Keywords:
Tungsten oxide (WO_3)
Reduced graphene oxide (RGO)
Nanocomposite
Polyol
Metal organic decomposition (MOD)
Room-temperature gas sensor

ABSTRACT

One-pot polyol process was combined with the metal organic decomposition (MOD) method to fabricate a room-temperature NO_2 gas sensor based on tungsten oxide and reduced graphene oxide (RGO/WO_3) nanocomposite films. Fourier Transform infrared spectrometer (FTIR), X-ray diffractometry (XRD), scanning electron microscopy (SEM) and atomic force microscopy (AFM) were used to analyze the microstructure and morphology of the fabricated films. The electrical and NO_2 gas-sensing properties of WO_3 to which various amounts of RGO were added were measured in detail as a function of concentration of NO_2 gas at room temperature, to elucidate the contribution of RGO to the NO_2 gas-sensing capacity. The NO_2 gas-sensing mechanism of the RGO/WO_3 nanocomposite films were explained by considering their composition and microstructures. The sensor that was based on a nanocomposite film of RGO/WO_3 exhibited a strong response to low concentrations of NO_2 gas at room temperature, satisfactory linearity and favorable long-term stability.

1. Introduction

Nitrogen oxides generated by combustion facilities and automobiles are known to be extremely harmful to the human body and are also a main cause of acid rain. Traditional, the detection of NO_2 gas has been carried out by using chemiluminescent or non-disperse infrared (NDIR) analysis. But these instruments are large, expensive and need a sampling system and complicated maintenance. Therefore, many researchers have been searching for a suitable NO_2 gas sensor for the exhaust monitoring.

Graphene consists of a two-dimensional (2D) array of carbon atoms that are covalently connected via sp2 bonds to form a honeycomb sheet [1]. Graphene exhibited intriguing properties such as high electron mobility at room temperature (250,000 cm^2/Vs), exceptional thermal conductivity (5000 $W\,m^{-1}\,K^{-1}$), and superior mechanical properties [2,3]. The electrical properties make it to be attractive candidates for new materials. Graphene oxide (GO) sheets have recently become attractive as possible intermediates in the manufacture of graphene [4]. In GO, carboxyl groups locate at the carbon sheet edges, and epoxy and hydroxyl functional groups decorate the surface of carbon sheets [5]. However, the oxygen functional groups of GO render it too electrically insulating for use as a conductance-based sensors. Moreover, GO can be chemically or thermally reduced to restore its conductivity several orders of magnitude by removal some of oxygen functional groups [6,7]. Therefore, reduced GO (RGO) exhibited conductive and chemically active defect sites making it an active material for sensor applications. Moreover, the RGO sheets have been used for chemiresistive sensors and exhibit great potential for gas sensing applications [8–12]. Moreover, in order to improve the sensing performance of these graphene-based sensors, the conducting polymers, metals, and metal oxides have been anchored on the surface of graphene sheets to improve the sensitivity of the resultant gas sensors [13–16].

Recently, metal oxide/graphene composite materials have attracted a great deal of attention due to potential applications in optoelectronics, energy conversion devices and gas sensors [1,17,18]. Many methods have been used to prepare metal oxide/graphene composite materials, including the hydro/solvothermal method, solution mixing method, the in-situ growth method and the photoreduction method, all of which have their own advantages and particular conditions of application [17,19–21]. Among these methods, hydro/solvothermal method is the most widely used to prepare metal oxide/graphene composite because chemical bonds form between metal oxides and graphene, which can improve the electric properties of the composite over those of the same metal oxides or graphene alone. Recently, composite films that are based on WO_3 nanopowders and graphene have been reported to be as new gas-sensitive materials to reduce further the operating temperature and to improve the sensitivity of sensors based on these materials [22,23]. Yu et al. fabricated WO_3 nanorodes/graphene nanocomposites using the hydrothermal

method for sensing NO_2 [22]. Senguttuvan et al. fabricated a more rapidly responding NO_2 gas sensor based on WO_3/graphene nanocomposites that were made by the hydrothermal method [23]. The sensing characteristics of these WO_3/graphene-based NO_2 gas sensors depend on their microstructure, which are determined by their fabrication process. Most NO_2 gas sensors have been fabricated by synthesizing graphene that is decorated with WO_3 nanomaterial and drop-coating it on a substrate.

Polyol-based synthesis route has been used for preparing nano-metal oxide materials, because the reaction conditions are easily established, and yield nano-sized particles in the form of dimensionally stable colloidal suspensions. Briefly, this approach uses a polyol with a high boiling point, including diethylene glycol, glycerol, glycol and others, as the reaction medium in the preparation of oxide materials. The polyols act as stabilizers, limiting particle growth and prohibiting agglomeration. Therefore, suitable reactants from homogenous solution (metal acetates/chlorides/alkoxides) are hydrolyzed at elevated temperature, forming nano metal oxides/precursors in suspension in polyol [24–26]. Additionally, the metal organic decomposition (MOD) method for depositing a metal oxide thick film is easily and inexpensively applied [27,28]. Briefly, a metal alkoxide is spin-coated on a substrate, and then MOD forms a strongly adhesive and homogeneous film of metal oxide. Tsai et al. [29–31] used the MOD method to prepare a SnO_2 film to detect amounts of alcohol and CO gases. No attempt has been made to fabricate an NO_2 gas sensor that is based on RGO/WO_3 nanocomposite films by combining the one-pot polyol process with the MOD method. Additionally, the pure WO_3 film typically must usually be used at temperatures from 200 to 500 °C [32,33]. To improve the high resistance and weak response of the WO_3 film operating at room-temperature for practical use, nanocomposite films of RGO and WO_3 were fabricated in this study by such a combination of methods. These films have the advantages of being highly effective, inexpensive and suitable for industrial for mass production. The key step in the fabrication of the RGO/WO_3 nanocomposite film was that the reduction of GO to RGO and the conversion of WO_3 nanoparticles from H_2WO_4 precursors were produced simultaneously in the one-pot polyol approach. The structural characteristics of the RGO/WO_3 nanocomposite films were investigated by X-ray diffraction (XRD) and Fourier Transform infrared spectrometer (FTIR). The surface characteristics of the RGO/WO_3 nanocomposite films were observed using atomic force microscopy (AFM) and scanning electron microscopy (SEM). The NO_2 sensing performance of RGO/WO_3 nanocomposite films with various amounts of the RGO loaded into the WO_3 matrix was studied as the function of concentration of NO_2 gas at room-temperature. Differences in the composition and microstructure were adopted to explain the effect of adding RGO on the sensing mechanism of the RGO/WO_3 nanocomposite films.

2. Experimental

2.1. Preparation of GO

GO was prepared from natural graphite by the Hummers method [34]. Briefly, 0.5 g graphite powder was reacted with a mixture of 2 g $NaNO_3$, 12 mL concentrated H_2SO_4 and 3 g $KMnO_4$; then 40 mL deionized water (DIW) and 10 mL H_2O_2 (30%) were added. The product was filtered and washed with 5% HCl solution and deionized water to yield a brown power. An exfoliated aqueous GO dispersion was produced after sonication for 2 h. The resultant mixture was filtered and washed with DIW by centrifuging until the solution attained a pH of 6, and was then sonicated to form a stable suspension of GO in aqueous media. The resulting aqueous GO solution had a concentration of 0.85 mg/mL.

2.2. Fabrication of gas sensors based on WO_3 films

Fig. 1 displays a picture of the structure of NO_2 sensors fabricated on an alumina substrate. The interdigited gold electrodes were made by screen printing. The electrode gap was 0.2 mm. Tungstic acid (H_2WO_4) (3.0 g) (99.9%, 5.59 g/cm^3, Merck) was added to 10 g of glycerol (99.5%, 1.259 g/cm^3, Merck) and the solution was heated to 190 °C for 1 h with vigorous magnetic stirring. The reaction can be easily followed by observing its distinctive color changes. Within minutes after the reaction's reaching 190 °C, the yellow solution turned pale green and then slowly changed to a deep blue suspension, indicating the formation of tungsten oxide nanoparticles in glycerol. The blue precursor was spin-coated on an alumina substrate with a pair of comb-like electrodes. Then, it was dried by heating to 170 °C in air for 2 h; MOD was then performed in a furnace at 500 °C for 4 h in the ambient atmosphere to form a film of WO_3. During the MOD process, the temperature was increased from the ambient temperature to 500 °C at a heating rate of 5 °C/min. Therefore, a gas sensor based on WO_3 film was obtained (Fig. 1).

2.3. Fabrication of gas sensors based on RGO/WO_3 nanocomposite films

The RGO/WO_3 nanocomposites were synthesized as follows. Tungstic acid (H_2WO_4) (3.0 g) and the required amounts of GO were added to 10 g of glycerol and the resultant solution was heated to 190 °C for 1 h with vigorous magnetic stirring. The solution was continuously stirred until a stable suspension was obtained. The level of doping with GO was varied among 1.6 wt%, 3.2 wt% or 11.8 wt% (of H_2WO_4). The RGO/WO_3 nanocomposite films were formed by MOD in the same manner as used in the fabrication of a gas sensor based on a WO_3 film. For fabricating the RGO/WO_3 nanocomposite films, an MOD temperature of 500 °C was maintained for 4 h.

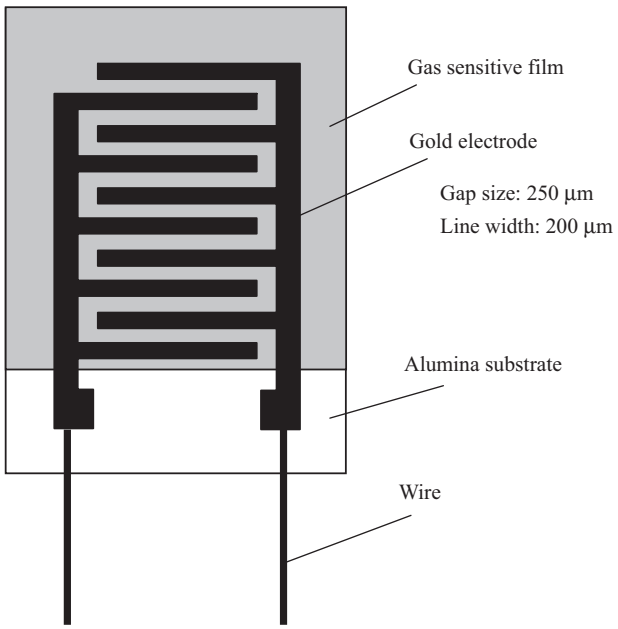

Fig. 1. Structure of NO_2 gas sensor.

2.4. Instruments and analysis

A Fourier Transform infrared spectrometer (FTIR, Nicolet 380) was used to obtain the IR spectra of the GO and RGO. The surface microstructure of the WO_3 film and RGO/WO_3 nanocomposite films coated on an alumina substrate was investigated using a field emission scanning electron microscope (FEI company, Nova Nano-SEM™ 230) quipped with an energy dispersive spectrometer (EDS) and an atomic force microscope (AFM, Ben-Yuan, CSPM 4000) in tapping mode which the horizontal and vertical resolution are 0.26 and 0.10 nm, respectively. The XRD powder pattern of the WO_3, GO and RGO/WO_3 nanocomposite films were measured using Cu K_α radiation (Shimadzu, Lab XRD-6000). The electrical and sensing characteristeristics were measured using a static state system at room temperature, as shown in Fig. 2. Each sensor was connected in series with a load resistor and a fixed 5V tension (DC mode) was continuously supplied to the sensor circuit from a power supply (GW, PST-3202). The resistance of the sensor was determined from the voltage at the ends of the load resistor using a DAQ device (NI, USB-6218) in various concentrations of gas. The standard NO_2, NH_3, and H_2S gases were purchased from Shen Yi Gas Co. (Taiwan). The concentration for standard NO_2, NH_3, and H_2S gases were 100,000, 1000 and 1000 ppm, respectively. The required various gas concentrations were produced by diluting the known volume of standard gas with dry air and then were injected into the chamber. The desired various gas concentrations were measured using a calibrated gas sensor system (Dräger, Mini-Warn). The interfering experiment was performed by measuring the resistance of the sensor exposure to NH_3, H_2S and H_2O gases, respectively. The volume of the chamber is 18 l. The gas inside the chamber was uniformly distributed using a fan. After some time, the chamber was purged with air and the experiment was repeated for another cycles. All experiments were performed at room temperature, which was about 23.0 ± 1.5 °C and the relative humidity was 40% RH.

3. Results and discussion

3.1. Preparation and structural characteristics of RGO/WO_3 nanocomposite films

3.1.1. IR spectra

GO was used as the precursor to prepare the RGO/WO_3 nanocomposite was prepared by the one-pot polyol reaction of H_2WO_4 in glycerol because that the GO had hydrophilic property to be homogenously dispersed in a H_2WO_4 matrix and easily reduced to RGO. To confirm the feasibility of the polyol method for reducing GO to RGO in the one-pot polyol synthesis of RGO/WO_3 nanocomposite, GO was the first reduced in the absence of H_2WO_4 in glycol. The IR spectrum of the GO in Fig. 3(a) includs a peak at 3350 cm^{-1} attributable to the O–H stretching vibration, peaks at 1740 and 1630 cm^{-1} attributable to the C=O stretching vibrations, and a peak at 1357 cm^{-1} attributable to the deformation of O–H. The one-pot polyol synthesis process reduced the heights of the peaks at 1740, 1630 and 1357 cm^{-1} (Fig. 3(b)), suggesting the successful reduction of GO in the one-pot polyol reaction. Therefore, partially reduced GO was formed in the RGO/WO_3 nanocomposite. Additionally, W(VI) was partially reduced to W(V) in polyol to yield a deep blue non-stoichiometric precursor because W(VI) is a moderate oxidizing agent [35]. Therefore, polyol acted as a reducing agent for W(VI), and GO was simultaneously reduced to RGO in the one-pot polyol reaction of H_2WO_4. Additionally, no new peak was observed from the RGO/WO_3 samples, indicating that no new bonding formed between the RGO and WO_3 matrix.

3.1.2. XRD characterization

Fig. 4 shows the XRD spectra of the GO, WO_3 film and RGO/WO_3 nanocomposite films that were prepared by the combined one-pot polyol and MOD method. For GO, a sharp diffraction peak (002) appears at 10.75°, which indicates that most of the graphite powder was oxidized into GO by expanding d-spacing of 6.70 Å [36]. The XRD patterns of WO_3 film show three main peaks at 2θ=23.1, 23.6 and 24.3°, which are identified as corresponding to (002), (020) and (200) orientations, respectively. The XRD patterns showed the formation of monoclinic WO_3, as in the Joint

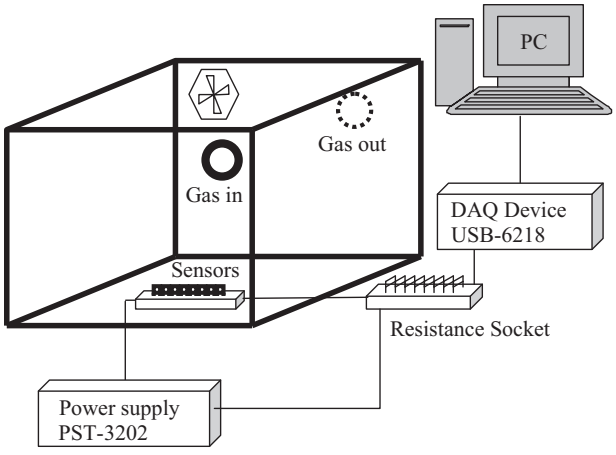

Fig. 2. Measurement system for testing gas sensors.

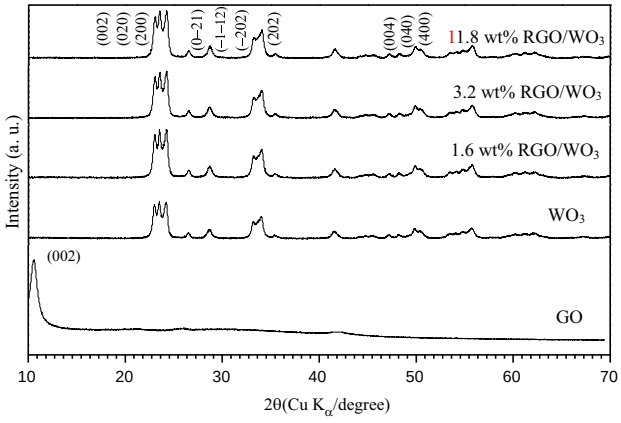

Fig. 4. XRD patterns of WO_3 film and RGO/WO_3 nanocomposite films that were fabricated by one-pot polyol process and MOD at 500 °C for 4 h.

Table 1
Crystallite size of RGO/WO_3 prepared by one-pot polyol process combined with MOD at 500 °C.

Sample	Crystallite size (nm)
WO_3	61.59
1.6 wt% RGO/WO_3	61.60
3.2 wt% RGO/WO_3	61.61
11.8 wt% RGO/WO_3	61.61

Committee of Powder Diffraction Standards (JCPDS 00-020-1324) [37]. For the RGO/WO_3 nanocomposite, by increasing the doping amount of GO in the precursor solution from 1.6 to 11.8 wt%, the XRD patterns showed no appreciable difference between the orientations and phases of WO_3 and RGO/WO_3 samples, probably due to the reduction of GO by glycerol or RGO was embedded in the WO_3 matrix and so could not be easily detected by X-ray diffraction. The crystallite size of WO_3 and RGO/WO_3 samples after MOD at 500 °C for 4 h was estimated from XRD peaks according to Scherrer's equation,

$$D = \frac{0.9\lambda}{(B\ \cos\ \theta)} \quad (1)$$

where D represents mean grain size; B represents the full width at half maximum of the peak; λ is the wavelength of the X-rays, and θ is the angle of the center of the peak. The crystallite size was estimated from the half width of the (200) peak. Table 1 shows the estimated sizes of the crystallite of the WO_3 and RGO/WO_3 samples. By increasing the doping amount of GO in the precursor solution from 1.6 to 11.8 wt%, no appreciable difference between the crystallite size of WO_3 and RGO/WO_3 samples was observed.

3.1.3. AFM and SEM analyses

Fig. 5 presents the surface morphology of the WO_3 film and 3.2 wt% RGO/WO_3 nanocomposite film that were prepared by the combined one-pot polyol and MOD method, determined using tapping-mode AFM. The size of each image is 5 μm × 5 μm. Both WO_3 film (Fig. 5(a)) and 3.2 wt% RGO/WO_3 nanocomposite film (Fig. 5(b)) exhibited a uniform granular morphology. The surface roughness of the WO_3 film and 3.2 wt% RGO/WO_3 nanocomposite film were 21.2 and 19.2 nm, respectively. Fig. 6 presents SEM images and EDS spectra of the WO_3 film and 3.2 wt% RGO/WO_3 nanocomposite film that were prepared by the combined one-pot polyol and MOD method. Both WO_3 film (Fig. 6(a)) and 3.2 wt% RGO/WO_3 nanocomposite film (Fig. 5(b)) exhibited a flat surface. In Fig. 6(b), a local dark region was clearly observed. Comparing the EDS spectra of the WO_3 film and the 3.2 wt% RGO/WO_3 nanocomposite film reveals that the RGO was doped into the WO_3 matrix. Additionally, no naked RGO was present on the surface of the RGO/WO_3 nanocomposite film, even when the amount of added RGO was 11.8 wt%.

3.2. Electrical and Gas sensing properties of RGO/WO_3 nanocomposite films

3.2.1. Effect of RGO content on the electrical properties and sensing mechanism

The sensor response (S) was calculated by the following equation:

$$S(\%) = \frac{(R_{gas} - R_{air})}{R_{air}} \times 100\% = \frac{(\Delta R)}{R_{air}} \times 100\% \quad (2)$$

where R_{gas} and R_{air} are the electrical resistances of the sensor in the tested gas and air, respectively. Fig. 7 plots the responses of the sensors that were based on WO_3 film and RGO/WO_3 nanocomposite films that were prepared using various amounts of GO, to

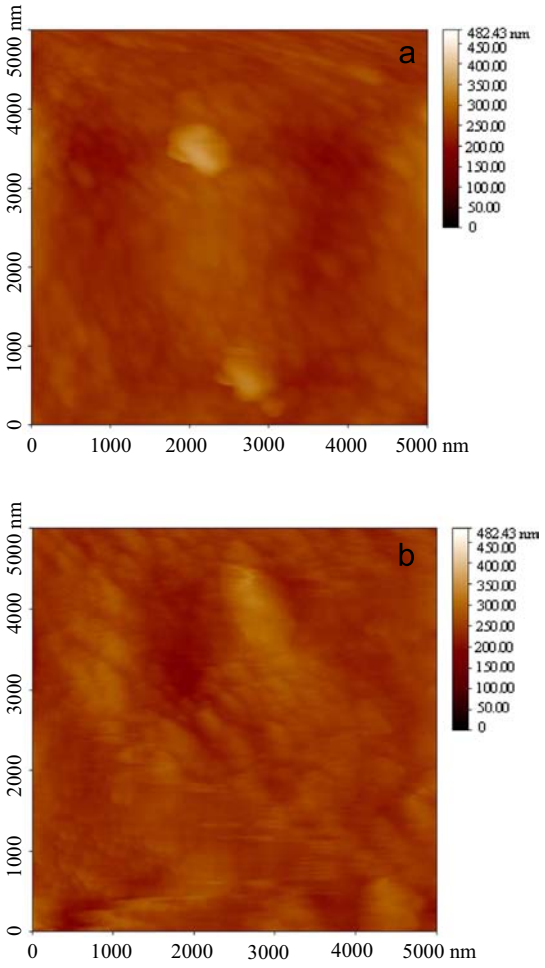

Fig. 5. AFM images of (a) WO_3 film and (b) 3.2 wt% RGO/WO_3 nanocomposite film that were fabricated by one-pot polyol process and MOD at 500 °C for 4 h.

various concentrations of NO_2 gas at room temperature. Clearly, the responses (S) of the sensors that were made of the RGO/WO_3 nanocomposite films were significantly stronger than that of the sensor that was made of the pure WO_3 film. When the amount of RGO added was below 3.2 wt%, the response (S) of the sensors increased and the concentration of NO_2 gas-sensing increased with increasing the amount of RGO added. However, when the mass of RGO added was increased to 11.8 wt%, the RGO/WO_3 nanocomposite film exhibited a small response (S) in the NO_2 gas range studied. When less than 3.2 wt% of RGO were added, as described in Section 3.1.3, the surface morphology of the WO_3 film did not obviously differ from that of the RGO/WO_3 nanocomposite film. Additionally, BET analysis reveals that the difference between the surface area of WO_3 and RGO/WO_3 films was very small. Therefore, differences in surface morphology may not be directly responsible for the improved in the NO_2 gas-sensing of the RGO/WO_3 nanocomposite films compared to that of the pure WO_3 film. Therefore, two main effects are proposed to the improvement in the response (S) of the sensors of the WO_3 film doped with RGO. First, the resistance of pure WO_3 film was around 800 kΩ. When the doping amount of RGO was 1.6 wt%, the resistance of the RGO/WO_3 nanocomposite film was reduced to ~98 kΩ. When the doping amount of RGO was increased to 3.2 wt%, the resistance of the RGO/WO_3 nanocomposite film was reduced further to ~9 kΩ. Therefore, revealing that the added GO was reduced to conductive RGO which formed new electrical paths in the WO_3 matrix in the one-pot polyol reaction. In this situation, a new conductive path was formed by the embedded RGO, and thus the

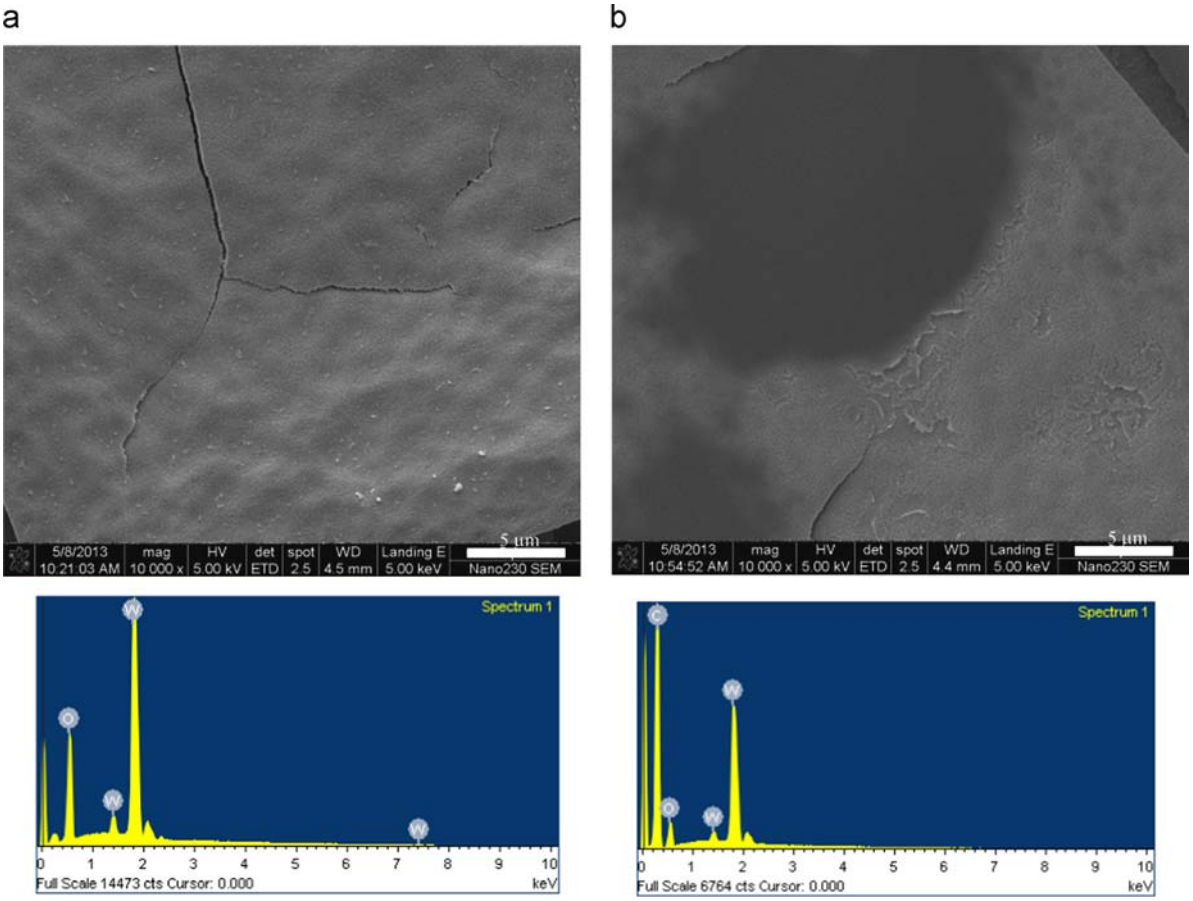

Fig. 6. FE-SEM images and EDS spectra of (a) WO_3 film and (b) 3.2 wt% RGO/WO_3 nanocomposite film that were fabricated by one-pot polyol process and MOD at 500 °C for 4 h.

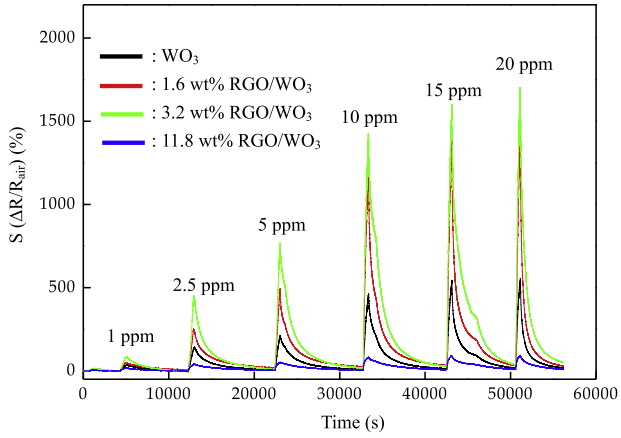

Fig. 7. Response (S) of NO_2 gas sensors based on RGO/WO_3 nanocomposite films that were prepared by one-pot polyol process and MOD at 500 °C for 4 h with various amounts of added RGO, as function of time (s) for various concentrations of NO_2 gas at room temperature.

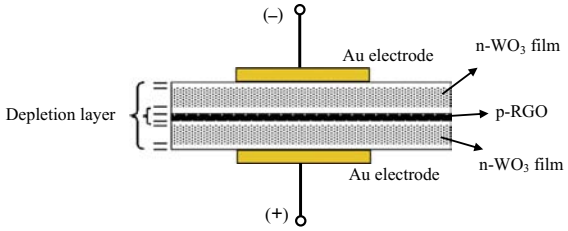

Fig. 8. Equivalent cross-sectional views of a NO_2 gas sensor based on RGO/WO_3 nanocomposite film with hetero-structure (Au/n-WO_3/p-RGO/n-WO_3/Au).

sensitivity of the RGO/WO_3 nanocomposite film was better than that of the WO_3 film. When the amount of added RGO was increased to 11.8 wt%, the amount of added RGO exceeded the percolation threshold so that the change in conductance of the sensing material due to adsorption of NO_2 gas molecules was not obvious. Second, the WO_3 behaved as an n-type semiconductor, and RGO behaved as a p-type semiconductor. Therefore, from the results of XRD and SEM analyses, the WO_3 matrix surrounds the RGO, the p–n hetero-junction that was formed by WO_3 and RGO, as presented in Fig. 8. This hetero-structure was associated with the co-existence of two depletion layers (and associated potential barriers). The first depletion layer was located at the surface of the WO_3 film and the second was at the interface between the RGO and the WO_3 film. Therefore, the p–n heterojunctions were responsible for the fact that the sensor that was based on WO_3/RGO nanocomposite film was much more sensitive than that based on WO_3 film [38,39]. Therefore, the RGO/WO_3 nanocomposite film easily detected the gas at room temperature, owing to the effects of by the combination of the percolation effect and its hetero-structure.

3.2.2. Gas-sensing properties

Fig. 9 plots the responses (S) of the sensor that was made of the 3.2 wt% RGO/WO_3 nanocomposite film to various concentrations of NO_2. The sensor had a response of 16.8% even at a low NO_2 testing concentration of 0.5 ppm. Therefore, the NO_2 gas sensor that was made of the RGO/WO_3 nanocomposite film that was doped with 3.2 wt% of RGO was chosen to study further its other

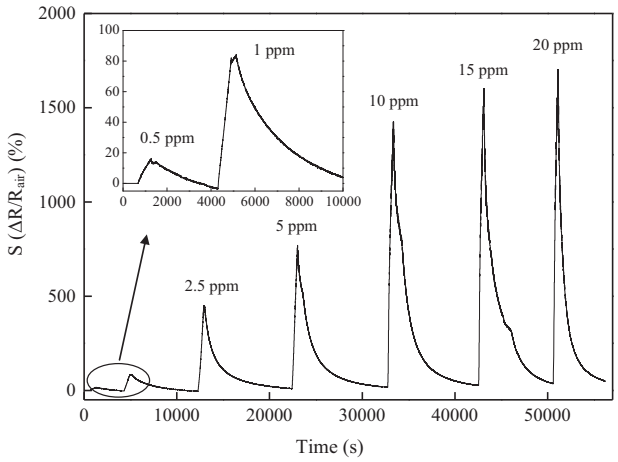

Fig. 9. Response (S) of NO_2 gas sensors based on 3.2 wt% RGO/WO_3 nanocomposite film, as function of time (s) for various concentrations of NO_2 gas at room temperature.

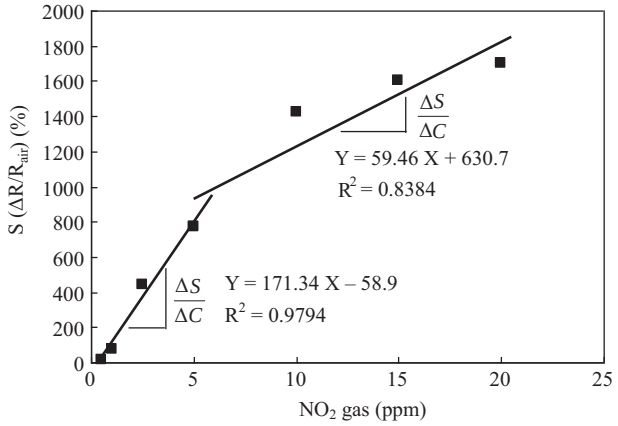

Fig. 10. Linear dependence of response of NO_2 gas sensor based on 3.2 wt% RGO/WO_3 nanocomposite film that was fabricated by one-pot polyol process and MOD at 500 °C for 4 h on concentration of NO_2 gas at room temperature. Sensitivity ($\Delta S/\Delta C$) is determined from the slope of the linear curve.

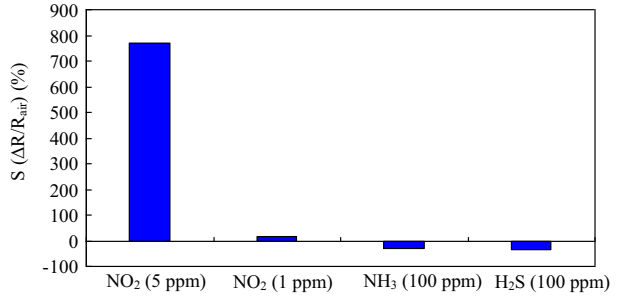

Fig. 11. Response (S) of NO_2 gas sensors based on (a) RGO/WO_3 nanocomposite films that were prepared by one-pot polyol process and MOD at 500 °C for 4 h to various gases.

gas sensing properties. Fig. 10 plots the response (S) as a function of concentration of NO_2 gas for the sensor that was made of the 3.2 wt% RGO/WO_3 nanocomposite film. The sensitivity ($\Delta S/\Delta C$) is determined from the slopes of the plots of response vs. gas concentration. A steep decrease in the slope was observed at from 5 to 20 ppm of NO_2 gas. Therefore, the sensitivity at 0.5 to 5 ppm NO_2 gas was higher than that at 5 to 20 ppm. Fig. 11 plots the results concerning the interfering effects of NH_3 and H_2S gases on the NO_2 gas sensor. NH_3 and H_2S gases may be regarded as having unobvious interference effects with NO_2 at a testing NO_2 concentration of 5 ppm. However, NH_3 and H_2S gases may be regarded having interference effects with NO_2 at a testing NO_2 concentration under 1 ppm. Additionally, from the results in Fig. 11, the sign of the response (S) for the considered adsorbates can be understood as indicating one of two charge transfer mechanisms. In this work, NO_2 doped the RGO/WO_3 film with holes, while NH_3 and H_2S doped it with electrons. Accordingly, the prepared RGO/WO_3 film exhibited the electrical behavior of an n-type semiconductor. During the sensing process, the adsorption of electron-withdrawing NO_2 molecules compensates for the hole carriers in the n-type RGO/WO_3, causing the electrical resistance of the RGO/WO_3 nanocomposite film to increase with concentration of NO_2. The electrical resistance of the RGO/WO_3 nanocomposite film decreased when the film was exposed to NH_3 and H_2S gases because NH_3 and H_2S are electron-donating gases. Fig. 12 plots the effect of ambient humidity on the response (S) of the NO_2 gas

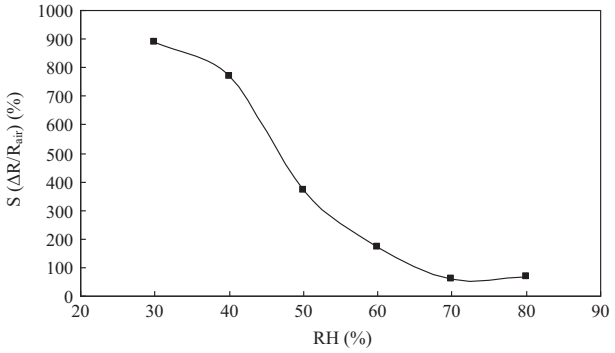

Fig. 12. Effect of ambient humidity on response of the NO_2 gas sensor based on 3.2 wt% RGO/WO_3 nanocomposite film that was fabricated by one-pot polyol process and MOD at 500 °C for 4 h to 5 ppm of NO_2 gas at room temperature.

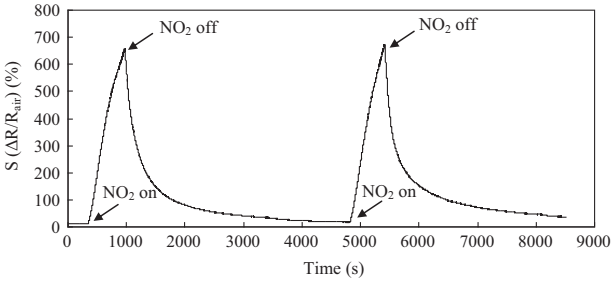

Fig. 13. Reproducibility of response of NO_2 gas sensor based on 3.2 wt% RGO/WO_3 nanocomposite film that was fabricated by one-pot polyol process and MOD at 500 °C for 4 h to 5 ppm of NO_2 gas at room temperature.

sensor at a testing NO_2 concentration of 5 ppm. The response (S) of the NO_2 gas sensor decreased as the ambient humidity increased, because the physisorbed water occupied the active sites of the sensing materials. Fig. 13 plots the real-time response of the NO_2 gas sensor at a testing concentration of NO_2 of 5 ppm. The response of the sensor increases significantly when the NO_2 gas was introduced into the chamber. However, we did not observe the saturated state of the NO_2 gas sensor, even when the exposure time was prolonged to 10 min. Additionally, two gas on/off cycles produced similar responses, indicating that the NO_2 gas sensor exhibited excellent reproducibility even when the exposure time was prolonged to 10 min. Therefore, we defined the exposure time of about 10 min as the effective response time for the NO_2 gas sensor. The recovery time is defined as the time required for the sensor to recover 90% of the decrease in resistance after the sensor is exposed to a dry gas. The recovery time of the NO_2 gas sensor was 18 min at a testing concentration of NO_2 of 5 ppm. Fig. 14 plots the long-term stability. The response (S) of the NO_2 gas sensor did not significantly vary for at least 45 days in a testing NO_2 concentration of 5 ppm. Table 2 compares the NO_2 gas sensing properties of the NO_2 gas sensor proposed herein with those of sensors in our previous work [39] and elsewhere in the literatures [22,23]. The response of the NO_2 gas sensor that was proposed herein was stronger than that of the NO_2 gas sensor that was fabricated by the hydrothermal method. Additionally, the NO_2 gas sensor that was made of RGO/WO_3 nanocomposite film exhibited higher response than that of the NO_2 gas sensor made of MWCNTs/WO_3 nanocomposite film because that the RGO had high electron mobility, favoring the transport process of electron easily in the RGO/WO_3 nanocomposite film at room temperature [2]. However, the response/recovery times of the NO_2 gas sensor that was proposed herein were longer than that of the NO_2 gas sensor that was fabricated by the hydrothermal method, perhaps because the former sensor had a compact sensing-film.

4. Conclusions

RGO/WO_3 nanocomposite film was fabricated on an alumina substrate by combining the one-pot polyol process with the MOD method. It was found that the introduction of RGO was effective for increasing the conductance of RGO/WO_3 nanocomposite film especially at low concentration of NO_2 gas. Therefore, the response of the RGO/WO_3 nanocomposite film to NO_2 gas increased dramatically when a few RGO was added to the WO_3 film. However, the amount of RGO added exceeded the percolation threshold, no variation in response versus concentration of NO_2 gas was clearly observed.

The NO_2 gas sensor that was based on a RGO/WO_3 film that was doped with 3.2 wt% of RGO responded more strongly than any of the tested sensors that were based on such films with different degrees of doping. The NO_2 gas sensor was very sensitive with acceptable linearity ($Y=171.34X-58.9$; $R^2=0.9794$) between 0.5 and 5 ppm, good reversibility and long-term stability (at least 45 days) when used at room temperature. NH_3 and H_2S gases may be regarded as having unobvious interference effects with NO_2 at a testing NO_2 concentration of 5 ppm. Ambient humidity significantly affected the NO_2 gas sensor. The response and recovery times were 9 and 18 min, respectively.

ABSTRACT

A novel electrochemical-sensing platform based on imprinted bimetallic Fe/Pd (BI-Fe/Pd) nanoparticle has been fabricated for point-of-care diagnostics of oxidative stress marker (3-nitrotyrosine) in biological fluids. Herein, BI-Fe/Pd nanoparticles are used as a platform on which 3-nitrotyrosine imprinted cavities are created using acrylamide as monomer and *N*-*N*′-methylene bisacrylamide as cross-linker. The performance of the obtained imprinted sensor is investigated by cyclic, differential pulse, and square wave voltammetry in stripping mode. The imprinted sensor exhibits high recognition ability and affinity for 3-nitrotyrosine in comparison with the non-imprinted one. In addition, the proposed sensor is capable of measuring 3-nitrotyrosine in aqueous as well as in human blood serum, plasma, and urine samples within the range of 4.90–867.57 $\mu g\ L^{-1}$ and 9.90–867.57 $\mu g\ L^{-1}$ with detection limit of 1.20 $\mu g\ L^{-1}$ and 3.25 $\mu g\ L^{-1}$ by square wave and differential pulse stripping voltammetry, respectively. Imprinted BI-Fe/Pd nanoparticle modified sensor shows high affinity and no interference from blood or urine components. Modified sensor was stored for 45 days at room temperature without any detrimental effects to their binding properties. The high affinity of proposed sensor and the lack of requirement for cold chain logistics make them an attractive alternative to the enzyme-linked immunosorbent assay (ELISA) technique.

1. Introduction

Nitration of tyrosine residue is a common post-translational modification to proteins that occurs *in vivo* especially under conditions of oxidative and nitrosative stress [1]. Tyrosine nitration of proteins (in *ortho* position to the phenolic hydroxyl group) is generated by reactive nitrogen species (peroxynitrite, nitrogen dioxide, nitrous acid, nitryl chloride *etc.*) either from the inflammatory cell defense mechanism or from a combination of nitric oxide synthase activity with a high rate of oxidative metabolism [2]. Tyrosine nitration can dramatically change protein structure and conformation. Subsequently it alter the biological half-life, inactivate enzymes and receptors that depend on tyrosine residues for their activity. This prevents phosphorylation of tyrosine residues, which is important for signal transduction. This modification is also associated with a number of pathologies [1], including neurodegenerative disorders such as Alzheimer's [2], atherosclerosis [3], osteoarthritis [4], rheumatoid arthritis [5], Parkinson's [6] and cardiovascular disease [7].

Now-a-days, 3-nitrotyrosine (3-NT) has been suggested and used as a biomarker for diagnosis of oxidative stress-induced pathological conditions. The predictive value of 3-NT was independent of other measures such as C-reactive protein, an inflammatory marker. Because of its utility in monitoring disease pathology and therapeutic intervention, a sensitive, specific and reliable method for measuring nitrotyrosine is crucial. Several analytical methods have been developed and used to measure free nitrotyrosine and/or nitrated proteins. Among all these methodologies reported so far, three major methodological approaches have been regularly used to measure 3-NT levels in biological matrices. The first methodology, mass spectroscopy (MS) technique, is usually coupled to either gas chromatography (GC–MS) [8] or liquid chromatography (LC–MS) [9]. Second, HPLC coupled with electrochemical detection has been widely used for the measurement of free and protein bound 3-NT [10]. The third and commercialized method reported for 3-NT detection is ELISA. According to the literature, more than five ELISA kits are available for 3-NT determination (Table 1). Based on the reaction with reactive nitrogen species, two forms of 3-NT are found *in vivo*, *i.e.* free

and protein-bound. Typically, identification and quantification of 3-NT has involved measuring the free 3-NT either in plasma or urine sample [11] and only ELISA techniques are able to detect protein bound 3-NT. All the ELISA kits are based on monoclonal and/or polyclonal natural antibodies against 3-NT. Although natural antibodies are highly selective and sensitive to their target molecule, they exhibit poor stability; require long production time, difficult handling, low temperature storage, and high costs.

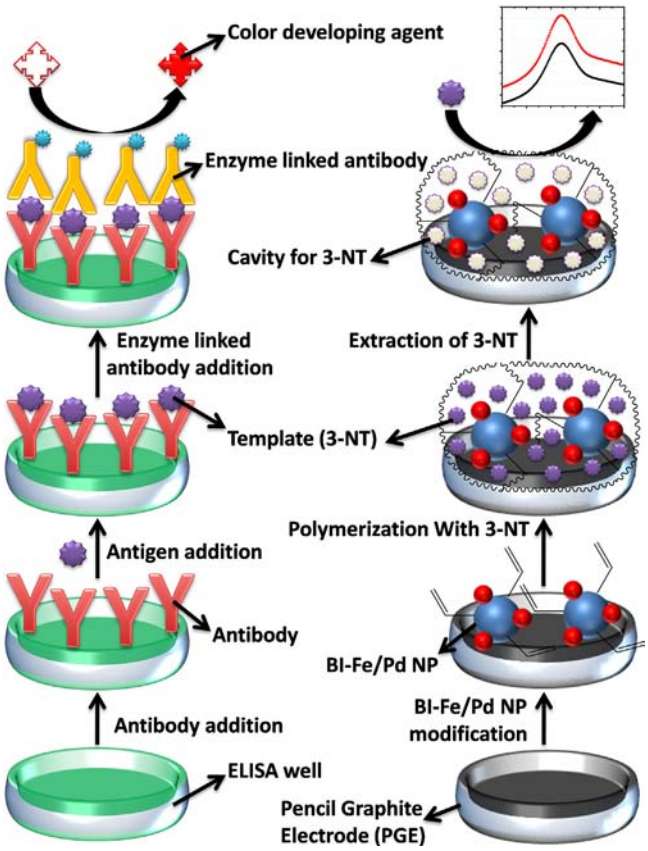
For these reasons, today, the research is focusing on the production of artificial antibodies which are capable of selectively binding target analyte with the same sensitivity of the natural antibodies but with simple steps and low cost of production. In this respect, molecularly imprinted polymers (MIPs) are in demand, in place of antibody, to design robust molecular receptors that are capable in recognizing target biological molecules at molecular level. Such MIPs can also mimic natural recognition entities, such as antibodies and biological receptors.

Mergola et al., have prepared 3-NT imprinted polymer as solid-phase extraction (SPE) sorbent material by bulk polymerization with methacrylic acid as functional monomer and acetonitrile as porogen [12]. Although their result showed high selectivity, but their application in real sample analysis (human blood) is not explored, which is the major agenda in 3-NT detection. Similarly, Schöneich et al., have done the 3-NT labeling with fluorogenic compound to visualize the cellular protein 3-NT by confocal microscopy [13]. But how much protein got converted or nitrated at tyrosine residue, *i.e.* the quantitative study, is not explored.

Bimetallic nanoparticles are of wide interest since they lead to many interesting size-dependent electrical, chemical, and optical properties. Recently, zero-valent iron (ZVI, Fe^0) is commonly utilized in biotechnological and biomedical industry, due to its nontoxic, paramagnetic behavior. According to the literature, the reductive activity of ZVI nanoparticles get enhanced in combination with some other metals [14]. A number of combinations has been reported so far to produce bimetallic ZVI systems like Pd/Fe [14], Cu/Fe [15], Ni/Fe [16], and Ag/Fe [17]. Among these alloys, Fe/Pd nanoparticle modification was preferred due to their biocompatibility, high electrical conductivity and inexpensiveness [14].

In this work, first time, we have synthesized 3-NT imprinted polymer as artificial receptor onto the surface of bimetallic nanoparticle for the fabrication of electrochemical sensor. The main aim of this study was to apply artificial receptor modified electrochemical sensor for detection of 3-NT as well as nitrated tyrosine residues in biologically available protein molecules. We have synthesized (*in situ*) a vinyl group modified bimetallic Fe/Pd nanoparticle (BI-Fe/Pd), using acrylic acid as stabilizing agent. The vinyl group modified BI-Fe/Pd was used as a platform for synthesis of 3-NT imprinted polymer in the presence of acrylamide (co-monomer), *N-N′*-methylene bisacrylamide (cross-linker) and ammonium peroxodisulphate (initiator), resulting in a biocompatible polymer matrix. Furthermore, the imprinted BI-Fe/Pd nanoparticles were used for fabrication of electrochemical sensor by drop coating onto the pencil graphite electrode (PGE) surface. The proposed sensor is to be used for the *in vitro* quantitative determination of free amino acid and/or total 3-NT levels in biological samples, without any acid hydrolysis or pronase digestion to release nitrotyrosine from nitrated proteins and peptides. Since the sensor can detect the modified amino acid present in protein, the assay is useful for proteins of all species. Moreover, the comparative study of proposed sensor with popular ELISA technique was also performed and it was found that the proposed sensor is much better than ELISA in terms of cost, time of analysis, handling, storage and reusability.

1.1. Materials and instruments



Acryl amide, acrylic acid, ammonium peroxodisulphate (APS), 3-NT, ferrous sulfate heptahydrate ($FeSO_4 \times 7H_2O$) ($>99.0\%$), sodium borohydride ($NaBH_4$) ($>98.0\%$), palladium acetate ($PdCl_2$), *N-N′*-methylene bisacrylamide (MBAA), and other interferents were purchased from Aldrich (Steinheim, Germany) and Fluka (Steinheim, Germany). Solvents, dimethyl sulphoxide (DMSO) and ethanol, were procured from Spectrochem Pvt. Ltd., (Mumbai, India). Standard stock solution of 3-NT ($5.0\ mg\ L^{-1}$) and interferents were prepared in double distilled water. For the binding characterization between imprinted nanoparticle and template, Fourier transform infrared spectroscopy (FT-IR) analysis was carried out on Varian FT/IR (USA) spectrometers. Morphological images and EDAX spectra of bare and modified SPE surfaces and BI-Fe/Pd nanoparticles were recorded using scanning electron microscope (SEM), Hitachi, model S-3400N. For BI-Fe/Pd nanoparticle characterization, UV–vis, X-ray diffraction (XRD), and high resolution transmission electron microscopy (HRTEM) analyses were performed on Perkin Elmer Lambda-35 spectrophotometer, Bruker D8 Focus X-ray diffractometer, and Tecnai T-30 (300 kV FEG TEM), respectively. Three kinds of biological fluids; human plasma, human serum, and human urine; were used to confirm the applicability of the proposed MIP sensor. All the pathological samples were obtained from the local pathology and were used as obtained. All the experiments were performed at room temperature ($25 \pm 1\ ^\circ C$).

1.2. Nitration of protein molecules

To explore the applicability of proposed sensor for protein bounded 3-NT analysis, bovine serum albumin (BSA) and ferritin molecules were nitrated in the laboratory by an earlier reported method [18]. First, protein was dissolved in 50 mM NH_4HCO_3 ($1\ mg\ mL^{-1}$) and nitrated with peroxynitrite ($ONOO^-$) by injecting the nitrating reagent into the protein solution while vortex mixing for 30 s at room temperature. Peroxynitrite was prepared, method described previously [19], by ozonolysis of sodium azide in 0.1 M NaOH and was stored at $-80\ ^\circ C$ until it was used. After nitration, the protein samples were dialyzed overnight against 50 mM NH_4HCO_3 buffer and stored at $-4\ ^\circ C$, before use.

1.3. Preparation of BI-Fe/Pd nanoparticle

Bimetallic Fe/Pd NPs were synthesized by earlier reported method with some modification [14]. Initially, dispersed solutions of acrylic acid with two different concentrations (0.5 v/v % and 1 v/v %) were prepared by deionized double distilled water. For preparation of BI-Fe/Pd nanoparticle, 10.0 mL of dispersant solution was added into 100.0 mL $FeSO_4$ solution ($0.05\ mol\ L^{-1}$). The resultant solution was homogenously mixed by vigorous magnetic stirring for 30 min. Then 125.0 mL of $NaBH_4$ solution (0.1 M) was drop wise added into the mixture for the formation of vinyl group modified zero-valent iron. The reaction mechanism is shown below for clarity:

Scheme 1. Comparative study between working methodology of ELISA and proposed method.

$$Fe^{2+} + 2BH_4^- + 6H_2O \rightarrow Fe^0\downarrow + 2B(OH)_3 + 7H_2\uparrow$$

The prepared, zero-valent iron NPs were washed by deionized water for 2 to 3 times followed by vacuum drying at room temperature. For Fe/Pd bimetallic NPs preparation, the above prepared zero-valent iron NPs were immersed into the solution of $PdCl_2$ (1 mmol, 10 mL ethanol) for 30 min, resulting, the deposition of Pd onto the surface of zero-valent iron NPs.

$$Pd^{2+} + Fe^0 \rightarrow Pd^0 + Fe^{2+}$$

Finally, the modified BI-Fe/Pd NPs were rinsed with ethanol and acetone, followed by vacuum drying at room temperature.

1.4. Fabrication of 3-NT imprinted BI-Fe/Pd NP based sensor

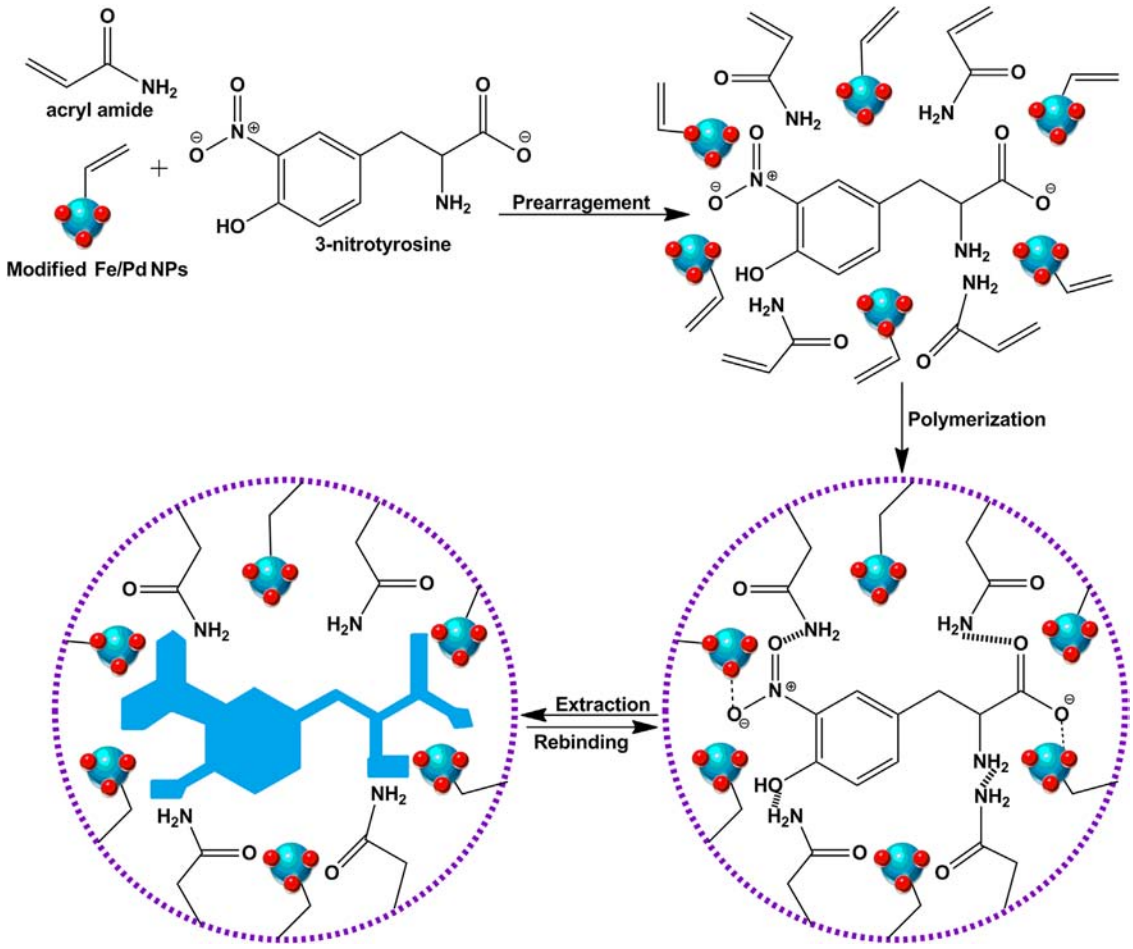
The surface of the PGE was polished with 1.0 μm and 0.05 μm wet alumina slurry followed by 5 min ultrasonication in distilled water. Then the electrode was subjected to drop coating of 5.0 μL of BI-Fe/Pd nanoparticle suspension prepared in THF solvent and kept for 12 h at room temperature for drying (Schemes 1 and 2). Later on, the pre-polymer mixture (purged with 99.999% pure N_2 for 10 min) containing optimized amount of template (3-NT, 0.05 mmol, 11.3 mg in 0.5 ml of DMSO), monomer (acryl amide, 0.1 mmol, 14.2 mg in 120 μL DMSO), cross-linker (MBAA, 0.1 mmol, 11.8 μl), and initiator (APS, 0.05 mmol, 11.4 mg) was casted on the bimetallic NP modified PGE. Finally, the modified PGE was placed in a pre-heated electric oven for 2 h at 50 °C. This results in the formation of polymer (adduct polymer) onto the surface of BI-Fe/Pd NPs modified PGE. For preparation of imprinted polymer, template molecule was extracted from adduct polymer. The adduct polymer modified PGE was placed in 1.0 M NaOH solution for 30 min. Complete template extraction was confirmed by no DPSV response for 3-NT. For control analysis, non-imprinted polymer (NIP) was also prepared by adopting the same procedure, but in the absence of template molecule.

1.5. Electrochemical measurements

All the electrochemical analysis [cyclic voltammetry (CV), differential pulse stripping voltammetry (DPSV), square wave stripping voltammetry (SWSV) and chronocoulometry (CC)] were performed on CH instrument (USA, model number 660C) with three electrode assembly in a electrochemical cell containing 10 mL KCl solution as supporting electrolyte (pH=8.0). Here imprinted nanoparticle modified PGE was used as working, Ag/AgCl as reference and Pt wire was used as counter electrode. Before any eletrochemical analysis, the blank run was taken in the absence of target analyte (3-NT). For qualitative and electrochemical study of 3-NT, CV and CC analyses were performed. CV was recorded in the potential window of +1.8 V to −0.2 V at different scan rates (50–200 mV s^{-1}). Moreover, for quantitative study, DPSV and SWSV were performed. Before DPSV and SWSV analyses, analyte was deposited at electrode for 60 s at −2.5 V vs. Ag/AgCl. Then, DPSV runs were recorded in the potential range varying from +1.3 V to +0.4 V (vs. Ag/AgCl) at a scan rate 10 mV s^{-1}, pulse amplitude 50 mV, and pulse width 50 ms. SWSV were recorded in the potential range varying from +1.3 V to +0.4 V (vs. Ag/AgCl) at a scan rate 10 mV s^{-1}, pulse amplitude 25 mV, and frequency 15.0 Hz.

The peak currents observed in SWSV and DPSV analysis were used for the quantitative measurement of 3-NT in real samples. The limit of detection (LOD) was calculated as three times the standard deviation for the blank measurement in the absence of template, divided by the slope of the calibration plot between 3-NT concentration and DPSV/SWSV current [20].

2. Results and discussions



2.1. Characterization of bimetallic Fe/Pd NPs

2.1.1. Composition and morphological characterization

UV–vis, XRD, FT-IR, FE-SEM, EDAX and TEM analyses were performed for characterization of modified BI-Fe/Pd NPs. Fig. 1 (A) shows UV−vis spectrum for the as-formed Fe/Pd bimetallic nanoparticles. Only one SPR band (λ_{max}=365 nm) is observed for the Fe/Pd nanoparticles, rather than two SPR bands. This observation indicates that the nanoparticles were basically an alloy structure with a homogeneous composition, rather than a physical mixture of monometallic Fe and Pd nanoparticles. In order to confirm the compositional homogeneity of the nanoparticles, XRD studies were also carried out. Fig. 1(B) shows the powder XRD spectra of the Fe and BI-Fe/Pd nanoparticles synthesized in the present work. XRD spectra show main peaks at the positions of 30.1°, 35.4°, 43.1°, 57.1° and 62.60°, which are in good agreement with the standard JCPDS file for Fe_3O_4 (JCPDS 89–0691, $a=b=c=8.38$ Å) and can be indexed as the face centered cubic structure of Fe_3O_4 having space group *Fd*3*m* (277). Furthermore, because of low concentration of Pd, no additional peaks related to Pd, were observed for BI-Fe/Pd nanoparticles. All available reflections of the present XRD phases have been fitted with a Gaussian distribution. The broadening of XRD peaks (*i.e.* Scherrer's broadening) attributes nanosized formation of Fe and BI-Fe/Pd nanoparticles. The particle size, *d*, of the synthesized Fe and BI-Fe/Pd nanoparticles were estimated by Debye–Scherrer's equation [21]:

$$d = \frac{0.9\lambda}{B\cos\theta} \quad (1)$$

where, *d* is the particle size, λ is the wavelength of X-rays, θ is the Bragg angle and B is the full width at half maxima (FWHM) on 2θ

Scheme 2. Binding mechanism between monomer, template and bimetallic Fe/Pd nanoparticle.

scale. The average particle size using Debye–Scherrer's equation was of the order of ~4 nm. The morphology and size of the synthesized BI-Fe/Pd nanoparticles are shown using SEM and TEM studies, Fig. 1 (C) and (D), respectively. As evident from Fig. 1(C), spherical microstructures of BI-Fe/Pd nanoparticles were observed in FE-SEM studies. The closure observation reveals that these microstructures are eventually composed of very tiny spherical nanoparticles of size 4–8 nm. In order to confirm the XRD and FE-SEM observations, HRTEM studies were also carried out. HRTEM studies, Fig. 1(D), confirm that the synthesized BI-Fe/Pd nanoparticles were spherical in shape and had average size ~4 nm. These observations are in good agreement with XRD and FE-SEM studies. Fig. 1(E), shows the EDAX spectra for the Fe/Pd bimetallic nanoparticles. The compositions of Fe and Pd are 92.49% and 7.51%, respectively. The uniformity in the particle-to-particle composition, and the concurrent presence of both Fe and Pd in each particle, confirmed that the particles had a Fe/Pd bimetallic structure. To study the vinyl group modification of BI-Fe/Pd NP, FT-IR spectrum was recorded (Fig. 1(F)). In the spectrum, three characteristic bands of vinyl group (–C=C–, 1680 cm^{-1}; =C–H, 3100 cm^{-1}; and =C–H (bend), 1000 cm^{-1}) were observed, which confirms the vinyl group generation on the surface of BI-Fe/Pd NPs.

2.1.2. Electrochemical characterization

The electrocatalytic behavior of the bimetallic NPs were studied in KCl solution (pH=8.0) containing 5.0 mmol L^{-1} $K_3Fe(CN)_6$, which acts as an electro-chemical probe. As shown in Fig. S1A, the cyclic voltammogram of $K_3Fe(CN)_6$ at bare PGE, shows an oxidation peak at +0.158 V and a reduction peak at +0.251 V. The peak current increased four-fold when ZVI NPs were immobilized on the electrode. This is attributed to an increase in effective working electrode surface area by coating of nanoparticles. However, two-fold increase in peak current was observed on BI-Fe/Pd NPs modified electrode as compared to ZVI NPs modified electrode. Similar results are obtained in the DPSV and SWSV analyses (S1 B and C), which confirm that the deposition of Pd onto the surface of ZVI enhanced the electrocatalytic activity.

2.2. Characterization of imprinted polymer

2.2.1. UV–vis spectroscopic evaluation for the template–monomer interaction

To study the binding interaction between monomer and template, UV–vis spectroscopic study was performed in aqueous medium (Fig. 2(A)). Herein, different concentrations of acryl amide monomer were added to the fixed concentration of template. Nitrotyrosine showed an absorption band with λ_{max}=625 nm, which decreases with increase in concentration of monomer (up to 2:1 ratio). But after this ratio, with increase in concentration of monomer, the absorbance peak remains constant (Fig. 2(A)). The decrease in absorbance value can be attributed due to the non-covalent interactions (mainly the hydrogen bonding interaction) between the functional group of monomer and template molecule (Scheme 2). So, the optimized molar ratio of 2:1 (monomer:template) is used for further studies.

2.2.2. Binding interaction between polymer and template by FT-IR analsis

FT-IR spectra of nitrotyrosine (B), adduct (C) and MIP (D) were shown in Fig. 2. As depicted in curve A, after binding with monomer in adduct polymer, the characteristic bands of nitrotyrosine

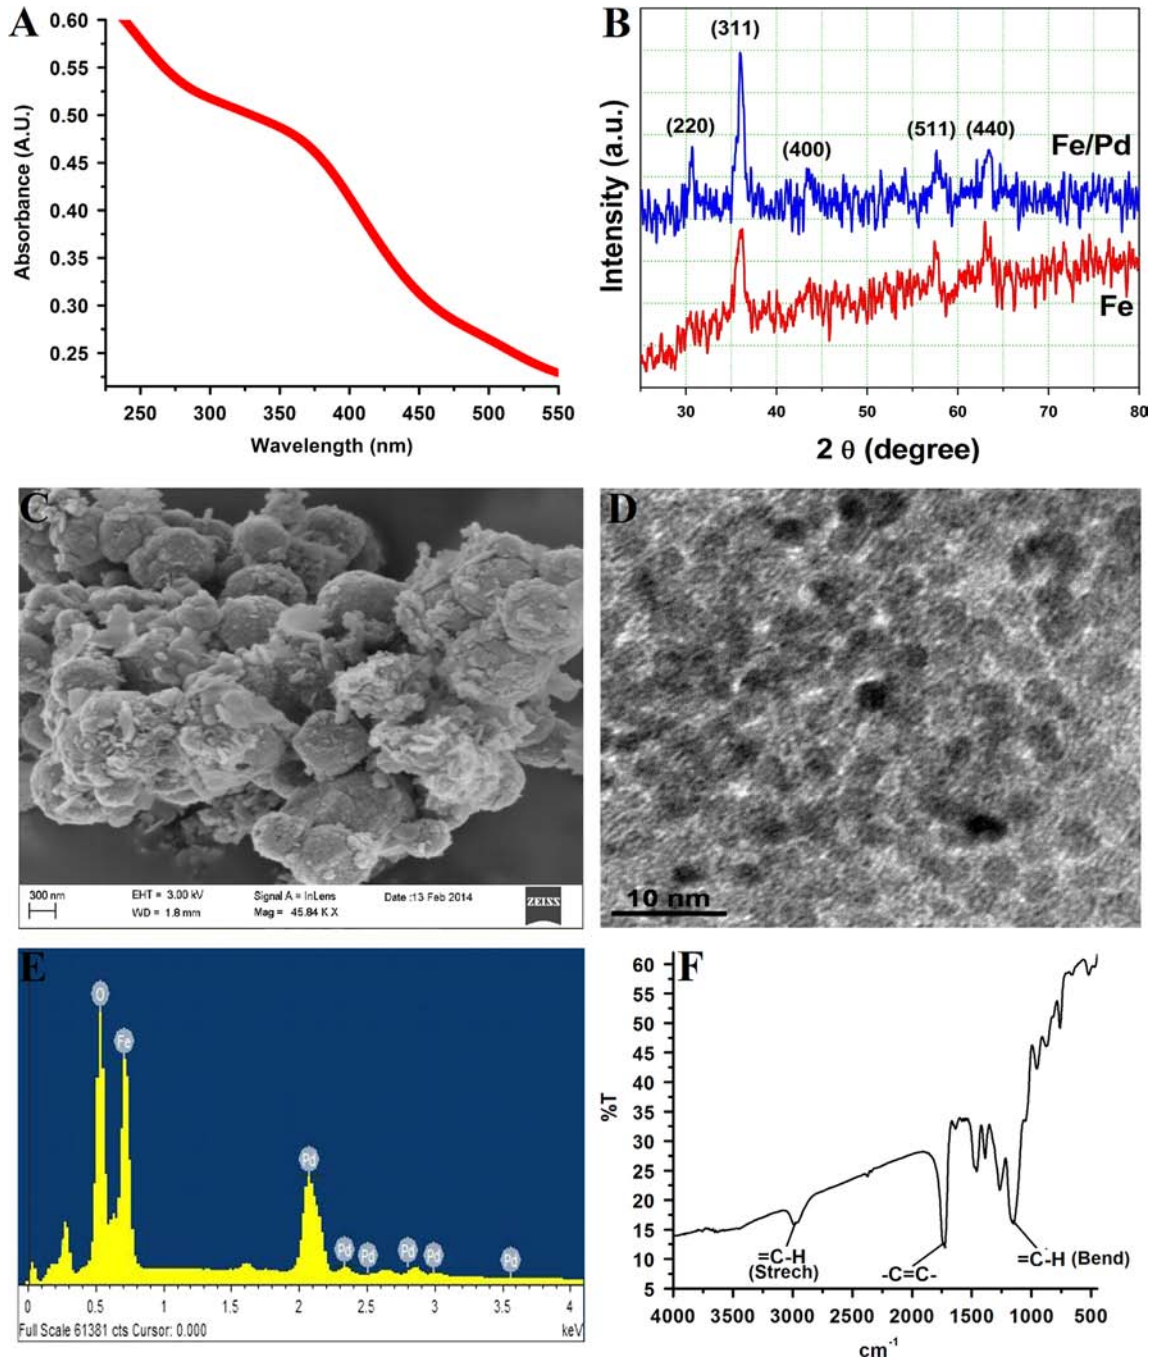


Fig. 1. Characterization of bimetallic Fe/Pd nanoparticle by: (A) UV, (B) XRD, (C) FE-SEM, (D) HR-TEM, (E) EDAX, and (F) FT-IR analyses.

[–CO (asym), 2000 cm^{-1}; –NO, 1440 cm^{-1}; –CO (Sym), 1120 cm^{-1}; and –OH, 3000 cm^{-1}] shifts to lower wavelengths side (1850 cm^{-1}, 1490 cm^{-1}, 1000 cm^{-1} and 2980 cm^{-1}). The bands due to the monomer skeleton remain constant at their original positions (1590 cm^{-1} and 3500 cm^{-1}) in adduct as well as in the spectrum of MIP (curve C and D). In the MIP spectrum (curve D), the template related band was absent. This suggests the complete removal of template from polymer cavity, after extraction.

2.2.3. *Morphological characterization of imprinted polymer by SEM and EDAX analyses*

The morphological differences between adduct and MIP-modified PGEs were studied by SEM analysis (Fig. 3(A) and (B)). As shown, adduct-modified PGE surface is uniform and very compact in comparison to the MIP-modified PGE, which shows a rough surface with clearly visible cavities. The cavities present at the MIP-modified PGE are generated after template extraction; suggest the successful imprinting of 3-NT in the polymer matrix. In order to explore compositional information about the polymer matrix, EDAX spectra of adduct (Fig. 3(C)) and MIP (Fig. 3(D)) modified PGEs were also recorded. Theoretically, both adduct and MIP has similar elemental composition but the intensity varies after template extraction. As observed, the characteristic peak for 'C', 'N', 'O' element are present in both adduct and MIP-modified PGEs surface but their percentage is less in MIP-modified surface (Table shown in Fig. 3(C) and (D)). The data obtained from both SEM and EDAX analysis confirms the successful imprinting of 3-NT.

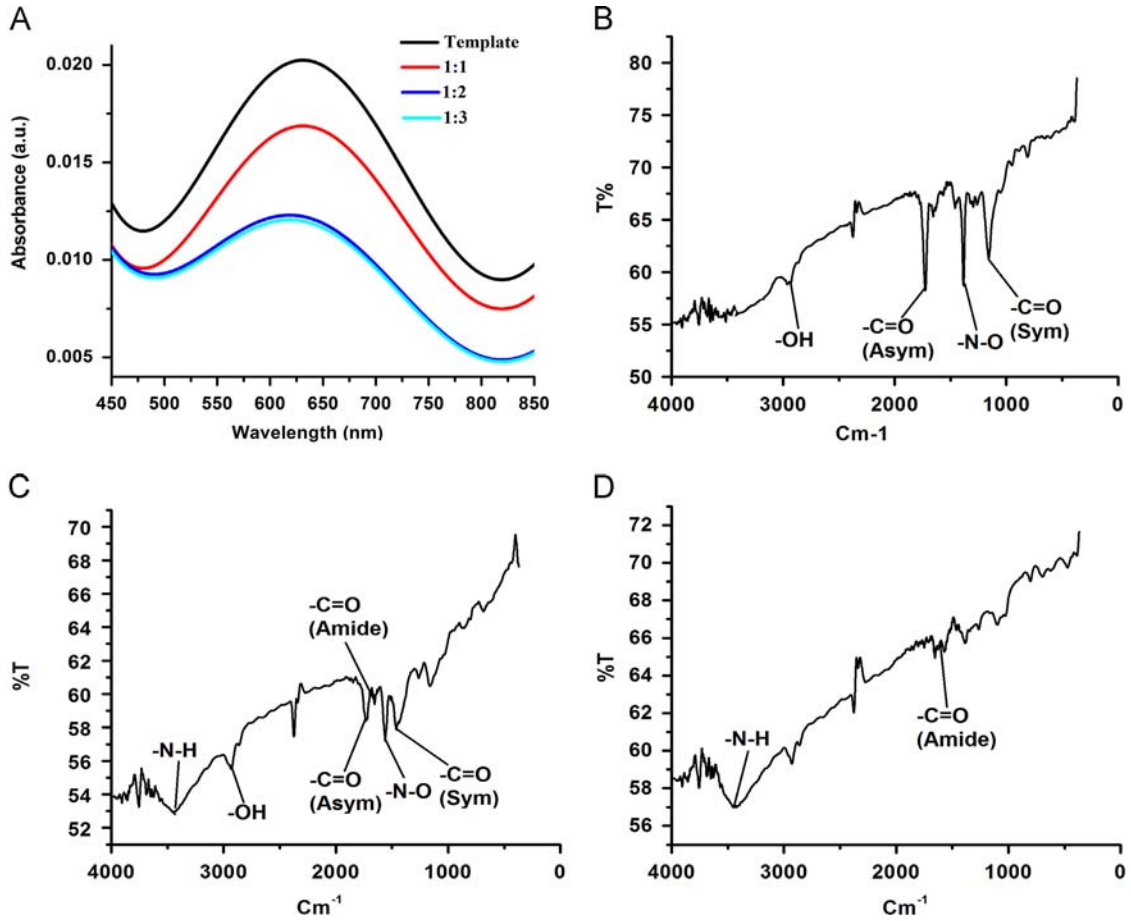

Fig. 2. (A) UV–vis spectra of template and monomer in different molar ratio and FT-IR spectra of (B) template (3-nitrotyrosine), (C) adduct, and (D) MIP.

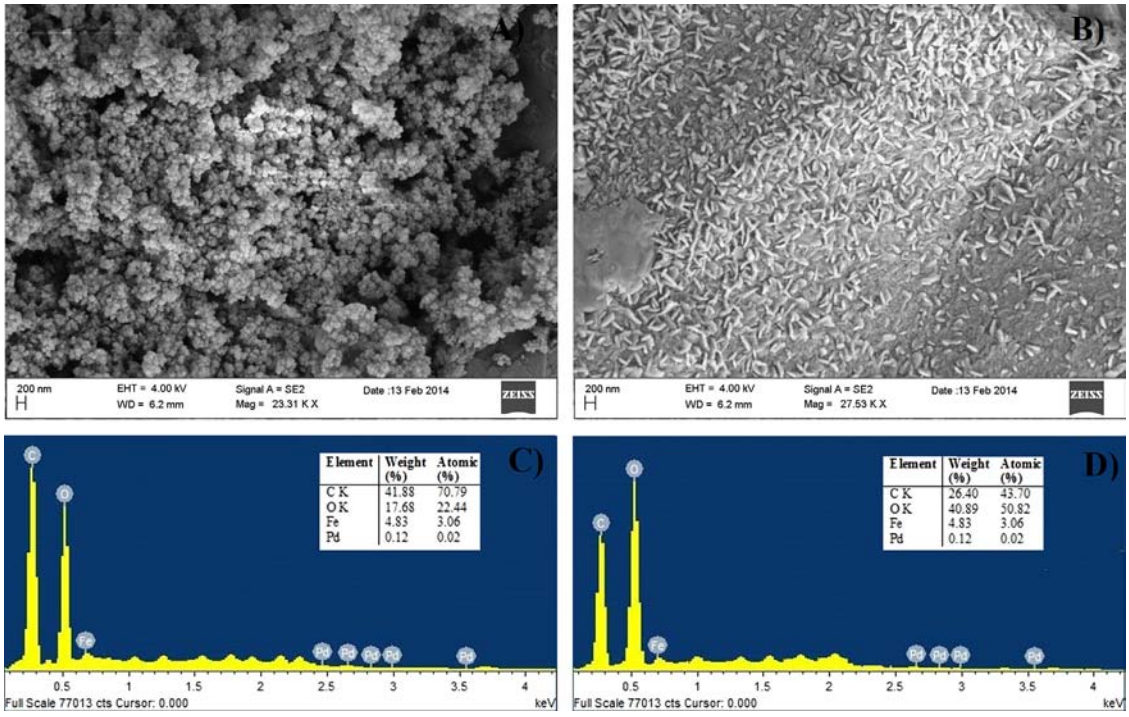

Fig. 3. SEM images and EDAX spectra of adduct ((A) and (C)) and MIP ((B) and (D)).

2.3. Electrochemical behavior of nitrotyrosine

Cyclic voltammety and chronocoulometric experiments were carried out to study the electrochemical behavior of nitrotyrosine at the bare, MIP, and NIP modified-PGE. Irreversible cathodic waves with reduction peak potential at +0.80 V can be observed on the surface of the PGE and MIP-modified PGE (Fig. S2). The reduction peak current (I_p) at MIP/PGE was significantly higher than that of bare PGE, indicating the significantly enhanced efficiency of the MIP nanoparticles modification on the PGE surface (Fig. S2). On the other hand, a weak current was observed on the NIP/PGE, which may be due to the non-specific adsorption of 3-NT (Fig. S2).

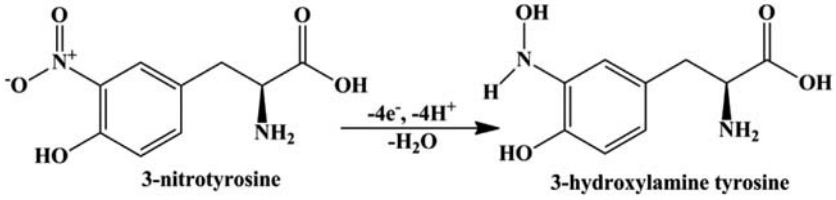
The reduction system was characterized by a cathodic peak at the negative-moving step but the anodic peak was absent on the reverse scan. This indicates the ir-reversible reduction of 3-NT molecule (Fig. 4(A)). The reduction reaction process was attributed to the four electrons reduction of the nitro group of 3-NT to generate the related hydroxylamine according to the currently accepted mechanism for the electro-reduction of aromatic and hetero-aromatic nitro compounds [22–24].

The effect of potential scan rate on the reduction peak current of 3-NT was investigated at the MIP/PGE. As can be been seen from Fig. 4(A), the I_p increased gradually with the increasing scan rate and there was a linear relationship between I_p (μA) and scan rate (50–200 mV s^{-1}) as shown in the linear regression equation:

I_p (μA)=(1.401 ± 0.085) ν+(119.87 ± 8.38); n=6; R^2=0.99, which suggests that the reduction of 3-NT on the MIP/PGE electrode is a controlled surface-adsorption process. The influence of pH value on the current response of 50.0 μg L^{-1} 3-NT was examined by DPSV with KCl solution in the pH range from 2.0 to 12.0. As can be seen in Fig. S4, initially, the I_p increases with an increase in pH from 2.0 to 8.0, and then decreases for further increasing pH values (8.0 to 12.0). Therefore, the optimum pH of KCl solution was set at 8.0 for further experiments. The number of protons, which participated during the reduction of 3-NT on a MIP-modified PGE, was evaluated through the relationship between peak potentials and pH. A linear shift of E_p toward negative potential with increasing pH from 2.0 to 12.0 indicates that protons are directly involved in the reduction of 3-NT and it follows following equation: $E_p = -0.412 - 0.0509$ pH (R^2=0.99). According to the Nernst equation:

$$E = E^0 - \left[\frac{(2.303mRT)}{(nF)}\right] \text{pH}$$

(where m and n are corresponding to the transference numbers of proton and electron, respectively) [25], the ratio of m/n was calculated nearly to be 1, suggesting the numbers of the involved protons and electrons were equal in the electro-reduction of 3-NT. Since it is known that four electrons (n=4) and four protons participated in electrocatalytic reduction of 3-NT, the diffusion coefficient (D) of 3-NT can be estimated from the known values of electrode surface area (A) and of anodic peak currents (I_p) at various scan rates (ν) in a 3-NT solution with fixed concentration (C^*) by Eq. (2) [26]:



$$I_p = 0.4463\, nF\, C^* A \nu^{1/2} D^{1/2} \left(\frac{nF}{RT}\right)^{1/2} \quad (2)$$

where the terms of F, R, and T have their universal meanings, C^*=50.0 μg L^{-1}. With the relation between peak current and square root of scan rate [I_p(μA)=(24.67 ± 1.08) $\nu^{1/2}$+(30.82 ± 9.38); n=6; R^2=0.99], diffusion coefficients of 3-NT were estimated to be 2.12×10^{-12} and 2.32×10^{-10} $cm^2\, s^{-1}$ (Table S1) on bare and modified PGE, respectively.

Chronocoulometry was also employed to measure the diffusion coefficient of 3-NT in solution. Fig. 4(B) shows the charge as a function of time with increase in concentration of 3-NT. Herein, the total charge is directly proportional to the current produce in the system, as expected, charge increases with increase in concentration of analyte (Fig. 4(B)). In CC, the net charge (Q) was also proportional to the inverse of the square root of transition time (t), known as Anson plot (Fig. S3). Since the mass transfer of 3-NT to electrode surface is diffusion controlled, the diffusion coefficient for 3-NT on MIP-modified PGE surface was calculated according to Eq. (3) [26]:

$$Q = 2nFA\, C(Dt)^{1/2}\pi^{1/2} \quad (3)$$

where the parameters have it meanings as described above, the diffusion coefficient was found 2.87×10^{-10} $cm^2\, s^{-1}$ (Table S1). Similarly, the value of diffusion coefficient of 3-NT was also calculated for bare PGE and was found to be 2.92×10^{-12} $cm^2\, s^{-1}$. Other kinetic parameters were also calculated to study the electrochemical behavior of 3-NT, the detailed calculation was given in supporting information and results are portrayed in Table S1.

2.4. Performance of the imprinted sensor

2.4.1. Calibration curve and detection limit

Under the optimal analytical conditions (accumulation potential of −2.5 V and 30 s deposition time, Fig. S4), determination of 3-NT was performed by DPSV and SWSV techniques. As can be seen from Fig. 4(C) and (D), the sharp and well-defined reduction peak current increased linearly with increasing concentration of 3-NT in both type of analyses but the current sensitivity is higher in case of SWSV. The calibration graph of the prepared sensor shows a linear relationship over 3-NT concentration in the range of 9.90 μg L^{-1} to 867.57 μg L^{-1} (for DPSV) and 4.90 μg L^{-1} to 867.57 μg L^{-1} (for SWSV). The linear regression equations are (Fig. S5):

$$I_p(\mu A) = (0.059 \pm 0.002)C + (4.042 \pm 0.753); \quad n = 9; \quad R^2 = 0.99,$$

$$\text{LOD} = 1.20\ \mu g\ L^{-1} (\text{SWSV})$$

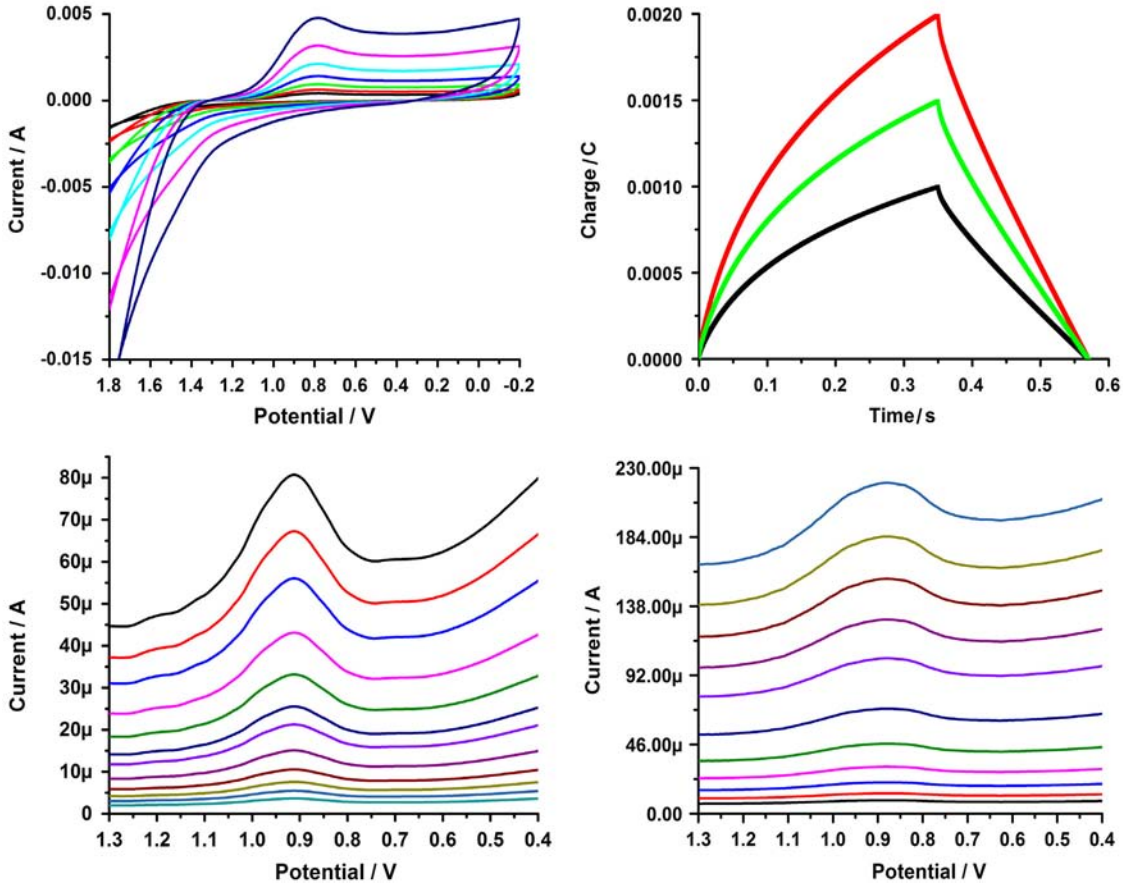


Fig. 4. (A) CV runs of 3-nitrotyrosine (50.0 μg L^{-1}) at different scan rates ranging from 50.0 mV s^{-1} to 200 mV s^{-1}; (B) chronocoulometry runs (Q–*t* curves) for differenet concentration of 3-nitrotyrosine; (C) DPSV response of nitrotyrosine on MIP-modified PGE with increasing concentration (9.90 μg L^{-1} to 867.57 μg L^{-1}), and (D) SWSV response of nitrotyrosin on MIP-modified PGE with increasing concentration (4.90 μg L^{-1} to 867.57 μg L^{-1}) in optimized conditions. Accumulation time 30 s, accumulation potential −2.5 V, in KCL solution at pH=8.0.

$$I_p(\mu A) = (0.037 \pm 0.002)C + (3.101 \pm 0.621); \quad n = 9; \quad R^2 = 0.99,$$

$$\text{LOD} = 3.25\ \mu g\ L^{-1}(\text{DPSV})$$

The proposed electrode is compared with a known solid phase microextraction method [12], by means of Student's *t*-test, where $t_{calculated}$ (1.13) is found to be less than $t_{tabulated}$ (2.77) at the confidence level of 95%. This revealed that, although, a similar order of precision is observed for both the methods, our proposed method is comparatively simple, selective, and cost-effective.

To study the recognition ability of MIP, the DPSV response of MIP and NIP-modified PGE were also tested for different concentration of 3-NT. We observed that the response of MIP-PGE was significantly increased with increasing the concentration of nitrotyrosine (Fig. S5). On the other hand, no significant change was observed with NIP-PGE (Fig. S5). This curtailed the chance of any non-specific adsorption and false positive results during analysis.

2.4.2. Selectivity of the imprinted sensor

To ensure selectivity of the imprinted sensor, SWSV response of 3-NT and various concentration of structural analogs including tyrosine, nitrophenol, nitroaniline, phenylalanine, tryptophan, histidine, aniline, and bisphenol were compared and the results are shown in Fig. 5. As depicted in Fig. 5, sensor shows negligible current response for any concentration of the individual interfering compounds ((A) 0 μg L^{-1}; (B), 200 μg L^{-1}; (C) 400 μg L^{-1}; (D) 600 μg L^{-1}; (E) 800 μg L^{-1}, and (F) 1000 μg L^{-1}). However, in the binary mixture of interferents and 3-NT (50.0 μg L^{-1}), the sensor shows 100% current response for target analyte (3-NT). The

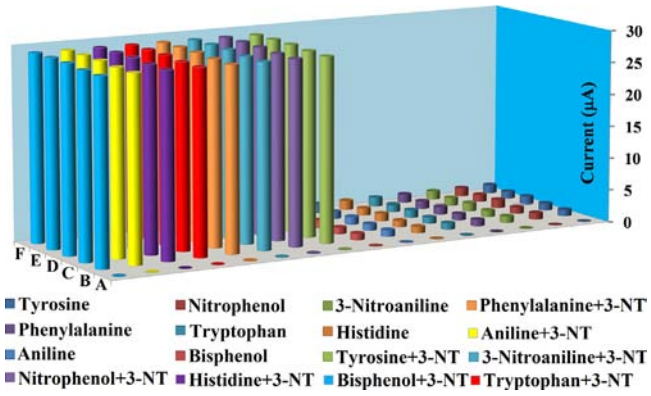

Fig. 5. Effect of structural analogues/interferents on the SWSV response of 3-nitrotyrosine on the MIP-modified PGEs.

result showed that the excess concentration of interfering compounds had no influence on the current response of 3-NT (Fig. 5). So, it can be easily concluded that the interference of the structural analouge compounds were negligible on the 3-NT determination, which clearly proved the reasonable selectivity of the proposed sensor.

2.4.3. Reproducibility and stability of imprinted PGE

To investigate the reproducibility of the as-prepared sensor, three different concentrations of 3-NT (low, 10.0 μg L^{-1}; middle, 50.0 μg L^{-1} and high, 500.0 μg L^{-1}) were measured using six MIP-modified PGEs

[b] RSD was calculated for three replicate determinations.

prepared independently under the identical experimental conditions. All the six electrodes (prepared independently) use the same standard curve and the relative standard deviation (RSD) was found in the rage from 1.1% to 1.8%. A good repeatability was also observed with relative standard deviation (RSD) of 2.0%, forthree parallel detection. The used MIP-modified PGE could be easily regenerated (25 times) by the method of template extraction. In the cycle of pre-concentration, determination, regeneration, and rinsing, the RSD for five replicate measurements was 1.5%. For evaluating the stability of the electrode, the peak current change of 50.0 $\mu g\ L^{-1}$ 3-NT was measured from day to day. When stored in air at room temperature, the sensor can retain 95.5% of its initial response even after 15 days, and decreased to 87.5% after 30 days. These results indicate that the prepared sensor has acceptable reproducibility and good stability for the detection of 3-NT.

2.5. Real sample analysis

2.5.1. Aanalysis of human blood and urine sample

Biological applicability of the imprinted sensor was investigated by measuring the 3-NT concentration in human blood plasma, serum as well as in urine samples using the standard addition method. Urine and blood samples of healthy volunteers were used for this analysis. The samples were used as obtained, without any pre-treatment. First, 0.1 mL of real sample was added to the electrochemical cell having 10.0 mL of supporting electrolyte. Then, samples were spiked with known concentration of standard 3-NT ranging from 10.0 $\mu g\ L^{-1}$ to 100.0 $\mu g\ L^{-1}$, and their square wave voltammograms were recorded using the MIP-modified PGE. A well-defined peak for the reduction of 3-NT was observed at the peak potential of +0.95 V, similar to the peak obtained in standard solutions. No other peaks were found in entire measurements. These measurements further confirmes the selectivity of imprinted sensor for 3-NT determination. To further explore the clinical applicability of the proposed sensor, the same sample obtained from local pathological laboratory were also analyzed by a commercially available ELISA kit (RAB0389 SIGMA, Human NT-3 ELISA Kit). The comparative data obtained from ELISA kit and proposed method was portrayed in Table 2. As shown in Table 2, almost similar results were obtained by both the methods and the recoveries were obtained in ranges of 98.9–100.9%. The recovery data showed acceptable range, which indicated that the proposed method can be utilized successfully for the detection of free and/or bound 3-NT in human biological fluids with adequate accuracy and reliability.

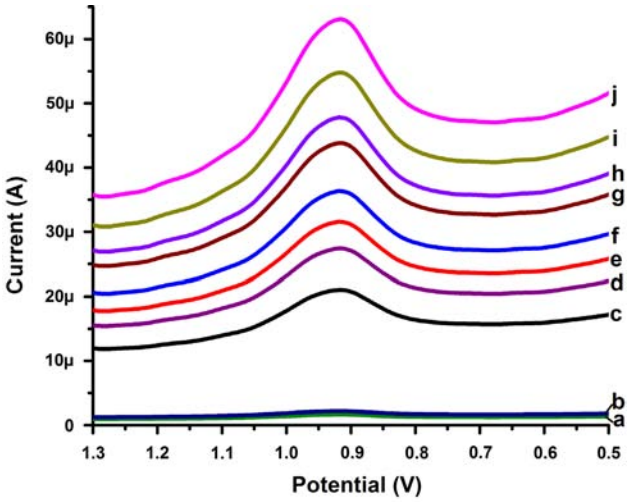

Fig. 6. SWSV runs for BSA (a), ferritin (b), nitrated BSA (c), nitrated ferritin (e), nitrated BSA+3-nitrotyrosine ((d) 135.0 $\mu g\ L^{-1}$; (f) 200.0 $\mu g\ L^{-1}$; (g) 255.0 $\mu g\ L^{-1}$) and nitrated ferritin+3-nitrotyrosine ((h) 280.0 $\mu g\ L^{-1}$; (i) 340.0 $\mu g\ L^{-1}$; (j) 400.0 $\mu g\ L^{-1}$).

2.5.2. Analysis of nitrated protein

To further explore the applicability of the proposed sensor, nitrated proteins BSA and ferritin were also analyzed. As shown in the Fig. 6, the sensor does not show any SWSV current response for unmodified proteins *i.e.* normal BSA and ferritin (curve a, b). But a clear response was obtained for nitrated BSA and ferritin molecules (curve c, e). Whereas, when a known concentrations of 3-NT was spiked in the above solution, 100% recovery was obtained (curve d, f, g, and h, i, j). This suggests that the proposed sensor is able to detect free as well as protein-bound nitrotyrosine.

2.6. Comparison with commercialy available 3-NT determination technique

The proposed method was also compared at several points and factors with comercially available ELISA technique for 3-NT determination. All the points considered during comparison were portrayed in Table 3. As proposed, our sensor is highly selective and low-cost device. It does not require any highly skilled professional for operation and also takes very less analysis time. So, the proposed sensor can be easily used for commercial analysis of 3-

Table 3
Comparative study between proposed BI-Fe/Pd modified molecularly imprinted sensor and commercially available ELISA techniques for 3-nitrotyrosine determination.

S. nos.	Comparative data	ELISA kit	Our technique
1.	Storage temperature	Individual components have to be store between 2 and 8 °C, samples have to be store preferably at −70 °C	Not necessary, all the experiments and reagents are performed and stored at room temperature
2.	Use of antigen and antibody	Biotinylated tracer antibody, streptavidin–peroxidise solution, TMB solutions, stop solutions are associated with this assay	All these are replaced by using a synthetic antibody: molecularly imprinted polymer (MIP)
3.	Detection technique	UV–vis study	More selective electrochemical study
4.	Analytical handling	Many more complicated step are associated with this technique like reagent preparation, standard preparation, qualified laboratory staff *etc.*	It is less complicated and very easy in operation and handling. No need of operator
5.	Cost	Highly expensive	Very cost-effective
6.	Analysis time	Very high, reported 3.5 h for hycult ELISA kit	Short, maximum 10 min
7.	Mode of determination	Indirect	Direct
8.	Storage ability	Expiration date, which is very less	It can be used after 6 month from the date of preparation
9.	Reusability	It has to be thrown away after the 1st use	A single sensor can be used 25times for analysis
10.	Dilution	Most important, used only in highly diluted samples. Requires 10,000 times dilution, some times	It can be measured in a wide range of concentration for high to more diluted solution. Without diluted or pre-treated blood sample can also be analyzed by this technique

NT as a replacement of costly, difficult and time-cumbersome ELISA techniques.

3. Conclusion

In this study, we have demonstrated a fresh role of BI-Fe/Pd nanoparticle as a platform for imprinting of 3-NT molecule. The resulting imprinted BI-Fe/Pd nanoparticles revealed higher selectivity for 3-NT in aqueous medium and their high molecular recognition ability was maintained in a complex environment of human serum, plasma, and urine. Unlike other reported methods, the proposed sensor can detect free as well as protein-bound nitrotyrosine. Furthermore, the imprinted nanoparticle was applied for fabrication of electrochemical sensor, which shows good recognition capacity, high sensitivity and selectivity, broad linearity, good stability, and excellent reproducibility during 3-NT determination. The proposed sensor is very well compared with ELISA, a commercially available technique for 3-NT detection and it was found that the proposed sensor is much better than ELISA in terms of cost, time of analysis, handling, storage and reusability. So the high affinity of proposed sensor and the lack of requirement for cold chain logistics make them an attractive alternative to the enzyme-linked immunosorbent assay (ELISA) technique.

ABSTRACT

For the first time, gold nanoparticles (AuNPs) modified screen-printed carbon electrode (SPCE) was developed as working electrode in ultra-high performance liquid chromatography (UHPLC) coupled with electrochemical detection (UHPLC-ED) for simultaneous determination of thiram, disulfiram, and *N,N*-diethyl-*N',N'*-dimethylthiuram disulfide, their derivative compound. The separation was performed in reversed-phase mode using C18 column, mobile phase consisting of 55:45 (v/v) ratio of 0.05 M phosphate buffer solution (pH 5) and acetonitrile at a flow rate of 1.5 mL min^{-1}. For the detection part, the amperometric detection was chosen with a detection potential of 1.2 V vs. Ag/AgCl. Under the optimal conditions, the good linear relationship was obtained in the range of 0.07–15, 0.07–12, and 0.5–15 μg mL^{-1} (correlation coefficient more than 0.9900) for thiram, *N,N*-diethyl-*N',N'*-dimethylthiuram disulfide, and disulfiram, respectively. The limits of detection (LODs) of thiram, *N,N*-diethyl-*N',N'*-dimethylthiuram disulfide, and disulfiram were 0.022, 0.023, and 0.165 μg mL^{-1}, respectively. Moreover, this method was successfully applied for the detection of these compounds in real samples (apple, grape and lettuce) with the recoveries ranging from 94.3% to 108.8%. To validate this developed method, a highly quantitative agreement was clearly observed compared to standard UHPLC–UV system. Therefore, the proposed electrode can be effectively used as an alternative electrode in UHPLC-ED for rapid, selective, highly sensitive, and simultaneous determination of thiram, disulfiram, and *N,N*-diethyl-*N',N'*-dimethylthiuram disulfide.

1. Introduction

Nowadays, the designing of electrochemical sensor has been developed in the field of electrochemistry to improve the analytical efficiency in the terms of sensitivity, selectivity, reliability, ease of fabrication and use, and low cost. Screen printing is the technology used for fabrication of biosensors and chemical sensors instead of using large-scale electrode. Their various advantages such as miniaturization, versatility, and low cost of production are really attractive [1]. In addition, many laboratories use the screen-printing for in-house production of sensors. Screen-printed carbon electrode (SPCE) is an alternative material used instead of using the traditional electrodes based on economic substrate. Recently, SPCE have been successfully used as the electrochemical sensor for various researches due to the simplicity to produce and still give the rapid responses [2]. Moreover, the main advantage of SPCE is able to use only once and then is discarded. This advantage can be used to solve the problems of surface fouling compared with those of conventional electrodes. However, the limitation of SPCE is small surface area of working electrode leading to the lack of sensitivity [3]. Therefore, electrode modification is necessary to solve this problem.

For electrode modification, metal-nanoparticles modified SPCE is focused to improve the electrochemical efficiency. Metal-nanoparticles are attractive catalyst in the electrochemical applications. Transition metals, especially precious metals, show very high catalytic abilities for catalyzing the redox process of some interested molecules, making the use of electroanalytical techniques for applications are extended [4]. Particularly, gold nanoparticles (AuNPs) have received significant attention in recent years. AuNPs are widely used in many fields due to their unique optical and physical properties, such as surface plasmon oscillations for labeling, imaging, and sensing [5]. For the electrochemical fields, AuNPs have been widely used for modification of electrode because of their benefits including catalysis, mass

transport, and high effective surface area [1]. AuNPs have the ability to improve the detection signal, electron transfer, which make the limit of detection in electrochemical sensor is reduced. Moreover, the most importance is AuNPs showed strong specific interaction with the sulfur-containing compounds [6]. Therefore, AuNPs became an interesting nanomaterial used as modifier onto working electrode for electrochemical detection of sulfur-containing compounds.

Thiram (tetramethyl thiuram) and disulfiram (tetraethyl thiuram) are oraganosulfur compounds in the group of dithiocarbamates (DTCs) fungicides. DTCs have been used in agriculture as fungicides in foliage vegetable and fruit [7]. Besides these agricultural applications, DTCs are also used in industry such as vulcanization accelerator and antioxidant in rubber. The use of DTCs results in their release into the environment causing the contamination in food and water which leads to hazardous effect in the living organisms through diverse pathways [8]. Environmental problem resulting from uncontrollable use of fungicides in agriculture is one of the most important evidence. Therefore, it is necessary to continuously develop simple, selective, and sensitive methods for analysis of fungicides [9].

Various methods have been developed for analysis of DTCs. Spectrometry [10–12] and head space gas chromatography [13] have been used as the methods for the determination of DTCs after their decomposition to carbon disulfide (CS_2). From these methods, most of DTCs can degrade to CS_2. Therefore, they are unable to distinguish among different DTCs. Moreover, gas chromatography [14,15], capillary electrophoresis [16–20], and high performance liquid chromatography (HPLC) were used for simultaneous determination of DTCs coupled with UV detection. Especially, HPLC is the simple technique used for easy separation of the disulfide substance. However, the drawback of the UV detection is low sensitivity. Therefore, HPLC coupled with electrochemical detection became an important choice for the determination of disulfides [21]. The main advantage of electrochemical detection compared to those of spectrometry is that the derivatization step is not needed, which makes the analysis time and cost reduced. In addition, the use of electrochemical detection after the separation by HPLC can provide more sensitive detection than UV [22].

Recently, ultra-high performance liquid chromatography coupled with electrochemical detection (UHPLC-ED) is a high potential alternative method for various analysis. UHPLC concerns to the development of short column packed with small particles for working at high pressures (>400 bar). The use of UHPLC can enhance chromatographic performances in terms of efficiency, resolution, and analysis time [23]. In the detection part, AuNPs modified electrode was used as amperometric detection. Amperometry is an attractive potential technique because of its fast response, high sensitivity, relatively low cost of equipment, no need for complicated operation, and simplicity for direct sulfur assay [24].

With such benefits from the mentioned background, the objective of this work is to develop AuNPs modified SPCE in UHPLC-ED system for simultaneous determination of DTCs with high sensitivity, specificity, and rapid analysis. Thiram (tetramethyl thiuram) and disulfiram (tetraethyl thiuram) are chosen as representative compounds of DTCs because they are importantly applied to control a variety of pest [25]. Typically, when thiram and disulfiram are mixed together, the intermediate of *N,N*-diethyl-*N',N'*-dimethylthiuram disulfide (DEDMTDS) appears as the derivative of thiram and disulfiram. This compound is one of DTCs that affects human health and has the same effect of thiram and disulfiram. The presence of *N,N*-diethyl-*N',N'*-dimethylthiuram disulfide can also use to monitor thiram and disulfiram in samples. Therefore, the detection of *N, N*-diethyl-*N', N'*-dimethylthiuram disulfide is important. This derivative compound is also determined along with the measurement of thiram and disulfiram.

To the best of our knowledge, there is no publication report about the use of AuNPs modified SPCE as working electrode for ED after the UHPLC separation to simultaneously determine thiram, DEDMTDS, and disulfiram. Moreover, this developed UHPLC-ED using AuNPs modified SPCE was applied for the first time to analyze thiram, DEDMTDS, and disulfiramthe DTCs in fruits and vegetables collected from local markets.

2. Materials and methods

2.1. Chemicals and reagents

All chemicals used in this work were of analytical grade, and all solutions were prepared using Milli-Q water from Millipore ($R \geq 18.2$ M Ω cm^{-1}). Acetonitrile (HPLC-grade), chloroform, and sulfuric acid were obtained from Merck (Darmstadt, Germany). Potassium dihydrogen phosphate (KH_2PO_4) was acquired from BDH laboratory supplies (VWR International Ltd., England). Disodium hydrogen phosphate (Na_2HPO_4) and sodium hydroxide (NaOH) were purchased from Merck (Darmstadt, Germany). Standard thiram (tetramethyl thiuram) was obtained from Chem Service (West chester, PA, USA). Standard disulfiram (tetraethyl thiuram) and gold (III) chloride solution were obtained from Sigma-Aldrich (St. Louis, MO, USA).

All of stock standard solutions (1000 μg mL^{-1}) were prepared by dissolving 10 mg of each analyte in acetonitrile. The solutions were then placed in an amber bottle and stored at 4 °C. To prepare working standard solution, the standard solution was mixed and diluted in suitable proportions of acetonitrile:Milli-Q water (50:50; v/v), and kept for 5 min before measurement. All solutions and solvents were filtered by 0.22 μm nylon membranes prior to use in UHPLC separation.

2.2. Fabrication and modification of screen-printed carbon electrode

The working electrode was fabricated using screen printing and modified by electrodeposition techniques. The Ag/AgCl electrode and Pt wire was used as reference and auxiliary electrodes, respectively. To fabricate the in-house screen-printed carbon electrode (Fig. S1), the Ag/AgCl ink was first printed on the PVC substrate for using as a conductive pad. Then, the carbon ink was printed to create a working electrode. The each step of printing electrode was allowed to dry in an oven at 55 °C for 1 h. The screen-printed carbon electrode was ready to modify in the next step.

For the electrodes modification, the 10 mM of gold (III) solution was used to modify onto electrode surface by electrodeposition technique. The three-electrode system was placed into cell containing 2 mL of solution of 10 mM of gold (III) solution in 0.5 M H_2SO_4 followed by deposition of gold onto the SPCE at a deposition potential of −0.6 V (vs. Ag/AgCl) for 50 s while the solution was stirred (by means of a mechanical stirrer bar). The gold nanoparticles (AuNPs) were obtained onto the electrode surface. After the modification, the AuNPs modified SPCE was carefully rinsed with distilled water and dried under N_2 gas prior to use.

2.3. Cyclic voltammetry

The electrochemical reaction and optimal parameters for electrodeposition step were studied by cyclic voltammetry (CV) using a CH instrument potentiostat 1232 A (CH Instrument, Inc., USA). The working electrodes used in this work were bare SPCE and AuNPs modified SPCE. The reference and auxiliary electrode were silver/silver chloride electrode and Pt wire, respectively. All experiments were done at room temperature.

2.4. UHPLC experiment and apparatus

The UHPLC system was performed in reversed-phase mode using an LC-20ADXR solvent deliver unit (Shimadzu Corporation,

Japan), an autosampler (SIL-20 A) with 0.1–100 mL loop and a Kinetex™ core-shell C18 column (50 mm x 4.6 mm i.d.; particle size, 2.6 μm, Phenomenex). The UHPLC-electrochemical measurement was carried out in 45:55 (v/v) ratio acetonitrile: 0.05 M phosphate buffer solution (pH 5), which was adjusted to pH 5 with 0.1 M sodium hydroxide solution, as mobile phase with an applied potential of 1.2 V vs. Ag/AgCl, an injection volume of 50 μL, and a flow rate of 1.5 mL min^{-1}. All chromatographic separations were performed at room temperature.

2.5. Electrochemical measurement

The thin-layer flow cell consisted of a working AuNPs modified SPCE, a reference Ag/AgCl electrode (Bioanalytical system Inc., USA), and a stainless steel tube counter electrode. The geometric area of the AuNPs modified SPCE in the flow cell was estimated to be 0.40 cm^2 with 1 mm thick silicon rubber gasket as a spacer. An electrochemical measurement for amperometric control and signal processing was performed using CH instrument potentiostat 1232 A.

2.6. Sample preparation

The three real samples including apple, grape and lettuce were obtained from local markets in Thailand. For analysis, 50 g of cut sample was weighted accurately and transferred to a blender. Then 50 μL of 500 μg mL^{-1} of standard mixture solution and chloroform were added. The mixture was homogenized with blender and transferred into centrifuge tubes. After centrifugation at 4000 rpm for 10 min, all of the organic phases were filtered through a Buchner funnel with Whatman filter paper No. 4 and transferred to 250 mL vessel of the rotary vacuum evaporator for evaporation to dryness at room temperature. The residues were dissolved in 4.5 mL of acetonitrile using ultrasonic stirring, filtered through the 0.2 μm pore size of nylon membrane, and collected in 5 mL of volumetric flask. After that, acetonitrile filtered through the 0.2 μm pore size of nylon membrane was added to adjust volume to 5 mL of solution. Finally, 50 μL of the solution was injected into the UHPLC system. The determination of DTCs in samples was analyzed within the linear dynamic range that obtained by adding different volume of 500 μg mL^{-1} of standard mixture solution into the blank sample and prepared following the above treatment.

2.7. Method validation

Standard solutions and samples were analyzed, and the currents were integrated. A calibration curve of standard solutions was performed under optimal conditions and treated with linear least square regression analysis using the Excel software package. The limit of detection (LOD) and limit of quantification (LOQ) were determined from the 3 S_{bl}/S and 10 S_{bl}/S, respectively, where S_{bl} is standard deviation of blank ($n=10$), and S is sensitivity of method, obtained from the slope of the linearity. For the precision of intra-day and inter-day, three concentrations of DCTs (1, 6, and 12 μg mL^{-1}) were observed for three times within a day and three different days. To validate the developed method, UHPLC-ED was compared to the standard method of UHPLC coupled with ultraviolet detection (UHPLC–UV) using the paired *t*-test.

3. Results and discussion

3.1. Surface morphology of AuNPs modified SPCE

Gold (III) solution was used to generate the AuNPs on the electrode surface by electrodeposition. The surface morphology of bare SPCE and AuNPs modified SPCE was investigated using scanning electron microscope (SEM) as shown in Fig. 1A and B, respectively. After the modification, the well dispersed gold particles in nanoscale was observed (Fig. 1B). The distribution of AuNPs on the electrode surface led to increase the surface area and improve the electrochemical sensitivity of the modified electrode.

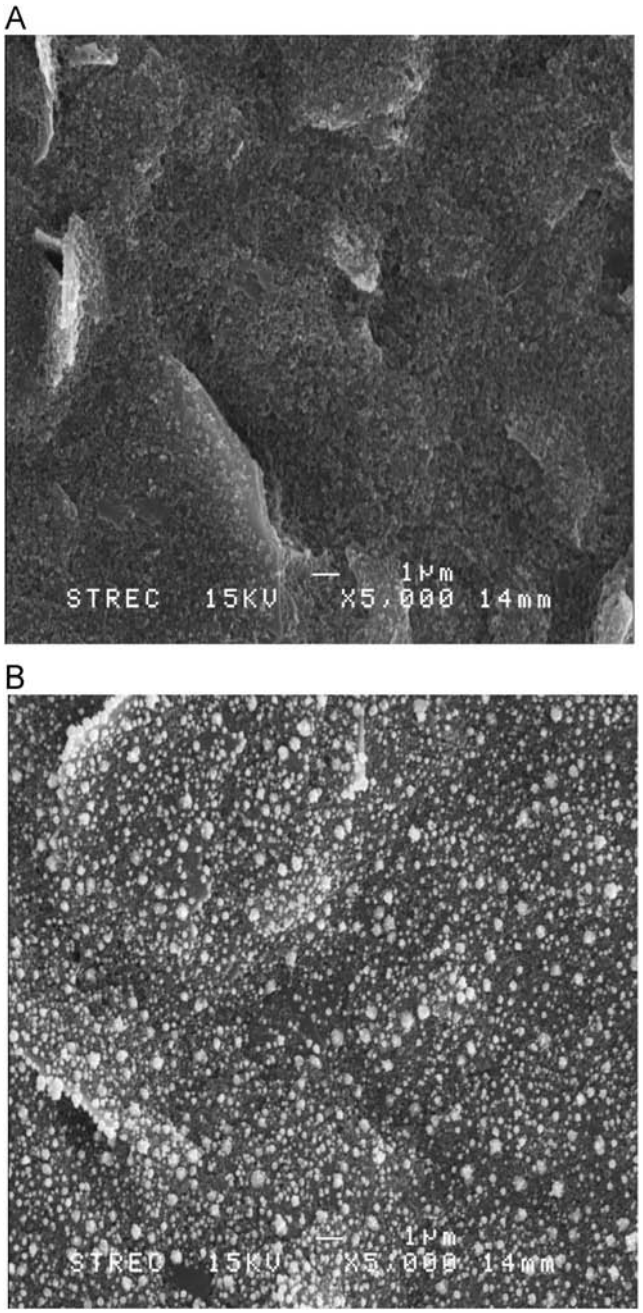

Fig. 1. SEM images of (A) bare SPCE and (B) AuNPs modified SPCE prepared by electrodeposition of 10 mM gold (III) solution at applied potential of -0.6 V for 50 s.

3.2. Optimization of the electrode modification

For the electrode modification using electrodeposition technique, the deposition potential and deposition time were optimized because these factors can effect to the analytical results. First, thiram was selected as the representative compounds because it is the best electrochemically active species at bare carbon electrode. Therefore, it is easy to observe the signal obtained from modified and unmodified electrode. To obtain the optimal condition of AuNPs modified SPCE, the dependence of deposition potential and

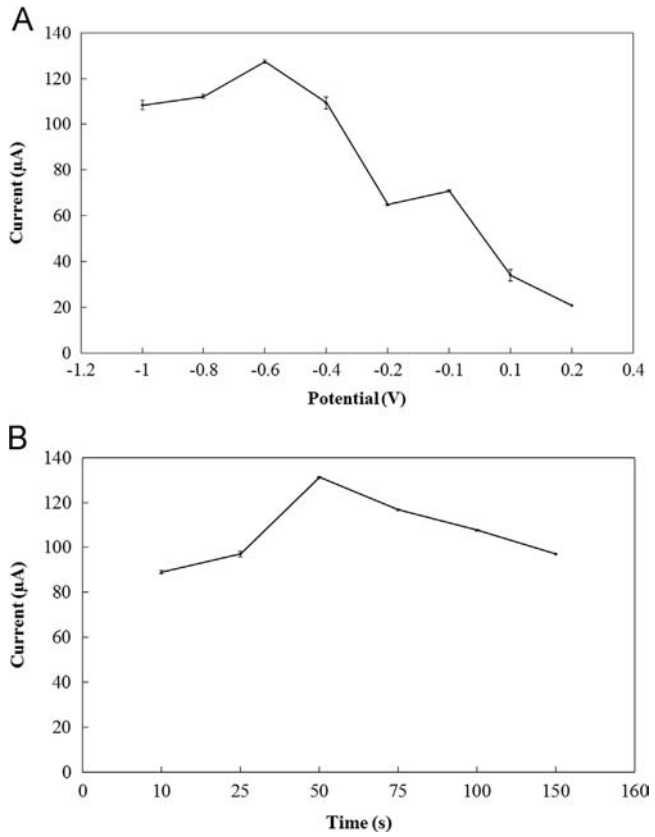

Fig. 2. Effect of the (A) deposition potential and (B) deposition time of thiram at AuNPs modified SPCE. Data are shown as the mean ± SD derived from three replicates.

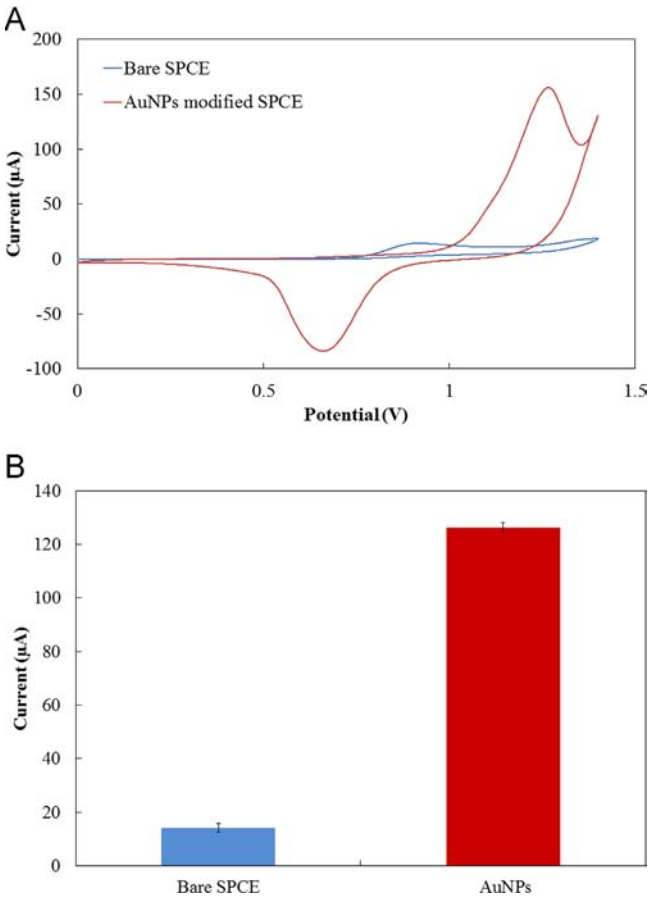

Fig. 3. (A) Cyclic voltammogram of thiram at the AuNPs modified SPCE (red line) compared to bare SPCE (blue line) and (B) comparison of oxidation current density between AuNPs modified SPCE (red rod) and bare SPCE (blue rod) vs. Ag/AgCl at the concentration of 10 μg mL^{-1} in 55:45 of 0.05 M phosphate solution pH 5: acetonitrile, scan rate 100 mV s^{-1}.

deposition time were studied using cyclic voltammetry, and the relationship between the studied parameter and current response of thiram was plotted. The deposition potential was studied in the range of −1.0 to 0.2 V. The current signal of thiram was initially increased as the function of deposition potential from −1.0 to −0.6 V and then decreased (Fig. 2A). For the deposition time, the current signal of thiram increased from 10 s to 50 s and then decreased (Fig. 2B). Therefore, the deposition potential of −0.6 V and the deposition time of 50 s were chosen as optimal parameters for modification of AuNPs onto the electrode surface.

3.3. Electrochemical response of thiram at AuNPs modified SPCE

As mentioned above, thiram is the best electrochemically active species. Thus, it was used as the representative of DTCs to study the electrochemical response. The cyclic voltammogram (CV) of 10 μg mL^{-1} of thiram obtained from bare SPCE and AuNPs modified SPCE at the potential range of 0.0 to 1.4 V was shown in Fig. 3. From CV results, the anodic current of thiram was investigated, and the current at AuNPs modified SPCE was significantly higher than the current obtained from bare SPCE due to the distribution of AuNPs on the electrode surface. We believe that the AuNPs on the electrode surface can enhance electron transfer and also improve the electrochemical determination of DTCs. For the comparison of oxidation current density between AuNPs modified SPCE and bare SPCE (Fig. 3B), the higher current density about nine times was observed at AuNPs modified SPCE. This result indicated that the AuNPs modified SPCE can be assuring electrode for the detection of thiram, disulfiram, and DEDMTDS. Therefore, this modified electrode can be an alternative electrode for using as working electrode with the advantages of low-cost material, simple fabrication and high sensitivity in case of detection DTCs.

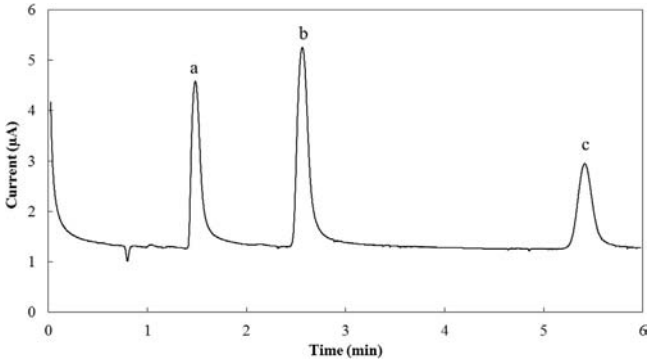

Fig. 4. Representative UHPLC-ED chromatogram of 12 μg mL^{-1} of thiram (a), DEDMTDS (b), and disulfiram (c) in a mobile phase (0.05 M phosphate solution (pH 5): acetonitrile), the detection potential of 1.2 V vs. Ag/AgCl using AuNPs modified SPCE, the injection volume of 50 μL, and the flow rate of 1.5 mL min^{-1}. Chromatograms are representative of at least three independent repetitions.

3.4. UHPLC separation

In this work, C18 column was used to separate thiram, DEDMTDS, and disulfiram by isocratic elution. The effect of percentage of acetonitrile used in the mobile phase on the

retention characteristics was first evaluated. When the percentage of acetonitrile ≤ 40 was used, the separation time was higher than 20 min and peak broadening of disulfiram was observed. On the other hand, at higher content of acetonitrile in mobile phase, the current signal of thiram, DEDMTDS, and disulfiram were decreased due to the low of diffusion coefficient with changing ionic strength of the medium. Therefore, the acetonitrile of 45% was selected as compromise to achieve the completely separated them within 6 min with good sensitivity. In addition, 0.05 M phosphate buffer solution (pH 5) was chosen as the electrolyte solution because the high concentration of salt in buffer solution was not suitable for the UHPLC system. The chromatogram for the separation of standard mixture solution was shown in Fig. 4. The retention time of thiram, DEDMTDS, and disulfiram was 1.5, 2.6, and 5.4 min, respectively, and the retention time stability was found in the range of 0.1% to 1.5%. The peak widths were 11.6 s for thiram, 14.2 s for DEDMTDS, and 18.8 s for disulfiram. Therefore, this proposed system offers the rapid time for separating DTCs.

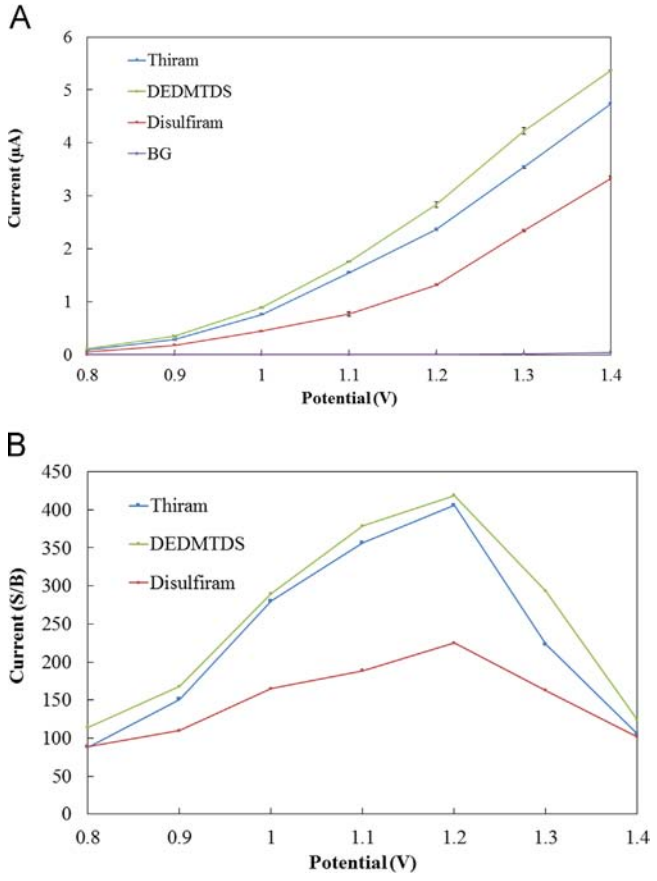

Fig. 5. Hydrodynamic voltammetric results at the AuNPs modified SPCE for a 10 μg mL^{-1} each mixture (50 μL total) of thiram and disulfiram. (A) thiram (blue line), DEDMTDS (green line), disulfiram (red line), and background (purple line); (B) hydrodynamic voltammogram of signal-to-background ratios. The other conditions are the same as in Fig. 4. Data are shown as the mean ± 1 SD derived from three independent repetitions.

3.5. Hydrodynamic voltammetry

Hydrodynamic voltammetry was used to optimize the detection potential. The potential was studied in the range of 0.8 to 1.4 V. The peak current after each injection at different potential was recorded corresponding to the background current. These data were plotted as a function of applied potential to obtain the hydrodynamic curves as shown in Fig. 5. The detection potentials significantly affected the oxidation current of the thiram, DEDMTDS, and disulfiram as well as the background current (Fig. 5A). Therefore, the net current after background subtraction was studied, and signal-to-background (S/B) ratios were plotted corresponding to the detection potential. It was found that the current increased when the potential increased up to 1.2 V for all compounds (Fig. 5B). Therefore, the detection potential of 1.2 V was selected as optimal detection potential for amperometric detection of thiram, DEDMTDS, and disulfiram after their separation with UHPLC.

3.6. Method validation

3.6.1. Analytical performance

The analytical performance of this proposed system was studied. The calibration curve between the concentration and current response of analytes was plotted as shown in Fig. 6. Under the optimal conditions, the linearity was observed in the range of 0.07 to 15 μg mL^{-1} for thiram, 0.07 to 12 μg mL^{-1} for DEDMTDS, and 0.5 to 15 μg mL^{-1} for disulfiram. The limit of detection (LOD) and limit of quantification (LOQ) were calculated from 3 S_{bl}/S and 10 S_{bl}/S, where S_{bl} is the standard deviation of blank measurements ($n=10$), and S is the sensitivity of the method or the slope of linearity. Good linearity value with $r^2 > 0.99$ was obtained. LODs and LOQs were summarized in Table 1. In addition, when the performance of AuNPs

modified SPCE was compared to the other previous electrodes for the detection of DTCs as shown in Table 2. It was found that the LODs obtained from the proposed electrode were lower than using cylindrical carbon fiber [7] and graphite-poly (tetrafluoroethylene) composite electrode [26]. However, few researches used the mercury electrode to provide lower LOD than this method but the mercury is toxic [27,28]. Therefore, the proposed electrode offers less toxicity, uncomplicated, and low cost. Additionally, the proposed electrode shows good electrocatalytic properties for DTCs detection to obtain a high electrochemical sensitivity.

3.6.2. *Application to real samples*

To assess the applicability of the proposed method, target compounds in samples from local supermarkets were investigated. The proposed method was applied for the detection of three different samples, including apple, grape, and lettuce. The standard addition method was chosen to investigate the reliability of this proposed system. The precision of the analytical process was evaluated by the repeatability of the process. The spiked concentrations in the dynamic linearity between 1 to 15 μg mL^{-1} were studied to calculate the RSD percentage. The summary of intra- and inter-day precision, and recovery that obtained from the proposed method was shown in Table 3. The RSDs and recoveries of intra-day were found in the range of 0.1–3.7% and 94.3–108.8%, respectively, while the inter-day RSDs and recoveries were found in the range of 0.1–5.7% and 95.8–107.7%, respectively. Therefore, this method is an alternative and suitable for rapid separation and simultaneous determination of DTCs.

To validate the proposed method, UHPLC-UV was used as a standard method to compare the acceptable and reliable. The results obtained from UHPLC-ED and UHPLC-UV were compared by a paired *t*-test at the 95% confidence for three samples that spiked with three standard concentrations (1, 6, and 12 μg mL^{-1} to represent the low, medium, and high level, respectively). The critical *t*-value was significantly higher than calculated *t*-values between two assays. From the results shown in Table 4, the calculated *t*-values of three concentrations were found in the range of –0.243 to 3.029 and lower than critical *t*-values (4.303). It can be concluded that there is no significant difference between UHPLC–ED and conventional UHPLC–UV method. Therefore, the results obtained from UHPLC coupled with amperometric detection using AuNPs modified SPCE is acceptable and reliable for applying to simultaneous determination of DTCs in food.

4. Conclusions

AuNPs modified SPCE was firstly developed for the determination of thiram, disulfiram, and DEDMTDS after their separation with UHPLC system. Under the optimal conditions, the separation was complete within 6 min, and the high current response signal was obtained at AuNPs modified SPCE. The main advantages for the use of AuNPs modified SPCE are in term of high sensitivity, low-cost and simple fabrication-based material. Reproducible signal from %RSD for intra- and inter-day were below 5%. These

results indicated that the high reproducibility was obtained using this system for long time. Moreover, the proposed UHPLC-ED system is an acceptable and reliable method compared to standard UHPLC-UV system using paired *t*-test. Ultimately, the UHPLC coupled with AuNPs modified SPCE amperometry is successfully applied for real samples. This proposed electrode could be a novel or an alternative electrode in UHPLC-ED system for the simultaneous determination of DTCs in fruits and vegetables with low cost material, simple fabrication, and high sensitivity.

Neutral loss scanning

ABSTRACT

The phenolic profiles of seven monovarietal virgin olive oils (VOOs) – *viz.* Arbequina, Arbosana, Cornicabra, FS-17, Hojiblanca, Picual and Sikitita – were characterized by using a quantitative strategy based on LC–MS/MS and the selected reaction monitoring (SRM) mode. Data dependent methods, based on precursor ion scanning, product ion scanning and neutral loss scanning, were developed for confirmatory analysis of secoiridoid derivatives. The observed phenolic profiles were used to find correlation between pairs of phenols and similarity trends among the monovarietal VOOs. A Pearson analysis revealed several correlations among phenols with p-value < 0.01 and correlation coefficient (R) > 0.75 in the seven monovarietal VOOs. Cluster analysis showed two main clusters between VOOs, formed by Arbequina/Hojiblanca/Cornicabra/Picual and Sikitita/Arbosana/FS-17. High correlations ($R > 0.7$) were observed for the following pairs of VOOs: Arbequina/Hojiblanca ($R=0.77$), essentially supported on levels of hydroxytyrosol acetate (3,4-DHPEA-AC) and dialdehydic forms of secoiridoids; Cornicabra/FS-17 ($R=0.81$) and Picual/FS-17 ($R=0.79$), by correlation of flavonoids and secoiridoid derivatives in general. The highest correlation was observed for the pair Picual/Cornicabra ($R=0.99$). This preliminary study allowed setting similarities and dissimilarities between monovarietal VOOs by analysis of the phenolic profile. The observed connections between phenols for different varieties have been tentatively interpreted according to the main pathways for phenols biosynthesis.

1. Introduction

The minor fraction of virgin olive oil (VOO), formed by a chemically heterogenous group that includes more than 230 compounds, represents about 2% (w/w) of VOO. This fraction encompasses non-polar compounds such as phytosterols, waxes or hydrocarbons, and a polar or mid-polar sub-fraction [1] mostly constituted by volatile and phenolic compounds. Phenols present in VOO are also characterized by a chemical diversity of families such as phenolic alcohols and derivatives, phenolic acids, hydroxy-isochromans, flavonoids, lignans and secoiridoids. Among them, secoiridoids, the most concentrated phenols present in VOO, are specific compounds of *Oleaceae* plants [2]; in fact, secoiridoids differentiate VOO as unique among other vegetable oils.

Phenolic compounds have been widely studied because of their nutraceutical effects, relevant contribution to the sensory properties of VOO with special emphasis on bitterness and pungency, and their stabilizing role to ensure the long shelf-life of VOOs as compared to other vegetable oils [3]. The nutraceutical and stability properties of phenolic compounds have been linked to the capability of the phenolic structure for inhibiting oxidation processes. Numerous studies have evaluated the oxidation inhibition capability of phenols present in VOO, which allowed identifying hydroxytyrosol as the VOO phenol with the highest oxidation inhibition power by the DPPH test, followed by oleuropein aglycon (3,4-DHPEA-EA) and decarboxymethyloleuropein aglycon (3,4-DHPEA-EDA) [4]. The EFSA (European Food Safety Authority) report has emphasized the inhibition activity of hydroxytyrosol and secoiridoids against the oxidation of phospholipids and LDL cholesterol [5]. In fact, the antioxidant capability of hydroxytyrosol is responsible for its prevention role against tumoral diseases, cardiovascular diseases such as atherosclerosis [6], and diabetic neuropathies [7]. Secoiridoids also possess several health properties such as their implication in the inhibition of blood platelet aggregation, involvement in the synthesis of thromboxane in human cells and protection of erythrocytes from oxidative damage [8]. Additionally, anti-inflammatory activity of decarboxymethyl ligstroside

aglycon (*p*-HPEA-EDA [9], and recent evidences about its action on Alzheimer's disease [10] have been reported. Complementarily, Lozano-Sánchez et al. have developed a study on the influence of the phenolic composition of five monovarietal VOOs on the cytotoxic activity against human breast cancer cells [11]. These authors deduced that the sensitivity of breast cancer cells to phenolic extracts from VOOs was up to 12 times higher when the extracts were from VOOs with high content of secoiridoids as compared to other with low/nil content of these phenolic compounds.

One other particular family of phenols such as flavonoids has also been associated to health benefits related with cancer and coronary heart diseases [12–14].

Also organoleptical properties of VOOs have been correlated with the level of individual phenols [15–17]; thus, bitter intensity has been mainly related to hydroxytyrosol derivatives [18,19]; pungency character associated to two other secoiridoids such as 3,4-DHPEA-EDA and *p*-HPEA-EDA [20]; and also a negative correlation has been found between the vanillin content of VOO and their bitter sensory attributes [21].

Numerous studies have been published dealing with the quantitative and qualitative analysis of phenols in VOO. However, few of them have been focused on determination of phenols in monovarietal VOOs despite all the benefits – in terms of health, sensory properties and stability – associated to this family of compounds. In this sense, there is a demand for the quantitative characterization of phenols in monovarietal VOOs in order to evaluate the presence of the most significant compounds such as hydroxytyrosol, tyrosol, secoiridoids, phenolic acids and flavonoids. A deep characterization of the phenolic content of monovarietal VOOs could aid consumers to select the optimum VOO according to their preferences. The aim of this study was to characterize the phenolic composition of seven monovarietal VOOs by using a quantitative strategy based on LC–MS/MS analysis in selected reaction monitoring (SRM) mode. The observed phenolic profiles were then used to find statistical correlations between pairs of phenols and define tentative similarity trends among the monovarietal oils.

2. Materials and methods

2.1. Monovarietal virgin olive oil samples

The monovarietal VOO samples used in this work were obtained from olive fruits collected from 15th to 22nd November 2013 at intermediate ripening from different cultivars located in different areas of the South of Spain: Arbequina (Sevilla), Arbosana (Córdoba), Cornicabra (Toledo), Hojiblanca (Málaga), Picual (Jaén), Sikitita (Córdoba) and FS-17 (Córdoba). Oils samples were stored in darkness at −20 °C.

2.2. Reagents

The solvents used for analysis of phenols from VOOs were LC–MS grade methanol and *n*-hexane both from Scharlab (Barcelona, Spain). MS-grade formic acid as ionization agent in the chromatographic mobile phases was also from Scharlab. Deionized water (18 MΩ cm) from a Millipore Milli-Q water purification system (Bedford, MA, USA) was used to prepare the aqueous chromatographic phase.

Standards of target phenols (*viz.* hydroxytyrosol and tyrosol as simple phenols, verbascoside as phenyletanoid, oleuropein representing secoiridoids; luteolin, apigenin, apigenin-7-glucoside, luteolin-7-glucoside, diosmetin, quercetin and rutin as flavonoids; and vanillin, caffeic acid, *p*-coumaric acid, ferulic acid and vanillic acid as phenolic aldehydes and acids) for quantitative analysis of these metabolites in VOO were from Extrasynthese (Genay, France). Syringic acid, used as internal standard (IS), was from Extrasynthese (Genay, France). Individual stock standard solutions and multistandard solutions were prepared by dilution of each compound in methanol. The solutions were stored at −20 °C.

2.3. Apparatus and instruments

An MS2 minishaker from Ika (Wilmington, USA) was used to enhance the transfer of phenols from oil to a methanol–water solution for individual quantitation of the target compounds. Phenols extracts were analyzed by an Agilent 6410 triple quadrupole (QqQ) detector furnished with an electrospray ionization (ESI) source.

2.4. Extraction of phenols from VOO

Phenolic compounds were extracted from VOO by shaking 1 g of oil with 1 mL of hexane and 1 mL of 60:40 methanol–water mixture for 1 min in the MS2 minishaker. The hydroalcoholic phase was directly injected into the LC–QqQ. This approach has been widely validated in previous research and is accepted as sample preparation strategy for analysis of phenolic compounds in VOO [22–24].

2.5. LC–MS/MS analysis of phenols extracts

Analyses were performed by reversed-phase liquid chromatography followed by negative electrospray ionization (ESI) and tandem mass spectrometry (MS/MS) detection. 10 μL of extract was injected in triplicate into the LC system for chromatographic separation of the target compounds using a Mediterranea C18 analytical column (150 mm × 0.46 mm i.d., 3 μm particle size) from Teknokroma (Barcelona, Spain). The column compartment was kept at 30 °C. The mobile phases were: phase A (0.1% formic acid in water) and phase B (0.1% formic acid in methanol). The gradient program, at 0.8 mL min^{-1} constant flow rate, was as follows: initially 96% phase A and 4% phase B kept for 2 min; from 2 to 17 min, the mobile phase A was from 96 to 34%; from 17 to 35 min, mobile phase A was from 34 to 0% A, while B ranged from 66 to 100% B. This last composition was kept for 5 min. After each analysis, the column was equilibrated for 7 min up to the initial conditions.

The entire eluate was electrosprayed and ionized in negative mode and monitored by MS/MS in Selected Reaction Monitoring (SRM) mode by monitoring selective transitions from precursor to product ions. The flow rate and temperature of the drying gas (N_2) was 10 L min^{-1} and 300 °C, respectively. The nebulizer pressure was 50 psi and the capillary voltage 3000 V. The dwell time was set at 200 μs. Identification and quantitation of the phenols were performed using commercial standards, except for hydroxytyrosol acetate (3,4-DHPEA-AC) and secoiridoid derivatives, for which commercial standards were not available. For this reason, these compounds were relatively quantified as oleuropein equivalents.

2.6. Statistical analysis

After LC–MS/MS analysis, a data set was built with the concentrations of phenols found in each analytical sample. Normalization by logarithmic transformation was used as preprocessing step. The definitive data set was exported to Statgraphic software (Centurion XV.I) for statistical analysis by Pearson correlation analysis. Additionally, the data set was also exported into the Mass Profiler Professional (MPP) software package (version 2.0, Agilent Technologies, Santa Clara, CA, USA)

Table 1
Optimization of the MS/MS step for qualitative and quantitative determination of phenols.

for Clustering Analysis, which allowed organizing samples into clusters based on similarity of their abundance profiles.

3. Results and discussion

3.1. Parameters of the selected reaction monitoring method

A panel of 16 phenols, which can be considered among the most important phenols in VOO with available commercial standards, was selected for determination purposes [22,25,26]. The monitored compounds were hydroxytyrosol and tyrosol, caffeic acid, *p*-coumaric acid, ferulic acid, vanillic acid, vanillin, verbascoside, apigenin, luteolin and their corresponding glucosides, diosmetin, quercetin, rutin and oleuropein.

The most sensitive transitions from precursors to product ions were used for quantitation of phenols, whereas secondary transitions were used as qualifiers for confirmatory analysis. The SRM transitions and the corresponding acquisition parameters such as isolation voltage of the first quadrupole and collision energy were optimized by using standard solutions resulting in the values listed in Table 1. SRM transitions with quantitative purposes agreed with those reported in methods previously published, which have also identified the chemical structure associated to product ions formed after MS/MS fragmentation [27,28].

Quantitation was carried out using the ratio between the peak area of each phenol and that of the IS. Calibration models were developed for each phenol using multistandard solutions. Nine concentration levels from 0.25 ng mL^{-1} to 5 μg mL^{-1} were analyzed in triplicate to obtain the calibration curves. The calibration equations, coefficients of regression (R^2) and quantitation limits (LOQs) are listed in Table 2.

Table 2
Calibration equations, regression coefficients and limits of quantification for analysis of phenolic compounds.

Phenol	Calibration equations	Regression coefficient (R^2)	LOQ (μg mL^{-1})
Hydroxytyrosol	$y=15.938x-0.5866$	0.993	0.25×10^{-3}
Tyrosol	$y=0.0108x-0.0128$	0.981	1
Caffeic acid	$y=31.8938x-0.6562$	0.995	0.25×10^{-3}
***p*-Coumaric acid**	$y=20.2813x+0.6944$	0.998	0.05
Ferulic acid	$y=7.1723x-0.6368$	0.991	0.01
Oleuropein	$y=4.1947x-2.0536$	0.995	0.25×10^{-3}
Luteolin	$y=33.6232x-0.7341$	0.998	0.25×10^{-3}
Apigenin	$y=40.7716x-19.5034$	0.993	0.25×10^{-3}
Vanillic acid	$y=0.7035x-0.0135$	0.994	0.01
Vanillin	$y=2.2616x-0.0659$	0.993	0.01
Diosmetin	$y=21.9695x-1.1352$	0.997	0.25×10^{-3}
Quercetin	$y=0.4437x-0.0163$	0.994	0.25×10^{-3}
Apigenin-7-glucoside	$y=33.3276x-1.2567$	0.992	0.25×10^{-3}
Luteolin-7-glucoside	$y=11.2851x-0.2514$	0.991	0.25×10^{-3}
Verbascoside	$y=2.3377x-0.0526$	0.992	0.25×10^{-3}

3.2. Confirmatory analysis of secoiridoid derivatives by data-dependent methods

Oleuropein is the major secoiridoid found in the pulp of olives [29], where its concentration reaches relatively high levels in immature fruits (around 2.7 mg g^{-1}) [30]. However, its concentration declines with progression of the maturation process of the fruit to form secoiridoid derivatives such as 3,4-DHPEA-EDA, *p*-HPEA-EDA, 3,4-DHPEA-EA and *p*-HPEA-EA as well as hydroxytyrosol, 3,4-DHPEA-AC, tyrosol and elenolic acid glucoside, which can be considered as indicators of the extent of olives maturation [31–33]. The formation of these secoiridoid derivatives and that of phenolic alcohols is significantly enhanced during the process for production of VOO by action of β-glucosidases, which are released during the pressing step. For this reason, these compounds are massively found in VOO instead of oleuropein. Among these compounds, it is worth mentioning the presence of secoiridoid derivatives such as 3,4-DHPEA-AC, *p*-HPEA-EDA and 3,4-DHPEA-EDA 3,4-DHPEA-EA and ligstroside aglycon (*p*-HPEA-EA) due to their relevance in VOO in terms of concentration as well as nutraceutical properties and sensory contribution.

Quantitative analysis of secoiridoid derivatives is critical to offer a comprehensive overview of the phenolic composition of VOOs. However, they were not preliminary included in the development of the SRM method due to the unavailability of commercial standards. Thus, confirmatory analysis was previously required to prove their presence in monovarietal VOO samples included in this study. For this purpose, data-dependent methods were used to scan the presence of these target metabolites by taking benefit from the versatility of the triple-quad mass analyzer, particularly, precursor ion scanning, product ion scanning and neutral loss scanning, which are selective tools to confirm the presence of derivatives that can be structurally associated to hydroxytyrosol and tyrosol. Thus, 3,4-DHPEA-EDA, 3,4-DHPEA-EA and 3,4-DHPEA-AC are esters of hydroxytyrosol, while *p*-HPEA-EDA and *p*-HPEA-EA are esters of tyrosol since the two sets of compounds are formed by hydrolysis of oleuropein and ligstroside, respectively. With these premises, a precursor ion scanning method by monitoring representative ions found for hydroxytyrosol and tyrosol

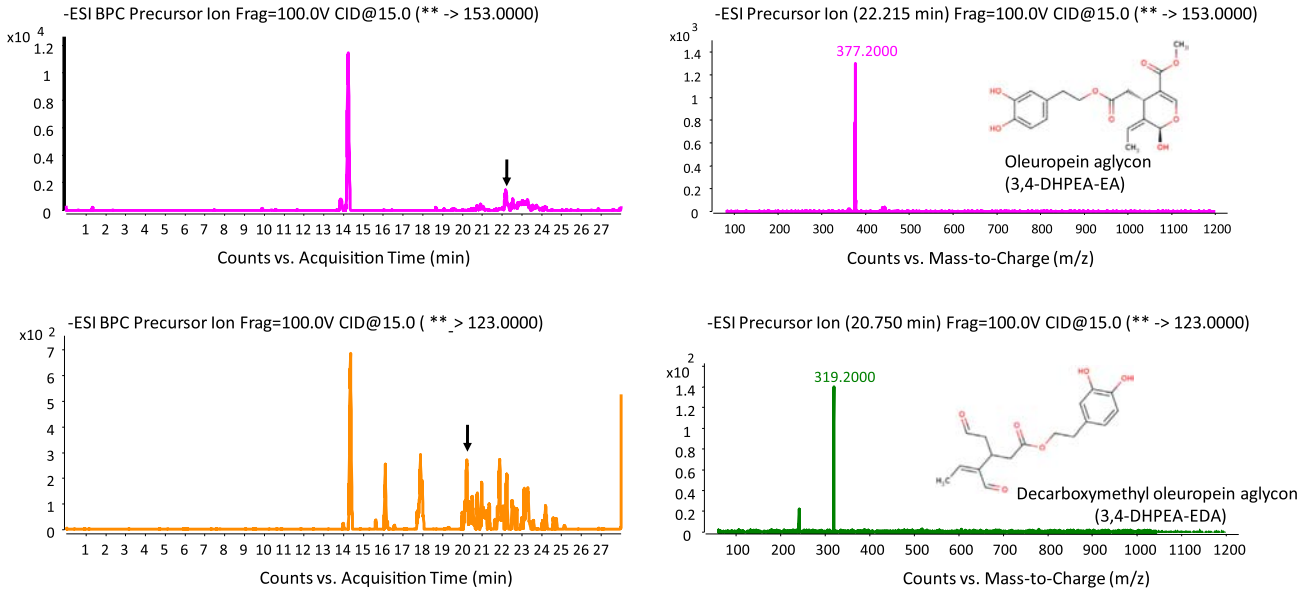

Fig. 1. Precursor ion scanning for qualitative analysis of 3,4-DHPEA-EA and 3,4-DHPEA-EDA.

(identified as molecular ions or stable fragments) at the third quadrupole (Q3) could scan compounds formed by condensation reaction of the two phenolic alcohols in the first quadrupole (Q1). Precursor ion scanning by monitoring the precursor ion for hydroxytyrosol *m/z* 153 at Q3 allowed detecting an ion with precursor ion *m/z* 377 at 22.2 min elution time as Fig. 1 shows, which fit to the $[M–H]^-$ ion of 3,4-DHPEA-EA. Similarly, one other compound with precursor ion *m/z* 319, which corresponded to 3,4-DHPEA-EDA, was detected by monitoring the *m/z* 123 at Q3 (20.75 min), which is the most stable product ion formed by fragmentation of hydroxytyrosol (Fig. 1). Product ion scanning for *m/z* 377 and 319 revealed two selective transitions with quantitative purposes for 3,4-DHPEA-EA and 3,4-DHPEA-EDA by monitoring product ions at *m/z* 275 and 59, respectively, which had previously been detected [27,28]. Neutral loss scanning analysis by monitoring 102 and 260 mass units allowed confirming the presence of these two secoiridoid derivatives, as Supplementary Fig. 1 shows.

The two derivatives obtained by hydrolysis of ligstroside, *p*-HPEA-EA and *p*-HPEA-EDA, were identified by the same strategy. The presence of the two derivatives was detected by precursor ion scanning by monitoring *m/z* 137 at Q3, which fits with the cleavage of tyrosol by the ester bound. Thus, two precursor ions with *m/z* 361 and 303 were detected at retention time 24.1 and 21.9 min (as Fig. 2 shows), which were identified as *p*-HPEA-EA and *p*-HPEA-EDA, respectively. Product ion scanning for both precursors enabled to find quantitative transitions from *m/z* 361 and 303 to product ions at *m/z* 291 and 59. Neutral losses observed for these transitions, 70 and 244 mass units, were scanned by tuning Q1 and Q3 to confirm the presence of both ligstroside derivatives (Supplementary Fig. 2).

The presence of 3,4-DHPEA-AC was verified by precursor ion scanning by monitoring *m/z* 59 at Q3, which provided a chromatographic peak at 19.9 min with precursor *m/z* 195. The identity of this secoiridoid derivative was confirmed by neutral loss scanning of 136 Da, which fit the fragment formed by hydrolysis of the ester bound. These results are illustrated in Fig. 3.

After verification and confirmatory analysis of oleuropein derivatives in monovarietal VOOs, an optimization study for selection of the SRM transitions for tentative quantitation of secoiridoid derivatives was developed to include them in the LC–MS/MS method. The optimization method was also carried out by using phenolic extracts from the analyzed VOOs. Table 3 summarizes the main results obtained by data-dependent methods, as well as qualitative and quantitative MS/MS parameters.

3.3. Statistical description of phenolic profiles in monovarietal VOOs

Despite the phenolic characterization of VOOs had been widely addressed, no special attention had been paid to profiling of this family of compounds in monovarietal VOOs. Thus, although several monovarietal VOOs had been analyzed, the studies were limited to quantitation of a reduced number of phenols. This is the case of the research developed by Oliveras-López et al., who quantified only nine representative phenols in three Spanish monovarietal VOOs [34]. In a lesser extent, other authors have focused their attention on a small number of VOO varieties (usually one to three) in which they have quantified up to 15 phenolic compounds [35–37].

It is quite difficult to compare the results of phenolic concentrations provided by different studies owing to the great variety of factors (including genetic, pedo-climatic, geographical origin, agronomic and technological factors) that influence the chemical composition of VOO [38–41]. Nevertheless, some trends can be visualized by overall evaluation of monovarietal VOOs. The averaged concentrations found for 16 target phenolic compounds in each monovarietal VOO and standard deviation (SD) values are listed in Table 4. Hydroxytyrosol, the most representative phenol in VOO [42], was found at levels below 5 $\mu g\, g^{-1}$ in all monovarietal VOO, which practically agrees with results provided by previous authors [11,44,45], except in FS-17 that provided very high levels of this phenol – around 25 $\mu g\, g^{-1}$ – (Fig. 4A). To the authors' knowledge, there are not other studies reporting such high levels of hydroxytyrosol in VOO. This monovarietal VOO also gave the highest concentration of tyrosol (23.6 $\mu g\, g^{-1}$), followed by Arbosana with 18.7 $\mu g\, g^{-1}$, while the resting varieties gave levels below 6 $\mu g\, g^{-1}$ (Fig. 4B). The high concentration of tyrosol found in this study for some varieties is more usual than for hydroxytyrosol since Gómez-Rico et al. found similar concentration of this simple phenol in Picual VOO [43].

