und Cd^{2+}-Ionen sowie Tl^+-Ionen ist bereits früher[1,2] durchgeführt worden.

Die vorliegende Arbeit über die Reaktionsgeschwindigkeit der Pb^{2+}-Ionen mit TAA in ammoniakalischen Lösungen ist die Fortsetzung dieser Untersuchungen.

Die Kinetik der Reaktion der Pb^{2+}-Ionen mit TAA in erhöhter Temperatur und in saurem pH-Intervall wurde bereits früher von Swift und Butler[3] untersucht. Die Ergebnisse der Untersuchungen dieser Autoren lieferten neues Material, wertvolles sowohl für die Anwendung des TAA in der systematischen qualitativen Analyse der Kationen als auch für das Problem des Mechanismus der Reaktionen zwischen TAA und Metallionen. Für die Arbeit über die Bestimmungsmethode der Pb^{2+}-Ionen in alkalischem pH-Gebiet sind sie jedoch nicht anwendbar, da ihre Geltung auf saures pH-Intervall begrenzt ist.

---

DER EXPERIMENTALE TEIL

Apparatur

Polarograph „Radiometr PO3 m" (Dänemark). Tropfende Quecksilberelektrode als Kathode und gesättigte Kalomelelektrode als Anode.

Generator zur elektrolytischen Gewinnung des Wasserstoffs.

Termostat nach Wobser.

Automatische 1-ml Mikrobürette (zur Dosierung des TAA).

Lösungen

$Pb(NO_3)_2$-Lösung wurde aus analytisch reinem Handelspräparat vorbereitet und komplexometrisch bestimmt.[4]

Thioacetamidlösung aus dem „reinen" Handelspräparat nach dreimaliger Kristallisation vorbereitet und amperometrisch bestimmt.[5]

$AgNO_3$, $NaNO_3$, NH_4NO_3 wurden aus „analytisch reinen" Handelspräparaten nach zweimaliger Kristallisation angewandt. $NaNO_3$ wurde als Grundelektrolyt und zugleich als Ionenenstärkestabilisator angewandt. Die Ionenstärke aller untersuchten Lösungen war dieselbe.

Der pH-Wert der Lösungen wurde mittels Ammoniakpuffer ($NH_3H_2O + NH_4NO_3$) konstant gehalten.

Zugabe der Tartrat-Ionen ermöglichte die Pb-Ionen in der Lösung zu erhalten.

Prozedur

Die experimentale Bestimmung der Sulfidbildungsgeschwindigkeit wurde polarographisch so wie vorher[1,2] durchgeführt.

ERGEBNISSE UND DISKUSSION

Alle Untersuchungen über die Geschwindigkeit der Reaktionen des TAA mit Pb^{2+}-Ionen wurden in ammoniakalischen, mit NH_4NO_3 gepufferten Lösungen dieser Ionen von der gleichen Ionenstärke durchgeführt.

Schon im Laufe der Anfangsuntersuchungen wurde die proportionale Abhängigkeit der Sulfidbildungsgeschwindigkeit sowohl von der Konzentration der Metallionen wie auch von der Konzentration des TAA festgestellt, mit der Beschränkung auf ziemlich kleine Werte der Geschwindigkeit (also auch kleine Werte der Bleiionen- und TAA-Konzentration).

Die Untersuchungen über den Einfluss der H^+-Ionenkonzentration auf die PbS-Fällungsgeschwindigkeit, welche den Hauptteil der vorliegenden Arbeit bilden, wurden in Serien von Lösungen durchgeführt von dem gleichen NH_3H_2O-, TAA- und $Pb(NO_3)_2$-Konzentrationswert aber verschiedenem pH-Wert.

Die H^+-Ionenkonzentration jeder untersuchten Lösung dieser Serien wurde rechnungsweise bestimmt. Der f_{H^+}-Wert und f_{Pb}-Wert wurde nach Kolthoff[6] berechnet.

Es erwies sich, dass die Reaktionsgeschwindigkeit mit dem Steigen der H^+-Ionenkonzentration—in sonst gleichen Bedingungen—immer geringere Werte annimmt, dass also die PbS-Bildungsgeschwindigkeit eine absteigende Funktion der H^+-Ionenkonzentration ist (Abb. 1).

Als mögliche Form dieser Funktion wurden drei Gleichungen berücksichtigt:*

$$-\frac{dc_{Pb}}{dt} = k' \frac{c_{Pb} \cdot c_T}{c_H} \cdot \frac{f_{Pb}}{f_H} \qquad (1,V)$$

$$-\frac{dc_{Pb}}{dt} = k'' \frac{c_{Pb} \cdot c_T}{c_H^{\frac{1}{2}}} \cdot \frac{f_{Pb}}{f_H^{\frac{1}{2}}} \qquad (2,V)$$

$$-\frac{dc_{Pb}}{dt} = k''' \frac{c_{Pb} \cdot c_T}{c_H^{\frac{1}{3}}} \cdot \frac{f_{Pb}}{f_H^{\frac{1}{3}}} \qquad (3,V)$$

Die Werte von k', k'', k''' aus den obigen Gleichungen wurden für jeden untersuchten Fall auf Grund der experimentalen Daten berechnet.

Die Ergebnisse der Untersuchungen vier solcher Serien sind in den Tabellen I bis IV zusammengestellt. Bei allen Lösungen solcher Serien wie die aus der Tabelle I und II (vom c_{Am}-Wert 1,12 Mol/L bis 2,25 Mol/L) mit Steigen des pH-Wertes verändert sich stufenweise der k'-Wert wie auch der k'''-Wert, während der k''-Wert dabei annähernd konstant bleibt.

4	$3,92 . 10^{-12}$	$9,65 . 10^{-10}$	$4,87 . 10^{-4}$	$3,96 . 10^{-2}$	$4,35 . 10^{-4}$
5	$1,95 . 10^{-12}$	$6,06 . 10^{-10}$	$4,80 . 10^{-4}$	$3,93 . 10^{-2}$	$3,84 . 10^{-4}$

Im Fall der Lösungen solcher Serien wie die aus der Tabelle III und IV (vom c_{Am}-Wert 3,37 Mol/L bis 4,50 Mol/L) mit Steigen des pH-Wertes verändert sich stufenweise der k'-Wert so wie der k''-Wert, der k'''-Wert dagegen annähernd konstant bleibt.

---

* Im folgenden werden in Gleichungen, Tabellen und im Text nachstehende Abkürzungen gebraucht:

c_T statt TAA-Konzentration
c_{Pb} statt $Pb(NO_3)_2$-Konzentration
c_H statt H^+-Ionenkonzentration
f_{Pb} statt $f_{Pb^{2+}}$
f_H statt f_{H^+}

Auf Grund solcher Ergebnisse wurde festgestellt, dass für die Lösungen aus c_{Am}-Intervall 1,12 Mol/L bis 2,25 Mol/L die Gleichung (2,V) die Geschwindigkeit als Funktion vom c_H-Wert richtig ausdrückt, für die Lösungen dagegen von grösserem als 2,25 Mol/L c_{Am}-Wert die Gleichung (3,V).

Aus den Tabellen I–IV folgt ausserdem, dass der Zahlenwert der Koeffizienten k'' und k''' von der Ammoniakkonzentration abhängig ist und mit dieser Konzentration steigt.

Die Reaktionsgeschwindigkeit ist also—wie daraus ersichtlich ist—von der NH_3H_2O-Konzentration abhängig.

Diese Abhängigkeit wurde in Serien der Lösungen von verschiedenem c_{Am}-Wert und demselben pH-Wert so wie demselben c_{T}- und c_{Pb}-Wert durchgeführt.

Die Untersuchungsergebnisse einer solchen Serie sind in der Abb. 2 und der Tabelle V dargestellt.

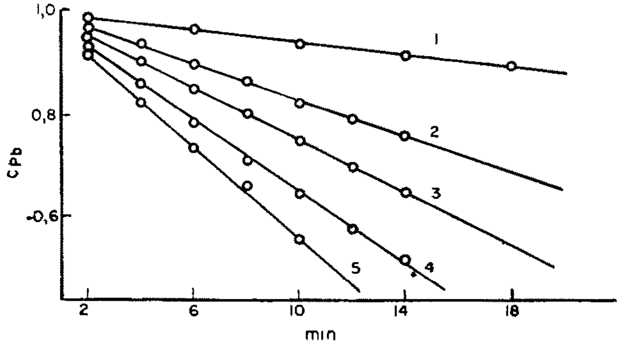

Abb. 2.—Reaktionsgeschwindigkeit der PbS-Fällung als Funktion der NH_3H_2O-Konzentration.
Temp. 25°: Pot. −1,0 v
$[Pb(NO_3)_2] = c_{\mathrm{Pb}} = 8{,}10 \cdot 10^{-4}$ Mol/L: $[CH_3CSNH_2] = c_{\mathrm{T}} = 5{,}82 \cdot 10^{-4}$ Mol/L:
$c_{\mathrm{H}} \cdot f_{\mathrm{H}} = a_{\mathrm{H}^+} = 3{,}92 \cdot 10^{-11}$
$[NH_3H_2O]$: 1 — 2,25 Mol/L: 2 — 3,37 Mol/L: 3 — 4,50 Mol/L:
4 — 6,75 Mol/L: 5 — 9,00 Mol/L

TABELLE V.—REAKTIONSGESCHWINDIGKEIT DER PbS-FÄLLUNG ALS FUNKTION DER NH_3H_2O-KONZENTRATION

Temp. = 25°
Pot. = −1,0 v
$\mu = 0{,}9$
$f_{\mathrm{H}^+} = 0{,}94$
$f_{\mathrm{Pb}^{2+}} = 0{,}15$

$[Pb(NO_3)_2] = c_{\mathrm{Pb}} = 8{,}10 \cdot 10^{-4}$ Mol/L
$[CH_3CSNH_2] = c_{\mathrm{T}} = 5{,}82 \cdot 10^{-4}$ Mol/L
$c_{\mathrm{H}} \cdot f_{\mathrm{H}} = a_{\mathrm{H}^+} = 3{,}92 \cdot 10^{-11}$

Nr	$[NH_3H_2O]$, *Mol/L*	k'''	k'''/c_{Am}
1	2,25	$4{,}00 \cdot 10^{-2}$	$1{,}83 \cdot 10^{-2}$
2	3,37	$6{,}10 \cdot 10^{-2}$	$1{,}85 \cdot 10^{-2}$
3	4,50	$9{,}00 \cdot 10^{-2}$	$2{,}03 \cdot 10^{-2}$
4	6,75	$1{,}30 \cdot 10^{-1}$	$1{,}95 \cdot 10^{-2}$
5	9,00	$1{,}67 \cdot 10^{-1}$	$1{,}96 \cdot 10^{-2}$

Die Abb. 2 illustriert, dass die Reaktionsgeschwindigkeit eine aufsteigende Funktion der NH_3H_2O-Konzentration ist.

Aus der Tabelle V folgt, dass der Ausdruck k'''/c_{Am} annähernd konstanten Wert für Lösungen der Serie aus dieser Tabelle hat. Denselben annähernd Wert hat dieser Ausdruck für Lösungen jeder übrigen untersuchten Serie, für welche der c_{Am} Wert nicht kleiner als 2,25 Mol/L ist, also auch für die Serien aus der Tabelle III und IV (was aus der letzten Kolonne dieser Tabellen ersichtlich ist).

Es ist also: $k'''/c_{\mathrm{Am}} = \text{constans} = k_2 \ldots\ldots (4,\mathrm{V})$. Aus den Tabellen I und II (letzte Kolonne) folgt, dass für Serien von c_{Am}-Wert 1,12 Mol/L und 2,25 Mol/L der Ausdruck k''/c_{Am} auch konstanten Wert hat. Dasselbe gilt auch für Lösungen jeder untersuchten Serie aus dem NH_3H_2O-Konzentrationsintervall vom 1,12 Mol/L bis 2,25 Mol/L. Für diesen Konzentrationsintervall ist also:

$$k''/c_{\mathrm{Am}} = \text{constans} = k_1 \qquad (5,\mathrm{V})$$

Aus Gleichungen (4,V) u. (5,V) folgt die proportionale Abhängigkeit der Reaktionsgeschwindigkeit von der NH_3H_2O-Konzentration.

Nach Einsetzen in die Gleichung (2,V) den Wert für k'' aus der Gleichung (5,V) und in die Gleichung (3,V) den Wert für k''' aus der Gleichung (4,V), bekommen die Gleichungen (2,V) und (3,V) folgende Form:

$$-\frac{dc_{\mathrm{Pb}}}{dt} = k_1 \frac{c_{\mathrm{Pb}} \cdot c_{\mathrm{T}} \cdot c_{\mathrm{Am}}}{c_{\mathrm{H}}^{1/2}} \cdot \frac{f_{\mathrm{Pb}}}{f_{\mathrm{H}}^{1/2}} \qquad (2',\mathrm{V})$$

$$-\frac{dc_{\mathrm{Pb}}}{dt} = k_2 \frac{c_{\mathrm{Pb}} \cdot c_{\mathrm{T}} \cdot c_{\mathrm{Am}}}{c_{\mathrm{H}}^{1/3}} \cdot \frac{f_{\mathrm{Pb}}}{f_{\mathrm{H}}^{1/3}} \qquad (3',\mathrm{V})$$

Der Zahlenwert der Geschwindigkeitskonstante k_1 und k_2 aus diesen Gleichungen wurde aus den experimentalen Ergebnissen—unter anderem auch aus den Daten der Serien aus der Tabellen I–IV—erhalten.

Für Temperatur 25° beträgt der Mittelwert von k_1: $3{,}67 \,.\, 10^{-4} \pm 0{,}65 \,.\, 10^{-4}$ $\mathrm{Mol}^{-3/2} \,.\, \mathrm{L}^{3/2} \,.\, \mathrm{Min}^{-1}$. Für dieselbe Temperatur beträgt der Mittelwert von k_2: $2{,}00 \,.\, 10^{-2} \pm 0{,}30 \,.\, 10^{-2}$ $\mathrm{Mol}^{-5/3} \,.\, \mathrm{L}^{5/3} \,.\, \mathrm{Min}^{-1}$. Die Geltung beider Gleichungen wurde überprüft. Die Reaktionsgeschwindigkeit wurde nämlich unter Anwendung entsprechend der Gleichung (2',V) oder (3',V) in jedem konkreten Fall berechnet (indem für k_1 und k_2 die eben angegebene Werte eingesetzt wurden) und der so erhaltene Geschwindigkeitswert wurde mit experimental gefundenem Wert verglichen.

Die Ergebnisse der Überprüfung sind in der Tabelle VI zusammengestellt. Die Übereinstimmung der berechneten Geschwindigkeitswerte mit den experimental gefundenen ist ziemlich gut wie aus der Tabelle VI ersichtlich ist.

Aus dieser Tabelle folgt zugleich, dass die Geltung der Gleichung (2',V) für c_{Am}-Gebiet vom 1,12 Mol/L bis 2,25 Mol/L im c_{H}-Intervall vom $2{,}09 \,.\, 10^{-12}$ bis $4{,}17 \,.\, 10^{-11}$ überprüft wurde und die Geltung der Gleichung (3',V) für c_{Am}-Gebiet vom 2,25 Mol/L bis 4,50 Mol/L in c_{H}-Intervall vom $1{,}26 \cdot 10^{-12}$ bis $8{,}31 \cdot 10^{-11}$. Die Lösungen der Serie vom c_{Am}-Wert 2,25 Mol/L haben vorübergehenden Charakter. Die Reaktionsgeschwindigkeit der Lösungen dieser Serie ist nämlich nicht nur durch die Gleichung (2',V) bestimmt sondern annähernd auch durch die Gleichung (3',V). Die auf Grund der Gleichung (3',V) berechneten Geschwindigkeitswerte sind für Lösungen dieser Serie von kleinem pH-Wert in ziemlich guter Übereinstimmung mit den experimental bestimmten. Mit Steigen des pH-Wertes aber steigt auch die Abweichung von den experimental bestimmten Werten, was aus der Tabelle VI ersichtlich ist.

Die Proben der Überprüfung der Gleichung (3',V) für die Lösungen von grösserer NH_3H_2O-Konzentration zeigten, dass diese Gleichung ihre Geltung auch im Gebiet

der c_{Am}-Werte vom 4,50 Mol/L bis 6,75 Mol/L, mit Beschränkung auf nicht hohe pH-Werte behält.

Doch für die Lösungen vom c_{Am}-Wert $> 4{,}50$ Mol/L ist der Verlauf der Reaktion nicht immer gut reproduzierbar.

Aus den hier dargestellten Untersuchungen folgt—unter anderem—dass die Geschwindigkeit der Reaktion zwischen TAA und Pb^{2+}-Ionen in NH_3H_2O-Lösungen im Gebiet der für amperometrische Bestimmungen entsprechender Werte enthalten sein kann.

Proben der Anwendung dieser Reaktion zu der amperometrischen Bestimmung dieser Ionen sind im Gange.

Die Ergebnisse dieser Untersuchungen sind aber nicht nur für amperometrische Zwecke anwendbar. Sie liefern auch neues experimentales Material, welches für das Problem des Mechanismus der Reaktionen der Metallionen mit TAA nützlich sein kann. Nicht ohne Bedeutung für dieses Problem ist z.B. die Feststellung, dass den untersuchten Reaktionen der Pb^{2+}-Ionen mit TAA zwei Geschwindigkeitsgleichungen (2′,V) und (3′,V) entsprechen.

Die untersuchten Reaktionen gehören zu den nicht durch Hydrolyse des TAA kontrollierten Reaktionen (die auch als direkte Reaktionen bezeichnet werden,[3] was sowohl aus ihrer ziemlich grossen Geschwindigkeit wie auch aus der Art der Abhängigkeit dieser Geschwindikgeit von dem c_H-Wert folgt.

Es gibt also—wie aus diesen Untersuchungen folgt—direkte Reaktionen von nicht ganz identischem Mechanismus, was auch früher im Fall der Cadmiumionen[1] gezeigt worden ist.

Summary—On the basis of polarographic investigations of the rate of precipitation of lead sulphide by thioacetamide (TAA), the following equations for the rate of reaction of Pb^{2+} with TAA have been derived:

$$-\frac{d[Pb^{II}]}{dt} = k_1 \cdot \frac{[Pb^{II}] \,.\, [TAA] \,.\, [NH_3.H_2O]}{[H^+]^{\frac{1}{2}}} \cdot \frac{f_{Pb^{2+}}}{f_{H^+}{}^{\frac{1}{2}}} \quad \ldots (1)$$

$$-\frac{d[Pb^{II}]}{dt} = k_2 \,.\, \frac{[Pb^{II}] \,.\, [TAA] \,.\, [NH_3 \cdot H_2O]}{[H^+]^{\frac{1}{3}}} \cdot \frac{f_{Pb^{2+}}}{f_{H^+}{}^{\frac{1}{3}}} \quad \ldots (2)$$

The value, at 25°, of the rate constant k_1 is $3{\cdot}67 \times 10^{-4} \pm 0{\cdot}65 \times 10^{-4}$ $mol^{-\frac{3}{2}} \,.\, litre^{\frac{3}{2}} \,.\, min^{-1}$, and of the rate constant k_2 is $2{\cdot}00 \times 10^{-2} \pm 0{\cdot}30 \times 10^{-2}$ $mol^{-5/3} \,.\, litre^{5/3} \,.\, min^{-1}$. The validity of equation (1) has been proved for $NH_3 \cdot H_2O$ concentrations from 1·12 mol/litre to 2·25 mol/litre in the c_H range $2{\cdot}09 \times 10^{-12} \leqslant c_H \leqslant 4{\cdot}17 \times 10^{-11}$, and of equation (2) for $NH_3 \cdot H_2O$ concentrations from 2·25 mol/litre to 4·5 mol/litre in the c_H range $1{\cdot}26 \times 10^{-12} \leqslant c_H \leqslant 8{\cdot}31 \times 10^{-11}$.

Résumé—En se basant sur les études polarographiques du taux de précipitation du sulfure de plomb par la thiocétamide (TAA), les équations suivantes relatives au taux de réaction de l'ion Pb^{2+} avec le TAA ont pu être établies:

$$-\frac{d[Pb^{II}]}{dt} = k_1 \,.\, \frac{[Pb^{II}]\, [TAA]\, [NH_3 \cdot H_2O]}{[H^+]^{1/2}} \times \frac{f_{Pb^{2+}}}{f_{H^+}{}^{\frac{1}{2}}} \qquad (1)$$

$$-\frac{d[Pb^{II}]}{dt} = k_2 \,.\, \frac{[Pb^{II}]\, [TAA]\, [NH_3 \cdot H_2O]}{[H^+]^{\frac{1}{3}}} \times \frac{f_{Pb^{2+}}}{f_{H^+}{}^{\frac{1}{3}}} \qquad (2)$$

à 25° la valeur de la constante de réaction k_1 est

$3{,}67 \times 10^{-4} \pm 0{,}65 \times 10^{-4}\ mol^{-3/2}.litre^{3/2}.min^{-1}$

celle de la constante k_2 est

$2{,}00 \times 10^{-2} \pm 0{,}30 \times 10^{-2}\ mol^{-5/3}.litre^{5/3}.min^{-1}$

La validité de l'équation (1) a été mise en évidence pour des concentrations $NH_3 \,.\, H_2O$ variant de 1,12 à 2,25 mole/litre dans un domaine de c_H de l'ordre de:

$2{,}09 \times 10^{-12} \leqslant c_H \leqslant 4{,}17 \times 10^{-11}$

ainsi que l'équation (2) pour des concentrations $NH_3.H_2O$ variant de 2,25 à 4,5 mole/litre dans un domaine de $c_H = 1{,}26 \times 10^{-12} \leqslant c_H \leqslant 8{,}31 \times 10^{-11}$.

SPECTROPHOTOMETRIC METHODS FOR THE DETERMINATION OF IMPURITIES IN PURE AND ANALYTICAL REAGENTS—I

PROPOSED METHODS AND ALGEBRAIC FORMULAE*

ABRAHAM GLASNER and PINCHAS AVINUR
Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Israel

(*Received* 11 *September* 1963. *Accepted* 12 *December* 1963)

Summary—Algebraic formulae are proposed for the spectrophotometric determination of impurity ions in chemically pure or analytical reagents which do not themselves absorb in the spectral region to be used. These formulae require absorption measurements on the solution at two specified wavelengths, and a knowledge of the absorption coefficients of the ion to be determined. No information about either the nature or the concentration of the interfering ions, or about the background absorption of the solution is necessary.

INTRODUCTION

THE molar absorptivity of many simple inorganic ions and complexes in the ultraviolet range of the spectrum is of the order of 10^3–10^4. These high values suggest the application of absorption measurements to the determination of trace amounts of such ions.[1,2] In some published analytical papers, the use of sulphuric[3–5] or perchloric acid[6] solutions have been proposed. Many authors have employed concentrated hydrochloric acid[7–9] or alkali halide solutions, proving the general usefulness of the method very convincingly. The practical applications have not necessarily been to trace amounts of the constituents determined. However, too often tests only on artificial solutions have actually been described.

For the determination of two or more components, absorption measurements were taken at their characteristic wavelengths, and simultaneous linear equations, with determinants containing the specific absorbance of each of the components at every wavelength, were solved.[8,9] This straightforward though cumbersome method is useless if unknown absorbing species are present.

Our objective was to apply ultraviolet spectrophotometry to the determination of impurities in pure or analytical reagents. The absorption spectra of solutions of pure chemicals show, as a rule, characteristic absorption bands of trace elements present, but their concentration cannot be determined because of background absorbance, composed of various unaccountable factors. This difficulty can be overcome by the addition of specific reagents to the solution.[1] Such reagents are not always readily available, and may cause technical complications. Hence, a mathematical device is preferable, and in the present paper algebraic formulae developed for this purpose are described.

THEORETICAL CONSIDERATIONS AND FORMULAE

Method I

The spectrum of a concentrated salt solution (see Fig. 1) may often show a characteristic absorption band riding on a general background absorption of the solution arising from unknown contaminations. Measuring the absorbance at the peak wavelength would not yield any information about the concentration of the required constituent, *M*; but if it is assumed that the background absorption of all contaminants in the proximity of the absorption peak does not vary, or varies only slightly with the wavelength, concentration can be estimated from the slope of the absorption band. For this purpose, measurements at two wavelengths are required: at λ_1 near the absorption peak; and at λ_2, somewhat below the half-width of the band (both on the long-wave side of the peak, see Fig. 2). The difference between these two absorbances, $\Delta A^s_{\lambda_1-\lambda_2}$, is then divided by the difference of the known specific absorbances of the constituent, *M*, at the same wavelengths, $\Delta q^M_{\lambda_1-\lambda_2}$, to give the concentration in any units:

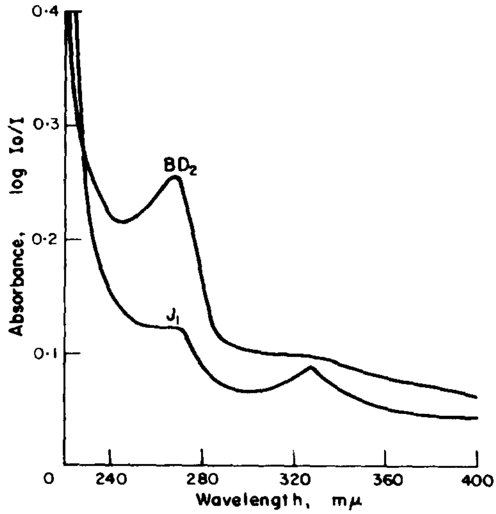

Fig. 1.—Absorption spectra of 4*M* KCl solutions with reference to water J_1 = J.T. Baker Analyzed Reagent; BD_2 = B.D.H. Laboratory Reagent.

$$Q^M = (\Delta A^s_{\lambda_1-\lambda_2})/(\Delta q^M_{\lambda_1-\lambda_2})$$

Q is expressed in ppm throughout this work.

The term $\Delta q^M_{\lambda_1-\lambda_2}$ can be evaluated by measuring the absorbance of a salt solution to which a known amount of the constituent has been added, with reference to another portion of the same salt solution which has not been treated.

There is a loss of precision involved in this method as compared to the spectrophotometric methods in common use: (*a*) the sensitivity is halved; (*b*) one measurement, at λ_2, is taken on the slope of the absorption curve. On the other hand, errors arising from the inequality of the cells containing the measured and the reference solutions are compensated for. The advantages of the simplicity of the method. and the elimination of the use of any specific reagents, are quite obvious.

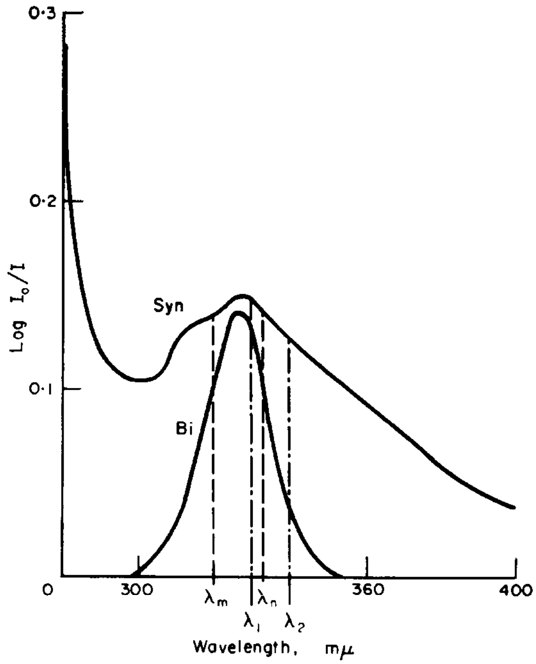

Fig. 2.—Absorption curves of 4*M* KCl solutions

Syn; contained 0·4 ppm of Bi^{3+}, 0·01*M* HCl, 3·4 ppm of Fe^{3+}, 10·5 ppm of Pb^{2+},
and various other cations and anions
(measured against distilled water)

Method II

The background absorbance of the solution often varies nearly linearly with the wavelength, since the absorption band of the sought constituent, *M*, rides on the tail of another absorption band. This interference can be dealt with by making two additional measurements at wavelengths λ_m and λ_n, and introducing an appropriate modification in formula I. The wavelengths λ_m and λ_n are two wavelengths situated on either side of the band peak of constituent *M*, at which the absorbances of *M* are equal, *i.e.*, $A^M_{\lambda_m} = A^M_{\lambda_n}$, as illustrated in Fig. 2. These wavelengths are found experimentally by measuring the absorption spectrum of a solution to which a known amount of the constituent *M* has been added. The modified formula, then, assumes the form:

$$Q^M = \frac{\Delta A^s_{\lambda_1-\lambda_2} - K\Delta A^s_{\lambda_m-\lambda_n}}{\Delta q^M_{\lambda_1-\lambda_2}} \qquad \text{II}$$

where

$$K = \frac{\lambda_1 - \lambda_2}{\lambda_m - \lambda_n}.$$

It is desirable that all four wavelengths chosen for measurement should be in a narrow region of the spectrum, otherwise this approximation is not valid. A similar formula has previously been proposed by Kress for the determination of lead in rubber products.[10]

Method III

The background absorbance of the solution can also be compensated for by introducing a correction factor, K_R, into formula I. This device is adopted whenever Method II is inadequate, either because the peak absorbance of the constituent is too far out in the short ultraviolet, or because the absorbance of the contamination varies abruptly on passing from the region $\lambda_1 - \lambda_2$ to the region $\lambda_m - \lambda_n$ of the spectrum.

The correction factor proposed is $K_R = K^M_R/K^S_R$,

where $$K^M_R = A^M_{\lambda_1}/\Delta A^M_{\lambda_1-\lambda_2} = q^M_{\lambda_1}/\Delta q^M_{\lambda_1-\lambda_2},$$

the "slope ratio" of the constituent,

and $$K^S_H = A^S_{\lambda_1}/\Delta A^S_{\lambda_1-\lambda_2},$$

the "slope ratio" of the solution at the two chosen wavelengths. The parameter K^M_R is characteristic of the constituent, and can be evaluated experimentally. Hence, the final formula has the form:

$$Q^M = \frac{\Delta A^S_{\lambda_1-\lambda_2}}{\Delta q^M_{\lambda_1-\lambda_2}} K_R = \frac{(\Delta A^S_{\lambda_1-\lambda_2})^2 \times K^M_R}{A^S_{\lambda_1} \times \Delta q^M_{\lambda_1-\lambda_2}} \qquad \text{III}$$

necessitating measurements at only two wavelengths. This correction is an approximation, valid only under certain conditions, *i.e.*, when the absorption gradient of the contaminants between λ_1 and λ_2 is (*a*) positive, and (*b*) less steep than that of the desired constituent.

Inspection of the curves given in Fig. 1 shows that both conditions are valid, for example, in the case of the absorption band of lead with a peak at $\lambda = 268{\cdot}5$ mμ.

Under these conditions $K^M_R < K^S_R$ always, and therefore $K_R < 1$, as it should be. Also, the correction factor K_R varies in the right direction with variations of the background absorbance of the contaminants at λ_1 ($= L_1$), and of the relative absorbance of the desired constituent ($A^M_{\lambda_1}$), as may be seen in the following:

$$K_R = \frac{A^M_{\lambda_1} \times \Delta A^S_{\lambda_1-\lambda_2}}{A^S_{\lambda_1} \times \Delta A^M_{\lambda_1-\lambda_2}} = \frac{A^M_{\lambda_1} \times (\Delta A^M_{\lambda_1-\lambda_2} + l)}{(A^M_{\lambda_1} + L_1)\Delta A^M_{\lambda_1-\lambda_2}} = \frac{1 + l/\Delta A^M_{\lambda_1-\lambda_2}}{1 + L_1/A^M_{\lambda_1}},$$

where $l = L_1 - L_2$.

Formula III has been applied by us to the determination of the nitrate ion with satisfactory results; the absorbance of 4*M* potassium chloride solutions was measured at the wavelengths 220 and 230 mμ (see Part II of this series[11]). The number of interfering contaminants increases at the shorter wavelengths, and in some cases it was found advantageous, when using Formula III, to deduct from the measured absorbances the absorbance of certain ions whose concentrations had previously been measured at longer wavelengths.

In conclusion, it is suggested that the concentration of certain impurity ions having characteristic absorption bands in the ultraviolet may be determined by taking measurements at two wavelengths. A choice of three different algebraic formulae is proposed. The simplest formula (I) is for use when the absorption band of the desired constituent stands out clearly, and retains its symmetrical form. Formula II or III should be applied when the absorption band is distorted. A test of the proposed method, applied to concentrated KCl solutions prepared in the laboratory, is described in a subsequent paper.[11]

Zusammenfassung—Für die spektralphotometrische Bestimmung von verunreinigenden Ionen in chemische reinen oder analytischen Reagentien, die im fraglichen Spektralbereich selbst nicht absorbieren, werden algebraische Formeln vorgeschlagen. Diese Formeln erfordern Absorptionsmessungen an der Lösung bei zwei festgelegten Wellenlängen und Kenntnis der Extinktionskoeffizienten des zu bestimmenden Ions. Keine Information über Natur oder Konzentration der störenden Ionen oder Untergrundabsorption der Lösung ist notwendig.

Résumé—On propose de formules algébriques pour la détermination spectrophotométrique des impuretés ioniques dans les réactifs chimiquement purs ou pour analyse et n'absorbant pas eux-mêmes dans la région spectrale utilisée. Ces formules nécessitent la mesure de l'absorption de la solution à deux longeurs d'ondes spécifiques, et la connaissance des coefficients d'absorption de l'ion. Aucun autre renseignement, soit sur la nature de la concentration des ions génants, ou l'absorption de base de la solution n'est nécessaire.