One other variety such as Arbequina was clearly outstanding in terms of 3,4-DHPEA-AC, 3,4-DHPEA-EDA and *p*-HPEA-EDA, which is clearly correlated to the bitter character of VOOs from Arbequina fruits (Fig. 4C). These data agree with the study of García-González

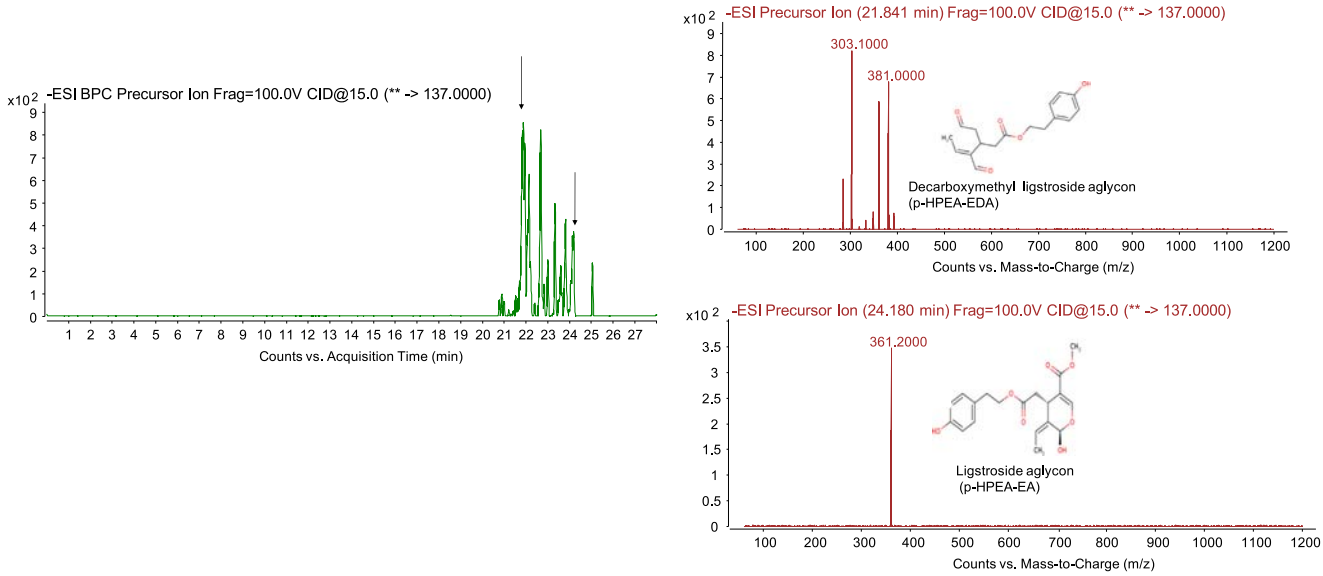

Fig. 2. Precursor ion scanning for qualitative analysis of *p*-HPEA-EA and *p*-HPEA-EDA.

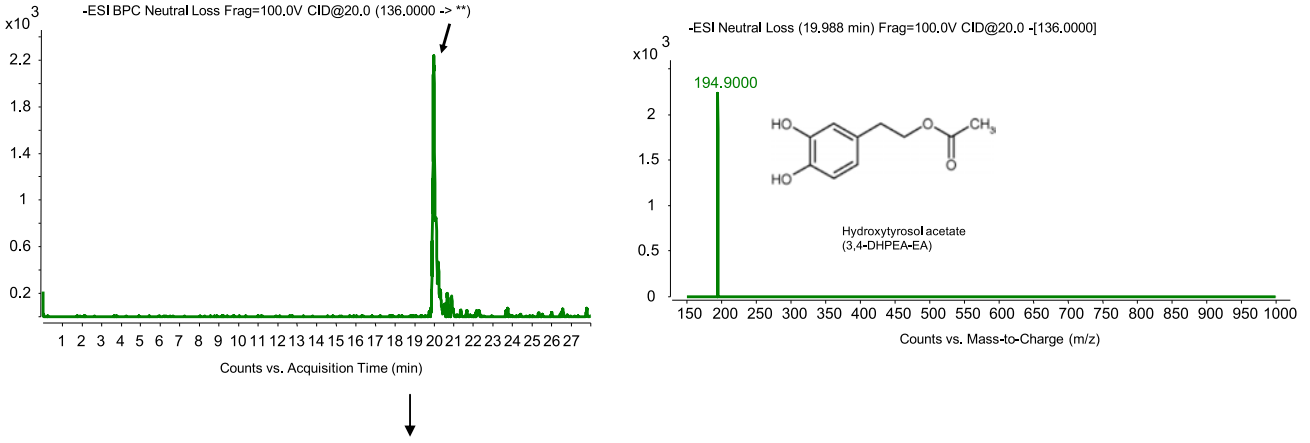

Fig. 3. Neutral loss scanning for qualitative analysis of 3,4-DHPEA-AC.

Table 3
Optimization of the MS/MS step for qualitative and quantitative determination of oleuropein derivatives.

Phenol	Precursor ion	Neutral loss	Fragmentor (V)	Collision energy (eV)	Quantitative transition (*m/z*)	Product ion confirmation (*m/z*)
3,4-DHPEA-AC	195.1	136	110	12	195→59	135
3,4-DHPEA-EDA	319.1	260	110	12	319→59	139
***p*-HPEA-EDA**	303.1	244	110	12	303→59	137
3,4-DHPEA-EA	377	102	110	12	377→275	307
***p*-HPEA-EA**	361.1	70	110	12	361→291	101

et al. and Lozano-Sánchez et al., who also found higher values of 3,4-DHPEA-AC and EDA secoiridoids for Arbequina VOO as compared to Picual VOOs from different zones [37,11]. Apart from Arbequina, the study proposed here also revealed extra levels of these secoiridoid derivatives in Hojiblanca VOO as compared to the resting VOO varieties.

On the other hand, four varieties (*viz.* Cornicabra, FS-17, Hojiblanca and Picual) reported VOOs with high levels of the aglycon forms of oleuropein and ligstroside, 3,4-DHPEA-EA and *p*-HPEA-EA, respectively (Fig. 4D). Levels of these two derivatives are strongly related to the pungent character of VOOs. Previous studies also offered similar results for these two relevant EA secoiridoids; thus, Gómez-Rico et al. found the highest concentrations of 3,4-DHPEA-EA and *p*-HPEA-EA in Cornicabra and Picual VOOs [43], and García-González et al. detected higher levels of both phenols in Picual VOO as compared to Arbequina VOO [37].

One other secoiridoid such as oleuropein, which is highly concentrated in olive pulp, did not exceed 0.03 $\mu g\, g^{-1}$ in the different varieties, while verbascoside was only detected in Arbequina and Sikitita VOOs.

Ferulic, *p*-coumaric and caffeic acids are synthesized through the phenylpropanoid pathway, by which *p*-coumaric acid is hydroxylated to caffeic acid, and that methoxylated to ferulic acid. As Supplementary Fig. 3shows, these phenolic acids were more concentrated in FS-17, Arbequina and Sikitita VOOs, which could

be attributed to a higher activity of the enzymes involved in this pathway. These results are in agreement with those obtained by García et al., who also found the highest level of phenolic acids in Arbequina VOO, followed by Hojiblanca, Picual and Cornicabra VOOs [44].

Vanillin and vanillic acid presented an opposite behavior. Thus, Cornicabra and Picual VOOs reported the lowest concentration of vanillic acid, whereas vanillin was high-concentrated in these VOOs as compared to the resting varieties (Supplementary Fig. 4). The activity of the oxidation enzyme involved in the pathway to convert vanillin into vanillic acid could be responsible for this result.

Concerning flavonoids, Arbequina, Arbosana, Hojiblanca and Sikitita VOOs provided higher levels of luteolin, apigenin and diosmetin than the other varieties (Supplementary Fig. 5). This trend was also found by García et al. [44]. Levels of quercetin were slightly higher in Arbequina and Sikitita monovarietal oils as compared to the resting varieties. Finally, no critical differences were observed between levels of glucoside flavonoids such as luteolin-7-glucoside, apigenin-7-glucoside and rutin.

3.4. Statistical correlation between phenolic compounds

Considering the data set formed by concentrations of phenols in the seven monovarietal VOO, a Pearson correlational analysis was carried out to find statistical correlations between phenolic compounds. Few studies have been focused on correlation analysis among phenolic compounds present in VOO. Pérez et al. studied the relationship among four groups of phenols in VOOs from Picual × Arbequina crosses [45]. However, this statistical evaluation has not been applied to different monovarietal VOOs. In the present work, several correlations were found between pairs of phenols with p-value < 0.01 and correlation coefficient $(R) > 0.75$, which are indicative of at least a moderate relationship between them (Supplementary Table 1). A strong positive correlation was found between p-HPEA-EA and 3,4-DHPEA-EA ($R=0.93$, p-value$=0.002$) as well as between p-HPEA-EDA and 3,4-DHPEA-EDA ($R=0.89$, p-value$=0.007$). These correlations could be tentatively explained according to the main pathways involved in the biosynthesis of phenolic compounds. Thus, in the synthesis of oleosides, ligstroside is converted into oleuropein by hydroxylation [46]. This process is quite active at the early stages of maturation through which fruits are highly-concentrated in oleuropein. However, it can be assumed that ripening as well as crushing and malaxation of olive fruits during oil production contribute to release β-glucosidases, which produce the aglycon forms of ligstroside and oleuropein (p-HPEA-EA and 3,4-DHPEA-EA) [29]. This fact would support the positive observed correlation. Additionally, the aglycon forms are hydrolyzed and turned into the dialdehydic form of secoiridoids (p-HPEA-EDA and 3,4-DHPEA-EDA) by action of a decarboxymethylase, which also tentatively justifies the positive correlation found for the two dialdehydic secoiridoid forms. Supplementary Fig. 6 shows the biosynthetic pathways of secoiridoids.

Consistent positive correlations were also found within the flavonoids class. The highest correlation was detected for apigenin and luteolin glucosides ($R=0.91$, p-value$=0.003$). Both compounds are formed through the flavone and flavonols biosynthesis from their respective aglycone by glycosyltransferase. This common pathway could explain the strong positive correlation. A significant negative correlation was observed between quercetin and vanillic acid ($R=-0.91$, p-value$=0.004$). Vanillic acid is synthesized through the phenylalanine pathway, whereas quercetin is obtained by biosynthesis of flavonoids. There is a connection between both pathways: the p-caffeoyl-CoA; therefore, depending on the activity of enzymes using p-caffeoy-CoA as substrate the prevalence of vanillic acid or quercetin would be tentatively justified. High activity of methyltransferase enzyme would imply the formation of vanillic acid, while the synthesis of quercetin would be supported on the activity of chalcone synthase (Supplementary Fig. 7).

Significant correlations with p-value between 0.01 and 0.05 were also found for some pairs of phenols. Thus, 3,4-DHPEA-EDA and 3,4-DHPEA-AC exhibited positive correlation ($R=0.89$, p-value$=0.03$) that could be explained because 3,4-DHPEA-AC is obtained by cleavage of 3,4-DHPEA-EDA [8]. Luteolin was also positively correlated to other two aglycon flavonoids such as diosmetin and apigenin ($R=0.81$, p-value$=0.03$ and $R=0.79$, p-value$=0.03$, respectively). Apigenin is the substrate for the synthesis of luteolin in the flavonoids pathway by action of a hydroxylase, which allows explaining this positive correlation. As previously mentioned, diosmetin is a methoxyderivative of luteolin and, for this reason, their concentrations in VOO could be correlated. Apigenin was also positively correlated with apigenin-7-glucoside ($R=0.82$, p-value$=0.02$), which could be ascribed to

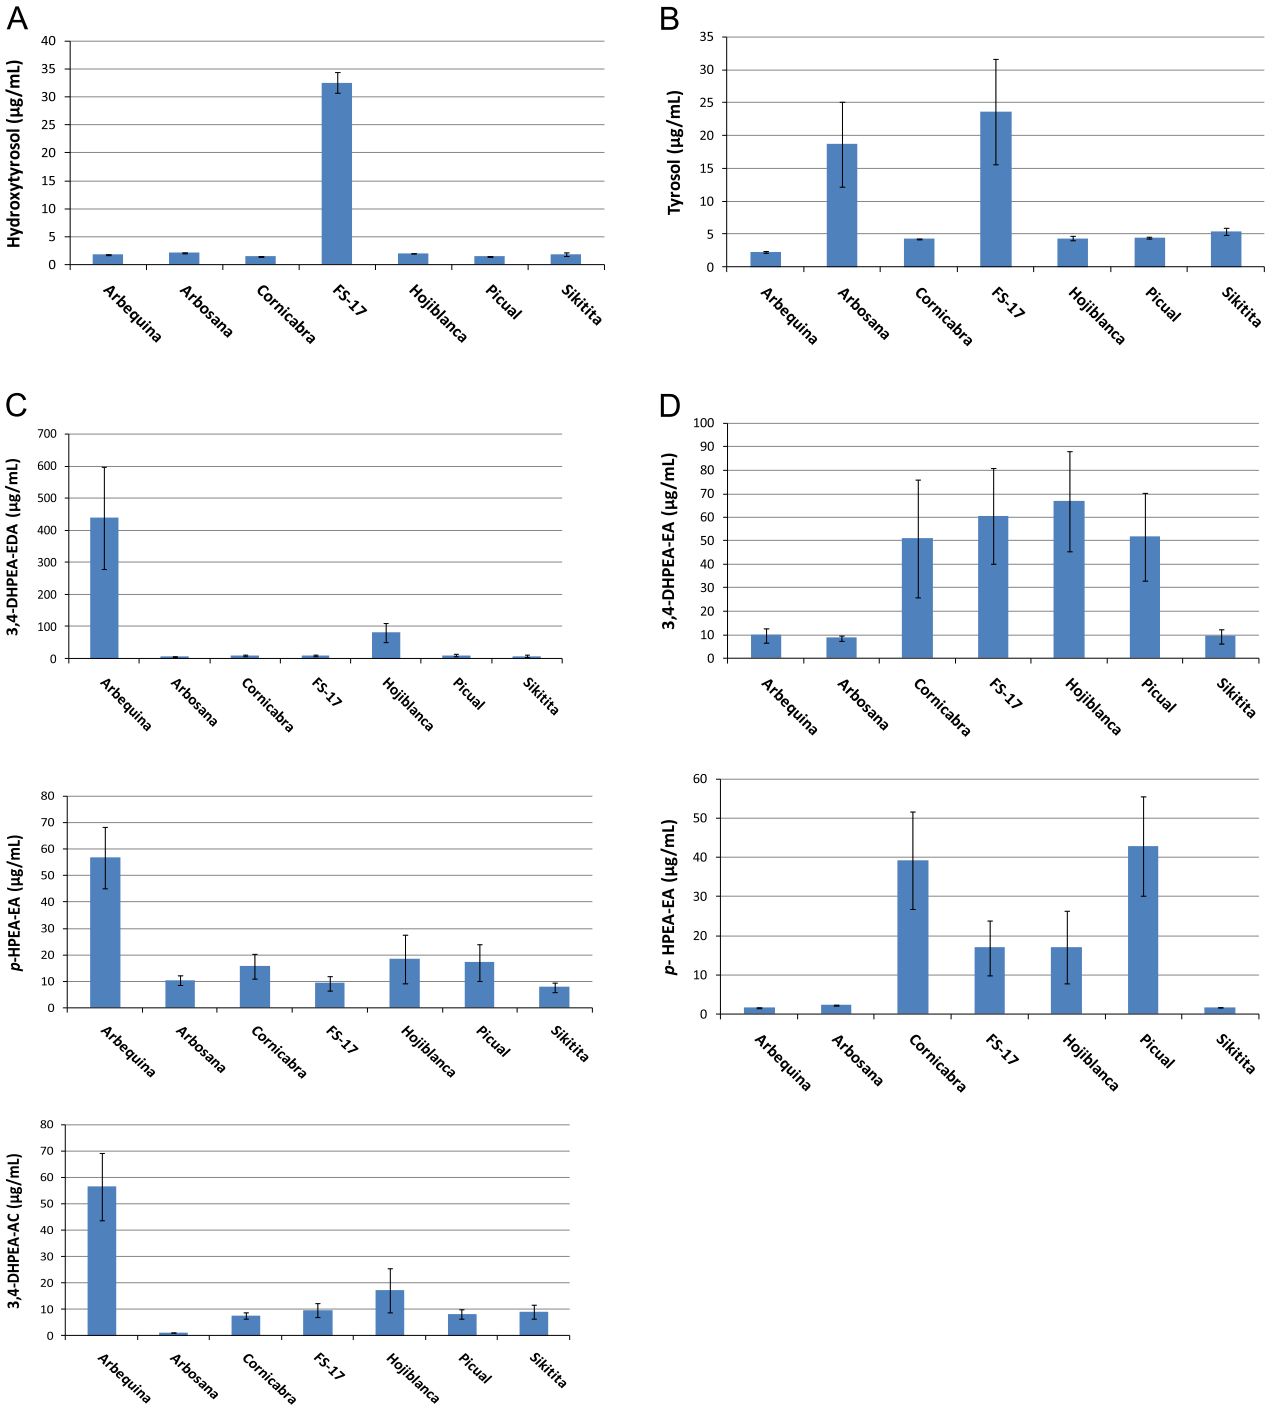

Fig. 4. Concentration plots corresponding to: (A) hydroxytyrosol (B) tyrosol; (C) 3,4-DHPEA-AC, 3,4-DHPEA-EDA and *p*-HPEA-EDA; (D) 3,4-DHPEA-EA and *p*-HPEA-EA.

the glycosylation step that favors storage of certain phenols in VOOs.

Other remarkable correlations were those between vanillin–vanillic acid and luteolin–caffeic acid ($R=-0.79$, p-value$=0.03$ and $R=-0.76$, p-value$=0.05$, respectively). The former correlation could be explained because vanillic acid is obtained by oxidation of vanillin. Luteolin and caffeic are produced in two different pathways: the flavonoids and phenylpropanoid pathways, respectively. However, there is a nexus between them through *p*-coumaric acid. Consequently, the degree of concentration of each compound should depend on the enzymatic activity. In this manner, higher concentration of caffeic acid would involve a high hydroxylase activity. On the other hand, high levels of luteolin could assume an increased activity of the flavonoids biosynthesis pathway (Supplementary Fig. 8).

3.5. Differences in the phenolic profiles of monovarietal VOOs

The next step was to find similarities and differences between the phenols profiles of the analyzed monovarietal VOOs by Clustering analysis. This analysis was applied to the complete data set. Supplementary Fig. 9 shows the cluster graph obtained by comparing phenolic profiles of monovarietal VOOs. The dendrogram reveals the relationships between phenols in one dimension and between VOO samples in the other dimension. Two main clusters can be observed in the graph: Arbequina, Hojiblanca,

Table 5
Correlation values between monovarietal VOO pairs.

VOO	Arbequina	Arbosana	Cornicabra	FS-17	Hojiblanca	Picual	Sikitita
Arbequina	–	0.24	0.10	0.06	**0.77**	0.11	0.52
Arbosana	0.24	–	0.36	0.56	0.41	0.36	0.63
Cornicabra	0.10	0.36	–	**0.81**	0.65	**0.99**	0.51
FS-17	0.06	0.56	**0.81**	–	0.62	**0.79**	0.58
Hojiblanca	**0.77**	0.41	0.65	0.62	–	0.65	**0.74**
Picual	0.11	0.36	**0.99**	**0.79**	0.65	–	0.51
Sikitita	0.52	0.63	0.51	0.58	**0.74**	0.51	–

Cornicabra and Picual were classified within the same cluster, whereas the second one was formed by Sikitita, Arbosana and FS-17. Each cluster was divided into subclusters, which were constituted by VOO pairs, except for Sikitita VOO. The detected subclusters were Arbequina/Hojiblanca, Cornicabra/Picual and Arbosana/FS-17. Among them, the higher similarity was observed between Cornicabra and Picual VOOs since a parallelism was found in the levels of most phenols both with positive and negative correlation. García et al. also found a high similarity in the phenolic profile of Picual and Cornicabra VOOs [44].

The main differences between VOO monovarietal samples were observed in the levels of certain groups of phenols. Thus, it was clear that levels of secoiridoids and derivatives are critical to establish differences between VOOs. In particular, levels of 3,4-DHPEA-AC, 3,4-DHPEA-EDA and *p*-HPEA-EDA followed an opposite trend to those observed for 3,4-DHPEA-EA and *p*-HPEA-EA. This was clearly detected in Arbequina and Hojiblanca VOOs, which provided high levels of EDA phenols and 3,4-DHPEA-AC (particularly Arbequina VOO) as compared to the other varieties. The opposite situation was observed for Sikitita and Arbosana VOOs, which were characterized by low levels of the EA secoiridoid derivatives, and for Cornicabra and Picual, which provided relatively high levels for these compounds. The described trends for secoiridoids have been discussed in other studies as mentioned in the previous sections, with special emphasis on Arbequina, Picual, Cornicabra and Hojiblanca VOOs [11,34,37,43,44].

One other aspect to be emphasized was the high concentrations of phenolic alcohols, hydroxytyrosol and tyrosol, and phenolic acids observed in FS-17. Table 5 shows the correlation between the pairs of VOO samples according the measured concentration of phenolic compounds. As can be seen, high correlations ($R > 0.7$) were observed for the following pairs of VOO: Arbequina/Hojiblanca ($R=0.77$), essentially supported on levels of 3,4-DHPEA-AC and EDA derivatives; Cornicabra/FS-17 ($R=0.81$), Picual/FS-17 ($R=0.79$) and Picual/FS-17 ($R=0.74$), by correlation of flavonoids and secoiridoid derivatives in general. The highest correlation was observed for the pair Picual/Cornicabra ($R=0.99$), which agrees with the parallelism between phenolic levels previously described.

4. Conclusions

This preliminary study allowed setting similarities and dissimilarities between monovarietal VOOs by analysis of the phenolic profile. The observed connections between phenolic compounds for different varieties have been interpreted according to the main pathways for phenols biosynthesis.

Sorptive extraction
Ultra-high performance liquid chromatography
Water analysis

ABSTRACT

A new straightforward and inexpensive sample screening method for both EPA and EU priority polycyclic aromatic hydrocarbons (PAHs) in water has been developed. The method is based on combined direct immersion and headspace (DIHS) sorptive extraction, using low-cost disposable material, coupled to ultraperformance liquid chromatography with fluorescence and UV detection (UPLC-FD-UV). Extraction parameters, such as the sampling mode, extraction time and ionic strength were investigated in detail and optimized. Under optimized conditions, water samples (16 mL) were concentrated in silicone disks by headspace (HS) and direct immersion (DI) modes simultaneously, at room temperature for 9 h for the majority of the 24 studied compounds. Ultrasound-assisted desorption of extracted analytes in acetonitrile was carried out also at room temperature. The optimized chromatographic method provided a good linearity ($R \geq 0.9991$) and a broad linear range for all studied PAHs. The proposed analytical procedure exhibited a good precision level with relative standard deviations below 15% for all analytes. Quantification limits between 0.7 and 2.3 $\mu g\ L^{-1}$ and 0.16 and 3.90 $ng\ L^{-1}$ were obtained for compounds analyzed by UV (acenaphtylene, cyclopenta[c,d]pyrene and benzo[j]fluoranthene) and fluorescence, respectively. Finally, the proposed method was applied to the determination of PAHs in different real tap, river and wastewater samples.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) constitute a broad group of organic compounds which have received much attention over the years because of their wide distribution in the environment as well as their well-known carcinogenic and mutagenic properties [1,2]. Due to the ubiquity of PAHs and their potential deleterious effects on human health, these compounds have been often monitored in air, soil, water, foods and beverages [3]. On the basis of risk assessment, 15 PAHs have been identified as priority hazardous substances by the European Union (EU) [4]. Moreover, in 2005, the Joint FAO/WHO Experts Committee on Food Additives appended to the list a 16th compound (benzo[c]fluorene, B[c]F) also considered as genotoxic. To distinguish this list from the set of 16 US EPA PAHs [5], the term "15+1 EU priority PAHs" is commonly used. The list of these PAHs comprises of B[c]F, cyclopenta[c,d]pyrene (CP[c,d]P), benz[a]anthracene (B[a]A), chrysene (Chry), 5-metylchrysene (5-MC), benzo[j]fluoranthene (B[j]F), benzo[b]fluoranthene (B[b]F), benzo[k]fluoranthene (B[k]F), benzo[a]pyrene (B[a]P), dibenzo[a,l]pyrene (DB[a,l]P), dibenzo[a,h]anthracene (DB[a,h]A), benzo[g,h,i]perylene (B[g,h,i]P), indeno[1,2,3-c,d]pyrene (I[1,2,3-c,d]P), dibenzo[a,e]pyrene (DB[a,e]P), dibenzo[a,i]pyrene (DB[a,i]P) and dibenzo[a,h]pyrene (DB[a,h]P). Because of the continued development of European legislation in this area, analytical methodology for multiple PAHs in water and other types of samples is required in order to get a clearer picture of human exposure.

A variety of analytical methods have been used for determining trace concentrations of PAHs in water samples. Aside from the classical liquid–liquid extraction (LLE), alternative sampling methods like solid phase extraction (SPE) [6], solid phase microextraction (SPME) [7], stir bar sorptive extraction (SBSE) [8] and silicone rods and tubes sorptive methods [9] have been developed. These procedures, based on equilibrium extraction, exhibit several advantages over LLE, regarding sample preparation speed and allows for improved sample throughput by parallel analyses [10].

The most widely used sorptive extraction phase is polydimethylsiloxane (PDMS). Absorptive interactions are much weaker compared to adsorption on active surfaces. Therefore, analyte desorption can be performed under softer conditions, such as

lower temperature and shorter desorption times and the degradation of unstable analytes is significantly impaired as compared to adsorptive processes [9,11].

Among the PDMS extraction techniques, solid-phase microextraction (SPME) has been widely used to extract PAHs from water samples [12–14]. Stir bar sorptive extraction (SBSE) which is more recent, has also been used for that kind of extraction [15–17]. In addition to PDMS coated fibers and stir bars (Twisters), PDMS is also available in bulk formats (sheets, tubes and rods). Silicone materials in form of rods (SRs) and tubes (STs) for the enrichment of organic compounds have been employed by Popp et al. [18,19]. In terms of analyte extraction the SRs and STs are similar to SPME and SBSE. Additional advantages of using bulk PDMS or equivalent materials as sorbent are the possibility of customizing the volume of polymer for each particular application, the availability of different formats and the very low cost of the sorbent in comparison with SPME fibers and Twisters. The latter feature makes it possible to use a new piece of sorbent for each extraction, which avoids problems associated with carry-over and cross contamination, allowing simultaneously processing as many samples as desired, and providing the possibility of considering the disposable sorbent material for analyte storage purposes [9].

The aim of this work was to develop and optimize a new one shot procedure based on sorptive extraction coupled with UPLC-FD-UV for determination of the 16 EPA priority PAHs and the "15+1" EU priority PAHs in water samples. The 24 PAHs are naphthalene (Naph), acenaphthylene (Acy), acenaphthene (Ace), fluorene (Flu), phenanthrene (Phe), anthracene (Anth), fluoranthene (Flt), pyrene (Pyr), B[c]F, CP[c,d]P, B[a]A, Chry, 5-MC, B[j]F, B[b]F, B[k]F, B[a]P, DB[a,l]P, DB[a,h]A, B[g,h,i]P, I[1,2,3-c,d]P, DB[a,e]P, DB[a,i]P and DB[a,h]P.

Disposable silicone in disks format, sampling simultaneously in direct immersion and headspace (DIHS) modes, was chosen as extractant phase and the influence of different experimental parameters (e.g. sampling mode, stirring rates, extraction time, etc.) on the analyte recoveries was investigated optimizing the operating conditions. Chromatographic conditions have been also optimized in order to obtain the satisfactory separation of 24 studied PAHs. Finally, the applicability of the developed procedure was tested for the determination of PAHs in some real tap, river and wastewater samples.

2. Materials and methods

2.1. Reagents, standards and materials

The disposable silicone sorbent was purchased from Goodfellow (Bad Nauheim, Germany) in sheets with a thickness of 0.6 mm. Silicone provided by Goodfellow is not pure PDMS but a phenyl-vinyl-methyl-polysiloxane (so-called PVMQ silicone Rubber). Disks (5 mm diameter × 0.6 mm thickness, 12 μL volume) were obtained by cutting the silicone sheet with a sharp hollow punch (internal diameter 5 mm). The obtained pieces were weighed and those differing by more than 2% in weight were discarded. Before being used for analytes extraction, disks were sonicated three times (5 min each) with methanol–acetone (1:1, v/v) mixture and then were conditioned overnight at 200 °C. Finally the pieces of silicone were sonicated three times (5 min each) with acetonitrile (ACN) and stored dry in sealed bags before use.

ACN and methanol (gradient-grade, Lichrosolv), and 2-propanol (analysis grade), were supplied by MercK (Darmstadt, Germany). Ultrapure water was produced by means of a Milli-Q Gradient A-10 system (Millipore, Billerica, MA, USA). Potassium carbonate and potassium hydrogenum carbonate were purchased from Sigma-Aldrich (Madrid, Spain). Sodium chloride (NaCl) was supplied by Prolabo (Fontenay-Sous-Bois, France). EPA-610 Polycyclic aromatic hydrocarbons mixture was supplied by Supelco (Bellefonte, PA, USA). 5-MC (10 μg mL^{-1}), DB[a,l]P (10 μg mL^{-1}), CP[c,d]P (10 μg mL^{-1}), B[c]F (10 μg mL^{-1}), DB[a,e]P (10 μg mL^{-1}), DB[a,i]P (10 μg mL^{-1}) and DB[a,h]P (10 μg mL^{-1}) were from Dr. Ehrenstorfer GmbH (Augsburg, Germany). Durapore filters (Millex GV, 13 mm, 0.22 μm) were supplied by Millipore.

2.2. Samples and sample preparation

Spiked and non-spiked ultrapure, tap, and river waters samples, and both raw (influent) and treated (effluent) wastewater samples were used in this study. All samples were used directly without preliminary filtration. Ultrapure and tap waters were obtained directly in the laboratory when needed. River water samples were collected in different points in Galicia (northwest Spain). Sewage water samples were obtained from the inlet and outlet of an urban wastewater treatment plant in operation near Santiago de Compostela (~100,000 inhabitants), equipped with a primary and aerobic secondary treatment, and which receives mostly municipal non-industrial wastewaters. Spiked samples were prepared by adding a standard solution of analytes at levels between 0.12 ng mL^{-1} and 2.5 ng mL^{-1}, depending on the considered compound.

Extractions were carried out in 22 mL capacity glass vials furnished with PTFE-lined septa (covered with aluminum foil) and aluminum caps. Vials and caps were supplied by Sugelabor (Madrid, Spain).

Under optimized conditions, 16 mL of water was transferred to extraction vials containing 4 g (25%w/v) of sodium chloride, 1 mL of 2-propanol (i-prOH) and a PTFE covered stirrer (6 mm × 3 mm). Analytes were extracted by night (c.a. 15 h approximately) at room temperature, with 5 silicone disks immersed directly in the stirred sample (900 r.p.m) and a sixth silicone disk in the headspace of the sample, fixed to the septum of the vial with a stainless steel pin (i.d. 0.4 mm). After extraction, the silicone disks were removed with clean tweezers, rinsed with ultrapure water and transferred into a small vial containing 0.25 mL of ACN and desorbed during 5 min in an ultrasonic (US) bath. Then, 0.1 mL of the obtained ACN extract was taken and diluted with 0.1 mL of water to match the initial mobile phase composition in the UPLC separation program. This diluted solution was filtered through a 0.22 μm Durapore filter and 5 μL was injected into the UPLC system.

2.3. Chromatographic method (UPLC-FD-UV)

UPLC chromatographic separations were developed in a system comprising a quaternary pump (Acquity H Class, Waters), an UV–vis diode array and a fluorescence detector (FD) in series (Waters, Singapore). The autosampler has a temperature controller for the samples and is fitted with a flow through needle system. Analytical column temperature was controlled with an integrated oven module. The analytical column was a 50 mm × 2.1 mm I.D. Zorbax Eclipse PAH Rapid Resolution HT C_{18} column, (particle size 1.8 μm). A filter guard cartridge (2.1 mm × 0.2 μm) was used to protect the analytical column (Waters, USA). Empower 2.1 Software was used for data acquisition.

A binary solvent system made of ACN and water was used for chromatographic separations. The gradient elution program was as follows: initial conditions, 47% ACN for 0.5 min, then a linear ramp to 80% ACN in 4.9 min and finally another linear ramp to 100% ACN in 1.9 min, holding in 100% ACN for 3.7 min.

The flow rate was also programmed. Initially it was set at 0.6 mL min^{-1} during 7.3 min, and then increased to 0.9 mL min^{-1} for 0.2 min, holding at 0.9 mL min^{-1} for 3.5 min. The column

temperature was set at 30 °C. Detection was performed using a fluorescence wavelength programming developed to obtain the better sensitivity and minimal interference by adapting detection conditions from a previously reported procedure [20]. The excitation/emission wavelengths pairs (nm) were set as follows: 267/330 for Naph; 275/315 for Ace and Flu; 247/357 for Phe; 238/418 for Anth, Flt, Pyr and B[c]F; 270/393 for B[a]A, Chry and 5-MC; 294/425 for B[b]F, B[k]F, B[a]P, DB[al]P, DB[ah]A and B[ghi]P; 245/500 for I[1,2,3-cd]P; 306/398 for DB[a,e]P; 290/434 for DB[a,i]P and 300/452 for DB[a,h]A. Acy, CP[c,d]P and B[j]F were analyzed by UV detection (254 nm) because these compounds do not exhibit fluorescence. Retention times and the characteristic UV absorbance spectrums of each PAH were used to confirm the identity of the chromatographic signals. The separation of the 24 PAHs was carried out in 9 min.

2.4. Experimental design analysis and software

Experimental designs were applied to carry out the optimization process of extraction using the extraction yield for the 24 PAHs as the objective function. Firstly, a full factorial design, 2^3, with 3 central points (11 runs) was developed to evaluate the significance of three operational factors. Levels for factors were (see Table 1): i-PrOH addition (0–10.6% v/v (0–1.75 mL)), NaCl concentration (0–22% w/v (0–3.5 g)), and silicone disks number (2–4, maintaining one of them always in the HS mode). Table S1 presents the experimental design matrix.

Later a central composite design (CCD) was developed moving the variable levels in the direction suggested by the former and were as follows (see also Table 2): i-PrOH addition (6.2–18.8% v/v (1–3 mL)), NaCl concentration (12.5–25% w/v(2–4 g)), and silicone disk number (3–6, one of them always at HS). The CCD was performed in 18 experiments, including 4 replicated central points. Table S2 presents the experimental plan for runs.

Finally a multi-objective optimization study using desirability functions [21] was carried out. By the evaluation of the responses with the help of desirability functions, the procedure finds for the best conditions to get better results in the extraction efficiency for the whole ensemble of PAHs. This function penalizes the decrease of this efficiency for each peak and finally, individual desirability functions are combined (geometric mean) in a global desirability function.

Experimental design analysis was performed with the software Statgraphics Centurion XVI.II for Windows (Statpoint technologies, Warrenton, VA, USA).

3. Results and discussion

3.1. Optimization of the chromatographic method (UPLC-FD-UV)

Reversed phase chromatography with C_{18} as stationary phase was employed to achieve the separation of 24 studied PAHs. ACN and water were selected as mobile phases. Chromatographic conditions, such as mobile phase gradient program, temperature column and flow rate, were evaluated in order to obtain the best resolution in the shortest analysis time.

Different proportions of ACN and water were tested. The mobile phase gradient was optimized until a satisfactory resolution of the 24 PAHs was achieved. Then, the influence of temperature on the PAHs resolution was investigated by setting the oven at 25, 30, 35, 40 and 45 °C. The best separation of the considered compounds was obtained at 30 °C. Good chromatographic profile with minimum runtime was obtained at 0.6 mL min^{-1}.

The optimized chromatographic conditions led to a suitable separation of 24 studied PAHs (Fig. 1), maintaining a good resolution and peak shape quality in a reasonable analysis time (9 min).

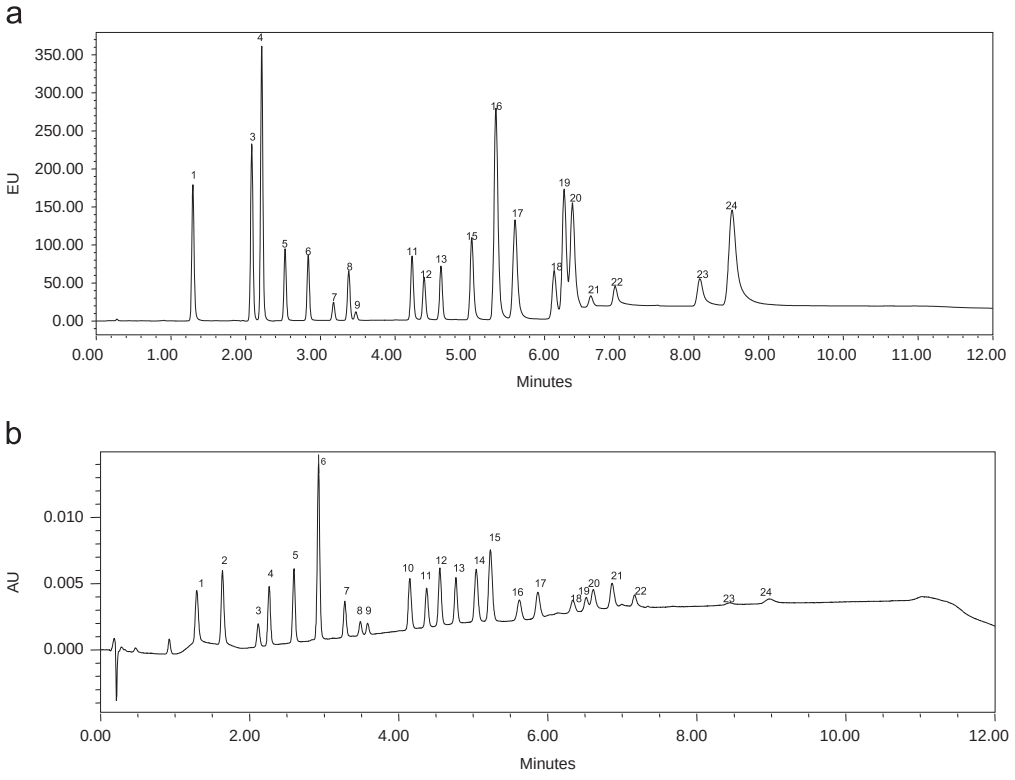

Fig. 1. Chromatograms obtained by UPLC: (a) Fluorescence and (b) UV–vis. Peak assignment:1) Naph; 2) Acy; 3) Ace; 4) Flu; 5) Phe; 6) Anth; 7) Flt; 8) Pyr; 9) B[c]F; 10) CP[c,d]P; 11) B[a]A; 12) Chry; 13) 5-MC; 14) B[j]F; 15) B[b]F;16) B[k]F);17) B[a]P); 18) DB[a,l]P, 19) DB[a,h]A; 20) B[g,h,i]P; 21) I[1,2,3–c,d]P; 22) DB[a,e]P; 23) DB[a,i]P; 24) DB[a,h]P.

3.2. Operating parameters

The extraction efficiency is usually affected by the stirring speed in sorptive extraction methods, since stirring favors migration of the analytes from the sample to the silicone phase. As expected, higher responses were measured for stirred samples versus non-stirred ones; however, significant differences were not observed when the extractions were carried out at three different stirring rates: 700, 900 and 1100 r.p.m. An intermediate value of 900 r.p.m. was selected as the best option.

3.2.1. Desorption conditions

In order to investigate the PAHs desorption, silicone disks were firstly desorbed with 250 μL of ACN for 5 min using an ultrasonic bath. ACN was chosen as desorption solvent on the basis of their compatibility with further LC reversed-phase separation. To verify the volume of ACN as well as the desorption time, the procedure was repeated twice using fresh solvent, but the recovery values in the second desorption stage represented in all experiments less than 5% of the analyte present (data not shown). Taking into account that silicone disks were considered as single-use sorbents, there was no risk of cross contamination problems, and therefore a single desorption step of 5 min was chosen.

Then, to evaluate the US influence, silicone disks were left to stand for 5 min with 250 μL of ACN helping or not the desorption process with the aid of US. Improved results (in the range 5–11% depending on the particular analyte) were obtained for US-assisted processes so a single US-assisted desorption step of 5 min using 250 μL of ACN was employed in all subsequent experiments.

3.2.2. Sampling mode arrangement and temperature

Kinetics of sorptive extraction processes change depending on the relative position of the sorbent and the bulk of sample (headspace (HS) and/or direct immersion (DI) in the sample). The choice of extraction mode will be dependent on the analyte volatility and/or sample complexity. Both modes (HS or DI) have been proposed for the extraction of PAHs from aqueous and solid samples with SPME fibers [22] or by cold-fiber solid phase microextraction(CF-SPME) [23]. The sample temperature is also an important factor, since temperature will influence the volatilization of the analytes and their subsequent pass to the HS. However, it is well known that the sorption of the analytes by the coating is an exothermic process and thus this variable has a double effect on the extraction yield. Previously reported approaches using CF-SPME [24] and conventional SPME [25] for the extraction of PAHs and other more volatile analytes in soil and water samples adopt a two stages procedure based on the successive (DI mode followed by HS extraction) sampling employing different temperatures in each stage which complicates the operational setup significantly. On the other hand, for SBSE, some studies have reported that extraction periods of 11–14 h (usually at room temperature) can be considered optimal for most of analytes to reach steady state [26,27]. That, it was decided to develop a one-shot procedure aiming at the quantitative extraction of all analytes of interest in a single sampling operation, preferably at room temperature that can be performed easily without special equipment requirements.

To do that, a series of assays were carried out in order to evaluate the sampling mode arrangement. In these experiments, aliquots of a water sample spiked with target compounds were transferred to extraction vials containing a fixed amount of salt. Comparative extractions were performed using only one silicone disk (in DI or HS sampling mode) or two silicone disks (configured to perform simultaneously DI and headspace (HS) sampling modes). As expected, the presence of one disk in the HS led, in general, to better response for the low molecular weight (lighter) PAHs, such as Naph, Acy, Ace, Flu, Phe or Ant (Fig. 2) but no improvement was observed for the heavier PAHs. The opposite behavior is observed for the direct immersion mode, which provided higher extraction efficiency for the high molecular weight PAHs. This behavior is in agreement with reported results for CF-SPME [24]. As can be clearly observed in Fig. 2, the combination of direct and HS sampling modes simultaneously did led to a satisfactory extraction for all the PAHs, opening a new approach for the one shot extraction of a large variety of PAHs, including all those currently considered in safety international regulations.

The influence of sampling temperature and the addition of i-PrOH to the samples before the extraction has been summarized in Fig. 3. As can be expected, at room temperature the efficiencies of the extraction for lighter PAHs are better than those at 100 °C and the opposite behavior was observed for the heavier PAHs. Moreover, the extraction efficiency of heavier PAHs at room temperature was improved by the addition of small percentages of i-PrOH to the water samples, so in the first instance 10% (v/v) of i-PrOH content was selected because of its positive effect on recovery. It should be noted that usually water samples for the analysis of PAHs contain appreciable proportions of i-PrOH, or another organic solvent, to compensate the natural tendency of PAHs to adhere to the glass walls [28]. Thus this unintended effect of i-PrOH in the extraction recoveries was considered a fortunate but positive result. Additionally, when extractions were performed at 100 °C some interferences appeared in the chrysene peak (probably due to degradation products of other PAHs at high temperature), in addition Ghiasvand et al. [23] reported a very high pressure in the extraction vial due to water evaporation at high temperatures (150 °C), which clearly represents a high source of inaccuracy in results due to leaking, so room temperature was selected for subsequent experiments.

The conclusion of these preliminary experiments was that combining both direct immersion and head space sampling (DIHS)

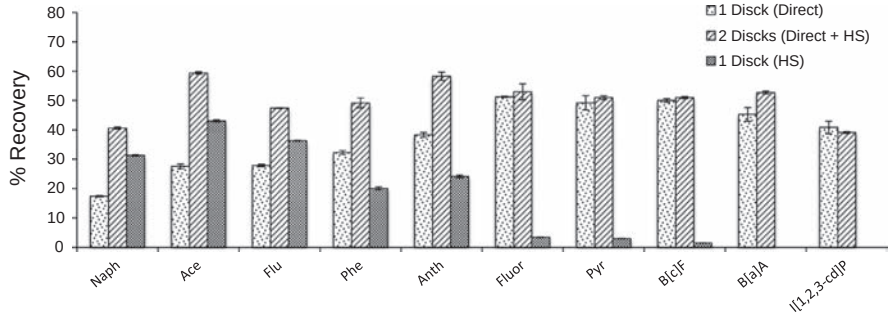

Fig. 2. Influence of the sampling mode on the efficiency of the sorptive microextraction process for some representative PAHs, $n=3$ replicates. Experiments at room temperature for 15 h. Sample volume: 9 mL with 10% (w/v) of NaCl and 10% (v/v) of i-PrOH.

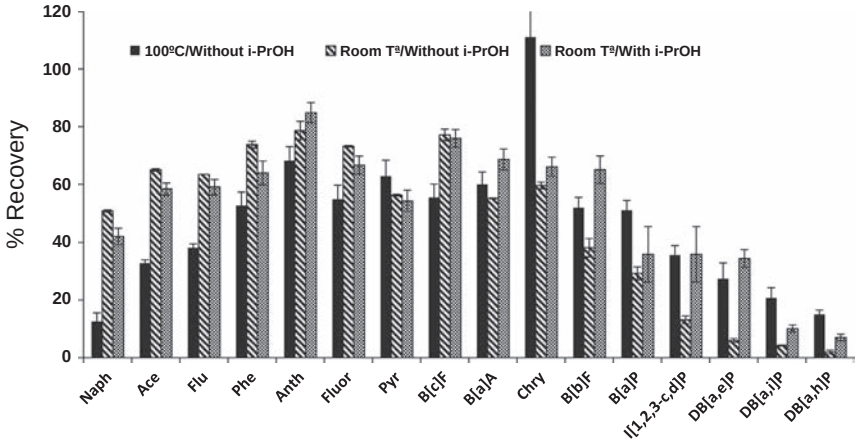

Fig. 3. Influence of temperature and i-PrOH on the efficiency of the DIHS microextraction process, $n=3$ replicates. Number of silicone disks: 2 (HS and DI). Sample: 9 mL of ultrapure water with 10% (w/v) of NaCl and 10% (v/v) of i-PrOH (only for experiments with i-prOH). Extraction time: 15 h at room temperature and 2 h at 100 °C.

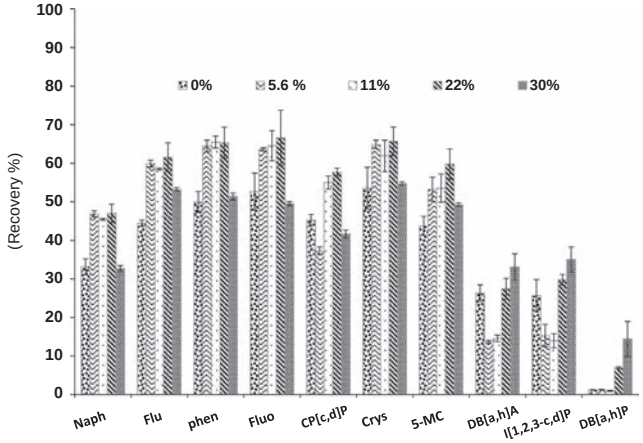

Fig. 4. Effect of ionic strength in the efficiency of the DIHS microextraction process, $n=3$ replicates.

modes simultaneously at room temperature could be a novel and advantageous approach in the development of an efficient sampling mode for PAHs in water samples.

Some additional preliminary tests were carried out in order to define the sampling format for combined DIHS extraction. In some of these tests, silicone disks were kept in fixed positions (separated approximately by 50 mm) relative to the sample by means of a stainless steel pin (i.d. 0.4 mm) fixed to the septum, in such a way that one of the disks kept immersed in the sample and the other remain in the headspace when the vial is closed. The other format consisted in placing one silicone disk in the headspace attached to the stainless steel pin while the other was loose into the sample. Comparison of results (data not shown) revealed better results for the heavier PAHs with the last option so this sampling mode was adopted in further experiments

3.2.3. Ionic strength

Adding a small amount of salt often improves extraction efficiency in most conventional extraction and microextraction procedures for PAHs [14,29]. The presence of salts in the samples increases the distribution coefficient of the non-ionized analytes thus improving recoveries. This effect could be explained by the decrease of the PAHs solubility in the aqueous sample, especially for high molecular weight PAHs.

To evaluate the influence of the ionic strength on the efficiency of the sorptive extraction, samples in triplicate with NaCl (0–30% (w/v)) were analyzed. Series of experiments were performed with 9 mL aliquots of spiked ultrapure water, and 2 silicone disks (DIHS mode). A relationship between ionic strength and extraction efficiency was observed and it is shown for representative analytes in Fig. 4. The addition of salt affects positively the recovery of the low molecular weight (lighter) PAHs. For the heavier PAHs higher responses were attained for samples containing 22% (w/v) of NaCl. This behavior could be probably related to a significant diminution of the solubility of the compounds in the aqueous phase. However, at high concentrations of NaCl (about 30% v/v) the efficiencies of the extraction for the PAHs were decreased except for the heavier PAHs such as DB[a,h]A, B[g,h,i]P or DB[a,h]P. As detailed later, the influence of the ionic strength was further examined during the optimization process.

3.2.4. Sample volume

Operating at the maximum levels imposed for PAHs by European directives constitutes a challenge for laboratories developing routine water analysis [30]. One obvious option to tackle this difficulty is to increase the sample volume. Different water volumes (9 and 16 mL) were compared and tested for triplicate. To do this, water samples containing about 22% (w/v) of sodium chloride and 10% (v/v) of i-PrOH were transferred to the extraction vial. The number of silicone disks was adapted proportionately to the sample volume. For 16 mL three silicone disks were exposed directly to the stirred sample and a fourth silicone disk was placed at the HS. With 9 mL of sample, one silicone disk was on HS and the second one loose in the solution. The results of these experiments (data not shown) showed that there are no significant differences between extraction efficiencies for 9 or 16 mL of sample, so a sample volume of 16 mL was adopted to achieve a reduction of the detection limits.

3.3. Optimization of the variables affecting the extraction

Once the amount of sample was fixed (16 mL), and on the basis of the preliminary studies, other operational parameters (NaCl concentration, i-PrOH addition, and sorbent area and volume) should be studied and optimized. A chemometrical approach based on experimental designs was applied to carry out this optimization process. Firstly, a full factorial design, 2^3, with 3 central points was developed to evaluate the significance of the three operational factors. The experimental domain of that design and the standardized main effects and multiplicative terms

for each compounds are summarized in Table 1; Table S1 shows the experimental design matrix.

Fig. S1 (Supplementary material) shows some effect's standardized Pareto charts for the above-mentioned parameters in representative analytes among the considered group. The length of depicted bars is proportional to the absolute effect of the considered factor (or two factor interactions) in the recovery of the particular analyte to which the chart belongs. A positive sign points out to an improvement in the efficiency of the extraction when the factor changes from the low to the high level, within the domain of the design and, a negative one indicates the opposite behavior. The vertical dotted line in the graphs represents the statistical significance bound, established at 95% confidence level. Considering Naph and Phen as representative compounds for the lighter PAHs, we can observe that factors A (i-prOH) and B (salt) had a statistically positive effect in the extraction efficiency. Factor C (disks number) appears significant for a few analytes. This can be explained because the addition of salt to the samples and the incorporation of some i-prOH favor the displacement of lighter PAHs to the head space. The variable influence of the number of disks in these results can be interpreted because all experiments were developed situating only one silicone disk in the HS, no matter the total number of disks considered. Also some interaction factors appear significant for lighter PAHs.

On the other hand, for heavier compounds such as B[ghi]P and DB[ah]A factors A and C exhibit a statistically significant positive effect while no statistical significance for factor B was observed. Also in that case, the observed results can be justified quite easily. Heavier PAHs are sampled essentially in the bulk liquid sample so the number of disks (the sorbent volume and exposed area) influences the extraction capacity and kinetics of the process. Also, the presence of larger amounts of i-PrOH favors the extraction by limiting the tendency of heavier PAHs to adhere to glass vial walls. Salt addition, on the contrary is less significant for heavier highly hydrophobic PAHs.

Table 1 shows clearly that the number of silicone disks, or in other words, the sorbent surface and volume, appears as the most important factor for the majority of considered analytes. Also, the i-prOH amount added to samples is significant for many analytes, especially for the heavier and the lighter ones. Finally, salt addition appears only critical for the lighter PAHs.

The above factorial design can only be used to fit a first order linear model to the experimental results. However, data at replicated central points indicated the existence of curvature for the response surface and response gradient pointing outside the experimental region actually explored. Consequently, a central composite design (CCD) was developed moving the variable levels in the direction suggested by the gradient. The experimental domain and the summary of conclusions obtained for the CCD design have been summarized in Table 2 and, main effects for some representative PAHs are shown in Fig. S2.

The amount of salt added to samples appears significant only for a few analytes (among the heavier PAHs) but practically in all cases the effect is negative so, taking into account results in Table 1, this means that some salt is needed to favor the extraction of the lighter PAHs although its level should be maintained at intermediate values to avoid the negative effect in the extraction of the remaining analytes of interest. The lower extraction efficiency for hydrophobic compounds when ionic strength increases have been explained by their adsorption tendency onto glass walls [27] and due to the increase in the viscosity of the sample, leading to slower extraction kinetics for lipophilic species [31], as well as the decrease of PAHs solubility in the aqueous sample, especially for the heavier PAHs [14,30]. Since they are repulsed to the water/headspace interface (the so-called oil effect), they cannot interact with the PDMS disk, fully immersed into the sample matrix, and therefore, lower extraction efficiencies were achieved.

Regarding the i-PrOH addition, its influence inhibiting the adsorption of analytes in glass walls appears mostly significant for the lighter PAHs but an excess of i-PrOH (see Fig. S2, for fluorene which can be considered a representative example of lighter PAHs) negatively affects the extraction. On the other hand, for heavier PAHs, the effect is not significant in the range 1–3 mL. Thus, water samples must contain a minimum level of 6% (1 mL if the alcohol is added to the sample portion analyzed) of i-PrOH.

Finally, for the number of disks factor (see Table 2 and Fig. S2) the influence is positive and significant for the heaviest PAHs.

Departing from the data obtained with CCD design, a multi-objective optimization study using desirability functions [21] was carried out. The 24 analytes were split into two groups (the primary motivation was that the statistical software used can only manage 16 response functions simultaneously): the more volatile PAHs (Naph, Acy, Ace, Flu, Phe, Anth, Flt, Pyr, B[c]F, CP[c,d]P, B[a]A, Chry, 5-MC, B[j]F, B[b]F on one side, and the less volatile (CP[c,d]P, B[a]A, Chry, 5-MC), B[j]F, B[b]F, B[k]F, B[a]P, DB[a,l]P, DB[a,h]A, B[g,h,i]P, I[1,2,3-c,d]P, DB[a,e]P, DB[a,i]P, DB[a,h]P on the other. This procedure finds a compromise overall optimum aiming at the quantitative extraction of each individual considered analyte and finally combining those individual desirability functions in a global desirability (D) which is the geometric mean of the individual ones. Fig. 5 shows the global desirability for each group of analytes, showing that quite similar operating conditions can be applied to both groups so it is possible finding a good compromise operating procedure for the extraction of the 24 PAHs in samples. For the first group (more volatile PAHs) the maximum appears when the extraction is developed using a volume of 0.32 mL (c.a. 2% v/v) of i-PrOH and 3.5 g (c.a. 22% w/v) of salt and 6 silicone

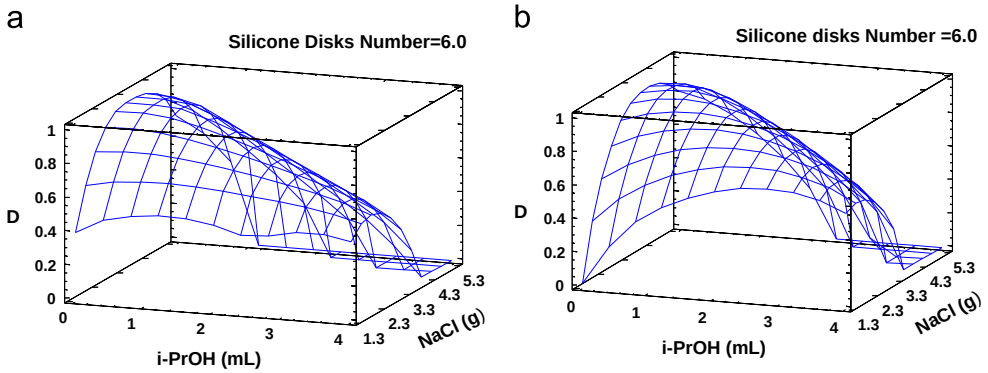

Fig. 5. Estimated global desirability response surface for PAHs: a) with low molecular weight and b) with high molecular weight.

disks. For the less volatile PAHs, the maximum involved extraction also with 6 silicone disks and 3.7 g (23%) of salt, but using 0.76 mL of isopropanol (5% v/v). Thus, a fine tune optimization of the added amounts of i-PrOH and salt amounts was carried out concluding that optimum extraction of 24 analytes can be performed employing 1 mL of i-PrOH, 4 g of NaCl and 6 silicone disks (one in the HS and five immersed in the water sample).

3.4. Extractions kinetics

The time-course for the sorptive extraction at room temperature was investigated with spiked aliquots (16 mL) of ultrapure water considering variable sampling times ranging from 1 to 24 h. As frequently occurs with sorptive techniques, the extraction process showed slow kinetics [32]. As illustrated in Fig. 6 for a number of representative PAHs of lower and higher volatility, maximum responses were obtained after 9 h for the majority of analytes except for the heaviest compounds (DB[ah]A, B[ghi]P, I[123-cd]P, DB[a,e]P, DB[a,i]P, DB[a,h]P), which needed 15 h to reach the extraction equilibrium. Taking this last value (15 h) allows for the unattended overnight extraction of several samples in parallel using a multiposition magnetic stirrer. Moreover, this sampling time is usual in SBSE protocols [27], although cost of extraction elements is not comparable.

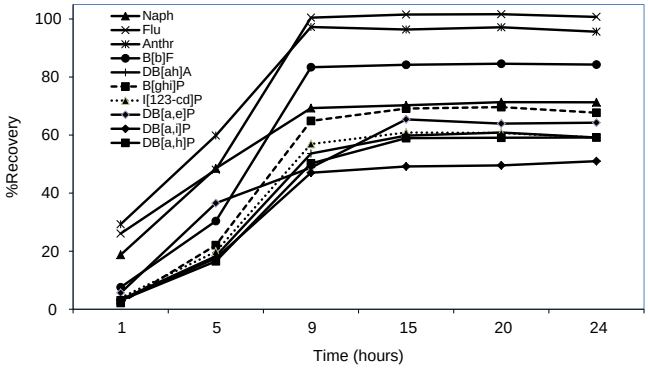

Fig. 6. Kinetics of the DIHS extraction procedure for selected compounds. Average responses for duplicate extractions.

3.5. Performance of the analytical procedure

The quality parameters of the developed chromatographic method were studied in terms of linearity, linear range, repeatability, reproducibility, detection limits (LODs) and quantification limits (LOQs). A signal-to-noise ratio of 3 and 10 was used to determine LODs and LOQs, respectively. Table 3 summarizes the performance of UPLC-FD-UV system for target species using the optimized conditions. As can be seen the proposed method exhibits excellent linearity ($R \geq 0.9991$) in the studied calibration ranges. RSD for injections of standards at different concentration levels was maintained below 6% for injections on successive days. Instrumental LOQs varied between 0.004 and 0.082 $\mu g\ L^{-1}$ in the case of PAHs determined by UPLC-FD, ranging from 17 to 57 $\mu g\ L^{-1}$ for compounds analyzed by UV, with recoveries between 46% and 103%. Recoveries in different types of water samples as well as LODs and LOQs for individual analytes have been summarized in Table 4.

Possible matrix effects of the extraction procedure were evaluated by extracting different kinds of real water samples. All the samples were spiked with the target compounds (0.12–2.5 $\mu g\ L^{-1}$) and also a parallel sample of ultrapure water was performed in order to compare the results. For wastewater and River B and C samples the response for each compound was corrected with that corresponding to non-spiked aliquots of the same sample. Spiked and non-spiked fractions were processed in triplicate and the extraction efficiency was compared with that achieved for ultrapure water (Table 4). Obtained results indicated that the efficiency of the

[a] Direct sorptive extraction with silicone rod.
[b] PDMS stir bar sorptive extraction.
[c] Direct sorptive extraction with Kevlar filament.
[d] SPME consecutive extractions with PDMS/DVB (65 μm).
[e] Solvent consumption only in the desorption stage; solvent consumption in clean-up, solvent exchanges and cartridges activation not included.
[f] Time employed in extraction stage; any other operations were not included. GC × GC-TOFMS, two-dimensional gas chromatography time-of-flight mass spectrometry.

extraction process was not much affected by the nature of water samples except for wastewater and the heavier PAHs. For ultrapure, tap and river waters, the efficiency of the extraction procedure remained the same. Therefore, simple external calibration can be used in the determination. On the contrary, for wastewater samples the standard addition method should be recommended.

Table 6
Concentrations of PAHs found in different water samples.

Compound	River B	River C	Treated wastewater	Raw wastewater
Flu	1.20 ± 4.1	1.20 ± 6.7	n.d	n.d
Phe	4.90 ± 0.3	111.0 ± 1.8	7.50 ± 7.5	11.00 ± 3.4
Anth	n.d	1.40 ± 11	n.d	n.d
Pyr	n.d	1.70 ± 1.1	n.d	n.d
Chry	1.80 ± 3.3	5.40 ± 5.5	n.d	n.d
5-MC	2.10 ± 9.3	2.00 ± 1.7	n.d	n.d
B[b]F	4.20 ± 2.3	4.50 ± 8.5	n.d	n.d

Average (ng L^{-1}) ± relative standard deviation (RSD %); $n=3$ replicates per sample; n.d., not detected.

Finally, Table 5 compares the analytical characteristics of similar previously published methodologies for the determination of PAHs in water samples. Comparison with the results of SBSE procedure shows that precision, recoveries and detection limits do no greatly differ. The obvious advantage of the described extraction method as compared with SBSE is that the silicone sorbent is very cheap. Kevlar sorptive extraction and SPME exhibit poorer quantification limits, while the silicone rod method provides lower recovery values for some PAHs. Additionally, the present procedure has the important advantage of enabling the determination of all 16 EPA and 15+1 EU priority PAHs.

3.6. Analysis of water samples

The applicability of the proposed extraction method was tested by the determination of PAHS in different water samples (tap, river, treated and raw wastewater). Table 6 summarizes the responses obtained for each sample. It is important to emphasize that the regions close to River B and River C were recently affected by a forest burning, so the appearance of some studied compounds was quite foreseeable. In fact, for those rivers we could determine the presence of some PAHs such as Flu, Phen, Chry or B[b]F among others. The studied PAHs were not detected in River A as well in tap water. Only phenantrene was quantified in wastewater.

4. Conclusions

An analytical procedure allowing the one-shot analysis of 24 priority PAHs as established both by the US EPA and the EU has been developed by resorting to a novel strategy based on the simultaneous combination of headspace and direct immersion sampling modes in the same water sample by means of the use of cheap, single-use silicone disks, which avoids cross-contamination and clean up processes. Desorbed analytes are separated and determined by UPLC coupled to UV/FD in only 9 min. The procedure appears very simple and many samples can be prepared simultaneously providing adequate sample throughput. The procedure appears free of interferences even for wastewater samples with recoveries in the range 46–103% and quantification limits allowing its application under international regulations. Combined use of HS and DI sampling modes appears clearly advantageous as compared to both individual modes in terms of analysis time, sample consumption, cost and manipulation.

ABSTRACT

In residue analysis of veterinary drugs in foodstuff, matrix effects are one of the most critical points. This work present a discuss considering approaches used to estimate, minimize and monitoring matrix effects in bioanalytical methods. Qualitative and quantitative methods for estimation of matrix effects such as post-column infusion, slopes ratios analysis, calibration curves (mathematical and statistical analysis) and control chart monitoring are discussed using real data. Matrix effects varying in a wide range depending of the analyte and the sample preparation method: pressurized liquid extraction for liver samples show matrix effects from 15.5 to 59.2% while a ultrasound-assisted extraction provide values from 21.7 to 64.3%. The matrix influence was also evaluated: for sulfamethazine analysis, losses of signal were varying from −37 to −96% for fish and eggs, respectively. Advantages and drawbacks are also discussed considering a workflow for matrix effects assessment proposed and applied to real data from sulfonamides residues analysis.

1. Introduction

Food containing veterinary drug residues above maximum residue limit (MRL) is of major concern, since it is related directly to public health as well as international trade relationships. The demand in food regulatory control has expanded dramatically in recent decades, and residues surveillance became an important factor to be considered in international trade of commodities [1,2].

In Brazil, veterinary drug and pesticide residues analysis in animal (and also in vegetable) products are under the Ministry of Agriculture, Livestock and Supply (MAPA) management [3]. Routine analysis and methods development and validation are attributed to MAPA official laboratories network – National Agricultural Laboratories (Lanagro) – and MAPA accredited private laboratories [4]. MAPA's demand on method development and validation in residue analysis has been increased in the last decade due to the increased role of the Brazilian livestock products in national and international markets and meanly to ensure that the products traded are compliant with the safety and quality criteria required by consumers [4,5]. Wherefore, our laboratory has absorbed one important fraction of this demand in developing, validating, and submitting for accreditation methods for analysis of antimicrobial and non-antimicrobial residues in different matrices, such as milk and edible tissues of different animal species including cattle, pork, poultry, and even fish [6–10]. For these purposes, international guidelines, such as Commission Decision 2002/657/EC concerning the performance of analytical methods and the interpretation of results, and others from the US Food and Drug Administration (FDA) and the International Conference on Harmonization (ICH), are used in order to obtain methods validated according to the most stringent international criteria [11–14]. Within this issue, especial attention is paid to matrix effect (ME), which is a fundamental parameter to be determined, assessed and minimized especially when

liquid chromatography–mass spectrometry (LC–MS) and/or tandem mass spectrometry (LC–MS/MS) methods are used [15–19]. The conceptualization of this phenomenon has been comprehensively reviewed by a number of authors [15,16,20,21]. Briefly, ME is related to the alteration of ionization efficiency in the ionization source by the presence of coeluting substances: the occurrence of endogenous substances originally present in the sample itself and that remains in the final extract, are appointed as the major source. A wide scope of molecules can lead to signal suppression or enhancement, especially when occurs in high concentration in the extract and elute in the same retention time window than the analyte [22]. A secondary cause are substances not originally present in the samples but able to migrate to extracts during sample preparation process as polymer and phthalates or material released by stationary phases, in bulk or in solid phase extraction (SPE) cartridges, for instance [20]. Normally, this alteration affects dramatically the method accuracy and precision and has been regarded as a critical validation item by most guidelines consulted. However, there is no consensus on how this phenomenon should be assessed during method validation. Beside, different experienced approaches of ME evaluation, based on procedures published in the scientific literature such as post-column infusion, calibration curves comparison, quantitative estimation based in standards, spiked samples and matrix-matched control comparison and control charts evaluation, has been experienced [23–27].

Although the knowledge on ME in mass spectrometry analysis has been improved in recent years, only few practical approaches has been reported for routine analysis [28–31]. In the present work, practical approaches to detect and estimate the occurrence of ME in qualitative and quantitative terms in LC–MS/MS methods for veterinary drugs residues analysis are presented and discussed. Tools for monitoring ME along the execution of routine methods are also reported. Without the purpose to exhaust the issue, the present study is proposed as a walkthrough based in relatively simple and easy techniques to be applied to analytical chemistry laboratories to deal with the critical theme of matrix effects in residues analysis.

2. Materials and methods

2.1. Analytical standards and reagents

Analytical standards with high purity ($\geq$99%) were obtained from Sigma-Aldrich (St Louis, MO, USA) namely sulfamerazine (SMR), sulfamethazine (SMZ), sulfamethoxazole (SMA), sulfamethoxypyridazine (SMPZ), sulfadiazine (SDZ), sulfapyridine (SPY), sulfadimethoxine (SDMX), sulfaguanidine (SGA), sulfacetamide (SCA), sulfabenzamide (SBZ), sulfisomidin (SIM), sulfamethizole (SMTZ), sulfaquinoxaline (SQX), sulfathiazole (STZ), sulfaisoxazole (SIX) and sulfadoxin (SDX). The metabolite N^4-acetyl-sulfamerazine (N^4-SMR) and the isotopically labelled compounds d^4-sulfamethoxazole (d^4-SMA), d^4-sulfamethazine (d^4-SMZ) and d^4-sulfadiazine (d^4-SDZ), used as surrogate and/or internal standards, were purchased from Toronto Research Chemicals (North York, Ontario, Canada).

Methanol (MeOH), acetonitrile (ACN), hexane and acetone of HPLC-grade were supplied by J. T. Baker (Deventer, The Netherlands). Diatomaceous earth was supplied by Agilent Technologies. Acetic acid and water (HPLC grade) were purchased from Merck (Darmstadt, Germany).

Individual stock standard solutions were prepared in MeOH: acetone (50:50) at 1 mg mL^{-1} and stored at −4 °C until use. Standard solutions of the mixtures of all compounds in appropriate concentrations were prepared by stock solutions dilutions using MeOH or acetone. Aliquots of each stock standard solution were diluted to obtain final concentrations of 10 μg mL^{-1} and 1 μg mL^{-1} and were stored at −20 °C.

2.2. Samples and sample preparation

Liver of different food production animals, chicken eggs, and fish muscle were obtained from Federal Inspection Service (SIF) or collected from treated animals in a farm. Liver and muscle samples were manual and finely chopped and homogenized in order to avoid slurring. Egg samples were manual and gently homogenized in order to avoid protein denaturation. After these processes, all samples were stored at −20 °C before extraction step.

Liver and fish samples were extracted by two different methods based on pressurized liquid extraction (PLE) and by ultrasounds-assisted extraction (US). A detailed discussion about these methods and validation results were submitted to publication. For PLE, an ASE 350 accelerated solvent extractor (Dionex, Sunnyvale, CA, USA) was used. Prior to extraction, d^4-SMA, d^4-SMZ and d^4-SDZ were added as surrogate standards in a concentration of 100 ng g^{-1}. Samples (0.5 g) were mixed into the PLE cells with diatomaceous earth as dispersing agent. Prior to extraction, the cells were submitted to a clean up method in order to remove lipids from the samples using hexane as solvent. PLE parameters were as follows: temperature 60 °C, 4 cycles of 5 min each one. Total flush volume of 80% and 300 s of purge with nitrogen flow were applied.

After that, the same PLE cells were submitted to a second extraction process using ACN with 0.2% acetic acid as extraction solvent. In this case, the extraction temperature was optimized at 90 °C. A preheating period of 8 min was selected and 3 cycles of 7 min each were carried out. A total flush volume of 80% and 60 s of purge with nitrogen flow were applied. Pressure was set at 1500 psi as it has been demonstrated that this parameter is not decisive in PLE.

The extracts were maintained in freezer by 1 h (at −18 °C) in order to promote protein precipitation. Following, samples were centrifuged at 1500 × *g* for 10 min in a 5810R centrifuge (Eppendorf). The supernatant was evaporated at 40 °C under nitrogen flow using a Turbo-Vap system (Zymark) until dryness. Extracts were redissolved in 1.0 mL of mobile phase mixture (water-ACN, 85:15) and transferred to a HPLC vial.

In ultrasound-assisted extraction, samples (0.5 g) were weighted in 15 mL polypropylene tubes and spiked as described for the PLE method. Following, 10 mL ACN were added and tubes were mixed in a mechanical vortex by 10 s. Afterwards all samples were placed into an ultrasonic bath for 1 h. and then stored in freezer (−18 °C) for 1 h. to promote protein precipitation. Then, samples were centrifuged at 1500 × *g* for 10 min. Supernatant was brought to dryness at 40 °C under a gentle nitrogen stream. The extracts were redissolved in 2.0 mL of the mobile phase mixture. An aliquot of 2 mL of hexane was added to remove the fat content. Afterwards, tubes were mixed in a vortex for 5 s followed by centrifugation (3500 rpm for 10 min). The lower layer was carefully transferred to a HPLC vial.

Sulfonamides analysis in eggs samples was performed as described elsewhere [32]. Briefly, samples were extracted with ACN and concentrated before reconstitution with mobile phase.

2.3. Instrumentation

LC analysis was performed with a Symbiosis™ Pico System (Spark Holland, Emmen, The Netherlands), equipped with a HPLC system consisting of an Alias™ autosampler, a loop injector and two binary pumps with a four-channel solvent selector for each one. Chromatographic separation was performed using a HPLC column Purospher® STAR (C18, ec, 150 × 4.6 mm, 5 μm) preceded by a guard column with the same packing material. The flow rate was set to 0.2 mL min^{-1}, being eluent (A) HPLC grade water acidified with 10 mM of formic acid, and eluent (B) ACN with

10 mM of formic acid. The elution gradient started with 25% of eluent (B), increasing to 80% in 10 min and to 100% in 11 min. During the next 2 min the column was kept at 100% (B), readjusted to the initial conditions in 3 min and equilibrated for 7 min. MS/MS analyses were carried out in a 4000 QTRAP hybrid triple quadrupole-linear ion trap mass spectrometer (Applied Biosystems, Foster City, CA, USA) equipped with a turbospray ionization source (ESI) working in the positive mode (ESI+).

For fish and egg analysis, the LC–MS/MS system was an Agilent 1100 series LC (Santa Clara, CA, USA) with a quaternary pump, a vacuum degasser, and an auto sampler, coupled with an API 5000 triple quadrupole mass spectrometer (Applied Biosystems, Foster City, CA, USA) with an electrospray ionization source (ESI).

The optimization of the MS/MS experimental conditions was performed in previous studies and are presented in our work published elsewhere (OR: in this same issue) [33]. For increased sensitivity and selectivity, MS/MS data acquisition was performed in the selected reaction monitoring (SRM) mode, recording the two most intense transitions from the precursor ions to the product ions.

2.4. Post-column infusion method

Post-column infusions of individual standards into the MS system were performed to verify the ME of the extracts obtained for all methods, in order to verify if the whole extract or some elution fraction of the extract cause signal suppression/enhancement. This procedure was based on the experiments described by Bonfiglio et al. [23]. Briefly, blank samples extracted by the above-mentioned methods were injected into the LC–MS/MS system under the chromatographic conditions optimized for each methodology. For each injection, a standard solution of individual compound was infused into the MS system using an infusion pump, at a flow rate of 10 μL min^{-1}, through a tee-joint installed post-column. Standard solution concentration was 100 ng mL^{-1}. ME were evaluated observing signal attenuation or signal enhancement on the response of the infused analyte.

2.5. Calibration curves evaluation method

A calibration curve was prepared using standard solutions diluted in pure solvent or in mobile phase (external Standard calibration curve or "*S*"). A second calibration curve was prepared spiking a blank matrix and following with the extraction and/or cleanup procedure (Recovery calibration curve or "*R*"). Finally, a third calibration curve was made using a extract of a blank sample, which was submitted to the whole extraction and/or cleanup procedure and was spiked with standard solution at the end of the protocol, generally in the final dilution, immediately before injection (Tissue Standard calibration curve (matrix-matched) or "*TS*"). These calibration curves were prepared with the same number of points or replicates to obtain the same expected concentration in the three kinds of curve. Usually, the MRL is the central point and are constructed with a minimum of 6 point. For a MRL value of 100 μg kg^{-1} (as in the case of sulfonamides in liver), calibration curves comprehends 0, 25, 50, 100, 150 and 200 μg kg^{-1} levels. All curves were prepared and analyzed in the same batch for a more accurate comparison. After analysis, the curves were plotted and inspected visually and statistically.

Alternatively, ME was evaluated using slope ratios comparison according to the approach proposed by Romero-Gonzáles et al. [34] and Sulyok et al. [35] in a modified application of the quantitative approach of Matuszewski et al. [24]. Slopes are compared between each pair of curves obtained in the linear calibration curves prepared by spiking mobile phase (*S*), blank sample (*R*), and extract of blank sample (*TS*). Slope ratios below 0.9 or above 1.1 were associated with ion suppression and ion enhancement, respectively. For values inside that range, ME was considered negligible.

To differentiate between extraction efficiency and matrix-induced signal suppression/enhancement, the slope ratios of the linear calibration functions were calculated to yield the recovery (RE), the signal suppression/enhancement due to ME and the relative recovery, i.e. the recovery of the extraction step (RE_R) as follows:

$$RE(\%) = 100 \times slope_{spikedsamples}/slope_{liquidstandards} \quad (1)$$

$$ME(\%) = 100 \times slope_{matrix-matched\ standard}/slope_{liquidstandards} \quad (2)$$

$$RE_R(\%) = 100 \times slope_{spikedsamples}/slope_{matrix-matched\ standard} \quad (3)$$

2.6. Matrix effect quantitative estimation

The quantitative estimation of a ME, when present, was performed using a modification of the equations previously proposed by Matuszewski et al. [24]. This procedure allows determination of the ME along with the RE_R and overall "process efficiency" or method overall recovery (RE) by comparing the absolute peak areas of 3 sets of samples. Set A is composed by standard solutions (*S*). Set B is composed by samples spiked after extraction (*TS*) and set C is prepared with samples spiked before extraction (*R*). Since the values have been obtained, ME, RE_R, and RE values can be calculated as follows:

$$ME(\%) = (B/A \times 100) - 100 \quad (4)$$

$$RE_R(\%) = C/B \times 100 \quad (5)$$

$$RE(\%) = C/A \times 100 = (ME \times RE_R)/100 \quad (6)$$

2.7. Control chart

Control charts are a useful tool for the monitoring of the analytical method behavior along with-in-batch and batch-to-batch variations including those due to ME. Within this purpose, for each analysis batch, 6 quality control samples (QC) spiked at the MRL concentration level for all compounds analyzed in each method were obtained. These QC samples, as described above, are composed by 3 samples spiked after (*TS*) and 3 samples spiked before extraction (*R*). Analyte peak area of each QC sample plus standards in pure solvent are plotted in a spreadsheet using Excel software. The cells include a formula to provide average, relative standard deviation and the upper and lower limits for ME, calculated according to the control chart parameters.

3. Results and discussion

As aforementioned, there is no consensus on how ME should be evaluated during method validation, neither on the criteria that should be adopted in establish when these effects are or not occurring [36]. However, according to recent literature, two main procedures have been used to determine ME on LC–ESI–MS/MS analysis: post-column infusion, which is a dynamic technique that provides qualitative information on where ME occur along the chromatographic run; and post extraction addition, which is a static technique that quantitatively provides the ME degree at the analyte retention time [20,37]. The last technique has been preferentially used to evaluate and compare ME of different matrices in terms of relative ME. In order to evaluate the most reported approaches to ME estimation, data of two in-house developed and validated methods were used as an example.

3.1. Case study: Determination of sulfonamides (SAs) in liver, muscle and fish using two extraction procedures

Two extraction methods were developed and validated for analysis of SAs residues in liver, muscle and fish. The complete development, optimization and validation data for both methods were recently submitted to publication. Both, the PLE and the US methods were previously evaluated by their potential ME using all the described approaches.

3.2. Post-column infusion method

First, blank extracts from each extraction method were injected in a post-column apparatus for comparison with pure mobile phase in order to evaluate the variation of the standards mixture signal.

The chromatographic separation of SAs was achieved using a modification of the method published elsewhere [33,38]. Some SAs had very similar chromatographic retention time (coeluting), but were well resolved as individual peaks in the MS/MS SRM mode. The detailed optimization and discussion about the chromatography method are presented in our report published in that same issue.

To evaluate ME, first we investigated if the extraction methods could contribute with co-extractive substances that might suppress selectively the different temporal regions of the chromatogram.

As can be observed in Fig. 1, both PLE and US extracts presented signal suppression in some regions of the chromatogram. This suppression effect is more intense in the 5–6 min region. Mobile phase signal (MP, grey line) shows a standard solution infused in a post-column "*T*" connection, over a mobile phase injection. PLE (black line) and US (dashed black line) represent the signal of the respective blank extracts. The standard solution was a mixture of all analytes at a concentration level of 100 ng mL^{-1}. Any line represents a TIC signal for all monitored SRM transitions (> 36). *TS* signal is a TIC chromatogram for a blank sample spiked at 100 ng mL^{-1} injected in normal mode. The signal was multiplied by a factor of 20 times for a better comparison with the post-column infusion chromatograms. PLE and US showed very similar matrix effects over the standard signal. In the region 11–22 min both signals were virtually overlaid. In summary, analytes do not elute in the most critical suppression zones. Thus, the chromatographic conditions could be used without modifications.

3.3. Calibration curves approach

As explained before, the use of calibration curves to estimate ME can be performed in many ways. Herein, examples of each interpretation mode are demonstrated.

3.4. Graphical plot—Visual and statistical analysis

Once the 3 curves are analyzed and plotted, the following situations are considered:

Situation 1. A similar slope, non-similar intercepts. Similarity between slopes show that matrix do not interfere in the linearity of the responses. The difference between intercepts is given by the losses caused by the sample preparation process. It is expected a lower response for *R* curve. If *TS* and *S* curve could be overlapped, there is no ME. If those curves have non-similar behaviour, ME is present, but it is affecting only the signal, not the linearity. Any kind of curve can be used in this method, if an appropriate correction is applied to adjust response losses. Fig. 2 shows an example of this situation.

Situation 2. Non-similar slopes: linearity is distinct between curves. If *TS* and *R* curves had similarity in the slopes, this means that the presence of the matrix itself change the responses. In this case, only *TS* or *R* calibrations curves may be used in this method. Fig. 3 gives an example.

Situation 3. TS and *S* curves are totally overlapped. There is no ME. However, if *R* curve shows differences in intercept and slope, this means that sample preparation process change significantly the response. Thus, *R* curves may be used. See Fig. 4 for an experimental data example.

Situations 4. All curves are perfectly overlapped. No ME and recovery equals or very closely to 100%. Presumably this is just a theoretical possibility.

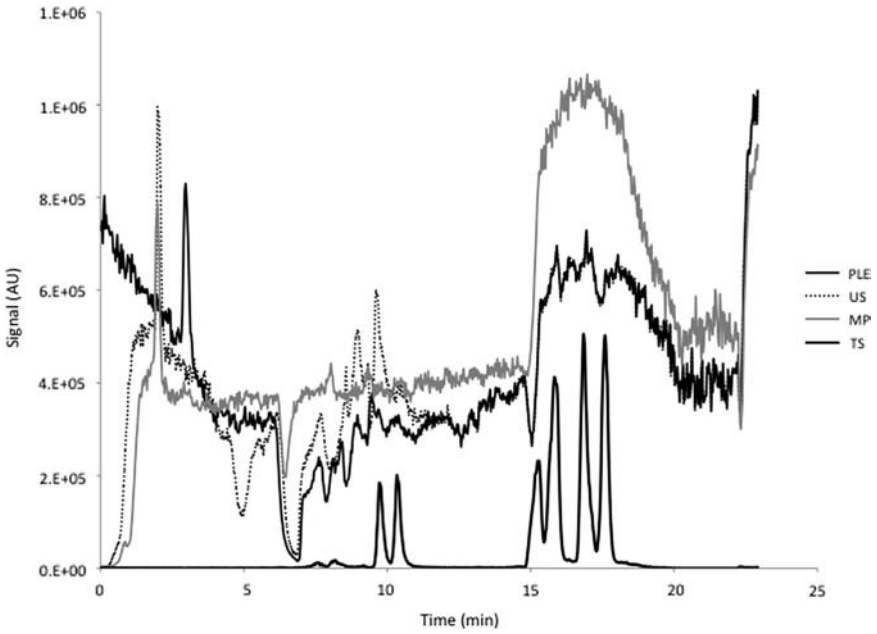

Fig. 1. Total ion chromatograms of post-column experiments. Continuous black line is a pressurized liquid extraction (PLE) blank extract; dashed black line is a ultrasound-assisted extraction (US) extract; grey line is mobile phase injection (MP) and the lower chromatogram in bold black line is a spiked tissue extract injected without post-column infusion in order to identify the elution window of the target analytes (*TS*).

In some cases, a matrix can exhibit high heterogeneity from sample to sample, which can cause significant alterations in ME [39]. This situation must be also evaluated in method development and validation. The simple superposition of plot is useful to distinguish between each calibration curve. But in some cases statistical analysis must be performed to elucidate the variation. For slope variation values, a *F*-test is applied. If $F_{cal} < F_{tab}$, the *F*-test is not significant (5% significance level), and it can be considered that the variances are similar.

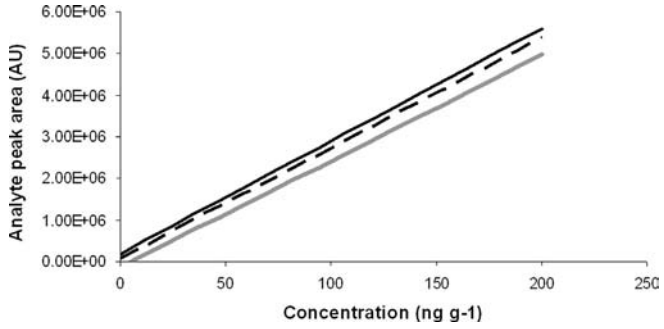

Fig. 2. Calibration curves comparison for ME evaluation: similar slopes, non-similar intercepts. Continuous line is *S* curve; dashed line is a *TS* curve and grey line represents an *R* curve.

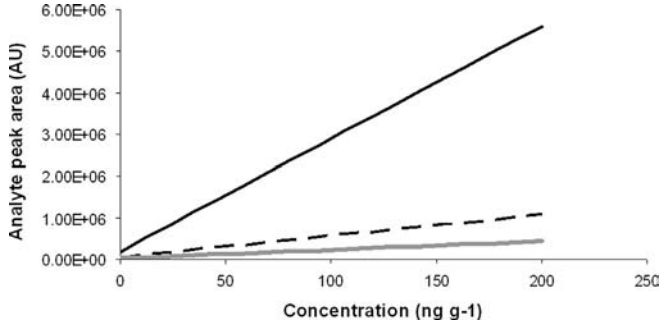

Fig. 3. Calibration curves comparison for ME evaluation: non-similar slopes. Continuous line is *S* curve; dashed line is a *TS* curve and grey line represents an *R* curve.

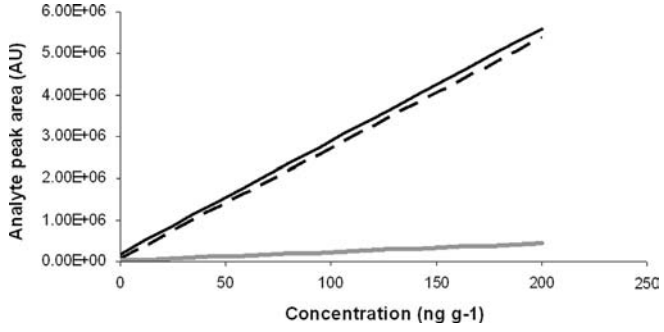

Fig. 4. Calibration curves comparison for ME evaluation: absence of ME. Continuous line is *S* curve; dashed line is a *TS* curve and dotted line represents an *R* curve.

For instance, from statistical comparison for sulfamerazine analysis in liver using matrix-matched calibration curves prepared by 2 distinct extraction methods (PLE and US) we obtained $F_{cal} < F_{tab}$ (F_{cal}=0.10 and F_{tab}=12.22 (0.05, 1, 4)) which means that the variation difference between extraction methods (PLE and US) is not significant. The slope, intercept and respective variances of both curves were calculated by the ordinary least squares method. Based on the results it was possible to conclude that PLE and US extraction methods gave equivalent responses for this analyte. In other words, matrix effects between these sample preparation methods are similar. In practical terms, it is possible to use a calibration curve prepared by US to quantify samples prepared by both methods or conversely. Similar behaviour was observed for other sulfonamides. Notwithstanding, a group of analytes was considered statistically distinct. Results are shown in Table 1.

3.5. Slope ratio and mathematical model for slopes comparison

Using Eqs. (1)–(3), quantitative values for ME and recovery were obtained (see Table 2). The slopes obtained in the calibration curve using matrix-matched samples were compared with the values obtained with standards in pure solvent. Besides the equations, slope ratio was calculated for each pair of curves to the 17 SAs included in the experiment. In this case, an acceptable range must be previously established. In the present study, a range from 0.9 to 1.1 was selected as lower and upper limits, respectively. The data were also demonstrated in Table 2.

As can be observed, using Eqs. (1)–(3), ME was very high varying from 9.4 to 73.5 % to PLE method and from 8.5 to 76.2% when US method was applied. That means an ion suppression extension as high as 91.6% in the case of SIZ, for instance. In general terms, both PLE and US methods presented very intense and highly similar ME. The use of slope ratio with acceptance limits of 0.9–1.1 shows agreement with the data obtained using the equations: an extremely intense ME for both PLE and US methods and a high degree of agreement between ME produced by PLE and US methods. When slopes of *R* and *TS* curves, some analytes showed a ratio value between tolerance range indicating no significant difference between those curves. The only analyte that showed a selective behaviour was SCA, which was the sulfonamide that suffered less effects of the matrix.

3.6. Quantitative estimation

Several degrees of ME were demonstrated, highlighting the huge variability among matrices. Depending on matrix nature, co-extractives can produce ion suppression or enhancement. For instance, Table 3 shows the quantitative ME data for some sulfonamides in fish and eggs. In the case of fish method, ME is present in the range of 30 to 40% of signal losses. RE and RE_R were in the ranges 25–41% and 46–79%, respectively. In other words, only ME can be responsible for approximately half of losses, if recovery will be considered as losses of extraction method plus

ME=matrix effects; RE=Recovery; RE_R=Relative recovery.

losses by ion suppression. In the case of eggs, matrix is characterized by the intense presence of phospholipids, which are also related with a highly intense ME, causing analytes losses from 95 to 97% [40]. However, in the case of sulfonamides in eggs, recoveries were satisfactory, from 80 to 102%. The selected cases demonstrate a common profile of ME (fish) besides an extreme case (eggs), but are useful to exemplify the co-existence between intense ME and high recovery values (> 80%). The data corroborate that ME is independent of the recovery. For the eggs case, another extraction protocols should be evaluated, in order to remove the co-extractives [32].

3.7. ME continuous monitoring using control charts

The estimation of the ME during a validation procedure is mandatory, because it is used for several matrices more or less distinct those used during validation. A method for ME behavior monitoring intra-batch and inter-batch will be always necessary. Moreover, monitoring itself is not the complete task: if ME are changing, QC samples must reflect this change and procedures to assess these modifications must be available to the analyst.

Using the same kind of QC samples (*S*, *R* and *TS*) in every batch, all necessary information about the method accuracy will be available at any moment, for any batch. Accuracy data for QC samples will provide data to build a control chart to monitor ME, recovery and method accuracy.

Control charts are very useful tools to monitor analytical methods behaviour. Over time, minor and major changes were naturally occurring in routine methods. Thus, ME could be suffering changes and method adjustments will be necessary to guarantee the adequate fitness to purpose. For ME monitoring, quality control samples were inserted in each analysis batch and the results were calculated according to the quantitative ME estimation. Control charts present lower and upper limits. These limits are based on the standard deviation observed in the series. Lower and upper limits can be used as warning limits (using the average multiplied by 2 times the standard deviation), to observe trends in the results and apply preventive action before the method exceed the upper or lower limits based in 3 standard deviation values.

Table 4
Accuracy acceptability criteria.

Concentration level	Range
$\leq 1\ \mu g\ kg^{-1}$	$-50a+20\%$
$>1\ \mu g\ kg^{-1}\ a<10\ \mu g\ kg^{-1}$	$-30a+10\%$
$\geq 10\ \mu g\ kg^{-1}$	$-20a+10\%$

Acceptance criteria follow those described in 2002/657/EC Commission Decision and Brazilian analytical quality assurance guidelines [11,41]. To evaluate accuracy obtained by routine data, a critical analysis of QC samples results is performed for every batch in accordance with limits showed in Table 4.

QC samples data ($n=3$ by batch) were plotted on control charts and critically analyzed. Results for each routine analysis should be reviewed, and in case of non-compliance with criteria, it must be recorded. For a batch, if the review of QC samples shows non-

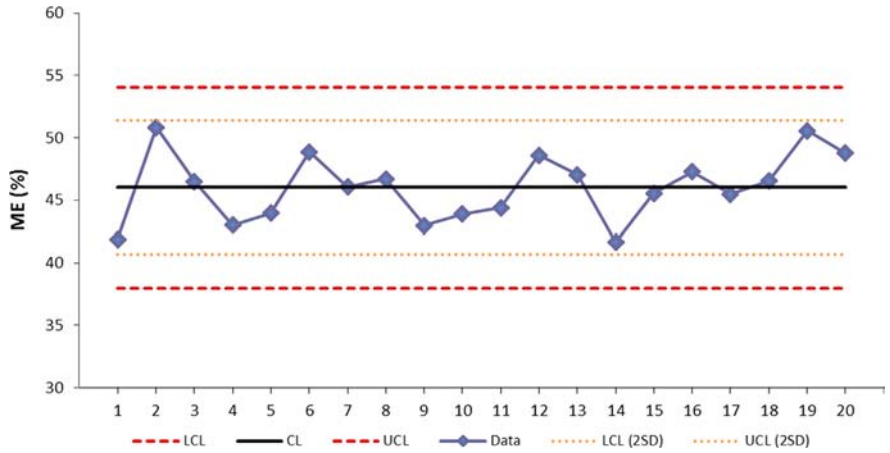

Fig. 5. Plot for matrix effects monitoring for sulfadiazine determination in liver. ME=Matrix effect; CL=central limit; UCL (2SD)=upper control limit based on 2 standard deviation; UCL=upper control limit; LCL (2SD)=lower control limit based on 2 standard deviation; LCL=lower control limit.

compliances in relation to acceptance criteria, appropriate corrective actions must be taken. Fig. 5 shows an example for ME monitoring to a sulfonamide residue analysis in liver samples. In that example, data of ME (in %) for SDZ obtained from 20 batches were plotted. The central limit (CL) was 46.4%, with an average standard deviation of 2.6%. Lower and upper control limits were obtained by adding or reducing the standard deviation value (multiplied by 2 or 3) from CL.

3.8. General remarks: Matrix effect assessment in routine methods

Concisely, in our laboratory, the following workflow is used to evaluate, minimize and monitor ME:

i. In method development, qualitative and/or quantitative approaches for ME determination can be used for analytes and surrogates/internal standards: the results can help to decide what kind of calibration curve could be used, depending on the extension of ME observed.
ii. Extraction protocols can be modified or improved to avoid co-extraction of matrix compounds: a SPE method could be more adequate than LLE, for instance. Different solvents or solvent mix can be critical to minimize ME.
iii. Once ME is observed, the post-infusion protocol is used to determine in what chromatogram region the suppression occurs.
iv. Mobile phase gradient and/or additives can be modified in order to provide analytes elution in a region with absence of suppression. Generally, just simple changes in the gradient composition are adequate to promote separation of the analytes elution window form zones with intense signal suppression. In extreme cases, solvent and even column change could be necessary.
v. Extract injection volume can be reduced in order to decrease ME, except when the analyte responses does reduce in the same extent.
vi. Evaluate the effect of surrogate/internal standards in the correction of ME.
vii. If even with these changes, ME still remain relevant, the magnitude of the effect can be monitored during routine analysis, using an accuracy control chart.

In validation data, a differentiation between recovery and ME must be clear. In mass spectrometry analysis, recovery can be deeply affected by ME although the sample preparation process showed high efficiency. As ME directly affects the yield of analytes ionization, method overall recovery have a correlation with the ME extension. In the present work, we refer to the IUPAC's recovery concept, which is the analyte yield obtained after the extraction procedure [42]. The "apparent recovery", according to IUPAC, is the degree of agreement between the nominated and calculated concentration. We use the term "relative recovery" to express the recovery value discounting the ME. Relative recovery represents the analyte losses caused only by the extraction procedure. Thus, this term should not be confused with the term "apparent recovery".

Summarizing, recovery includes losses of target compounds throughout the whole sample preparation process (extraction, concentration, derivatization, etc) plus the eventual ME. RE_R is the loss of analytes caused by the sample preparation but not include the ME.

Several approaches were considered to ME evaluation. Clearly, the methods that can be used before the method validation are more useful. The obtained data can be used to make changes or adjustments in the extraction and/or chromatography conditions to avoid or minimize the impact of ion suppression/enhancement. Once adequate conditions were established, remaining ME could be estimate using a simple approach as those based in calibration curves or QC samples. If ME is relevant in a routine method, ME could be monitored using a control chart in order to detect advance changes in method behaviour.

4. Conclusions

ME is a very frequent issue in bioanalytical methods, especially in LC–MS and LC–MS/MS based methods. Despite the fact that currently there are no established acceptable limits for ME, it is a consensus that their magnitude must be estimated and, if possible, minimized. Thus, analytes extraction procedures and/or chromatographic conditions changes could be carried out. In literature, several approaches to estimate ME were reported. Herein, we report our experience with ME estimation, minimization and continuous monitoring, applying several ME estimation strategies for analytical methods which are used in routine analysis in our laboratory. Each technique was discussed and their advantages and/or drawbacks were appointed, in order to provide a practical guide for researchers interested in assessment of ME. Based on the experience with these several techniques, the ME evaluation must be performed before the validation, using the quantitative estimation and post-column infusion, concomitantly. Using this procedure, all necessary changes and adjustments could be assessed before the validation process, improving the quality of the results and overcoming the undesirable ME.

Sargassum muticum
Geographical origin discrimination
Latitudinal gradient

ABSTRACT

Two recent techniques based on chemical footprinting analysis, HRMAS NMR and FTIR spectroscopy, were tested on a brown macroalgal model. These powerful and easily-to-use techniques allowed us to discriminate *Sargassum muticum* specimens collected in five different countries along Atlantic coasts, from Portugal to Norway. HRMAS NMR and FTIR permitted the obtaining of an overview of metabolites produced by the alga. Based on spectra analysis, results allowed us to successfully group the samples according to their geographical origin. HRMAS NMR and FTIR spectroscopy respectively point out the relation between the geographical localization and the chemical composition and demonstrated macromolecules variations regarding to environmental stress. Then, our results are discussed in regard of the powerful of these techniques together with the variability of the main molecules produced by *Sargassum muticum* along the Atlantic coasts.

1. Introduction

Sargassum muticum is a brown macroalga native from Japan and widely spread along the European Atlantic coasts [1–6]. Distributed from Northward to Southward of Europe, it can be found nowadays from Norway to Portugal, demonstrating its large capability to adapt to different climate conditions (temperature, irradiance, hydrodynamism). This large sustainable biomass could represent a viable biotechnological asset in the European resource development programs. For this reason, *S. muticum* was collected in three sites of five countries (Portugal, Spain, France, Ireland and Norway). The present study is integrated in a global approach to find applications of the huge biomass of *S. muticum* observed along the Atlantic coasts. Previous works carried out on French populations highlighted interesting properties such as anti Reactive Oxygen Species (ROS), i.e. antioxidative [7–11] or antibacterial, antibiotic or antifouling, properties [12–15] of polar and apolar extracts and semi-purified fractions from *S. muticum*. The aim of our present study was then to obtain an overview of the global biochemical composition of specimens from different countries using new techniques for this purpose, and for the end, to know if *S. muticum* populations present or not a chemical adaptation along Atlantic coasts. Results on the lipid, protein or glucid macromolecules quantification are very used as indicators in biotechnology, especially in having information about the physiological state of the studied organism, reflecting for example the metabolic changes in answer to a given environmental stress.

In this context, we were interested in studying the biochemical composition of *S. muticum* populations collected along a latitudinal gradient, by using two non invasive techniques: the *in vivo* ^{1}H HRMAS NMR (High Resolution Magic Angle Spinning Nuclear Magnetic Resonance) and the infrared (IR) spectroscopy in order to pointing out or not the sources of chemical profile differences. These two techniques are used for about twenty years in various domains; the HRMAS NMR was already used in chemotaxonomy on various marine models to point out the differences between bacterial strains or algal species for example [16–20]. But this technique had only rarely used to follow physiological processes, in particular on seaweeds. Fourier Transform IR spectroscopy (FTIR) was still never used on macroalgae but was previously used to differentiate species of microorganisms or even strains [21–24]. These two rapid techniques are convenient as they use small

amount of sample thus permitting repeated manipulations (allowing a better reproductibility of the results). Finally, these two techniques allowed studying a wide range of molecules, and thus, pointing out very fine differences between samples. We selected then these two interesting techniques as a source of complementary information, FTIR allowing a global chemical variations analysis and the possibility to access to the content in the main macromolecules while HRMAS NMR allows to point out complementary chemical fingerprinting for a species or a given sample [17,19–20].

2. Materials and methods

2.1. Sampling sites and sample preparation

Thalli of *Sargassum muticum* were collected between March and May 2011 in three sites of five countries along a latitudinal gradient in Europe. Samples were collected, from South (March) to North (May), in respectively Portugal, Spain, France, Ireland and finally Norway (Table 1). Sampling period was chosen according to the physiological state of the alga in all the countries. During these periods, *Sargassum muticum* was still immature [1,6]. During collection, only the apical and median parts of the thalli were retained and the holdfast was left in place to allow regrowth and thus minimize collecting impact. Immediately after collection and epiphytes removal, specimens were firstly washed with filtered seawater then with distilled water in order to get rid of residual sediments and salts. The cleaned algal materials were then surface dried with blotting paper towel, chopped into fragments, freeze-dried, powder reduced with a Waring Blender and finally sieved at 250 μm.

2.2. HRMAS-NMR spectroscopy

All HRMAS NMR spectra were obtained using a Bruker DRX 500 spectrometer (Bruker BioSpin, Wissembourg, France) equipped with an indirect HRMAS $^{1}H/^{31}P$ probehead with gradient Z at 25 °C. A typical proton ^{1}H HRMAS spectrum consisted of 64 scans and it was performed with presaturation of the water peak. Each spectrum was phased and baseline-corrected using a polynomial function. Spectra data processing was performed using the software MestReNova 6.0.2 for Windows (Mestrelab Research S.L., Spain). Afterwards the data were subjected to statistical analysis using the Statistica 8 (StatSoft ®) software for PC. For HRMAS NMR, three independent samples per site were analyzed, which represent then a pool of 45 samples analyzed. About 5 mg of each sample were put in a zirconium oxide vial and set into a 4 mm MAS rotor. Around 30 μL of D_2O were added into the rotor with the sample for 2 H field locking (depending on the quantity of the freeze-dried powder). The sample was placed in a rotor spinning around an axis, which is oriented at the so-called magic angle of 54°7 with respect to the magnetic field B_0. Good homogenization and synchronization were obtained at a spinning rate of 5000 Hz. In this study, three HRMAS NMR spectra, corresponding to three independent records for each sample, were obtained by sample.

The statistical procedure used in this study was based on a cluster analysis to illustrate *S. muticum* geographical origin discrimination using HRMAS NMR analysis. Variables used to perform this analysis were the form of the peak (single, double, triple or massive peaks) together with the peak position (δ). These variables were determined for each HRMAS NMR spectrum (three for each site) between 0 and 7 ppm, since some chemical shifts appeared to be different in the samples depending on sites and countries all along this spectral region. We took into account only positive peaks with a noise factor of 4.00. The cluster analysis was then made using a matrix of absence/presence of the observed signals in order to summarize the *in vivo* chemical diversity of the samples.

2.3. FTIR spectroscopy

Infrared spectra were recorded in reflection mode directly on the single reflexion diamond crystal of the ATR (Attenuated Total Reflexion) accessory loaded with few milligrams of freeze-dried algal powder. The Bruker tensor 27 FTIR spectrometer equipped with the ATR platinum module, with a deuterated triglycine sulfate detector RT-DLaTGS and the OPUS v7.0.122 software (Bruker Optics, Germany) was set up with the following parameters. The spectral resolution was fixed to 1 cm^{-1}, the number of scans to 32, the selected spectral range between 4000 and 400 cm^{-1}. Background spectra were collected using the same instrument settings as those employed for the samples and was performed against air. Spectra were recorded for 3 technical replicates, i.e. 3 biological replicates, per site, representing a total of 45 samples analyzed for all studied countries. The recorded spectra were treated in group to compensate the CO_2/H_2O and the base-line effects and with the correction tools integrated into the OPUS software. The spectra were then smoothed using the Savitzky–Golay algorithm [25] but for presentation purpose only. For the multivariate analysis, the spectra pre-processing sequence was different and excluded the smoothing step, since it could

impact the resolution of the data, and therefore decrease the detection of putative important vibrators and their contribution to the FTIR signature. The CO_2/H_2O and base-line effects corrected replicate spectra were averaged to generate a new spectrum from the three original spectra of the same type, i.e. the new spectrum intensities were calculated by averaging original spectra intensities. Then, mean spectra were vector normalized first to account for differences in samples thickness commonly found when working on powders, and second derivative transformed to detect a maximum of vibrators (peak position) and enhance their contribution to the FTIR signature on the whole spectral range [26–29].

Multivariate analysis was performed on the mean, vector normalized, second derived spectra using the Metaboanalyst 2.0 pipeline [30]. Principal component analysis (PCA) and Cluster analysis were performed on those pre-processed spectra. Then the replicate spectra were averaged to generate a new spectrum from the three original spectra of the same type, i.e. the new spectrum intensities were calculated by averaging original spectra intensities. Afterwards the data were subjected to cluster analysis employing the Ward's algorithms and using the second derivative and vector normalization preprocessing method to calculate inter-spectral distances (Euclidian distance).

3. Results and discussion

The ^{1}H HRMAS NMR spectra comparison shown on Fig. 1A (only one spectrum was selected for each country) revealed some differences between the five different sampled countries. As visible on the Fig. 1B, countries presenting the least homogeneous grouping are Spain and Ireland, where the site 1 is different from the two others. This corresponds to the measured geographical distances between the different sites (Table 1). In every case we can notice a clear distinction between the five countries. Some areas present a larger variability, as for example: the aromatic domain towards 5.5 and 6.5 ppm, the edge of peaks between 3.0–5.5 ppm, which corresponded to polyols described as mannitol in *S. muticum* [19], the proportions of the amino acid glutamine/glutamates (carboxylate anions and salts of glutamic acid), against the malic acid/malates (esters and salts of malic acid) (peaks around 2.0–2.5 ppm As N. Kervarec is a co-author of this paper) and some unsaturated fatty acids towards 1.0–1.5 ppm (Fig. 1A). Some countries are recognizable rather easily thanks to certain characteristic peaks, as for example the peak towards 2.6 ppm very marked in Spain and the peak at 2.91 ppm very marked in Ireland (Fig. 1A). We can also observe in a general way that sugars (3.0 to 5.5 ppm) are more plentiful and diversified in Norway, France and Portugal while more lipidic compounds (0.8 to 3.0 ppm) are found in Ireland, France and Spain. In view of spectrum it would be rather saturated lipids; even if some unsaturated ones are visible in France and Spain for example towards 4.8 ppm. Differences of composition in fatty acids were already observed in other *Sargassum* species collected from two different geographical zones but never within the same genus [31]. Fig. 1 shows that chemically closed populations resulted from places geographically closed, which is not the case of FTIR dendogram presented on Fig. 3, where the grouping is different. Indeed, populations in Spain and France are the most similar while populations in Norway present the "most original" profile compared with those of the other countries. Samples providing from Norway contained a great amount of malate and sugars (3.5 and 4.5 ppm). The geographical position of populations belonging to the same species has a real effect on chemical composition and this effect is adequately important for allowing their differentiation according to their origin. However, some authors affirm that, in brown algae, geographical variations of marine algae metabolites composition were non-significant [32–33] and could be further due to seasonal variations in *S. muticum* metabolites content [34]. This bias was avoided by

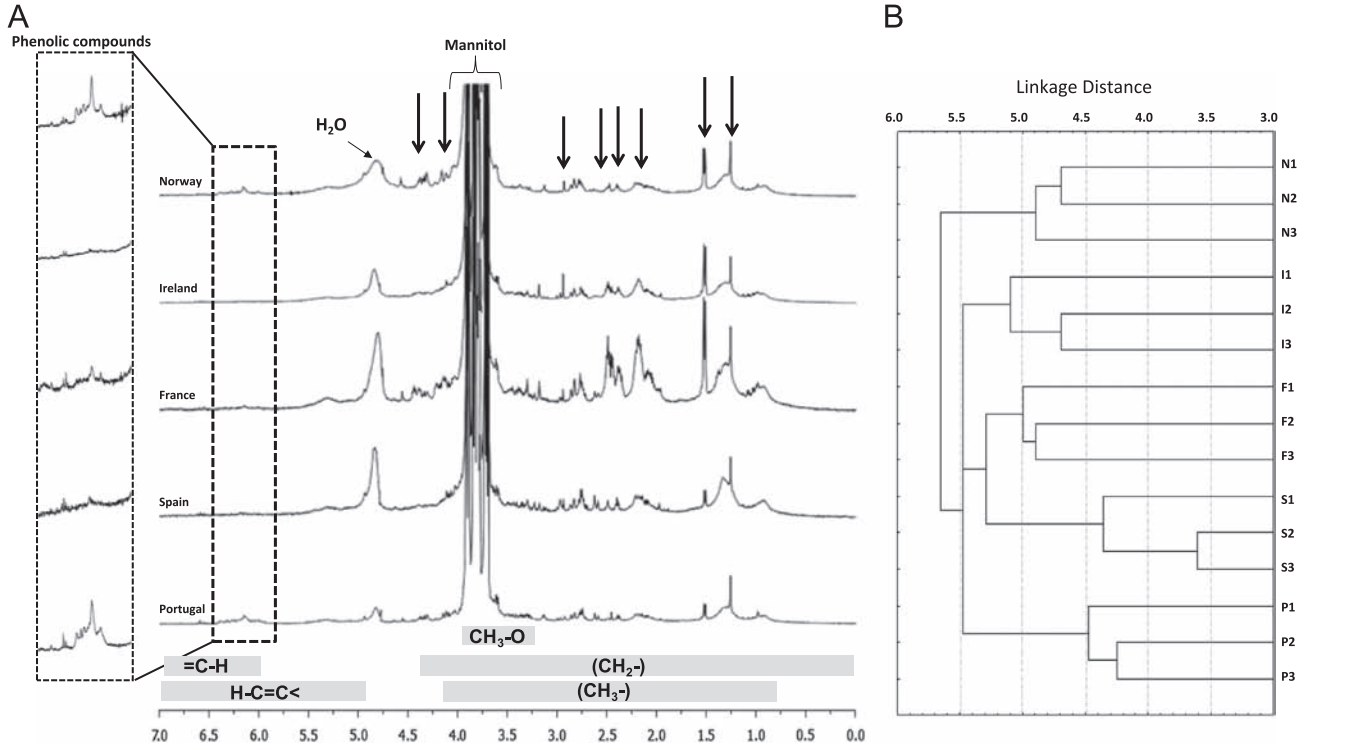

Fig. 1. (A) Typical ^{1}H HRMAS NMR spectra of *Sargassum muticum* sampled in five different countries (only one spectrum is represented by country as the three spectra by site were all identical). Spectral regions are indicated in gray at the bottom and specific differences between countries by arrows at the top. (B) Cluster analysis based on 45 spectral observations issued from Norway (N), Ireland (I), France (F), Spain (S) and Portugal (P) with the numbers 1,2,3 representing the three sites sampled by country, regrouping the triplicate per site.

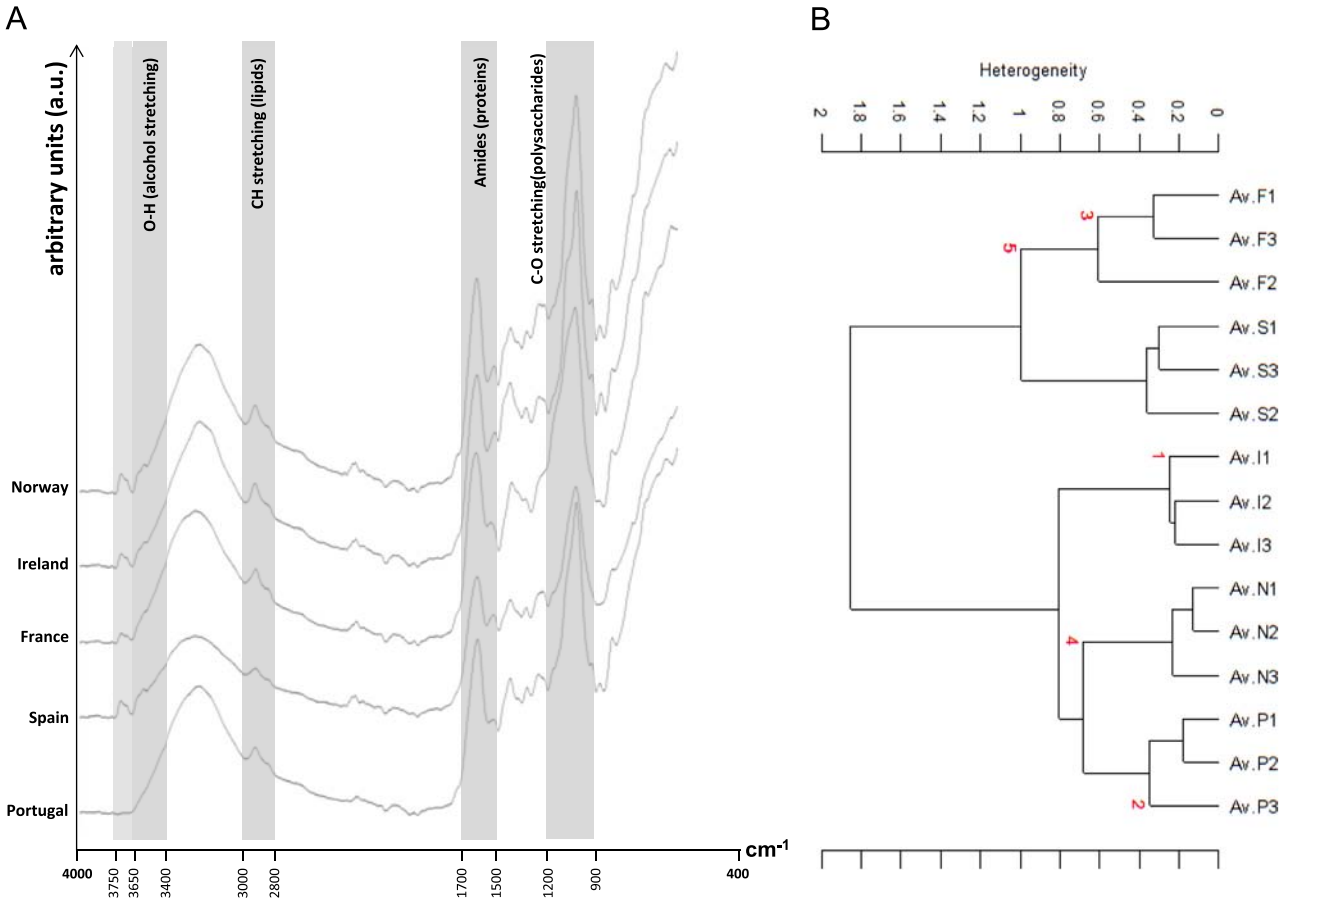

Fig. 2. (A) Spectra from analysis in FTIR of samples of *Sargassum muticum* (averaged spectra calculated by averaging the 3 sites spectra intensities for each country). (B) Cluster analysis performed using the second derivative and vector normalization of the spectra from 400 to 4000 cm^{-1}. The Ward's algorithm was used to build the dendrogam. Letters and numbers as on Fig. 1.

harvesting seaweeds in the various countries at the same physiological state during spring 2011 (Table 1). Nevertheless, the same experiment should be carried out during the other seasons to test the seasonality effect on the chemical contents. In addition, it would be also interesting to pursue this experiment on seaweeds collected at the same period the following years to see if the tendencies are confirmed from one year to the next. This technique showed that seaweeds coming from different geographical places could be differentiated by their biochemical profile. Blind assays were realized on spectra of unknown origin allowing to recognize their geographical origin (country and site) with 100% success except for samples resulting from Ireland where sites can be confused; the success rate was then 60% (data not shown). Those scores are upper than those obtained for similar studies [35–36] for food applications on aliment origin.

Fig. 2 permitted to obtain an overview of the intensity of peaks in specific areas of FTIR spectra. The highlighted areas corresponded to the major macromolecules spectral region [37]. Thus, few peaks are characteristic of a single sample. On the other hand, we can quote for example: a peak at 2965 cm^{-1} only visible in France and Spain; at 688 and 3594 cm^{-1} present for samples originated from Norway, Ireland and Spain. A great variability between countries was observed between 800 and 950 cm^{-1} and 1930–2560 cm^{-1}. The intensity of the vibrators bands composing an IR spectrum is proportional to the abundance of the chemical groupings in the analyzed sample (Beer–Lambert law). It is thus possible to obtain, besides the usually exploited qualitative data, quantitative or rather semi-quantitative information. FTIR spectroscopy permitted then to distinguish samples by their geographical origins (Fig. 2). The vector normalized second derivative spectral data were qualitatively analyzed using principal component analysis (PCA) for each algal sample, taking also into account the location of the collection in the considered country. In Fig. 3, results indicated that the five algal samples were clustered into five distinct groups, clearly associated to each geographical origin (axis 2, with a contribution superior to 17% of the total variability). Inside each cluster, it was moreover possible to distinguish subgroups according to the specific location of collection in a considered country (axis 1, with a contribution superior to 36% of the total variability). The clustering results clearly revealed that each algal sample could be distinguished according to its FTIR spectrum, exhibiting moreover differences for the three tested sampling sites for a considered country. Those observations suggested that each algal sample presented its own FTIR signature, depending on its particular chemical composition. Indeed, according to the work of [27–29] this spectral signature could be directly related to the relative amount of the matrix main constitutive molecules (at least lipids, proteins and carbohydrates), which were moreover in our case geographical/climate dependent.

Actually, numerous approaches are developed for the estimation of the relative or absolute intracellular metabolites abundance on the whole cell [38–39]. IR spectroscopy expresses here all its analytical potential compared with classical dosage techniques, because it is not invasive, fast and requires only some milligrams or even micrograms of biomass [40]. The recent works of [41] demonstrated in particular the possibility to estimate the effect of the light intensity variations or the nitrogen and sulfur concentrations on the lipids accumulation for the microalga *Chlamydomonas reinhardtii*. These spectral data immediately inform on the

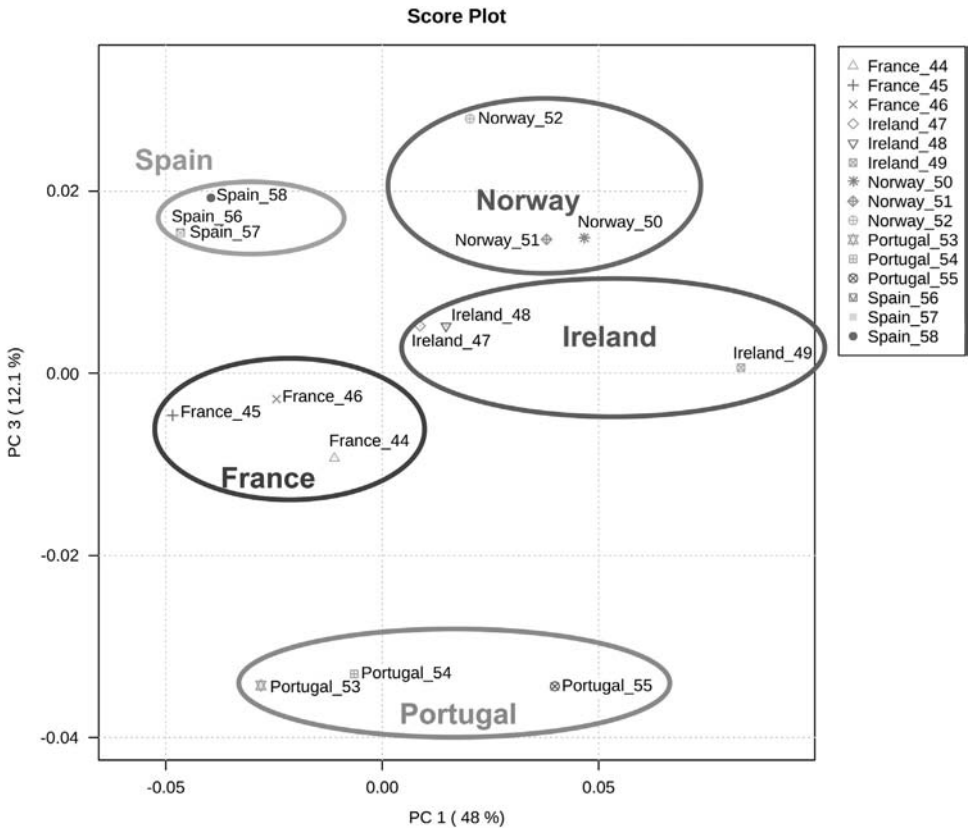

Fig. 3. PCA score plot of the vector normalized second derivative FTIR signatures of the various sample of *Sargassum muticum* collected in Norway, Ireland, France, Spain and Portugal. The legend in the upright corner details the name of the algal samples together with their site of collection and the geographical clusters are highlighted on the score plot.

presence or the absence (of detection) of a family of macromolecules with regard to another one for a given sample. It is also possible to compare the relative abundances of these molecules (since the concentration of one of them does not vary during the studied process) [38]. On the other hand, the exploitation of the bands intensity in the quantification applications absolved from these macromolecules requires taking precautions because the sources of IR spectra variations are numerous and they may modify the recorded intensities. Here, we can see on Fig. 3 that the proteins compartment (1400–1800 cm^{-1}) did not vary between samples while polysaccharides (1000–1200 cm^{-1}) and lipids (2800–3000 cm^{-1}) area were very variable [37]. Thus, polysaccharides were more present in Norway and France and lipids more present in France, Norway and Portugal. Except for the lipids compartment where the Spanish samples seemed to contain a lot of lipids in HRMAS NMR and not in FTIR, the results were close between the HRMAS NMR and the FTIR method. The fact is that for present Spanish samples, lipids were saturated for the greater part and thus very visible in HRMAS NMR while the IR gives us an image of total lipids content. But numerous factors influence the appearance of the recorded IR spectra. The relevant works of [42] underlined clearly the importance of these effects, which were widely ignored in numerous studies previous to their investigations. According to these authors, the spectral variations for a succession of samples can be attributed to four different factors: (i) the dispersal effect of a radiation produces wide fluctuations which overlap on the spectra [43] (ii) the presence of a nucleus is also going to modify and to amplify this distortion effect [42] (iii) the variations of intensity observed on the whole IR spectra can be attributed to the heterogeneousness of thickness of the sample and finally, (iv) the significant contribution of the signal of the water on the amide I (primary amide) area (3300–3400 cm^{-1}) [44] which can make difficult the interpretation of the obtained results. To get away from this type of problem it seems thus essential to choose bands with the least possible covering or when it is not possible, because of the complexity of the sample for example, to use more global processing methods which will thus exploit the influence of all the spectral contributions for a given sample. We found recently approaches of relative estimations of macromolecular microalgal contents using IR spectrometry as a routine technique. Stehfest et al. [45] were among the first ones to study the effect of nitrogenous and phosphorous stresses on phytoplanktonic species with IR spectrometry. Recently, Di Giambattista et al. [46] used FTIR as an efficient method to diagnostic the presence of tumor cell death, showing the great potential of this technique also in medical studies.

We can thus admit that whatever the used technique and the observed variations, no specific major molecule seems to be really produced by the seaweeds from the different studied countries, along our chosen latitudinal gradient (Portugal to Norway). Only the relative proportions of each molecule seem to evolve along the latitudinal gradient, as it was already shown in the particular phenolic compounds studied in a previous study [47]. Complementary analyses carried out at the laboratory allowed, thanks to chemical analysis techniques, to validate the variations and the tendencies observed in HRMAS NMR and FTIR. Indeed the colorimetric tests used for the determination of protein and carbohydrates contents for example, show a weak variability of the protein compartment following countries while, on the other hand, lipids and polysaccharides are subjected to big variations in *S. muticum* populations collected along Atlantic coasts [48].

4. Conclusion

In our study both HRMAS NMR and FTIR appeared as two quick and reliable methods for geographical origin discrimination studies together with the obtaining of an overview of biochemical composition of samples. These two relevant techniques provided results analogous to those obtained by standard chemical tests. Their main advantages are that they are quick and easy to use methods, which need low biomass consumption (some milligrams). These techniques are then promising for this type of investigation because they would allow, without preliminary extraction, the simultaneous and fast qualitative overview of macromolecules for a given species with the possibility of connection with the environmental variations. These results are exciting as no DNA polymorphism could be highlighted in populations of *Sargassum muticum* collected in Europe (Viard, pers. comm.). Our chemical procedure could then represent a real tool of traceability for further studies of *S. muticum* in Europe.

Acknowledgments

This study is part of the Ph.D. thesis work carried out by the first author within the Laboratoire des Sciences de l'Environnement Marin (LEMAR UMR 6539) set at the IUEM (UBO-UEB). It was supported by the Ministère de l'Education Nationale, de l'Enseignement Supérieur et de la Recherche (UBO allocation for the first author). This study is part of the BIOTECMAR project contract no. 2008-1/032 for the collection of samples in Europe, and was co-financed with the support of the European Union ERDF – Atlantic Area Program. This study is also related to the research projects INVASIVES (Era-net Seas-era, 2012–2016) and COSELMAR for the analysis of samples.

ABSTRACT

In this work, chemiluminescence (CL) from peroxynitrous acid (ONOOH)–carbonate system greatly amplified by carbon dots was observed. The CL mechanism of the ONOOH–carbonate–carbon dots system has been investigated and the results reveal that the carbon dots could serve as the energy acceptor, which gives us new insight into the optical properties of the new emerging carbon nanomaterial. There is a good linear relationship between the CL signal and the concentration of the nitrite using for ONOOH formation, which provides us a nitrite sensing method with sensitivity as high as 5.0×10^{-9} M (S/N=3). The method has been successfully applied to the determination of nitrite in tap water with the recovery of 98%. The standard deviations are within 2.5%.

1. Introduction

Peroxynitrite is a powerful oxidizing agent of biological importance, which exists in many forms, such as *trans*-peroxynitrous acid (ONOOH), *cis*-ONOOH, activated form of ONOOH, and peroxynitrous anion [1–3]. ONOOH, as a weak acid with a pKa of 6.8, is an important form of peroxynitrite [4]. In acid solution, ONOOH is an unstable compound with lifetime less than 1 s [5]. In basic solution, ONOOH could be converted to peroxynitrous anion ($ONOO^-$) that is fairly stable and can decompose slowly to nitrite and superoxide anion radical. The oxidation reaction by peroxynitrite is beneficial for destroying invading organism. However, peroxynitrite is also involved in protein and lipid nitration, which has been found to be an early event in the etiology of some pathologies. The study concerning peroxynitrite has attracted many attractions.

Certain chemical reactions released their energy through light emission, which was called as chemiluminescence (CL). Large amount of excited species with short life are involved in CL reaction. Hence, CL could be a useful tool in reactive species investigation. Since 1999, Starodubtseva et al. had reported weak CL emission from excited ONOOH. ONOOH/$ONOO^-$ also oxidized pholasin [6], chloroquine [7,8] and bilirubin [9] to produce strong CL. There are some reports concerning the CL from the decomposition of $ONOO^-$, which is enhanced by some energy acceptors, such as fluorescent compounds [10], CdTe quantum dots [11]. Materials, including Mg–Al–carbonate layered double hydroxides [12] and gold nanoparticles [13], could increase the CL from ONOOH related system. Carbonate solution was reported to react with $ONOO^-$ to produce $ONOOCO_2^-$ that had a lifetime less than 3 ms and decomposed rapidly into $\bullet NO_2$ and carbonate radical ($\bullet CO_3^-$)[14,15]. $\bullet CO_3^-$ changed to carbon dioxide in its excited form that brought in the CL emission [16].

Carbon dots, as a new type of fluorescent carbonaceous nanoparticle, owned lots of advantages, such as environmental benign, optical stability, low cost and easy preparation. Nowadays, fluorescent carbon dots have been successfully applied in bioimaging for cells [17,18]. The new properties of carbon dots, such as catalytic activity [19,20], fluorescent probe [21,22] and photocatalyst [23,24], have been reported recently by several groups. The CL enhanced role of carbon dots was firstly reported in our group and the CL mechanism was revealed. There are several possible mechanisms explaining the enhancing effect of carbon dots: (1) Carbon dots have catalysis effect on the reaction [25]. (2) Carbon dots concentrated the excited CL emitter, which facilitated the CL emission [26]. (3) Carbon dots were involved in the CL reaction and the CL emission was through the annihilation of hole-injected and electron-injected carbon dots [27].

We firstly found that carbon dots had enhancing effect on the ONOOH system [27]. In the present work, we further find that carbon dots could greatly amplify the CL from ONOOH–carbonate system. Furthermore, the carbon dots–ONOOH–carbonate CL system has higher CL intensity than that from carbon dots–ONOOH system. More interestingly, a linear relationship between the

nitrite for the formation of ONOOH and CL signal produced from the carbon dots–ONOOH–Na_2CO_3 system was found. Hence, the proposed method can be employed for the determination of nitrite with improved sensitivity. The CL enhanced mechanism of carbon dots on ONOOH–Na_2CO_3 system was also illustrated in details, and its role of energy acceptor was further discussed.

2. Experimental

2.1. Reagents and materials

All chemicals were of analytical grade and were used as received. Sodium nitrite ($NaNO_2$) was from Sinopharm Chemical Reagent Co., Ltd (Shanghai, China). Hydrogen peroxide (H_2O_2, 35%) was obtained from Alfa Aesar China Ltd. Serine and polyethylene glycol 1500 (PEG 1500) were purchased from Merck Company (Darmstadt, Germany). 5, 5-Dimethyl-1-pyrroline N-oxide (DMPO) was from Sigma-Aldrich Chemical Co. (St. Louis, USA). Sulfuric acid (H_2SO_4, 98%) and glycerine were bought from Beijing Chemical Reagent Co. (Beijing, China).

2.2. Apparatus

Flow injection experiments were performed with a LumiFlow LF-800 detector (NITI-ON, Funabashi, Japan). Batch CL experiment was performed with a BPCL ultraweak CL analyzer (Institute of Biophysics, Chinese Academy of Science, Beijing, China). Two peristaltic pumps (SJ-1211, Atto, Tokyo, Japan) were used to deliver the solution into the spiral flow CL cell, which was installed in front of the photomultiplier tube (PMT). The fluorescent spectra were performed using a FL-7000 spectrofluorometer (Hitachi, Japan). Electron paramagnetic resonance (EPR) spectra were measured on a JEOL spectrometer (JES-FA200, Japan).

2.3. CL system

Carbon dots were prepared by microwave heating of serine in the presence of 15 mL glycerine and 1.0 g PEG 1500 by microwave oven for 10 min. Carbon dots were dialyzed against pure water before the batch experiment. While in the flow injection experiment, carbon dots were used without any further treatment. CL kinetic curves were obtained by batch experiments, which were carried out in the glass cuvette. The CL profiles were displayed and integrated for 0.1 s interval. A microliter syringe was used for the injection of the solution from the upper injection port. The addition orders of the reagent were changed to investigate the interaction of the reagent and design the CL flow injection analysis system.

The manifolds of the flow injection system were shown in Fig. S1. The solution of $NaNO_2$ and H_2O_2 was mixed at the three-way channel, where HNOOH was produced and reached the flow cell through channel AB. Carbon dots and Na_2CO_3 were pumped by pumps 1 and 2 to mix with HNOOH in the flow cell. The CL signal was collected by the LF-800 detector. The peak height of the signal recorded was measured as CL intensity.

2.4. Sample preparation

For the determination nitrite in tap water, the water was firstly filtered by 0.25 μm and then was passed through a cation-exchange resin to eliminate interferences from metal cation.

3. Results and discussions

3.1. CL from carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system by flow injection system

Flow injection system with precise control of the sample volume, flow rate and mixing time of the reagent has been employed to compare the CL intensity from several systems. The manifolds of the flow injection system were shown in Fig. S1. The interaction of $NaNO_2$ and H_2O_2 in acid medium produced ONOOH [28]. The solution of $NaNO_2$ and H_2O_2 was mixed at the three way channel AB to generate HNOOH. Carbon dots enhanced the CL from ONOOH system, and its CL has been recorded in Fig. 1a. The baseline of curves b and c in Fig. 1 stands for the CL intensity caused by the reaction of ONOOH–NaOH and ONOOH–Na_2CO_3 systems. The introduction of carbon dots further increased the CL intensity from ONOOH–NaOH and ONOOH–Na_2CO_3 system (Fig. 1b and c). ONOOH, as a weak acid with pKa of 6.8 [4], is suggested to be turned to $ONOO^-$ related species in alkaline medium. The CL enhancement of carbon dots in alkaline medium is suspected to be attributed to the interaction between carbon dots and $ONOO^-$ related species [29]. Compared with the CL from carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system (Fig. 1d), the CL from carbon dots–H_2O_2–Na_2CO_3 system in the absence of $NaNO_2$ was rather low, which confirmed the main role of nitrite and its related species (ONOOH, $ONOO^-$, and $ONOOCO_2^-$) in the CL reaction.

3.2. CL from carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system by batch experiment

The CL dynamic curves under different reagent injection orders have been obtained by batch experiment. The injection of solution of Na_2CO_3 and carbon dots together into ONOOH was accompanied by very strong CL (Fig. 2), which was stronger than the CL intensity obtained when Na_2CO_3 and carbon dots were added in that order into ONOOH. In the absence of nitrite, very weak CL emission as low as 120 count was observed in Fig. 2, which further verified the important role of ONOOH, $ONOO^-$ and $ONOOCO_2^-$ in the CL system.

$$HNO_2 + H_2O_2 \rightarrow ONOOH + H_2O \quad (1)$$

$$ONOOH + OH^- \rightarrow ONOO^- + H_2O \quad (2)$$

$$ONOO^- + CO_2 \rightarrow ONOOCO_2^- \quad (3)$$

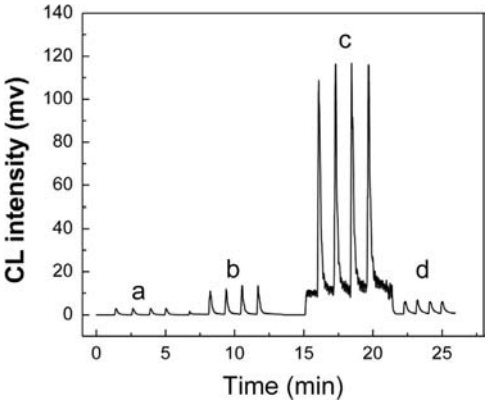

Fig. 1. The CL signal in the flow injection system for carbon dots–$NaNO_2$–H_2O_2, carbon dots–$NaNO_2$ H_2O_2 NaOH, carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 and carbon dots–H_2O_2–Na_2CO_3 systems. Conditions: 0.1 M H_2O_2 in 0.025 M H_2SO_4, 1.0×10^{-5} M $NaNO_2$, 0.1 M Na_2CO_3, carbon dots with a dilution of 1: 1000.

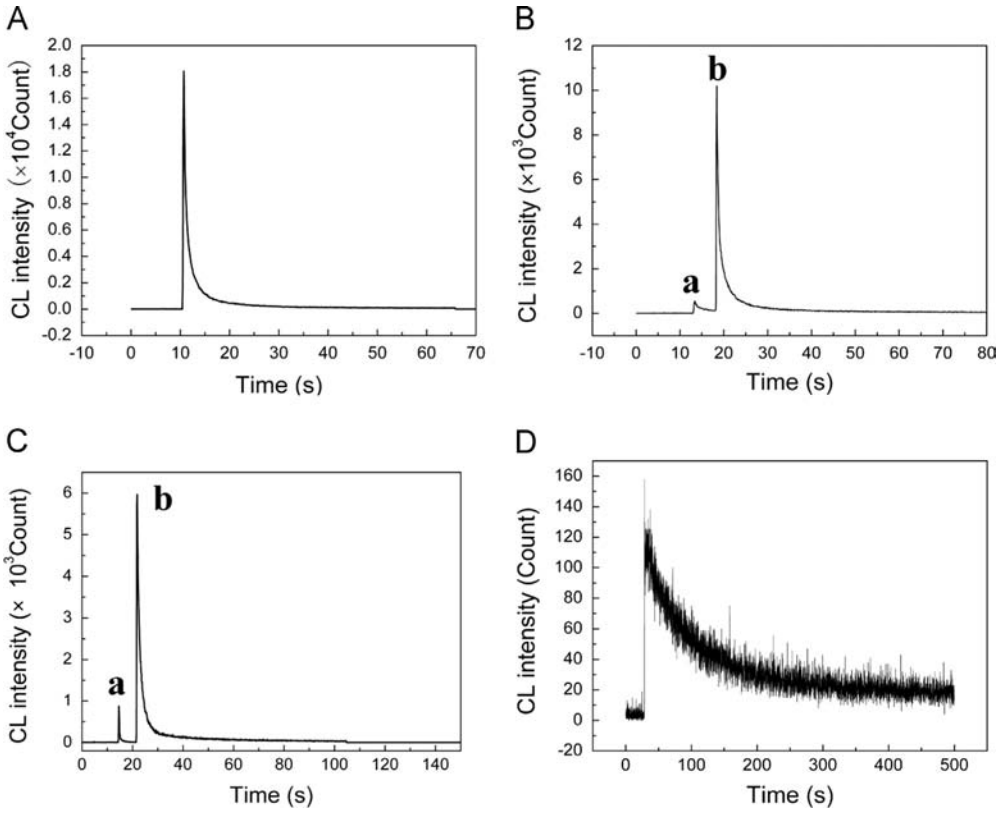

Fig. 2. CL kinetic curves of carbon dots–$NaNO_2$–H_2O_2 system with different reagent mixing orders: (A) injecting Na_2CO_3 and carbon dots solution together into the mixture of H_2O_2 and $NaNO_2$, (B) injecting carbon dots and Na_2CO_3 successively to $NaNO_2$–H_2O_2 solution, (C) injecting Na_2CO_3 and carbon dots successively to $NaNO_2$–H_2O_2 solution, and (D) Na_2CO_3 and carbon dots were injected simultaneously into H_2O_2 solution. Curve a in (B) stands for the CL caused by injecting Na_2CO_3 into $NaNO_2$–H_2O_2 solution. Curve b in (B) is the CL resulting from the injection of carbon dots into the solution containing Na_2CO_3–$NaNO_2$–H_2O_2. Conditions: 0.1 M H_2O_2 in 0.025 M H_2SO_4, 1.0×10^{-5} M $NaNO_2$, 0.1 M Na_2CO_3, carbon dots with a dilution of 1: 1000.

3.3. The determination of nitrite

The batch CL signals increased with the concentration of nitrite. Hence, this system can be developed as a flow injection analysis method for the determination of nitrite. To establish the optimal conditions for the analysis of nitrite, the effects of the pH on the CL reaction, the length of the channel as well as the flow rate of the solution on the CL analysis were investigated. It has been found that maximum CL intensity is observed in solution with pH value around 7.0, which is slightly higher than the pKa of ONOOH (6.8). It is known that ONOOH is generated from $NaNO_2$ and H_2O_2 in acid medium. While only ONOOH in its anion ($ONOO^-$) form could react with CO_2 to form $ONOOCO_2^-$ [30]. Solution with the pH value around 7.0 is not only beneficial for the formation of $ONOO^-$ but also facilitates the generation of CO_2.

ONOOH is generated from $NaNO_2$ and H_2O_2 in channel AB (Fig. S1). Short mixing channel could reduce the decomposition of ONOOH and brought in higher CL intensity. The flow rate of the solution affected the mixing efficiency of the reagent, the decomposition of unstable compound as well as the detection time in spiral CL detection cell. Fig. 3A showed that $NaNO_2$ and H_2O_2 solution with flow rate as high as 4.5 mL min^{-1} could greatly reduce the decomposition of ONOOH and obtain optimal signal. The optimized flow rate for Na_2CO_3 and carbon dots solution is 2.4 mL min^{-1} (Fig. 3B).

The CL intensity increased linearly with the nitrite concentration in the range of 1.0×10^{-7} to 1.0×10^{-5} M and the correlation coefficient is 0.9956 (Fig. 4). The relative standard deviations (R. S. D) (n=10) of the analysis were 1.8 %, 2.5 %, and 1.9 % for 1.0×10^{-7}, 1.0×10^{-6}, and 5.0×10^{-6} M nitrite, respectively. The limit of detection (S/N=3) for nitrite was 5.0×10^{-9} M. The flow-injection CL analysis has been applied successfully to detect nitrite in tap water. The concentration of nitrite in the tap water from Haidian district (Beijing, China) is 1.8×10^{-7} M and the result is in good agreement with the value obtained by spectrophotometric method (1.9×10^{-7} M)[31]. The recovery calculated by spiking the tap water with 1.0×10^{-6} M nitrite is 98%. Some metal cations have positive interference on the CL detection. Cation-exchange resins could effectively eliminate the interferences from cations. With the using of cation-exchange resins, ions such as 1000-fold Na^+, Ca^{2+}, F^-, Cl^-, Br^-, NO_3^-, SO_4^{2-}, 200-fold Mg^{2+}, Fe^{2+}, Fe^{3+}, Zn^{2+} and 100-fold Co^{2+} have no interferences on the CL detection of 1.0×10^{-6} M nitrite.

3.4. CL mechanism

Carbon dots could greatly enhance the CL in $NaNO_2$–H_2O_2–carbonate system. In order to identify the enhanced mechanism of carbon dots, CL spectrum was measured by a fluorescence spectrometer with the xenon lamp turned off. The maximum CL spectrum for carbon dots–$NaNO_2$–H_2O_2–carbonate system presented in Fig. 5A is around 500 nm, which is blue-shifted compared with maximum CL spectrum for carbon dots–$NaNO_2$–H_2O_2 system (520 nm). $ONOOCO_2^-$ and its related radical, $\bullet CO_3^-$, is suggested to be generated and is also confirmed by using DMPO as the trapping reagent (Fig. 6A) [32] in carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system. Carbon dioxide in its excited form, $(CO_2)_2^*$ is suggested to be formed through $\bullet CO_3^-$ (Reactions 4 and 5) [33,34]. $(CO_2)_2^*$ could release to its basic ground with CL emission in 440 nm (Reaction 6). It could be found from the fluorescence spectrum of carbon dots whose emission wavelength was located at 500 nm with 440 nm as the excitation wavelength. Hence, it is

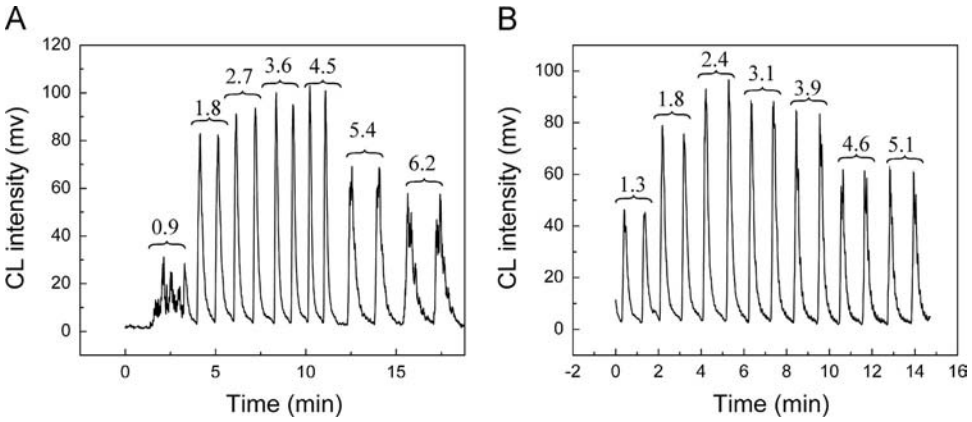

Fig. 3. The effects of the flow rate of $NaNO_2$ and H_2O_2 solution (A), Na_2CO_3 and carbon dots solution (B) on the flow-injection CL detection system.

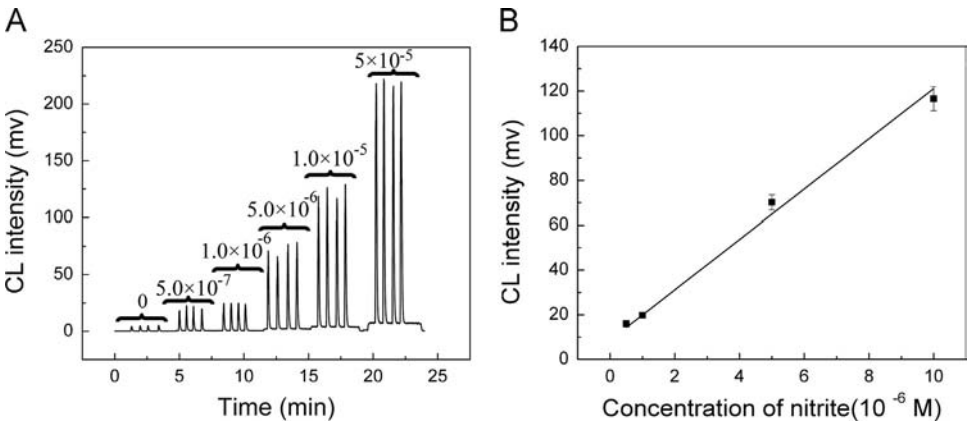

Fig. 4. Flow injection signals (A) and standard curve (B) for the nitrite concentration ranging from 1.0×10^{-7} to 1.0×10^{-5} M. Experimental conditions: 0.5 M H_2O_2 in 0.05 M H_2SO_4, 0.1 M Na_2CO_3, carbon dots in a dilution of 1: 1000, high voltage: −800 V, and 100 μL samples were injected.

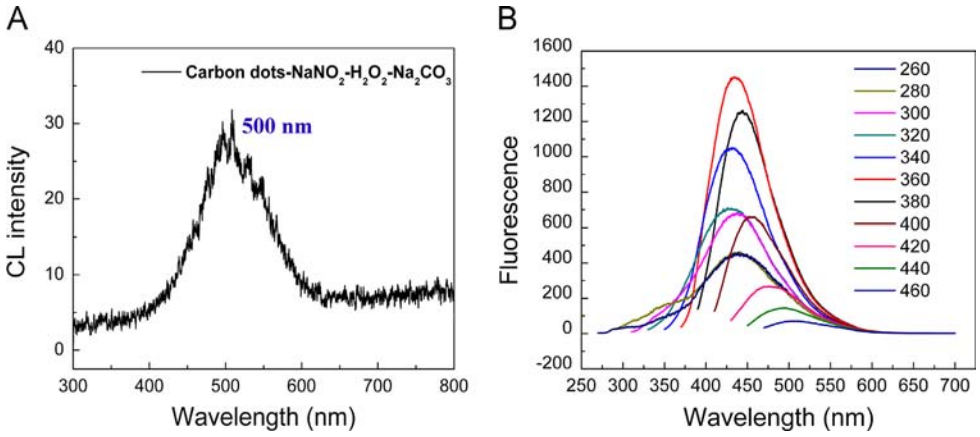

Fig. 5. (A) The CL spectrum of carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system and (B) the fluorescent spectra for carbon dots excited at wavelengths from 260 nm to 460 nm with 20 nm increment.

reasonable to deduce that carbon dots partially serve as the energy acceptor in the CL system (Reactions 7 and 8), which gives us new insight into the role of carbon dots. The EPR signal of carbon dots changed greatly in the presence of $NaNO_2$–H_2O_2. The presence of carbonate in carbon dots-$NaNO_2$-H_2O_2 system decreased the EPR signal changing of carbon dots, which further confirmed its energy acceptor role (Fig. 6B).

$$ONOOCO_2^- \rightarrow \bullet CO_3^- + \bullet NO_2 \quad (4)$$

$$2(\bullet CO_3^-) \rightarrow (CO_2)_2^* + O_2^{2-} \quad (5)$$

$$(CO_2)_2^* \rightarrow 2CO_2 + h\nu\ (440\ \text{nm}) \quad (6)$$

$$(CO_2)_2^* + R \rightarrow CO_2 + R_a^* \quad (7)$$

$$R_a^* \rightarrow R_a + h\nu(500\ \text{nm}) \quad (8)$$

It is noted that CL spectrum for carbon dots–$NaNO_2$–H_2O_2–carbonate system is partially overlapped with that from carbon dots–$NaNO_2$–H_2O_2 system (520 nm). The overlapping indicated that the CL is partially aroused from the radiative electron–hole annihilation between hole-injected and electron-injected carbon dots ($R^{\bullet+}$ and $R^{\bullet-}$) [35,36] (Reactions 13 and 14). Oxidant species

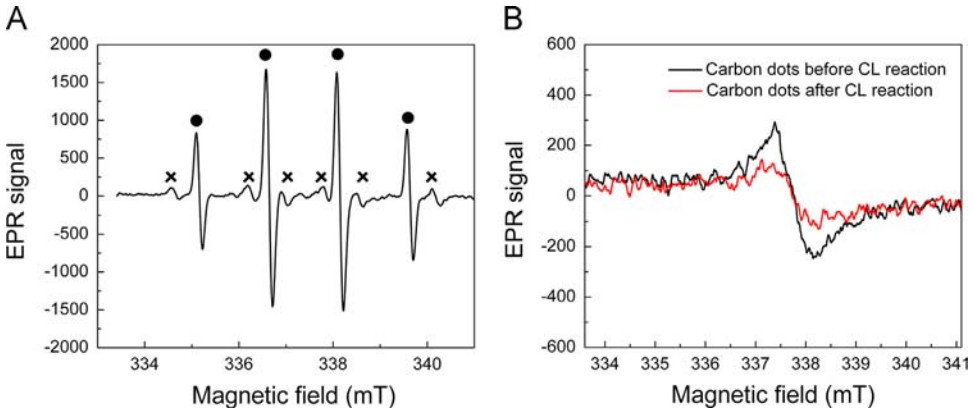

Fig. 6. (A) EPR spectra of carbonate and hydroxyl radicals generated by reaction of DMPO probe in carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system and (B) EPR spectra of the carbon dots before and after the CL reaction.

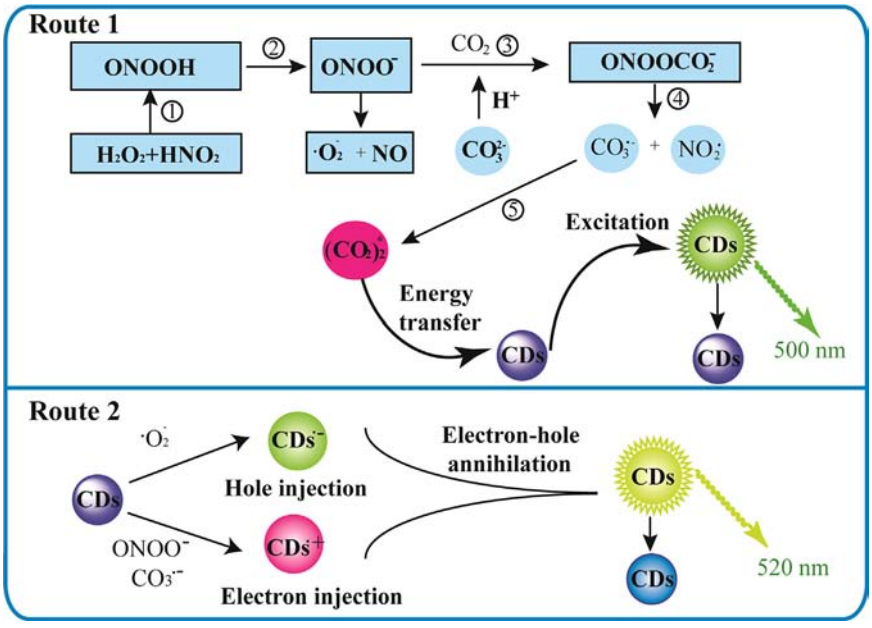

Fig. 7. Schematic illustration of CL mechanism of carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system. CDs stand for carbon dots.

that existed in the carbon dots–$NaNO_2$–H_2O_2–carbonate system, including $ONOO^-$, OH● and $\bullet CO_3^-$, could serve as the hole injector and convert carbon dots into $R^{\bullet+}$ (Reactions 11and 12). $O_2^{\bullet-}$ generated from the decomposition of $ONOO^-$could donate its electron to carbon dots to produce carbon dots with negative charge (Reactions 9 and 10) [37].

$$ONOO^- \rightarrow \bullet O_2^- + NO \quad (9)$$

$$R + \bullet O_2^- \rightarrow R^{\bullet-} + O_2 \quad (10)$$

$$R + ONOO^- \rightarrow R^{\bullet+} + \text{product} \quad (11)$$

$$R + OH\bullet \rightarrow R^{\bullet+} + OH^- \quad (12)$$

$$R^{\bullet-} + R^{\bullet+} \rightarrow R_b^* \quad (13)$$

$$R_b^* \rightarrow R_b + h\nu\ (525\ \text{nm}) \quad (14)$$

The discussion above indicated that carbon dots could enhance the CL from $NaNO_2$–H_2O_2–Na_2CO_3 system through two pathways (Fig. 7). Firstly, carbon dots acts as the energy acceptor in carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system. This kind of enhancement in the system is related with the excited species generated from $ONOOCO_2^-$ and $\bullet CO_3^-$. With pH value above the pKa of ONOOH, ONOOH converted to its anion form ($ONOO^-$). $ONOO^-$ reacted with CO_2 that was generated from the protonation of carbonate to produce $ONOOCO_2^-$. The decomposition of $ONOOCO_2^-$ resulted in the formation of $\bullet CO_3^-$ and $(CO_2)_2^*$. $(CO_2)_2^*$ acted as the energy donor and donated its energy to carbon dots and excited the carbon dots, whose energy releasing brought in the CL emission (Route 1 in Fig. 7). CL is also partially generated from the radiative electron–hole annihilation between hole-injected and electron-injected carbon dots (Route 2 in Fig. 7).

4. Conclusion

Carbon dots were found to have CL enhancement on $NaNO_2$–H_2O_2–Na_2CO_3 system. The CL mechanism has been investigated. $(CO_2)_2^*$ is suggested to be existing in the system and donates its energy to excite carbon dots to its excited form, which released their energy to ground-state by CL emission. The radiative electron–hole annihilation between hole-injected and electron-injected carbon dots also had contribution for the CL. The investigation not only gave us new insight into the characteristic of carbon dots but also showed a broad prospect for the application of carbon dots in CL system. With the advantage of the CL from carbon dots–$NaNO_2$–H_2O_2–Na_2CO_3 system, a sensitive and

simple flow-injection CL method for nitrite sensing has been developed. The established method has been successfully applied to the determination of nitrite in tap water with good recoveries and precision.

Mercury ions

ABSTRACT

This paper reports the development of an ultra-sensitive colorimetric method for the detection of trace mercury ions involving DNAzymes, Au nanoparticle aggregation, magnetic nanoparticles and an endonuclease. DNAzyme-sensing elements are conjugated to the surface of Au nanoparticle-2, which can crosslink with the T-rich strands coated on Au nanoparticle-1 to form Au nanoparticle aggregation. Other T-rich stands are immobilized on the surface of MNPs. The specific hybridization of these two T-rich strands depends on the presence of Hg^{2+}, resulting in the formation of a T-Hg^{2+}-T structure. Added endonuclease then digests the hybridized strands, and DNAzyme-modified Au NP aggregation is released, catalysing the conversion of the colourless ABTS into a blue-green product by H_2O_2-mediated oxidation. The increase in the adsorption spectrum of $ABTS^+$ at 421 nm is related to the concentration of Hg^{2+}. This assay was validated by detecting mercury ion concentrations in river water. The colorimetric responses were not significantly altered in the presence of 100-fold excesses of other metal ions such as Zn^{2+}, Pb^{2+}, Cd^{2+}, Mn^{2+}, Ca^{2+} and Ni^{2+}. The inclusion of both Au NP aggregation and an endonuclease enables the assay to eliminate interference from the magnetic nanoparticles with colorimetric detection, decrease the background and improve the detection sensitivity. The calibration curve of the assay was linear over the range of Hg^{2+} concentrations from 1 to 30 nM, and the detection limit was 0.8 nM, which is far lower than the 10 nM US EPA limit for drinking water.

1. Introduction

Mercury is a highly toxic global pollutant with an environmental residence time from 0.5 to 2 years [1,2]. This kind of persistent toxic substance occurs naturally and releases into the environment through both natural and anthropogenic processes. Mercury has a strong affinity to organic substances, which plays an important role in mobilization and transportation of mercury from forest ecosystems to water ecosystems [3,4]. Consumption of polluted water or seafood can lead to the accumulation of mercury in the human body, leading to some serious illnesses, including neuropsychological dysfunction and chronic mercury poisoning syndrome. Among various mercury pollutants, Hg^{2+} is the most stable inorganic form in water environments [5]. Moreover, methyl mercury, the most common organic source and bioaccumulative form of mercury, is generated from Hg^{2+} by microbial biomethylation [6]. Hence, the sensitive and specific detection of Hg^{2+} is important for water pollution control and drinking water safety.

The determination of trace amounts of mercury has commonly been carried out using cold vapor atomic absorption spectrometry (CVAAS) or inductively coupled plasma mass spectrometer (ICP-MS). These instrumental analysis of Hg require that all chemical forms of mercury are needed to reduce to elemental mercury (Hg^0) [4]. However, these extra pretreatment steps can lead to increased risk of contamination and/or mercury volatilization from sample. Therefore, it is very urgent to develop the novel and sensitive methods for the detection of Hg avoiding the environmentally hazardous pretreatment steps. Hg sensors based on T-Hg^{2+}-T conjugation have been developed to meet the requirement [7–10]. These electrochemical [11–13], fluorescence [14] and optical sensors [15–17] have been used to monitor aqueous Hg^{2+}. Due to its high sensitivity and low production costs, electrochemical sensing is one of the most popular Hg^{2+} detection system designs. However, its unstable performance, poor reproducibility, and high non-specific absorption lead to imperfect detection. While fluorescence is another attractive detection method, it requires sophisticated instrumentation, an expensive and complicated labelling procedure, and it tends to result in a high background. Compared with the methods described above, colorimetric systems are stable and easy to control, but less sensitive. Hence, to meet the requirements of Hg ion detection in drinking water (within the 10 nM US EPA limit), the sensitivity of the colorimetric method should be improved. In this work, we use Au nanoparticle aggregation modified with DNAzymes as signal amplification elements and demonstrate that this approach reduces the detection limit.

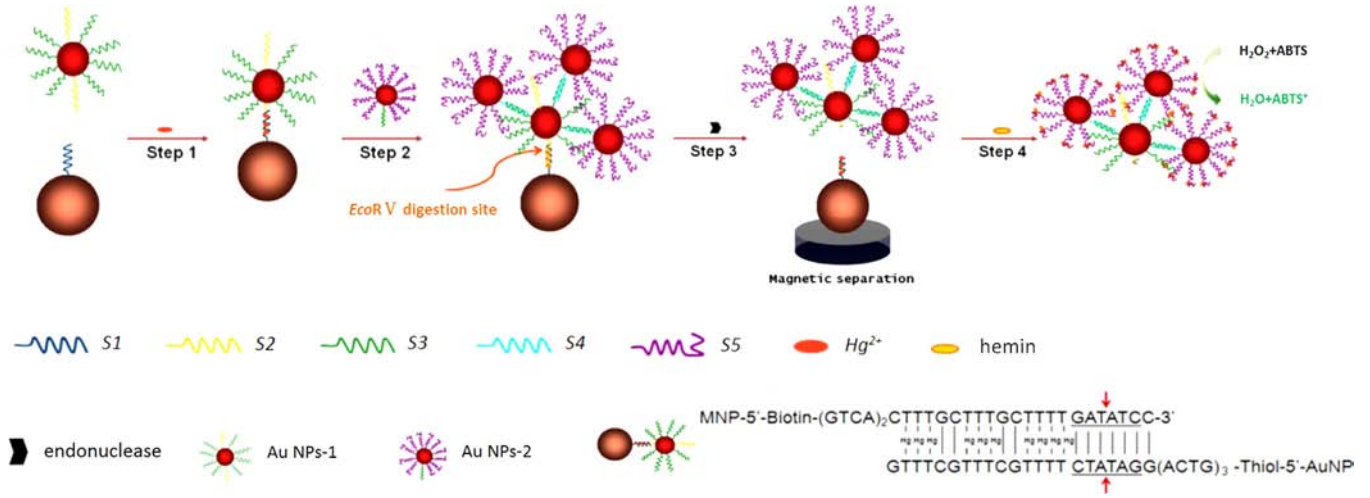

Fig. 1. A schematic illustration of the amplified Hg^{2+}-sensing assay.

Due to their favourable biocompatibility, it is easy to modify magnetic nanoparticles (MNPs) with biologically active groups to achieve the enrichment and separation of components of interest [18]. MNPs have been employed in this way to powerful effect in a number of applications [19–21]. However, MNPs have been reported to exhibit an intrinsic peroxidase-like activity, which could cause a background signal in colorimetric assays [22]. Moreover, the use of MNPs in an optical detection system could lead to uneven scattering, leading to some bias in the results. To eliminate these disadvantages, this assay uses an endonuclease with a specific recognition and hydrolysis ability to release the sensing element into the liquid phase for UV-visible spectrophotometric detection. This paper reports the development of a novel, selective and sensitive colorimetric Hg^{2+}-sensing assay based on Au NP aggregation coated with DNAzyme, MNPs and an endonuclease (*Eco*RV). As illustrated in Fig. 1, this strategy uses several DNA strands and consists of four main steps. First, in the presence of Hg^{2+}, MNPs coated with the T-rich S1 strands (S1/MNPs) specifically hybridize with AuNP-1s modified with the T-rich strands (S2) and with AuNP-1s modified with cross-linking strands (S3). Second, the Au NP-2s covered with a different type of cross-linking strand (S4) and with DNAzyme strands (S5) are added to the Au NP aggregation formed in the first step. The excess AuNP-1s, AuNP-2s and interfering substances are then removed by magnetic separation. Then, *Eco*RV is used to digest the DNA double-strand to release Au NP aggregation, contributing to the amplification of the optical signal. After incubating the supernatant of the digested Au NP aggregation with hemin, the colorimetric measurement is carried out, with the optical signal of $ABTS^+$ at 421 nm directly related to the concentration of the Hg ion in solution.

2. Experimental procedures

2.1. Materials

An HZQ-C Swing bed machine (Donglian Electrical Technology Co. Ltd., China) was used to assemble the oligonucleotide strands onto the surfaces of the Au NPs and MNPs. Colorimetric measurements were performed on a Cary 50 UV–visible Spectrophotometer (Varian, Palo Alto, USA). A JEM-2100F field emission electron microscope (JEOL, Japan) was used to observe the structure of the nanoparticles.

Tris-(2-carboxyethyl) phosphine (TCEP), saline sodium citrate (SSC) buffer (15 mM SSC, 150 mM NaCl, pH 7.0), bovine serum albumin (BSA) and hemin were purchased from Sigma Chemical Co. (Shanghai, China). Chloroauric acid and 2,2′-azino-bis(3-ethylbenzo-thiazoline-6-sulfonic acid) diammonium salt (ABTS) were obtained from Sangon Biotechnology Co. (Shanghai, China). *Eco*RV and 100 × BSA were purchased from New England Biological Technology Co. Ltd. (Beijing, China). Streptavidin-coated magnetic nanoparticles (MNPs, hydrodynamic diameter of 100 nm, 10 mg/mL) were obtained from Chemicell GmbH (Germany). All oligonucleotides were synthesized by Shanghai Sangon Biotechnology Co. and purified by HPLC. The oligomer sequences and the buffers used are listed in the supporting information.

2.2. Preparation of oligonucleotide-modified MNPs

A 100-μL solution of MNPs modified with streptavidin (10 mg/mL) was washed three times with SSC buffer to remove sodium azide. Then, 0.38 nmol S1 in 200 μL of SSC buffer was added to the collected MNPs. After 1 h of gentle shaking at room temperature, the mixture was washed to remove free DNA. A 1% BSA solution was used to block the MNP surface and eliminate further non-specific adsorption. After 1 h of blocking treatment, these S1/MNPs were stored in 200 μL of Hg^{2+} capture buffer at 4 °C.

2.3. Preparation of oligonucleotide-modified Au NPs

Au NPs with an average diameter of 13 nm (estimated by TEM) were prepared by the citrate reduction method [23]. S2 and S3 (0.36 nmol and 3.6 nmol, respectively) were treated with TCEP (2.5 mM, dissolved in 0.1 M Tris-HAc, pH 7.4) for 1 h. Then, 200 μL Au NPs (10.4 nM) were added to the reduced S2 and S3 solution. The mixture was gently stirred at room temperature for 42 h while the salt concentration was gradually adjusted to a final value of 0.3 M NaAc. The solution was centrifuged (13000 rpm, 15 min) and rinsed with water twice to remove the excess oligonucleotides. Then, 10 μL of 20% BSA was added for 1 h to block the surface of the Au NPs. The resulting solution was suspended in 200 μL capture buffer and named Au NPs-1. The Au NPs-2 (S4 to S5 ratio of 1:100) and Au NPs-3 (S2 to S5 ratio of 1:10) were prepared by the same procedure and dispersed in hybridization or capture buffer, respectively. All of the Au NPs were stored at 4 °C until further use.

2.4. Hg^{2+} recognition

The recognition of Hg^{2+} was carried out by following steps. Briefly, 10 μL S1/MNPs, 40 μL S2/S3/Au NPs and certain volumes of Hg^{2+} were added to a tube and gently shaken at room

temperature for 30 min. Then, 1200 μL S4/S5/Au NPs was added to form Au NP aggregation. The hybridization was carried out at 37 °C for 40 min. The aggregations were washed with water and then resuspended in 20 μL 10 × NE buffer 3, 1 μL of 100 × BSA and 4 U *Eco*RV in a final volume of 100 μL. After vigorous shaking at 37 °C for 2 h, the aggregations were washed twice with water. The supernatants from all washes were collected and diluted with 2 × HEPES to a final volume of 1 ml. Then, 500 μL of hemin (190 nM) was added, and the mixtures were incubated with gentle shaking to form the DNAzyme complexes.

2.5. Colorimetric measurements

After 5.6 μmol of ABTS and 0.6 μmol of H_2O_2 were added to the above solutions, the absorption spectrum of $ABTS^+$ was measured from 380 to 520 nm. The $A_{421\ nm}$ recorded after a 10-min reaction was used for quantitative analysis.

3. Results and discussion

3.1. The characteristics of the Hg^{2+}-sensing assay

Several experiments were conducted to test the feasibility of the proposed Hg^{2+} assay. First, only S1/MNPs and Au NPs-3 were used to confirm the ability of the assay to capture Hg^{2+} (Fig. 2a). The assay gave out a very lower response ($A_{421\ nm}$) while no Hg^{2+} existed (curve a). When Hg^{2+} ions were introduced into this system, they induced the two strands of DNA (S1 and S2) to intertwist by forming T-Hg^{2+}-T bonds; meanwhile, an *Eco*RV digestion site was formed by complementary base-pairing reactions [24,25]. After *Eco*RV treatment, the absorbance at 421 nm (A_{421}) was progressively higher when the concentration of Hg^{2+} in the solution increased from 100 nM to 500 nM (curves b and c, respectively). This result demonstrates that the immobilization of T-rich strands on the surface of nanoparticles such as Au NPs and MNPs does not disturb the specific recognition of Hg^{2+} or the endonuclease activity. The increased A_{421} of curve c illustrates that the colorimetric responses of the assay depends on the mercury ions by formation of T-Hg-T structure. However, further signal amplification was limited by the number of active sites on the Au NP surface, restricting the detection limit.

As in our previous work, the Au NP surface influences the efficiency of target recognition and the signal amplification ability [26]. That is, higher S5 (the sensing strands) to S2 (the capture strands) ratios on individual Au NPs will enhance the absorbance signal at the expense of target capture efficiency, which ultimately restricts the amplification of signal intensity. Au NP aggregation was introduced to overcome this problem. The lowest signal in Fig. 2b is the response of the assay with only S1/MNPs (curve a), representing the background signal with no sensing element. Although the Au NPs-3 coated with an S2 to S5 ratio of 1:100 produce a clear signal (curve b), the limited number of active sites due to the low S2 to S5 ratio limits Hg^{2+} capture, resulting in a low signal. Curve c is the result of the assay using Au NP aggregation as the sensing element, with a S2 to S5 ratio on the Au NP aggregation of 1:100. The increase in the catalytic absorbance signal indicates the superiority of the Au NP aggregation in amplifying the absorbance signal and effectively capturing the target at the same S2 to S5 ratio.

In contrast with the individual Au NP-3s, in the Au NP aggregation, the capture strands (S2) and the DNAzyme sensing strands (S5) are immobilized on different Au NPs. To maximize the signal amplification, the S5:S4 ratio on the surface of the sensing Au NPs was increased while controlling the S3:S2 ratio at a lower level (10:1) to ensure effective target capture. A large absorbance signal was observed when the S5:S4 ratio on the sensing Au NPs

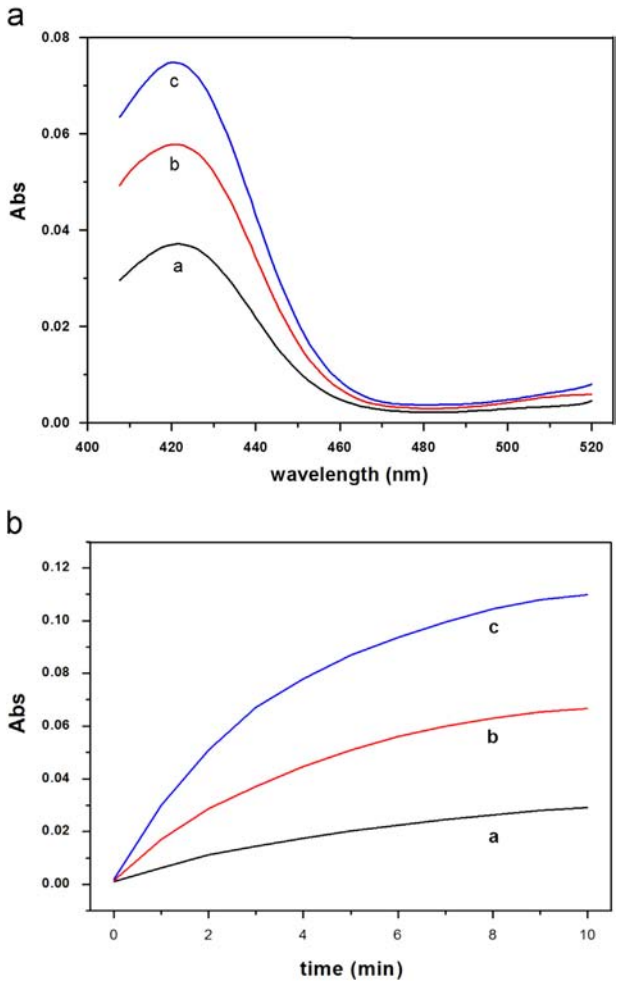

Fig. 2. (a) Spectra produced by assays performed with S1/MNPs and Au NPs-3 without target (a), with 100 nM Hg^{2+} (b) and 500 nM Hg^{2+} (c) in the presence of 63 nM hemin and 60 U *Eco*RV after 10 min of catalysis. (b) Kinetic absorbance *vs.* time curves of assays with different sensing elements: (a) none, (b) Au NPs-3 and (c) Au NP aggregation in the presence of 500 nM Hg^{2+}, 63 nM hemin and 60 U *Eco*RV, with an S2 to S5 ratio of 1:100.

was fixed at 100:1 (Fig. 3, curve c). This almost fourfold increase in the response (compared with Fig. 3, curve b) enabled ultrasensitive detection of Hg^{2+} in drinking water.

TEM was used to monitor the deposits after magnetic separation and confirm the formation of Au NP aggregation. Fig. 4a presents the results without Hg^{2+} ions, which lead to the collection of MNPs alone. Compared with Fig. 4a, several darker particles representing DNAzyme-modified Au NPs are observed in Fig. 4b after discarding the free Au NPs, thus demonstrating the success of the MNP-Hg^{2+}-Au NP sandwich structure. The abundant deposits of Au NPs on MNPs due to the binding between S1/MNPs and Au NP aggregation, yielding a lot of relatively dark spots (Fig. 4c) [27,28]. It confirms the feasibility of assay in efficient capture of the target and sensitive amplification of the signal. After *Eco*RV treatment, the DNA duplex between MNPs and Au NP aggregation was digested. Most Au NPs are separated from the deposit, leading to a dramatic decrease in the presence of darker particles in the TEM image as shown in Fig. 4d. The results of this TEM experiment verify the ability to detect trace mercury ions by the strategy discussed above.

3.2. Optimization

To determine the optimal conditions for the colorimetric Hg^{2+}-sensing assay, several key parameters were varied, including

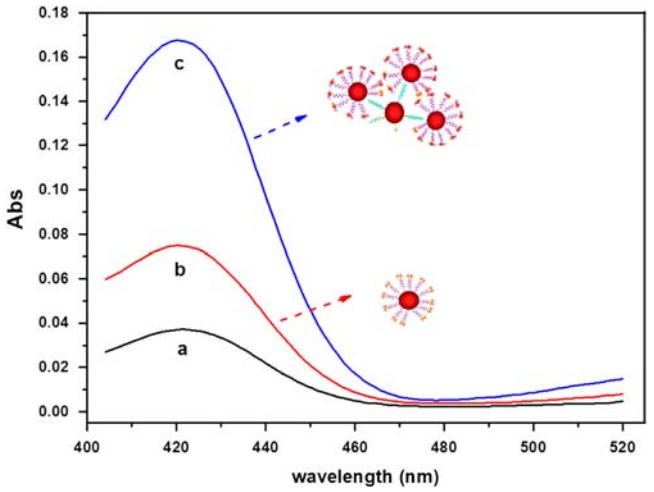

Fig. 3. The catalysis spectra of the assay consisting of S1/MNPs and Au NPs-3 without target (a) and with 500 nM Hg^{2+} (b), and of the assay consisting of S1/MNPs and Au NP aggregation (with a S5:S4 ratio of 100:1) (c) in the presence of 63 nM hemin and 60 U *Eco*RV recorded after a 10 min catalysis period.

mercury ions capture time, the dosages of *Eco*RV and the salinity in target capture and the formation of Au NP aggregation respectively. Fig. 5a presents data on capture time determination over the range from 10 to 60 min at room temperature. These data reveal that the $\Delta A_{421\ nm}$ of the supernatant increases sharply as capture time increases up to 40 min, with further increases in capture time having no effect. Therefore, we deduce that 40 min ensures adequate combination between Hg^{2+} and the two capture elements. The incubation time was also varied. The salinity in the Au NP aggregation and mercury ions capture has been shown to affect the optical signal (S1 and S2). After comparing the results under different conditions, the salinity of each Hg^{2+} capture and Au NP aggregation was fixed at 0.6 M and 1 M.

We observed that adding *Eco*RV has a dampening effect on the catalytic reaction, suggesting that this step should be optimized. The effect of adding different concentrations of *Eco*RV on $\Delta A_{421\ nm}$ is shown in Fig. 5b. The $\Delta A_{421\ nm}$ first increased as the amount of *Eco*RV increased, reaching a peak at 60 U. We expect that less than 60 U of *Eco*RV is insufficient to completely digest the DNA duplex. However, adding more than 60 U of *Eco*RV interferes with the catalytic reaction rather than influencing digestion.

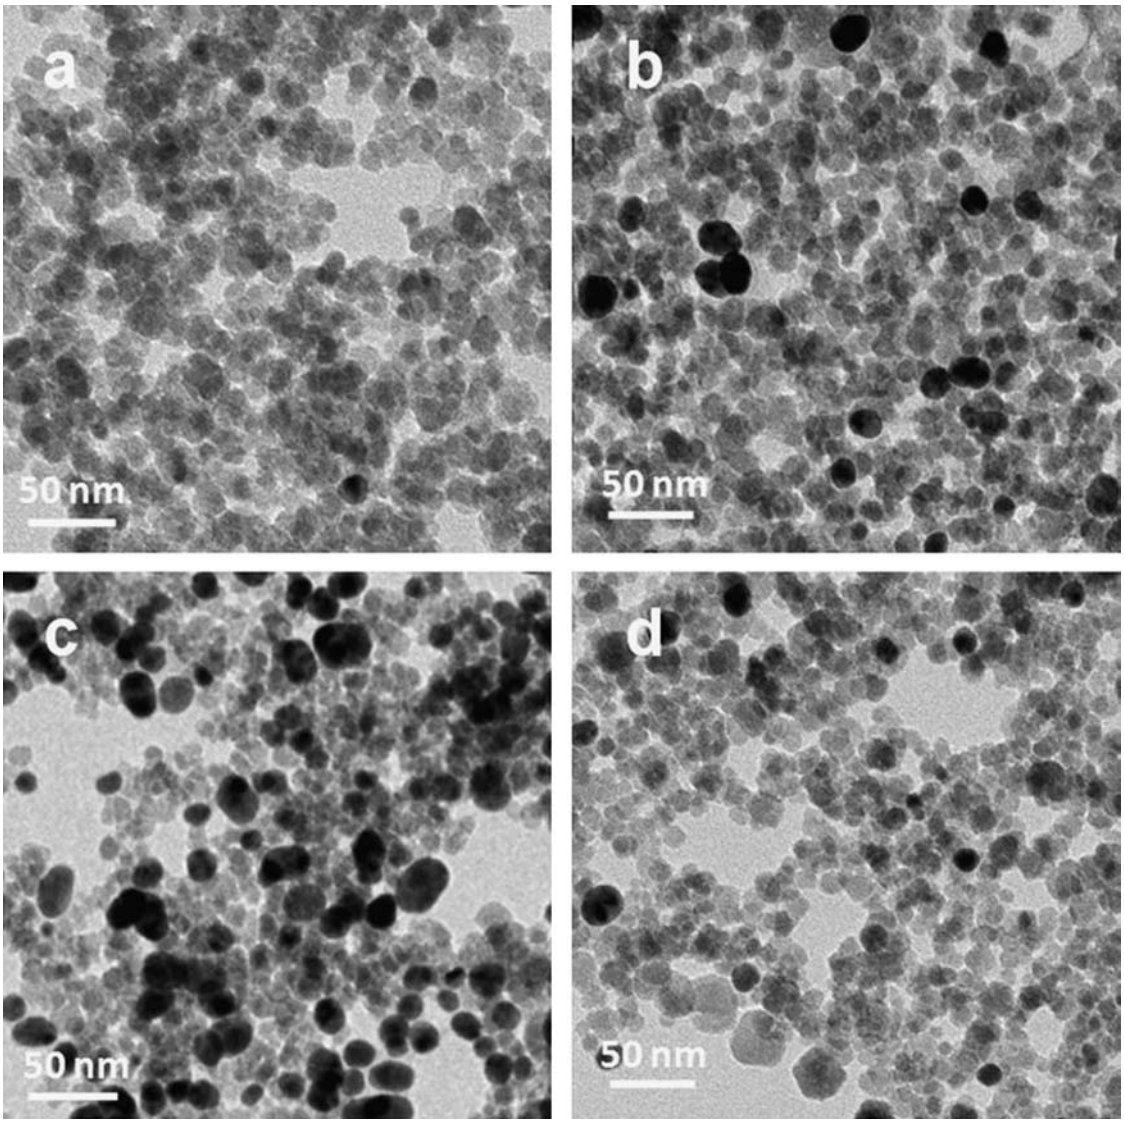

Fig. 4. TEM images of deposits for the assay consisting of S1/MNPs and Au NP-3 s without Hg^{2+} (a) and in the presence of 500 nM Hg^{2+} (b); the deposits for the assay consisting of S1/MNPs and Au NP aggregation (with S4:S5 = 100:1) before (c) and after (d) *Eco*RV digestion in the presence of 500 nM Hg^{2+}.

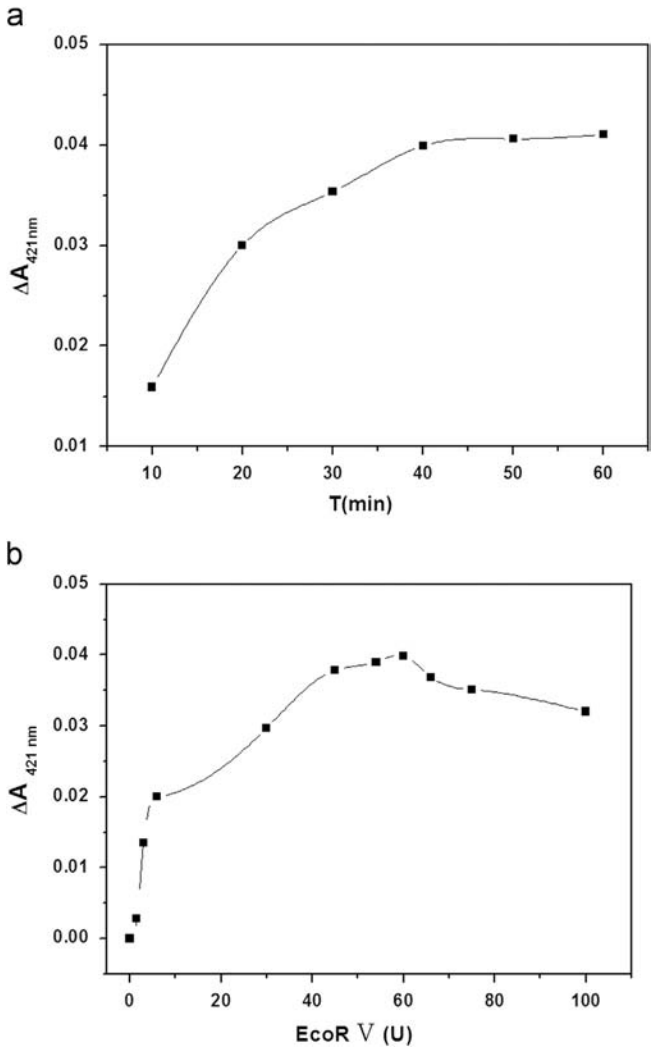

Fig. 5. (a) Influence of the Hg^{2+} capture time on the $\Delta A_{421\ nm}$ of the assay and (b) influence of the amount of *Eco*RV on $\Delta A_{421\ nm}$ in the presence of 63 nM hemin and 25 nM Hg^{2+}.

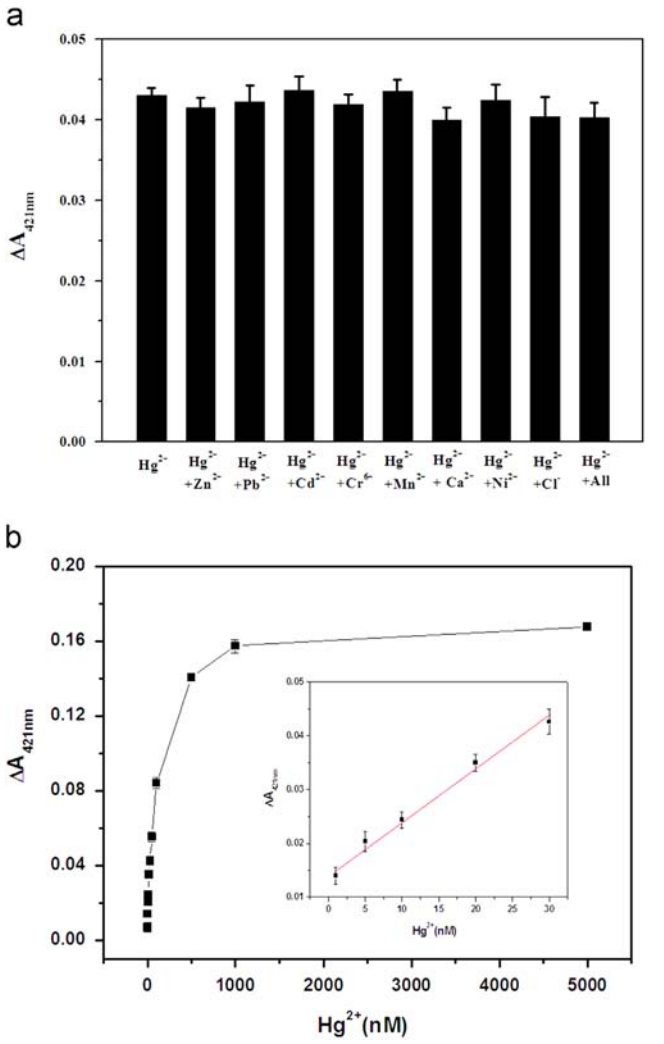

Fig. 6. (a) The selectivity of the Hg^{2+} sensing assay in the presence of 25 nM Hg^{2+} and 2.5 μM of other metal ions. (b) The calibration curve corresponding to the $\Delta A_{421\ nm}$ of the Hg^{2+} sensing assay with different Hg^{2+} concentrations after 10 min catalytic reactions. The inset presents the amplification of the linear range from 1 nM to 30 nM with a correlation coefficient of 0.9923. All data were obtained from five independent experiments, and the error bars denote standard deviations.

3.3. Selectivity of the Hg^{2+}-sensing assay

To test the selectivity of the Hg^{2+}-sensing assay, 2.5 μM aliquots of other metal ions including Zn^{2+}, Pb^{2+}, Cd^{2+}, Cr^{2+}, Mn^{2+}, Ca^{2+}, Ni^{2+} and Cl^- were added individually or in combination to the detection solution together with 25 nM Hg^{2+}. The $\Delta A_{421\ nm}$ signal was measured, and the results are reported in Fig. 6a. It can be seen that only slight effects of co-existent ions has been observed on the UV absorption of the Hg^{2+} sensor. Even when all of the metal ions were present in the detection solution together, little interference was exhibited. This result verifies the high selectivity of the assay for Hg^{2+} against interfering materials and demonstrates its applicability in complex aqueous systems.

3.4. Quantitative detection of mercury ions

Various amounts of Hg^{2+} (1 nM-5 μM) were incubated under the optimal conditions to obtain the calibration curve. The data in Fig. 6b presented that the increase in $\Delta A_{421\ nm}$ depends on the increase in the Hg^{2+} concentration. However, when Hg^{2+} concentration is higher than 1 μM, the absorbance intensity was not obviously enhanced and a plateau is reached, because the interaction between the thymine residues and Hg^{2+} reaches a balance and saturation. A liner response was obtained for Hg^{2+} concentrations ranging from 1 nM to 30 nM, according to the equation $\Delta A_{421\ nm} = 0.0147 + 1.0 \times 10^{-3} c_{Hg2+}$ (nM) with correlation coefficient 0.9923 and P-value 0.037 at 95% confidence level. A detection limit of 0.8 nM Hg^{2+} was determined by evaluating the average response of the blank plus three times the standard deviation, and this limit is far lower than the 10 nM US EPA limit for drinking water. In comparison with previous colorimetric sensors [16], the use of Au NP aggregation significantly improves the sensitivity of Hg^{2+} detection.

3.5. Application to sample analysis

As the quantitative analysis and effective detection of Hg^{2+} in practical aqueous systems is of great importance for human health and the environment, our sensor was applied to analyse three real samples (tap water, river water and industrial wastewater) before and after the addition of certain amounts of Hg^{2+}. The analytical results corresponding to the determination of Hg^{2+} in the three samples are shown in Table 1. The concentration of mercury ions in the first two samples was too low to be detectable. However, when 10 nM of Hg^{2+} standard solution was added, the readable signals were observed. The response of industrial wastewater

Table 1
Detection of Hg^{2+} in aqueous samples.

Sample	Hg^{2+} measured (nM)[a]	CVAAS (nM)[b]	Addition of Hg^{2+} (nM)	Detection of Hg^{2+} (nM)[a]	Recovery (%)
Tap water	Not found	Not found	10.0	10.4	104.0
River water	Not found	Not found	10.0	9.3	93.0
Industrial wastewater	12.3	12.5	12.0	25.4	109.2

[a] All data were obtained from three independent experiments.
[b] All data were obtained by cold vapor atomic absorption spectrometry.

sample was measurable and the addition of 12 nM Hg^{2+} showed about twice signal enhancement more than the original indicating that interfering materials in the samples did not influence Hg^{2+} detection. Compared with the data of cold vapor atomic absorption spectrometry (CVAAS) the results obtained by proposed Hg^{2+}-sensor were satisfied. The recovery values between 93.0 and 109.2% clearly manifest the potential of this sensing assay to detect Hg^{2+} in real aqueous samples.

4. Conclusion

The colorimetric detection strategy proposed here demonstrates the feasibility of specific, sensitive and convenient detection of trace amounts of mercury ions in drinking water. The application of Au NP aggregation, MNPs and an endonuclease results in efficient amplification of the colorimetric signal of Hg^{2+}, elimination of the interference from co-existing substances and reduction of the background. Compared with individual Au NPs, the use of Au NP aggregation almost quadruples the catalytic capacity. Moreover, the endonuclease digestion and the separation of MNPs enable convenient detection of Hg^{2+} in the liquid phase. This assay enabled the measurement of absorbance signals of Hg^{2+} from 1 nM to 30 nM with a detection limit of 0.8 nM, which is much lower than the US Environmental Protection Agency (EPA) limit of Hg^{2+} for drinkable water (10 nM). The sensing assay can also be applied in practical aqueous systems to determine the Hg^{2+} content. Given the sensitivity and specificity of this method, we expect that it will be a promising tool for practical Hg^{2+} analysis.

Seven metabolites derived from five VOCs
Human urine

ABSTRACT

Recently, the International Agency for Research on cancer classified outdoor air pollution and particulate matter from outdoor air pollution as carcinogenic to humans (IARC Group 1), based on sufficient evidence of carcinogenicity in humans and experimental animals and strong mechanistic evidence. In particular, a wide variety of volatile organic compounds (VOCs) are volatized or released into the atmosphere and can become ubiquitous, as they originate from many different natural and anthropogenic sources, such as paints, pesticides, vehicle exhausts, cooking fumes, and tobacco smoke. Humans may be exposed to VOCs through inhalation, ingestion, or dermal contact, which may increase the risk of leukemia, birth defects, neurocognitive impairment, and cancer. Therefore, the focus of this study was the development of a simple, effective and rapid sample preparation method for the simultaneous determination of seven metabolites (6 mercaptic acids+*t*,*t*-muconic acid) derived from five VOCs (acrylamide, 1,3-butadiene, acrylonitrile, benzene, and xylene) in human urine by using automated on-line solid-phase extraction (SPE) coupled with liquid chromatography–electrospray tandem mass spectrometry (LC–MS/MS). An aliquot of each diluted urinary sample was directly injected into an autosampler through a trap column to reduce contamination, and then the retained target compounds were eluted by back-flush mode into an analytical column for separation. Negative electrospray ionization tandem mass spectrometry was utilized for quantification. The coefficients of correlation (r^2) for the calibration curves were greater than 0.995. Reproducibility was assessed by the precision and accuracy of intra-day and inter-day precision, which showed results for coefficient of variation (CV) that were low 0.9 to 6.6% and 3.7 to 8.5%, respectively, and results for recovery that ranged from 90.8 to 108.9% and 92.1 to 107.7%, respectively. The limits of detection (LOD) and limits of quantification (LOQ) were determined to within 0.010 to 0.769 ng mL^{-1} and 0.033 to 2.564 ng mL^{-1} in this study. A stability study test included 3 freeze/thaw cycles during short-term storage at room temperature for 36 h and long-term storage at −20 °C for 1 month, and the CV (coefficient of variation) showed less than 8.4, 7.4 and 9.7%, respectively. To the best of our knowledge, this is the first study to provide simple, small injection volumes (40 μL) and a rapid LC–MS/MS method combined with an on-line SPE step for the simultaneous detection, identification, and quantification of seven metabolites derived from five VOCs in human urine for evaluation of the future risk of human exposure to volatile organic compounds.

1. Introduction

Recently, the International Agency for Research on cancer classified outdoor air pollution and particulate matter from outdoor air pollution as carcinogenic to humans (IARC Group 1), based on sufficient evidence of carcinogenicity in humans and experimental animals and strong mechanistic evidence [1]. Air pollutants belong to diverse groups of chemical compounds that are generally grouped into four categories: gaseous pollutants (volatile organic compounds (VOCs), including benzene); persistent organic compounds (polycyclic aromatic hydrocarbons (PAHs), including benzo[a]pyrene (BaP); heavy metals; and, particulate matter (PM).

In particular, volatile organic compounds (VOCs) are high-production chemicals with several common industrial applications such as chemical intermediates, dry-cleaning chemicals, and solvents, and also are present in cigarette smoke, gasoline, factory fumes and automobile exhaust [2]. According to EPA reports, several VOCs are mutagenic, neurotoxic, genotoxic, and/or carcinogenic and may increase the risk of leukemia, birth defects, neurocognitive impairment, and cancer from both short- and long-term exposure to humans [2–5]. Examples such as benzene and 1,3-butadiene all are proven carcinogens [6]. Acrylamide and acrylonitrile are IARC class 2 carcinogens [7,8]. Xylene has been classified by the IARC as group 3, but it is an important industrial chemical and is a constituent of tobacco smoke [9]. These findings strongly suggest a potential link between exposure to VOCs and diseases in humans.

Over the past few years, exposure to VOCs has often been assessed by the determination of VOC metabolites in urine, and the main advantages of monitoring urinary VOC metabolites are as follows: non-invasive, longer physiological half-life of metabolites compared with parent compounds, and the specificity of mercapturic acid (MAs) metabolites. MAs can be regarded as the final product of the mercapturate metabolic detoxification pathway, and also have been recognized as *N*-acetyl-L-cysteine-*S* conjugates. MAs are released into circulation and removed from the blood by the kidneys for excretion in urine [10,11]. In the present study, we monitored urinary VOC metabolites as biomarkers of exposure to acrylamide, 1,3-butadiene, acrylonitrile, benzene, and xylene. These seven metabolites (Fig. 1) were included: *N*-acetyl-*S*-(2-carbamoyl-2-hydroxyethyl)-L-cysteine (GAMA), *N*-acetyl-*S*-(3,4-dihydroxybutyl)-L-cysteine (DHBMA), *N*-acetyl-*S*-(4-hydroxy-2-buten-1-yl)-L-cysteine (MHBMA3), *N*-acetyl-*S*-(2-cyanoethyl)-L-cysteine (CYMA), trans,trans-muconic acid (*t,t*-MA), *S*-phenylmercapturic acid (PMA), and *N*-acetyl-*S*-(2,4-dimethylphenyl)-L-cysteine (2,4-DPMA).

Various traditional analytical approaches with different sensitivities and specificities can be used to measure VOC metabolites in urine samples. These approaches include gas chromatography with flame ionization detection (GC–FID) [12], gas chromatography with electron capture detection (GC–ECD) [13], gas chromatography with mass spectrometry (GC–MS) [14], high-performance liquid chromatography with ultraviolet absorption detection (HPLC–UV) [15], and high-performance liquid chromatography with fluorescence (HPLC–FD) [16]. All those approaches have specificity for individual VOC metabolites, but a sample preparation protocol such as that used for chemical derivatization reactions is needed or the result could be a lack of sensitivity for low concentrations of VOC metabolites. E-nose analysis of exhaled breath is a new method for assessing VOC profiles in humans [17,18]. Recently, liquid chromatography tandem mass spectrometry (LC–MS/MS) methods have proven to be highly selective, sensitive, accurate, and with the capacity to simultaneously quantify VOC metabolites in human urine [2,11,19,20].

Most published methods for the determination of VOC metabolites in urine involve a labor-intensive and time-consuming procedure that requires purification by solid-phase extraction (SPE) [21–25], such as molecularly imprinted polymers (MIPs) [26] and C18 [27] or liquid–liquid extraction (LLE) [28,29]. To avoid the drawbacks of the extraction method, therefore, we developed a simple, quick and cheap sample preparation method and combined it with on-line SPE-LC–MS/MS, which was rapid, automated, and required only a small sample volume with a decreased matrix effect that provided an accurate, precise and simultaneous determination of these seven metabolites derived from five VOCs (acrylamide, 1,3-butadiene, acrylonitrile, benzene, and xylene.) in human urine samples. Combining these two technologies not only enhanced the signal but also improved the sensitivity compared with other existing methods currently in use. To the best of our knowledge, this is the first study to provide simple, small-injection volumes (40 μL), and a rapid LC–MS/MS method combined with an on-line SPE step that was developed for the simultaneous detection, identification, and quantification of these seven metabolites derived from five VOCs in human urine for an estimation of the possible risk of human exposure to volatile organic compounds.

2. Experimental

2.1. Chemical and reagents

N-acetyl-*S*-(2-hydroxy-3-propionamide)-L-cysteine dicyclohexylammonium salt (GAMA), *N*-acetyl-*S*-(2-hydroxy-3-propionamide)-L-cysteine-d_3 dicyclohexylammonium salt (GAMA-d_3),

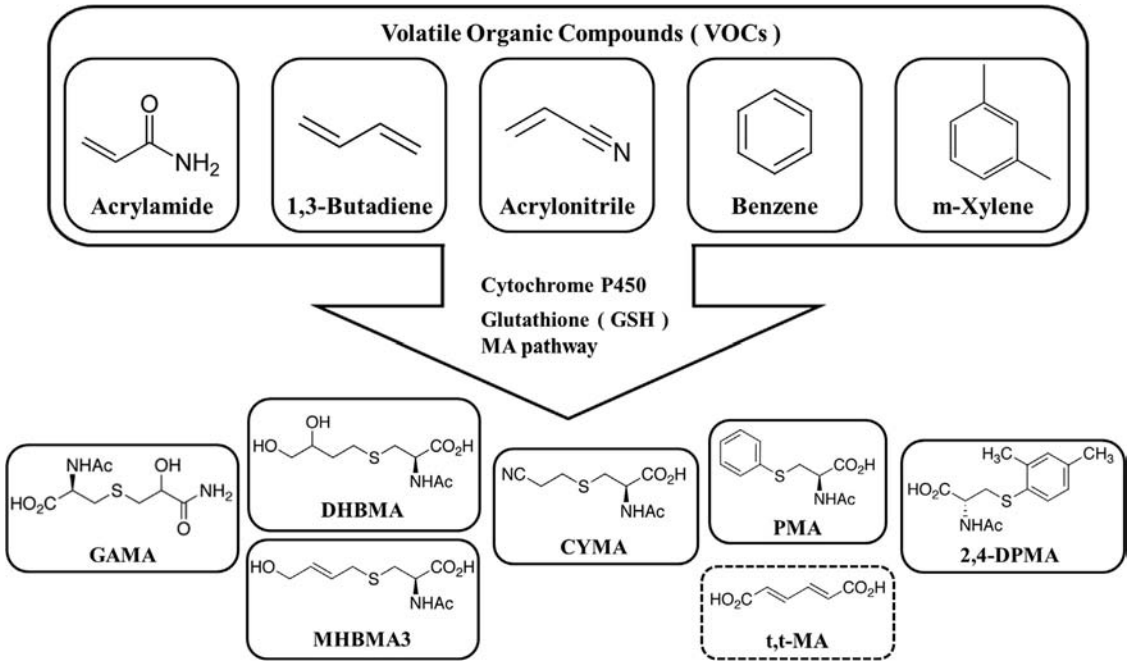

Fig. 1. Metabolic pathway of seven metabolites derived from five VOCs (6 mercapturic acids + *t,t*-muconic acid) in this study.

trans, trans-muconic acid (*t,t*-MA), trans, trans-muconic acid-d_4 (*t,t*-MA-d_4), *S*-phenylmercapturic acid (PMA), *S*-phenyl-d_5-mercapturic acid (PMA-d_5), *N*-acetyl-*S*-(2-cyanoethyl)-L-cysteine (CYMA), *N*-acetyl-*S*-(2-cyanoethyl)-L-cysteine-d_3 (CYMA-d_3), *N*-acetyl-*S*-(3,4-dihydroxybutyl)-L-cysteine (DHBMA), *N*-acetyl-*S*- (3,4-dihydroxybutyl) -L-cysteine-d_7 (DHBMA-d_7), *N*-acetyl-*S*-(4-hydroxy-2-buten-1-yl)-L-cysteine (MHBMA3), *N*-acetyl-*S*-(4-hydroxy-2-buten-1-yl)-L-cysteine-d_3 (MHBMA3-d_3), *N*-acetyl-*S*-(2,4-dimethylphenyl)-L-cysteine (2,4-DPMA) and *N*-acetyl-*S*-(2,4-dimethylbenzene)cysteine-d_3 (2,4-DPMA-d_3) were obtained from Toronto Research Chemicals.

HPLC-grade methanol (MeOH) and HPLC-grade acetonitrile (ACN) were purchased from J.T. Baker. Formic acid (FA) and Ammonium acetate (AA) were purchased from Sigma-Aldrich. Acetic acid (HOAc) was purchased from Merck.

2.2. Sample preparation method

The urinary samples were thawed from −20 °C and immediately centrifuged at 3000 rpm and 4 °C for 10 min. To a 40 μL aliquot of each urinary sample supernatant after centrifugation was added 10 μL 20% HOAc (v/v), the sample was allowed to acidify, and then it was diluted with 350 μL 5% ACN (v/v)+10 mM AA. Finally, a 25 μL aliquot of diluted sample was spiked with 25 μL of internal standards (IS) solution (400 ng mL^{-1} *t,t*-MA-d_4, 50 ng mL^{-1} DHBMA-d_7, and 100 ng mL^{-1} PMA-d_5, 2,4-DPMA-d_3, MHBMA3-d_3, CYMA-d_3, GAMA-d_3) prior to vortex mixing, and then the sample was kept frozen at −20 °C until it could be analyzed. A 40 μL aliquot of diluted urine sample was injected into the analytical system.

2.3. Automated on-line SPE

The column-switching system used in the present study is described in detail elsewhere [30]. This system consisted of a switching valve (10-port, 2-position microelectric actuator from Valco Instrument Co., Ltd.) and an Inertsil ODS (33 mm × 4.6 mm, 5 μm) column. The switching valve function was controlled by Analyst 1.4.2™ software (AB SCIEX, Canada). The column-switching operation, including the LC gradients, used during the online cleanup and the analytical procedures are summarized in Table 1. When the switching valve was at position A, 40 μL of the prepared urine sample was loaded onto the trap column via an autosampler (Agilent 1200 Series; Agilent Technology, U.S.A.), and a binary pump (Agilent 1200; Agilent Technology) delivered 100% solvent A (100% H_2O) at a flow rate of 1 mL min^{-1} as the loading and washing solvent (Eluent I). After the trap column was flushed with the loading solvent for 1.5 min, the valve was switched to the injection position (position B) to inject the sample into the analysis column. At 3.0 min after injection, the valve was switched back to position A, and the column again was eluted with solvent A (Eluent I) using a linear gradient from 100% solvent A to 100% solvent B (90% ACN, v/v with 0.1% formic acid) for 6.0 min, followed by 100% solvent A for 1.9 min for equilibration of the trap column and preparation for the next analysis. The total run time was 11 min.

2.4. LC–MS/MS analysis

40 μL aliquots of diluted urine were separated on an Inertsil ODS-80 Å (150 mm × 4.6 mm, 5 μm) column at a flow rate of 1.0 mL min^{-1} using the Agilent 1200 HPLC system. The optimized mobile phase gradient involved the following alternations of mobile phase A (5% ACN, v/v with 0.1% formic acid) and mobile phase B (90% ACN, v/v with 20 mM ammonium acetate). The gradient was started at 100% mobile phase A, which was maintained for 3 min, then changed to 90% mobile phase A in 0.1 min. This composition was held for 5.0 min then ramped to 0% mobile phase A for 3.5 min, then ramped again to 100% mobile phase A in 0.1 min, and held for 2.4 min at 100% mobile phase A to finish the 11 min cycle of analysis before the next sample was injected. The mass spectrometric data were collected using a triple–quadrupole mass spectrometer, API 3000 (Applied Biosystem, MDS SCIEX, Concord, Ontario, Canada), operating with a TurboIonSpray source. The mass spectrometer coupled with electrospray ionization (ESI) interfaces was operated in negative ion mode at an ion spray voltage of −4200 V. The turbospray settings were as follows: nebulizer and curtain gas at 15 psi, collision-assisted dissociation (CAD) at 6 psi, and the source heater probe temperature at 550 °C.

2.5. Method validation

The aim of this study was to develop a sensitive, precise, and accurate method, so we discussed the parameters as follows and obeyed the criteria from the US FDA [31]. The urine was collected and then pooled from 5 healthy volunteers (nonsmoker) and analyzed by LC–MS/MS for the presence of the seven metabolites derived from five VOCs; three of the VOC metabolites revealed no signals, ($S/N < 3$). The exceptions were GAMA, DHBMA, CYMA and DHBMA (the level close to $S/N \leq 10$), and the pooled urine was also used as the blank urine matrix for the matrix effect test.

2.5.1. Stock solution and calibration curve

The seven stock standard solutions were prepared in MeOH, and they were stored in polypropylene screw-top tubes at −20 °C.

Table 1
Chromatographic conditions of the on-line SPE LC–MS/MS.

11.0	1.0	100	0	8.5	1.0	0	100			
				8.6	1.0	100	0			
				11.0	1.0	100	0			

[a] Eluent I:Solvent A: 100% H_2O; Solvent B: 90% ACN (v/v) with 0.1% FA.
[b] Eluent II: Solvent A: 5% ACN (v/v) with 0.1% FA; Solvent B: 95% ACN (v/v) with 20 mM AA.

In order to evaluate the amounts of analytes in the urine, a set of nine concentrations of standard solutions were diluted from 0.1 to 50.0 ng mL^{-1} (2.5 to 50.0 ng mL^{-1} for *t,t*-MA) with 5% ACN (v/v)+ 10 mM AA and blank urine matrix, and were spiked with a fixed amount of 400 ng mL^{-1} *t,t*-MA-d_4, 50 ng mL^{-1} DHBMA-d_7, and 100 ng mL^{-1} PMA-d_5, 2,4-DPMA-d_3, MHBMA3-d_3, CYMA-d_3, and GAMA-d_3 as internal standards (IS). The reagent blank (5% ACN, v/v with 10 mM AA) and quality control (QC) samples were also injected after every twenty sample injections to test the total analytical process. The QC sample was prepared daily at 10 ng mL^{-1} standard solution containing IS in a solvent.

2.5.2. Precision and accuracy

Precision and accuracy were investigated at four spike levels (1, 5, 10, and 20 ng mL^{-1}) of the standard solutions into the pooled urine samples. The accuracy and precision of the assay was determined by analyzing replicates ($n=5$) spiked with 1, 5, 10 and 20 ng mL^{-1} in the pooled urine samples and by calculating the CV (coefficient of variation).

2.5.3. Intra-day and inter-day analysis

Experiments on intra-day and inter-day variations were assessed by identical analyses of pooled urine samples. The intra-day accuracy and precision of the assay was determined by analyzing replicates ($n=5$) spiked with 1, 5, 10 and 20 ng mL^{-1} in the pooled urine samples and calculating the accuracy and CV (coefficient of variation). The inter-day was assessed by analyzing replicates of the pooled urine samples ($n=5$) obtained on different days (replicates per day for 6 days) from the same subject.

2.5.4. Matrix effect

Matrix effects were assessed at two concentrations for each of the seven metabolites derived from five VOCs by comparing the peak areas of quintuplicate runs at each concentration for analyte standards in a neat solvent and in the spiked pooled urine samples. The relative matrix effect was established according to the following formula:

$$\mathrm{ME}\% = A_{(\text{analyte standards (in diluted urine)})}/A_{(\text{analyte standards (neat solvent)})} \times 100\%.$$

2.5.5. Freeze–thaw and stability

Stability was investigated by spiking with four levels (1, 5, 10, and 20 ng mL^{-1}) of standard solutions into pooled urine samples, and the accuracy were calculated to check the stability in the replicates under different conditions: (1) three freeze–thaw cycles, (2) short-term storage in an autosampler for 36 h, and (3) long-term storage at −20 °C for one month.

2.6. Statistical analysis

Data were analyzed using SPSS software (Version 17.0 for Windows; SPSS Inc., Chicago, IL, USA), and were compared using a Student's *t*-test ($p<0.05$ significance level).

2.7. Subjects

The present study was approved by the Institutional Review Board of the Fu Jen Catholic University. Spot urine samples were collected at randomly time in the morning and stored at −20 °C until analysis. The average age of the 55 male smokers was 38.67 ± 7.83 years and the average age for the 55 male nonsmokers was 40.20 ± 9.26 years.

3. Results and discussion

3.1. Optimization of the LC–MS/MS condition

The enzymatic pathways for metabolism (GSH, CYP 450, and MA pathway) in humans were used to select the target VOC metabolites in the present study [7,32–34]. Our goal was to develop an effective and rapid method with demonstrated validity for the quantification of VOC metabolites in urine samples. Herein, to achieve a more sensitive product ion, the optimal mass fragmentations of target compounds for the achievement of a multiple reaction monitoring (MRM) mode were investigated by directly infusing 1 μg mL^{-1} each of the standard solutions and the internal standard solutions (IS) at 10 μL min^{-1} into a mass spectrometer using a syringe pump (KD Scientific, KDS 100). The negative electrospray ionization mode was most efficient at generating the $[M-H]^-$ precursor ions that provided the best sensitivity for all target analytes. Under these conditions, the tandem mass spectrometry parameters were optimized for the sensitive and selective isolation of the precursor ions and their fragmentations, and all the parameters were summarized for this study (Table 2): quantitative pair (Q1/Q3), declustering potential (DP), focusing potential (FP), collision energy (CE), and collision cell exit potential (CXP).

Six of the seven metabolites (except for *t,t*-MA) are known to have similar structures (Fig. 1), and another consideration was the testing of different mobile phases and columns that would lead to the selection of a chromatographic method that could achieve higher retention, the greatest intensity, and peak shapes for all compounds. For example, we evaluated mobile phase compositions such as acetonitrile with either ammonium acetate (10 or 20 mM AA) or formic acid (0.1% FA). The addition of ammonium acetate improved the peak shape and intensity, and all the VOC metabolites achieved the highest peak responses and the greatest peak shapes using acetonitrile with ammonium acetate (95% ACN+20 mM AA (v/v)) rather than with formic acid (95% ACN+0.1% FA (v/v)). As a result, the optimal separation of VOC metabolites occurred using (A) 5% ACN+0.1% FA (v/v) and (B) 95% ACN+20 mM AA (v/v) in a total run of 11 min, as shown in Fig. 2. Moreover, in order to solve the matrix effect problem, we developed an automated on-line C18 SPE column-switch technique for the measurement of VOC metabolites. The composition of the

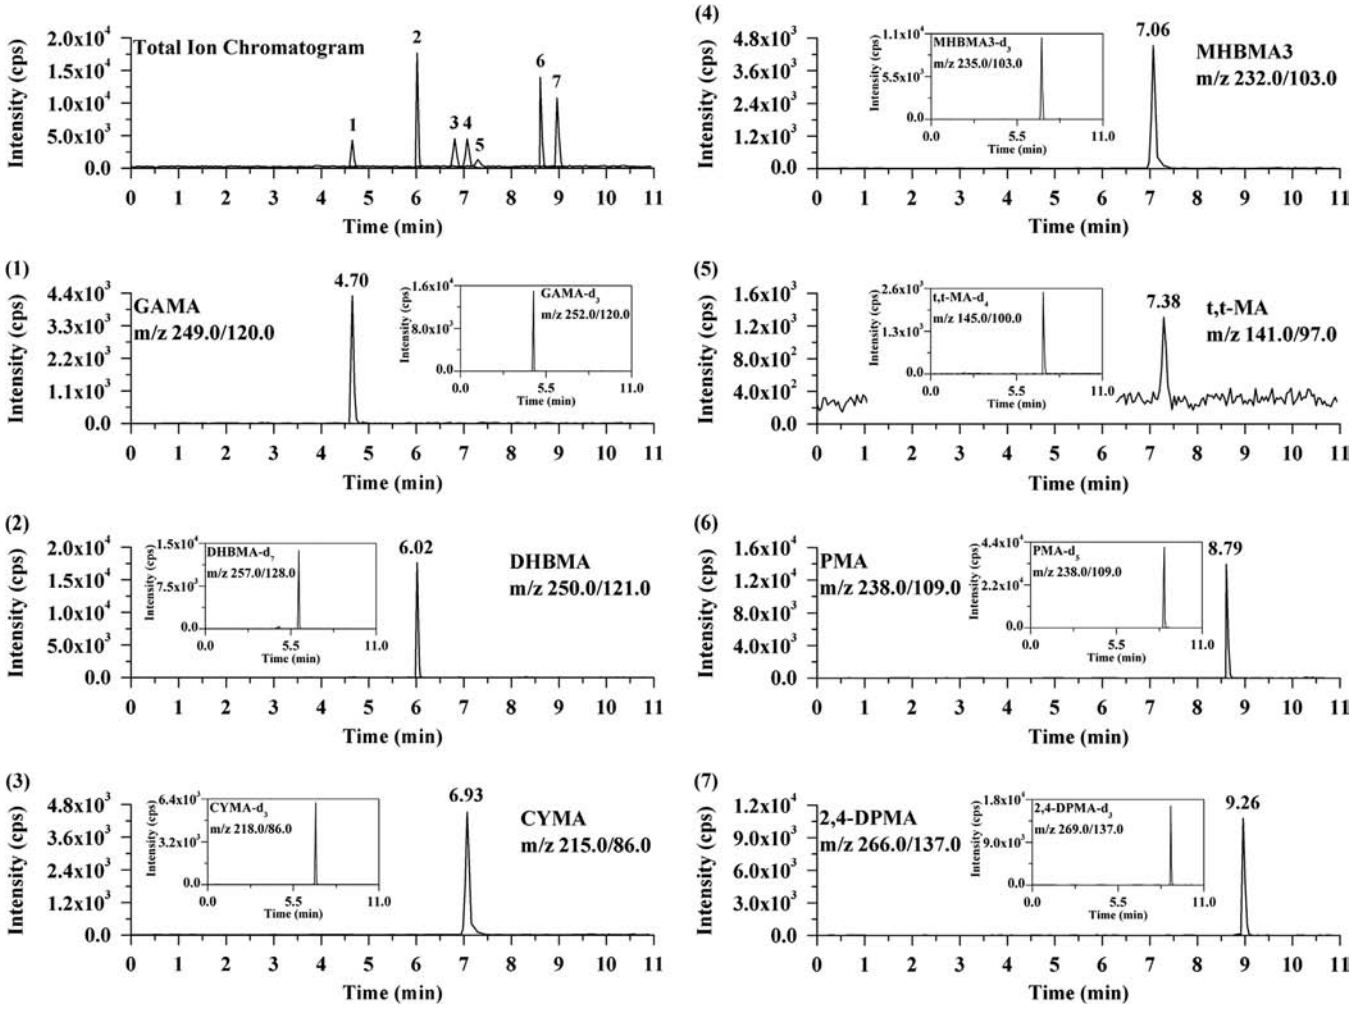

Fig. 2. MRM chromatograms of on-line SPE LC-MS/MS analysis of 10 ng mL^{-1} standards: (1) GAMA, (2) DHBMA, (3) CYMA, (4) MHBMA3, (5) *t,t*-MA, (6) PMA, and (7) 2,4-DPMA.

whole system included the mobile phase, an on-line SPE trap column and an analytical column, which enhanced the chromatographic selectivity and reproducibility, as shown in Table 1. However, when the on-line C18 SPE column-switch technique and the off-line (by direct injection to the analytical column) chromatogram were compared, the latter resulted in matrix effects that led to either the suppression or the enhancement of the analyte response, as shown in Fig. 3. When comparing the signal-to-noise (*S*/*N*) ratio for the seven analytes, the *S*/*N* ratio signals using the on-line C18 SPE column-switch technique were 1.03- to 7.81-fold (data not shown) more sensitive than the off-line method.

To the best of our knowledge, this is the first study to determine the seven metabolites derived from five VOCs using on-line SPE coupled with LC–MS/MS, this method can indeed reduce the endogenous contaminants and offers a new analytical approach to the identification of selected metabolites in human urine for an estimation of the possible risk of human exposure to volatile organic compounds.

3.2. Optimization of the sample preparation method

A rapid and simple sample preparation method played an important role in the present study. In order to assess whether the acidification procedure affected the signal response we only spiked the solvent blank with an IS solution (5% ACN (v/v)+ 10 mM AA). The results showed that the seven metabolites derived from five VOCs had no signal ($S/N < 3$) during the analytical process. Thus, we used identical sample preparation methods to evaluate three different acids, 20% HOAc, 20% FA, and 20% HCl (v/v) to determine the optimal acidification conditions, as described in Section 2.2. When the data were compared (Fig. 4), it was apparent that the best recovery was provided from 20% HOAc. A non-acidified urinary sample may cause a high matrix effect for all metabolites from the addition of acid into a urinary sample and the resultant precipitation of protein and the need for centrifuge to remove interferences. To investigate this acidification effect, working solution with different percent values ranging from 5% to 20% (v/v) were studied and indeed found increased DHBMA and PMA levels. The results showed that by increasing the percentage of HOAc, the recovery was satisfied in (Fig. 4B). As mentioned above, the optimal sample preparation method involved adding10 μL 20% HOAc (v/v) to 40 μL of a urinary sample in order to acidify it, followed by dilution. Finally, the diluted sample was spiked with a specific amount of IS solution prior to analysis.

3.3. Calibration curves and limits of quantitation

There are two significant considerations in the development of any analytical method: the linearity range and the sensitivity of the method. Calibration curves were calculated by plotting a peak-area ratio of the standards and IS against the concentration, according to the following formula: Ratio$=(A_{\text{STD in neat solvent}})/(A_{\text{IS in neat solvent}})$.

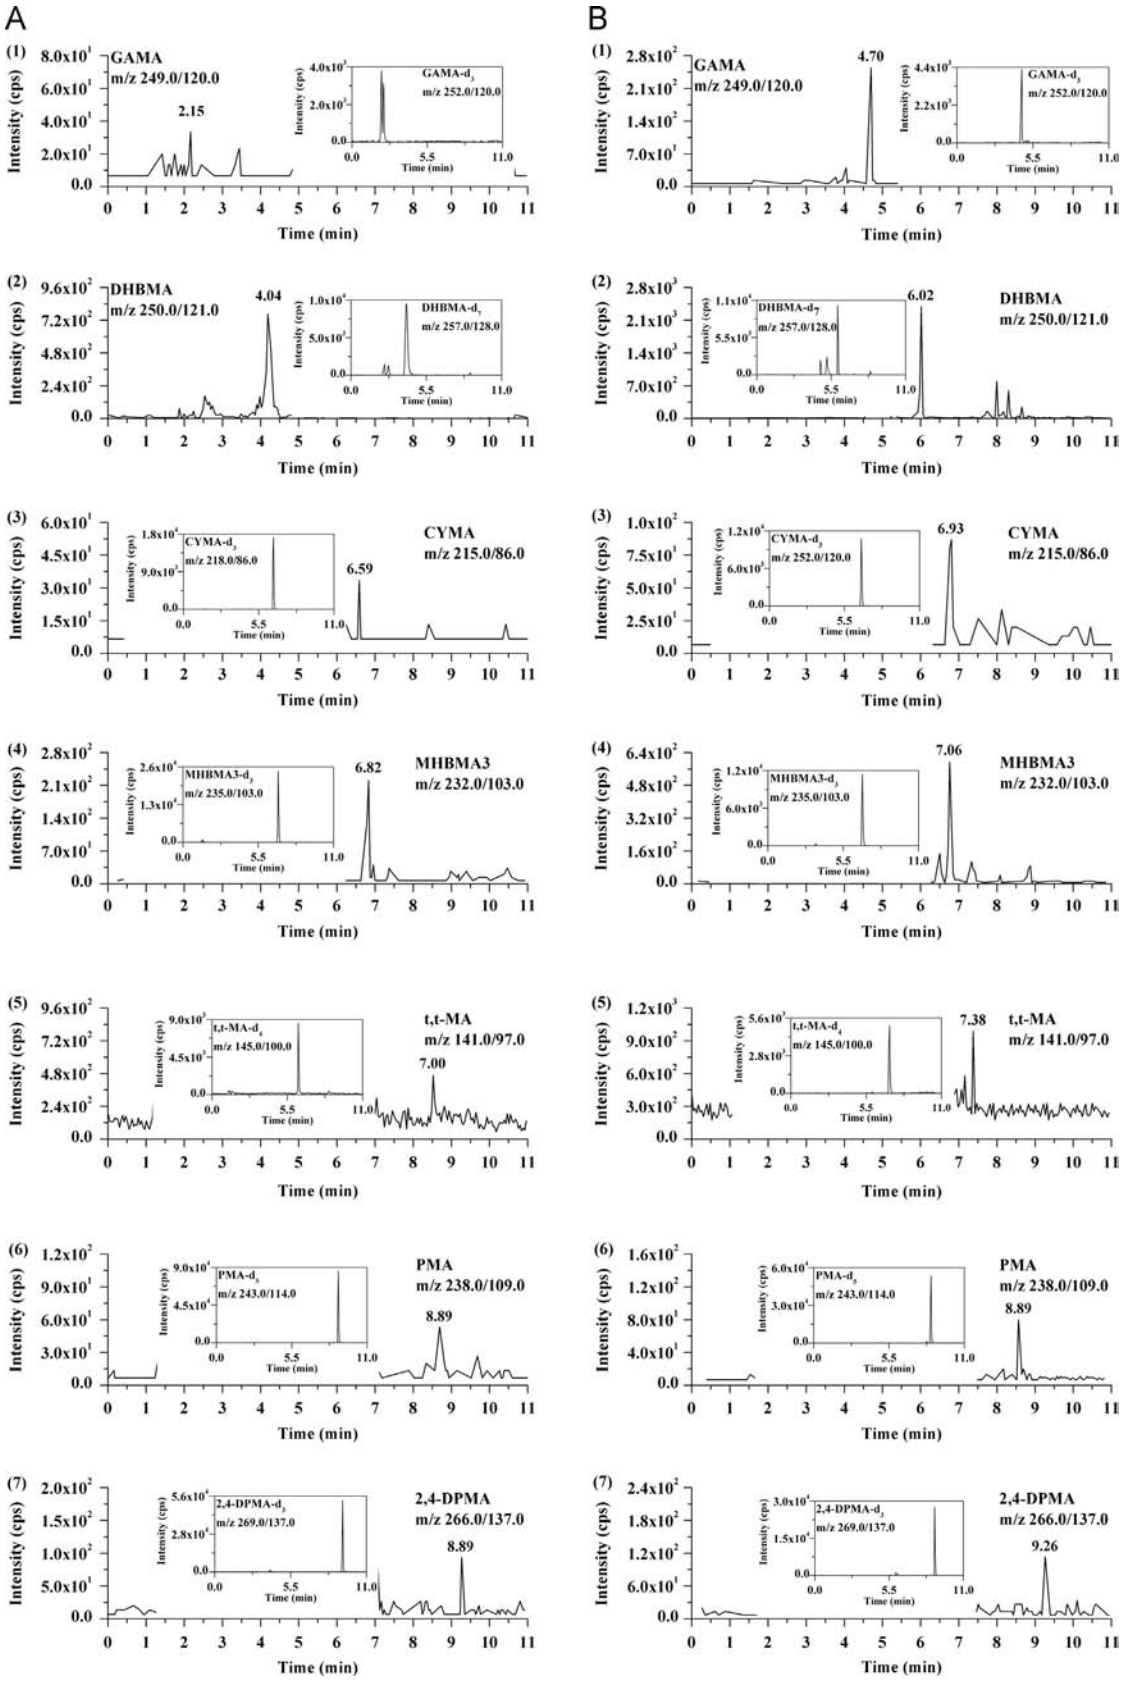

Fig. 3. Representative MRM chromatograms of (A) off-line SPE (B) on-line SPE LC-MS/MS analysis for the 10 ng mL^{-1} spike of seven metabolites derived from five VOCs in a blank urine sample.

Our calibration curves ranged from 0.1 to 50.0 ng mL^{-1}, except for *t*, *t*-MA, which ranged from 2.5 to 50.0 ng mL^{-1}, and the calibration curves had correlation coefficients higher than 0.995, with the neat solvent as well as with the blank urine matrix.

A comparison of the slopes showed no significant differences and the calibrators in the neat solvent had slopes that were similar to those prepared with the blank urine matrix (slopes were 0.92 to 1.18 for the seven metabolites derived from five VOCs, respectively). Therefore, since no analyte-free matrix is available, the limits of detection (LOD) and the limits of quantification (LOQ) were calculated using the lowest concentration of the calibration curve methodology with signal-to-noise ratios of 3 and 10 in neat solvent, which were found within 0.010 to 0.769 ng mL^{-1} (on column 0.40 to 30.76 pg in an injection volume of 40 μL) and 0.033 to 2.564 ng mL^{-1}(on column 1.32 to 102.56 pg in an injection volume of 40 μL), respectively. The performances found in this study were compared with those of the other methods reported in the literature, and the results are shown in Table 3. The advantages of the on-line SPE/LC–MS/MS over the other methods included lower LOD, LOQ and smaller sample volumes, it was relatively fast, and it was simple.

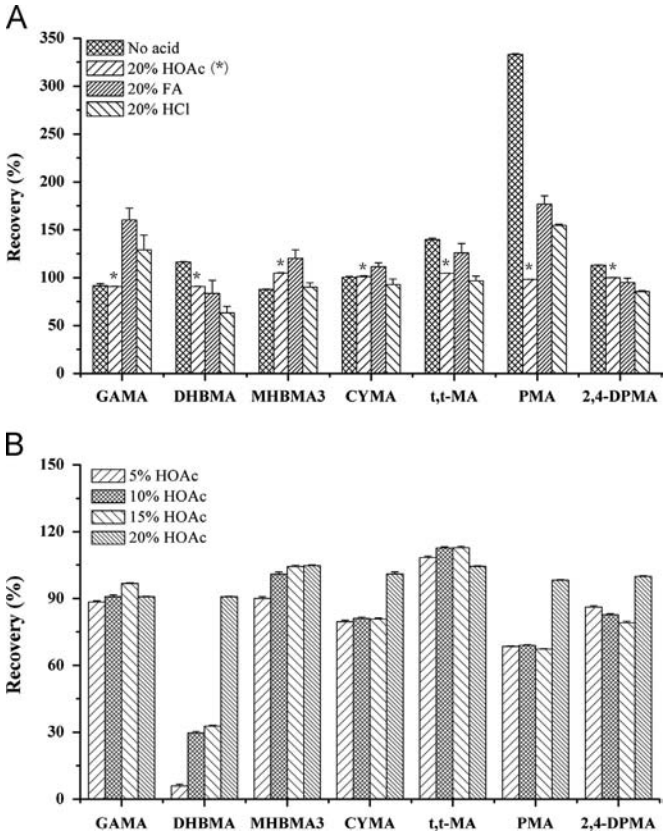

Fig. 4. (A) Effect on the recovery of the seven metabolites derived from five VOCs in human urine with different sample pretreatments by spiking of the seven internal standard solutions. (B) Effect of the different percent acetic acid (HOAc) on the recovery of the seven metabolites derived from five VOCs in human urine.

3.4. Method validation

Method validations were performed using blank urine as a sample matrix. Precision, accuracy, matrix effect, freeze/thaw, and stability were determined in Sections 3.4.1–3.4.4. Based on the results, the precision and accuracy were satisfactory, and this analytical method achieved robustness and was suitable for the simultaneous analysis of the seven metabolites derived from five VOCs in human urine.

3.4.1. Precision and accuracy

Using on-line SPE for the determination of the seven metabolites derived from five VOCs was effective and rapid. The precision and accuracy were calculated by spiking at four different known levels (1, 5, 10, and 20 ng mL^{-1}) into a blank urine matrix, and the accuracy was expressed as accuracy (%)=[(measured concentration − blank urine matrix concentration)/spiked concentration] × 100%. The detection accuracy (n=5) of the seven metabolites derived from five VOCs ranged from 90.8 to 108.9%, and the precision ranged from 0.9 to 6.6%. More than 200 urinary samples were assayed continuously without a significant occurrence of contamination to the curtain plate (data not shown). The results are summarized in Table 4.

3.4.2. Intra-day and inter-day analysis

The accuracy of the procedure was demonstrated by spiking blank urine matrix samples with four concentrations (1, 5, 10, and 20 ng mL^{-1}) of standards to evaluate inter-day and intra-day assay precision. These preparations were also used as quality control samples to monitor the day-to-day performance of the assays. The intra-day ($n=5$) and inter-day ($n=30$) assay variations were 0.9–6.6% and 3.7–8.9%, respectively, as shown in Table 4.

3.4.3. Matrix effects

There was a need to assess the possibility of a matrix effect caused by ionization competition between the analytes and coeluting compounds during on-line SPE LC–MS/MS analysis. Two concentration levels of the seven metabolites derived from five VOCs standards were compared according to the peak areas of quintuplicate runs at each concentration for analyte standards for a solvent and for spiked pooled urine samples. The observed concentrations due to either ion suppression or ion enhancement ranged from 86.7 to 120.1% for spiked concentrations of two of the seven metabolites derived from five VOCs standards showing a matrix effect in the pooled human urine samples (Table 4). The CV ranged from 1.3 to 8.4%, so it was concluded that the matrix effect did not influence the method reliability. Therefore, the use of a stable istotope-labelled internal standard compensated for by internal standards is one of the best approaches to correct for a matrix effect.

3.4.4. Freeze/thaw stability

We evaluated the stability of the seven metabolites derived from five VOCs in a blank urine matrix based on three parameters: (1) three freeze/thaw cycles, (2) short-term stability in an autosampler for 36 h, and (3) long-term stability at −20 °C for one month. We measured the accuracy after adding four concentrations into a blank urine matrix. The data showed that all of the seven metabolites derived from five VOCs were stable under different conditions, and the accuracy ranged from 80.5 to 116.8%, as shown in Table 5.

3.5. Application of the method

The optimized methodology was applied to the determination of the seven metabolites derived from five VOCs by analyzing

human urine (Table 6). The average age of the 55 male smokers was 38.67 ± 7.83 years and the average age for the 55 male nonsmokers was 40.20 ± 9.26 years. In general, the formation of the seven metabolites derived from five VOCs is complicated, involving occupational and environmental exposures, life style, stress, genetic polymorphisms of the metabolizing enzymes and physiological factors [2,7,11]. Therefore, a large intra-individual variation in the seven metabolites derived from excretion of the five VOCs was found, with RSDs ranging from 40.2–84.5% to 29.0–118.5% for smokers and nonsmokers, respectively. Many reports have shown the MHBMA consisted of three isomers (MHBMA1, MHBMA2, and MHBMA3, with the same mass (common transitions, 232/103), which were similar in chemical structure [2,11]. Thus, an appropriate chromatographic optimization was crucial for the correct quantification of all the MHBMA (Table S1 and S2). According to Alwis et al. [11] as mentioned earlier among MHBMA isomers, MHBMA3 was detected in a majority of the samples (99.0%) tested, MHBMA1 and MHBMA2 were not (< LOD) found in nonsmokers. Therefore, we monitored urinary VOC metabolites as biomarkers of exposure to 1,3-butadiene major focused on the MHBMA3, which acted as a target compound. Simultaneously, we have indicated that MHBMA3 existed and also there was no detection of either MHBMA1 or MHBMA2 in human urine for this study (Fig S1A–C). The metabolic ratio DHBMA/(DHBMA+ MHBMA), excretion of these two metabolites is mainly influenced by the activity of epoxide hydrolase (DHBMA) and glutathione-*S*-transferase (MHBMA) after 1,3-butadiene exposure [2,9,11]. However, comparisons of previous studies have found to be about 0.88–0.98 for humans [19,21], as shown in (Table S3). As a result, metabolic ratios for our subjects are somewhat lower were 0.72 ± 0.15 (0.38–1.00) in nonsmoker and 0.70 ± 0.16 (0.35–1.00) in smoker, respectively (Table 6). Although *t*,*t*-MA and DHBMA were not specific biomarker of tobacco smoke, led to lack of specificity resulting from the multiple sources of exposure can perplex the interpretation of experimental data. However, determining multiple biomarkers of different parent compounds can provide complementary information and also further get a stronger data set for assessing the potential health risk of exposure to a mixture of environmental chemicals [7,11]. For examples, both DHBMA and *t*,*t*-MA have been used as biomarkers of exposure in a large occupational study [2,11] and also distinguish groups with different exposure conditions such as environmental, occupational and cigarette smoking [6]. However, before the excretion of *t*,*t*-MA might be influenced by the uptake of sorbic acid (a popularly used food preservative), *S*-PMA is considered to be a more specific biomarker for low-level exposures to benzene [2]. According to Pouli et al.'s [35] report has shown that GC analysis of the tobacco smoke gas phase passing through acetate or 3C filter. Values are reported in 5.4 μg/Cigarette (*m*-xylene) and also information has shown the composition of xylene produced from petroleum is a mixture containing approximately 1:2:1 ratio of the *o*-xylene, *m*-xylene and *p*-xylene, respectively [27]. It is noteworthy that Gonzalez-Reche et al.'s [27] report was demonstrated the ratios of DMPA isomers (2,5 DPMA 3.3 ng mL^{-1}, 2,4 DPMA 9.9 ng mL^{-1} and 3,4 DPMA 3.7 ng mL^{-1}) in human metabolism are reflect in the ratios of xylene isomers in the air [27]. Therefore, 2,4 DPMA was major amount and easier to be examined for biological monitoring of xylene exposed workers. Thus, our method can develop a powerful tool for the estimation of internal exposure to these substances. Despite the relatively small number of samples analyzed, these data were broadly consistent with the values previously reported using different approaches (Table S3) [11]. The results of the present study found GAMA, DHBMA, MHBMA3, CYMA, *t*,*t*-MA, and PMA VOC metabolite levels that were signifcantly higher in smokers than in nonsmokers. The methods will be combined with environmental monitoring and should be useful for future epidemiological studies of exposure to VOCs in the general population.

4. Conclusion

A simple, rapid LC–MS/MS method combined with an on-line SPE step was developed for the simultaneous detection, identification, and quantification of seven metabolites found in human urine. Due to low sample consumption (40 μL of urine), the pretreatment procedure was extremely simple and involved neither costly time- nor labor-consuming sample preparation steps. The method accuracy for intra-day and inter-day assays ranged from 90.8 to 108.9% and precision was measured at 0.9 to 8.9% for the seven metabolites in human urine samples. The high selectivity and sensitivity of this method during the simultaneous measurement of the seven metabolite profiles in human urine samples offers a new analytical approach to the identification of selected metabolites in human urine for an estimation of the possible risk of human exposure to volatile organic compounds.

ABSTRACT

Bcl-2 protein is one of the anti-apoptotic members in Bcl-2 family proteins. It can regulate apoptosis in response to a wide variety of toxic agents, which has a close relationship with drug-resistance of tumor cells. Electrochemical impedance spectroscopy measurements were employed to quantify the cell concentration and analyze the expression of Bcl-2 protein on tumor cells and drug-resistant tumor cells based on the competitive immunoassay. Bcl-2 antibody and bovine serum albumin were adsorbed on Au nanoparticles to construct nanocomposites that could be captured on the Bcl-2 protein modified electrode. The binding of the nanocomposites resulted in a great increase of the charge-transfer resistance (R_{ct}) due to the strong steric hindrance effect and this effect was inhibited in the presence of MCF-7 cells and MCF-7/ADR cells owing to the competitive immunoreaction between the nanocomposites and Bcl-2 proteins on cells. Under the optimal conditions, the charge-transfer resistance change (ΔR_{ct}) is proportional to the logarithm of the cells concentration from 5×10^2 to 1.6×10^6 cell mL^{-1} with a detection limit of 170 cell mL^{-1}. The expression of Bcl-2 protein on MCF-7/ADR cells was found to be significantly higher than that in MCF-7 cells, indicating that the up-regulation of Bcl-2 protein is one of characteristics of drug-resistant tumor cells.

1. Introduction

One of the major obstacles to successful chemotherapy is that tumors frequently are resistant to certain forms of chemotherapy or develop resistance during the course of initial therapy. Three main categories of chemotherapy resistance, such as agent-specific resistance, multidrug resistance and comprehensive resistance, which influence each other, are regarded to be active on the cellular level [1]. The comprehensive resistance theory attempts to explain resistance with mechanisms that induce or prevent apoptosis. Apoptosis is a programmed death program and it can be induced by a multitude of stimuli, including growth factor withdrawal, DNA damage, and oncogene activation [2]. It is known that apoptosis plays a vital role in normal development, tissue homeostasis, and the removal of damaged and infected cells. Disruption of the normal apoptotic process is implicated in a variety of human diseases [3]. An imbalance between pro- and anti-apoptotic proteins leads to the accumulation of cells and the inability to respond correctly to apoptotic stimuli in many forms of cancer. As a result, these cancers do not respond well to cancer therapies that rely on the induction of apoptosis for their effect [4]. The Bcl-2 family of proteins are known to regulate apoptosis in response to a wide variety of toxic agents [5,6]. Bcl-2 family members possess up to four conserved Bcl-2 homology (BH) domains designated BH1, BH2, BH3, and BH4, which correspond to α-helical segments. Some proteins contain BH1–BH4 domain, and some contain only one or several of such domains [7,8]. Bcl-2 family members are given the different biological functions due to the difference between domains. This family includes both death antagonists such as Bcl-2, Bcl-xL, Mcl-1, Bcl-w and A-1 which suppress cell death, and death agonists such as Bax, Bak, Bik, Bad and Bid which promote cell death [9]. They have attracted intensive interest in both basic research to understand the fundamental principles of cell survival and cell death and drug discovery to develop a new class of anticancer agents. It is now generally accepted that the anti-apoptotic member Bcl-2 protein can protect cancer cells from apoptosis induced by a variety of anticancer agents [10,11] although the precise mechanism is unclear. Several

studies have demonstrated that high Bcl-2 expression in cancers (particularly lymphomas) correlates with poor response to chemotherapy [12,13].

The classical techniques for analysis on gene and protein expression on cells in molecular biology and cytobiology research include enzyme-linked immunoassay [14], western blotting [15], immunohistochemistry [16], flow cytometry [17], and so on. Although these methods are valid and sensitive, most of them require special equipment, talented operator and the use of labels including fluorescein and isotope. Electrochemical impedance spectroscopy (EIS) has become a very popular method in fundamental and applied electrochemistry and materials science in recent years. It is now applied to the characterization of electrode processes and complex interfaces. Moreover, this label-free technique has found its wide application in the bioanalysis and the detected objects include antigen [18], DNA [19], bacteria [20], cells [21], and so on. The most common Nyquist plot of impedance spectroscopy consists of a semicircle at higher frequencies and a line at lower frequencies that are characteristic of a kinetic controlled process and a mass-transfer controlled process at the electrode interface, respectively. The typical electrochemical interface can be represented as an electrical circuit including four parameters, in which the ohmic resistance of the electrolyte solution (R_s) and the Warburg impedance (Z_w) represent bulk properties of the electrolyte solution and diffusion features of the redox probe in solution while the double-layer capacitance (C_{dl}) and the charge-transfer resistance (R_{ct}) reveal interfacial properties of the electrode [22]. The information of surface-modification and -assembly on an electrode can be effectively obtained by EIS measurement at a proper frequency.

In the present work, the nanocomposites composed of Au nanoparticles, Bcl-2 antibody and bovine serum albumin were prepared and characterized by transmission electron microscope, UV–vis and infrared spectrophotometry, respectively. Bcl-2 proteins were immobilized on the modified glassy carbon electrode with poly-L-lysine using a covalent crosslinking method. The EIS measurements were performed to analyze the modification process and the binding of nanocomposites on the electrode surface. Tumor cells and drug-resistant tumor cells were introduced in the process of capture of the nanocomposites and their effect on the charge-transfer resistance was studied. A sensitive and label-free electrochemical method for the quantitative detection of tumor cells and analysis on Bcl-2 protein expression on cells was developed based on the competitive immunoreaction.

2. Experimental

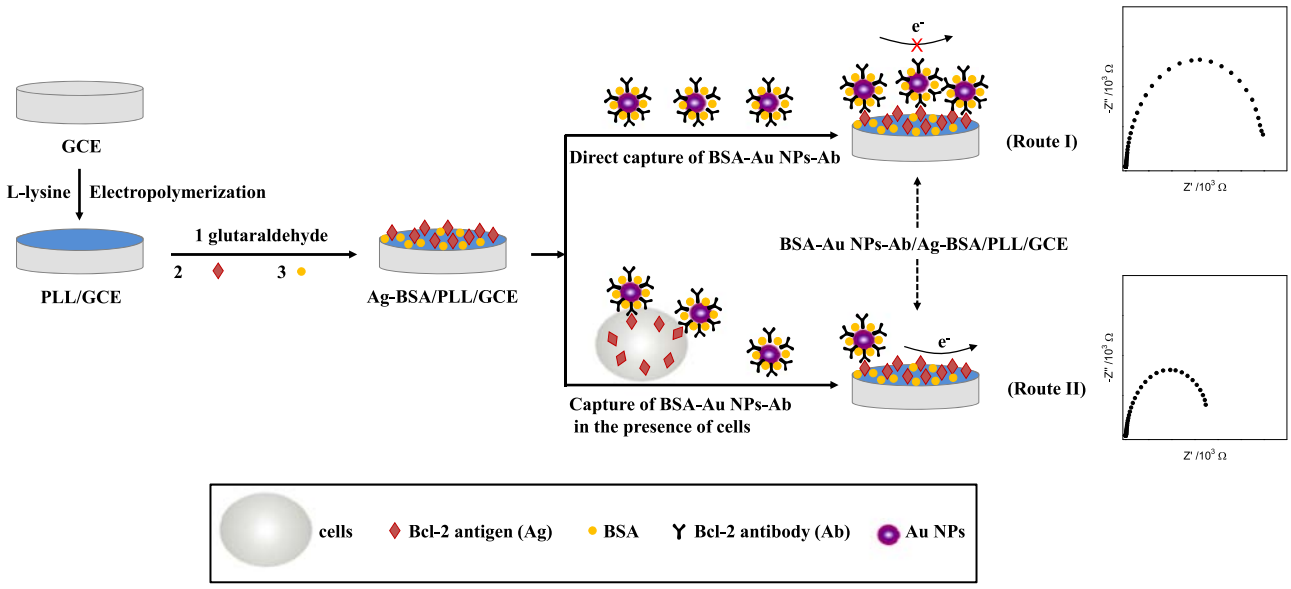
2.1. Materials and apparatus

Rabbit anti-human Bcl-2 antibody (Ab) and Bcl-2 protein (antigen, Ag) were purchased from Beijing Bio synthesis Biotechnology Co., Ltd. (China). L-lysine was obtained from Jill Biochemical Company (China). Bovine serum albumin (BSA, Sigma-Aldrich) was used as received. $HAuCl_4$ and trisodium citrate were purchased from Shanghai Chemical Reagent Co., Ltd. (China). Phosphate buffer solution (PBS, pH 7.4) consisting of 136.8 mmol L^{-1} NaCl, 9.7 mmol L^{-1} Na_2HPO_4, 2.7 mmol L^{-1} KCl and 1.5 mmol L^{-1} KH_2PO_4 was used in the experiments. Doxorubicin hydrochloride (adriamycin, ADR) was obtained from Zhejiang Hisun Pharmaceutical Co., Ltd. (China). Other chemicals were of analytical reagent grade and all aqueous solutions were prepared and diluted with doubly-distilled water.

EIS detections were performed with a CHI660 electrochemical workstation (CH Instruments, China) by using a conventional three-electrode system. Glassy carbon electrode (GCE, 3 mm in diameter) acted as the working electrode. A KCl saturated calomel electrode (SCE) served as the reference electrode. A platinum plate served as the counter electrode. The absorption spectra were recorded on a UV-2450 UV–vis spectrophotometer (Shimadzu, Japan). The sizes of gold nanoparticles (Au NPs) and BSA-Au NPs-Ab nanocomposites were characterized ex situ by a Tecnai G2 20ST transmission electron microscope (TEM, FEI, USA). The images of modified electrode surface were obtained with a JSM-6700F field emission scanning electron microscope (FESEM, JEOL, Japan). The cell-modality observation was performed with an inverted optical microscope (OLYMPUS CKX41, Japan).

2.2. Preparation of gold nanoparticles and BSA-Au NPs-Ab nanocomposites

Colloidal gold nanoparticles were prepared by a classic citrate-reduction method according to literature [23]. In brief, a 50 mL aqueous solution of 0.01% $HAuCl_4$ (w/w) was heated to boiling in a conical flask. 2 mL of 1% trisodium citrate was added to this solution drop by drop under vigorous stirring. The color of the solution changed from gray, purple, to wine red, indicating the formation of gold nanoparticles. Then, the mixed solution was stirred continuously until it was cooled to room temperature and was stored in a brown glass bottle at 4 °C for further use.



The preparation of BSA-Au NPs-Ab nanocomposite suspension was performed as following: while gently stirring, 1 mL of Ab (100 μg mL^{-1}) was added into 2.0 mL Au NPs suspension (adjusted to pH 7.4 with 0.1 M NaOH) and continuously stirred for at least 5 h. The mixed solution was centrifugated at 13,000 rpm for 20 min and the precipitate was dispersed with 1 mL pH 7.4 PBS. Then 200 μL of 5% BSA solution was added to cover the nonspecific sites. After stirring for at least 2 h, the solution was centrifugated at 13,000 rpm for 20 min. The red precipitate was re-dispersed in 1 mL pH 7.4 PBS. The such-made composite suspension could be stored at 4 °C for more than 1 month without significant decrease in activity.

2.3. Cell culture

Human breast cancer MCF-7 cells and adriamycin-resistant human breast cancer MCF-7 cells (MCF-7/ADR) were obtained from XiangYa Central Laboratory of Central South University, China. They were cultured using RPMI-1640 growth medium (from Gibco) supplemented with 10% newborn calf serum in the absence and presence of 1 mol L^{-1} ADR, respectively, in an incubator (5% CO_2, 37 °C). When the adherent cells spread over the bottom of the culture bottle, they were trypsinized and collected, then washed for three times with a sterile pH 7.4 PBS. The sediments were re-suspended in pH 7.4 PBS and then employed in the assembly processes of BSA-Au NPs-Ab nanocomposites. The density of resuspended cells was determined with a hematocytometer.

2.4. Fabrication of biosensor and measurement procedures

As shown in Scheme 1, an indirect competitive immunoassay of the expression of Bcl-2 protein on tumor cells is presented in this work. Prior to modification, GCE was polished with 0.05 μm α-Al_2O_3 power slurries until a mirror shiny surface appeared, and it was sonicated sequentially in acetone, HNO_3 (1:1, v/v), NaOH (1 mol L^{-1}) and double-distilled water for 3 min. The treated electrode was scanned between −1.0 and 1.0 V vs. SCE in 0.5 M H_2SO_4 aqueous solution for sufficient cycles to obtain reproducible cyclic voltammograms. And then the electrode was thoroughly rinsed with double-distilled water and dried with a stream of nitrogen gas. The electropolymerization of L-lysine was performed

Scheme 1. The assembly processes on the GCE surface and the measurement principle.

in 0.1 M pH 9.0 PBS containing 5 mM L-lysine by cyclic potential scanning from −1.0 to 2.2 V for 5 cycles with a scan rate of 100 mV s^{-1}. The obtained electrode was denoted as PLL/GCE. The modified electrode was then immersed in 2.5% glutaraldehyde aqueous solution for 1 h at room temperature (25 °C). A 5 μL 100 μg mL^{-1} Bcl-2 protein solution was dropped on the PLL/GCE surface and allowed to dry in refrigerator at 4 °C for overnight. Next, 5% BSA was employed to block the non-specific sites, which produced Ag-BSA/PLL/GCE. These antigen-modified electrodes were stored at 4 °C when not in use. Finally, Ag-BSA/PLL/GCEs were dipped into the BSA-Au NPs-Ab solution for 3 h at room temperature in the absence and presence of pH 7.4 PBS containing freshly trypsinized cells, respectively, which achieved the capture of the nanocomposites based on the immunoreaction. The prepared electrode was marked as BSA-Au NPs-Ab/Ag-BSA/PLL/GCE. The electrode was gently washed with pH 7.4 PBS after each step in the assembly processes. The EIS measurements were carried out in pH 7.4 PBS containing 1 mM $K_3Fe(CN)_6$, 1 mM $K_4Fe(CN)_6$, and 0.2 M NaCl at room temperature. The working electrode potential was fixed at the formal potential of the ferricyanide/ferrocyanide couple and the amplitude was 10 mV. The impedance spectrograms were collected within the frequency range between 1 mHz and 100 kHz.

3. Results and discussion

3.1. Characterization of BSA-Au NPs-Ab nanocomposites

Fig. 1A shows the UV–vis spectra of Au NPs, Bcl-2 Ab, BSA and BSA-Au NPs-Ab nanocomposites in aqueous solution from 200 to 800 nm. Au NPs had an obvious peak at about 523 nm that is regarded as a characteristic absorbance peak of Au NPs [24]. Two prominent absorption peaks at 217 nm and 280 nm, which were derived from peptide bonds [25] and Tyr and Trp residues [26], respectively, were presented on the spectrum of Bcl-2 Ab. One can find the similar absorption peaks at 213 nm and 280 nm on the spectrum of BSA. The above characteristic absorption peaks of Au NPs and proteins could be all observed in the spectrum of BSA-Au NPs-Ab nanocomposites with red shifts of some peaks. It suggests that proteins were successfully assembled on Au NPs surface. FTIR spectra of Au NPs, Bcl-2 Ab, BSA and BSA-Au NPs-Ab nanocomposites in the range of 4000-500 cm^{-1} are shown in Fig. 1B. The characteristic peaks of Au NPs at ~673, ~1402 and ~1610 cm^{-1} were ascribed to the out-of-plane bending vibration, the symmetric and asymmetric stretching vibration of $-COO^-$, respectively [27], which means that citrate was adsorbed on Au NPs that were prepared based on the redox reaction using $HAuCl_4$ and trisodium citrate. Bcl-2 Ab had two bands at ~1647 and ~1532 cm^{-1} corresponding to the absorption bands I and II of amino acids, respectively [27]. The two similar absorption bands at ~1656 and ~1532 cm^{-1} were presented on the spectrum of BSA. The absorption bands at ~1647, ~1532, ~1402 and ~673 cm^{-1} could be all found in the spectrum of BSA-Au NPs-Ab nanocomposites, indicating that the prepared nanocomposites were composed of Bcl-2 Ab, Au NPs and BSA.

Fig. 2A and B shows the TEM images of Au NPs and BSA-Au NPs-Ab nanocomposites, respectively. The average size of prepared Au NPs, which were linked each other, was measured to be around 20 nm. BSA-Au NPs-Ab nanocomposites were highly monodispersed and their mean diameter was increased in comparison with that of Au NPs, suggesting that Bcl-2 Ab and BSA were successfully assembled on the surface of Au NPs and the electrostatic repulsion was presented between the nanocomposites due to the electronegativity of the adsorbed proteins.

3.2. Capture of BSA-Au NPs-Ab nanocomposites on the antigen-modified electrode

It is known that the EIS measurement is a sensitive technique for investigating the changes of interfacial properties at electrode surfaces. Fig. 3 illustrates the Nyquist plots of the impedance spectra of the different modified electrodes. GCE exhibited almost a straight line, which indicates the excellent conductivity of the bare electrode (curve a). A low-frequency linear response and a high-frequency semicircle in the Nyquist plot, which were characteristic of a mass-transfer controlled electrode process and a kinetic controlled process at the electrode interface, respectively, could be found in the impedance spectra of PLL/GCE (curve b). The typical electrochemical interface can be represented as an electrical circuit shown in the inset of Fig. 3, which consisted of four parameters. The charge-transfer resistance, R_{ct}, was calculated to be 1500 Ω, indicating that the PLL film on the GCE surface was conductive though its conductivity was inferior to the bare GCE. The

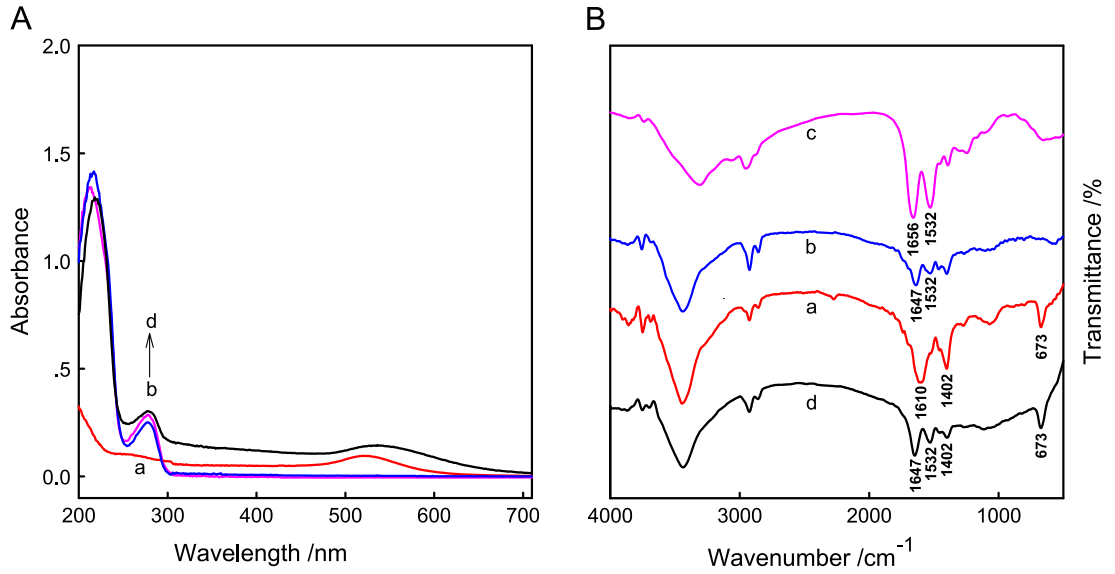


Fig. 1. UV–vis absorption spectra (A) and FTIR spectra (B) of Au NPs (a, red line), Bcl-2 Ab (b, blue line), BSA (c, pink line) and BSA-Au NPs-Ab nanocomposites (d, black line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

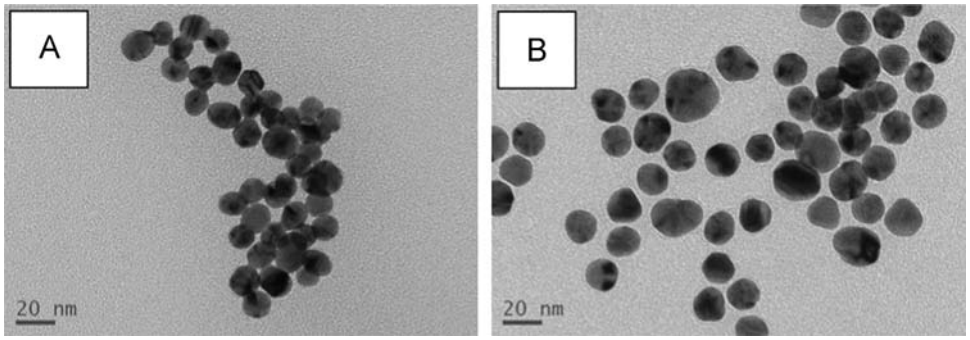

Fig. 2. TEM images of Au NPs (A) and BSA-Au NPs-Ab nanocomposites (B).

immobilization of Bcl-2 protein resulted in the increased charge-transfer resistance on Ag/PLL/GCE (R_{ct}=36,000 Ω, calculated from curve c), suggesting that the antigen was successively assembled onto PLL/GCE. The semicircle diameter of the Nyquist plot was increased to 77,000 Ω with the addition of BSA (calculated from curve d), proving that BSA could block the non-specific sites on the antigen-modified electrode. A further increased R_{ct} value (R_{ct}=128,000 Ω) after the introduction of BSA-Au NPs-Ab nanocomposites in the absence of MCF-7 cells was noticed (calculated from curve e). It proves the serious steric hindrance effect of the captured nanocomposites, on which Bcl-2 antibodies could be bound to Bcl-2 proteins on the electrode surface, leading to the result that the charge transfer between solution and electrode was significantly inhibited (as shown by Route I in Scheme 1). In addition, the charge-transfer resistance of BSA-Au NPs-Ab/Ag-BSA/PLL/GCE assembled in the presence of MCF-7 cells (calculated from curve f) was larger than that of Ag-BSA/PLL/GCE but it was much smaller than that of BSA-Au NPs-Ab/Ag-BSA/PLL/GCE assembled in the absence of MCF-7 cells. It means that a competition occurred between the cells and Bcl-2 proteins immobilized on the electrode surface for binding with the nanocomposites. Once the tumor cells were introduced in the assembly process of nanocomposites, some nanocomposites could automatically react with Bcl-2 proteins on the tumor cells and suffered sedimentation with these cells under gravity. As shown by Route II in Scheme 1, only the partial nanocomposites were linked on Ag-BSA/PLL/GCE, which would weaken the steric hindrance effect on electrode surface and result in the decline of the charge-transfer resistance. Hence, it is feasible to develop an EIS method for measuring Bcl-2 protein expression on cells based on the negative effect of the cells on the assembly of BSA-Au NPs-Ab nanocomposites.

SEM measurement was also employed to testify the proposed scheme. Fig. 4A and B shows the FESEM images of Ag-BSA/PLL/GCE surface and BSA-Au NPs-Ab/Ag-BSA/PLL/GCE surface, respectively. It was observed that a rough and thick protein coating was presented on the PLL modified GCE electrode. Obviously some BSA-Au NPs-Ab nanocomposites were distributed on Ag-BSA/PLL/GCE, indicating the immunoreaction of Bcl-2 antibodies with Bcl-2 proteins immobilized on the electrode surface and the capture of the nanocomposites.

3.3. Condition optimization of the EIS measurements

It is concluded from Fig. 3 that the binding of BSA-Au NPs-Ab nanocomposites and the introduction of tumor cells had influence on the charge-transfer resistance of the modified electrode. Some factors, which were closely related to the assembly processes on the electrode surface and could affect the EIS signals, were investigated. Here the charge-transfer resistance of BSA-Au NPs-Ab/Ag-BSA/PLL/GCE assembled in the absence of cells and that assembled in the presence of cells were represented as $R_{ct(a)}$ and $R_{ct(p)}$, respectively, and $R_{ct(a)} > R_{ct(p)}$. Fig. 5A shows the effect of the dilution times of BSA-Au NPs-Ab nanocomposites on $R_{ct(a)}$. One can find that the $R_{ct(a)}$ value was remained almost unchanged

when the dilution times of the nanocomposites was increased from 1 to 5, and then decreased at the higher dilution times. It indicates that the steric hindrance effect, which could dominate the charge-transfer resistance, depended on the adequate amount of BSA-Au NPs-Ab nanocomposites on the electrode surface. Thus, the optimal dilution times was selected at 5 in order to obtain the maximum $R_{ct(a)}$ value and save the nanocomposites. Fig. 5B shows the effect of the incubation time of BSA-Au NPs-Ab nanocomposites with cells on the charge-transfer resistance change (ΔR_{ct}), which is the difference between $R_{ct(a)}$ and $R_{ct(p)}$. The ΔR_{ct} value was enhanced with the increasing incubation time from 30 to 180 min and then suffered a little decrease when the incubation time was further prolonged. Enough incubation time was beneficial to the effective capture of the nanocomposites but too long time might lead to cell lysis or breakdown in the absence of growth medium since the tumor cells was suspended in pH 7.4 PBS. So the optimal condition for the incubation time was chosen at 180 min.

3.4. Analysis on Bcl-2 protein expression on tumor cells

Fig. 6A and B shows the microscopic images of MCF-7 cells and MCF-7/ADR cells in logarithmic growth phase, respectively. The drug-resistant MCF-7 cells on the substrate, presenting vague cellular outline, were closely interconnected and owned the increased contact area in contrast with MCF-7 cells that were regular polygon- or spindle-shaped. The nucleus and vesicles in MCF-7/ADR cells could be dimly observed. The above observation results indicate that apparent characteristic distinction exists between the tumor cells and the drug-resistant tumor cells. It can lead to the difference in the expression of some proteins such as cellular adhesion molecules on cells [28].

The analysis on the expression of Bcl-2 protein on MCF-7 cells and MCF-7/ADR cells based on a competitive immunoreaction using the EIS measurements were performed. Fig. 7A and B shows electrochemical impedance spectra of BSA-Au NPs-Ab/Ag-BSA/PLL/GCE assembled in the presence of MCF-7 cells and MCF-7/ADR cells with different concentrations, respectively. The high-frequency semicircle in the Nyquist plot was decreased when the cell concentration was enhanced, which suggests that the amount of the captured BSA-Au NPs-Ab composites on the electrode surface was diminished due to the competitive immunoreaction between the nanocomposites and the Bcl-2 proteins on cells and the steric hindrance effect on electrode surface was inhibited. In addition, MCF-7/ADR cells exerted more remarkable influence on the R_{ct} responses than MCF-7 cells with the same concentration, indicating that less nanocomposites were immobilized on BSA-Au NPs-Ab/Ag-BSA/PLL/GCE in the presence of MCF-7/ADR cells. It also suggests that the expression of Bcl-2 protein on MCF-7/ADR cells was significantly higher than that on MCF-7 cells. As we know, drug-resistant tumor cells can survive in the presence of anti-tumor drugs, upregulating the level of anti-apoptotic protein or downregulating the expression of pro-apoptotic protein. Bcl-2 protein is a gene protein inhibiting cell apoptosis. Surely the up-regulation of Bcl-2 protein can improve the survivability of MCF-7/ADR cells in the presence of the anti-tumor drug adriamycin.

Fig. 8 exhibits the plot of the ΔR_{ct} value (its definition is shown in Section 3.3 and $\Delta R_{ct}=R_{ct(a)}-R_{ct(p)}$) vs. the concentration of MCF-7 cells and MCF-7/ADR cells (c_{cell}). The measurements were performed three times to assess the reproducibility of the developed immunosensor using the three independently prepared Ag-BSA/PLL/GCE based on the same fabrication procedure. The RSD of the detection results was all lower than 7%, showing acceptable performance. Obviously the ΔR_{ct} value was increased with the enhancement of the cells concentrations and gradually reached a plateau at higher c_{cell}. In addition, the ΔR_{ct} value responding to MCF-7/ADR cells was higher than that responding to MCF-7 with the same concentration. As shown in the inset of Fig. 8, ΔR_{ct} exhibited a linear response with respect to $\lg c_{cells}$ over the range of cell concentration from 5×10^2 to 1.6×10^6 cells mL^{-1}. The regression equations were $\Delta R_{ct}=1.188\times10^4 \lg c_{cells}-3.166\times10^3$ with a correlation coefficient of 0.993 for MCF-7 cells and $\Delta R_{ct}=1.234\times10^4 \lg c_{cells}+5.280\times10^3$ with a correlation coefficient of 0.977 for MCF-7/ADR cells, respectively, and the detection limit for cells, based on three times of the standard deviation of the reagent blank (3σ), was

4. Conclusion

Nanocomposites consisted of Au NPs, Bcl-2 antibody and BSA were successfully prepared and they could be captured on the Bcl-2 protein-modified electrode based on the immunoreaction, leading to a great increase of the charge-transfer resistance on the electrode surface due to the serious steric hindrance effect. This binding was inhibited in the presence of tumor cells owing to the competitive immunoreaction between the nanocomposites and the Bcl-2 proteins on cells, which resulted in the retraction of R_{ct}. The change extent of the charge-transfer resistance was found to be closely related to the concentration of cells. It developed a sensitive and label-free electrochemical method for the quantitative detection of tumor cells. MCF-7/ADR cells exerted more remarkable influence on the R_{ct} responses than MCF-7 cells with the same concentration, suggesting that the expression of Bcl-2 protein on the drug-resistant tumor cells was significantly higher than that on the tumor cells. The research results support the conclusion that the up-regulation of Bcl-2 protein is one of important factors leading to drug resistance of tumor cells.

ABSTRACT

The salivary peptidome, which can represent up to 20% of total secreted proteins in human saliva, is highly influenced by proteolytic events. However, the development of strategies to understand the dynamics underlying the generation of salivary peptides has been a challenging task. In order to disclose in more detail the proteolytic events taking place in saliva, we aimed to characterize salivary peptidome and predict salivary proteases by applying, for the first time, a filter-aided sample preparation (FASP) approach to saliva. Thus, as a proof-of-concept of this application, harvested saliva samples from healthy individuals were incubated in 30 kDa cut-off spin filters for 18 or 115 h, at 37 °C, to promote saliva autolysis and the attained peptidome was characterized and compared with the naturally occurring one. In *ex vivo* conditions, proline-rich proteins, P-B peptide, histatin 1 and statherin were found to be the most susceptible salivary proteins to proteolysis. Peptide fragments were mainly attributed to the activity of cathepsin L1 and *K* at 18 h, whereas at 115 h, the attained peptide fragments were attributed to the activity of cathepsins *K* and L1, and MEP1A. Overall, the described endoProteoFASP approach makes the most of saliva's own protease pool and avoids the use of synthetic peptides and exogenous proteases to understand the proteolytic events occurring in the oral fluid. Hence, it could be very helpful in future studies targeting the characterization of salivary proteases and peptidome from different pathophysiological conditions.

1. Introduction

Human whole saliva (WS) is a complex body fluid which bathes the oral hard and soft tissues. Its constituents are responsible for essential functions such as food tasting and initiation of digestion, as well as protecting the oral mucosa from pathogenic microbiota, in order to maintain a healthy oral condition [1]. From the proteinaceous composition of WS, several enzymes were already identified, including amylase, carbonic anhydrase, catalase and proteases [2,3]. Indeed, proteases present in oral fluid effectively modulate the structure and function of some salivary proteins and have been implicated in tissue destruction in oral disease, e.g. salivary neutrophil collagenase, lactotransferrin and MMP-9 were associated to periodontal destruction [4]. As a consequence of such modulation, low-molecular-weight (LMW) proteins and peptides become a relevant fraction of the salivary proteome. Thus, characterization of salivary peptidome and identification of the salivary proteases represent pivotal steps towards molecular comprehension of the oral microenvironment equilibrium, as well as regarding proteolysis-associated, inflammatory and infectious diseases [5,6]. Moreover, those approaches allow the development of molecular tools for disease diagnosis, to establish accurate prognosis and to follow-up available therapies for the disease [5,7]. Thus, efforts have been made in an attempt to characterize salivary peptidome, resulting up to date, in the identification of over 2000 peptides [7]. Despite all attempts to achieve an accurate identification, the proteolytic cleavage is currently regarded as a complex and not well known process, involving a set of endo- and exo-proteinases that generate a multitude of small peptides, which might be seen as an individual "fingerprint" [3,6,8]. Previous studies performed on saliva showed that the majority of proteolytic fragments belong to proline-rich proteins (PRPs) family, histatin family and statherin. Aiming to disclose the protease activity of the saliva and the consequent peptide formation, different strategies have been developed. For instance, through the analysis of cleavage sites on the main salivary peptide classes, generation of small peptides has been sugested to

emerge from cathepsin D activity [9] or from enzymes with activity resembling those of the gastrointestinal tract, namely trypsin, chymotrypsin or elastase [10]. A different strategy using histatin 5 as a substrate in zymography allowed the identification of a total of 13 proteases with cleavage specificities towards arginine and lysine residues [11]. Neverthless, the identification of glutamine endoproteinase that recognizes KPQ↓ as the main consensus sequence remains unconclusive, though being suggested that it probably derives from dental plaque and it is likely of microbial origin [12].

Conventionally, proteomic approaches pointing the identification of salivary proteins follow one of two main strategies. A SDS-PAGE approach proceeded by "in-gel" digestion can be pursued. This decreases the complexity of the sample and simultaneously, confers robustness against impurities. Alternatively, a *shotgun* approach may be utilized with proteins being digested "in-solution". This reduces sample manipulation and, therefore, eases protocol automation. The combination of such advantages is provided by filter-aided sample preparation (FASP) method [13,14], which confers proper sample clean-up, minimizing the risk of interfering substances; provides a reactor environment for protein digestion; and guarantees the separation of the digestion products. Nonetheless, the FASP protocol is associated with significant sample loss, a drawback that can be overcome by prepassivating the filter unit with a detergent, such as Tween®-20, which may reduce peptide loss by 300%. This and other modifications have been proposed by Erde et al. [15] to achieve better sensitivity, and increase peptide recover and proteomic coverage. An example of other adaptations is provided by Wiśniewski and Mann, which developed a multienzyme digestion FASP (MED-FASP) approach that increases the proteome coverage, due to consecutive proteolysis of the retained material with two or more proteases [16]. The combination of FASP with isobaric mass tagging (iFASP) was also proven possible with higher peptide labeling efficiency than the conventional protocols provided by manufacturers [17]. The versatility of FASP is notorious in numerous studies, which describe protocol adaptations to attain different purposes. For instance, an *N*-glyco-FASP approach was developed to enrich *N*-glycopeptides, retrieving over 6000 *N*-glycosylation motifs in proteins from mouse brain, kidney, liver, heart and plasma [18]. Posterior studies were performed following the same approach in other biological samples such as mouse microglial cells [19], human spermatozoa [20] and supernatants of cultured breast cancer cell lines [21]. The combination of FASP with size-exclusion chromatography was also performed to map another posttranslational modification, the phosphorylation. A previous report has addressed the expression of phosphorylated peptides in the mouse brain proteome [22]. In the same study, another FASP variation is described, the filter aided antibody capturing and elution (FACE), in which a monoclonal phosphotyrosine antibody is added to the FASP filter, to obtain an enriched mixture of peptides displaying phosphotyrosine sites. Those two approaches combined resulted in over 12,000 mapped phosphorylation sites [22].

Overall, while the FASP approach seems to be an effective methodology for peptide-related research, to the best of our knowledge, the use of FASP approach for saliva processing and analysis has not been conducted before. In this way, we hypothesize that FASP allow an effective enrichment of salivary peptidome and, simultaneously, can assure the retention of high-molecular weight (HMW) material with valuable information with regard to proteolytic activity taking place in the oral fluid. We believe that FASP represents a potential technique to establish the referred connection between saliva degradome and salivary proteases. Hence, as a proof-of-concept, we aim to characterize the salivary peptidome and to predict human salivary proteases activity in two healthy individuals, by making use, for the first time, of the FASP technique.

2. Experimental section

2.1. Saliva sampling and processing

Unstimulated whole saliva (UWS) was collected from two healthy men, aged 22 and 32 years, reporting the absence of systemic or oral pathologic conditions. Samples were collected one hour after breakfast by passive drooling and were immediately centrifuged at 12000*g* for 30 min at 4 °C to remove insoluble material, cell debris, bacteria and possible food remnants. Samples from each individual were randomly designated as S1 and S2. UWS supernatants were collected carefully and stored at −80 °C. Protein from processed saliva samples was quantified with a colorimetric assay from BioRad® (DC kit). The following procedures were performed in duplicate.

2.2. FASP–collecting natural peptidome

Saliva samples were divided into two fractions. One fraction from each sample was incubated with 20 mM dithiothreitol (DTT) at 100 °C, for 45 min, to prevent proteolysis (control). The other fraction was kept intact. Spin filters (30 kDa cut-off) were washed and conditioned with 200 μL of ammonium bicabornate (ABC) solution, by centrifugation at 14000*g* for 10 min at 20 °C. Filtrates were discarded. Then, spin filters were loaded with 150 μg of protein and natural occurring peptides were eluted by washing the filter system 5 times with 500 μL of ABC solution. All filtrates were vacuum-dried in SpeedVac®.

2.3. FASP–collecting peptides originated by saliva autolysis

In order to retrieve peptides originated by saliva autolysis, filters were incubated 18 or 115 h at 37 °C, acting as proteomic reactors (Fig. 1). To prevent filter drying and possible damage, 500 μL of ABC solution was added to the reactors before incubation. Generated peptides were then collected by centrifugation at 14,000*g* for 10 min at 20 °C. Filters were washed once more with 500 μL of ABC solution and the filtrates were saved. Then, filters were successively washed with 400 μL of SDS 1% and with 400 μL of ABC solution. A final trifluoroacetic acid (TFA) 0.1% wash was performed. All filtrates were vacuum-dried in SpeedVac®. Final retentates were resuspended in 20 μL of MiliQ water and stored at −80 °C.

2.4. Peptide separation by nanoHPLC

Dried peptide extracts were resuspended in 5 μL of a 50:49.7:0.3 acetonitrile/water/TFA (v/v/v) solution and then sonicated for 3 min. Then, 25 μL of a 0.1% trifluoroacetic acid solution was added and the samples were, once again, sonicated for 3 min. 10 μL of each sample was separated onto a 150 mm × 75 μm Pepmap100 capillary analytical C18 column with 3 μm particle size (Dionex, LC Packings) at a flow rate of 300 nL/min. The mobile phases A and B were 2% ACN 0.1% TFA in water and 95% ACN, 0.045% TFA, respectively. The gradient started at 10 min and ramped to 60% B till 50 min and 100% B at 55 min and retained 100% B till 65 min. The chromatographic separation was monitored at 214 nm using a UV detector (Dionex/LC Packings) equipped with a 3 nL flow cell. The eluted peptides were collected directly on a MALDI plate in 20 s fractions using an automatic fraction collector Probot (Dionex, Amsterdam), with addition of 270 nL of α-cyano-4-hydroxycinnamic acid matrix (3 mg/mL α-cyano-4-hydroxycinnamic acid in 70% acetonitrile and 0.1% TFA, spiked with Glu–Fib (15 fmol)).

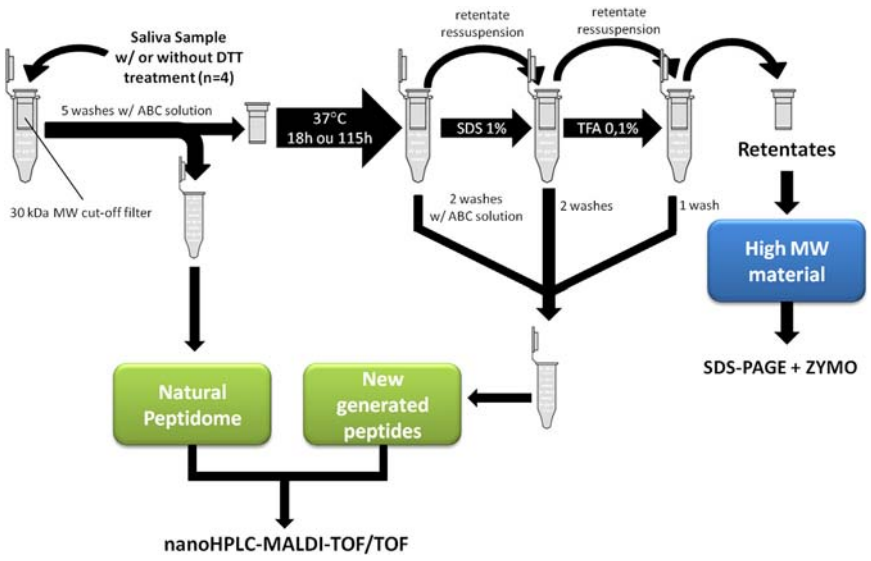

Fig. 1. Experimental Workflow. Natural peptidome from two saliva samples was washed away taking advantage of a 30 kDa cut-off filter. Then, samples were incubated at 37 °C for 18 hours or 115 hours and the newly generated peptides were retrieved with subsequent washes of ABC solution, SDS 1% and TFA 0,1%. A parallel protocol was followed were samples were pre-treated with DTT to prevent proteolysis. Peptides were separated and identified using an offline nanoHPLC-MALDI-TOF/TOF strategy. Retentates were subjected to electrophoretic and zymographic analysis.

2.5. Mass spectrometry analysis and identification of peptides

Mass spectra were acquired on a MALDI-TOF/TOF mass spectrometer (4800 Proteomics Analyzer, Applied Biosystems, Foster City, CA, USA) in the positive ion reflector mode and in the 700–4100 Da mass range. A data-dependent acquisition method was created to select the 16 most intense peaks in each samples spot for subsequent tandem mass spectrometry (MS/MS) data acquisition. Internal pattern Glu-Fib peak (m/z 1570.68 Da) was used as an internal caliber for the MS device. MS/MS data was searched against the Swissprot protein database for *Homo Sapiens* (release date 21032013) using Mascot software (v.2.1.0.4., Matrix Science Ltd., UK). Search parameters included the "none" option for enzyme selection, MS tolerance for precursor ions was set at 40 ppm and 0.4 Da for fragment ions. Positive identification was considered for individual ion scores above 40 and default significance threshold $p < 0.05$.

2.6. Protease prediction

Prediction of proteases was conducted with Proteasix[beta] software [23]. The peptide list to be processed was created accordingly to the significant proteins identified and admitting the unique peptides for a given experimental condition, i.e., sample, time of incubation and presence/absence of DTT treatment.

2.7. Protein retentate separation by SDS-PAGE

The HMW material retained in the filters was separated by gel electrophoresis under reducing and denaturing conditions, applying a 200 V electric current and making use of 12.5% SDS-PAGE gels prepared accordingly to Laemmli [24]. Prior to this, HMW retentates were precipitated in acetone and resuspended in Laemmli loading buffer to be boiled at 100 °C for 5 min, for subsequent gel electrophoresis. After finishing the run, the gels were incubated with fixation solution (methanol/acetic acid, 40:10 v/v) for 45 min. Then, the gels were stained with colloidal coomassie blue overnight and destained with 20% methanol until the background color was removed.

2.8. Protein retentate zymography

From the total retentate, 5 µL of sample was saved for zymography, before protein precipitation. In order to perform gelatin zymography, 10% SDS-PAGE gels were prepared with 0.1% (w/v) gelatin incorporated. Then, 10 µL of sample buffer, containing 0.5 M Tris–HCl pH 6.8, 5% (w/v) SDS, 20% (w/v) glycerol and 0.1% bromophenol blue, were added to each aliquot of retentate. Samples were incubated 10 min at room temperature. Gel electrophoresis was performed applying a constant voltage of 120 V. After finishing the run, the gels were incubated with renaturation buffer, with 2.5% (w/v) Triton X-100, for 2×30 min. Next, gels were placed in developing buffer, containing 50 mM Tris–HCl pH 7.4, 5 Mm NaCl, 100 mM $CaCl_2$, 1 µM $ZnCl_2$ and 0.06% (w/v) Triton X-100, and allowed to incubate overnight. Finally, the gels were stained with colloidal coomassie blue for, at least, 3 h. SDS-PAGE and zymogram gels were scanned with the Molecular Imager® Gel Doc™ XR+ System (Bio-Rad®).

3. Results

In order to characterize salivary peptidome and to disclose the potentially associated human salivary proteases, we reasoned that FASP approach would give a valuable contribute since it guarantees proper peptide separation, providing, at the same time, a reactor-like environment for the proteolytic activity. Thus, we enrolled two healthy individuals as biological replicates, in order to conduct a proof-of-concept experimental workflow based on the classic FASP approach, the endoProteoFASP. This allowed the collection and comparison of both naturally occurring peptides and those generated after saliva autolysis, as outlined in Fig. 1. A prior centrifugation was performed before sample filtration, in order to exclude bacterial material from saliva. In this way, only the soluble proteases, present within the saliva supernatant were the target of the analysis. Two incubation times were selected, a short (18 h) and extended (115 h) which produced minimal and significant alterations, respectively, in saliva SDS-PAGE profile. In this sense, natural peptidome ($t=0$ h, T0) was washed away from whole saliva samples taking advantage of the 30 kDa cut-off filter, which prevented the elution of the HMW material, containing

endogenous proteases. Then, saliva samples were incubated at 37 °C, for 18 h (T18) or 115 h (T115) to promote saliva autolysis. The newly created peptides were then eluted by subsequent washes with ABC solution, SDS 1% and TFA 0.1%. A SDS wash was included to increase the probability of recovering peptides of higher hydrophobicity, since it was demonstrated that the use of a SDS spin column retrieves more hydrophobic species when compared to FASP [25]. Moreover, the use of a detergent seems to reduce the probability of peptide loss [15]. In the end of the experimental protocol, over 500 salivary peptides were identified, of which 225 unique peptides were found in untreated sample 1 (S1) and 588 in untreated sample 2 (S2), distributed along T0, T18 and T115, as depicted in Venn diagrams (Fig. 2), created by Venny web tool [26], and listed in Supplemental Table S1.

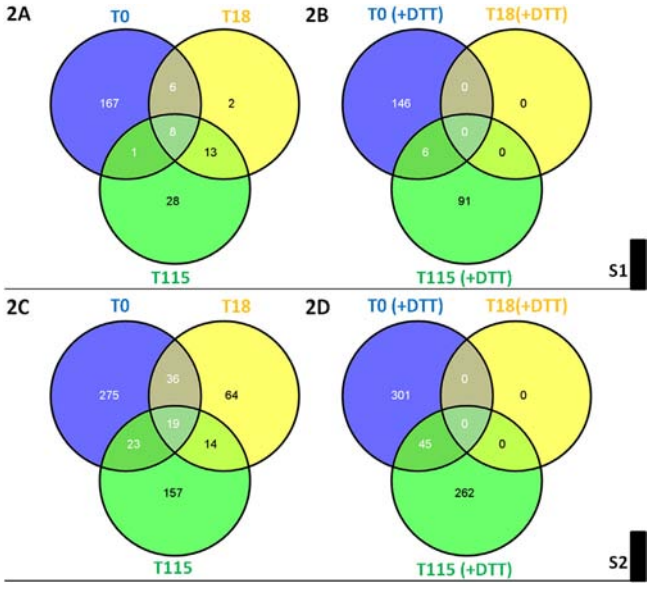

Fig. 2. Distribution of the number of identified peptides before autolysis (T0, blue), after 18 hours of incubation (T18, yellow) and after 115 hours of incubation (T115, green) for untreated sample 1(2A) and 2 (2C) and DTT-treated sample 1(2B) and 2 (2D).

Naturally occurring peptides (T0) identified from S1 and S2, covered several salivary proteins, mainly PRPs, which represented almost 50% of all assigned peptides. P-B peptide (SMR3B), statherin, histatin 1 and mucin 7 followed as the proteins with higher peptide identification, with an average of 17%, 13%, 12% and 5% of the overall set of assigned peptides (Table 1 and Supplemental Table S2). A high variability is noticeable in the individual peptidome, as in S1 and S2, only 27.7% of the identified peptides were shared, as depicted in Fig. 3A.

Following the first cleanup, samples were incubated at 37 °C for 18 h in order to attain a new peptidome following autolysis (T18). To assure that the new set of peptides was a consequence of the activity of the endogenous proteases, parallel protocols were performed in an attempt to completely inhibit salivary autolysis. Firstly, whole saliva samples were boiled at 100 °C, for 10 min, in the presence of SDS 1% (w/v). However, retentates displayed gelatinolytic activity, after 18 h, regardless of the denaturing conditions (Fig. S1). This data shows that salivary proteases are resistant to heat and to SDS, in a concentration similar to Laemmli loading buffer. In a second attempt, samples were boiled at 100 °C, for 45 min in the presence of DTT, a well-known reducing agent, at a final concentration of 20 mM. In this case, the proteolytic activity was completely inhibited, as shown by the absence of gelatinolytic activity (Fig. S1) and by the absence of peptides, at T18, in DTT-treated samples (Fig. 2B and D).

At T18, saliva autolysis resulted in the formation of 29 more peptides for S1 and 133 for S2, which further highlights the differences between individuals (only 8% of the peptides were shared at T18, see Fig. 3B). Comparing T0 to T18 peptidome, we detected that more than half of the set of peptides at T18 had not been identified at T0 (Fig. 2A and C). Indeed, at T18, the vast

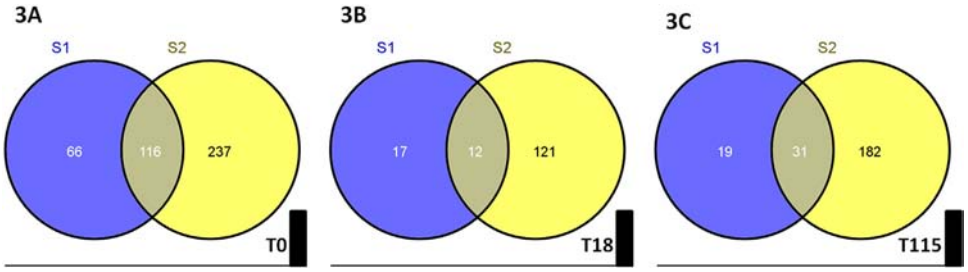

Fig. 3. Venn diagrams depicting inter-individual variability in salivary peptidome, at T0 (3A), at T18 (3B) and at T115 (3C).

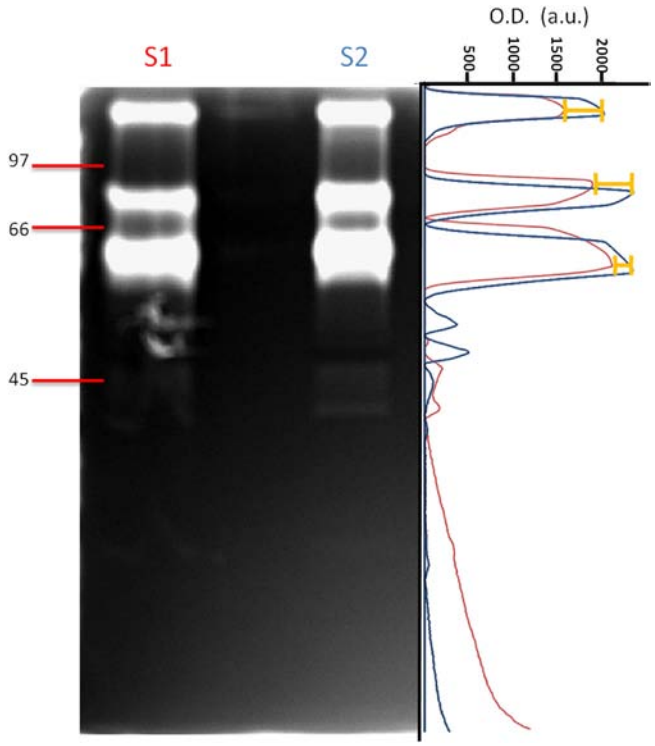

Fig. 4. Gelatin zymograms of the samples after 115 hours of incubation. At the left, zymographic profile of samples 1 (S1) and 2 (S2). At the right, optical density (in arbitrary units) profile of samples 1 and 2, showing higher gelatinolytic activity of sample 2 (yellow symbols).

majority of the attained peptides seems to result from proteolysis of PRPs, mostly basic PRPs 1 (PRP1) and 2 (PRB2), while at T0, peptides derived from a wide range of proteins (Table 1). This data suggests that PRPs are the group of salivary proteins more prone to proteolysis *ex vivo*. When samples were subjected to 115 h of incubation (T115), a larger set of peptides was obtained. In this case, 50 more peptides were eluted from S1, whereas 213 more peptides were eluted from S2. Again, a high inter-individual variability was observed, with only 13.4% of the peptides being detected in both samples (Fig. 3C). At T115 (Table 1), PRPs were again the main source of peptides, though, with a larger group of PRP isoforms being responsible for the generation of new peptides (i.e., PRP1, PRB2, PRB3, PRB4 and PRPC).

Interestingly, in all experimental time points (T0, T18 and T115) a higher production of peptides was verified in S2, in spite of the fact that all experiments were conducted with the same starting protein mass (150 μg). This apparent higher rate of peptide formation is also suggested by the higher gelatinolytic activity of S2, when compared to the one of S1, as depicted in the gelatin zymogram in Fig. 4.

As a consequence of the activity of endogenous proteases, some differences were expected to be found in the SDS-PAGE profile of the salivary proteins. Those differences are evident in Fig. 5. When comparing the electrophoretic profile of the sample retentates at T18 and T115, it is notorious the appearance of new bands between 35 and 45 kDa, around 25 kDa, 17–18 kDa (only in S1) and below 15 kDa, at T115. These new bands can be attributed to the fragments of HMW proteins that underwent proteolysis. Surprisingly, those differences were more expressive in DTT-treated samples, after 115 h of incubation.

An extensive proteolysis was observed in PRPs, with proteases attacking preferably between Gln–Gly residues, but also between Pro–Gln, Pro–Pro, Arg–Ser residues, at the N-terminal of the peptides, and between Arg–Ser and Tyr–Gly, at the C-terminal of the peptides (Supplemental Tables S3 and S4). Indeed, the common peptide sequences among T0, T18 and T115, in both samples, were ^{49}GPPPPPGKPQ^{58}, ^{70}GPPPPPGKPQ^{79} and ^{92}SPPGKPQGPPPQ GGNQPQ^{109}, ^{52}SPPGKPQGPPPQGGNQPQ^{69}, which belong to PRP1 and PRB2, respectively; ^{148}GPPPQGGRPQGPPQGQSPQ^{166} which belong to PRPC and ^{268}GPPPPGGNPQQPLPPPAGKPQ^{288} and ^{17}QSLN EDVSQEESPSVISGKPEGR^{39} to PRB3. Taking the above sequences as an example, 122 out of 185 cleavage sites took place between Gln–Gly, and the remaining 63 occurred between Arg–Ser, Arg–Gln, Gln–Gln and Pro–Ser. In order to predict the salivary proteases responsible for the production of the identified peptides, a Proteasix^{BETA} [23] analysis was performed, accordingly to the particular peptide set of each experimental group. As depicted in Table 2, the proteases cathepsin L1 (CTSL1) and meprin A (subunit alpha, MEP1A), a cysteine and a metalloprotease, respectively, were predicted ubiquitously in the different experimental conditions, except in the presence of DTT, at T18 (due to the absence of peptides). Hence, these data suggest that these proteases are the most resistant to time and to reducing conditions. In fact, CTSL1 and CTSK have specificity for substrates displaying Gln in position P1 and Gly in P1', thus explaining the higher frequency of cleavage sites between Gln–Gly. At T18, in untreated samples, which yielded 150 peptides, cleavage sites appeared to result from the activity of a large range of predicted proteases, including cysteine-, serine- and metalloproteinases (Table 2). At T115, samples were further decomposed, regardless of the treatment with DTT. Nevertheless, a minor set of proteases remained active, comprising cathepsins K and L1, MMP9, MEP1A and a disintegrin and metalloproteinase with thrombospondin motifs 5 (ADAMTS5), the later only figuring in DTT-treated samples.

4. Discussion

This work describes, for the first time, the use of a FASP approach to profile salivary peptidome and to disclose potentially associated human salivary proteases. The dual use of a 30 kDa cut-off filter as a sample cleaner device and as a "proteomic reactor" allowed proper separation of peptides and, at the same time, an increase in the activity of soluble salivary proteases. Thus, we provided the proof-of-concept of a novel peptidomic approach, the endoProteo-FASP, to understand the dynamics of the salivary peptidome, making

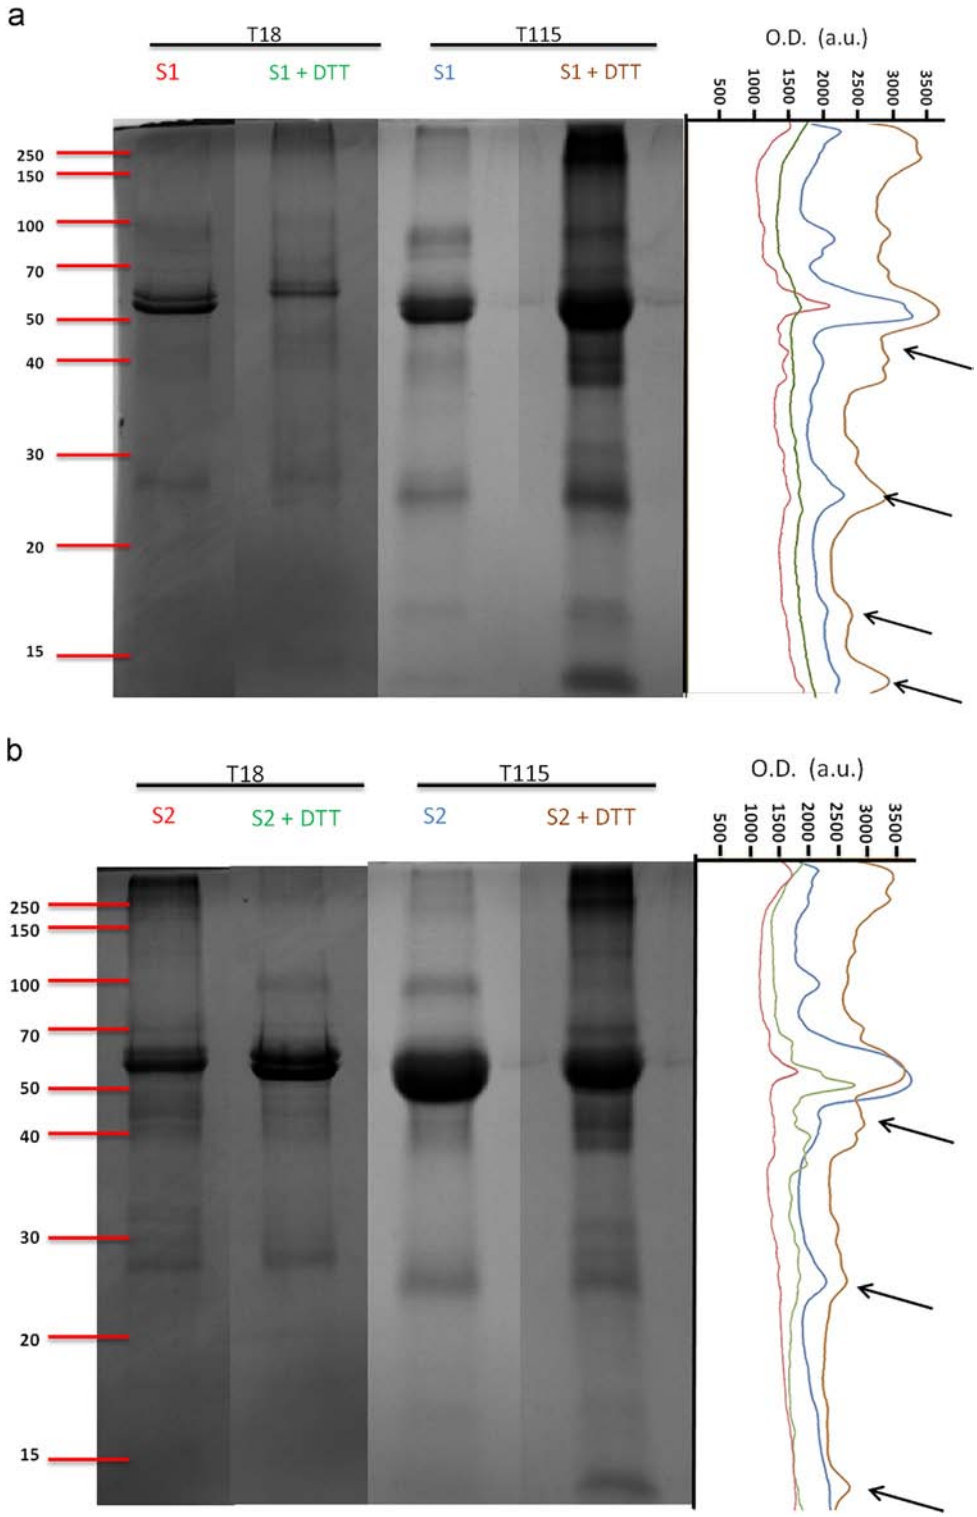

Fig. 5. SDS-PAGE of the retentates for sample 1 (a) and 2 (b), after 18 and 115 hours of incubation. At the left, red lines identify molecular weight ladders. At the right, optical density (in arbitrary units) profile of sample 1 in the different experimental conditions (red, untreated sample at T18; green, DTT-treated sample at T18; blue, untreated sample at T115 and brown, DTT-treated sample at T115). Black arrows indicate prominent changes in the electrophoretic profile from T18 to T115.

the most of saliva's own protease pool and avoiding the use of synthetic peptides and exogenous proteases, as previously reported in the literature [12,15–22,27]. Additionally, our work confirmed the utility of the combination of the ammonium bicarbonate extraction method with sample filtration in order to enrich salivary peptides, as reported previously by our group [28].

With the endoProteoFASP approach we provided a novel time-based experimental approach that gives valuable information with regard to the process of saliva autolysis. If, on one hand, we could identify the susceptible proteins to proteolysis in a time-course manner, on the other hand, we were able to understand which endogenous proteases may be involved in those proteolytic events.

Table 2
Predicted proteases by Proteasix[BETA] software (> 15% of cleavage) derived from unique peptides identified before autolysis, after 18 h autolysis and after 115 h autolysis, in untreated and DTT-treated samples.

Experimental Condition		**Predicted proteases** (UniProt gene name)
Before autolysis	Untreated samples	CTSL1, MEP1A
	DTT-treated samples	CTSL1, MEP1A
After 18 h autolysis	Untreated samples	CTSL1, CTSB[a], CTSK, CTSS[a], KLK2[a], KLK4[a], MEP1A[b], MMP12[b], MMP9[b], NLN[a], PLG[a], PREP[b], THOP1[a]
	DTT-treated samples	None (there was not any peptide identified)
After 115 h autolysis	Untreated samples	CTSK, CTSL1, MEP1A, MMP9[b]
	DTT-treated samples	ADAMTS5, CTSK, CTSL1, MEP1A, MMP9[b]

[a] Predicted only in sample 1.
[b] Predicted only in sample 2.

A major concern with this approach was to guarantee proper sample clean-up before incubation and, therefore, to assure that the new peptides, identified at different times, resulted from saliva autolysis, rather than being part of the natural peptidome. Indeed, the identified peptides could be attributed to the activity of proteases in the oral fluid, as evidenced by the absence of shared peptides before and after sample incubation (Fig. 2B and D). Moreover, the inexistence of peptides at T18 corroborates an effective clean-up of the samples and a successful inhibition of the proteolytic activity.

Despite inter-individual variability, PRPs, P-B peptide, histatin 1 and 3, mucin 7, polymeric immunoglobulin receptor and statherin represented the most susceptible salivary proteins to proteolysis *in vivo*, as proven by the number of peptides identified to these proteins at T0 (Table 1) which is corroborated by the LC-MS/MS-based characterization of whole salivary peptidome [29–31]. Protein fragments at T0 were attributed to the activity of CTSL1 and MEP1A. To date, CTSL1, but not MEP1A, was already identified in saliva through the combination of histatin 5 zymography and LC-ESI-MS/MS [11]. The presence of MEP1A in saliva remains to be confirmed, though it seems a relevant protease in saliva autolysis, as confirmed by its prediction in all incubation time points. After 18 h and 115 h of incubation, the majority of the eluted peptides belonged almost exclusively to the different PRP isoforms, suggesting that these proteins display the highest susceptibility to *ex vivo* proteolysis. Cleavage site analysis showed that the peptide bond between Gln–Gly residues was the preferential site for proteolysis, which is in agreement with previous findings [29–32]. Interestingly, the formation of the new PRPs peptides is associated with a time-dependent profile of proteases, a variation never reported so far, to the best of our knowledge. At T18, a wide range of cathepsins (K, S, L and B), serine proteases (kallikreins 2 and 4, plasminogen and prolyl endopeptidase) and metalloproteinases (MMP 9 and 12, MEP1A, neurolysin and thimet oligopeptidase) seems to be responsible for PRPs degradation. At T115, however, only CTSL1 and K, MMP9 and MEP1A were predicted, a factor that can be explained due to irreversible denaturation or due to proteolysis of susceptible proteases. The association of PRPs fragments with different sets of proteases (T18 *vs* T115) highlights the dynamism underlying saliva autolysis, with proteases being permanently active (CTSL1 and MEP1A) and others being active at particular periods.

The consistent prediction of CTSL1 and MEP1A at T0 (reflecting the proteolytic events before secretion) and at T18 and T115 (reflecting the proteolytic events in the soluble fraction of saliva) suggest that human proteases are largely responsible for proteome modulation. Nonetheless, taking into account that Proteasix software is based on the prediction of human proteases, we acknowledge that proteolysis may also result, to some extent, from the activity of bacterial proteases with the same substrate specificity as the proteases covered by this software. The activity of microbial proteases might help to explain inter-individual variability regarding the number of peptides of each salivary protein. This whole hypothesis is supported by the findings of Helmerhorst et al. [11], who found that histatin degradation is 7.5 times faster in whole saliva's pellet, where bacteria is deposited, than in whole saliva supernatant. Nonetheless, care was given to harvest saliva samples from healthy individuals that did not shown any form of periodontal disease or active caries lesions. While differences may still exist between the oral microbiota of the participants, the absence of oral inflammation or infectious processes minimizes the risk of sample contamination with proteases from pathogenic microbiota.