A SPECTROPHOTOMETRIC STUDY OF THE COMPLEX FORMED BETWEEN THE ACID CHLORANILATE AND MOLYBDATE IONS IN AQUEOUS SOLUTIONS

WALTER F. LEE, NIRMAL K. SHASTRI and EDWARD S. AMIS
Department of Chemistry, University of Arkansas, Fayetteville, Arkansas, U.S.A.

(*Received* 11 *October* 1963. *Accepted* 7 *December* 1963)

Summary—Using the method of continuous variations of Job, a 1:1 complex between molybdate and acid chloranilate ions has been found in aqueous solutions at various values of pH and temperature. The pH has to be controlled to within 0·05 for obedience to Beer's law of the chloranilic acid. The dissociation constants of the complex at constant temperature decrease linearly with increasing pH up to pH 4, then increase linearly with pH. The changeover from the complex of one polymolybdate ion to another is suggested as the cause of this minimum in the K_d versus pH curve. This assumption is supported by the absorbance versus pH curve of the complex. This curve shows a rather sharp downward trend from the expected value beginning at pH 4. Thermodynamic data for the dissociation of the complex are presented.

CHLORANILIC acid (2,5-dichloro-3,6-dihydroxyquinone) has been investigated by several workers,[1,2] and it has been noted for its capacity to form complexes with various ions, such as calcium and zirconium. Because a chloranilic acid solution undergoes a colour change in the presence of the molybdate ion, it was decided to investigate the system to determine the empirical formula of the complex or complexes formed and to determine the thermodynamical properties.

Chloranilic acid, which forms a deep purple aqueous solution, turns light violet in the presence of molybdate ion. For this reason it was decided to employ a spectrophotometric approach. Several spectrophotometric methods have been applied to the investigation of the empirical formulae of coloured complexes in solution.[3–6] In this work, the continuous variations method of Job[4] was used.

The stability constants of a complex can be determined from the data used in the determination of the empirical formula of the complex. In this work, the method of Foley and Anderson[7] was used to determine the constants. The enthalpy of formation of the complexes would normally be determined by calculating the stability constant at different temperatures and plotting the logarithm of the stability constant versus the reciprocal of the absolute temperature. In this study, the concentrations of the complexes formed were found to be independent of temperature. This indicates that the enthalpy of formation is zero.

EXPERIMENTAL

Apparatus

Wavelengths that give maximum absorption at various pH values were measured on a Beckman DK-1 recording spectrophotometer using a tungsten lamp and silica cells of 10·00 ± 0·01-mm light path. Absorption values in the continuous variation runs were measured on a Beckman DU quartz spectrophotometer using a tungsten lamp and cells of 10·00 ± 0·01-mm light path. Measurements on the Beckman DK-1 were made from 400 to 700 mμ. The peaks at the different pH values ranged from 532 to 578 mμ. All measurements were made at the maximum sensitivity of the instruments. A Beckman Model G pH Meter was used to measure the pH of all solutions.

Reagents

Chloranilic acid. Reagent-grade material obtained from the Fisher Chemical Company, U.S.A., was used without further purification. A sample was also prepared by the purification method of Thamer and Voigt.[1] The purified sample melted at 283·8° and the unpurified sample melted at 283·65°. A maximum difference of $0·5 \times 10^{-3}$ was noted in the absorption values. This was not sufficient to cause any measureable differences.

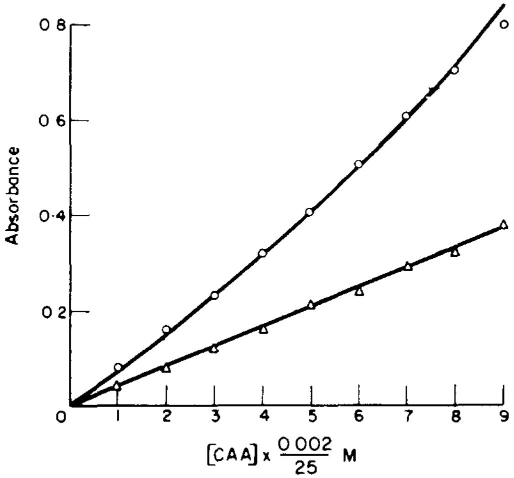

FIG. 1.—Obedience to Beer's Law:
O-pH controlled within 0·1,
Δ-pH controlled within 0·05.

Sodium molybdate. Reagent-grade material obtained from the Fisher Chemical Company, U.S.A., was used without purification.

Solutions of the above compounds were made with conductivity water at 25°. The buffer solutions were standard Clark and Lubb's[8] buffers. The chloranilic acid and sodium molybdate were prepared 0·002016 *M* by weight. All other solutions were prepared by weight.

Procedure

In the method of continuous variations, a series of solutions was prepared* in which the proportions of the molybdate and acid chloranilate ions were varied but the total concentration was constant. Before each run at any given pH the obedience of the choranilic acid to Beer's Law was determined. It was found that the pH had to be controlled within 0·05 in order to obtain obedience to Beer's Law. In Fig. 1 the absorbance is plotted against the concentration of chloranilic acid. The expected straight line through the origin is obtained only when the pH is controlled as described above.

The ionic strength in all runs was maintained constant at 0·37 by adding the necessary amount of purified sodium perchlorate. Except for added sodium perchlorate, the ionic strength in each run was derived mainly from the buffer solution. For this reason no ionic strength effect was observed on the absorption and therefore upon the formula of the complex or the values of the dissociation constants.

---

* The order of preparation of solutions for absorption measurement was first to measure into a volumetric flask the requisite amount of acid chloranilate. To this was added the amount of buffer which by trial and error was found to give the desired pH in the final solution. Water was then added to the solution in an amount just short of the volume to give a correct final volume after molybdate was added to give the desired ratio of molybdate to acid chloranilate. The final volume was adjusted to the mark on the flask with a few drops of distilled water. Consistent results were obtained using this procedure.

This was proved by finding the same values for the absorption in the same concentrations of chloranilic acid, sodium molybdate and buffer, when the ionic strength was not controlled as when the ionic strength was controlled.

In the method used for calculating the equilibrium constants, calculations are based on comparisons between two solutions of equal optical density.

For the 1:1 complex found, solutions containing molybdate and acid chloranilate ions in a 1:1 ratio were prepared. The original solution for the 1:1 complex was diluted successively and hence each succeeding solution contained a smaller total concentration of the ions but each was maintained at the same pH by the addition of the appropriate buffer solutions. By this method solutions were obtained that had the same optical density as those of other ratios. Pairs of solutions with the same optical density have the same concentration of complex. These pairs have, however, different total concentrations of the reactants. Because the equilibrium constant would be the same for the two solutions, the constant may be calculated from the expression:

$$K = \frac{(a_1 - X)(b_1 - X)}{X} = \frac{(a_2 - X)(b_2 - X)}{X}$$

where a and b denote the original concentrations of the acid chloranilate and molybdate ions in the two solutions and X is the concentration of the complex.

The free energy of formation, ΔF°, of the complexes may be calculated from the relationship:

$$\Delta F^\circ = -2{\cdot}303\ RT \log K_s$$

where K_s is the stability constant of the complex, equal to the reciprocal of the equilibrium constant as calculated above.

The change in entropy, ΔS°, of the complex may be determined from the relationship:

$$\Delta F^\circ = \Delta H^\circ - T\Delta S^\circ = -T\Delta S^\circ.$$

It was determined that ΔH° was too small to be measured by the methods used in this work. Runs were made at temperatures of 25, 35, and 45°. No difference in the absorption was noted at the different temperatures.

For all spectrophotometric measurements, the blank for each sample contained the same amount of chloranilic acid as the sample with appropriate buffer to maintain the pH.

The pK_a of both chloranilic acid and the 1:1 complex was found. The ionisation constant of the chloranilic acid was also determined from pH measurements. A study of the dissociation constant of the complex versus the pH was also made.

RESULTS AND DISCUSSION

The results of the spectrophotometric investigations are presented in this section in both tabular and graphical form.

In graphical presentation, the optical density from the complex formation was plotted against the ratio of chloranilic acid to the total concentration. At every pH value employed (0.8–5.9), a 1:1 complex was found (see Fig. 3).

The ionisation equilibrium constants for chloranilic acid were determined in order to ascertain the charge on the complex. K_1 was found to be infinite and K_2 was found to be $5{\cdot}98 \times 10^{-4}$. The work of Thamer and Voigt[1] was repeated in order to check the technique. Because unbuffered chloranilic acid solutions do not obey Beer's law and a spectrophotometer with a 50-mm light path was not available, it was not possible to reproduce this data spectrophotometrically. By pH measurements it was possible to repeat the critical range of the data within an error of 10·5%. It was not possible to repeat the data in very concentrated perchloric acid-lithium perchlorate solutions with any degree of accuracy.

The dissociation constants of the complex were plotted against the pH. Instead of the expected smooth curve slowly approaching the ordinate, a sharply descending straight line was found from pH values of 0·8–4·0. This line intersected with another similar straight line that was found from pH values of 4·0–5·9 (see Fig. 3).

In an effort to explain this phenomenon, the pK_a values of both chloranilic acid and the 1:1 complex were determined. The pK_a of the chloranilic acid was found to be 2·75 while the pK_a of the 1:1 complex was found to be 2·30 (see Fig. 4).

TABLE I.—SUMMARY OF THERMODYNAMICAL DATA

pH	λ, *mμ*	Complex ratio	$K_d \times 10^{-5}$	$-\Delta F°$, *cal/mole*	$\Delta S°$, *cal/mole*	$\Delta H°$, *cal/mole*
0·8	532	1:1	5·44	5794	19·44	0
2·1	535	1:1	3·60	6036	20·25	0
2·7	556	1:1	2·91	6150	20·30	0
4·0	576	1:1	1·13	6722	22·58	0
4·5	578	1:1	2·51	6251	20·97	0
4·9	567	1:1	4·23	5943	19·94	0
5·9	542	1:1	7·20	5628	18·89	0

Observing Fig. 4 it is seen that the absorption versus pH curve* for the 1:1 complex has a normal shape out to pH 4, *i.e.*, there is a horizontal portion in the lower pH-range, followed by a rather vertical portion, which in turn is followed by an approximately horizontal portion extending to about pH 4. Beginning at pH 4 the curve turns down sharply. In Fig. 3 it will be observed that the minimum in the K_d-versus pH curve also occurs at pH 4. Now it is known that the normal molybdates, *e.g.*, Na_2MoO_4, form polymolybdates, the complexity of which depends on the hydrogen ion concentration.[9] The complex polyions and the corresponding pH-values include: $(Mo_{24}O_{78})^{12-}$, pH 1·0; $(Mo_{12}O_{41})^{10-}$, pH 1·25; $(Mo_6O_{21})^{6-}$, pH 1·5–4·5; $(Mo_3O_{11})^{4-}$, pH 4·5–6·3; MoO_4^{2-}, pH 6·5–14. One might interpret the data from Figs. 3 and 4 as arising from complexes of acid chloranilate ion with different polymolybdate ions, but in all cases the complexes had the ratio of constituents of 1:1 based on calculations using the normal molybdate. Evidently, over most of the range from pH 1·0 to 4·5, the complexing of the acid chloranilate ion was principally with the $(Mo_6O_{21})^{6-}$ polyion, though, at pH less than 1·5 the more complex polyions may be involved. However, not much of the data was taken at this lower pH range.

Whatever complexing of these higher polyions took place was evidently in harmony as to dissociation and absorbance with the complex of the $(Mo_6O_{21})^{6-}$ polyion.

The complexing of the acid chloranilate ion in the pH range 4·5–6·5 was principally with the $(Mo_3O_{11})^{4-}$ polyion. The critical region is where the $(Mo_6O_{21})^{6-}$ is converting to $(Mo_3O_{11})^{4-}$, as shown by the minimum at pH 4 in Fig. 3 and the beginning of the rapid decrease in absorbance at aboutp H 4 in Fig. 4. The ratio of the components based on the normal molybdate is always one, but the degree of dissociation and consequently the absorbance depends on which polyion is predominant in the formation of the complex. The decreased dissociation with increasing pH of the complex involving the $(Mo_6O_{21})^{6-}$ polyion is eventually balanced and eventually dominated by the increased dissociation of the complex with the $(Mo_3O_{11})^{4-}$ polyion. The changeover from the complex of one polyion to the other is rather sharp as is evidenced by the straight line segments meeting in the sharp minimum as given in Fig. 3 and by the rather abrupt decrease in absorbance above pH 4 as shown in Fig. 4. This rather abrupt change is to be expected because of the rather sharply delineated pH regions in which the two polyions exist. Because the ratio of the two constituents

---

* The shapes of absorbance versus pH curves in the wavelength range 532–578 mμ were practically identical to that shown in Fig. 4 for 556 mμ, which is about the mid-point in wavelengths studied. The curves were merely raised or lowered along the absorbance axis, depending on wavelength.

was always 1 : 1 based on the normal molybdate one might speculate that the empirical formulae of the complexes in the pH ranges 1·0–4·5 and 4·5–6·5 were, respectively, $[(Mo_6O_{21})(HCh)_6]^{12-}$ and $[(Mo_3O_{11})(HCh)_3]^{7-}$, though the twice ionised acid chloranilate and even water may have entered into the formation of the complex. In the formulae, HCh^- represents the once ionised chloranilic acid.

Zusammenfassung—Mit der Methode der kontinuierlichen Variationen von Job wurde zwischen Molybdat und saurem Chloranilat in wäßriger Lösung bei verschiedenen p_H-Werten und Temperaturen ein 1:1-Komplex gefunden. Damit die Chloranilsäure dem Beerschen Gesetz gehorchte, mußte der p_H auf 0,05 Einheiten konstant gehalten werden. Die Dissoziationskonstante des Komplexes fiel bei konstanter Temperatur linear mit steigendem p_H bis 4 und wuchs dann linear mit dem p_H. Als Grund dieses Minimums in der $K_\alpha p_H$-Kurve wurde der Übergang des Komplexes von einem Polymolybdation zu einem andern vermutet. Diese Annahme wurde durch die Extinktions-p_H-Kurve des Komplexes gestützt. Diese Kurve zeigte von p_H 4 an einen ziemlich scharfen Abfall unter den erwarteten Wert. Thermodynamische Daten für die Dissoziation des Komplexes werden angegeben.

Résumé—Par l'emploi de la méthode des variations continues de Job, on a trouvé un complexe 1:1 entre les ions molybdate et chloranilate acide en solutions aqueuses à diverses valeurs du pH et de la température. Le pH doit être respecté à 0,05 unité près pour que l'acide chloranilique obéisse à la loi de Beer. Les constantes de dissociation du complexe à température constante décroissent linéairement lorsque le pH croît jusqu'à pH 4, puis croissent linéairement avec le pH. On suggère le passage du complexe d'un ion polymolybdate à un autre comme cause de ce minimum dans la courbe du K_d en fonction du pH. Cette supposition est appuyée par la courbe d'absorption en fonction du pH du complexe. Cette courbe montre une tendance assez accentuée à décroître par rapport aux valeurs attendues à partir de pH 4. On présente des données thermodynamiques relatives à la dissociation du complexe.

ISOTOPIC-DILUTION ANALYSIS BY ION EXCHANGE—II*

SUBSTOICHIOMETRIC DETERMINATION OF TRACES OF INDIUM

JAROMÍR RŮŽIČKA and JIŘÍ STARÝ†
Department of Nuclear Chemistry, Faculty of Technical and Nuclear Physics
Praha 1, Břehová 7, Czechoslovakia

(*Received* 16 *October* 1963. *Accepted* 29 *November* 1963)

Summary—A highly selective, substoichiometric method for determination of traces of indium has been developed. The procedure consists of the addition of a substoichiometric amount of EDTA to the test solution labelled with a known amount of radio-indium, followed by the separation of the complex formed from the excess of unreacted indium on a Dowex-50 column. Using a preliminary cupferron extraction, the procedure becomes highly selective. The average precision of the determination of indium for amounts of 1·1 μg/10 ml is 1·6% in the presence of an excess of many metals. The maximum sensitivity of the method is about 5 × 10^{-5} μg/10 ml.

INTRODUCTION

IN a previous paper[1] the essential conditions were given for the determination of traces of metals using isotopic-dilution analysis by ion exchange. This method can be used if the following conditions are fulfilled:

1. A radiotracer of suitable half-life and high specific activity is available.
2. It is possible to isolate very small and equal amounts of the metal under investigation from solutions containing it in different amounts.

The second condition can be fulfilled by adding equal amounts of a complexing agent to a standard solution containing only the radioisotope used and to the test solution to which a known amount of standard solution has been added. The amount of complexing agent added has to be smaller than stoichiometrically corresponds to the amount of the metal to be determined. This substoichiometric amount of the reagent must react quantitatively with the metal to be determined and the complex formed must be easily separated from the excess of unreacted metal ions. Obviously, EDTA is a very suitable reagent because it forms stable neutral or negatively charged complexes which are easily separable from the excess of unreacted metal ions on a cation-exchange column.

With EDTA indium forms a very stable negatively charged complex (log K_1 = 25·0: see Table I). Also, two radioisotopes of indium (^{114m}In and ^{115m}In) are available, and therefore isotopic-dilution analysis by ion exchange can be used for the determination of traces of this metal. Uni-, bi-, quinque- and hexavalent metals will not interfere in the determination because the stability constants of their complexes with EDTA are much lower than those of indium (see Table I). However, interference from some ter- and quadrivalent metal ions can be expected. Using a preliminary cupferron extraction followed by back-extraction of indium into dilute hydrochloric acid, indium

can be separated from most interfering metals. However, as with all other methods based on the isotope-dilution principle, this preliminary separation need not be quantitative.

EXPERIMENTAL

Apparatus

Scintillation counter: Well-type NaI(Tl) crystal.

Geiger-Müller end-window counter

pH-meter: Radiometer TTT 1 (Copenhagen, Denmark).

Glass test-tubes: With ground stopper.

Ion-exchange columns: A set of 12 columns, each 0·4 cm diameter and 10 cm high.

Reagents

Triple-distilled water: Used for dissolving all reagents and for all other operations.

Cupferron (ammonium salt of N-nitrosophenylhydroxylamine) solution: Prepared by extraction of a

0·005M solution of AnalaR cupferron in 0·001M hydrochloric acid with an equal volume of chloroform. This solution was prepared freshly before each series of experiments.

Hydrochloric acid: AnalaR grade purified by repeated distillation.

Ascorbic acid solution: 10% solution in water of the AnalaR reagent.

Ethylenediaminetetra-acetic acid (EDTA): AnalaR disodium salt.

Acetate buffer solution (pH 3·0): Purified by cupferron extraction.

Cation exchanger: Dowex 50 Wx in the Na-form, 50/100 mesh.

Indium chloride (carrier) solution: Prepared by dissolving 99·999% pure metallic indium in hydrochloric acid and diluting with water to the appropriate concentration.

Radioisotopes

^{114m}In ($t_{1/2}$ = 50 *day*, β, γ): Prepared by irradiation of metallic indium in a nuclear reactor.
^{115m}In ($t_{1/2}$ = 4·5 *hr*, β, γ): Carrier-free ^{115m}In was prepared by the nuclear reaction

$$^{115}\mathrm{Cd} \xrightarrow{43\ \mathrm{day}} {}^{115}\mathrm{In}$$
$$^{115}\mathrm{Cd} \xrightarrow{53\ \mathrm{hr}} {}^{115}\mathrm{In}$$
$$^{114}\mathrm{Cd}(n\gamma)^{115m}\mathrm{Cd} + {}^{115}\mathrm{Cd}.$$

The cadmium (as $CdCl_2$) was purified, before irradiation, from traces of indium originally present by acetylacetone solvent extraction. After irradiation, the sample was dissolved in slightly acidified water, the pH adjusted to *ca.* 5 and carrier-free indium extracted with 0·1M acetylacetone in chloroform.[3] The indium was stripped into 0·1M hydrochloric acid, evaporated to dryness and the residue dissolved in an acidified indium carrier solution of appropriate concentration.

Preparation of cation-exchange columns

The columns were filled with cation-exchanger Dowex 50 and washed 3-5 times with EDTA solution, then 3-5 times with water. This purification was repeated before each series of experiments.

Procedure

To 10 ml of a solution containing in addition to the indium to be determined an excess of other metal ions, a precisely known amount of radio-indium* (y) was added. The pH of the solution was

[b] In general, 3 samples (A_2) were examined for 1 standard (A_1).

adjusted to 2-3 by adding hydrochloric acid or acetate buffer solution. This prepared solution was successively extracted with two 5-ml portions of cupferron solution in chloroform. The combined extracts were shaken with 2-3 ml of $0{\cdot}1M$ hydrochloric acid, then transferred into polyethylene bottles. The amount of indium recovered can be controlled by measuring the activity of the hydrochloric acid with a Geiger-Müller counter. However, this separation need not be quantitative. To the treated solutions some drops of ascorbic acid solution were added to reduce the last traces of iron^{III} present. After adding a substoichiometric amount of EDTA, the pH was adjusted to 2-3 with acetate buffer and the solution passed through a cation-exchange column at the rate of 0·3 ml/min. After washing the column with water, the activity (A_2) of the eluate was measured with a scintillation or Geiger-Müller counter. A standard solution containing only radio-indium was treated in exactly the same way. The amount of radio-indium present in this solution need not be known precisely, but it must be higher than stoichiometrically corresponds to the EDTA present. Furthermore, the amount of EDTA must be precisely the same as in the test solution. After measuring the activity of the eluate (A_1), the amount of indium (x) present in the test solution was calculated from the relation

$$x = y\left(\frac{A_1}{A_2} - 1\right).$$

Some results of the determination of indium in the range 1·1 μg/10 ml to about 5×10^{-5} μg/10 ml are summarised in Tables II and III.

DISCUSSION

From the results given in Table II it follows that the determination of traces of indium is very selective. Using the preliminary cupferron separation many metals are extracted simultaneously with indium (*i.e.*, metals for which $pH_{1/2} < 3{\cdot}5\text{–}4{\cdot}0$: see Table I). By shaking the extract with dilute hydrochloric acid, indium passes into the aqueous phase, whereas iron^{III}, zirconium, hafnium, *etc.*, remain in the organic phase (see Table I). Using a substoichiometric amount of EDTA, only indium and bismuth react, forming negatively charged complexes (see Table I). This fact was verified experimentally. It was found that a one hundred- to one thousand-fold excess of alkali metals, alkaline earths, copper, mercury^{II}, zinc, silver, cadmium, lead, nickel, cobalt^{II}, thallium^{I}, vanadium^{V}, molybdenum^{VI}, tungsten^{VI}, uranium^{VI}, chromium^{III}, iron^{III}, lanthanum, germanium, arsenic^{III} and tin^{IV}, and a ten-fold excess of titanium, zirconium, thorium and gallium, did not interfere. Bismuth interferes when present in excess, but its interference was eliminated by a preliminary extraction with $10^{-3}M$ dithizone in chloroform at pH 2–3.

The maximum sensitivity of the method (about 5×10^{-5} μg of In/10 ml) was reached using carrier-free indium. Correction was made for the ^{117m}In and ^{117}In present in the carrier-free indium as a result of

$$^{116}\text{Cd}\,(n\gamma)\,^{117m}\text{Cd}$$

$$^{117m}\text{Cd} \longrightarrow {}^{117m}\text{In} + {}^{117}\text{In}.$$

CONCLUSION

It has been shown that the use of EDTA for the substoichiometric determination of indium is advantageous not only for the high selectivity of the method, but also for the high stability of the EDTA solution against oxidation even at the lowest concentration. Thus, better reproducibility of the determination of a minute amount of the metal can be reached in comparison with isotopic-dilution analysis by solvent extraction.

Acknowledgement—The authors thank Dr. M. Williams for his interest in this work, and Professor V. Majer and Dr. G. B. Briscoe for critical discussion.

Zusamménfassung—Eine hochselektive unterstöchiometrische Methode zur Bestimmung von Indiumspuren wurde entwickelt. Man gibt eine unterstöchiometrische Menge EDTA zu der mit einer bekannten Menge Radio-Indium markierten Probelösung. Dann wird der Komplex vom überschüssigen, nicht gebundenen Indium auf einer Dowex 50-Säule abgetrennt. Nach vorhergehender Kupferronextraktion wird das Verfahren hochselektiv. Die mittlere Genauigkeit der Indiumbestimmung bei Mengen von 1,1 μg/10 ml ist 1,6% in Gegenwart eines Überschusses vieler Fremdmetalle. Die maximale Empfindlichkeit der Methode liegt bei etwa $5 . 10^{-5}$ μg/10 ml.

Résumé—On a élaboré une méthode substoechiométrique, hautement sélective, de dosage de traces d'indium. La technique consiste en l'addition d'une quantité substoechiométrique d'EDTA à la solution étudiée, marquée d'une quantité connue de radio-indium, suivie de la séparation du complexe formé de l'excès d'indium qui n'a pas réagi, sur une colonne remplie de Dowex 50. En procédant à une extraction préliminaire au cupferron, la technique devient hautement sélective. La précision moyenne du dosage de l'indium pour des quantités de 1,1 μg/10 ml est de 1,6% en présence d'un excès de nombreux métaux. La sensibilité maximale de la méthode est d'environ 5×10^{-5} μg/10 ml.

Summary—The possibilities of substoichiometric determination of traces of metals by activation analysis and isotope-dilution analysis are critically discussed and optimum conditions given for the determination of 24 metals.

INTRODUCTION

DURING the last few years procedures for the substoichiometric determination of traces of zinc, mercury, copper, iron, silver, molybdenum, indium, arsenic, antimony, cobalt and gallium in highly pure materials (*e.g.*, germanium dioxide, silicon, lead, *etc.*) have been developed in our laboratory.[1–15,22] Because of the high selectivity and simplicity the possibilities of this method are now being studied in other laboratories, but not in all cases are the best conditions (especially as regards suitability of reagent and pH for determination) selected. To stimulate the development of this method optimum conditions for the determination of 24 metals are given in the present paper.

Substoichiometry can be used in activation analysis and isotope-dilution analysis because in both methods the element to be determined need not be isolated quantitatively from the test sample, the amount being calculated from the activity of its radioisotope. It has previously been shown that for the substoichiometric determination of any element two basic conditions need to be fulfilled:[1,7,16,18]

1. A suitable radioisotope of the element to be determined is available.
2. It is possible to isolate *equal* amounts of the element to be determined from the standard and test solutions containing it in different amounts.

Radioisotopes suitable for the determination of traces of metals by activation analysis and isotope-dilution analysis are summarised in Table I.[19]

The second condition can be accomplished by adding a substoichiometric amount of a complexing agent. This reagent must be consumed quantitatively, forming a complex easily separable from the excess of unreacted metal ions. In our experience the most suitable reagents are organic reagents forming complexes extractable into organic solvents and complexones forming neutral or negatively charged complexes readily adsorbed on cation-exchange columns.

In activation analysis the amount of element handled is relatively high because 1 to 10-mg amounts of isotopic carrier are usually added. For this reason 10^{-2}–$10^{-3}M$ solutions of the organic reagents can generally be used and their stability towards oxidising agents and decomposition by light need not be so high as in the case of isotope-dilution analysis. For well known reasons any non-active trace contaminants carried into the treated sample after irradiation (originating from reagents, walls of

---

* Present address: Institute of Nuclear Research, Dubna, U.S.S.R.

vessels, *etc.*) cannot influence the result of the analysis. The disadvantages of activation analysis are:

1. The total activity handled is often high.
2. The nuclear interferences and shielding effects must be considered.
3. The proposed separation procedure has to be highly selective.

In isotope-dilution analysis an isotopic carrier cannot be added; therefore the amount of the element handled is often very low (10^{-6}–10^{-10} g) and the solutions of organic reagents used for substoichiometric determination are very dilute (10^{-5}–10^{-9} *M*). For this reason complexones are more advantageous than the organic reagents used in solvent extraction because their stability towards oxidising agents is much higher. In the later case it seems to be promising to use instead of organic reagents their metal complexes (*e.g.*, copper dithizonate can be used for the substoichiometric determination of mercury). The second disadvantage of isotope-dilution analysis, as in other destructive analytical methods (*e.g.*, spectrophotometry, polarography, *etc.*), lies in the fact that contamination of the treated sample by the element to be determined influences the result of the analysis. Therefore, in this type of determination, the reagents, vessels and distilled water must be especially purified. The advantages of isotope dilution are as follows:

1. The activity handled is negligible.
2. It is not necessary to irradiate the sample in a nuclear reactor.
3. In some cases (if a carrier-free isotope or one of high specific activity is available), a higher sensitivity can be reached than by activation analysis.

From the above it follows that activation analysis is more suitable than isotope-dilution analysis for determining traces of elements in such materials as metals, ores and minerals, the decomposition of which requires a large amount of reagents (*e.g.*, acids, hydroxides, *etc.*). Isotope-dilution analysis is advantageous for determination of traces of metals in easily decomposed or water-soluble materials. This method, when the neutron-activation cross section is low and/or when the half-life of the radioisotope formed is very short, is more sensitive than activation analysis.

SELECTED SEPARATION PROCEDURES FOR SUBSTOICHIOMETRIC DETERMINATION OF TRACES OF METALS

Selective procedures for the substoichiometric determination of traces of 24 metals by activation analysis (AA) or by isotope-dilution analysis (IDA) are now summarised. The conditions for the determination of 11 of these metals have been verified experimentally. Optimum conditions for the determination of the other metals are predicted on the basis of the theory of substoichiometry. However, this method can also be used for the determination of many other elements, but, because of the lack of stability constants or extraction constants, conditions for their substoichiometric determination cannot be predicted. Ion-association complex extraction systems and precipitation reactions (especially precipitation from homogeneous solution) have not been considered, although these methods might be useful in activation analysis.

Antimony and arsenic can be determined by AA using diethylammonium diethyldithiocarbamate or lead diethyldithiocarbamate solution in chloroform as an organic reagent.[15] In the case of antimony cupferron can also be used.[22] Interfering metals are removed by preliminary extraction with the same reagents before the reduction of antimony^{V} and arsenic^{V} to the tervalent state. These reagents are not suitable for IDA because of their low stability in very dilute solutions. The determination of antimony^V by IDA was worked out by extraction with a substoichiometric amount of methyl violet into toluene from 1:1 hydrochloric acid.[20]

Bismuth can be determined using a substoichiometric amount of EDTA at pH 1–2. Using a preliminary dithizone extraction in the presence of potassium cyanide,[19] the method becomes very selective. This procedure can be used both in AA or IDA. For nuclear reasons (see Table I), a higher selectivity can be reached by means of IDA.

Cadmium can be determined at pH 4–5 using a substoichiometric amount of EDTA. However, this procedure in not very selective and a preliminary dithizone extraction from basic solution must be carried out to increase its selectivity.[17] The proposed procedure is suitable for AA as well as for IDA.

Chromium will probably be best determined by formation of the very stable chromium^{III}-EDTA complex. Interfering metals can be removed by preliminary extraction with dithizone and oxine.[17]

Cobalt, in trace quantities, has been determined by AA in iron^{II} sulphate. After a preliminary cupferron extraction using fluoride as masking agent, cobalt was determined by extraction with 1-nitroso-2-naphthol.[12] The substoichiometric determination of cobalt by IDA using EDTA was shown to be unsuitable, because many elements interfered.[12]

Copper has been determined by AA[8] and by IDA[5] using dithizone extraction into carbon tetrachloride. Using potassium iodide as masking agent and the technique of successive extraction with several substoichiometric amounts of reagent, the method becomes highly selective.

Gallium has been determined by AA using a preliminary α-benzoinoxime extraction for removing molybdenum, vanadium and tungsten, followed by extraction of gallium with a substoichiometric amount of oxine in chloroform at pH 3.6.[13] Thiosulphate and ascorbic acid were used as masking agents for copper and iron. A substoichiometric determination of gallium based on the formation of the gallium^{III}-EDTA complex at pH 2–2·5 seems to be advantageous for IDA.

Gold, in trace amounts, can be determined both by AA and IDA using extraction with a substoichiometric amount of dithizone in chloroform. Interference from palladium can be removed by a preliminary dimethylglyoxime extraction; bromides or iodides can be used for masking mercury and silver.

Indium, in trace quantities, in germanium dioxide, has been determined by AA using a substoichiometric amount of EDTA at pH 2–3.[11] This procedure becomes very selective if a preliminary dithizone or cupferron extraction is followed by back-extraction of indium into dilute mineral acid. The same procedure has been applied to the substoichiometric determination of indium by IDA. Using carrier-free indium, down to about 5×10^{-11} g of indium/10 ml was determined.[14]

Iron^{III} down to 2×10^{-9} g/5 ml has been determined using IDA. Separation procedures using a substoichiometric amount of EDTA[4] or substoichiometric extraction with cupferron[6] are both very selective. The separation procedure will also be valuable for AA.

Lead cannot be determined by AA for nuclear reasons. On the other hand, it can be determined by IDA because a carrier-free isotope of lead (see Table I) is available. The proposed procedure consists of adding a substoichiometric amount of EDTA at pH 4–5 and separation of the resulting complex on a cation-exchange

[a] Data corrected to July 1961 from Chart of the Nuclides, Second Edition, prepared at Institute of Radiochemistry, Nuclear Research Centre Karlruhe, West Germany.

column. A preliminary dithizone extraction in the presence of potassium cyanide followed by back-extraction of lead into dilute acid increases the selectivity of the determination.[17]

Mercury has been determined by means of extraction with a substoichiometric amount of dithizone in carbon tetrachloride. This procedure is very selective and no preliminary separation steps need be carried out. It has been used successfully both in AA[16] and in IDA.[3]

Molybdenum has been determined by AA using extraction with a substoichiometric amount of oxine.[9] The method is very selective because only palladium interferes. To propose a substoichiometric separation for the determination of traces of molybdenum by IDA is very difficult because the extraction constants of molybdenum chelates are not known. However, the application of cupferron extraction for this purpose would be very interesting.