As one may notice, at T115, the electrophoretic profile of the samples changed, due to the appearance of new LMW bands. This is particularly true for DTT-treated samples (4th lane of the gels, Fig. 5A and B). In these samples 91 new peptides were identified for S1, and 262 for S2. This data suggests that DTT enhanced protein hydrolysis due to the denaturation of salivary proteins. Although, at this time point, the eluted peptides resulted mainly from PRPs and from only 3 novel proteins, namely, FYN-binding protein (85.4 kDa), protein transport protein Sec31A (133 kDa) and WAS/WASL-interacting protein family member 2 (46.3 kDa). Probably, by increasing the incubation time of the samples, one would address interesting information with respect to saliva's most resistant proteins to endoprotease activity. Additionally, our data evidences the resistance of salivary proteases to denaturing conditions. This resilience was found when saliva samples depicted gelatinolytic activity after being boiled in the presence of SDS and also when DTT-treated samples yielded peptides, after 115 h of incubation. This particular robustness of salivary proteases has also been observed by other authors. For instance, Thomadaki et al. [12] showed that the addition of an inhibitor cocktail to whole saliva (containing AEBSF, aprotinin, pancreatic trypsin inhibitor, leupeptin, antipain and EDTA), spiked with histatin 5, statherin or PRP1, did not prevent the degradation of these susceptible proteins. Robinson and colleagues [27] demonstrated, through a PALeO (proteinase activity labeling employing ^{18}O-enriched water) experiment, that sample freezing, *per se*, is not effective to inhibit proteolysis. Another example is provided by Xiao et al. [33], which showed that salivary proteome is stable only for two weeks, if stored at 4 °C with protease inhibitors, or at room temperature with addition of ethanol, when comparing to samples stored at −80 °C with protease inhibitors. de Jong et al. [34] also provided evidence for proteome instability, pointing the freezing rate as an additional concern with regard to the peptidome composition and demonstrating a decrease in the abundance of peptides in samples kept at room temperature, for 24 h. Therefore, our work along with the above referred studies [12,27,33,34] contributes to the body of evidence of the great resilience of salivary proteases, an important factor that should be stressed in future works where inhibition of those enzymes is pointed. Moreover, this work emphasizes the huge importance of sample pre-treatment to assure the quality of the samples over time, given that, despite the initial denaturation, salivary proteases may, most certainly, restore their activity, which can lead to sample degradation.

In spite of the similar zymographic profile of S1 and S2 retentates, optical density analysis suggests a higher gelatinolytic

activity of the latter. Indeed, S2 autolysis attained to a bigger set of eluted peptides, regardless of the time of incubation. This data provides an evidence of inter-individual variability, which might be attributed to differential activity of the proteases present in the oral fluid. Indeed, MMP9 and MMP2, two proteases with gelatinolytic activity, were predicted exclusively from S2 peptidome. Furthermore, several proteases were predicted in S1, whilst absent in S2, namely cathepsins B and S, neurolysin, kallikrein 2 and 4, plasminogen and thimet oligopeptidase. Future validation of the differential activity of such proteases should be performed, to ensure the conformity of the peptidome data (sample filtrates) with proteome data (sample retentates). Nevertheless, these observations point at the potential application of the endoProteoFASP approach to clinical research, with regard to biomarker discovery, since it is possible to address variations in individual peptidome and attribute those changes to the variation of a protease profile.

5. Concluding remarks

This work addresses the first exploratory study regarding salivary proteases and peptidome with a FASP approach. A remarkable dynamism of salivary peptidome was notorious and could be attributed to the differential participation of proteases with substrate specificities close to human cathepsins, serine proteases and metalloproteinases, in a time-course. Several hallmarks of proteolytic events taking place in saliva were confirmed with this approach, such as the identification of PRPs, P-B peptide, histatin 1 and statherin, as proteolysis-susceptible proteins, instead of other salivary proteins. Furthermore, the relative higher abundance of Gln–Gly cleavage site can be attributed for the first time to cathepsins L1 and K. Additionally, it seems that there is a correlation between the intensity of the gelatinolytic activity and the number of identified peptides, with this methodology. Therefore, this optimized endoProteoFASP approach to saliva samples could be useful in future studies aiming not only the characterization of salivary proteases, but also other biological fluids and peptidome from different pathophysiological conditions.

Acknowledgments

This study was supported by QOPNA: Fundação para a Ciência e a Tecnologia (FCT, Portugal), European Union, QREN, FEDER and COMPETE for funding the QOPNA research unit (project PEst-C/QUI/UI0062/2013), RNEM (Portuguese Mass Spectrometry Network) and EXPL/BBB-BEP/0317/2012 (FCOMP-01-0124-FEDER-027554) and COST action BM1307. The authors would like to acknowledge Dr. Julie Klein for her help in processing data with Proteasix^{beta} software.

ABSTRACT

Surface-assisted laser desorption ionization mass spectrometry (SALDI-MS) is an emerging technique used for the detection of small molecules (< 700 Da) such as illicit drugs. In recent times, this technique has been employed for the detection of illicit drugs in various body fluids including saliva. Three common SALDI techniques, desorption ionization on porous silicon (DIOS), nanostructure-initiator mass spectrometry (NIMS) and nanostructured laser desorption ionization (NALDI™) are compared for the detection of four drug classes, amphetamines, benzodiazepines, opiates and tropane alkaloids. We focus in our comparison on structural and chemical characteristics, as well as analytical performance and longevity.

1. Introduction

Matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF-MS) is a soft ionization technique which is typically used for the analysis of organic molecules (> 700 Da) such as peptides, proteins and oligonucleotides [1–3]. The analyte is typically dissolved into a UV-absorbing organic acid matrix, which vaporizes upon irradiation with a pulsed UV laser. A limitation of MALDI-TOF-MS is the difficulty to detect small organic molecules (< 700 Da) in the noisy spectra produced in the low mass range as a result of matrix adduct formation [4,5]. Matrix-free techniques, referred to as surface-assisted laser desorption ionization mass spectrometry SALDI-MS have been introduced for the detection of small molecules [6–9]. Successful implementations of SALDI-MS include those based on nanostructured silicon such as desorption ionization on porous silicon (DIOS) [10], nanostructure-initiator mass spectrometry (NIMS) [11] and nano-assisted laser desorption ionization (NALDI™) [12]. DIOS and NIMS substrates are both based on porous silicon but differ in wafer dopant, pore size, depth and surface chemistry. DIOS substrates are macroporous with pore depths (< 500 nm) whereas NIMS fall into the mesoporous regime with pore depths in excess of 10 μm. Furthermore, DIOS substrates are generally functionalized with a perfluorinated silane [13], whilst NIMS is functionalized with a heavily fluorinated siloxane in 1,3-bis(heptadecafluoro-1,1,2,2-tetrahydrodecyl)tetramethyldisiloxane ($BisF_{17}$) [11,14].

NALDI™, on the other hand is a commercially available – and recently discontinued – substrate from Nanosys, Inc. and Bruker Daltoniks, Inc [12]. The substrates comprise of silicon nanowires (SiNWs) grown from vapor liquid solid deposition on silicon or steel [4]. The SiNWs are parallel to the surface, 100 to 500 nm in length and 10 to 20 nm in diameter [15]. The nanostructures are functionalized with pentafluorophenylpropyldimethylchlorosilane (F_5PhPr). The NALDI™ surface has a high nanostructure density (> 100 /μm^2), which has been shown to cause dramatic increases in observed signal intensities for small molecule analysis [4]. NALDI™ has been used for the detection of low molecular weight compounds between 50–1500 Da [12,15,16].

One potential application for SALDI is for the detection of illicit drugs at the roadside [17,18]. Since 2004, countries including Australia, Finland and France have introduced screening procedures for a range of illicit drugs including amphetamines and tetrahydrocannibinol [19] at the roadside. The use of oral fluid testing allows for non-invasive screening of drugs, which have been administered within a 24 h time frame [20]. Furthermore, the majority of drug molecules (with the exception of benzodiazepines) are found in oral fluids at higher concentrations in comparison to blood, serum or urine [19,21,22]. However, current immunoassays for saliva in use on the roadside are only presumptive and samples providing positive results are submitted for confirmatory laboratory analysis using gas chromatography mass spectrometry (GC–MS) or high performance liquid chromatography-mass spectrometry (HPLC-MS).

In this paper, we compare the characteristics of DIOS, NIMS and NALDI™ and their analytical performance in relation to the detection of four different drug classes, amphetamines, opiates, benzodiazepines and tropane alkaloids at concentrations relevant to body fluid testing. Quantitative SALDI analysis on the three substrates is also presented for oxycodone in both water and PBS. Finally, the longevity of the three substrates was investigated by comparing the average signal-to-noise (S/N) produced for flunitrazepam on fresh and six-month old samples. This was done since nanostructured substrates often have high surface areas that can be contaminated upon exposure to air, which causes strong interferences in the mass spectra.

2. Materials and methods

2.1. Reagents

Hydrofluoric acid (HF) (48%) was obtained from Fischer Scientific (United Kingdom). Ethanol (EtOH) (100% undenatured), methanol (99.9%), acetone and DCM were purchased from Chem Supply (Australia). Water was purified using a Labconco water purifier (USA) (referred to as milliQ water). Tridecafluoro-1,1,2,2-tetrahydrooctyldimethylchlorosilane (F_{13}) and $BisF_{17}$ were purchased from Gelest Inc (USA). α-Cyano-4-hydroxycinnamic acid (CHCA) was purchased from Bruker-Daltonics (Germany). Phosphate buffered saline (PBS, pH 7.4, 1 X) was purchased from Sigma Aldrich (Australia).

Certified standard solutions of methadone, flunitrazepam, oxycodone, 3,4-methylenedioxymethamphetamine (MDMA) and cocaine were kindly provided by Forensic Science South Australia (Australia).

2.2. DIOS fabrication

Monocrystalline (0.008–0.02 Ωcm) antimony doped n-type Si (1 0 0) wafers from Silicon Quest International (CA, USA) were cut with a diamond cutter into 3.5 cm x 3.5 cm squares. The cleaning processes were carried out by sonicating the wafers in 99.9% methanol and drying under a stream of nitrogen. Porous silicon (pSi) was fabricated by light-assisted anodic etching of cut Si wafers using a photomask. The photomask was 2.4 cm x 2.4 cm containing 100 spots approximately 1 mm in diameter. In brief, photopatterned pSi arrays were clamped into a custom-built Teflon anodization cell contacting a gold foil anode (Space Products International, CA, USA). A 0.5 mm diameter platinum wire (99.9%, Aldrich, WI, USA) formed into a ring was used as a cathode. A 1:1 HF:EtOH electrolyte solution was filled into the Teflon well. The Si wafer was illuminated using a fiber optic light source which passed through a photomask and then through a set of two aspheric lens, $f=80$ mm (OptoSigma, CA, USA) for collimation. A constant current of 3.2 mA/cm^2 was then applied across the cell for 2 min using a source meter program, created in LabView 6.1 to control a 2425 current source meter (Keithley, Ohio, USA). The generated pSi films were then subjected to several methanol washes, before being dried under a stream of nitrogen gas.

2.3. Oxidation and functionalization

The freshly etched pSi was ozone-oxidized at a flow rate of 3.25 g/h using an Ozone-Generator 500 (Fischer, Germany). Following oxidation, the wafer was subjected to a second pore broadening etch using 5% HF/H_2O for 30 s. Subsequently, the double etched surface was ozone oxidized (as above) for a second time. The hydroxyl-terminated surface was then silanized via the addition of 80 μL of neat F_{13} for 15 min at 90 °C. After silanization, the pSi arrays were washed with methanol, dried under a stream of nitrogen gas and then stored in a desiccator until required.

2.4. NIMS fabrication

Monocrystalline (0.01–0.02 Ωcm) boron doped p-type Si (1 0 0) wafers from Silicon Quest International (CA, USA) were etched in a 2:1 HF:EtOH electrolyte solution at a constant current of 27 mA/cm^2 for 5 min. The freshly etched pSi was ozone-oxidized at a flow rate of 3.25 g/h using an Ozone-Generator 500 (Fischer, Germany). The hydroxyl-terminated surface was then functionalized via the addition of 80 μL of neat $BisF_{17}$ for 60 min at room temperature. To assist removal of excess derivitizing agent the NIMS substrate was placed in the oven for 3–5 s and then blown off with a stream of nitrogen gas.

NALDI™ target plates, purchased from Bruker Daltonics (Germany) were used as supplied.

2.5. Preparation of drug solutions

Stock solutions of each drug at 0.1 mg/mL were prepared by diluting the content of each certified standard ampoule to a final volume of 10 mL in a volumetric flask. Solutions were stored at −20 °C. Working solutions at 1000 ng/mL were obtained by diluting the stock solutions with milliQ. Working solutions were kept at +4 °C and prepared fresh every two weeks. Illicit drug solutions at varying concentrations (~0.5–100 ng/mL in water) were prepared from the working solutions immediately prior to analysis. For salt analysis, oxycodone was diluted at various concentrations (5–500 ng/mL) in PBS.

2.6. Sample deposition method for illicit drug solutions in water

Aliquots of drug solutions (1 μL) were deposited onto SALDI-MS substrates. The solvent was allowed to completely evaporate under ambient conditions. Upon evaporation, pSi chips were mounted on a modified MALDI target plate (MTP384, Bruker Daltonics, Germany) and analyzed. The NALDI™ chip was attached to a MTP NALDI™ adapter (Bruker Daltonics, Germany).

2.7. SALDI-MS analysis

Mass spectra were collected using an Autoflex Series III Bruker MALDI-TOF-TOF mass spectrometer equipped with a SmartBeam (337 nm, Nd:YAG) 200 Hz pulsed laser, operated at 200 Hz frequency. The laser attenuator offset was optimized for each drug on the NIMS, NALDI™ and DIOS surface so as to maximize the productions of protonated species whilst reducing background noise. Briefly, the laser attenuator offset was set to approximately 40%, 55% and 60% for NALDI™, NIMS and DIOS respectively in reflectron positive (RP) mode unless otherwise stated. Mass spectra were generated by averaging 500 individual laser shots. Data acquisition used flexControl 3.3 (build 85) software and data analysis was performed using flexAnalysis version 3.3. Instrumental parameters for the RP acquisition were set as follows: 19.00 and 16.80 kV for the ion source 1 and 2, respectively, 8.25 kV for the lens and 21.00 and 9.40 kV for reflector 1 and 2, respectively. Quadratic external calibration of the TOF tube was performed before each acquisition on the monoisotopic masses of CHCA adducts, namely $CHCA[M+H\text{-}H_2O]^+$, $CHCA[M+H]^+$, $CHCA[M+Na]^+$, $CHCA[2M+H\text{-}CO_2]^+$, $CHCA[2M+H]^+$ and $CHCA[3M+Na_2]^+$.

2.8. Scanning electron microscopy (SEM) analysis

For DIOS, NIMS and NALDI™ SEM micrographs, in-plane and cross sectional surface morphologies were investigated using a FEI

Quanta 450 FEG environmental SEM fitted with an SSD detector operated at an accelerating voltage of 30 kV.

2.9. Infrared (IR) spectroscopy

Transmission IR spectroscopy was performed using a Nicolet Avatar 370MCT spectrometer (Thermo Electron Corporation, USA). IR spectra were recorded and analyzed using OMNIC version 7 software (Thermo Electron Corporation, USA). Spectra were recorded over a range of 650–4000 cm^{-1} at a resolution of 4 cm^{-1} and taken as an average of 64 scans.

2.10. X-ray photoelectron spectroscopy (XPS)

XPS analysis was used to confirm surface functionalization of DIOS, NIMS and NALDI™ substrates. The XPS spectra were recorded on a SPECS SAGE XPS spectrometer using Mg Kα radiation source (hv = 1253.6 eV) operating at 10 kV and 20 mA. The elements present in the sample surface were identified from a survey spectrum recorded over the energy range of 0–1000 eV at a pass energy of 100 eV and a resolution of 0.5 eV and take off angle of 90° with respect to the sample surface. The areas under the selected photoelectron peaks in the spectrum were used to calculate the percentage of atomic concentrations. All the binding energies (BEs) were referenced to the C 1 s neutral carbon peak at 285.0 eV to compensate for the effect of surface charging. The analysis area was circular with a diameter of 3 mm. CasaXPS software was used to process spectra.

2.11. Water contact angle measurements

Water contact angle (WCA) using the sessile drop method was performed by placing a 1 μL droplet of milliQ water on the sample surface in ambient atmosphere. A Panasonic Super Dynamic wv-BP550 Closed Circuit TV camera was used to obtain images of the droplet. This was done on two separate surfaces and on six different spots per surface. The WCAs were measured using ImageJ version 1.41 using the Drop Analysis-DropSnake plug in.

2.12. Statistical analysis

The statistical significance of the difference between the performances of the three different SALDI substrates was assessed by performing a Three Way Analysis of Variance (ANOVA). The chosen factors were substrate, type of drug and level of concentration and the response data was the average signal intensity ratio from three experimental replicates. G*Power 3.1 was used to run the analysis setting the confidence to 95% and the TukeyHSD method was used for the pairwise multiple comparison procedures.

All precision measurements (coefficient of variation) were expressed as the percentage relative standard deviation (% RSD).

3. Results and discussion

3.1. Characterization of SALDI substrates

SEM micrographs of NIMS, DIOS and NALDI™ substrates are depicted in Fig. 1A-C respectively. For NIMS substrates, SEM analysis showed that homogeneous pSi pores with approximately 10 nm in diameter (Fig. 1A) and 13 μM in depth (Fig. S-1A) were consistently obtained via electrochemical etching.

In contrast, DIOS substrates had pore diameters and cross sections of approximately 100 nm (Fig. 1B) and 450 nm (Fig. S-1B), respectively. Etching conditions for the pSi-based NIMS and DIOS substrates were highly consistent from etch to etch. The NALDI™ surface is covered by SiNWs that are 10 nm in diameter with lengths ranging from 100–500 nm.

DIOS and NIMS substrates were functionalized with F_{13} and $BisF_{17}$, respectively. NALDI™ substrates on the other hand are reportedly functionalized with F_5PhPr which is a common silane used to functionalize silicon based SALDI substrates [12]. The chemical composition of the nanostructures hydrophobic coating was investigated using XPS and spectra are shown in Fig. S-2. A summary of the chemical composition from XPS survey spectrum for DIOS, NIMS and NALDI™ is presented in Table 1. As expected, each of the substrates investigated had a high fluorine content consistent with the perfluorinated silanes and the siloxane used during functionalization, respectively.

Infrared (IR) spectroscopy was used to characterize NIMS and DIOS pSi surfaces. Fig. S-3 displays a series of IR spectra for each surface modification. In the case of Fig. S-3A, the hydride terminated pSi surface displays vibrations at 900 cm^{-1} and 2100 cm^{-1} attributed to the SiH_2 scissor vibration and Si-H stretching vibrations in SiH_2-SiH or Si_3-SiH, respectively. Upon ozone oxidation these peaks disappeared and new peaks were observed, in particular the characteristic silicon oxide vibrational modes at 1100 cm^{-1} and 3500 cm^{-1}, corresponding

Table 1
Elemental composition (in atomic percentage, Atom. %) as determined by XPS for functionalized DIOS, NIMS and NALDI™ substrates.

Substrate	O 1s Atom. %	C 1s Atom. %	F 1s Atom. %	Si 2p Atom. %
DIOS-F_{13}	28.5	14.3	13.8	43.4
NIMS-$BisF_{17}$	20.9	23.3	25.6	30.2
NALDI™-F_5PhPR	16.1	28.1	31.2	24.6

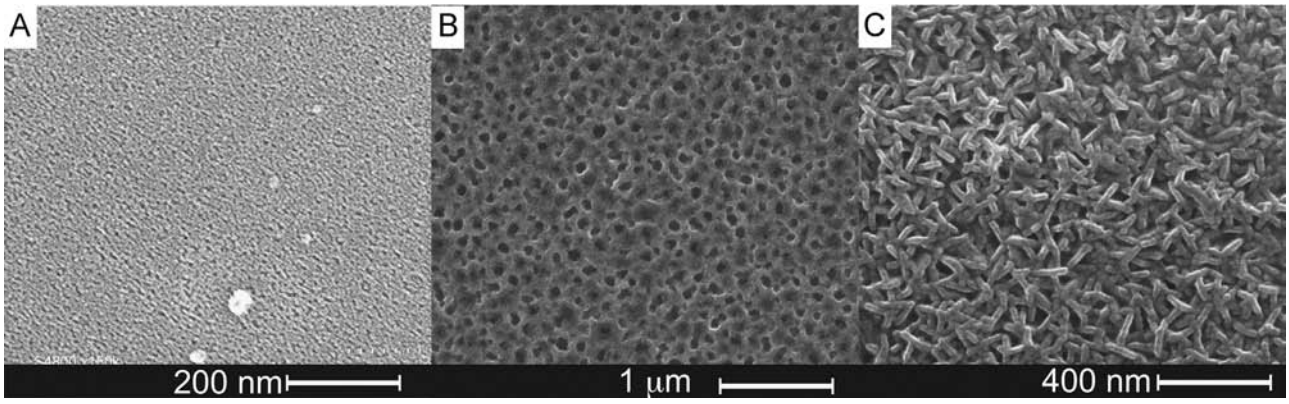

Fig. 1. SEM micrographs showing top view of a) NIMS, b) DIOS and c) NALDI™ substrates.

to stretching vibrations of the silicon oxide (Si-O) and silanol (SiO-H) functional groups, respectively (Fig. S-3B). Once the oxidized pSi surface was reacted with $BisF_{17}$ for NIMS (Fig. S-3C) and F_{13} for DIOS (Fig. S-3D), overtones were observed at 1140 cm^{-1} and 1220 cm^{-1} attributed to CF_2 stretching and at 1280 cm^{-1} for CF_3 asymmetric stretching vibrations. Additional peaks were observed for the F_{13}

Table 2
Comparison of S/N values with SD ($n=3$) and % RSD for four drug molecules at 100 ng/mL concentration using SALDI analysis on DIOS, NIMS and NALDI™ substrates.

Drug	DIOS	NIMS	NALDI™	% RSD	% RSD	% RSD
Methadone	91.6 ± 9.6	98.7 ± 8.1	139.2 ± 63.8	10.5	8.2	45.8
Oxycodone	460.8 ± 33.1	489.8 ± 29.9	232.6 ± 14.2	7.2	6.1	2.5
Flunitrazepam	10.1 ± 2.9	34.6 ± 11.5	11.8 ± 2.7	29.5	33.3	22.8
MDMA	480.9 ± 61.5	200.9 ± 105.3	229.0 ± 33.2	12.8	52.4	14.5
Cocaine	1713.0 ± 215.8	2715.0 ± 66.0	1235.0 ± 199.4	12.6	2.4	20.2

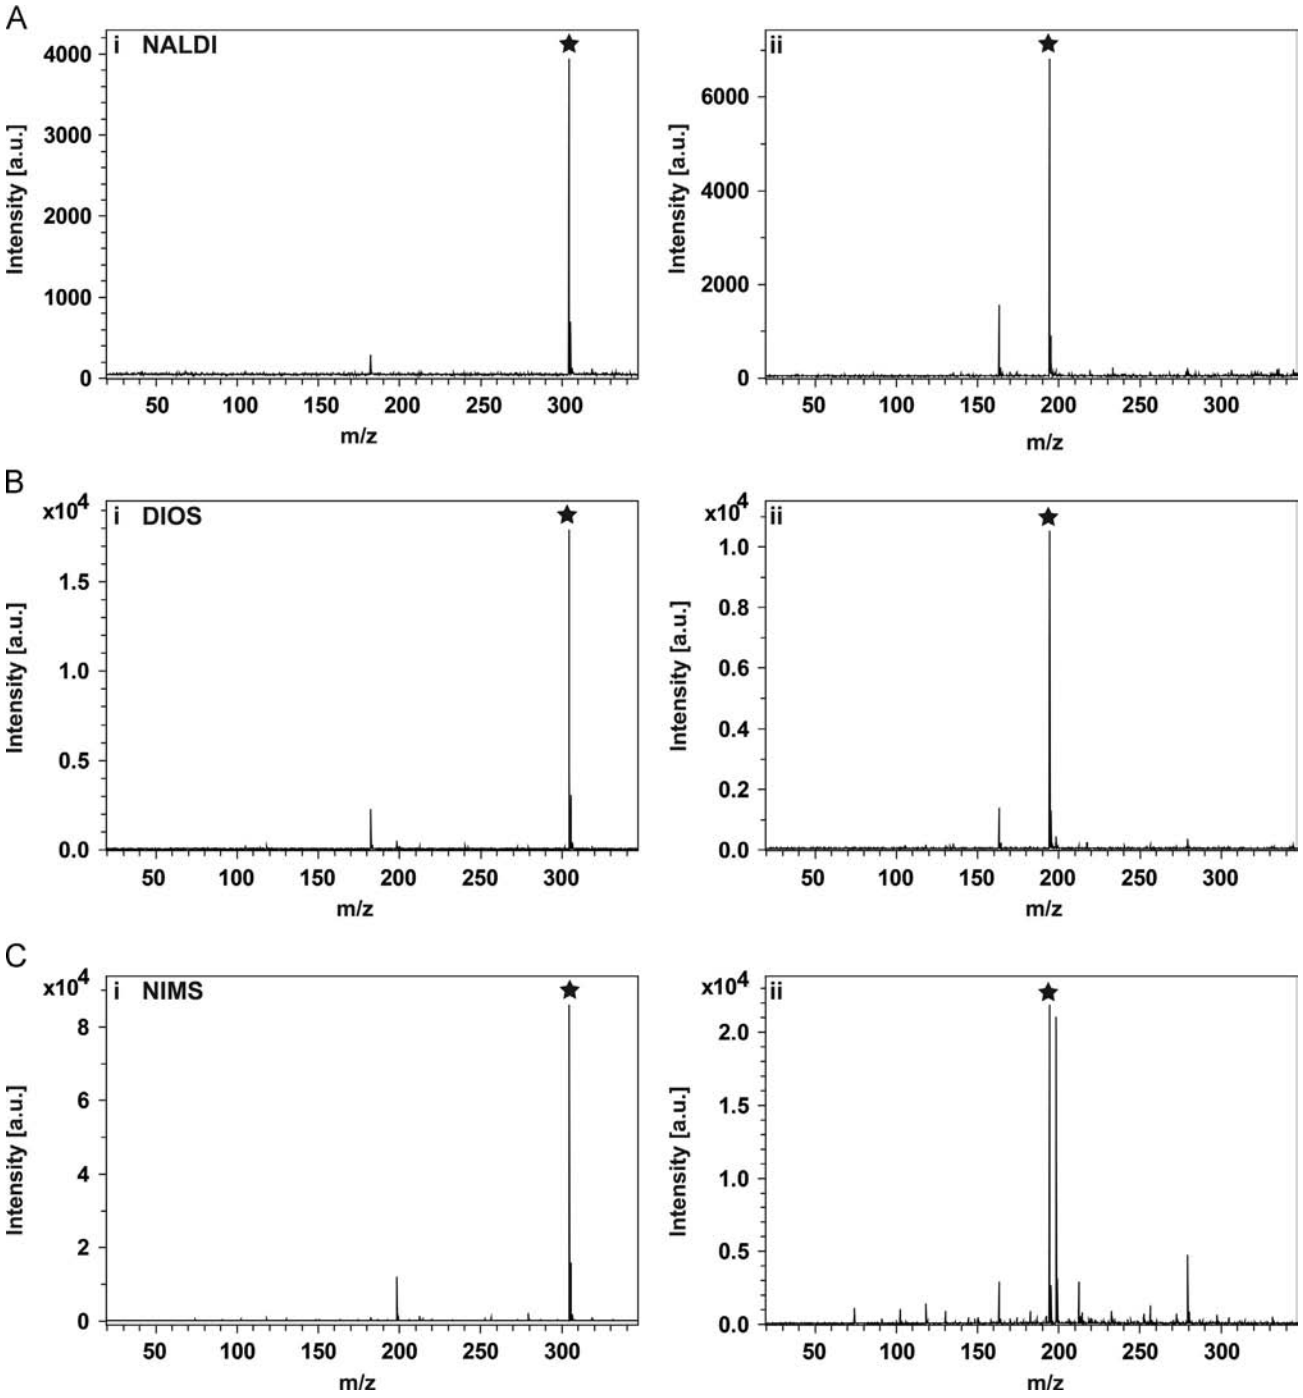

Fig. 2. Comparison of SALDI mass spectra on A) NALDI™, B) F_{13}-DIOS and C) $BisF_{17}$-NIMS substrates for i) cocaine and ii) MDMA at 100 ng/mL using optimized laser energies for each substrate. Star represents the m/z for each drug detected.

functionalized pSi in the region of 2850–3000 cm^{-1} (See Fig. S-3D), corresponding to CH_2 stretching vibrations.

The WCAs for NALDI™, NIMS and DIOS were 138°, 110° and 124° showing that all three surfaces are very hydrophobic (Fig. S-4). Hydrophobic surfaces are desirable since a drop of body fluid is confined on a small footprint of the chip, instead of spreading out, as would be the case for hydrophilic surfaces. This results in concentration of the analyte within a small area and translates into higher sensitivity.

3.2. Analytical performance

The analytical performance of each substrate was investigated for four drug classes: amphetamines, benzodiazepines, opiates and cocaine. Each of the substrates (NIMS, NALDI™ and DIOS) generated good quality SALDI mass spectra for methadone, oxycodone, MDMA, flunitrazepam and cocaine, as representative of different classes of drugs, at forensically relevant concentrations (100 ng/mL), with the exception of flunitrazepam. On each SALDI substrate, the drug molecules were predominately detected as the molecular ion $[M+H]^+$ due to their proton affinities (PA)[23].

Average S/N was recorded in replicates of three and averaged for comparison (Table 2). DIOS and NIMS substrates produced average S/N that were not statistically different for the opiates, methadone and oxycodone. The S/N for oxycodone (100 ng/mL) on the NALDI™ substrate was half that of DIOS and NIMS, and was statistically different ($P < 0.01$). For MDMA, DIOS produced

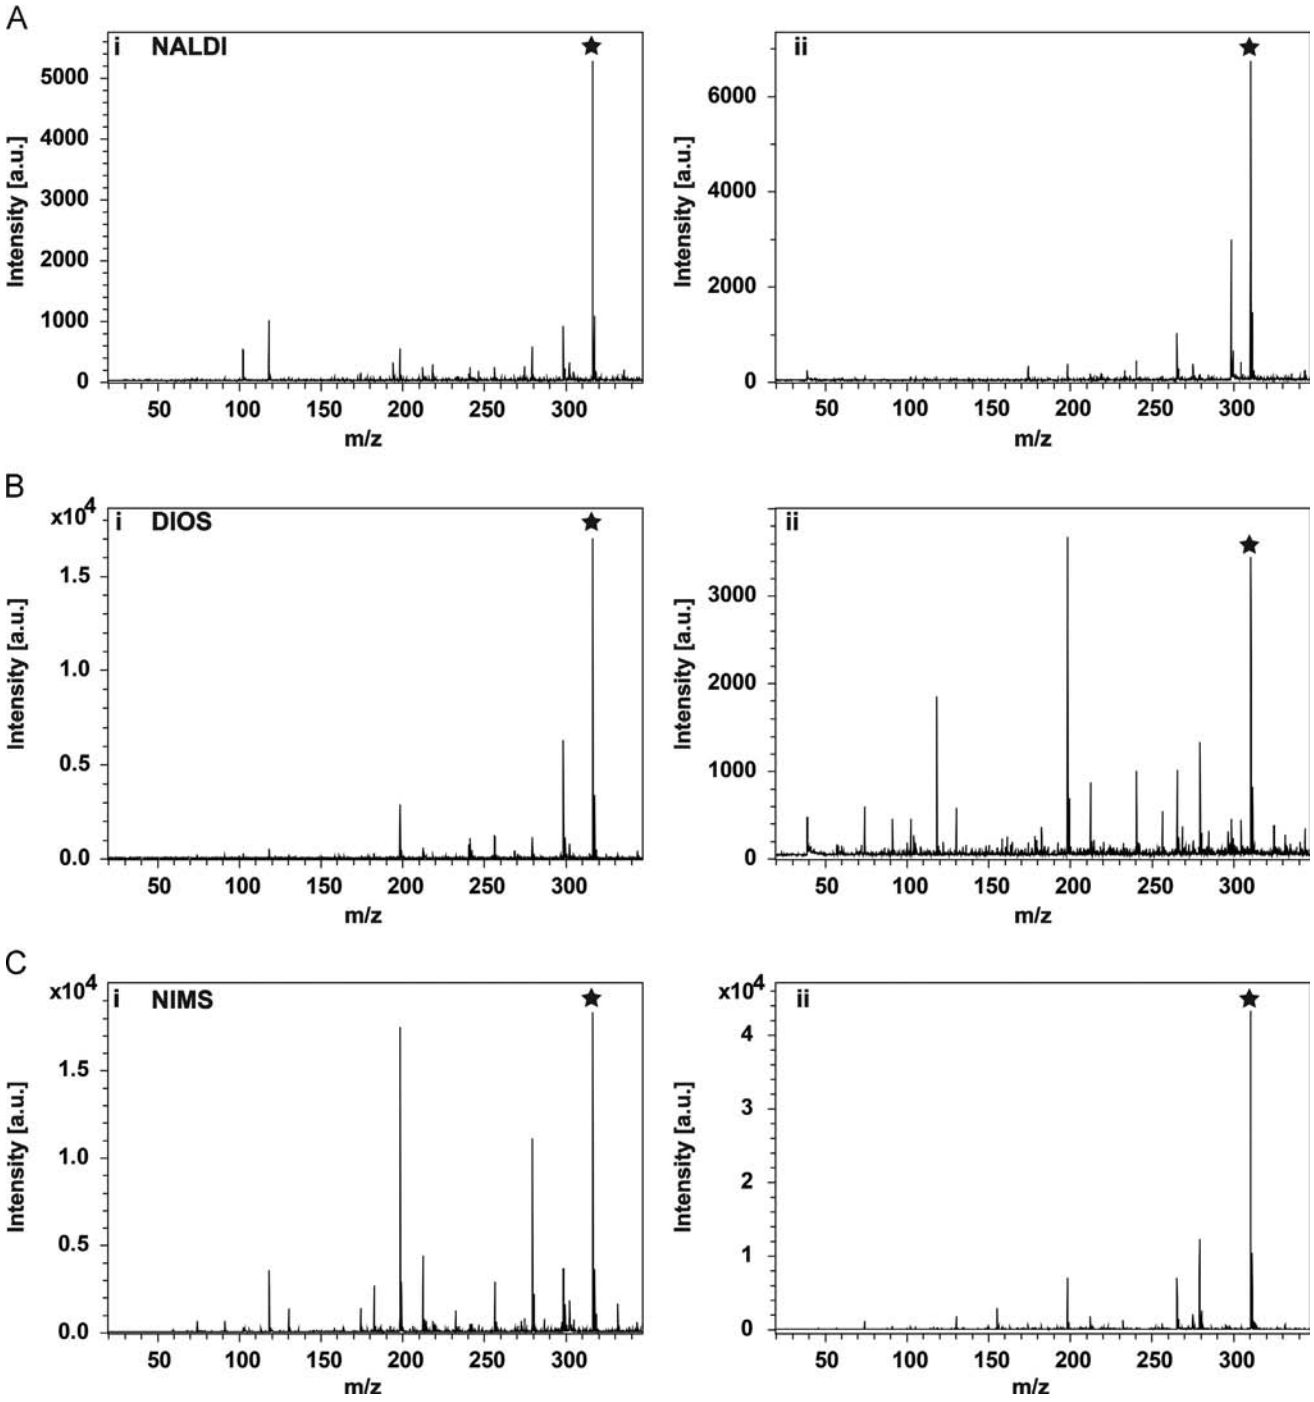

Fig. 3. Comparison of SALDI mass spectra on A) NALDI™, B) F_{13}-DIOS and C) $BisF_{17}$-NIMS substrates observed for i) oxycodone and ii) methadone at 100 ng/mL using optimized laser energies for each substrate. Star represents the m/z for each drug detected.

statistically significant ($P < 0.01$) higher S/N in contrast to NIMS and NALDI™ which both produced similar S/N on average. As a result of the average S/N for MDMA observed on DIOS substrates (Table 2) and the clean spectra generated, DIOS would therefore be considered more appropriate for amphetamine detection. In contrast, NIMS produced higher S/N for flunitrazepam in comparison to NALDI™ and DIOS but this difference was not statistically significant. For cocaine on the other hand, NIMS produced average S/N that were statistically higher in comparison to both NALDI and DIOS with a 95% confidence interval (Table S-1).

The precision of each substrate was also assessed using the % RSD for the observed S/N. For RSD % values of $< 20\%$ the average S/N are considered precise [24]. For each of the drugs, with the exception of flunitrazepam, the DIOS and NIMS surfaces both showed

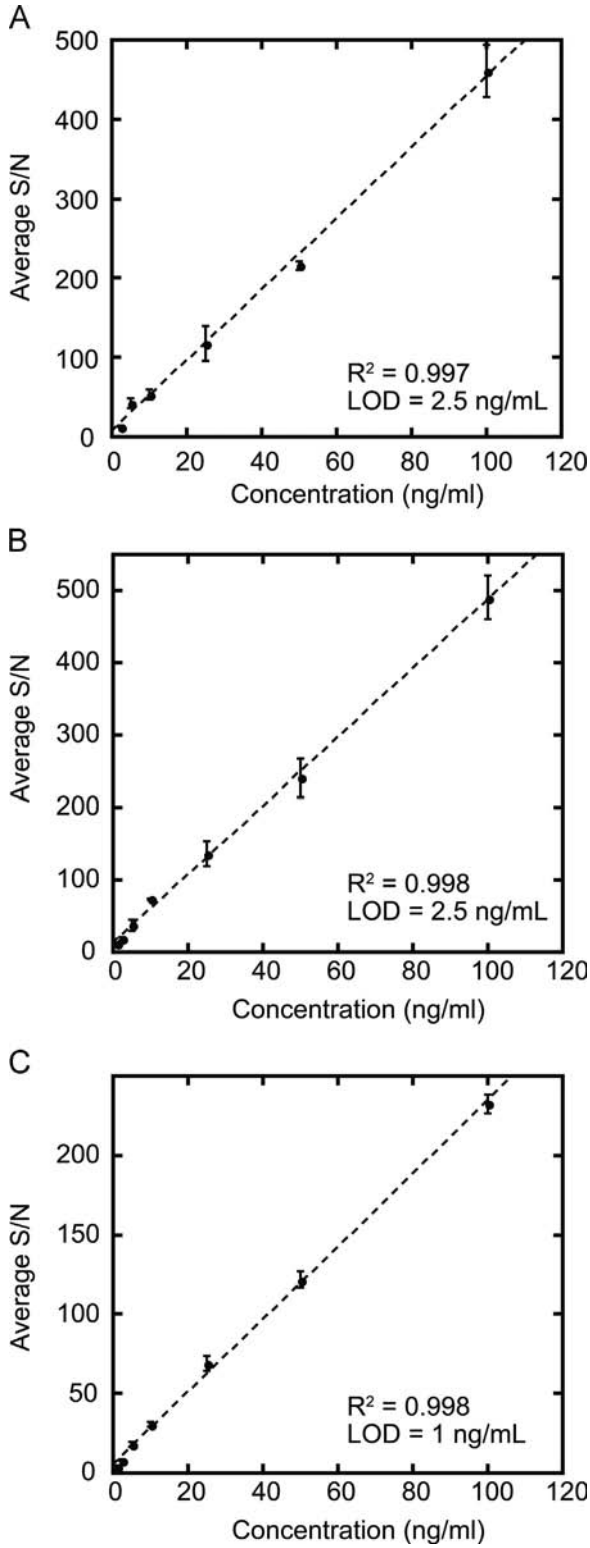

Fig. 4. Average S/N for oxycodone (0–100 ng/mL) in water on A) NALDI™, F_{13}-DIOS and C) $BisF_{17}$-NIMS substrates.

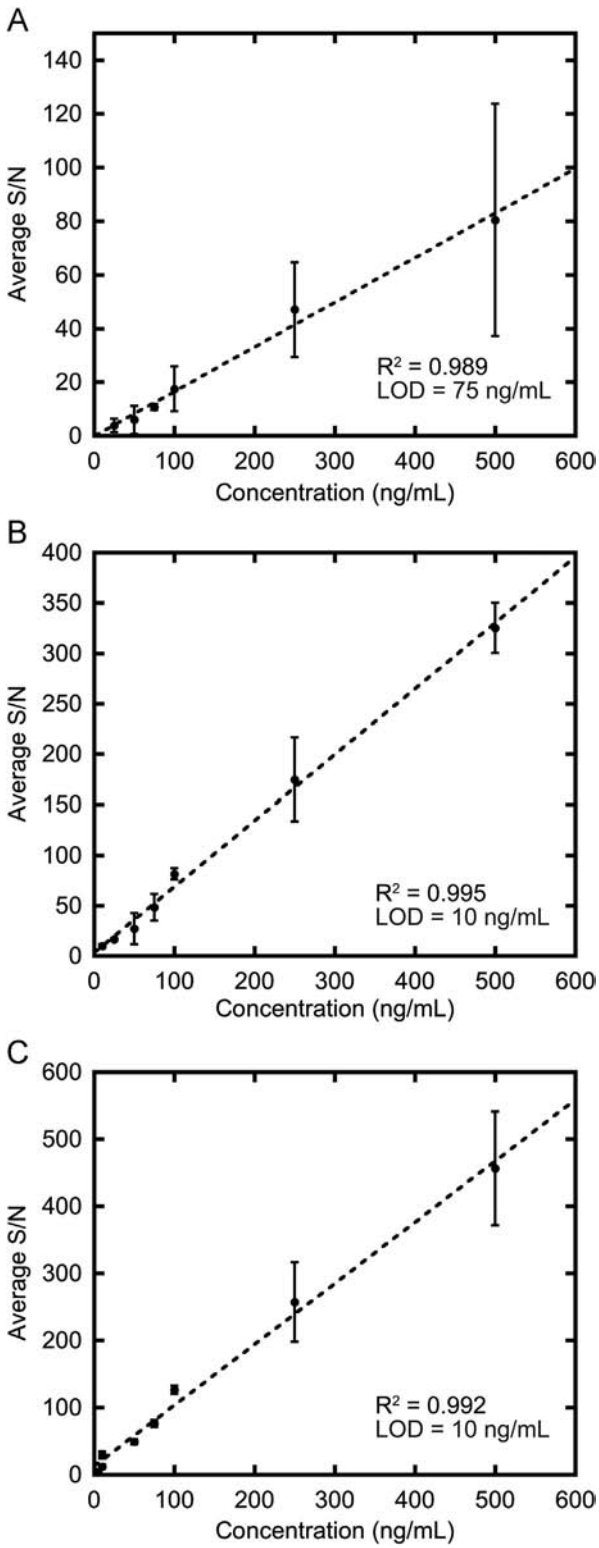

Fig. 5. Average S/N for oxycodone (0–500 ng/mL) in PBS on A) NALDI™, B) F_{13}-DIOS and C) $BisF_{17}$-NIMS substrates.

good precision (Table 2). However, for the detection of MDMA on the NIMS substrate the RSD % was 52.4, which suggests a high variability in S/N. The NALDI™ surface had higher RSD % in comparison to both DIOS and NIMS for the detection of each drug molecule except for oxycodone (RSD % 2.5) and MDMA (RSD % 14.5).

Fig. 2 shows representative positive ion NALDI™, DIOS and NIMS mass spectra for cocaine and MDMA at 100 ng/mL, respectively. For cocaine at 100 ng/mL, the mass spectra did not suffer any interferences or contaminants on any of the substrates. Fragment ions were present for NALDI™ and DIOS alongside the protonated molecular ion for cocaine at 304 m/z. The loss of $C_6H_5CO_2$ results in the fragment peak at 182 m/z being observed in good agreement with the literature [25].

For MDMA (molecular ion at 194 m/z, fragment ion ($-CH_3NH_2^+$) at 163 m/z), on the other hand, a high signal intensity background peak at 198 m/z was observed for the NIMS surface. This peak is present on all three substrates, but its intensity appears to be dependent on the efficiency of desorption/ionization of the analyte. At lower MDMA concentrations, this peak and other background peaks become more prominent and may obscure the MDMA signal. The presence of this peak was also observed on the DIOS and NALDI substrate during MDMA analysis but to a lesser degree.

Fig. 3 shows representative positive ion DIOS, NALDI™ and NIMS mass spectra for oxycodone, and methadone at 100 ng/mL. For oxycodone, high intensity background ions were present in the spectra for NALDI™, NIMS, and to a lesser extent DIOS, due to the difference in sensitivity of the three substrates for the detection of oxycodone. High signal intensities were observed for NALDI™ and NIMS with minimal background ions present within the spectra for methadone (Fig. 3Aii and Fig. 3Cii). However, for DIOS, as a result of high intensity background peaks in and around methadone the spectrum was convoluted (Fig. 3Bii). A peak observed at 265 m/z on NIMS and DIOS substrates can be attributed to the loss of $C_2H_5N^+$. This peak was not observed on the NALDI™ substrate perhaps as a result of the lower laser energy required to desorb/ionize methadone from the NALDI™ target. Interestingly, for both of the opiates, methadone and oxycodone, many background ions were present in the spectra which is due to the increase in laser energy required to desorb and ionize the opiates from each of the SALDI substrates.

The limit of detection (LOD) [26] for oxycodone in water was evaluated for NIMS, NALDI™ and DIOS substrates (Fig. 4A-C). The LOD was defined as the minimum concentration giving a S/N > 10. For NIMS, NALDI™ and DIOS, the LOD was determined to be approximately 1 ng/mL (S/N 12.1 ± 2.9), 2.5 ng/mL (12.3 ± 1.3) and 2.5 ng/mL (13.0 ± 0.9), respectively. All of the substrates showed good linearity ($R^2 > 0.99$) over the concentration range tested, demonstrating that analyte quantitation can be achieved [26].

The LOD for oxycodone in PBS was calculated on NALDI™, DIOS and NIMS substrates (Fig. 5A-C) to simulate the detection of oxycodone from human body fluids and to assess each substrate for salt resistance. Interestingly, the observed LOD on the NALDI™ substrate was > 75 ng/mL, 30 times higher than in water, perhaps due to salt interference/intolerance. The observed LOD for oxycodone on NIMS and DIOS was approximately 10 ng/mL with S/N of 11.9 ± 3.5 and 9.7 ± 1.9, respectively.

For NALDI™, the % RSD (Table S-2) was calculated to assess and compare the precision of the observed S/N values for oxycodone in PBS. A summary of the results is displayed in Table S-2. At each concentration, except for 75 ng/mL (% RSD 10.1) a high % RSD was observed ranging from 37.5–88.2%, which suggests a lack of precision. In contrast, % RSD values for DIOS (Table S-3) were below 19.8% demonstrating good precision with the exception of 250 ng/mL, 75 ng/mL and 50 ng/mL with % RSD 23.8%, 27.5% and 56.6%, respectively. Better overall precision was observed for NIMS substrates (Table S-4) at all oxycodone concentrations except for 250 ng/mL and 10 ng/mL (% RSD 22.9% and 29.6%, respectively).

For NIMS and DIOS good linearity ($R^2 > 0.99$) was observed and the LOD only decreased by one order of magnitude suggesting better desalting capabilities. A poorer linear fit was observed for NALDI™, suggesting that quantitation may be difficult to achieve for more complex mixtures. The technical note for the NALDI™ target suggests that desalting of samples is necessary prior to analysis [27]. Unlike DIOS and NIMS substrates, processing steps are therefore required for NALDI™. Furthermore, the technical note suggests that the entire chip should be immersed in 200 mL of deionized water, which may lead to cross contamination on sample spots.

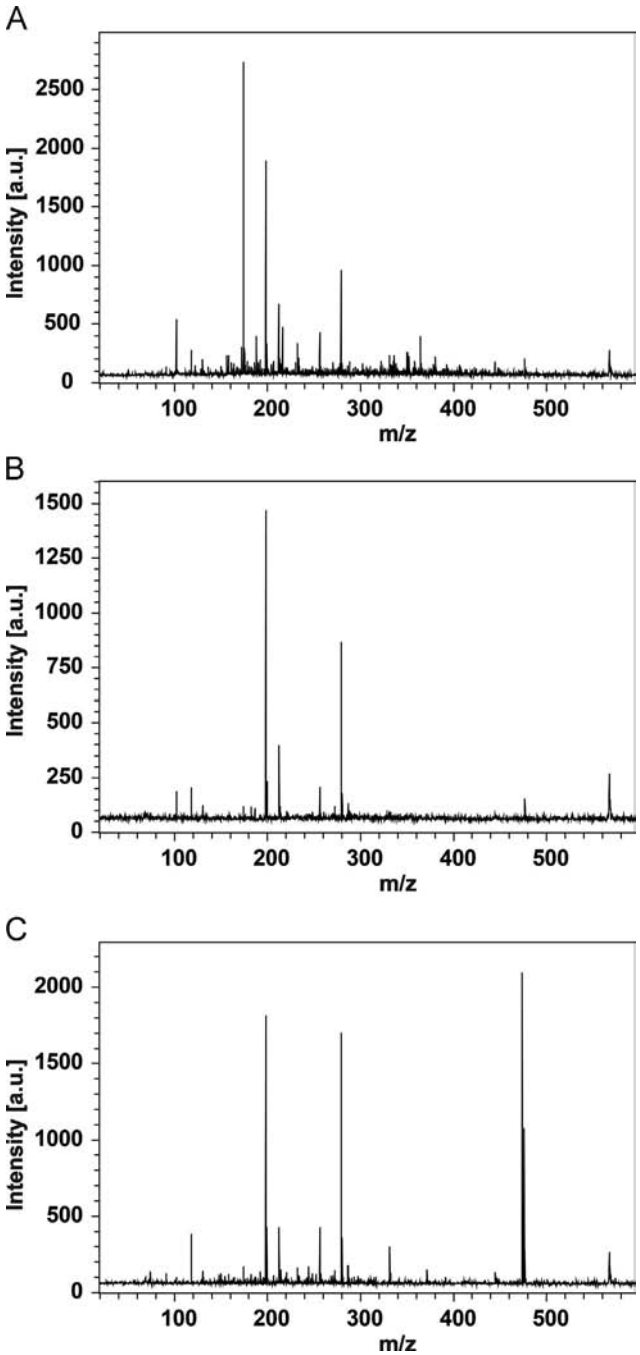

Fig. 6. Background spectra observed for freshly opened or prepared A) NALDI™, B) F_{13}-DIOS and C) $BisF_{17}$-NIMS substrates.

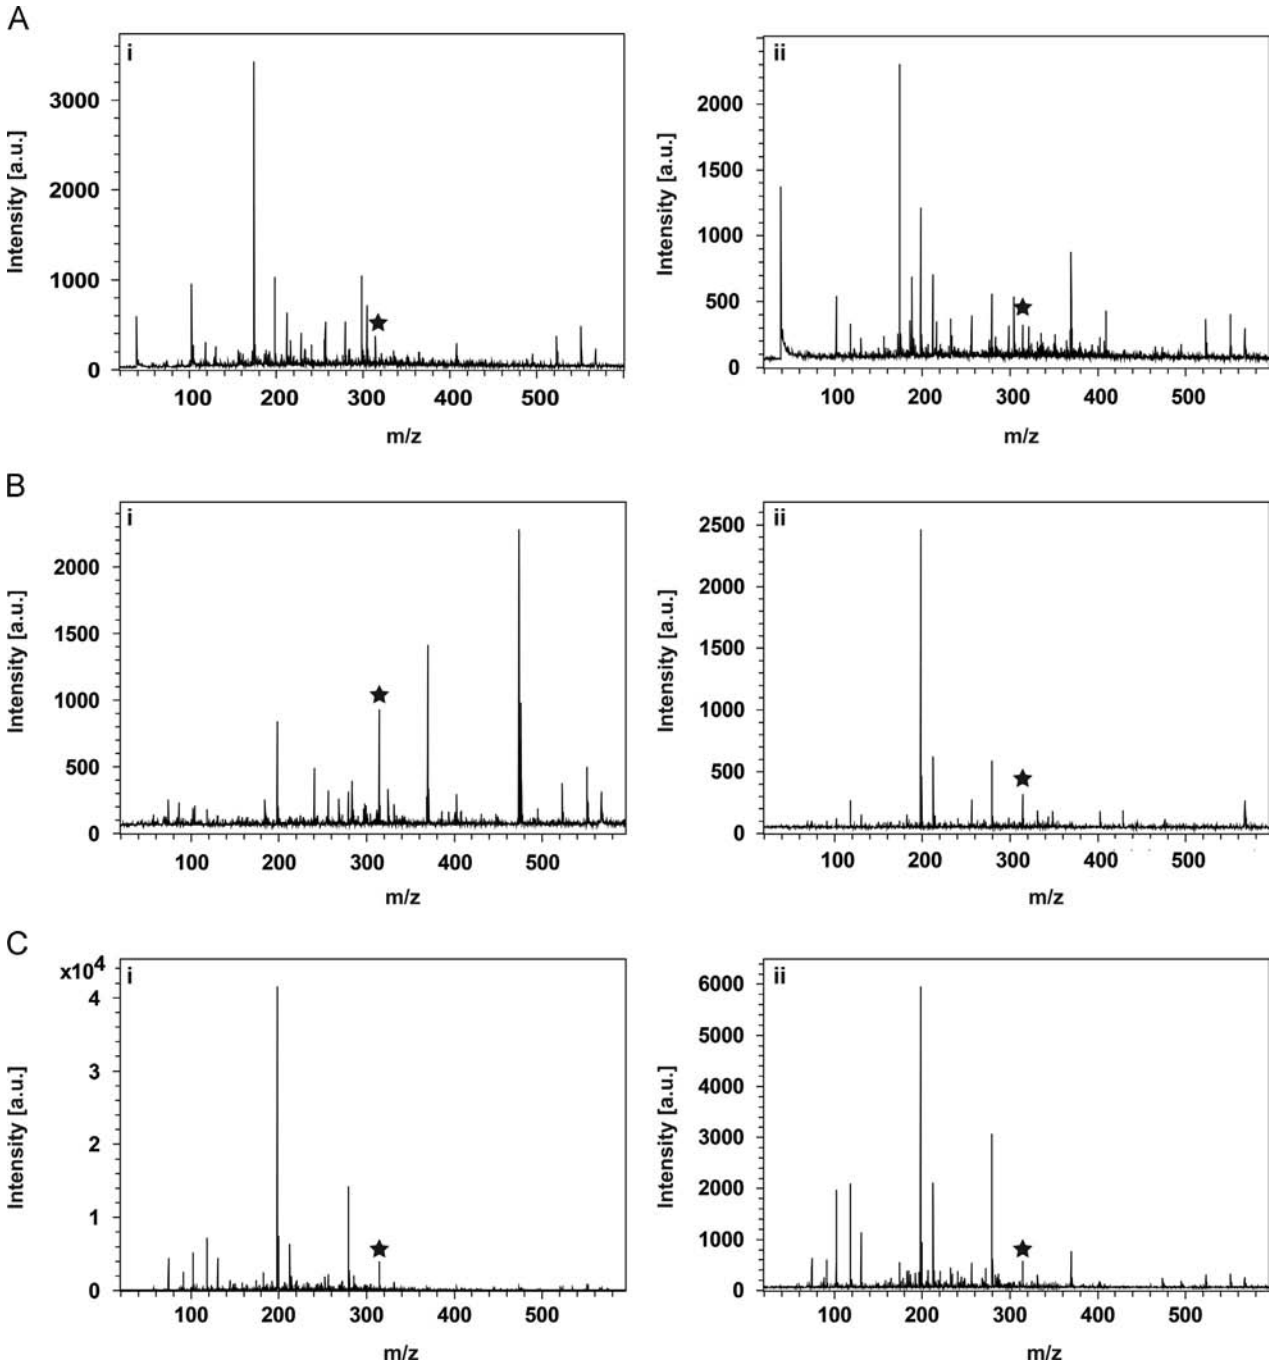

Fig. 7. Mass spectra for flunitrazepam (100 ng/mL) on A) NALDI™, B) F_{13}-DIOS and C) BisF_{17}-NIMS on i) freshly opened or prepared substrates and ii) six-month old substrates. Star represents the m/z for each drug detected. The laser attenuator offset required for detection of flunitrazepam on NALDI™, F_{13}-DIOS and BisF_{17}-NIMS was 42%, 58% and 62%, respectively.

3.3. *Background ions and long-term storage of the SALDI substrates*

Fig. 6 displays background spectra observed for NALDI™, NIMS and DIOS substrates on sample spotted with water without the presence of any illicit drug molecules. Interestingly, similar high intensity peaks at 102, 130, 198, 212, 279 and 567 m/z were observed for each of the three functionalized substrates. A comparison of spectra for the freshly etched and oxidized DIOS and NIMS substrates revealed that the majority of background peaks observed are due to the oxidation step since none of these peaks were observed for the freshly etched pSi substrates (Fig. S-5). This presence of background ions was attributed to the restructuring of the nanostructured silicon surfaces (NALDI™, NIMS and DIOS), which results in the formation of surface ion (Si_n^+ and $OSiH^+$), previously investigated by Northern et al. [28]. In any case, F_{13} functionalized DIOS chips produced the lowest number and intensity of background signals.

The longevity of each substrate was investigated for flunitrazepam since each of the substrates showed similar S/N (Table 2) at 100 ng/mL (Fig. 7). Several background peaks were present for NALDI™ on both the freshly opened substrate (Fig. 7A-i) and a six-month old target (Fig. 7A-ii). We also observed a high intensity peak (38.96 m/z) for both the freshly opened and six-month old NALDI™ target, potentially corresponding to potassium. This peak was only present during the detection of flunitrazepam and not in background spectra (Fig. 6). Since DIOS and NIMS required no increase in laser fluence to desorb/ionize flunitrazepam the potassium peak was not observed (Fig. 7B-C).

Upon further investigation it became clear that the presence of this peak was a result of an artifact that occurred upon increasing the laser energy. Fig. S-6 displays overlaid mass spectra for flunitrazepam (zoomed into the mass region for potassium) on NALDI, DIOS and NIMS substrates at increased laser energies all of which show the presence of potassium. Another disadvantage of NALDI™ for the detection of flunitrazepam was the presence of numerous peaks ranging from 300–350 Da that obscured the signal of the target analyte in the freshly opened and six-month old NALDI target. For both DIOS and NIMS, no significant decrease in S/N from freshly etched to six-month old samples was observed. Furthermore, contaminant peaks close to the protonated mass of flunitrazepam (314 m/z) were not observed. Whilst DIOS and NIMS produced relatively clean mass spectra for flunitrazepam, NIMS produced higher signal intensities compared with NALDI™ and DIOS, suggesting a better sensitivity for benzodiazepine detection.

3.4. Ease of fabrication and use

An advantage of DIOS and NIMS (pSi-based substrates) is the ease and cost of fabrication. DIOS and NIMS chips can be fabricated using simple electrochemical etching processes that require minimal equipment. As a result automated assemblies for etching pSi have been developed for mass production [29]. However, since DIOS is fabricated using photo electrochemical etching an additional light source and lens set-up is required, which limits up scaling procedures [29, 30]. In any case, within our laboratory the current cost of fabrication is approximately AUS $9 for chips of similar dimensions to NALDI™.

Unlike pSi based SALDI, NALDI™ is fabricated via complex chemical vapor deposition techniques. These complex fabrication procedures, whilst allowing for large-scale fabrication result in a costly product, up to AU $900 for five NALDI™ target plates.

4. Conclusions

We have compared three common SALDI substrates (NALDI™, NIMS and DIOS) for their analytical performance for specific drug classes, namely amphetamines (MDMA), opiates (methadone and oxycodone), benzodiazepines (flunitrazepam) and tropane alkaloids (cocaine). NIMS was observed to produce better LODs for oxycodone in both water and PBS in comparison with DIOS and NALDI™. Each of the substrates produced similar low intensity background spectra, which did not obscure the drug molecules investigated. Finally, this study showed that each of the substrates could be used for the detection of illicit drugs after six months of storage in ambient conditions. All three substrates show strong potential for illicit drug detection, but our study shows that the performance of the substrates depends on the nature of the drug, the medium and the storage term.

ABSTRACT

Testing for traces of different pesticides (triazinic, organophosphates and chlorurates), present in hydrophobic matrices such as sunflower oil was checked using new immunosensors working in organic solvent mixtures (OPIEs). The competitive process took place in an n-hexane–chloroform 75% (V/V) mixture, while the subsequent final enzymatic measurement was performed in decane using tert-butylhydroperoxide as substrate of the enzymatic reaction. A Clark electrode was used as transducer and peroxidase enzyme as marker. A linear response of between about 10 nM and 4 μM was usually obtained in the presence of sunflower oil. Immunosensors show satisfactory selectivity and precision and recovery tests carried out on commercial sunflower oil samples gave excellent results. Lastly, theoretical confirmation of the possibility that immunosensors can act positively in organic solvent mixtures was discussed on the basis of Hill's coefficient values.

1. Introduction

In recent years several authors [1–4] discovered that some antibodies were capable of retaining activity and selectivity in the non-aqueous phase, while, until recently, it was believed possible only in aqueous environment. Consequently a start was made also on the development of immunosensors working in the organic phase [5–7]. Even though the field of organic phase immunosensing is still not highly developed, the potential benefits of this approach for the measurement of poorly water-soluble analytes in organic solvent are manifold [6]; indeed many analytical methods involving non-polar analytes require solvent extraction prior to measurement. The analytical assay is therefore greatly simplified if the method is able to function effectively in non-polar solvent extract. However, several phytopharmaceutical compounds are more soluble in organic solvent than in aqueous solutions (see Table 1), and can therefore be rightly included in the category of compounds described above; also testing for them thus encounters difficulties linked to the low solubility of several pesticides in aqueous medium. These difficulties increased further when the low solubility in water solution of the analyte to be determined was coupled with the very low solubility of the real matrix in which the analyte was contained, as in the case of edible oily matrices. To overcome these difficulties, in the last two years, immunodevices were fabricated that are capable of operating in organic solvent, i.e. organic phase immuno electrodes (OPIEs) [8]. To this end, in a first investigation [8], in accordance with what is reported in literature [9–11], several different aspects of the new type of immunosensor were optimized. In particular different competitive formats [8,12] were tested and the results confirmed as the ELISA type format was found to be quite suitable [12]. Furthermore, the practicality of immobilizing the antibody used on the polymeric membrane support was confirmed [8,12]. However, the choice of the organic phase solvent was the most important and difficult point, although the factors governing antibody–antigen binding in organic solvent were clearly more complex and required further elucidation. Solvent properties such as hydrophobicity, molecular mass and fraction can all affect the binding process [6], but also the antigen and the real matrix solubility in the selected solvent play an important role. Furthermore, of equal importance is the fact of whether also the last enzymatic reaction involved in the enzyme immunoassay method was performed in the organic solvent or not. It is actually surprising that greater efforts appear not to have been made in this area [6], although basic research is not lacking [9–11,13–18]. Studies reported in literature concerning choice of solvent refer above all to alcoholic and hydroalcoholic solutions [19–22] and often do not agree among themselves [6,19–22] also because of the different antibody systems used in these studies. For this reason the organic phase immunoassay development has continued to rely on an empirical rather than mechanistic approach [6]. Also our approach to this problem was therefore of this type in our first research [8] involving the analysis of traces of triazinic pesticides in olive oil. A series of tests were thus carried out by

Table 1
Comparison of solubility of several pesticides in chloroform and in water.

Pesticide	Solubility in chloroform ($g\,L^{-1}$)	Solubility in water ($g\,L^{-1}$)
Atrazine	52.0	0.028
Simazine	0.9	0.006
Carbaryl	200	0.040
Parathion	0.50	0.060
2,4-D	32	0.9
2,4,5-T	32	0.2

the present authors in previous work [8] using different solvents, different electrochemical transducers and different immunosensor constructions, or operating measurement format. This series of trials led to the development of suitable amperometric immunosensors for the analysis of triazinic, organophosphate and chlorurate pesticides in olive oil and olive oil by-products [8,23], with the competitive format of the immunological test (ELISA type) performed in 50% (V/V) chloroform n-hexane mixture, which was found [8] to be the best compromise among the different solubility requirements mentioned above, using as transducer a classical Clark electrode for oxygen with the external cup and the gas permeable membrane both made of PTFE and a pesticide–BSA conjugated hapten marked using horseradish peroxidase enzyme. These devices were certainly innovative compared to what had previously been reported in literature, but produced good results also for the applications in real olive oil samples and derivatives [8,23]. The success obtained in these researches involving pesticide measurement in olive oil matrices using the new OPIE aroused our interest in this field and so in the present research also the possibility of testing for the above pesticides in other kinds of edible oils was investigated. Since the literature contains several reports concerning the presence of traces of several pesticides such as atrazine, simazine, 2,4-D, 2,4,5-T and parathion in sunflower oil [24–29], it was decided to apply the OPIEs developed also to determine these pesticides in sunflower oil. Of course our approach was very similar to that successfully used for pesticide analysis in olive oil. However, also in this case the choice of solvent was a central point, considering that sunflower oil does not have exactly the same solubility as olive oil in the different organic solvents. For this reason measurements in the present work were performed in n-hexane–chloroform 75% (V/V) mixture instead of in the same 50% (V/V) mixture as used in the previous research aimed at measuring pesticide traces in olive oil [8].

2. Materials

2.1. Apparatus

The amperometric measurements were performed in a 5 mL thermostated glass cell at 23 °C under constant stirring. The Clark electrode, supplied by Universal Sensor Inc., New Orleans (U.S.A.), was connected to an amperometric biosensor detector provided by the same firm and to an analogue recorder mod. 868 Amel (Milan, Italy). In all experiments performed in the organic phase, the plastic cap of the electrodes was replaced by a PTFE cap.

2.2. Reagents and materials

Anti-atrazine monoclonal antibody, anti-dichloro-phenoxyacetic acid and anti-trichloro-phenoxyacetic acid antibodies, as well as atrazine and simazine carboxyderivative, dichloro-phenoxyacetic acid (i.e. 2,4-D) and trichloro-phenoxyacetic acid (i.e. 2,4,5-T), were provided by Dr. S. Eremin (Department of Chemical Enzymology, Faculty of Chemistry, Moscow State University, Russia). Anti-parathion was a commercial antibody and was obtained from Acris (Acris Antibodies, Herford, Germany). 1-Chloro-3-ethylamino-5-isopropylamino-2,4,6-triazine (i.e. Atrazine), 6-chloro-N,N′-diethyl-1,3,5-triazine-2,4-diamine (i.e. simazine), N-tert-butyl-6-chloro-N′-ethyl-1,3,5-triazine-2,4-diamine (i.e. tert-buthylazine), 2-amino-4-chloro-6-(isopropylamino)-s-triazin (i.e. atrazine desethyl), 1-naphthyl methylcarbamate (i.e. carbaryl), 2-methyl-2-(methylthio)propanal O-(N-methylcarbamoyl)oxime (i.e. aldicarb), diethyl 4-nitrophenyl phosphate (i.e. Parathion) were supplied by Pestanal Sigma-Aldrich (Sigma-Aldrich, Milan, Italy). Potassium chloride, dibasic and monobasic anhydrous potassium phosphate RPE, chloroform RPE, dichloromethane RPE and diethyl ether RPE were supplied by Carlo Erba Reagents (Carlo Erba, Milan, Italy). Ny+ Immobilon Affinity membrane (porosity 0.65 μm) was provided by Millipore (Millipore Corporation, Vimodrone, Milan, Italy). The biotinylation kit, supplied by Sigma Immunochemicals (Sigma, Milan, Italy), was composed of biotinylation reagent (BAC-SulfoNHS, namely biotinamido hexanoic acid 3-sulfo-N-hydroxysuccinimide ester), 5 M sodium chloride solution, micro-spin column (2 mL) (in practice, a small empty cylindrical vessel prepackaged with Sephadex G-50), 0.1 M sodium phosphate buffer pH 7.2, 0.01 M phosphate buffer saline (PBS) pH 7.4 (reconstituted with 1 L of deionised water to give 0.01 M phosphate buffer, 0.138 M NaCl, 2.7 mM KCl, pH 7.4); lastly extravidin® peroxidase (containing 0.2 mL of extravidin Peroxidase conjugate at 2.0 $mg\,mL^{-1}$, with 0.01% thimerosal). Phenol, dialysis membrane (art. D-9777), 1-ethyl-3 (3-dimethylaminopropyl) carbodiimide, albumin (from bovine serum) (BSA) and TRIS (hydroxymethyl-aminomethane), tert-butylhydroperoxide solutions in decane solvent and TWEEN® 20, provided by Sigma-Aldrich (Sigma-Aldrich, Milan, Italy).

2.3. Samples

Edible sunflower oil samples, produced by the most important industrial Italian sunflower oil producer firms, were purchased from a local shop and stored in sealed glass bottles.

3. Methods

3.1. Immunosensor assembly and electrochemical format

The electrochemical transducer used was an amperometric gaseous diffusion amperometric electrode for O_2 determination (see Fig. 1). The transducer consisted of a Clark type electrode, equipped with PTFE cup and a gas permeable membrane of the same material. For the immunosensor assembly, in practice, three membranes were mounted on the PTFE cap of the Clark electrode, in the following order: the gas-permeable membrane, the dialysis membrane and the Immobilon membrane with the antibody immobilized on it. The membranes were kept in place by a nylon net and a PTFE O-ring. A constant potential of −650 mV with respect to an $Ag/AgCl/Cl^-$ anode was applied to the Pt cathode of the oxygen electrode. Horseradish peroxidase enzyme was used as marker for immunocomplex detection. The cathode and anode of the Clark type amperometric electrode were immersed in an internal solution of phosphate buffer saline (PBS), pH 7.4 (reconstituted with 1 L of deionized water to give 0.01 M phosphate buffer, 0.138 M NaCl and 2.7 mM KCl). The current, which was measured and flowed in the external circuit, was obviously a function of the concentration of dissolved oxygen present in the internal solution. This concentration was regulated (through the diffusion of the oxygen across the gas permeable membrane) by the enzymatic reaction, which took place in decane (see Fig. 1); in this enzymatic reaction the reduction in the oxygen consumed was a function of the reduction in the concentration of the peroxidase enzyme present in the antibody complex formed on the Immobilon membrane as a result of the competitive process

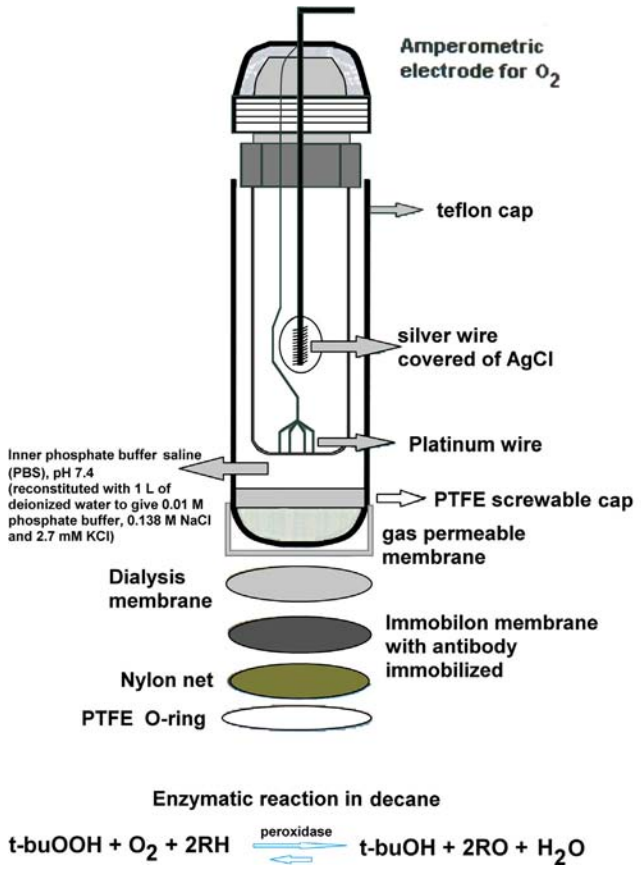

Fig. 1. Amperometric immunosensor used for pesticide determination in organic solvent using a Clark electrode as transducer and horseradish peroxidase as marker.

performed in the 75% (V/V) chloroform–hexane mixture. Of course, the higher the concentration of the antigen to be determined the lower the quantity of enzyme remaining fixed in the antibody complex on the Immobilon membrane, and therefore the less the enzymatic reaction was shifted to the right and so the less oxygen was consumed, that is, the greater the quantity of oxygen passing through the gas permeable membrane into the internal buffer solution. As a result the greater the quantity of oxygen reduced at the cathode the higher the intensity of the circulating current and the stronger the amperometric signal.

3.2. Antibody immobilization on Immobilon membrane

A commercial Immobilon membrane was used for antibody immobilization. It consisted of a positively charged nylon membrane with polyester reinforcement optimized for reliable and reproducible transfer, immobilization, hybridization, and subsequent reprobing. The Immobilon Ny+ membrane was cut into 1 cm^2 surface area disks and 50 μL of a 0.01 M antibody solution was directly deposited on the membrane surface. The membrane was then dried at room temperature for about 24 h and stored at 4 °C.

3.3. Atrazine pesticide carboxylation

To a stirred heterogeneous mixture of 1.01 g of atrazine (i.e. 5.01 mM) in 100 mL of absolute ethanol a solution of 0.574 g of 3-mercaptopropanoic acid was added (i.e. 5.40 mM) together with 0.714 g of 85% KOH (i.e. 10.8 mM) in 10 mL of absolute ethanol, under N_2. At reflux the mixture became homogeneous and soon a precipitate (KCl) began to form. Reflux was continued (4 h). The hot mixture was filtered, and the filtrate concentrated to a white solid. The solid was triturated with 25 mL of 5% $NaHCO_3$ and filtered [30].

3.4. Parathion carboxylation

A solution of 3.0 g of 4-nitrophenol (i.e. 21.6 mM) in 15 mL of acetonitrile was added dropwise to a stirred solution containing 4.59 g (i.e. 27.8 mM) of methyldichlorothiophosphate, 20 g of finely ground K_2CO_3 and 20 mL of acetonitrile. After stirring for 1 h at room temperature the mixture was filtered through celite and the solvent removed. The following format was applied to obtain the synthesis of the hapten: to a stirred solution of 500 mg of O-methyl-O-(4-nitrophenyl)phosphorochloridothioate (i.e. 1.87 mM) in 3 mL of MeOH cooled in an ice–water bath, a solution of 274 mg (i.e. 4.88 mM) of KOH and 229 mg of 4 aminobutyric acid (i.e. 2.22 mM) in 1.7 mL of MeOH was added dropwise. After stirring for 5 min, the reaction mixture was filtered and extracted with 1 M HCl–chloroform. The extract was dried over $MgSO_4$, and the solvent was evaporated [31].

3.5. Albumin–pesticide conjugation

The carboxylate pesticide was dissolved in 5 mL of dichloromethane to which 38 mg (i.e. 0.33 mM) of N-hydroxysuccinimide ester, 68 mg (i.e. 0.33 mM) of N,N-dicyclohexylcarbodiimide and 3.7 mg (i.e. 0.03 mM) of 4-dimethylaminopyridine were added. The mixture was stirred for 3 h and filtered, and the solvent removed. The format for coupling the carboxylate pesticide, for example the carboxylated atrazine, to the carrier protein to prepare hapten–BSA conjugates was as follows: 20 mg (i.e. 0.3×10^{-3} mM) of BSA were dissolved in 2 mL of borate buffer (0.2 M, pH 8.7) to which 0.4 mL of DMF was added. A solution of active ester (0.018 mM) in 0.1 mL of DMF was then added to the stirred protein solution, and stirring was continued for one day at 4 °C [31,32].

3.6. Albumin–pesticide biotinylation and peroxidase conjugation scheme

The avidin–biotin peroxidase technique is based on the use of a biotinylated antigen and of avidin horseradish peroxidase conjugate as part of the labelling system [33,34]. The technique exploits the high affinity binding of biotin to avidin. The BiotioTag kit is specially designed for the small scale labelling of antibodies using biotinamido hexanoic acid 3-sulfo-N-hydroxysuccinimide ester (BAC-SulfoNHS) as the labelling reagent. This reagent is particularly useful when mild reaction conditions are required for the biotinylation of sensitive biomolecules such as antibodies, enzymes and surface proteins. After the labelling reaction, the biotinylated protein is separated from the unreacted or hydrolyzed reagent by a fast gel-filtration step using G-50 microspin columns. BAC-SulfoNHS reacts with free amino groups of proteins to form stable amide bonds. In brief: 0.1 mL of 4.5×10^{-4} M pesticide-albumin solution in sodium phosphate buffer (pH 7.2; 0.1 M) was prepared. BAC-SulfoNHS solution 5 mg mL^{-1} was also prepared separately by dissolving 5 mg of biotinamido hexanoic acid 3-sulfo-N-hydroxysuccinimide ester in 30 μL DMSO (dimethylsulphoxide) and adding sodium phosphate buffer (pH 7.2; 0.1 M) for a final volume of 1 mL. 10 μL of BAC-SulfoNHS solution were immediately added to the pesticide-albumin solution with gentle stirring and the mixture incubated under stirring for 30 min at 2–8 °C. Then the resin contained in a micro-spin G-50 column was re-suspended in the column by vortexing and equilibrated with 0.2 mL of PBS, (pH 7.40; 0.01 M); this buffer was needed also for the elution of the labelled protein from the column. The biotinylation reaction mixture was applied to the top-center of the resin and the column was centrifuged for 5 min at 700g. The purified sample was then collected at the bottom of an Eppendorf test tube.

This step was repeated twice more and a total of three fractions were collected. As extravidin binds to biotin with a high affinity and specificity, an extravidin peroxidase solution (20 μL, 2.0 mg mL^{-1}), diluted 1:100 in PBS containing 1% BSA solution, was added to the collected fractions and incubated for 1 h at room temperature, then gently rinsed with PBS, (pH 7.4; 0.01 M).

3.7. Determination of pesticide by immunosensor. (Competitive format between pesticide biotin–avidin–peroxidase conjugated and non-conjugated, both free in n-hexane–chloroform 75% (V/V) mixture, for the respective antibody immobilized in membrane).

For this purpose, the Immobilon membrane, on which the antibody was immobilized, was fixed to the head of the amperometric Clark type electrode as described in Section 3.1. Before measurement, the immunosensor was dipped into a Tris–HCl buffer solution, (pH 8.0; 0.1 M), containing 0.05% Tween-20 by weight and 2.5% BSA by weight (bovine albumin was used to minimize non specific adsorption on the membrane). The pesticide to be determined was added in 5 mL of n-hexane–chloroform mixture 75% (V/V) contained in the measurement cell, together with a fixed supply of pesticide Biotin-Avidin-peroxidase conjugated, i.e. 20 μL (0.01 M solution) of conjugated pesticide in the same solvent mixture. The peroxidase-conjugated pesticide was allowed to compete for 30 min with the non-conjugated pesticide, both free in solution, in binding with the antibody immobilized on the Immobilon membrane. After washing with the same solvent mixture to remove all the unbound labelled pesticide, the specific substrate of the enzyme, i.e. 20 μL of tert-buthylhydroperoxide solution 1% (V/V) in decane was added to 5 mL of the selected organic solvent, i.e. decane, in which the immunosensor was dipped, under stirring. The measured signal (as nA) of the transducer correlated directly with the pesticide concentration to be measured. The higher the pesticide concentration to be measured, the lower the O_2 consumed in the enzymatic reaction, the higher the signal of the O_2 reduced at the Clark electrode (see the enzymatic reaction in decane illustrated in Fig. 1) [35–39]. The sequence for measuring the pesticide using the above format is schematized in Fig. 2. Using this format a calibration curve was constructed by plotting the current variation ΔI (nA) as a function of the log of pesticide concentration (as M) and employed to determine the unknown concentration of pesticide contained in the sample. In this way the original data of the immunosensor response to increasing antigen concentration, which always display logarithmic trends, take on a sufficiently linear trend. Moreover, the application of other, even more complex, methods, described in the literature to obtain the same result, for instance the so-called logit–log method, or equations with three-four parameters [40,41], do not provide better results than those described above. The enzymatic reaction response took about 15–20 min. A membrane already used in a previous test can be regenerated by suitably rinsing it in a solution of glycine 0.1 M and MgCl 2.5 M, at pH 2. This solution was apparently capable of splitting the antibody complex [12]. However, it was found that the immunosensor response when using a regenerated membrane may be up to 15% lower than in the previous measurement. This would of course affect the sensitivity and the repeatability of the measurement and thus the method's precision. Therefore all individual measurements reported in this paper were performed each time using a new (not regenerated) immunological membrane.

3.8. Pesticides measurement in sunflower oily samples and recovery tests

Immunosensors described in this paper were used first of all to measure respectively the triazinic (atrazine, simazine), organophosphate (i.e. parathion) and chlorurate (i.e. 2,4-D and 2,4,5-T) pesticides possibly present in commercial sunflower oil samples examined “as is” using the respective calibration curves. To this end, 0.5 mL of the oily sample were added in 4.5 mL of n-hexane–chloroform 75% (V/V) mixture and the measure was performed as described above in the paragraph 3.7, using the respective pesticide calibration curves to obtain the final concentration of pesticides. In addition, recovery tests were carried out on the oily samples spiked with known concentrations of each pesticide in order to obtain a final pesticide concentration of about 10^{-7} M. For this purpose 200 μL of the organic phase mixture solution of pesticide 10^{-5} M was dissolved in 4.5 mL of n-hexane–chloroform 75% (V/V) mixture, to which 0.5 mL of commercial sunflower oil samples were added. Also in this case the measurements were performed as described in paragraph 3.7 and using the respective calibration curves to obtain the concentrations of spiked solutions.

4. Results and discussion

As explained in the introduction of the present paper, the choice of the organic solvent in which to perform the competitive format involved taking multiple factors into consideration, and an ad hoc table, Table 2, shows how the n-hexane–chloroform 75% (V/V) mixture used in the present work represents a good compromise between all the various requirements set out in the “Introduction”. Indeed, both the checked analyte and the oily samples are completely soluble in this solvent mixture, as is also the marked antigen. The hydrophobicity value of this mixture ($\log P$ is about 2.5) is still satisfactory; lastly, the dielectric constant ($\xi = 2.92$) is neither too high nor too low. In other words the choice fell on an organic but non-alcoholic mixture, very similar to the one that had previously proved to be particularly suitable also when enzymatic OPEEs were being developed [42]. Lastly, other tests, performed in the previous research [8] and in similar conditions, evidenced that also the signal obtained from the final peroxidase enzymatic reaction was more satisfactory when performed in organic solvent, particularly in decane and using tert-butylhydroperoxide as substrate, than in aqueous solution, since, as reported in the literature [8,11,24,42], the enzymatic sensor's response may be better when operating in organic solvent (or solvent mixture) than in aqueous buffer (owing to the lower interference from hydrophilic ionic species, lower microbial contamination, enhanced thermostability, and so on). Furthermore, the difference in the behaviour of the catalase and peroxidase enzymatic reactions taking place in a non-polar hydrophobic solvent like decane (see Fig. 1), instead of in aqueous buffer, was extensively discussed in previous papers [8,35–37,42] and biosensor features were compared with those of biosensors working in more polar organic [43] or aqueous [44] solvents. With regard to the fabrication of the labelled pesticide required in the functioning of the immunosensors constructed, it should be noted that, in the case of atrazine, as described in the preceding Section 3.3, it had first to be carboxylated. The latter could thus be conjugated with the BSA (see Section 3.5). Lastly, as far as the enzymatic labeling is concerned, the classical method involving avidin and extravidin was used [34,40], as described in Section 3.6. Also in the case of the parathion it was necessary to follow the same reaction formats, as described in Sections 3.4 and 3.5, to obtain the enzyme labeled BSA hapten. Of course, the reactions to achieve carboxylation were slightly different [30,31] from those used to carboxylate the atrazine. Lastly, in the case of the 2,4-D and the 2,4,5-T, it was naturally not necessary to perform pesticide carboxylation, as their molecule already possesses a carboxyl group. It was therefore sufficient directly to perform the conjugation with BSA, and thus the customary enzymatic labeling with avidin and extravidin as illustrated in Sections 3.5 and 3.6. The optimization of other factors such as the ELISA type measurement format, or the concentration of the labelled antigen used free in solution, or

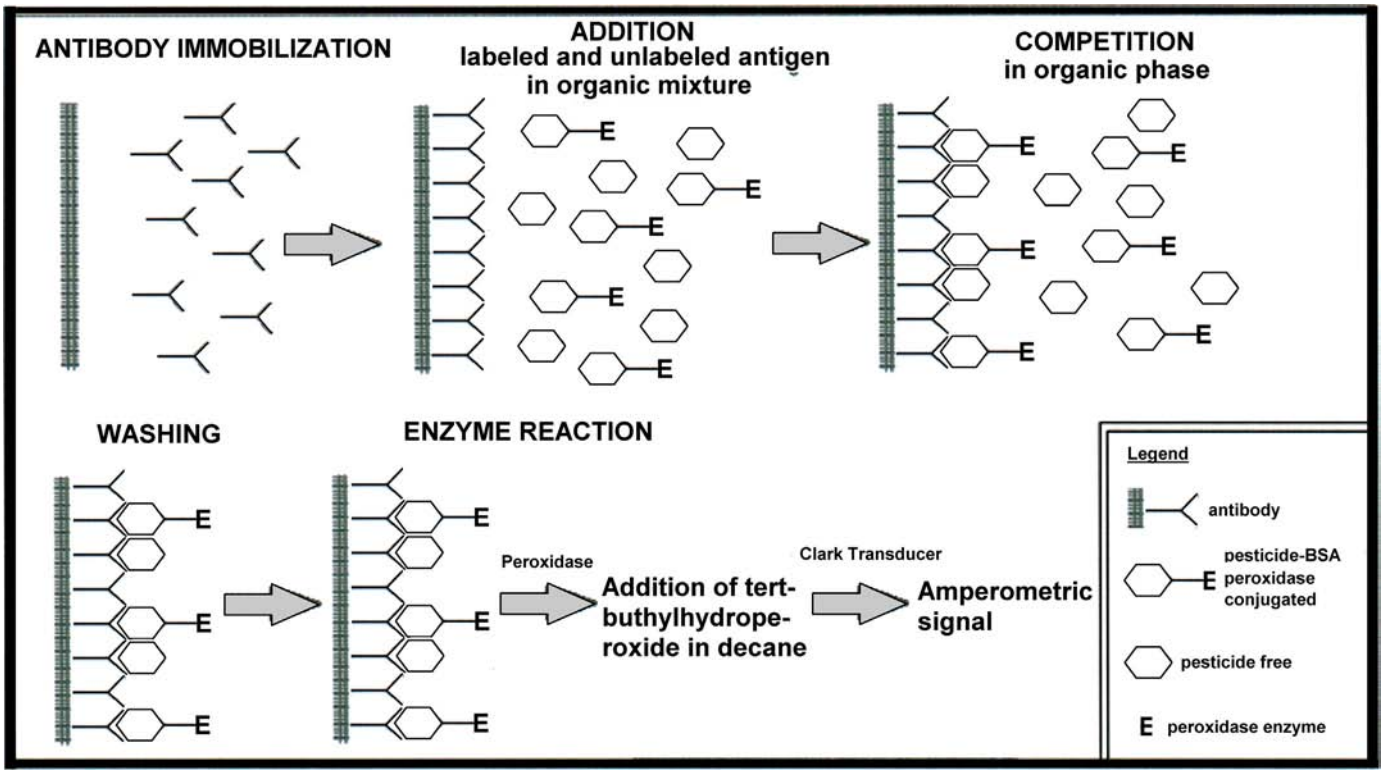

Fig. 2. Measurement: competitive format between the pesticide to be measured and a fixed concentration of peroxidase-pesticide conjugated, both free in organic phase solution, for the antibody immobilized in immobilon membrane.

Table 2
Comparison of solubility of sunflower oil samples, analyte and enzyme substrate in different solvents or solvent mixtures and values of some properties of these solvents. In this case the best compromise is found to be the n-hexane–chloroform 75% (V/V) mixture.

Solubility of (a) → (g) Properties (h) → (i)	Chloroform	Solution n-hexane–chloroform 50% (V/V) mixture	Solution n-hexane–chloroform 75% (V/V) mixture	Hexane
(a) Sunflowers oil (1 mL in 5 mL of solvent)	Opaque	Not completely clear	Clear	Clear
(b) Atrazine (10^{-5} M)	Clear ($S=52$ g L^{-1})	Clear	Clear	Suspension
(c) Simazine	Soluble ($S=0.9$ g L^{-1})	Clear	Clear	Low soluble ($S=3.1\times10^{-3}$ g L^{-1})
(d) 2,4-D (10^{-5} M)	Soluble ($S=32$ g L^{-1})	Clear	Clear	Low soluble ($S=30\times10^{-3}$ g L^{-1})
(e) Parathion (10^{-5} M)	Low soluble ($S=50\times10^{-1}$ g L^{-1})	Clear	Clear	Soluble ($S=20$ g L^{-1})
(f) 2,4,5-T (10^{-5} M)	Soluble ($S=32$ g L^{-1})	Clear	Clear	Low soluble ($S=30\times10^{-3}$ g L^{-1})
(g) Substrate: tert-butylhydroperoxide in decane (0.038 M)	Partially miscible	Miscible	Miscible	Miscible
(h) Log P (hydrofobicity)	2.0	2.6	2.5	3.5
(i) Relative dielectric constant	4.81	3.70	2.92	1.89

the choice of substrate and its concentration, used in the final enzymatic reaction, the competitive step time and so on, were optimized in previous investigations [8,12,23]. As far as transducer choice is concerned, the classical Clark type electrode was used as, in practice, the gas-permeable membrane of this probe protects the working and reference inner electrodes. This ensures that the system is more repeatable and the method more 'robust' [45]. The decision to use an amperometric transducer of this type, i.e. classical, and certainly not particularly modern, compared for instance with more recent transducers based on silica chips, or screen-printed devices and so on, was based precisely on the simplicity with which the classical Clark type gas diffusion amperometric electrode can operate also in organic solvent provided that its outside cap and gas permeable membrane are made for example of PTFE. While more modern transducers, such as those mentioned above, in order to be used in organic solvents, must be completely coated with hydrophobic resin, which, however wisely selected, are usually unlikely to remain fully intact when immersed in organic solvent, especially during the competition step which necessarily cannot be too short in an immunological method of the ELISA type.

Fig. 2 shows the scheme of the measurement used and the competitive format between the pesticide and a fixed concentration of peroxidase pesticide conjugated, both free in the organic phase mixture, for the antibody immobilized in the membrane. The new OPIE response as a function of increasing 2,4-D, 2,4,5-T, or parathion pesticide concentration, the corresponding calibration curves and the confidence intervals for three pesticide determinations, obtained using a semilogarithmic scale, are shown in Fig. 3, while the analytical data obtained for the respective calibration

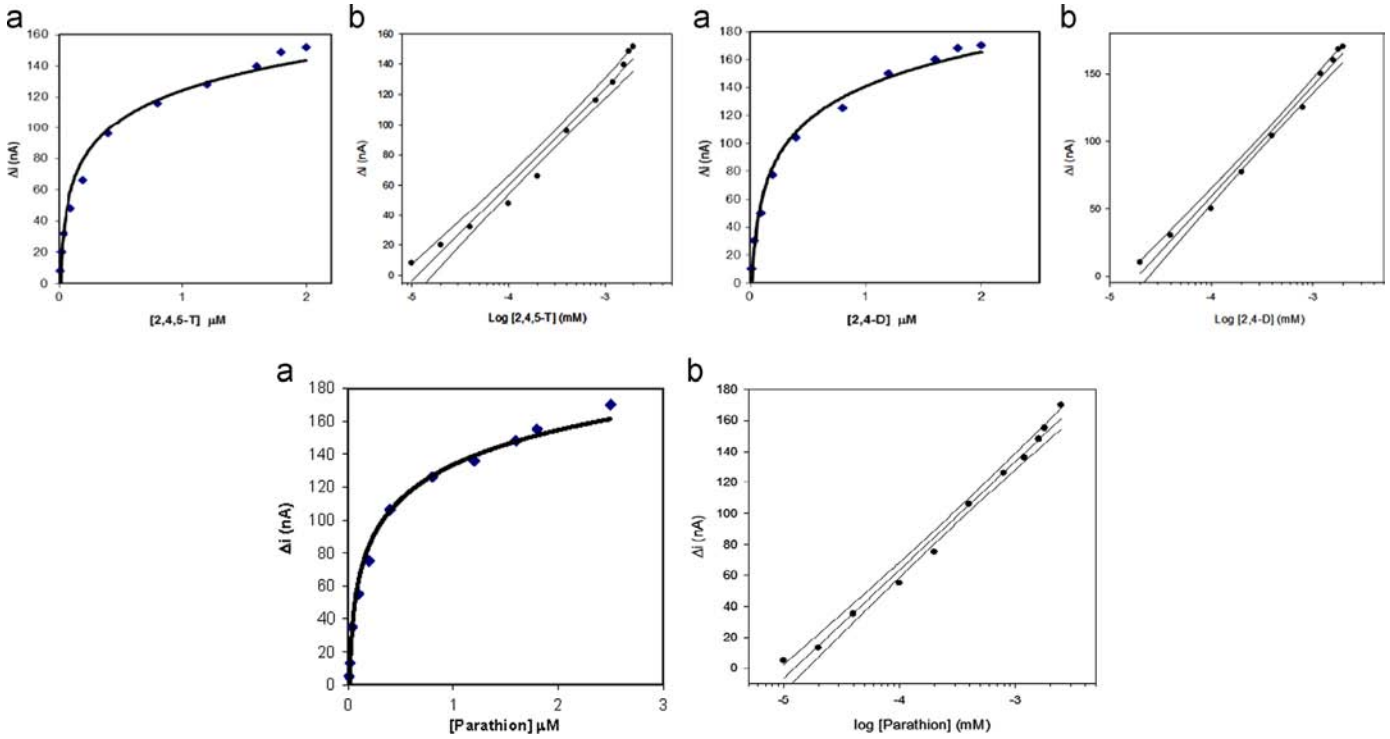

Fig. 3. (a) Trends in the response to 2,4,5–T, 2,4-D and parathion of respective OPIEs, as a function of growing pesticide concentration in sunflower oil. Competition in n-hexane–chloroform 75% (V/V); final enzymatic measurement in decane; and (b) corresponding calibration curve and confidence interval for the same pesticides determination, obtained using a semilogarithmic scale.

Table 3
Analytical data of new OPIEs obtained for calibration curves of different pesticides, for the measurement of 2,4-D, 2,4,5-T and parathion, in the presence of sunflower oil, using: in all cases n-hexane–chloroform mixture 75% (V/V) in the competitive step of the immunoassay, decane as solvent and tert-butylhydroperoxide in decane as substrate for the final enzymatic reaction, and Clark electrode as transducer.

Pesticide	2,4,5-T	2,4-D	Parathion
Regression equation ($y=\Delta i$ (nA), $x=M$)	$Y=64.3\ (\pm 1.4)\log X+124.2\ (\pm 10.1)$	$Y=98.1\ (\pm 1.9)\log X+468.6\ (\pm 14.9)$	$Y=70.0\ (\pm 1.8)\log X+343.2\ (\pm 10.2)$
Linear range (M)	1.0×10^{-8}–2.5×10^{-6}	1.2×10^{-8}–6.0×10^{-6}	1.0×10^{-8}–2.5×10^{-6}

curves in the analysis of these pesticides in sunflower oil are summarized in Table 3. Conversely, the same data for the analysis of atrazine and simazine are displayed in Table 4 and in Fig. 4. Significantly, the linear range is very similar in all cases (between about 10–20 nM and 2–4 μM, respectively) as well as the LOD (between about 8 and 12 nM, respectively). The highest calibration sensitivity was found to be that of the immunosensor for atrazine towards atrazine itself (≈ 104 nA/log *M*), i.e. almost double that of the same immunosensor to simazine. However, also in the case of the other immunosensors, the sensitivity towards the respective pesticides was always found to be good (lying between about 64 and 98 nA/log *M*). Generally speaking, the precision was of the same order and always acceptable (the pooled SD was found to lie between 6.6% and 7.5%, in any case). Lastly, Table 5 illustrates some selectivity data of the immunosensor devices developed with regard to different pesticides (i.e. triazinic, chlorurate and organophosphate), comparing the % response of each respective immunosensor to different pesticides. It may be observed that the selectivity among pesticides of the same class is only appreciable and poor for the cases in which the structural formula of the pesticide being tested is very similar to that of the specific antigen of the antibody used (for instance, this is the case for simazine versus atrazine, or of 2,4,5-T versus 2.4-D), but it is noteworthy that the antibody response to antigens belonging to different classes of pesticide, (i.e. paraoxon and carbaryl) is very low or even negligible. This means that each of the immunosensors constructed possesses a good selectivity versus other classes of pesticide that differ from the class of pesticides for which it was constructed. Lastly, it was decided to test the validity of new immunodevices also from the point of view of immunological methods. For this purpose, a comparison is made in Table 6 between the k_{aff} and IC_{50} values obtained for the different pesticides tested using the Langmuir curve [46,47] for the respective immunosensors. In Table 6 the k_{aff} values obtained by performing the competitive process in n-hexane–chloroform 75% (V/V) mixture are compared, for the reader's convenience, with those obtained in previous research [8] performing the same process but in 50% (V/V) mixture. It is noteworthy that the k_{aff} values all lie between about (3.3×10^6 and 5.6×10^6) M^{-1}; in the case of simazine, the value is slightly lower (about 2.4×10^6), which is only to be expected as it was determined using the immunosensor constructed for atrazine. It is only logical that, although having obtained a k_{aff} value again of the same order as atrazine, it should be slightly lower. Moreover, this is in agreement with the results reported in Table 4, observing different calibration sensitivity values. Lastly a series of tests were run on real samples

Table 4
Analytical data of atrazine OPIE, obtained for calibration curves of atrazine and simazine pesticides in the presence of sunflower oil, using: in all cases n-hexane–chloroform mixture 75% (V/V) in the competitive step of the immunoassay, decane as solvent and tert-butylhydroperoxide in decane as substrate for the final enzymatic reaction, and Clark electrode as transducer.

Table 8
Hill's coefficients in different tests for the analysis of all the pesticides to be determined in sunflower or olive oils. The first five tests were obtained using a competitive format, in the presence of sunflower seeds oil, in n-hexane–chloroform 75% (V/V), while the second five tests used a competitive format, in the presence of olive oil, in chloroform–n-hexane 50% (V/V); for both tests the final enzymatic measurements were carried out in decane and tert-butylhydroperoxide in decane was used as substrate.

Solvent mixture	Oily matrix	Pesticide tested	Hill's coefficient (n) using Eq. (1). In all cases RSD% $\leq$ 5.0	Hill's coefficient (x) using Eq. (2). In all cases RSD% $\leq$ 5.5
75% (V/V)	Sunflowers	Atrazine	Slope = 0.89	Slope = 1.96
75% (V/V)	Sunflowers	Simazine	Slope = 0.87	Slope = 1.68
75% (V/V)	Sunflowers	2,4-D	Slope = 0.91	Slope = 1.87
75% (V/V)	Sunflowers	2,4,5-T	Slope = 0.81	Slope = 1.83
75% (V/V)	Sunflowers	Parathion	Slope = 0.95	Slope = 1.88
50% (V/V)	Olive	Atrazine	Slope = 0.85	Slope = 2.35
50% (V/V)	Olive	Simazine	Slope = 0.91	Slope = 2.05
50% (V/V)	Olive	2,4-D	Slope = 0.86	Slope = 2.72
50% (V/V)	Olive	2,4,5-T	Slope = 0.75	Slope = 2.15
50% (V/V)	Olive	Parathion	Slope = 0.83	Slope = 2.02
Aqueous buffer	Olive	Atrazine	Slope = 0.60	Slope = 1.51

Table 9
Iwuoha–Smith function (I.S.F.): $1/\eta\xi$ (where η is the absolute viscosity of the solvent and ξ its dielectric constant). The higher the I.S.F. value, the greater the diffusion of the analyte from the solvent to the enzymatic membrane.

Final enzymatic reaction performed in:	η (mPa s)	ξ	I.S.F. value ($1/\eta\xi$)
Aqueous buffer solution	0.89	78.4	0.014
n-Hexane–chloroform 50% (V/V) solution	0.65	3.70	0.42
n-Hexane–chloroform 75% (V/V) solution	0.36	2.92	0.95
n-Hexane solution	0.29	2.02	1.70
Decane solution	0.92	2.00	0.54

method's detection limit, i.e. about $< 10^{-8}$ M. However, also several recovery tests were carried out on spiked sunflower oil samples. In this case the tests were performed alternatively using both atrazine and simazine, or else 2,4-D or 2,4,5-T, or the parathion pesticide. The same Table 7 illustrates how recoveries always lie between about 96.4% and 103%, and are thus quite satisfactory. Lastly, even though the results obtained in the present and previous researches [8,23] are a positive indication of the possibility of being able to work in organic solvents, a theoretical confirmation, as it were, was sought by applying well-known equations for this purpose reported in the literature. In particular, as far as the value of Hill's coefficient (n) is concerned, in its original acceptance [48]:

$$\text{Log } Y/(1-Y) = n \log [A]/K \quad (1)$$

(where, Y represents the ratio of the immunocomplex formed on the membrane and the total immobilized antibody; [A] the unlabeled pesticide concentration and K the dissociation constant); (n) theoretically indicates the number of binding sites per molecule, that is, in the present case, the number of binding pesticide molecules per molecule of antibody. As may be observed in Table 8, it is evident that, if the competition takes place in an n-hexane–chloroform 75% or 50% (V/V) mixture, the value found in all tests lies between 0.75 and 0.95, in practice generally close to one (i.e. the theoretical value), while, if the competition (as well as the final enzymatic measure) takes place in aqueous buffer solution (see the last line of Table 8), the coefficient is found to have a value of about 0.6. It thus seems that, when operating in organic solvent, this value comes closest to the theoretical behaviour of the Hill plot.

It is also quite apparent from Table 8 that the value found in the various tests with different pesticides is never an integer. This of course is due partly to experimental error, but also to the fact that, as reported in the literature, [48,49], the Hill coefficient (n) can evidence any type of deviation from normal saturation behaviour in which the value of the slope would theoretically tend towards one [50].

On the other hand, in view of literature reports [51] and applying Hill's equation in the form used by Adeyoju et al. [52]:

$$\log Y/(1-Y) = x \log (\Delta I/I_{50}) \quad (2)$$

(where, ΔI is the change in the current caused by the immunocomplex formed for a given concentration of pesticide and I_{50} is the current when the immunocomplex formed is 50%). It can be seen (Table 8) that the Hill coefficient (x), if the competition takes place in organic solvent mixture, is generally greater than 1 (equal to, very close to, or higher than 2), whereas, if the competition takes place in aqueous solution it amounts to about 1.5. This would mean [53,54] that the immunosensor is more sensitive if the competition between free antigen and enzyme labelled antigen takes place in the organic solvent mixture, in which the deviation from unit value is greater than in aqueous solvent [53]. However, none of this is surprising as the same thing had been observed in previous research [8,23,24]. Nevertheless, in the present case something that did not emerge in previous work was observed: Table 8 itself, for instance, also shows the Hill coefficient values found using Eqs. (1) and (2), both when the competition is performed in an n-hexane–chloroform mixture 75% (V/V) and in the 50% (V/V) mixture.

It is interesting to observe that, using Eq. (1), the (n) coefficients found working in the 75% mixture do not differ substantially from those found using the 50% (V/V) mixture, whereas in the case of Eq. (2), working with the 75% (V/V) mixture, the coefficient (x), although always greater than 1, is systematically lower than the corresponding value observed when the 50% (V/V) mixture is used. In the latter case, the coefficient is actually found to be always greater than 2. This is in good agreement with findings both in the case of the k_{aff} values (see Table 6), for which it is observed that, although of the same order as and indeed very similar to, those obtained using the 50% (V/V)

Table 10
Comparison of main analytical data among some organophosphate, or atrazine OPIEs and OPEEs, or classical inhibition enzyme electrodes.

Solvent	Sensor type	Pesticide	Linearity range (M)Ref.	Reference	LOD (M)	RSD (%)	Selectivity
Chloroform–hexane 50% (V/V)	OPIE	(a) Parathion	1.0×10^{-8}–2.5×10^{-6}	[23]	8.0×10^{-9}	7.0	Good selectivity to
		(b) Atrazine	1.2×10^{-8}–5.0×10^{-6}	[8]	8.0×10^{-9}	6.1	all other classes of pesticides
Chloroform–hexane 50% (V/V)	OPEE	(c) Malathion	3.0×10^{-8}–1.2×10^{-7}	[42]	1.4×10^{-8}	13.2	Poor selectivity to
		(d) Paraoxon	3.5×10^{-8}–2.0×10^{-7}	[42]	1.6×10^{-8}	7.5	all classes of pesticides
		(b) Atrazine	2.0×10^{-9}–2.0×10^{-4}	[43]	1.0×10^{-9}	8.0	
Water–glycine buffer 0.1 M; pH= 8	Classical inhibition	(c) Malathion	3.0×10^{-8}–3.0×10^{-7}	[44]	1.8×10^{-8}	2.8	Poor selectivity to
	enzyme electrode	(d) Paraoxon	1.8×10^{-8}–$1.8\times10^{-}$	[44]	7.0×10^{-9}	1.7	all classes of pesticides

mixture, they are always slightly higher than those found with the 75% (V/V) mixture. Furthermore, the same is observed even when comparing the values of the respective calibration sensitivities, displayed in the calibration straight line equations set out in Tables 3 and 4 of this paper and obtained when operating with the 75% (V/V) mixture, with the corresponding values reported in the previous research [8], obtained using the 50% (V/V) mixture of n-hexane–chloroform. All this, while also confirming the internal consistency of the various data obtained in the present work, would allow us to conclude that the properties of the solvent mixture actually play a non negligible role in the sensitivity of the immunosensor method and that, at least as far as organic solvents (and mixtures thereof) are concerned, a given increase in the polarity of the organic solvent (and thus of its dielectric constant) favours the sensitivity of the immunological method. Moreover, this appears to be in agreement with the results reported in the literature by several authors [5,6]. Of course this argument appears not to be valid on going from organic to aqueous solvents. In this case other factors probably outweigh the simple polarity of the solvent. Lastly, if the Iwuoha and Smith (I.S.F.) function [51,52] $1/\eta\xi$ is applied (where η is the absolute viscosity of the solvent and ξ is the dielectric constant) to estimating the solvent effect on the diffusion of the substrate to the enzyme, in the final enzymatic reaction, according the results reported in Table 9, the higher the value of the I.S.F. function (that is, the lower the value of the viscosity η and/or of the dielectric constant ξ of the solvent), the greater the diffusion of the analyte from the solvent to the enzymatic membrane [24,54]. However, the viscosity and dielectric constant values are very low for organic solvents, for instance, for n-hexane at room temperature ($\eta=0.29$ mPa s; $\xi=2.02$, respectively) when compared with the corresponding value for water ($\eta=0.89$ mPa s; $\xi=78.4$); therefore diffusion is more favourable in n-hexane and in all the other organic solvents considered than in water and therefore, on going from aqueous solvents to organic solvents, there is a considerable increase in the I.S.F. index which therefore enhances the diffusion of the substrate towards the enzyme. On the other hand, the use of decane, which also has a slightly lower I.S.F. index than the 75% (V/V) mixture, is certainly preferable in view of the very high solubility of tert-butylhydroperoxide in decane. Lastly, it is interesting to note that even if also the final enzymatic reaction is performed in an n-hexane–chloroform mixture the diffusion of the analyte from the solvent to the enzymatic membrane would be enhanced by performing the reaction in water and that moreover, going from the n-hexane–chloroform 50% (V/V) to the 75% (V/V) mixture, the I.S.F. index increases and therefore, as far as the final enzymatic reaction is concerned, the 75% (V/V) solvent would work better (as expected) than the 50% (V/V) mixture. It must nevertheless be pointed out that no absolute value can be attributed to the equations and mathematical relations discussed above. However, all authors agree that their 'indicative' value is undeniable [24,48–51,54]. Lastly, if the principal analytical data obtained in the present work are compared with those obtained using inhibition enzymatic sensors, as we investigated in the past [8,23,42,43,44] and not just involving triazinic pesticides but also organophosphates, observing Table 10 it may be concluded that (even if the linearity range and the calibration sensitivity [8,23] are generally found to be better in the case of the OPIEs), on the whole, important analytical data, such as the LOD are not much different in the case of the immunosensor or inhibition enzymatic biosensors. What is found to be substantially different is the selectivity (much better for the immunosensor than for the inhibition enzymatic biosensors).

5. Conclusions

Several immunosensors operating in an n-hexane–chloroform 75% (V/V) solvent mixture were developed for the purpose of determining traces of atrazine, simazine, parathion, 2,4-D and 2,4,5-T in sunflower oil. Good results were obtained using a Clark type transducer and performing not only the competitive assay but also the actual final enzymatic reaction in organic solvent instead of in aqueous solution, i.e. in practice carrying out the final electroenzymatic measurement by a classical OPEE, using as substrate for the peroxidase catalyzed enzymatic reaction a solution of tert-buthylhydroperoxide in decane. Therefore the experimental conditions were practically the same as used by us to determine atrazine traces in olive oil [8], although with the important difference of performing the test in n-hexane–chloroform 75% (V/V) mixture instead of in the 50% (V/V) mixture. The simplicity of the method, the relatively low cost and the possibility of using these new immunodevices to easily detect traces of different types of pesticide in such an important food oil as sunflower oil, means that the method is of great practical interest to the modern food industry. Fresh research is therefore already under way to extend the method also to other types of food seed oil, in which for instance the detection of several of the pesticides tested, such as 2,4-D and 2,4,5-T, is generally even much more frequent than in sunflower and olive oil.

Acknowledgements

Authors are indebted to Prof. S. Eremin (Moscov State University), who supplied antibodies of atrazine, 2,4-D and 2,4,5-T. This work was funded by "La Sapienza" University of Rome, "Ateneo and University Projects".

Voltammetric sensor

ABSTRACT

A novel efficient differential pulse voltammetric (DPV) method for determination gallic acid (GA) was developed by using an electrochemical sensor based on $[Cu_2tpmc](ClO_4)_4$ immobilized in PVC matrix and coated on graphite (CGE) or classy carbon rod (CGCE). The proposed method is based on the gallic acid oxidation process at formed $[Cu_2tpmcGA]^{3+}$ complex at the electrode surface. The complexation was explored by molecular modeling and DFT calculations. Voltammograms for both sensors, recorded in a HNO_3 as a supporting electrolyte at pH 2 and measured in 2.5×10^{-7} to 1.0×10^{-4} M of GA, resulted with two linear calibration curves (for higher and lower GA concentration range). The detection limit at CGE was 1.48×10^{-7} M, while at CGCE was 4.6×10^{-6} M. CGE was successfully applied for the determination of the antioxidant capacity based on GA equivalents for white, rosé and red wine samples.

1. Introduction

Gallic acid, a type of phenolic acid, is occurring in plants in the form of free acids, esters, catechin derivatives and hydrolysable tannins [1]. As one of the most biologically-active phenolic compounds of plant origin, gallic acid is commonly used in the pharmaceutical and food industry. Plant polyphenols are multifunctional and can be reducing agents, hydrogen donating antioxidants, singlet oxygen quenchers and in some cases metal chelating agents [2]. Gallic acid is used as a standard for determining the phenol content of various analytes by the Folin–Ciocalteau spectrophotometric method and the results are reported in gallic acid equivalents. The measurement of "total phenols" is a good indication of the level of antioxidants present in the sample [3].

The importance of the phenolic compounds has led to the development of various methods for their determination in various types of samples, including chemiluminescence [4] spectrophotometry [5] and capillary electrophoresis [6,7] as well as chromatography [8]. Electrochemical methods were also employed for this purpose. Gallic acid and other phenolic compounds were determined in wine samples and plant extracts at a glassy carbon electrode [9–13], at hanging mercury drop electrode [14,15] and at carbon paste electrode modified with nanotubes [16,17]. Electrodes with polyphenols at carbon-polyvinil chloride [18], polyepinephrine modified glassy carbon electrode [19] and a natural bentonite, modified with different quaternary ammonium cations [20] have also been described and successfully analytically applied. Cyclyc, diferential pulse and adsorptive stripping voltammetric techniques were mostly used in those reported works [21]. Recently, a photoelectrochemical sensor applied to sense gallic acid has been designed with polyaniline–reduced graphene oxide–titanium dioxide [22], while a voltammetric electronic tongue system (ET) made from an array of modified graphite-epoxy composites plus a gold microelectrode was used in qualitative and quantitative analysis of polyphenols found in wine [23].

Bearing in mind the most of past research in electrochemical determination of GA and other phenols, the main disadvantage of GCE was polymerization and adsorption of investigated and other species on the electrode itself. Therefore, GCE should be polished to provide new active surface before any electrochemical measurement. Inability for determination of more samples in a row with the same electrode without previous preparation and better electrode sensitivity were the reasons for the taken electrode modifications [16–20]. Polymer modified electrodes however, have many advantages such as improved electro catalysis, absence of

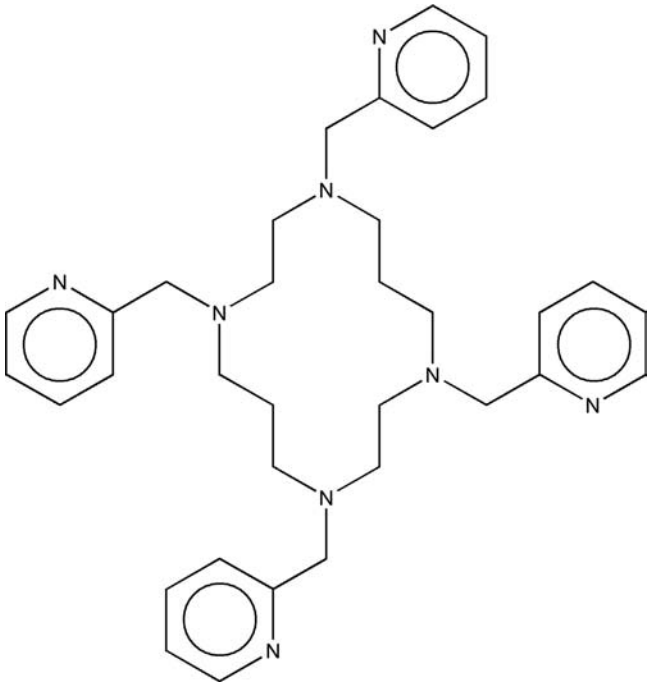
surface fouling and prevention of undesirable reactions competing kinetically with the desired electrode process. On the other hand, DPV technique has many advantages compared with conventionally used CV, e.g. a better sensitivity, selectivity and response [24].



It is important to mention biosensors as powerful specific analytical devices that also have been used for the detection of phenolic compounds. Biosensors based on several types of copper-containing enzymes which catalyze the oxidation of a wide range of phenolic compounds by utilizing molecular oxygen, such as tyrosinase [25,26] and laccase [27,28] were coupled to electrochemical or optical techniques for this purpose.

The general idea of this work was to examine application possibility of simple and efficient sensor for rapid differential pulse voltammetric determination of GA at low concentrations, based on previously synthesized $[Cu_2tpmc](ClO_4)_4$ complex immobilized in a PVC matrix. To the best of our knowledge, there is no report which relates to the application of complexation agent immobilized in PVC matrix as a modifier for graphite or classy carbon rod and the determination of gallic acid or antioxidant capacity of real samples. Similarly as in the case of copper containing enzymes, it could be very useful and interesting to examine the possibility of polyphenols oxidation in a presence of synthetic copper macrocyclic complex. Also, modification of the electrode surface should prevent polymerization on the electrode itself. Furthermore, the probability of formation of GA sensitive reversible $[Cu_2tpmcGA]^{3+}$ complex could be investigated by molecular modeling and Differential Function Theory (DFT) calculations. The determination of structural parameters obtained by molecular modeling is a powerful tool to add chemical and physical information to those obtained by other techniques.

2. Experimental

2.1. Chemical and reagents

The initial macrocyclic ligand *N,N′,N″,N‴*-tetrakis(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane (*tpmc*) (Scheme 1) and the next synthesized $[Cu_2tpmc](ClO_4)_4$ complex which was electroactive sensor material, were prepared by the procedure described in literature [29,30]. 1,4.8.11-tetraaza-cyclotetradecane 98%, as a starting compound, was used as received from Aldrich Chemical Company. The purity of synthesized ligand and complex were tested by elemental analyses performed by standard micromethods (Anal. Calcd. for ($C_{34}H_{44}N_8$) (%): C, 72.30; H, 7.85; N, 19.84. Found: C, 72.48; H, 7.89; N, 19.68). Poly(vinyl chloride), PVC, was used as Pevicon made by Fostatbolaget, Sweden. Dibutyl phthalate (DBP) and gallic acid (GA) were used as received from Fluka. Nitrite and sulfuric acid, potassium nitrate (all p.a.) and appropriate mixture of acetic acid and sodium hydroxide for acetate buffer, all purchased from Merck and Sigma-Aldrich, were used in supporting electrolyte investigations. Tetrahydrofuran (THF) was available from Merck and distilled before use and high purity water (Millipore, 18 MΩ cm resistivity) were used as solvents.

Scheme 1. *N,N′,N″,N‴*-tetrakis(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane (*tpmc*).

2.2. GA standard

Gallic acid (p.a) was used for preparation test solutions and as standard for measurement of the antioxidant capacity. The stock solution of gallic acid (1×10^{-3} M) was prepared in methanol (HPLC grade). Once prepared standard was protected from light with aluminum foil and kept in refrigerator. It was stable for at least 1 month. The working standards were prepared freshly from the stock solutions for each new measurement.

2.3. Electrode preparation

The PVC membrane contained 5 % (w/w) $[Cu_2tpmc](ClO_4)_4$, 38 % PVC and 57 % dibutyl phthalate. A total of 0.270 g of these reagents was mixed with 2.5 mL THF. A glassy carbon (GC) rod (ϕ 3 mm) (Sigardur-Sigri Electrographite, GmbH, Germany) was directly coated by dipping two times in the mixture. The same procedure was used for coating graphite rod (ϕ 6 mm) made by Sigma Aldrich. The formed coating bead on the GC and graphite was allowed to dry in air over night and then, electrode was kept in 10^{-4} M GA solution for about 24 h. This modified GC and graphite electrodes were finally used as voltammetric sensors for determination of GA. The voltammetric responses of the electrodes were measured in the series of standard GA solutions within the range of 2.5×10^{-7} to 1.0×10^{-4} M in a 10^{-2} M solution of HNO_3 as a supporting electrolyte.

2.4. Electrochemical measurements

Cyclic and differential pulse voltammetric measurements were recorded on a Metrohm 797 VA Computance instrument (Herisau, Switzerland). The triple-electrode system was consisted of a working electrode, GC or graphite electrode modified with PVC membrane with activated dinuclear Cu(II)/*tpmc* complex as sensor component, a reference Ag/AgCl, KCl (3 M) (Model 6.0728.010) and anauxiliary separate platinum rod electrode (Model 6.0340.000). The cyclic and the differential pulse voltammograms of standard GA solutions were recorded in the potential range from 0.0 to 1.0 V, using a scan rate of 100 mV/s (for CV) and 10 mV/s (for DPV). A modulation time was varied from 20 to 80 ms, and pulse amplitude was changed in range of 10 to 90 mV. The measurements were performed in unaerated solutions. The pH measurements were carried out using a Hanna Instruments pH-meter with a Hanna Instruments combined pH reference electrode. All of the experiments were done at room temperature (25 °C).

2.5. Sample preparation

Determination antioxidant capacity presented as mg/L of GA in white, rosé and red wine samples were done using an extremely

simple procedure involving the direct addition of a sample aliquot in the electrochemical cell without any sample pretreatment. The wine samples in triplicate, commercially available in Serbia were analyzed by the proposed voltammetric method used as a standard for determination of antioxidant capacity. An aliquot of 1 mL of wine was added to 9 mL of 10^{-2} M HNO_3 solution in electrolytic cell and homogenized with a magnetic stirrer before voltammetric measures described in previous section.

2.6. Spectrophotometric determination of total phenolic content

The total phenolic content (TP) of the wines was determined using the Folin–Ciocalteu micro method (F–C) as adapted for wine analysis [31]. Gallic acid was used to obtain the calibration curve and results were expressed as mg gallic acid equivalents per litre of wine (mg/L of GA). Red and rosé wine samples required dilution.

2.7. Computation details

Based on Cambridge Structural Database search published in our previous paper [32] starting structure for optimization copper complexes with *tpmc* ligand were chosen. Geometries of all structures were fully optimized with DFT (Differential Function Theory) method, according to procedure described before [32]. Reaction energies were calculated as a difference between ZPE corrected electronic energies of reaction products and reactants [33].

3. Results and discussion

For better understanding the general idea of this work, the attention should be drown to several issues regarding the construction and operation of working electrode. Polymer modified electrodes are often prepared by casting solution droplet containing dissolved polymer onto the surface and allowing the solvent to evaporate, by dip or spin coatings, or via electropolymerization in the presence of the dissolved monomer. The purpose of polymer film, from the chemical point of view is to immobilize sensor component, promote electron transfer and to prevent electrode surface contamination by other species presented in the sample [34]. This electrode was prepared by simple coating technique using PVC matrix as carrier of active component. The more conductive polymer nafion was not compatible with $[Cu_2tpmc](ClO_4)_4$ complex, so less conductive but more durable polymer matrix consisted from PVC and DBP as plasticizer was used instead. Membrane was coated on a GCE and graphite for comparison. $[Cu_2tpmc](ClO_4)_4$ complex immobilized in PVC matrix is activated by GA solution. The probable operation mechanism of the sensor involved complexation between dinuclear Cu(II)/tpmc complex immobilized in membrane and GA determined in the solution, and two step electrochemical oxidation of captured GA, probably in the complex ion $[Cu_2tpmcGA]^{3+}$.

A number of dinuclear metal(II) complexes with *tpmc* and additional bidentate ligand are known [35,36], but there is no evidence of dinuclear copper *tpmc* complex with GA. Assuming that reversible formation of this complex on the surface of the membrane is sensitive to different concentration of GA in solution, the next step was to investigate formation possibility of proposed dinuclear copper *tpmc* complex with GA.

3.1. Structure of $[Cu_2tpmcGA]^{3+}$ complex ion and DFT calculations

Based on the results of the extensive CSD search [32] and molecular modeling, the structure of optimized $[Cu_2tpmcGA]^{3+}$ complex ion was obtained (Fig. 1). Details are given in Supplementary materials. This structure is in agreement with other structures found in CSD [30,37–39].

Complex stability was examined by calculation of value for the energy of reaction (please see Supplementary material) which is 10.4 kcal/mol in favor of $[Cu_2tpmcGA]^{3+}$complex. The results of energy calculations clearly indicated that gallic acid would have high preference for binding to $[Cu_2tpmc]^{4+}$ complex in aqueous solution, and that the $[Cu_2tpmcGA]^{3+}$complex will be formed even in the case of very low concentration of gallic acid.

3.2. Electrochemical investigation

Electrochemical behavior of GA on the surface of bare and coated glassy carbon and graphite electrode was investigated by CV technique. Cyclic voltammograms of 10^{-4} M GA in HNO_3 solution as supporting electrolyte (pH about 2) at graphite (a) and glassy carbon electrode (b) (GE and GCE) are presented in Fig. 2. CV at modified both electrodes with activated $[Cu_2tpmc](ClO_4)_4$ complex immobilized in PVC matrix (CGE and CGCE) (Fig. 3) were recorded under the same conditions. Voltammograms exhibited two anodic oxidation peaks on both bare electrodes (both parts of Fig. 2). The first peak of GA appeared in the region of 0.5–0.6 V and it originated primarily from the oxidation of the ortho-hydroquinone group in the ring of the molecule. The second oxidation peak about 0.9 V was caused by the oxidation of the third –OH group of GA [40]. On the basis on analysis of the voltammograms it could be noticed that the peak current decreased in every next cycle due to absorption and polymerization of GA on the bare electrodes surfaces. On the other hand, coating of the membrane over the GCE and GE decreased a current density on the electrode, but prevent polymerization Fig. 3. In both coated electrodes cycling barely changed the shape of the cyclovoltammograms. The most significant changes were observed between the first and second cycles. Further cycling led to stabilization of the electrodes, which achieved steady state already after 2–3 cycles.

Differential pulse voltammetry (DPV) was selected for determination of GA as a suitable electroanalytical technique due to its low background currents and low detection limits. Working conditions were studied by variation of modulation time and modulation amplitude in order to provide lowest detection limit. After

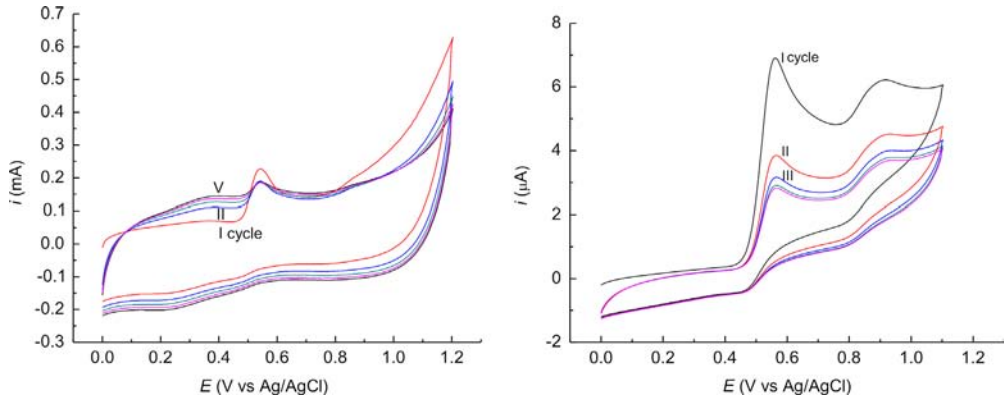

Fig. 2. Cyclic voltammetric profiles for the electrochemical oxidation of 10^{-4} M gallic acid in HNO_3 solution (pH about 2) at GCE (a) and CGCE (b); scan rate of 100 mV/s.

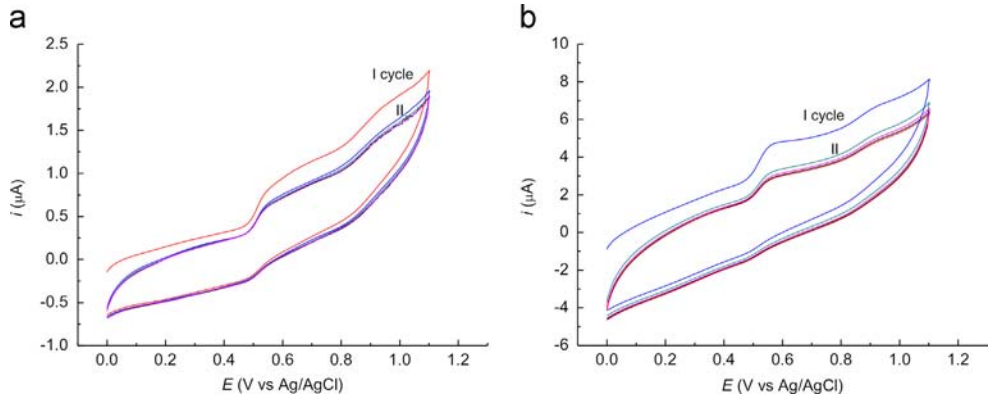

Fig. 3. Cyclic voltammetric profiles for the electrochemical oxidation of 10^{-4} M gallic acid in HNO_3 solution (pH about 2) at GE (a) and CGE (b); scan rate of 100 mV/s.

variation of modulation time from 20 to 80 ms, and changing pulse amplitude in range of 10 to 90 mV, the optimal modulation time of 40 ms and pulse amplitude of 50 mV were chosen taking into account the distortion and height of the peak of quantification, and also forego peak.

3.3. Selecting of supporting electrolyte and optimal pH

Bearing in mind that the sensory component, dinuclear Cu/*tpmc* complex could be blocked at higher pH values where the smaller OH^- ion could easily bridge two copper centers in macrocyclic complex and form $[Cu_2OH(tpmc)]^{3+}$ ion [30], the acidic environment was selected for GA determination.

Different supporting electrolytes were tested: HNO_3, H_2SO_4 and acetate buffer. All voltammetric features exhibited small shoulder before the first oxidation peak of GA (Fig. 4(a)) and the origin of forego peak is described to oxidation of obtained nitrate, sulfate or acetate bridged dinuclear copper complex itself, obtained by complexation of dinuclear copper/*tpmc* complex and anion from supporting electrolyte. These and similar structures were already reported in literature [30,37,38]. The highest and well pronounced signal for GA was recorded in H_2SO_4 and HNO_3, with better baseline and smaller forego peak in HNO_3. Therefore, the nitric acid was chosen for supporting electrolyte in following investigations. Differential pulse voltammograms in HNO_3 solution with different pH values were analyzed by construction of diagram of the influence of the pH on peak potential and peak current (Fig. 4(b)). The previous assumption that GA oxidation became difficult with an increase in pH was confirmed by those results. The value of pH=2 was chosen for further studies.

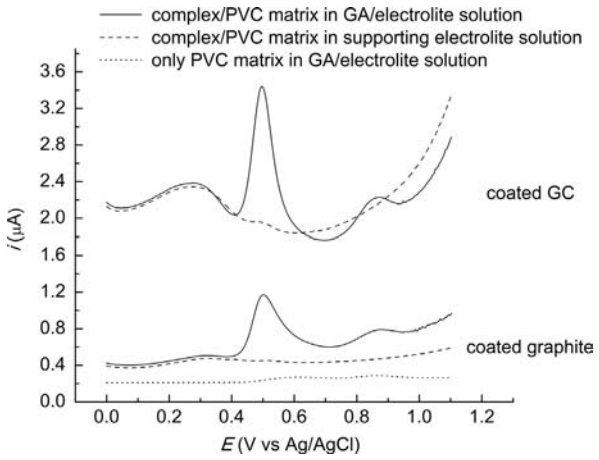

Fig. 4. Differential pulse voltammograms of 10^{-5} M GA in HNO_3, H_2SO_4 and acetate buffer as supporting electrolyte at CGE (a); the influence of the pH on peak potential and peak current obtained from differential pulse voltammograms of 10^{-6} M GA in aqueous solution of different concentrations of HNO_3 (b).

3.4. DPV study with different electrodes

In order to investigate impact of PVC matrix and different electrode material on voltammetric response, DPV was recorded at coated graphite and GC with and without complex in the polymer matrix (Fig. 5). It was obvious that supporting electrolyte in absence of GA gave a good baseline and electrode coated with PVC matrix without sensory component - $[Cu_2tpmc](ClO_4)_4$ respond barely even to large amounts of GA in the standard

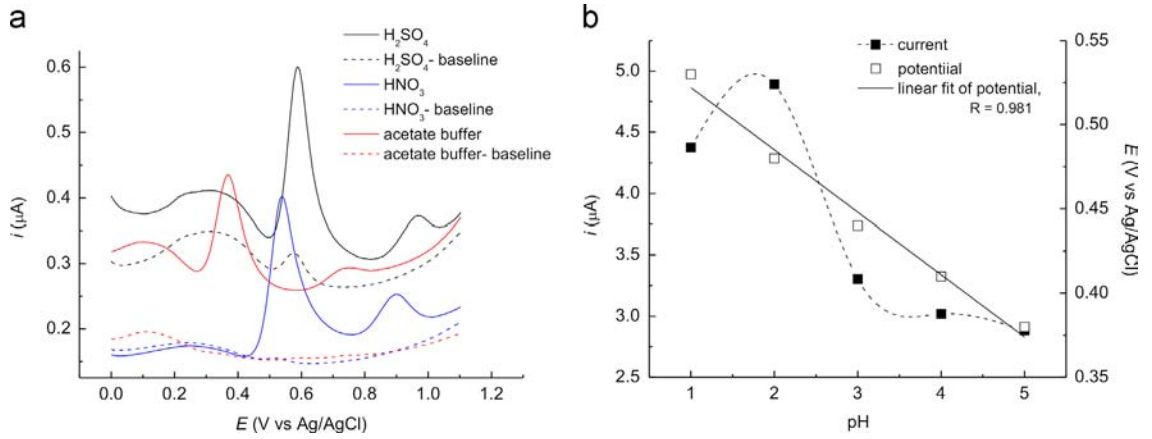

Fig. 5. Comparison of voltammetric responses provided by GC and graphite electrodes modified with/without copper complex: $[Cu_2tpmc](ClO_4)_4$ complex incorporated in polymer matrix, recorded in 10^{-4} M GA and supporting electrolyte (solid line); $[Cu_2tpmc](ClO_4)_4$ complex incorporated in polymer matrix, recorded only in a HNO_3 as a supporting electrolyte, pH about 2 (dash line); polymer matrix without $[Cu_2tpmc](ClO_4)_4$ complex, recorded in 10^{-4} M GA (doth line); scan rate, 10 mV/s.

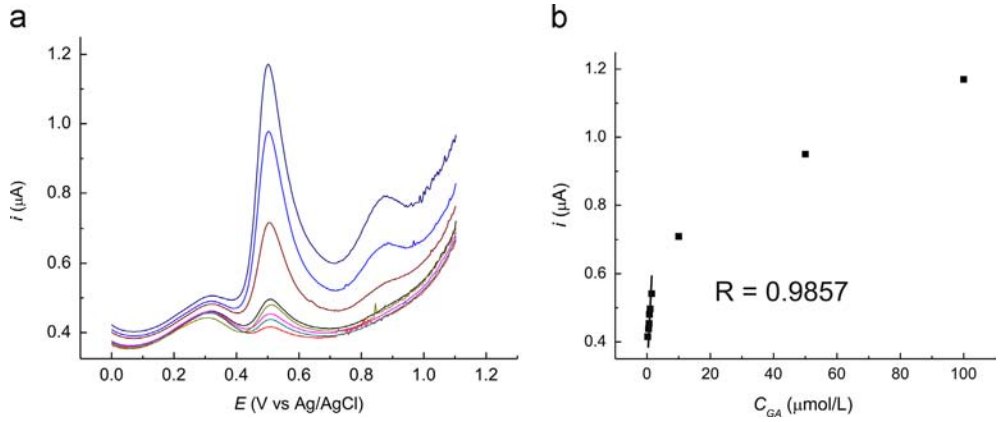

Fig. 6. DPV of CGE with GA added in concentration of 2.5×10^{-7}–1×10^{-4} M, pH=2 (a); calibration curves for GA (b).

solution. In such way, DPV response of the CGE and also CGCE came only from the dinuclear copper/*tpmc* complex immobilized in a polymer matrix. The peaks were now well-defined (Fig. 5). The origin of forego peak as a consequence of oxidation of obtained nitrate bridged dinuclear copper complex itself, made by complexation of $[Cu_2tpmc](ClO_4)_4$ and nitrate from supporting electrolyte, is confirmed due to absence of this peak in voltammogram of CGE coated only with PVC matrix. The first oxidation peak of GA on both electrodes was recorded on 0.50 V, while second less expressive oxidation peak appeared on 0.87, but it was lost for GA concentrations smaller than 10^{-6} M for CGE and 10^{-5} M for CGCE. Although CGCE exhibited higher peak current, it was found that faster loses its response to GA concentrations (limit was about 10^{-6} M), while with CGE it was possible to detect concentrations of 10^{-7} M order of magnitude. Larger surface and porosity of the graphite electrode could be a possible reason for that behavior.

3.5. Construction of the calibration curve

Differential pulse voltammograms of various concentrations of GA from 2.5×10^{-7} to 1.0×10^{-4} M recorded on more sensitive CGE (compared with CGCE) were shown in Fig. 6(a). The first anodic peak of GA was chosen for quantification of GA due to its reversibility, very good reproducibility and linear dependence on current density of this peak vs. the concentration of gallic acid. The calibration curve was constructed by plotting the current density of first anodic peak vs. the concentration of GA. There were two resulting calibration linear plots (Fig. 6(b)). The higher concentration range is described by the regression equation: *Ip* (10^{-7} A)= $5.06\times10^{4}\times C_{GA}+6.8209$, where *Ip* is the current density of first anodic peak and C_{GA} is the concentration of gallic acid expressed in mol/L. The lower concentration range is expressed by the relationship: *Ip* (10^{-7} A)=$3.895\times C_{GA}+1.14\times10^{6}$ (R=0.9857), and with detection limit (LOD) of GA determination of 1.48×10^{-7} M. Detection limit was estimated from three times the standard deviation. The limiting point, 2.63×10^{-6} M vs. 6.9310^{-7} A, obtained by extrapolating of the linear plots, determined which of these two mentioned equations should be used. Standard deviations of 0.025 μA in the oxidation peak current and 0.006 V in the peak potential for three repeated detections of GA concentration of 5×10^{-5} M as well as the decrease in peak current to 23.5% of the initial current after three months, suggests good reproducibility and stability of results when the modified electrode was used.

Two regression equations were obtained from voltammograms for CGCE: *Ip* (μA)=$4.4\times10^{3}\times C_{GA}+0.93$ for higher concentration range, and *Ip* (μA)=$2.4\times10^{5}\times C_{GA}+0.03$ for lower concentration range, with LOD of 4.6×10^{-6} M of GA.

For comparative purposes, relevant characteristics of some of the modified electrodes [16–19] were listed with data of the proposed electrode for GA determination (Table 1). The proposed CGE is comparable in LOD and in linear range with reported ones. In some cases it had better characteristics.

Table 1
Some response characteristics of different modified electrodes for GA determination.

Electrode	Technique	Supporting electrolytes and working pH	Linear range	Detection limit (LOD)	Ref.
CPE modified with carbon nanotubes	DPV	Phosphate buffer solution, pH 2.5	0.5–15 μM	0.3 μM	[16]
CPE modified with multi-walled carbon nanotubes	DPV	Britton–Robinson buffer solution, pH 2	1.00–6.25 μM,	0.27 nM	[17]
Carbon–poly(vinyl chloride) composite electrode	DPV	Phosphate buffer solutions, pH 5.0	29 μg/L–0.45 mg/L	0.16 μg/L	[18]
Polyepinephrine/GCE	AdSV	Phosphate buffer solution, pH 1.88	1.0–20.0 μM	0.663 μM	[19]
Graphite modified with $[Cu_2tpmc](ClO_4)_4$ immobilized in PVC matrix	DPV	Nitric acid, pH 2	0.25–1 μM 5 μM–0.1 mM	0.148 μM	Proposed electrode

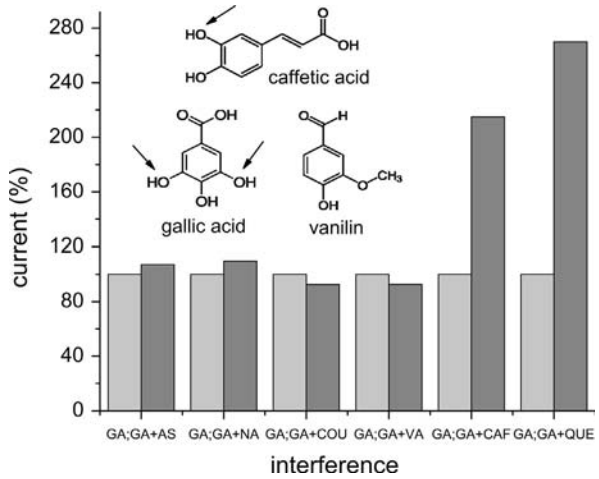

Fig. 7. Histogram of influence of the interfering compounds on current obtained for determination of GA under optimized experimental conditions. Some molecule structures are with and without electroactive OH^- groups.

3.6. Interference study

The potential interfering agents for electrochemical determination of gallic acid are phenolic acids, flavonoids and other organic molecules in minor amounts such as ascorbic acid. The studied compounds (ascorbic acid—AS, naringin—NA, *p*-coumaric acid—COU, vanillin—VA, caffetic acid—CAF and quercetin—QUE) were chosen due to differences and complexity in structure. The influence of possible interfering compound was examined by comparing peak current produced by GA and peak current of GA and studied compound mixture (1:1, concentrations of 10^{-5} M). Higher interferences were obtained in presence of caffeic acid and quercetin while the other substances (vanillin, naringin, ascorbic and *p*-coumaric acid) produced smaller change of the signal (Fig. 7). According to the literature [3,10], the first anodic peak could be ascribed to the oxidation of different polyphenolic compounds that had a structure with orthodiphenol (catechol) groups at B-ring, like catechin, gallic, caffeic, quercetin and some others.

3.7. Determination of the antioxidant capacity of the wine samples

In the present study, the estimation of the antioxidant capacity of the wine samples was based of gallic acid current oxidation using DPV technique. As the first anodic peak could be ascribed to the oxidation of different polyphenolic compounds present in wines that had a structure with orthodiphenol groups at B-ring, thus, these compounds were the major contributors to the antioxidant capacity in wine determined by electrochemical method. Five different wine samples were analyzed with proposed CGE. The results of antioxidant properties of the wine samples were presented as mg/L of GA calculated from calibration curve and presented in Table 2. The same wine samples were determined at a bare GCE by CV technique. The surface of GC was refreshed before each experiment because surface polymerization, while the same CGE electrode was used for all determinations. The total phenols were determined by Folin–Ciocalteu method and results were not comparable with those obtained by the electrochemical methods. The reason is detection of all phenols by spectrophotometric method (not only polyphenols with orthodiphenol groups at B-ring). Furthermore, F–C reagent may react with many non-phenolic organic substances (sugars, proteins, ascorbic acid, etc.) and inorganic substances (Fe(II), metabisulfite, sodium phosphite, etc.), giving an overestimation of the phenolic content [41].

Table 2
The antioxidant capacity of wine samples determined by electrochemical and spectrophotometric methods.

Samples	DPV on CGE (mg/L of GA)	CV on GCE (mg/L of GA)	F–C (mg/L of GA)
White wine	406.58	437.38	748.34
Rosé wine	406.58	445.20	671.75
Red wine 1	420.17	448.37	534.19
Red wine 2	365.76	368.99	578.88
Red wine 3	581.81	611.41	701.42

4. Conclusion

The application of complexation agent $[Cu_2tpmc](ClO_4)_4$ immobilized in PVC matrix as a modifier for coating graphite or classy carbon rod and the determination of gallic acid and antioxidative capacity of wine samples was presented in this paper. Electrode with synthesized macrocyclic complex showed the same effect on oxidation of polyphenols as a biosensors based on natural macrocycles in copper-containing enzymes. Electroactive $[Cu_2tpmcGA]^{3+}$ was used as a sensor material for determination of low concentrations of GA at simple coated CGE and CGCE by sensitive DPV technique. The practical usefulness of the CGE was demonstrated by the estimation of the antioxidant capacity, expressed as gallic acid equivalents, in white, rosé and red wine samples, using an extremely simple procedure without any sample pretreatment.

The proposed electrode had advantages such as simple preparation, good reproducibility and electrochemical surface stability. Its detection limit is quite comparable with reported modified and unmodified electrodes for determination of GA. CGE was chosen for real sample analysis due to better voltammetric response and lower LOD, which is 1.48×10^{-7} M. Still, we rightly assumed that application of more conductive polymer matrix coated on transducer surface could provide lower LOD of the electrode. Hence, the next task would be to find suitable and compatible CP for better adopting

of complexation agent $[Cu_2tpmc](ClO_4)_4$ and to provide electrode which might have better analytical characteristics.

In-situ sensing

ABSTRACT

A low-cost optical sensor for monitoring the aquatic environment is presented, with the construction and design described in detail. The autonomous optical sensor is devised to be environmentally robust, easily deployable and simple to operate. It consists of a multi-wavelength light source with two photodiode detectors capable of measuring the transmission and side-scattering of the light in the detector head. This enables the sensor to give qualitative data on the changes in the optical opacity of the water. Laboratory tests to confirm colour and turbidity-related responses are described and the results given. The autonomous sensor underwent field deployments in an estuarine environment, and the results presented here show the sensors capacity to detect changes in opacity and colour relating to potential pollution events. The application of this low-cost optical sensor is in the area of environmental pollution alerts to support a water monitoring programme, where multiple such sensors could be deployed as part of a network.

1. Introduction

The monitoring of European water bodies has historically been limited but there has been a step change owing to the adoption of the Water Framework Directive (WFD) in Europe [1]. In response to this as well as other legislations including the Bathing Water Directive [2], the Birds Directive [3] and the Habitats Directive [4], the monitoring of water within Europe will increase in coming years. Additionally the pressures of climate change, which will lead to resource scarcity and water quality changes, give a strong scientific and economic argument for the expansion of aquatic monitoring. All of these factors will drive the increase in environmental monitoring by regulatory agencies, although it should be noted that the high cost associated with physical sample collection and the transportation to, and subsequent analyses in, laboratories is one of the reasons for the low level of monitoring over the years [5]. The precision and accuracy of these techniques, along with their adherence to standard techniques for legal and regulatory procedures has maintained the need for these methodologies. The initiative for more monitoring has not necessarily been matched by an increase in funding for these activities, which means that new technology should be employed to meet the desired increase in spatial and temporal monitoring.

The use of *in-situ* sensors, capable of continuously monitoring chemical and physical parameters, has been increasing in the recent past and offers a potential solution to some of the challenges outlined above. They can also provide real-time information and contribute to a better representation of long-term trends in aquatic environments [6]. It is now technologically conceivable to envision a network of sensors being deployed at key spatial locations, capable of autonomous operation in the field for a year or more and providing real-time alerts for key events [7]. The area of wireless networked sensors is fast becoming one of the most dynamic and important areas of multi-disciplinary research [8,9]. The communications and data gathering abilities of the network need to be of a high quality and suit the tasks at hand. The data from remote continuous monitoring of the environment can be, and is already being, used for a variety of applications, in addition to environmental protection [10,11]. Despite the promise of such a system many challenges remain using currently available technology, including a limitation in the analytes measurable, interferences, bio-fouling issues, expense, power requirements and the need for frequent calibrations. In essence the major issue for environmental sensing remains, in some instances, being able to accurately measure and detect environmental pollutants in laboratory conditions, but struggling to reproduce these results in the field with continuous *in-situ* monitors [12].

If these networks of sensors are to become not only a reality but commonplace it is necessary to produce reliable, inexpensive *in-situ* sensors. This means costs need to be considerably reduced

but also, and as importantly, retain and increase the accuracy of the measurements. Some of the recent developments in the this field have included *in-situ* fluorometers for the measurement of phytoplankton [13], chemical sensors for pH measurements [14], and the use of optical refractive index measurements for generic water event detection [15]. While some of these sensors are less precise than laboratory techniques or some existing continuous monitoring sensors they can produce extremely useful data. A barrier to deployment of successful monitoring networks up to now has been cost and availability of analyte specific sensors. The sensor described here proposes to address the cost issue – enabling the development of a low-cost network to provide valuable qualitative information on water quality that can lead to more informed decisions. These devices can be used to inform grab sampling and lead to the desired quantitative analytical approaches at appropriate times and locations. They can give indications of pollution, as early warning systems, or observe trends in environmental conditions.

This paper presents a low-cost, robust and easily deployable sensor for the monitoring of aquatic environments. This multi-wavelength optical sensor has been designed so that it can be operated on an autonomous basis or in a network of sensors and thus is equipped with telecommunications. The sensor is capable of measuring the transmission of light emitted by five separate LED light sources through water, while simultaneously measuring the side-scattering of the light measured at right angles to the transmission path. The optical colorimetric sensor (OCS) is devised to give data on bulk water property changes, particularly opacity and colour changes.

The OCS is not a turbidimeter or a chlorophyll sensor, though it can clearly provide valuable data relating to turbidity events and primary productivity events. The analytical objectives of the OCS are the determination of qualitative variations in water quality based on opacity or colour changes due to pollution events or temporal environmental events. By qualitative it is meant that the optical responses observed using the system are related to opacity changes in the aquatic environment. This qualitative response is confirmed by co-deploying and correlating the trends of the OCS with a sensor sonde measuring multiple environmental parameters over the test period. The target water quality parameters are water opacity based on transmission measurements of different coloured LEDs. The advantages over existing devices include its autonomous nature, low cost and environmental robustness that could lead to multi-sensor deployments for a sensor network. The device can be used to detect pollution events that result in an increase in suspended solids, algal blooms or other environmental events.

Commercial water sensing equipment, in the form of either multi-parameter sondes or single parameter sensors, dominate the environmental sensing market. The cost of these sensors can be prohibitive and when anti-fouling measures and logging systems are taken into the account purchase costs can be further elevated. All sensors require cleaning and maintenance at regular intervals by well trained personnel, which makes the cost of ownership sometimes prohibitively expensive – particularly during the summer. The OCS described here would reduce the purchase and maintenance costs of the sensor (including anti-fouling and logging systems). This makes it possible to build a sensor network over a large spatial area of an interesting aquatic system with a high spatial resolution thereby allowing for the creation of a real-time pollution alert system.

This paper is structured as follows; an introduction of the topic of low-cost optical monitoring in a marine environment is given in this section. The Experimental section gives the details of all the materials and methods used in the construction and testing of the sensor in the laboratory and in field deployments. The Results and discussion section analyses and presents the data gathered in the laboratory and in the environment and discusses the outcomes. The Conclusions section reviews the paper, highlighting the ability of the low-cost sensor to detect shifts in water colour and opacity in both the laboratory tests and field trials.

2. Experimental

This section describes how the optical sensor is designed and built, as well as outlining all key elements of the sensor. Sections 2.3 and 2.4 delineate the tests carried out both in the laboratory to characterise the sensor and the field trials undertaken to observe the performance under real-life conditions.

2.1. Materials

The photodiodes were manufactured by Texas Instruments (OPT101P) and were purchased from Farnell electronics (www.farnell.com), as was the Raspberry Pi (Model B) and its accessories. The LEDs were obtained from Radionics via RS-online (www.rs-online.com) and were manufactured by Avago Technologies (Amber; HLMP-3850), Kodenshi (IR; OPE5685) and Knightbright (Red; L-7113EC, Blue; L-53MBC and Green; L-7113VGCK). The Wixel module was from Pololu Robotics and Electronics and was purchased via Cool Components (www.coolcomponents.co.uk).