Nickel, using a substoichiometric amount of EDTA, can probably be determined by AA. However, a preliminary dimethylglyoxime extraction will be necessary for removing interfering elements.[17]

Palladium, because the extraction constant of palladium-dithizonate is very high, will be determined very selectively using a substoichiometric dithizone extraction. Thio-oxine also seems to be very promising for this purpose.

Platinum can be determined using a substoichiometric amount of dithizone in the presence of tin^{II} chloride. All interfering metals can be removed by a preliminary dithizone extraction when platinum is present in the solution in the tervalent state.[17]

Scandium can probably be determined by AA or by IDA with a preliminary oxine extraction[17] followed by substoichiometric EDTA separation at pH 2·5–3.

Silver. IDA by the extraction of silver with a substoichiometric amount of dithizone has been employed for the determination of traces of this element in biological materials.[21] EDTA was a suitable masking agent for many metals. The above procedure has also been applied to the determination of traces of silver by AA. In this case a high selectivity was obtained by the technique of successive extraction with a substoichiometric amount of dithizone.[10]

Thallium. The best separation procedure for its substoichiometric determination is based on the formation of the very stable thallium^{III}-EDTA complex at pH 2. The selectivity can be increased by a preliminary dithizone extraction.

Thorium, using a preliminary thenoyltrifluoracetone extraction,[17] can be separated from most metal ions which would interfere in a subsequent separation of the thorium-EDTA complex at pH 2–3, using a substoichiometric amount of EDTA. This method will probably be more advantageous for IDA than for AA.

Vanadium can be determined by AA using a substoichiometric extraction with oxine.

Zinc, in trace quantities, can be extracted very selectively with a substoichiometric amount of dithizone in carbon tetrachloride in the presence of diethanoldithiocarbamate at pH 7–9. This method has been used successfully for the determination of zinc both by AA[8] and IDA.[2]

Zirconium forms with EDTA one of the most stable complexes.[17] For this reason the determination of this element using a substoichiometric amount of EDTA at pH 1 will be very selective.

Acknowledgement—The authors thank Dr. M. Williams for his interest in this work and Professor V. Majer and Dr. G. B. Briscoe for critical discussion.

Zusammenfassung—Unterstöchiometrische Bestimmung von Metallspuren. Die Möglichkeiten zur unterstöchiometrischen Bestimmung von Metallspuren durch Aktivierungsanalyse und Isotopenverdünnung werden kritisch diskutiert und optimale Bedingungen für die Bestimmung von 24 Metallen angegeben.

Résumé—On discute de façon critique des possibilités de dosage substoechiométrique de traces de métaux par analyse par activation et par dilution isotopique, et l'on donne les conditions optimales de dosage de 24 métaux.

A NEW OXIDIMETRIC REAGENT: POTASSIUM DICHROMATE IN A STRONG PHOSPHORIC ACID MEDIUM—II*

TITRIMETRIC DETERMINATION OF VANADIUM^{IV}

G. Gopala Rao and P. Kanta Rao
Department of Chemistry, Andhra University, Waltair, India

(*Received* 12 *November* 1963. *Accepted* 4 *December* 1963)

Summary—Results are presented of investigations leading to the development of a procedure for the titrimetric determination of vanadium^{IV} with potassium dichromate in a strong phosphoric acid medium ($> 12M$) at room temperature, using a potentiometric end-point. Cerium^{IV}, iron^{III}, chromium^{III}, tungsten^{VI}, molybdenum^{VI}, uranium^{VI}, cobalt^{II} and nickel^{II} do not cause any interference. Methods have also been developed for the differential potentiometric titration of iron^{II} plus vanadium^{IV}, manganese^{II} plus vanadium^{IV}, and iron^{II} plus manganese^{II} plus vanadium^{IV} in the same solution. The new reagent thus possesses several advantages over potassium permanganate and cerium^{IV} sulphate. Application of the new reagent to the analysis of a ferro alloy and an alloy steel is considered.

Müller and Just[1] observed that a temperature of 70–80° is necessary for the potentiometric titration of vanadium^{IV} with potassium permanganate, even though the difference in potential of the two redox couples involved is about 0·45 V. Willard and Young[2] investigated the visual titration of vanadium^{IV} with potassium permanganate in a solution buffered with sodium acetate using ferroïn as indicator. Because the reaction is observed to be slow at room temperature, they recommended the titration to be carried out at 50°, adding the oxidising agent slowly. Recently, Gopala Rao and Dikshitulu[3] improved the method by using phosphoric acid (2·5 ml of syrupy phosphoric acid/50 ml of mixture) as catalyst, which enables the titration of vanadium^{IV} with potassium permanganate to be made at room temperature at the usual speed using ferroïn as indicator in 0·1–0·15M sulphuric acid. Issa and Daes[4] proposed adding a known excess of potassium permanganate to the vanadium^{IV} solution in the presence of a barium salt, then making the solution alkaline and titrating the excess permanganate with a standard solution of formic acid or thallium^{I} salt solution. The barium salt precipitates both the products of reaction, manganate and vanadate, the first being formed by the reduction of permanganate and the second by the oxidation of vanadium^{IV}. If telluric acid is used in place of a barium salt, the permanganate is reduced to manganese^{IV}, which forms a manganese^{IV} tellurate complex.

Willard and Young[5] reported that the potentiometric titration of vanadium^{IV} with cerium^{IV} sulphate is quantitative in sulphuric, hydrochloric or perchloric acid solution at 70–75°. The break in potential at the end-point decreases as the acidity is increased. Furman[6] independently found that the potentiometric titration of vanadium^{IV} with cerium^{IV} sulphate gives accurate results when carried out at 50–60°.

---

* Part I: see reference 13.

Gopala Rao and Dikshitulu[7,8] found that the reaction between vanadium^{IV} and cerium^{IV} sulphate is catalysed by phosphoric acid, so that the titration of vanadium^{IV} can be made with cerium^{IV} sulphate at room temperature in 0·75–1·25*M* sulphuric acid with a potentiometric end-point or using Rhodamine-6G as a fluorescent indicator.

Smith and Getz[9] found that vanadium^{IV} perchlorate can be titrated at room temperature in 8*M* perchloric acid with a solution of ammonium hexanitratocerate(IV) in perchloric acid with a potentiometric end-point. Obviously the method has little practical significance, because it is tedious to obtain vanadium^{IV} as a perchlorate in a perchloric acid medium.

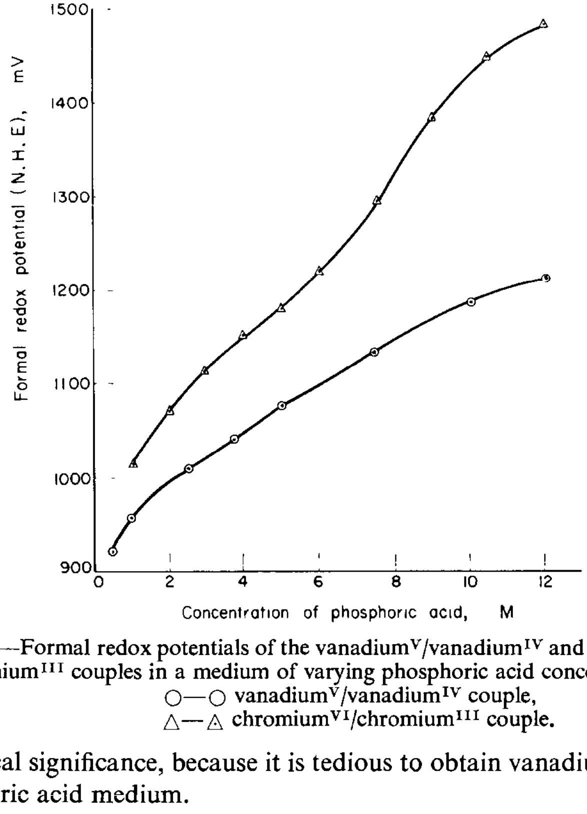

FIG. 1.—Formal redox potentials of the vanadium^{V}/vanadium^{IV} and chromium^{VI}/chromium^{III} couples in a medium of varying phosphoric acid concentration:[13,14]
○—○ vanadium^{V}/vanadium^{IV} couple,
△—△ chromium^{VI}/chromium^{III} couple.

Riolo and Soldi[10] proposed boiling a vanadium^{IV} solution to eliminate all dissolved oxygen and treating the same with a known excess of alkaline sodium chlorite. The vanadium^{IV} is instantaneously oxidised to vanadium^{V} by the chlorite. The vanadium^{V} is precipitated as barium vanadate and the excess sodium chlorite determined iodometrically. It is obvious that the method is indirect and tedious. Willard and Manalo[11] recommended the use of 2-carboxy-2′-methoxydiphenylamine and similar diphenylamine derivatives in the titration of alkaline hexacyanoferrate(III) with vanadium^{IV} at room temperature.

Willard and Merritt[12] found that vanadium^{IV} is rapidly and completely oxidised by ozone in a dilute sulphuric acid medium at room temperature. The addition of phosphoric acid to give an over-all concentration of 0·75*M* is recommended. The resulting vanadium^{V} is titrated with a standard solution of Mohr's salt, after the excess of ozone is eliminated. The method has the disadvantage that it is indirect and is subject to interference by manganese^{II}, which is partially oxidised to permanganate.

From the foregoing review of the literature, it is seen that potassium dichromate has not been tried as an oxidant for vanadium^{IV} in an acid medium. Therefore we have now undertaken such a study. We[13] have previously reported the formal redox potential of the chromium^{VI}/chromium^{III} couple in a medium of varying phosphoric acid concentration. These values and those of the formal redox potential of vanadium^{V}/vanadium^{IV} couple as determined by Gopala Rao and Dikshitulu[14] in a medium of varying phosphoric acid concentration are graphically represented in Fig. 1. From the curves it will be observed that in a 12*M* phosphoric acid medium, the difference in the formal potential of the two couples is 0·273 V at 28°, which is sufficient for a rapid oxidation of vanadium^{IV} by chromium^{VI} to proceed. Using this value the equilibrium constant of the reaction can be calculated from the cell reaction

$$6VO^{2+} + Cr_2O_7^{2-} + 5H_2O \rightarrow 6VO_3^{-} + 2Cr^{3+} + 10H^{+}$$

to be $K = 2{\cdot}692 \times 10^{27}$ ($\log_e K = nF \times E_{cell}/RT$). Several electrometric titrations have shown that the time required for the attainment of steady potentials in the vicinity of the equivalence point is about 6 min when the concentration of phosphoric acid is 9*M*, about 3 min when the concentration of phosphoric acid is 10·5*M* and only 1 min when the concentration of phosphoric acid is about 12*M*.

EXPERIMENTAL

Reagents

0·1M Vanadium^{IV} sulphate solution. Prepared by reducing an aliquot volume of about 0·2*M* sodium vanadate solution in a sulphuric acid medium with sulphur dioxide at boiling temperature, driving off the excess of sulphur dioxide by passing a rapid stream of carbon dioxide, then making up the solution to the desired volume. The solution is standardised potentiometrically with a standard solution of cerium^{IV} sulphate according to the procedure of Dikshitulu and Gopala Rao.[7]

0·033M Potassium dichromate solution. Prepared from "Pro Analysi" grade potassium dichromate supplied by E. Merck (Germany).

Phosphoric acid. Syrupy phosphoric acid of AnalaR grade supplied by British Drug Houses Limited (England) and syrupy phosphoric acid of "Pro Analysi" grade of E. Merck (Germany) have both been used successfully in this investigation. The potential break at the equivalence point with the B.D.H. phosphoric acid is about 35 mV and with the Merck phosphoric acid about 40 mV in the titration of 2–10 ml of about 0·1*M* vanadium^{IV} sulphate solution (diluted to 50 ml)/0·04 ml of 0·033*M* potassium dichromate solution.

Apparatus

The potentiometric assembly consists of a Cambridge potentiometer and a suspension galvanometer. A bright platinum rod electrode is used as indicator electrode and a saturated calomel electrode as reference electrode. The salt bridge consists of an inverted U-tube with porous end plates. The indicator electrode and reference electrode are connected through two salt bridges, one filled with saturated sodium perchlorate and the other filled with saturated sodium nitrate. The mixture is stirred during the titration by means of an electromagnetic stirrer.

Experiments have shown vanadium^{IV} to be quite stable in a strong phosphoric acid medium so that the titration of vanadium^{IV} with potassium dichromate can be made safely in air. It may be of interest to note in this connection that Del Fresno and Mairlot[15] carried out the titration of chromate in 6·0*M* sodium hydroxide solution at 70° with vanadium^{IV} sulphate solution, an inert atmosphere being maintained because of the sensitivity of quadrivalent vanadium in an alkaline medium.

Potentiometric Titration of Vanadium^{IV}

From 2 to 10 ml of 0·1*M* solution of vanadium^{IV} are taken in a 150-ml Pyrex beaker and treated with 40–50 ml of syrupy phosphoric acid (90%). The mixture is connected to the saturated calomel electrode through a saturated sodium perchlorate bridge and a saturated sodium nitrate bridge, then titrated with a standard solution of 0·033*M* potassium dichromate while it is stirred by means of an electromagnetic stirrer. Potentials are measured 1 min after the addition of each portion of the titrant using the potentiometric assembly already described. A typical potentiometric titration curve

(E *vs.* V) is given in Fig. 2. Because the potential break at the equivalence point is not very high, the equivalence point of the titration is better read from the curve obtained by plotting ΔE/ΔV against V. A representative curve of this type is shown in Fig. 3. A large number of titrations of vanadium^{IV} have been carried out in this manner and some typical results are given in Table I. The method enables vanadium^{IV} to be determined with an error not exceeding ±0·3%.

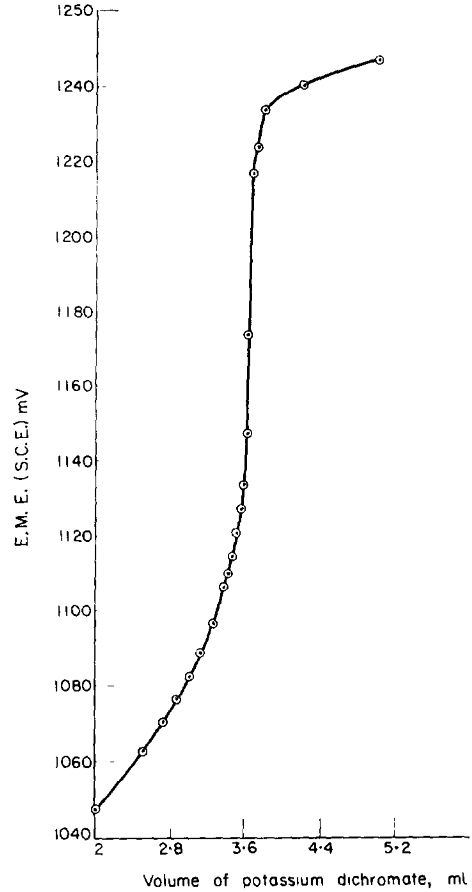

FIG. 2.—Potentiometric titration of vanadium^{IV} (37·32 mg) with 0·033*M* potassium dichromate in a 12*M* phosphoric acid medium.

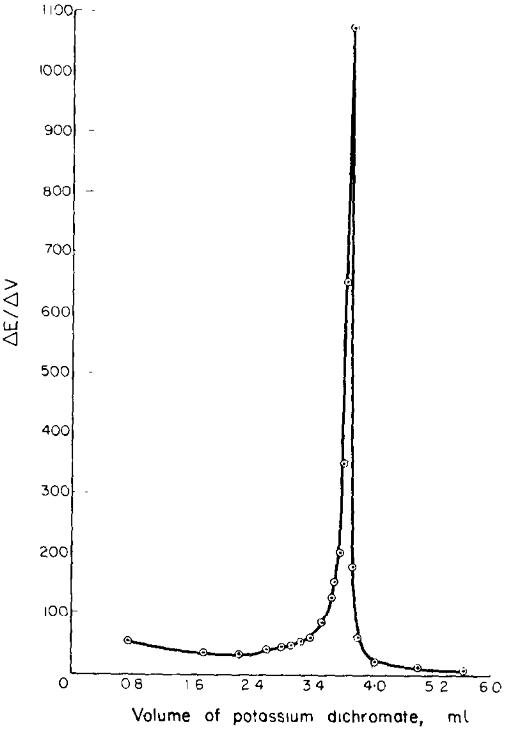

FIG. 3.—Potentiometric titration of vanadium^{IV} (37·32 mg) with 0·033*M* potassium dichromate in a 12*M* phosphoric acid medium.

If a higher break in potential is desired, the alternative procedure prescribed later in this paper may be followed.

Interferences

In the presence of chloride no potential break is found at the equivalence point. Nitrate interferes by slowly reacting with vanadium^{IV}. When the over-all concentration of nitrate is 0·5*M* and 1·0*M* the results are low by 1·7% and 2·5%, respectively. Iron^{II}, uranium^{IV}, molybdenum^{V}, tungsten^{V}, cerium^{III}, arsenic^{III}, antimony^{III} and manganese^{II} are also oxidised by potassium dichromate under the conditions proposed for the titration of vanadium^{IV}. Cobalt^{II}, cerium^{IV}, nickel^{II}, iron^{III}, tungsten^{VI}, molybdenum^{VI}, uranium^{VI} and chromium^{III} do not interfere as can be seen from Table II. Calcium, aluminium, and magnesium also do not interfere. Sulphuric and perchloric acids do not interfere even up to an over-all 1*N* concentration.

Differential Potentiometric Titration of a Mixture of Iron^{II} and Vanadium^{IV}

Willard and Young[5] achieved the differential potentiometric assay of iron^{II} and vanadium^{IV} with cerium^{IV} sulphate by titrating the mixture first at 5–10°, then at 70–75°. The first break in potential corresponds to iron^{II} and the second break to vanadium^{IV}. Furman[6] published a somewhat similar procedure almost simultaneously. The first part of the titration with cerium^{IV} sulphate is recommended to be carried out at room temperature and the second part at 50–60°. However, the method has the disadvantage that the first break in potential is very low. Gopala Rao and Dikshitulu[7] reported the simultaneous differential titration of iron^{II} and vanadium^{IV} in a 0·5–1.0*M* sulphuric acid medium with cerium^{IV} sulphate at room temperature using a small quantity of orthophosphoric acid as a catalyst for the oxidation of vanadium^{IV} by cerium^{IV} sulphate. They found that the potential breaks are about 60–70 mV and 55–65 mV/0·05 ml of 0·05*M* cerium^{IV} sulphate for the oxidation of iron^{II} and vanadium^{IV}, respectively.

[a] 37·20 mg of vanadium^{IV} taken.

When one attempts the titration of a mixture of iron^{II} and vanadium^{IV} with potassium dichromate in a strong phosphoric acid medium, two different cases arise, firstly when the iron^{II} is in excess of vanadium^{IV} (Case I) and secondly when the amount of iron^{II} is less than that of the vanadium^{IV} (Case II). Vanadium^{IV} is reduced to vanadium^{III} by iron^{II} as soon as phosphoric acid is added, as already reported by Gopala Rao and Dikshitulu,[16] so that in Case I there will be a mixture of vanadium^{III}, iron^{II} and iron^{III} and in Case II there will be a mixture of vanadium^{III}, vanadium^{IV}

and iron^{III}. Because iron^{II} is unstable to atmospheric oxygen in a strong phosphoric acid medium, strict precautions should be taken to see that in all experiments corresponding to Case I, the phosphoric acid is added only after all atmospheric oxygen is driven off by a strong current of carbon dioxide, which is also maintained during the subsequent titration. The titrations should also be made with a solution of potassium dichromate which is free from dissolved oxygen. In titrations of Case I, three potential breaks have been observed, the first corresponding to the oxidation of iron^{II} to iron^{III}, the second corresponding to the oxidation of vanadium^{III} to vanadium^{IV} and the third corresponding to the further oxidation of vanadium^{IV} to vanadium^{V}. When the amount of iron^{II} (Case II) is less than that of vanadium^{IV}, an amount of vanadium^{III} equivalent to that of iron^{II} is formed. Only two breaks are observed, the first corresponding to the oxidation of vanadium^{III} to vanadium^{IV} and the second corresponding to the oxidation of vanadium^{IV} to vanadium^{V}. An advantage with these systems is that it is not necessary to maintain an inert atmosphere, because the vanadium^{III} formed is resistant to atmospheric oxidation for the duration of a titration. The results presented in Table III show that the error is $\pm 0{\cdot}4\%$ for the iron^{II} determination and $\pm 0{\cdot}3\%$ for the vanadium^{IV} determination. Figs. 4 and 5 give potentiometric titration curves typical of Cases I and II, respectively. The potential at the first equivalence point attains a steady value only after 8 min, in titrations corresponding to Case I. After the first break is obtained the potentials are noted 2 min after each addition of potassium dichromate solution. After the second break the potentials are noted 1 min after each addition of potassium dichromate solution. The first break in potential amounts to about 120 mV, the second to about 200 mV, and the third to about 40 mV/0·04 ml of 0·033*M* potassium dichromate solution, when the total volume of titration mixture is about 50 ml. Because the potential break for vanadium^{IV} oxidation is not very high, a plot of $\Delta E/\Delta V$ *vs.* V is also given for the vanadium^{IV} part of the titration in Figs. 4 and 5.

Alternative Procedure for Potentiometric Titration of Vanadium^{IV}

In the procedure described above, it has been noted that during the potentiometric titration of vanadium^{IV} in a 12*M* phosphoric acid medium, the potential jump at the inflection point is about 40 mV/0·04 ml of 0·033*M* potassium dichromate solution. If a more satisfactory jump is desired, one can resort to the expediency of adding an amount of iron^{II} sulphate in excess of that required for reducing vanadium^{IV} to vanadium^{III}. Gopala Rao and Dikshitulu[16] have already reported that vanadium^{IV} is quantitatively reduced by iron^{II} in a strong phosphoric acid medium. Thus, when an excess of iron^{II} is added to vanadium^{IV} in a strong phosphoric acid medium, the mixture will contain unreacted iron^{II}, vanadium^{III} and iron^{III}. If this mixture is titrated with potassium dichromate solution, three inflections will be observed in the titration curve, the first corresponding to the oxidation of iron^{II} to iron^{III}, the second corresponding to the oxidation of vanadium^{III} to vanadium^{IV} and the third corresponding to the oxidation of vanadium^{IV} to vanadium^{V}. Because one is interested only in the determination of vanadium^{IV}, the exact amount of iron^{II} added does not matter, provided it is somewhat in excess of vanadium^{IV} and the titration can also be carried out under ordinary atmospheric conditions. The advantage of this procedure for vanadium^{IV} is twofold. Firstly, the inflection corresponding to the oxidation of vanadium^{III} to vanadium^{IV} is about

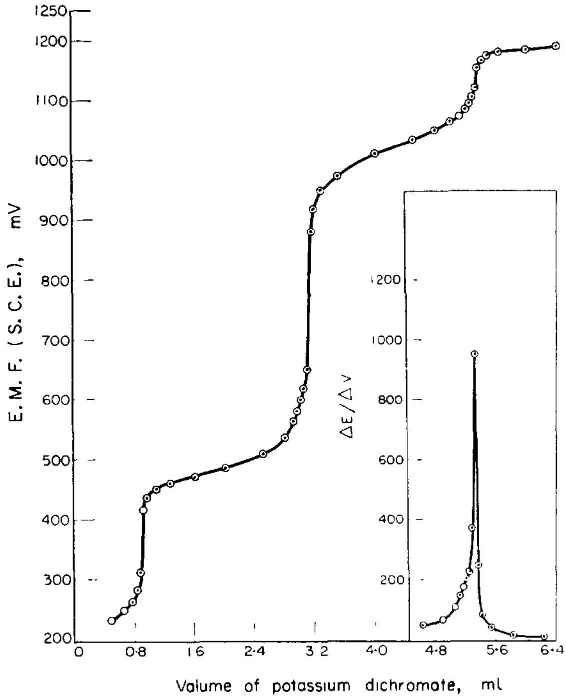

FIG. 4.—Differential potentiometric titration of a mixture of iron^{II} (34·85 mg) and vanadium^{IV} (22·47 mg) with 0·033*M* potassium dichromate in a 12*M* phosphoric acid medium (Case I).

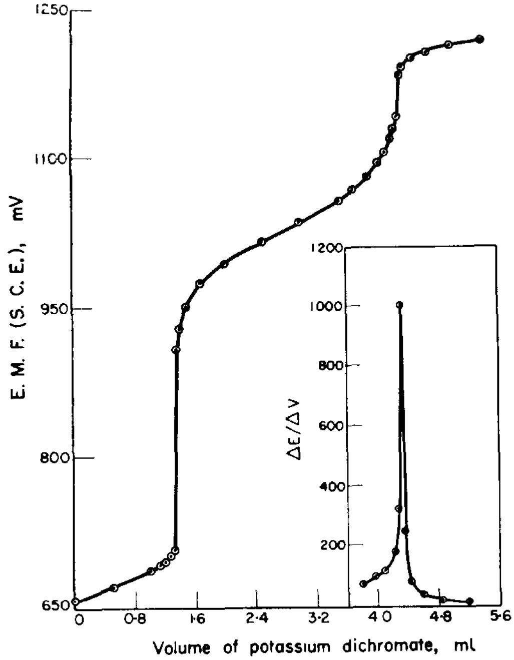

FIG. 5.—Differential potentiometric titration of a mixture of iron^{II} (14·92 mg) and vanadium^{IV} (30·20 mg) with 0·033*M* potassium dichromate in a 12*M* phosphoric acid medium (Case II).

200 mV/0·04 ml of 0·033*M* potassium dichromate solution; secondly, the last part of the titration (corresponding to the oxidation of vanadium^{IV} to vanadium^{V}) gives a check on the determination of vanadium. A large number of assays of vanadium^{IV} according to the above alternative procedure indicates that the error for vanadium^{IV} is not greater than ±0·3%.

Differential Potentiometric Titration of a Mixture of Vanadium^{IV} and Manganese^{II}

When a mixture of vanadium^{IV} and manganese^{II} is titrated with potassium dichromate in a 12*M* phosphoric acid medium only one potential break is observed, vanadium^{IV} and manganese^{II} reacting simultaneously with the oxidant. However, this difficulty can be overcome by the expediency of adding an excess of iron^{II} sulphate solution. When an amount of iron^{II} greater than required to reduce vanadium^{IV} to vanadium^{III} is added to a mixture of vanadium^{IV} and manganese^{II} in 12*M* phosphoric acid and the mixture titrated in air with potassium dichromate, three different breaks are obtained. The first inflection corresponds to the oxidation of unreacted iron^{II} to iron^{III}, the second inflection corresponds to the oxidation of vanadium^{III} to vanadium^{IV} and the third inflection corresponds to the simultaneous oxidation of vanadium^{IV} and manganese^{II} to vanadium^{V} and manganese^{III}, respectively. In titrations conducted with 0·033*M* potassium dichromate solution, the jump at the first inflection point is found to be about 120 mV/0·04 ml of the titrant, the jump at the second inflection point is found to be about 200 mV/0·04 ml of the titrant and the jump at the third inflection point is found to be about 25 mV/0·04 ml of the titrant. In view of the small break, the third inflection point is better obtained from the $\Delta E/\Delta V$ *vs.* V curve. The amount of dichromate added between the first and second inflections corresponds to the amount of vanadium^{III} (or vanadium^{IV}). The amount of dichromate between the third and second inflections corresponds to vanadium^{IV} plus manganese^{II}. Hence the amount of manganese^{II} can also be calculated. Some typical results are given in Table IV. They show that vanadium^{IV} and manganese^{II} can be determined with an error not exceeding ±0·3% and ±0·4%, respectively.

Differential Potentiometric Titration of a Mixture of Iron^{II}, Manganese^{II} and Vanadium^{IV}

When it is desired to assay a mixture for iron^{II}, vanadium^{IV} and manganese^{II}, it is desirable to carry out the potentiometric titration under the conditions described for the assay of a mixture of iron^{II} and vanadium^{IV}, having the iron^{II} in excess. If in the experimental mixture, the amount of iron^{II} is actually less than that required for the reduction of vanadium^{IV}, it is necessary to add a known amount of iron^{II} to the mixture and allow for the same in the calculations. Table V gives some typical results, showing that iron^{II}, vanadium^{IV} and manganese^{II} can be determined in the same solution with an error not exceeding ±0·45%, ±0·3% and ±0·4%, respectively.

TABLE V.—DIFFERENTIAL POTENTIOMETRIC TITRATION OF IRON^{II}, VANADIUM^{IV} AND MANGANESE^{II}.

Analytical Applications

Determination of vanadium in ferrovanadium

About 3 g of the alloy (dried at 110°) are decomposed in a platinum dish with a mixture of 60 ml of sulphuric acid (1:3) and 25 ml of nitric acid (1:1) and any silica is expelled by heating with hydrofluoric acid to dryness. The residue is treated with a mixture of sulphuric and nitric acids and evaporated until copious fumes of sulphuric acid are evolved. After cooling, the solution is made up to 250 ml in a volumetric flask. To 10 ml of this solution 50 ml of syrupy phosphoric acid (90%) are added and treated with a slight excess of iron^{II} sulphate, which reduces the vanadium^{V} to vanadium^{III}. The mixture is then titrated potentiometrically with $0{\cdot}033M$ potassium dichromate solution. The first break in potential may be neglected. The volume of titrant between the first and second breaks corresponds to that required for the oxidation of vanadium^{III} to vanadium^{IV} and that between the second and third breaks to the oxidation of vanadium^{IV} to vanadium^{V}.

Determination of vanadium in chrome-vanadium-tungsten steel

About 2 g of the steel are taken in a 250-ml Pyrex beaker, treated with 15 ml of water, 10 ml of syrupy phosphoric acid (90%) and 6 ml of concentrated sulphuric acid, and gently heated to decompose the steel completely; then 3 ml of concentrated nitric acid are added and the solution evaporated to fumes of sulphuric acid. The solution is cooled and made up to 100 ml in a volumetric flask. A 15-ml portion of this solution is taken in a beaker, treated with enough phosphoric acid so that the over-all concentration is $12M$, then with enough iron^{II} solution to reduce the vanadium^{V} to vanadium^{III}. The mixture is finally titrated potentiometrically with $0{\cdot}033M$ potassium dichromate. Results of some typical analyses are presented in Table VI.

TABLE VI.—ANALYSIS OF VANADIUM IN ALLOYS

Sample	Vanadium found by present method, %	Vanadium found[7] using cerium^{IV}, %

Zusammenfassung—Die Ergebnisse von Untersuchungen werden vorgelegt, die zur Entwicklung eines Verfahrens zur titrimetrischen Bestimmung von Vanadin^{IV} mit Kaliumdichromat führten, und zwar in starker Phosphorsäure ($>12M$) bei Zimmertemperatur mit potentiometrischer Endpunktsanzeige. Cer^{IV}, Eisen^{III}, Chrom^{III}, Wolfram^{VI}, Molybdän^{VI}, Uran^{VI}, Kobalt^{II} und Nickel^{II} stören nicht. Es wurden auch Methoden entwickelt zur gleichzeitigen potentiometrischen Titration von Eisen^{II} und Vanadin^{IV}, Mangan^{II} und Vanadin^{IV}, sowie Eisen^{II}, Mangan^{II} und Vanadin^{IV} in derselben Lösung. Das neue Reagens hat daher verschiedene Vorteile vor Kaliumpermanganat und Cer^{IV}-Sulfat. Die Anwendung des neuen Reagens zur Analyse einer Ferrolegierung und eines legierten Stahls wird ebenfalls erörtert.

Résumé—On présente les résultats d'études conduisant au développement d'une méthode de dosage volumétrique du vanadium (IV) au moyen de bichromate de potassium en milieu acide phosphorique concentré ($>12M$) à température ambiante, avec détermination potentiométrique du point de virage. Les cérium (IV), fer (III), chrome (III), tungstène (VI), molybdène (VI), uranium (VI), cobalt (II) et nickel (II) n'interfèrent pas. On a également développé des méthodes de dosage potentiométrique différentiel pour fer (II) avec vanadium (IV), manganèse (II) avec vanadium (IV), et fer (II) avec manganèse (II) et vanadium (IV) dans la même solution. Le nouveau réactif possède

ainsi plusieurs avantages sur le permanganate de potassium et le sulfate de cérium (IV). On considère aussi l'application du nouveau réactif à l'analyse d'un alliage de fer et d'un alliage d'acier.

PRELIMINARY COMMUNICATION

Silver^{II} in aqueous perchlorate solutions

(*Received* 24 *December* 1963. *Accepted* 7 *January* 1964)

BECAUSE of its potential usefulness as a powerful homogeneous oxidising agent, silver^{II} is of considerable interest to analytical chemists. A few analytical applications of silver^{II} as an oxidising agent have already been reported,[1-3] but relatively little is known concerning the characteristics and behaviour of silver^{II} as a solution species. Apart from a comprehensive review by McMillan[4] on the higher oxidation states of silver, a recent optical and kinetic study of silver^{II} in aqueous solution, reported by Kirwin *et al.*,[5] is particularly noteworthy.

The present investigation was undertaken to examine the absorption spectra of silver^{II} from the analytical standpoint and, if possible, to gain some information on the nature of silver^{II} species in aqueous perchlorate media.

EXPERIMENTAL

Silver^{II} oxide of 98·5% minimum purity was obtained from Handy and Harman Company, New York, U.S.A.; perchloric acid, silver^{I} perchlorate, and sodium perchlorate (all reagent-grade) from G. F. Smith Chemical Company, Columbus, Ohio, U.S.A. Spectra were recorded using a Beckman Model DB ultraviolet-visible spectrophotometer equipped with matched quartz cells held at 10·00 ± 0·15°. Solid silver^{II} oxide was dissolved in pre-cooled solvent and pipetted directly into the thermostatted spectrophotometer cell. Decomposition rates were determined from slopes of absorbance-time curves recorded at 475 mμ, and rate constants were calculated using standard kinetic techniques.

RESULTS AND DISCUSSION

Ultraviolet and visible spectra of silver^{II} in perchloric acid solutions revealed a previously unknown maximum at 265 mμ, as well as the 475-mμ peak reported by Kirwin *et al.*[5] The effect of perchloric acid concentration on the 265-mμ and 475-mμ peaks was investigated in the 6–11·5*M* range, and showed a steady (roughly three-fold) increase in the ratio of absorbance at 265 mμ to that at 475 mμ over the range studied. No isosbestic point was found, however, suggesting that silver^{II} is appreciably complexed by perchlorate and that at least three different solution species of silver^{II} are involved.

Kinetic experiments for the decomposition of silver^{II} at constant acidity and ionic strength yielded an empirical rate law second order in silver^{II} and inverse first order in silver^{I} concentration, with an over-all activation energy of 11·6 Kcal/mole. These findings are in complete agreement with the results of Kirwin *et al.*,[5] who suggest a rate-determining step of the type

$$2\,Ag^{II} \rightleftarrows Ag^{I} + Ag^{III}.$$

If this disproportioning step is, in fact, rate-determining, the equilibrium must be strongly shifted to the left, and absorbance studies at zero time should show that silver^{II} obeys Beer's law. Plots of reciprocal absorbance *versus* time were, therefore, constructed from decomposition rate experiments carried out with no silver^{I} initially present. The resulting straight lines were extrapolated to zero time, and the corresponding absorbance values were plotted against initial silver^{II} concentrations. These plots showed that silver^{II} does obey Beer's law, and indicate that the steady-state concentration of silver^{III} must indeed be small compared with the concentration of silver^{II}.

Efforts are in progress to determine the stoichiometry and formation constants of the silver^{II} perchlorate complexes observed, and to elucidate the role of higher oxidation states of silver in several reactions of analytical interest.

SHORT COMMUNICATIONS

Absorptiometric determination of indium with Thorin

(*Received* 17 *October* 1963. *Accepted* 5 *December* 1963)

IT has already been shown that microgram quantities of indium interfere seriously in the absorptiometric determination of bismuth with Thorin [2-(2-hydroxy-3,6-disulpho-1-naphthylazo)-benzenearsonic acid] or its disodium salt in 0·02*M* perchloric acid.[1] Consequently, it was decided to examine the use of Thorin as an absorptiometric reagent for indium.

EXPERIMENTAL

Apparatus

Spectrophotometer: Beckman Model B, with 1-cm Pyrex cells.

pH meter: Beckman Model 76, with Type E-2 glass electrode.

Reagents

Thorin: Supplied as its disodium salt by J. T. Baker Chemical Co., U.S.A. (Analysed Reagent). It was used without further purification as a 0·1% aqueous solution.

Standard indium solution: Indium metal ("Spec-pure", Johnson Matthey & Co., England) was dissolved in the smallest possible amount of analytical-reagent grade acid (perchloric, hydrochloric or sulphuric) and made up to the appropriate final volume with distilled water. All other solutions were prepared from analytical-reagent grade materials.

Effect of variables on colour development

Preliminary tests showed that indium and Thorin form a red-orange compound in moderately acidic solution or a red precipitate when indium is in a great excess. The reagent blank solution is yellow under such conditions. The absorption spectra of the indium–Thorin complex obtained at different hydrogen ion concentrations, using the corresponding reagent blank as reference, indicated an absorption maximum at about 520–525 mμ with an inflection around 490 mμ. The wavelength of the absorption peak remains constant with pH but the sensitivity is markedly pH dependent. The value of the absorbance at the wavelength of the absorption peak remains practically constant between pH 3·0 and 5·0, but decreases considerably at higher or lower pH. No difference in absorption from the blank was observed at a pH lower than 1·5 or higher than 6·0.

The colour is formed rapidly and is stable up to 150 μg of indium/25 ml. The absorbance decreases about 0·5% after standing for 48 hr at room temperature (solutions exposed to daylight and/or fluorescent light). Indium concentrations higher than 150 μg/25 ml gave non-reproducible results with absorbance falling off with time. This behaviour is considerably pronounced above 200 μg of indium/25 ml.

The colour may be developed either in perchloric, sulphuric or hydrochloric acid. The absorption spectra obtained are similar. Nitric acid must be free from nitrogen oxides if used to provide the acid medium. The sensitivity in hydrochloric acid is somewhat lower than in perchloric acid or sulphuric acid. Sensitivity values expressed as proposed by Sandell[2] are 0·022 μg of indium/cm^2 for log Io/I = 0·001 in perchloric acid or sulphuric acid (plus sodium hydroxide to obtain a pH of *ca.* 3·5). It was observed that the reproducibility is increased if Thorin is added in an acidic medium (pH *ca.* 2), the solution made basic (pH $\geqslant$ 9), then the pH adjusted to the desired value with dilute acid.

The spectra of solutions with different ratios of reagent to metal were measured against reagent blanks and at varying pH. No isobestic point was observed. The absorption spectrum of the indium-Thorin complex at pH *ca.* 3·5 is shown in Fig. 1. Higher concentrations of Thorin than the recommended $1{\cdot}4 \times 10^{-4}M$ do not increase the sensitivity appreciably; this concentration was chosen to limit the blank.

The effect of Thorin concentration on the absorbance of the indium-Thorin complex at 520 mμ showed that a concentration near $1{\cdot}4 \times 10^{-4}M$ seems to be the most suitable for photometric measurements.

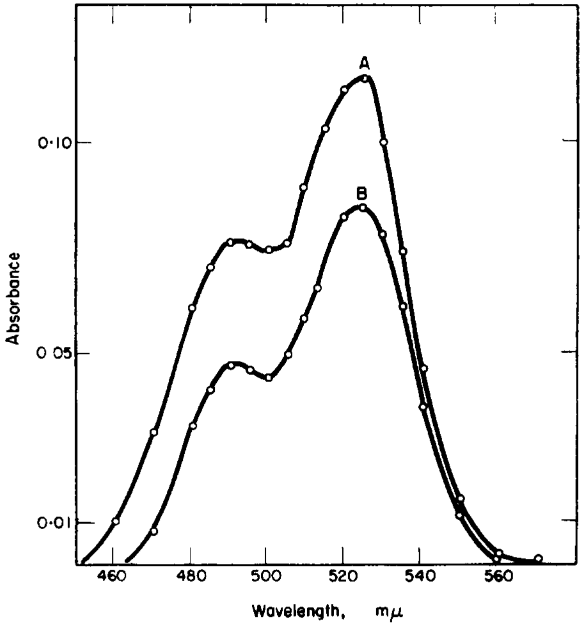

FIG. 1.—Absorption spectrum of indium-Thorin complex (pH *ca.* 3·5, with pH adjustment according to *Procedure*; perchloric acid-sodium perchlorate medium; 1-cm cell; 0·07–0·12 mm slit width; reagent blank as reference)
(A) 1·4 × $10^{-4}M$ Thorin and 0·24 × $10^{-4}M$ indium,
(B) 0·35 × $10^{-4}M$ Thorin and 0·24 × $10^{-4}M$ indium.

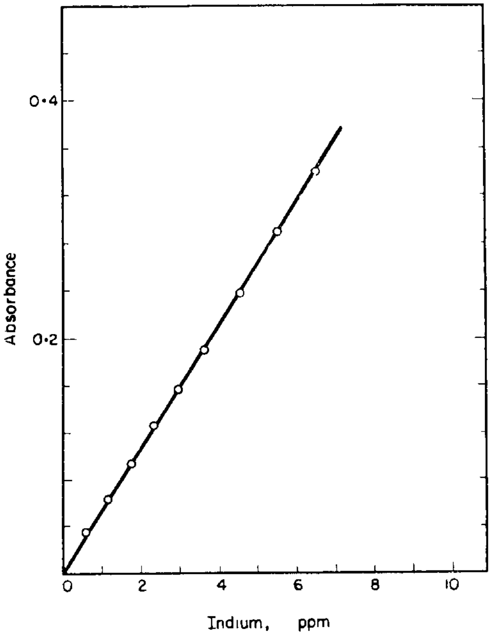

FIG. 2.—Calibration curve for determination of indium with Thorin (1·4 × $10^{-4}M$ Thorin pH *ca.* 3·5; perchloric acid-sodium perchlorate medium; 520 mμ; 0·1 mm slit width; reagent blank as reference)

Under the experimental conditions reported here the absorbance is proportional to the indium concentration from approximately 15 to 150 μg of indium/25 ml (0·6 to 6 ppm). The average of 10 determinations in pure solution run according to the directions given in the *Procedure* was 100·1 (standard deviation 1·3) for 100 μg of indium/25 ml, and 15·5 (standard deviation 1·5) for 15 μg of indium/25 ml.

A Ringbom plot[3] of the data in Fig. 2 shows that the concentration range for the highest accuracy lies between 2·5 and 6 ppm. From least square calculation, the molar absorptivity (based on indium) is 6,100 at 520 mμ.

The great variation in absorbance with time and the poor reproducibility of results when the indium concentration is higher than 150 μg/25 ml do not allow the determination of the molar ratio indium: Thorin by known methods.[4,5] Consequently, the use of the reaction in photometric titrations gives poor results.

The foreign species which interfere in the determination of bismuth with Thorin[1] are expected to interfere in this determination of indium. It may be noted that gallium under similar conditions and at 520 mμ shows a sensitivity value of 0·015 μg of gallium/cm[2] for log Io/I = 0·001. Lead interferes above 25 μg/25 ml. Bismuth does not interfere up to 0·25 mg/25 ml. As much as 10 mg of thallium[1] failed to show interference.

Procedure

Transfer the acidic solution, containing 15–140 μg of indium, to a 100-ml beaker. The volume of the solution must be less than 18 ml. Add 2 ml of 0·1% Thorin solution, then 10% sodium hydroxide solution dropwise until the colour changes to red. Adjust the pH to *ca.* 3·5 (pH meter) by adding drops of a dilute solution of acid. Transfer to a 25-ml volumetric flask, make up to volume with distilled water and measure the absorbance at 520–525 mμ against a reagent blank solution as reference. Prepare a standard curve from known amounts of indium following the same procedure.

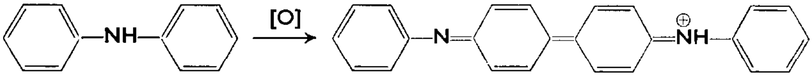
Spot tests for chlorate, bromate and iodate in admixture

(*Received* 18 *November* 1963. *Accepted* 6 *January* 1964)

THE three halates, chlorate, bromate and iodate, are well known primary standard reagents in analytical chemistry. Selective identification methods for them are usually based on the difference between the three oxidation potentials. Clear-cut differentiation is, however, difficult, and we propose new selective reactions utilising the potential difference of the three halates in oxidising three different organic compounds. The colour reactions described here are selective for each of the halates in the presence of the remaining two.

Detection of Chlorate

It has recently been found[1] that diphenylamine in suitable media (ethyl acetate and trichloracetic acid) shows selective properties towards oxidising material. Thus, it is oxidised by elementary chlorine, but not by bromine or iodine, to the meriquinoidal diphenylbenzidine blue:



It was expected that chlorine dioxide might behave in the same manner. Indeed, when concentrated sulphuric acid acts on chlorate (solid or in solution), the evolved gas (chlorine dioxide) oxidises diphenylamine. Bromate and iodate were tested for the same reaction, but gave negative results. Because neither gives a dioxide by the action of concentrated acid and the bromine slightly liberated from the bromate does not oxidise diphenylamine, the reaction between chlorine dioxide liberated from the chlorate and diphenylamine is specific for the latter in the group of the halates.

Horovka and Holzbecher[2] proposed a method also involving the liberation of chlorine dioxide for detecting chlorate. The reagent used by them, benzidine acetate, is, however, oxidised not only by the chlorine dioxide but also by the bromine liberated by the action of concentrated acid on the bromate, which prevents the detection of chlorate in the presence of bromate by this method.

Procedure

One drop of the test solution is mixed with 1 drop of concentrated sulphuric acid in a micro test tube and immersed in a boiling water bath. A disk of filter paper is moistened with freshly prepared diphenylamine reagent solution and placed over the tube. The appearance of a green fleck within a few min is indicative of the presence of chlorate. Even large quantities of the other halates and perhalates do not interfere.

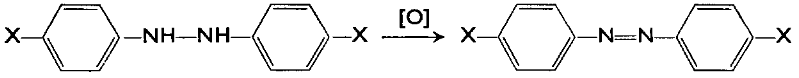
Diphenylamine reagent solution. To 10 ml of a saturated solution of diphenylamine in ethyl acetate, *ca.* 0·5 g of solid trichloracetic acid is added.

Limit of identification: 3 μg of chlorate.

Detection of Bromate

It is well known that the oxidation potential of bromate is higher than either that of chlorate or iodate. Bearing this fact in mind, a reagent was sought which would be oxidised by the compound with the higher potential, *i.e.*, by bromate alone.

It was found that aromatic amines, which contain an acidic group in the *p*-position, are oxidised selectively by bromate in nitric acid to a violet-blue compound which is subsequently transformed to a yellowish-brown colour. The oxidation probably proceeds via a hydrazo intermediate to the azo compound:



Chlorate and iodate in the same conditions give negative results. This reaction can be carried out by sulphanilic acid, arsanilic acid and *p*-amino-benzoic acid.[3]

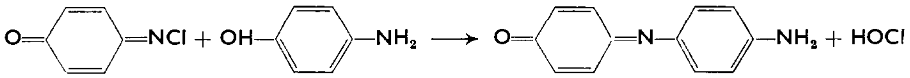
Procedure

To 1 drop of the test solution, 2 drops of 6*M* nitric acid are added and mixed in a micro test tube with 1 drop of a saturated aqueous solution of sulphanilic acid. The appearance of a violet colour within a few min is a positive response for the presence of bromate. This violet colour slowly changes to brown. None of the other halates and perhalates interferes.

Limit of identification: 0·5 μg of bromate.

Detection of Iodate

A mixture of quinonechlorimide and *p*-aminophenol gives a blue-violet indamine dye:



I

The hypochlorite liberated by this condensation can easily be detected as chlorine in the gas phase. *p*-Aminophenol can be oxidised to quinonimine which subsequently condenses with any remaining unchanged *p*-aminophenol. Thus, mild oxidants will give the coloured indamine dye similar to I with *p*-aminophenol, while strong oxidants convert it wholly to the colourless quinone via the quinonimine intermediate. This is the reason for the absence of a colour reaction in the case of bromate and chlorate, while the weaker oxidising agent iodate[4] yields the indamine dye on the partial oxidation of *p*-aminophenol. Minute quantities of periodate interfere, because they give the same reaction.

Procedure

To 1 drop of the test solution 1 drop of *p*-aminophenol reagent is added in a micro test tube. A violet colour appearing within a few min is a positive response for iodate. The other halates do not interfere, but periodate must be absent.

p-Aminophenol reagent solution. A 5% *p*-aminophenol chloride aqueous solution is used, and it should be nearly colourless.

Limit of identification: 0·5 μg of iodate.

ION EXCHANGE IN NON-AQUEOUS SOLVENTS

ADSORPTION BEHAVIOUR OF URANIUM AND OTHER ELEMENTS ON STRONG-BASE ANION-EXCHANGE RESIN FROM ORGANIC ACID-ORGANIC SOLVENT MEDIA

METHODS FOR THE SEPARATION OF URANIUM

J. Korkisch and S. Urubay*
Analytical Institute of the University of Vienna, IX, Währingerstrasse 38, Austria

(*Received* 19 *June* 1963. *Accepted* 1 *December* 1963)

Summary—In the present paper the anion-exchange behaviour of hexavalent uranium and of a number of other elements in organic solvents containing organic acids is described. The solvents employed include aliphatic alcohols, acetone and dioxan. As organic acids the monocarboxylic acids, *i.e.*, formic, acetic and propionic acid, and also chloro-derivatives of acetic acid, have been investigated. Through the determination of the distribution coefficients and separation factors in the various media, separation methods for uranium from other elements have been developed.

INTRODUCTION

Investigations of the isolation of uranium, and its separation from other elements by employing anion-exchange resins in combination with monocarboxylic acids acting as complexing agents for uranium, have been carried out in the past.[1–9] For this purpose, buffered aqueous solutions of acetic acid[1–5] were successfully employed. Similar experiments performed in buffered solutions of monochloro- and trichloro acetic acid did not, however, give promising results.[1] But ascorbic acid proved to be a valuable complexing agent for uranium and a series of other elements.[6–9]

In continuation of work on the ion-exchange behaviour of uranium and thorium in mixed and non-aqueous solvents,[10–13] the use of some organic acids in combination with various organic solvents, has now been investigated for the separation of uranium from other elements. Previous results using mineral acid-organic solvent mixtures showed that a great increase of adsorption could be observed by employing organic solvents in place of water. The next logical step was to investigate the adsorption behaviour of uranium and other elements in the presence of both organic acid and solvent. In the conditions selected, similar results were obtained to those when using mineral acids, *e.g.*, hydrochloric, nitric or sulphuric acids.

The experimental conditions selected and the results obtained in organic acid-organic solvent mixtures, using the strongly basic anion-exchanger Dowex 1, are here reported.

EXPERIMENTAL

Reagents

Ion-exchange resin: That used was the strongly basic anion-exchanger Dowex 1, ×8 (100–200 mesh, chloride form). For the equilibrium and separation experiments in organic acid-organic

solvent solutions, the resin was transformed into the corresponding organic acid forms, *i.e.*, the formate, acetate, monochloroacetate, dichloroacetate, trichloroacetate (this form of the resin slowly decomposed into the carbonate form and chloroform; see also page 740) and propionate forms. This was done by treating the chloride form of the resin with an aqueous solution of the acid in question, in the presence of an excess of its ammonium salt. This treatment, which should preferably be carried out on an ion-exchange column, was continued until no more chloride ions could be detected in the effluent. Thereafter, the resin was thoroughly washed with distilled water in order to remove the excess of the organic acid and its salt. (For the column separations the resin was then treated with the corresponding solution used for pretreatment; see also *Column operations*). Then the resin was washed with methanol and dried in air.

Standard solutions of uranium and other elements: Hydrochloric- or nitric acid solutions of the chlorides or nitrates, of exactly known element content, were employed. For each individual experiment an aliquot portion corresponding to the desired amount of the element to be tested was evaporated to dryness on a water-bath, and the residue was dissolved in the organic acid.

Organic acids: The following reagent-grade acids were employed: formic acid, acetic acid, monochloroacetic acid, dichloroacetic acid, trichloroacetic acid and propionic acid.

Organic solvents: The following reagent-grade solvents were employed: methanol, ethanol, n-propanol, isopropanol, n-butanol, isobutanol, acetone and dioxan.

Apparatus

Ion-exchange columns: The column operations were carried out in columns of the same type and dimensions as described earlier.[5]

Spectrophotometer: For the spectrophotometric determination of all elements investigated with the exception of uranium, which was determined fluorometrically, the Beckman Model B spectrophotometer was employed.

Fluorimeter: The photoelectric fluorimeter employed was a Galvanek Morrison Fluorimeter, Mark V.

Quantitative determinations

Determination of uranium: The quantitative determination of uranium in the eluates or filtrates (after removal of the resin by filtration) was usually performed fluorimetrically by means of a procedure described by Schönfeld, El Garhy, Friedmann and Veselsky.[14] Polarographic[2] or spectrophotometric methods, as described previously,[15,16] were also employed.

Determination of other elements: The most suitable and accurate photometric procedures described by Sandell[17] and Snell and Snell[18] were used. For the determination of lanthanum and gadolinium, representing the rare earths, a spectrophotometric method employing the azo dye Solochromate Fast Red was used.[12]

Determination of distribution coefficients

The distribution coefficients given by the equation

$$\text{Distribution coefficient} = \mathrm{K_d} = \frac{\mu\text{g element/g of resin}}{\mu\text{g element/ml of solution}}$$

were determined employing the batch equilibrium method (batch method).[10–13,19–28] Each $\mathrm{K_d}$-value for uranium, shown in Figs. 2, 5, 6, 8, 9 and 11, was obtained by equilibrating 1 g of the resin with 10 ml of solvent + 0–4 ml of acid (or 0–4 g of acid if solid) containing 10 mg of uranium. In the case of the results recorded in Figs. 1, 4, 7 and 10, varying ratios of solvent to liquid acid, with a constant volume of 10 ml of mixture, were used. The distribution coefficients for the other elements (see results shown in Tables I–VI) were obtained by employing mixtures consisting of 9 ml of solvent (10 ml in the case of the pure acids) + 1 ml of acid (if solid 1 g of acid) + 5 mg of the element + 1 g of resin. The relative experimental error in the determination of the $\mathrm{K_d}$-values was usually ±10% for low and ±20% for high $\mathrm{K_d}$-values. Not much reliance can, however, be placed on the $\mathrm{K_d}$-values measured at zero concentration of acid, because in those media hydrolysis or insolubility of the uranium salt is to be expected.

From the distribution coefficients thus obtained, the separation factors shown in Tables I–VI were calculated using the simple relationship:

$$\text{Separation factor} = \frac{\mathrm{K_d}\ \text{element}}{\mathrm{K_d}\ \text{uranium}}.$$

Because uranium is the key element in these investigations, all values for the separation factors have therefore been expressed relative to uranium.

Column operations

The column operations for the individual separation methods were performed in a standard manner. The resin (2 g of the corresponding form) was transferred to the ion-exchange column, and the resin bed was pretreated with a solution of the same composition as that employed as a sorption solution. After passage of the sorption solution the resin was usually treated with a "wash solution," also of the same composition. Thereafter the adsorbed elements (mostly uranium) were eluted by means of 1*M* hydrochloric acid.

RESULTS AND DISCUSSION

(1) *Adsorption of uranium from organic solvents containing formic acid*

In this section, and in sections (2), (4) and (6), the effect of the concentration of the organic acid on the K_d of uranium will be displayed twice in the case of each of the liquid acids, in order to show the influence of very low acid concentrations more clearly, and to demonstrate the effect of many organic solvents.

Fig. 1 shows that the adsorption of uranium is decreasing by orders of magnitude when the concentration of formic acid is increased from 0% to 100%. In pure formic acid, as well as in all mixtures of this acid with water, the adsorption is too low to be of any practical analytical importance.

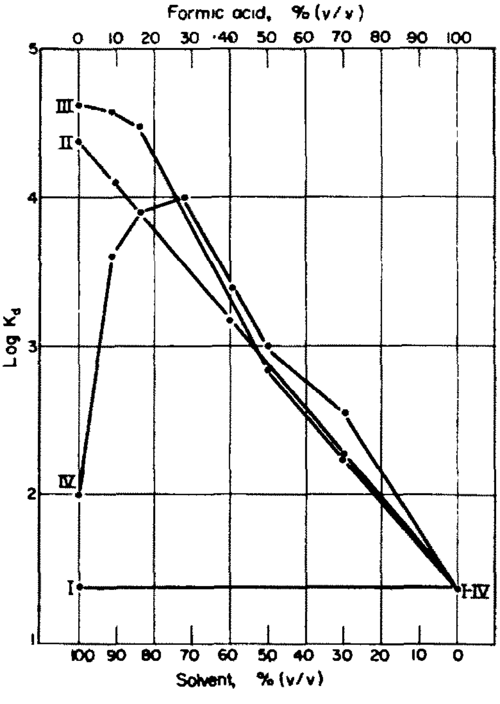

FIG. 1.—Influence of formic acid concentration:

I—Water	III—Acetone
II—Methanol	IV—Dioxan

In the range of concentration from 10% to 80% formic acid and from 90% to 20% organic solvent, the distribution coefficients of uranium have convenient values. In this region uranium is strongly adsorbed; *i.e.*, it is forming a relatively stable negatively charged formate complex.

In Fig. 2 the effect of the formic acid concentration on the distribution coefficients of uranium in aliphatic alcohols, acetone and dioxan is shown.

As can be seen from the curves shown in Fig. 2, the K_d of uranium has in all formic acid-organic solvent mixtures high values, which decrease, in the case of the aliphatic alcohols and acetone, regularly with an increase in the formic acid concentration. In dioxan-formic acid solution the K_d reaches a minimum and a maximum; and finally a relatively low value is obtained at zero formic acid concentration, suggesting hydrolysis of the uranyl ions in this medium. In the presence of 1 ml of formic acid the distribution coefficients of uranium show, in all media, log K_d-values ranging from 4·25 to 5·0, which means that in all these cases identical or very similar conditions of adsorption seem to exist. For this reason, all further experiments (for instance those relating to the effect of the uranium concentration or of the salt concentration on the distribution coefficient of uranium, and the determination of the distribution coefficients of other elements) were always performed in mixtures in

IX—Dioxan	

which the ratio of formic acid to organic solvent was 1:9 (usually 1 ml of formic acid + 9 ml of solvent).

Investigations of the influence of concentration of uranium on its K_d have shown that the K_d of uranium regularly decreases with increasing uranium concentration in the solutions containing formic acid and in all the solvents shown in Fig. 2. At a uranium concentration of 200 mg/10 ml of mixture, a log K_d value of 1·8–2·3 is reached; this does not decrease appreciably when higher uranium concentrations are employed. In the concentration range 0–100 mg of uranium/10 ml of mixture, the K_d of uranium remains constant, *i.e.*, the coefficient is independent of the uranium concentration in the solution. This means that a quantitative enrichment of mg- amounts of uranium from such mixtures is feasible, and is suitable for analytical purposes.

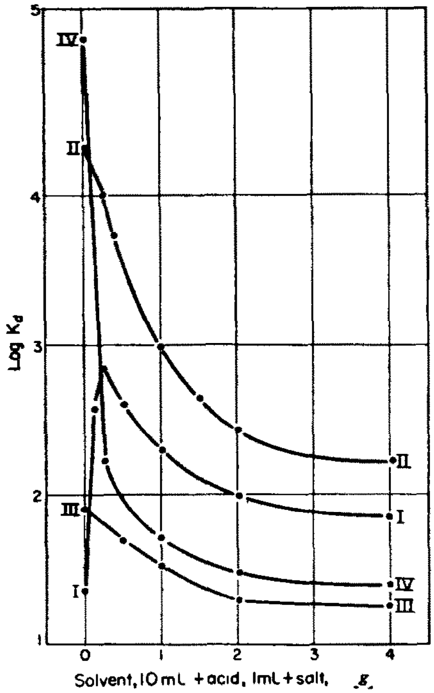

FIG. 3.—Influence of salt concentration on the adsorption of uranium:
I—Water-formic acid-ammonium formate
II—Methanol-formic acid-ammonium formate
III—Water-acetic acid-ammonium acetate
IV—Methanol-acetic acid-ammonium acetate

In Fig. 3 the influence of ammonium formate and ammonium acetate on the distribution coefficients of uranium is shown. Because the influence of the salt concentration on the K_d of uranium was investigated only in formic and acetic acid solutions, the results obtained in acetic acid medium have also been recorded in this diagram.

From Fig. 3 it is seen that the K_d of uranium in aqueous formic acid-formate solution first increases with increasing concentration of ammonium formate, but decreases at higher formate concentration. In methanol solution the decrease of adsorption with an increase of the formate concentration is regular, without formation of a maximum. In acetic acid-acetate-methanol solution the K_d of uranium in all cases decreases rapidly with increasing ammonium acetate content of the solutions. This means that for the analytical separation of mg-amounts of uranium, only acetic or formic acid solutions which contain very small amounts of acetate or formate salts can be employed. Previous experiments[2] showed that the breakthrough capacity for uranium in aqueous acetic acid solution buffered with acetate was only around 50 μg of uranium under the conditions employed. The results shown in Fig. 3 serve as examples of the effect of salts containing the same anion as that which complexes the uranium. This salt effect was not further investigated in other organic acid-organic solvent mixtures because it is assumed that in all cases a decrease will occur with increasing salt concentration. A similar effect has earlier[9] been observed in hydrochloric acid-ethanol solution where an increase of the sodium or ammonium chloride concentration is followed by a decrease of the K_d of uranium. In nitric acid-organic solvent mixtures, however, no change of the K_d of uranium by the addition of alkali or ammonium nitrate could be found. In pure aqueous nitric acid solutions, on the other hand, the K_d of uranium and the distribution coefficients of other elements frequently increase with increasing nitrate ion concentration.

Investigations on the adsorption behaviour of other elements in formic acid-organic solvent mixtures furnished the results recorded in Table I, in which the distribution coefficients of these elements, and the separation factors (in brackets), are shown. In this and in Tables II–VI water has been included amongst the solvents for the purpose of comparison.

The results in Table I show that the distribution coefficient and the separation factor of uranium usually differ by orders of magnitude from those of the other elements, so that the following three separation methods, which were developed in formic acid solutions, always gave quantitative results irrespective of whether μg- or mg-amounts of the elements uranium, copper, lead and gadolinium were employed for the separation experiments.

(*a*) *Separation of uranium from copper*

Ten ml of formic acid containing uranium and copper were diluted with 90 ml of methanol, and the solution was passed through the ion-exchange column (the resin having been pretreated appropriately; see *Experimental*) at a flow rate of 0·5 ml/min. During this sorption operation uranium $K_d = 2 \times 10^4$) was strongly adsorbed, whereas copper ($K_d = 11{\cdot}7$) passed into the effluent. Thereafter the resin was washed with 100 ml of a wash solution (see *Experimental*) in order to remove the last traces of copper from the column. Afterwards the uranium was eluted by means of 100 ml of 1*M* hydrochloric acid, and was determined quantitatively as described earlier (see *Experimental*).

(*b*) *Separation of uranium from lead*

The same experimental conditions were used here as described above under (*a*).

(*c*) *Separation of uranium from gadolinium*

Ten ml of formic acid containing uranium and gadolinium were mixed with 90 ml of isobutanol, and the solution was passed through an appropriately pretreated (see *Experimental*) resin bed at a flow rate of 0.5 ml/min. During this operation uranium ($K_d = 57 \times 10^3$) and gadolinium ($K_d = 2 \times 10^3$) were adsorbed simultaneously. Afterwards, a mixture consisting of 90 ml of methanol and 10 ml of acetic acid was percolated through the column; the gadolinium ($K_d = 47{\cdot}0$) was eluted, whereas uranium ($K_d = 64 \times 10^3$) was still strongly retained by the resin (compare with the results shown in Table II). The elution and quantitative determination of uranium in the eluate was performed as has been described above under (*a*).

From the results shown in Table I it can be seen that a great number of other separation possibilities exist, *e.g.*, separation of uranium from copper, nickel or lead

in formic acid-ethanol solution; separation of uranium from copper in formic acid-dioxan mixture; simultaneous adsorption of uranium and gadolinium from all formic acid-solvent mixtures except aqueous and methanol mixtures; separation of cobalt from uranium, nickel, lead, lanthanum and gadolinium in aqueous formic acid solution, *etc.*

Many of these separations can, of course, also be performed successfully by other anion-exchange methods, *e.g.*, in pure aqueous hydrochloric acid solutions of various molarities. However, the separation of various elements can be effected by changing the solvent only, without any change in the other experimental conditions. The results in Table I show that the simultaneous adsorption of uranium and cobalt from a formic acid-n-propanol mixture is possible. For the separation of the two coadsorbed elements the resin needs only to be washed with a formic acid-ethanol solution in order to remove the cobalt from the resin, thus effecting the separation of these two elements from one another. A simultaneous adsorption of uranium and cobalt from a pure aqueous hydrochloric acid solution (around $10M$ in HCl) is also possible. To separate the adsorbed elements the resin is washed with $6M$ hydrochloric acid, whereby cobalt is eluted whereas uranium is still retained by the resin. Comparison of these two separation possibilities shows that the exchange of solvent in the first method has the same effect as the change of the concentration of the complexing agent (hydrochloric acid) in the second case. This is one of the fundamental differences between ion exchange in pure aqueous solutions and in organic acid mixtures.

Determinations of distribution coefficients of a number of other elements in pure formic acid showed that these elements, in common with uranium, were only little or not at all adsorbed by the resin.

(2) *Adsorption of uranium from organic solvents containing acetic acid*

In Fig. 4 the influence of acetic acid concentration on the distribution coefficients of uranium in acetic acid-water, -methanol -acetone and -dioxan solutions is shown.

By comparing Fig. 4 with Fig. 1 it can be seen that the adsorption of uranium in acetic acid mixtures is high in the whole concentration range; and even in pure acetic acid the coefficient of uranium is high enough to guarantee the quantitative retention of even mg-amounts of this element by the resin. This also means that uranium forms a negatively charged acetate complex of high stability.

In Fig. 5 the effect of acetic acid concentration on the distribution coefficient of uranium in the acid concentration range 0–4 ml of acid + 10 ml of solvent is shown.

Fig. 5 shows that the distribution coefficients of uranium, in all solvents except water and n-propanol, have log K_d-values between 4·4 and 5·2 in the range 0·5–4 ml of acetic acid. Because here also, as in the case of formic acid mixtures (see Fig. 2), the difference of the log K_d values is smallest in the presence of 0·5–2·0 ml of acetic acid, all further experiments were performed in mixtures each of which contained 1 ml of acetic acid and 9 ml of the solvent, or a ratio of acetic acid to solvent of 1:9. As can further be seen from Fig. 5, uranium is adsorbed very strongly by the resin from all acetic acid-solvent mixtures, which means that all of these media are suitable for analytical purposes (see Table II). The adsorption from aqueous acetic acid is, however, lower by two orders of magnitude, although still high enough to effect the quantitative retention of even mg-amounts of uranium by the resin. In dioxan-acetic acid solution of low acidity the uranyl ions also hydrolyse, as was the case in the formic acid solutions of the same acidity (*cf.* Fig. 2) so that the K_d of uranium reaches a very low value. Up to a concentration of 50 mg of uranium/10 ml of solvent (in all solvents) no change of the K_d could be observed. At higher uranium concentrations the K_d decreases rapidly with increasing concentration, and then reaches in some solvents (*e.g.*, water and the aliphatic alcohols) a value at 150 mg of uranium/10 ml of solvent, which does not decrease appreciably with a further increase of the uranium concentration in the solutions.