The PVC-U tubing for the body of the sensor, the stainless steel parts and the copper plating were acquired from local hardware and marine boating suppliers. The clamps and O-rings were purchased from Alfa Laval (http://www.alfalaval.com/). The enclosures for the electronics were obtained through Radionics Ireland and Dexgreen (http://www.dexgreen.com/).

The food dyes used were E133 Brilliant Blue FCF (blue), E124 Ponceau 4R (red), E102 Tartrazine and E142 Green S (green) and E110 Sunset Yellow (yellow), from Goodall's of Ireland. The two turbidity standards were a Formazin solution (246142) from HACH and a Styrenedivinylbenzene copolymer solution (6073G) from YSI (a Xylem brand).

2.2. Design and construction

The complete sensor system, illustrated in Fig. 1, has the following features: an LED array light source, two photodiode detectors (90° and 0° to the light source), a low cost (Table 1), a robust re-deployable design, flexible electronic control, in-built antifouling measures, optional GSM communications, an optional integrated temperature sensor and a custom built data logger. Table 1 gives a breakdown of the components cost at the time of manufacture.

2.2.1. Sensor body

The OCS is constructed using low cost, robust materials (stainless steel 308 and 304, PVC-U, copper, rubber and IP 67 and IP 68 rated enclosures). It consists of a stainless steel sensor head protected by copper, a foam-filled floatation chamber, double sealed electronics housing, stainless steel mooring point and ballast chain.

Fig. 1(a) gives an exploded view of the device with the numbering corresponding to Table 2 which lists all of the labelled components and materials. Fig. 1(b) presents a schematic of the sensor head showing the configuration of the LED array, along with relative locations of photodiodes. The OCS can be moored in various ways, including standalone (floating), buoy integrated or pier attached. The OCS is positively buoyant; with the ballast chain attached and connected as a single point mooring, it floats at the surface. In this configuration the sensing elements are submerged to a depth of 1 m, with the electronic and communication housing above the surface.

2.2.2. Sensor head design and Optics

The sensor head is the part of the sensor which houses the optics and the detection abilities of the sensor. As the sensor is

designed to be deployed in marine and other aquatic environments, biofilms will most likely form on all components [16]; to minimise this effect the sensor head is constructed of copper which has strong anti-fouling properties [17]. This includes a copper shroud around the light source and detectors and electroplating any exposed stainless steel housing with copper.

The schematic in Fig. 1(b) shows the sensor head consisting of a light source containing five LEDs of differing wavelengths: IR (λ_{PEAK}=850 nm, FWHM=45 nm), red (λ_{PEAK}=627 nm, FWHM=45 nm), amber (λ_{PEAK}=583 nm, FWHM=36 nm), green (λ_{PEAK}=515 nm, FWHM=30 nm) and blue (λ_{PEAK}=430 nm, FWHM=60 nm). The schematic also illustrates the configuration of the various LEDs within the array. Two silicon photodiode detectors (PDs), having a >20% efficiency spectral response ranging from 410 to 1080 nm, are used to detect the light. These photodiodes are placed at 90° and 0° to the optical path of the light emitted from the LEDs. The pathlength between the LED array and the 0° PD is approximately 6 cm, with the 90° PD placed 3 cm from the optical path at right angles to it midway along the path. This enables the transmission of light from multiple optical wavelengths through the water and the side-scattering of the light from the water (and from particulate matter in the water) to be measured simultaneously. The LEDs and the photodiodes are held in place by an epoxy resin and left exposed to the environment with no additional interfaces to the water; they are then encased within a piece of T-shaped copper tubing to prevent non-scattered light from entering the 90° PD. These specific LEDs have been chosen as they are readily and inexpensively available, while providing good coverage across the majority of the visible spectrum.

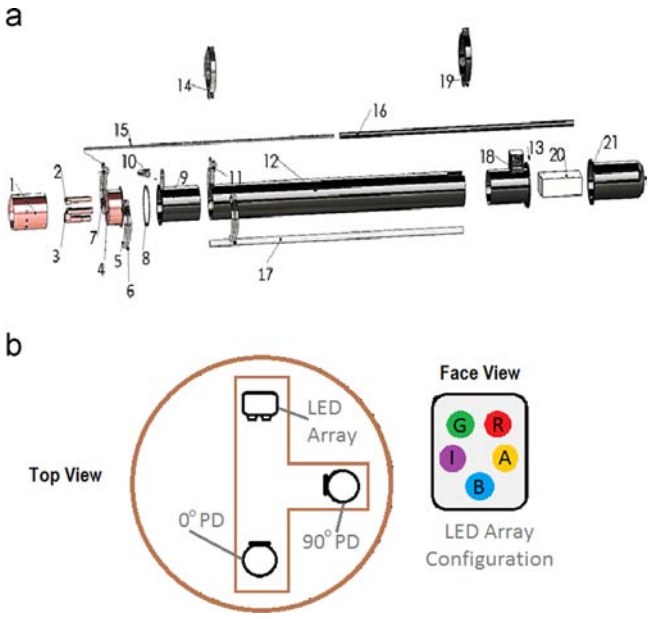

Fig. 1. (a) An exploded view of the mechanical components making up the sensor, with the numbering relating to Table 2. (b) Schematic of the sensor head showing the orientation of the LED array and photodiodes relative to each other and the configuration of the five LEDs (green [G], red [R], amber [A], blue [B] and IR [I]) within the array. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Table 1
System component costs at time of manufacture (not including R&D costs).

Components	Approximate cost (€)
Mechanical	150
Opto-electronics	250
Logger box	150
Mooring	<100
Total	**<650**

2.2.3. Electronics

The OCS system is controlled by a Texas Instruments CC2511F32 micro-controller programmed in a variant of C. This is achieved using a Wixel, a general-purpose programmable module, mounted on a board with additional inputs and outputs. In the current configuration the sensor is programmed to read the signals from the two photodiodes for each LED and the ambient light level (*i.e.* the signal level for the photodiodes with all LEDs off) every 10 s. Light levels are recorded by the PDs connected via trans-impedance amplifiers to the 12 bit analogue to digital convertor of the microcontroller. Individual measurements are produced by averaging a number of readings, to reduce electronic noise. The data is outputted via an RS232 and captured by the logger detailed below. The system can be reprogrammed to use USB, GSM or low-power RF communications and to vary the optical sampling rate and sensitivity. A circuit schematic of the key components is shown in Fig. 2, including the Wixel, the LEDs, the PDs, the array of amplifiers and the power regulator.

The sensor can be powered from any rechargeable, on-board 6 V lead acid battery or using a power cable to connect the mains via an adaptor. During a measurement cycle the OCS draws approximately 250 mW of power while communication via GSM can draw up to 2.5 W. The system is programmed to sleep outside of the measurement and communication cycles, reducing the power consumption to below 1 mW. If the OCS is configured to measure and transmit, using GSM, every minute it can operate off battery power for approximately 85 h.

Table 2
Mechanical components list.

Part no. (Fig. 1)	Component	Material	Supplier
1	Detector shroud	Formed copper plate	Hardware store
2	Optical detector	Photodiodes in copper tube	Farnell Electronics
3	Light source	Five LEDs in copper tube	Radionics Ireland

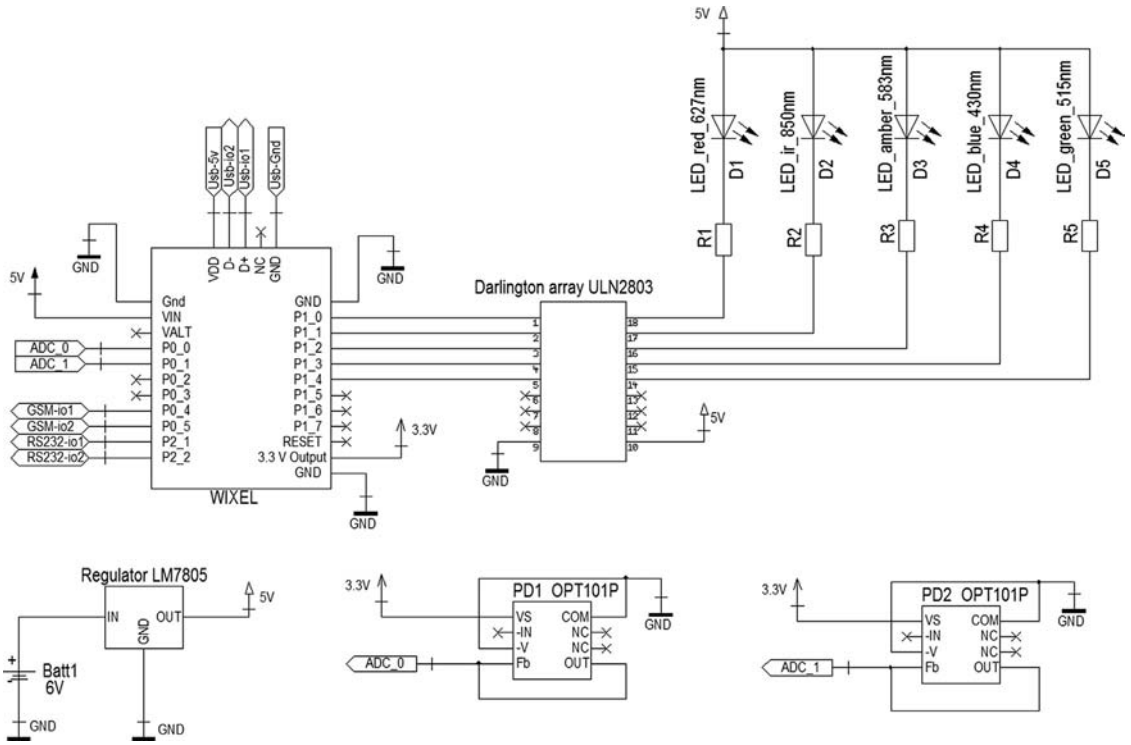

Fig. 2. A simplified circuit diagram showing the keys elements of the electronic control system for the sensor.

2.2.4. Data logger

To record the data obtained by the OCS a low-cost prototype data logger, based on an off-the-shelf single board computer (SBC) called "Raspberry Pi® (R-Pi)," was built. R-Pi consists of a 700 MHz ARM11 processor, Broadcom VideoCore IV GPU, 512 MB RAM, 2 × USB 2.0 ports, general purpose input–output (GPIO) interface, RJ-45 LAN connector and an SD card slot for on-board storage. The board can be powered by a 5 V DC power supply via a Micro USB or GPIO header. The power consumption of the R-Pi is 3.5 W maximum depending on the peripherals attached.

One limitation of the R-Pi is that it does not have a real time clock (RTC) module on-board; to solve this issue a RasClock® was purchased and installed on the R-Pi. The cost of the logger and its housing amounts to under €150, when all parts are purchased separately without economy of scale.

Fig. 3 shows the structure of the system. A data tunnel between the logger and OCS is established through a USB to Serial converter. The USB Wi-Fi access point (AP) allows the operator to download data onto a mobile device such as a smart phone or laptop wirelessly within a range of up to 45 m, through HTTP protocol. The unit is also compatible with a GSM/3G dongle, which can send data back to a data centre in real-time. In addition the data is saved onto the SD card on-board the logger. The R-Pi is powered by a 5 V external power source. The AP module (Edimax ew-7711uan) is powered directly from power supply to increase the system stability.

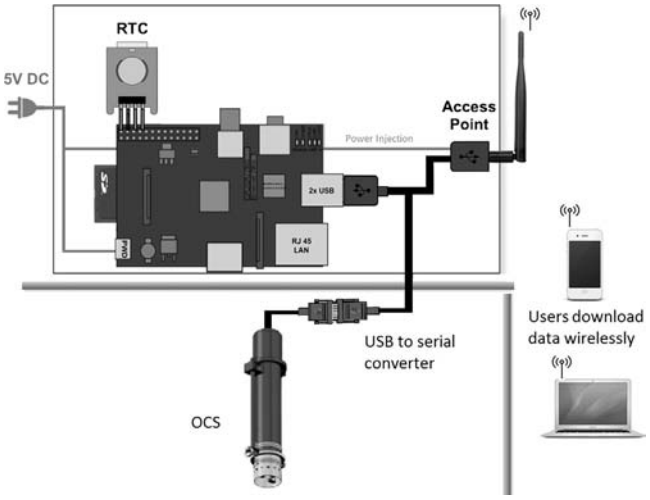

Fig. 3. Block diagram of the structure of the logger and its communication with the sensor and users.

2.3. Laboratory characteristics of the OCS

Communication between the computer and the laboratory test sensor was established using a terminal program, via a USB port. 230 V mains electricity was used as the power source via a 12 VDC convertor. The sensor was positioned in the sample solution and data logged via the PC terminal. All of the laboratory experiments were made using a black container in 1.5 L of water, as this covered the head of the sensor. The tests were performed in triplicate, collecting the data for 5 min, obtaining 25 measurements for each sample. Deionised water was used to dilute the food dyes and the turbidity standards.

In order to test the response of the sensor to different colours, food dyes were used in various concentrations diluted in water. Food dyes were chosen to mimic the colour effects of impurities in the water in an effective and cost efficient manner. All of the dyes listed above were extracted using an electronic micro-pipette and mixed with water in concentrations of 0, 10, 20, 30, 40, 50, 60 and 70 μL of food dye per L of water.

The effect of opacity on the sensor was also investigated. For these experiments turbidity standards were diluted in water and the turbidity of the sample was quantified. Inhomogeneous mixing of the turbidity standard in water necessitated that the turbidity

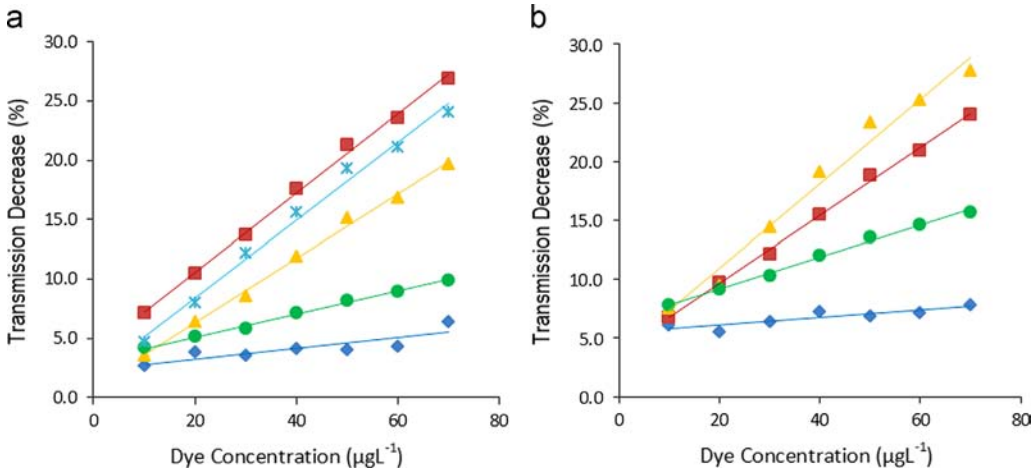

Fig. 4. Average attenuation data ($n=3$) recorded for the red (squares), amber (triangles), green (circles), blue (asterisk) and IR (diamonds) LEDs in the green dye solution for (a) 0° photodiode and (b) 90° photodiode.

level was cross-checked using a commercial turbidimeter (a TURB 430 IR/T from WTW). Five turbidity measurements were taken for each dilution and an average was calculated to give the final concentration. The concentrations of the standards prepared were 2.2, 3.1, 4.3, 5.2, 5.9, 8.1, 14.7, 21.4, 42.4 and 54.2 NTU.

2.4. Field deployments

Two sites in the Dublin vicinity have been used to perform field trials of the OCS; Malahide estuary (lat.: 53° 27' 14'', long.: −6° 9') and Poolbeg marina (lat.: 53° 20' 39', long.: −6° 13'). These trials have been carried out beside commercial sensors for turbidity, chlorophyll and other parameters to enable a true comparison of results and validation of the OCS.

In Malahide, north of Dublin city, the deployment took place in a typical estuarine body characterised by an elongated shallow channel. The inner estuary is fed with freshwater from a river and does not drain at low tides. The outer estuary is mainly influenced by the Irish Sea, which drains almost completely at low tides. The average water movement is towards the sea as with all estuaries, but it is a mixed estuary as the river flow is less dominant than the tidal flow. The main pressures affecting the estuarine catchment water quality is the presence of waste water treatment plants and sewer overflows.

Poolbeg Marina is in a busy port environment on the lower Liffey estuary, with the deployment site located in an area of less intense ship traffic. The topography of the estuary is heavily modified, being walled for its whole length and undergoing regular dredging. At the site the water depth is approximately 8 m and the width of the channel from wall-to-wall is approximately 260 m. The area acts as a buffer zone for the freshwater input from the river upstream and the tidal flow. Anthropogenic effects have an influence also, with the input of pollutants (run-off, storm drains, sewage treatment discharges, industrial discharges, port activity and recreational boating) and the modification of water flow (upstream dam releases).

The deployments at Poolbeg and Malahide consisted of the OCS and a commercial sonde which were deployed off a pontoon in the marina. The commercial system was a YSI sonde (V4 6600) and measured temperature, conductivity, pH, depth, chlorophyll, turbidity, dissolved oxygen and blue-green algae concentration. The OCS sensor and the YSI system were deployed at a depth of approximately 1 m.

3. Results and discussions

3.1. Laboratory tests

The results obtained from the laboratory tests on the food dyes and turbidity standards are presented here. The response of the OCS to water opacity trends, and hence water quality, can be observed by evaluating it with known turbidity standards in the laboratory and subsequently with a turbidity sensor in the field. Fig. 4 shows the percentage change in the optical signal recorded on the PD for each LED *versus* the concentration of colour dye, compared to water, with the ambient light subtracted to correct for light pollution and dark current effects. All of the proceeding results for the 90° PD exclude the blue LED data sets as the signal recorded by the photodiode for this particular LED is extremely weak and subject to large variations, producing potentially inaccurate data. The low light levels of the LED are exacerbated by the fact that the 90° PD universally returns a lower signal than the 0° PD due to the right-angled optical path and the blue LED is spectrally situated where the PD response is the weakest, meaning that a much lower percentage of the light is detected. It should be noted that the amber LED for the 90° PD can give a low signal level and thus a larger than average variance, but the results are included.

In Fig. 4 the response of the 0° PD to the increasing concentration of dye for the LEDs is shown to be linear. The R^2 value for the red, blue, amber and green LEDs is >0.99, with the R^2 value for the IR LED equal to 0.732. The results for the 90° PD are also quite linear with the R^2 value for the red, amber and green LEDs >0.98 and the R^2 value for the IR LED is equal to 0.781. These results highlight that, for the LEDs in the visible range the green is the most transmitted and the red and blue are the least transmitted, when the green dye is used, as expected.

The results from laboratory testing of the OCS with turbidity standards are presented in Fig. 5. The results for the green LED is depicted in Fig. 5, giving the change in optical signal for the (top) 0° PD and the (bottom) 90° PD. It was found that the performance of the OCS differs in its response to the turbidity standards compared to the food dyes. Fig. 5 shows that the response of the 0° PD to turbidity standards was similar to that of the food dyes. The other colour LEDs were also found to be transmitting less light to the PD with increasing concentration of turbidity standard. The results for the 90° PD, however, show a different reaction with a general growth in optical signal recorded for increasing

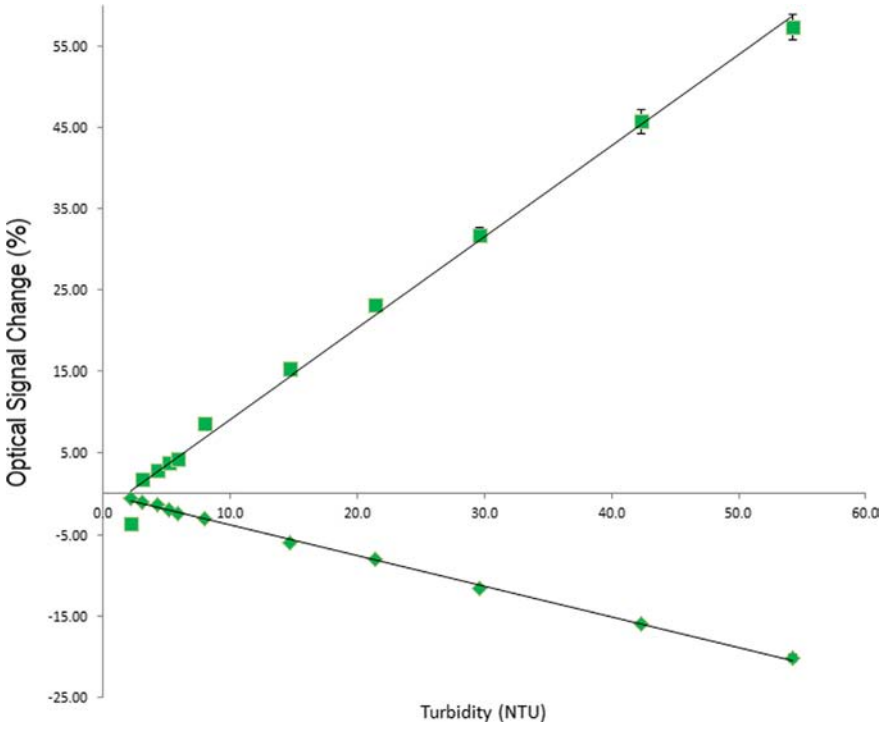

Fig. 5. Average signal response ($n=3$) of the green LED for varying concentrations of turbidity standards for both the 0° (diamonds) and 90° (squares) photodiodes.

concentration of turbidity standard. This figure shows that the response of green LED has a linear relationship with increasing turbidity standards for both the 0° ($R^2=0.9986$) and 90° ($R^2=0.9939$) PDs. This trend is evident also in the other colour LED results, although not in as significant a manner as that of the green LED.

The increase in signal in the 90° PD for turbidity (compared with a decrease for the dyes) is as expected and it indicates that the light is being scattered off particulate matter in the water and some of the side-scattered portion is subsequently detected by the 90° PD. It should be noted that at very low levels of turbidity (<5 NTU) the results become more unstable with standard deviations of greater than 5% being observed. Turbidity is used as a surrogate variable for suspended solids concentration [18] and the levels of both turbidity and suspended solids levels are important drivers of population, community and ecosystem level dynamics of phytoplankton and bacterioplankton in estuarine systems [19]. Sustained and sporadic increases in turbidity levels are associated with fluctuations in microbial populations and concentration of re-suspended contaminants such as heavy metals and other pollutants [20]. In a number of estuarine systems, strong correlations have been found between suspended particle concentration and the number of attached bacteria, an important parameter in estimating microbial population of bacteria such as *E. coli* and faecal coliforms [21]. Re-suspension of benthic sediment leading to higher turbidity levels can create elevated *E. coli* concentrations in estuarine waters.

3.2. Field deployments

During the deployment periods of the sensor in the field it was found that the system performed successfully in terms of measuring, acquiring and logging the data. The data logger recorded all the data onto the SD card while allowing it to be accessed also via Wi-Fi. Although other embedded systems, such as Arduino®, are widely used in marine sensor networks [22,23] the R-Pi provides much more functionalities than these traditional embedded systems. These include the supporting of Linux kernel-based operating systems which provides the capability of communication with a wide range of USB enabled or TCP/IP based devices and support for many programming languages such as C, C++, Java, and Python. The initial cost of R-Pi (€35) is higher than that of the Arduino® (€23–Arduino Due) but add-on devices for internal sensor communications and external data transmission are much cheaper, reducing the overall cost.

A drawback of the R-Pi is that it consumes more power (typically 700 mA) than that of some other embedded systems (as low as 100 mA) but due to its high processing capability only one logger unit would be required for a medium–large scale sensor network, lowering the overall power usage. The Raspberry PI also provides high computation capability which allows for raw sensor data to be processed on board. Anomaly detection and event detection could be performed on-site and alert messages would be sent to the base station only once outliers or abnormal events are detected. The raw sensor data could be stored on site and would not need to be transmitted to the base station. Using the two-way communication capability, the operator can query the raw data associated with the events detected; such a system would reduce the communication (data transmissions) costs which generally consume the majority of the power in a large scale wireless sensor network.

The performance of the sensor in an environmental setting provided further evidence of the ability of the OCS to measure colour and opacity changes in the water. The physical set-up of the light source and the detectors allows for various potential methods of determining turbidity and chlorophyll content, including spectral bands [24,25] and the ratios of the transmitted to side-scattered light detected by the PDs. In the laboratory studies it was found that the green LED gave the strongest signal and most significant response for water opacity and colour changes. Therefore the results presented relate to the green LED data, using two straightforward methods described below.

In Fig. 6, the turbidity recorded by the YSI sonde is shown along with a scaled version of the optical signal response recorded by the 0° PD for the green LED on the OCS. This illustrates clearly the inverse relationship between a rise in turbidity and a fall in optical

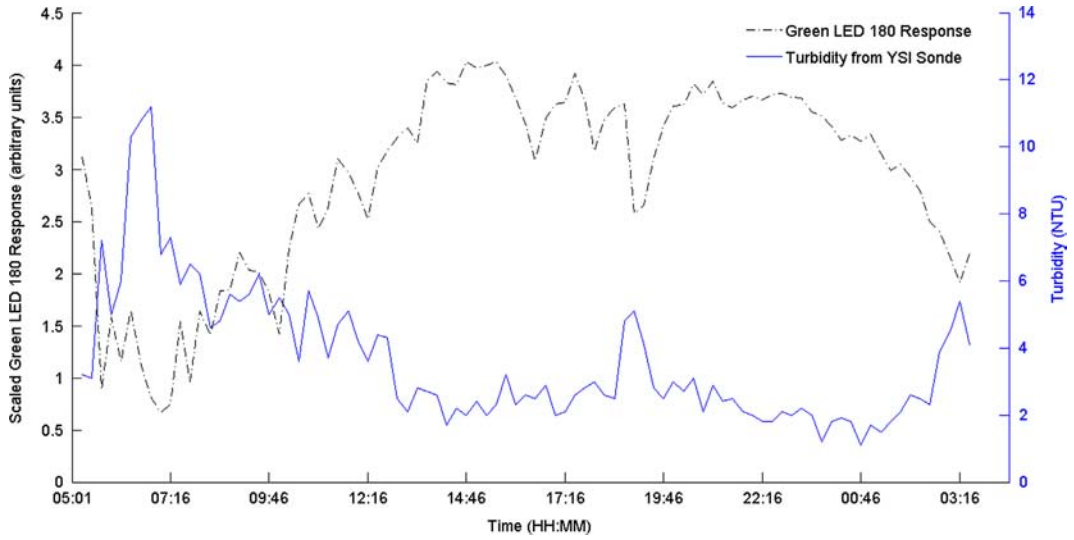

Fig. 6. Turbidity measured at Poolbeg marina by the YSI sonde (solid blue line) over a 26 h period, with the response of the 0° PD to the green led also plotted (dashed line). This response has been scaled to show it on the same plot. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

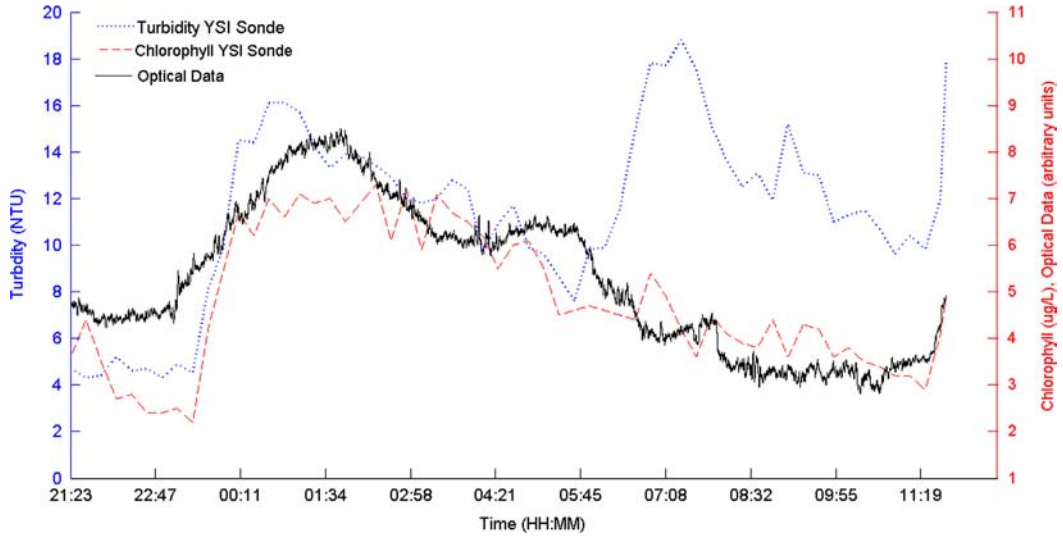

Fig. 7. Turbidity (dotted blue line) and scaled chlorophyll (dashed red line) measured at Malahide by the YSI sonde over a 14.5 h period, along with optical data from the green LED (solid black line). The method for calculating the optical data is given above. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

signal for the 0° PD, which is in agreement with the results obtained in the laboratory tests depicted in Fig. 5. The signal response has been corrected for ambient light and has been smoothed using a moving average filter. The optical signal response in Fig. 6 has been scaled and thus has arbitrary units. The correlation between the 0° PD response and the YSI measured turbidity was calculated using the Pearson method to be −0.8322.

The results shown in Fig. 7 illustrate how it may be possible to do the same for the assessment of colour presence in the water; here chlorophyll is used as an example. In Fig. 7 the turbidity and a scaled set of chlorophyll concentrations measured by the YSI sonde are given, along with optical data from the OCS. This data was recorded during the Malahide deployment and the section of the data displayed covers approximately 14.5 h. The optical data shown is for the green LED. The raw signal has been adjusted using the following calculation:

$$G_{\mathrm{LED}} = \left(\frac{G_{90} - D_{90}}{G_0 - D_0}\right) \times S,$$

where G_{LED} is the green LED result, G_0 and G_{90} are the optical signals for the green LED from the 0° and 90° PDs respectively, D_0 and D_{90} are the ambient light signals from the 0° and 90° PDs and S is a scaling factor.

Performing this has the effect of smoothing out the event driven spikes in turbidity, dominated by particulate matter, from the optical data, leaving a more stable signal; the residual optical data tracks the changes in the chlorophyll concentration. A question remains as to whether the parameter being represented by the optical data will always be a reliable indicator of chlorophyll. It is clear from the measurements that there is a relationship between this optical dataset and a surrogate chlorophyll value which gives an indicator of chlorophyll occurrence and variation. A Pearson correlation carried out on the residual optical data and the chlorophyll concentration measured by the YSI sonde gives a value of 0.8123.

Based on the results to date it is believed that this sensor could be employed, within a network of sensors, to identify event changes in the bulk water quality parameters, such as variations in water clarity and primary productivity-related turbidity. The low-cost

nature of the OCS means that multiple sensors could be deployed across a large area, with a high spatial density. It is envisaged that a small number of auto-samplers and/or more expensive, sophisticated sensors could be deployed in tandem with multiple low-cost OCS units to ground truth the data and verify the bulk water property changes. Alternatively the events detected by the low-cost sensor network could inform and drive the location and timing of manual grab sampling for laboratory analysis.

4. Conclusions

The design, building and operation of a low-cost, multi-wavelength optical system for water quality monitoring has been illustrated and described. The OCS is capable of measuring the change in optical signal along two different optical paths (transmitted and side-scattered). The performance of the system has been tested in the laboratory with food dye and turbidity standard solutions of varying concentrations. These results show strong linear correlations between the optical signal response and turbidity concentration, as well as colour change from the food dyes. The system was deployed in the field at different locations and the recorded data correlated well with commercial water quality sensors. The results from the field trials highlight that the system has the ability to detect both sudden and significant changes in water opacity arising from environmental events.

The work presented in this paper has outlined the first generation of the sensor development and results. Further work and potential adaptations are required to produce a sensor that can be easily and quickly calibrated in the field; along with more sophisticated data analysis, this will enable the sensor to produce the most desirable results from the data collected. In order to facilitate this, additional longer term deployments in test locations are planned. It is now possible to gather this type of data over a large spatial area, in real-time, at a reasonable cost; this would make these kinds of systems particularly attractive to lower income countries struggling with the effects of climate change and water related challenges. The intention is to commercialise the OCS as a real-time pollution monitoring system.

ABSTRACT

The objective of the study is to develop a facile and highly sensitive solid phase microextraction-gas chromatography/mass spectrometry method for the analysis of volatile organic compounds in human exhaled breath vapor. For the purpose, a highly ordered nanoporous anodic alumina coating was prepared by a two-step anodic oxidization method based on aluminum substrate. To have a good knowledge of the fiber, some features were characterized and the results indicate that the coating has several advantages, including excellent chemical and thermal stability, high mechanical strength, large surface area and good extraction performance. In addition, some parameters related to extraction efficiency were also studied. Under the optimal conditions, the coating was used to quantitatively extract volatile organic compounds. Good linearity and wide linear range were obtained with correlation coefficients (R^2) ranging from 0.9933 to 0.9999. The detection limits of benzene homologues, aldehydes and ketones were between 0.7 and 3.4 ng L^{-1}. Relative standard deviations ($n=5$) ranged from 1.8 to 15.0%. Satisfied recovery (89–115%) was obtained at two spiked concentration levels. Finally, the developed method was successfully applied for the analysis of volatile organic compounds in human exhaled vapor samples of lung cancer patients and the controls, and the results were statistically analyzed with Independent-Sample *T* Test. The proposed method exhibits some outstanding merits, including convenience, non-invasion, low cost and sensitivity. It provides a potential tool for rapid detection of volatile organic compounds in human exhaled breath.

1. Introduction

As biological terminal metabolites, volatile organic compounds (VOCs), including olfactive and non-olfactive VOCs are the carriers of useful and significant bio-information [1–3]. They contain much important information linked to disease diagnosis [4,5], food security [6,7] and quality test [8]. However, due to its trace μg-to-ng concentration level with strong volatility and liquidity in complicated biological sample matrices, especially in gaseous matrix (air, exhaled vapor), sample preparation is of great necessity before quantitative analysis. The most common sample preparation approaches for VOCs in gaseous matrix are sorbent tube trap [9–11], fibers coated sorbent materials for solid phase microextraction (SPME) [12,13] and direct cryofocusing [14]. As to sorbent tube trap, needle trap is an emerging preconcentration method. It can be used for both active and passive sampling, and extraction capacity can be increased by adding the amount of sorbent inside the needle [15]. However, it is a tough and time-consuming work to pack the sorbent materials and the analytical performance heavily relays on sorbent materials [15,16]. With cooled preconcentration device using a liquid cryogen such as carbon dioxide or nitrogen, the method of cryofocusing can efficiently trap targets. But the disadvantages of high-cost and poor retention of ultra-volatiles limit its application [11].

SPME has been a powerful sample preparation method since introduced by Pawliszyn in the early 1990s, which combines sampling, extraction, pre-concentration and sample introduction in one step [17]. Owing to its time-efficient, simplicity, solvent-free, field usable and linkup with detection instruments (SPME-gas chromatography, SPME-high performance liquid chromatography and SPME-capillary electrophoresis), SPME has been broadly applied in different fields, such as environment [18], food [19], forensics [20] and pharmaceuticals [21]. This technique depends on distribution of analytes between sample matrix (or its headspace) and stationary phase, such as fiber coating. UP to now, some SPME coatings, including polydimethylsiloxane (PDMS), polyacrylate (PA), and some combinations such as PDMS/divinylbenze (DVB),

carboxen (CAR)/PDMS, DVB/CAR/PDMS, carbowax (CW)/DVB and CW/template resin, have been applied to commercial SPME fibers [22]. However, they suffer from the drawbacks of high cost and instability at high temperature, for example, the maximum temperature for 100 μm PDMS is 280 °C, 65 μm PDMS /DVB is only 270 °C. The substrate for most commercial fibers is fused silica, which is fragile and should be treated with great care, its lifetime is therefore limited. In addition, the kinds of coating materials for commercial SPME fibers are numbered, restricting the wide application of SPME [23].

In this regard, a number of researches have been devoted to the development of new fiber coating. New materials utilized in fiber coating for SPME include zinc oxide nanorod [6], porous anodized alumina [24–26], molecularly imprinted polymer [27], polymeric ionic liquid [28], metal–organic framework [29] and carbon materials [30]. Of which, nanoporous anodized alumina, a kind of aluminum (Al)-substrate inorganic nanomaterial has attracted increasing attention in recent years, owing to its remarkable properties such as chemical, thermal stability and high surface area. Nanoporous anodic alumina (NPAA) with one dimensional nanostructure is made up of some parallel cylindrical nanopores which are vertical to the surface of Al substrates [31]. It can be obtained by a two-step anodic oxidation method. Pore structures are tunable by changing the anode voltage, anodic oxidation time or electrolyte [31–33]. It has been widely used in different fields, such as the template material for the fabrication of other nanostructured arrays nonmetals [34], the support of sensors [35], functional electrodes [36] and filtration [37]. Due to high surface area, NPAA has drawn the attention of chemists for gas absorption material [24,26]. Li and co-workers fabricated NPAA fibers and applied for the analysis of VOCs in plants [24]. However, to our knowledge, nothing has been reported on the utilization of NPAA coated fibers for the adsorption of VOCs in human exhaled breath vapor (EBV).

Exhaled breath analysis has been one of the important diagnostic methods because of its safety, low cost and non-invasive nature [38,39]. However the sample matrix of human EBV is complex, the existence of nitrogen, oxygen, carbon dioxide, inert gases and water [38,40] may seriously interfere with the analytical signal.

In this work, a simple, rapid, low-cost and sensitive solid phase microextraction–gas chromatography/mass spectrometry (SPME–GC/MS) method was proposed and validated for the analysis of VOCs in human EBV. For the purpose, a highly ordered NPAA SPME fiber coating was fabricated on aluminum substrate by a two-step anodization strategy. VOCs studied in our work include benzene homologues, aldehydes and ketones. Some features of fiber including morphology, extraction selectivity and durability were investigated. Parameters related to extraction and desorption performance were optimized systematically. Finally, the developed method was applied for the quantitative analysis of VOCs in EBV of lung cancer patients and the healthy volunteers.

2. Materials and methods

2.1. Chemicals and materials

Ethanol (HPLC grade) was purchased from Biologic-Reagents (USA). Benzene (99.5%), octanal (98%), undecane (99%), 2-heptanone (98%) and 2-pentanone (99%) were provided from TCI Development Co. LTD (Shanghai, China). Pentanal (98.5%) and ethylbenzene (99.7%) were obtained from Amethyst Chemicals (Beijing, China). Hexanal (98%) and heptanal (97%) were bought from ABCR GmbH & Co. KG (Germany). Decane (99.5%) was purchased from Dr. Ehrenstorfer GmbH (Germany). Nonanal (97%), 2-methylvaleraldehyde (98%) and 2-ethylbutanal (97%) were purchased from Alfa Aesar (Tianjin, China). Oxalic acid, acetone, sodium hydroxide, phosphoric acid, chromium trioxide and perchloric acid were analytical reagent-grade and provided by Sinopharm Chmical Reagent Co. Ltd (Shanghai, China). Ultra-pure water was used in all experiments (arium® pro Ultrapure Water Systems, Sartorius Stedim Biotech, Gottingen, Germany). Five microliter microsyringe was bought from Feige, China. Aluminum wire (99.999% purity, 0.25 mm diameter, annealed) was purchased from Beijing Jiamingboye Yousejinshu Co. Ltd (Beijing, China). Gas-tight syringe (10 mL) was purchased from Agilent Technologies Inc (USA).

2.2. Standard solution and gas calibration sample

Stock solution of 8 analytes (benzene, pentanal, 2-pentanone, hexanal, heptanal, 2-heptanone, octanal and nonanal) was prepared in ethanol at 1650 μg mL^{-1}, stock solution of internal standard (IS, 2-methylvaleraldehyde) was prepared in ethanol at 1650 μg mL^{-1}. In order to investigate extraction selectivity, stock solution of 5 analytes (pentanal, hexanal, heptanal, octanal and nonanal) and stock solution of 7 analytes (2-ethylbutanal, 2-methylpentanal, hexanal, 2-heptanone, heptanal, decane and undecane) were prepared in ethanol at 1650 μg mL^{-1}, respectively. The daily standard working solutions were prepared by diluting the corresponding stock solution. All of them were stored at −20 °C in the dark. The mixed gas calibration samples, involving 8 analytes and known concentrations of IS (5 ng mL^{-1}) were prepared by direct vaporization of 2.0 μL working solution in a 25 mL evacuated sealed vial in water bath (50 °C, 20 min).

2.3. Preparation of NPAA fiber

NPAA fiber was prepared as described in previous literature [24] with a minor modification. The steps are as follows: (1) A straight aluminum wire with the length of 17.0 cm was ultrasonically washed with acetone and ultrapure water for 20 min. (2) To get a fresh aluminum surface, the wire was immersed in a 0.1 mol L^{-1} sodium hydroxide solution until many bubbles were produced. Then it was electropolished under the constant voltage of 9 V in a mixture solution of perchloric acid and ethanol (1:5, v/v) for 1 min, and ultrasonic cleaning in ultrapure water was followed to make the surface smooth. (3) With aluminum wire as anode and graphite bar as cathode, the first anodic oxidization was carried out at a constant 45 V voltage in 0.3 mol L^{-1} oxalic acid solution (10 °C, vigorous stirring), and the process lasted for 2 h. (4) The tip 2 cm of the oxidized aluminum wire was soaked in a mixed acid (6% phosphoric acid + 1.8% chromic acid, 70 °C) for 90 min and ultrasonically cleaned with ultrapure water to get a rough and uneven aluminum matrix. (5) Under the same conditions as step 3, the anodization process was repeated for another 6 h. (6) The prepared fiber was dried in an air tight bag containing desiccant for 10 h (room temperature) and conditioned at GC injector for 30 min with the temperature programming from 65 to 265 °C at a rate of 20 °C min^{-1} and hold at 265 °C for 20 min.

2.4. SPME procedure

The prepared SPME fiber with the effective length of 1.5 cm was installed into a home-made SPME holder (5 μL microinjector) according to literature [17]. Before every usage, the fiber was inserted into GC injector to condition for 20 min (265 °C) in order to remove the possible residues. During exposure, 2 μL working solution was injected into a 25 mL sealed glass vial with a PTFE-lined septum cap, and evaporated in water bath (50 °C, 20 min). Then, the conditioned NPAA SPME fiber coating was pushed out from the holder cartridge and exposed for an appropriate time.

At the end of extraction, the fiber was retracted into needle and injected immediately into GC for thermal desorption at 265 °C for 6 min.

2.5. Instrumentation

The GC–MS QP2010 Plus system (Shimadzu, Japan) coupled with a split/splitless injector was employed for all chromatographic analysis experiments. The mass spectrometry was operated in EI mode at 70 eV. All separations were carried out on a CP-Pora bond Q column (30 m × 0.32 mm × 0.5 μm, Varian Chrompack, USA). Helium was used as carrier gas at a constant velocity of 1.62 mL min^{-1}. GC oven temperature was programmed as follows: initially maintained at 80 °C for 2 min, then up to 140 °C at a rate of 8 °C min^{-1} and held for 2 min, subsequently programmed at 5 °C min^{-1} to 250 °C and held for 12 min. The transfer line and the ion source temperatures were set at 250 °C and 200 °C, respectively. Data acquisition was performed in selected ion monitoring (SIM) mode. The qualitative ions for each analytes were as follows, benzene: *m*/*z* 77, 52; 2-pentanone: *m*/*z* 86, 41; pentanal: *m*/*z* 41, 58; hexanal: *m*/*z* 41, 56; 2-heptanone: *m*/*z* 58, 71; heptanal: *m*/*z* 41, 70; octanal: *m*/*z* 41, 56; nonanal: *m*/*z* 41, 56.

Surface morphology of the proposed fiber was obtained by scanning electron microscope (SEM, JEOL, JSM-6700F, Japan).

2.6. Breath sample collection

Before collection, all Tedlar® bags were cleaned by flushing with nitrogen gas and then filled with nitrogen and heated at 70 °C for 10 h to get rid of any contaminations. Breath samples, involving ten lung cancer patients (Hubei Cancer Hospital, Hubei, China) and ten healthy volunteers (Central China Normal University, Hubei, China) who had fasted overnight were collected in a 1 L Tedlar® bags through a disposable mouthpiece. Then, a 25 mL sample was transferred into a crimped and evacuated glass vial by a gastight syringe.

2.7. Statistical analysis

The samples of controls and patients were statistically analyzed with Independent-Sample *T* Test (*t*-test) by SPSS statistics version 19.0.0 (IBM, New York, NY, USA). The level of significance was determined by two-sided test. A *P* value of < 0.05 was considered statistically significant.

3. Results and discussion

3.1. Preparation and characterization of the fiber

3.1.1. Fabrication of NPAA coating

During the anodizing of metal aluminum wire, two different kinds of films, namely barrier-type oxide films and porous oxide film were generated, of which, the formation of porous oxide layer is a self-organized process [41]. Due to the volume expansion of alumina at the metal/oxide interface, tensile stress which creates repulsive force between the neighboring pores is generated. Moreover, the compressive stress makes the steady-state oxide grow upward in the vertical direction [42,43]. As a result, the porous oxide layer covers all of metal aluminum surface. The whole course is heavily controlled by the type of electrolyte, re-anodization time and anodizing voltage, especially anodization time, because the preparation of anodic alumina is the result of dynamic equilibrium between the oxide growth and the oxide dissolution [43].

In this work, to achieve better extraction efficiency, re-anodization time (4 h, 6 h, 8 h, 11 h) were investigated. The results indicated that extraction efficiency increased with time and reached to the maximum at 6 h, then followed with a plateau. Because the thickness of fiber coating increases with the re-anodization time, better surface morphology and extraction efficiency can be obtained [43]. The stable extraction efficiency after 6 h is ascribed to dynamic equilibrium between the oxide growth and the oxide dissolution. Therefore, 6 h was chosen to be the optimal re-anodization time of the potential application.

3.1.2. Morphology of coating

To obtain the morphology of the prepared fiber, scanning electron microscopy (SEM) analysis was carried out in our work. The anodic alumina is a kind of one dimensional nanomaterial. As shown in Fig. 1(A), the surface of the fiber is almost covered with series of parallel cylindrical nanopores. The uniform nanopores are about 50 nm in diameter, which can provide a relatively large specific surface area for extraction. From Fig. 1(B), we can see that they are perpendicularly grown on the surface of aluminum wire and parallel to each other. The thickness of the coating is about 20 μm. The results indicated that a highly order nanoporous anodic alumina fiber was successfully prepared. The fiber with high area-to-volume ratio can provide abundant adsorption sites for extraction and facilitate fast mass transfer.

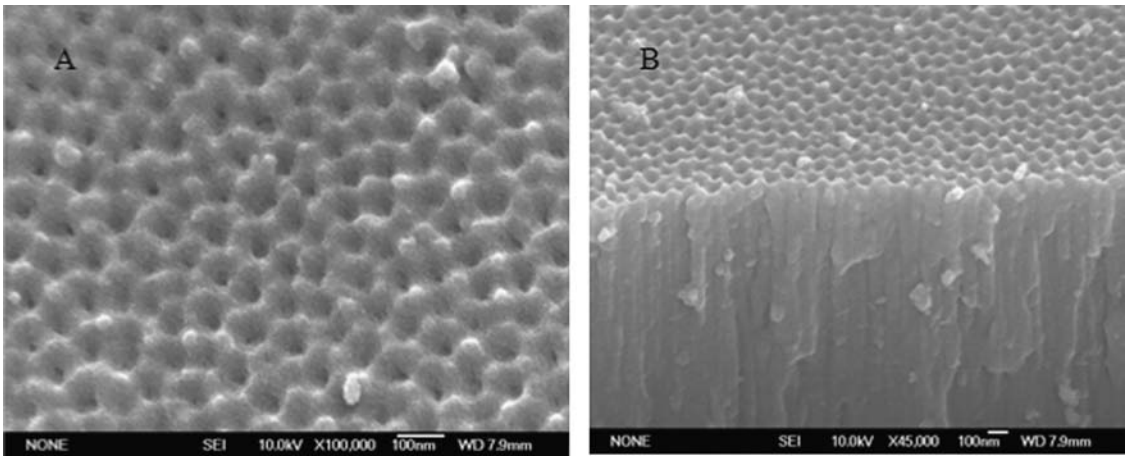

Fig. 1. Scanning electron microscope images of NPAA fiber: (A) top view, 100,000 × ; (B) cross-section view, 45,000 × .

3.1.3. Extraction selectivity

To study the extraction selectivity of the NPAA fiber, enrichment factors (EFs) of five straight chain aldehydes, including pentanal, hexanal, heptanal, octanal and nonanal were investigated with the NPAA coating as extraction phase by direct injecting of 1 μL solution, whose concentration was the same as that of gas calibration samples. EF is defined as the ratio of the peak area of the extracted gaseous analytes to that by direct injection of liquid solution. Octanol-water partition coefficient, log*P* is related to the polarity of analytes and used as an indicator for hydrophobicity. The higher log*P* means the weaker polarity of analytes. The polarity of compound decreases with the growth of carbon chain. The alumina coating is hydrophilic [37], thus, the compound with the strong and medium polarity can be easily captured by the hydrophilic coating. In the study, we find that the value of log*P* increases with the growth of the carbon chain length of aldehyde molecules (from 1.44 to 3.56, not shown), while EFs gradually reduce from pentanal to nonanal (Fig. 2A). In addition, with the increasing of carbon chain, the volatility of analytes decreases, thus the amount of analytes captured by NPAA coating lessens.

Then, EFs of the following two groups of isomers were also studied to evaluate the effect of analyte structure on the extraction selectivity of fiber: (a) 2-ethylbutanal, 2-methylpentanal, hexanal; (b) 2-heptanone, heptanal. The results in Fig. 2B indicate that isomers with larger log*P* values usually have smaller EFs. For example, the EF of hexanal (log*P*, 1.97) is lower than those of 2-ethylbutanal (log*P*, 1.78) and 2-methylpentanal (log*P*, 1.78). Similar result is obtained for heptanal (log*P*, 2.50) and 2-heptanone (log*P*, 1.97). The results indicate that the analyte structure, such as carbon chain and isomerizaiton can directly affects the polarity of analyte and further the extraction selectivity of fiber. From Fig. 2B, we also can find that the EF values of aldehydes and ketones are much higher than that of the *n*-alkanes. The better extraction selectivity to aldehydes and ketones mainly results from their lower log*P* and the relatively strong Lewis acid-base interaction where aldehydes and ketones (electron-pair donor) are acted as Lewis base and the Al surface provides Lewis acid sites [44]. The results indicate that the NPAA fiber is suitable for the extraction of polar and volatile compounds.

3.1.4. Fiber durability

Fiber durability is an important issue when the material is used as extraction phase. It was studied by investigation of the mechanical strength, thermal and chemical stability, and lifespan of the NPAA fiber. Aluminum substrate can provide better mechanical strength than silica substrate, which is commonly used in commercial SPME fiber. And the in-situ anodized alumina is hardly stripped from the substrate when compared with other coatings. In addition, the inorganic oxide coating fiber has relatively better thermal and chemical stability [44] compared with polymer and organic coating prepared by sol–gel or electrodeposition methods. To investigate the reusability of the fiber, numerous extraction-desorption-conditioning cycles were carried out at the VOCs concentration of 5 ng mL^{-1}, and the peak signal was recorded. The results in Fig. 3 indicate that there is no significant difference in extraction efficiency of the NPAA fiber after 140 replicate extractions. Excellent thermal, chemical and mechanical stability and long lifespan (over 140 times usage) demonstrates the robustness of the fiber. Besides the excellent durability, low cost and high precision are also the remarkable advantages of the fiber for analytical application.

3.2. Selection of SPME conditions

The prepared nanoporous fiber was used to extract VOCs, several parameters closely related to extraction performance, such

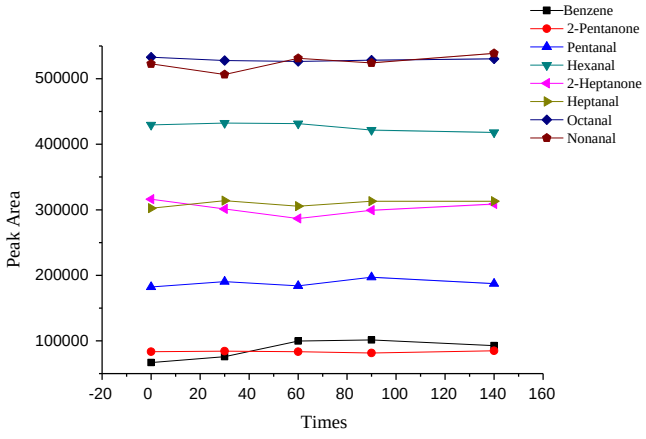

Fig. 3. Use times of the fiber, conditions: concentration of the analytes, 5 μg L^{-1}; extraction temperature, 50 °C; extraction time, 20 min; desorption temperature, 265 °C; and desorption time, 6 min.

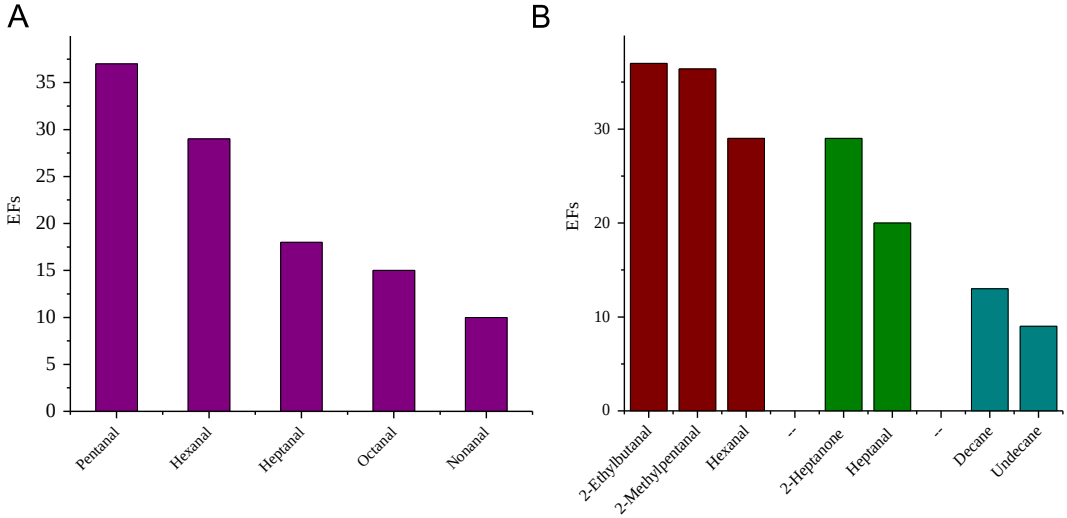

Fig. 2. Extraction selectivity of NPAA SPME fiber coating toward different analytes. (A) five straight chain aldehydes. (B) two groups of isomers and a group of homologous compounds.

as desorption temperature and time, extraction temperature and time were optimized systematically.

In order to achieve better desorption efficiency, thermal desorption temperature was investigated in the range of 230–275 °C. The result in Fig. 4A indicates that the best desorption temperature is 265 °C. Complete desorption can be realized at high desorption temperature. It will take a long time to desorb analytes from the NPAA fiber at low desorption temperature. Thus, the desorption temperature for subsequent experiments was set at 265 °C.

For SPME-thermal desorption model, carryover effect can affect the repeatability of analytical method. Even though desorption is carried out at elevated temperatures, carryover may still exist. Therefore, a relative longer desorption time should be required.

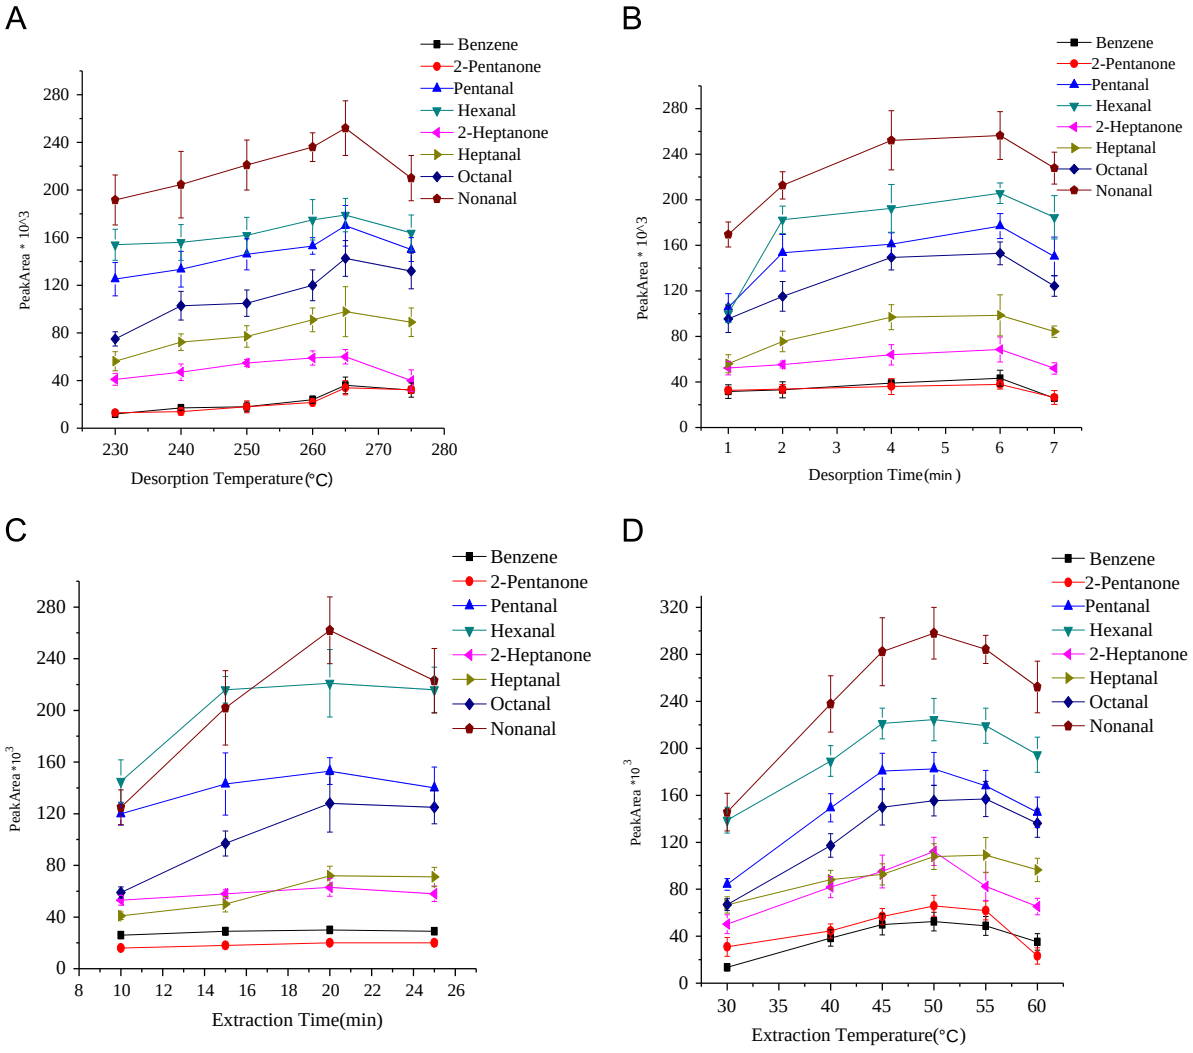

Fig. 4. The selection of (A) desorption temperature, (B) desorption time, (C) extraction time and (D) extraction temperature, concentration of the analytes: 2 μg L^{-1}.

In this work, thermal desorption time ranging from 1 min to 7 min was investigated. As shown in Fig. 4B, the best desorption time is 6 min. And we also studied the desorption efficiency of the nanoporous fiber, the results showed that after 6 min nearly all of the adsorbed analytes could be desorbed from the fibers. Hence, thermal desorption time of 6 min was selected for the following experiments.

Solid phase microextraction is an equilibrium-based process. Extraction time, a key factor in SPME is closely related to extraction efficiency. The selection of extraction time has direct impact on the sensitivity and repeatability of the proposed analytical method. The influence of the extraction time on extraction efficiency was studied at 10, 15, 20 and 25 min. The extraction time profile is shown in Fig. 4C. We can find that extraction efficiency increases with time within 20 min and slightly decreases in 25 min. Thus, the extraction time of 20 min was selected for the following studies. The relatively short equilibration time is attributed to the porous structure of the NPAA fiber which accelerates mass transfer from and to fiber.

Generally, high temperature can enhance distribution velocity, which is benefit for the diffusion of gaseous analytes to fiber, thereby improving extraction ability of SPME. But adsorption is an exothermic process, high temperature will decrease partition coefficient of analytes towards extraction phase. Fig. 4D demonstrates the extraction temperature profiles for VOCs and we can see that the extracted amount increases with the elevated temperature (from 30 to 60 °C), but decreases obviously after 50 °C. Therefore, 50 °C; was chosen to be the optimum extraction temperature.

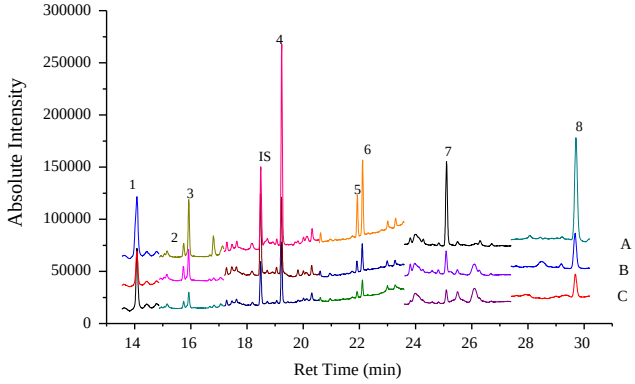

Fig. 5. GC–MS-SIM Chromatograms of VOCs in EBV samples (A: spiked EBV of healthy volunteer (1 μg L^{-1}), B: lung cancer patient, C: healthy volunteer). Peaks: 1. benzene; 2. 2-pentanone; 3. pentanal; 4. hexanal; 5. 2-heptanone; 6. heptanal; 7. octanal; 8. nonanal.

3.3. Analytical validation

The analytical evaluation parameters, including linearity range, correlation coefficients (R^2), limit of detection (LOD), recovery, reproducibility and repeatability of the developed SPME-GC/MS method were investigated by analysis of eight VOCs under the optimized conditions. Calibration curves were plotted using internal standard method. To get a series of gas calibration standards containing known concentrations of IS (5 μg L^{-1}), 2 μL standard working solution was injected into a sealed glass vial. Table 1 illustrates the quantitative analytical results. The proposed method showed good linearity with R^2 ranging from 0.9933 to 0.9999 in relatively wide concentration ranges. The limits of detection (LODs) with signal-to-noise ratio of 3 ($S/N=3$) were between 0.7 and 3.4 ng L^{-1}. The relative standard deviations (RSDs), including intra-day and inter-day of one fiber and fiber-to-fiber were both measured at three spiked concentration levels. The RSDs of one fiber ($n=5$) were in the range of 1.8–13.5%, which showed the good repeatability of the method. The RSDs of fiber-to-fiber ($n=5$) ranging from 2.2 to 15.0% indicated good reproducibility. The recoveries which were determined by the spiked experiments at two concentration levels in the EBV sample of controls were between 89% and 115%. The high recovery indicated the low matrix effect of the method. GC/MS-SIM chromatograms of VOCs in EBV samples are shown in Fig. 5 (A: spiked EBV of healthy volunteer, B: lung cancer patient, C: healthy volunteer). The results show that the NPAA fiber-based analytical method is effective and reliable.

3.4. Comparison with other methods

The intercomparison with several previously reported methods [45,46,16] was also carried out. The analytical results are shown in Table 2. The common methods for the analysis of aldehydes, ketones and benzene series in gaseous matrix are on- fiber-derivatisation solid phase microextraction method (method 1) and needle trap micro-extraction method (method 2). In comparison with method 1, NPAA coating shows relativity higher precision in a much wider linear range. In addition, the process of derivatization is not needed in our proposed method, which provides a rapid and simple analysis. Better sensitivity is obtained when compared with method 2. And it is a tough and time-consuming work to pack the sorbent materials into needles.

3.5. Application to real samples

To assess the viability of the proposed method, the NPAA SPME fiber was used to extract VOCs in EBV from both lung cancer

[d] $P<0.05$ was considered significant.

patients ($n=10$) and healthy volunteers ($n=10$). The results were statistically analyzed with Independent-Sample T Test (Table 3). As shown, average concentrations of 2-pentanone, pentanal, 2-heptanone, heptanal and nonanal were overtly higher in patients when compared to the control group ($P<0.05$). In contrast, no significant differences in benzene, hexanal and octanal were found between the two groups. The phenomenon may result from relatively small sample size, different stage of lung cancer patients and so on. Long-term and extensive research with more statistical data is required in further study. In general, the proposed method is feasible and acceptable for the analysis of VOCs in human EBV.

4. Conclusion

In this work, a novel nanoporous anodic alumina fiber was prepared by a simple two-step anodization method. The prepared NPAA fiber features the characteristics of facile preparation, low cost, environment-friendly, thermal, chemical and mechanical stability and long lifetime. Moreover, the porous and ordered structure of the coating exhibits a large surface-to-volume ratio, which enables high extraction efficiency and fast mass transfer. The fiber was successfully applied for the extraction of eight VOCs in EBV samples of lung cancer patients and healthy people. The quantitative results indicate that the proposed method is rapid, sensitive and reliable and robust, it provides a potential tool for rapid detection of VOCs in human exhaled breath.

Adulteration
Melaminium bis(trichloroacetate) dihydrate
Trichloroacetic acid precipitation
Ethyl acetate extraction

ABSTRACT

A combination of a simple pretreatment for melamine extraction and direct analysis in electrospray ionization tandem mass spectrometry (ESI–MS/MS) is proposed. Three pretreatments were evaluated. The first was based on suppressing interference using acetonitrile. The second used sulphuric acid and trichloroacetic acid to suppress interference and for melamine extraction, respectively. The third used sulphuric acid to suppress milk interference, trichloroacetic acid for melamine precipitation, and ethyl acetate for melamine extraction. However, only the last pretreatment suppressed milk interference in melamine detection and a good linearity (R^2=0.99) was obtained. The presence of MS/MS 85 on melamine fragmentation spectrum showed the selectivity of this method. The limit of detection and limit of quantification were 0.269 μg L^{-1} and 0.897 μg L^{-1}, respectively. The recoveries and relative standard deviation (RDS) of method were lower than 114% and 7.86%, respectively. Further, the research was extended to elucidate the nature of the melamine in the extract through infrared spectroscopy and microscopy analyses. The precipitate was characterized as melaminium bis(trichloroacetate) dihydrate, which is generated through hydrogen bound formation in an interaction between melamine and trichloroacetic acid. Therefore, a simple, fast, and easy method for melamine extraction and direct ESI–MS/MS analysis was developed.

1. Introduction

Milk is a complete food and source of essential nutrients, including carbohydrate, protein, fatty acids, calcium, phosphorus and magnesium. Moreover, the milk constituents can affect dairy products performance and quality; therefore, the industries usually define milk quality based on the nutrient levels, mainly protein and fat. These parameters have been used to calculate the payout to the supplier [1]. Unfortunately, adding nonauthentic nutrients has been used to adulterate milk and, consequently, increase economic gain [2].

This adulteration is defined as the removal or replacement of milk components and addition of substances without a purchaser's knowledge, including water, whey, sucrose, starch, salt, sodium hydroxide, and formaldehyde [2,3]. Melamine is a nitrogen-rich compound commonly used to manufacture plastics, laminates, glues and adhesives [4]. Although it is not an ingredient in food, it was reported as present in Chinese powdered milk and infant formula in 2008. It was used to falsely increase the apparent milk protein and was not discovered because the routinely used methods could not distinguish between nitrogen from protein and non-protein sources, which resulted in incorrectly high protein measurements [5]. Consuming tainted products by the Chinese population affected 294,000 infants and children with more than 50,000 hospitalizations and at least 6 deaths [6]. This scandal scared the world and created the need for sensitive, specific, rapid, and reliable screening methods.

The Food and Drug Administration (FDA) from the United States of America (USA) established a liquid chromatography–mass spectrometry (LC–MS/MS) method to detect melamine in infant formula. This technique is accurate, but it is time consuming and requires hazardous solvent [7,8]. Many researchers have reported analytical methods for melamine detection and quantification, such as gas chromatography-single quadrupole mass spectrometry [9], a spectrophometric method [10], liquid chromatography tandem mass spectrometry [1,4,11–14], and an enzyme-linked immunosorbent assay [7]. However, these most available methods are time-consuming,

labor-intensive and expensive. Therefore, to simplify the sample preparation and improve the methods for detecting melamine, it is important to monitor contamination and prevent damage to consumer health.

Recent advances in ambient ionization mass spectrometry facilitate direct, rapid, real-time, and high-throughput analyses with little or no sample pretreatment [19,20]; it has been used to characterize food and identify adulterants, and authors report it as a reliable method [21,22]. In this paper, we proposed a simple and rapid sample preparation to detect melamine in powdered milk using electrospray ionization tandem mass spectrometry (ESI–MS/MS). Further, the research was extended to infrared spectroscopy and microscopy analyses to identify the nature of the precipitate formed during extraction.

2. Material and methods

2.1. Sample and reagents

Powdered milk was prepared from pasteurized milk (Grain Lait, Perdões, Brazil; high temperature short time [HTST]). Melamine was obtained from Sigma (St. Louis, USA) with chemical purity of greater than 98% and dissolved in Milli-Q purified water.

2.2. Powdered milk preparation

Triplicates of powdered milk were produced from pasteurized milk concentrated in a rotary evaporator (70 °C, TE-0581, TE-210, Tecnal, Piracicaba, Brasil) until the concentration of 52% of total solids; thereafter, the concentrate was dried in mini spray dryer (MSD 1.0, Labmaq, Ribeirão Preto, Brasil). The temperature for the inward and outward drying air was 160 and 100 °C, respectively, and the feed flow rate was 0.79 L h^{-1} in system with dual fluid nozzle atomization.

2.3. Melamine-added milk standards

Melamine stock solutions (500 mg L^{-1}) were prepared by dissolving melamine in water. The powdered milk was diluted in water and contaminated with melamine at different concentrations (0, 2.5, 5, 10, 15 and 20 mg L^{-1}).

2.4. Melamine extraction

Three extraction procedures were evaluated. The first pretreatment was performed in accordance with the methodology described by Desmarchelier et al. [12]. The powdered milk (1 g) and melamine aliquots were placed into a falcon polypropylene tube that was mixed and allowed to stand for 10 min. The water (5 mL) and acetonitrile (5 mL) were added successively, and the resulting slurry was thoroughly mixed after each solvent was added. The slurry was further diluted with acetonitrile (30 mL) and water (10 mL) and placed onto an automated shaker for 5 min. The tube was then centrifuged at 4000*g* at room temperature for 10 min (Centrifuge, Beckman, GS-15R), and the liquid supernatant was used for direct injection into ESI–MS/MS.

The second pretreatment was performed by adjust to pH 4.6 with 2 mol L^{-1} sulphuric acid (pHmeter, Quimis, Q400AS); thereafter, the samples were filtered. The filtered aliquot (5 mL) was added to 24% trichloroacetic acid (5 mL) and left to stand for 15 min. The mixture was filtered and the permeate was divided in two parts. The first aliquot of extract was used for injection into ESI–MS/MS. The remaining portion (4 mL) was added to ethyl acetate (4 mL) followed by stirring (Vortex, Phoenix-AP56); thereafter, the supernatant was used for direct injection into ESI–MS/MS (the third pretreatment sample). The extraction steps are described in Fig. 1.

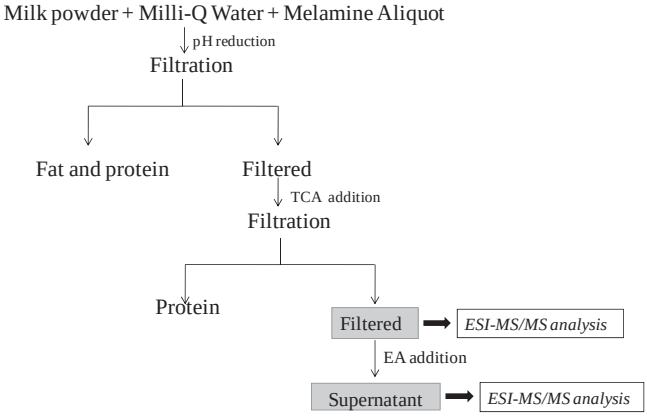

Fig. 1. The second and third pretreatment steps for powdered milk. TCA—trichloroacetic acid; EA—ethyl acetate; ESI–MS/MS—electrospray ionization tandem mass spectrometry.

2.5. ESI–MS/MS analysis

An aliquot of formic acid was added to yield 0.1% as the final concentration in the extract. Sample introduction was performed by using a micro syringe at a flow rate of 10 μL min^{-1}. To avoid cross-interference between samples, HPLC-grade methanol (Merck, Brasil) was injected between each infusion.

ESI–MS/MS analyses were performed using Agilent 1100 Series LC/MSD trap equipment in positive ion mode to identify the melamine. The spectra were obtained through 50 scans at 0.2 s intervals. The MS parameters were as follows: heat capillary temperature 350 °C, dry gas flow 6 L min^{-1}, nebulizer pressure 15 psi, and capillary voltage −3.5 kV. Mass spectra were acquired and accumulated over 60 s.

2.6. Method performance

The linearity (R^2) was evaluated from three calibration curves with six levels of melamine concentrations in powdered milk [23].

The limit of detection (LOD) and limit of quantitation (LOQ) were detected on blank samples ($n=10$) and calculated by Eqs. (1) and (2), respectively:

$$\mathrm{LOD} = 3\frac{sb}{b} \quad (1)$$

$$\mathrm{LOQ} = \frac{10sb}{b} \quad (2)$$

where *sb* is the standard deviation of the areas of the blank samples in mass spectrum, and *b* is the slope of the calibration curve [23]. The recovery and accuracy (%) were calculated according to Eq. (3), using blank matrices spiked with melamine at two fortification levels (8 mg L^{-1}; 12 mg L^{-1}).

$$R(\%) = \frac{(C_1 - C_2)}{C_3} \times 100 \quad (3)$$

where C_1 is the melamine concentration determined in adulterated milk, C_2 is the melamine concentration determined in blank sample, and C_3 is the concentration added [24]. The precision was calculated by the relative standard deviation (Eq. (4)).

$$\mathrm{RSD} = \frac{s}{x} \times 100 \quad (4)$$

where *s* is the standard deviation of replicate, and *x* is the mean of replicate. The selectivity was evaluated by the presence of melamine fragment MS/MS 85 [24].

2.7. Infrared spectroscopy analysis

The infrared spectra were recorded on a Shimadzu FT-IR Prestige 21 spectrometer. The melamine (500 mg L^{-1}) and trichloroacetic acid (24%) solutions were in a 1:1 ratio. The precipitate (2 mg) was dried and mixed with potassium bromide powder (200 mg) and pressed to form a thin, transparent disk. Infrared absorption spectra within the range 4000–400 cm^{-1} at a 2 cm^{-1} resolution using 32 scans were recorded at room temperature.

2.8. Optical and electronic microscopy analysis

The melamine (500 mg L^{-1}) and trichloroacetic acid (24%) solutions were at a 1:1 ratio, and the crystals images were obtained using optical microscopy (Meiji ML 5000, Meiji Techno América, Santa Clara, USA) coupled with a camera (Cle-Palmer 49901-35, Cole-Palmer, Vernon Hills, USA).

The melamine (15 mg L^{-1}) and trichloroacetic acid (24%) solutions were at a 1:1 ratio, and 60 µL of this mixture was added to a blade, to which Poli-L-Lisin was previously added. After 30 min, the Karnovsky solution was added until the blade was covered and stored at 8 °C over 3 h. The sample was washed with cocodilato buffer (0.05 M) three times over 10 min and washed with water three times. Then, the dehydration process began by adding 25, 50, 75, 90% acetone over 10 min then three times in 100% acetone for 10 min each, followed by drying in a critical point dryer. The sample was placed in the gold bath then observed in microscope (LEO Evo 040).

3. Results and discussion

3.1. Melamine extraction and detection

Melamine, 1,3,5-triazine-2,4,6-triamine, has 126.1 Da molecular mass. Detection of this compound in milk can be affected by matrix interference because powdered milk has a compound with similar molecular mass, namely 5-hydroxymethylfurfural (HMF), which has a 126.1 Da molecular mass. HMF is a natural compound formed when milk is heated; its ESI–MS spectrum is characterized by the presence of the *m*/*z* 127.1 [21]. However, HMF fragmentation produces the MS/MS fragments 109, 84, and 71, whereas protonated melamine generated ions with *m*/*z* 110, 85, and 60, showing that fragmentation can be used to differentiate these compounds [25].

To analyse the melamine in powdered milk samples and suppress matrix interference, extraction procedures were performed. First, the extraction procedure by Desmarchelier et al. [12] was performed for samples spiked with melamine. The mass spectrum for this extract is presented in Fig. 2.

The mass spectrum presented a number of *m*/*z* signals related to the presence of disaccharide from milk. Lactose is the main carbohydrate in milk and could be identified by two peaks in the spectrum. The signal detected at *m*/*z* 381 and 365 were generated from lactose association with sodium and potassium, respectively. However, the low 127.1 signal hampers the fragmentation, which does not show whether this signal is from melamine or HMF, indicating that the high lactose signal disrupts the detection; this occurred at all concentrations evaluated. The additional ions in the spectrum arose from the other powdered milk components.

Desmarchelier et al. [12] successfully used this method to detect melamine through liquid chromatography, which separates matrix components from melamine and, consequently, suppresses matrix interferences. On the other hand, ESI–MS/MS does not provide proper separation, which favours matrix effects during melamine detection.

To assess melamine in powdered milk through ESI–MS/MS by suppressing milk interference, another pretreatment procedure was evaluated, which was based on eliminating milk interference; this procedure was performed in two steps. The first step consisted of eliminating the insoluble protein and fat. The decrease in pH for milk from 6.6 to 4.6 promoted protein precipitation; and filtering this mixture formed an extract without casein micelles and fat. The fat was eliminated based on the solubility difference from the extract, and the insoluble protein was eliminated based on the characteristic isoelectric points at pH 4.6 [26]. In the second step, the trichloroacetic acid reacted with melamine to form a precipitate; thereafter, it was filtered to eliminate the soluble protein and directly injection into the ESI–MS/MS. The mass spectrum for this extract is shown in Fig. 3.

Melamine detection is affected by interference from milk compounds, mainly the ions from lactose and mineral interactions. The *m*/*z* 127.1 has a small intensity, which limited the fragmentation and distinction between melamine and HMF, showing that this pretreatment was not efficient to suppress the interference. Many authors have reported interference by the milk matrix during melamine detection. Ibáñez, Sancho and Hernández [27] reported that the matrix interference affected melamine detection in mass spectrometry. Xia et al. [28] reported that the matrix affected melamine determination even using hydrophilic interaction liquid

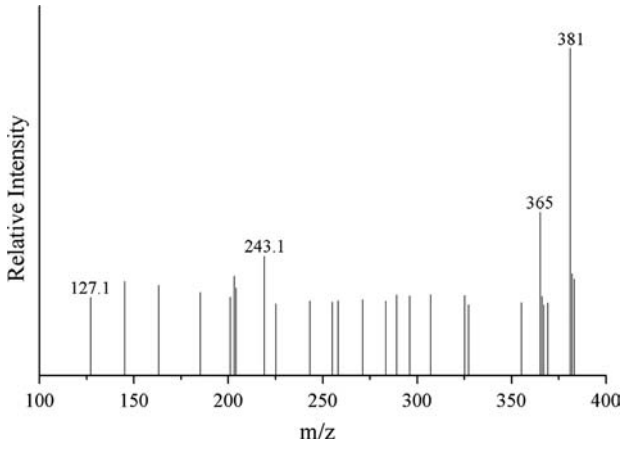

Fig. 2. The mass spectrum for the melamine extract obtained according Desmarchelier et al. [12]. The sample includes 15 mg L^{-1} of melamine, and the peaks show the *m*/*z* 381 $[Lactose+Na]^+$ and *m*/*z* 365 $[Lactose+K]^+$.

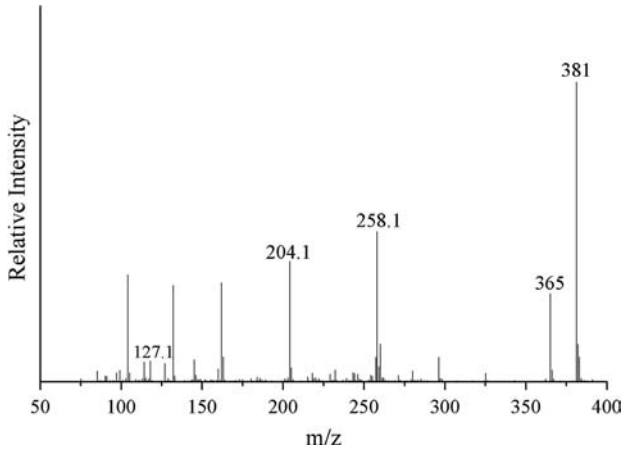

Fig. 3. The mass spectrum for the extract obtained by precipitating melamine using trichloroacetic acid (samples with 15 mg L^{-1} of melamine). *m*/*z* 381 $[Lactose+Na]^+$; *m*/*z* 365 $[Lactose+K]^+$.

chromatography coupled to ESI–MS. He et al. [4] observed that the melamine signal was suppressed by milk compounds. Gonzalez-Antuña et al. [29] described how the matrix interferes with the mass spectrometry, showing that the competition between matrix analyte compounds and modifying the physical properties of the droplets can affect analysis efficiency.

Nevertheless, different solvents have been used to clean the sample for melamine detection, including acetonitrile, methanol, diethyl ether, and dichloromethane [1,9,13,14,30–34]. Thus, an additional step in the extraction procedure was performed to suppress the matrix interference. The sample was prepared over three steps; the first consisted of suppressing the insoluble protein and fat followed by melamine precipitation and ethyl acetate addition to the melamine extract. Thereafter, the supernatant was injected into an ESI–MS/MS, and the results were shown in Figs. 4 and 5.

This extract produced a mass spectrum with high intensity for the *m/z* 127.1 (Fig. 4), which favoured fragmentation (MS/MS) (Fig. 5). As expected for the milk sample spiked with melamine, the fragmentation of *m/z* 127.1 confirms the presence of melamine through identification of the MS/MS 85.2 peak, which is produced through loss of the N_2CH_2 group [12]. Moreover, the MS/MS 99 is formed by ionization of $C_2N_5H_5^+$ which is produced by HNC elimination [35].

Many authors have reported melamine detection in milk and its discrimination from HMF in milk. Yang et al. [25] showed interference by HMF in melamine detection and proposed that the fragment MS/MS 85 can be used to exclude false positive signals. Dane and Cody [21] reported that the low levels of melamine may be difficult to identify in the presence of HMF. Chen and Yan [36] used capillary electrophoresis coupled with diode array detection to differentiate melamine from HMF and demonstrated melamine detection.

In addition, a calibration curve was obtained using five concentrations of milk contaminated with melamine. The response range was discerned, and the calibration curve is represented by the equation shown in Fig. 6.

A linear relationship was observed between the melamine concentration and absolute mass spectral intensity of ion 127, which indicated that the ESI–MS/MS can be efficiently used for melamine detection.

The LOD and LOQ were 0.269 μg L^{-1} and 0.897 μg L^{-1} respectively, showing that the third extraction can be successfully applied to detect and quantify melamine in powdered milk with a limit below 1 μg L^{-1}. The accuracy of this method was found by melamine addition in milk and quantitative analysis, showing

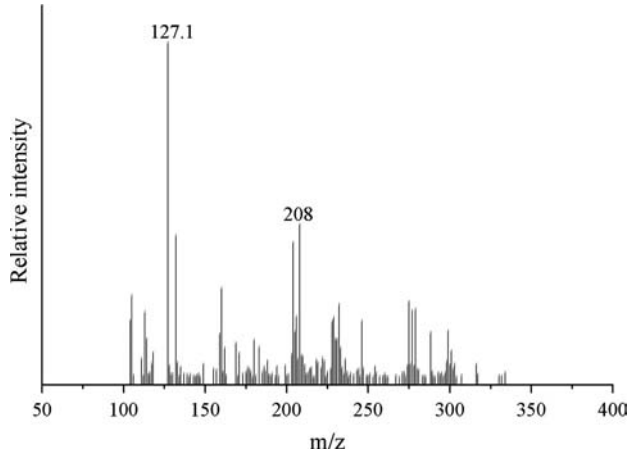

Fig. 4. The mass spectrum for the extract obtained by melamine precipitation with trichloroacetic acid and solubilized in ethyl acetate (sample with 15 mg L^{-1} of melamine) as well as *m/z* 127.1 fragmentation.

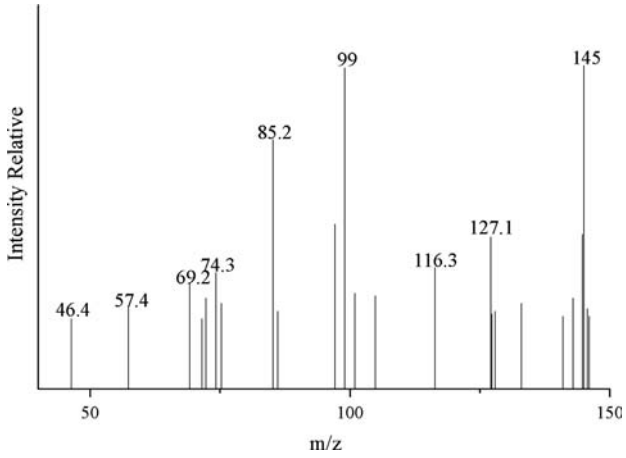

Fig. 5. Mass spectrum of *m/z* 127.1 fragmentation for the extract obtained by the third extraction technique (powdered milk contaminated with 15 mg L^{-1} of melamine).

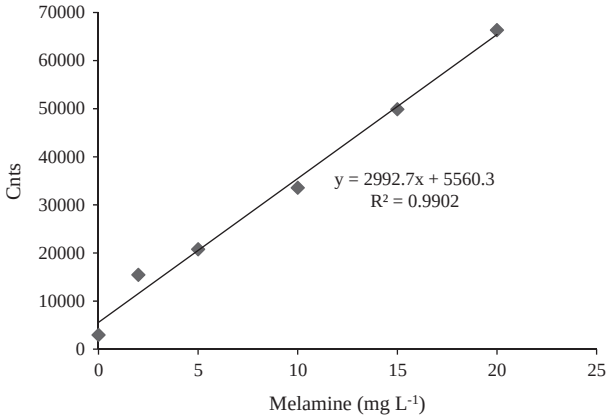

Fig. 6. The relationship between mass intensity and melamine concentration.

acceptable recovery (109 and 114%). Thus, the satisfactory data was obtained, showing the accuracy of the method developed. Cao et al. [7] reported recovery rates of 72.8–123% for melamine detection using enzyme-linked immunosorbent assay (ELISA). Yang et al. [25] using surface desorption atmospheric pressure chemical ionization to detect melamine in milk products showed 97–113% of recovery.

The method precision was lower than 7.86%, showing it can be used to detect melamine in powdered milk. Thus, the extraction followed by ESI–MS/MS is a precise and accurate method to detect melamine in powdered milk. Ibáñez et al. [27] using LC–MS/MS showed good precision (RSD < 5%) for melamine detection and reported that the RSD < 20% is acceptable. Cao et al. [7] showed that the precision of ELISA method was lower than 18.9%. Yang et al. [25] reported that the precision of surface desorption atmospheric pressure chemical ionization mass spectrometry to detect melamine was lower than 11.9%.

The presence of MS/MS 85 on melamine fragmentation spectrum (Fig. 5) showed that the method can remove the interference of milk compounds [12]. These results show that melamine could be simply and rapidly detected by ESI–MS/MS. It can be concluded that the method had a good precision and accuracy for melamine detection.

Many authors reported different methods to detect melamine and showed the sensibility of these, although most of than are time-consuming, labor-intensive and expensive [4,7,13,14,27,28,32,33]. In this sense, the developed method is a promising technique to melamine detection since it is sensitive, simple and practical. In

addition, this method does not require a long extraction procedure and can be applied in routine analysis of powdered milk.

3.2. The nature of the melamine in the extract

Melamine precipitation was based on a reaction with trichloroacetic acid, which forms of melamine salt crystals. The interaction between melamine and trichloroacetic acid facilitates crystal formation, and this complexation adds an interesting aspect to the intramolecular hydrogen bond (HB) system formed [37–41]. Thus, to investigate the nature of the precipitate, infrared spectroscopy was employed. The infrared spectrum of melamine and precipitate were shown in Fig. 7.

The melamine N–H stretching vibrations absorb in an interference-free region (3500–3300 cm^{-1}) of the infrared spectrum; thus, they are suitable bands for HB assignment. The presence of HB moves the N–H stretching band to a lower wavenumber due to a weaker of N–H bond. The strong peak at 3419 cm^{-1} (melamine spectrum) is attributed to NH_2 symmetric stretching (ν_{sym}), which was shifted to 3414 cm^{-1} in the melaminium salt, as observed by Kanagathara et al. [42], while asymmetric stretching (ν_{asym}=3470 cm^{-1}) did not change the wavenumber. In addition, the side chain C–N stretching [39], which occurs at 1439 cm^{-1} is shifted to 1335 cm^{-1}, which provides insight into the presence of HB during formation of the precipitate, melaminium bis (trichloroacetate) dihydrate, as reported by Perpétuo and Janczak [43] and Kanagathara et al. [42]. The melamine salt crystals are shown in Fig. 8.

The melaminium bis(trichloroacetate) dihydrate crystal was detected using different microscopy techniques, which demonstrated the characteristic structure of the salt formed during the second sample pretreatment step, which consists of adding trichloroacetic acid and a reaction with melamine. However, Kanagathara et al. [42] reported a different morphology, which can be explained by the using of trichloroacetic acid at a different concentration.

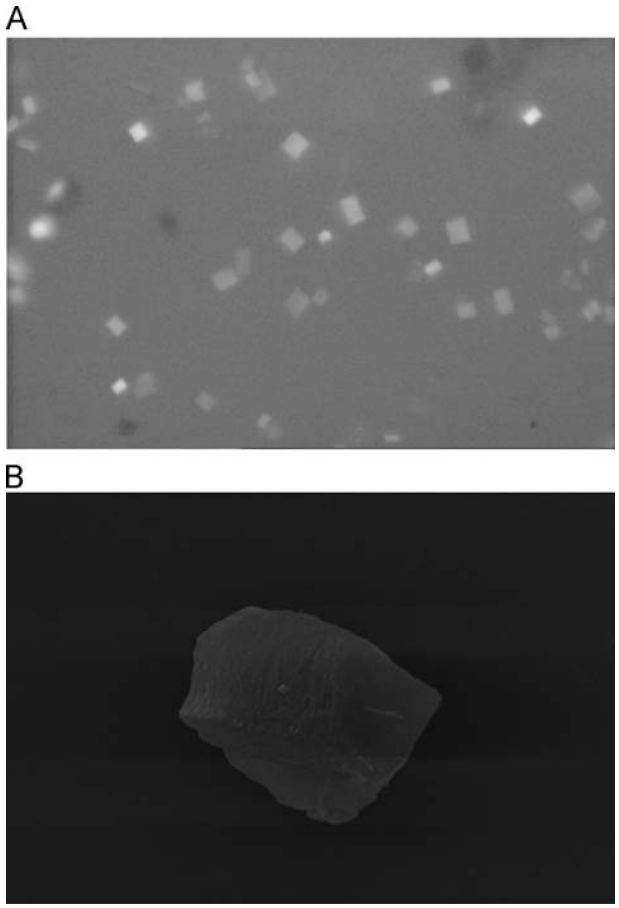

Fig. 8. A melaminium bis(trichloroacetate) dihydrate crystal observed using optical microscopy (A) (500 mg L^{-1} of melamine) and electronic (B) microscopy (15 mg L^{-1} of melamine).

4. Conclusion

The first and second pretreatments were based on melamine extraction using acetonitrile and trichloroacetic acid, respectively. However, these techniques did not efficiently suppress milk interference for melamine detection.

For the third pretreatment sulphuric acid was used to suppress protein and fat, and trichloroacetic acid and ethyl acetate were used for melamine precipitation and extraction, respectively. The ESI–MS/MS analysis showed that the matrix interference was removed, and a linear correlation was observed between the melamine concentration and the mass spectrometry results, showing that the adulteration can be detected and quantified. The recovery and precision were accepted. The LOD and LOQ were below than 1 μg L^{-1}.

The protocol for melamine extraction was based on melaminium bis(trichloroacetate) dihydrate formation by trichloroacetic acid addition and solubilization with ethyl acetate, which was not previously reported; and we showed that it as a simple, fast, and easy method for melamine extraction from powdered milk and direct ESI–MS/MS analysis. Future studies could use this extract for additional analytical methods to extend the sample pretreatment application.

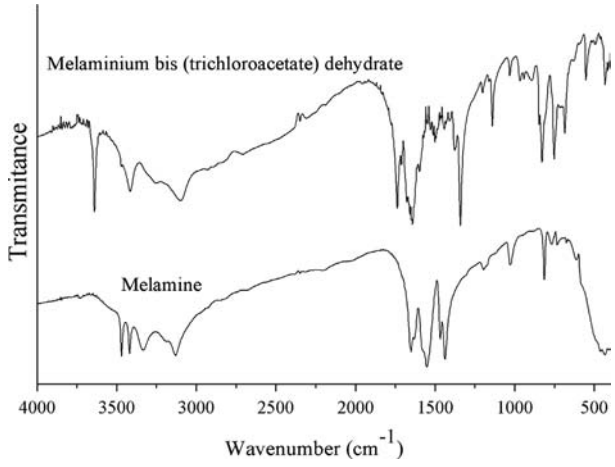

Fig. 7. The near infrared spectrum for melamine and its precipitate using trichloroacetic acid.

Benfield sample
Artificial sample

ABSTRACT

Vanadium(IV) and vanadium(V) can be determined by using differential pulse cathodic stripping voltammetry technique (DPCSV). Cupferron (ammonium *N*-nitrosophenylhydroxylamine) was used as ligand to form complex compounds with vanadium ions in Britton–Robinson buffer (BRB) solution. At concentration lower than 1.0×10^{-6} M, both V(IV) and V(V) cupferron complexes showed a single cathodic peak at −0.576 V in BRB of pH 4; thus V(IV) and V(V) ions cannot be differentiated at low concentration. However, the ionic species of vanadium can be differentiated at high concentration in the presence of cupferron. Parameters including pH of BRB solution, initial potential and accumulation potential were optimized. Under the optimized parameters, the limit of detection (LOD) was 0.09 nM, and the peak current was linear in the concentration range 0.01–0.9 μM total vanadium ions. The determination of V(IV) and V(V) ions was carried out at higher concentration in the sample using calibration plot method. At higher concentration range of 10–60 μM V(IV) and V(V) ions were determined with LOD of 1.2 and 1.1 μM, respectively. The developed method was successfully applied to 10,00,000 fold diluted Benfield sample and 0.6227 M total vanadium ions were determined. The determination of V(IV) and V(V) ions were also successfully carried out in artificial sample as well as Benfield sample (dilution factor, 10,000). The concentration of V(IV) and V(V) ions was 22.52 μM and 38.91 μM, respectively, giving total vanadium concentration of 0.6143 M in Benfield sample.

1. Introduction

Vanadium(V) is widely used and released into environment from various industrial processes [1]. Natural sources like weathering of soil, marine aerosols and volcanic emissions also contribute their concentration to the atmosphere. Vanadium exists unbound in nature. Various vanadium ores are known but none is mined as such for the metal and generally; vanadium is obtained as byproducts of other ores. Vanadium has been identified in the sun, stars, meteorites, variety of plants and animals [2]. The majority of vanadium release in the atmosphere results from human activity, particularly by the combustion of oil and coal and as by-product of petroleum refining. Vanadium enters water bodies from deposition of airborne particulates, weathering of vanadium rich soils, and direct dumping. Most of the vanadium in aquatic systems is natural and result of soil runoff [3].

The toxicity of vanadium depends on its physico-chemical state; particularly on its valence state and solubility. Pentavalent V_2O_5 has been reported more toxic as compared to trivalent V_2O_3. Vanadium compounds are poorly absorbed through the gastrointestinal system. Inhalation exposures to vanadium and vanadium compounds result primarily in adverse effects to the respiratory system. Quantitative data are, however, insufficient to derive a sub-chronic or chronic inhalation. There is little evidence that vanadium or its compounds are reproductive toxins or teratogens. There is also no evidence that any vanadium compound is carcinogenic [4].

The analytical methods most often used to determine vanadium in environmental samples are; high performance liquid chromatography (HPLC) [5–7], ion chromatography hyphenated with inductively coupled plasma-optical emission spectrometry (ICHICP-OES)

[8], atomic absorption spectrometry (AAS) [9,10], spectrofluorimetry [11], atomic emission spectrometry (AES) [12], adsorptive stripping voltammetry (AdSV) with different complexing agents, such as alizarin violet [13], cupferron [14,15], gallic acid/catechol [16] chloranilic acid [17], catalytic effects [18–20] and differential pulse polarography (DPP) [21,22]. Cathodic stripping voltammetry (CSV) has wide range of applications in the determination of metal ions [23,24], organic species [25] and complexes [26].

The main aim of the undertaken study was to develop novel, robust, highly sensitive and selective method for the quantitative determination vanadium ions and to apply the developed method to Benfield sample solutions. Artificial samples were also screened for respective vanadium ions by the currently developed method.

2. Experimental

2.1. Instrumentation and chemicals

Trace analyzer of Metrohm, Autolab with GPES 4.9.005 software has been used for the determination of vanadium(IV) and vanadium(V) ions. The electrochemical cell comprised of Hanging Mercury Drop Electrode (HMDE) as working electrode, Ag/AgCl 3 M KCl_{sat} as reference electrode and Platinum as auxiliary electrode. Cyber Scan 500 pH meter was used for pH measurements. All chemicals; vanadium(IV) oxide sulfate hydrate, ammonium metavanadate, cupferron, boric acid, *ortho* phosphoric acid, sulphuric acid, hydrochloric acid, sodium hydroxide and glacial acetic acid were of analytical grade and purchased from Merck (Germany). Britton–Robinson buffer solution was prepared by dissolving 2.47 g of boric acid in 200 mL deionized water. 2.3 mL of glacial acetic acid and 2.7 mL of *ortho* phosphoric acid were added into the boric acid solution. The mixture was transferred into 1 L volumetric flask and deionized water was added up to the calibration mark. The pH range of buffer from 2–12 was adjusted and maintained with 2 M NaOH and 2 M HCl.

2.2. Methodology

100 μL standard solution of analyte (vanadium ions) in 20 mL BRB solution was taken into the voltammetric cell. The solution in the cell was also treated with sufficient amount of pH adjuster so that we get a pH 4.0 at the end. Nitrogen gas was purged through the solution for 5 min to create an inert gas atmosphere inside the cell and in order to remove the dissolved oxygen from the analyte solution. During pretreatment and accumulation process for 30 s, the solution was stirred at 0 V initial potential. After accumulation for 30 s, stirring was stopped and solution was equilibrated for 2 s used as a quiescent time. Then, the solution was scanned at 200 mV/s and voltammograms were recorded via current-potential measurement using DPCSV electrochemical technique. Similar procedure was employed for standard solutions of V(IV) and V(V) ions. Sensitivity, reproducibility and linearity of response were checked by addition of standard solutions and triplicate analyses.

2.3. Determination of vanadium in Benfield sample solution

In the experiment, a few microliter of Benfield sample mixed with BRB and required amount of cupferron was added into voltammetric cell and scanned. Sample dilution is needed if the voltammograms of vanadium–cupferron complexes are out of range. Such problem may also be caused by high content of carbonate ions in sample or if the sample is too concentrated. If content of carbonate ion is too high, dilution of sample should be done by adding a few microliter of 1.0 M sulphuric acid into sample based on the ratio needed. The pH was adjusted to 4.0 ± 0.1 with 2 M NaOH solution. The rest of the voltammetric procedure is same as true in case of standard vanadium solution. Nearly similar protocol was followed in case of vanadiumV(IV) and V(V) ions determination via developed voltammetric method.

3. Results and discussion

3.1. Effect of pH

Buffer solutions were used as electrolytes to enhance the conductivity, avoid the current shifting and allow the metal ions adsorption on the surface of electrode [27,28]. Due to the limitation of Britton–Robinson buffer solution, HCl and NaOH were used for pH adjustment. The pH range from 2-12 was optimized (Table 1 and Figs. 1–3).

Based on Table 1, the V(IV) ions did not show any peak current after addition of 100 μL of 0.1 mM V(IV). The peak current was found to increase with increasing the cupferron concentration for each pH. As the concentration of cupferron was increased to 50 μM the current increased drastically. Peak current increased from pH 2 to pH 4 and decreased at pH 5. The peak potential shifted towards more negative value i.e. from −0.463 V to −0.601 V. Table 1 also shows the effect of pH on peak shifting. The range of peak potential was found between −0.538 V and −0.626 V. pH 4 gave maximum peak current (592 nA) at peak potential (−0.588 V).

Low peak current values (7–10 nA) were obtained for pH 10 to pH 12 while no peak was recorded at pH 13. Maximum peak current values for both V(IV) and V(V) ions were obtained at pH 4.

Table 1
Effect of pH on peak current values for vanadium ions.

pH	Cupferron (μM)	0.5 μM [V(IV) and V(V)] without cupferron		0.5 μM V(IV) with cupferron		0.5 μM V(V) with cupferron

Peak potential = *E* (V), peak current = *I* (nA).

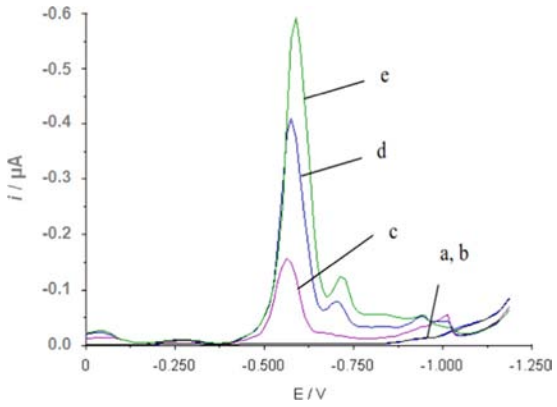

Fig. 1. Voltammogram of vanadium(IV) ions; pH 4; (a) 20 mL of 0.04 M BRB as supporting electrolyte; (b) 100 µL V(IV); (c) 100 µL V(IV)+20 µL cupferron; (d) 100 µL V(IV)+60 µL cupferron, (e) 100 µL V(IV)+100 µL cupferron. E_i=0 mV, E_{acc}=0 mV, t_{acc}=30 s, scan rate=200 mV/s, concentration of BRB=0.04 M; V(IV) ions=0.0001 M, concentration of cupferron=0.01 M.

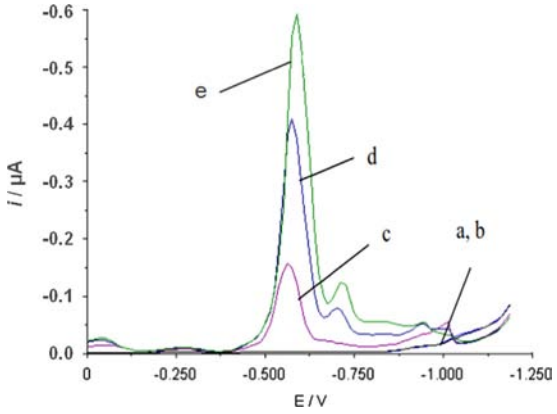

Fig. 2. Voltammogram of V(V) ions at pH 4 with BRB 0.04 M as supporting electrolyte. (a) 20 mL BRB pH 4, (b) 100 µL V(V), (c) 100 µL V(V)+20 µL cupferron, (d) 100 µL V(V)+60 µL cupferron, (e) 100 µL V(V)+100 µL cupferron. E_i=0 mV, E_{acc}=0 mV, t_{acc}=30 s, scan rate=200 mV/s, concentration of V(V) ions=0.0001 M, concentration of cupferron=0.01 M.

The overall peak potential was proportional to pH and shifted towards negative value.

The shape and pattern of voltammograms at different pH values were almost same. However, peak current values at pH 2–pH 5 were higher than pH 6–pH 12. It is evident from Table 1 that peak current decreases with shift of pH from acidic to basic medium. The lower peak current values may be due to the formation of unstable complexes.

3.2. Comparison of electrochemical results obtained for V(IV) and V(V) ions

The shifting of peak potential and variations in magnitude of peak current are highly sensitive to pH change. Fig. 3(a) and (b) show voltammograms for V(IV) cupferron and V(V) cupferron complexes at pH 3 to pH 12, respectively. Fig. 3(a) and (b) show that pH 4 is the optimum parameter, which generates maximum peak currents −592.6 nA and −575.2 nA for both V(IV) and V (V) complexes, respectively. The corresponding peak potential values −0.588 V and −0.601 V were true for V(IV) and V(V), respectively.

It is evident from Fig. 3(c) that variations in pH and application of 0.04 M BRB as supporting electrolyte greatly affect the magnitude of peak currents. The magnitude of peak current −592.6 nA for V(IV) ions is slightly higher than −575.2 nA for V(V) ions.

3.3. Effect of initial potential

Initial potential effect was optimized to get well-resolved and best-shaped voltammograms with maximum peak current values. Initial potential, E_i was used for cleaning the electrode's surface while accumulation potential, E_{acc} was used for the deposition of analyte on the electrode's surface. Electrode potentials control the deposition and stripping of analyte based on oxidation/reduction processes. Peak current is function of stripping process and its magnitude is the measure of analyte concentration [8]. The range of initial potentials from 0 mV to −900 mV was used to study the effect of initial potential for the determination of V(IV) and V(V) ions as shown in Fig. 4(a) and (b). The highest peak current values −28.22 nA at E_{peak}=−0.188 V with E_i=0 mV and −72.61 nA at E_{peak}=−0.963 with E_i=−200 mV were obtained for V(IV) and V (V) ions respectively.

The trend of the peak currents was decreased for the initial potential from −200 mV to −900 mV. Initial potential of −200 mV gave the highest peak current at −73.9 nA, whereas, the 0 mV initial potential gave the second high peak current at −72.61 nA. Since the difference between peak currents in case of -200 mV and 0 mV of initial potential was very small which is less than 1 nA, therefore, initial potential at 0 mV for V(V) ions can be chosen as optimum initial potential.

The range of accumulation potentials from 0 mV to −900 mV was also optimized to get maximum peak currents for the determination of V(IV) and V(V) ions (Fig. 5). The highest peak current values −28.63 nA at E_{acc}=0 mV and −75.5 nA at E_{acc}=0 mV were obtained for V(IV) and V(V) ions, respectively. While, the lowest peak current values −11.12 nA at E_{acc}=−900 mV and −16.58 nA at E_{acc}=−900 mV were obtained for V(IV) and V(V) ions, respectively. However, the trend of the accumulation potential effect for both V (IV) and V(V) ions was almost similar. The graph showed the decreasing of peak currents from 0 mV to −900 mV of accumulation potential for the determination of both V(IV) and V(V) ions. The peak currents obtained for V(V) ions were always greater than V(IV) ions. The maximum peak current values in both cases can be obtained at E_{acc}=0 mV.

3.4. Effect of cupferron concentration on peak current

Variable concentrations of cupferron (ligand) and vanadium species (analyte metal ions) were mixed and electrochemically scanned. The range of volumetric proportions was 20–100 µL while range of molar concentrations was 0.001–0.01 M in each analysis. The addition of V(IV) and V(V) ions into the voltammetric cell without cupferron did not show any voltammogram (peak current). However, after the addition of cupferron, peak currents were obtained (Table 2). In case of V(IV) ions, maximum peak currents for both concentrations (0.001 M and 0.01 M) of cupferron were obtained at E_{peak}=−0.576 V. In case of 0.01 M cupferron, peak currents −171.6 nA, −278.4 nA and −425.2 nA were obtained for 20 µL, 60 µL and 100 µL of cupferron, respectively. However, in case of 0.001 M cupferron, peak currents −10.81 nA, −66.94 nA and −109.5 nA were obtained for 20 µL, 60 µL and 100 µL of cupferron, respectively. Addition of 0.01 M cupferron gave higher results as compared to 0.001 M cupferron. The same trend and pattern of electrochemical results were observed for V (V) ions, (Table 2).

3.5. Analysis of vanadium ions in Benfield samples

The developed method was successfully applied to Benfield samples, which were collected from the oil and gas company in Terengganu, Malaysia. Calibration curves method was used to

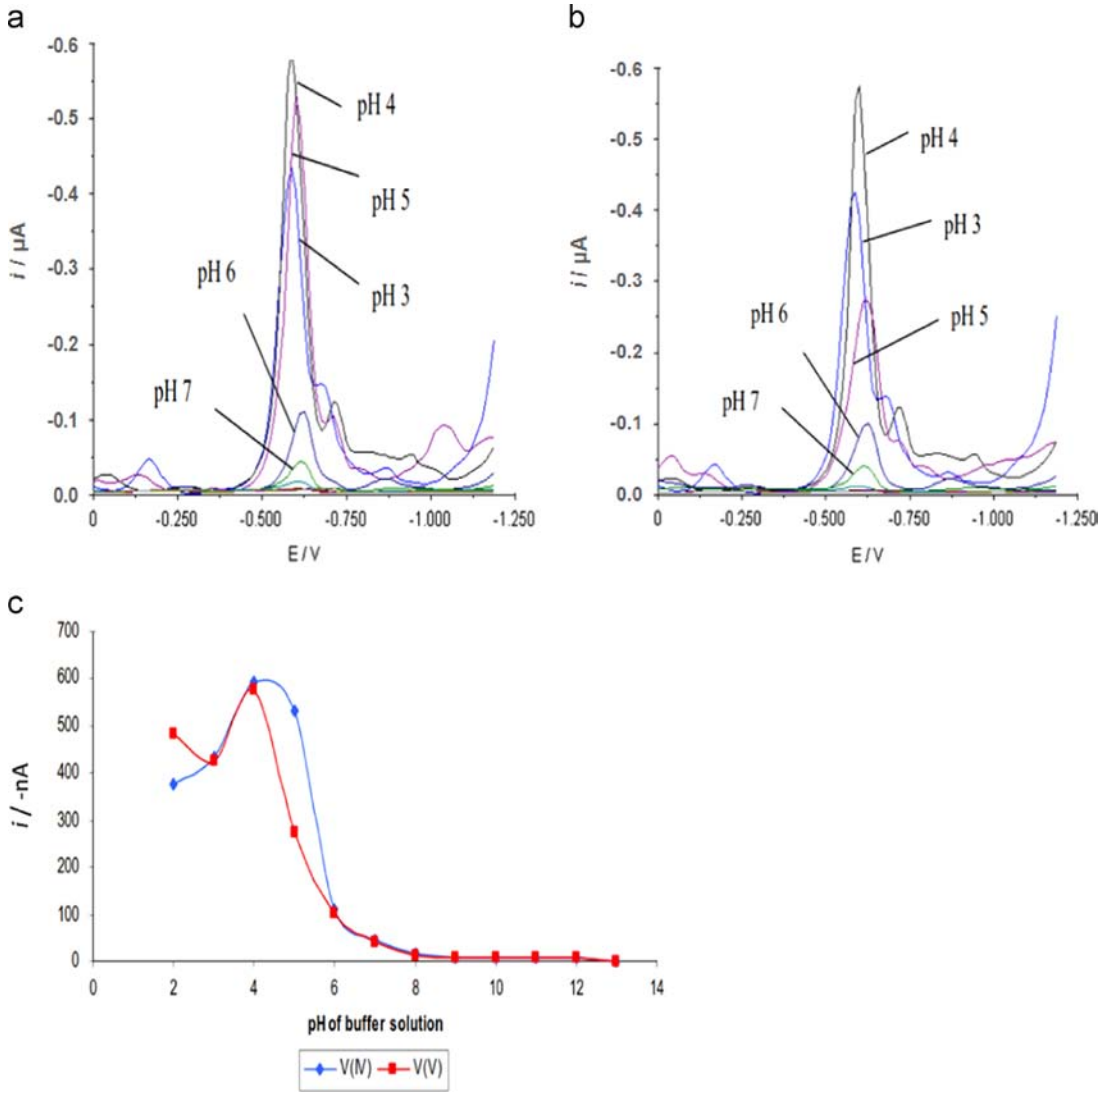

Fig. 3. (a and b) Voltammogram of peak currents for (a) V(IV) and (b) V(V) ions from pH to pH 12 with BRB 0.04 M as supporting electrolyte. E_i=0 mV, E_{acc}=0 mV, t_{acc}=30 s, scan rate=200 mV/s, concentration of V(IV) and V(V) ions=0.0001 M, concentration of cupferron=0.01 M. determine the unknown concentrations and LOD for vanadium ions.

Under the optimized parameters, the concentration range 0.01–0.9 μM of vanadium ions showed linear relationship to peak currents. The linear regression coefficient R^2=0.9858 and limit of detection 0.09 nM were calculated using calibration plot method, (Fig. 6). In each case, 100 μL of 5000 fold diluted Benfield sample (giving a total dilution factor of 10,00,000) was electrochemically scanned to determine the unknown concentration of vanadium ions. This gives a concentration of 6.227×10^{-7} M vanadium. Using the calibration equation and multiplication by dilution

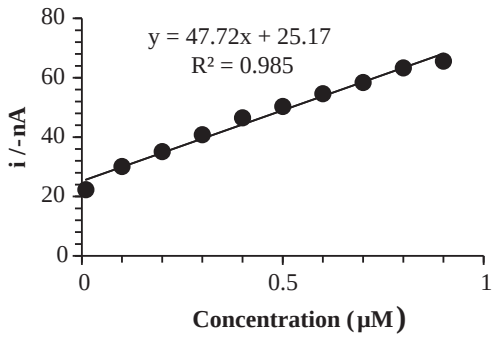

Fig. 6. Caliberation Plot; BRB 0.04 M at pH 4 as supporting electrolyte, E_i & E_{acc}=0 mV, t_{acc}=30 s, scan rate=200 mV/s, concentration range of vanadium ions, 0.01–0.9 μM, concentration of cupferron=0.001 M.

factor, concentrations of total vanadium ions in Benfield sample becomes 0.6227 M. The results of calibration plots were validated by using standard addition method which gave nearly same results. The amount of V(IV) and V(V) ions in Benfield sample was also carried out at higher concentration range in sample with low dilution of 10,000 (see below).

3.6. Calibration of V(IV) and V(V) at higher concentrations

The estimation of V(IV) and (V) ions were also achieved in the concentration range of 10–60 μM at under similar condition as true for calibration curve at lower range as mentioned in Section 3.5. It was noticed that the detection limit of in case of V(IV) was 1.2 μM and 1.1 μM in case of V(V) ions. Calibration plots are displayed in Figs. S1a and S1b (see Supplementary data). In order to verify the determination of V(IV) and V(V) ions by respective linear calibration plots, we analyzed these ions in an artificial sample with different concentration of ions as depicted in Table S1 of supplementary data file. The results show very close recovery among the added and determined values of these ions in the sample, which validate this method very well regarding the separation of V(IV) and V(V) ions in higher concentrations range. In addition we determined the concentration of V(IV) and V (V) ions in Benfield sample by taking 100 μL of 100 fold diluted (giving a total dilution factor of 10,000). The amount V(IV) ions came out to be 22.52 μM which is equal to a concentration of 0.2252 M V(IV) ions while amount of V(V) ions was 38.91 μM in diluted sample giving a total concentration of V(V) ions of 0.3891 M. By adding the amount of V(IV) and V(V) ions in the mixture a total amount of 0.6143 M vanadium is obtained which is nearly equal to total vanadium concentration of 0.6227 M as determined by calibration plot method at lower concentration in Section 3.5. This result further strengthens the validation of developed method.

3.7. Figure of merits

The presently developed voltammetric method in higher concentration ranges for determining V(IV) and V(V) ions was and total V(V) ions determination at lower concentration range was compared with several electrochemical methods for vanadium determination. Table 3 shows the comparison of data regarding the linear ranges of determination of vanadium ions and respective LODs with respect to our developed method shown in Refs. [17,21,32–37].

The data listed in Table 3 clearly indicates the superiority of our methods over the cited method especially in regards to separation and determination of V(IV) and V(V) as illustrated in Fig. S1a and b as well as in Table S1. In other words, this approach is a novel

Table 3

finding where the specific concentration of cupferron plays a crucial role in separation and determination of both the mentioned ions of vanadium. This strategy could be employed to estimate the respective ions of vanadium in other types of samples as well.

4. Conclusions

The differential pulse cathodic stripping voltammetry is the most sensitive voltammetric technique and used for trace level determinations. This technique was used in the determination of vanadium(IV) and vanadium(V) ions. The V(IV) and V(V) ions showed no peak at low concentration without cupferron (a complexing agent). High peak currents were produced when cupferron was added as a ligand. The optimum values of initial potential, final potential and accumulation time (t_{acc}) were 0 mV, −1.2 V and 30 s, respectively. The metal deposition on electrode's surface was held at 0 mV accumulation potential. The electronic structures of metals significantly affect the formation of complexes. Different ionic species of a metal have different affinity for a complexing ligand. When higher amounts of cupferron was added, more cupferron-vanadium complexes may be formed, which produce maximum peak currents. While, at lower amounts of cupferron, less formation of complex may occur, this gives small peak currents and makes it difficult to differentiate ionic species of vanadium. At higher concentration, cupferron may form different complexes with V (IV) and V(V) ions. The variations in the geometrical pattern and electrochemical behavior of these different complexes may affect the shifting of peak potential and magnitude of peak current for the respective ionic specie of vanadium. Hence, peak shifting and variation in the magnitude of peak currents cause the differentiation of V(IV) and V(V) ions. Comparatively, the developed method has high selectivity and sensitivity for vanadium ions. It is highly cost effective and easy in preparation of stable electrochemical cell set-up. In the undertaken study, the LOD was found to be 1.2 μM and 1.1 μM for V(IV) and V(V) ions in the higher range and 0.09 nM for total vanadium in lower range. Such findings highlight a clear edge of developed method over other method cited elsewhere [13,17,21,23,24,29–37].

ABSTRACT

A needle trap (NT) device filled with HF Bondesil-C18 as a sorbent material was evaluated for the dynamic headspace analysis of a family of nine synthetic musks compounds that include two nitro musks, six polycyclic musks (with galaxolide and tonalide as the most widespread used polycyclic musks) and the degradation product of galaxolide (galaxolidone) in wastewater samples. Different parameters affecting the adsorption capacity of the sorbent were studied (e.g. extraction mode, extraction temperature, salt concentration, preincubation time fill and ejection speed or fill volume). Furthermore, injection parameters used with the NT device (e.g. desorption mode, desorption temperature and time) were evaluated to optimize the desorption and transfer of the target compounds into the GC column. Method detection limits obtained with gas chromatography–tandem mass spectrometry (GC–MS/MS) detection were found in the low ng L^{-1} range, between 2.5 and 10 ng L^{-1}, depending on the target compounds. Moreover, under optimized conditions, the method gave good levels of intra-day and inter-day repeatabilities in wastewater samples with relative standard deviations ($n=5$, 100 ng L^{-1}) less than 11 and 17%, respectively. The developed method was satisfactorily applied to the analysis of aqueous samples obtained from three wastewater treatment plants. All the polycyclic musks studied were detected in influent samples with cashmeran, galaxolide and tonalide as the most representative compounds. The analysis of effluent wastewater showed a decrease in the concentrations of all of the polycyclic musk detected in influent samples and an increase in the concentration of galaxolidone until a maximum value of 820 ng L^{-1}.

1. Introduction

Sample preparation is the cornerstone of chemical analysis. Preconcentration is a crucial step when synthetic musk fragrances often occurring in concentrations as low as μg L^{-1} or ng L^{-1} are to be determined in environmental water samples. Some preconcentration techniques such as liquid–liquid extraction (LLE) [1–3], solid-phase extraction (SPE) [4–7], dispersive liquid–liquid extraction (DLLME) [8–10], solid phase microextraction (SPME) [11,12], single drop microextraction (SDME) [13,14], microextraction by packed sorbents (MEPs) [15,16] or dispersive microsolid-phase extraction (D-μ-SPE) [17] have been reported. Of all the extraction techniques mentioned, SPE is the most widely used in the environmental analytical field because it consumes minimal amount of organic solvents and a great diversity of sorbents is commercially available.

Nevertheless the development of economical and ecological small scale sample preparation techniques that are able to meet requirements such as enhanced sensitivity and selectivity, robustness and simple handling are desirable [18,19]. In this way, solvent-free extraction methods based on the partitioning of analytes between gaseous or liquid phase and stationary phase have become important and have been widely applied in research over the last decade, with SPME as one of the most successfully approaches [20,21].

Although Raschdorf [22] developed the first device based on a needle filled with Tenax sorbent in the 1970s, needle trap (NT) extraction devices have only recently become popular due to their combination of advantages of SPME (e.g. solvent-free, fast, sensitive and one-step sample preparation and injection method) and SPE (e.g. sensitivity of the method can be increased by increasing the sample volume) with robustness, easier handling during sampling and desorption, and the fact that they permit a high degree of automation and on-line coupling to GC instruments [23–26]. The literature found up to now can be divided in two categories depending on the NT device used: (a) internally coated needles [27–29] and (b) needles packed with commercially

0039-9140/© 2014 Elsevier B.V. All rights reserved.

available sorbents [26,30–36] or chemically synthesized polymers [37,38]. Regardless of the kind of NT used, the extraction by NT has the advantages of being solvent-free and of having sampling and analysis times that are significantly shorter than most existing methods.

In this study, two different needles packed with 20 mm or 30 mm of HF Bondesil-C18 sorbent were evaluated in order to determine the optimal configuration to extract the synthetic musks fragrances present in wastewater samples prior to analysis by GC–MS/MS. The different parameters affecting the adsorption capacity of the NT as well as the desorption and transferring of the target compounds into the GC were also studied. Once the most appropriate experimental conditions were found, the NT methodology was compared in terms of method validation parameters with other microextraction techniques and was successfully applied for the analysis of synthetic musk fragrances in wastewater samples.

2. Experimental part

2.1. Chemical standards

The nitro musk fragrances 2,4,6-trinitro-1,3-dimethyl-5-tert-butylbenzene (MX, musk xylene) and 1,1,3,3,5-pentamethyl-4,6-dinitroindane (MM, musk moskene) were purchased as 100 μg mL^{-1} solutions in acetonitrile from Sigma-Aldrich (Steinheim, Germany) and Riedel de Haën (Seelze, Germany), respectively. The six polycyclic musks studied were supplied by Promochem Iberia (Barcelona, Spain) and were the following: 6,7-dihydro-1,1,2,3,3-pentamethyl-4(5H)-indanone (DPMI, cashmeran), 4-acetyl-1,1dimethyl-6-tert-butyllindane (ADBI, celestolide), 6-acetyl-1,1,2,3,3,5-hexamethylindane (AHMI, phantolide), 5-acetyl-1,1,2,6-tetramethyl-3-isopropylindane (ATII, traseolide), 1,3,4,6,7,8-hexahydro-4,6,6,7,8,8-hexamethylcyclopenta-(*g*)-2-benzopyran (HHCB, galaxolide), and 7-acetyl-1,1,3,4,4,6-hexamethyl-1,2,3,4-tetrahydronaphthalene (AHTN, tonalide). International Flavors & Fragances Inc. (Barcelona, Spain) provided1,3,4,6,7,8-hexahydro-4,6,6,7,8,8-hexamethylcyclopenta-[*g*]-2-benzopyran-1-one (HHCB-lactone, galaxolidone) and the deuterated analogue ^{2}H15-Musk xylene (^{2}H15-MX, surrogate standard) was supplied as a 100 μg mL^{-1} solution in acetone by Symta (Madrid, Spain). Table 1 shows the boiling point and the octanol/water partition coefficient of each target compound.

Individual standard solutions of the synthetic musks were prepared in acetone at concentrations of 4000 μg mL^{-1} for polycyclic musks and 1000 μg mL^{-1} for HHCB-lactone. A standard mixture solution of 100 μg mL^{-1} was prepared in ethyl acetate. MX, ^{2}H15-MX and MM standards were supplied directly at a concentration of 100 μg mL^{-1} and used as received. Acetone and ethyl acetate were GC grade with purity >99.9% from Prolabo (VWR, Llinars del Vallès, Barcelona, Spain).

Ultrapure water was obtained using an ultrapure water purification system from Veolia waters (Sant Cugat del Vallés, Barcelona, Spain). Helium gas with a purity of 99.999% was used for the chromatographic analysis (Carburos Metálicos, Tarragona, Spain).

2.2. Sampling

Influent and effluent wastewater samples were collected from three urban wastewater treatment plants (WWTPs) located in Tarragona (WWTP A), Reus (WWTP B) and Vila-seca/Salou (WWTP C) between October and December 2013. The WWTPs receive urban sewage and industrial discharges from a population of about 130,000 inhabitants. The three WWTPs use activated sludge for biological treatment and the WWTP C also employs a tertiary treatment based on reverse osmosis (RO). All samples were collected by using pre-cleaned amber glass bottles and were filtered using a 1.2 μm glass fibre filter (Fisherbrand, Loughborough, UK) and a 0.22 μm nylon filter (Scharlab, Barcelona, Spain). Samples were analysed within three days of their collection (stored at 4 °C in the fridge).

2.3. Preparation of the needle trap

Hamilton (Bonaduz, Switzerland) 22 gauge stainless steel (metal hub) needles (O.D.=0.718 mm, I.D.=0.413 mm and 51 mm length) with point style 5 (Fig. 1) were filled with HF Bondesil-C18 sorbent (120 μm) from Agilent Technologies (Palo Alto, USA). Stainless steel wire (AISI 316L, GoodFellow, Huntingdon, UK) of 100 μm diameter was used to prepare spiral plugs to hold sorbent particles inside the needles. First, a small piece of spiral plug (five turns, ~1.5 mm) was fixed in the tip of the needle to prevent sorbent particles from being fixed in the side hole of the needle. Then, 20 mm or 30 mm of C18 sorbent particles were positioned inside the needle. Finally, another spiral plug was carefully introduced in the upper position of the needle until it reached the end of the sorbent layer to fix the sorbent particles. Using this needle configuration, needle traps were conditioned in the GC injector at 230 °C for 30 min to eliminate any contaminations from the manufacturing process or shipping. Each needle was stored inside a closed vial until analysis.

2.4. Needle trap extraction

A CombiPAL autosampler (CTC Analytics, Zwigen, Switzerland) equipped with a single Magnet Mixer, a 100 μL Hamilton syringe and controlled by the Cyclo Composer Macro Editor 1.4 Software was used for the fully automated needle trap (NT) micorextraction. The general microextraction procedure was as follows: 10 mL of sample or standard solution was introduced into a 20 mL HS glass vial and immediately sealed with a Teflon septum. When the temperature of the heat/stir accessory reached 60 °C, the vial was automatically transported there and the headspace was allow to equilibrate with the sample at the extraction temperature for 15 min. The needle with 30 mm of HF Bondesil-C18 sorbent was inserted in the vial to perform the HS dynamic extraction. 500 μL of headspace vapours

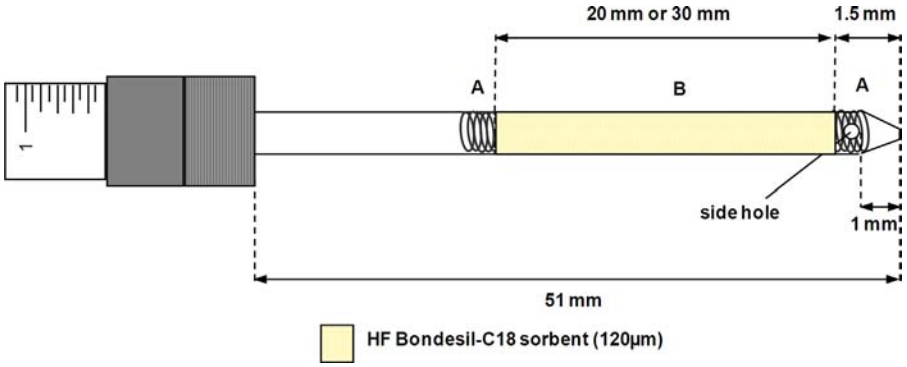

Fig. 1. Sorbent-packed needle trap device: (A) spiral plugs and (B) sorbent material.

were then percolated by pumping up through the sorbent 5 cycles of 100 μL at 10 μL s^{-1} fill and 30 μL s^{-1} ejection speeds. Afterward, the desorption was conducted at 230 °C for 3 min and the compounds were subsequently analysed by GC–MS/MS.

2.5. Gas chromatography–tandem mass spectrometry

GC–MS/MS analyses were performed on a Varian 3800 gas chromatograph (Varian, Walnut Creek, CA, USA) connected to a Varian 4000 ion trap detector. The GC was equipped with a 1079 programmable temperature injector and a 0.8 mm i.d. insert liner (Varian) and a CombiPal autosampler (CTC Analytics, Zwigen, Switzerland). A fused silica capillary column (3 m × 0.25 mm i.d.) from Micron Phenomenex (Torrance, CA, USA) was used as a guard column. The chromatographic separation was done in a midpolarity phase capillary analytical column with 50% diphenyl/50% dimethylpolysiloxane (30 m × 0.25 mm i.d.; 0.25 μm film thickness) from Micron Phenomenex. The oven temperature was programmed as follows: 70 °C hold for 3 min, raised at 40 °C min^{-1} to 180 °C, then 5 °C min^{-1} to 220 °C and finally 20 °C min^{-1} to 280 °C (hold 3.25 min). The carrier gas employed was helium with purity of 99.999%, at a constant flow of 1 mL min^{-1}. During the thermal desorption the injector was operated in splitless mode at 230 °C. Temperatures of transfer line, manifold and trap temperatures were 280 °C, 50 °C and 200 °C, respectively. A filament-multiplier delay of 3 min was established in order to increase filament's service life. The mass spectrometer analysed the substances after electron impact ionization in tandem mass spectrometry mode (MS/MS).

3. Results and discussion

3.1. GC–MS/MS optimization

A mixed solution of 10 μg mL^{-1} of the target musk fragrances and 1 μg mL^{-1} of ^{2}H15-MX as surrogate standard (SS) was prepared in ethyl acetate and 1 μL of this solution was directly injected into the GC–MS, using electron ionization fragmentation in full scan mode. All compounds were separated in just 17 min using the chromatographic conditions described in Section 2.4. Under optimum chromatographic conditions, the chromatogram (Fig. 2a) also shows the separation of two galaxolide stereoisomers (4S, 7S; 4S, 7R). The galaxolide was quantified by integrating the 4S and 7R/S peaks together due to the fact that both stereoisomers are responsible for the musky odour [39]. In order to achieve maximum sensitivity/selectivity of the compounds, the MS/MS method was carried out by selecting appropriate precursor/product ions and the MS/MS parameters optimized in a previous paper [14]. The three product ions selected for a correct identification of the target analytes as well as the retention time and the parent ion of each analyte are summarized in Table 1. Each compound was acquired separately in one segment, except, HHCB and AHTN and the target nitro musks (^{2}H15-MX, MX and MM).

3.2. Needle trap optimization

To optimize needle trap (NT) microextraction conditions, two different NT were tested, the first one contained 20 mm of HF Bondesil-C18 sorbent while the second one was filled with 30 mm of the same sorbent. HFBondesil-C18 sorbent was selected as extraction sorbent due to its ability to extract a wide range of non polar compounds, including synthetic musk fragrances, by establishing nonpolar interactions [4,6,16]. More selective SPE sorbents previously used to extract synthetic musk fragrances from environmental samples, as Oasis HLB [5] or Bond Elut Nexus [7], were discharged because they are not commercially available at higher particle sizes (100–250 μm). The particle size would affect the packing density and consequently affect the capacity, the extraction efficiency and desorption efficiency of the NT device. As has been demonstrated by Zhan and Pawliszyn [40], NTs packed with small particles possess higher extraction capacity and efficiency but much higher resistances to flow as well. In addition, the use of low particle size sorbents could make pneumatic restrictions and generation of bubbles and important factor to take into account.

The main parameters that affect the sorption and desorption process in NT microextraction were optimized for each needle in order to maximize the chromatographic peak area of the compounds by analysing a standard mixed solution of 1 μg L^{-1} of all the target musks and the SS ^{2}H15-MX in 10 mL of ultrapure water. To obtain the best conditions for each needle, such variables as extraction mode, extraction temperature, salt concentration, preincubation time, fill and ejection speed, fill volume and desorption parameters (temperature and time) were optimized because these factors were expected to be the most influential in the extraction process. Taking into account our previous experience in the determination of synthetic musk fragrances in wastewater samples by SDME and previous literature on synthetic musks [12,14,41,42], the initial experimental conditions selected were as follows: 300 g L^{-1} NaCl, 80 °C extraction temperature, 5 min preincubation time, 200 μL fill volume (2 cycles × 100 μL), 30 μL s^{-1} fill and ejection speed, and 3 min of desorption time at 230 °C. In the same way, sample volume and stirring rate were fixed at 10 mL (20 mL HS vials) and 750 rpm, respectively.

Firstly the extraction mode was optimized. As musk fragrances are semi-volatile compounds two extraction modes were tested, immersion [43] and headspace [26,30]. The results showed that immersion mode provided higher peak areas than those obtained by headspace mode for all of the target compounds using both 20 mm and 30 mm NTs (data not shown). However, due to the trap's pneumatic

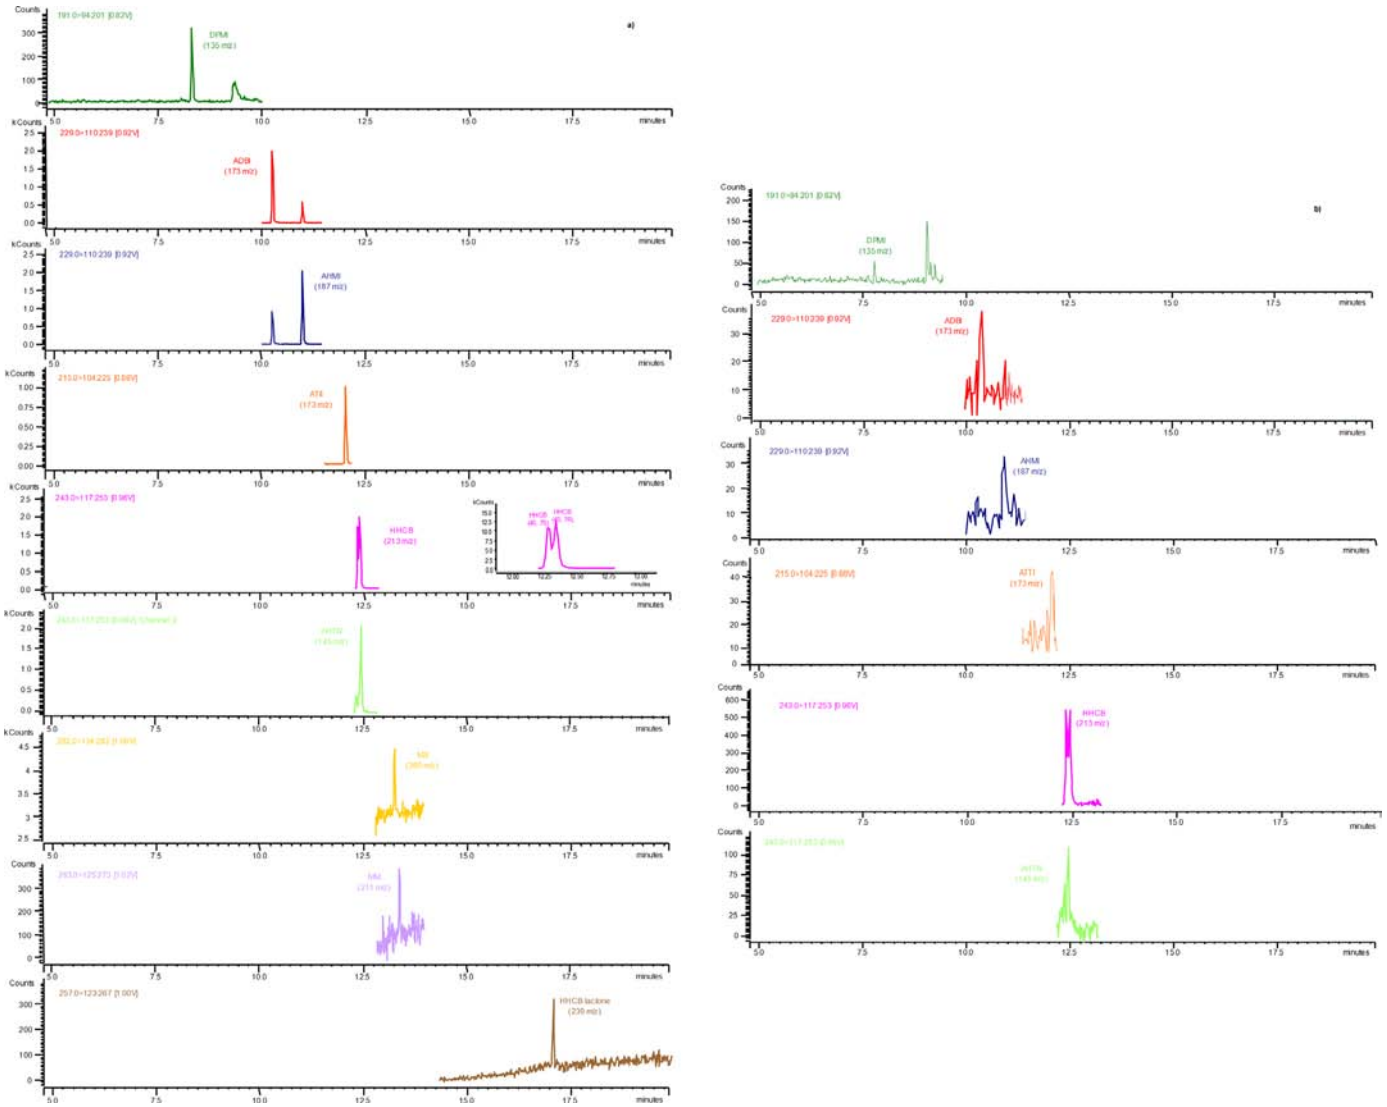

Fig. 2. MRM chromatograms of a influent wastewater sample from WWTP B. (a) Sample spiked with 1 μg L^{-1} of musk fragrances and (b) unspiked sample.

restrictions and the bubble formation it was impossible to ensure a constant flow rate of the sample inside the needle and the exact sample volume that pass through the sorbent, obtaining non reproducible results. So, headspace mode was selected to optimize the NT microextraction. In the same way NT desorption with organic solvent was discarded and replaced by thermal desorption.

Then the extraction temperature was studied by comparison of the peak areas obtained at 30 °C, 45 °C, 60 °C, 80 °C and 100 °C. The other extraction conditions were the same as described previously. Independently of the NT used, a progressive increase in the peak areas was observed for all of the polycylic musks up to an optimum extraction temperature of 60 °C after which there was a decrease when the extraction temperature was extended up to 100 °C (Fig. 3). While nitro musks compounds reached the highest peak areas at 80 °C with slightly better peak areas than those obtained at 60 °C. However, as a compromise 60 °C was chosen as the optimum extraction temperature.

To study the influence of adding salt on the efficiency of NT microextraction, the ionic strength of the ultrapure water solutions was modified by adding NaCl in the range of 0–360 g L^{-1}. 300 g L^{-1} was selected as the optimal salt concentration because maximal peak areas were obtained for most of the target compounds (data not shown). DPMI and HHCB-lactone showed maximal peak areas at 200 g L^{-1} NaCl but only a slight decrease in those analytical signals was observed at 300 g L^{-1} NaCl. It is clear that the addition of NaCl increased the ionic strength and thus promotes the transport of the analytes to the headspace and hence to the NT [44]. Therefore, it is to be expected that this will drive additional analytes into the headspace or gaseous phase and NT.

Regarding the preincubation time, 5, 15 and 30 min were also studied in order to enhance the efficiency of the NT efficiency. The best results were obtained working with 30 min (data not shown). However due to the fact that no statistical differences were observed between 15 and 30 min (differences $<10\%$ of peak areas), 15 min of preincubation time was selected as optimum in order to reduce the analyses time.

Fill and ejection speed were studied in the range of 1–100 μL s^{-1} with a 100 μL Hamilton syringe. Higher fill/ejection speeds were discarded for pneumatic restrictions of the NT that can lead in repeatability problems [23]. Theoretically, lower fill speeds increase the sampling time to help musks to diffuse through the sorbent, so the extraction efficiency of the NT should be better working at low fill speeds than working at high fill speeds [23]. Experimental results (Fig. 4) showed that the highest peak areas and therefore the best extraction efficiency was achieved working at 1 μL s^{-1} fill and 30 μL s^{-1} ejection speeds for all of the target analytes independently of the NT used. However, since no statistical differences were observed between

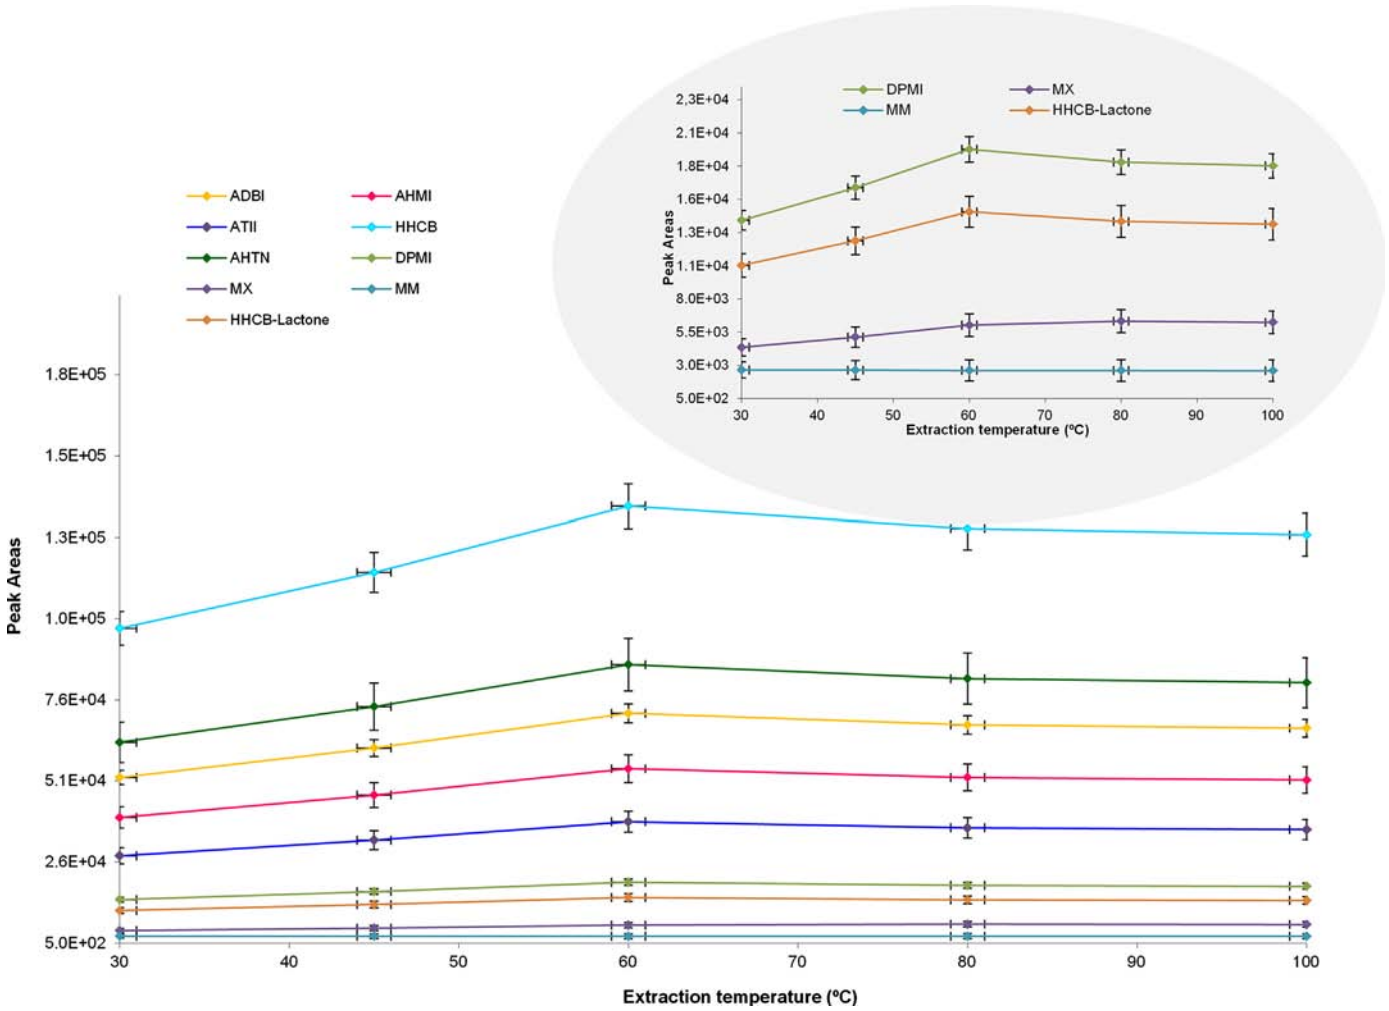

Fig. 3. Effect of the extraction temperature on the chromatographic peak areas obtained with NT microextraction (1 μg L^{-1}, $n=3$). Experimental conditions: 30 mm HF Bondesil-C18 sorbent NT, 10 mL sample volume poured in a 20 mL HS vial stirred at 750 rpm, 30% NaCl addition, preincubation time of 5 min, 200 μL fill volume, 30 μL s^{-1} fill and ejection speed and 3 min desorption time (230 °C).

working at 1 μL s^{-1} or 10 μL s^{-1} fill speeds and not to lengthen the extraction time, 10 μL s^{-1} fill speed was chosen as optimal.

Then, fill volume was optimized under optimal conditions for both 20 mm and 30 mm sorbent NTs. The range of volumes studied was between 100 μL and 1000 μL and were percolated by drawing and discarding between 1 and 10 cycles of 100 μL. In concordance with the results obtained by Eom et al. [35] and Alonso et al. [45] for the determination by NT microextraction of BTEX (benzene, toluene, ethylbenzene and p-xylene) and volatile organic compounds in water and blood, respectively, increasing sampling volume, the extracted amount of analyte was increased; this occurred because sampling more headspace induced the transfer of more target analytes from the solution to the headspace, resulting in higher trapping efficiency. The results show that working with a 20 mm sorbent NT a proportional increase of the response of all of the target compounds up to 300 μL was observed (data not shown). At higher fill volumes the analytical signal remains constant. Whereas the 30 mm sorbent NT reached the highest peak areas at 500 μL or 750 μL depending on the target compounds. Due to the compounds that reached the highest peak areas at 500 μL are the less sensitive ones (nitro musk), 500 μL was chosen to work with a 30 mm sorbent NT.

Finally desorption parameters as desorption time and temperature were tested. Working with a 20 mm sorbent NT the highest peak areas were obtained at holding for 1 min the NT at 230 °C while no statistical differences were observed increasing the desorption time to 3 or 5 min, and carryover problems were not detected. Moreover, with a 30 mm NT the best peak areas were reached at 3 min desorption time and 230 °C desorption temperature. Not statistical differences were observed for the vast majority of the target compounds between 1 or 3 min of desorption time but carryover problems were detected for HHCB and AHTN working at 1 min desorption time.

Under the optimized conditions decribed in Table 2, as can be seen in Fig. 5, the 30 mm sorbent NT presented higher peak areas for all the target analytes, so this was the NT selected to validate the method.

3.3. Method validation

As NT microextraction may be strongly influenced by the sample matrix, before validating the method, the matrix effect was studied by statistically comparing the slopes of the calibration curves for influent and effluent WWTPs samples with that obtained with ultrapure water. As expected, the matrix effect was observed in both kinds of water, especially in influent samples. The feasibility of the microextraction procedure must be demonstrated with real samples spiked at different concentrations.