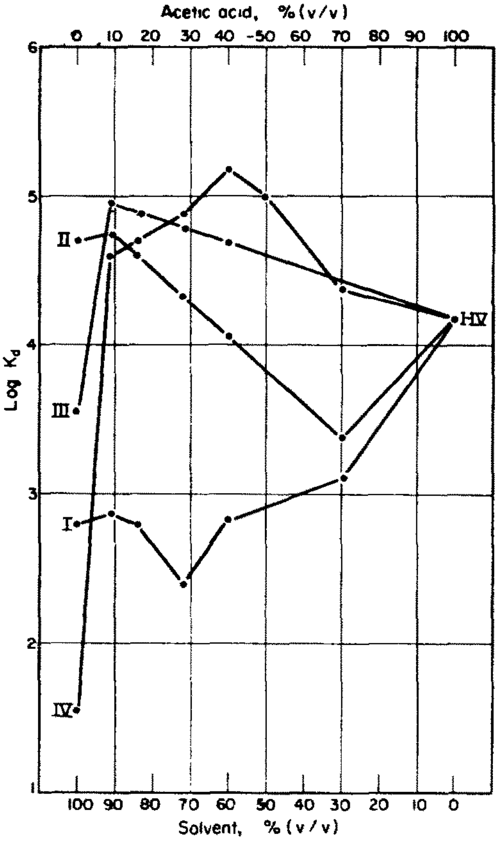

FIG. 4.—Influence of acetic acid concentration:
I—Water II—Methanol
III—Acetone IV—Dioxan

In Table II the distribution coefficients and separation factors (in brackets) of several elements in acetic acid-organic solvent mixtures are shown. Each mixture consisted of 1 ml of acetic acid and 9 ml of solvent. Pure acetic acid has also been incorporated into Table II, which means that those results were obtained in solutions which consisted of 10 ml of acetic acid only. Besides the elements recorded in Table II, the adsorption behaviour of a series of other elements in pure acetic acid was investigated. Practically only uranium is adsorbed, whereas other elements, as for instance Fe^{III}, the rare earths, alkaline earth metals, Mn^{II}, Zn^{II}, Cd^{II}, Mg, Be, In, *etc.*, are not retained by the resin; therefore the analytical separation of these elements from uranium should readily be achieved. In this medium the elements Al, Th and Bi hydrolyse; Pb, Sr and Ba are practically insoluble.

Based on the results shown in Table II a further series of ion-exchange separations

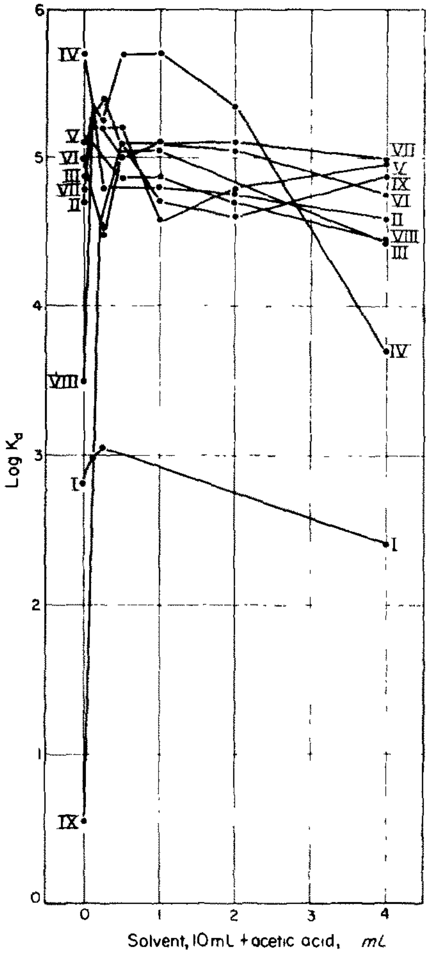

FIG. 5.—Influence of acetic acid concentration:

I—Water	II—Methanol
III—Ethanol	IV—n-Propanol
V—Isopropanol	VI—n-Butanol
VII—Isobutanol	VIII—Acetone
IX—Dioxan	

can be carried out. All these methods have in common that uranium is always strongly adsorbed, but the other elements are not adsorbed on the resin. As examples the following separation methods can be mentioned: separation of uranium from copper, nickel, cobalt, lanthanum and gadolinium in aqueous acetic acid solution; separation of uranium from copper, cobalt, lanthanum and gadolinium in acetic acid-methanol mixture; separation of uranium from copper, nickel and cobalt in

acetic acid-isobutanol mixture; separation of uranium from copper, nickel, cobalt, lanthanum and gadolinium in pure acetic acid.

Because in some solvents uranium and other elements are strongly adsorbed by the resin, the simultaneous adsorption of two or more elements becomes possible. By a change in the solvent the separation of the coadsorbed elements on the resin column can be effected. Examples for such solvent exchange separations are: simultaneous adsorption of uranium and cobalt from acetic acid-acetone solution followed by elution of cobalt by means of acetic acid-ethanol mixture (see below); simultaneous adsorption of uranium and gadolinium from acetic acid-isopropanol mixture and elution of gadolinium with acetic acid-methanol mixture; simultaneous adsorption of uranium, lanthanum and gadolinium from acetic acid-dioxan solution and elution of the rare earths by means of pure acetic acid, *etc.*

Closer investigation of the first example enabled the following separation method to be developed.

Separation of uranium from cobalt

Ten ml of acetic acid, which contained uranium and cobalt, were diluted with 90 ml of acetone, and the solution was passed through an appropriately pretreated resin column at a flow rate of 0·5 ml/min. During this process uranium ($K_d = 7 \times 10^4$) and cobalt ($K_d = 7 \times 10^2$) were adsorbed simultaneously. The separation of cobalt from uranium was effected by washing the resin with 100 ml of a solution consisting of 90% ethanol and 10% acetic acid. The cobalt ($K_d = 0{\cdot}48$) was eluted, but uranium ($K_d = 11{\cdot}3 \times 10^4$) still remained adsorbed. For the removal of uranium the resin was treated with 100 ml of 1*M* hydrochloric acid.

A series of separation experiments performed in this manner showed that μg- and mg-amounts of uranium and cobalt can quantitatively be adsorbed and separated by the method described.

(3) *Adsorption of uranium from organic solvents containing monochloroacetic acid*

Because monochloroacetic acid at room temperature is a solid acid, the effect of its concentration on the distribution coefficient of uranium could not be determined over the complete concentration range 0–100% acid; this can be investigated only for the liquid acids (see Figs. 1, 4, 7 and 10).

In Fig. 6 the influence of the concentration of monochloroacetic acid on the K_d of uranium is shown.

From Fig. 6 it is seen that the difference between the K_d-values of uranium under similar experimental conditions is smallest in the presence of 1 g of acid. The difference in this case is 0·84 log K_d units. Except with isopropanol, isobutanol and dioxan, the log K_d of uranium increases linearly with decreasing concentration of monochloroacetic acid. In dioxan solution the K_d shows first a small regular, and later a steeper, decline. This sharp decrease of the K_d of uranium at low monochloroacetic acid concentration is very probably caused by hydrolysis of the uranyl ions. As in formic acid-water mixtures (*cf.* Fig. 2) the adsorption from aqueous monochloroacetic acid solutions is also relatively low, so that only at low concentrations of monochloroacetic acid were somewhat higher values obtained.

The K_d for uranium in the solvents, except methanol and ethanol, starts to decrease steeply in the region of 10–25 mg of uranium/10 ml of mixture, in spite of the fact that the distribution coefficients of uranium in these media are fairly high. In methanol and ethanol solutions the K_d of uranium remains constant up to a concentration of uranium of 60 mg/10 ml of solution; the decrease in the case of ethanol is more pronounced than in methanol medium. For the analytical separation of mg-amounts of uranium these two solvent systems are therefore the most suitable.

In Table III the distribution coefficients and separation factors (in brackets) of all the elements recorded in the previous two Tables are shown. These results were obtained by using solutions consisting of 10 ml of solvent + 1 g of monochloroacetic acid.

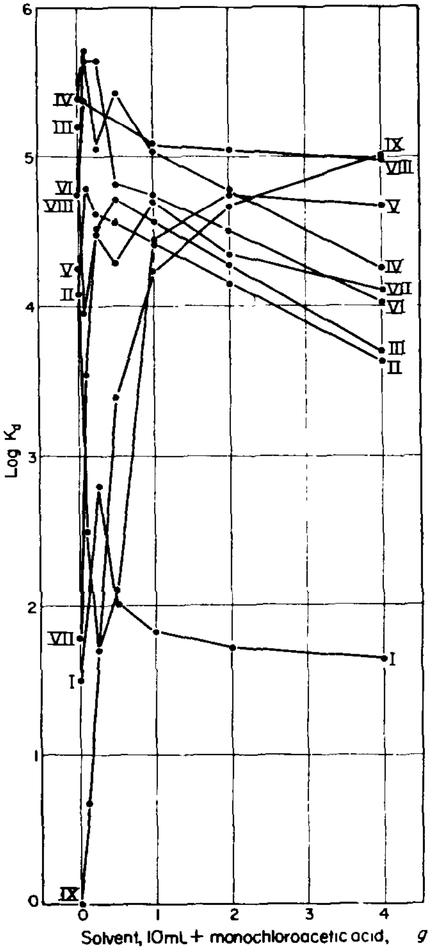

FIG. 6.—Influence of monochloroacetic acid concentration:

I—Water II—Methanol
III—Ethanol IV—n-Propanol
V—Isopropanol VI—n-Butanol
VII—Isobutanol VIII—Acetone
IX—Dioxan

Based on the results recorded in Table III the following method for the separation of uranium from nickel was developed.

Separation of uranium from nickel

The chlorides or nitrates of uranium and nickel were dissolved in 100 ml of ethanol containing 10 g of monochloroacetic acid, and the solution was passed through a pretreated (see *Experimental*)

resin bed at a flow rate of 0·5 ml/min. During this operation uranium ($K_d = 37 \times 10^3$) was adsorbed whereas nickel ($K_d = 0 \cdot 4$) passed into the effluent. Afterwards, 100 ml of a washing solution (of appropriate composition) was percolated through the column in order to remove the last traces of nickel. Finally, the uranium was eluted by means of 100 ml of 1*M* hydrochloric acid.

The results of several experiments performed in this manner have shown that this method is suitable for the quantitative separation of μg- and mg-amounts of uranium and nickel.

Other simple separation procedures are: separation of uranium from cobalt in monochloroacetic acid-methanol solution; separation of uranium from lanthanum in the same medium; separation of cobalt from nickel in monochloroacetic acid-n-propanol solution; separation of copper from nickel in the same medium; separation of lathanum from gadolinium in monochloroacetic acid-isobutanol solution.

It is also possible to adsorb two or more elements simultaneously, and to separate these subsequently on the resin by a change in the solvent. As an example, the simultaneous adsorption of copper and cobalt from monochloroacetic acid-n-propanol solution may be mentioned. After the adsorption of these two elements their separation can be effected by means of monochloroacetic acid-isobutanol solution, whereby the cobalt is eluted and the copper remains adsorbed.

(4) *Adsorption of uranium from organic solvents containing dichloroacetic acid*

In Fig. 7 the influence of the concentration of dichloroacetic acid on the distribution coefficient of uranium is shown.

The K_d of uranium in the non-aqueous solvents first increases with increasing concentration of the acid, and then reaches a maximum, subsequently decreasing to its value in pure dichloroacetic acid. In pure aqueous acid mixtures (curve I) a minimum is obtained, from which a strictly linear increase of the K_d in both directions (*i.e.*, to 0 and 100% dichloroacetic acid) takes place.

The dependence of the distribution coefficient of uranium on the concentration of dichloroacetic acid in all solvents previously used (see Figs. 2, 5 and 6) is shown in Fig. 8.

In water, methanol and ethanol only, the curves show a similarity with those shown in Figs. 2 and 5. In all other solvents containing dichloroacetic acid the K_d of uranium increases with increasing dichloroacetic acid content of the solutions after passing through a minimum. This is a phenomenon which was not observed in other solvents containing organic acids (*cf.* Figs. 2, 5 and 6) and is only weakly recognisable in trichloroacetic acid solutions (see Fig. 9). The extremely steep increase of the K_d in n-propanol solutions low in dichloroacetic acid could be explained by the assumption that in such media a decarboxylation of dichloroacetic acid, $CHCl_2COOH$, into carbon dioxide and methylene dichloride (CH_2Cl_2) takes place under the catalytic action of the resin. It cannot, however, be explained why this reaction should occur only in n-propanol solution and not in the other solvents. In trichloroacetic acid solution, however, a similar reaction can actually take place [see Section (5)].

Under the experimental conditions employed (1 ml of dichloroacetic acid + 9 ml of solvent + uranium), the K_d of uranium is independent of the concentration, in the region from 0 to about 30 mg of uranium/10 of mixture if methanol, ethanol or acetone is used as solvent. In the other solvents the K_d of uranium starts to decrease rapidly when the uranium concentration in the solution exceeds 10 mg/10 ml. For the adsorption of mg-amounts of uranium, therefore, only the three solvents in which uranium has its highest K_d values can be employed successfully.

Although media containing dichloroacetic acid were not used for separation purposes, the adsorption behaviour of other elements in such mixtures was investigated. The results of these experiments, performed in mixtures each containing 1 ml of dichloroacetic acid and 9 ml of solvent, are recorded in Table IV in which the distribution coefficients of several elements, together with the separation factors (in brackets) expressed relative to uranium, are recorded.

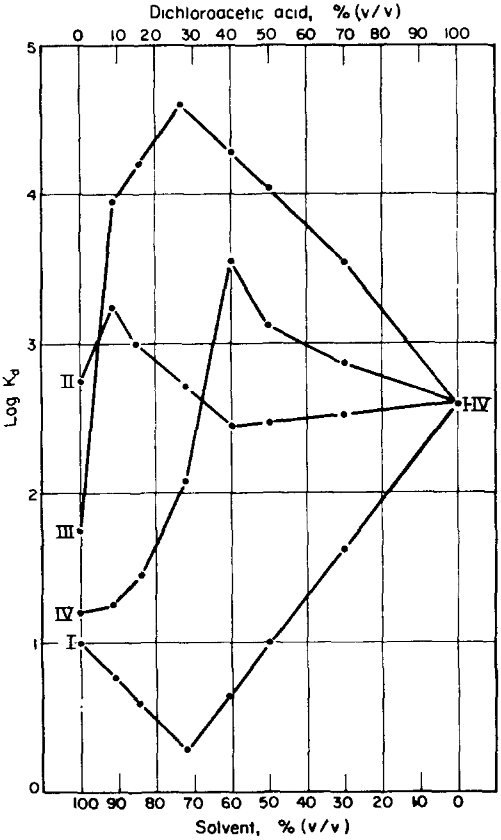

Fig. 7.—Influence of dichloroacetic acid concentration:
I—Water II—Methanol
III—Acetone IV—Dioxan

These results show that it would be easily possible to separate uranium in dichloroacetic acid-methanol solution from all elements investigated except lead. On the other hand, lead could be separated from uranium by elution of uranium with aqueous dichloroacetic acid solution, when lead is still retained by the resin.

Other combinations will not be discussed here, because they can easily be deduced from the results presented in Table IV.

(5) *Adsorption of uranium from organic solvents containing trichloroacetic acid*

In Fig. 9 the adsorption behaviour of uranium in solutions containing 0–4 g of trichloroacetic acid/10 ml of solvent is shown.

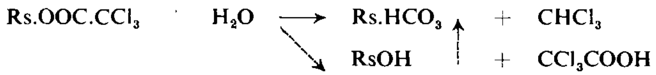
Uranium is only appreciably adsorbed by the resin from solutions consisting of trichloroacetic acid and acetone, *i.e.*, only from such solutions is the quantitative adsorption of uranium on the resin possible. In the presence of less than 0·25 g of trichloroacetic acid/10 ml of acetone, however, the K_d of uranium decreases rapidly because of the hydrolysis of uranyl ion. The steep increase in the K_d value of uranium in water and methanol solutions in the presence of 0–0·1 g of trichloroacetic acid/10 ml of solvent can be explained by the occurrence of the following reaction preventing the adsorption of the uranium as a negatively charged trichloroacetate complex (which has high stability only in acetone solutions) but as a uranyl carbonate complex:



(Rs = resin phase; ⇢ possible side reaction)

As was stated earlier (see *Experimental*), the above reaction already occurs in the dry resin (trichloroacetate form) because of the humidity of the air. In aqueous solution, therefore, this reaction will be speeded up, and will not only be restricted to the counter ion (trichloroacetate ion on the resin) but will also extend to the acid molecules in solution, which will thus be decomposed either directly in the solution, or on the resin, forming carbon dioxide and chloroform, as long as free molecules of this acid are present in solution. After the free acid has been completely decomposed only chloroform will be formed until all counter ions of the resin are transformed into bicarbonate ions. The reason why this reaction also takes place in methanol solution, to an even greater extent, is probably because the chloroform formed during this reaction is much more readily soluble in methanol than in water, so that the chloroform cannot block the exchange sites of the resin (as they can in an aqueous solution) and thus slow down the rate of decomposition. This seems to be the reason why the K_d of uranium in methanol solution, in which the formation of bicarbonate can proceed unobstructed, is markedly higher than in aqueous solution.

The K_d did not change with increasing uranium concentration in the solution except when acetone is employed as a solvent. The K_d values of uranium are, however, very low, which means that uranium, if at all, only forms a very weak nagatively charged trichloroacetate complex. In acetone solution, however, the effect of uranium concentration on the K_d shows the usual results, *i.e.*, it remains constant first, in this case up to 30 mg of uranium/10 ml of mixture, and then decreases in order to reach, at 100 mg of uranium/10 ml of mixture, a value which does not further change appreciably with an increase of uranium concentration in the solution. Therefore acetone can be regarded as the most suitable solvent from which to adsorb uranium quantitatively in the presence of trichloroacetic acid.

In Table V the adsorption behaviour of other elements is shown (as determined in the presence of 1 g of trichloroacetic acid + 10 ml of solvent).

Not only is uranium strongly adsorbed from trichloroacetic acid-acetone solution, but so also are copper and gadolinium; these can, however, not be separated on the resin by a change of solvent. From the other solvents uranium and practically all other elements investigated can only be adsorbed weakly, so that the analytical application of trichloroacetic acid solutions is rather limited. An exception may be made for lead, which can be adsorbed fairly strongly from three solvents, and can thus be

TABLE V.—DISTRIBUTION COEFFICIENTS AND SEPARATION FACTORS OF URANIUM AND OTHER ELEMENTS IN TRICHLOROACETIC ACID-ORGANIC SOLVENTS

separated from all the other elements investigated. By comparing Table V with Tables I–IV, it may be seen that solutions containing trichloroacetic acid are the least suitable for analytical purposes.

(6) *Adsorption of uranium from organic solvents containing propionic acid*

From experiments performed in nitric acid-propionic acid mixtures, it was found that the adsorption of uranium from such solutions was higher than from corresponding mixtures containing acetic acid. It was expected, therefore, that in pure propionic acid, or in solutions containing a high percentage of propionic acid, the K_d of uranium would also be higher than in acetic acid mixtures of comparable composition (*cf.* Fig. 10 with Fig. 4).

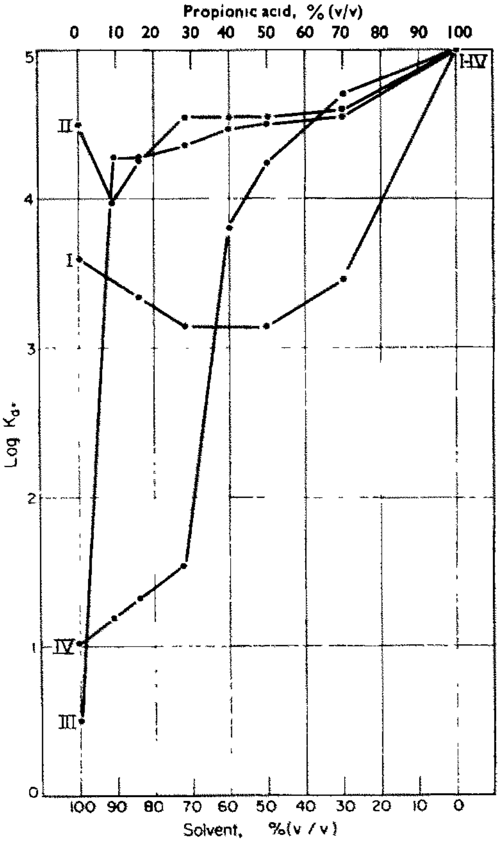

Fig. 10.—Influence of propionic acid concentration:
I—Water II—Methanol
III—Acetone IV—Dioxan

In Fig. 10 the influence of the percentage of propionic acid on the K_d of uranium is shown.

The K_d of uranium, apart from a few breaks, increases with an increase of the concentration of propionic acid, and reaches a maximum in 100% propionic acid. This means that pure propionic acid, compared with pure formic, acetic and dichloroacetic acids (*cf.* Fig. 10 with Figs. 1, 4 and 7), is a solvent which is more suitable for the adsorption of uranium, because in it the K_d of uranium has a much higher value than in the other liquid acids.

Investigation of the adsorption behaviour of uranium in mixtures consisting of 10 ml of solvent containing 0–4 ml of propionic acid gave the results shown in Fig. 11.

Contrary to the results obtained in formic and acetic acids, the influence of propionic acid on the K_d of uranium is rather irregular. Especially remarkable is the steep decline of the K_d with decreasing concentration of propionic acid in the case of the butanols (curves VI and VII of Fig. 11) and acetone (curve VIII); this is attributable to the hydrolysis of the uranyl ions in these media of low acid concentration. By employing 1 g of acid/10 ml of solvent, all solvents except the butanols

X—In these media either insoluble or hydrolysed.

and dioxan will be suitable for analytical purposes, because the distribution coefficients of uranium in these solvents will be sufficiently high to guarantee the quantitative adsorption of uranium on the resin. Also, the K_d of uranium reaches a value of 10^6 in ethanol solution containing 0·1–0·25 ml of propionic acid. Such a high adsorption of uranium has previously been reported to occur only in sulphuric acid-organic solvent mixtures.[10]

Studies of the influence of the uranium concentration on the K_d of uranium showed that the K_d first remained constant from 0 to 50 mg of uranium/10 ml of solvent (in all solvents except the butanols and dioxan) and then decreased with increasing uranium concentration in the solution.

The adsorption behaviour of a series of other elements has also been measured. The distribution coefficients and separation factors are recorded in Table VI.

Based on the results shown in Table VI the following method for the separation of uranium from lanthanum in propionic acid-acetone and -water mixtures was developed.

Separation of uranium from lanthanum

The nitrates of uranium and lanthanum were dissolved in 100 ml of a mixture consisting of 90 ml of acetone and 10 ml of propionic acid, and the solution was passed through a pretreated resin bed (see *Experimental*) at a flow rate of 0·5 ml/min. During this operation a simultaneous adsorption of uranium ($K_d = 2 \times 10^4$) and lanthanum ($K_d = 480$) took place. Thereafter the resin was washed with 100 ml of a solution consisting of 90 ml of water and 10 ml of propionic acid; the lanthanum ($K_d = 7{\cdot}0$) was eluted, but uranium ($K_d = 2{\cdot}8 \times 10^3$) was still retained on the resin. Afterwards the uranium was eluted by means of 100 ml of $1M$ hydrochloric acid, and the quantitative determination was carried out as described earlier.

The results of a series of column operations carried out in this manner showed that μg- and mg-amounts of uranium and lanthanum can be separated quantitatively from one another by means of this procedure.

Table VI suggests many other separation possibilities, *e.g.*, separation of uranium from copper, nickel, cobalt, lanthanum and gadolinium in pure propionic acid; separation of uranium and nickel from lanthanum and gadolinium in propionic acid-dioxan solution. In these conditions only lanthanum and gadolinium are adsorbed, whereas uranium and nickel pass into the effluent. In order to separate lanthanum from gadolinium on the resin column, the resin is washed with propionic acid-ethanol solution; lanthanum is eluted, whereas gadolinium remains still adsorbed.

The fact that lanthanum and gadolinium have high distribution coefficients in propionic acid-dioxan solution, whereas uranium shows only little adsorption from such a medium, could be of importance for the separation of uranium from the rare earth fraction of its fission products. The use of such a mixture would thus make it possible to separate high amounts of uranium (from the spent reactor fuel uranium) from the rare earths which are formed in lesser amounts and could thus be adsorbed on relatively small amounts of resin.

CONCLUSION

From the experimental results presented it can be seen that anion-exchange in non-aqueous media containing organic acids can be employed to solve many separation problems encountered in analytical chemistry. In particular, the examples cited show that these organic media can successfully be used to separate uranium from other elements, a fact which is of special importance in reactor chemistry.

Zusammenfassung—In der vorliegenden Arbeit wird das Anionenaustauschverhalten von Uran(VI) und einer Anzahl anderer Elemente in organischen Säuren-organischen Lösungsmittelgemischen beschrieben. Als organische Lösungsmittel wurden einige aliphatische Alkohole, Aceton und Dioxan verwendet. Als organischen Säuren widen untersucht Ameisen-, Essig- und Propionsäure sowie einige Chlorderivate der Essigsäure. Auf Grund von Bestimmungen der Verteilungskoeffizienten und Trennungsfaktoren in den verschiedensten Medien konnten Trennungsmethoden des Urans von anderen Elementen entwickelt werden.

Résumé—Dans le présent mémoire, on décrit le comportement, au point de vue échange anionique, de l'uranium hexavalent et d'un certain nombre d'autres éléments, en solvants organiques contenant des acides organiques. On a utilisé comme solvants quelques alcools aliphatiques, l'acétone et le dioxane. Comme acides organiques, on a étudié les acides monocarboxyliques suivants: formique, acétique, propionique. ainsi que les dérivés chlorés de l'acide acétique. Par l'intermédiaire de la détermination des coefficients de distribution et des facteurs de séparation dans les différents milieux. on a développé des méthodes de séparation de l'uranium d'autres éléments.

EXTRACTION OF THE ZIRCONIUM–ALIZARIN S COMPLEX WITH BUTANOL

C. DRĂGULESCU,® T. SIMONESCU and SEPTIMIA POLICEC
Academia, Republicii Populare Romîne, Baza de Cercetari Stiintifice,
Timisoara, Romania.

(*Received* 25 *June* 1963. *Accepted* 13 *December* 1963)

Summary—Optimum conditions are established for the formation of the zirconium–alizarin S lake. Trichloracetic acid exerts a stabilisation action over the lake in hydrochloric acid solutions, enabling extraction of the lake with butanol over a large range of pH. The butanol lake solutions are stable almost indefinitely. The distribution constant has been determined, and the 1:1 composition of the complex in butanol proved by the continuous variations, the slope ratio and the molar ratio methods. Lambert-Beer's law is obeyed up to at least 11 μg of zirconium. The influence of elements commonly associated with zirconium in its natural compounds is less in butanol than in the case of determinations in an aqueous medium.

THE sodium salt of alizarin sulphonic acid (alizarin S), was proposed as a reagent for the identification of zirconium by de Boer.[1] About 20 years later, Yoe and Overholser[2] studied the possible use of this reagent in quantitative analysis. Green[3] was the first to present a method for the colorimetric determination of zirconium with alizarin S. Subsequently, Dorta-Schaeppi and his coworkers[4] showed that formation of the coloured zirconium–alizarin S lake takes place with an equimolar ratio of the constituents.

The reproducibility of the analytical results by colorimetry was contested by Mayer and Bradshaw[5] who attributed low values of the optical densities obtained to an irreversible hydrolysis of the zirconium ions. The formation of zirconium isopolyoxocations also often produces complications in the colorimetric determination of zirconium with alizarin S.[6] This polymerisation had already been observed by Nazarenco.[7] It can be avoided by working with freshly prepared solutions.[8] More systematic research in this direction was undertaken by Gübeli and Jacob,[9] who demonstrated the reversibility of the polymerisation process caused by hot concentrated acids. Kuznetsov and coworkers[10] accorded great attention to this behaviour.

Though many new reagents have recently been proposed for the colorimetric determination of zirconium, the zirconium–alizarin S lake still remains of great interest.[10,11] In the present paper we have studied conditions for the liquid–liquid extraction of this lake from aqueous solution with butanol* in order to establish its composition and stability as well as the possibility of a colorimetric determination of zirconium in this medium.

EXPERIMENTAL

Apparatus

The colorimetric determinations were carried out with a Pulfrich photometer (C. Zeiss, Jena, DDR) and the pH determinations with an Orion KTS type 2518/S potentiometer (Hungary).

---

* Butanol was chosen as the extractant because among several solvents investigated it gave the best results; it was also readily accessible.

Reagents

0·001*M Zirconyl chloride solution.* Obtained by dissolving reagent grade $ZrOCl_2.8H_2O$ in 0·01*M* hydrochloric acid. The zirconium content was determined gravimetrically as ZrO_2.

0·001*M Alizarin S solution.* The sodium salt of alizarin sulphonic acid (Riedel de Haen A.G. indicator) was purified by extraction with ether and recrystallisation from ethanol,[5] then dissolved in 0·01*M* hydrochloric acid.

25% *aqueous trichloracetic acid* (TCA) *solution.* Prepared from reagent-grade material.

n-Butyl alcohol. C.p. reagent.

0·01*M Hydrochloric acid*

Procedure

The basic working procedure was as follows. To a mixture of equal volumes (1–3 ml) of 0·001*M* zirconyl chloride and alizarin S solutions, 25% TCA solution was added, and the whole diluted to the mark with 0·01*M* hydrochloric acid in a 100-ml flask. The dark cherry-red coloured zirconium–alizarin S lake was subsequently extracted with butanol.

RESULTS AND DISCUSSION

Optimum conditions for formation of the zirconium–alizarin S lake

In Fig. 1 are shown the absorption spectra of the zirconium–alizarin S lake in butanol measured against alizarin S in butanol and against pure butanol, as well as the absorption spectrum of alizarin S in butanol measured against the pure solvent. At 531 mμ the absorption of the reagent is small compared with that of the complex, and all subsequent optical density measurements were carried out with the "S 53" filter of our photometer corresponding to this wavelength, using the pure solvent as reference solution.

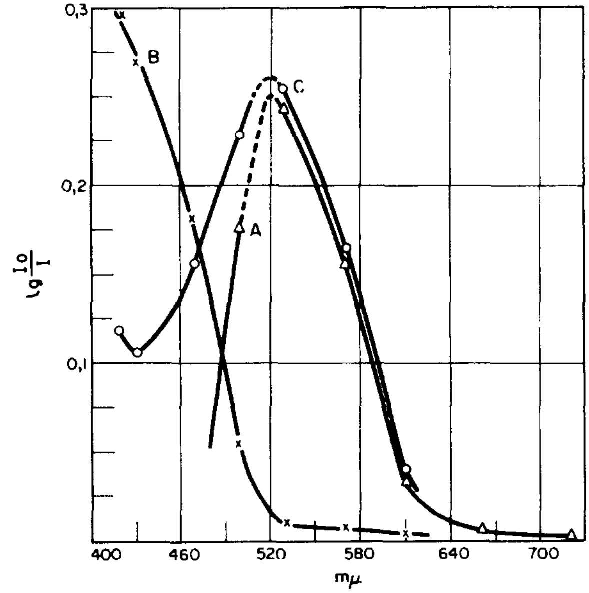

Fig. 1—Absorption spectra:
A—zirconium-alizarin S lake in butanol against alizarin S in butanol,
B—alizarin S in butanol against pure butanol,
C—zirconium-alizarin S lake in butanol against pure butanol.

Fig. 2 shows that the optimum pH conditions for formation of the zirconium–alizarin S lake are limited to a very narrow range (optimum at pH 1·15).

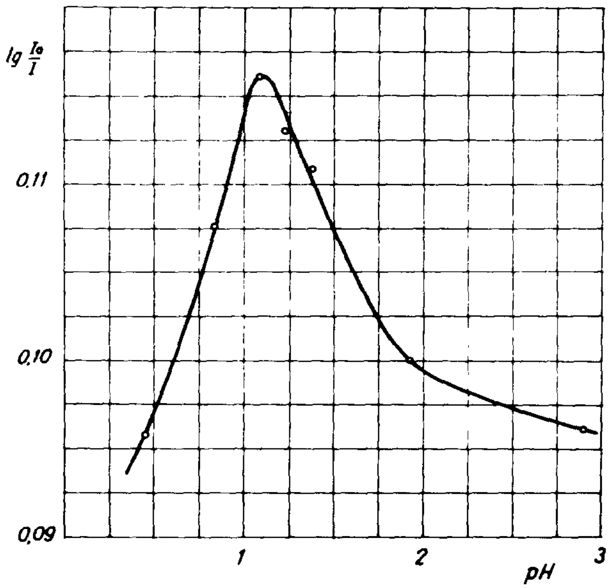

Fig. 2—Influence of pH on absorption of zirconium-alizarin S lake (3 ml of 0·001*M* zirconyl chloride and 3 ml of 0·001*M* alizarin S diluted to 100 ml with various quantities of hydrochloric acid).

It is known[3] that the reaction which leads to the formation of the lake takes some time to be completed. Fig. 3 shows that after 60 min the reaction is almost complete and continues to develop sufficiently slowly (2% during the next 50 min) to allow reproducible measurements to be made.

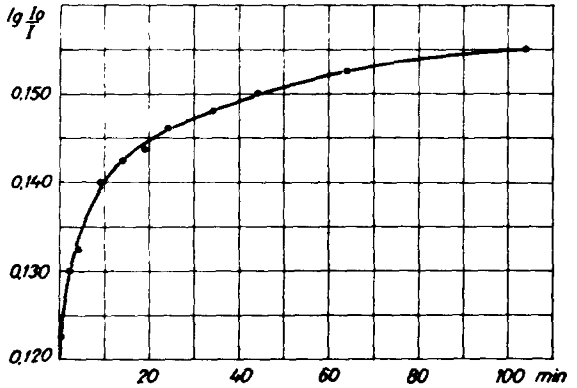

Fig. 3—Influence of time on formation of the zirconium-alizarin S lake (equimolar quantities of zirconyl chloride and alizarin S plus 5 ml of 25% TCA, diluted to 100 ml with 0·01*M* hydrochloric acid; pH 1·15)

With regard to the excess of reagent used, Fig. 4 shows that it has no influence on the optical density of the lake once the amount of alizarin S present exceeds that required for formation of the lake.

Conditions for extraction of the lake

For high concentrations of acid, extraction of the lake with butanol from aqueous hydrochloric acid is complete. The butanol phase becomes dark cherry-red and the

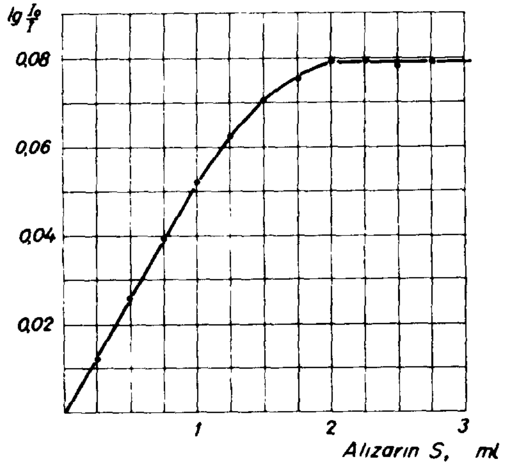

FIG. 4—Influence of amount of alizarin S on formation of the zirconium–alizarin S lake (483 μg of zirconyl chloride and variable amounts of alizarin S plus 5 ml of 25% TCA, diluted to 100 ml with 0·01*M* hydrochloric acid; pH 1·15)

aqueous phase colourless. With less acid solutions (pH 0·8–3), but otherwise the same conditions, the lake is no longer extracted and it settles out as a film at the interphase. Extraction becomes possible for the whole pH range studied (pH 0·8–3) if trichloracetic acid (TCA) is added.

Large amounts of TCA acid have little influence on the pH of the solution and thus do not alter the acidity required for a favourable extraction. The optimum extraction conditions (pH 1·15) are obtained when the lake formation takes place in 0·01M hydrochloric acid solutions containing 1·25% of TCA.

The extractions were carried out 60 min after mixing of the reagents (because the lake has then become sufficiently stable) first with a volume of butanol approximately 30%, then 20% of that of the aqueous solution. The combined organic extracts were centrifuged to separate traces of water, and the colour measured photometrically.

TCA exerts a definite stabilising action on the aqueous lake solutions. Under the given working conditions the lake solutions are stable for 168 hr, whereas in the absence of TCA 25% decomposition occurs within 68 hr. Butanol solutions of the lake are stable almost indefinitely compared with the aqueous solutions.

Under the above conditions, the distribution constant of the zirconium–alizarin S complex between water and butanol is K = 0·054, and the percentage extraction[12] is E = 85·6%.

Stability of zirconyl chloride solutions

Because polymerisation of the zirconyl ion to form polyoxocations of zirconium is well known,[7,8] the same behaviour is to be expected for the zirconium–alizarin S lake formation under our conditions. To illustrate this, we present in Fig. 5 absorption spectra of the zirconium–alizarin S lake prepared from zirconyl chloride solutions of varying age (0–14 days). The spectra show that as the age of the zirconyl solution increases there is a gradual lowering of the absorption maximum (Fig. 6). This supports the existence of an equilibrium between a monomer and polycation of zirconium.

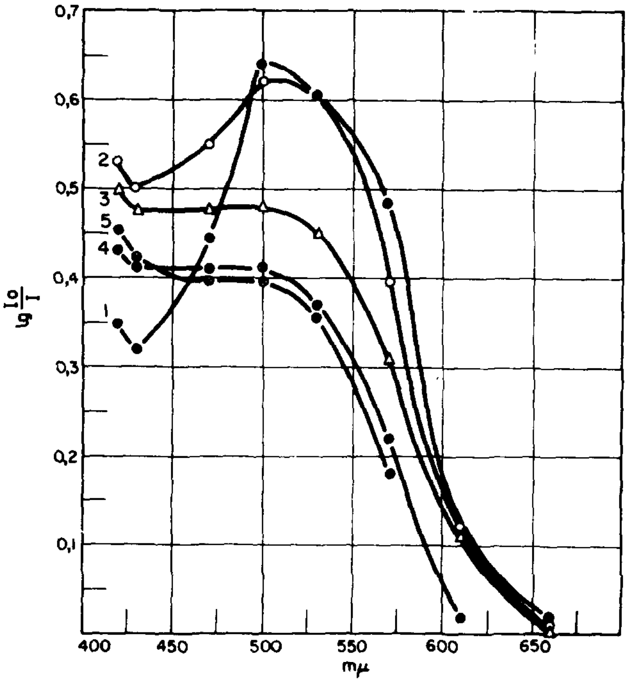

FIG. 5—Absorption spectra of zirconium-alizarin S lake prepared from zirconyl chloride solutions of varying age:

1—fresh solution, 3—7-day old solution,
2—2-day old solution, 4—12-day old solution,
5—14-day old solution.

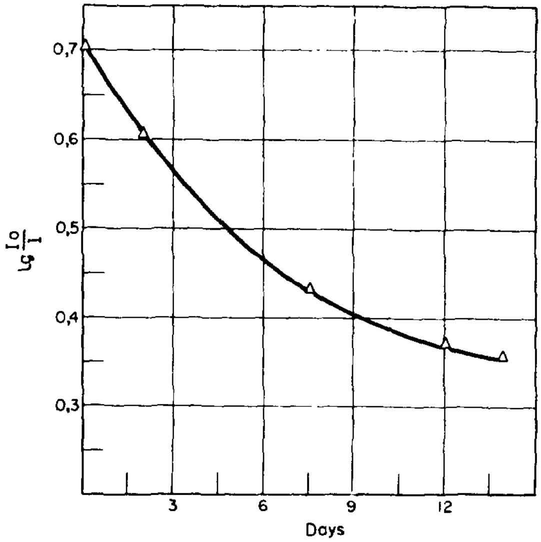

FIG. 6—Influence of age of zirconyl chloride solution on absorption maximum of the zirconium-alizarin S lake.

The absorption spectrum of the lake derived from the 14-day old zirconyl solution (curve 5 of Fig. 5) is very similar to that of the lake obtained under the same condition from a freshly prepared zirconyl solution of half the strength. This leads us to assume that in the 14-day old solution, 50% of the original zirconium is present in a polymerised form.

Validity of Lambert-Beer's law and colorimetric determination of zirconium

From Fig. 7 it follows that for both aqueous and butanol media the Lambert-Beer law is obeyed up to at least 11 µg of zirconium.

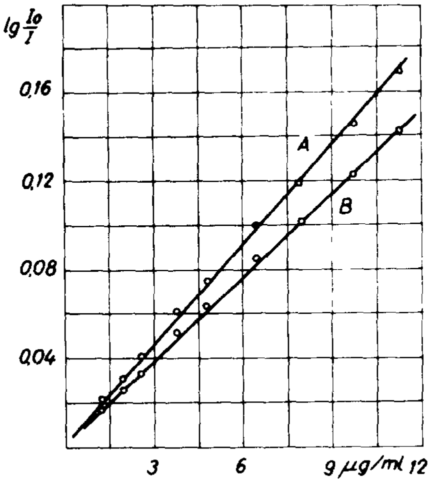

FIG. 7—Absorption of the zirconium–alizarin S lake:
A—aqueous solution,
B—butanol extract.

For the colorimetric determination of zirconium, the optical density of the lake developed from the test solution is measured and compared with a calibration curve obtained with a freshly prepared solution of zirconyl chloride. The error does not exceed 3%.

Effect of foreign ions

Al^{3+}, Fe^{3+}, Ca^{2+}, Cd^{2+}, Mg^{2+}, In^{3+}, Ga^{3+}, La^{3+}, Mn^{2+}, Pb^{2+}, Zn^{2+} and Fe^{2+} do not interfere unless present in a quantity 100 times as large as that of zirconium. Thorium up to a concentration 150 times and chromium 25 times that of the zirconium are also without effect. Anions with which zirconium forms complexes influence its determination.

Composition of the zirconium–alizarin S complex

The optical densities of the complex are plotted against wavelength in Fig. 8 for various molar ratios. Because the curves have the same characteristics, with their maxima at the same wavelength, the formation of a single complex is indicated. We have confirmed this as well as its 1:1 composition. The methods used were those of continuous variations (Fig. 9),[13] the slope ratio method (Fig. 10)[14] and the molar ratio method (Fig. 11).[15]

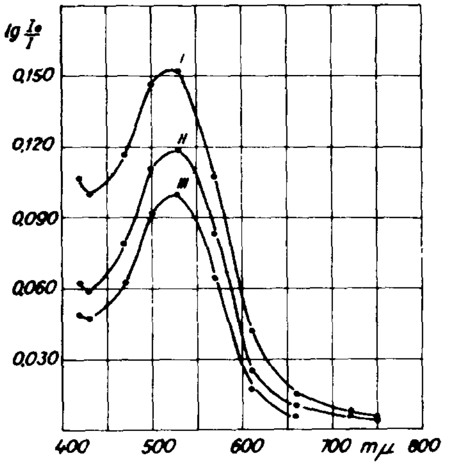

FIG. 8—Absorption spectra of zirconium-alizarin S lake for various molar ratios of zirconium: alizarin S:—I—1:1, II—1:2, III—1:2·5.

III, IV—butanol extract, ○, △—alizarin S variable.

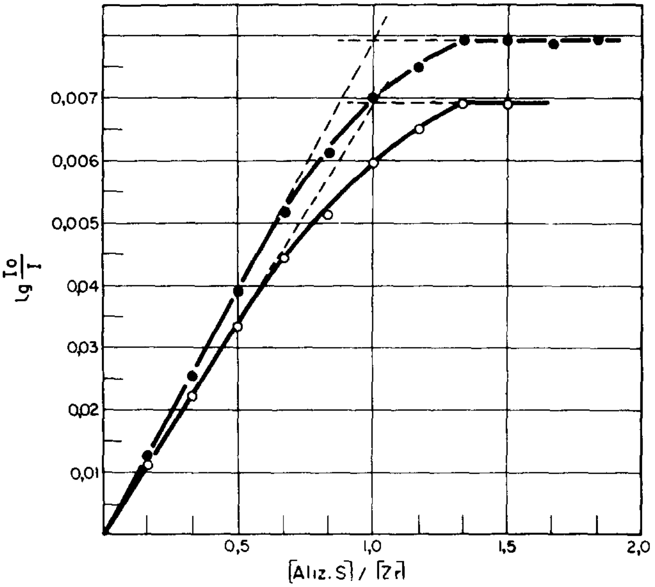

FIG. 11—Molar ratio curves for zirconium–alizarin S lake (483 μg of zirconium and variable amounts of 0·001*M* alizarin S, diluted to 100 ml of solution): ●—aqueous solution, ○—butanol extract.

Degree of dissociation and equilibrium constant

The curves in Fig. 11 demonstrate the existence of an appreciable dissociation in the system as studied by us, which makes possible the calculation of the degree of dissociation, α, from the relationship[15]

$$\alpha = (E_m - E_s)/E_m$$

where E_m is the maximum optical density for the horizontal portion of the curve, corresponding to complete reaction of the zirconium, and E_s is the optical density for the stoichiometric molar ratio of alizarin S to zirconium. From the molar ratio curves (Fig. 11), we have obtained for E_m and E_s, respectively, the values 0·0792 and 0·0700, which lead to $\alpha = 0{\cdot}1314$.

The instability constant of the zirconium–alizarin S complex

$$K = \frac{\alpha^2 \cdot c}{1 - \alpha}$$

where c, the total concentration of the complex, equal to the zirconium concentration is $1{\cdot}5 \times 10^{-5}$ mole/l., was found to be $2{\cdot}98 \times 10^{-7}$ mole/l.

Zusammenfassung—Die optimalen Bedingungen für die Bildung des Zirkonium-Alizarin S-Farblacks werden festgelegt. Trichloressigsäure stabilisiert den Farblack in salzsauren Lösungen und ermöglicht seine Extraktion mit Butanol in einem großen p_H-Bereich. Die Lösungen des Farblacks in Butanol sind fast unbegrenzt stabil. Die Verteilungskonstante wurde bestimmt und die Zusammensetzung des Komplexes in Butanol mit den Methoden der kontinuierlichen Variationen, des Neigungsverhaltnisses und der molaren Verhältnisse bewiesen. Das Lambert-Beersche Gesetz gilt bis 11 μg Zirkonium. In Butanol ist die Störung durch Elemente, die gemeinhin mit Zirkonium zusammen in dessen natürlichen Verbindungen auftreten, geringer als bei Bestimmungen in wäßrigem Medium.

Résumé—On a établi les conditions optimales de formation de la laque zirconium-alizarine S. L'acide trichloracétique exerce une action stabilisatrice sur la laque en solutions chlorhydriques, rendant possible son extraction au butanol dans un grand domaine de pH. Les solutions butanoliques de laque sont stables presqu'indéfiniment. On a déterminé la constante de distribution, et établi la composition du complexe en butanol par les méthodes des variations continues, du rapport de pente et du rapport molaire. La loi de LAMBERT-BEER est respectée jusqu'à 11 μg de zirconium. L'influence des éléments communément associés au zirconium dans ses composés naturels est plus faible dans le butanol que dans le cas des dosages en milieu aqueux.

PRECIPITATION FROM MIXED SOLVENTS—VI

NICKEL DIMETHYLGLYOXIMATE

JERRY L. JONES and LESTER C. HOWICK[R]
Department of Chemistry, University of Arkansas
Fayetteville, Arkansas, U.S.A.

(*Received* 21 *June* 1963. *Accepted* 16 *January* 1964)

Summary—The addition of dimethylglyoxime to an acetone–water solution of nickel results in the production of nickel dimethylglyoximate crystals much larger than those obtained from aqueous solution. Immediate filtration yields reproducible results about 3 parts per 1000 low. Filtration following an evaporation period allows quantitative recovery. In either case the precipitate is more easily filtered and more free from diverse ions than that normally obtained.

EARLIER reports have described the advantages to be obtained by precipitating the 8-hydroxyquinolates of aluminium,[1] nickel,[2] magnesium,[3] copper[4] and uranium[5] from acetone–water mixtures. In these cases, with the exception of magnesium, the initial solution composition was such as to keep all materials in solution. Gradual volatilisation of the acetone resulted in decreased solubility and eventual precipitation of the metal 8-hydroxyquinolate. The present investigation was undertaken to explore the behaviour of other metal chelate precipitates when formed under these conditions.

This report describes the investigation of nickel dimethylglyoximate. Although the precipitate forms very rapidly, without the heating period required for most 8-hydroxyquinolates, a great increase in particle size is still achieved, and a marked reduction in diverse ion coprecipitation is effected. The method may readily be adopted to routine analysis, or to the rapid separation of nickel from solutions.

EXPERIMENTAL

Reagents

Nickel: Nickel solutions were prepared from reagent-grade $NiSO_4 \cdot 6H_2O$ (Fisher Scientific Company, Fair Lawn, New Jersey, U.S.A.) and standardised by precipitation with dimethylglyoxime.[6] Such solutions contained approximately 3 mg of nickel per ml of solution.

Copper: Reagent-grade copper shot (Fisher Scientific Company, Fair Lawn, New Jersey, U.S.A.), 99·98% assay, was used to prepare a solution of copper^{II} ion as previously described.[4]

Cobalt: Reagent-grade $Co(NO_3)_2 \cdot 6H_2O$ (J. T. Baker Chemical Company, Phillipsburg, New Jersey, U.S.A.) was used to prepare a solution which contained 3 mg of cobalt per ml.

Iron: Reagent-grade $Fe(NO_3)_3 \cdot 9H_2O$ (Mallinckrodt Chemical Works, St. Louis, Missouri, U.S.A.) was used to prepare a solution which contained 10 mg of iron per ml. Dilute nitric acid was added to prevent hydrolysis.

Dimethylglyoxime: Reagent-grade powder (Mallinckrodt Chemical Works, St. Louis, Missouri, U.S.A.) was used without further purification. The reagent was used as a 1% solution in 95% ethanol.

Acetone: Reagent-grade acetone was distilled through a 30-cm Vigreaux column.

All other chemicals were reagent-grade and used without further purification.

Procedure

Nickel precipitation: To a 250-ml beaker were added, in the order given, about 10 ml of a solution containing 5–30 mg of nickel, 50 ml of distilled water, 75 ml of acetone, and 10 ml of a tartaric acid solution which contained 250 g of solute per litre. Concentrated ammonia was added dropwise until the solution developed a pale blue color and the odour of ammonia was noticeable. The mixture was then heated to 65°, and 18 ml of 1% dimethylglyoxime solution were added. When less than 10 mg of nickel was in the sample the amount of reagent solution was reduced to 10 ml to prevent precipitation of excess reagent. The samples were heated for up to 2 hr at 65° on the water-bath, cooled, filtered, washed with water, dried for 1 hr at 150° and weighed as Ni $(C_4H_7N_2O_2)_2$. The gravimetric factor is 0·20319. All filtrates were found to have a pH in the range 8·1–8·4.

Coprecipitation: The effect of copper, cobalt and iron, as diverse ions, was studied by introducing various amounts of these materials into the initial solution. The above procedure was then followed except in the presence of cobalt, in which case the amount of reagent was increased so as to be 10% in excess above that required to form the bis-complex of both cobalt and nickel.

RESULTS AND DISCUSSION

The most striking result of these experiments was the increased size of the individual particles that are produced. This effect is demonstrated in Figs. 1 and 2 which show, with the same degree of magnification, precipitates obtained by the conventional direct addition method and those obtained by the above procedure. For comparison, Fig. 3 shows a sample of nickel dimethylglyoximate obtained by the method of Gordon and Salesin,[7] in which biacetyl and hydroxylamine hydrochloride react to effect the *in situ* generation of dimethylglyoxime. In all observed respects of color, particle size, crystal habit, filterability, *etc*., the precipitates obtained by the *in situ* generation of the reagent are identical to those produced when the reagent is directly introduced into a solution with a high acetone content. It is, therefore, surprising to learn that the precipitation from the acetone-water medium is nearly complete within 2 min after the addition of the reagent. While some crystal growth, probably mainly Ostwald ripening, does occur during the 2-hr heating period, this change is small when compared with the difference in particle size obtained if precipitations are compared between aqueous and acetone–aqueous media. It is also interesting to note that the very similar crystals produced by the *in situ* reagent generation are formed slowly over a 3-hr period.

TABLE I.—EFFECT OF EVAPORATION TIME UPON RECOVERY OF NICKEL DIMETHYLGLYOXIMATE

Number of samples	Evaporation time, *hr*	Nickel added, *mg*	Nickel found, *mg*	Error, *mg*
8	0	29·88	29·78	−0·10
6	1	29·88	29·85	−0·03
7	2	29·88	29·89	0·01
3	3	29·88	29·88	0·00

Table I shows the effect of the length of evaporation time on the amount of nickel recovered. The eight samples which were not heated were filtered approximately 2 min after the addition of the reagent. In all cases the precipitates were easily and rapidly filtered and washed. It is seen from these results that the direct filtration of the water–acetone mixture yields results which are low by 3 parts per 1000. Assuming this loss to be caused by the increased solubility of the chelate in this medium (an assumption supported by the observation that heating the filtrate at 65° for 2 hr results in the formation of a red film on the solution) and approximating the solution volumes employed, one calculates on approximate value for the solubility of 60×10^{-8} g of nickel per ml of solution. The aqueous solubility is reported as 8×10^{-8} g per ml.[8]

29·88	Cu	60	29·86	−0·02
14·94	Cu	45	14·88	−0·06
14·94	Cu	60	14·90	−0·04
14·94	Cu	75	14·91	−0·03
29·88	Co	9	29·78	−0·10
29·88	Co	15	29·84	−0·04
29·88	Co	30	29·92	0·04
29·88	Co	45	29·96	0·08
29·88	Co	60	29·98	0·10
14·94	Co	45	14·96	0·02
14·94	Co	60	14·94	0·00
14·94	Co	75	15·05	0·11
29·88	Fe	30	29·86	−0·02
29·88	Fe	40	29·90	0·02
29·88	Fe Co	10 9	29·88	0·00

yielded an average value of 29·88 mg of nickel with a standard deviation of 0·03 mg. This result is in exact agreement with that obtained when the dimethylglyoximate was precipitated in the normal manner.[6] Table II reports the results of the analysis of varying nickel concentrations. In addition to the values reported in this Table, analysis of samples containing up to 60 mg of nickel were successfully performed by increasing the amount of reagent added.

Table III reports the results obtained when nickel was precipitated in the presence of copper, cobalt or iron. These results indicate that the separation of nickel from equal amounts of copper or cobalt may easily be achieved, and that analysis of solutions containing an excess of these diversions is attainable. It was observed in initial experiments that the presence of cobalt led to a brown filtrate, and when the larger amounts of cobalt were present low results were obtained. This is believed to be the result of the formation of a soluble cobalt-dimethylglyoxime complex. The low results were replaced by those of the Table when the amount of reagent was increased as described above.

Separations from equal amounts of iron were also effective, but when iron and cobalt were present simultaneously in amounts greater than 10 mg of iron or 9 mg of cobalt, consistently high results were obtained, and a suspension of a dark brown material appeared in the filtrates.

CONCLUSIONS

The precipitation of nickel dimethylglyoximate from a water–acetone solution is an effective and efficient means of generating this precipitate. The material thus obtained is of much larger particle size and much more easily filtered than that produced from strictly aqueous media. Quantitative recovery of the nickel is possible after heating at 65° for 2 hr.

Zusammenfassung—Zugabe von Dimethylglyoxim zu einer Aceton–Wasser-Lösung von Ni liefert viel größere Dimethylglyoximnickelkristalle als in wäßriger Lösung. Sofortige Filtration gibt reproduzierbarum 0,3% zu niedrige Resultate; schaltet man eine Verdunstungszeit ein, dann ist die Ausbeute quantitativ. In jedem Fall läßt sich der Niederschlag leichter filtrieren und enthält weniger Fremdionen als bei der normalen Fällung.

Résumé—L'addition de diméthylglyoxime a une solution de nickel dans l'acétone et l'eau fournit des cristaux de diméthylglyoximate de nickel plus gros que ceux obtenus à partir des solutions aqueuses. La filtration immédiate fournit des résultats reproductibles à environ 3 pour 1000 au minimum. La filtration après évaporation permet la récupération complète. Dans chacun de ces cas le précipité est plus facilement filtré et plus pur que celui obtenu par voie normale.

SPECTROPHOTOMETRIC METHODS FOR THE DETERMINATION OF IMPURITIES IN PURE AND ANALYTICAL REAGENTS—II*

SOME ABSORPTION SPECTRA IN CONCENTRATED CHLORIDES AND THEIR APPLICATIONS

ABRAHAM GLASNER and PINCHAS AVINUR
Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Israel

(*Received* 11 *September* 1963. *Accepted* 12 *December* 1963)

Summary—The ultra-violet spectra of Bi^{3+}, Cu^{2+}, Cu^{+}, Fe^{3+}, Pb^{2+} and NO_3^- in 4*M* KCl and in other concentrated chloride solutions have been recorded, and their absorptivities, at wavelengths useful for analytical purposes, have been evaluated. Similar values for the cyano-complexes, $[Cu(CN)_4]^{3-}$ and $[Ni(CN)_4]^{2-}$, in 4*M* KCl solutions, have also been obtained. These values have then been used for the independent determination of six ions in "synthetic" KCl solutions by the methods already proposed (A. GLASNER and P. AVINUR, *Talanta*, 1964, **11**, 677). Some of the results are given in detail.

INTRODUCTION

A COMPARATIVELY large amount of information on the ultraviolet absorption spectra of cations in concentrated halide solutions has accumulated since the first publications of Fromherz *et al.*[1] Much of this material is qualitative. Also, in most cases the wavelengths of the absorption peaks as well as the absorbances vary with the concentration of the halide and with the medium in general.[2] For these reasons, it was found necessary to repeat the measurement of some of the spectra already recorded in the literature, and to evaluate the absorption coefficients at various wavelengths, the adherence to Beer's law, *etc.*, under well-defined experimental conditions.

Results thus obtained were then introduced into the formulae developed in Part I, and the usefulness of these formulae was tested with 4*M* KCl solutions to which trace amounts of various salts were added in different combinations. The additions were chosen to simulate impurities indicated on the labels of chemically pure or analytical reagents. The impurities determined were bismuth, iron, lead, copper, nickel and the nitrate ion. Typical results obtained from the seventy solutions tested are given in tabular form.

EXPERIMENTAL

Materials

For the preparation of concentrated salt solutions, KCl, KBr, KI, NaCl, NaBr, $MgCl_2·6H_2O$, $CaCl_2·2H_2O$, $AlCl_3·6H_2O$ and $ZnCl_2·2H_2O$, J. T. Baker Analyzed reagents, were used. Other reagents employed were also of analytical grade, mostly J. T. Baker. CuCl was prepared in the laboratory.

---

* Part I: *Talanta*, 1964, **11**, 679.

Only specially purified water was used. The laboratory distilled water was passed over ion exchangers and was then double-distilled in an all-Pyrex apparatus with alkaline permanganate and phosphoric acid in series. The water thus purified was sometimes stored in polyethylene bottles for a few days, but solutions were mostly prepared from freshly distilled water.

Preparation of solutions

Stock solutions containing 1 mg/ml of the desired cation were prepared by dissolving 150–450 mg of the chloride, accurately weighed, in 100-ml volumetric flasks. To salts liable to hydrolyse, HCl was added to give a final concentration of 0·01*M*; or other variations were adopted as necessary.

These solutions were then further diluted to 40 ppm in concentrated alkali halides or other concentrated salt media as required.

Solutions containing any number of ppm (from 1 to 20) of a cation were prepared by mixing the 40-ppm standard with an equi-normal pure concentrated salt solution in the proper proportion in 50-ml volumetric flasks. Mixtures containing several "impurities" of a known concentration were prepared in a similar manner. Calibrated full pipettes or burettes were used for all volumetric measurements, and all solutions were prepared close to the time of taking their spectra, and were kept in stoppered polyethylene bottles.

Apparatus

For the spectrophotometric measurements an Optica CF4 Grating Spectrophotometer, Single Beam, Manual Model, was employed with four matched 1-cm (or 4-cm) quartz cells. Small corrections for the self-absorption of the cells had to be made, varying with the wavelength in the 200–400 mμ range. and were evaluated by comparison of the cells when filled with distilled water.

Keeping the slit width fixed at 0·05 mm, deviations of repeated measurements in absorbance units (log I_0/I) were less than ±0·003. By very careful manipulations, the deviations were reducible to ±0·002 – 0·001 unit.

All measurements were made at room temperature, 25° ± 3°, with no corrections for temperature variations.

For the evaluation of the spectrum and absorption coefficients of each individual ion a reference solution of an identical medium was employed. The absorption spectrum of the synthetic 4*M* KCl solutions, when determining the amount of impurities present, was taken with reference to distilled water.

RESULTS AND DISCUSSION

Absorption spectra in the ultraviolet

Some representative absorption spectra of various ions are given in Figs. 1–4. In Table I, the positions of the measured absorption peaks, their molecular extinctions

E: 10 ppm of Fe in 6*M* $ZnCl_2$.

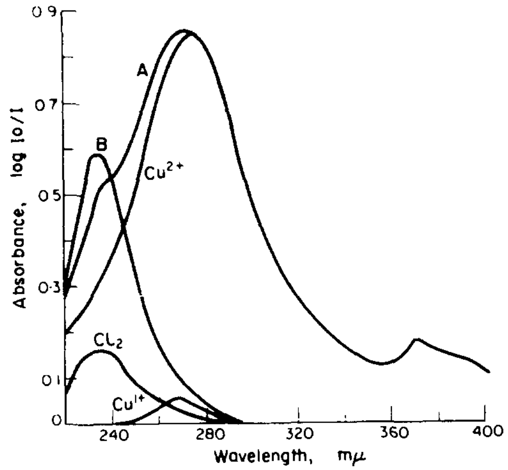

FIG. 2.—Spectrum of 12 ppm of Cu^{2+} in 5*M* CaCl$_2$ (A), and its resolution to Cu^{2+}, Cu^{+} and Cl$_2$ spectra. (B). Spectrum of Cl$_2$.

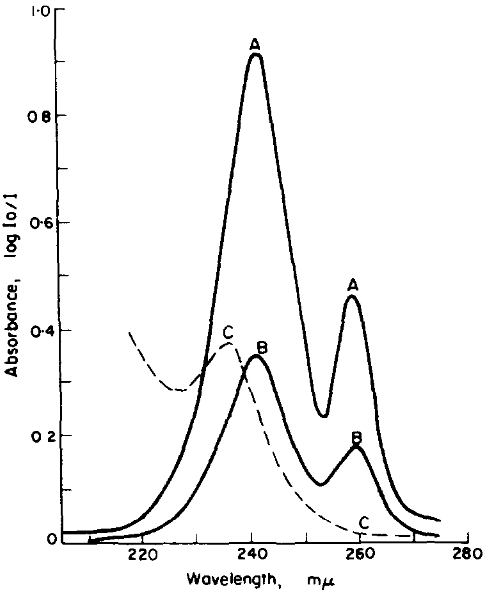

FIG. 3.—[Cu(CN)$_4$]$^{3-}$ and [Ni(CN)$_4$]$^{2-}$ spectra in 4*M* KCl:

A: 5 ppm of Ni; C: 2 ppm of Cu.
B: 2 ppm of Ni;
The wavelength scale is for [Cu(CN)$_4$]$^{3-}$; for the Ni-complex add 25 mμ units.

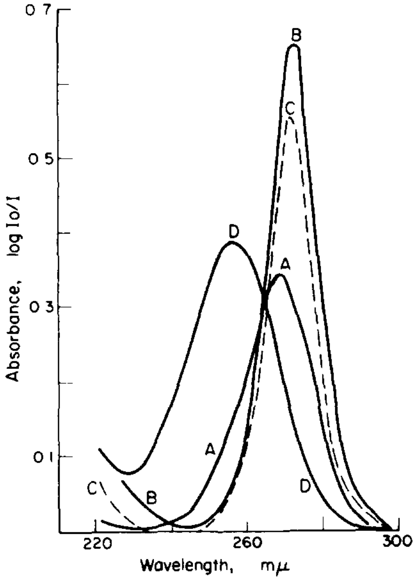

FIG. 4.—Spectra of Pb^{2+} in concentrated chloride solutions:

A: 8 ppm of Pb in 2*M* MgCl$_2$;
B: 9 ppm of Pb in 4*M* MgCl$_2$;
C: 8 ppm of Pb in 5*M* CaCl$_2$;
D: 10 ppm of Pb in 6*M* ZnCl$_2$.

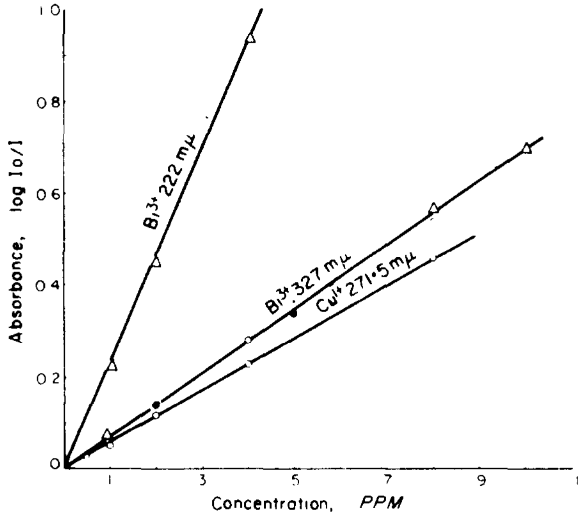

Fig. 5.—Variation of absorbance of Bi^{3+} (in 4*M* KCl at 222 mμ, and in 4*M* KCl, 2*M* $MgCl_2$ or 4*M* $MgCl_2$ at 327 mμ) and of Cu^+ (in 4*M* KCl at 271 mμ) with concentration.

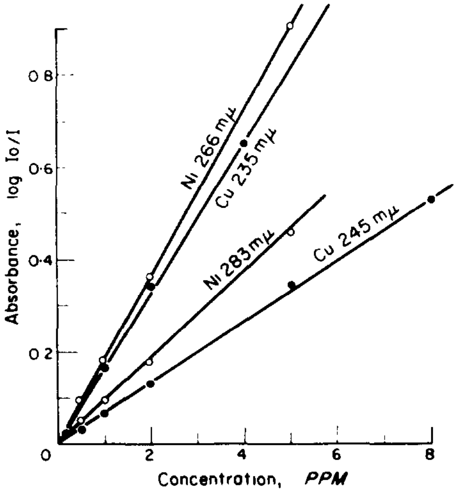

Fig. 6.—Variation of absorbance of $[Cu(CN)_4]^{3-}$ (at 235 and 245 mμ), and of $[Ni(CN)_4]^{2-}$ (at 266 and 283 mμ), with concentration, in 4*M* KCl solutions.