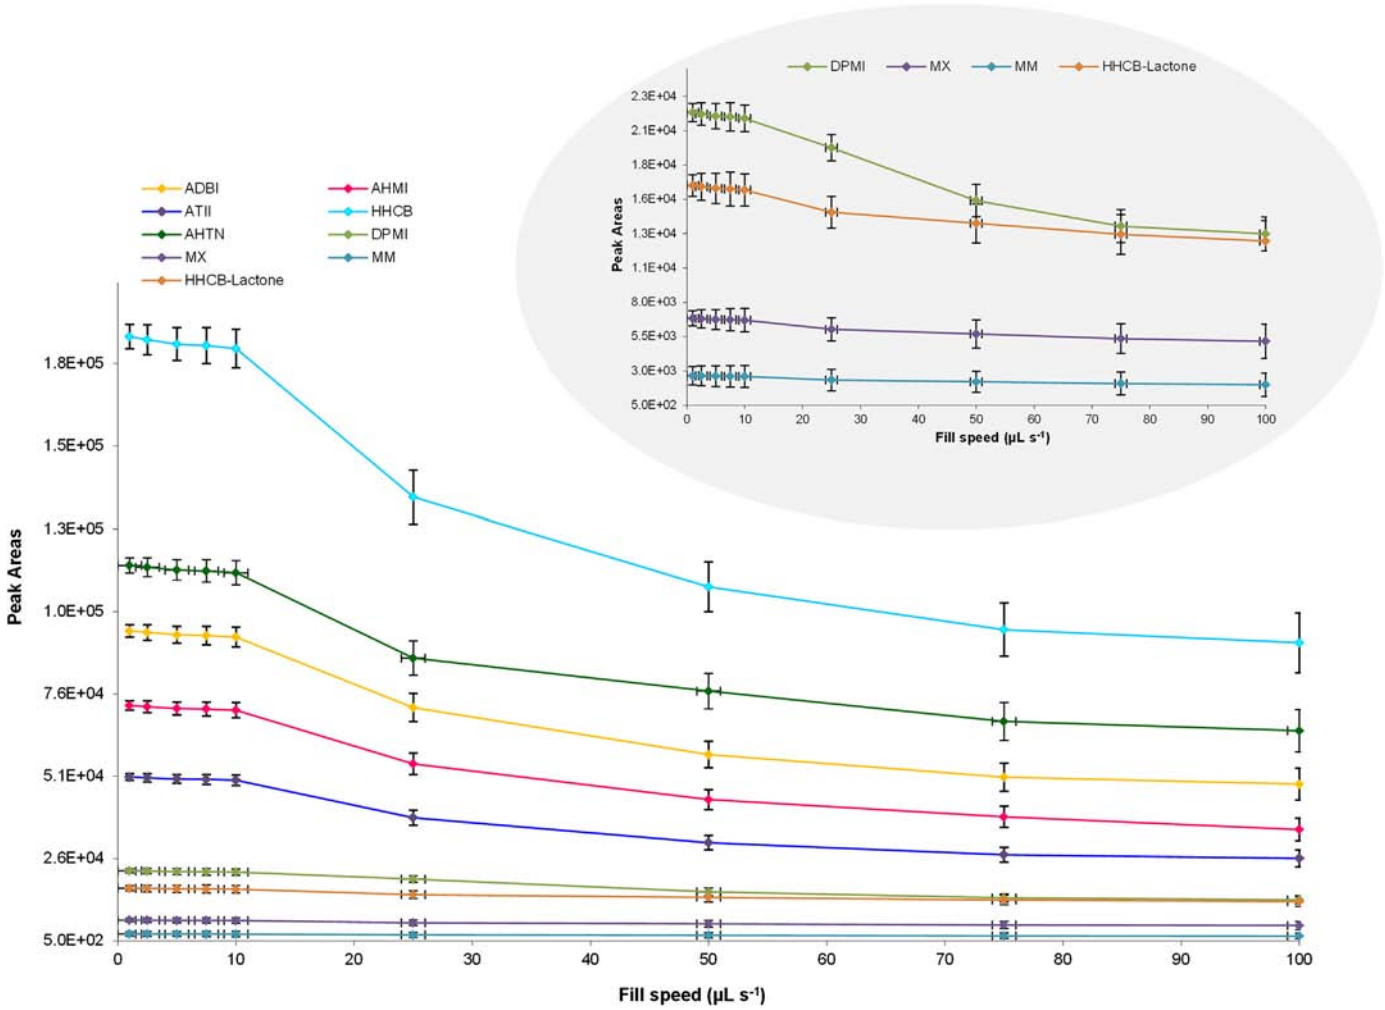

Fig. 4. Effect of the fill speed on the chromatographic peak areas obtained with NT microextraction (1 μg L^{-1}, $n=3$). Experimental conditions: 30 mm HF Bondesil-C18 sorbent NT, 10 mL sample volume poured in a 20 mL HS vial stirred at 750 rpm, 30% NaCl addition, an extraction temperature of 60 °C, preincubation time of 15 min, 200 μL fill volume, 30 μL s^{-1} ejection speed and 3 min desorption time (230 °C).

Table 2
NT microextraction optimum conditions for each HF Bondesil-C18 needle studied.

Process	Parameters	20 mm Sorbent NT	30 mm Sorbent NT
Extraction	Mode	Headspace	Headspace
	Temperature (°C)	60	60
	NaCl (g L^{-1})	30	30
	Preincubation time (min)	15	15
	Fill/ejection speed (μL s^{-1})	10/30	10/30
	Fill volume (μL)	200 (2 cycles × 100 μL)	500 (5 cycles × 100 μL)
Desorption	Mode	Temperature	Temperature
	Temperature (°C)	230	230
	Time (min)	1	3

The method was then analytically validated with an influent and an effluent sample from WWTP A by establishing the linear ranges, method detection limits (MDL), method quantification limits (MQL), intra-day and inter-day repeatabilities (expressed as relative standard deviation (RSD)). Procedural blanks of the conditioned NT were performed before NT microextraction in order to prevent carryover effects and ensure the repeatability of the analytical method.

The WWTP A samples used to validate the method were analysed ($n=5$), and the peaks of t HHCB and AHTN appeared in the chromatogram of the influent sample, while in the effluent sample peaks of HHCB, AHTN and also HHCB-lactone were found. The averaged peak area of each detected compound was subtracted from the corresponding peak area of each spiked sample.

The linear range of the method was obtained by analysing the WWTP A samples spiked with all of the target analytes at concentrations between 2.5 ng L^{-1} and 5000 ng L^{-1} while the SS concentration remained constant at 1000 ng L^{-1}. The method was linear in all ranges between MQL and 5000 ng L^{-1} for all of the target

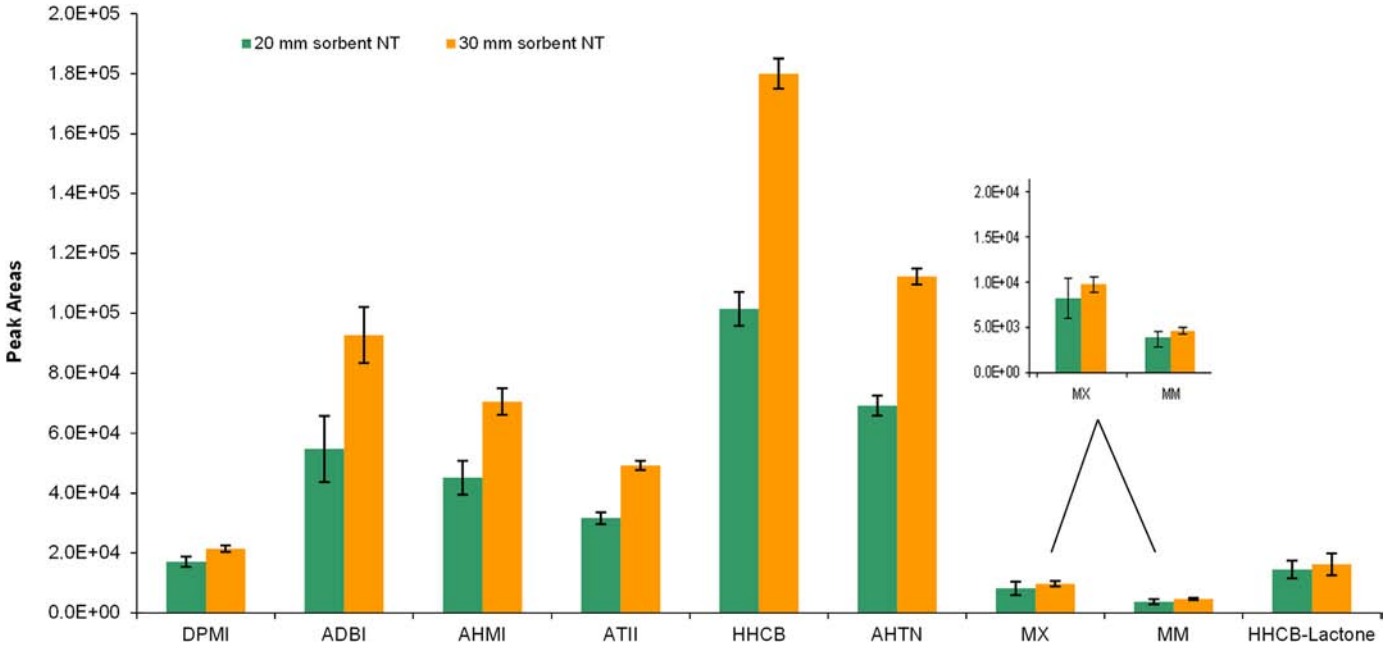

Fig. 5. Comparison of the chromatographic peak areas obtained with the 2 sorbent-packed needle traps in the optimal NT microextraction conditions for extracting the target musk fragrances from 10 mL water samples spiked at 1 μg L^{-1} (n=3).

* Estimated.

analytes and matrices. In addition, the presence of SS enabled us to improve the determination coefficients (r^2) of the calibration curves to values higher than 0.997 for all the target compounds. MQLs were the lowest point of the calibration curve and MDLs were evaluated by spiking WWTP A influent or effluent samples in order to obtain a signal-to-noise ratio higher than three, for the compounds that did not appear in these samples. MDLs for HHCB, AHTN and HHCB-lactone were estimated as the concentration that gave a signal average of plus three times the standard deviation of the influent or effluent sample signal (n=10). These limits are shown in Table 3. Thus, MQLs ranged from 5 ng L^{-1} to 25 ng L^{-1} and MDLs ranged from 2.5 ng L^{-1} to 12 ng L^{-1} depending on the compound and matrix studied. These limits are better than those reported in the literature, which reports MDLs between 5 ng L^{-1} and 63 ng L^{-1} for influent and effluent waters working with microextraction by packed sorbents [16], dispersive liquid–liquid microextraction [9,10] or ultrasound-assisted emulsification-microextraction [8] as extraction techniques. However, slightly better MDLs (from 0.25 ng L^{-1} to 9 ng L^{-1}) were obtained working with solid phase microextraction as the preconcentration technique [41,46].

Intra-day and inter-day repeatability were obtained with five replicates of influent and effluent sample spiked at 100 ng L^{-1} (see Table 3). Intra-day repeatability (%RSD, n=5) was always less than 11% for both influent and effluent samples. Inter-day repeatability was always less than 17% or 15% (%RSD, n=5) for influent and effluent samples, respectively.

3.4. Needle trap extraction versus ionic liquid-based headspace single drop microextraction

The NT methodology was compared in terms of method validation parameters with an ionic liquid-based headspace single drop microextraction (IL-HS-SDME) methodology, which was successfully applied by our research group for the determination of musk fragrances in wastewater samples [14]. Both microextraction techniques are considered environmental friendly because of the use of 1 μL of an ionic liquid as extraction solvent instead of an organic solvent in the case of the IL-HS-SDME or because it is a solventless technique as NT. In addition both extraction procedures were fully automated by a CombiPal autosampler to ensure the repeatability of

Table 4
Concentrations of the target musks found in wastewater samples ($n=8$) in ng L^{-1}.

Compounds	WWTP A		WWTP B		WWTP C

< MQL—values under the method quantification limit.

the methodology when dispensing a drop of ionic liquid (IL-HS-SPME) or to control the fill/ejection speed (NT).

Method validation parameters were obtained by the analysis of 10 mL influent and effluent samples spiked at different concentrations by using GC–MS/MS as separation and detection technique. The results showed that better MDLs were obtained with NT microextraction with values between 2.5 ng L^{-1} and 12 ng L^{-1}, while IL-HS-SDME MDLs ranging between 10 ng L^{-1} and 30 ng L^{-1}. The main reason of the increase of the MDLs when working with IL-HS-SDME is that because of the low volatility of the ionic liquids, residues could be accumulated in the glass wool placed inside the GC liner. In the same way, higher MQLs were obtained with IL-HS-SDME (50–100 ng L^{-1}). Both methods were linear between the MQLs and 5000 ng mL^{-1} with NT microextraction and up to 10,000 ng mL^{-1} with IL-HS-SDME. On the other hand, slightly better repeatability results were obtained with IL-HS-SDME, with intra-day repeatability values between 2 and 6% and inter-day repeatabilities ranging between 5 and 11%.

Summarizing, both methodologies were successfully applied for the determination of musk fragrances in wastewater samples but the validation results as well as daily work have led me to conclude that the NT microextraction is preferable to IL-HS-SDME.

Furthermore, NT microextraction validation values can also be compared with those obtained by Moeder et al. [15] working with MEPs as extraction technique. MEPs is a microextraction technique that can be considered as a miniaturized solid-phase extraction in which the sorbent (~1 mg) is inserted between the needle and the barrel as a cartridge but not in the needle. Moeder et al. [15] obtained MDLs of 42 ng L^{-1} and 37 ng L^{-1} for HHCB and AHTN, respectively, while working with NT as extraction technique slightly better MDLs, between 2.5 and 3.5 ng L^{-1} for HHCB and AHTN, respectively, were obtained. These values can be explained by the differences in sorbent position. NT design allows working in headspace mode and thermal desorption, and that makes this technique ideal for the extraction of volatile organic compounds from air or wastewater samples. On the other hand, MEPs bin is ideal for work in immersion mode and desorption with organic solvents and is normally used to extract polar compounds from environmental or biological samples [47].

3.5. Method application

To demonstrate the applicability of the NT-GC–MS/MS, influent and effluent wastewater samples from three WWTPs (A, B, C) on different dates were analysed ($n=8$). All the polycyclic musk compounds were detected in some of the influent samples from WWTP A and WWTP B, with HHCB (20–1160 ng L^{-1}) and AHTN (< MQL-430 ng L^{-1}) as the only compounds present in all the samples analysed (Table 4). For instance, Fig. 2b shows MRM chromatograms of the influent from WWTP B for the sample spiked with 1000 ng L^{-1} of musk fragrances (a), and the unspiked sample (b). As expected, the concentrations of polycyclic musk found in effluent WWTP A and B samples were lower than those detected in influent samples and with DPMI (n.d.– 180 ng L^{-1}), HHCB (10–550 ng L^{-1}) and AHTN (< MQL-240 ng L^{-1}) as the compounds that showed the highest concentrations. None of the samples contained detectable traces of nitro musk compounds. HHCB-lactone was only detected in effluent WWTP A and B samples as a result of the degradation of HHCB to HHCB-lactone during the WWTP treatment [48,49].

In the same way, HHCB (70–240 ng L^{-1}) and AHTN (< MQL-50 ng L^{-1}) are the only compounds present in all the influent samples of RO taken from WWTP C. The remaining polycyclic musk as well as HHCB-lactone were detected in some of the samples in minor concentrations. In effluent RO samples all targets musks were detected at values below the MQL or were not detected.

Previous works [4,7,50,51] that have focused on the determination of synthetic musk fragrances in wastewater samples confirms the finding of the present study, i.e. that the most abundant fragrances found in wastewater samples are the polycyclic musks HHCB and AHTN, although other polycyclic musks as DPMI, ADBI or AHMI can also be present in minor concentrations.

4. Conclusions

In this study, a NT microextraction followed by GC–MS/MS procedure was developed for determining nine musk fragrances in water samples. The NT-GC–MS/MS method was shown to be completely automated, simple and environmentally friendly. It also provided low ng L^{-1} MDLs and satisfactory precision (RSD between 3 and 11%) for wastewater samples.

The following main parameters involved in the NT microextraction were evaluated and optimized: sorbent-packed needle trap, extraction mode, extraction temperature, salt concentration, preincubation time, fill and ejection speed, fill volume and desorption parameters (temperature and time). Two sorbent-packed needle traps were tested (20 mm HF Bondesil-C18 sorbent and 30 mm HF Bondesil-C18 sorbent), and the best conditions were found to be the following: 30 mm HF Bondesil-C18 sorbent needle trap, 10 mL sample volume placed in a 20 mL HS vial and stirred at 750 rpm, 30% NaCl addition, an extraction temperature of 60 °C, preincubation of 15 min, 10 μL s^{-1}/30 μL s^{-1} fill and ejection speed, 500 μL fill volume and 3 min desorption time (230 °C).

The applicability of the method was also tested with water samples from influent and effluent WWTPs. The most abundant compounds were found to be DPMI, HHCB and AHTN while the remaining polycyclic musk fragrances were present at lower concentrations. None of the samples analysed contained detectable

traces of nitro musk compounds and HHCB-lactone was only detected in effluent samples as a degradation product of HHCB.

Acknowledgements

L. Vallecillos would like to thank the Department of Innovation, Universities and Enterprises and the European Social Fund for a Predoctoral Grant (FI-DGR 2012).

We would also like to thank the personnel at the wastewater treatment plants for their cooperation with all aspects of this study.

ABSTRACT

A novel magnetic graphene oxide nanocomposite was synthesized by one-step coprecipitation method and characterized by transmission electron microscopy, X-ray photoelectron spectroscopy and vibrating sample magnetometer. The nanocomposite beard many intriguing properties, including chemical stability, high adsorption capacity, and superparamagnetic. These properties evoked great interest and desire of its exploration in magnetic solid-phase extraction of heavy metal ions from complex samples. Several parameters effecting the analytical performance, such as the sample pH, amounts of adsorbent, sample volumes, elution volumes, and coexisting ions, had been investigated in detail. The adsorbed metal ions were easy eluted by controlling the pH condition and the materials could be reused more than 20 times. Under the optimized conditions, the limits of detection were 0.016, 0.046, 0.395, 0.038, 0.157 μg L^{-1} for Co^{2+}, Ni^{2+}, Cu^{2+}, Cd^{2+}, and Pb^{2+}, respectively. The intra-day relative standard deviations ($n=5$) were in the range of 1.8–5.5% at 10 μg L^{-1}. The proposed method was successfully applied to biological sample analysis and got excellent recoveries in the range of 81–113% even the matrix was complex.

1. Introduction

The rapid development of industrial production causes serious pollution, especially heavy metal pollution [1]. From both natural and anthropogenic origin, heavy metals have been introduced into the environment and organism. The heavy metals cycle in the living creature chain and eventually endanger human health. The levels of heavy metal ions in human urine and plasma can indicate the existence of environment pollution, which benefits for controlling the pollution in time [2]. Therefore, the simultaneous evaluation for different heavy metals in biological samples is highly demanded. Compared to the technologies for detecting metal ions [3–5], inductively coupled plasma mass spectrometry (ICP-MS) possesses higher sensitivity, accuracy, and the capacity of simultaneously detecting various metal ions [6]. However, the low level of heavy metal ions and the complex matrix of the biological sample restrict its application [7]. Thus, a sample preparation prior to instrumental analysis to separate the matrix is essential [8].

Recently, magnetic solid phase extraction (MSPE) has been proposed from traditional solid phase extraction (SPE) and widely used due to its high recovery and ease of operation [9,10]. By taking advantage of both magnetic and non-magnetic adsorbent material, the MSPE method exhibits excellent adsorption efficiency and rapid separation from the matrix by an external magnetic field. The most important component of the MSPE technique is the adsorbent material, which dominates the sensitivity and selectivity of the method [11,12]. Graphene, a carbon-based material, has attracted considerable research interests in separation application areas due to its ultrahigh specific surface area [13–16]. Some works about its application in separating organic substance by π-π interaction had been reported by our research group [9,17,18]. However, its application in separation of metal ions was rarely reported [19]. Alvand et al. [20] used chelating agent to form stable complex with metal ions, which was separated due to π—π stacking interaction between graphene and the complex. However, as for graphene, there were strong π—π stacking interactions between neighboring sheets which might lead to restacking and agglomeration, resulting the loss of effective surface areas. Ethylene diamine tetraacetic acid (EDTA) was modified to the surface of graphene oxide (GO) by Hou group [21] and the synthesized EDTA-GO was used as an idea adsorbent for metal ions by conjugate action. However, several problems also exist, for instance, lacking of sufficient stability as well as hard to be separated because of the small size. Also, the complex synthesis and operation process will introduce interfering metal ions. In addition, most of the reported methods were applied to simple matrix samples, such as environmental water [22–24]. The separation of

heavy metal ions from complex biological samples required higher selectivity and higher adsorption capacity of the adsorbent material [2,6].

GO, an idea adsorbent material, has abundant active sites and in rich of hydroxyl and carboxyl, which is suit to bind with metal ions. The adsorbed analytes could be easy eluted by acid according to the H^+ competing. However, it is difficult to separate the GO from aqueous solution because of its good dispersibility and high hydrophilicity [25], which restricts its direct application as an adsorbent. As one kind of grapheme hybrid materials, tri-iron tetroxide (Fe_3O_4)/GO possesses high adsorption capacity for heavy metal ions and could be easy separated via an external magnetic field. The preparation methods for Fe_3O_4/GO, including solvothermal reaction and covalent bonding, are complex and require rigorous conditions [9]. In this paper, an easy controlled one-step chemical coprecipitation method [26] was used to introduce the Fe_3O_4 to the surface of GO. It was characterized by transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), and vibrating sample magnetometer (VSM) and applied to MSPE. The parameters influencing the extract recovery, including the sample pH, amounts of adsorbent, sample volumes, elution volumes, and coexisting ions were optimized in detail. The proposed method was also successfully applied to human urine and plasma for simultaneously detecting five kinds of heavy metal ions.

2. Experimental

2.1. Reagents and materials

Expanded graphite powder (100 mesh) was purchased from the Xinghe Graphite Co. Ltd. (Qingdao, China). The stock standard solutions (1000 mg L^{-1}) of Co^{2+}, Ni^{2+}, Cu^{2+}, Cd^{2+}, and Pb^{2+} (M^{2+}) were supplied by National Research Center for Certified Reference Materials (Beijing, China). The working standard solution was prepared daily by mixing individual standard solution and diluting to obtain a desired concentration. All reagents used in the experiment were of analytical reagent grade. High purity water (18.2 MΩ cm) prepared by Aifeibo Super Water-Purifiend Apparatus (Aifeibo Co. Ltd., China) was used throughout this work.

2.2. Instrumental and analytical conditions

TEM image were taken out using an H-7650B transmission electron microscope (Hitachi, Japan). XPS data were collected using a PHI-5300 ESCA X-ray photoelectron spectrometer (PHI, America). Magnetization curves were recorded using a 7307 Vibrating Sample Magnetometer (LakeShore, America).

A Thermo Scientific iCAP Q ICP-MS instrument (Thermo Fisher Scientific GmbH, Germany) was used for all ICP-MS experiments. Instrument tuning was performed prior to analysis by using a tuning solution according to the recommendation from manufacturer. The plasma power was 1548.6 W. High-purity argon was supplied as the cool gas, nebulizer gas, and auxiliary gas at the flow rates of 13.91 L min^{-1}, 1.03 L min^{-1}, and 0.80 L min^{-1}, respectively. The sample uptake time was set at 60 s and the wash time was set at 120 s.

2.3. Synthesis of GO

GO was prepared from expanded graphite according to the modified Hummers method [9]. About 1 g of sodium nitrate and 6 g of potassium permanganate were added into 46 mL of 98% sulfuric acid in an ice bath. Expanded graphite powder was slowly added with vigorous agitation. Then the mixture was maintained at 4 °C in an ice bath for 24 h. Afterwards, the reaction was transferred to a 35 °C oil bath for 30 min. Subsequently, 92 mL of high purity water was gradually added and the mixture was kept at 98 °C for 15 min. The expanded graphite in the solution was significantly oxidized and became aureate. After the temperature was reduced to 60 °C, 30% hydrogen peroxide was added slowly until visible bubbles were generated. The above mixture was centrifuged to remove the supernatant, and the GO was washed by 5% sufficient hydrochloric acid and high purity water to remove excess acid. Finally, the material was dried in oven at 60 °C for 6 h.

2.4. Synthesis of Fe_3O_4/GO

Fe_3O_4/GO was synthesized by chemical coprecipitation method [26]. The synthesized GO was dispersed in high purity water (1 mg mL^{-1}) and ultrasonicated for 3 h to obtain a clear dispersion of GO. 25 mg ferric chloride and 150 mg ferrous chloride were added slowly to 50 mL of 1 mg mL^{-1} GO at 50 °C under N_2. The ammonia solution was added slowly to precipitate Fe^{2+} and Fe^{3+} ions for synthesis of magnetite particles. After being rapidly stirred for 30 min by constant mechanical stirring, the solution was cooled to room temperature. Then, the dark black colored solution was applied by external magnetic field to separate the Fe_3O_4/GO. Afterwards, the Fe_3O_4/GO was washed with high purity water 5 times and dispersed in high purity water (5 mg mL^{-1}).

2.5. MSPE procedures

First, the adsorbent solution (5 mg mL^{-1}) was shaked fully to make sure the contents of Fe_3O_4/GO were homogeneous. 1.2 mL of the above adsorbent solution (containing 6 mg adsorbent) was placed into a beaker. The solution was magnetically separated via an external magnetic field to isolate the adsorbent. Second, the pH of solution was adjusted to 6.5 and 50 mL of 4 μg L^{-1} aqueous sample solution was transferred into the beaker. The mixture was shaked for 7 min and magnetically separated via an external magnetic field. Third, the adsorbed analytes were desorbed from the isolated adsorbent with 2 mL of 1 mol L^{-1} HNO_3 by shaking for 7 min. Finally, the adsorbent was removed via an external magnetic field and the supernatant was collected for the determination of M^{2+} by ICP-MS. High purity water was chosen as the blank solution and subjected to MSPE as described above.

2.6. Sample preparation

Urine samples were collected from the healthy volunteers. The sample was filtered through a 0.22 μm filter and its pH was adjusted to 6.5. Then, the homogeneous sample was 10 times diluted with high purity water and applied to the MSPE procedure given above.

Human plasma samples were obtained from different healthy volunteers and stored at -20 °C before use. For analysis, the samples were placed in an oven at 37 °C for 3 h. Then, a certain volume of acetonitrile was added into plasma sample to remove the proteins and centrifuged at 3500 rpm for 10 min. Afterwards, the clear supernatant was 10 times diluted and the MSPE procedure was followed under optimum conditions.

3. Results and discussion

3.1. Characterization of the Fe_3O_4/GO

Using dispersable GO as matrix, the Fe_3O_4/GO was prepared by chemical coprecipitation method of iron ions. Fe^{3+} and Fe^{2+} ions were captured by carboxylate anions on the surface of GO sheets and then ammonia solution was added slowly to precipitate Fe_3O_4. Generally the ratio of Fe^{3+} and Fe^{2+} ions for preparation of Fe_3O_4 was controlled

as 2:1. As Fe^{3+} had a much higher affinity than Fe^{2+} for carboxylic groups, a large excess of Fe^{2+} was adopted. Fe_3O_4/GO was characterized with TEM, XPS, and VSM.

3.1.1. TEM

The morphologies of GO and Fe_3O_4/GO were characterized with TEM. As could be seen from Fig. 1a, GO had a typical flake-like shape with some corrugations. Fig. 1b showed that well separated Fe_3O_4 nanoparticles were homogeneously and uniformly decorated on the surface of GO, which indicated that the Fe_3O_4 was successfully prepared [9]. Besides, the studies on the regeneration of the prepared Fe_3O_4/GO in section 3.5 showed the strong interaction between Fe_3O_4 and GO which exhibited excellent stability even in the acidic solution.

3.1.2. XPS

The chemical state of element in Fe_3O_4/GO was further investigated by XPS. As shown in Fig. 2a, the wide scan XPS spectra of the GO and Fe_3O_4/GO showed the same photoelectron lines at binding energies of about 285 and 530 eV, attributed to C1s and O1s, respectively [26]. However, the sharp peaks approximately 710 eV, which corresponded to the characteristic peaks of Fe2p in Fe_3O_4/GO, which indicated the existence of carbon, oxygen and iron in the composite [9]. In the spectrum of Fe2p in Fig. 2b, the peaks of $Fe2p_{3/2}$ and $Fe2p_{1/2}$ were located at 711.12 and 724.79 eV, not at 710.34 and 724.02 eV, which were for γ-Fe_2O_3. The result was in accordance with the reported data of $Fe2p_{3/2}$ and $Fe2p_{1/2}$, which indicated the formation of Fe_3O_4 phase in the composites [26]. Three peaks were present in the O1s spectrum of GO (Fig. 2c), which corresponded to C (O) OH at 531.8 eV, C=O at 532.5 eV and C-OH at 533.4 eV. The discrepancy was the peak at 530.4 eV in the O1s spectra of Fe_3O_4/GO nanocomposite (Fig. 2d), which was the contribution of the anionic oxygen in Fe_3O_4.

3.1.3. VSM

The magnetization curve of Fe_3O_4/GO was measured at room temperature using a supper conducting quantum interference device by cycling the field between -10 and 10 kOe, as shown in Fig. 3. The magnetic hysteresis loop was S-like curves. The magnetic remanence of the sample was 0.785 emu g^{-1}, almost no remaining magnetization when the external magnetic field was removed, suggesting that Fe_3O_4/GO exhibited a superparamagnetic behavior. The specific saturation magnetization (Ms) of the composites was 48.6 emu g^{-1} which was smaller than the reported value of bulk Fe_3O_4 of 92 emu g^{-1} [27]. The reduction in the value of Ms could be attributed to the relatively low amount of Fe_3O_4 loaded on GO [26]. However, Fe_3O_4/GO still could be separated rapidly under the external magnet. What was more, the more amounts of GO could increase the adsorption capacity of Fe_3O_4/GO.

3.2. Adsorption capacity

To investigate the adsorption capacity of the prepared Fe_3O_4/GO, 50 mL solutions of various concentrations of M^{2+} were equilibrated with 1 mL of adsorbent solution (containing 5 mg adsorbent). The adsorption capacity was calculated according to the following equation [28]:

$$Q_e = \frac{(C_i - C_e)V}{m} \quad (1)$$

where Q_e is the adsorption capacity (mg g^{-1}), C_i and C_e are the initial and equilibrium concentrations (mg L^{-1}) of M^{2+} in solution, V is the volume of the aqueous solution in L and m is the weight of the sorbent in g based on the dry weight of Fe_3O_4/GO. The experimental adsorption data were applied to the modified Langmuir equation

$$\frac{C_e}{Q_e} = \frac{C_e}{Q_m} + \frac{1}{K_L Q_m} \quad (2)$$

where K_L is the Langmuir isotherm constant (L mg^{-1}), and Q_m is the maximum adsorption capacity. The plot of C_e/Q_e versus C_e yielded a straight line revealing that the adsorption of five metal ions obeyed the Langmuir isotherm. The Q_m calculated from the slope are 1.28 mg g^{-1} for Co^{2+}, 1.55 mg g^{-1} for Ni^{2+}, 1.64 mg g^{-1} for Cd^{2+}, 6.58 mg g^{-1} for Cu^{2+}, and 9.71 mg g^{-1} for Pb^{2+}, respectively. The higher adsorption capacity of Cu^{2+} and Pb^{2+} was due to the strong complexation ability for Cu^{2+} and Pb^{2+} with carboxylic groups in GO.

3.3. Optimization of the MSPE conditions

Due to the high surface area, superparamagnetism and excellent absorbent ability, the Fe_3O_4/GO was used in MSPE for M^{2+}. The effects of the pH, amounts of adsorbent, adsorption time, sample volume, sedimentation time, HNO_3 concentration, elution volume and elution time were investigated.

3.3.1. Effect of the pH

The pH played an important role to the adsorption due to its influence on the solution chemistry of heavy metals and surface charge of the adsorbent. The sample solutions of pH range of 2–10 containing M^{2+} were investigated and the result was showed in

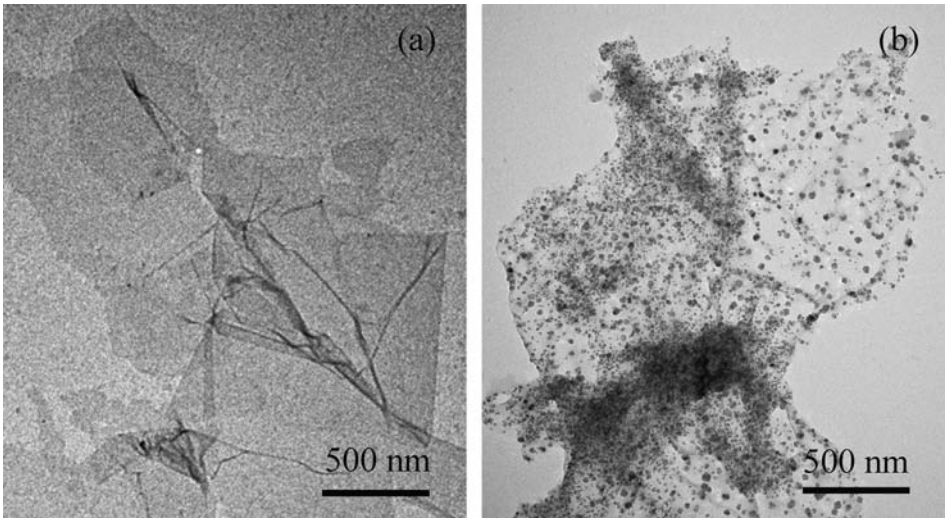

Fig. 1. TEM images of (a) GO, (b) Fe_3O_4/GO.

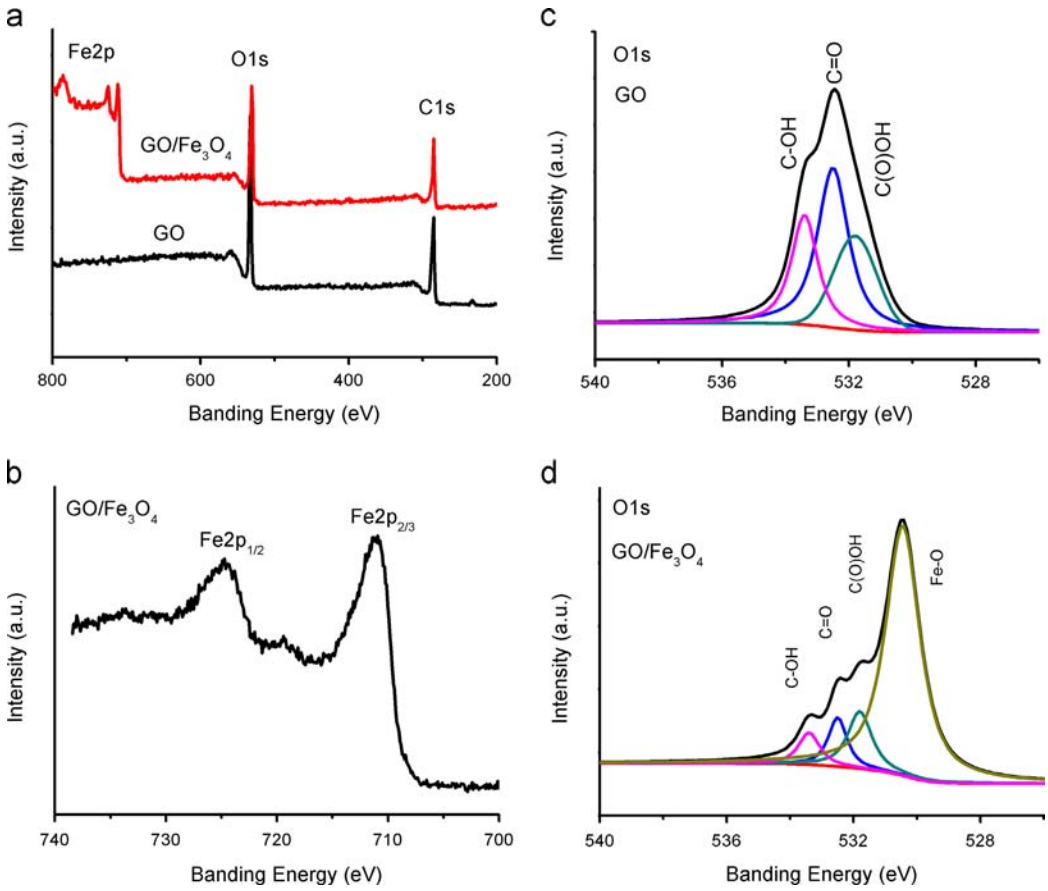

Fig. 2. XPS spectra of (a) wide scan of GO and Fe_3O_4/GO, (b) Fe 2p spectrum, (c) O1s spectrum of GO, (d) O1s spectrum of Fe_3O_4/GO.

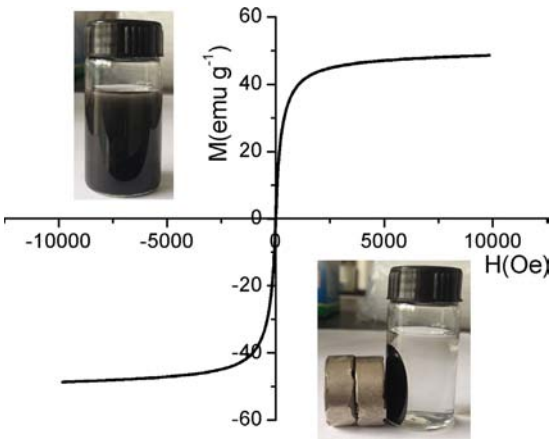

Fig. 3. The magnetization hysteresis loop of Fe_3O_4/GO.

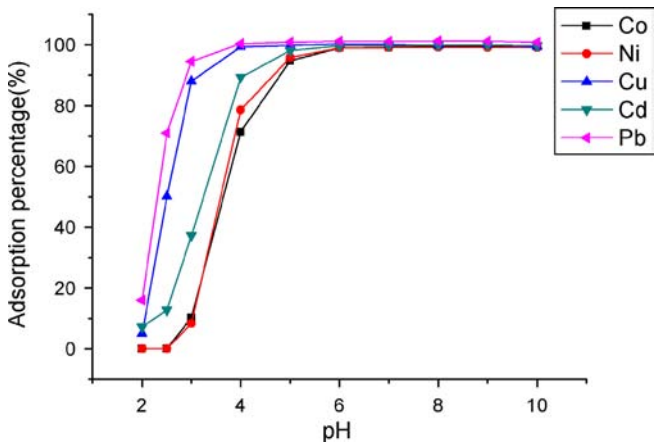

Fig. 4. Effect of pH on the adsorption percentage of the M^{2+} (4 μg L^{-1}) on the Fe_3O_4/GO; sample volume: 50 mL; adsorption time: 7 min.

Fig. 4. When pH was 2, the adsorption percentages were below 20% for all five metal ions. The lower adsorption capacity might be ascribed to the competition of M^{2+} with H^+. In other words, an excess of H^+ tended to occupy the surface active sites and competed effectively with M^{2+} due to electrostatic forces at low pH, which leaded to fewer available binding sites for M^{2+}. With the increase of pH, the –COOH and –OH groups converted to $–COO^-$ and $–O^-$, and surface charge was more negative to adsorb the positively charged metal ions. As can be seen, the adsorption percentages of Cu^{2+} and Pb^{2+} increased rapidly with the increase of pH from 2 to 4 and quantitative adsorption percentages were achieved in the pH range of 4–10. However, the adsorption percentages of Co^{2+}, Ni^{2+}, and Cd^{2+} got quantitative adsorption percentages when pH > 6. That might because of the strong complexation ability for Cu^{2+} and Pb^{2+} with carboxylic groups in GO which also leaded to a relatively high adsorption capacity for Pb^{2+} and Cu^{2+} in section 3.2. In addition, the relative high adsorption percentages at high pH (> 8) were attributed to the precipitation between M^{2+} and OH^-. Finally, a sample pH of 6.5 was selected to guarantee excellent adsorption percentages and used acid solution to elute the M^{2+} for further experiments.

3.3.2. Effect of the volumes of adsorbent solution

The effect of the volumes of adsorbent solutions was investigated by using different volumes of adsorbent solutions (0.3, 0.6, 0.9, 1.2, 1.5, 1.8, 2.1, 2.4 mL of 5 mg mL^{-1}) for 50 mL of 4 μg L^{-1} of heavy metal ions solution. The mixture was applied under the MSPE procedures in section 2.5. As shown in Fig. 5, 1.2 mL of adsorbent solution (containing 6 mg adsorbent) was enough to obtain quantitative recovery. So 1.2 mL of adsorbent solution was selected for further experiments.

3.3.3. Effect of the adsorption and elution time

In order to obtain an appropriate adsorption time, 50 mL of sample solution containing 4 μg L^{-1} of heavy metal ions was adsorbed for 1, 2, 5, 7, 10, and 15 min and the recoveries were studied, respectively. The results showed that 7 min was the appropriate adsorption time which got excellent recoveries with minimal time required for sample processing. Also, the effect of the elution time was examined and the results from Fig. 6 showed that 7 min was the optimizing elution time.

3.3.4. Effect of the sample volume

The effect of the sample volume on the recoveries was studied to obtain a higher enrichment factor. The sample solutions of 5, 10, 20, 50, 100, and 200 mL containing 200 ng of each metal ions were subjected to the general MSPE procedure, respectively. The results showed that the recoveries were excellent when the sample volumes were in the range of 5–50 mL, and then slightly decreased with further increase of sample volume to 200 mL. 50 mL sample volume was used in further experiments.

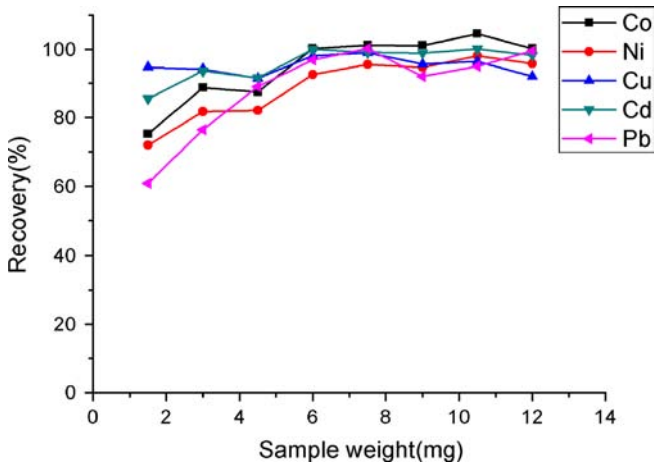

Fig. 5. Effect of the sample weight on the recovery of the M^{2+} (4 μg L^{-1}); sample volume: 50 mL; adsorption time: 7 min; eluent: 2 mL 1 mol L^{-1} HNO_3; eluent time: 7 min.

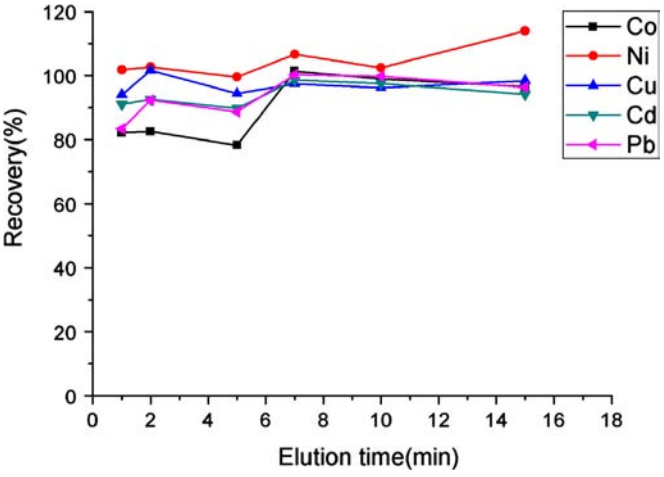

Fig. 6. Effect of the eluent time on the recovery of the M^{2+} (4 μg L^{-1}); sample weight: 6 mg; sample volume: 50 mL; adsorption time: 7 min; eluent: 2 mL 1 mol L^{-1} HNO_3.

3.3.5. Effect of the elution concentration and volume

It could be seen from Fig. 4 that M^{2+} had lower adsorption percentage at lower pH, which indicated that acid could desorb M^{2+} in adsorbent. What is more, HNO_3 is the mostly harmless acid to ICP-MS which was recommended. Therefore, HNO_3 was selected as the eluent and the concentration was investigated in the range of 0.1–2 mol L^{-1}. The results in Fig. 7 showed that the recoveries slightly increased along with the increase of HNO_3 concentrations. Considering that the instrument could not stand too strong acid, 1 mol L^{-1} HNO_3 was selected as eluent in following experiments. 1, 1.5, 2, 2.5, 3, and 4 mL of 1 mol L^{-1} HNO_3 were used to investigate the effect of elution volume, respectively. The results indicated that the recoveries slightly increased along with the increase of elution volumes. In order to achieve high enrichment factor, the volume should be as small as possible. 2 mL of 1 mol L^{-1} HNO_3 was sufficient to quantitatively elute all the metal ions and was employed as the optimum elution volume.

3.4. Effect of coexisting ions

Diverse ions which existed in experimental environment and sample matrix may interfere the recoveries of M^{2+}. To study the effect of coexisting ions, interferences from representative monovalent metal ions K^+, Na^+, bivalent metal ions Mg^{2+}, Ca^{2+}, and trivalent metal ions Al^{3+}, Fe^{3+} were investigated on 50 mL solutions containing 4 μg L^{-1} of M^{2+}. The tolerance limit was set as the largest amount of coexisting ions that reduce the recoveries of M^{2+} to less than 85%. The results indicated 100 mg L^{-1} of K^+, 100 mg L^{-1} of Na^+, 20 mg L^{-1} of Mg^{2+}, 20 mg L^{-1} of Ca^{2+}, 2 mg L^{-1} of Fe^{3+}, and 1 mg L^{-1} of Al^{3+} had no significant interference on the extraction and determination of 4 μg L^{-1} M^{2+}. The results indicated that the sorbent had excellent selectivity to analyte metal ions and was suitable for the analysis of biological samples with complex matrix.

3.5. Regeneration of the prepared Fe_3O_4/GO

In order to examine the regeneration of the prepared Fe_3O_4/GO, it was washed to neutral pH by high purity water and reused for

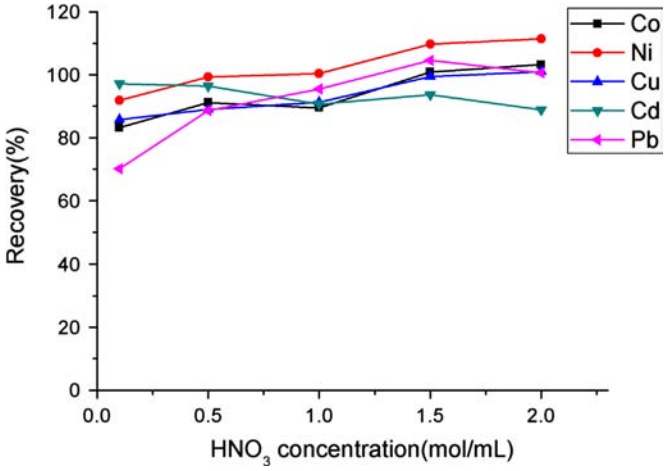

Fig. 7. Effect of the HNO_3 concentration on the recovery of the M^{2+} (4 μg L^{-1}); sample weight: 6 mg; sample volume: 50 mL; adsorption time: 7 min; eluent volume: 2 mL HNO_3; eluent time: 7 min.

proposed MSPF procedures. The results showed that the absorbent could be reused for more than 20 times without a significant decrease of the recoveries.

3.6. Validation of the ICP-MS coupled with the proposed MSPE method

To evaluate the analytical performance of established method, a series solution in the concentration were prepared and applied to the MSPE procedures. Limits of detection (LOD) were determined from the three times of standard deviation of 10 consecutive runs of blank solution. As showed in Table 1, the LODs of this method were 0.016, 0.046, 0.395, 0.038, 0.157 μg L^{-1} for Co, Ni, Cu, Cd, and Pb, respectively. The relative standard deviations (RSDs, $n=5$) were in the range of 1.8–5.5% at 10 μg L^{-1}. The linear range covered 1–150 μg L^{-1} with correlation coefficient (r) higher than 0.9981. The LODs of the developed sorbent in comparison with other sorbents for extraction of heavy metal ions was given in Table 2. As can be seen, the LODs obtained by this work were lower than that reported methods. Besides, compared to these reported methods, the present MSPE method was fast, precise, easy to operate, and had high adsorption capacity.

	10	13.7 ± 0.5	95	10	29.6 ± 1.1	81
	20	23.6 ± 1.0	97	20	44.1 ± 0.8	113

3.7. Analysis of biological samples

In order to validate the suitability of proposed method, the method was applied to the biological samples (urine and plasma) and the analytical results along with the recoveries at two spiked concentrations (10 and 20 μg L^{-1}) were given in Table 3. It can be seen that the recoveries for the spiked samples were between 81 and 113%.

4. Conclusions

A novel magnetic nanocomposite Fe_3O_4/GO was successfully synthesized through one-step chemical coprecipitation method. The material displayed high adsorption capacity for five heavy metal ions and was stable even in acid solution. The adsorbent ability increased in high pH, which showed higher adsorption capacity for Cu^{2+} and Pb^{2+} due to the strong complexation ability with carboxylic groups. It could be separated rapidly under external magnet, reused at least 20 times, and successfully applied to MSPE. The method was fast, precise, easy to operate, and had low LODs. What was more, the proposed method was successfully applied to biological sample and got the excellent recoveries even the matrix was complex. The detecting results could indicate the existence of environment pollution, which benefited for controlling the pollution in time.

ABSTRACT

In this study, a stainless steel wire/ionic liquid-solid phase microextraction technique was developed for the direct extraction of APs from water samples. Some parameters were optimised, such as selection of the substrate and ILs, extraction time, extraction temperature, stirring rate and sample pH, etc. The experimental data demonstrated that the etched stainless steel wire was a suitable substrate for IL-coated SPME. The coating was prepared by directly depositing the ILs onto the surface of the etched stainless steel wire, which exhibited a porous structure and a high surface area. The $[C_8MIM][PF_6]$ IL exhibited maximum efficiency with an extraction time of 30 min, and the aqueous sample was maintained at 40 °C and adjusted to pH 2 under stirring conditions. The enrichment factor of the IL coating for the four APs ranged from 1382 to 4779, the detection limits (LOD, S/N=3) of the four APs ranged from 0.01 to 0.04 ng mL^{-1} and the RSD values for purified water spiked with APs ranged from 4.0 to 11.8% (n=3). The calibration graphs were linear in the concentration range from 0.5 to 200 ng mL^{-1} ($R^2 > 0.9569$). The optimised method was successfully applied for the analysis of real water samples, and the method was suitable for the extraction of APs from water samples.

1. Introduction

Alkylphenols (APs) are ubiquitous environmental contaminants resulting from the degradation of alkylphenol polyethoxylates (APnEOs). APnEOs are surface-active agents that are commonly used in household cleaning products, agricultural applications and the chemical industry [1]. The residual surfactants and their degradation products are directly discharged to plants or surface water without any treatment, and the residuals can disperse into different environmental compartments. APs possess lipophilic properties, are stable in the environment and exhibit a tendency to accumulate in living organisms. The European Union (EU) listed APs as endocrine-disrupting chemicals (EDCs) in 1996. Emerging research suggests that APs are widely distributed in various environmental matrices, and an increased awareness of the presence of APs in the environment has led to an intensified interest in the trace analysis of these compounds [2,3].

The determination of APs from environmental samples at low concentrations remains a challenging task, and major studies on APs have focused on the development of rapid and simple extraction methods. The conventional methods for extracting APs from an environmental sample are liquid–liquid extraction (LLE) [4] and solid-phase extraction (SPE) [5,6]. However, these methods are tedious, time-consuming and require large amounts of high-purity organic solvents, which are expensive, toxic and cause additional environmental problems. Over the past decade, special attention has been focused on sample preparation methods that ensure a reduction in the amount of organic solvents required or even eliminate them completely and limit the number of operations and processes to a minimum.

Solid-phase microextraction (SPME) is a sample preparation technique that integrates sampling, isolation, enrichment and injection into one step [7–9]. SPME has sparked great interest in the scientific community because it is solvent-free, sensitive, fast, simple to operate and easily incorporated into chromatographic analysis. A polymer-coated microfibre plays the key role in the SPME procedure; the fibre can adsorb certain organic analytes and concentrate them from the various phases of a sample [10].

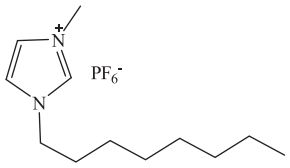
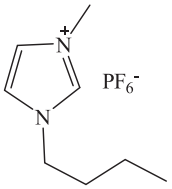
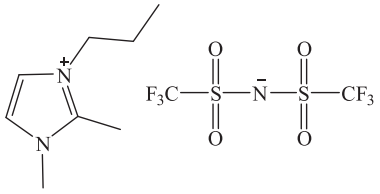
The fibre has a crucial effect on the accuracy and selectivity of the SPME procedure. Certain commercial fibres of this have been developed; however, these fibres are expensive, fragile and unstable under extreme thermal and chemical conditions, which limit the applications of SPME for real samples. To meet the requirements of complex analysis, new SPME coatings with remarkable properties, such as enhanced sensitivity [11], high thermal stability [12], mechanical and chemical stability and low cost, have been continually developed using new preparation methods [13] or new materials [14,15]. Moreover, fused silica has the disadvantages of being fragile and expensive. Therefore, recent studies have focused primarily on the development and further extension of supports with a long lifetime [16]. Other materials have been explored to replace silica rods as the SPME substrate [17–20]. Stainless steel, which is flexible and durable and exhibits good mechanical properties, is a suitable SPME substrate [21–23]. Stainless steel is resistant to corrosion in various environments, such as in acidic solutions and under alkaline conditions.

Room-temperature ionic liquids (ILs) are ionic compounds that are liquid over a temperature range near or below room temperature. ILs are non-molecular solvents consisting of a heterocyclic cation and an anion. ILs exhibit good thermal stability, negligible vapour pressure and convenient use. Because the cations and the anions can be integrated in different combinations, we can also obtain ILs with specific functions by specially designing the structure thereof. ILs exhibit good extractability for various organic compounds and metal ions [24–26]. Considering the above mentioned characteristics and advantages, ILs may be potential adsorbents for SPME. Jiang [27] and Amini [28] demonstrated that [C_8MIM][PF_6] can be physically adsorbed on the surface of fused silica tubing or stainless steel wire as the coating for SPME.







In this study, we prepared a SPME fibre based on the deposition of an ionic liquid on an etched stainless steel wire, instead of a commercial polyacrylate (PA) fibre, to analyse APs in water samples. Four oestrogenic APs (4-*n*-pentylphenol, 4-*n*-hexylphenol, *p*-*tert*-octylphenol and nonylphenols) were used as the target compounds. The goal of this study was to develop a sensitive, robust and inexpensive SPME method that can be used for the analysis of APs in water samples. Therefore, we also investigated the effects of the various experimental parameters that affected the extraction efficiency. Under the optimised conditions, we compared the enrichment factor with that obtained from a commercial PA fibre. Finally, the fibres were applied to extract APs from actual river-water samples to evaluate their applicability in real sample analysis.

2. Experimental

2.1. Chemicals and materials

The alkylphenol standards (4-*n*-pentylphenol, 4-*n*-hexylphenol, *p*-*tert*-octylphenol and nonylphenols), the silylation reagent BSTFA (N,O-bis(trimethylsilyl)trifluoroacetamide) and the internal standard (phenanthelene-d_{10}) used in this study, whose purities were higher than 99%, were purchased from Chem. Service (Hatfield, PA, USA). Standard solutions (1000 mg L^{-1}) of each compound were prepared in HPLC-grade methanol and stored in a refrigerator. A mixture of these alkylphenol compounds was prepared by diluting the standard solution with methanol, and additional diluted working solutions were prepared daily by diluting the standard solution with purified water or river water. The ILs used in this study were 1,2-dimethyl-3-propylimidazolium bis (trifluoromethylsulphonyl)imide [C_3MIM][NTf_2], 1-butyl-3-methylimidazolium hexafluorophosphate [C_4MIM][PF_6] and 1-octyl-3-methylimidazolium hexafluorophosphate ([C_8MIM][PF_6]), which were purchased from Sigma-Aldrich (Bellefonte, PA, USA). The structures and densities of the three ILs are shown in Table 1. The organic solvents used (dichloromethane, acetonitrile, methanol and acetone) were of HPLC grade and obtained from Caledon (Georgetown, Ont., Canada). Trifluoroacetic acid was of HPLC grade and purchased from Sigma-Aldrich (Bellefonte, PA, USA). Purified water was provided by a Milli-Q water purification system. Hydrofluoric acid (40.0%) was purchased from a local chemical reagent agent.

Table 1
Property of the three ILs selected in our experiment.

Abbreviation	ILs structure	Mw	Density (g cm^{-3})
[C_8MIM][PF_6]		340.29	1.24
[C_4MIM][PF_6]		284.18	1.38
[C_3MIM][NTf_2]		419.36	1.47

Solid-phase microextraction fibres composed of polyacrylate with a film thickness of 85 μm (PA, 85 μm) were purchased from Sigma-Aldrich (Bellefonte, PA, USA). The PA fibres were conditioned before every use in the hot injector of a gas chromatography system for 30 min at 230 °C according to the instructions provided by the supplier. A fibre holder for manual use was purchased from Sigma-Aldrich (Bellefonte, PA, USA). The needle core of a 1-μL microsyringe (Zhenhai, Zhejiang, Jiangsu) was used. PTFE stir bars (5 mm × 1 mm × 1 mm) were obtained from Sigma-Aldrich (Bellefonte, PA, USA). All glassware and other equipment were thoroughly washed with methanol and dried in an oven at 400 °C for 12 h after use.

2.2. Instrumentations

The chromatographic conditions of APs analysis were similar to those reported by Yang et al. [29,30]. Specific as follows:

HPLC analysis was performed using an Agilent 1100 series (Palo Alto, CA, USA) HPLC system. The HPLC system consisted of a quaternary pump, a vacuum degasser, a high-performance autosampler and a temperature-controlled column compartment. An Agilent G1315A diode array detector (Palo Alto, CA, USA) was employed. A ZORBAX Eclipse XDB-C_8 analytical column (150 mm × 4.6 mm, 5 μm) was used for chromatographic separation, and the constant flow of the mobile phase was maintained at 1 mL min^{-1}. A 4.6 mm × 12.5 mm Eclipse XDB-C_8 column (4.6 mm × 12.5 mm, 5 μm) drop-in guard cartridge (Agilent, CA, USA) was attached in line after the sample injector port and before the analysis column to trap residual contaminants that may have been contained in the mobile phase and/or the HPLC system. The solvent composition used as the mobile phase

was a mixture of ACN and H_2O (ACN:H_2O=5:5), and the UV detection wavelength was set to 225 nm. The water used in the mobile phase was filtered through 0.45-μm nylon membranes and degassed with ultrasonic waves; the water contained 0.1% trifluoroacetic acid.

GC analysis was performed on a Shimadzu GC 2010 equipped with a DB5 fused-silica capillary column (30 m × 0.25 mm; film thickness 0.25 μm), and detection was performed on a Shimadzu QPMS 2010 mass spectrometer with a quadrupole mass spectrometer system. The column temperature was maintained at 80 °C for 2 min and then programmed to increase by 20 °C min^{-1} to 100 °C, by 10 °C min^{-1} to 200 °C, finally ramped to 280 °C at the rate of 20 °C min^{-1} and then held for 20 min; the column flow was 1.20 mL min^{-1}. The other operating conditions consisted of an injection temperature of 280 °C in the splitless mode and the use of helium (99.99%) as the carrier gas. The GC–MS interface temperature was 280 °C. The electron ionisation-selected ion mode (EI-SIM) was used for quantification of the analytes. The solvent cut time was 8.0 min. The ion source temperature and the energy of the ionising electron were set to 200 °C and 70 eV, respectively. The selected *m*/*z* ratios of the ions used for quantification and identification of the target analytes were 179 and 207.

SEM micrographs of the stainless steel wire before and after etching were recorded on a Hitachi S-3500N scanning electron microscope at 20.0 kV.

2.3. SPME fibre preparation

The SPME device (Fig. 1) used in this study was prepared in our laboratory and modified from a 1-μL gas chromatography microsyringe with a stainless steel needle wire. The stainless steel needle of the microsyringe measured approximately 5 cm in length, from which a 1.5-cm portion was cut, resulting in the exposure of 1.5 cm of the stainless steel wire. The stainless steel wire could be exposed and retracted by pulling the upper end of the handle. Before etching, the needle wire was successively washed with methanol and dichloromethane and then conditioned at 200 °C under nitrogen gas for approximately 30 min. The stainless steel wire was etched by hydrofluoric acid for 20 min; the surface of the stainless steel wire became black and rough after etching. Then, the stainless steel wire was also conditioned at 200 °C to eliminate any possible contaminants. During the coating procedure, we prepared the dichloromethane and ILs mixture as reported by other researchers [27,28] in a ratio of 1:9, which was used as the coating solution. We dipped the etched stainless steel wire directly into the coating solution for 3 min and removed it; the dichloromethane evaporated immediately when the fibre was exposed to the surrounding air, and the ILs formed a thin layer on the etched stainless steel wire. The coating process was repeated three times. The coated stainless steel wire was directly used as the SPME fibre for the extraction of APs from water samples.

2.4. Stainless steel wire/IL–SPME procedures

For the experiment, the standard solution was gradually diluted using triple-distilled water until the concentration of each target compound was 500 ng mL^{-1}. A 1.3-mL aliquot of the APs aqueous samples was placed in a 1.5-mL glass vial. In this study, the SPME sampling method was performed by direct immersion, with the immersion depth and the vial position held constant. During the extraction, the aqueous samples were continuously stirred with a magnetic stir bar on a stir plate. Unless otherwise noted, prior to the extraction step, the pH of the aqueous sample was adjusted to 2 with hydrochloric acid. The temperature of the solution was maintained at 40 °C in a thermostatic water bath, and all of the experiments were conducted for a period of 30 min. After extraction, the compounds retained on the fibre were desorbed using an off-line static-state desorption mode.

Samples of river water were collected from the Buerhatong River (Yianji, Jilin Province), and the water was directly analysed by the optimised SPME process after sampling without any pretreatment. Because the matrix of the real sample was complex and the sensitivity of HPLC–UV is rather low, GC–MS analysis was performed on the real sample to ensure accuracy. Due to the polarity of the APs, a derivatisation procedure was performed before the GC–MS analysis. The derivatisation procedure has been thoroughly studied in our laboratory [31]. The concentration of each target compound after extraction was defined as the ratio of the amount of the target compound to the volume of the ILs. The amount of each IL can be calculated from the peak area of the corresponding liquid chromatograph due to the IL's ultraviolet absorption. A volume of 1 μL for each IL was injected into the liquid chromatography system, and the obtained peak area was used for quantification of the ILs adsorbed on the etched stainless steel wire. A gas chromatographic internal standard, phenanthelene-d_{10}, was added to every sample prior to GC injection.

2.5. Desorption procedures

The optimisation experiments were performed by HPLC. After extraction the fibre was placed into a vial filled with an organic solvent for desorption, and ensuring its total immersion. And desorption for 5 min was carried out at ultrasonic treatment. A subsample was subjected to further analysis by HPLC.

Analytical performance characteristics and real sample analysis were performed by GC–MS. The procedure involved the use of a 50-μL mixture of BSTFA and acetone (1:1), and the headspace (HS) derivatisation was performed on fibre, the derivatisation time was 10 min. The fibre was direct injected into the GC injector, a subsample was subjected to GC–MS for further analysis.

3. Results and discussion

The amount of analytes adsorbed by the ILs at equilibrium is directly related to their concentrations in the sample and can be expressed by the following equation [32]:

$$n_A = K_{fs} V_f V_s C_0 / (K_{fs} V_f + + V_s) \quad (1)$$

where n_A is the amount of analyte A extracted by the coating when equilibrium is reached, V_s and V_f are the volumes of the sample solution and the coating, respectively, C_0 is the initial concentration of the analytes in the sample and K_{fs} is the distribution coefficient. If V_s is very large ($V_s >> K_{fs}V_f$), and the amount of analyte extracted by the ILs coating can be expressed by

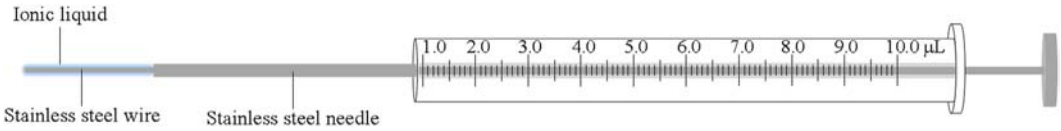


Fig. 1. Schematic representation of the etched stainless steel wire/ionic liquid-solid phase microextraction technique.

the following equation [32]:

$$n_A = K_{fs} V_f C_0 \quad (2)$$

According to the operating principle of SPME, when equilibrium is reached, the amount of the adsorbed target compounds is proportional to the volume of the ILs and K_{fs}. Therefore, the chemical and physical properties of the substrate and the ILs are the primary factors that determine the extraction efficiency. For the quantitative analysis of trace levels of APs in water samples, the extraction efficiency is especially crucial; therefore, selecting a suitable SPME substrate is important in the SPME fibre coating technique. The extraction efficiency of the IL-SPME technique can be improved by increasing the amount of ILs adsorbed on the substrate, which can be achieved by modifying the substrate surface.

3.1. Selection of the substrate

A stainless steel wire was used as the substrate for SPME instead of a commercial fibre due to the former's strong mechanical properties and its ability to be modified easily [14,21,33]. A previous study [27,28] showed that the surface of a stainless steel wire is smooth and the amount of ILs adsorbed on the stainless steel is limited due to the low adsorption interaction between the ILs and stainless steel or fused silica; therefore, the extraction efficiency is limited. The amount of ILs that coat the supporting material depends on the surface properties of the supporting material. To improve the adsorption of the ILs on the stainless steel wire, the wire was etched using hydrofluoric acid for 20 min that partially dissolved the wire and increased the surface area. Physical characteristic of the wire before and after the etching procedure have been studied by SEM: as reported in Fig. 2, etched wire showed more roughness, porosity, and then a greater surface area if compared with non-etched wire (Fig. S1 and Table S1).

To evaluate the adsorption capacity of the stainless steel wire, the two different surfaces of the wire were compared, and the amount of ILs adsorbed on the different surfaces was calculated from the ILs' absorption peak area on the corresponding liquid chromatograph. Fig. 2B shows the peak area of the $[C_8MIM][PF_6]$ IL adsorbed onto the stainless steel wire and the etched stainless steel wire. The amount of the ILs adsorbed onto the etched stainless steel wire was observed to be approximately two times that adsorbed on the unetched wire. This result indicates that the etched stainless steel wire favoured enhanced extraction efficiency because it adsorbed more ILs than the original stainless steel wire. Therefore, the etched wire was selected as the SPME substrate in the following study.

3.2. Selection of ILs

Similarly to the conventional SPME, the extraction efficiency of the IL-coated SPME is dependent on the physiochemical properties of the fibre coating material and the target analytes, such as the functional groups and structure of the chemicals. The different kinds of the ILs can change the partition coefficient (K_{fs}) of the target compounds between the extraction phase and the sample. A preliminary ILs selection was carried out taking in consideration ILs with appropriate physico-chemical characteristics, such as water solubility, viscosity and hydrophobicity. On the base of this preliminary selection, three ILs were candidate as the coating materials: 1,2-dimethyl-3-propylimidazolium bis(trifluoromethylsulphonyl)imide ($[C_3MIM][NTf_2]$); 1-butyl-3-methylimidazolium hexafluorophosphate ($[C_4MIM][PF_6]$) and 1-octyl-3-methylimidazolium hexafluorophosphate ($[C_8MIM][PF_6]$). The coating materials feature a cationic imidazolyl group and anionic $[NTf_2]$ or $[PF_6]$ groups. The purpose of this study was to directly extract the target analytes from water samples; therefore, the fibres were directly immersed in the water phase. To protect the dissolution of the ILs from the coating into the water system, we selected ILs that

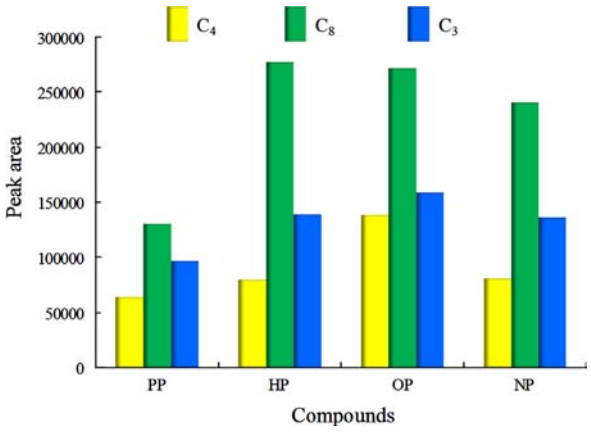

Fig. 3. The effect of the nature of the ILs on the extraction efficiency. Deionised water (1.3 mL) spiked with 500 ng mL^{-1} of each of the four APs, with direct-immersion SPME at 40 °C for 30 min.

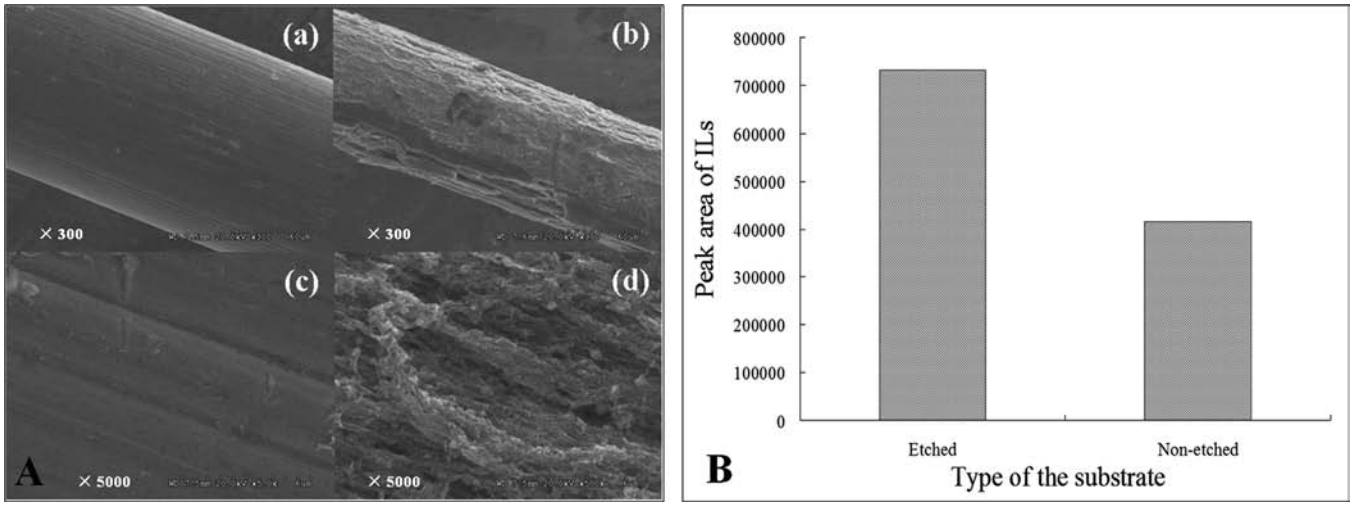

Fig. 2. A) Scanning electron micrographs of the surface of the stainless steel wire before (a and c) and after (b and d) etching. Images a and b were captured at a magnification of 300; images c and d were captured a magnification of 5000. B) The amount of ILs adsorbed onto the SPME fibre with and without etching, as analysed by LC-UV.

contain a hydrophobic anion. The length of the lateral chain linked to the imidazolyl group also affected the physical and chemical properties of the ILs. The ILs with a longer lateral chain exhibit higher viscosity, which can increase the amount of ILs adsorbed onto stainless steel. Furthermore, the different lateral chain lengths of the ILs will affect the extraction efficiency because the K_{fs} values of the ILs are also different. Therefore, we also selected two ILs that contain the same anion but a different cationic lateral chain for comparison. Fig. 3 shows the effect of the different ILs on the extraction efficiency of the four types of APs. Among the three types of ILs selected, [C_8MIM][PF_6] exhibited the best extraction efficiency due to its high viscosity and hydrophobicity; thus, a relatively large amount of ILs can be adsorbed onto the etched stainless steel. Furthermore, the strong interaction between the octyl group in the [C_8MIM][PF_6] and the analytes and the lower solubility of $[PF_6]^{-1}$ than $[NTf_2]^{-1}$ leads to the high viscosity, strong adsorbability and low solubility of the IL. Consequently, [C_8MIM][PF_6] displays higher extractability compared with the other two types of ILs. Therefore, [C_8MIM][PF_6] was chosen as the fibre coating material in the following experiments.

3.3. Optimisation of the SPME parameters

3.3.1. Extraction time

SPME is an equilibrium-based and non-exhaustive extraction technique. The target compounds are then distributed between the matrix and the extraction phases obeying to the partition constant when equilibrium is reached. Under non-equilibrium conditions, EE is dependent from extraction time: in order to study this influence, the EE of the IL-SPME was analysed in a time range of 10–50 min. Results are displayed in Fig. 4A: during the first 30 min, a high dependence from extraction time was observed, while only slight increases (sometimes not noticeable) were recorded for higher times. Thus, 30 min was chosen as the extraction time for further experiments.

3.3.2. Extraction temperature and stirring rate

For the direct-immersion SPME, the diffusion and mass transfer of the target compounds to the extraction phase are vital for obtaining good extraction efficiency and reproducibility. Stirring the sample and increasing the extraction temperature can improve the extraction efficiency by increasing the K_{fs} value by accelerating the diffusion and mass transfer of the analytes to the extraction phase. At a suitable extraction temperature and stirring rate, good extraction efficiency can be obtained within an economic analysis time.

To investigate the effect of the extraction temperature, a temperature range of 20 °C to 80 °C was studied. As shown in Fig. 4B, a higher extraction efficiency was obtained when the temperature increased from 20 °C to 40 °C; however, above 40 °C, the extraction efficiency decreased sharply. A high temperature could accelerate the diffusion and mass transfer and further improve the extraction efficiency. However, when the temperature was higher, the solubility of the analyte and the ILs in water also increased; therefore, the target dissolved in the water phase from the coating materials, and the extraction efficiency decreased. Thus, 40 °C was selected as the extraction temperature in the following experiments.

A series of experiments using different stirring rates was also conducted to investigate the effect of the stirring rate on the extraction efficiency. According to the experimental results, a positive effect was obtained by increasing the stirring rate. The extraction efficiency was satisfactory when the stirring rate was 400 rpm. Above this rate, the magnetic stir bar was difficult to operate. In addition, rapid agitation causes the mass transfer of the analytes from the water phase to the headspace by splatter, which is unfavourable for the direct SPME mode used in the present study.

3.3.3. Sample pH

Phenolic compounds are weak organic acids, and there are different forms of such compounds that occur depending on the acidity of a sample. Thus, in this study, the extraction efficiency was also greatly affected by the form of the target compounds that occurred in the aqueous sample. The compounds dissociated to their ionic form when the pH value of the aqueous sample exceeded the acidic dissociation constant (pKa) values of the compounds, and the compounds primarily existed in their molecular form when the pH value of the aqueous sample was lower than the pKa values of the compounds. The adsorption behaviour of the dissociated form of a molecule is very different from that of the non-dissociated form. It was important to control the pH of the extraction media to enhance the affinity of each compound to the fibre and improve the extraction efficiency. Referring to previous studies [30], the pH of sample solution was set to 2, 5, 7, and the results were compared (the data not shown). The experimental results showed that better extraction efficiency was obtained when the pH value of the sample solution was 2.0. In the following experiments, the pH of the aqueous sample was adjusted to 2.0 with hydrochloric acid.

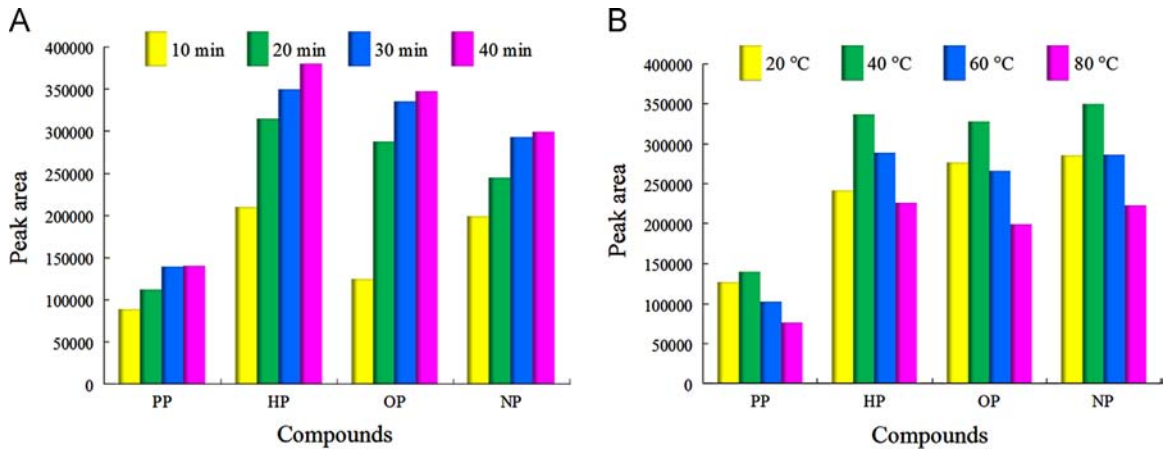

Fig. 4. A) The effect of the extraction time on the extraction efficiency. Deionised water (1.3 mL) spiked with 500 ng mL^{-1} of each of the four APs, with direct-immersion SPME at 40 °C with the [C_8MIM][PF_6] coating. B) The effect of the extraction temperature on the extraction efficiency. Deionised water (1.3 mL) spiked with 500 ng mL^{-1} of each of the four APs, with direct-immersion SPME for 30 min with the [C_8MIM][PF_6] coating.

3.3.4. Desorption procedure

Complete desorption of the analytes from the fibre enhances the reproducibility of the method and ensures that no crossover pollution exists in subsequent analysis. Additionally, the complete desorption of the analytes can minimise damage to the chromatographic instrument; therefore, we carefully investigated the effects of the desorption solvent and desorption time. In this study, a desorption procedure using a fibre-based, etched stainless steel IL substrate in the off-line mode and static state was adopted. The organic solvent used as the desorption solvent was required to have good solubility towards the target compounds and be compatible with the subsequent chromatographic analysis. APs show good solubility in methanol, which is suitable for the mobile phase in liquid chromatography analysis; therefore, methanol was used as the desorption solvent. The experimental results indicated that 5 min was the optimum desorption time, and no carryover was observed.

Table 2
Characterisation of the etched stainless steel wire/ILs SPME method determined by GC–MS.

Compound	Linear range (ng mL^{-1})	R^2	LOD* (S/N=3) (ng mL^{-1})	RSD (%)	logKow[a]	EFs		Increased multiple of EFs
						ILs	PA	
4-*n*-Pentylphenol	0.5–200	0.9734	0.03	11.2	3.747	1382	212	-
4-*n*-Hexylphenol	0.2–200	0.9692	0.01	7.6	4.675	1560	178	8.8
p-tert -Octylphenol	0.1–200	0.9917	0.01	4.0	5.139	4046	372	10.9
Nonylphenols	0.1–200	0.9569	0.04	8.3	5.603	4779	285	16.8

logKow[a] is the indicator for hydrophobicity, namely n-octanol_water partition coefficients. Data taken from ChemExper: (http://www.chemexper.com/).

3.4. Analytical performance characteristics

The GC–MS method is widely used because of its good selectivity and high sensitivity. In addition, the reliability and accuracy of analysis have been significantly improved by applying highly specific and sensitive instrumentation. The matrix of the real sample analysed in this study was complex, and the sensitivity of the HPLC-UV method is rather low; therefore, GC–MS analysis was performed on the real sample to ensure accuracy. Due to the polarity of the APs, a derivatisation procedure was performed prior to the GC–MS analysis.

In this study, four types of AP standard mixtures were used to evaluate certain analytical performances and validate the proposed method. The linearity and the limits of detection (LODs) were evaluated using purified water spiked with four APs at five different concentration levels. These spiked samples were subjected to all of the stainless steel wire/IL–SPME procedures and the derivatisation experiment. The LODs were verified by analysing the different concentrations of the APs and calculated as three times the signal-to-noise ratio, according to published guidelines. Three replicate analyses were performed for each spiked levels (0.5, 2, 5, 50, 200 ng mL^{-1}) to evaluate the repeatability of the experiment. The figures of merit, including the linear ranges, correlation coefficients, repeatability and the limits of detection (LODs), are listed in Table 2. The linear range reached as wide as 10^3 for all of the analytes, with good correlation coefficients varying from 0.9569 to 0.9917. The LODs for the four alkylphenols ranged from 0.01 to 0.04 ng mL^{-1}. The enrichment factors ranged from 1382 to 4779. The repeatability of the adsorption on the fibre-based etched stainless steel substrate was represented by the relative standard deviation (RSD), which was observed to be less than 11.2% for the three repeated experiments under the optimised conditions.

In this study, a PA fibre was selected to perform the control experiment and to further validate the performance of the IL-coated stainless steel wire prepared in our laboratory. A PA fibre is typically employed in the polar polymer extraction phase used in common SPME. PA exhibited a high extraction efficiency and selectivity towards phenolic compounds in a previous study [23]. Because SPME is a non-exhaustive extraction technique, the EF value was used to evaluate the enrichment ability of the coatings. The EF value was defined as the ratio of the concentration of the target compounds after extraction to that before extraction. The EF values of the four APs obtained from the two coatings are listed in Table 2. As shown, for all of the target compounds, high EF values were recorded for the IL-coated stainless steel wire, and the EF values of the IL coatings were significantly higher than the EF value obtained from the PA fibre. This result demonstrates that the IL-coated etched stainless steel wire exhibited higher enrichment efficiency towards the APs than did the PA fibre, indicating that the IL coating extraction was suitable for the SPME of the APs.

3.5. Real sample

The proposed technique was successfully applied for the determination of the APs in river-water samples (three sites, three samples were collected at each site) from the Buerhatong River, which were collected in Yanji City, China. Among the four types of APs, only the NPs were detected in the river samples (as shown in Fig. 5); the concentration of the NPs was 46.65 ng mL^{-1}, and the RSD of the NPs was between 9.3% and 11.8%. To validate the analytical behaviour of other chemicals in real sample analysis, the river-water sample was spiked with 100 ng mL^{-1} of the AP standard mixture, and the sample was subjected to IL coating extraction and the above-described derivatisation procedures. As shown in Fig. 5, signals associated with all of the chemicals clearly appeared in the spiked real sample chromatograph. The enrichment factors of the APs ranged from 1328 for 4-*n*-pentylphenol to 3925 for nonylphenols, with an average RSD of 10.2%.

4. Conclusions

An economical, simple, rapid, environmentally friendly and highly efficient etched stainless steel/ionic liquid SPME technique was developed. The amount of the ILs adsorbed significantly increased using the etching method due to the formation of a rough surface on the wire substrate. This method favours a high extraction efficiency for stainless steel/ionic liquid SPME. The substrate, IL type, extraction time, extraction temperature and pH value are the main parameters that affect the extraction efficiency. The optimised conditions of the extraction procedure were determined to be as follows: etched stainless steel, [C_8MIM][PF_6], 30 min, 40 °C and pH 2. The enrichment factors and detection limits for the four alkylphenols ranged from 1382 to 4779 and from 0.01 ng mL^{-1} to 0.04 ng mL^{-1}, respectively. The low detection limits of the method allowed for its use in routine analysis. The etched stainless steel/ionic liquid SPME was coupled with the GC–MS method to successfully detect low levels of APs from river-water samples. Relative to the enrichment factor of a commercial PA fibre, the enrichment factors of the coated stainless steel wire reached values 6.5 to 16.8 times as great. The optimised and validated SPME technique was demonstrated to be useful for the qualitative and quantitative analysis of APs in water samples.

ABSTRACT

A new and facile method for the determination of critical micelle concentration (CMC) of ionic and non-ionic surfactants is proposed in this article. Carbon dots exhibited substantial fluorescence and therefore enhanced the sensitivity of this evaluation. Understanding the formation of surfactant micelles is vital for the applications of biomedicine such as drug fabrication and smart molecular vehicles in delivering therapeutic dosage to various molecular sites. The fluorescence property of carbon dots was utilized for the first time to estimate the critical micelle concentration of surfactants. The central concept of the approach is based on the Stokes shift determination of a system composed of constant amount of carbon dots with varying concentrations of ionic and non-ionic surfactants. The synthesized carbon dots were characterized by FTIR, TEM, XRD, Raman, UV, and fluorescence spectroscope. The carbon dots were excited at 280 nm so as to obtain maximum emission for the Stokes shift measurement. The CMC value of cetyltrimethyl ammonium bromide (CTAB), sodium dodecyl sulfate (SDS), Triton X-100, dodecyldimethyl(3-sulfopropyl)ammonium hydroxide (SB-12) evaluated by this approach was found to be 0.98, 7.3, 0.19, and 3.5 mM, respectively. The signals of spectra were assigned and explained in terms of both electron transitions between specific molecular orbital and the interaction with solvent.

1. Introduction

Surfactant is a unique group of compounds containing both a hydrophobic long-chain (tail) and a hydrophilic polar group (head) in their structures [1,2]. When the concentration reaches a specific narrow range, called critical micelle concentration [3], the molecules tend to self-associate with tails aggregating inward into an assembled micellar structure which is favored thermodynamically in polar solvents [4]. The formed micelles have a center of hydrophobic (tail) moiety and an outward head (hydrophilic) moiety took place in a continuous phase generally observed in aqueous phase. In contrast, when the outer portion of micelles is comprised of tail (hydrophobic) moiety and the head moiety assembled in center of the micelles it is called as the reverse micelle which is formed in oil phase. In this study all the experiments were specifically conducted in aqueous phase. The formed micelle has been described as structure of aggregate; it has characteristically various interactions such as hydrophobic, electrostatic interaction and hydrogen bonding. These micelles comprise unique characteristics such as uniform nanosize, core-shell structure, and being stable thermodynamically in physiological conditions due to their low critical micelle concentration [5,6]. With this amphiphilic structure, surfactants have been extensively employed in applications including the fields of chemistry [7], biotechnology, and pharmacy [8]. A variety of surfactants have been utilized with their capability to enhance the permeability of drugs across biological membranes [9]. In complex systems, surfactants were widely used in membrane protein separation, crystallization, purification and stabilization. Since the physicochemical properties of solutions below and above CMC demonstrate drastic changes, such as surface tension, electrical conductivity,

turbidity, osmotic pressure, density, viscosity, and light scattering [10]. Many methods have been proposed to determine the CMC of plethora of surfactants, e.g. spectrophotometry [11], colorimetric [12], potentiometry, refractometry, conductometry, capillary electrophoresis, light scattering [13], pyrene 1:3 ratio method [14], and so forth. Among these methods, spectrophotometry is a simple and reliable tool for determination of CMC. Due to the outstanding fluorescence exhibited by carbon dots (C-dots) [15], the nanodots were introduced in an attempt to enhance the sensitivity for the fluorophotometric determination of CMC.

Most of the methods reported for the determination of critical micelle concentration have several disadvantages such as low sensitivity, the necessity of dye or probe, large volume of sample, tedious experimental techniques as well as the interpretation tools required. Additionally, some methods are particularly applicable to the CMC determination of a specific surfactant which is one of the major drawbacks of those methods [16]. In the present work, in order to solve these problems, we have developed a modified technique based on the fluorescence and the Stokes shift of C-dots, which is one category of highly fluorescent materials based on carbon materials [17] to investigate the CMC of CTAB, SDS, Triton X-100, and SB-12.

C-dots are growing popular among the families of quantum dots because of the excellent optical and biomedical properties [18]. The advantages of being able to emit intense and tunable photoluminescence (PL) have made C-dots to be a favorable ingredient for the applications in the fields of catalysis and energy [19]. Additionally, carbon quantum dots demonstrated special characteristics, e.g. non-blinking, high aqueous solubility, and non-toxicity [20]. There are many established protocols for the synthesis of amorphous as well as crystalline C-dots using facile routes such as thermal cracking of organic compounds [21], microwave mediated synthesis [22], laser ablation of graphite [23], electro-oxidation of graphite, and oxidation of candle soot [24].

The central concept of this work is based on the Stokes shift, the difference of peak maxima in excitation and emission spectra [25], of C-dots in the presence of varying concentration of surfactants. The C-dots decorated with both positive as well as negative charged moieties were found to be efficiently interacting with charged or non-charged head group surfactants. This phenomenon leads to the exhibition of sharp Stokes shift in the presence of the surfactants. Herein, cationic cetyltrimethyl ammonium bromide (CTAB), anionic sodium dodecyl sulfate (SDS), non-ionic Triton X-100, as well as zwitterionic dodecyldimethyl (3-sulfopropyl)ammonium hydroxide (SB-12) surfactants were investigated and the CMC were evaluated. Note that this zwitterionic surfactant has seldom been studied [26]. Since the zwitterionic surfactant is electrically neutral in nature, it is easily to be distinguished from others. For the determination of CMC values, the intersection of the extrapolation of curves in a graph of Stokes shift versus concentration was perceived as a point of change and was typically denoted as the CMC. All of the experiments were performed at room temperature.

2. Materials and methods

Sucrose was purchased from J.T. Baker (USA). Cetyltrimethyl ammonium bromide (CTAB), sodium dodecyl sulfate (SDS), Triton X-100, sulfuric acid and sodium hydroxide were purchased from Sigma-Aldrich (USA). Quinine sulfate was supplied by Alfa Aesar (Great Britain). Dodecyldimethyl(3-sulfopropyl)ammonium hydroxide (SB-12) was supplied by Tokyo Chemical Industry Co., Ltd. (Japan). Ultrapure water from a Milli-Q Plus water purification system (18.2 MΩ, Millipore, and Bedford, MA, USA) was used for all experiments.

2.1. Preparation and purification of fluorescent carbon dots (C-dots)

C-dots were prepared by controlled carbonization of sucrose modified method proposed by Minghong Wu group [27]. 2.5 g of sucrose was weighed and dissolved by adding 2 mL of deionized water. Add 3 mL concentrated sulfuric acid dropwise into the solution with continuous vigorous stirring. The yellowish brown colored reaction mixture was neutralized with sufficient amount of NaOH. The dark brown color reaction mixture was isolated by a centrifuge operated at 18,000 rpm for 10 min. It was further purified by dialysis (MW cutoff 12–14 kD) against Milli-Q water for 24 h under constant stirring condition. In order to concentrate the amount of C-dots the solution was dried in a rotary vacuum evaporator (Büchi, Germany) and frozen dried for the quantification of C-dots.

2.1.1. Quantum yield measurement

The quantum yield (Q) of the C-dots has been calculated using the following equation, Eq. (1). Quinine sulfate (Q is 0.54) was chosen as a reference to determine Q, where Q denotes for quantum yield, I represents measured integrated emission intensity, n denotes the refractive index, and E is the optical density. R represents the fluorophore of known quantum yield for reference [28,29].

$$Q = Q_R \frac{I}{I_R}\frac{E_R}{E}\frac{n^2}{n_R^2} \quad (1)$$

2.2. Determination of critical micelle concentration of surfactants

2 mg of dried C-dots was mixed with varying concentrations of CTAB, SDS and Triton X-100 and make up to 5 mL as the total volume. The stock solutions of all surfactants were prepared and used for further experiments. The concentrations of stock solutions for CTAB, SDS, Triton X-100, and SB-12 were 10 mM, 50 mM, 5 mM, and 25 mM. In case of CTAB, aqueous dilutions were prepared from 0.2 to 2 mM at the interval of 0.2 mM from a stock solution. As for SDS, 2–20 mM diluted solutions were prepared with increment of 2 mM from stock solution. In the case of Triton X-100, various dilutions prepared from 50 to 500 μM with increment of 50 μM from the stock solution. For SB-12, solutions were prepared from 0.5 mM to 6.0 mM with increment of 0.5 mM from the stock solution. 2 mg of highly purified C-dots was added in all the dilutions and make up the volume up to 5 mL. These solutions were sonicated for 5 min in order to equilibrate the solution. Similar procedure was followed for SDS except the dilutions were varied from 2 to 20 mM from a stock of 50 mM. 10 mM Triton X-100 stock solution was prepared and 50 to 500 μM dilutions were prepared from the stock solution. After equilibrating the C-dots-surfactants solution, the excitations as well as the emission spectra were recorded using the fluorescence spectroscope (Hitachi F 2700, Japan). The excitation maxima relative to emission maxima were recorded for each concentration of dilution sample.

The Stokes shift was calculated using the following equation:

$$\Delta\nu(\text{Stokesshift}) = \nu_{ex} - \nu_{em} \quad (2)$$

where ν_{ex} and ν_{em} refer to the excitation and the emission maximum, respectively.

From the graphical representation of the Stokes shift versus concentration, CMC values of the surfactants were evaluated.

2.3. Characterization of carbon dots (C-dots)

The morphology and uniformity of C-dots were measured by a high resolution transmission electron microscope (JEOL, Japan). Spectral properties of C-dots were studied by a UV–vis spectroscope

(Thermo, Evolution 201, USA) and fluorescence spectroscope (Hitachi-2700, Japan) using a standard quartz cuvette having a path length of 1 cm. Functional groups of C-dots were studied using a Fourier transform infrared spectrometer (Perkin Elmer, USA). The crystallinity of C-dots were studied using an X-ray diffraction (XRD) (Phillip, The Netherlands). Raman spectra were recorded from the Horiba, Jobin–Yvon Labram spectrometer with 630 nm laser sources.

3. Results and discussion

3.1. The characterization of C-dots

The brown colour C-dots solution exhibited intense green fluorescence strongly under UV light (λ_{ex}=365 nm), as shown in schematic illustration of Fig. 1. C-dots are spherical in shape and are highly mono-dispersed with uniform size (Fig. 2A). Moreover, the TEM micrograph depicts the nanoscale size of C-dots with average particle diameter ranging from 3 to 6 nm with maximum population of C-dots as 5 nm (diameter), (see Fig. 2B). The UV–vis spectrum (Fig. 2C) of C-dots displayed continuous absorbance increasing from 280 nm to 380 nm which is in agreement with relevant literatures [27]. Fig. 2D showed the combined photoluminescence spectra of aqueous solution of C-dots with different excitation wavelengths. The aqueous C-dots solution was excited at 260–400 nm with 20 nm increment. The maximum intensity for emission spectra observed 387 nm was excited at 280 nm. The emission peak was shifted to a higher wavelength with the increase of the excitation wavelength. All experiments were carried out at 280 nm (excitation wavelength) to determine the critical micelle concentration (CMC) for all surfactant-C-dots dilutions. An FTIR technique was used to identify the functional groups on the surface of C-dots. As shown in Fig. 3A, the band of the ester group appeared at 1719 cm^{-1} and the peak of the C=O group found at 1719 cm^{-1} depict aromatization. The broad peak at 3438 cm^{-1} and the band in the range of 1000–1400 cm^{-1} implied the existence of a large amount of hydroxyl groups and C-O groups. X-ray diffraction (XRD) of C-dots (Fig. 3B) reveals a characteristic peak at 2θ=20.12°, which can be assigned to the plane (002) with an interlayer spacing of 4.2 Å, which is larger than that of bulk graphite (3.3 Å), indicating poor crystallization [30]. The Raman spectrum shown in Fig. 3C reveals the typical graphitic nature of C-dots. C-dots exhibited D- and G-bands corresponding to 1345 and 1540 cm^{-1} with no 2D peak in graphite. It can clearly be seen that the D peak is more prominent than G peak. This indicates the presence of amorphous carbon nanomaterials in the form of C-dots. The ratio of I_D/I_G, which is the characteristic peak of the disorder extent and the ratio of sp^3/sp^2 carbon, implying the extent of structural defects [30]. The I_D/I_G ratio of 2 indicates highly crystalline graphite. We calculated the I_D/I_G ratio for the as-synthesized C-dots and the estimated ratio of 0.873 indicating high purity of C-dots. The quantum yield of C-dots calculated with the reference to Quinine sulfate was found out to be 42%, which was summarized in Table 1.

3.2. The evaluation of critical micelle concentration (CMC) for CTAB, SDS, Triton X-100, and SB-12

Fig. 4A displays the impact of varying concentration of CTAB on the fluorescence properties of C-dots excited at 280 nm, which is the preliminary criterion of the determination of CMC. Generally, cationic surfactants such as CTAB acquire positively charged headgroups that are partially neutralized by anions, while anionic surfactants possess negatively charged head groups that are partially neutralized by cations [31]. As CTAB concentration increases, there was consistent decrease in fluorescence intensity (emission) of C-dots (Fig. 4A). Another noteworthy finding was the comparable intensities of both emission and excitation spectra of C-dots-CTAB mixture. The red shift observed from 375 nm to 425 nm may be due to the surface protection of C-dots with CTAB which may affect the PL properties of C-dots. In the close proximity of miniature scale of C-dots in the solution, due to monomers of surfactants, many thermodynamically favoured reactions are initiated leading to the change of the surface as well as the optical properties of the materials. Due to the negative charge exhibited by the C-dots in aqueous solution [31], as the concentration of CTAB monomers increases, the interaction of

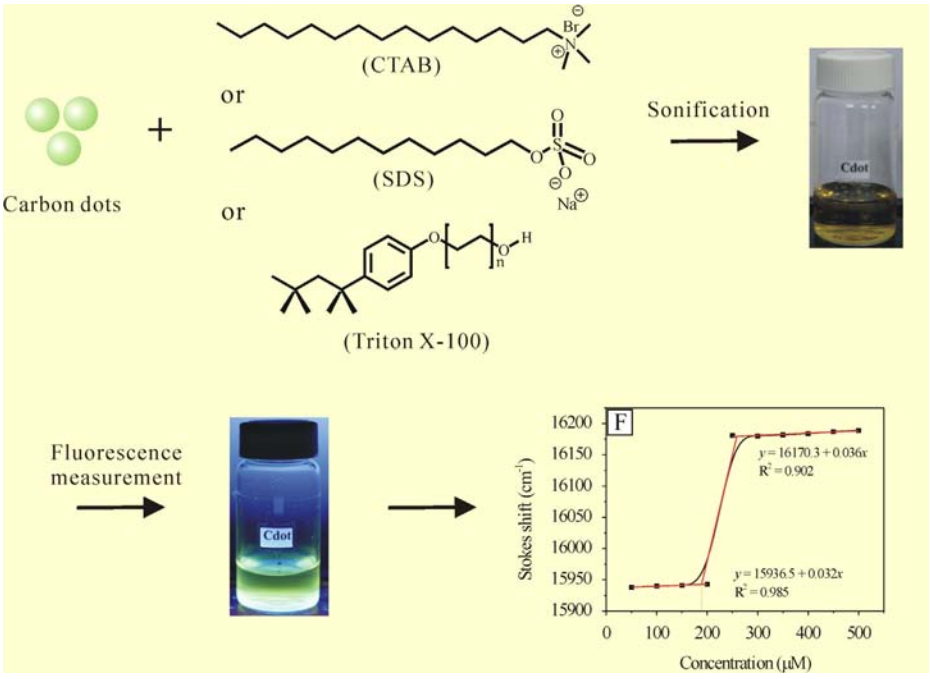

Fig. 1. Schematic illustration of experimental procedures.

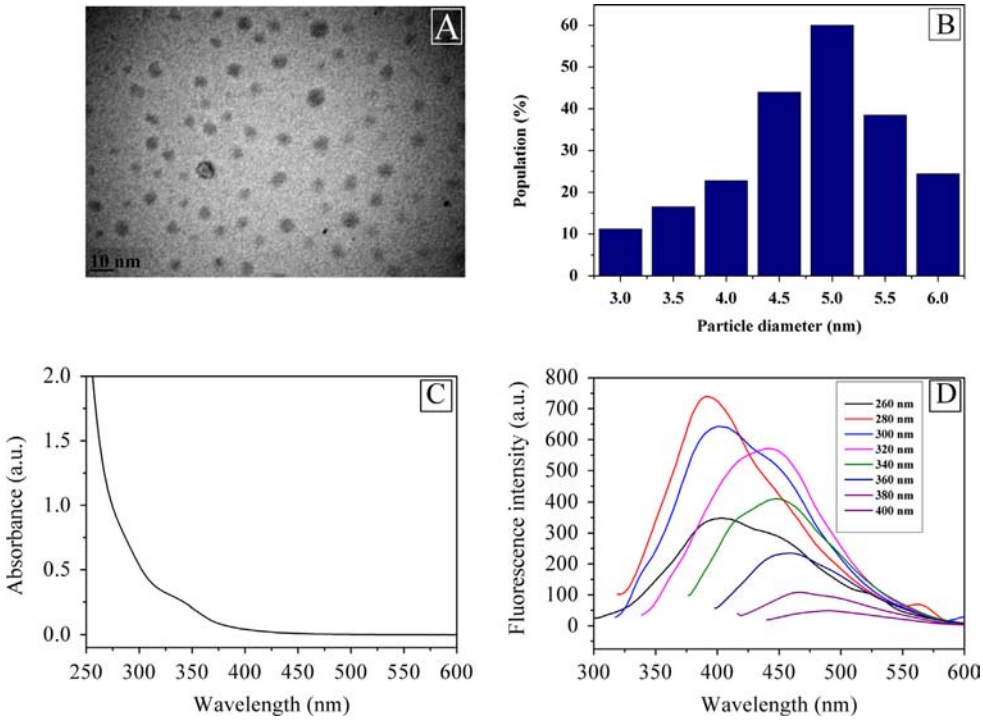

Fig. 2. Characterization of carbon dots: (A) TEM image, (B) histogram of particle diameter distribution, (C) UV–vis spectra, and (D) fluorescence spectra excited at different wavelengths.

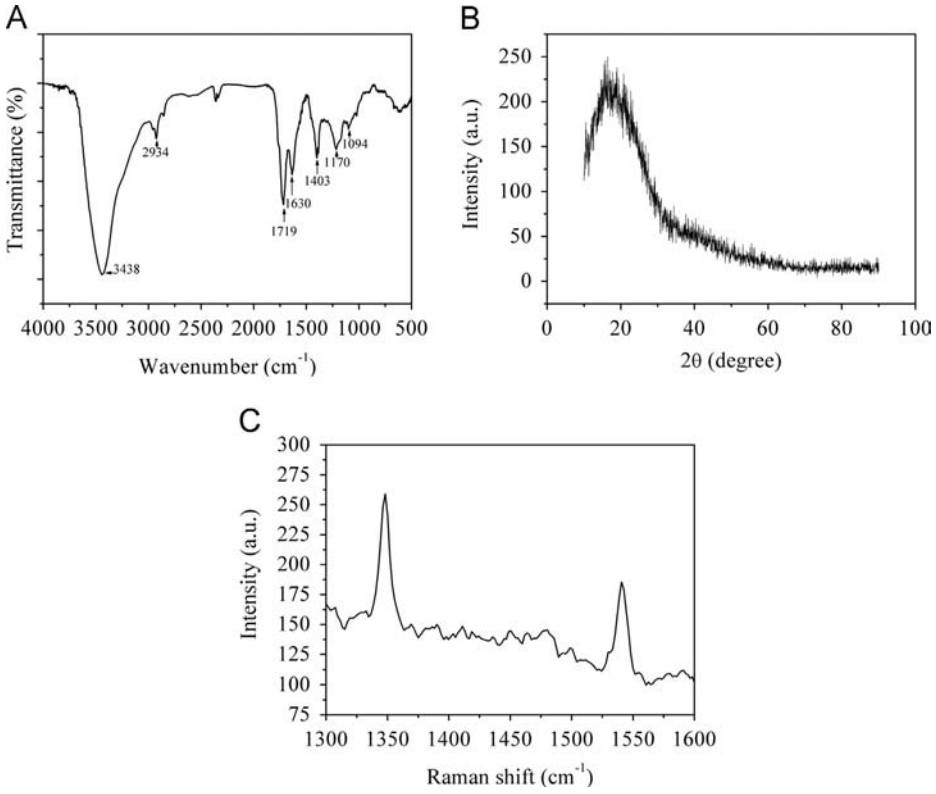

Fig. 3. Continued characterizations of carbon dots: (A) FTIR spectra, (B) XRD pattern, and (C) Raman spectra.

C-dots with positively charged CTAB becomes more frequent and results in greater stability of the C-dots-surfactant aggregate and consequently causing larger Stokes shift [25]. The utilization of the Stokes shift for the evaluation of CMC is based on two key points: higher Stokes shift of monomers compared to micelles and the adsorption of CTAB molecules on C-dots. The surfactant molecules were scattered throughout the aqueous solution at lower concentration of CTAB (below CMC). As the concentration increased, the surfactant molecules began to aggregate at the air-solution interface. There is no sign of monomers remained after the CMC point and the Stokes shift decreased drastically which was shown in Fig. 4B. The capability of C-dots to exhibit such sharp transition

Table 1
Determination of quantum yield of carbon dots with quinine sulfate as the reference.

Sample	Integrated emission intensity (I)	Abs. at 360 nm (A)	Refractive index of solvent (n)	Quantum yield at 360 nm (Q)
Quinine sulfate	41,301	0.07	1.33	0.54
C-dots sample	101,334	0.23	1.33	0.42

reveals their suitability as an excellent molecular sensor for the present work. Due to this magnificent property observed in selected fluoro-probes, there is change in the emission as well as excitation spectrum and hence the considerable Stokes shift.

Fig. 4B explains the Stokes shift with respect to concentration of CTAB. It can be observed that, by virtue of pre-micellar concentration (concentration just before critical micelle concentration), the Stokes shift was found to be less with increasing concentration of CTAB. After a particular concentration of CTAB, there was a steep decrease in the Stokes shift and finally it levels

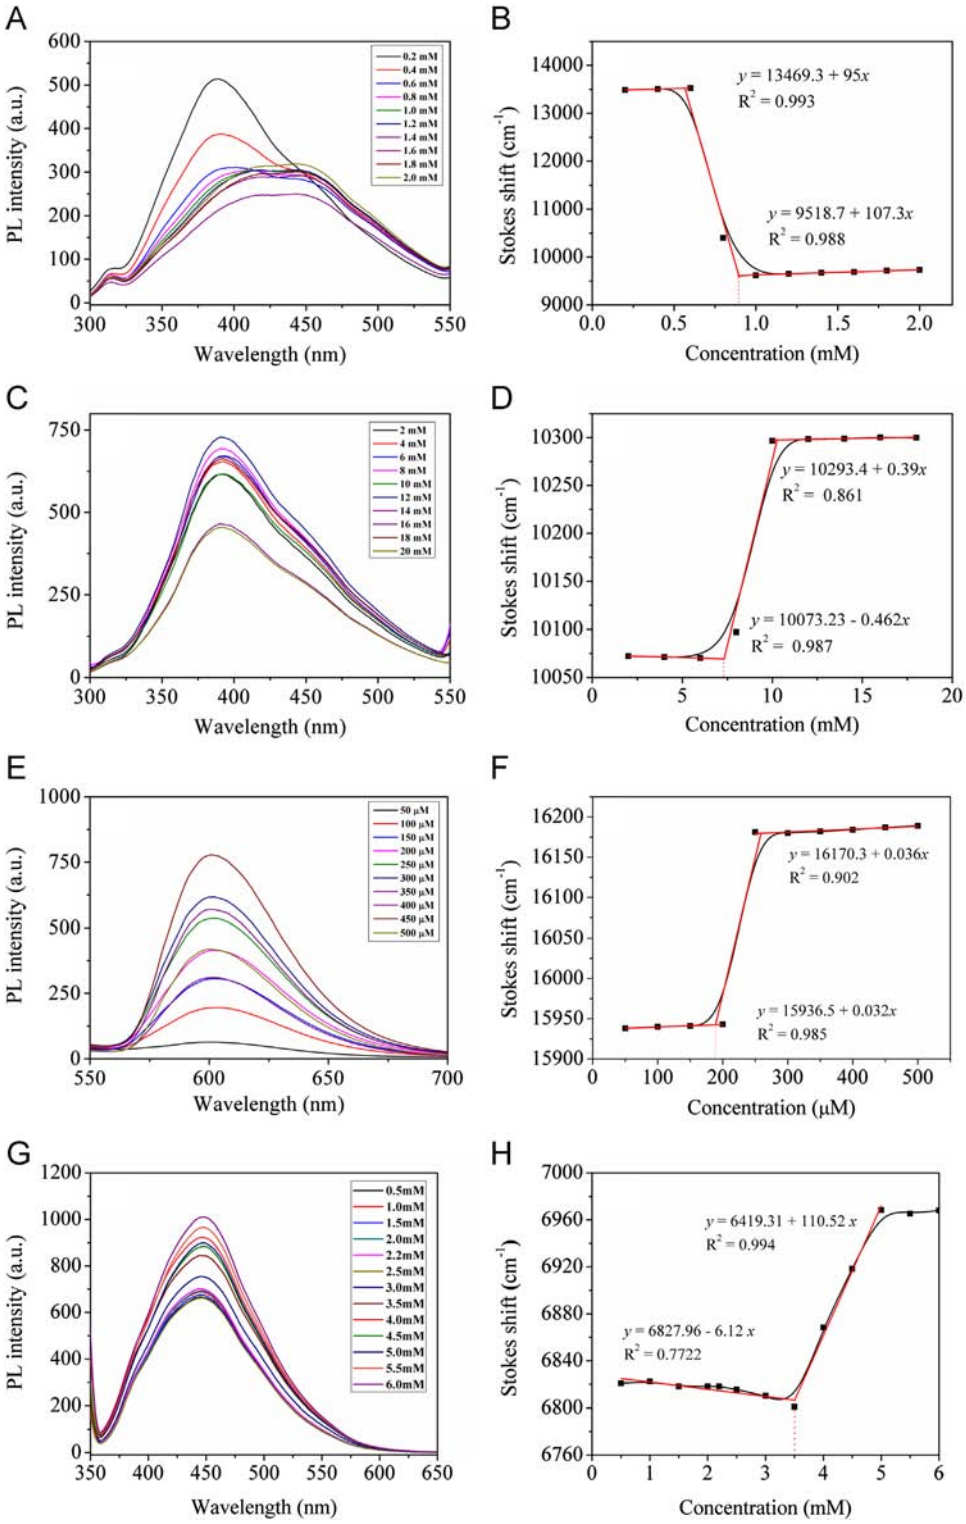

Fig. 4. Excitation and emission fluorescence spectra, and the corresponding relationship of the Stokes shift and the concentration of surfactant CTAB (A and B), SDS (C and D), Triton X-100 (E and F), and SB-12 (G and H), respectively.

off after a particular concentration indicating the accumulation of the CTAB monomers and this concentration is equivalent to CMC of CTAB. To calculate the critical micelle concentration (CMC), the lines on the plateau were extrapolated as shown in Fig. 4B. The point of intersection of the two lines was considered as the critical micelle concentration. The critical micelle concentration of CTAB was found to be 0.98 mM which was in strong agreement with earlier findings [32].

Fig. 4C explains the impact of anionic surfactant such as sodium dodecyl sulfate (SDS) on PL properties of C-dots. In Fig. 4C, because of the considerable dissipating energy significant Stokes shift between excitation and emission was observed in this figure. This indicated that these Stokes shifts were found to be sensitive to SDS concentration. Since the electrostatic interactions exist predominantly between SDS and C-dots due to the negative charge of the surface head group of SDS, the Stokes shift increased rapidly when the concentration reached CMC at which circular pattern of SDS micelles formed despite the fact that very low Stokes shift of the monomers exhibited initially. This also indicates that very low energy fluorescence was observed for micelles as compared to that of monomers. Therefore, C-dots were unlikely remained and were saturated on micelles which showed nearly straight line in the figure as the concentrations higher than CMC. Fig. 4D displays the relation between the Stokes shift and the concentrations of the SDS. The sharp increase of Stokes shift from low value of SDS monomers to high value of micelles makes the point of change be clearly indicative of CMC value. As the concentration reached to CMC constant Stokes shift was observed from the surfactant and C-dots aggregate even with increased concentration of SDS. Using the aforementioned method, the CMC of SDS was determined to be 7.3 mM which was in good agreement with the earlier findings.

In the case of non-ionic surfactant, Triton X-100 was considered as the model molecule for the CMC evaluation. Due to the absence of charge on the surface of head portion of the surfactant, weak interaction with C-dots was exhibited. Apart from this, the interactions of van der Waals force, steric repulsion or interface may play important roles in intermolecular forces. As shown in Fig. 4E, the minimum fluorescence range was observed from the PL spectra of Triton X-100 despite the change of concentration. Wide disparity in intensity between the excitation and emission spectra was clearly observed from Fig. 4E. Compared to cationic and anionic surfactants, non-ionic counterpart exhibits insignificant interaction between molecules and C-dots. Even with UV excitation a small Stokes shift was displayed demonstrates this weak interaction compare to the charged surfactants. Moreover, the weak fluorescence intensity shown compare to the charged counterparts of surfactants further confirms this hypothesis. As the surfactant is non-ionic the interactions with C-dots is prolonged and hence exhibited the different optical behavior. At low surfactant concentration very large excitation intensity was observed but the emission intensity was very low relatively. As the surfactant concentration increases, reverse excitation intensity was observed and the similar pattern occurred to emission. Fig. 4F demonstrates the relation between the Stokes shift and the concentration of Triton X-100; it reveals that monomers exhibited smaller Stokes shift compared to that of micelles. And very minute change in Stokes shift was observed even at CMC compared to ionic surfactants. The relationship between the variations of the Stokes shift in accordance with the alteration of surfactant concentration was plotted and the CMC value was indicated in Fig. 4F. As the concentration increased the Stokes shift was very small initially and sudden increase occurred as the concentration approached CMC and then the curve levelled off. As the fluorescence property of C-dots was negligibly influenced by the micelles of non-ionic surfactant Triton X-100 which was formed at CMC. Constant Stokes shift was observed above CMC as the concentration increased implying that insignificant change occurred in Stokes shift. Using the aforementioned method, the CMC of Triton X-100 was determined to be 0.19 mM which was in good agreement of the earlier findings.

CMC determination of the zwitterionic surfactant was performed with the model molecule of dodecyldimethyl(3-sulfopropyl)ammonium hydroxide. Different concentrations of surfactant were prepared and were mixed with constant concentration of C-dots. From the measurements of the fluorescence pattern at a particular excitation wavelength of 340 nm, the zwitterionic surfactant displayed distinct behavior. The fluorescence spectrum was recorded in Fig. 4G and the relationship of the Stokes shift vs concentration was demonstrated in Fig. 4H. Since the zwitterionic surfactant contain both cationic [+] and anionic [−] charges on different positions of the same molecule. From the mixing of the C-dots with the zwitterionic surfactant, the fluorescence pattern regarding the excitation wavelength exhibited unexpected consistency which is remarkably different from other surfactants. The maximum of excitation wavelength was fixed at the particular wavelength of 280 nm for all concentrations. Just like other surfactants, the intensity of excitation varies. For greater clarity, the relationship between the Stokes shift, which was calculated from the energy difference of excitation and emission, and the surfactant concentration was illustrated in Fig. 4H. The Stokes shift decreased initially as concentration of surfactant increased, and as, the concentration reached to the particular concentration, namely CMC, the Stokes shift sharply increased and then proceeded to level off on a plateau. CMC of SB-12 was estimated to be 3.5 mM according to the intersection of the extrapolation of curves in the graph of Stokes shift versus concentration in Fig. 4H. The close similarity of this Stokes shift correlation and those of anionic or non-ionic surfactants may result from the mild interaction of the zwitterionic surfactant with the cationic moiety of C-dots. For comparison, Table 2 presented some proposed protocols for CMC evaluation, including the results obtained in this work for CTAB, SDS, Triton X-100, and SB-12. It is clear that the results are in good agreement.

4. Conclusions

We have successfully developed a new and facile fluorophotometric approach for the determination of critical micelle

concentration (CMC) of ionic and non-ionic surfactants with the assistance of C-dots. C-dots exhibited substantial fluorescence and therefore enhanced the sensitivity. The spectra were assigned and explained in terms of both electron transitions between specific molecular orbitals and the interaction with solvent. CMC values of cationic cetyltrimethyl ammonium bromide (CTAB), anionic sodium dodecyl sulfate (SDS), nonionic Triton X-100, and zwitterionic dodecyldimethyl(3-sulfopropyl)ammonium hydroxide surfactant (SB-12) evaluated by this approach was found to be 0.98, 7.3, 0.19, and 3.5 mM, respectively. The CMC values acquired were consistent with those obtained formerly by other methods. By introducing C-dots in the CMC evaluation of surfactants via fluorophotometric method opens new avenues for broader applications in the near future.

ABSTRACT

Mapping of elements in biological tissue by laser induced mass spectrometry is a fast growing analytical methodology in life sciences. This method provides a multitude of useful information of metal, nonmetal, metalloid and isotopic distribution at major, minor and trace concentration ranges, usually with a lateral resolution of 12–160 μm. Selected applications in medical research require an improved lateral resolution of laser induced mass spectrometric technique at the low micrometre scale and below. The present work demonstrates the applicability of a recently developed analytical methodology – laser microdissection associated to inductively coupled plasma mass spectrometry (LMD ICP–MS) – to obtain elemental images of different solid biological samples at high lateral resolution. LMD ICP–MS images of mouse brain tissue samples stained with uranium and native are shown, and a direct comparison of LMD and laser ablation (LA) ICP–MS imaging methodologies, in terms of elemental quantification, is performed.

1. Introduction

Laser microdissection (LMD) is a technology that isolates specific cell populations from heterogeneous tissue sections under direct microscopic visualization by means of a highly focused laser beam [1,2]. The development of laser-based tissue microdissection systems has provided the basis for the rapid acquisition of specific morphologically and/or phenotypically distinct types of cells for different types of molecular analysis. This has permitted the cell-type specific molecular analysis of solid tissues, especially biopsies (samples of tissue taken for determine the presence or extent of a disease), and has provided new insights into both physiological cell mechanisms and pathomechanisms [3]. For example, a specific part of the hippocampus of brain tissue, cornu ammonis (CA1) pyramidal neurone layer, could be isolated for targeted proteome analysis from a transgenic rat carrying a human amyloid precursor protein transgene using LMD [4].

Recently, Becker and coworkers [5–8] proposed the coupling of LMD to an inductively coupled plasma (ICP) mass spectrometer in order to obtain elemental images of thin biological tissues. In this methodology, LMD acts as an ablation system, where a glass chamber is placed over the sample and a flow of a carrier gas transports the ablated material, and the ICP mass spectrometer operates as the detector for metals, semimetals and non-metals that are present in the biological tissue sample [7].

In the pioneer LMD ICP–MS work [5], a lateral resolution of 3 μm was obtained for a brain tissue impregnated with a droplet of highly concentrated copper solution (1000 mg L^{-1}). It is expected that with the insertion of a more powerful laser in the LMD microscope and the coupling to a more sensitive mass spectrometer (sector field ICP–MS instead of the currently used quadrupole ICP–MS), a lateral resolution up to 300 nm range should be possible in future investigations, opening up the field of quantitative single cell analysis and imaging.

The improvement of LMD ICP–MS analytical features can make possible to acquire more precise and detailed information on elemental distribution in brain samples and other biological tissues at low-micrometre and nanometre scale, as a LMD microscope allows the observation and selection of specific structures and single cells, which can be ablated by the focused laser beam with a lateral

resolution down to the low and sub-micrometre scale [5,9]. Table 1 illustrates the LMD ICP–MS imaging experiments described in the literature until the present moment.

In this work, the application of LMD ICP–MS to elemental imaging of native and metal-stained mouse brain tissues is shown. Uranium was chosen for tissue staining since it is important when

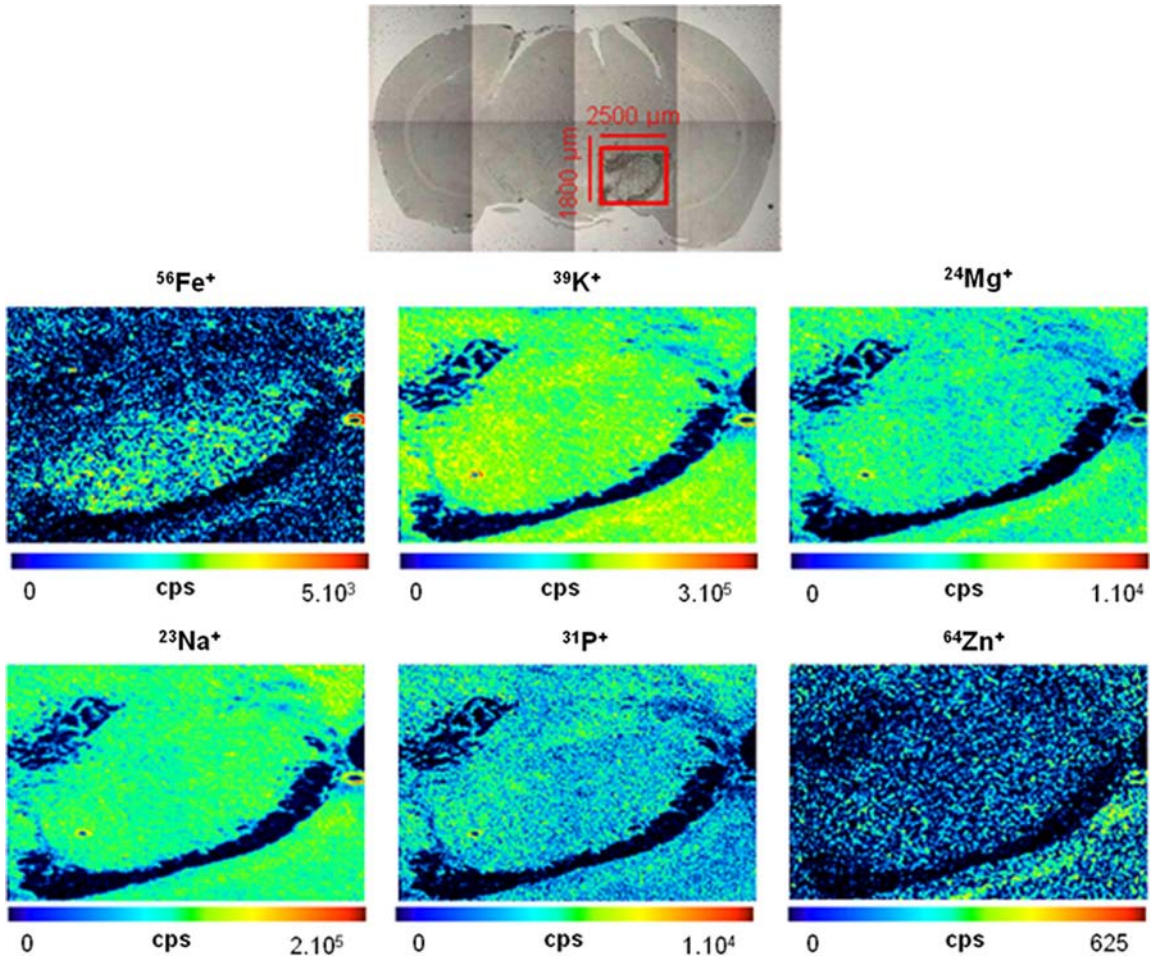

Fig. 1. LMD ICP–MS qualitative images with lateral resolution of 6 µm for a native mouse brain tissue (substantia nigra region).

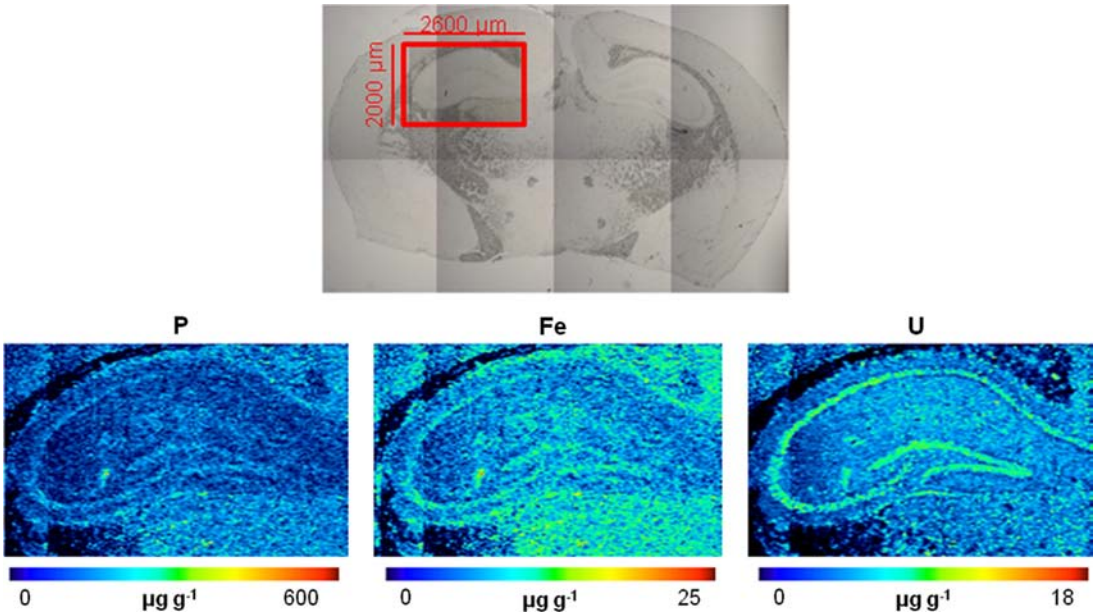

Fig. 2. LMD ICP–MS quantitative images with lateral resolution of 4 µm for a mouse brain tissue (left hippocampus region) stained with ^{238}U solution at 100 µg L^{-1}.

toxicology studies (in extreme conditions) are considered [10]. This methodology provided high resolution images (4 μm) using a low concentrated (100 μg L^{-1}) uranium solution as staining agent. Two interesting brain regions, substantia nigra and hippocampus, were selected for LMD ICP–MS imaging experiments. Substantia nigra plays a role in reward, addiction and movement functions, and is also related to the pathophysiology of Parkinson's disease [11] and schizophrenia [12]. Hippocampus acts in short and long-term memory and is involved in the development of stress, epilepsy [13], schizophrenia [14], and other diseases.

2. Experimental

For LMD ICP–MS experiments, a small laser ablation glass chamber mounted on the microscope glass slide containing the sample and constituting the bottom was inserted in the LMD device (MMI SmartCut Plus, Molecular Machines and Industries, Zürich, Switzerland) and coupled to a quadrupole-based inductively coupled plasma mass spectrometer (XSeries II, Thermo Fischer Scientific, Bremen, Germany) [5,6,8].

For comparative experiments by LA ICP–MS, a laser ablation system (New Wave UP213, Fremont, CA, USA) coupled to the same mass spectrometer previously described was employed [15,16].

Table 2
Figures of merit from the quantification by LMD ICP–MS of mouse brain tissue (hippocampus region) after staining with 100 μg L^{-1} ^{238}U solution.

Analyte	Analytical calibration function	Correlation coefficient (R)	Limit of detection (μg g^{-1})[a]	Limit of quantification (μg g^{-1})[b]
^{31}P	$y=6.0597x+5612$	0.9823	143	476
^{56}Fe	$y=158.2x+2941$	0.9904	7.2	24
^{238}U	$y=384.82x-229.48$	0.9876	0.39	1.3

[a] Calculated as 3 times the standard deviation of the blank sample divided by the slope from the calibration curve.
[b] Calculated as 10 times the standard deviation of the blank sample divided by the slope from the calibration curve.

Schematics and analytical workflows for LMD and LA ICP–MS imaging experiments can be found in previous references from J.S. Becker's working group [5,7,9].

Mouse brain samples were collected, cryo-cutted (thickness of 10 μm) and placed in microscope glass slides. For metal-staining experiments, the brain samples were immersed in the solution of interest for at least 1 h and then dried at room temperature overnight before LMD ICP–MS imaging experiments.

When quantification of the imaging data was performed, metal spiked tissue homogenates were employed. They were prepared from brain homogenates of analogous mice without any treatment and doped with trace elements with defined concentrations, as described elsewhere [15,17]. To validate the ion images, at least two isotopes, if available, were analyzed. Possible isobaric interferences of single-charged analyte ions with polyatomic or double-charged ions were studied systematically and minimized under optimized experimental conditions.

Data treatment was performed as described in reference [18]. Signal normalization in relation to ^{13}C was made for all obtained images, including the qualitative ones, where no quantification was performed and only signal intensities are shown.

3. Results and discussion

LMD ICP–MS qualitative images with lateral resolution of 6 μm for a native mouse brain (substantia nigra region) tissue are shown in Fig. 1. The lateral resolution is improved to 4 μm when brain tissue is stained with ^{238}U solution at 100 μg L^{-1}. Tissue staining

Table 3
Comparison between LA and LMD ICP–MS results and characteristics.

	LMD ICP–MS	**LA** ICP–MS
Detected elements	Fe, P and U	P and U
Lateral resolution	4 μm	13 μm
Tissue thickness	Below 14 μm	10–40 μm
Routine scale	No	Yes
Quantification	Challenging	Using metal spiked tissue homogenates

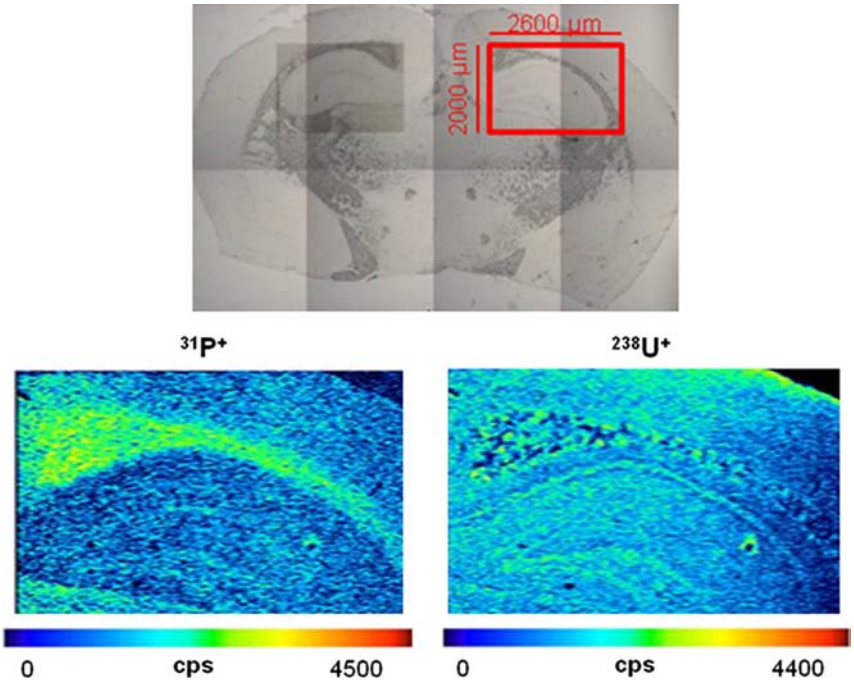

Fig. 3. LA ICP–MS qualitative images with lateral resolution of 13 μm for a mouse brain tissue (right hippocampus region) stained with ^{238}U solution at 100 μg L^{-1}.

allowed the detection of enhanced intensities that provided a very good differentiation of the brain substructures (layers). Fig. 2 shows the LMD ICP–MS quantitative images for the stained mouse brain (left hippocampus region) and Table 2 describes the figures of merit of the quantification procedure for the detected elements in brain: iron, phosphorus and uranium (coming from the staining procedure).

The same stained mouse brain sample, in this case the right hippocampus region, was used for a comparison between LMD and LA ICP–MS. Fig. 3 shows the results obtained by LA ICP–MS. The lateral resolution was worse than when LMD ICP–MS was employed (13 μm in contrast to the 4 μm previously obtained) and it was not possible to detect iron in the sample. In a previous work [10], uranium- and neodymium-stained rat brain tissues were analyzed by LA ICP–MS, but the obtained resolution was only 100 μm and it was not possible to observe brain substructures so clearly as in the case of LMD ICP–MS analyses. Moreover, only the staining agents were quantified in the LA ICP–MS images. These results together demonstrate the potentiality of LMD ICP–MS in obtaining elemental images with high resolution, in the low micrometer range, for metal-stained biological tissues.

Table 3 summarizes a comparison between LA and LMD ICP–MS results and characteristics. It is important to point out that LMD ICP–MS is a methodology still under development and needs to be improved. Future steps involve the improvement of imaging resolution by using a more powerful laser source that allows the enhancement of the ablation process. The laser spot size can be reduced as more material is transported to the ICP source and, then, the lateral resolution is improved. The use of a more sensitive mass spectrometer, such as an ICP–SFMS, is also required in order to analyze elements in single cells. The development of alternative calibration strategies (e.g., solution-based calibration [19] or printed patterns [20]) and/or the improvement of standard samples preparation [21] for obtaining quantitative images is also an important point to be further studied.

Acknowledgements

The authors would like to thank Dr. Andreas Matusch for providing the brain samples and preparing the mouse brain sample standards for quantification of analytical data. A.S. would like to thank the Alexander von Humboldt Foundation (Bonn, Germany) for the post-doctoral fellowship. The last author (J.S.B.) would like to acknowledge to Thermo Scientific (Bremen, Germany) and to Deutsche Forschungsgemeinschaft (DFG grant number BE 2649/5-1) for instrumental support of the BrainMet laboratory.

Flow-through monitoring

ABSTRACT

Potential threat on drinking water requires monitoring solutions, such as the one proposed herein, as a real-time, wide ranged, water monitoring system to detect the presence of toxicants in water. We studied the role of a selected number of parameters affecting performance and, thus, improved the prototype into an optimized next-generation device, resulting in enabling increased measurement duration, coupled with increased sensitivity. The chosen parameters in question were the peristaltic flow system, the fiber probe matrix stability through a re-design of the fiber probe holder and flow unit cell, as well as the modulation of bacterial medium concentration to increase bioreporter performance while keeping biofouling in check. Measurements were made with spiked samples and validated with polluted field-collected samples.

1. Introduction

Increasing population and activities thereof, produce large varieties and quantities of waste chemicals [1], which oftentimes affect drinking water quality [2–4]. In order to safeguard our water supplies, it must be monitored constantly to prevent its contaminated form from reaching the consumers [5–7], while being diverted to processing centers for its remediation.

There are two main forms of water monitoring. One requires the tester to go to the field and make an on-site test or alternatively taking the sample to an accredited test laboratory. The main disadvantage is that the user must go to the place in question. However, the advantage of the first possibility is that the dispatchable equipment includes disposable elements and the answer is quasi-immediate enabling a response. The second form involves use of a continuous monitoring system, with near real-time monitoring, that will give the user continuous feed on the particular point, where the tests are being conducted, such as a chosen river site, which is advantageous as only infrequent human dispatch would then be required. However, the sophisticated mechanics involved complicates the overall system from a number of engineering parameters.

There are two main analytical categories in monitoring water [8], the classical chemical chromatographic ones and the bioassay-based ones. The former (HPLC, GC, GC/MS [9]) is aimed at both identification and quantification. Their disadvantage is their specificity: an unfamiliar toxicant will not be detected. In addition, these are costly and require both sophisticated instrumentation as well as qualified personnel. They are nonetheless very useful and remain today the workhorse of the chemical identification industry. On the other hand, bioassays assess a potential toxic effect on a living organism, however, they lack the ability to measure a specific concentration or even provide most of the times an identification of the monitored toxicant. Despite these disadvantages, those sensing systems have one great advantage: the toxicant monitoring range is very broad [8,10–14]. In this particular area, bacterial-based bioassays, have shown promising applicative results. These consist in using genetically modified bioreporter organisms that generate light as a response to toxic compounds (see Section 2.2).

Bioassays using bacterial bioreporters are used either in their classical liquid-phase bacterial suspension [15–17] or immobilized in biosensor systems [18–20]. In both cases, the tested water

samples must be disposed of via a septic step according to licensed (MLI or II) laboratory regulations,, so as to prevent contamination of the environment, which is protected by stringent regulations. Disposable bioassays are usually autoclaved, although one may imagine chemical neutralization could also be used, while immobilized-phase on-line biosensors require asceptization of the test effluent, despite the fact that one can create stable immobilized probes with virtual non-leaching of the said bioreporters [10,13,20], while still retaining good levels of sensitivity.

The aim of this study was to improve on some of the limitations found in the earlier system [13]. It was then discovered that the bacterial on-line system required that the user provide growth medium continuously, so as to sustain the immobilized bacteria in a continuous stream of water. Indeed, the signal improved, however, an increase in biofouling occurred, which could affect the overall sensor performance. Therefore, we checked two types of such growth media at different concentrations so as to obtain that concentration of either growth medium, which is really necessary to reduce increased biofouling potential while helping the system increase its performance. We also then noticed that increased sample flow rate had a detrimental mechanical effect on the hydrogel structure that was used to entrap the bacteria, thus we designed herein, a protective proprietary fiber optic probe flow cell. This study therefore looked at improving both sensor sensitivity and increasing measurement time, while retaining simplicity of operation, size, and real-time monitoring capability.

2. Materials and methods

2.1. Chemicals

Tryptone (T7293), Yeast Extract (92144), NaCl (S7653), alginate (B25266), $CaCl_2$ (C1016), p-chlorophenol, copper sulfate (209198), kanamycin (K1377), and ampicillin (A0797) were obtained from Sigma. All stock solutions were diluted with distilled water (dW) and stored at temperatures as suggested by the manufacturers' instructions.

2.2. Bacterial strain

The bioluminescent *Escherichia coli* bioreporter strain TV1061 [21] used in this study is sensitive to metabolic changes, such as with cytotoxic substances. It harbors plasmid-borne fusions with a specific heat-shock *grpE* promoter adjacent to the *luxCDABE* reporter operon, whose activation is detected by light emission (bioluminescence). The *Lux* operon has five promoterless structural genes. These are responsible for both the heterodimeric luciferase units (*lux* A and B) and the synthesis of the luciferase substrate, tetradecanal, by an ATP- and NADPH-dependent multienzyme complex composed of fatty acid reductase, transferase, and a synthetase (*lux* C, D and E) [22]. Strain stocks were stored at −80 °C with 20% (v/v) glycerol as a cell cryoprotectant additive [12]. Stock bioreporter strains were placed on LB-agar plates (NaCl 5 g L^{-1}, yeast extract 5 g L^{-1}, tryptone 10 g L^{-1}, agar 15 g L^{-1}) supplemented with 50 μg mL^{-1} kanamycin and, thereafter, incubated at 37 °C in a rotary thermo-shaker overnight (MaxQ 4450, ThermoScientific, USA). These were then stored at 4 °C for future experimentation.

2.3. Bacterial growth

Bacterial cultivation prior to measurements was performed in 10 mL LB-medium (NaCl 5 g L^{-1}, yeast extract 5 g L^{-1}, tryptone 10 g L^{-1}) supplemented with 50 μg mL^{-1} kanamycin for TV1061. Cells were grown overnight at 37 °C in a rotary thermo-shaker (MaxQ 4450, ThermoScientific, USA) at 120 rpm in the presence of the antibiotic. Cultures were then diluted to approximately 10^7 cells/mL and re-grown in 25 mL LB at 26 °C without shaking and without antibiotics, to an early exponential phase (OD 600_{nm} of 0.2) as determined by an Ultrospec 2100 pro spectrophotometer (Amersham, England).

2.4. Fiber optic probe bioreporter immobilization procedure

The harvested cells were mixed 1:1 (v/v) with a filter-sterilized 2% (w/v) low viscosity sodium alginate solution. Multimode optical fibers, PUV 400 BN (CeramOptec, GmBH, eramOptecBonn), were used in these experiments. They present a pure silica core diameter of 400 μm, with a refractive index of 1.4571 (at 633 nm) and a cladding diameter of 440 μm, with a refractive index of 1.4011 (at 633 nm). Their black nylon jacket was stripped away from a 1-cm long optical fiber proximal tip, which was then used for the immobilization of the bioluminescent bioreporter bacteria [23]. The 1-cm optical fiber tip was first exposed (for a few seconds) to the bacterial alginate suspension, and then dipped (for a few seconds) into a sterile 0.5 M calcium chloride solution [20], thus entrapping the bacteria onto the fiber proximal tip within a hardened calcium alginate matrix. Six to seven layers have been shown to be the optimal number of layers when previously tested [13]. Thereafter, the optical fiber probe, with immobilized bioluminescent bacteria at its tip, was immediately used after preparation for experimentation (Fig. 1C).

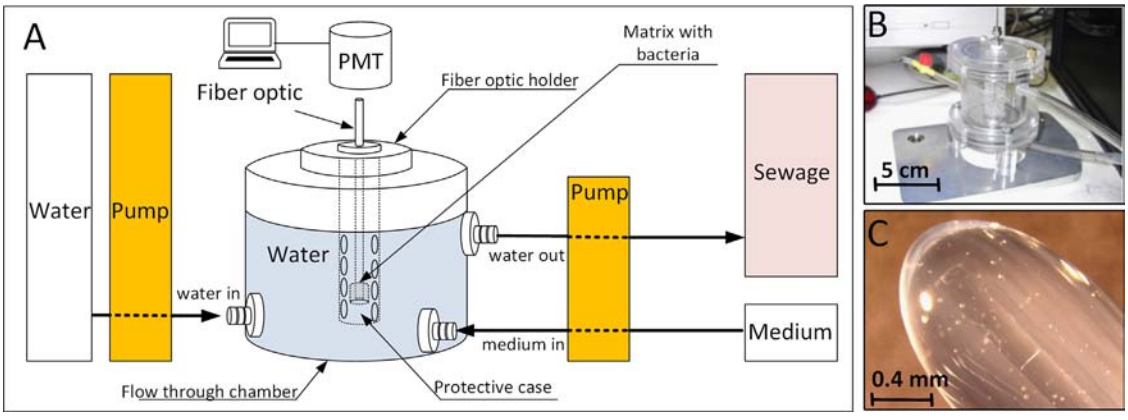

Fig. 1. A. Scheme of the perspex "protective" flow unit holding the fiber optic probe and its connected peristaltic pumps; B. Photo of perspex flow unit; C. Calcium (2% v/v)-polymerized alginate with six adlayers forming the fiber optic probe.

2.5. Instrument setup

A field-operable fiber-optic photodetector device was previously designed [10] and in order to monitor toxicity in a flow-through manner, it was modified in a recent study [13] including improvements, such as an added flow cell, (Fig. 1) which was placed in the light-tight box, so as to prevent any damage to the photon-counting unit by the surrounding light. A Hamamatsu HC135-01 PMT Sensor Module was used for bioluminescence measurements, combining the sensitivity of a photomultiplier tube (PMT) with the intelligence of a microcontroller. The detector was optimized to the blue light region and included a 21-mm diameter active area to gather light radiation without any optical focusing elements.

In order to increase the flow rate of the incoming water sample, while retaining the fiber probe matrix integrity, a new design of its configuration was made (Fig. 1A) due to the fact that a pressure issue was discovered and affected the bacterial performance. In this system, water flows through a workshop-made inner cell, whilst the chamber is made of transparent perspex, thus both protecting the fiber-optic from the water current and also enabling, when needed, a visual supervision of the biosensor probe integrity (Fig. 1B). The cell module design includes two inlets, one for incoming water and the other for supplementary growth medium ($d=3.5$ mm), and one outlet, for the exiting water stream ($d=3.5$ mm), while a separate entrance was made for the fiber optic probe housing the immobilized bacteria. Initially, the water flow in the new setup was conducted with only one peristaltic pump, which brought water into the flow unit; however, we observed a continual underperformance of the immobilized bioluminescent bacteria, which we eventually determined to be due to a pressure build up inside the flow through chamber (Fig. 1A), thus preventing the bioreporters from functioning properly. So as to release the said pressure from developing due to the single peristaltic pump use, an additional pump was connected to the system exit, so as to continually remove the water from the operation unit, with both pumps working at equal flow rates. The upper lid of the fiber optic probe cell includes an inlet for the fiber optic probe, which bathes continually in the water flow, and secured at four different points, so as to prevent it from moving due to the sheer forces caused by the water flow. The said optic fiber probe is thus contained within a porous cylinder. Multiple pores (diameter = 2 mm) were drilled in a regular array over the surface of the cylinder, while the distance between them was 3.5 mm. The main purpose of this structure was to protect the fragile biosensor probe matrix – placed at the proximal end of the fiber – which is exposed to the incoming water sample sheer forces. An added benefit is a decrease in the flow velocity around the matrix. The water flow was measured by a rotometer (1017, Burkert) localized in the inlet water stream. To record and analyze the data, a specific driver was developed using LabView (version 3.1, National Instruments Corporation), which allowed to record and analyze the bioluminescence signal in real time.

2.6. Optimization procedures

2.6.1. Comparative effect of two different growth media and concentrations thereof on bioreporter signal response

Two sterile bacterial media 2 YT (Yeast extract tryptone; composed of 16 g L^{-1} Yeast extract 10 g L^{-1} and 16 g L^{-1} Tryptone) and LB (Luria Bertani broth; composed of Tryptone 10 g L^{-1}, Yeast extract 5 g $L^{-1,}$ and NaCl 10 g L^{-1}) were fed into the on-line system at different concentrations ranging between 0 and 7.5% (v/v), in tap water, through the water flow of a calibrated peristaltic pump (Masterflex® 7754-57, Cole Parmer Instrument Company, USA). The sensor response to the target water pollutant (e.g. 2% (v/v) ethanol) was measured over a period of 4–10 h and any changes or improvements noted.

2.6.2. Effect of the flow system management on sensor activity

As explained above, the original system used one peristaltic pump to bring water into the flow unit, which increased pressure onto the resident immobilized bacteria and therefore prevented the bioreporters from functioning properly. The putative effect of the pressure on bacterial sensor activity was further examined by the addition of another peristaltic pump to the exit of the system, so as to continually remove the water from the operation unit, with both pumps working at equal flow rates. At first, the effect on the bacterial cell activation, when using one working pump, was measured without the addition of any chemicals. Bacterial activity in the flowing tap water (with the addition of medium) was measured with either a working (kinetic mode) or an inactive (static mode) inlet pump. Thereafter, the effect of the addition of a second pump to the flow system was examined. In both approaches (system with one or two pumps), bacteria were exposed (at $t=0$ minutes) to 2% (v/v) ethanol as model toxicant.

2.6.3. Effect of the flow rate on stability of the probe matrix

The stability brought by the protective fiber probe cell module on previously observed matrix erosion to the bacterial immobilization matrix of the fiber probe was examined periodically by visual observation and overall evaluation by light microscopy, before and after a system run of 24 h, occurring at differential flow rates from 0 to 10 L h^{-1}.

2.6.4. Effect of the flow unit design on biosensor sensitivity

Two different architectures of the flow unit (old version (without a flow cell unit) and present version (as described throughout notably in Section 2.5) were tested and compared in this work, so as to evaluate their effect on the sensor probe performance, while being exposed to various concentrations of a positive control (e.g. 0.02, 0.2 and 2% (v/v) of ethanol).

2.7. Increased measurement duration

In order to evaluate the analytical performance of the biosensor device, at a longer measurement duration, bioluminescent bioreporter cells were exposed thrice to water pollutants over a 48-h period (compared to our previous work which was for only a useful 24 h): once at the onset of the experiment, and twice after at 24-h time periods ($t=0$; $t=24$ h; $t=48$ h). Strain TV1061 was exposed to three different model toxicants known to be optimal test concentrations in our previous device (2% (v/v) ethanol, p-chlorophenol (1 mg mL^{-1}) and copper (5 ppm)) in separate experiments.

2.8. Environmental water samples

The 24-h experiments were performed using environmental water from Lakhish River (Israel, Lat.31°48'56.68"N Lon. 34°38'35.66"E) with the TV1061 strain, and the improved experimental prototype setup (Fig. 1B). We only tested 24 h due to the fact that we measured the water in our lab and not on-site so had insufficient amounts of environmental water to increase the monitoring time. Freshly collected Lakhish water was stored at 4 °C and used within five days of collection to reduce field composition changes. In order to determine if any putative effect from water salinity may affect the immobilized cells, bacteria were exposed to synthetic water that was made from deionized water with the addition of 48 mg L^{-1} $NaHCO_3$, 30 mg L^{-1} $CaSO_4 \cdot 2H_2O$, 30 mg L^{-1} $MgSO_4$, and 2 mg L^{-1} KCl, with a hardness of 40 mg L^{-1}.

2.9. Viability measurements

Evaluation of the viability of bioreporter bacterial cells after their exposure to toxicants during each experimental run (24 h) was accomplished via the viable plate counting method [24]. Serial 10-fold dilutions of bacterial samples were made in sterile PBS buffer and 10 μL samples were thereof evenly spread onto non-selective solidified nutrient LB agar surface plates. The number of viable colony forming units (cfu) was enumerated as bacterial colony plaques after 24 h incubation at 37 °C.

3. Results and discussion

3.1. Effect of water pressure on the bacterial response.

The effect of water pressure caused by a single peristaltic pump on the immobilized bacteria was evaluated by observing the bioreporter response in the prototype setup (Fig. 1A), with and without an additional water exit pump (which helps remove the water from the flow unit). In the first mode, we observed that when only one pump (placed before the measuring unit) is used in the sensor system, a high pressure seemed to be created in the measuring unit. In the second mode, where an additional pump was added to the system, and placed after the flow unit, and operated at the same flow rates as those of the input pump, it was observed that bacterial performance increased. Indeed, this step was expected to prevent the generation of pressure inside the measuring unit. Fig. 2 presents the effect of the pressure on the immobilized bacteria. Increased water pressure inside the flow unit housing the immobilized bacteria had an inhibitory effect on the activity of the bioreporter cells (Fig. 2A), exemplified by decreased luminescence in the presence of normally inducing pollutant concentrations in water [25]. Others have shown that increased pressure could affect the membrane integrity [26], fluidity [27], or protein denaturation [28] in bacteria. Fig. 2B shows that the addition of the second pump into the system solved the inhibitory issue. Immobilized bacteria regained their capacity to respond to the toxicant (Fig. 2B) and this dual peristaltic pump mode was adopted in all future experiments.

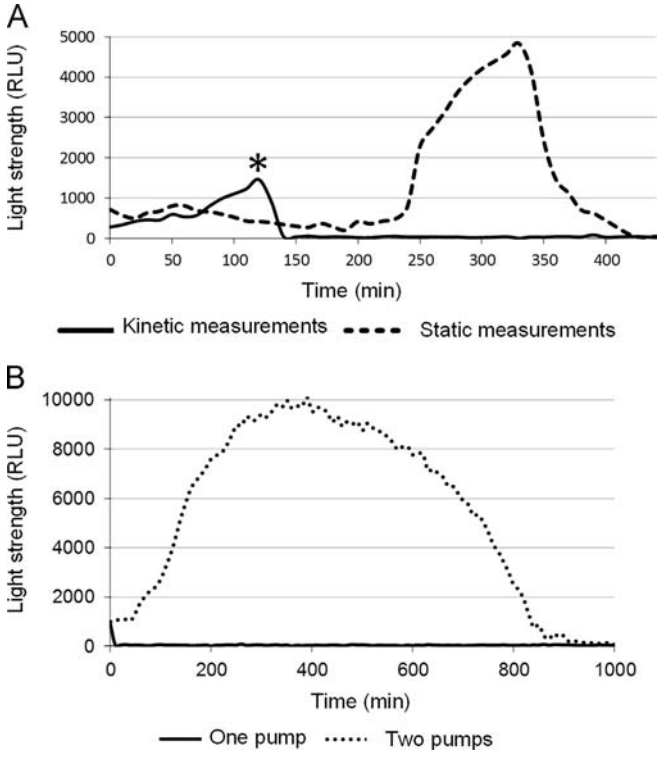

Fig. 2. Effect of pressure on immobilized bacteria in the newly designed instrument. A. Response of the cells once the peristaltic pump is turned on. The solid line represents the flow system with one working pump (*pump operation starts at $t=120$ min) and dash line represents the system without the peristaltic pump. B. Effect of the addition of a second pump to the system, 2% (v/v) ethanol was added at time $t=0$ min.