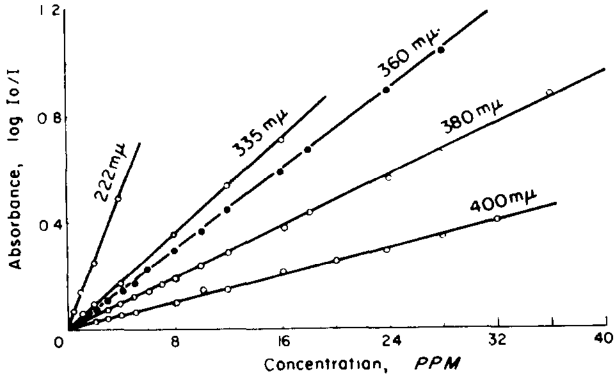

Fig. 7.—Variation of absorbance of Fe^{3+} with concentration in 4*M* KCl solutions, at the wavelengths indicated.

and other relevant values are summarised. Figs. 5–7 show the linearity of the absorbances at selected wavelengths; concentrations are expressed in ppm, *i.e.*, μg per ml of solution.

Bismuth: The absorption spectrum of bismuth was measured in 4*M* KCl and in 2*M* and 4*M* $MgCl_2$ solutions (see Fig. 1). There are two absorption bands peaking at 327 and 222 mμ (the latter is slightly shifted to longer wavelengths in the $MgCl_2$ solutions). Newman and Hume[3] attribute the 327-mμ band to the species $[BiCl_5]^{2-}$, and assign to it a molecular extinction of 16·1 × 10^3. This value is slightly higher than that obtained by other authors[2,4,5] in 6*M* HCl (0·0694–0·0720 for 1 ppm). Our results agree with the lower values (see Table I). Beer's law is observed (see Fig. 5), and there is no change in absorbance on passing from 6*M* to 10*M* HCl[2] or from 2*M* to 4*M* $MgCl_2$ solutions.

Incidentally, the short wavelength band at 222 mμ coincides with an absorption peak attributed by Newman and Hume[3] to Bi^{3+} ion, but the chloro- complex has a four-fold intensity in absorbance. In spite of this high molar extinction, the use of the

TABLE I.—A SUMMARY OF SPECTRAL DATA

Ion	Medium	Absorption peak, mμ	Specific absorptivity, *ppm*	Molar absorptivity	Miscellaneous

long wavelength band is more convenient for analytical purposes. Tervalent iron, which has in concentrated chloride solutions a nearly level absorption in the 327-mμ region (see Fig. 1), is the element most liable to interfere. The absorbance of Fe^{III} was found to be identical at the two wavelengths 330 and 340 mμ; hence it is proposed to determine the concentration of bismuth by taking measurements at these two wavelengths; the difference in the specific absorptivities is $\Delta q^{Bi}_{330\;\;340} = 0{\cdot}0460 \pm 0{\cdot}0004$ per ppm of bismuth.

Copper^{II}: The absorption spectrum of the cupric ion in concentrated chloride (or bromide) solutions is anomalous. In a previous publication[6] it has been suggested that this anomaly results from a partial decomposition to cuprous halide and halogen molecules. The evidence with respect to the identity of the absorbing species is inconclusive.[7,8] It may be observed (Table I) that as the activity in the chloride solutions increases there is a shift of the peak absorbance to longer wavelengths with a parallel increase in molar absorptivity. As a rule, such behaviour indicates the gradual formation of a more highly co-ordinated chloride complex, probably $[CuCl_4]^{2}$. In Fig. 2 the absorption spectrum of copper^{II} in 5*M* $CaCl_2$ is shown with three distinct peaks at 370, 273 and 235 mμ. The spectra of cupric chloride in 4*M* $MgCl_2$ and in 6·7*M* HCl[4] appear very much alike, in contrast to the single-peaked spectra in 4*M* KCl[6] and in 6*M* HCl.[2] On passing chlorine through a pure $CaCl_2$ solution, a band with a peak at 235 mμ is also obtained. The shape of the chlorine band together with a knowledge of the absorption spectrum of the cuprous chloride (see below) allows the complete resolution of the original irregular cupric chloride spectrum to its constituents, as shown by the thin lines in Fig. 2. Accordingly, the highly co-ordinated chloro complex of copper^{II} has a maximum absorbance at 276 mμ and a secondary band at ~370 mμ.[9]

Copper^{I}: Cupric salts may be reduced to the cuprous state by hydroxylamine more conveniently than by other reducing agents, in slightly acid or neutral solutions but not in concentrated acid solutions.[2] As a rule, heating the solution (to which a few grains of the solid reagent, $NH_2OH.HCl$, were added) below boiling for 1–2 sec was found to be necessary in order to complete the reduction, which was also successfully accomplished by sulphite or hydrogen peroxide. In these last cases, the solutions had to be boiled to destroy the excess of the reagents which absorb in the ultraviolet.[6] Beer's law is observed (see Fig. 5), but because of the closeness of the absorption band of the cuprous complex to that of Pb^{2+}, the use of this band for the determination of copper cannot be recommended wherever lead is present in larger amounts. A trial determination of copper in pure zinc metal, after dissolution in hydrochloric acid and reduction, proved promising.

Cupric chloride is readily converted to the cuprous cyanide complex,[10–12] $[Cu(CN)_4]^{3-}$, even in concentrated KCl solutions, on adding a small excess of KCN. The cyano complex has two narrow absorption bands with peaks at 215 and 235 mμ (see Fig. 3), which serve for the safe identification of copper. The excess of cyanide does not interfere with the determination of copper in the region of the long wavelength band. The absorbance of the neutral or slightly alkaline 4*M* KCl solution at 235 and 245 mμ is to be measured with reference to a portion of the same solution to which no cyanide has been added. Beer's law is observed; the difference in absorptivities is $\Delta q^{Cu}_{235-245} = 0{\cdot}098 \pm 0{\cdot}008$ per ppm of copper, in good agreement with results recorded by the authors cited above (see Fig. 6 and Table I).

Iron^{III}: Solutions of tervalent iron in 4*M* KCl absorb strongly in the whole range of the ultraviolet. There are two distinct bands with peaks at 222·5 and 335 mμ, the latter being less intense and very broad. The absorption spectrum is attributed[13] to the four co-ordinated species $[FeCl_4]^-$.

In neutral solutions the absorption is less intense throughout, and the iron is hydrolysed and precipitates with time. All solutions were therefore made up to contain 0·01*M* HCl, and were found to be stable and to give reproducible results. Typical absorption spectra in KCl (and other concentrated chlorides) are shown in Fig. 1, the relevant values being recorded in Table I. Beer's law is observed at all wavelengths (Fig. 7). Methods for the determination of iron in concentrated HCl have been previously proposed.[5,14]

For the determination of iron in KCl solutions, the use of method I (see Part I) is advised, taking measurements at the wavelengths 360 and 380 mμ. The difference in absorptivities $\Delta q^{Fe}_{360-380} = 0{\cdot}0143 \pm 0{\cdot}0005$ per ppm of iron. Most common cations (including Bi^{3+}) and anions do not interfere with the determination of iron at these wavelengths. The most serious deviations were observed in the presence of Sn^{2+} (because of reduction), BrO_3^-, IO_4^- and $S_2O_8^{2-}$ ions.

As a rule, a part of the iron in KCl products is present in the reduced bivalent state. Hence the solutions should be oxidised by adding 1 drop of an $S_2O_8^{-2}$ or ClO_3^- solution, containing 5 mg/ml of the reagent, and boiled.

In 4*M* $MgCl_2$ solutions the absorption peaks of Fe^{III} shift to longer wavelengths, being identical in position and intensity with those recorded in 6·7*M* HCl solutions.[4] The deformation of the spectrum is even more pronounced in 5*M* $CaCl_2$ solutions, whilst in 6*M* $ZnCl_2$ solutions there is a gradual rise in absorbance towards shorter wavelengths, but no well-defined absorption bands may be distinguished (see Fig. 1).

Hydroxylamine hydrochloride reduces iron^{III} to iron^{II} on boiling the solutions. The absorbance of the latter is comparatively small, and the reaction may be used for the determination of iron by a differential method,[15] or for elimination of the interference of iron in the determination of other ions.

Nickel: The absorptivity of the chloro complex of Ni^{2+} is too small for its determination in the ppm range. On the other hand, nickel yields an extremely stable cyano complex, $[Ni(CN)_4]^{2-}$, on the addition of the slightest excess of cyanide.[16] The absorption spectrum of this complex in 4*M* KCl solutions has two narrow and intense bands with peaks at 266 and 284 mμ (Fig. 3 and Table I), in excellent agreement with results obtained in aqueous solutions by previous investigators.[10,17,11] The cyano-nickel complex has already been used for the spectrophotometric determination of nickel in the 0·2–2·5 ppm range.[18] Beer's law is observed at both wavelengths, and the nickel may be determined by using Method I and either, or both, absorption bands. Acid solutions should be neutralised by ammonia before adding 20–40 ppm of KCN (according to the concentration of the nickel present) to the test solution. A blank to which no cyanide has been added serves as reference solution. $\Delta q^{Ni}_{265-275} = 0{\cdot}115 \pm 0{\cdot}005$ and $\Delta q^{Ni}_{284-293} = 0{\cdot}083 \pm 0{\cdot}005$ per ppm of nickel. The determination of 1 ppm of Ni in KCl solutions containing up to 150 ppm of various cations resulted in a deviation of 0·01–0·02 ppm. The interference of Fe^{3+} and of Pb^{2+} was more serious than that of other cations, and results obtained were too low by 0·08 ppm. This interference may be eliminated by making the solutions slightly alkaline with ammonia, before adding the cyanide.

Lead: The spectrum of the chloro complexes of Pb^{2+} was investigated by Fromherz,[1] and more recently by other authors,[2,4,5] with analytical purposes in mind, using concentrated HCl solutions. Two effects were noted[2] with increases in concentration of HCl: (*a*) a shift of the absorption peak towards longer wavelengths (maximum 271 mμ), and (*b*) a simultaneous increase in absorptivity. The absorption band at 271 mμ is attributed to the species $[PbCl_4]^{2-}$, whilst those at shorter wavelengths result from chloro complexes with less than four chlorine ions.

Parallel changes in the spectra of Pb^{2+} with increase in the concentration of $MgCl_2$ solutions were observed in the present work (Table 1) and Fig. 4. It is notable that in 6*M* $ZnCl_2$ solutions the Pb^{2+} band has a peak at 257 mμ, and is much broader and less intense that the absorption spectra in the other concentrated chloride solutions, in accord with the low activity coefficients of concentrated $ZnCl_2$ solutions[19] and the binding of the Cl^- ions in the complex $[ZnCl_4]^{2-}$. The intensity of absorbance of Pb^{2+} in concentrated chloride solutions may thus be considered to be a measure of the relative activity of the chloride ion in these solutions. Another aspect which characterises the formation of the tetrachloro-complex, $[PbCl_4]^{2-}$, is the half-width of the absorption band; in 2*M* $MgCl_2$ and in 4*M* KCl the half-width is 22 mμ, whilst in 4*M* $MgCl_2$, 2·6*M* $AlCl_3$ and 5*M* $CaCl_2$ it is only 14 mμ.

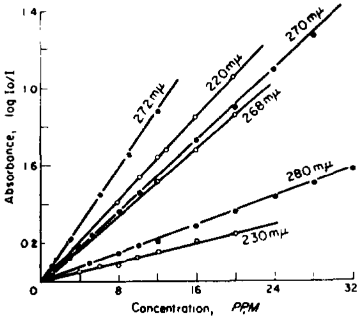

FIG. 8.—Variation of absorbance of Pb^{2+} with concentration in 4*M* KCl (at 270 and 280 mμ) and in 2*M* and 4*M* $MgCl_2$ (at 268 and at 272 mμ) solutions. NO_3^- in 4*M* KCl at 220 and 230 mμ.

In KCl, as well as in the other chloride solutions, Beer's law is observed if the concentration of the "mother salt" is kept constant (Fig. 8). $\Delta q^{Pb}_{270-280}$ (in KCl solutions) = 0·0270 ± 0·0006 ppm of lead.

In actual determinations of lead present in solid KCl, Cu^{2+} and Fe^{3+} interfere to a great extent. Therefore Method I is not valid. Kress[20] proposed a method formally resembling Method II of the present authors. It has been found that Method III yields much more satisfactory results, and this has been used by us in the synthetic test solutions, as well as for the determination of lead present in pure and analytical grade KCl. The characteristic correction ratio necessary for this method, $K^{Pb}_{R} = A^{Pb}_{270}/\Delta A^{Pb}_{270-280} = 1{\cdot}62 \pm 0{\cdot}02$.

Nitrate: The absorption spectrum of the nitrate ion in aqueous and in electrolyte solutions has recently been investigated by a number of authors.[21,22] It is characterised by two absorption bands with peaks at 300 mμ and in the region of 200 mμ. The first band is too weak to serve for the determination of the nitrate ion in small concentrations. The intense band is too far out in the ultraviolet, hence only Method

III can be expected to be of analytical use, taking measurements on the long-wave tail of this band.

In 4*M* KCl solutions, Beer's law is observed at wavelengths 220 and 230 mμ (see Fig. 8), the specific absorptivity at these wavelengths being 0·051 and 0·011 per ppm of NO_3^- in solution, *i.e.*, $\Delta q_{220-230}^{NO_3^-} = 0{\cdot}0398 \pm 0{\cdot}0018$, and the correction ratio $K_R^{NO_3^-} = A_{220}^{NO_3^-}/\Delta A_{220-230}^{NO_3^-} = 1{\cdot}27 \pm 0{\cdot}03$.

Cations and anions which do not absorb in this range of the spectrum do not disturb the determination of the nitrate ion, even if present in a concentration of 100–1000 ppm. Relatively high concentrations of SO_4^{2-}, PO_4^{3-}, ClO_3^- and Br^- ions also do not interfere seriously. On the other hand, many cations, such as Bi^{3+}, Fe^{3+}, Cu^{2+} and Pb^{2+}, if present in concentrations higher than a few ppm, distort the results. When the concentration of these ions is known from previous determinations, appropriate corrections may be introduced in Formula III (see Part I of this series. For example:

$$\Delta q_{220-230}^{Bi} = 0{\cdot}095\ ; \qquad q_{220}^{Bi} = 0{\cdot}220$$

$$\Delta q_{220-230}^{Pb} = 0{\cdot}018\ ; \qquad q_{220}^{Pb} = 0{\cdot}020.$$

It has also been found that the interference of many of these cations can be eliminated simply by making the solution slightly alkaline with ammonia; the slight precipitates remain in suspension and do not disturb the determination of the nitrate ion.

TABLE II.—EQUATIONS AND EXPERIMENTAL RESULTS ON THE QUANTITATIVE DETERMINATION OF IONS IN 4*M* KCl SOLUTIONS

Ion detd.	[a]Equation used	Sensitivity of method, *ppm*	Mean deviation, *ppm*	No. of detns.
Bi^{3+}	$\frac{\Delta A^s_{330-340}}{0{\cdot}0460}$	±0·06	±0·2	9
[c]Cu^{2+}	$\frac{\Delta A^s_{235-245}}{0{\cdot}0980}$	±0·03	±0·08	29
Fe^{3+}	$\frac{\Delta A^s_{360-380}}{0{\cdot}0143}$	±0·2	±0·4	62
[b]Ni^{2+}	$\frac{\Delta A^s_{265-275}}{0{\cdot}1150}$	±0·03	±0·05	37
Pb^{2+}	$\frac{(\Delta A^s_{270-280})^2 \times 60}{A^s_{270}}$	±0·06	±0·2	64
NO_3^-	$\frac{(\Delta A^s_{220-230})^2 \times 31{\cdot}9}{A^s_{220}}$	±0·08	±0·7	55

[a] On substituting the measured absorption values in the equation the concentration of the ion is obtained in ppm.

[b] Equation $Q_{ppm}^{Ni} = \frac{A^s_{284-293}}{0{\cdot}083}$ may also be used; results recorded are the mean of both determinations.

[c] Determination in the form of the cyanide complex $[Cu(CN)_4]^{3-}$.

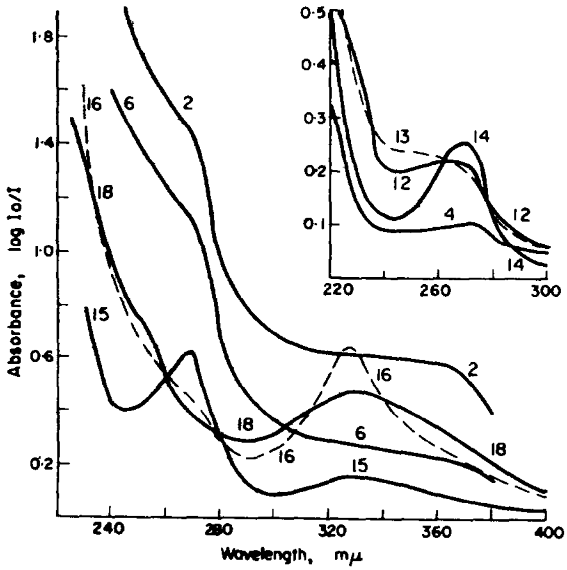
* Absorbance at 220 mμ was too high, and therefore NO_3^- could not be determined.

Determination of Bi^{3+}, Cu^{++}, Fe^{3+}, Ni^{2+} *and* NO_3^- *in synthetic solutions of* 4*M* KCl

Seventy "synthetic" solutions of 4*M* KCl (0·01*M* in HCl) were prepared in order to test the proposed method for the determination of the above "impurities". The KCl solutions were prepared from a J. T. Baker Analyzed stock (lot No. 27162), to which the sought cations were added up to 10 ppm, and many other ions (Ca^{2+}, Sr^{2+}, Ba^{2+}, Na^+, NH_4^+, Zn^{2+}, Br^-, I^-, NO_3^-, ClO_3^-, SO_4^{2-} and PO_4^{3-}) in widely varying concentrations.

Determinations were made by the use of the equations tabulated in Table II. The sensitivity of the method was calculated by assuming that the precision of the absorbance readings was ±0·003.

Table III records the concentrations (*P*) of 18 (of the 70) "synthetic" solutions and the concentrations of each ion found (*F*). Only the total concentrations, and that of the main constituent of the ions not determined, is given in the Table. In the case of the first 4 solutions, the "pure" 4*M* KCl solution served for reference, whilst the rest were compared to distilled water. The absorbance of the cyanide complexes of copper and nickel was measured in all cases by reference to the same KCl solutions without cyanide. A few of the measured spectra are shown in full in Figs. 9–11, the numeration and order being those of the solutions in Table III. The mean deviations, and the number of determinations of each ion, are also given in Table II.



FIGS. 9–10.—Spectra of synthetic 4*M* KCl solutions (with reference to water, except for Nos. 2 and 4). The composition of the solutions is given in Table III.

The following remarks are thought to be of some interest.

The presence of Fe^{III} in a concentration of more than 1 ppm is clearly indicated by the slope of the spectra in the region of the wavelengths 360–380 mμ.

Four ppm of bismuth are distinctly revealed by an absorption band with a peak at 327 mμ (spectrum No. 16), but even less than 1 ppm may be apprehended by the presence of a hump in this region of the spectrum (Nos. 15 and 18).

The absorption band of Pb^{2+} (peak at 268 mμ) stands out clearly if comparatively small amounts of Fe^{III} and Cu^{II} are present (spectra Nos. 4, 12, 14); otherwise the presence of lead is indicated only by the inflections on the spectral curve (Nos. 2, 6, 16).

The cyanide determinations of nickel were very satisfactory, but the results for copper were too low in some cases. Apparently this discrepancy results from insufficient additions of the cyanide reagent (25 ppm), especially when large amounts of iron were present (compare, for example, solutions No. 14 and 15). For the development of the $[Cu(CN)_4]^{3-}$ spectrum itself, at least 20 equiv of CN^- are required.

All spectra of the KCl solutions show a steep rise in absorbance below 240 mμ. This strong absorbance in the short wavelength region of the ultraviolet may result from a large number of other cationic and anionic impurities in addition to the nitrate ion. In some cases (Nos. 2 and 16), the absorbance was too high and the concentration of the nitrate ion could not be determined.

Whenever distilled water was used as the reference solution, 1·3 ppm were deducted from the determined values of the nitrate ion, this being the amount of the nitrate ion found in "Baker Analyzed" KCl (see Part III of this series of articles*). No corresponding corrections were made in the case of the cations determined here. The absorbance of lead (if more than 5 ppm were present) and the absorbance of bismuth (if more than 2 ppm were present) were deducted from the measured absorbances at 220 and 230 mμ before estimating the nitrate ion by Method III (Nos. 1, 15 and 18).

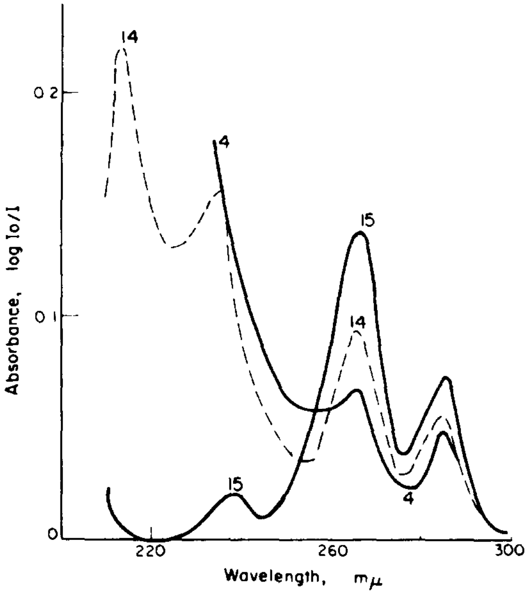


FIG. 11.—Cyanide spectra of synthetic 4*M* KCl solutions (with reference to KCl solution of the same composition).

In conclusion, the test carried out on the synthetic solutions proves that each of the six ions dealt with can be determined by the methods proposed, with an accuracy of less than 1 ppm. Best results were obtained with nickel: mean deviation ±0·05 ppm (see Table II).

In Part III of this series of articles, the method is applied to the determination of "impurities" present in chemically pure and analytical grades of KCl.

Preliminary work provides evidence that the same methods can be applied to the determination of "impurities" in other halides, such as KBr, $MgCl_2$, $CaCl_2$, $AlCl_3$ and $ZnCl_2$, or to the metals and alloys, oxides, carbonates, *etc.*, of the above salts after dissolution in HCl.

The methods proposed may improve the results and help in the spectrophotometric determination of constituents present in multicomponent solutions in general.

---

* Part III, Talanta, 1964, **11**, 775.

Résumé—Les spectres d'absorption ultraviolets du Bi^{3+}, Cu^{2+}, Cu^+, Fe^{3+}, Pb^{2+} et NO_3^- dans KCl 4M et dans d'autres solutions concentrées de chlorure ont été enregistrés et leur absorptivité aux longueurs d'ondes important pour l'analyse a été évaluée. Des valeurs analogues pour les complexes cyanés tels $[Cu(CN)_4]^{3-}$ et $[Ni(CN)_4]^{2-}$ en solution KCl 4M ont été aussi obtenues. Ces valeurs sont ensuite utilisées pour le dosage de 6 ions en solution KCl "synthétiques" (méthode déjà proposée par A. GLASNER et P. AVINUR, *Talanta*, 1964, **11**, 679). Certains de ces résultats sont donnés en détail.

Zusammenfassung—Die ultravioletten Absorptionsspektren von Bi^{3+}, Cu^{2+}, Cu^+, Fe^{3+}, Pb^{2+} und NO_3^- in 4m KCl und anderen konzentrierten Chloridlösungen wurden aufgenommen und ihre Extinktionskoeffizienten bei analytisch geeigneten Wellenlängen berechnet. Diese Werte wurden auch für die Cyanokomplexe $[Cu(CN)_4]^{3-}$ und $[Ni(CN)_4]^{2-}$ in 4m KCl ermittelt. Diese Werte wurden für die unabhängige Bestimmung von sechs Ionen "synthetische" KCl-Lösungen nach den vorher (A. GLASNER, P. AVINUR, *Talanta*, 1964, **11**, 679) entwickelten Methoden verwendet. Einige Ergebnisse werden im Detail angegeben.

SPECTROPHOTOMETRIC METHODS FOR THE DETERMINATION OF IMPURITIES IN PURE AND ANALYTICAL REAGENTS—III*

THE DETERMINATION OF SIX IONS IN KCl

ABRAHAM GLASNER and PINCHAS AVINUR
Department of Inorganic and Analytical Chemistry, The Hebrew University
of Jerusalem, Israel

(*Received* 11 *September* 1963. *Accepted* 12 *December* 1963)

Summary—The absorption spectra of $4M$ KCl solutions of 15 different products have been measured, and the concentrations of the impurities, bismuth, copper, iron, lead, nickel and nitrate, present in these salts, have been determined by the methods already developed (A. GLASNER and P. AVINUR, *Talanta*, 1964, **11**, 679, 761). Pairs of products, of two different grades of purity, originating from the same firm, have been compared. The results are critically discussed.

INTRODUCTION

THE methods developed in Parts I and II have been applied to the determination of 5 metallic ions and the nitrate ion, present as impurities in KCl products from different sources. The products were from 9 different firms, and in most cases 2 grades from the same firm were taken for examination. The results are relevant only with respect to the ions actually determined, and contain no information on impurities which do not absorb in the ultraviolet.

EXPERIMENTAL

Samples of 14·912 g of KCl, dried at 120°, were weighed out of the freshly-opened containers and dissolved in triply-distilled water and 5 ml of $0{\cdot}1M$ HCl, in 50-ml volumetric flasks. The solutions of two products (from the Dead Sea Works and from J. T. Baker USP) were turbid, supposedly because of the presence of organic matter, and were filtered through fritted-glass crucibles. The spectra were measured by comparing with distilled water in an "Optica" CF4 spectrophotometer (single beam, manual model) using matched quartz cells of 1- and 4-cm width. The measurements of each spectrum were repeated 2 or more times, and at least 2 samples of each product were prepared.

Iron was determined in the freshly prepared solution, and again after oxidising the solution, as explained in Part II. In this way, information on both iron^{III} and iron^{II} has been obtained.

For the determination of copper and nickel, 1 drop of concentrated NH_4OH (B.D.H. AnalaR) was added to the solution to make it slightly alkaline (pH = 7–8). A portion of this neutralised solution was poured into the reference cell, while to another portion (10 ml) 1 more drop of a KCN solution containing 5 mg of CN^- per ml was added.

Absorption measurements over the whole range of the ultraviolet were taken, although absorbance values at only two wavelengths, for each ion determined, are required. The equations employed for calculating the amount of impurity present in the solid KCl, in ppm (or $10^{-4}\%$), have been tabulated in Part II (Table II). When measurements were made in 4-cm quartz cells, final results were obtained after division by a factor of 1·2.

RESULTS AND DISCUSSION

Table I lists the firms and qualifying specifications of the KCl products examined by us.

The determined amounts of the ions Fe^{3+}, Bi^{3+}, Pb^{2+}, Ni^{2+}, Cu^{2+} and NO_3^-

---

Dead Sea Works, Israel.	1. Twice recrystallised in this laboratory	D_1
	2. No. 2868, 97·69% KCl, 1·87% NaCl	D_2
Mallinckrodt Chemical Works, St. Louis. Mo., U.S.A.	U.S.P. granular, 6838	MK
Riedel-de Haën AG, Seelze, Hannover, Germany.	für Analyse, 31248, Lot. No. 503121	R
Baker and Adamson, New York, U.S.A.	A.C.S. reagent, Code 2150	BA

present in 15 different products of KCl are listed in Table II. 0·0 or 0·00 indicate results within the limits of the sensitivity of our methods. In the case of iron, the amount determined after oxidation is shown, whilst that found in the freshly prepared solutions is given in brackets. The difference is supposedly Fe^{2+}. The determined amount of the "impurities" is invariably less than that declared on the labels of the analysed reagents. Considering that the latter are "maxima", determined as a rule by the sensitivity of the test applied, this favourable result was to be expected.

TABLE II.—IMPURITIES IN VARIOUS KCl PRODUCTS, *ppm*, OR 10^{-4}%

Source of KCl		Fe		Heavy metals					NO_3^-	
		Found	Declared	Bi	Pb	Ni	Cu	Declared	Found	Declared

Figs. 1–3 show the absorption spectra of the solutions, marked by the initials of the firms, and numbered according to the grade of the product, for easy reference. These spectra are similar to those of the "synthetic" solutions given in Part II, and their general forms and singularities, with respect to the "impurities" determined, are discussed there.

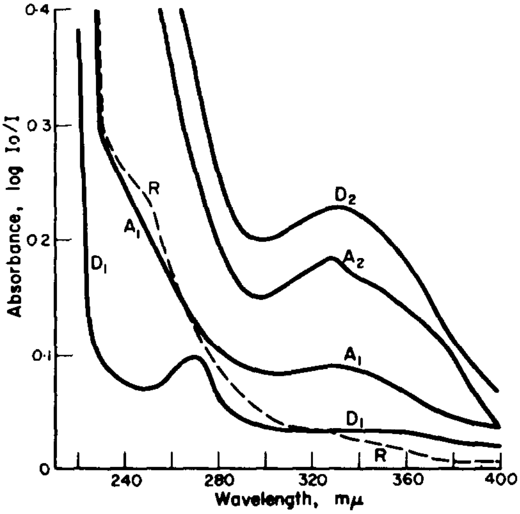

FIG. 1.—The absorption spectra of 4*M* KCl solutions of Dead Sea Works (D_1 and D_2), Agan (A_1 and A_2) and Riedel de Haën (R) products.

The total absorbance of the "chemically pure" (or similar lower-grade products) is always higher than that of the analysed reagent of the same firm. Evidently this results from the presence of further impurities, apart from those determined here, including finely divided solids and organic material. The absorption curves of such pairs of products exhibit a parallel run, indicating that the purer product was obtained from the lesser reagent, by recrystallisation or another process. The same applies to the two Merck products, both marked "*pro analysi*" (see Fig. 2). A study of such pairs should therefore be instructive with respect to the utility of the purification process employed. An exception are the two May and Baker products, which seem to differ only in packaging. (see Fig. 3).

In the case of the Dead Sea product (D_1), recrystallised in this laboratory, iron and bismuth were effectively removed, but lead appears to be more tenaciously retained (the least amount of lead in any of the analysed products was 0·3 ppm). On the other hand, the recrystallised product was contaminated by spurs of nickel and copper (see Table II). Two sources are suspect as sources of this contamination: (*a*) the filter paper used (with a Buchner funnel) for filtration, and (*b*) small particles of the floating agent present in the original product. The floating agent seems to be able to remove these (and other) metals from the mother liquor, but releases them on dissolving the salt in hot water.

The large amount of nitrate originally present in D_2 has been only partly removed; even so, the total absorbance of this recrystallised salt is quite low (Fig. 1, D_1). The absorbance of the small amount of lead present (0·7 ppm) is brought into clear relief (the absorption band being somewhat distorted on the short wavelength side

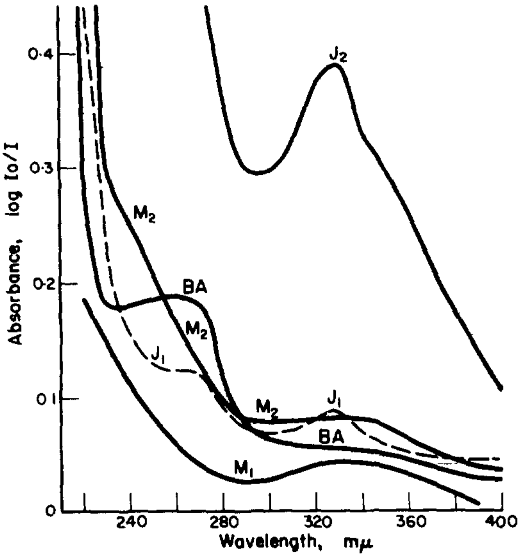

FIG. 2.—The absorption spectra of 4*M* KCl solutions of J. T. Baker (J_1 and J_2), Merck (M_1 and M_2) and Baker and Adamson (BA) products.

by the copper) and the greater part of the absorbance at 230 mμ is caused by the NO_3^- ion. Hence, the steep continuous rise in absorbance, starting at 250–240 mμ towards the shorter wavelengths, that may be observed on the absorbance spectra of some of the analytical reagents (J_1, MK), cannot be attributed to the NO_3^- ion. This absorbance is indicative of the presence of a number of impurity cations (*e.g.*, Tl^+) and anions (*e.g.*, MoO_4^{2-}) not studied in this work.