3.2. Effect of medium type and concentration thereof on bioreporter sensor responsiveness

A living organism needs a continuous source of nutrients to maintain its routine metabolism. The use of bioreporter bacteria as a sensing element raised the issue of the need of supplying any (or enough) nutrients to maintain normal cell functionality when integrated into a continuously operated biosensor device so as to produce reliable measurements. It is known that a sub-minimal amount of nutrients will cause a detrimental effect on natural metabolic processes in the cell, resulting in unreliable responses of the biosensing system [29]. The bioluminescence signals of exposed bio-reporter bacteria to medium-free tap water have already been investigated in previous studies [10,13,23], where exposure to medium-free water resulted in a strong and rapid increase in light induction (without toxicant addition), followed by a sharp decrease which stabilized at a basal level. The proposed flow-through prototype compared two different and popular media (LB and 2 YT) at three different concentrations: 2.5%, 5% and 7.5% (v/v), to which was added 2% (v/v) ethanol as the model toxicant. Ethanol is commonly used as an antimicrobial compound and is known to cause protein damage and to induce a protein damage sensitive *grpE*-dependent bioluminescent response in TV1061 [21].

Fig. 3A represents the different effects on sensor activity, from the nature of the growth medium tested, and this in combination with its various concentrations. The addition of LB to the cells induces the best bioluminescence response. It is important to remember that 2 YT medium differs from LB media in its amino acid concentration (tryptone/yeast extract) (twice lower in LB), while NaCl in LB is twice higher, suggesting that salt may have a more central role in the bacterial bioluminescence response to the toxicants. We will not speculate further here, although this physiological response is worthy of further investigation, just as other parameters would likewise need investigation such as

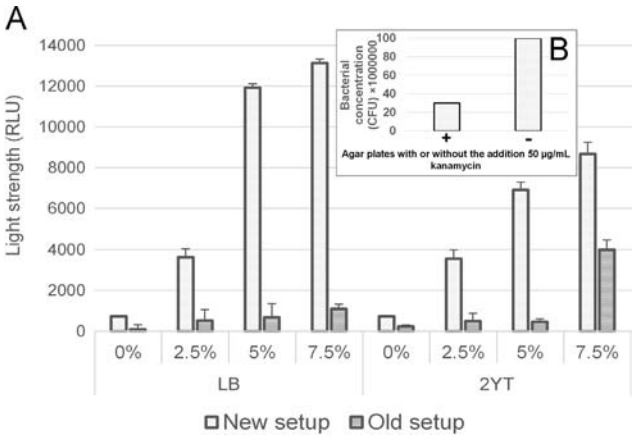

Fig. 3. A. Differential response obtained with TV1061 strain using 2% (v/v) ethanol with the addition of either 2 YT or LB growth media at different concentration. B. Viability count of bacteria (bioreporters versus biofouling bacteria) on agar plates differentiated by the addition or absecence of 50 μg mL^{-1} kanamycin. The previous setup is the tubing mode and new cell unit design.

temperature, pH, incubation time, and matrix composition [30]. The complicated relationship between bioreporter bioluminescence expression on biosensor performance and its bathing medium [31], endogenous aldehyde and internal ions (e.g. potassium, sodium, calcium and magnesium) [32–34] requires careful regulation. Interestingly, there were no significant differences in the cell response, namely in the signal obtained, with the higher concentrations of either 5% or 7.5% (w/v) of LB (Fig. 3A). Possibly the required threshold of essential components are thus satisfied with 5% (w/v). Thus, to help reduce the inevitable bacterial contamination to the system, a lower LB concentration was chosen.

An additional modification brought to the present (dual pump) setup was to add the medium directly into the fiber probe cell unit, unlike previously, when this was done at the onset of the water flow (Fig. 1). This step decreased the contamination rates of the system from biofouling activities on the alginate matrix [35–37], from unwanted bacterial overgrowth, originating in the water tubing and inner cell. These may also cause false positive signals from the inlet stream by reducing toxicant exposure to the immobilized bio-reporter cells, by preventing (or reducing) diffusion of both the nutrients and any putative toxic agents to the immobilized reporter bacteria. This phenomenon is obviously enhanced in systems that are rich with nutrients, thus minimal optimal levels of nutrients need to be carefully controlled. Fig. 3A demonstrates that a good and reliable signal response can still be obtained with a reasonable level of medium (5% (v/v)) maintained in the inlet flow. To determine the ratio between biofouling bacteria (kanamycin sensitive) and those immobilized (genetically engineered bioreporters resistant to kanamycin) in the alginate matrix, a water flow (with the addition of 5% (v/v) LB) was passed for 24 h. Fig. 3B shows the presence of resistant and non-resistant bacteria at the probe matrix. Calcium alginate hydrogel was decomposed and the released cells were grown on agar plates (with or without antibiotic). Indeed, there was an increase in the bacterial concentration on the agar plates without any antibiotic addition (Fig. 3B), suggesting the occurrence of biofouling upon the immobilization matrix. We cannot discard the fact that an additional possible reason for these results is that during long-term exposure some bacteria may remove their plasmid and thus loose their resistance to kanamycin.

3.3. Effect of flow rate on matrix stability

It has been reported that bacteria used in real-time flow experiments cannot afford a flow rate higher than 3 L h^{-1} [17,38] as this may cause an erosion of the probe matrix with a consequent loss of bacterial cells, thus altering the analytical performance of the water-pollutant detection device. Parameters enabling decreased response time and increased sensitivity are important for real-time monitoring of drinking water, using reasonable sampling volumes at a reasonable pace. The ability to work under high flow rates is an elegant solution for this issue. In designing a dual pump device, the effect of the water flow rate on the bacterial probe matrix integrity is evaluated qualitatively by its exposure to a range of different flow rates for 24 h (Table 1). As explained hereabove, the effect of the the water flow was examined by visual observation and overall evaluation by light microscopy, before and after a system run of 24 h. The diameter of the fiber optic was measured before after water exposure. Each (+) logged in the table represents 25% of the initial matrix diameter. It can be clearly seen that the present new design (Fig. 1A) shows higher consistency with a reduced visible damage within the reported range of tested flow rates. The proximal probe matrix in the old setup [13] was partially reduced at 3 and 4.5 L h^{-1}, and vanished totally from 6 L h^{-1}, unlike in the present system, thanks to its new design. In the previously published system, the fiber optic was placed directly into the water flow and was thus exposed to the direct shear stresses made by the passing liquid. In the present configuration, there was no direct pressure from the water flow on the matrix, as the fiber optic was placed in a special protective casing and this reduced the damaging effect of the water flow.

3.4. Effect of the flow unit design on sensor sensitivity

An ideal biosensor has two key properties, i.e. high sensitivity (response to a low concentration of analytes) and high specificity (the ability to discriminate between species according to the immobilized biorecognition elements) [39]. The immobilized bioreporter bacteria confer the biosensor's specificity. Indeed, various strains may be designed to be sensitive to different chemicals and stresses (heavy metals, oxidative compounds, general stresses and antibiotics).

In the present research, the effect of the flow-measurement unit design on sensor sensitivity was determined by exposure of the immobilized bacteria to cytotoxic stress (i.e. ethanol and p-chlorophenol). It was noticed that in the two compared flow units, the immobilized cells responded in different manners (Fig. 4). The possible reasons for this phenomenon are the differences in the design of the water flow unit and, consequently, the important changes in the rate flow. One should mention that in both tested devices, the presence of the toxicants was not constant, i.e. the toxicant was added to the system only for half an hour (as a pulse), while for the rest of the measurement, the immobilized bacteria were exposed to a clear tap water flow, with or without supplementary growth medium. It is assumed that the

Table 1
Effect of water flow rate on the stability of the bacterial matrix. Decrease in the number of (+) symbols implies higher matrix erosion (when (++++) no damage is observed in matrix) and (–) represents the absence of matrix on the fiber.

Flow rate (l/h)	Old setup	New setup
0	++++	++++
1.5	++++	++++
3	++	++++
4.5	+	++++
6	–	+++
8	–	++
10	–	++

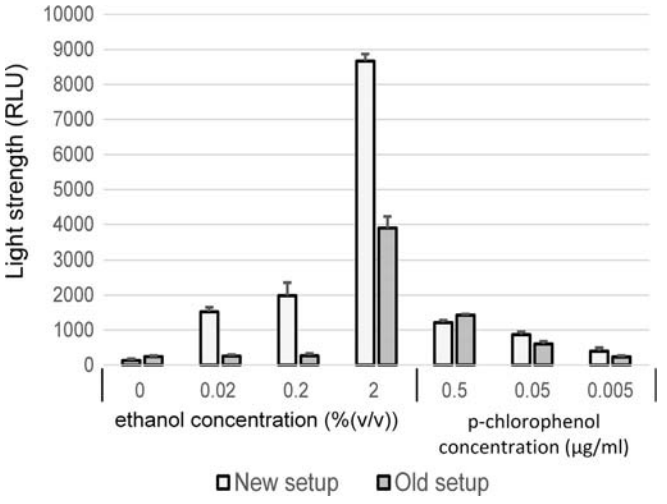

Fig. 4. Improved sensitivity with the use of the new flow unit design tested with different concentrations of ethanol and p-chlorophenol.

diffusion rate of the toxicant into the alginate matrix depended on several main parameters: the concentration of the chemical in the liquid, the time of exposure of the toxicant, as well as, the matrix density. In the tubing-based optical–fiber setup [13], toxicants were passed into the measuring unit much faster and, once simple non-medium containing tap water came as a replacement, they were washed out of the system sooner. In the dual pump setup, the fiber optic is exposed to a reduced toxicant concentration at the beginning, as compared to the previous design. Therefore, it takes longer to reach the same toxicant concentration and the same for nontoxic water to replace it. Thus, immobilized bacteria are exposed to the toxicant for a longer duration, allowing increased diffusion inside the matrix. Our supposition is confirmed by the recent reviews that showed that the longer bacteria are exposed to toxicants, the more material diffuses to its surface and into its cytoplasm [40]. Fig. 4 shows that the new flow cell design allowed an increase in sensor sensitivity (100-fold higher in the case of ethanol) when compared to the previous setup. Ethanol is a model cytotoxic compound that was used as a positive control in many previous publications using TV1061 as the bioreporter bacteria [41–43]. Our probes were also exposed to different concentrations of p-chlorophenol, oftentimes found in wastewaters and sewage [44] and the sensitivity of the previously published setup was roughly comparable to that of the earlier static system [45,46]. However, it was not sensitive enough to detect typical contaminations of surface water in developed countries, which usually range from <1 ng L^{-1} to 1 μg L^{-1}. The new system has, however, demonstrated a higher sensitivity (10-fold higher) compared to the previous setup (Fig. 4) and is now comparable to other methodologies (e.g. electrochemical [47,48]). Obviously solving other engineering issues may help increase further the sensitivity of the system albeit the fact that the bioreporters are themselves limiting. Solving physiological parameters may also help increase their sensitivity.

3.5. Increased on-line measurement duration

The challenge of on-site analysis requires elongated tests [49], during continuous measurements, and this was done here for longer periods of time (two days) using a single optical fiber probe, as compared to previous studies (one day). Experimentally, two setups (previously published one and present one) were operated for 48 h, while the immobilized cells were exposed to different toxicants (copper, ethanol and p-chlorophenol) each for 24 h (at $t=0$, $t=24$ and $t=48$ for 30 min). Indeed, many environmental compounds, such as metal ions, phenols and ethanol, may induce heat shock response in bacteria [50], including toxic copper [51] [52].

It was found that 48-h experiments with the previous setup showed much lower cell response to test controls after 20 h of sensor operation [13], and no activity by 48 h of measurements (data not shown). Many different factors may be responsible for these results, such as biofouling formation on the immobilization matrix, destructive effect of the water flow on the probe matrix, washing out of the matrix calcium, with subsequent loss of alginate polymer and then release of the bacteria from the fiber [13]. In the new setup, on the other hand, bacteria remained active for twice as long (Fig. 5), albeit even longer periods were not yet tested. As immobilized cells respond differently (e.g. time of response, recovery time, strength of the signal) to the pandemonium of possible contaminating compounds due to their available concentration as well as toxic effect, it is suggested that a putative role in the future may be found for the use of data-mining tools to provide analyte detection and identification using panels of bioreporters producing specific fingerprints.

Bioreporter bacteria used in this research were “tailored” to respond in a dose-dependent manner to changes in environmental conditions with luminescence amplitude being proportional to bacterial damage [13,20,53–55]. However, after each exposure (three different times), the responsiveness decreased which could be due to the formation of biofouling (Fig. 3), decrease in their repair mechanism ability or some other reason. An additional and important issue is the recovery capability of the device-based bacteria (i.e. the time required by the system to return back to the unstimulated mode). A faster recovery rate increases the availability of the device for detecting further contaminants, thereby decreasing the possibility of overlooking passing pollutants [49]. In both setups (previous [13] and present), decreasing the toxicant concentration decreases the time needed for recovery, thus lowering the damaging effect of the toxicants on the immobilized cells, which enables faster recovery rate. Furthermore, after the second and third exposure to the same toxicants, there was a further decrease in the recovery time. As explained above, a

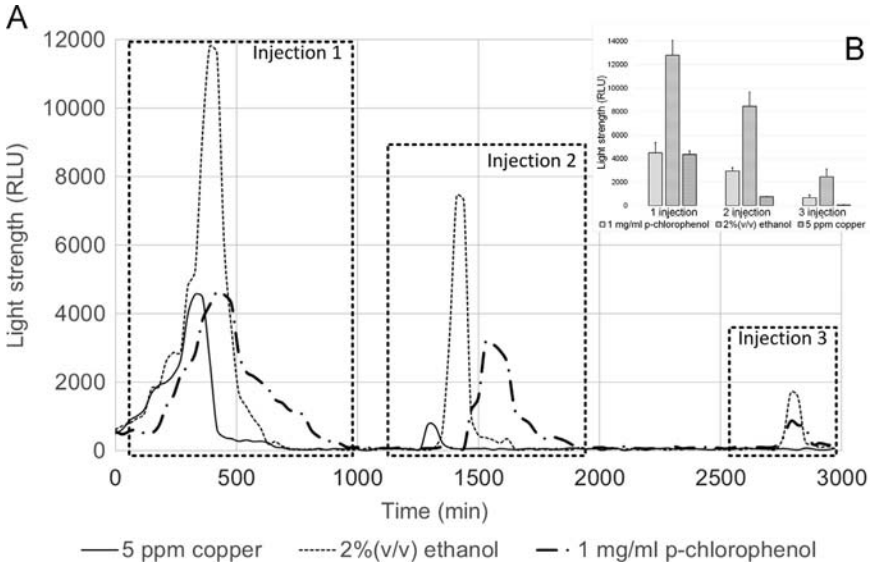

Fig. 5. (A) kinetic response of strain TV1061 to 2% (v/v) ethanol, 5 ppm copper and 1 mg/mL p-chlorophenol. Chemicals were added at $t=0$, $t=1{,}200$ and $t=2{,}680$ min with the addition of 5% (v/v) LB. (B) Summary of results from all experiments ($n=10$) using 2% (v/v) ethanol, 5 ppm copper and 1 mg mL^{-1} p-chlorophenol.

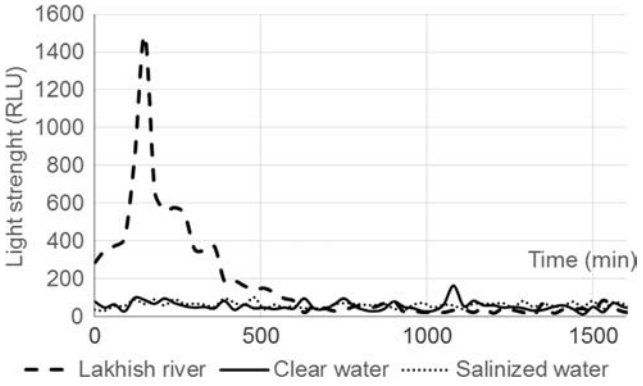

Fig. 6. Response of TV1061 strain to Lachish River water samples with the addition of 5% (v/v) LB.

possible reason is that their defense system may still be active from the first exposure, sensitizing the cells to the next damage.

3.6. *Environmental toxicity*

To evaluate the capability of the newly designed setup (Fig. 1B) to sense the presence of pollutants in environmental samples, bacteria were exposed to Lakhish (Israel) River water. Sewage and waste in the 70-km Lakhish River, which flows through the northern part of Ashdod, have plagued the city's residents over the years. Moreover, rainwater carrying large amounts of contaminations from road surfaces is drawn off into the sea without any treatment and consequently, both the coastal strip and Lachish River are now polluted [56]. Fig. 6 represents a 24-h experiment showing a strong inducing response suggestive of the presence of pollutants. To test the possible salinity effect of river water on immobilized bacteria, cells were exposed to synthetic saline water [57]. In this case the bioreporter bacteria response were similar to clear water, suggesting that the positive signal with the Lakhish samples was indeed due to presence of the contaminating chemicals. Thus, our system can test positive environmental samples, albeit without identification of the actual pollutants, therefore it can only be considered a first line of defense alarm. The kinetics of the response differed from some of the tested chemicals (Fig. 5), surely due to chemical mixtures at various concentrations [58,59].

4. Conclusions

Herein, a further optimized on-line fiber-optic system for monitoring water pollutants is reported after tweaking several engineering parameters. The designed architecture of the fiber-containing measuring unit decreased the shear stress forces, thus preventing its degradation and subsequently, the release of bioreporter bacteria into the tested water sample. Such a system, thus, allows for a higher flow rate of larger volumes of sample to be tested in less time.

ABSTRACT

The article presents the optimisation, validation and application of the microwave induced plasma optical emission spectrometry (MIP–OES) dedicated for a routine determination of Ag, Al, B, Ba, Bi, Ca, Cd, Cr, Cu, Fe, Ga, In, K, Li, Mg, Mn, Mo, Na, Ni, Pb, Sr, Tl, Zn, in the geological samples. The three procedures of sample preparation has been proposed: sample digestion with the use of hydrofluoric acid for determination of total concentration of elements, extraction by aqua regia for determination of the quasi-total element concentration and extraction by hydrochloric acid solution to determine contents of the elements in acid leachable fraction. The detection limits were on the level 0.001–0.121 mg L^{-1} (from 0.010–0.10 to 1.2–12 mg kg^{-1} depend on the samples preparation procedure); the precision: 0.20–1.37%; accuracy 85–115% (for recovery for certified standards materials analysis and parallel analysis by independent analytical techniques: X-ray fluorescence (XRF) and flame absorption spectrometry (FAAS)). The conformity of the results obtained by MIP–OES analytical procedures with the results obtained by XRF and FAAS analysis allows to propose the procedures for studies of elemental composition of the fraction of the geological samples. Additionally, the MIP–OES technique is much less expensive than ICP techniques and much less time-consuming than AAS techniques.

1. Introduction

The microwave induced plasma optical emission spectrometry (MIP–OES), besides different spectrometric techniques as inductively coupled plasma optical emission spectrometry (ICP–OES), inductively coupled plasma mass spectrometry (ICP–MS), atomic absorption spectrometry (AAS) or atomic fluorescence spectrometry (AFS) techniques has been designed for elements determination in various samples [1]. The relatively short history (the first analytical application in 1963 [2]) and late (2011) commercialization of instruments [3] caused a small popularity of the technique. The application of determination of selected elements as e.g. Na [4], Cu, Cr, Mn, Fe, Cd, Zn, Ni, Au [5], Ag, Pd, Pt [6], Hg [7], K, Ca, Mg, Sr [8], Cl, Br [9], Si [10], Ba, Pb [11] first of all have based on laboratory-made analytical instruments. The different plasma gases has been used in MIP–OES technique: argon [5,6] or helium [7,9], but the use of nitrogen [12] (generating from atmospheric air) allowed significantly decrease the operating costs [10] and made the technique competitive to inductively coupled plasma based techniques [3].

The most of MIP–OES studies were concentrated on the optimisation of the analytical systems to obtain the lowest detection limits with satisfactory precision and accuracy [7]. The more efficient nebulisers (as ultrasonic nebuliser (US)) [13], the hydride generation and introducing in the plasma, connected with the US nebulizer [14,15] or direct solid samples introduction as a slurry [16–18] have been applied.

The MIP–OES spectrometry (besides ICP–OES, ICP–MS, AAS or AFS techniques) has been successfully used as chromatographic detector in hyphenated techniques [19,20]. Both in gas chromatography (GC) [21,22], capillary electrophoresis (CE) [23,24] or high performance liquid chromatography (HPLC) [25] the MIP–OES detectors allowed to determine elements (e.g. Se, [22] Cu, [23] As, [24] Cr [25]) species. Commercialisation of GC–MIP–OES instrumentation made this hyphenated techniques the most popular utilization of MIP–OES technique [26].

The article presents the application of the new analytical technique of MIP–OES to multielemental analysis of geological samples using Agilent 4100 MP-AES spectrometer, the first commercially

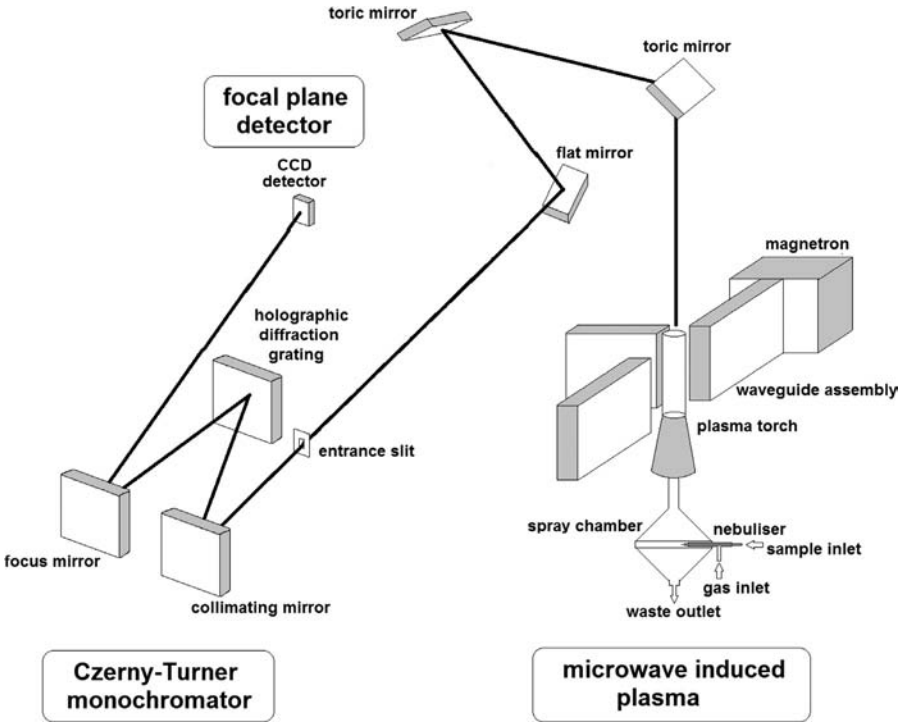

Fig. 1. Schematic diagram of the MP-AED 4100 spectrometer.

available MIP–OES analytical instrument. The validation of proposed samples preparation procedures and spectrometric measurements of real geological samples has been done. The results obtained for MIP–OES technique have been compared with independent methods: XRF and FAAS The compliance of the results obtained by different techniques allows to propose the MIP–OES based analytical procedures for routine analysis.

2. Experimental

2.1. Instruments

The nitrogen (with on-line nitrogen generator) microwave induced plasma optical emission spectrometer MP-AED 4100 (Agilent, USA), with SPS-3 autosampler (Agilent, Australia), worked in multielemental mode has been used (Fig. 1). The wavelengths selected for element determination and relative emission intensity for indicated spectral lines are put together in Section 3.2. The spectrometer was equipped with Czerny-Turner monochromator with 600 mm focal length with fixed entrance slit, holographic diffraction grating with 2400 lines/mm (wavelength range 178–780 nm) and CCD detector (532 × 128 pixel) directly cooled to 0 °C using a thermoelectric Peltier device. The microwave excitation assembly was an aircooled magnetron operating at 2450 MHz (fixed plasma power of 1 kW, vertically-oriented plasma with end-on or axial viewing). The plasma gas flow was fixed at 20 L min^{-1} and the auxiliary gas flow was fixed at 1.5 L min^{-1}. The glass spray chamber, glass concentric Meinhard nebuliser and quartz plasma torch (Agilent, Australia) have been used. For all elements determinations common settings have been used: the uptake time (the time of sample introduction to the plasma) 5 s, the plasma stabilisation time with sample aspiration 5 s, read time 2 s, read in triplicates. The mode of automatic background correction (off-peak left, off-peak right or off-peak left+right) has been used. The operating parameters: viewing position and nebuliser pressure were optimised for each element respectively and discussed in the text. The sequential analysis has been performed automatically with the appropriate (optimized) changes of operating parameters: viewing position and nebulizer pressure while the nebulizer pressure indicates the sequence of analysis (the elements determination has been grouped from the lowest to the highest value of the pressure).

Table 1
The spectral condition for FAAS determination.

element	wavelength (nm)	slit (nm)
Ca	422.7	0.5
Mg	202.6	1.0
Fe	248.3	0.2
Cr	357.9	0.2
Cu	324.8	0.5
Mn	279.5	0.2
Ni	232.0	0.2
Cd	228.8	0.5
Pb	217.0	1.0
Zn	213.9	1.0

As the reference analytical instrument the flame (air-acetylene) atomic absorption spectrometry SpectrAA 240FS (Varian, Australia) equipped with the SIPS-20 automatic system for standard solution preparation and on-line sample dilution (Varian, Australia) has been used in fast-sequention multielemental mode. The following determination conditions were used: a stoichiometric flame (13.5 L min^{-1} air and 2.0 L min^{-1} acetylene) was used except determination of chromium, where a flame with excess of inflammable gas was used (11.5 L min^{-1} air and 4.0 L min^{-1} acetylene), using the hollow cathode lamps (HCL) and background correction with a deuterium lamp (except Ca, Mg and Fe determination). The spectral condition has been placed in Table 1. The lamp current was equal to 7 mA (Ca/Mg lamp), 10 mA (Co/Cr/Cu/Fe/Mn/Ni lamp), and 5 mA (Ag/Cd/Pb/Zn lamp). The detection limits were on the level of 0.01 mg L^{-1}. The uncertainty (understood as a parameter characterizing the dispersion of the values attributed to a measured parameter, the main component of uncertainty was precision) of the entire analytical process (sample preparation and spectrometric measurements) did not

exceed 10% for Ca, Mg, Fe and Mn, and 15% for the other elements determined.

The second reference technique was X-ray fluorescence. The X-ray spectrometer Tracer IV Handheld XRF (Bruker, USA): the voltage range 4–45 kV; current 1–45 μA; the Silicon Drift Detectors (SDD) has been used. The spectrometer was equipped with portable vacuum pomp and worked in quantitate mode (determination of Al_2O_3, SiO_2, P_2O_5, S, K_2O, CaO, TiO_2, V_2O_5, Cr_2O_3, MnO, Fe_2O_3, NiO, ZnO, ZrO_2, SnO_2 with detection limit 0.01%) elaborated by manufacturer for geochemical analysis. The uncertainty of the measurements was below 5.0% for all elements determined.

For sample decomposition two microwave laboratory systems MW500 and MW520 (Merck, Germany) with fixed by manufacturer microwave power, equipped with high-pressure close Teflon units have been used. No temperature or pressure measurement and control have been available. For sample homogenisation the laboratory agate grinder Pulverisette (Fritsch, Germany) and plastic sieves (2.00 mm; 0.20 mm and 0.02 mm (Cisa, Spain)) have been used.

2.2. Reagents

Only reagents of analytical purity and deionised water produced in a Milli-Q device (Millipore, USA) were used. For MIP–OES analysis the 23-elements ICP commercial analytical standard (Merck, Germany) and for FAAS analysis the AAS commercial standards (Merck, Germany) have been used. For sample preparation the hydrochloric acid (diluted to concentration 2 mol L^{-1}), hydrofluoric acid (40%), nitric acid (65%) and boric acid (the 5% (w/v) solution), (Merck, Germany) have been used. For analysis quality control the standard reference materials BCR667 (JRC's Institute for Reference Materials and Measurements, European Commission), NIST2709 (National Institute of Standards & Technology, USA) and IAEA405 (International Atomic Energy Agency, Austria) have been used.

2.3. Methodology

2.3.1. Sample preparation

After initial homogenisation and elimination of coarse material (fractions with a particle diameter larger than 5 mm), the material was divided into laboratory samples weighing approx. 100 g. In the laboratory, the samples were dried at room temperature and the coarse material (particle diameter larger than 1 mm) was removed on a plastic sieve. Next the samples were grinded and sieved on plastic sieve (0.02 mm).

2.3.2. Sample extraction or digestion

2.3.2.1. Hydrofluoric acid digestion. The amount of 0.50 ± 0.01 g of sample were put in Teflon high-pressure unit and 6 mL of concentrated nitric acid were added. After reaction of the nitric acid with carbonates, 3 mL of concentrated hydrofluoric acid were added and unit was closed by Teflon cap. After reaction the unit was opened and 10 mL of boric acid solution were added immediately.

2.3.2.2. Aqua regia extraction. The extractions by aqua regia were prepared in compliance with the ISO 11466.3 procedure. The representative sample of 1.00 ± 0.01 g was extracted with concentrated nitric acid and concentrated hydrochloric acid (3.0 mL of nitric acid to 9.0 mL of hydrochloric acid) using microwave heating with a laboratory microwave unit.

2.3.2.3. Sample hydrochloric acid leaching. The hydrochloric acid extracts (acid leaching) methodology [27] has been prepared follow the previous geochemical studies [28]. The amount of 2.00 ± 0.01 g of the sample was weighed and put in a conical flask to which a hydrochloric acid solution (2 mol L^{-1}) was poured carefully in small portions (20 mL). After the reflux condenser was connected, the flask was heated up to approx. 80 °C. This temperature was then maintained for about 30 min.

The sample obtained after extraction or digestion was drained quantitatively through a paper filter (previously rinsed with 200 mL of distilled water) using polyethylene funnel into a plastic test tube; and finally the water was added up to a volume of 20.0 mL. In the case of hydrofluoric acid digestion 30 mL of boric acid solution were added to the solution and finally the water was added up to a volume of 50.0 mL.

3. Results and discussion

3.1. The stability of wavelength observation (off-set)

The accuracy of wavelength selection was checked for following spectral lines: Zn 213.857 nm; Mn 279.482 nm; Cu 327.395 nm; Sr 407.771 nm; Ba 493.408 nm; Ba 614.171 nm and K 766.491 nm, respectively. The long term stability of wavelength accuracy has been shown in Fig. 2. Generally, the offset value didn't exceed 0.020 nm and the long-time offset changes range was 0.001 nm to 0.004 nm. The highest wavelength deviation from the exact value has been noticed for Cu line 327.395 nm – the 60 days offset mean value 0.021 ± 0.001 nm, the lowest for Ba line 493.408 nm – the 60 days offset mean value 0.001 ± 0.001 nm. The highest offset changes have been observed for instrument zero order (the assumed position of optics by the manufacturer)—the standard deviation for 60 days offset value 0.004 nm.

3.2. Optimisation of MIP–OES spectrometer working condition

3.2.1. The nebuliser gas pressure

To obtain the highest analytical signal the user can optimize the nebulizer pressure for each element. The changes of analytical signal with the increase of gas pressure in nebulizer have been shown in Fig. 3, the optimal values recommended for routine analysis have been specified in Table 2. For most elements (Al, Ba, Ca, Ga, In, K, Li, Mn, Mo, Na, Sr, Tl) the pattern was the signal increase with the increase of nebuliser pressure. However, the changes of signal level with the increase of the nebuliser pressure were inconsiderable. In multielemental analysis the order of the elements determination has been automatically decide based on the results of optimisation of the nebuliser gas pressure: from the lowest to the highest value of the pressure to increase the analytical capability.

3.2.2. The position of plasma observation

The plasma is viewed from the top, and different elements/lines may have a slightly different offset from the centre view. Generally, the highest analytical signal has been obtained for the defined by

the manufacturer as the central under the torch (0) or similar to central (± 20) viewing position. For molybdenum and in particular lead and bismuth the viewing position outside the axis of plasma symmetry has given the highest analytical signal. The changes of analytical signal during the shift of viewing position have been shown in Fig. 4. The optimal values recommended for routine analysis have been specified in Table 2.

3.3. The validation of analytical procedure

3.3.1. Analytical figures of merit: Calibration, limits of detection and quantification, precision

Optimized analytical methodology was validated follow ISO17025 criteria. The following parameters were defined: detection limits (defined follow 3 sigma criteria, where sigma is a standard deviation of series of 6 replicates of a blank) and limits of quantification (6 sigma criteria), range of calibration using non-linear algorithm provides a least second order least squares line of best fit in the intensity vs. concentration domain, and instrumental precision of determinations (Table 2). The obtained values of parameters characterising the analytical method showed a real possibility to apply MIP–OES technique in the determinations of elements content in the extracts of environmental samples [29]. Additionally, the uncertainty of the whole analytical procedure (including sample preparation step), involving the repetition of the extraction cycle and measurement of elements content, assuming the values below 20% (that was mainly produced by the sample preparation stage), confirms the possibility to apply the described procedure in the studies of element content in

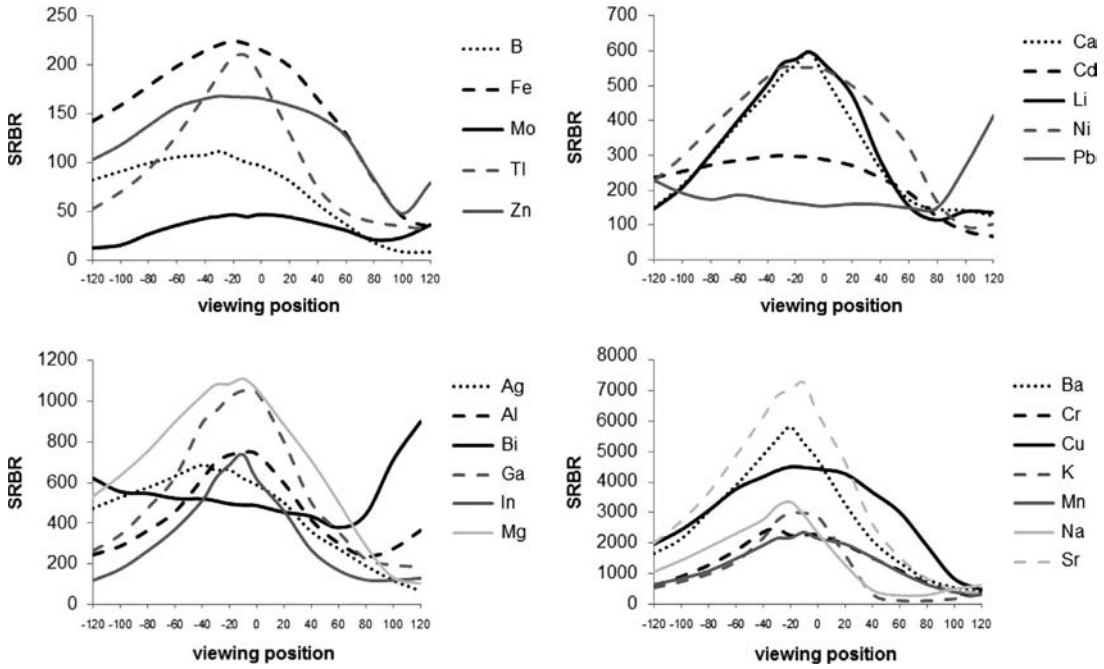

Fig. 4. The analytical signal changes with the changes of plasma viewing position in MIP–OES. SRBR—signal to root background ratio, viewing position in dimensionless manufacturer units.

geological samples [3]. The quality of analysis of the samples series has been controlled by the reslope or "known sample" analysis with the use of Shewhart's control cards. Additionally, the differences of the values of detection limits obtained during validation procedure and calculated for routine analysis were inconsiderable.

3.3.2. *The accuracy studies*

For the accuracy studies for the determination of the total content of element after hydrofluoric acid sample decomposition the independent analytical method has been used. The X-ray fluorescence, as the method designed for total element content determination without sample preparation, has been chosen. The measurements have been performed parallel for five geological samples (A–E) with the use the portable XRF spectrometer and after sample HF decomposition MIP–OES analysis. The results comparison (Table 3) showed the high conformity of results obtained by both analytical methods (the MIP–OES recovery from 91.7% to 115%). Additionally, for selected elements (Ca, Cd, Co, Cr, Cu, Fe, Mg, Mn, Ni, Pb and Zn) the FAAS analysis parallel to MIP–OES have been done. The results obtained by FAAS were similar in the range of uncertainty to the results obtained by MIP–OES. Both methods are complementary (Table 2) and may be

x—Not measured, boric acid was used in digestion procedure, xx—not measured, hydrochloric acid was used for leaching.

alternatively used in analysis of environmental samples [29]. The MIP–OES measurements accuracy was good in comparison with the results obtained (Table 2) by independent techniques XRF and FAAS (the mean value of accuracy obtained from 5 independent analyses). For results obtained by MIP–OES and reference techniques: XRF and FAAS measurements the statistical analysis has been done. The distribution tests: chi2 and Kolmogorow–Smirnow indicate the normal distribution of data (and the need of the use parametric test) and the results have been compared using Student's *t*-test. The results of the *t*-test indicates no statistically significant differences with the level of probability $p < 0.05$. Additionally, the proposed procedure of total element content determination by MIP–OES is safe for glass or quartz parts of analytical instrument.

3.3.3. *The traceability studies*

The traceability studies have been performed with the use of standard reference materials: BCR667 (the estuarine sediment), NIST2709 (the agricultural soil from San Joaquin Valley in the central California) and IAEA405 (the estuarine sediment from Tagus estuary (Portugal)). Additionally five geological samples (described by the letters A–E) have been used as in—laboratory standards.

The traceability studies for aqua regia samples extraction (procedure of quasi-total elements content determination) have been done with the use of three standard certified materials (geological matrix). The results of recovery (Table 4) were high (from 88.4% to 105%). The worst recovery has been found for aluminum determination, it was caused by the lack of decomposition of aluminosilicates by aqua regia. The results conformity allows use the procedure in analysis of environmental samples.

The traceability studies for leaching procedure (hydrochloric acid extraction) have been performed for NIST2709 certified reference material (the certified values of elements content in leachable fraction were available). The obtained recovery values (in the range from 84.5% 118%) were high (Table 5) and the usefulness of acid leaching procedure has been confirmed. To find the recovery level for acid leaching procedure the analysis of three certified materials has been done and the obtained results has been compared with the certified value for total concentration of the elements. The recovery values were in the range from 10.5% to 89.9%, for most elements were under 60%.

The validation procedure was carried out for 66 separately prepared samples and 1374 instrumental measurements (903 (MIP–OES), 396 (FAAS) and 75 (XRF)) have been done. The results of recovery, discussed below, were comparable with the works of different authors [11,13]. Additionally, the good MIP–OES results accuracy and compliance with the results obtained using diffe rent techniques (FAAS and XRF) are evidence of not significant interferences.

3.4. *Application for geological samples*

With the use of prepared application the analyses of geological samples (river sediments: 89–95% SiO_2, 3–5% organic matter) have been done. The MIP–OES technique allows the fast determination of 23 elements content in several hundred of samples with satisfactory accuracy and precision. The results of geochemical analysis have been specified in Table 6.

4. Conclusion

The MIP–OES techniques may become the very useful tool in geochemical analysis. The low cost of instrumentation and operation (comparable with FAAS) and fast and multielemental analysis (comparable with ICP–OES [30]) allow use the MIP–OES technique in the analysis of various geological samples. Good accuracy and precision, obtained in MIP–OES analysis let to recommend this technique both for determination of the total concentration of elements and quasi-total and acid leachable elements concentration. The availability of first commercial MIP–OES analytical instrument may precipitate the use the MIP–OES technique in analytical chemistry.

Acknowledgements

The authors thank to Professor Jan Milecki from Faculty of Chemistry Adam Mickiewicz University in Poznan for the possibility to use the MIP–OES instrument. The studies were partially financed by National Science Centre Poland, based on the decision No. DEC-2013/09/B/ST10/00610 and the described procedure will be used in the geochemical analysis.

ABSTRACT

In this paper, we report an amplified electrochemical immunoassay for *Escherichia coli* as indicator bacteria relevant to the quality of dairy product using the functionalized gold nanorod-based labels ({$_d$Ab–AuNR–FCA}). The {$_d$Ab–AuNR–FCA} labels were designed by exploiting silica-functionalized gold nanorods (AuNR@SiO_2) as the carriers for immobilization of detection antibody ($_d$Ab) and ferrocenecarboxylic acid (FCA), in which $_d$Ab was used for recognition of *E. coli* and FCA tags served as signal-generating molecule. Greatly amplified signal was achieved in the sandwich-type immunoassay when enormous FCA linked to AuNR@SiO_2. Compared with the commercially available {$_d$Ab–FCA}, the {$_d$Ab–AuNR–FCA} labels exhibited a better performance for *E. coli* assay due to the advantages of AuNR@SiO_2 as carriers. Under optimal experimental conditions, it showed a linear relationship between the peak current of FCA and the logarithmic value of *E. coli* concentration ranging from 1.0×10^2 to 5.0×10^4 cfu mL^{-1} with a detection limit of 60 cfu mL^{-1} ($S/N=3$), and the electrochemical detection of *E. coli* could be achieved in 3 h. Moreover, the proposed strategy was used to determine *E. coli* in dairy product (pure fresh milk, yogurt in shelf-life, and expired yogurt), and the recoveries of standard additions were in the range of 95.1–106%. This proposed strategy exhibited rapid response, high sensitivity and specificity for *E. coli* assay in dairy product, and could become a promising technique to estimate the quality of dairy product.

1. Introduction

Dairy product is rich in protein, fat and other nutrients, and could be easily contaminated with pathogenic bacteria during the process of manufacture, storing, transporting and selling [1–3]. Increasing numbers of human infections and outbreaks associated with contaminated dairy product have been reported in China and many other countries. Various investigations demonstrate that these outbreaks are often linked with *Escherichia coli* levels present in dairy product [4,5]. As a consequence, the presence of *E. coli* in dairy product is considered as a possible threat or indicator of microbiological dairy product quality deterioration [6,7]. In many countries, health departments routinely detect *E. coli* in dairy product to protect people from bacterial infections.

Conventional methods for *E. coli* detection are standard plate count, most probable number (MPN), Petrifilm™ aerobic count plate method, etc. [8–10]. Although these methods have the advantage of high accuracy, they are complicated in operation, lack of specificity and time-consuming, which delays the time to market and results in a serious backlog of dairy product. Moreover, other microorganisms potentially present in dairy product could interfere with *E. coli* assay to cause false positive results. Therefore, the development of rapid, sensitive and specific methods for *E. coli* analysis has become a great challenge for in-time estimating the quality of dairy product.

Recently, some microbiological techniques such as polymerase chain reaction [11], immunoassay [12] and in situ hybridization technique [13] have been developed as alternatives to the conventional methods for *E. coli* detection. Among the above techniques, immunoassay-based protocols employing antibody–antigen interaction has been regarded as one of the most important analytical techniques in biological assay [14]. In comparison with other immunological methods such as fluorescence [15], chemiluminescence [16], or surface-plasmon resonance [17], electrochemical immunoassay provides a promising

approach for specific and rapid analysis because of the advantages of simple instrumentation, easy signal quantification, low cost of the entire assay, and potential ability for real-time and on-site detection [18–20].

In order to achieve a successful electrochemical immunoassay, signal amplification is a critical need for obtaining low detection limit and high sensitivity [21]. At present, the advantages of nanotechnologies have provided alternative approaches for sensitive detection of biological analytes [22]. Various nanomaterials including nano tubes [23], nanorods [24], and nanoparticles [25] have been used as excellent carriers for the preparation of labels by loading numerous signal tags, and the prepared labels can greatly amplify the transduction signal of a recognition event in bioassay. Among these nanomaterials, gold-based nanomaterials [26], especially gold nanorods (AuNRs), have attracted considerable interest in biomolecule analysis due to their variable length–diameter ratio and large surface area [27,28]. However, cetyltrimethylammonium bromide (CTAB), serving as the essential inducer and stabilizer in the fabrication process of AuNRs, could interfere with the biological process because of its toxicity, which results in some limitations to AuNRs in the biocompatibility. Considerable efforts have been made to circumvent these drawbacks [29,30], in which silica-functionalized AuNRs (AuNR@SiO_2) has been proved to be an effective strategy to increase the functional surface area of AuNRs, facilitate the biocompatibility and enrich the practical applications [31].

In this paper, an amplified electrochemical immunoassay was proposed for *E. coli* analysis in dairy product using the functionalized AuNR-based labels ({$_d$Ab–AuNR–FCA}). The {$_d$Ab–AuNR–FCA} labels were fabricated by exploiting AuNR@SiO_2 as the carriers for immobilization of detection antibody ($_d$Ab, anti-*E. coli* polyclonal antibody) and ferrocenecarboxylic acid (FCA), in which $_d$Ab was used for recognition of *E. coli* and FCA tags served as signal-generating molecule. Here, AuNR@SiO_2 had large surface area to load enormous FCA, and thus played important roles in signal amplification to improve detection sensitivity. In the case of the electrochemical assay, L-cysteine was self-assembled on a gold electrode surface through Au–S bonding, which introduced a high density of capture antibody ($_c$Ab, anti-*E. coli* monoclonal antibody). The sandwich-type system was formed by the specific recognition of the electrode surface-confined $_c$Ab to *E. coli*, followed by the attachment of the {$_d$Ab–AuNR–FCA} labels. The analysis of *E. coli* was performed by electrochemical detection of FCA in the bound labels on the electrode surface. The results confirmed that the electrochemical immunoassay gave a useful protocol for *E. coli* analysis with rapid response, high sensitivity and specificity, and thus provided a powerful tool for estimating the quality of dairy product.

2. Experimental

2.1. Reagents and materials

Ferrocenemonocarboxylic acid (FCA), 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), N-hydroxysuccinimide (NHS) and bovine serum albumin (BSA) were purchased from Sigma Chemicals (St. Louis, MO, USA). *E. coli* (DH5α) was supplied by School of Food and Biological Engineering, Jiangsu University (Zhenjiang, China). Anti-*E. coli* monoclonal antibody (serving as capture antibody, $_c$Ab), and anti-*E. coli* polyclonal antibody (serving as detection antibody, $_d$Ab) were obtained from Beijing Biosea Biotechnology Co. Ltd. (Beijing, China). 3-Aminopropyltriethoxysilane (APTES, 99%) and tetraethoxysilane (TEOS) were obtained from Aladdin Reagent Database Inc. (Shanghai, China). L-cysteine, $HAuCl_4$ and other chemical reagents were purchased from Shanghai Chemical Reagents Co. Ltd. (Shanghai, China). All the reagents used were of analytical-reagent grade and all solutions were prepared with pure water from Millipore (Milli-Q, 18.2 MΩ cm). The glassware was autoclaved prior to be used.

2.2. Apparatus

All electrochemical measurements were performed on a CHI660 electrochemical working station (CH Instruments Inc., Austin, TX, USA) with a conventional three-electrode system comprised of a platinum wire as the auxiliary, a saturated calomel electrode (SCE) as the reference, and the modified gold working electrode. Electrochemical impedance spectroscopy (EIS) was carried out within frequency range of 0.10 Hz–100 kHz at the amplitude of 5 mV and the applied potential of 0.24 V. Transmission electron microscopy (TEM) was collected on JEM-2100 (JEOL Ltd., Tokyo, Japan). UV–visible spectroscopic data were obtained on a Cary 500 UV–vis-NIR spectrometer (Varian Comp, USA).

2.3. Preparation of the {$_d$Ab–AuNR–FCA} labels

AuNRs were first synthesized by using the seed mediated method (see Supplementary Data) [27,32]. Next, the freshly AuNRs were dispersed in 10 mL Milli-Q water by sonication for 10 min, and 100 μL of 0.10 mol L^{-1} NaOH was added, followed by 60 μL the mixtures of TEOS, APTES and ethanol in the volume ratio of 1:1:5 with stirred effectively for 24 h. The resulting solution was centrifuged at 10,000 rpm for 10 min to obtain the precipitate of AuNR@SiO_2. The precipitate was washed several times with water and redispersed in 5 mL PBS. Then, AuNR@SiO_2 was mixed with 4.0 mg mL^{-1} $_d$Ab and stirred for 2 h. The resulting $_d$Ab–AuNR was centrifuged at 12,000 rpm for 10 min to remove the non-conjugated $_d$Ab and then redispersed in 5 mL PBS. Last, the {$_d$Ab–AuNR–FCA} labels were fabricated by addition of 1.0 mL of saturated FCA solution (dissolved in PBS) to the $_d$Ab–AuNR. After incubation for 2 h under shaking, the labels were isolated by 5000 rpm for 10 min to remove the unbound FCA, and then dispersed in 5 mL PBS to form homogeneous dispersions. The obtained {$_d$Ab–AuNR–FCA} labels were stored in a refrigerator at 4 °C before use.

2.4. Fabrication of the capture antibody ($_c$Ab)-based immunosensor

A gold electrode (3 mm in diameter) was used to fabricate the $_c$Ab-based immunosensor. Prior to surface modification, the electrode was polished with 0.05 μm alumina slurry, followed by successive sonication in anhydrous ethanol and water. Subsequently, the electrode was electrochemically cleaned in 0.50 mol L^{-1} H_2SO_4 solution by cyclic potential scanning between −0.40 V and 1.5 V at 100 mV s^{-1} until a stable cyclic voltammogram was obtained. Afterwards, the cleaned electrode was modified by immersing in 0.02 mol L^{-1} L-cysteine in HAc–NaAc buffer solution (pH 5.0) for 6 h to form a self-assembled membrane (SAM), and the electrode surface was rinsed with water and PBS. Next, 10 μL of 0.40 mol L^{-1} EDC and 0.10 mol L^{-1} NHS in PBS were cast on Au/L-cysteine electrode to activate carboxyl group of L-cysteine for 1 h. The activated electrode was rinsed with PBS and incubated with 1.0 mg mL^{-1} $_c$Ab for 1 h to prepare the $_c$Ab-based immunosensor. The immunosensor was then treated with 1.0% (wt/vol) BSA/PBS for 30 min to block the non-specific adsorption.

2.5. Electrochemical detection of E. coli

After being rinsed and dried, the $_c$Ab-based immunosensor was incubated with *E. coli* sample at a certain concentration for 50 min at 37 °C. Subsequently, 10 μL of the {$_d$Ab–AuNR–FCA} labels were dropped on the *E. coli*-captured electrode and incubated for 50 min. The resulting electrode was rinsed with water, and then immersed in an electrochemical cell containing 5.0 mL of 0.10 mol L^{-1} $KClO_4$ in PBS to detect the immobilized FCA with differential pulse voltammetry

(DPV) from 0.10 to 0.50 V (vs. SCE) with pulse amplitude of 50 mV and width of 50 ms.

3. Results and discussion

3.1. Mechanism of electrochemical immunoassay with the {$_d$Ab–AuNR–FCA} labels

The mechanism of electrochemical immunoassay with the {$_d$Ab–AuNR–FCA} labels for the analysis of *E. coli* is illustrated in Fig. 1. In the preparation process of the electrochemical immunosensor, L-cysteine was first self-assembled on gold electrode surface through Au–S bonding (step a), and the carboxyl group of L-cysteine was activated by using EDC/NHS (step b), which introduced a high density of $_c$Ab through amide bond (step c). After further treated with BSA to block the non-specific adsorption, the $_c$Ab-based immunosensor could effectively capture *E. coli* in sample solution by the first immunoreactions (steps d and e). Finally, the {$_d$Ab–AuNR–FCA} labels were introduced to the electrode surface during the secondary binding event (step f). The anchored FCA tags, serving as signal-generating molecule, were detected by DPV in this immunoassay. Since FCA was only present when the {$_d$Ab–AuNR–FCA} labels reacted with *E. coli*, the peak current reflected the concentration of *E. coli* in sample solution, providing a strategy for estimating the quality of dairy product.

3.2. Characteristics of AuNR@SiO_2

AuNRs were fabricated by using the seed mediated method, and then SiO_2 coating has been accomplished when APTES and TEOS were added to the reaction solution together (Fig. 2, top). Transmission electron microscopy (TEM) was conducted to characterize AuNRs and AuNR@SiO_2. As shown in Fig. 2A, AuNRs exhibited typically rod-like shapes, measuring about 10 nm in mean diameter and about 40 nm in length. After active sites were generated on the surface of AuNRs, TEM image was recorded to depict the size and morphology characterization of AuNR@SiO_2 (Fig. 2B). As can be seen, the shape of AuNRs had no obvious change after surface modification, and each AuNR was coated with a thick SiO_2 shell. UV–vis absorption spectrometry was also used to characterize AuNRs and AuNR@SiO_2 (Fig. 2C). Apparently, AuNRs exhibited two characteristic peaks at 730 nm and 500 nm, which were assigned to the oscillation of electrons along the short and long axis, respectively. When SiO_2 was attached to AuNRs, the slightly red-shifted peak position was probably due to a change of surrounding dielectric function induced by the SiO_2 shell formed on AuNRs.

3.3. Characteristics of the electrochemical immunosensor

The fabrication process of the electrochemical immunosensor was characterized by electrochemical impedance spectroscopy (EIS), which

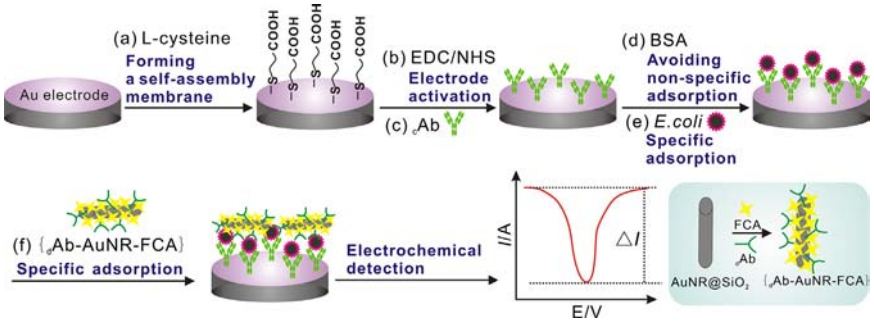

Fig. 1. Schematic illustration of the electrochemical immunoassay of *E. coli* based on the {$_d$Ab–AuNR–FCA} labels.

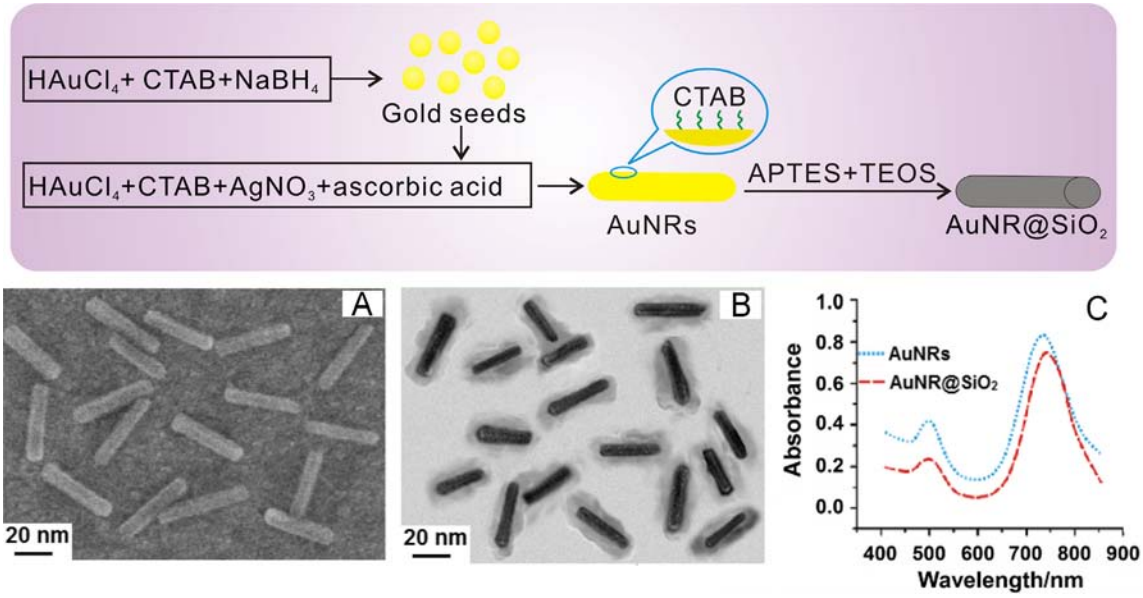

Fig. 2. Top: scheme showing the fabrication steps of AuNRs and AuNR@SiO_2. Bottom: TEM images of AuNRs (A) and AuNR@SiO_2 (B), UV adsorption spectra of AuNRs and AuNR@SiO_2 (C).

was performed in 0.01 moL L^{-1} PBS (pH 7.4) containing 0.10 moL L^{-1} KCl and 2.5 mmoL L^{-1} $Fe(CN)_6^{3-/4-}$ as the redox probe (Fig. 3). As expected, the gold electrode modified with L-cysteine (Au/L-cysteine, curve b) resulted in a great increase in the electron-transfer resistance (R_{et}) value compared to that at the bare gold electrode (bare Au, curve a). This indicated that the self-assembly membrane could inhibit the electron transfer. After $_c$Ab was assembled on the Au/L-cysteine, the R_{et} increased drastically (Au/L-cysteine/$_c$Ab, curve c), indicating that antibody acts as mass-transfer blocking layer and hinders the diffusion of $Fe(CN)_6^{3-/4-}$ toward the electrode surface. As expected, Au/L-cysteine/$_c$Ab modified with BSA resulted in a great increase in the R_{et} value (curve d). Subsequently, the R_{et} increased again once *E. coli* was captured by the immobilized $_c$Ab on the electrode surface (Au/L-cysteine/$_c$Ab/*E. coli*, curve e). Finally, the treatment of the electrode with the {$_d$Ab–AuNR–FCA} labels gave rise to an additional barrier towards the access of the redox probe to the electrode (Au/L-cysteine/$_c$Ab/*E. coli*/{$_d$Ab–AuNR–FCA}, curve f). These observations were consistent with the fact that the electrode was fabricated as expected, which confirmed the success in design of the proposed immunosensor.

3.4. Optimization of detection conditions

Incubation time and temperature were important factors of the immunological reaction. The effect of incubation time on peak current was studied from 20 to 70 min (Fig. 4A). It was found that the peak current increased gradually with increasing incubation time and reached a constant value after 50 min. A longer incubation time did not improve the peak current. Thus, an incubation time of 50 min was used for the immunoassay of *E. coli* in this study.

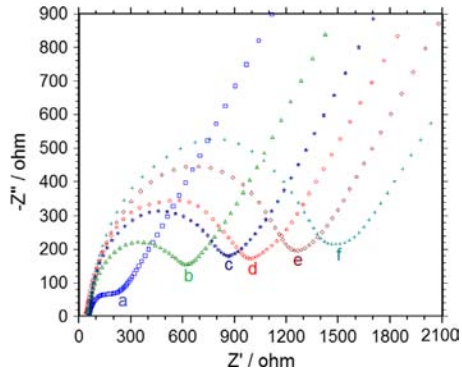

Fig. 3. (A) Electrochemical impedance spectra (EIS) on (a) bare Au electrode; (b) Au/L-cysteine; (c) Au/L-cysteine/$_c$Ab; (d) Au/L-cysteine/$_c$Ab treated with BSA; (e) Au/L-cysteine/$_c$Ab/*E. coli*; (f) Au/L-cysteine/$_c$Ab/*E. coli*/{$_d$Ab–AuNR–FCA} in 0.01 moL L^{-1} PBS (pH 7.4) containing 0.10 moL L^{-1} KCl and 2.5 mmoL L^{-1} $Fe(CN)_6^{3-/4-}$ as the redox probe at the applied potential of 0.24 V.

The relationship of peak current with incubation temperature ranging from 20 to 45 °C is shown in Fig. 4B. The maximum response was obtained at 37 °C and the peak current reduced when the temperature was higher than 37 °C. This might be attributed to the decrease of the biomolecule activity at a high temperature. Thus, 37 °C was chosen as the optimum incubation temperature.

3.5. Electrochemical immunosensor for E. coli assay based on the {$_d$Ab–AuNR–FCA} labels

Under optimal conditions, the electrochemical immunosensor was used for the detection of *E. coli* at different concentrations. As shown in Fig. 5A, the peak current of FCA increased with increasing *E. coli* concentration in the recognition solution, which was attributed to the increasing amount of the {$_d$Ab–AuNR–FCA} labels to bind the electrode surface. The corresponding calibration curve presented a linear relationship between the current response and the logarithmic value of *E. coli* concentration ranging from 1.0×10^2 to 5.0×10^4 cfu mL^{-1} with a slope of 2.03 (curve a, Fig. 5B). The detection limit of the electrochemical immunosensor was 60 cfu mL^{-1} ($S/N=3$) and the electrochemical detection of *E. coli* could be achieved in 3 h.

In order to demonstrate the enhanced sensitivity caused by the application of the {$_d$Ab–AuNR–FCA} labels, the commercially available {$_d$Ab–FCA} was used to replace the labels for performing the same procedure. As shown in curve b (Fig. 5B), the peak current was proportional to the logarithmic value of *E. coli* concentration from 1.0×10^3 to 1.0×10^7 cfu mL^{-1} with a slope of 0.66, and the detection limit was 400 cfu mL^{-1} ($S/N=3$). By comparison between the two slopes, the detection sensitivity of the proposed strategy was much higher than that obtained from {$_d$Ab–FCA}, verifying the advantages of the designed {$_d$Ab–AuNR–FCA}.

The performance of the electrochemical immunosensor has been compared with those reported in the literatures for *E. coli* analysis. Characteristics such as the linear range and detection limit are summarized for all of them in Table 1. As can be observed, the proposed immunosensor exhibited a wide linear range and low detection limit for *E. coli* assay. The reason might be that AuNR@SiO_2 took the advantages of large functional surface area and good biocompatibility, and could be used as efficient carriers for loading enormous FCA and $_d$Ab to design the {$_d$Ab–AuNR–FCA} labels for signal amplification.

3.6. Specificity, accuracy, stability and reusability of the immunosensor

The specificity of the immunosensor for *E. coli* assay was performed by using different microorganisms (e.g. *Staphylococcus aureus*, *Salmonella enteritidis*, and *Microzyme*), which were known

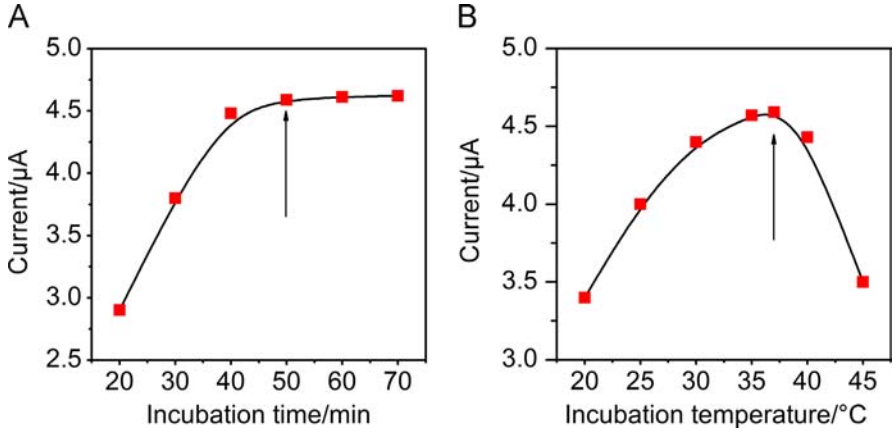

Fig. 4. Effect of incubation time (A) and temperature (B) on peak current of the electrochemical immunosensor for *E. coli* analysis at the concentration of 4.0×10^3 cfu mL^{-1}.

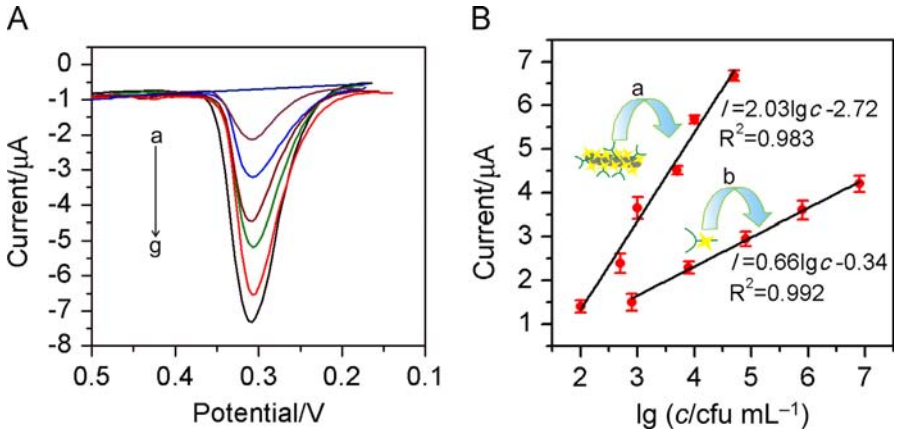

Fig. 5. (A) DPV response of the proposed strategy using the {$_d$Ab–AuNR–FCA} labels for *E. coli* analysis at the concentrations of (a) 0; (b) 1.0×10^2 cfu mL^{-1}; (c) 5.0×10^2 cfu mL^{-1}; (d) 1.0×10^3 cfu mL^{-1}; (e) 5.0×10^3 cfu mL^{-1}; (f) 1.0×10^4 cfu mL^{-1}; (g) 5.0×10^4 cfu mL^{-1}. (B) Calibration curve for *E. coli* detection measured with the electrochemical immunoassay by using (a) the {$_d$Ab–AuNR–FCA} labels and (b) {$_d$Ab–FCA} in 5.0 mL PBS containing 0.10 moL L^{-1} $KClO_4$.

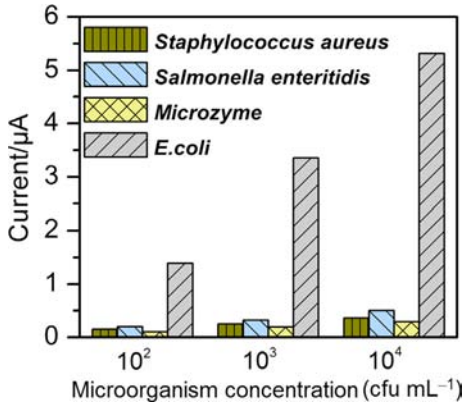

Fig. 6. The specificity diagram to compare the current response of FCA for different microorganisms.

to be potentially present in dairy product. As shown in Fig. 6, the current response obtained from *E. coli* was much higher than that obtained from other microorganisms. The observation signified that the electrochemical immunosensor could be used to detect *E. coli* in the presence of other microorganisms. Therefore, the proposed strategy could reduce the risk of false positive determination caused by other microorganisms. The application of sandwich-type immunoassay of *E. coli* played important roles in improving the specificity.

Five *E. coli* samples were detected to estimate the precision of the electrochemical immunosensor and six repetitive measurements were made for each *E. coli* sample. It was found that the average value was closed to the result obtained from the standard plate count method and the relative error (R.E.) maximum was less than 7.4%. The results confirmed that the proposed strategy exhibited acceptable accuracy for *E. coli* assay.

When the Au/L-cysteine/$_c$Ab-modified immunosensor and the {$_d$Ab–AuNR–FCA} labels were stored in a refrigerator at 4 °C, the current response still remained at 92% of the initial response after a storage period of 2 weeks, showing a quite satisfying stability. The long-term stability might be attributed to the strong interaction between Au/L-cysteine-modified electrode and $_c$Ab, and the strong covalently immobilization of $_d$Ab and FCA molecules on the surface of AuNR@SiO_2.

The reproducibility of the immunosensor was also evaluated from the current response of the Au/L-cysteine/$_c$Ab-modified immunosensor. A series of five measurements from the batch resulted in a relative standard deviations (RSD) of 5.6%, indicating the reproducibility of the proposed immunosensor was acceptable.

The regeneration of the immunosensor was performed by rinsing with 0.10 moL L^{-1} glycine-hydrochloric acid (Gly-HCl, pH 2.8) to dissociate the antigen–antibody complex. After each sandwich immunoassay, the electrode was treated with Gly-HCl for 8 min to remove *E. coli* and the {$_d$Ab–AuNR–FCA} labels. The as-renewed immunosensor could restore 89.6% of the initial value after five assay runs, indicating acceptable reusability.

3.7. Evaluation of E. coli in dairy product

In order to further verify the accuracy of the method for practical analysis of *E. coli*, the electrochemical immunosensor was used to determine *E. coli* in pure fresh milk, yogurt in shelf-life, and expired yogurt by the calibration curve method. For preparation of the dairy product samples, 1 mL of dairy product was diluted to 10 mL with 0.01 moL L^{-1} PBS (pH 7.4), and then spiked with desired concentrations of 5.0×10^2, 1.0×10^3 and 5.0×10^3 cfu mL^{-1} *E. coli*, respectively. Subsequently, the samples were detected by exploiting the proposed strategy. As shown in Table 2, the recoveries of standard additions are in the range of

Table 2
Determination results and recoveries of samples ($n=5$).

Sample	Detected (cfu mL^{-1})	Spiked (cfu mL^{-1})	Found (cfu mL^{-1})	Recovery (%)	RSD (%)
Pure fresh milk	No detected	5.0×10^2	482	96.4	4.25
Yogurt in shelf-life	No detected	1.0×10^3	1060	106	2.76
Yogurt expired for 10 days	216	1.0×10^3	1157	95.1	2.82
Yogurt expired for 20 days	648	5.0×10^3	5885	104.2	3.18
Yogurt expired for 30 days	2695	5.0×10^3	7526	97.8	1.92

95.1–106%, indicating acceptable accuracy of the electrochemical immunosensor. The results demonstrated that the proposed strategy can be applied to real samples and has great potential in practical applications.

4. Conclusions

In this paper, we developed an amplified electrochemical immunosensor for sandwich-type analysis of *E. coli* based on the {$_d$Ab–AuNR–FCA} labels. The prepared AuNR@SiO_2 provided an effective way to improve properties of AuNRs and was used as efficient carriers for loading enormous FCA and $_d$Ab to design the {$_d$Ab–AuNR–FCA} labels. Under optimal experimental conditions, a linear relationship between the current response of FCA and the logarithmic value of *E. coli* concentration was found ranging from 1.0×10^2 to 5.0×10^4 cfu mL^{-1} with a detection limit of 60 cfu mL^{-1} ($S/N=3$), and the electrochemical analysis could be achieved in 3 h. The proposed strategy was also used to determine *E. coli* in dairy product, and the recoveries of standard additions were in the range of 95.1–106%. The results confirmed that the electrochemical immunoassay exhibited good performance for *E. coli* with rapid response, high sensitivity and specificity, and thus could potentially become a promising technique for the assay of *E. coli* in dairy product.

Graphene oxide

ABSTRACT

In this paper, a sensitive time-gated fluorescent sensing strategy for mercury ions (Hg^{2+}) monitoring is developed based on Hg^{2+}-mediated thymine (T)–Hg^{2+}–T structure and the mechanism of fluorescence resonance energy transfer from Mn-doped CdS/ZnS quantum dots to graphene oxide. The authors employ two T-rich single-stranded DNA (ssDNA) as the capture probes for Hg^{2+}, and one of them is modified with Mn-doped CdS/ZnS quantum dots. The addition of Hg^{2+} makes the two T-rich ssDNA hybrids with each other to form stable T-Hg^{2+}-T coordination chemistry, which makes Mn-doped CdS/ZnS quantum dots far away from the surface of graphene oxide. As a result, the fluorescence signal is increased obviously compared with that without Hg^{2+}. The time-gated fluorescence intensities are linear with the concentrations of Hg^{2+} in the range from 0.20 to 10 nM with a limit of detection of 0.11 nM. The detection limit is much lower than the U.S. Environmental Protection Agency limit of the concentration of Hg^{2+} for drinking water. The time-gated fluorescent sensing strategy is specific for Hg^{2+} even with interference by other metal ions based on the results of selectivity experiments. Importantly, the proposed sensing strategy is applied successfully to the determination of Hg^{2+} in environmental water samples.

1. Introduction

Hg^{2+} is a highly toxic metallic pollutant as it has strong bioaccumulation. The cell functions will be inhibited when Hg^{2+} is accumulated in the vital organs and tissues, and then causes a variety of human health problems [1]. The exposure to Hg^{2+} even at very low concentrations still has potential risks for human beings [1,2]. The contamination of Hg^{2+} is a serious environmental health problem in the world, especially the contamination of drinking water and other environmental water resources [3]. Therefore, the monitoring of Hg^{2+} levels with highly sensitivity and selectivity in aquatic ecosystems is still an important and urgent issue. Traditional methods including atomic absorption spectroscopy (AAS), atomic fluorescence spectrometry (AFS), inductively coupled plasma mass spectrometry (ICPMS), and X-ray absorption spectroscopy have been widely used for the determination of Hg^{2+} [3–7]. Although these traditional analytical techniques are very sensitive and selective, the development of new and efficient Hg^{2+} detection methods that are cost-effective, rapid, sensitive, selective, and applicable in routine and in situ is also important and necessary. In previously reported works, it is found that T–T mismatches could selectively capture Hg^{2+} to form stable T–Hg^{2+}–T base pairs due to the intrinsic specific interaction between Hg^{2+} and thymine [8,9]. Based on the intrinsic specific interaction between Hg^{2+} and thymine, a series of fluorescent, colorimetric, and electrochemical sensors were proposed for Hg^{2+} quantification [10–29]. As far as fluorescent sensors are concerned, many of them could be applied to the determination of Hg^{2+} in aquatic ecosystems due to the low detection limits which are lower than the toxic level reported by the U.S. Environmental Protection Agency. However, most fluorescent sensors for Hg^{2+} are based on organic dyes or QDs that usually have short lifetime fluorescence. The background noises caused by the scattering light from solid substrates, the luminescence from the optical components, and samples themselves might affect the sensitivity of the methods. Hence, it is of interest to develop a highly sensitive fluorescence method based on luminophor with long lifetime fluorescence, which can use time-gated mode to decrease the background noises. It has been previously reported that Mn-doped QDs have the features of high quantum yield, photostability, size-tunable optical properties, and long lifetime fluorescence [30–34]. What's more, it has been proved that water soluble Mn-doped CdS/ZnS QDs with long lifetime fluorescence (~4.8 ms) and excellent stability in aqueous solution exhibited outstanding performances in our previously reported works [26,27].

The authors thought that the Mn-doped CdS/ZnS QDs are good choices for time-gated fluorescent methods as a fluorescence label.

In recent years, graphene oxide (GO) has emerged and attracted considerable attention in the biological and medical applications because of its superior surface properties, unique electronic properties, and good biocompatibility [35–39]. Especially, GO is an efficient quencher of an organic fluorophore or inorganic luminescent nanomaterial through either energy transfer or electron transfer process [40–43]. Without any surface modification, GO can strongly adsorb unfolded single-stranded DNA (ssDNA) *via* the π–π stacking interactions while adsorption of well-folded or double-stranded DNA (dsDNA) is disfavored [44]. Therefore, a series of GO-based biosensors have been fabricated due to their superior and unique features [45–50]. What's more, compared with the papers using GNPs as the quencher, there are three main reasons which make us employ graphene oxide (GO) as a new quencher: (1) better quenching efficiency; (2) stronger adsorption for ssDNA; and (3) higher anti-interference ability (such as GO cannot be affected by salt concentration). Based on these advantages, the authors employ GO as an effective quencher and want to propose a method with higher sensitivity and selectivity.

Combining advantages of the Mn-doped CdS/ZnS QDs and GO together, a highly sensitive and selective time-gated fluorescent sensing strategy is designed for Hg^{2+} detection in aqueous solution based on the principle of fluorescence resonance energy transfer (FRET). The Mn-doped CdS/ZnS QDs act as the energy transfer donor while the GO serves as the energy transfer acceptor. Two T-rich ssDNA, which specifically bind to Hg^{2+} to form T–Hg^{2+}–T coordination chemistry, are selected as the Hg^{2+} recognition probes. It is found that the proposed time-gated fluorescent method exhibits highly sensitivity and superior selectivity toward Hg^{2+}. In addition, the determination of Hg^{2+} in spiked environmental water samples is performed to demonstrate the applicability of this kind of method.

2. Experimental section

2.1. Chemicals and apparatus

Two oligonucleotides used in the present study were synthesized and HPLC purified by Shanghai Sangon Biological Engineering Technology & Services Co., Ltd. (Shanghai, China) and dissolved in buffer (0.010 M Tris–acetate, pH=7.6), then stocked at −20 °C for future usage. The sequences of the two oligonucleotides were shown as follows: 5′TTTGTTTGTTGG3′ (ssDNA1); 5′SH-CCTTCTTTCTTA3′ (ssDNA2). 3-mercaptopropionic acid (MPA, 99+%) was purchased from Sigma-Aldrich and used as received without further purification. Tetrabutylammonium chloride was obtained from Tianjin Guangfu Fine Chemical Co., Ltd. (Tianjin, China). Graphite powder was purchased from Tianjin Kemiou Chemical Reagent Co., Ltd. (Tianjin, China). GO was prepared using a modification of Hummers and Offeman's method from environmental graphite powder [51–53]. Mn-doped CdS/ZnS QDs were synthesized according to the previously reported papers, and the characterization and various performance of this kind of quantum dots were also presented in previously reported papers [30,31]. All metal salts used in this work were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). All other chemicals and solvents were of analytical reagent grade and obtained from the commercial sources, and then were used without further purification. Ultrapure water was used throughout the experiments. The time-gated fluorescence intensity was measured and recorded with a Perkin-Elmer LS-55 spectrofluorimeter (United Kingdom). UV/vis absorption spectra were recorded by using a Shimadzu UV Spectrophotometer (UV-2550, Kyoto, Japan). Atomic fluorescence measurements were performed on an Atomic Fluorescence Spectrometer (AFS-9700) (Beijing, China).

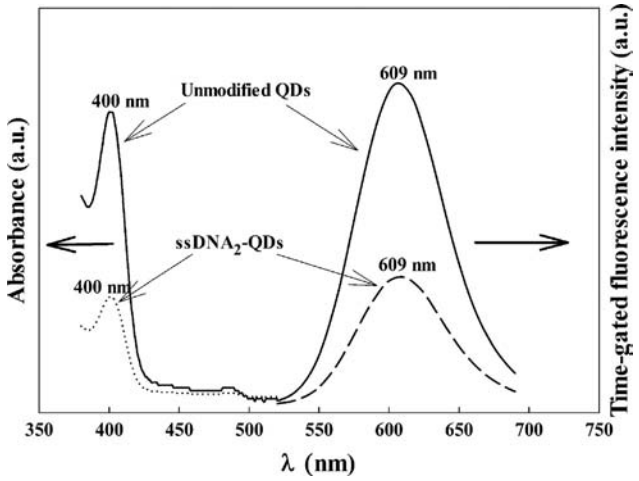

Fig. 1. The absorbance and fluorescence emission spectra of water soluble Mn-doped CdS/ZnS QDs and ssDNA2-modified Mn-doped CdS/ZnS QDs.

2.2. Synthesis of water soluble Mn-doped CdS/ZnS QDs

The Mn-doped CdS/ZnS QDs are hydrophobic. The characteristic of hydrophobic is a stumbling block for the reaction between QDs and the water soluble alkylthiol-capped oligonucleotides. Therefore, the ligand-exchange was carried out using hydrophilic 3-mercaptopropionic acid to prepare the water soluble QDs. The details of the ligand-exchange experiment are as follows. Firstly, 2.0–5.0 mg of Mn-doped CdS/ZnS QDs was dissolved in 1.0 mL of chloroform, and then 1.0 mL MPA solution (1.0 mL of MPA was dissolved in 1.5 mL water which contained 1.0 g KOH) was dropped into the QDs chloroform solution with stirring in a glass bottle with a capacity of 10 mL. Stirring was continued for 8.0 h. After that, 2.0 mL of methanol was added to the mixture and blended well by vortex. After standing for 10 min, a large amount of acetone was added to the mixture, generating a lot of precipitation. To obtain the precipitate, the suspension was centrifuged at 4000 rpm for 5.0 min. After throwing away the supernatant, the precipitate was dissolved in 2.0 mL water, and then the solution was centrifuged at 12,600 rpm for 20 min using Centrifugal Filter Devices (Amicon Ultra-0.5) to remove impurities. Finally, the pure water soluble Mn-doped CdS/ZnS QDs were redispersed into 5.0 mL of Tris–acetate buffer (0.010 M, pH=7.6) by vortex and stored at 4 °C for future usage. The fluorescence excitation and emission of this kind of QDs were 400 nm and 609 nm, respectively. The absorbance spectrum and fluorescence emission spectrum of the resulting QDs are shown in Fig. 1. The concentration of the resulting QDs was about 5.7×10^{-7} M according to the absorbance at 400 nm. The resulting water soluble Mn-doped CdS/ZnS QDs have long lifetime fluorescence (~4.8 ms) and excellent stability in aqueous solution.

2.3. Preparation of ssDNA2-modified Mn-doped CdS/ZnS QDs

ssDNA2 was conjugated to the Mn-doped CdS/ZnS QDs according to a previously reported work with minor modifications [54]. Firstly, the Mn-doped CdS/ZnS QDs solution and ssDNA2 solution were mixed together at a mole ratio of 1:5 (1.0 mL, 5.7×10^{-7} M Mn-doped CdS/ZnS QDs mixed with 30 μL, 0.10 mM ssDNA2). After standing for 12 h, the mixture was brought to 0.15 M NaCl and the particles were aged for an additional 12 h. After that, the NaCl concentration was then raised to 0.30 M, and the mixture was allowed to stand for a further 40 h. The mixture was centrifuged using Centrifugal Filter Devices (Amicon® Ultra-0.5) to remove the unreacted ssDNA2 afterwards. Finally, the ssDNA2-modified Mn-doped CdS/ZnS QDs (ssDNA2-QDs

complex) were redispersed into 5.0 mL Tris–acetate buffer (0.010 M, pH=7.6) by vortex and stored at 4 °C for future usage. The number of ssDNA2 immobilized on the Mn-doped CdS/ZnS QDs was estimated by measuring the absorbance difference at 260 nm before and after modification with ssDNA2. The average ssDNA2 loading was about one ssDNA2 per QD. The final concentration of ssDNA2-modified Mn-doped CdS/ZnS QDs was about 1.0×10^{-7} M according to the absorbance at 400 nm. The absorbance and fluorescence emission spectra of the ssDNA2-modified Mn-doped CdS/ZnS QDs are also shown in Fig. 1, indicating that the spectra remain unchanged compared to the unmodified QDs.

2.4. General procedures for Hg^{2+} monitoring

Briefly, 40 μL of 2.0×10^{-7} M ssDNA1, 40 μL of 1.0×10^{-7} M ssDNA2-QDs complex, 40 μL of different concentrations of Hg^{2+}, and 100 μL of buffer (0.010 M Tris–acetate, 0.10 M $NaNO_3$, pH=7.6) were mixed uniformly by vortex and incubated for 30 min to form T–Hg^{2+}–T coordination chemistry firstly. Then, 50 μL of 0.30 mg/mL GO was added to the mixture to differentiate the unfolded and folded ssDNA. The final step is to monitor the time-gated fluorescence intensity of the mixture above. Similar procedures were used to test the selectivity of the proposed sensing strategy. The concentrations of Hg^{2+} used in the sensitivity experiments were 0, 0.20, 0.40, 0.60, 0.80, 1.0, 2.0, 4.0, 6.0, 8.0, 10.0, 50.0, 100.0, and 1000.0 nM. 1.0 μM of Hg^{2+} was used in the optimization experiments. Various other metal ions of 2.0 μM were used in the selectivity experiments. The other metal ions used in the selectivity experiments are as follows: Ag^{+}, Co^{2+}, Ni^{2+}, Ca^{2+}, Cd^{2+}, Al^{3+}, Fe^{3+}, Au^{3+}, Cr^{2+}, Mn^{2+}, Pb^{2+}, Cu^{2+}, Mg^{2+}, Zn^{2+}, and Ba^{2+}. The lake water samples were taken from Taozi Lake in Hunan University. The river water samples were taken from Xiangjiang River. The spring water samples were taken from the Lush Maple Spring in Yuelu Mountain. The time-gated fluorescence spectra were measured and recorded by a Perkin-Elmer LS-55 spectrofluorimeter. The parameters of the spectrofluorimeter were set as λ_{ex}=400 nm, λ_{em}=609 nm, delay time, 0.10 ms, excitation slit, 15 nm, and emission slit, 20 nm.

3. Results and discussion

3.1. Experimental principle

The proposed sensing strategy was designed based on the principle of FRET from ssDNA2-QDs complex to GO. The fundamental of the proposed sensing strategy is shown in Fig. 2. In this study, the proposed strategy comprises two ssDNA: one is a 12-mer T-rich oligonucleotide (ssDNA1), and the other is a 12-mer T-rich oligonucleotide with an alkanethiol moiety at the 5′-terminus (ssDNA2). Both ssDNA1 and ssDNA2 consist of seven thymine units, which interact specifically with Hg^{2+} to form T–Hg^{2+}–T coordination chemistry. ssDNA2 was functionalized with Mn-doped CdS/ZnS QDs via the alkanethiol moiety at the 5′-terminus. The ssDNA2-QDs complex exhibited strong and stable fluorescence emission at 609 nm when excited at 400 nm. ssDNA1 and ssDNA2-QDs complex could not hybridize each other because of the seven mismatched T–T base pairs in the absence of Hg^{2+}. Upon addition of the Hg^{2+} solution to the mixture of ssDNA1 and ssDNA2-QDs complex, Hg^{2+}-mediated base pairs (T–Hg^{2+}–T) induce ssDNA1 and ssDNA2 with seven T–T mismatches hybridizing each other. It has been previously reported that Hg^{2+} binding to the DNA strand is a synergistic process, and the binding of one Hg^{2+} facilitates the binding of another Hg^{2+} to the same strand [55]. What's more, the T–Hg^{2+}–T pair is more stable than the A–T Watson–Crick pair [8]. The hybridization of ssDNA1 and ssDNA2 formed a stable and rigid structure in aqueous solution. When

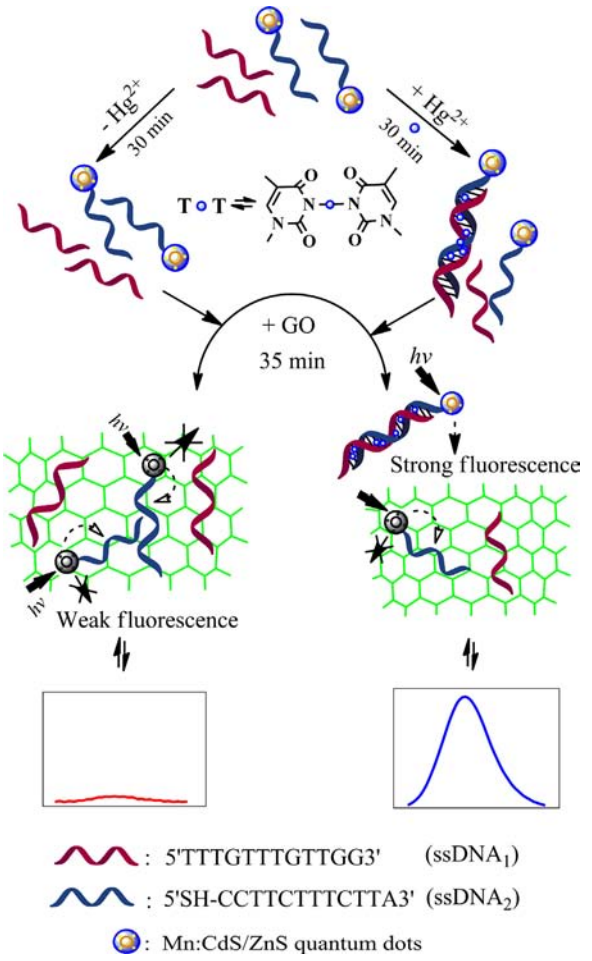

Fig. 2. Schematic description of the proposed sensing strategy for Hg^{2+} monitoring.

the hybridization solution is mixed with GO solution, the well-folded structure after hybridization could not be adsorbed on the surface of GO which makes the Mn-doped CdS/ZnS QDs far away from the surface of GO. As a result, the fluorescence intensity of the Mn-doped CdS/ZnS QDs was observed upon light excitation. The time-gated fluorescence intensity of Mn-doped CdS/ZnS QDs will be changed upon sequential addition of different concentrations of Hg^{2+} and equivalent GO to the mixture of ssDNA1 and ssDNA2-QDs complex. Therefore, we can monitor the concentration of Hg^{2+} according to the change in time-gated fluorescence intensity of Mn-doped CdS/ZnS QDs using the proposed sensing strategy. The time-gated fluorescence spectra with and without the addition of Hg^{2+} are shown in Fig. 3. In addition, a certain amount of Hg^{2+} was added to the solution that only contains ssDNA2-QDs complex to evaluate the effect of Hg^{2+} to Mn-doped CdS/ZnS QDs. The results indicated that the fluorescence performance was not sensitive to Hg^{2+} no matter whether the presence of different concentrations of Hg^{2+} or in the 1.0 μM of Hg^{2+} solution with reaction time increases.

3.2. Optimal conditions for the proposed sensing strategy

The GO concentration was studied firstly because of the intense effect on ssDNA2-QDs complex. Various concentrations of GO were added to the ssDNA2-QDs complex solution. The time-gated fluorescence intensity of the mixture above is monitored and recorded in Fig. 4(A). As shown in Fig. 4(A), the time-gated fluorescence intensity decreased with an increase in the GO concentration, and the complete quenching was observed when 0.30 mg/mL or more GO was added.

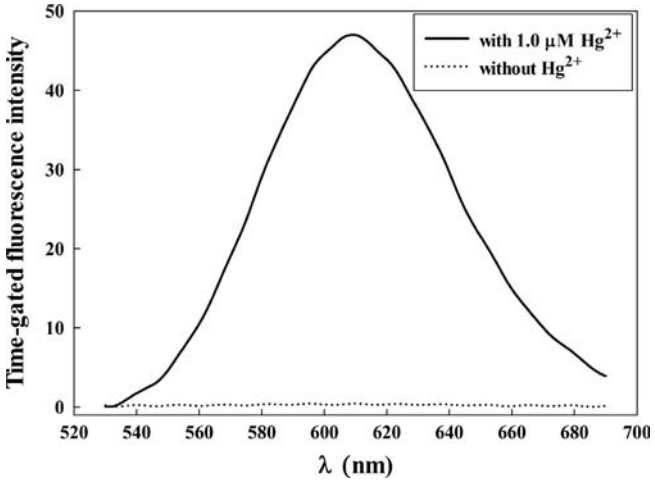

Fig. 3. Time-gated fluorescence emission spectra of the proposed sensing strategy without and with 1.0 μM Hg^{2+}.

The reason may be that all of the ssDNA2-QDs complexes were adsorbed on the surface of GO because of the strong π–π stacking interactions between ssDNA and GO, which resulted in the maximized fluorescence quenching of Mn-doped CdS/ZnS QDs. As a result, the authors chose 0.30 mg/mL as the suitable concentration of GO.

The incubation time after the addition of Hg^{2+} to the mixture of ssDNA1 and ssDNA2-QDs complex to form the T–Hg^{2+}–T pairs was investigated afterwards, and the results are shown in Fig. 4(B). The time-gated fluorescence intensity increased with the increase of incubation time and remained constant after 30 min. Hence, the authors chose 30 min as the optimum incubation time. The adsorption time after the addition of GO to the mixture of ssDNA1, ssDNA2-QDs complex, and ssDNA1/ssDNA2-QDs was also studied due to the important role in the detection sensitivity. As indicated in Fig. 4(C), the time-gated fluorescence intensity decreased with the increase of adsorption time and remained constant over 35 min. Consequently, the authors chose 35 min as the optimum adsorption time. In addition, room temperature (28 °C–30 °C) was selected as the operational temperature for convenience and the media pH of 7.6 (Tris–acetate buffer) was used throughout the experiments. Because PO_4^{3-}, Cl^-, or S^{2-} can react with Hg^{2+} to generate precipitation, it is best to avoid these anions in the buffer used in the system of Hg^{2+} detection. Hence, Tris–acetate buffer is selected as the media buffer. Herein, 1.0 μM was selected as the concentration of Hg^{2+} in all optimal experiments.

3.3. *Determination of Hg^{2+} in buffer using the proposed sensing strategy*

Based on the optimum conditions, various concentrations of Hg^{2+} were introduced to evaluate the sensitivity of the fluorescent sensing strategy. The fluorescent spectra upon addition of various concentrations of Hg^{2+} are recorded in Fig. 5(A). As shown in Fig. 5 (A), it is clear that higher concentration of Hg^{2+} resulted in more fluorescence intensity enhancement. Importantly, even very low concentration of Hg^{2+} can induce perceptible change of the time-gated fluorescence intensity which indicated that the proposed sensing strategy is very sensitive for Hg^{2+}. The calibration curve of time-gated fluorescence intensity as a function of the concentration of Hg^{2+} of the sensing strategy is shown in Fig. 5(B). Fig. 5(C) shows that the time-gated fluorescence intensity was linearly dependent on the concentration of Hg^{2+} in the range from 0.20 to 10 nM. The equation for the linear calibration curve was $y=4.17x+1.89$ (x is the concentration of Hg^{2+}, y is the time-gated fluorescence intensity) with correlation coefficient of 0.9937. According to the standard

deviation of 0.15 for the blank signal with 20 parallel measurements, a limit of detection was estimated to be 0.11 nM based on a $3\alpha/slope$ standard (α is the standard deviation of the blank signal). The detection limit is much lower than the standard of the U.S. Environmental Protection Agency (EPA). The EPA regulates the maximum allowable level of Hg^{2+} in drinking water to be 10 nM. The detection

(B) The calibration curve of time-gated fluorescence intensity as a function of the concentration of Hg^{2+}. (C) Linear region of (B). The concentrations of Hg^{2+} in (C) are 0.2, 0.4, 0.6, 0.8, 1.0, 2.0, 4.0, 6.0, 8.0, and 10 nM. Each data point is the mean of three measurements. The error bars are the standard deviation.

limit of the proposed sensing strategy is much improved in comparison to those previously reported colorimetric methods and fluorescent methods for Hg^{2+} [10–12,14,16,18–20,25–29,56]. The results

are summarized in Table 1. The exceptionally low detection limit for Hg^{2+} of the proposed sensing strategy may be attributed to four vitally important factors: (1) the super quenching capability of GO; (2) the strong interaction between ssDNA and GO via π–π stacking interactions; (3) the specific interaction between Hg^{2+} and thymine which can form stable T–Hg^{2+}–T coordination chemistry; and (4) the long lifetime fluorescence of Mn-doped CdS/ZnS QDs which can use time-gated mode to reduce the background noises and increase the signal to noise ratio.

To test the repeatability of this sensor, three kinds of modified QDs and GO were prepared with the same procedure and the RSD is about 2.1% for determination of 100 nM Hg^{2+} under the optimum conditions.

3.4. Selectivity of the proposed sensing strategy for Hg^{2+} determination

Excellent selectivity is important and necessary for a robust practical method. Herein, two experiments were conducted to investigate the selectivity of the proposed sensing strategy. First, every metal ion was studied as an independent sample to investigate the selectivity of the sensing strategy. The metal ions are Hg^{2+}, Ag^{+}, Co^{2+}, Ni^{2+}, Ca^{2+}, Cd^{2+}, Al^{3+}, Fe^{3+}, Au^{3+}, Cr^{2+}, Mn^{2+}, Pb^{2+}, Cu^{2+}, Mg^{2+}, Zn^{2+}, and Ba^{2+}. It can be seen from Fig. 6 that only the sample of Hg^{2+} exhibited significant response. Second, Hg^{2+}

and other metal ions were mixed together to form a mixture solution as a sample for selectivity testing. As shown in Fig. 6, the sample also exhibited remarkable response. These results above indicated that these metal ions have little effect on the determination of Hg^{2+}. Hence, the proposed sensing strategy shows excellent anti-jamming capability and selectivity toward Hg^{2+} based on the specific interaction between Hg^{2+} and thymine. 1.0 μM was selected as the concentration of Hg^{2+}, while the concentrations of other metal ions were 2.0 μM in the section.

3.5. Determination of Hg^{2+} in environmental water samples

The proposed sensing strategy was further tested with environmental water samples to demonstrate its applicability. The environmental water samples were spring water, river water, lake water, and tap water samples. These samples were filtered (0.20 μm filter membrane) and then centrifuged for 15 min at 12,000 rpm to remove the visible impurities before use. The concentrations of total mercury in these samples were 0.019, 0.057, 0.041, and 0.021 nM which were measured by the Atomic Fluorescence Spectrometer (AFS). It was found that the concentration of Hg^{2+} in these samples was too low to be detected using the proposed sensing strategy. Hence, extra Hg^{2+} was added to the samples to test the feasibility of the sensing strategy. The environmental water samples were spiked with different concentrations of Hg^{2+} (0, 0.80, 4.0, and 8.0 nM), and then tested according to the general procedure with four replicates using the proposed sensing strategy and AFS. The results are summarized in Table 2 and are in good agreement with the results obtained by AFS. According to the results, the authors think that the present sensing strategy can be applied to detect Hg^{2+} in environmental water samples.

In the experiments of real samples, all the solutions were prepared and diluted with Tris–acetate buffer except water samples, and when all the solutions were mixed together, the pH of the mixture was about 7.6 (the same with the pH of Tris–acetate buffer); hence, the effect of pH is not considered in the paper. If the pH of the environmental water samples is serious acid or alkali polluted, the pH of the samples should be adjusted to 7.6 using Tris–acetate buffer before usage.

Table 2
Determination of Hg^{2+} in environmental water samples using the proposed sensing strategy and AFS.

Samples	Added Hg^{2+} (nM)	Proposed method (mean[a] ± SD[b])	AFS (mean ± SD)	Recovery (%)
Spring water 1	0	c	0.019 ± 0.001	–
Spring water 2	0.80	0.77 ± 0.05	0.79 ± 0.02	96.25

4. Conclusions

In summary, the authors developed a highly sensitive and selective time-gated fluorescent sensing strategy for Hg^{2+} determination. The proposed method is mainly based on the super quenching capability of GO with strong adsorption function toward ssDNA *via* π–π stacking interactions, the specific and selective T–Hg^{2+}–T coordination chemistry between two neighboring T-rich strands, and the long lifetime fluorescence of Mn-doped CdS/ZnS QDs with unique photophysical properties. Compared to some other previously reported works for Hg^{2+}, this fluorescent sensing strategy exhibited an extremely low detection limit. In addition, the present sensing strategy showed excellent selectivity and a broad linear range from 0.20 to 10 nM. Particularly, the proposed fluorescent sensing strategy can also work very well in environmental water samples. Based on the results of the study, the authors believe that the proposed fluorescent sensing strategy is applicable in routine and in situ Hg^{2+} monitoring in environmental water samples.

Lead

ABSTRACT

Highly sensitive colorimetric detection for Pb^{2+} has been developed using maleic acid (MA) functionalized GNP. The –COOH on MA was used to modify GNP surface whereas the other –COOH functional group have strong affinity to coordination behavior of Pb^{2+} allowing the selective formation more than other ions. MA–GNPs solution changed from red to blue color after the addition of Pb^{2+} due to nanoparticle aggregation. The different optical absorption and discriminate of particle size between the MA–GNPs solution with and without Pb^{2+} were characterized by UV–visible spectroscopy and transmission electron microscopy (TEM), respectively. The color intensity as a function of Pb^{2+} concentration gave a linear response in the range of 0.0–10.0 $\mu g\,L^{-1}$ (R^2=0.990). The detection limit was found at 0.5 $\mu g\,L^{-1}$ by naked eye and can be completed the analysis within 15 min. The MA–GNPs aggregated with Pb^{2+} showed high selectivity when was compared to other metal ions (As^{3+}, Ca^{2+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+}, Pb^{2+} and Zn^{2+}) and anions (Cl^-, NO_3^- and SO_4^{2-}). Our proposed method was also applied for the determination of Pb^{2+} in real drinking water samples from 5 sources. The result of real water samples were not statistically significant different from the standard methods at the 95% confidence level (pair *t*-test method). Moreover, we evaluated our proposed method for the determination of trace Pb^{2+} concentration in real breast milk samples. The recoveries were acceptable and ranged from 101 to 104% for spiked Pb^{2+} in real breast milk samples. Thus, MA–GNP colorimetric sensing provides a simple, rapid, sensitive, easy-to-use, inexpensive and low detection limit for the monitoring of Pb^{2+}.

1. Introduction

The present food and drinking water are often contaminated with harmful substances for humans, either as part of the production process, natural or caused by the additives added to it. Lead (Pb^{2+}) is a major environmental pollutant and ranks second in the list of toxic substances that cause renal malfunction and damage to the brain and kidneys [1]. It has also been classified as carcinogenic agents by the World Health Organization (WHO) and International Agency for Research on cancer. Moreover, the long-term exposure to low concentrations of these metals causes adverse health effects. Therefore, WHO controlled level of lead in drinking water is not over 10 $\mu g\,L^{-1}$ [2]. Several methods have been used for the detection of lead such as atomic absorption spectrometry (AAS) [3–5], inductively coupled plasma mass spectrometry (ICP/MS) [6], inductively coupled plasma atomic emission spectroscopy (ICP/AES) [7], electrochemical method [8] and X-ray fluorescence spectrometry [9]. Although, these methods can detect lead sensitively and accurately, but there are limits in their complicated sample preparation processes, expensive, and required any specialized as well as sophisticated instrumentation [10].

Colorimetric sensors for Pb^{2+} determination attract much attention for their conveniences of visual observation and simple operations. They allow the direct analysis by the naked eyes without costly instruments compared with other methods. In recent year, gold nanoparticles (GNPs) have been widely used for colorimetric assays because their extinction coefficients are high relative to common organic compound [11–13]. GNPs have been extensively employed as colorimetric sensors for the detection of small concentrations of toxic metals such as arsenic, cadmium, cobalt, nickel and lead [14–16]. Kim et al. used GNPs capped with 11-mercaptoundecanoic acid to be capable of detecting Pb^{2+} through the coordination between the carboxylic groups and Pb^{2+} [17]. Moreover, Lu and co-workers reported a colorimetric sensor for Pb^{2+} detection using DNA-functionalized GNPs [18]. In 2010, GNPs capped with gallic acid (GA–GNPs) for the detection of Pb^{2+} has been reported. Huang and

co-workers have also demonstrated the aggregation of GA–GNPs in aqueous solutions and its minimum detectable concentration for Pb^{2+} in drinking water is 10 nM or 2.1 μg L^{-1} [12]. The detection limits of GA–GNPs are lower than the maximum allowable contamination level of Pb^{2+} in drinking water (WHO). However, the European Food Safety Authority (EFSA) reported that even using a low concentration of Pb^{2+} in drinking water (2.1 μg L^{-1}), adverse effect children's intelligence development can be observed [19,20]. In the absence of a safe exposure limit of children to Pb^{2+} and because of its ability to accumulate in the body for a long time, a great interest in the evaluation of the adverse effects of Pb^{2+} in low concentrations has emerged. Moreover, Human Health State of the Science in Canada has studied the trace Pb^{2+} concentration in breast milk because it is good biomarkers of maternal and infant exposure to Pb^{2+}. The Pb^{2+} level in human milk was found in the range from 0.025 to 15.8 μg L^{-1} in 210 mothers cross Canada [21,22]. Therefore, a highly sensitive, selective, simple and rapid method for the detection and quantification of trace Pb^{2+} is still required not only for the acceptance criteria of food safety but also toxicology.

Maleic acid, which has two carboxylic groups ($HO_2CCH=CH-CO_2H$), should be suitable for the modification of nanoparticles surface. In the previous reports, GNPs was modified by thiol compounds such as glutathiol [10], cysteine [23], alkyl phosphate [24] and 11-mercaptoundecanoic acid [25] for the determination of Pb^{2+} in micromole level but maleic acid functionalized GNPs has been not investigated for the colorimetric detection of Pb^{2+}. Thus, the aim of this work was to develop the highly sensitive, selective, simple and rapid colorimetric sensor for trace Pb^{2+} determination using maleic acid modified GNPs. Maleic acid is easy to modify on GNPs surface within 1 h. MA–GNPs solution changed from red to blue color after the addition of Pb^{2+} and can be observed by the naked eye. The pH effect and the reaction time were studied in this work. The low limits of detection for Pb^{2+} at sub μg L^{-1} level with a short analysis time of 15 min were obtained by our proposed assay. Finally, our developed method was successfully applied for determination of trace levels of Pb^{2+} in drinking water samples and the human breast milk samples.

2. Experimental

2.1. Chemicals and materials

All chemicals used in experiment were analytical reagent (AR) grade and solutions were prepared using high pure water with a resistance of 18 MΩ cm^{-1}. Dithiothreitol (DTT), glutathione (Glu), homocysteine (Hcy), L-cysteine (L-cys), maleic acid (MA), metal ions (As^{3+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+} using atomic absorption grade), KCl, KNO_3 and K_2SO_4 were bought from Sigma-Aldrich (St. Louis, Missouri). Whatman No. 1 filter paper was bought from Cole-Parmer (Vernon Hills, IL). All glassware was thoroughly cleaned with freshly prepared 1:1 HCl/HNO_3 and rinsed with high pure water prior to use. All metal ions stock solutions were prepared in 50 mM phosphate buffer pH 5.8.

2.2. Instrumentation

UV–visible absorption spectra were recorded in a quartz cuvette (1-cm pathlength) using a UV–visible spectrometer (Lambda 35, Perkin Elmer Instruments, USA). Size distribution of particles was recorded by Transmission Electron Microscope (TEM, TECNAI T20 G^2, FEI, Netherland). Photographic results were recorded using a digital camera (PowerShot S95, 10.1 Megapixels, Canon). An atomic absorption spectrometer (AAS) with a hollow cathode lamp and standard air/acetylene flame (Analyst 300, Perkin Elmer Instruments, USA) was used for atomic absorbance measurements. A hollow cathode lamp was used under the following operations conditions: wavelength: 283.3 nm; slit-width: 0.7 H nm; lamp current: 10 mA.

2.3. Synthesis of GNPs

100 mL of $HAuCl_4$ (0.01%) was added into a 250 mL Erlenmeyer flask and then boiled. After that, 3.5 mL of trisodium citrate (1%) was added and further rapidly stirred for 15 min. We continually stirred for 30 min without heating. The solution was cooled to room temperature which was stored in the refrigerator 4 °C before further use [15].

The MA–GNPs solution was prepared using self-assembly of the organic compound on the GNP surface. A red of GNP solution (~20 nm in diameter) was first prepared from GNPs stock solution. Then, 0.20 mL of 0.01 M MA was added into 0.40 mL of GNP solution to generate MA–GNPs. Organic compound was self-assembled on to the surface of GNPs by incubating the GNPs with the MA solutions for 1 h at room temperature. After this step, the GNP aggregation was characterized using UV–visible Spectrometry.

2.4. Detection of lead

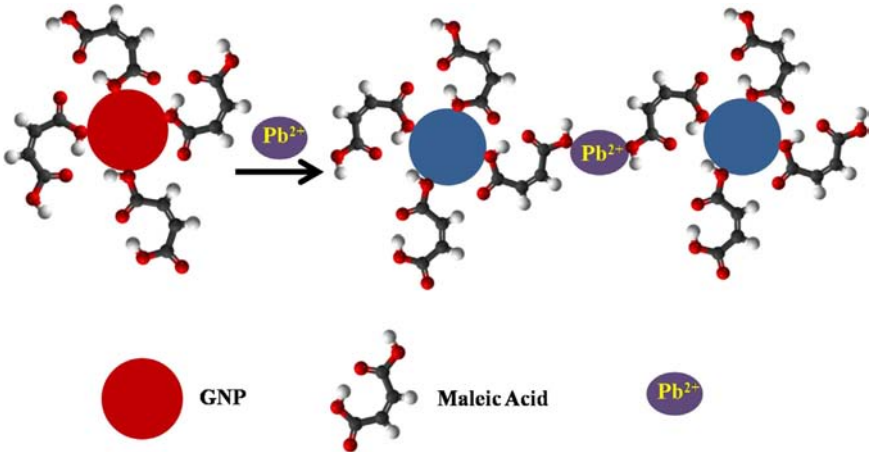
0.60 mL of MA–GNP solution in the eppendrof was mixed with 0.40 mL of metal ion solutions (As^{3+}, Ca^{2+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+}, Pb^{2+} and Zn^{2+}) and anions solutions (KCl, KNO_3 and K_2SO_4) in 50 mM phosphate buffer at pH 5.8. For background (Bg), 0.40 mL of buffer was mixed 0.60 mL of MA–GNP solution (Bg–MA–GNPs). Then, the mixture was incubated for 15 min at the room temperature and analysis by the spectrometer and TEM.

2.5. Sample preparation for transmission electron microscopy (TEM)

Transmission electron microscope (TEM) measurements were performed on TECNAI T20 G^2 instrument which operated at an accelerating voltage of 120 kV and the 25000× magnification. The sample solutions for TEM studies were prepared by placing a drop of GNPs, MA–GNPs, Bg–MA–GNPs and Pb^{2+}–MA–GNPs on a formvar coated copper grid. The films on the TEM grids were allowed to dry for 1 h. The size of nanoparticle studies was performed in aqueous solution by Center of Nanoimaging, Mahidol University.

2.6. Applications

To evaluate the utility of our proposed method, the Pb^{2+} in the drinking water samples from five different sources was quantified. Our method was validated against AAS. Prior to analysis by AAS, preconcentration was carried out on all samples. 1.5 L of sample was mixed with 1 mL of 0.1 M HCl and then heated to evaporate excess water until 5.0 mL of samples remained. For AAS, samples were adjusted to a final volume of 10 mL with deionized water. For our proposed method, 0.60 mL of MA–GNP solution in the eppendrof was mixed with 0.40 mL of the water sample without any pretreatment. Then, the mixture was incubated for 15 min at the room temperature and analysis by spectrometer. For testing of trace levels of Pb^{2+} in the human breast milk, the sample was divided two parts. The first was analyzed by our method without spiking Pb^{2+} and the second was spiked with the standard Pb^{2+} solution at 10.0, 25.0 and 50.0 μg L^{-1} to obtain the final concentration at 1.0, 2.5 and 5.0 μg L^{-1}, respectively. Prior to analysis, spiked samples were precipitated the protein by adding 0.75 mL of sample with 0.15 mL of 10% w/v TCA (Tri chloroacetic acid). After that, samples were stored at 4 °C for 15 min and then subjected to centrifugation at 14,500 rpm for 10 min. The precipitate was removed from the supernatant and kept only supernatant for analysis.



3. Results and discussion

3.1. Characterization of GNP aggregation

Maleic acid has two carboxylic groups ($HO_2CCH=CHCO_2H$) so one carboxylic group should be suitable for the modification of nanoparticles surface and the other carboxylic group can capture Pb^{2+} in aqueous solution as shown in Scheme 1. In this experiment, the color of solution change from dark pink to blue after adding 1.0 μg L^{-1} of Pb^{2+} in the MA–GNPs solution (Fig. 1). MA–GNPs in the presence and absence of Pb^{2+} were characterized by UV–vis Spectroscopy and Transmission Electron Microscope (TEM). A characteristic band of MA–GNPs was observed at approximate 520 nm. After the addition of Pb^{2+}, the wavelength at 520 nm decreased and a new red-shifted change at 600 nm (Fig. 1), so Pb^{2+} can induce aggregation of MA–GNPs. To confirm the mechanism of the interaction between MA–GNPs and Pb^{2+}, the solution of GNPs, MA–GNPs, Bg–MA–GNPs and Pb^{2+}–MA–GNPs were analyzed by TEM as shown in Fig. S1. The prepared GNPs were dispersed an average particle size under ~20 nm in diameter, whereas the nanoparticles remain isolated and randomly distributed in the absence of Pb^{2+} ions (Fig. S1a–c). Upon addition of Pb^{2+}into MA–GNPs, the solution turned blue color. TEM studies clearly indicate that Pb^{2+} induces aggregation of nanoparticles (Fig. S1d). Possible mechanism is the obstructive aggregation of MA–GNPs in the absence of Pb^{2+} due to the electrostatic repulsion against van der Waals attraction of carboxylic of MA on the GNPs surface [13]. After the addition Pb^{2+}, the other –COOH group of MA can binds with Pb^{2+} and it is specificity than other metals (Fig. 1) because of the coordination number of Pb^{2+} more over the other metal cations. Other metal cations interact only with lesser numbers of ligands, leaving the nanoparticles isolated; hence, no spectral change and no color of solution change were observed under the experimental conditions [26].

3.2. Selectivity study

We investigated the change in values of absorption ratio ($A_{600/520}$) for MA–GNPs that measured after 15 min upon the addition of the metal ions. The concentration of other metal ions was studied for 15 min at higher than 100 times of Pb^{2+} concentration (1.0 μg L^{-1} of

Scheme 1. Schematic of aggregating process of MA–GNPs induced by adding Pb^{2+}.

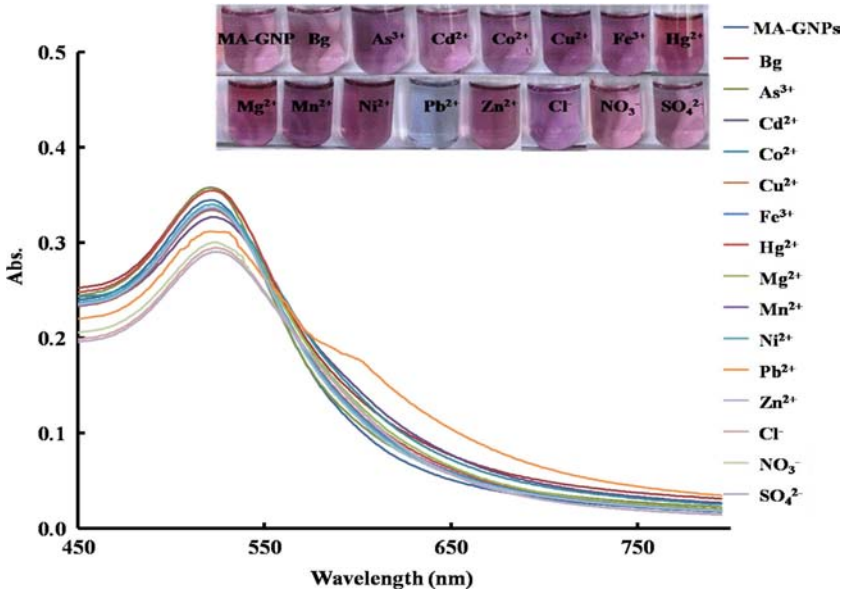


Fig. 1. UV–visible spectra of MA–GNPs solutions with cations (1.0 μg L^{-1} of Pb^{2+} and 0.1 mg L^{-1} of other cations) and anions (250.0 mg L^{-1} Cl^-, 45.0 mg L^{-1} NO_3^- and 200.0 mg L^{-1} SO_4^{2-} following Guidelines for drinking-water quality by [2]). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Pb^{2+} and 0.1 mg L^{-1} of As^{3+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+} and Zn^{2+}). Most interference levels in this study were higher than the permissible limit in the drinking water by WHO (For example; 0.003, 0.05 and 0.02 mg L^{-1} for Cd^{2+}, Co^{2+} and Ni^{2+}, respectively). Moreover, interference effect of anions at the levels containing in drinking-water (250.0 mg L^{-1} Cl^-, 45.0 mg L^{-1} NO_3^- and 200.0 mg L^{-1} SO_4^{2-} by [2]) was studied. The result showed that the color of solution didn't change to blue color after the addition of anions and other metal ions as shown in Fig. 1. The absorbance ratio ($A_{600/520}$) of MA–GNPs with different metal ions and anions is shown in Fig. 2. Only Pb^{2+} can be observed a significant $A_{600/520}$ value. Possible mechanism is the unique coordination behavior of Pb^{2+} as $[Xe]4f^{14}5d^{10}6s^2$ electronic configuration. It appears as a borderline acid, able to bind to wide families of ligands within very flexible bond length and geometry so it allows the formation of a stable supramolecular complex. Other metal cations interact only with lesser numbers of ligands, leaving the nanoparticles isolated because of the rigid coordination geometry or may result from other factors e.g., the change in particle geometry. Hence, no spectral and color change were observed under the experimental conditions [26,27]. On the aforementioned results, MA–GNPs can be utilized to detect Pb^{2+} with high selectivity.

GNPs surface can be typically modified by carboxylic, amino, and thiols group to achieve selective cross-linking (and thus aggregation) therefore we also investigated the effect of cross-linking group in this part. DTT, Hcy, L-Cys and Glu were studied due to the active group in their molecules. All modified GNPs synthesized by our method showed an absorbance at 520 nm wavelength and observed a red solution. After adding 1.00 μg L^{-1} various metals including Pb^{2+}, As^{3+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+} and Zn^{2+} in the solution of DTT–GNPs, Hcy–GNPs and L-Cys–GNPs at pH 5.8, the color of the solution for all metals changes from red to violet and spectra shifts from 520 nm to 600 nm (Fig. S2a–c). Whereas, Glu–GNPs (Fig. S2d) showed no change occurs, the absorption spectrum is still intact. Therefore, Glu–GNPs, DTT–GNPs, Hcy–GNPs and L-Cys–GNPs gave no specificity to Pb^{2+} under this condition.

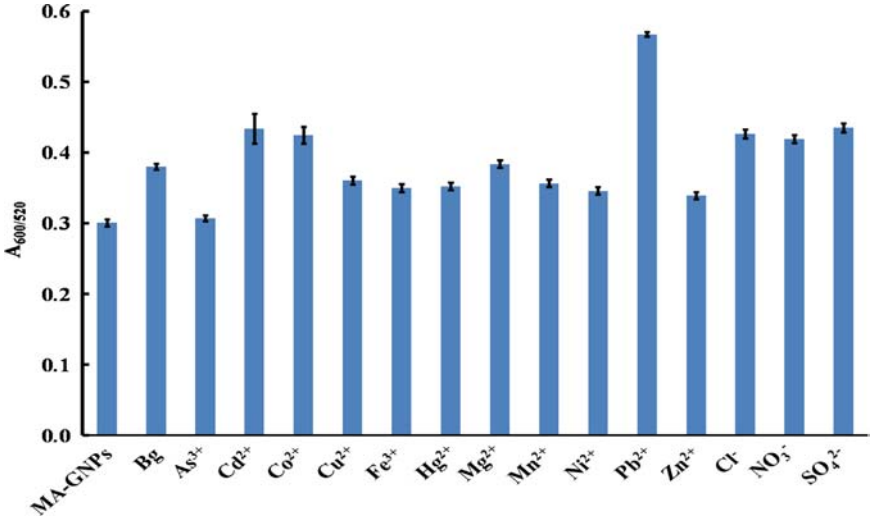

Fig. 2. The values ($A_{600/520}$) of MA–GNPs upon the addition of 1.0 μg L^{-1} Pb^{2+} and 0.1 mg L^{-1} of other cations and 250.0 mg L^{-1} Cl^-, 45.0 mg L^{-1} NO_3^- and 200.0 mg L^{-1} SO_4^{2-}. The error bars represent standard deviations based on three independent measurements.

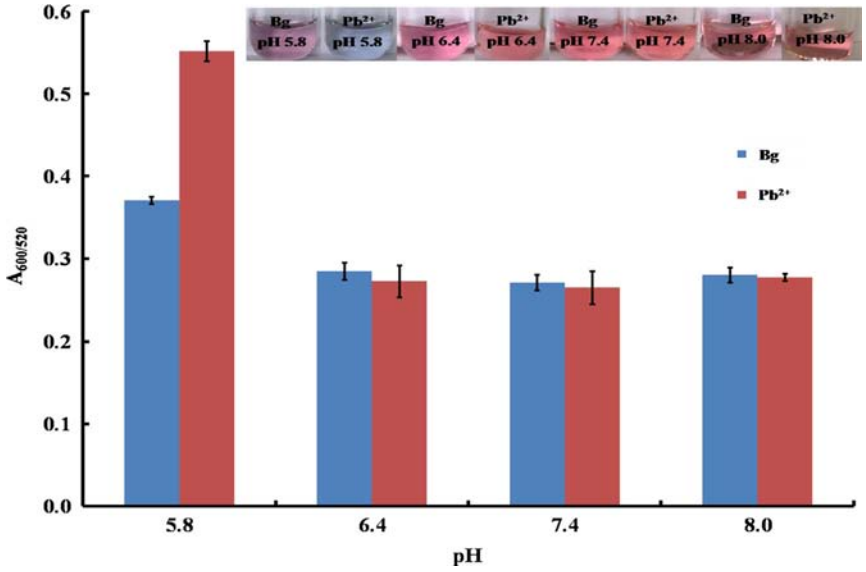

Fig. 3. Effect of pH 0.6 μL of MA–GNPs mixed 0.4 μL of Pb^{2+} (1.0 μg L^{-1}) in phosphate buffer pH 5.8, 6.4, 7.4 and 8.0 for 15 min error bar at $n=3$.

3.3. Effect of pH and reaction time

We investigated the colorimetric response of MA–GNPs with Pb^{2+} at different pH (5.8, 6.4, 7.4 and 8.0). Only MA–GNPs with Pb^{2+} at pH 5.8 showed the color change and higher absorbance ratio ($A_{600/520}$) than buffer (Bg). While at pH 6.4, 7.4 and 8.0 show no significant difference of the absorbance ratio ($A_{600/520}$) and color solution between presence and absence of Pb^{2+} (Fig. 3). Additionally, Bg–MA–GNPs slightly change color at low pH (<6.58) and the absorbance ratio was larger than at high pH (Fig. 3). MA–GNPs ionizable of structure would be affected by the pH value, which was high enough for ionization, taking the pK_{a1} (1.93) and pK_{a2} (6.58) value of MA into consideration. The electrostatic repulsion between the MA–GNPs would increase and disintegrated to all ions at pH more than pK_{a2}, while the electrostatic repulsion between the MA–GNPs would decrease and occur van der Waals attraction between –COOH group of MA with GNPs at pH less than pK_{a2}. The mechanism can be attributed to the function of Pb^{2+} with MA–GNP in a chelating reaction. The aggregation of MA–GNPs was induced by the coordination between Pb^{2+} and carboxylate of MA at pH 5.8. The various metal cations including As^{3+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Mg^{2+}, Mn^{2+}, Ni^{2+}, Pb^{2+} and Zn^{2+} no changed of color occurs after adding into the MA–GNPs at pH 6.4, 7.4 and 8.0 (Fig. S3). Therefore, we selected the optimum pH at pH 5.8 for Pb^{2+} detection by the naked eye.

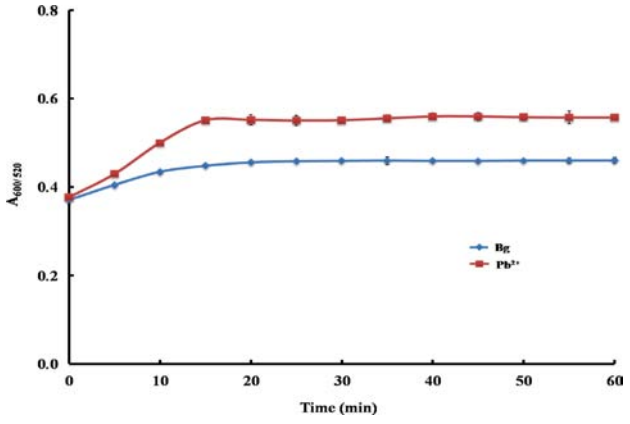

Fig. 4. Effect of reaction time between 0 and 60 min (0.6 μL of MA–GNPs mixed 0.4 μL of Pb^{2+} (1.0 μg L^{-1}) in phosphate buffer pH 5.8) Error bar at $n=3$.

The effect of reaction time between MA–GNPs and Pb^{2+} was investigated. The ratio between the absorbance at a wavelength of 520 nm to 600 nm was used to evaluate as shown in Fig. 4. We found that for low concentration of Pb^{2+} (1.0 μg L^{-1}) absorbance ratio reached reach equilibrium within 15 min. This result represents the fast performance of this assay for Pb^{2+}.

3.4. Calibration

The different concentrations of Pb^{2+} were added to MA–GNPs. The degree of aggregation of MA–GNPs depended on concentration of Pb^{2+}. Fig. 5 shows that the absorbance changed with the addition of different concentrations of Pb^{2+}. The maximal absorption at 520 nm decreased and a new peak at 600 nm increased with increasing Pb^{2+} concentration, which indicated the aggregating between MA–GNPs and Pb^{2+} has a relationship with the concentration. Thus, the MA–GNPs for the detection of different concentrations of Pb^{2+} was processed directly using the UV–vis absorbance ratio ($A_{600/520}$). A linear correlation existed between the absorbance ratio ($A_{600/520}$) and the concentration of Pb^{2+} ranging from 0.0 to 10.0 μg L^{-1} ($R^2=0.990$) as shown in Fig. 5. The detection limit was found at 0.5 μg L^{-1}. In the presence of high concentration of Pb^{2+} more than 10.0 μg L^{-1}, the UV–Vis absorption spectra of Pb^{2+}–MA–GNPs became broader and shifted to much longer wavelength (>600 nm). The value is not in a linear range. Consequently, the concentration of Pb^{2+} ranging from 0.0 to 10.0 μg L^{-1} made this assay suitable for the determination of Pb^{2+} in aqueous solution. Compared with the other colorimetric methods based on nanoparticles (Table 1), our method has the higher sensitivity and more rapid.

3.5. Analytical applications

To validate our assay for the determination of Pb^{2+} in real samples, drinking water samples from 5 sources were analyzed by our assay and the traditional method (Atomic Absorption Spectroscopy, AAS) as shown in Table 2. The data were then compared by a paired *t*-test. Our results were not statistically significant different from the standard methods at the 95% confidence level

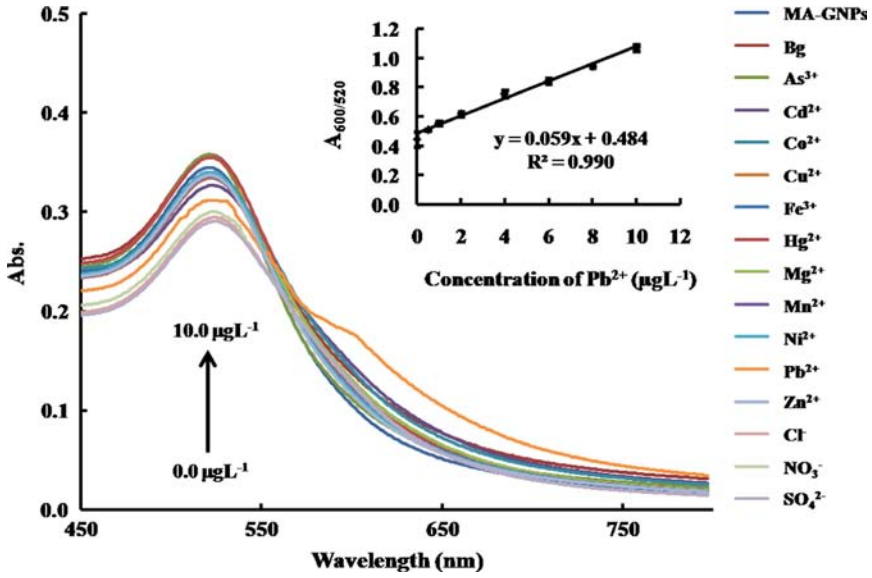

Fig. 5. UV–visible spectra of MA–GNP solutions with various concentrations of Pb^{2+} in the range from 0.0 to 10.0 μg L^{-1} at 15 min.

Table 1

Table 2
Levels of Pb^{2+} in drinking water samples were measured using our method and AAS.

Water samples	Concentration of Pb^{2+} (μg L^{-1})	
	AAS	Our method
Sample 1	6.74+0.02	6.42+0.51
Sample 2	7.71+0.03	7.95+1.38
Sample 3	7.90+0.01	9.21+0.77
Sample 4	7.74+0.03	8.68+0.79
Sample 5	10.20+0.06	11.42+0.04

The standard deviation of water samples at $n=5$.

(t-test value=0.67, t critical value=2.31). Moreover, we also evaluated the utility of our method by analysis low level of Pb^{2+} in human breast milk samples. We found that Pb^{2+} in the human breast milk samples were not detectable under our detection limit (0.5 μg L^{-1}). Thus, known amounts of Pb^{2+} were spiked into milk samples to get the final concentration at 1.0, 2.5 and 5.0 μg L^{-1}. It was found the level of Pb^{2+} at 1.09+0.20, 2.93+0.62, and 5.06+0.29 μg L^{-1}, respectively ($n=7$) and the percentage recovery in the range 101–105%. Therefore, the MA–GNPs can be used to measure the low amount of Pb^{2+} in real samples. It is an easy to measure without the need for analyze complex or expensive, used of less levels and does not require expert analysis.

4. Conclusions

In summary, a simple, rapid, highly sensitive, easy-to-use, inexpensive, and portable alternative point-of-measurement monitoring for Pb^{2+} using MA–GNPs colorimetric assay has been developed. The Pb^{2+}-induced MA–GNPs aggregation results in a marked red shift in the UV–vis absorption spectra and a visible color change from red to blue. The detection limit of this method by the detection of naked eye is 0.5 μg L^{-1} which lower than other GNPs colorimetric probs. Furthermore, Pb^{2+} was clearly distinguish able color change from the other heavy metal ions under the optimum conditions at the critical level of Pb^{2+} in drinking water prescribed by WHO. Finally, our method was successfully applied to analysis of Pb^{2+} in water samples and the human breast milk samples. Therefore, this method should be applicable to detect low level of Pb^{2+} in drinking water and some biological samples.

ABSTRACT

Thiocyanate (SCN^-) is a small anion byproduct of cyanide metabolism. Several methods have been reported to measure SCN^- above the micromolar level. However, SCN^- is derived from many sources such as cigarettes, waste water, food and even car exhaust and its effect is cumulative, which makes it necessary to develop methods for the detection of trace SCN^-. In this paper, a simple and ultrasensitive turn-on fluorescence assay of trace SCN^- is established based on the fluorescence resonance energy transfer (FRET) between gold nanoparticles (AuNPs) and fluorescein. The detection limit is 0.09 nM, to the best of our knowledge, which has been the lowest detection LOD ever without the aid of costly instrumentation. The fluorescence of fluorescein is significantly quenched when it is attached to the surface of AuNPs. Upon the addition of SCN^-, the fluorescence is turned on due to the competition action between SCN^- and fluorescein towards the surface of AuNPs. Under an optimum pH, AuNPs size and concentration, incubation time, the fluorescence enhancement efficiency $[(I_F-I_0)/I_0]$ displays a linear relationship with the concentration of SCN^- in the range of 1.0 nM to 40.0 nM. The fluorescein–AuNP sensor shows absolutely high selectivity toward SCN^- than other 16 anions. The common metal ions, amino acids and sugars have no obvious interference effects. The accuracy and precision were evaluated based on the recovery experiments. The cost effective sensing system is successfully applied for the determination of SCN^- in milk products and saliva samples.

1. Introduction

As an important chemical raw material, thiocyanate (SCN^-) is widely employed in many industrial processes such as pesticide production, textile dyeing, electroplating, printing, photofinishing and hydrometallurgy. Compared with the lethal cyanide ion, SCN^- is a less toxic anion that can be found at μM in human bodies through the digestion of glucosinolate-containing brassica vegetables (broccoli, cauliflower, cabbage, etc.), or by ingesting cheese and milk, which contain SCN^- [1]. SCN^- ranks after perchlorate as a potent inhibitor of iodide uptake by the thyroid but may be more concentrated in some food items such as milk products [2]. And it is more serious for pregnant woman, infant or population in iodine deficiency area [3]. Besides, another significant source of SCN^- in the body is from smoker. Cyanide in tobacco, once absorbed, is eliminated through its conversion to SCN^- by the enzyme rhodanese, which is found in the mitochondria of liver and kidney cells [4]. Therefore, the concentration levels of SCN^- in human body liquids are considered to be an important indicator for assessing habitual smoking behavior as well as distinguishing nonsmokers from smokers [1]. For the general population, low levels of serum SCN^- may predispose them to inflammatory or inflammation-mediated diseases [5]. All of these aspects underscore the importance of SCN^- determination.

Several methods for the SCN^- detection have been developed over the recent years, including ion chromatography [6], gas chromatography/mass spectrometry [7], colorimetry [4,8,9], electrophoresis [10], electrochemistry [11], fluorimetry [12], and surface-enhanced Raman scattering (SERS) [13,14]. However, some of these methods lack sufficient sensitivity to detect SCN^- at low levels (5–8.5 mg L^{-1}) [15], which correspond to the SCN^- levels typically found in milk samples. And most of them are time-consuming and costly or require sophisticated instrumentation and professional staffs. Hence, exploring an accurate, rapid, sensitive and low-cost method to detect SCN^- in milk and human body liquids still remains a challenge.

Fluorescence resonance energy transfer (FRET) has been widely exploited as an extremely useful tool in analytical and sensing applications [16,17]. FRET is a kind of non-radiation energy transfer form, and the energy of the donors is transferred to the acceptors by the interaction of electric dipoles. The efficiency of FRET is determined by many factors including the overlap extent between the emission spectrum of the donors and the absorption

spectrum of the acceptors, the distance between the donors and acceptors, the relative orientation of the electric dipoles of the donors and acceptors and so on. Gold nanoparticles (AuNPs) have been widely exploited for chemical and biochemical sensing [18–21] because of their high surface area-to-volume ratios, size-dependent optical properties, and easy to be modified or functionalized chemically. Particularly, AuNPs have been explored as the efficient energy acceptors to substitute for organic acceptors [22] and selected for establishing a FRET system as a fluorescence quencher [23], which have been developed for detection of DNA [24] in the presence of Rhodamine B, protein [25] with aptamer as part of the biosensor, iodide and iodate [26] based on fluorescein-5-isothiocyannate-modified AuNPs, thiols [27] based on Nile Red-Absorbed AuNPs, medicine captopril [28], glyphosate [29] based on the FRET between charged CdTe quantum dots and AuNPs, metallic ions [30] using quantum dots and AuNPs co-sensing system. It was reported that fluorescein can be absorbed on the surface of AuNPs, resulting in fluorescence quenching due to FRET between fluorescein and the AuNPs to detect acetylthiocholine with the aid of enzyme [31] and melamine [32]. Inspired by these works, we have examined the potential of FRET between fluorescein and AuNPs as a novel and sensitive probe for the determination of SCN^- in milk products and saliva. Upon addition of SCN^- that competed with fluorescein molecules to absorb on the surface of the AuNPs, fluorescein molecules were freed from the surface of AuNPs and the fluorescence was recovered (Scheme 1). We have tested another 16 different kinds of anions and only the presence of SCN^- was able to restore fluorescence, allowing the ultrasensitive and selective determination of SCN^- concentration within 5 min. The aim of present work is to propose an alternative methodology with economic aspects, on site, real time and operating simplicity to conventional techniques for SCN^- detection in water, milk products and saliva samples of smokers and nonsmokers.

2. Experimental

2.1. Materials

Chemicals were of analytical grade and used without further purification unless otherwise stated. Hydrogen tetrachloroaurate hydrate ($HAuCl_4 \cdot 4H_2O$) was bought from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). Amino acids including L-arginine (Arg), L-histidine (His), L-lysine (Lys), L-tyrosine (Tyr), L-valine (Val) and L-threonine (Thr) were purchased from Shanghai Jingchun Technology Co. Ltd. (Shanghai, China). Na_2SO_4, Na_2SO_3, $Na_2S_2O_3$, Na_2S, Na_2CO_3, $Na_2C_2O_4$, CH_3CO_2Na, $NaNO_3$, $NaNO_2$, $KClO_4$, NaF, NaCl, kBr, KI, $FeCl_3$, $MgCl_2$, $CaCl_2$, $ZnCl_2$, and NH_4Cl were purchased from Shanghai Qingxi Technology Co. Ltd. (Shanghai, China). All the carbohydrates including D-fructose, D-glucose and sucrose were purchased from Shanghai Lanji Technology Co. Ltd. (Shanghai, China). The pH value of the solution was adjusted by mixing different volume ratio of NaH_2PO_4 and Na_2HPO_4.

Scheme 1. Schematic illustration for the sensing of SCN^- based on FRET.

2.2. Apparatus

All fluorescence measurements were carried out on F-4600 spectrofluorimeter (Hitachi, Japan) equipped with a xenon lamp source and a 1.0 cm quartz cell, and the scan speed was 12,000 nm min^{-1}. UV–vis absorption spectra were recorded using UV-2550 spectrophotometer (Shimadzu, Kyoto, Japan) with a 1.0 cm quartz cell at room temperature. Transmission electron microscopy (TEM) was carried out with a JEM-2010 transmission electron microscope (JEOL Ltd. Japan). The samples were prepared by drop-coating the AuNPs solution onto the carbon-coated copper grid and were loaded onto a specimen holder for the purpose of TEM.

2.3. Preparation of colloidal Au NPs

All pieces of the experimental glassware used were cleaned in a bath of freshly prepared aqua regia solution (HCl:HNO_3, 3:1) and then rinsed thoroughly with H_2O and finally dried in the oven at 100 °C prior to use. Citrate capped gold nanoparticles with different sizes was synthesized based on the well-documented Frens' method [33] (trisodium citrate was used as reducing agent). In this method, it was possible to control the size of the particles by varying [Au(III)]/[citrate] ratio during the reduction step as listed in Table S1. A standard procedure for the preparation of AuNPs with size 13 nm was summarized as follows. A 50 mL aqueous solution of $HAuCl_4$ (0.25 mM) was heated to boiling point and 1.3 mL of trisodium citrate (1%) was added. The end point of the reaction was right after the solution reached a wine red color. The obtained wine-red solution was stored at 4 °C for further use. The UV–vis spectral characteristics and sizes for different sets of gold nanoparticles are summarized in Table S1 and results are in agreement with Frens' method. The molar concentration of 13 nm sized AuNPs was calculated according to Beer's law [34] (the molar extinction coefficient for 13 nm AuNPs is 2.78×10^8 $(mol\ L^{-1})^{-1}$ cm^{-1} at 520 nm).

2.4. Preparation of real samples

The pretreatment of liquid milk samples was carried out following the general procedure [35]. Briefly, 2 g milk product was added into 1.5 mL of 10% trichloroacetic acid and 5.0 mL of acetonitrile mixture to remove proteins in milk samples. The mixture solution was transferred to centrifugal tube to undergo sonication for 10 min and then centrifuged at 12,000 rpm min^{-1} for 15 min. The supernatant was filtered through a 0.22 μm membrane filter to remove lipids. The pH of filtrate was adjusted to 6.8, and the filtrate was filtered through 0.22 μm membrane filter again after centrifugation. The filtered liquid was diluted with water to 10 mL for further analysis.

In the case of infant formula, about 0.6 g sample was used for the determination. First, sample was dissolved with 2.0 mL water in a centrifuge tube, 1.5 mL of 10% trichloroacetic acid and 5.0 mL acetonitrile mixture were added to undergo 15 min ultrasonic treatment. Then, the mixture was centrifuged at 12,000 rmp min^{-1} for 15 min. The rest of operation was the same as the pretreatment of liquid milk.

Saliva is a cleaner matrix. Saliva samples from healthy smoking and non-smoking volunteers were collected and refrigerated for 30 min at 4 °C, then centrifuged at 3000 rpm for 10 min. After centrifugation, 100 μL of the supernatant solution was transferred into 10.0 mL volumetric flask and diluted to the mark with deionized water.

2.5. Detection of SCN^-

Typically, a stock solution of 10 μM fluorescein was prepared with Milli-Q water for the further use. 30 μL of 10 μM fluorescein was added into 200 μL AuNPs (15 nM), the resulted mixture was equilibrated at the room temperature for 10 min. Then, 770 μL of

0.01 M (pH 7.0) PBS (NaH_2PO_4–Na_2HPO_4) containing various concentrations of SCN^- was mixed with above mixture solution and further incubated for 10 min. The fluorescence intensities at 531 nm (excitation wavelength was 459 nm) of the mixture in the presence (I_F) and absence (I_0) of SCN^- were recorded, respectively.

2.6. Accuracy and precision

A recovery study was conducted by adding known amounts (5 nM, 10 nM, 15 nM) of the SCN^- to the real samples, followed by pre-treatment. Each concentration was replicated in triplicate. Degree of accuracy expresses the concordance between the accepted value and the value found. The evaluation of inter-day precision (intermediate precision) of the assay was performed on two different days by different analysts. The repeatability was evaluated on the same day for intra-day precision in 3 vessels used for the dissolution test. The relative standard deviation (RSD) and the relative mean square error prediction (RMSEP) from the results was calculated.

3. Results and discussion

3.1. Characterization of AuNPs

Transmission electron microscope datum was used to characterize the size and shape of AuNPs. We synthesized various sized AuNPs and chose the AuNPs sized 13 nm as an example shown in Fig. 1 A, the prepared AuNPs were dispersed uniformly with spherical shape and the sizes were measured to be an average diameter of 13.1 nm with relative standard deviation as 24% (shown in Fig. S1). The characterizations of other sized AuNPs were listed in Table S1.

3.2. Interaction between SCN^- and fluorescein–AuNPs assembly

The fluorescence quenching of fluorophores by AuNPs was dominated by the mechanisms of FRET, the inner filter effect and electron transfer [31]. FRET requires good overlap between the emission of the fluorophores and the SPR band of AuNPs. The emission spectrum of fluorescein (peak at 531 nm) was partially overlapped with the absorption spectrum of AuNPs in different sizes (as shown in Fig. 2A). It has been reported that the fluorescein can be adsorbed onto the surface of citrate-stabilized AuNPs to form a fluorescein–AuNPs assembly due to the electrostatic interaction. The overlap integral areas of absorption spectrum of different sized AuNPs with emission spectrum of fluorescein were shown in Table S2. The fluorescence of fluorescein exhibits a maximum wavelength at 531 nm and the SPR peak of AuNPs with size 13 nm is 520 nm, indicating the largest overlap integral area (4063) between the fluorescence of fluorescein and the SPR band of 13 nm AuNPs. Fig. S2A shows the fluorescence intensity change at 531 nm of the AuNPs–fluorescein system following successive addition of different size AuNPs and Fig. S2B shows the resulting emission spectral change of addition of 13 nm sized AuNPs. It is clear that the fluorescence emission intensity decreased gradually with increasing the AuNPs concentration for all four different sized AuNPs. The fluorescence quenching efficiency can be quantified by the Stern–Volmer equation:

$$\frac{I_0}{I} = 1 + K_{sv}[Q] \quad (1)$$

where I_0 and I are the fluorescence intensity in the absence and presence of the quencher (AuNPs), respectively. K_{sv} is the quenching constant and Q is the concentration of quencher.

The Stern–Volmer plots (see Fig. 2B) show that the different quenching efficiency with the different size of the AuNPs. The quenching constants derived from the slope of the different sized AuNPs were shown in Table S2. It is obvious that the 13 nm sized AuNPs had the largest quenching efficiency. The result is consistent with the conclusion that this type of AuNPs possess maximal FRET overlapping integral area.

We also investigated the effect of the different size of AuNPs on the fluorescent enhancement efficiency with the addition of SCN^- (as shown in Fig. S3). The result indicated that when the SCN^- was added to the fluorescein–AuNPs with different sizes, the 13 nm sized fluorescein–AuNPs showed the maximum level of fluorescence recovery. The results may be due to that SCN^- had good ability to interact with 13 nm sized AuNPs. To sum up, the 13 nm sized AuNPs was selected as the FRET acceptor for the further experiments.

Fluorescein molecules adsorbed on the surface of AuNPs can be released by introducing another compound, which can interact with the AuNPs, resulting in the recovery of the fluorescence [26–28]. To validate the competition between fluorescein and SCN^-, the effect of SCN^- on the fluorescence of the fluorescein–AuNPs mixture was performed and shown in Fig. 2C. The fluorescence spectrum of fluorescein (curve '*a*' in Fig. 2C) was almost identical to that of the mixture of fluorescein and SCN^- (curve '*b*' in Fig. 2C). The results provided clear evidence that there was no interaction between fluorescein and SCN^-. When fluorescein was mixed with AuNPs sized 13 nm, the fluorescence was significantly quenched (curve '*c*' in Fig. 2C) due to the FRET between fluorescein and AuNPs. Upon the addition of SCN^- to the solution of fluorescein–AuNPs, the fluorescein was detached from the AuNPs surface, leading to the recovery or turn-on of the fluorescence (curve '*d*' in Fig. 2C). In addition, we found that the SPR peak was slightly shifted after the addition of 3.0 μM SCN^-

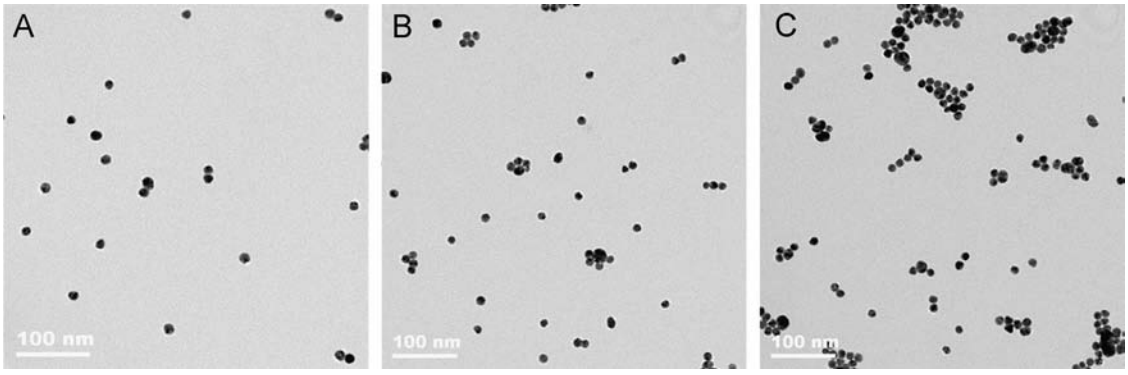

Fig. 1. TEM images of (A) AuNPs, (B) AuNPs with fluorescein (0.3 μM) and low concentration of SCN^- (0.5 μM), and (C) AuNPs with fluorescein (0.3 μM) and a high concentration of SCN^- (3.0 μM). The concentration of AuNPs is 3.0 nM with 13 nm size.

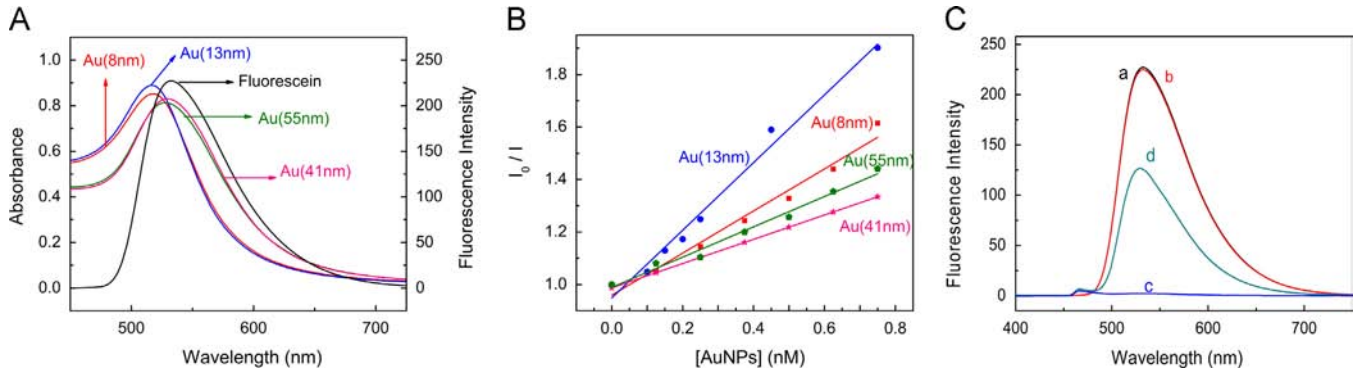

Fig. 2. (A) Emission spectra of fluorescein (0.3 μM) and absorption spectra of AuNPs (3.0 nM) with different sizes (8, 13, 41 and 55 nm), respectively; (B) Stern–Volmer plots. The quenching efficiencies of AuNPs as a function of particle sizes; (C) Fluorescence spectra of (a) fluorescein, (b) fluorescein and SCN^- mixture, (c) fluorescein and AuNPs sized 13 nm, (d) AuNPs sized 13 nm, fluorescein and SCN^- in pH 7.0 buffer (0.01 M Na_2HPO_4–NaH_2PO_4). Fluorescein, 0.3 μM; SCN^-, 0.2 μM; AuNPs, 3 nM.

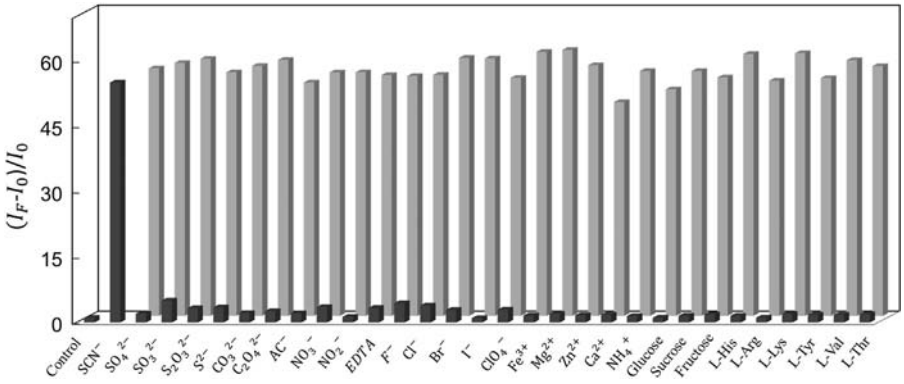

Fig. 3. The fluorescent enhancement efficiency $[(I_F-I_0)/I_0]$ of fluorescein (0.3 μM)–AuNPs (3.0 nM) in the presence of different kinds of foreign ions and compounds (0.1 μM) without (Black bars (Blue in print version)) and with SCN^- (0.1 μM) (Grey bars (Red in print version)) in pH 7.0 buffer (0.01 M Na_2HPO_4–NaH_2PO_4). The concentrations of testing substances were 50 μM for Ca^{2+}, Mg^{2+}, Zn^{2+}, Fe^{3+}, Na^+, K^+, SO_4^{2-}, $S_2O_3^{2-}$, $S_2O_3^{2-}$, S^{2-}, CO_3^{2-}, $C_2O_4^{2-}$, AC^-, NO_3^-, NO_2^-, EDTA, F^-, Cl^-, Br^-, ClO_4^-, glucose, fructose, sucrose, L-tyrosine, L-valine, and L-threonine, 10 μM for L-histidine, L-arginine, L-lysine and 0.1 μM for I^-, respectively.

(Fig. S4). As shown in Fig. 1B and C, 0.3 μM SCN^- can make the AuNPs aggregate slightly, which became stronger in the presence of 3.0 μM of SCN^- (Fig. 1C).

3.3. Effect of AuNPs concentration and pH

To improve the sensitivity of the sensor, we investigated the effect of the AuNPs concentration and the pH of the solution on the displacement of fluorescein from the surface of AuNPs by SCN^-. Fig. S5A shows the fluorescent enhancement efficiency $[(I_F-I_0)/I_0]$ in the presence of 15 nM SCN^- as a function of AuNPs concentration. The efficiency was gradually increased with increasing the concentration of AuNPs and reached maximum when the concentration was up to 3 nM. The fluorescent enhancement efficiency started decreasing when the concentration was beyond 3 nM, which may be attributed to the fact that high concentration of the AuNPs increased the collisional encounter, leading to an enhancement in collisional quenching of released fluorescein. Thus, 3 nM of AuNPs was chosen for the following experiment. The effect of pH was also investigated in the range from pH 5.0 to 9.0. As shown in Fig. S5B, the fluorescent enhancement efficiency is highly dependent on pH value of solution and the highest point was obtained at pH 7.0. Therefore, the optimized pH value for SCN^- detection system is 7.0.

3.4. Effect of incubation time

The effect of the incubation time of SCN^- was investigated as well. Fig. S6 shows the plot of fluorescence intensity variation over the different concentrations of SCN^-. It can be deduced that the fluorescence recovery was almost 90% completed within 10 min. Therefore, all the fluorescence measurements were performed 10 min after initiation of the reaction.

3.5. Effect of potentially interfering ions

To assess the recognition ability of fluorescein–AuNPs probe, the fluorescent enhancement efficiency responses from metal ions (including Ca^{2+}, Mg^{2+}, Zn^{2+}, Fe^{3+}, Na^+, K^+), anions (including SO_4^{2-}, SO_3^{2-}, $S_2O_3^{2-}$, S^{2-}, CO_3^{2-}, $C_2O_4^{2-}$, AC^-, NO_3^-, NO_2^-, $EDTA^{2-}$, F^-, Cl^-, Br^-, I^-, ClO_4^-), sugars (glucose, fructose, sucrose) and amino acid (L-histidine, L-arginine, L-lysine, L-tyrosine, L-valine, L-threonine), which possibly existed in the real samples were performed. As shown in Fig. 3 (blue/black histograms), the addition of SCN^- to a solution of 3.0 nM fluorescein–AuNPs resulted in a dramatic increase in the fluorescent enhancement efficiency $[(I_F-I_0)/I_0]$, while the other ions and compounds exhibited no such change. It turns out that this fluorecein–AuNPs probe showed excellent selectivity of SCN^- over the other ions and compounds. To expand the field of application, the interference from these ions and compounds were further investigated as shown in Fig. 3 (red/gray histograms). This was conducted through the analysis of a standard solution of SCN^- (0.1 μM) in the presence of the excess amounts of coexisting compounds. Ca^{2+}, Mg^{2+}, Zn^{2+}, Fe^{3+}, Na^+, K^+, SO_4^{2-}, SO_3^{2-}, $S_2O_3^{2-}$, S^{2-}, CO_3^{2-}, $C_2O_4^{2-}$, AC^-, NO_3^-, NO_2^-, EDTA, F^-, Cl^-, Br^-, ClO_4^-, glucose, fructose, sucrose, L-tyrosine, L-valine, and L-threonine did not interfere at the concentrations of 50 μM, and L-histidine, L-arginine, L-lysine did not interfere at the concentrations of 10 μM, and 0.1 μM of I^- did not interference. In practical assays, the potential interference from amino acids may

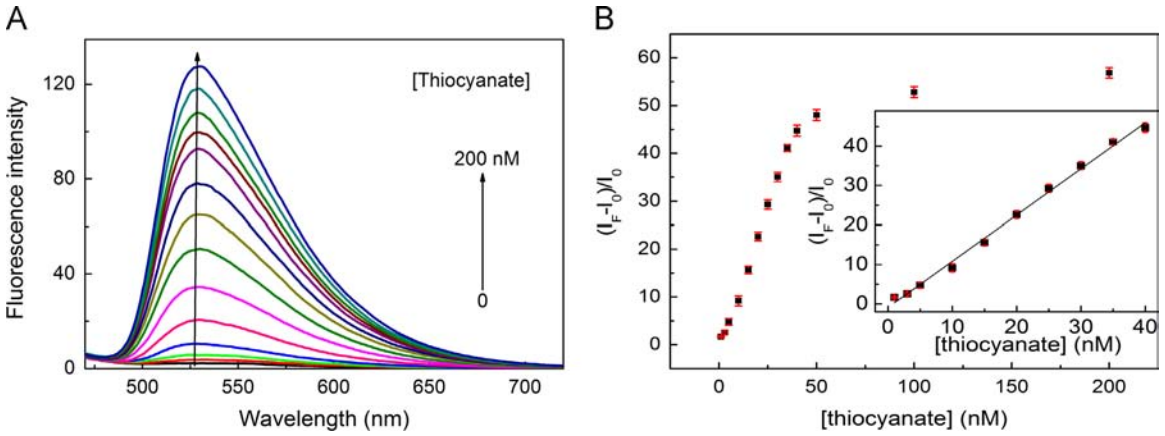

Fig. 4. (A) Fluorescent spectra of fluorescein–AuNPs in the presence of SCN^- at various concentrations in pH 7.0 buffer (0.01 M Na_2HPO_4–NaH_2PO_4). Amounts of SCN^- were 1.0, 3.0, 5.0, 10.0, 15.0, 20.0, 25.0, 30.0, 35.0, 40.0, 50.0, 100.0 and 200.0 nM from bottom to top, respectively. (B) Effect of the SCN^- concentration on the fluorescent enhancement efficiency. Inset is the calibration curve.

be insignificant and could be eliminated during sample pretreatment by removing the protein from the samples.

3.6. The sensitivity for the detection of SCN^-

Under the optimized conditions, the capability of this sensing system for quantitative detection of SCN^- was evaluated. The fluorescent spectra of fluorescein–AuNPs in the presence of different amounts of SCN^- were shown in Fig. 4A. A linear relationship between the fluorescent enhancement efficiency $[(I_F-I_0)/I_0]$ and the concentration of SCN^- ($C_{\overline{SCN}}$, nM) was observed in the range of 1.0 nM to 40.0 nM (as shown in Fig. 4B) with a detection limit of 0.09 nM (3 s/K). The calibration equation was: $Y=-0.8974+1.172C_{\overline{SCN}}$ with the satisfactory correlation coefficient ($R^2=0.998$), where Y referred to the fluorescent enhancement efficiency $[(I_F-I_0)/I_0]$ and X was the concentration of SCN^-.

3.7. Analysis of real samples

In order to validate the applicability of the fluorescein–AuNPs probe for SCN^- sensing, a recovery study was conducted by adding known amounts of SCN^- to the real samples. Each concentration was replicated in triplicate. That is to say, none and various concentration of SCN^- were spiked into the milk and saliva samples according to the procedure described in Section 2.4. The accuracy and precision evaluation of the results of such measurements were then processed with the use of recoveries (%) and the relative mean square error prediction (RMSEP)[36] (Table 1). Degree of accuracy expresses the concordance between the accepted value and the value found. The measured recovery is typically between 90% and 110% with RSD lower than 10%, indicating the good accuracy of the method. The precision results of the proposed method in real samples were evaluated by analyzing repeatability and intermediate precision. The assay evidenced a low RSD ranging from 0.9% to 8.6% for intra-day precision and from 0.3% to 8.5% for inter-day precision performed by the different analysts. The t-value of 2.57 is obtained with 95% significance. Analytical data in Table 1 showed that the recoveries varied from 102% to 104% in the spiked liquid milk sample, 100% to 107% in the spiked infant milk sample, 100% to 101% in the non-smoker saliva sample, and 101% to 108% and 101% to 105% Smoker 1' saliva and Smoker 2' saliva, respectively. The good recoveries, lower RSD and RMSEP (shown in Table 1 and Table S3) demonstrate the accuracy and reliability of the present fluorescence method for detecting SCN^- in practical applications.

Table 1
The application of the proposed method for analysis of milk and saliva samples spiked with different amounts of SCN^-.

Sample	Determination	Added (10^{-9} M)	Amount found (10^{-9} M)[a]	RSD (%, $n=6$)	Recovery (%)	RMSEP[b] (%)
Liquid milk	Not found	5.0	5.1 ± 0.3[c]	5.2	102	3.7
		10.0	10.3 ± 0.4	3.3	103	
		15.0	15.6 ± 1.2	6.4	104	
Infant milk	Not found	5.0	5.0 ± 0.4	7.0	100	5.7
		10.0	10.7 ± 0.7	5.8	107	
		15.0	15.8 ± 1.0	5.5	106	
Non-smoker saliva	Not found	5.0	5.0 ± 0.5	8.6	100	0.5
		10.0	10.1 ± 0.6	5.6	101	
		15.0	15.0 ± 0.4	2.4	100

		10.0	10.5 ± 0.7	5.6	105	
		15.0	15.1 ± 0.9	5.3	101	

[a] The range amount found is evaluated by $\bar{x}\pm t(s/\sqrt{n})$, the value of $t_{0.95,5}$ is 2.57.
[b] RMSEP means relative mean square error prediction, RMSEP $=\sqrt{\left(\sum(x_{found}-x_{added})^2/\sum(x_{added})^2\right)}$.
[c] Average $\pm$ standard deviation (SD) of the three replicate measurements for each test sample.

4. Conclusions

In summary, a sensitive turn-on fluorescent detection method for SCN^- based on FRET from fluorescein to AuNPs is developed. It has been found that the 13 nm sized AuNPs exhibit higher quenching efficiency than other sized AuNPs, which is rationalized that this type of AuNPs shows the maximal overlap between its SPR absorption and the emission of fluorescein. This method offers a couple of advantages over the published SCN^- detection techniques (as shown in Table S4). First, this method can be operated without expensive instrument, which simplifies operations and reduces the associated costs. Second, it allows detection of concentrations as low as 0.09 nM, resulting in the rapid and sensitive detection of SCN^- in milk and saliva samples. Finally, this sensor exhibits unbelievable selectivity for SCN^- over the other ions and

compounds. We will focus on the practical applications in the future research.

ABSTRACT

A new Cu^{2+}-selective chromogenic probe system based on the oxidative coupling of phenols with 4-aminoantipyrine was developed. Cu^{2+} ions promoted facile coupling of phenols with 4-aminoantipyrine to yield quinoneimine dyes. Signaling with a number of phenols having no para-substituent, such as *o*-cresol and *m*-cresol, as well as *p*-chlorophenol having para substituent that could be expelled during the oxidation process was possible. The signaling of Cu^{2+} ions was not interfered by the presence of representative metal ions except for Al^{3+} ions. The possible interference from Al^{3+} ions was successfully removed by using fluoride ions as a masking agent. The phenol-4-aminoantipyrine probe system showed chromogenic Cu^{2+} signaling by prominent color change from colorless to pink with a detection limit of 8.5×10^{-7} M. The signaling of Cu^{2+} ions in practical samples using tap water and simulated semiconductor wastewater was also tested.

1. Introduction

Copper ions are the third most biologically important transition metal ions after iron and zinc [1,2]. It is a key constituent of the copper proteins involved in oxygen transport, oxygenation, electron transport, and antioxidative functions [3]. Copper has also been known as an important environmental pollutant [4]. The copper concentration in the environment varies widely with an average concentration of 0.01 mg/L in surface water and up to 100 mg/L in semiconductor wastewater [5]. Owing to the extensive use of copper in modern industrial applications, sensitive and selective chemosensors for Cu^{2+} ions have attracted much attention in environmental monitoring [6,7].

Recently, chemodosimeters or chemical probes using a reaction-based signaling approach have received much research interest [8]. The advantages of this strategy are cumulative, and specific chemical reactions between the probe molecule and analytes allow high sensitivity and excellent selectivity in signaling [9]. In particular, development of selective reaction-based probes for Cu^{2+} ions has been successfully realized. A number of probes have been devised based on the spirolactam ring-opening process of rhodamine derivatives [10,11]. In addition, Cu^{2+}-induced hydrolysis processes have become another important strategy for the design of Cu^{2+}-selective probes. A classical example reported by Czarnik's group is the spirolactam ring-opening of rhodamine-hydrazide followed by hydrolysis [12]. Other probes are generally based on activated esters, Schiff-bases, and hydrazone function containing dyes [13–16]. Cu^{2+}-mediated oxidation and oxidative cyclization processes have also been successfully used for the development of selective and sensitive probes for Cu^{2+} ions [6,17,18].

4-Aminoantipyrine (AAP) has been used as a useful chromogenic reagent for the determination of various phenols in aqueous solution [19]. The determination is based on the oxidative coupling of phenols with AAP by oxidants such as H_2O_2, persulfate, and $K_3Fe(CN)_6$ to yield highly colored diagnostic quinoneimine dyes [20,21]. On the other hand, coupling reaction of phenols with 4-aminoantipyrine is a well-established process for the determination of oxidants, such as hydrogen peroxide, in industrial analytes [22,23]. The same reaction can also be used for the determination of glucose in blood by using phenol, AAP, and glucose oxidase [24]. Interestingly, Cu^{2+} ions have been reported to act as an oxidant in the coupling of catechol with 4-aminoantipyrine [25]. However, no studies have been carried out on the construction of Cu^{2+}-selective probes employing this useful reaction. In this paper, we report a new colorimetric signaling system for Cu^{2+} ions based on a metal ion-induced coupling of phenols with 4-aminoantipyrine. Upon treatment with Cu^{2+} ions, coupling of phenols with 4-aminoantipyrine smoothly

proceeded to form a new quinoid dye with a prominent color change from colorless to pink.

2. Experimental section

2.1. General

4-Aminoantipyrine, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), and ammonium persulfate were purchased from Sigma-Aldrich Co. Boric acid was obtained from Wako Co. Phenol, 4-nitrophenol, 2,4,6-trimethylphenol, *m*-cresol, *o*-cresol, and *p*-chlorophenol were obtained from commercial sources. For the spectroscopic studies, perchlorate salts of Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Ba^{2+}, Al^{3+}, Mn^{2+}, Fe^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Ag^+, Cd^{2+}, Hg^{2+}, and Pb^{2+} were obtained from Sigma-Aldrich Co. Chromium(III) nitrate nonahydrate was purchased from Sigma-Aldrich Co. Sodium fluoride and ethylenediaminetetraacetic acid (EDTA) were purchased from Fluka. UV–vis measurements were performed using spectroscopy grade acetonitrile obtained from J.T. Baker. All chemicals and solvents were used without further purification. ^{1}H NMR (600 MHz) and ^{13}C NMR (150 MHz) spectra were acquired on a Varian VNS spectrometer and referenced to the residual solvent signal. UV–vis spectra were acquired using a Jasco V-550 spectrophotometer and Scinco S-3100 equipped with a Peltier temperature controller. Column chromatography was performed using silica gel (240 mesh). Electron-impact (EI) mass spectra (LRMS) were recorded on a Micromass Autospec spectrometer. Compound **1** was prepared following the reported procedure [26].

2.2. Purification of Cu^{2+} signaling compound

Phenol (0.48 g, 5.1 mmol) and copper (II) perchlorate hexahydrate (1.26 g, 3.4 mmol) were dissolved in 100 mL of HEPES-buffered 90% aqueous acetonitrile solution. 4-Aminoantipyrine (70 mg, 0.34 mmol) dissolved in 10 mL of distilled water was added dropwise to the solution. The reaction mixture was stirred at room temperature for 1 h, and 100 mL of dichloromethane was poured in order to extract the Cu^{2+}-signaling product. After separation of the dichloromethane layer, the organic solution was concentrated under reduced pressure. The residue was purified by simply passing through a silica gel plug using dichloromethane/methanol (9:1, v/v) to obtain 52 mg (52% yield) of the Cu^{2+}-signaling compound as a dark orange powder. ^{1}H NMR (600 MHz, $CDCl_3$) δ 8.50 (dd, J=10.3, 2.7 Hz, 1H), 7.53–7.34 (m, 5H), 7.24 (dd, J=9.9, 2.7 Hz, 1H), 6.54 (dd, J=9.9, 2.3 Hz, 1H), 6.44 (dd, J=10.3, 2.3 Hz, 1H), 3.36 (s, 3H), 2.50 (s, 3H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 188.01, 156.88, 153.43, 150.37, 143.72, 133.93, 133.24, 130.40, 129.58, 129.09, 128.52, 126.13, 119.92, 35.18, 10.78; MS (EI): m/z calcd for M^+ ($C_{17}H_{17}N_3O_2$): 295.13, found 295.16.

2.3. Measurement of signaling behaviors

UV–vis signaling behaviors of the probe system towards Cu^{2+} ions and other metal ions were measured in a mixture of CH_3CN and HEPES-buffered solution (pH 7.5) (1:9, v/v). The stock solutions of phenol and 4-aminoantipyrine were prepared in acetonitrile, and metal ions and buffer solutions were made in distilled water. Sample solutions for measurement were prepared by successively adding the stock solutions of metal ions (37.5 μL, 10 mM), HEPES buffer (30 μL, 1.0 M), phenol (225 μL, 5.0 mM), and 4-aminoantipyrine (75 μL, 1.0 mM) in each vial. The solution was diluted with CH_3CN and HEPES-buffer solution to make a final volume (3.0 mL) with a composition of 1:9, v/v. Final concentrations of metal ions, phenol, 4-aminoantipyrine, and HEPES buffer were 1.25×10^{-4} M, 3.75×10^{-4} M, 2.5×10^{-5} M, and 10 mM, respectively.

2.4. pH effects on the signaling towards Cu^{2+}

The effects of pH on the signaling towards Cu^{2+} were elucidated by measuring the responses in a pH range between 4.0 and 10.0 that adjusted with buffer solutions. The buffer solutions used were acetate buffer for pH 4.0–5.8, HEPES buffer for pH 7.0–8.0, and borate buffer for pH 9.0–10.0. Final concentrations of Cu^{2+}, phenol, 4-aminoantipyrine, and each buffer solution were 1.25×10^{-4} M, 3.75×10^{-4} M, 2.5×10^{-5} M, and 10 mM, respectively, under the same measurement conditions.

2.5. Preparation of simulated semiconductor wastewater

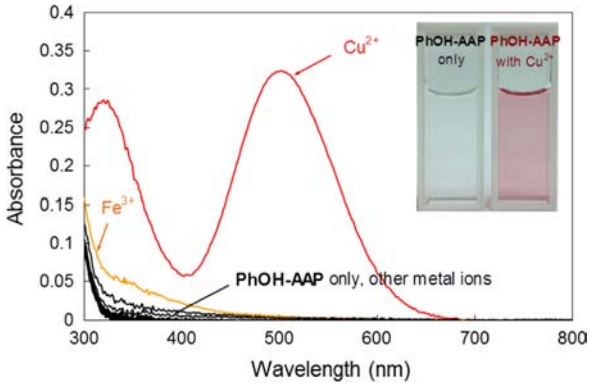
Referring to the two relevant literatures on wastewater compositions [27,28], the following metal concentrations were used for the preparation of the simulated semiconductor wastewater: $[Al^{3+}]=8.64\times10^{-5}$ M, $[Fe^{3+}]=5.37\times10^{-5}$ M, $[Pb^{2+}]=7.24\times10^{-6}$ M, $[Mn^{2+}]=1.82\times10^{-6}$ M, $[Zn^{2+}]=1.07\times10^{-5}$ M, and $[Ni^{2+}]=1.36\times10^{-5}$ M.

2.6. Determination of the detection limit for Cu^{2+} ions

Following IUPAC recommendations, the detection limit for the Cu^{2+} ions was determined using the equation $3\times s_{bl}/m$, where s_{bl} denotes the standard deviation of the blank signal (the number of measurements=20) and m represents the slope of the calibration curve [29].

3. Results and discussion

A novel colorimetric signaling system for Cu^{2+} ions based on a metal ion-induced coupling of phenols with 4-aminoantipyrine was developed. The signaling behavior of the probe system toward metal ions was investigated by UV–vis spectrophotometry. A mixture (15:1 mole ratio) of phenol and 4-aminoantipyrine (**PhOH-AAP**) showed no significant absorptions above 400 nm in 90% aqueous acetonitrile solution buffered at pH 7.5 (HEPES buffer). The molar ratio was chosen on the basis of the observation that Cu^{2+} signaling increased proportionally as the phenol concentration increased up to 15:1 mole ratio of phenol and AAP and then became constant (Fig. S1, Supplementary information). Upon treatment of this **PhOH-AAP** system with various metal ions,



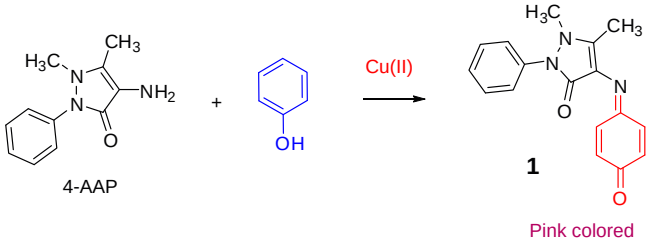


Fig. 1. Changes in UV–vis spectra of the **PhOH-AAP** system in the presence of various metal ions. $[AAP]=2.5\times10^{-5}$ M, $[PhOH]=3.75\times10^{-4}$ M, $[M^{n+}]=1.25\times10^{-4}$ M, $[Pb^{2+}]=2.5\times10^{-5}$ M in a mixture of CH_3CN and HEPES buffer solution (pH 7.5, 10 mM), (1:9, v/v). Spectral data for Cr^{3+} and Fe^{2+} were obtained against a reagent blank.

a pronounced change was observed exclusively with Cu^{2+} ions (Figs. 1 and S2, Supplementary information). In the presence of Cu^{2+} ions, a new strong absorption at 501 nm developed and the solution color of the **PhOH-AAP** system prominently changed from colorless to pink. No significant responses were observed from the other metal ions. On the other hand, meaningful fluorescence properties of **PhOH-AAP** were not observed for the signaling of any surveyed metal ions.

The prominent colorimetric signaling of Cu^{2+} ions by the **PhOH-AAP** system is due to the transformation depicted in Scheme 1. Phenol and AAP were oxidatively coupled to form a highly colored quinoneimine dye **1** promoted by Cu^{2+} ions. The formation of the aminoantipyrine-coupled product of phenols such as **1** by a practical persulfate oxidant was already known [26]. The proposed signaling process was confirmed by ^{1}H and ^{13}C NMR spectroscopy. For this, the ^{1}H NMR spectrum of the Cu^{2+}-signaling **PhOH-AAP** system was measured after purification of the reaction mixture. The resulting spectrum was identical to that obtained for compound **1** prepared independently using persulfate as an oxidant (Fig. 2 and Fig. S3, Supplementary information). In particular, the resonance peaks for the para-H (6.87 ppm) of phenol disappeared and the remaining four protons of the quinoid subunit appeared as two pairs of doublets (8.50 and 6.44 ppm for H-6 and H-5, 6.54 and 7.24 ppm for H-3 and H-2). One of the resonance peaks (H-6), assigned by means of a 2D ^{1}H–^{13}C HSQC spectrum (Fig. S4, Supplementary information), experienced a large shift to the lower field from 7.20 to 8.50 ppm due to a large anisotropic effect of nearby antipyryl group [26]. ^{13}C NMR and UV–vis spectral evidences also confirmed the formation of **1** under the signaling conditions (Fig. S5 and Fig. S6, Supplementary information). Furthermore, treatment of the Cu^{2+}-signaling **PhOH-AAP** system with chelating EDTA did not affect the UV–vis spectrum of the resulting solution, indicating the irreversible nature of the suggested reaction-based signaling process (Fig. S7, Supplementary information).

[AAP]$=2.5\times10^{-5}$ M, [phenol]$=3.75\times10^{-4}$ M, [Cu^{2+}]$=1.25\times10^{-4}$ M in a mixture of CH_3CN and HEPES buffer solution (pH 7.5, 10 mM), (1:9, v/v). (a) 4-Nitrophenol, (b) 2,4,6-trimethylphenol, (c) *m*-cresol, (d) *o*-cresol, and (e) *p*-chlorophenol.

The Cu^{2+}-selective signaling was not affected by the presence of common alkali, alkaline earth, and transition metal ions except for Al^{3+}, Cr^{3+}, and Fe^{2+}, as background. The signaling ratio $A_{Metal+Cu(II)}/A_{Cu(II)}$ observed at 501 nm varied across a narrow range, from 0.99 for Li^{+} ions to 1.02 for Fe^{3+} ions (Fig. 3). On the other hand, considerable interference was observed with Al^{3+} ions with a $A_{Al(III)+Cu(II)}/A_{Cu(II)}$ ratio of 0.70. However, the interference from Al^{3+} ions was successfully removed by using fluoride ions as a masking agent [30]; in the presence of 40 equiv of fluoride ions, the interference from Al^{3+} ions disappeared completely (Fig. S8, Supplementary information). In the presence of Fe^{2+} or Cr^{3+}, the Cu^{2+}-signaling of the probe system decreased to 53% by Fe^{2+}, or totally suppressed by Cr^{3+}. These interferences are due to the fact that undesirable interaction of Cu^{2+} ions with redox-active Fe^{2+} and Cr^{3+} ions [31,32]. The reaction of Cu^{2+} ions with Fe^{2+} or Cr^{3+} ions resulted in the decreases in Cu^{2+} level in the analytes, and leads to a significantly reduced signal for Cu^{2+}-triggered oxidative condensation between phenol and AAP. This observation implies that the present system could work as a practically applicable Cu^{2+}-selective probe in commonly encountered environmental systems except for the analytes rich in redox-active metal ions of Fe^{2+} or Cr^{3+}.

To check the quantitative analytical behavior of the **PhOH-AAP** system for Cu^{2+} signaling, a UV–vis titration was carried out in 90% aqueous acetonitrile (buffered at pH 7.5 using HEPES). As the concentration of Cu^{2+} ions increased, the absorption profile of the **PhOH-AAP** system changed progressively to that of **1** while showing a steadily increasing new band at 501 nm (Fig. 4). From the titration data, the detection limit in the determination of Cu^{2+} ions by the **PhOH-AAP** system was estimated to be 8.5×10^{-7} M in 90% aqueous acetonitrile solution (Fig. S9, Supplementary information) [29].

The effects of pH on the signaling were assessed by measuring the responses of the **PhOH-AAP** system as a function of the pH of the medium. As shown in Fig. S10 (Supplementary information), the Cu^{2+} signaling was most pronounced between pH 7 and 8. Signaling speed was fast and the response was completed within 10 min after mixing the analyte solutions (Fig. S11, Supplementary information). Additionally, the **PhOH-AAP** mixture was stable under the ambient temperature and open laboratory atmosphere for more than 1 day. The Cu^{2+}-selective signaling was possible for a number of phenols, such as *o*-cresol and *m*-cresol as well as *p*-chlorophenol (Figs. 5 and S12, Supplementary information). In the case of *p*-chlorophenol, the para-chloro substituent is known to be expelled during the oxidative process to form a quinoid dye [26]. Furthermore, practical applicability of the Cu^{2+}-selective signaling by the **PhOH-AAP** system was confirmed in tap water and simulated semiconductor wastewater (Fig. S13 and S14, Supplementary information). In particular, the interference from Al^{3+} in simulated semiconductor wastewater was successfully removed by using fluoride ions as a masking agent (Fig. S15, Supplementary information). The Cu^{2+} signaling by **PhOH-AAP** system in simulated semiconductor wastewater was possible up to 1.0×10^{-4} M.

4. Conclusion

In summary, a new chromogenic probe system for the selective signaling of Cu^{2+} ions was developed based on the Cu^{2+}-induced oxidative coupling of phenols and 4-aminoantipyrine. The mixture of phenol and 4-aminoantipyrine exhibited pronounced Cu^{2+}-selective chromogenic signaling with a color change from colorless to pink. Interference from Al^{3+} ions was successfully eliminated by using fluoride ions as a masking agent. The detection limit for the determination of Cu^{2+} ions was 8.5×10^{-7} M in 90% aqueous acetonitrile solution. The reported sensing approach would be useful as a convenient and practical colorimetric signaling system for Cu^{2+} ions in chemical and environmental applications, such as preliminary monitoring of Cu^{2+} levels in tap water and semiconductor wastewater.

ABSTRACT

The blooms of toxic phototrophic microorganisms, such as microalgae and cyanobacteria, which are typically found in freshwater and marine environments, are becoming more frequent and problematic in aquatic systems. Due to accumulation of toxic algae, harmful algal blooms (HABs) exert negative effects on aquatic systems. Therefore, rapid detection of harmful microalgae is important for monitoring the occurrence of HABs. Mass spectrometry-based methods have become sensitive, specific techniques for the identification and characterization of microorganisms. Matrix-assisted laser desorption/ionization (MALDI) with time-of-flight (TOF) mass spectrometry (MS) allows us to measure a unique molecular fingerprint of highly abundant proteins in a microorganism and has been used for the rapid, accurate identification of bacteria and fungi in clinical microbiology. Here, we tested the specificity of MALDI-TOF MS using microalgal strains (*Heterocapsa*, *Alexandrium*, *Nannochloropsis*, *Chaetoceros*, *Chlorella*, and *Dunaliella* spp.). Our research suggested that this method was comparable in terms of the rapid identification of microalgea to conventional methods based on genetic information and morphology. Thus, this efficient mass spectrometry-based technique may have applications in the rapid identification of harmful microorganisms from aquatic environmental samples.

1. Introduction

Harmful algal blooms (HABs), commonly called red tides [1], result from accumulation of various microalgae and are known to cause outbreaks of shellfish poisoning and death of fish, mammals, and sea plants [2]. HABs affect global coastal regions [1], and some algal toxins can cause diarrheic, paralytic, amnesic, and neurotoxic shellfish poisoning, thereby endangering human health and negatively affecting the tourism industry and fishery resources [3]. Most HABs are formed by blooming microscopic algae, phytoplankton, or specific cyanobacteria and occur when microalgae rapidly proliferate and when a large biomass of toxic or noxious microalgae accumulates in marine ecosystems or freshwater ecosystems [1]. Therefore, in order to respond quickly and appropriately to dissipate HABs, studies are needed to understand the ecology of microalgae as aquatic microbial eukaryotes and for enumeration and identification of harmful microalgae. Traditionally, identification of microalgae in HAB events has been achieved by light or electron microscopy examination. However, these methods may be difficult and time-consuming. Within the last decade, real-time polymerase chain reaction (PCR) assays [3] have been developed for rapid detection of microalgae in HABs. Molecular tools such as real-time PCR are known to be very useful for the detection of microorganisms [3]. However, exact identification of individual strains is nearly impossible using real-time PCR because of the limited availability of specific primer-probe sets.

Mass spectrometry (MS)-based methods have been established as an indispensable technology for interpretation of the information encoded in genomes, complementing DNA-based approaches [4].

Currently, MALDI-time-of-flight (TOF) MS has been applied for the detection of ribosomal protein mass patterns for the confirmation of pathogens [5]. Additionally, MALDI-TOF MS provides identification of pathogen and microorganisms and can be used to determine microbial taxonomy [6]. Reproducibility and accuracy of taxonomic identification of microorganisms using MALDI-TOF MS were confirmed by the previous studies under different cultivation conditions [7,8]. In another study, identification of filamentous fungi through spores was carried out using MALDI-TOF MS [9]. Importantly, the use of MALDI-TOF MS can reduce costs and time required for identification of microorganisms [10] and elucidation of microbial taxonomy can be used to determine microbial diversity based on natural relationships without identification of functional taxonomy or isolation of microorganisms [11].

Taxonomic system mirroring 'order in nature' [12] is established by phylogenetic analysis that can identify unknown organisms and classification in taxonomic groups on the bases of relationships. In this study we focused on developing a MALDI-TOF MS-based method for the phylogenetic analysis of harmful microalgal strains belonging to the genus *Alexandrium*, *Chaetoceros*, and *Heterocapsa*, as well as strains of the genus *Nannochloropsis*, *Chlorella*, and *Dunaliella* and we compared identification using MALDI-TOF MS to classical morphological methods and molecular genetic methods based on ribosomal RNA (rRNA) genes.

2. Experimental

2.1. Cultures of microalgal strains

Eight microalgae (*Chlorella* sp. J31 and J37, *Dunaliella* sp. J33, *Chaetoceros* sp. J28 and J32, *Alexandrium tamarense* J18, *Heterocapsa* sp. J3, and *Nannochloropsis granulata* J34) were obtained from the University of Nagasaki in Japan. Each strain was maintained and cultured using Erd-Schreiber modified (ESM) medium in plant growth chambers (VS-3DM, Vision Scientific, Korea). The ESM medium contained the following: 120 mg/L $NaNO_3$, 5 mg/L K_2HPO_4, 0.1 mg/L vitamin B_1, 0.01 mg/L vitamin B_{12}, 0.001 mg/L biotin, 0.26 mg/L EDTA–Fe^{3+}, 0.33 mg/L EDTA–Mn^{2+}, and 1000 mg/L Tris dissolved in artificial seawater; the pH was adjusted to 8.0. The seawater used for ESM medium was prefiltered through a membrane filter with a 0.2-μm pore size made of cellulose acetate. The cultures were stored in sterilized 500-mL Erlenmeyer flasks and inoculated in a plankton chamber under controlled conditions at 26 °C with 60% humidity and a 12/12 h light/dark cycle. The cool-white fluorescent lamp used for incubation supplied approximately 45.8 W/m^2 of light intensity. Each species of microalgae was tested in the exponential growth phase.

2.2. Morphological analysis using microscopy

Morphologies and sizes of the eight microalgae strains were observed on slides using the phase-contrast mode of a fluorescence microscope (FSX100, OLYMPUS, JPN).

2.3. Phylogenetic analysis based on 18S rRNA gene sequences

For phylogenetic analysis based on the 18S rRNA gene sequences, microalgal DNA was extracted using a DNA extraction kit (DNeasy Blood & Tissue Kit, Qiagen, Netherlands) in order to remove PCR inhibitors from the microalgae [13]. Then, the 18S rRNA gene amplification was carried out using a PCR premix (AccuPower, Bioneer, Korea) and two eukaryotic primers (Ecol-7F, 5′-ACCTGGTTGATCCTGCCAG-3′ and Ecol-1534R, 5′-TGATCCTTCYGCAGGTTCAC-3′). The PCR protocol was as follows: initial denaturation for 10 min; 30 cycles of denaturation at 94 °C for 1 min, annealing at 55 °C for 2 min, extension at 72 °C for 3 min, and a final extension for 5 min. The PCR products were sequenced using an automated DNA analyzer system (PRISM 3730xl DNA Analyzer, Applied Biosystems, USA) with a BigDye Terminator Cycle Sequencing Ready Reaction Kit (Applied Biosystems) according to the manufacturer's instructions. The 18S rRNA gene sequences of microalgae, verified using the BLAST search program (http://blast.ncbi.nlm.nih.gov/Blast.cgi), were aligned by CLUSTAL_W. Phylogenetic dendrograms were constructed using MEGA5 and the neighbor-joining method with 1000 randomly selected bootstrap replicates.

2.4. Spectral fingerprinting analysis using MALDI-TOF MS

We carried out the direct transfer method to analyze protein profiling of whole microorganism cells by MALDI-TOF MS without protein extraction and inactivation steps [14]. MALDI-TOF MS samples in triplicate were air-dried and mixed with α-cyano-4-hydroxycinnamic acid (CHCA) in 33% acetonitrile (ACN) and 33% ethanol (EtOH) with 3% trifluoroacetic acid (TFA) at a 1:1 ratio. Prepared samples were then homogenized. Ion spectra providing protein profiles were obtained in linear mode and positive-ion mode (laser frequency of 1000 Hz) with a mass range of 2000–20,000 Da using an UltrafleXtreme TOF/TOF mass spectrometer (Bruker Daltonics, Germany). Extraction delay time, lens, and ion sources 1 and 2 were set to 150 ns, 6.47, 25, and 23 kV, respectively. Adjustment and analysis of obtained MALDI-TOF MS spectra data were carried out using Excel 2010 (Microsoft, USA) and MultiExperiment Viewer (MeV) 4.8.1. Ion spectra of protein profiles from 2000 to 20,000 Da (Fig. 1) for each microalga were used to construct dendrograms by hierarchical clustering analysis (HCA) in MeV. The ordering optimization was sample leaf order, the distance metric was Euclidean distance, and the linkage method was complete linkage clustering. The sensitivity of the MALDI-TOF MS approach was analyzed to determine the amount of cells required for mass spectra analysis using each microalgae strain of *Heterocapsa* sp. J3, *Chaetoceros* sp. J28, and *Dunaliella* sp. J33. We first established the number of cells present in dense cultures using a hemocytometer with direct viable counts of 10-fold serial dilutions. Based on these counts we prepared samples containing 10^1–10^6 cells which were then analyzed using MALDI-TOF MS as previously described.

3. Results and discussion

We rapidly identified a total of eight species of microalgae using MALDI-TOF MS and compared these results with those of other techniques, i.e., morphological observations and phylogenetic analyses. First, we observed microalgal samples using light microscopy to identify morphologies.

3.1. Morphology

The eight microalgae exhibited proper morphologies for each of their species (Fig. S1). However observation of morphology can be easily confusing and is not as accurate as other techniques, such as phylogenetic analysis for taxonomy. Moreover, strains J31, J34, and J37 exhibited similar morphologies; this may cause difficulties in correctly identifying such strains by morphological and taxonomical evaluations. While observation of the ultrastructural morphology of microalgae by transmission electron microscopy has been carried out and can be much more precise in taxonomy analysis, it is costly, time-consuming, and difficult.

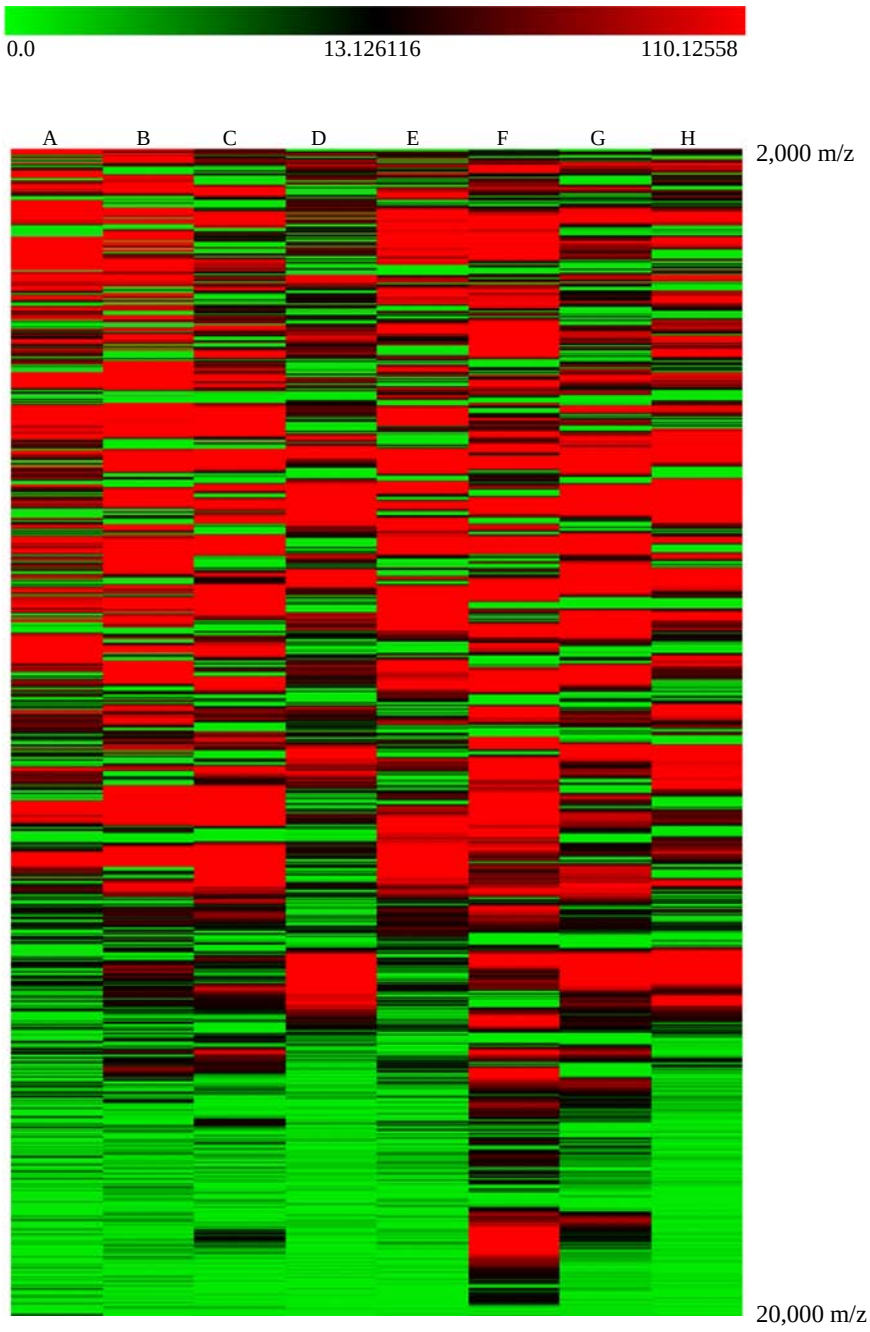

Fig. 1. Mass spectra for proteins in spectra from 2000 to 20,000: A, strain J3; B, strain J18; C, strain J28; D, strain J31; E, strain J32; F, strain J33; G, strain J34; and H, strain J37.

3.2. Phylogenetic analysis

The 18S rRNA genes of microalgae in this study are accessible at the NCBI GenBank; J28 and J32 of *Chaetoceros* sp. are KF289814 and KF289816, J31 and J37 of *Chlorella* sp. are KF289815 and KF289811, J34 of *N. granulata* is KF289818, J33 of *Dunaliella* sp. is KF289817, J3 of *Heterocapsa* sp. is KF289812, and J18 of *A. tamarense* is KF289813. The obtained 18S rRNA gene sequences were used to construct a phylogenetic dendrogram to determine the relationships between microalgae strains and other microalgae genes registered in the NCBI (Fig. S2). The microalgae strains used in our study are identified in Table 1. The phylogenetic dendrogram of 18S rRNA genes of microalgae strains showed that the closely related genera *Nannochloropsis* and *Chaetoceros* corresponded to the class *Stramenopiles*, the closely related genera *Chlorella* and *Dunaliella* corresponded to the class *Viridiplantae*, and the closely related genera *Heterocapsa* and *Alexandrium* corresponded to class *Alveolata*. Accordingly, genomic taxonomy analysis could separate each microalga to taxonomy based on a phylogenetic dendrogram. However, genomic taxonomy analysis is costly and time-consuming compared to mass spectrometric taxonomy analysis.

3.3. Mass spectrometric taxonomy analysis and comparison of taxonomy based on mass spectrometry and the phylogenetic marker gene

Ion spectra of protein profiles obtained from 2000 to 20,000 Da (Fig. 1) that were identical with only minor shifts from triple measurements for each microalga were generated and used to construct a phylogenetic dendrogram (Fig. 2). This dendrogram based on mass spectra was different from the phylogenetic dendrogram

Table 1
Microalgae strains identified from a BLAST search of the NCBI database in our study.

Strain	Taxon	BLAST result (accession number)	Query cover (%)	Identity (%)
J28	*Chaetoceros* sp.	*Chaetoceros* sp. NMBguh003-2 (DQ886407)	100	100
J32	*Chaetoceros* sp.	*Chaetoceros* sp. NMBguh003-1 (DQ886406)	100	100
J31	*Chlorella* sp.	*Chlorella* sp. KMMCC C-185 (GQ122357)	100	99

J3	*Heterocapsa* sp.	*Heterocapsa* sp. HE04 (FJ549370)	100	99
J18	*Alexandrium tamarense*	*Alexandrium tamarense* ATHK (JF906994)	100	99

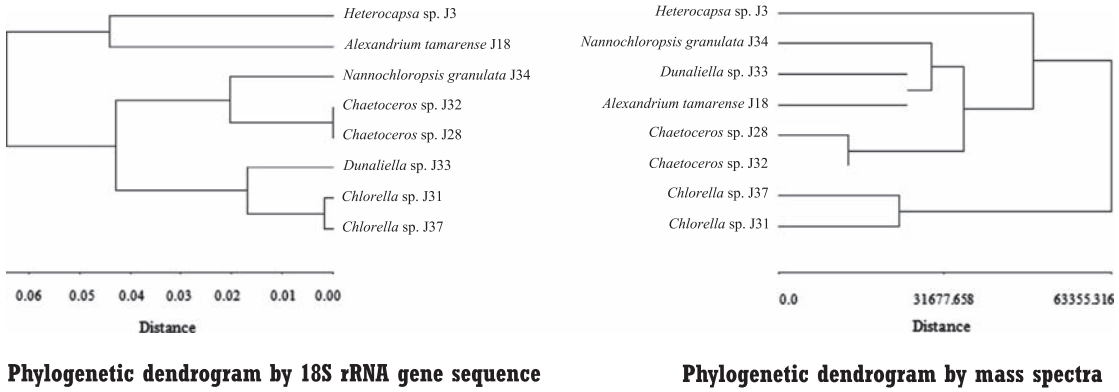

Fig. 2. Comparison between the 18S rRNA gene phylogenetic and mass spectral dendrograms for microalgae.

based on genomic taxonomy using the 18S rRNA gene sequence, and strains of the same genus were shown to be closely related (*Chlorella* sp. J31 and J37; *Chaetoceros* sp. J28 and J32). While genomic taxonomy bound closely related strains corresponding to each class in the phylogenetic dendrogram, MS-based taxonomy did not bind closely related strains corresponding to each class in the sequence-based dendrogram. The dendrograms based on mass spectra and the rRNA gene sequences were compared (Fig. 2). The MS-based dendrogram yielded relationships that were distinguishable at the taxonomic level of the genus. However, the dendrogram based on the rRNA gene sequences yielded relationships that were distinguishable at all taxonomic classification levels. Phylogeny by genotype is known to determine the taxonomy of microorganisms [15], and the restrictions of MS-based taxonomy have been previously described in a mini-review by Welker and Moore [6]. Interestingly our MS-based dendrogram positions the green alga of the genus *Dunaliella* (sample J33) with the dinoflagellate *Alexandrium* (sample J18), rather than in a clade with other green algae of the genus *Chlorella* (samples J31 and J37), as expected based on the sequence analysis. Utilizing MALDI-TOF MS with the construction of diverse microalgae MS profiles may resolve the discrepancy between sequence- and MS-based identification and prove to be an efficient method since it is more rapid and cost-effective than sequence-based identification. Currently, some databases providing protein MALDI-TOF MS libraries for bacteria with some eukaryotes are available, such as SARAMIS (AnagnosTec) and BioTyper (Bruker Daltonics); these databases have been used to rapidly identify bacteria and yeast from clinical samples [16]. Sensitivity tests demonstrated that the MALDI-TOF MS approach requires at least 10^4 cells of *Heterocapsa* sp. J3 and 10^5 cells of either *Chaetoceros* sp. J28 or *Dunaliella* sp. J33 to produce similar MS profiles containing all the abundant peaks.

3.4. Possibility of rapid identification of microalgae during HAB events using MALDI-TOF MS

Next, we sought to investigate the potential application of this method for identification of HABs. Microalgae were analyzed using MALDI-TOF MS to obtain highly abundant protein spectra. The obtained spectra from 2000 to 20,000 Da were used to construct a phylogenetic dendrogram with highly abundant protein profiles of microalgae strains; the strains were rapidly identified using MALDI-TOF MS. Though Lee and colleagues carry out dinoflagellates identification of protein profiling using MALDI-TOF MS [17], their analysis method is slower than our methods due to protein extraction phase. This MS-based method does not necessitate protein extraction and inactivation steps, and requires only a few minutes from sample collection and preparation to MS analysis and identification. Therefore, we suggest that this method can be used for rapid identification of dominant microalgae during HAB events in aquatic environments. MALDI-TOF MS can rapidly detect cyanobacteria and microalgae during HAB events in fresh water and ocean environments more rapidly than morphological and genetic identification. A previous study reported using MALDI-TOF MS to distinguish between pathogenic and non-pathogenic genotypes of the achlorophyllous microalgae species [18]. Thus the MALDI-TOF MS approach can be used to discriminate between toxic and non-toxic strains of the same species, or species of the same genus if MS databases including diverse toxic and non-toxic strains are first established. Additionally, MALDI-TOF MS may be able to provide rapid identification of microalgae or cyanobacteria in wastewater treatment facilities; however, we do not expect that this method would be applicable for complicated aquatic systems where specific microalgae are not dominant.

Identification of microalgae by morphology may be relatively simple, but classification of morphology for identification of microalgae requires expert knowledge of microalgae morphology; therefore, mistakes in the classification and identification of microalgae may occur. Taxonomic classification of microalgae can be performed by genotyping of ribosomal genes; however, this method is more expensive and time-consuming than identification of microorganisms by MALDI-TOF MS. Because MALDI-TOF MS will work only if the target microalga is present in high amounts, samples may be centrifuged and concentrated or the use of a plankton net may be helpful. Otherwise, Jadhav's method [19] to

enrich the target microorganism with specific culture media can be considered in order to increase the detection of specific target microalgae. Additionally classification and identification of microalgae based on the MALDI-TOF MS method can be performed with a user-friendly dedicated equipment and software, such as the BioTyper system. Based on our analysis, we have constructed a flowchart (Fig. S3) for rapid identification of microalgae from environments during HAB events.

4. Conclusion

In this study we described the MALDI-TOF MS-based method for monitoring the occurrence of HABs by rapid identification of harmful microalgae, as shown in previous studies for infectious bacteria [20] and achlorophyllous microalgae [18]. This rapid identification method, in combination with comprehensive profile databases of the highly abundant proteins of diverse toxic and non-toxic strains, could be effectively applied to identify eukaryotic microalgae or cyanobacteria during HAB events in fresh water and ocean environments. Furthermore, the use of MALDI-TOF MS could allow for identification of microalgae in HABs at reduced cost and in shorter times. Additionally MALDI-TOF MS profiling can be combined with other separation techniques, such as high-performance liquid chromatography and capillary electrophoresis, as demonstrated by Horká and colleagues, who analyzed the probiotic bacteria present in cow-milk using a combination of capillary electrophoresis and MALDI-TOF MS [21]. Therefore, MALDI-TOF MS combined with other separation techniques could be a useful tool to rapidly identify many microorganisms (i.e., in addition to microalgae in HABs) in the environment. In conclusion, MALDI-TOF MS can be applied for direct analysis of microalgae during a HAB event in an aquatic system by measurement of harmful microalgae.

Molecular identification

ABSTRACT

Flame retardants (FRs), a class of commonly used chemical additives in consumer products such as polyurethane foams, are well known for their persistence in the environment, bioaccumulation and potential toxicity [1]. In order to address the potential health concerns and environmental impacts associated with the wide-spread use these chemicals, it is essential to identify them efficiently in the environment and consumer products. Raman spectroscopy (RS) offers an attractive option for the non-invasive, in-situ identification of flame retardants in a variety of sample formats [2–4]. RS based chemical identification relies on the availability of spectral libraries for identification through spectral matching with reference chemicals. Here we present the application of Raman spectroscopy for identifying FR additives in select consumer products using an acquired spectral library of commonly used FRs. The RS based method described here enables simultaneous identification of multiple components within a sample, which can offer important insights into the sources of FR contamination, in addition to identification of the FR component itself. The availability of Raman spectral library of commercially used FRs, such as the one presented here, will facilitate the identification of these chemicals in consumer products.

Published by Elsevier B.V.

1. Introduction

Since establishment of the Technical Bulletin in 1975 [5], by which the California Bureau of Electronic and Appliance Repair, Home Furnishings and Thermal Insulation (BHFTI) regulated the flammability of upholstered furniture and bedding products, a wide variety of flame-retardants (FR), especially brominated flame-retardants (BFR), have been used by US manufacturers for decades to comply with the flammability standards outlined in the bulletin. Consequently, demand for FR chemicals in the US has increased by 4.6% each year, and is expected to reach 938 million pounds in 2016 according to the Global Information Inc. [6] At the same time, numerous studies have shown that the wide spread use of FRs is not safe as they pose potentially significant health risks [1]. As early as 1973, there were reports of adverse health effects resulting from the contamination of animal feed with polybrominated biphenyls (PBBs) in Michigan, and as a result PBBs were banned from production [7,8]. Over the last decade a number of widely used FRs including polybrominated diphenyl ethers (PBDE) such as penta- and octa-brominated diphenyl ethers (BDE), which are known for their toxicity effects [9], have either been banned by the state government or voluntarily phased out by US manufacturers. To further reduce US manufactures' reliance on synthetic flame retardants, a new flammability standard TB117-2013 was issued recently by BHFTI [10]. TB117-2013 requires all upholstered furniture to pass a smolder resistant test rather than an open flame test [10]. In other words, US foam manufacturers are no longer required to add FR chemicals to pass the flammability test. Despite the restrictions on production and usage of toxic FRs, consumer products previously treated with banned chemicals are still in use. In addition, the proposed alternative FR species, such as tris(1,3-dichloro-2-propyl) phosphate (TDCPP), also pose significant environmental and health hazards [11]. As a result of these concerns, it has become necessary to monitor the prevalence and distribution of these chemicals in various consumer products and the environment in order to better understand and thus mitigate any associated health and environmental impacts.

Numerous studies have been conducted to characterize flame retardants both in the environment and in consumer products using a variety of different techniques. Kierkegaard et al. identified decabromodiphenyl ethane, in sewage sludge, sediment, and indoor air using high-resolution mass spectrometry (MS) and quantified it with low-resolution MS [12]. Guardia et al. have reported a method for determining the concentration of PBDEs in multiple FR mixtures using gas chromatography/mass spectrometry (GC/MS) [13]. Stapleton et al. used GC/MS coupled with a portable X-ray fluorescence analyzer (XRF) to identity FR chemicals in polyurethane foam collected from baby products [14].

While Webster et al. analyzed the presence of deca-BDE in indoor dust samples using scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM/EDS) as well as a micro-XRF [15]. MS based methods for the identification of FRs are not applicable for chemicals which are thermally labile, such as hexabromocyclododecane (HBCD) [16]. Moreover, MS based techniques often rely on invasive and time consuming sample preparation steps in order to provide molecular level information. Fluorescence and electron microscopy techniques offer elemental and morphological information, but lack FR specific molecular identification. Therefore, an analytical approach that offers direct, non-invasive molecular-level identification of FR chemicals in consumer products and in environmental samples with minimal sample preparation would be of considerable interest.

Raman spectroscopy has been widely used as a non-invasive analytical tool for the characterization of both organic and inorganic materials since its inception in the 1930s [17]. The molecular specificity of Raman analysis can be combined with high spatial resolution afforded by a microscopy platform and the resulting technique is referred to as Raman micro-spectroscopy (RMS), which is a highly versatile tool for a broad range of analytical applications. In particular, access to spatially resolved chemical information without extensive sample preparation or water interference makes the RMS technique appropriate for a variety of sample formats [17,18]. We have previously demonstrated the application of RMS for identifying individual fungal spores [19] as well as FR species in environmental samples [2,3]. Kikuchi et al used Raman spectroscopy for the analysis of brominated FRs in electrical and electronic equipment [4]. Raman spectroscopy based chemical identification involves qualitative/quantitative spectral matching of an unknown spectrum with a spectral library of reference chemicals, and hence relies on the availability of well-documented spectral libraries. Raman spectral libraries related to various applications have been created in order to facilitate the increasing use of Raman spectroscopy in a variety of fields including forensic science, archaeology, art, medicine, solid-state physics, and pharmaceutical chemistry. Given the suitability of RMS for environmental analysis, it is necessary to create tailored spectral libraries for particular applications such as the detection/identification of specific environmental contaminants. Here we present the acquisition of Raman spectral library of FR chemicals commonly used in consumer products. The acquired spectral library is subsequently used to identify of FR additives in representative consumer items. This study illustrates the application of Raman spectroscopy for the identification of FR additives and polymer matrices associated with consumer products through the matching of unique spectral signatures. Simultaneous identification of FR with the associated polymer matrix is essential for linking FR contaminants to specific consumer materials, which is an important step towards source attribution. Creation of a reference spectral library for commonly used FRs is essential for the RS based identification of FRs in a broad range of samples.

2. Material and methods

2.1. FR materials

FR reference chemicals for the creation of FR specific spectral library were acquired from various commercial sources. These include Sigma-Aldrich, St-Louis, MO; Pfaltz and Bauer, Waterbury, CT, and AccuStandard, New Haven, CT. The various FR species analysed in this study are—decabromodiphenyl ether (deca-BDE,); hexabromodiphenyl ether (hexa-BDE); 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB); bis(2-ethylhexyl)-tetrabromophthalate (TBPH); tris(1,3-dichloro-;2-propyl) phosphate (TDCPP); tris(2-chloroethyl) phosphate (TCEP); hexabromocyclododecane (HBCDD); tetrabrom obisphenol A (TBBPA); brominated polystyrene (Br-PS); tris(2-chloropropyl) phosphate (TCPP); triphenyl phosphate (TPP) and antimony trioxide (Sb_2O_3). Reference spectrum of pentabromodiphenyl ether (penta BDE) was acquired from polyurethane foam containing 5.3% Penta-BDE as measured by bulk GC–MS [20] and was validated by comparison with penta-BDE spectrum available in the literature [21]. Melamine spectrum was available from in-house Raman spectral libraries.

2.2. Consumer materials

Representative consumer materials for this study were collected from commonly used consumer items, which are typically known to contain FRs. These included materials from a VCR and a computer monitor (CRT) casings as well as the fabric from a car visor. The exact manufacture dates of these items were not known, but they were estimated to have originated between the years of 1985–2005 and had been subjected to extensive use. Additional consumer materials included several samples of polyurethane foam (PUF)—these samples were kindly provided by Dr. Thomas Webster (Boston University) and Dr. Heather Stapleton (Duke University) and had been collected as part of their study on FR exposure among gymnasts [20]. Approximately 1 mm^2 sized samples were extracted from each material using a clean scalpel blade. The samples were then placed on double-sided adhesive carbon substrates mounted on standard aluminum SEM stubs.

2.3. Confocal Raman spectroscopy

Raman spectroscopy measurements were performed using two commercially available micro-Raman setups, each equipped with a near-infrared 785 nm diode laser—(1) Senterra Dispersive Raman microscope (Bruker Optics Inc., Billerica, MA), and (2) Renishaw inVia Raman microscope (Renishaw Plc., Old Town, Wotton-under-Edge, Gloucestershire, U. K.). On the Senterra Raman microscope, all spectra were recorded and analyzed using OPUS 6.0.72 dll 3.0.1.1 software (Opus Software Inc., San Rafael, CA) with a spectral resolution of $\sim$3–5 cm^{-1}. The Senterra system is equipped with Sure_Cal® function for continuous automated laser and Raman frequency calibration using an integrated neon laser light. On the Renishaw system, GRAMS WiRE software package (Galactic Industries Corp., 395 Main St., Salem, NH) was used for instrument control and data acquisition. The spectral resolution was $\sim$2.5 cm^{-1}. Wavelength calibration was performed periodically using neon laser light. On both systems a silicon wafer spectrum was acquired on a daily basis as a quality control step to monitor and correct for minor wavelength offsets. Samples were excited using 1–100 mW of 785 nm laser light focused onto the sample typically through a 20× or 50× objective. Signal acquisition times varied between 60 and 120 s per measurement. Spectra for the liquid FR samples were acquired using a Macrokit (Renishaw Plc) sample holder coupled to the Renishaw microscope, which enables spectral acquisition in the liquid phase. Raw spectra were processed to eliminate dark noise and contributions from the spectrometer's optical parts. The spectra were baseline corrected using a Fixed Multi-point Baseline Correction algorithm (GRAMS/AI version 9.1) or a Concave Rubberband Correction method (Opus Software Inc., San Rafael, CA) and smoothed using Savtisky–Golay smoothing algorithm (GRAMS/AI version 9.1). Preprocessed spectra of the reference FR samples were compiled into a spectral database using the GRAMS Spectral ID software from Thermo Fisher Scientific Informatics. Molecular identification of sample composition was accomplished through spectral library searches using both commercial and laboratory acquired Raman spectral libraries. Spectral library searches were performed using

an automated correlation based search algorithm (GRAMS Spectral ID, version 9.1). The quality of the match between the sample and the various library spectra was evaluated based on visual inspection of the spectra as well as calculated Hit Quality Index (HQI) values, which ranged from 0 to 1, with 0 representing a perfect match.

3. Results and discussion

3.1. Acquisition of FR spectral library

In order to identify an unknown chemical through spectral library search it is necessary to use a reference spectral library of relevant chemicals against which the unknown spectrum can be evaluated for a potential match. Fig. 1 shows the acquired Raman spectra of a number of FR reference chemicals commonly found in consumer products. The spectral range shown in Fig. 1 extends from 100 to 2000 cm^{-1}, where majority of the FR related spectral features are typically located. Each FR species displays a unique spectral fingerprint, which distinguishes it from other members of the FR family and can be used to identify it. This is true even for closely related FRs such as PBDEs, which differ in terms of the number and arrangement of Br ions per molecule. For example, hexa- and deca-BDE (containing 6 and 10 Br ions, respectively) both have peaks in the 100–250 cm^{-1} region (Fig. 1), typically associated with brominated FRs [22]. However, each can be individually identified based on their unique spectral features. Deca-BDE is characterized by triplet peaks centered at ~224 cm^{-1}, while hexa-BDE has a broad peak at ~212 cm^{-1}. In both cases, the general peak position is indicative of the C-Br bond [22], but the detailed features are representative of their unique molecular structure. Spectral feature corresponds to distinct molecular vibrations and as such are characteristic of the analyte's unique molecular and structural composition.

Since the ban on use of various BFRs, phosphorus based flame retardants (PFRs) have often been proposed as potential alternatives. PFRs can be broadly classified into three groups i.e. inorganic, organic and halogen containing PFRs [23]. Raman spectra of some of the commonly used PFRs are shown in Fig. 1. The three chlorine containing PFRs (TCEP, TCPP, TDCPP) all show prominent peaks in the 600–800 cm^{-1} region typically associated with C–Cl stretching [22]. As with BFRs, the individual PFR species are clearly distinguishable based on their unique spectral signatures. The acquired FR spectral library, shown in Fig. 1, highlights the utility of Raman spectral analysis for distinguishing between broad classes of FRs such as BFR versus chlorinated PFR, as well as identifying individual FR species. This will be illustrated in greater detail in subsequent sections, where we present the identification of FR additives in representative consumer products.

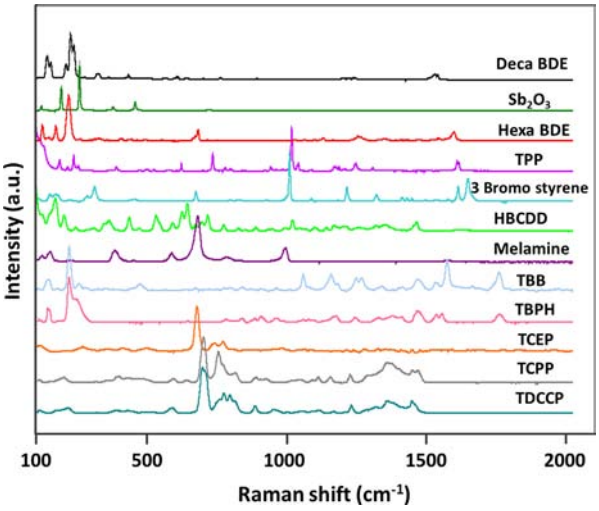

Fig. 1. Reference Raman spectra of FRs commonly present in consumer products.

3.2. Identification of FR additives in polyurethane foam

Polyurethane foam is one of the most extensively used polymer materials, with widespread applications in furniture and a variety of other consumer products. The widespread use of PUF makes it potentially a significant source of PUF related FR contamination in the environment. In recent years, Stapleton et al and Carignan et al. have investigated this particular class of FRs in terms of their presence in consumer products and the environment [14,20]. Here we present RMS based identification of FRs in PUF samples that have been previously characterized by Carignan et al. using gas chromatography negative chemical ionization mass spectrometry (GC/ECNIMS) and X-ray fluorescence spectroscopy (XRF) [20]. Given the detailed analytical information already available about these samples, they represent a unique opportunity for exploring the feasibility of RMS based identification of FRs in consumer products.

Table 1 lists the PUF samples examined in this study along with the associated FRs and their respective concentrations as reported by Carignan et al. [20]. Carignan et al. identified TDCPP to be the primary FR in PUFs 7 and 8, with measured concentrations of 6.6% and 5.6%, respectively [20]. RMS analysis of PUFs 7 and 8 is shown in Fig. 2 along with the reference spectra for melamine and TDCPP. Melamine was identified as a major constituent in both PUF 7 and 8 based on spectral matching analyses. Melamine and its derivatives are classified as non-halogenated flame retardants and have been proposed as viable alternatives to Penta-BDE [23–25]. It is currently used in flexible polyurethane foam in concentration ranging from 30% to 40% melamine per weight of the polyol and is typically applied as a crystalline powder [25]. Strong melamine specific peaks (967.3 cm^{-1}, 984 cm^{-1}) evident in PUF 7 and 8 spectra suggest significant presence of melamine in the foams. This is consistent with the typical concentrations of melamine reported in the literature (30-40%) [25], which is considerably higher than the TDCPP concentrations (< 10%) reported by Carignan et al. [20]. In addition to melamine, PUF 7 spectrum also showed evidence of TDCPP along with peaks related to the polymer matrix (600–1800 cm^{-1}) (Fig. 3). Polymer related peaks representing the PUF matrix were common to all the PUF samples examined in this study.

The two individual PUF 7 spectra shown in Figs. 2 and 3 were acquired at two different locations on the sample and are spectrally distinct. The observed differences in spectral features correspond to differences in molecular composition at these two sites and as such are indicative of spatial heterogeneity in sample composition. The PUF 7 spectrum shown in Fig. 2 is characterized by strong melamine peaks suggestive of a melamine hotspot. The observed heterogeneous distribution of melamine in PUF 7 is

consistent with the application of melamine as crystalline powder, which can create localized hotspots.

A particular advantage of RMS analysis is that it enables simultaneous identification of multiple constituents in the sample by probing the entire Raman active compositional profile. For instance, in case of PUF 7, we were able to identify several components including melamine, TDCPP and the polymer matrix based on the acquired spectrum. In Raman analysis, spectral response is determined by concentration and Raman cross-section of the constituent molecular bonds. Therefore, the spectral response can be dominated by signals from constituents with higher concentration and/or Raman cross-section. An example of this can be seen in case of PUF 6, which was reported as containing multiple FR species—TPP, TBB and TBPH [20]. Fig. 4 shows acquired spectrum of PUF 6 along with reference spectra of the three constituent FR species. The PUF 6 spectrum is dominated by peaks arising from the polymer matrix, which is the primary constituent. In comparison, the FR related peaks are less prominent. TPP is identifiable based on two sharp peaks located at 1005 cm^{-1} (P–O–C anti-symmetric stretch in organ-ophosphorus compounds) and 3063 cm^{-1} (=C–H stretch of the benzene ring) [22]. TBB and TBPH

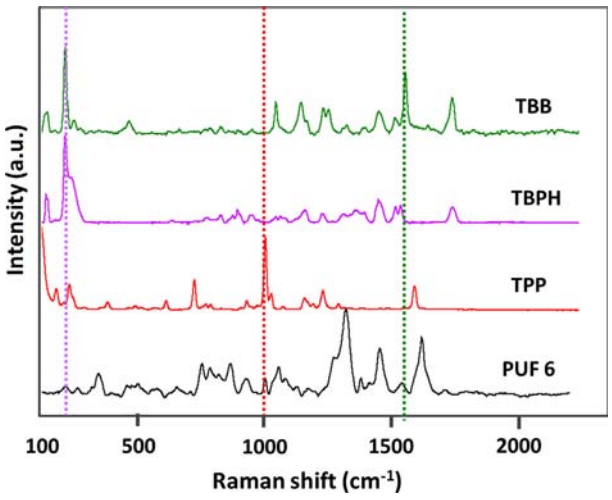

Fig. 4. Raman spectrum of the PUF 6 foam sample showing spectral matches with reference Raman spectra of 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB), bis(2-ethylhexyl)-tetrabromophthalate (TBPH), triphenyl phosphate (TPP). Dotted green, purple and red lines identify positions of the strongest peaks for TBB, TBPH and TPP, respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

both show a sharp peak around 216 cm^{-1}, indicative of the C-Br bond [22]. In addition to the 216 cm^{-1} band, TBB also has a sharp peak at 1555 cm^{-1} (benzene ring stretch), which distinguishes it from TBPH [22]. All of these FR related peaks are evident in the PUF 6 spectrum though they are less prominent compared to the PUF peaks. In addition to the above mentioned FR species, PUF 6 also showed some localized presence of melamine.

The three remaining PUF samples (PUF 3, 4, and 5) were all reported as containing TPP and Penta-BDE in varying concentrations, Penta-BDE being the dominant FR species [20]. Fig. 5 shows acquired spectra of the three PUF samples. All three spectra have a sharp peak at 1005 cm^{-1} from TPP. They also contain singlet and doublet peaks in the 100–250 cm^{-1} region, which are characteristic of penta BDE [21]. Similar to PUF 6, these spectra also show strong response from the polymer matrix.

In summary, RMS analysis of the PUF samples confirmed the presence of FR species previously identified by Carignan et al [20]. In addition, RMS analyses also identified the presence of melamine, not reported by Carignan et al [20]. These results also illustrate the simultaneous identification of multiple constituents in a sample, which is a particularly advantageous in terms of contaminant and source attribution in environmental monitoring. This is discussed further in the following section where we present RMS based characterization of select consumer products, simultaneously identifying both the polymer matrix and the associated FR species.

3.3. Identification of FR species and polymer matrices in consumer products

Consumer products are a major source of FR related contamination, particularly in indoor environments [15,26–29] where migration of FRs from consumer items into the surroundings can take place via volatilization and/or physical weathering of products [15,30,31]. Several studies have highlighted the necessity of linking FR contaminants in the environment to their original sources [15,26]. In case of mechanical transfer of FRs via physical weathering of products, FR chemicals are often transferred in association with the product matrix. We have previously reported the identification of FRs together with the associated polymer matrix, in residential dust samples, which is suggestive of

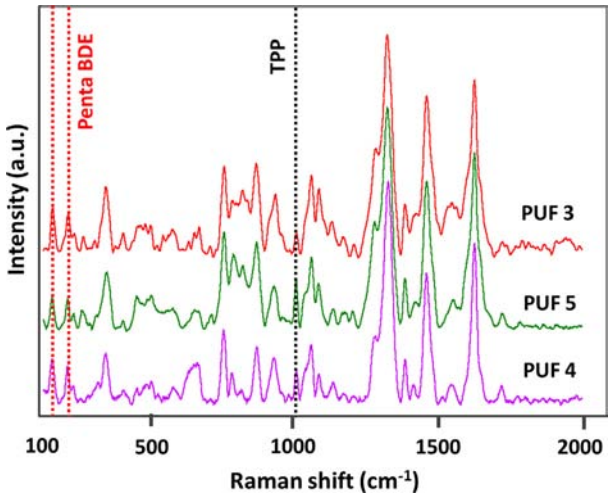

Fig. 5. RMS analyses of foam samples from three different sources with peak assignments for the identified FR species, penta BDE and triphenyl phosphate (TPP). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

mechanical transfer of FRs from consumer items into the environment via physical weathering [2,3]. Linking FR contamination to a specific consumer item necessitates knowledge of the product composition i.e. FR species and polymer matrix associated with the item. As mentioned earlier, Raman spectroscopy is well suited for this type of multicomponent analysis. To illustrate this point, we present RMS based characterization of three consumer items (car visor covering and, casing materials from a VCR and a computer monitor) with the goal of identifying the polymer matrices and the associated FR species.

Fig. 6 shows acquired spectra of the three consumer materials along with reference spectra of the polymer and FR constituents identified through spectral library search. In all three cases, both the polymer matrix and the associated FR species are readily identifiable based on their unique spectral signatures. The car visor material consists of two FRs, deca-BDE and antimony trioxide, incorporated into a polyvinyl chloride (PVC) polymer matrix (Fig. 6a). The VCR casing material was identified as high-impact polystyrene (HIPS) with deca-BDE as the FR component (Fig. 6b). The polymer and FR components of the CRT casing were determined to be polycarbonate (PC) and TPP, respectively (Fig. 6c). Product specific spectral fingerprints offered by the RMS method

described here can be used for FR identification and source attribution in a variety of environmental samples and consumer products.

4. Conclusion

The results presented here highlight the utility of Raman spectroscopy as a non-invasive analytical tool for the identification and source attribution of FRs in consumer products and environmental samples. RS based identification relies on the availability of relevant spectral libraries of reference chemicals in order to accomplish chemical identification through spectral matching. We have compiled a reference spectral library of several commonly used FR chemicals to facilitate the identification process. The acquired spectral library has been used successfully to identify FR additives in a selection of commercially used polyurethane foam samples. The foam samples had been previously characterized by GC–MS as part of a separate study [20]. Our results are in excellent agreement with the previous study and also offer additional information such as the presence of melamine, another FR species. We have also identified polymer matrices and FR species associated with three commonly used consumer items to illustrate the applicability of RS for source characterization.

Microelectrodes arrays (MEA)

ABSTRACT

Boron doped diamond microelectrodes arrays (MEA) have been prepared in order to be used as new amperometric sensors in electrochemical cells for HPLC detectors. The following parameters were studied: number and diameter (15–40 μm) of the electrodes, distance between them (50–240 μm), and effect of the flow rate (0.1–3 mL/min). It was thus possible to find the optimum value of the parameters which give a good signal/noise ratio in the chronoamperometric responses, with a size of the electrochemical sensors as small as possible.

1. Introduction

Electroanalysis is a powerful tool for analytical chemistry, especially considering flow analysis and amperometric HPLC detection. Forty years ago, Adams and Kissinger have started their contributions to the development of the electrochemical (EC) detection associated to liquid chromatography (LC) [1]. The principle of these detectors is based on an electron transfer reaction during the oxidation/reduction process of a target analyte, after its separation in a chromatography column, at a millimetric/centimetric solid electrode for the major part of the modern systems [2,3].

The use of these detectors in HPLC is attractive because of their qualities: selectivity and sensibility. Generally these detectors are not very expensive; they are composed of a simple efficient potentiostatic electronic part, associated with a high gain current follower and a sensor: a three-electrode flow-cell, which is the sensitive part of the detector. The principle of the amperometric detectors is to apply an appropriate electric potential between the reference and the working electrode and to measure the faradaic current resulting from the analyte reaction at the working electrode. This current is proportional to the concentration of the sample after baseline correction of the residual current. Several kinds of materials were used in those cells for the working electrode considering their respective electrochemical window and stability: carbon paste, gold, platinum, silver, glassy carbon, etc. In the active volume of a cell, three mass transport mechanisms exist: convection far from the electrode surface, migration and diffusion close to the active surface of the working electrode. A number of works were done to simulate these mass transfers and provide interesting ways to improve the design of the electrochemical cells [4,5]. In a LC–EC flow-cell, it is assumed that the hydrodynamic regime is controlled by the competition between the convective part and the diffusional part. Péclet adimensional number is the suitable parameter for the quantification of the ratio of the convection transport rate to the diffusion transport rate.

In addition, microelectrodes [6] were widely studied for their use in analytical electrochemistry, because of the increase of the current density by the hemispherical diffusion effect, leading to a better signal/noise ratio and to a short response time [7]. However, if the current density may be high on one microelectrode, when the concentration of the sample is low the total current remains very small and generally arrays of microelectrodes are used to get an amplification of the current measured for signal treatments [8–11]. Theoretical studies were led to propose the best arrangement of the microelectrodes in the arrays. Usually done in static medium, they give a good idea for the distances between microelectrodes to get the different signal regimes for further studies in continuous flow [12].

In 1987, it was shown by Pleskov et al. [13] that synthetic diamond doped with boron (BDD) becomes conductive and offers a high overpotential for oxygen or hydrogen evolution. There is an important focus on the development of this material which could be attributed to its numerous qualities: chemical inertness, mechanical durability, low background current and wide electroactive window.

For that reason, it has been proposed as an anodic material for the oxidation of organic pollutants [14]. In addition, it is easy to clean in situ [15].

The research of the lowest concentration detection is a constant goal in HPLC. This goal can be reached by combining the qualities of the diamond material and the array of microelectrodes in an amperometric detector. The parameters which must be taken into account to manufacture optimized BDD microelectrodes array (MEA) for HPLC amperometric detection are studied in the present work.

To our knowledge, the first operational application of microelectrodes for the use in HPLC was done by Kissinger and colleagues [16]. An interdigitated array of microelectrodes was used to enhance the current obtained in a redox cycling process in a flow stream at the output of an HPLC column. The results show a higher current density and lower noise due to the size effect of the microelectrodes array used, compared to a macro-electrode with the same geometric area.

The interest of microelectrodes has met a fast development, the microdisc electrodes were widely used to study rapid electron transfer processes and theoretical models were proposed for the mass transport on different shapes of microelectrodes in static cells [17,18].

More and more techniques were employed to machine arrays of microelectrodes, for example, sealed wires in epoxy with a polishing of the surface [19], easy to produce but with a poor reproducibility; arrays have been constructed on silicon substrates using electron beam lithography [20], or multilayer systems with conductive carbon ink laid on a polymer surface and covered by an insulator film. The electrodes are obtained by laser drilling, leading to small holes through the insulator down to the carbon ink [21]. This process offers numerous possibilities to modify the diameter of the electrodes, their number and their spacing. It allows the manufacturing of different arrays and so, verifying if the tests are in agreement with the theory.

The first use of these arrays is for cyclic voltammetry with the electrodes in a static cell with fast-scan technique [17]. However, Aixill et al. [22] demonstrated the good agreement between the theory to predict the current at a micro-strip electrode taking into account the lateral diffusion, normal diffusion and axial convection and the experimental results obtained with a home-made cell with platinum strips as working electrodes and the oxidation of tris(4-bromophenyl)amine in continuous flow-cells. The results show an enhanced mass transport characteristic compared with equivalent macro-electrodes. In practical devices, the machining of the micro-arrays introduces a finite thickness of the insulating layer or a recessed geometry of the conductive part, responsible of the local perturbation of the flow. A simulation of the effect was realized [23] for the two cases with the strips across the flow and for different linear speeds of the liquid. For recessed micro-band electrodes, the formation of eddies inside the cavities led to an increase of a stagnant flow at the bottom which prevents the renewal of the electro-active species. The industry of semiconductors has introduced new technologies to produce thin insulating films with hard materials; the applications of these techniques allowed the production of arrays of microelectrodes with the recess depth of 500 nm [24]. In reference with a previous work of Heinze [25] for recessed single microdisc electrodes, a new equation has been proposed [24] for the steady state current:

$$I_{lim} = \pi a^2 nFD\frac{C}{a+h} \quad (1)$$

where a is the radius of the microdisc; n, the number of electrons exchanged; F, the Faraday constant; D, the diffusion coefficient; h, the height of the recess and C the concentration of the electro-active species.

If the electrode may be considered as a single inlaid microdisc, equation can be used as follows:

$$I_{lim} = 4anFDC \quad (2)$$

Several arrays were made with different radii, from 2.5 μm up to 100 μm and distances between the electrodes from 30 μm to 750 μm. In static mode and cyclic voltammetry, larger electrodes produced a current more important than predicted by Eq. (1) because that equation is only valid for microelectrodes. As expected, the current obtained from calculations and from experiments is similar when the distance/radius ratio is large [24].

The chemical vapor deposition (CVD) of diamond and the possibility to introduce a p-type dopant during the growing process of diamond provide a material which becomes conductive with the physical properties of diamond. It was very attractive to use this material in electroanalysis. Several hundreds of reviews [26–28] were published on applications of these electrodes in cyclic voltammetry for the analysis of pesticides, herbicides, pharmaceutical products [29–31]. The conductive diamond was also used to manufacture electrodes for electrochemical detection in HPLC and flow injection [32–38] electrochemical reactions [39].

The applications were extended to arrays of microelectrodes [39,40,41]. The techniques employed for manufacturing the diamond arrays of electrodes where more or less sophisticated, from photolithography up to pattern the isolation surface with a powerful laser beam [42]. Multi-layers arrays were obtained by the deposition of conductive and non-conductive diamond on a solid substrate. 0.6 μm electrodes were obtained by etching with an oxygen/argon plasma process [43].

It was interesting to investigate the possibility to combine the properties of the BDD with the principle of microelectrodes as fabricated by Fujishima and colleagues [36,40] to manufacture new sensors for HPLC.

In this paper, the parameters which drive the responses of the detector were studied to provide a cell for electrochemical detection in HPLC.

2. Experimental

With HPLC, the sensor works in continuous flow, to avoid a mixture of the products separated in the column. The volume of the cell must be as small as possible (less than 5 μL); the classical flow rate was set at 1 mL/min, which roughly led to a velocity of the flow of 1–1.5 m/min in the cell considering the cell geometry.

2.1. Chemicals

The electrochemical tests were mainly realized using hydroquinone as a model analyte related to interesting molecules separated through HPLC.

Quinone/hydroquinone redox functional group is encountered in many natural or synthetic biological, pharmaceutical and environmental important analytes (catecholamine neurotransmitters, ubiquinone coenzymes, emodine pharmaceutical agent, chloranil analog pesticides, etc.). The solutions were prepared with the eluent for chromatography: 8% CH_3CN in a 10^{-3} M solution of $LiClO_4$ (Sigma-Aldrich, France). The solutions were prepared every day and kept in an ice bath. The water (resistivity: 18 MΩ cm) was obtained from a Milli-Q apparatus (Millipore, France).

2.2. Apparatus

Electrochemical experiments were performed with an Eldec 105 (Precision Instruments, Marseille, France) amperometric detection unit. The three-electrode cell of the detector is shown

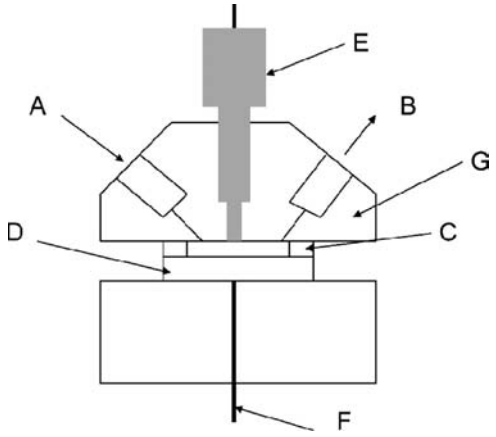

Fig. 1. Electrochemical flow-cell fitted with a BDD microelectrodes array as the working electrode: A: inlet, B: outlet, C: seal, D: diamond microelectrodes array, E: reference electrode, F: contact for working electrode, G: auxiliary electrode.

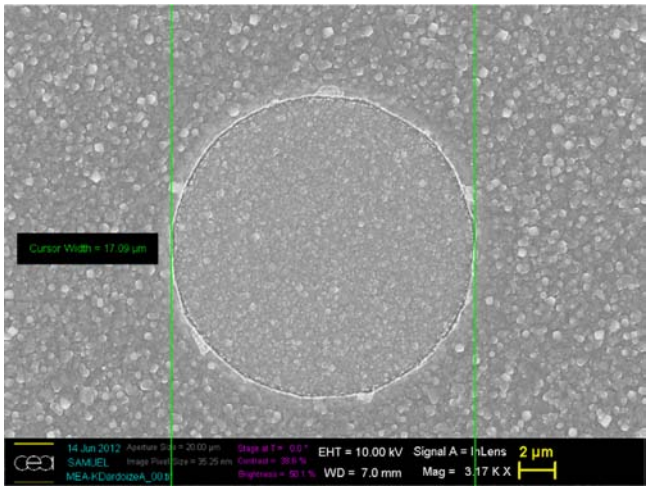

Fig. 2. Electron microscope picture of one microelectrode. Diameter of the BDD electrode: 17 μm, thickness of the insulator: 300 nm.

in Fig. 1. It has been adapted to receive the BDD electrodes array as working electrode, an Ag/AgCl reference electrode and a stainless steel counter electrode. The inlet and outlet of the flow and a hole for inserting the reference electrode are located at the upper part of the cell. The inlet and outlet diameters are: 0.4 mm and the channel height is about 50 μm. The potential of the working electrodes was 0.7 V vs Ref for all the experiments in order to investigate hydroquinone functional group oxidation process (the standard potential of the quinone/hydroquinone redox couple is about 0.5 V vs Ag/AgCl). The chromatography experiments were carried out using a Dionex pump (Montigny le Bretonneux, France), an injection valve Negretti and Zambra (UK), a 15 cm column, 4.6 mm inside diameter, C 18.5 μm Waters Symmetry. The chromatograms were directly recorded on a Kipp and Zonen BD 111 recorder or a Shimadzu CR 6 A integrator.

2.3. Arrays of electrodes

Several arrays of microelectrodes were manufactured in accordance with our drawings by the Commissariat à l'Energie Atomique (CEA, Saclay, France) to investigate the problems which arise with the use of the microelectrodes in a continuous flow. The manufacturing procedure was described elsewhere [44], and may be summarized rapidly: on a p-Si boron-doped substrate, a conductive boron-doped diamond film was grown using microwave plasma chemical vapor deposition. Then, non-conductive diamond was deposited to cover the first film to produce an insulator. Finally, this last layer was patterned with a laser beam to obtain the arrays of microelectrodes through the insulator down to the conductive diamond. The sensor (15×15 mm^2 geometrical area, 1.5 mm thick) was placed in the cell described in Fig. 1. A seal is used to insure the water-tightness between the upper block of the cell and the array, a Kel-F block with a hole to get the contact with the array. A film of indium/gallium alloy was laid on the back of the silicon substrate under the array in order to have an ohmic electric contact. The two parts of the cell were screwed together to compress the seal.

3. Results

3.1. Tests with one microelectrode

A single microelectrode with a diameter of 17 μm was prepared and examined by Scanning Electron Microscopy (see Fig. 2) in order to check the quality of the preparation procedure. From SEM experiments, it was shown that the thickness of the diamond insulator was about 300 nm.

The 17 μm microelectrode was inserted in the cell of the electrochemical detector and a chromatography test was realized by the injection of 20 μL of a solution which contains 18 μg of hydroquinone. A peak of 0.8 nA was obtained with a retention time of 5 min with our conditions, a good signal/noise ratio and a fast equilibration time of the electrode, less than observed on millimetric BDD electrodes.

Another single disc microelectrode with a diameter of 40 μm was prepared for studying its voltammetric response. A 3-dimension AFM picture and a schematic profile of that electrode are given in Fig. 3A. As the ratio h/a is very small (about 0.01), Eq. (2) may be used, instead of Eq. (1). The radius, a, of the inlaid microdisc electrode may be calculated from the measurement of steady state limiting current I_{lim}. The cyclic voltammogram shown in Fig. 3B was performed with ferrocenemethanol 1 mM in phosphate buffer saline solution with a scan rate of 5 mV s^{-1}. From Eq. (2), one can calculate the experimental radius $a \approx 20$ μm, in agreement with the AFM image (Fig. 3A). It can be established from that behavior that the insulating diamond layer has no pinholes defects.

3.2. Tests with arrays of microelectrodes

A simple idea was to increase the number of electrodes in order to inject lower quantities of product and increase the signal.

Several arrays were manufactured, suitable for the geometry of the electrochemical cell. As can be seen from Fig. 4, very regular hexagonal arrangements of electrodes could be obtained. On the center of a multi-layer piece as described previously, an array was machined: about 16,000 electrodes with a diameter $\Phi = 2a = 15$ μm, with a distance $d = 45$ μm between the electrodes ($d/a = 6$), were arranged in a circle with a diameter of 6 mm. This regular arrangement gave an active surface of around 2.8 mm^2. After an equilibration time of 12 min, a sensitivity of 0.1 nA/FS (Full Scale) was reached on the detector with a flat base line; the injection of 90 pg of hydroquinone in 20 μL (corresponding to a concentration of 4×10^{-8} mol L^{-1}) gave a peak of 0.03 nA with a signal/noise ratio of 30/1 (Fig. 5).

3.3. Study of the arrays geometry

In order to enhance the sensibility of electrode arrays and get the best signal/noise ratio, several parameters have to be

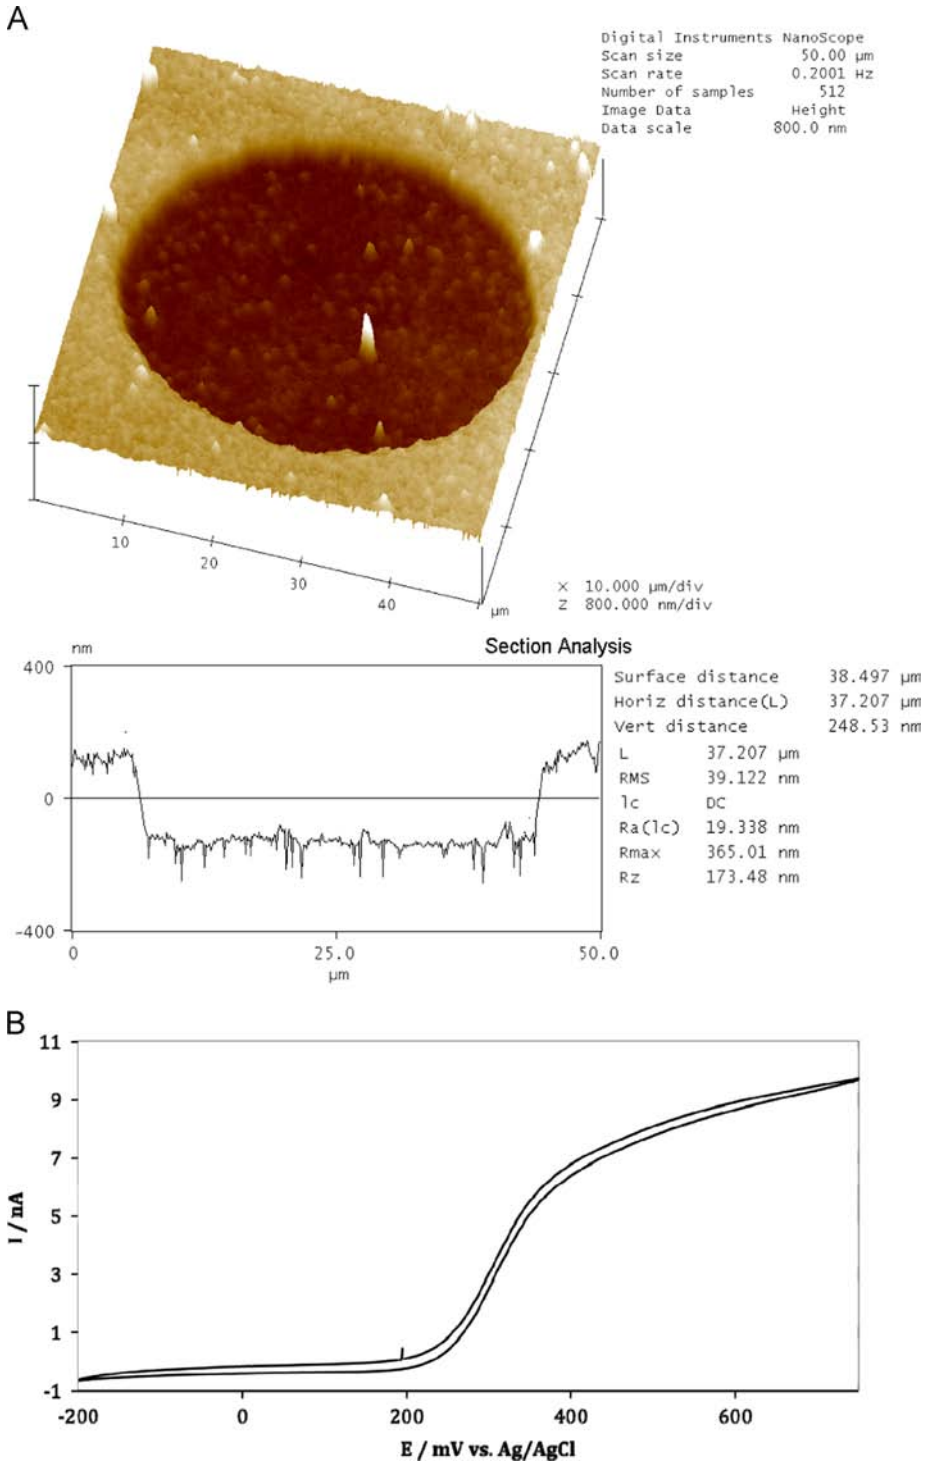

Fig. 3. Study of a single 40 µm BDD microelectrode (A): AFM picture and schematic profile of the recess of the electrode. (B): cyclic voltammetric response. Ferrocenemethanol 1 mM in phosphate buffer saline solution with a scan rate of 5 mV s^{-1}.

studied: number of electrodes, diameter of the electrodes, distance between the electrodes and effect of the flow rate.

3.3.1. *Distance between the electrodes*

In our cell, a flow rate value of 1 mL/min was chosen, corresponding to a velocity of the flow inside of the cell around 1.5 m/min, taking into account its volume (4.5 µL), whilst most of the works on microelectrodes array found in the literature were done without flow. It was necessary to determine the distance between the electrodes which produces the highest signal and exhibits the benefit of microelectrodes. Three arrays were manufactured with 68 disc microelectrodes with a diameter of 15 µm and a depth of 300 nm. The distance between two consecutive electrodes in the flow was 50, 120 or 240 µm, in a hexagonal geometry (d/a=6.7, 16 or 32, respectively). The arrays were successively placed in the cell of the electrochemical detector. After equilibration at a flow rate of 1 mL/min, a solution of 80 ng of hydroquinone in 20 µL was injected (concentration: 3.5×10^{-5} mol L^{-1}). The arrays with a distance between the electrodes of 120 and 240 µm provide a

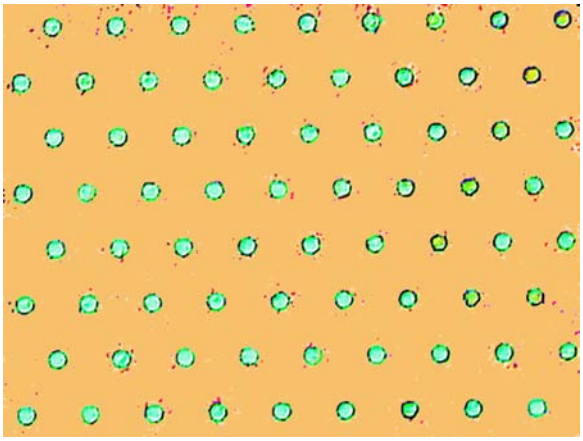

Fig. 4. Array of microelectrodes. The diameter of each microelectrode is 15 μm with a distance of 60 μm between the electrodes. Size of the picture: 542 μm × 407 μm.

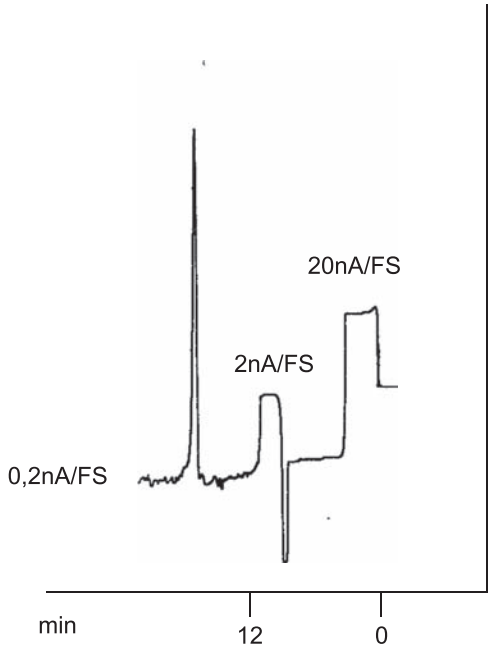

Fig. 5. Chromatogram of the injection of 90 pg of hydroquinone. Quick equilibration time of the cell: 12 min to reach the sensitivity of 0.1 nA/FS. Signal of 0.03 nA with a ratio $S/N=30/1$.

signal of 0.9 nA, while the array with a distance of 50 μm gives a signal of only 0.64 nA (Fig. 6). One can conclude that, for the chosen diameter $\Phi=15$ μm, the value $d/a=6.7$ is not sufficient for optimizing the signal-to-noise ratio for the same number of microelectrodes.

Taking into account the velocity of the flow inside the cell, we think that, due to the depletion, the hydroquinone molecules, oxidized at the electrode, are not completely renewed by forced convection if the electrodes are too close. Hereafter, a ratio $d/a=16$ has been chosen for the subsequent experiments.

3.3.2. *Effects of the flow rate*

The study of the chronoamperometric response of a recessed micro-band electrode was done by other authors by simulation [23]. In this case, it was clearly demonstrated that there is a relation between the chronaoamperometric response of the electrode and the velocity of the flow via the Péclet number. The Péclet number can be calculated from the average flow velocity, u, the channel height, h, and the diffusion coefficient D:

$$Pe = uh/D \quad (3)$$

In our experiments, Pe is in the range 250–5000.

Several arrays were prepared to determine the arrangement of electrodes which provides the best signal/noise ratio in chromatographic conditions with different flow rates.

The electron transfer occurring at the electrode is a function of several parameters. Several tests, reported in Fig. 7, were done using an array of 68 electrodes ($\Phi=15$ μm, $d=120$ μm, and $d/a=16$) increasing the flow rate from 0.1 mL/min up to 3 mL/min. The same samples were injected: 70 ng of hydroquinone in 20 μL (concentration: 3×10^{-5} mol L^{-1}). A decrease of the normalized peak area was observed (black full circles in Fig. 7). It can be attributed to the change of the residence time of the analyte in front of each microelectrode with the variation of the flow rate. For flow rates that have been tested in this work, in the magnitude order of 1 mL/min, the characteristic residence time, τ_r, of analyte flux over each microelectrode surface is shorter than the diffusion time, τ_d, at each microelectrode. The τ_r/τ_d ratio can be understood as an efficiency parameter linked to the amount of analyte detected at the microelectrodes array sensor. τ_r is controlled by the flux rate in the cell and by the thickness of the flow cell, whereas τ_d is controlled by the geometry of the electrodes.

We have calculated the collection efficiency of the microelectrodes array with a standard injection volume of 20 μL of analyte from the experimental measurement of the electric charge consumed for the detected peak. The collection efficiency of the flow-cell detector can be defined as the ratio of the experimental charge to the calculated charge needed to oxidize the whole amount of injected analyte. When the flux rate increases the collection efficiency diminishes (Fig. 7). It means that the amount of analytes reacting at the electrodes diminishes drastically due to the decrease of the residence time of species close to each microelectrode.

From those experiments, it should be noticed that the critical parameter for an HPLC amperometric detector is not the collection efficiency alone, but also the highest possible signal-to-noise ratio compatible with on-line detection at the outlet of the HPLC column.

3.3.3. *Diameter and number of the electrodes*

An important parameter in the detector for HPLC is the void volume of the sensor, the smallest as possible not to lose the quality of the separation by dilution inside the cell. The simplest solution for amplifying the signal is to increase the number of electrodes or/and to increase the size of the electrodes. Taking into account the previous results, an array was manufactured for reaching a good compromise: the electrodes, with $\Phi=30$ μm are placed in staggered rows, at a distance of 100 μm between the electrodes ($d/a=6.7$). The 5800 electrodes are gathered in a circle with a diameter of 8 mm, the active area is around 4.1 mm^2 and the internal volume of the cell is close to 4.5 μL. A typical result is displayed in Fig. 8. After 12 min equilibration time, the detector is set at 0.1 nA/FS, the injection of 16 pg of hydroquinone gave a peak of 0.07 nA with a high signal/noise ratio 55/1. Indeed, the d/a parameter in not the only pertinent criterion. The diameter of the microdisc electrode must also be taken into account for the optimization of the detector.

4. Conclusion

Boron-doped diamond has been used as a highly efficient electrode material for electrochemical detectors in high flow rate conditions. It offers a wide range of electro-activity, a quick equilibration time and an easy in situ cleaning. By combining its

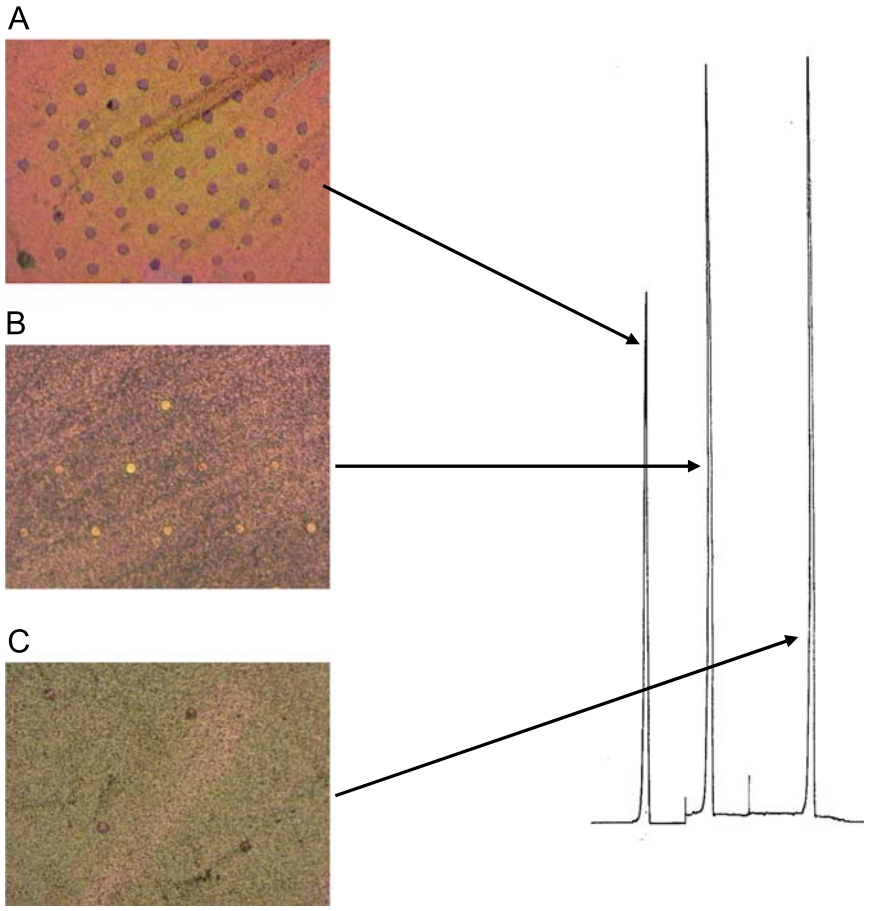

Fig. 6. Chromatograms obtained by the injection of 80 ng of hydroquinone on three different arrays with 68 electrodes of 15 μm of diameter on each array. The electrode spacing was: 50 (A), 120 (B) or 240 (C) μm. A signal of 0.64 nA was recorded for the array A. With the arrays B and C the same signal of 0.9 nA was recorded.

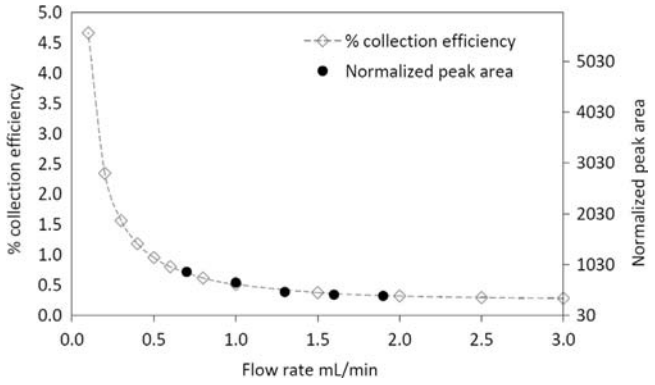

Fig. 7. Correlated variations of the area of the peak and the collection efficiency of the flow-cell versus the flow rate. An array of 68 electrodes was used, with a distance between the electrodes of 120 μm.

remarkable qualities with the particular properties of arrays of microelectrodes, new sensors for the electrochemical detection in HPLC were designed. Several series of arrays were prepared to determine the effect of the size of the electrodes, their spacing, disposition and number. Taking into account these results, a sensor was manufactured to be inserted in the cell of an electrochemical detector, leading to the detection of very small amounts of hydroquinone at the picogram scale, after a short equilibration time, less than 15 min, and a high signal/noise ratio.

Three key parameters have been identified for the optimization of the detection: the flux velocity, which controls the collection

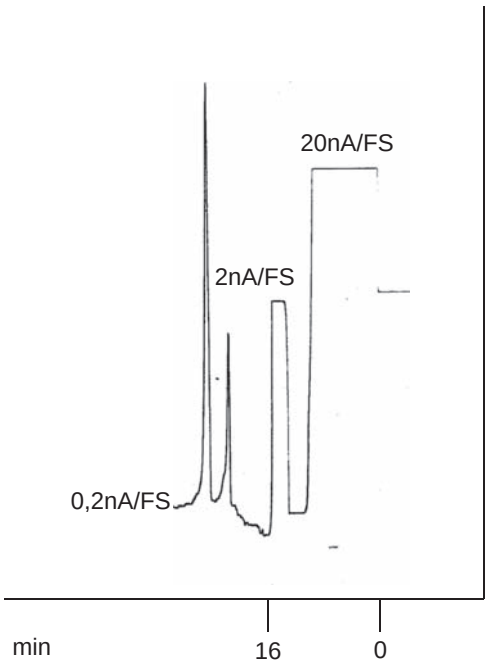

Fig. 8. Chromatogram obtained with the selected array: diameter of the electrodes: 30 μm, distance between the electrodes: 100 μm, active surface area: 4.1 mm^2. Injection of 16 pg of hydroquinone. After equilibration, the change of the sensitivity set on the detector was directly noted on the chromatogram, a peak of 0.07 nA was obtained with a ratio $S/N=55:1$.

efficiency; the d/a ratio, which controls the signal to noise ratio and, at last, the diameter of the microdiscs, which is related to the sensitivity. A more extensive study should lead to the optimal electrochemical detector for HPLC.

Acknowledgements

The authors wish to thank Dr P. Bergonzo and his group of the LIST, CEA (Saclay, France) for the manufacturing of the arrays and the fruitful discussions which have allowed the development of this work. Precision Instruments (Marseille, France) is also acknowledged for financial support and industrial development of the cells fitted with BDD arrays for electrochemical detection in HPLC.

ABSTRACT

In this study, facilitated extraction with enzyme was employed for the first time to extract fluorine (F) from plants. Feasibility of the proposed method for F analysis was assessed by comparing with the alkali fusion-ion selective electrode (ISE) method. In the extraction procedure, 30 mg of a protease and 0.1 g of a plant sample were added in 10 mL of deionized water. In the absence of sonication, the solution was mechanically shaken for 10 s. A variety of parameters (i.e., the amounts of enzymes used, physical treatment conditions applied, extraction time, temperature, and pH) were optimized to enhance the extraction efficiency of the proposed method. The suitability of the proposed method for various plant samples (i.e., grass, perilla, peanut, hot pepper, and eggplant) was also evaluated. The proposed method involves decreased operation time, simplified extraction procedures, and minimal consumption of hazardous reagents and solvents in comparison with other existing methods. Experimental results demonstrated that facilitated extraction with enzyme is appropriate for the rapid determination of F content in plant samples.

1. Introduction

Fluorine (F) as a harmful pollutant in fluoride compounds and soluble fluoride has received considerable attention because of its effects on both ecosystem and human health. Although an appropriate intake of F is known to prevent dental caries, continuous intake of vegetation accumulated with F seems to cause dental and skeletal fluorosis and osteoporosis [1–3].

F present in atmosphere and vegetation is generally determined as tracers following hydrogen fluoride (HF) leakage accidents. The concentration of HF leaked into the atmosphere can be calculated using the concentration of F in plant samples by a reverse tracking method on the basis of the high diffusion velocity of F [4]. In addition, the extent of exposure and environmental pollution was assessed by determining F content of plants in the vicinity of the HF leakage accident area [5]. It is therefore important to determine F concentrations in crops because of their potential to accumulate F in the human body through the dietary pathway.

Various methods for the determination of F concentrations in plants have been extensively studied for decades. The alkali fusion-ion selective electrode (ISE) technique combining the use of filtration under slightly alkaline conditions for the removal of the interfering cations was widely used to determine the F contents in plant samples [6,7]. Pyrohydrolysis and oxygen bomb combustion techniques [8–10] were also employed to determine F contents in coal and plants, respectively. However, these methods were time-consuming and complicated procedures, which generate a large volume of hazardous wastes to extract F from plant samples.

Currently, facilitated extraction with the aid of enzyme has been predominantly applied for the determination of arsenic (As) and selenium (Se) [11–14] present in plant samples. Enzymes are used to catalyze chemical reactions by which plants are formed, and enable the hydrolysis of chemical bonds in plants to dissociate. The α-amylase and protease hydrolyze the peptide bonds of polysaccharide cell membranes of plants [15]. One of the main advantages of the extraction with enzyme is its simplicity and rapidity owing to its high reaction rate through the alleviation of activation energy. In addition, the usage of organic solvents and hazardous chemicals can be avoided. To date, there are no reports on the application of the extraction method with the use of enzyme for the rapid determination of F contents in plant samples.

In this study, extraction conditions (e.g., amounts and combination of enzymes, sonication applied, extraction time, temperature, and pH) of the proposed facilitated extraction with enzyme

were examined and optimized to increase the extraction recovery. The extraction procedure presented in this paper has been derived from a method described by Sanz et al. [11,12], who studied the applicability of the use of enzyme for the analysis of As in plant samples. The proposed method is used to hydrolyze proteins and other components in plant samples by the combined use of α-amylase and protease. Feasibility of facilitated extraction with enzyme proposed in this study was assessed by comparing with alkali fusion-ISE technique as a reference method. It was also applied to analyze F contents in various plant samples to confirm its versatility. The proposed method aims to remove complicated and time-consuming extraction procedures for the rapid determination of F contents in plant samples.

2. Materials and methods

2.1. Reagents

Starch and proteins make up to 80–90% of plant samples. Therefore, α-amylase (*Bacillus* sp.) and protease (*Streptomyces griseus*) (Sigma-Aldrich, St. Louis, MO, USA) were used to degrade cell membranes of the F containing plant samples. The α-amylase breaks down starch into smaller carbohydrate molecules such as maltose and glucose. The protease breaks down certain chemical bonds in proteins into smaller peptides and amino acids. Deionized (DI) water (Milli-Q Element System, Millipore, USA) was used as the extraction solvent. A total ionic strength adjustment buffer (TISAB) solution obtained from Fluka (Sigma-Aldrich, St. Louis, MO, USA) was used to maintain the ionic strength of solutions prior to the analysis of F using ion electrode (pH-270L, Istek, Korea). Sodium hydroxide (NaOH, $\geq$98%, Samchen Chemicals, Korea) and hydrochloric acid (HCl, Dongwoo Fine-Chem, Korea) solutions were used for pH adjustment in the alkali fusion-ISE method.

2.2. Sample collection

Rice was used as a representative sample of plants because of its dietary importance. Rice samples affected and unaffected by HF exposure (leakage accident (2012) in Gumi city, Republic of Korea) [16] were collected in the vicinity of the HF spillage. Rice A was collected from the site that was directly affected by HF exposure. Conversely, Rice B, as the control sample, was collected from the background area unaffected by HF exposure. Rice A* and Rice B* were taken from the aforementioned points, respectively after one year has passed. The samples were naturally dried at room temperature and were ground by a Gyral Grinder (Chemplex, USA). In order to prevent the samples from absorbing moisture, the ground samples were stored in a desiccator.

Other plant samples such as grass, perilla (*Perilla frutescens var. japonica Hara*), peanut (*Arachis hypogaea*), hot pepper (*Capsicum annuum*), and eggplant (*Solanum melongena*) were also used to evaluate the versatility of the proposed extraction method. These plants were representative of crops cultivated in the HF leakage accident area. The plant samples were collected in the vicinity of the sampling point of rice samples and prepared using the same procedure as rice samples.

2.3. Extraction procedures

The extraction procedure for the F analysis in rice samples was followed by Sanz et al. [11,12] with some modifications. 0.1 g of the sample was added to 10 mL of DI water in a 50 mL polyethylene tube followed by the addition of 10 mg of α-amylase. In order to accelerate the extraction reaction of rice samples, an ultrasonic probe was introduced into the sample suspension and the sample was subjected to ultrasound irradiation for 120 s at 20% amplitude. The probe tip was cleaned with DI water between the sonication processes to prevent sample contamination. After preliminary sonication, 30 mg of the protease was added and sonication was repeatedly employed. The suspension was filtered through a 0.4 μm polycarbonate Whatman filter using a vacuum pump and the effluent was collected. The effluent was mixed at 1:1 (v/v) ratio with TISAB solution to maintain the ionic strength and F concentration was determined by ISE.

As the reference values, the alkali fusion-ISE technique developed by McQuaker and Gurney [7] was used to analyze F concentration in a plant sample. Briefly, 0.5 g of sample with 6 mL NaOH solution was incubated at 600 °C and then neutralized using HCl. This solution was filtered through Whatman no. 40 filter paper to remove interfering cations including Fe and Al and the filtrate was subsequently analyzed by ISE for the determination of F. The F concentrations in rice samples determined using both the extraction method with aid of enzyme and alkali fusion-ISE method were compared with each other to calculate the recovery efficiency of facilitated extraction with enzyme method proposed in this study.

2.4. Optimization procedures

The optimized conditions of facilitated extraction with enzyme were determined by assessing the effects of selected parameters on the recovery efficiency of F from the rice sample. Recovery efficiency was defined as the ratio of F concentration determined using the method proposed in this study to pseudo total F concentration determined using the alkali fusion-ISE method. Optimization parameters included the amounts of enzymes used (0–30 mg corresponding to 0–30% enzyme/sample ratio), the combination of different enzymes applied (α-amylase and protease), physical treatment (in the presence and in the absence of sonication), and the extraction time (10–120 s). These various extraction conditions were optimized based on preliminary experiments. Versatility of facilitated extraction with enzyme under the optimized conditions to other plant samples was also tested. All experiments were performed in triplicate.

3. Results and discussion

3.1. Optimization of facilitated extraction with enzyme

3.1.1. The amounts and combinations of enzymes used

The effect of enzyme concentration on the extraction efficiency of F in the rice sample was studied to determine the optimum amounts of α-amylase and protease. Different amounts (0, 10, 20, and 30 mg corresponding to 0%, 10%, 20%, and 30% enzyme to sample ratio) and combinations of α-amylase and protease were separately tested to find optimal conditions. In all experiments, sonication time and wave amplitude of ultrasound were set 120 s and 20%, respectively. F concentrations extracted using different amounts of enzymes are shown in Table 1. It can be inferred that the F concentration is completely recovered with 30 mg of protease. The recovery of the extracted F increased from 44.9% to 98.8% when the amount of the protease increased from 10 to 30 mg. However, there was no effect on the recovery when only α-amylase was used. These results suggested that the major enzyme extracting the F from the rice sample is a protease rather than α-amylase. It supported the fact that F is bound to proteins like other elements despite small total protein content (7–8%) [11,12]. Almost 100% of the F was successfully recovered from the rice samples when using the protease regardless of the addition of α-

Table 1
F concentrations obtained from facilitated extractions with varying amount of enzymes.

Amounts of enzymes (mg)		F concentration (μg g^{-1})[a]	Recovery (%)[b]
α-amylase	Protease		
0	0	4.83 ± 1.31[c]	15.0
0	10	14.5 ± 1.08	44.9
0	20	22.4 ± 0.99	69.3
0	30	31.9 ± 1.07	98.8
10	0	3.13 ± 0.58	9.67
10	30	34.2 ± 1.16	106

	120	32.4 ± 1.38	100
	1800	32.2 ± 1.03	99.6

[a] Mean ± standard deviation (n=3).

amylase. In consequence, 30 mg of the protease was selected as the optimum enzyme concentration.

3.1.2. Effects of sonication and extraction time

The efficiency of F extraction in the presence and in the absence of the sonication was investigated. Without the use of sonication, the suspension (containing 0.1 g of rice sample and 10 mL of DI water) was mechanically shaken for 10 s to evenly blend the enzyme. The results obtained from both methods are shown in Table 2. In general, sonication disrupts the cell membrane and thereby enables rapid transfer of extraction solution to the target compounds, resulting in high extraction recovery [17]. On the other hand, there was no effect of sonication on the reaction rate of enzymes for F extraction regardless of sonication time, as shown in Table 2. In the absence of enzymes, F was scarcely extracted during sonication (Table 1). These results demonstrated that sonication could not hydrolyze the proteins associated with F but broke down the cell membranes into smaller products.

It is widely recognized that sonication is capable of decreasing extraction time owing to its physical effects on the cell membrane [17–19]. However, in F analysis, there is no effect of sonication on F extraction. Furthermore, total dissolved solid (TDS) in solutions extracted with sonication was higher than that of solutions extracted without sonication. This could increase the filtration time and make it difficult to filtrate using vacuum pump. As shown in Table 2, F was effectively recovered within a short time (i.e., 10 s) even without sonication. Hence, sonication process was avoided in the proposed extraction method in order to reduce the filtration time.

Extraction time is one of the important parameters for rapid analysis of F contents. Therefore, F concentrations extracted at different extraction times with and without sonication were measured and compared. As shown in Table 2, the recovery of facilitated extraction with enzyme was not influenced by extraction time because overall extraction processes were completed during 10 s without sonication. It indicated that protease immediately reacted with the protein associated with F, indicating that the proposed extraction method is suited for the rapid analysis of F in rice samples. The reaction rate was fairly high when a sufficient amount of protease was used for the hydrolysis of cell membranes. After the addition of protease, mechanical shaking of the solution for 10 s followed by filtration could sufficiently extract F from rice samples and it was used as an optimum condition of the physical treatment.

3.1.3. Temperature and pH

Since enzymes could be significantly affected by temperature and pH of the solution, their effects on F extraction were assessed. In general, the optimum values of temperature and pH of α-amylase and protease were 25–35 °C and 6–8, respectively [20,21]. In our preliminary tests, the difference of recoveries between the solutions incubated at room temperature and at 35 °C was negligible. Furthermore, DI water without adjusting pH (i.e., pH 5.5–6) seemed to have sufficient ability to extract F from the rice sample when employing enzymes concurrently. Hence, there was no need to be taken concerning temperature and pH of solution and consequently the proposed method was performed at room temperature and unaltered pH levels (5.5–6).

3.2. Feasibility of facilitated extraction with enzyme for the determination of F concentration

The proposed method for the determination of total F concentration in the rice samples was compared with the alkali fusion method in order to assess its feasibility. The alkali fusion-ISE method was usually used as a reference method for the analysis of total F concentration in vegetation samples [6,7]. The experimental conditions of facilitated extraction with enzyme are as follows: 0.1 g of sample, 30 mg of protease, 10 mL of DI water as solvent, and mechanically shaking for 10 s without sonication. Results obtained by facilitated extraction with enzyme are in good agreement with those obtained by the alkali fusion method from 0.012 to 0.378 of relative error (defined as the ratio of difference between F concentrations determined using alkali fusion-ISE and the proposed method to total F concentration determined using alkali fusion-ISE) (Fig. 1), indicating the suitability of the proposed

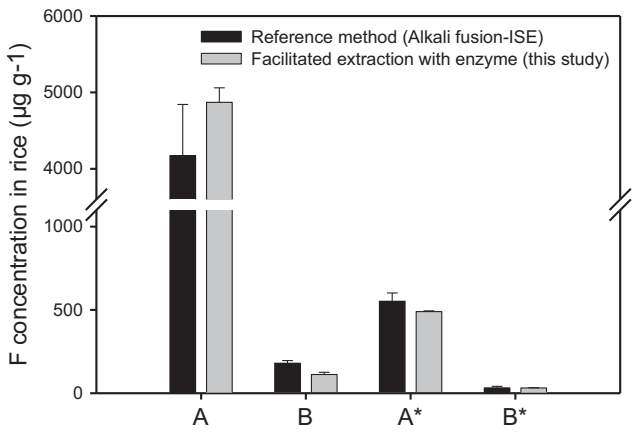

Fig. 1. Comparison of F concentrations in rice samples determined using alkali fusion-ISE and facilitated extraction with enzyme methods. Rice A is collected from the site that is directly affected by HF exposure. Conversely, Rice B, as the control sample, is collected from the background area unaffected by HF exposure. Rice A* and Rice B* are taken from the aforementioned points, respectively after one year has passed.

Table 3
Comparison of several extraction methods for the determination of F concentration in plant samples.

Order	Analytical method	Sample type	Solvent used	Time required (h)[a]	Waste generated (mL sample^{-1})[b]	Source
1	Alkali fusion+ISE	Vegetation	NaOH, HCl	8.0	100	[6,7]
2	Pyrohydrolysis+ISE	Coal	DI water	4.5	100	[8,9]
3	Oxygen combustion+ISE	Coal	$NaHCO_3$, Na_2CO_3	0.5	1000	[10]
4	Facilitated extraction with enzyme+ISE	Rice	DI water	0.5	10	This study

[a] Time required is calculated by adding times for sample preparation, extraction process, and the ISE analysis.
[b] Waste generated is calculated by adding solvent, and acid/alkali solution used.

extraction method for F analysis in rice sample over a wide range of F concentrations (31.9–4870 μg F^-/g sample). The standard deviations of facilitated extraction with enzyme (1.07–190 μg F^-/g sample) were much smaller than those of alkali fusion method (8.70–670 μg F^-/g sample). This result indicated that facilitated extraction with enzyme was more precise method for F analysis in the rice samples. The F concentrations of unaffected rice samples (31.9 and 112 μg F^-/g sample) were comparable to those of other rice samples studied previously [22,23]. On the other hand, owing to the influence of HF exposure, the obtained values from Rice A and Rice A* (4870 and 490 μg F^-/g sample, respectively) were one or two orders of magnitude higher than previously reported values [22,23].

3.3. The figures of merit

Facilitated extraction with enzyme for the analysis of F contents in rice samples is a rapid and simple method compared to conventional methods such as alkali fusion, pyrohydrolysis, and oxygen combustion (Table 3). Although alkali fusion method achieved limit of detection (LOD) of 3 ppm that is quite low to determine F contents in solid samples [7], it necessitates complicated and time-consuming procedures, resulting in the generation of excessive waste. In thermal hydrolysis method, although 3.7–5.1% of standard deviation and 20 ppm LOD were obtained, it requires proficient skills in its application and complex apparatus to meet the condition of high temperature about 1000 °C [8,9]. Oxygen bomb combustion method can prevent the loss of F through volatilization because of using enclosure flask and combustion process is completed within 10 min. Despite these advantages, it has complicated procedures and generates overfull waste about 1000 mL [10].

The proposed method can simplify the extraction procedures and thereby saving the pretreatment time, as shown in Table 3. In the existing methods, the suspension originated from the extraction process is generally centrifuged for at least 10–20 min, and the supernatant is filtered and then analyzed [11,12]. On the other hand, in the proposed method, centrifugation step can be avoided and the suspension is directly filtered by a 0.4 μm polycarbonate filter, resulting in the additional reduction of the extraction time by approximately 5 min. Furthermore, only 10 mL of DI water is used as the extraction solvent, which is a relatively smaller quantity compared to those used in other methods. In addition, the proposed method eliminates acid/base solutions and organic solvents, and consequently diminishes hazardous wastes generated and analytical error.

3.4. Application to various plant samples

30 mg of protease and 0.1 g of sample were added to 10 mL of DI water and the solution was mechanically shaken for 10 s without sonication. F concentrations in different plant samples were determined to evaluate the applicability of the proposed method for a wide range of plant samples. Grass, perilla, peanut, hot pepper, and eggplant samples were used in this study. All the plant samples were analyzed using both the alkali fusion-ISE and the proposed facilitated extraction with enzyme. F concentrations of various plant samples are presented in Table 4. F concentrations in plant samples varied from 28.0 to 121.5 μg F^-/g sample. These values were comparable to the F contents of 9–248 μg F^-/g sample reported in previous studies [24]. As shown in Table 4, results obtained from both the extraction methods are in good agreement with 0.072–0.284 of relative error regardless of plant species. Therefore, it clearly confirmed that facilitated extraction with enzyme for the analysis of F contents is suitable for a wide range of plant samples.

Table 4
F concentration in different plant samples using both alkali fusion-ISE and facilitated extraction with enzyme methods.

Plant samples	Total F concentration (μg g^{-1})		Relative error (RE)[a]
	Alkali fusion-ISE	Facilitated extraction with enzyme	
Grass	169 ± 19.0[b]	122 ± 0.50	0.284
Perilla	30.6 ± 2.24	36.4 ± 4.50	0.190
Peanut	47.2 ± 11.5	54.3 ± 0.50	0.150
Hot pepper	28.2 ± 8.76	30.2 ± 0.20	0.072
Eggplant	25.4 ± 4.60	28.0 ± 3.50	0.102

[a] Relative error is defined as the ratio of the difference between F concentrations determined by alkali fusion-ISE and facilitated extraction with enzyme to F concentration determined by alkali fusion-ISE.
[b] Mean ± standard deviation (n=3).

4. Conclusions

In this study, novel facilitated extraction method with enzyme using protease for the rapid determination of F contents in plant samples was developed. Important parameters including the amounts of enzymes used, physical treatment conditions applied (sonication), extraction time, temperature, and pH were optimized. The feasibility of the proposed method was evaluated by comparing with alkali fusion-ISE technique, which is a reliable method for F analysis. Compared with other methods, facilitated extraction with enzyme is a rapid and simple method, eliminating complicated and time-consuming procedures. In addition, only a small amount of the solvent was used and the use of hazardous chemicals can be avoided. Hence, the proposed method is efficient and environmentally friendly for the rapid determination of F contents in plant samples.

ABSTRACT

In this work, the competitive interaction between dibucaine and three fluorescent probes (i.e., berberine, palmatine, and coptisine) for occupancy of the cucurbit[7]uril (CB[7]) cavity was studied by fluorescence spectra, UV–visible absorption spectra, ^{1}H NMR spectra, and theoretical calculations in acidic aqueous solution. Based on the fluorescence enhancement of berberine, palmatine, and coptisine upon binding with CB[7], respectively, a series of fluorescence detection methods for dibucaine were proposed. At the optimized conditions, the fluorescence intensity of berberine-CB[7], palmatine-CB[7], and coptisine-CB[7] complexes showed negative correlation to the concentration of dibucaine, which led to a series of simple and sensitive fluorescence methods for the determination of dibucaine for the first time. Linear ranges obtained in the detection of the dibucaine were 0.018–3.34 μmol L^{-1}, 0.032–4.47 μmol L^{-1}, and 0.079–4.42 μmol L^{-1} with detection limits of 6.0 nmol L^{-1}, 12.0 nmol L^{-1}, and 25.0 nmol L^{-1}, respectively. Moreover, the proposed method was successfully applied for the determination of the drug in biological fluids. The competitive mode based on CB[7] superstructure provided a promising assay strategy for fluorescence detection in various potential applications.

1. Introduction

Dibucaine, 2-butoxy-N-(2-diethylaminoethyl)-4-quinolinecarboxamide hydrochloride (DC) (Scheme 1) has attracted great clinical interest for its 15 times more potent than procaine and five times than cocaine in producing local anesthesia, but with considerably more poisonous property [1]. A number of assays have been reported for detection of DC in biological and pharmaceutical samples, including differential-pulse polarographic [1], chromatography [2–9], atomic absorption spectrometry [10] and spectrophotometry [11]. However, chromatography requires the use of organic solvents, expensive instruments, and time-consuming operating steps [2–9]. Though easier to operate, the reported method of spectrophotometry also need the use of haematoxylin in the presence of boric acid to give a reddish-violet chromogen fluorescent product, and showed low sensitivity and limited extending potential [11]. Some other methods are not sensitive enough [1,10]. Therefore, simple and sensitive detection method is in urgent need for determination of DC especially in biological fluids. To the best of our knowledge, no fluorescence analyst method is available for the detection of DC.

Supramolecular chemistry provides a possibility for selective detection of DC due to the steric effect of macrocyclic compounds. Supramolecular complex formation of macrocyclic compounds is widely utilized as molecular-scale devices, sensors, fluorescent probes due to the amphiprotic properties of macrocyclic compounds [12–14]. Specially, the cucurbit[*n*]urils (CB[*n*], *n*=5–8, 10), which are comprised of *n* glycoluril units bridged by 2*n* methylene groups, possess considerable negative charge density in their carbonyl-fringed portals for the binding of metal ions and cationic organic compounds. Meanwhile the extremely nonpolarizable cavity preferably accommodates hydrophobic moieties [15–18]. The CB[7] host (Scheme 1) has been of particular interest in fluorescent assay since its remarkable ability to form host–guest complexes with organic molecules [19–26].

Herein, we employ berberine hydrochloride (BER), palmatine hydrochloride (PAL), and coptisine (COP) as signal probes for the fluorescence detection of DC in biological fluids samples (Scheme 2). When DC was added into the aqueous solution of CB[7], there was no distinct fluorescence change. However, dramatic increase in fluorescence intensity was observed when BER, PAL, or COP was added to CB[7] solution. As such, when DC was mixed with CB[7]–berberine, CB[7]–palmatine, or CB[7]–coptisine complexes, the significant decrease of fluorescence intensity can

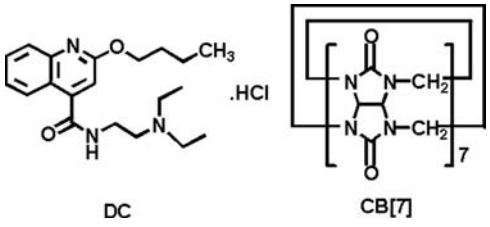
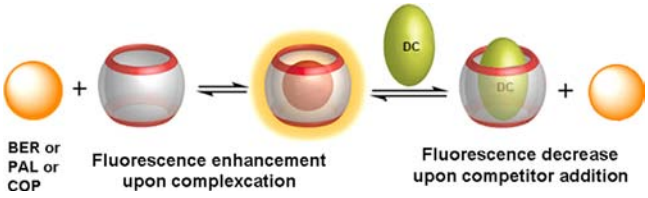
be observed. The fluorescence intensity showed a negative correlation to the concentration of DC with a linear calibration plot in the ranges of 0.018–3.34, 0.032–4.47, and 0.079–4.42 μmol L^{-1}, with detection limits of 6.0 nmol L^{-1}, 12.0 nmol L^{-1}, and 25.0 nmol L^{-1} for the above three complexes, respectively. Moreover, the designed method was successfully applied in the detection of DC in urine samples, which showed promising application in various practical scenarios.



2. Experimental

2.1. Materials and reagents



Berberine hydrochloride (BER), palmatine hydrochloride (PAL), coptisine (COP), and DC were obtained from the Chinese National Institute for the Control of Pharmaceutical. CB[7] was prepared and characterized according to the reported procedure [17,18]. CB[7] stock solutions of 1.0 mmol L^{-1} were prepared by dissolving CB[7] in a 100 mL volumetric flask with doubly-distilled water. All the stock standard solutions were stable for several weeks at room temperature. All other reagents used were of analytical grade, and double-distilled water was used thoroughly.

2.2. Apparatus

The fluorescence measurements were performed on a Cary Eclipse spectrofluorometer (America). The slit widths of both excitation and emission monochromators were set to 5 nm. All measurements were performed in a standard 10 mm path-length quartz cell set to a temperature of 25.0 ± 0.5 °C. Absorption spectra were measured on a U-3010 UV–visible spectrophotometer (Hitachi, Japan). ^{1}H NMR spectra were obtained using a Bruker AV-600 MHz spectrometer (Switzerland) in D_2O buffered with DCl (0.10 mol L^{-1}). Molecular modeling calculations were optimized at the B3LYP/6-31 G(d) level of density functional theory with the Gaussian 03 program.

Scheme 1. Structure of DC and CB[7].

Scheme 2. Competitive recognition of CB[7] to DC against BER, PAL, or COP.

2.3. Spectra measurement procedure

The fluorescence measurements were carried out with the excitation wavelength of 345, 344, and 358 nm in the absence or presence of DC solution. In a 10 mL colorimetric flask, 0.5 mL 0.1 mmol L^{-1} CB[7] solution, 0.5 mL 0.1 mmol L^{-1} probe molecular solution (i.e. BER, PAL, or COP), followed by 1.0 mL of 1.0 mol L^{-1} hydrochloric acid, and a given concentration of DC standard solution or sample solution were sequentially added. The mixture was diluted to the volume with water and shaken for 15 min at room temperature.

2.4. Analysis of spiked human urine

Urine samples were handled according to the previous protocol [27]. Briefly, each urine sample (10.0 mL) was placed into a centrifuge tube, spiked with 1.0 mL drug stock solution and then centrifuged at 5000 rpm for 5 min. The clear supernatant of the spiked urine sample was extracted by solid phase extraction (SPE) using 001 × 7 strong-acid cation exchange resin. The procedure was as follows: 1 mL of the spiked urine sample was transferred into the SPE cartridge (with the resin height being 1 cm and the diameter 1 cm). After allowing the sample to pass through to waste under gravity, the resin was washed with 1 mL 1% sodium hydroxide solution and 2 mL double-distilled water (amino acids can be removed). The filtrate was discarded. Finally, the analyte was eluted into a colorimetric flask with 4 mL of methanol/water (1:1, v/v) and then the general procedure was followed.

3. Results and discussion

3.1. Spectral characteristics

Because the same trends showed for three fluorescent probes (i.e., BER, PAL or COP), the following research used the BER as example. The UV–visible spectra of DC and BER showed absorption bands at 202, 246, 321 nm and 228, 263, 345 nm, respectively

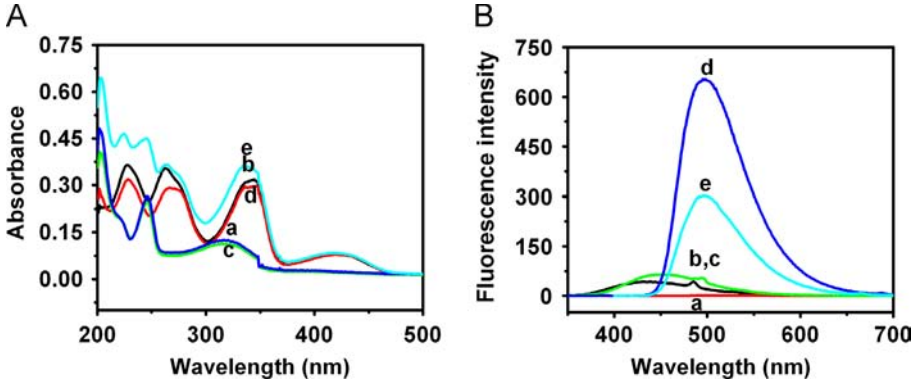


Fig. 1. (A) UV–visible spectra of (a) DC, (b) BER, (c) DC+CB[7], (d) BER+CB[7] and (e) BER+CB[7]+DC. The concentrations of BER, CB[7] and DC are 10.0 μmol L^{-1}, pH=1. (B) Fluorescence spectra of (a) BER, (b) DC, (c) DC+CB[7], (d) BER+CB[7] and (e) BER+CB[7]+DC. The concentrations of BER, CB[7] and DC are 5.0, 5.0, and 3.34 μmol L^{-1}, respectively, pH=1.

(Fig. 1A, curve a and b). After the addition of CB[7] into DC or BER solution, a slight hypochromicity was observed (Fig. 1A, curve c and d). This should be attributed to the inclusion of DC or BER by CB[7] and produce supramolecular complexes. However, a increase in absorption spectra was observed upon addition of DC into BER–CB[7] complex solution (Fig. 1A, curve e). This should be attributed to the BER molecule expelled from the CB[7] cavity because of the introduction of DC.

The solution of BER alone showed undetectable fluorescent emission, meanwhile, DC also exhibited very weak native fluorescence in acidic aqueous solution (Fig. 1B, curve a and b). After the addition of CB[7] into DC solution, no distinct change of fluorescence was observed (Fig. 1B, curve c). However, a dramatic increase in fluorescence intensity was observed upon addition of CB[7] in BER solution (Fig. 1B, curve d). This should be attributed to the inclusion of BER by CB[7] to change the space structure or conformation of BER and produce a fluorescent complex. Interestingly, the addition of DC to the mixture of CB[7] and BER led to significant decrease of fluorescence intensity (Fig. 1B, curve e). Furthermore, with the increasing concentration of DC, the fluorescence intensity became smaller (Supporting information, Figs. S1–S3). The fluorescence intensity decrease to the amount of added DC led to a series of simple and sensitive fluorescence methods for the determination of DC.

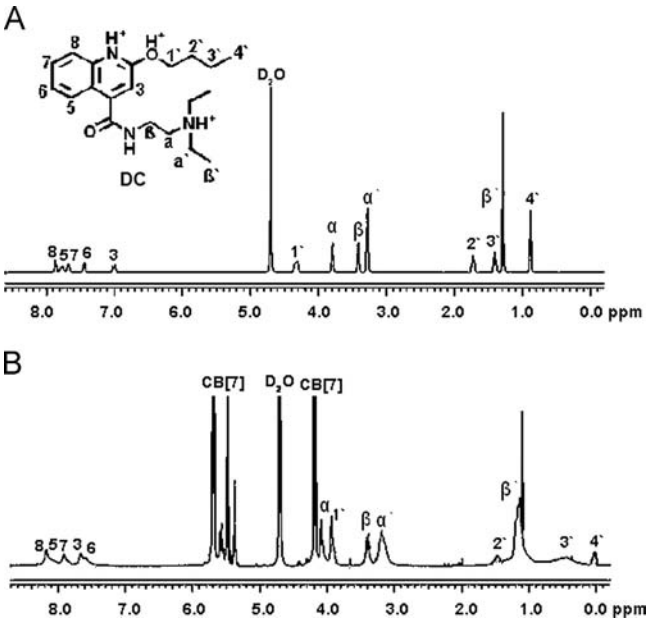

Fig. 2. ^{1}H NMR (600 MHz) spectra of (A) DC and (B) DC in the presents of CB[7] in D_2O buffered with DCl (0.10 mol L^{-1}).

3.2. Interaction mechanism of the fluorescent probe

Although the fluorescent emission of pure BER, PAL, and COP was very weak or undetectable, the fluorescence intensity greatly enhanced after they entered the hydrophobic cavity of CB[7], which showed a good linear relationship between $1/F$ and $1/c_{CB[7]}$, indicating the existence of a 1:1 complex. The binding constant (K) for these complexes were determined to be 9.57×10^4, 4.26×10^4, and 1.86×10^5 L mol^{-1} [19–21].

When DC was added to CB[7]-complexes solution, DC could compete to occupy the CB[7] cavity with BER, PAL and COP. Due to the greater $K_{DC-CB[7]}$ ($1.1 \pm 0.2 \times 10^7$ L mol^{-1}) value [28] than $K_{CB[7]-BER}$, $K_{CB[7]-PAL}$, and $K_{CB[7]-COP}$, which showed the stronger binding of DC with CB[7], BER, PAL, and COP in CB[7] cavity was displaced by DC. As a result, the fluorescent intensity of CB[7]–BER, CB[7]–PAL, CB[7]–COP complex weakened.

The formation of CB[7]–DC inclusion complex could be confirmed by ^{1}H NMR spectroscopy (Fig. 2). Compared with the proton resonance of the unbound DC molecule (Fig. 2A), the resonance of protons $H_{1'}$, $H_{2'}$, $H_{3'}$, and $H_{4'}$ of the bound DC in the ^{1}H NMR spectrum of CB[7]–DC complex experienced a progressively up-field shift (Fig. 2B), indicating that CB[7] binds selectively to the protonated oxygen-terminal butyl residues due to cooperative hydrophobic and ion–dipol interactions. Because of the excellent matched size and morphology, butyloxy residues was enclosed in the cavity of CB[7] more tightly than triethylammonium groups in acidic aqueous solution. The resonance of protons H_3 of DC experienced a slightly down-field shift, indicating this part of the molecule was located just outside the carbonyl portal of the CB[7] host.

Molecular modeling calculations were optimized at the B3LYP/6-31G(d) [29] level of density functional theory [30,31] using the Gaussian 03 program. The results confirmed the partial inclusion of DC in the hydrophobic cavity of CB[7] (Fig. 3). It can be seen from molecular simulation that both butyloxy group and quinolyl group were protonated in acidic solution, giving the cationic form of DC. This indicated that, in the energy-minimized structure, butyloxy group of the molecule located inside the host, however, quinolyl group of the molecule located just outside the carbonyl portal of the CB[7] host.

3.3. Analytical performance

From Supporting information (Figs. S1–S3), in the solution of 5.0 μmol L^{-1} BER–CB[7], PAL–CB[7], and COP–CB[7] complexes, the plots of fluorescence intensity vs the concentration of DC showed a series of linear relationship in the ranges of 0.018–3.34 μmol L^{-1}, 0.032–4.47 μmol L^{-1}, and 0.079–4.42 μmol L^{-1}, respectively. The linear regression equations were $I = -90.42c + 602.08$, $I = -80.23c + 626.08$, and $I = -86.69c + 819.81$ (c denotes the concentration of DC in μmol L^{-1}) with the correlation coefficients of 0.9997, 0.9991, and 0.9995, and the detection limits of 6.0 nmol L^{-1}, 12.0 nmol L^{-1}, and 25.0 nmol L^{-1} at 3σ for the same order, respectively. A comparison of the results obtained by the proposed method with those obtained by the other spectroscopic approaches shows the sensitive is satisfactory (Table 1).

Prior to the application of the proposed fluorescence method in analysis of the drug in human urine samples, the effect of common ingredients in human urine on the determination of DC was examined. The criterion for interference was fixed at a ±5%

[a] Average of five determination.

variation in the average fluorescence intensity calculated for the established level of DC. The results showed no interference of the common ingredients in urine samples. However, the components such as cysteine, alanine, phenylalanine, and valine could change the fluorescence intensity of the complex to a certain degree. Hence, they should be separated prior to the determination.

3.4. Analytical application

Due to the high sensitivity, good selectivity and stability shown in the proposed fluorescent method, the method was applied in the determination of the DC in spiked samples of human urine. The results are presented in Table 2 (using the CB[7]–BER complex as signal probe). The standard deviations obtained from the proposed method were less than 1.40%. The recoveries examined with a standard addition method were in the range of 98.0–103.5%.

4. Conclusion

In this work, the supramolecular systems of CB[7] were designed for the first time in the determination of DC. The CB[7]–BER, CB[7]–PAL, and CB[7]–COP complexes were indentified to have a greatly enhanced fluorescent emission due to strong coplanar and rigidity of BER, PAL, and COP, respectively. Since the interaction of DC with CB[7] was stronger than BER, PAL, and COP, the CB[7]–BER, CB[7]–PAL, and CB[7]–COP superstructures would be disintegrated upon addition of DC considering the thermodynamic factor, which led to a significant fluorescence reduction, respectively. Based on the competitive mode, a series of novel fluorescence methods for the determination of DC were established with high sensitivity, cost-effectiveness, and easy operation, which was successfully applied in biological fluids. The interaction mechanism between the DC and the CB[7] also confirmed that the butyloxy group of the DC molecule located inside the host in acidic aqueous solution via UV–visible absorption spectra, the ^{1}H NMR spectrum and the theoretical calculations.

Fluorescence detection

ABSTRACT

In this work, we use for the first time single layer MoS_2 as the fluorescence quencher to design a detection method for Ag^+ with excellent robustness, selectivity and sensitivity. To maintain the ultrathin MoS_2, bulk MoS_2 materials have been exfoliated by intercalation with lithium followed by reaction with water. As-prepared two-dimensional MoS_2 not only has good water-solubility but also obtains high fluorescence quenching efficiency within 5 min. Importantly, the detection limit of this assay for Ag^+ (1 nM) was lower than the maximum limitation guided by the United States Environmental Protection Agency (EPA) and the World Health Organization (WHO). Further, this new Ag^+ probe was demonstrated in monitoring Ag^+ in lake water samples with satisfactory results.

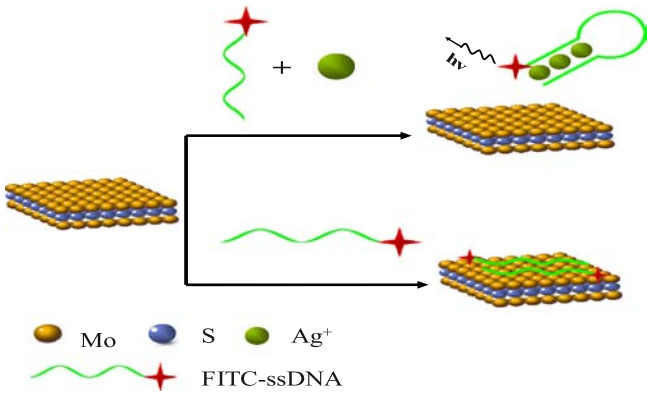
1. Introduction

As we all know, heavy metals are highly toxic and carcinogenic even at a trace level, which can enter the environment due to increasing industrial activities. They are non-biodegradable and can accumulate in the food chain, posing a severe threat to the environment and human health. Therefore, heavy metal pollution becomes a major concern for global sustainability. Among these heavy metal ions, silver ions (Ag^+) have received considerable attention in recent years because the use of silver, silver nanoparticles, and silver compounds has increased and recent studies emphasized bioaccumulation and the potential negative impact of Ag^+ on aquatic organisms [1–3]. Long term exposure of Ag^+ in water causes the death of exposed organisms such as environmentally benign bacteria [3]. Even nanomolar concentration of Ag^+ in water perturbs Na^+ and Cl^- homeostasis of fishes and invertebrates [2]. It is therefore essential to monitor Ag^+ in the environment, drinking water, food and biological fluids.

Conventional methods for Ag^+ measurement include atomic absorption spectroscopy (AAS), inductively coupled plasma/mass spectrometry (ICP-MS), inductively coupled plasma/atomic emission spectrometry (ICP-AES), ultraviolet–visible (UV–vis) spectroscopy, etc. Although these techniques are highly sensitive and selective, they require tedious sample preparation and preconcentration procedures, expensive instruments, and professional personnel. Moreover, they are inappropriate to be used as portable devices for real-time and on-site detection. In contrast, biosensors, especially fluorescent sensing, have great potential in high throughput detection of Ag^+ on-site [4–7]. Further, rapid development of nanotechnology has provided new opportunities for improved performance of fluorescence sensors in terms of sensitivity, selectivity and reproducibility. Fluorescent sensing is based on analyte-induced changes in the physicochemical properties of fluorophores such as fluorescence intensity, lifetime, and anisotropy, which are related to charge transfer or energy transfer processes [8,9]. However, relatively a few fluorescent sensors for Ag^+ have been reported compared with fluorescent sensors for other metal ions [10–16]. Furthermore, most of the fluorescent sensors for Ag^+ showed limitations in practical application due to low water solubility or other drawbacks. Hence, it remains essential to develop much simple, efficient and robustness methods of silver ion probe that can be used for detection of Ag^+ in complex water samples.



The rise of graphene has recently inspired great research interest in other types of ultrathin nanomaterials due to their attractive properties and various potential applications [17,18]. Therefore, following the same vein on graphene study, researchers have started the exploration of graphene analogs materials comprising stacked atomic or molecular layers. Strong covalent bonds in layers and weak Van der Waals interaction between layers allow the graphene analogs to form a robust two-dimensional (2D) nanostructure. Layered molybdenum disulfide (MoS_2) is one of the typical graphene analogs and a prototypical transition metal dichalcogenide material, which consists of covalently bonded Mo and S atoms [19]. Single-layer MoS_2 can be viewed as an "S–Mo–S" [10] sandwich structure, stacking a positively charged molybdenum plane between two negatively charged sulfur planes. Every

Mo is coordinated in a trigonal prismatic geometry to six S atoms. Owing to the specific 2D confinement of electron motion and the absence of interlayer perturbation, the MoS_2 monolayer possesses a direct band gap, showing dramatic improvement in photoluminescence quantum efficiency [20–22] and leads to an attractive electrocatalytic activity [23].To our surprise, it has been found that some fluorescent dyes underwent drastic quenching in the presence of MoS_2 nanoparticles (MoS_2NCs). Zhu et al. [24] designed single-layer MoS_2 based nanoprobes which have been successfully used as a sensing platform for the detection of DNA and small molecules. Goswami et al. [25] reported that fluorescence of Hoechst 33258 was efficiently quenched in the presence of MoS_2 nanoparticles and estimated the probability of the distance distribution between the donor (Hoechst 33258) and acceptor (MoS_2NCs) by employing a statistical method based on Forster resonance energy transfer (FRET)-based model. Compared with other nano-materials, except high fluorescent quenching efficiency, cheap bulk MoS_2 materials are engineered easily and single layer MoS_2 has good water solubility. Such reports imply that single or fewer layers MoS_2 could also be one of the most valuable quenching materials in environmental, biomedical, and other applications.

Considering all of these mentioned above, to the best of our knowledge, we report for the first time a novel FRET-based method for Ag^+ based on single-layered MoS_2. It is known that oligonucleotides can interact with some types of metal ions with high specificity [26]. It has been previously demonstrated that Ag^+ can selectively bind in between two DNA cytosine (C) bases and promote these C–C mismatches to form stable C–Ag^+–C base pairs. The Ag^+-mediated C–Ag^+–C pairs are more stable and have higher melting temperature than the Watson–Crick C–G pairs. Further, Ag^+ can be incorporated into the DNA duplex without largely altering the double helical structure because the van der Waals radius of silver (≈ 1.44 Å) is smaller than the base pair spacing of the DNA duplex (≈ 3.4 Å) [27,28]. In this work, the excellent quenching performance of single layer MoS_2 was combined with Ag^+-mediated base pairs "C–Ag^+–C" to sensitively and selectively detect Ag^+. Scheme 1 shows the design of fabrication of the assay for Ag^+ on single layer MoS_2. Compared with other reported methods, the proposed method has some advantages of simple instrument, low background and high sensitivity both in aqueous buffer and complex water.

Scheme 1. Schematic representation of fluorescent detection of Ag^+ on single layer MoS_2 platform (a FITC-labeled Ag^+ specific oligonucleotide, rich in cytosine, is employed as the fluorescent probe in sensing targets. When FITC-labeled DNA probe is in the state of random coil ssDNA, FRET from FITC-ssDNA to single layer MoS_2 occurs and fluorescence disappears. However, when the DNA probe is in formation of dsDNA due to the addition of Ag^+, the energy donor FITC is far away from the surface of single layer MoS_2 and fluorescence will be recovered).

2. Materials and methods

2.1. Materials

(5′-FITC-CTCTCTTCTCTTCATTTTTCAACACAACACAC-3′) were purchased from Sangon Biotech (Shanghai, China) Co., Ltd. and purified by HPLC. Bulk MoS_2 and *n*-butyllithium were from Aladdin (