It should be further observed, in this connection, that the absorption spectra of products which contain a large amount of iron start to rise at about 290 mμ (A_1 and A_2, J_2, MB, D_2, *etc.*) The spectra of the two Merck products also exhibit this

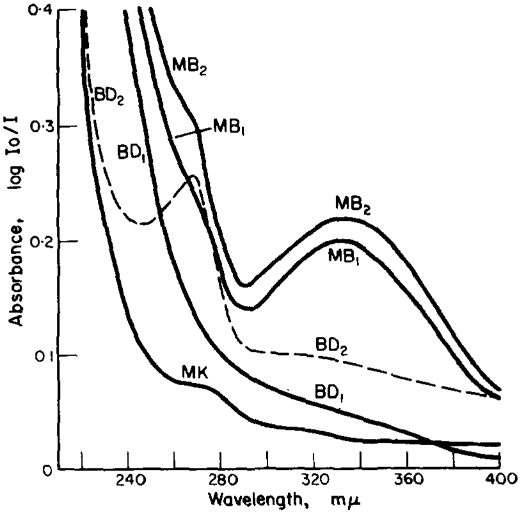

FIG. 3.—The absorption spectra of 4*M* KCl solutions of B.D.H. (BD_1 and BD_2), May and Baker (MB_1 and MB_2) and Mallinckrodt (MK) products.

feature, because of the presence of a relatively large amount of iron. Apparently these products were processed in Ni-steel vessels. The same may be said of B.D.H. "AnalaR", which contains more iron than the "Lab. Reagent" (Fig. 3); and of J. T. Baker U.S.P. (J_2, Fig. 2), which contains more iron than any of the other products examined.

The J. T. Baker products also contain more bismuth than the other products. The presence of bismuth is clearly observed on both absorption spectra. Similar amounts of bismuth (0·3 ppm) were detected in other bottles of the "Analyzed" reagent in our stock room, with the exception of one (Lot No. 25119).

Mallinckrodt's U.S.P. can be favourably compared to "Analyzed" reagents either in respect of the "impurities" determined, or the total absorbance of the solution of the product (Fig. 3).

The concentration of NO_3^- was calculated in each case by Equation III (Part I):

$$Q^{NO_3^-} = \frac{(\Delta A^s_{220-230})^2\, 31{\cdot}9}{A^s_{220}},$$

taking measurements at 220 and 230 mμ. In a few cases of comparatively low total absorbance, the more simple Equation, I: $Q^{NO_3^-} = \Delta A^s_{220-230}/0{\cdot}0398$, can also be used in two ways: (*a*) by assuming that the total difference of the absorbance of the solution at the above wavelengths is caused by the nitrate ion (I) and (*b*) by correcting the absorbance readings for the absorbance of the cations which were previously determined (I*). In the latter case, there is still a possibility of obtaining too high values owing to unknown impurities. The results obtained by the two methods are compared in Table III for 3 KCl products, backing up the reliability of Method III.

TABLE III.—A COMPARISON OF METHODS I AND III FOR THE DETERMINATION OF NO_3^- ION

Source of KCl	NO_3^- determined by method, *ppm*		
	I	I*	III
D_1	6·0	5·7	5·7
M_1	1·0	0·7	0·3
BA	2·1	1·2	0·9

I* After correction of absorbance readings for the cations Fe^{3+}, Pb^{2+} and Bi^{3+} present.

The authors wish to apologise for any misapprehensions, or unfounded conclusions; they will be grateful for comments and corrections from those concerned.

Acknowledgement—A. G. wishes to express his deep gratitude to the Department of Chemistry, Princeton University, Princeton, N.J., U.S.A., for the Visiting Lectureship granted to him in 1961–2. The many-sided discussions at Princeton and elsewhere in the U.S.A. contributed much to this and other publications by him.

Zusammenfassung—Die Absorptionsspektren von Lösungen 15 verschiedener Substanzen in 4m KCl wurden gemessen und die Konzentration der Verunreinigungen Wismut, Kupfer, Eisen, Blei, Nickel und Nitrat in diesen Salzen wurde nach den vorher (A. GLASNER und P. AVINUR, *Talanta*, 1964, **11**, 761) angegebenen Methoden bestimmt. Paare von Substanzen verschiedenen Reinheitsgrads derselben Herstellerfirma werden verglichen und die Ergebnisse kritisch diskutiert.

Résumé—Les spectres d'absorption de 15 produits différents en solution KCl 4M ont été mesurés. La concentration des impuretés, bismuth, cuivre, fer, plomb, nickel et nitrate présents dans ces sels, a été déterminée par la méthode déjà proposée par (A. GLASNER et P. AVINUR, *Talanta*, 1964, **11**, 761). Un ensemble de 2 produits de deux degrés de pureté différents venant du même endroit a été comparé. Discussion critique des résultats.

THE DETERMINATION OF MERCURY IN ROCKS BY NEUTRON-ACTIVATION ANALYSIS

D. F. C. Morris and R. A. Killick
Department of Chemistry, Brunel College, London W.3, England

(*Received* 1 *October* 1963. *Accepted* 16 *January* 1964)

Summary—A radioactivation method for the determination of the small concentrations of mercury which occur in rocks is described. The procedure involves assay of the radioactivity of ^{197}Hg by use of a thin NaI(Tl) crystal scintillator. The applicability of such a detector in neutron-activation analysis is discussed.

THE determination of mercury in rocks poses major problems. An analytical method of high sensitivity is required, because the abundance of the element in an average igneous rock has been estimated[1] to be 0·06 ppm. In addition, contamination of specimens for analysis is by no means unusual, for mercury has an appreciable vapour pressure at room temperature, and most chemical laboratories contain the metal. Moreover, a number of compounds of mercury are readily volatilised, and losses may occur during chemical processing.

Neutron-activation analysis provides outstanding advantages for obviating these difficulties. The method gives adequate sensitivity, and the possibility of errors from contamination by traces of mercury after irradiation is eliminated. Furthermore, after exchange between activated mercury and inactive carrier has been achieved, any chemical purification need not be quantitative. There is the possibility of contamination of rock samples before activation, but a feature of the radioactivation method is that samples require little pretreatment before irradiation.

NEUTRON ACTIVATION OF MERCURY

When mercury of natural isotopic composition is irradiated with neutrons of thermal energies, radiative capture reactions occur which give rise to radioisotopes of the element. Relevant nuclear data are presented in Table I. These nuclear reactions can be used for activation analysis of mercury.[2–13] In the present work 65 h ^{197}Hg was counted. For an irradiation period of 1 week the use of ^{197}Hg can be shown to give a sensitivity 50 times better than that attainable with ^{203}Hg. In the present study chemical and counting operations were performed at a distance from the neutron source, and therefore the short-lived nuclides ^{199m}Hg and ^{205}Hg could not be used.

The decay scheme of ^{197m}Hg and ^{197}Hg is shown in Fig. 1. The electromagnetic radiations emitted by ^{197}Hg are 77 keV gamma rays (IC 80%), X-rays of 68 keV (average energy of two α satellites) and 10 keV following electron capture, and gamma rays of energy 191 keV. Detailed discussion of the decay of ^{197}Hg and its application to activation analysis of mercury has been given by Westermark and Sjöstrand.[6]

EXPERIMENTAL

Irradiation

About 0·8-g samples of rock were accurately weighed and sealed in cylindrical aluminium capsules of 6-mm diameter. Standards were prepared by weighing out 0·1-ml aliquots of a dilute standard

Table I.—Nuclear data for thermal neutron activation of mercury

solution of mercury^{II} nitrate (50 mg of Hg/litre) into silica tubes of 4-mm internal diameter. The silica tubes were sealed with a burner, the lower parts being cooled to avoid any possibility of losses by evaporation. Containers of samples and standards were packed together with silica wool in a standard 1 inch diam. × 3 inch long screw-top aluminium can, and sent to Harwell for irradiation. Irradiations were for 6 days in a nuclear reactor flux of $1 \cdot 2 \times 10^{12}$ thermal neutrons. cm^{-2}. sec^{-1}.

Radiochemical separation

Because of the complex nature of rocks, non-destructive analysis using scintillation spectrometry was impossible. On the other hand, a simple radiochemical procedure for separating mercury from other contaminants was easily developed. Experimental details are as follows:

Step 1: Remove the irradiation capsules containing portions of rock from the can, open them, and transfer the samples to 60-ml platinum crucibles, each containing 1 ml of standard mercury carrier [10 mg of Hg/ml as mercury^{II} nitrate in 1*M* nitric acid; standardised gravimetrically through bis(ethylenediamine) copper^{II} tetra-iodomercurate(II)]. Wash out the capsules with a little warm 6*M* nitric acid and transfer the washings quantitatively to the crucibles (*Note* 1).

Step 2: To each sample add 10 ml of 40% hydrofluoric acid, cover the crucible loosely with the platinum lid, and digest on a steam-bath until the sample has completely dissolved. Add 3 ml of 9*M* perchloric acid and 2 ml of 16*M* nitric acid, and heat the mixture till white fumes of perchloric acid begin to be given off, taking care to avoid spattering. Replace the cover loosely, and continue to heat for about 5 min at a temperature at which the perchloric acid fumes moderately but does not rapidly evaporate. Heat for 5–10 min longer and finally evaporate carefully almost to dryness (*Note* 2).

Step 3: Transfer the residue with 10 ml of water to a 50-ml centrifuge tube. Add 5-6 drops of 20% tin^{II} chloride solution. Centrifuge and discard the supernate. Wash the precipitate of mercury^{I} chloride thoroughly with water and ethanol. Discard the supernates.

Step 4: Slurry the mercury^{I} chloride with acetone and transfer to the bottom of a long cold-finger condenser packet (17 × 2 cm) using a long-tipped dropping pipette for the purpose. Evaporate the acetone with gentle heating. Cover the solid mercury^{I} chloride with powdered iron, and insert the cold finger. Apply increasing heat from a microburner, and maintain the flame for a few min to drive all the mercury on to the tip of the cold finger (*Note* 3). Allow to cool completely before removing the jacket and replacing it with another containing 6 drops of 12*M* hydrochloric acid and 4 drops of 16*M* nitric acid. Gently distil the acid on to the finger (water flow now shut off) until the grey film of mercury is dissolved. Cool again and dismantle, rinsing the cold finger thoroughly as it is withdrawn.

Step 5: Transfer the acid solution from the outer jacket to a 50-ml centrifuge tube. Wash thoroughly with water and add the washings to the contents of the centrifuge tube. Make the resulting solution faintly ammoniacal and add 5 ml of 2% potassium iodide solution. Heat on a steam-bath and add, dropwise, a hot concentrated aqueous solution of bis(ethylenediamine) copper^{II} nitrate. Allow to cool to room temperature. Centrifuge, wash the precipitate several times with a solution containing 0·2 g of KI and 0·2 g of $[Cu\ en_2](NO_3)_2 \cdot 2H_2O$ in 200 ml of water, and then with ethanol. Slurry the precipitate with ethanol on to a weighed aluminium counting tray and dry under an infrared lamp. Cool and weigh to determine the chemical yield (usually $\sim 80\%$).

Treatment of irradiated mercury standards: At a suitable time open the silica irradiation tubes containing the mercury standards. Using a transfer pipette drawn out almost to a point, transfer the irradiated mercury solution quantitatively to a 50-ml volumetric flask. Make up to the mark with 3*M* nitric acid. Transfer a 10-ml aliquot to a 50-ml centrifuge tube containing 1 ml of standard mercury carrier. Precipitate $[Cu\ en_2][HgI_4]$, mount, dry and weigh it as described in Step 5 of the procedure for rock samples.

Notes

(1) Where pieces of rock, as opposed to powdered samples, are irradiated, remove surface contamination by cleaning with warm 6*M* nitric acid. After attack of the cleaning solution has proceeded for 1·5 min, remove the portion of rock and wash it thoroughly with water.

(2) When an irradiated standard was put through Steps 1 and 2 of the radiochemical procedure, it was found that no loss of radiomercury occurred before exchange with carrier had been achieved.

(3) The vapour pressure of mercury at 400° is 2·07 atm.

Activity determination

The electromagnetic radiations from ^{197}Hg in final precipitates from samples and standards were measured at constant geometry by scintillation spectrometry using counting techniques rather similar to those employed by Westermark and Sjöstrand.[6] In the present work a thin (3 inch diam. × 0·25 inch thick) NaI(Tl) crystal with a beryllium window was used as a detector to reduce the effect of any high-energy gamma radiation. The ^{197}Hg spectrum was generally studied after 3 days from the end of irradiation in the region 0–150 keV. This region is lower than the Compton distribution resulting from any higher-energy gamma rays, and the background is relatively low and flat. With the present technique the 68-keV X-rays and 77-keV gamma rays could not be resolved. Typical spectra obtained are shown in Fig. 2. and the activity of ^{197}Hg was determined from the area under the composite peak. Background correction was made by extrapolation as indicated in the figure. This method of subtraction proved practical and reproducible, although a more refined method could possibly be devised. A self-absorption correction curve, prepared in the conventional manner by precipitating different amounts of [Cu en_2][HgI_4] with fixed amounts of mercury, showed that with the range of weights of precipitates obtained from the radiochemical procedure count rates could be compared directly. A total photopeak area of 100 cpm was considered to be the practical limit of detection.

Decay curves indicated that only mercury activities were assayed (Fig. 3).

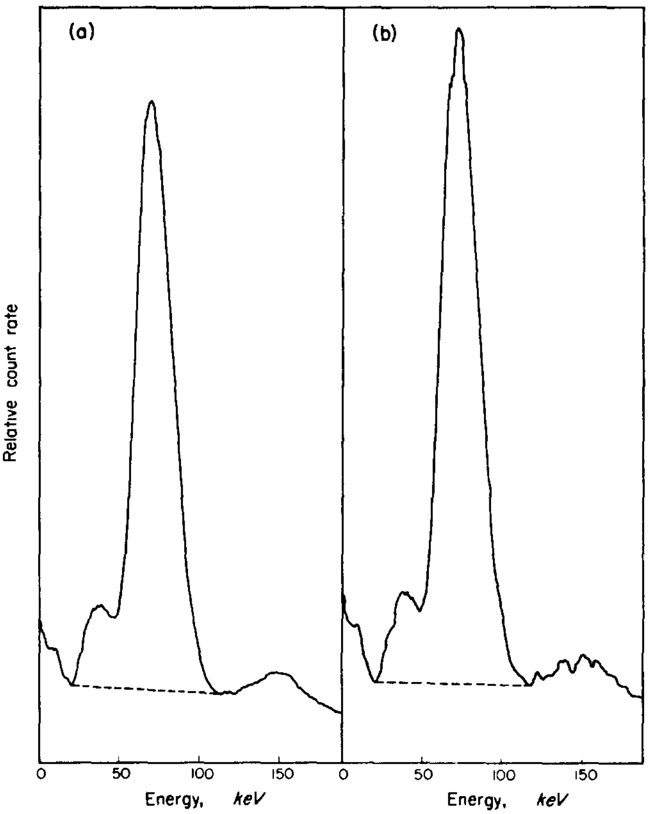

FIG. 2.—Spectra of final precipitates:
A from a mercury standard,
B from a rock sample,
as detected by a 3 × 0·25-inch NaI(Tl) crystal.
(The bump at the low energy side of the photopeak results from *K*-escape in the crystal. The dotted lines represent suggested background. Spectra measured using a single-channel pulse-height analyzer.)

DISCUSSION

Results obtained from activation analyses of international standard rocks are summarised in Table II, and give a general indication of the precision obtainable with this method. It is felt that these results must be accepted as maximum values for mercury in the standard rocks, because the samples were supplied in powder form by the U.S. Geological Survey and could possibly have become slightly contaminated before irradiation.[14]

Neutron self-shielding effects are unimportant in the application of the method to the analysis of an "average rock".[15–17] In the case of rocks or minerals enriched in elements which have high neutron absorption cross sections, *e.g.*, lepidolite, special steps may need to be taken to avoid serious self-shielding differences between samples and standards. In such circumstances it is probably most desirable to irradiate two similar quantities, *a* and *b*, of the sample, a very small known amount *c* of a suitable mercury compound having been mixed homogeneously with *b* to form the standard.[18]

It seems appropriate to make some general observations on the utility in activation analysis of a NaI(Tl) crystal 3 inch diam. × 0·25 inch thick fitted with a beryllium window 0·008 inch thick. A thin crystal is of particular advantage when it is necessary to record low-energy quanta (15–100 keV) in the presence of high-energy quanta. An illustration of this is shown in Fig. 4, which refers to the *K* X-radiation of barium in the spectrum of ^{137}Cs. The spectra were obtained with crystals of 3-inch diameter under analogous conditions.

In the recording of spectra in the 33–150 keV range, for every photoelectric peak corresponding to energy E keV an additional "escape peak" appears corresponding to energy (E — 28·6) keV. This effect, caused by the escape of the characteristic K X-ray quanta of iodine from the surface layer of the front face of the crystal where the recording process mainly occurs, reduces the intensity of the main photopeak.[19,20] Generally, the main peak is reduced more the closer the recorded energy approaches the absorption edge of iodine (K_{ab} = 33·6 keV), but the reduction also depends to some extent on the divergence of the incident beam of rays and increases as the measurement geometry deteriorates.

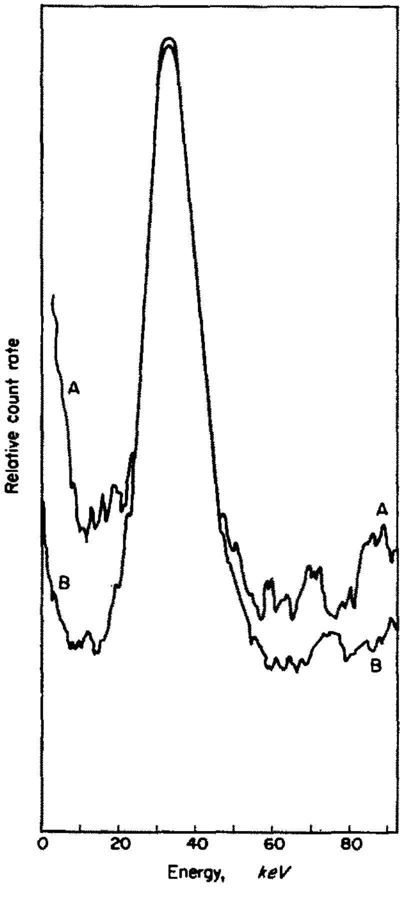

FIG. 4.—Photopeak from Ba K X-ray in the spectrum of ^{137}Cs measured with crystals of 3-inch diameter:
A. Spectrum obtained with NaI(Tl) crystal 3 inch thick.
B. Spectrum obtained with NaI(Tl) crystal 0·25 inch thick

Górski[21] has calculated the total photoelectric efficiency as well as the photoelectric efficiency recorded for the main photopeak without the escape peak for thin crystals.

Values for estimating neutron-activation sensitivities for certain elements have been determined in our laboratory (Table III). The neutron source was the reactor

BEPO at the Atomic Energy Research Establishment, Harwell, and samples were irradiated for 1 week or to saturation, whichever was shorter. Activities were measured with the irradiated samples mounted on aluminium trays (3 cm diam. and 3 mm deep) and placed on standard shelf 1 of counting assemblages. A Geiger-Müller counter of the EHM 2/S type (window thickness 1·7 mg/cm^{2}) and a NaI(Tl) crystal 3 inch diam. × 0·25 inch thick with a 0·008 inch thick beryllium window were used for measurement. The latter detector was mounted on a 9531B E.M.I. photomultiplier tube. Discriminated scintillation count rates were determined using a single-channel pulse-height analyser. All count rates were normalised to 6 hr after the end of irradiation and 1 μg of target element.

Acknowledgement—The authors wish to record their indebtedness to the United Kingdom Atomic Energy Authority for the loan of the thin NaI(Tl) crystal used in the work.

Zusammenfassung—Eine Radioaktivierungsmethode zur Bestimmung der kleinen in Gesteinen vorkommenden Quecksilberkonzentrationen wird beschrieben. Dabei wird die Radioaktivität von ^{197}Hg mit Hilfe eines dünnen NaJ(Tl)-Kristallszintillators gemessen. Die Anwendbarkeit eines solchen Detektors bei der Neutronenaktivierungsanalyse wird diskutiert.

Résumé—On décrit une méthode de dosage par radioactivation des petites concentrations de mercure que l'on trouve dans les roches. Le procédé comprend l'essai de la radioactivité de ^{197}Hg par emploi d'un scintillateur à cristal mince de NaI(Tl). On discute de l'applicabilité d'un tel détecteur à l'analyse par activation aux neutrons.

COULOMETRIC TITRATION OF WEAK ACIDS IN NON-AQUEOUS SOLVENTS

GILLIS JOHANSSON
Institute of Analytical Chemistry, University of Lund, Lund, Sweden

(*Received* 28 *October* 1963. *Accepted* 16 *January* 1964)

Summary—The coulometric generation of base will proceed with 100% current efficiency in isopropanol and in some solvent mixtures containing isopropanol. The conditions for non-aqueous titration of weak acids have been investigated. The best results were obtained when the anode was separated from the test solution by sintered-glass discs; 50–100 μmole of acid were titrated with a standard deviation of less than 0·5 μmole.

DEVELOPMENTS in coulometric analysis and coulometric titration have been reviewed.[1,2] The coulometric generation of base in non-aqueous solvents offers many advantages. The instability of many standard solutions, especially of dilute solutions, makes frequent standardisation necessary. Preparation, storage and handling are less convenient than for aqueous solutions.

Carson and Ko[3] described a method for base generation in isopropanol–water solutions, but were unable to carry out successful coulometric titrations in nonaqueous solutions. The main advantage of the coulometric generation of the base was that interference from carbon dioxide was reduced.

Methods for the coulometric titration of bases have been the subject of more investigations than methods for the titration of acids. Streuli[4] titrated amines in acetonitrile + 0·3% water. Mather and Anson[5,6] generated hydrogen ion in acetic acid-acetic anhydride by oxidation of a mercury electrode. The method developed by Mather and Anson is a completely non-aqueous titration. They have also studied the electrode reactions at platinum electrodes[7] in acetic acid-acetic anhydride solutions.

In this paper an investigation has been made of the conditions necessary for coulometric base generation, especially for the titration of small amounts of acid.

EXPERIMENTAL

Supporting electrolyte

It has been shown[8] that lithium methoxide behaves as a weak base in non-aqueous titrations. If it were not for this the good solubility of lithium salts in organic solvents would make it a natural choice as a supporting electrolyte. The best inorganic electrolyte is, in fact, sodium perchlorate. Tetra-n-butylammonium iodide has also been used in some titrations. Other quaternary ammonium salts have not been tried. Differences in the behaviour of these electrolytes in acetonitrile have been reported,[9] but in the media used in this investigation no differences have been observed.

Solvents

The ideal solvent for non-aqueous coulometric titration should dissolve sufficient quantities of supporting electrolyte. The conductivity of the solution should be high, so that large currents can be passed through the solution.

The substance formed in the cathodic reduction must be a suitable titrant for weak acids. Sodium alkoxides have been used extensively as titrants. These bases can easily be formed by reduction of the corresponding alcohol. Thus, the solvent must contain an alcohol.

The possibility of the existence of extremely strong bases in non-aqueous acetonitrile[9] would make this solvent suitable. There might be difficulties, however, because of the more severe reduction of the substance to be titrated.

Solutions of supporting electrolyte containing methanol have higher conductivity than those containing isopropanol. The acidic properties of methanol may, however, limit its usefulness. For this reason isopropanol has been used as the most generally suitable solvent constituent.

Apparatus

Non-aqueous solvents have much lower conductivity than aqueous solutions. If constant-current coulometry is to be used, an electronically regulated constant-current source must be used for accurate results.

An alternative method, which has been used by the present author, is to use an inexpensive current source and compute the time integral. The integrator employed a chopper-stabilised operational amplifier. It was similar to that described by Booman.[10] Different ranges were obtained by changing the input resistor. The voltage was read by a bridge circuit. The integral could be read to 1 part in 10,000; the accuracy is 3 parts in 10,000. The integrator was calibrated by connecting a known voltage to the input for a known time. No change in the calibration has been observed over a period of 6 months.

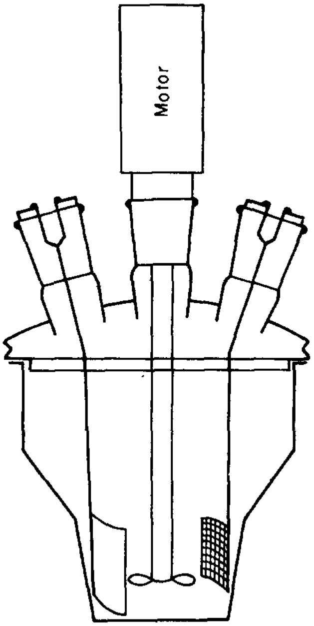

FIG. 1.—Cell for coulometric titration with cathode and anode in the same solution.

The electrolysis current could be adjusted by a variable resistor in series with the cell. The current was reduced near the end-point of a titration.

A Metrohm glass electrode, type EA 109U, and a Radiometer calomel electrode, type K 100, were used in the potentiometric measurements. The calomel electrode was connected to the non-aqueous solutions *via* a saturated solution of KCl in alcohol. The tube containing this solution was separated from the titration vessel by a fine-porosity glass filter.

Chronopotentiometric measurements were made with an arrangement similar to that described by Lingane.[1]

Cells

A titration cell for externally generated reagent, similar to that described by DeFord *et al.*[11] was tried. In this work it was found, however, that the electrode surfaces of the cell were too small for use in non-aqueous solvents. Bett *et al.*[12] have described a cell which seemed to be more suitable. When this cell was used in non-aqueous solvents it was found that the current efficiency was less than 100%. The highest efficiency, about 90%, was obtained for the fastest flow rates. Obviously, the mobility of the ions is so high that the generated base and acid move into the central compartment and neutralise each other.

The cell used when both electrodes were in the same solution consisted of a Metrohm titration vessel EA 615 (Fig. 1). All electrodes, nitrogen inlet, *etc.*, were inserted through the five ground joints on the top. The bottom of the vessel could be removed for easy changing of solutions. The solution was stirred by a Teflon propeller. The motor was fitted into the ground joint at the top of the vessel. Fifty ml of solvent were used throughout.

In most of the titrations a cell similar to that described by Smith and Taylor[13] was used. Two titration vessels, EA 615, were sealed together by a glass tube into which three sintered-glass discs were fused (Fig. 2). The solutions in the compartments between the glass discs could be transferred into the cathode compartment or could be titrated separately. In this cell 120 ml of solvent were required. The cathode compartment then contained about 50 ml of solvent.

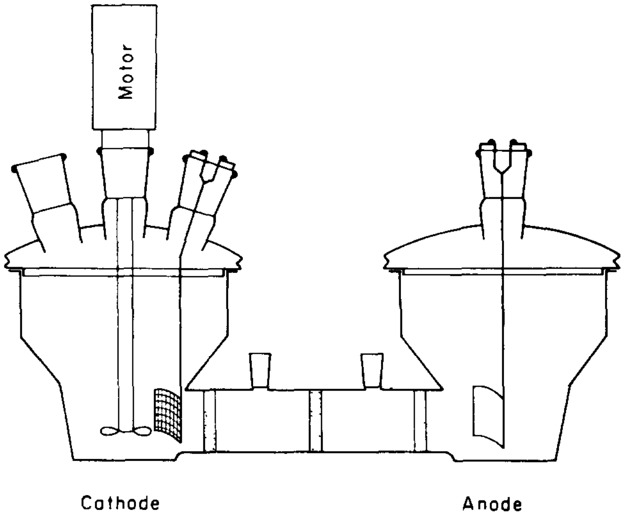

FIG. 2.—Cell for coulometric titration with cathode and anode separated by 3 sintered-glass discs.

The resistance between the electrodes was measured when the cells were filled with isopropanol-methyl ethyl ketone containing 4 g of $NaClO_4$ per litre. The resistance of the cell in Fig. 1 was 1000 ohms and the resistance of the cell in Fig. 2 was 5000 ohms.

Reagents

Pro analysi quality solvents were used throughout. The last traces of water were removed by the procedures recommended by Vogel.[14] Sodium perchlorate was dried at 115°. The water content was checked by a Karl Fischer titration. It was less than 0·1 %.

RESULTS

Current efficiency and electrode reactions

The weak acid HA can be titrated by either of the following cathode reactions.

$$2HA + 2e^- \rightarrow H_2 + 2A^- \qquad (1)$$

$$2i\text{-}PrOH + 2e^- \rightarrow 2i\text{-}PrO^- + H_2 \qquad (2a)$$

$$i\text{-}PrO^- + HA \rightleftharpoons i\text{-}PrOH + A^- \qquad (2b)$$

In either case, 1 mole of hydrogen ion is consumed per faraday, and this is all that matters stoichiometrically.

Coulometric titrations were performed to determine if base generation will proceed with 100 % current efficiency in the absence of the acid HA.

Non-aqueous solvents containing $NaClO_4$ were electrolysed in the cell shown in Fig. 2 using a silver anode and a platinum cathode. Sodium tetraphenylboron was added to the anode solution. Oxygen was removed from the cathode solution by a nitrogen stream. The base generated in the cathode compartment was continuously titrated with non-aqueous perchloric acid in isopropanol, so that the solution was almost neutral all the time. When 10 ml of perchloric acid had been added, the solution between the glass filters was transferred to the cathode compartment. Base was then generated in small increments so that the end-point could be determined potentiometrically. The results are shown in Table I.

TABLE I.—COULOMETRIC TITRATION OF PERCHLORIC ACID

Solvent	Acid, *µmole*	Generated base, *µmole*	No. of samples	Standard deviation, %	Dev. from calculated, %
Isopropanol, 50% Methyl ethyl ketone, 50%	165·1	164·9	5	0·4	−0·1
Isopropanol	260·2	258·7	3	0·8	−0·6

White[15] has found that the current efficiency was only 96%. The results presented in Table I show that the current efficiency is 100% within experimental error. (The titrations in Table IV also confirm this.)

The stoichiometric generation of base does not prove conclusively that the electrode reaction is that of Equation (2a). In the mixed solvents the other constituents might take part in the electrode reactions. It was found, however, that the form and size of a potentiometric titration curve was the same for a coulometric titration as for a titration using sodium isopropoxide in isopropanol. The electrolysed solutions were analysed by gas chromatography and by ultraviolet spectrophotometry. It was not possible to detect any impurity which could be an indication of side reactions.

End-point determination

It has been found[6] that the flow of current will interfere with the operation of the glass electrode. This has been verified in the present investigation. The interference was less if the glass electrode could be placed in a region where the voltage drop was very small. Ground loops may cause erroneous readings of the potential of the glass electrode. It was necessary to disconnect the coulometric apparatus completely when the potential measurements were made.

Because of the convenience of indicator titrations, Thymol Blue was used in most of the end-point determinations. The indicator end-point was checked by potentiometric titration. No interference from Thymol Blue on the coulometric reaction has been observed.

Shain and Svoboda[16] used constant-current potentiometry to indicate end-points in non-aqueous titrations. This technique was also tried in the present work, but it was found to be inferior to indicator titrations. In some cases no change at all could be observed. The reason for the failure of constant-current potentiometry may be, as Shain and Svoboda pointed out, that oxygen was removed from the solutions.

Both electrodes in the same solution

Lingane[1] pointed out that diaphragm cells are troublesome and that electrodes placed directly in the test solution are more convenient. A similar arrangement to that described by Lingane and Small[17] was set up. Titrations were performed in non-aqueous solution using a silver anode (20 cm^2) and a platinum cathode (8 cm^2). The cell shown in Fig. 1 was used. Various concentrations of LiCl, NaCl, NaBr, and NaI, together with an inert salt, such as Na_2SO_4 or Na_2ClO_4, were tried as electrolytes. The solubility product for AgX is much smaller in the non-aqueous solvents than in water. In spite of this it was found that large quantities of silver were deposited on the cathode. Unexpectedly, the results were low in a few cases. Some results are shown in Table II.

Table II.—COULOMETRIC TITRATION WITH PLATINUM CATHODE AND SILVER ANODE IN THE SAME SOLUTION

Substance	Solvent	Electrolyte	Taken, *μmole*	No. of samples	Found, *μmoles*	Standard deviation
Malonic acid	Isopropanol 50% Methyl ethyl ketone, 50%	KBr saturated	57·66	5	55·34	2·07
Malonic acid	Isopropanol	KBr saturated	19·22	3	19·18	0·92
Malonic acid	Isopropanol, 50% Acetone, 50%	KBr saturated	57·66	5	59·33	2·08
Malonic acid	Isopropanol, 50% Methyl ethyl ketone, 50%	NaBr saturated	57·66	6	58·34	4·98
Malonic acid	Isopropanol, 50% Methyl ethyl ketone, 50%	NaBr saturated	96·10	2	92·60	0·82
Salicylic acid			36·06	10	37·23	1·82

No silver was deposited on the cathode if sodium tetraphenylboron was used to precipitate the silver formed in the anode reaction. Typical results are shown in Table III. It was observed that a white-grey precipitate was formed at the anode.

TABLE III.—COULOMETRIC TITRATION WITH PLATINUM CATHODE AND SILVER ANODE IN THE SAME SOLUTION WITH SODIUM TETRAPHENYLBORATE PRESENT

(Electrolyte: sodium perchlorate, 4 g per litre)

Substance	Solvent	Taken, *μmole*	No. of samples	Found, *μmole*	Standard deviation
Salicylic acid	Isopropanol 50% Methyl ethyl ketone 50%	35·77	8	35·21	1·22
Salicylic acid	Isopropanol	35·77	3	33·14	1·91
Salicylic acid	Isopropanol, 99% Water, 1%	36·45	5	33·92	1·94
Salicylic acid	Methanol	36·24	2	32·41	0·59
Salicylic acid	Isopropanol, 50% Dioxan, 50%	36·45	5	35·25	0·72
Malonic acid	Isopropanol, 50% Methyl ethyl ketone, 50%	58·06	4	58·48	6·11
Malonic acid	Isopropanol, 50% Methyl ethyl ketone, 50%	246·78	1	229·37	—

Small deposits on the cathode were also observed. The results tend to be low, which indicates that side reactions probably occurred.

Geske[18] has studied the electro-oxidation of tetraphenylboron ion at a platinum anode. His work gives some idea of the side reactions to be expected. It is evident that the inconvenience of separated electrode vessels has to be accepted in order to obtain accurate results.

Separate anode and cathode compartments
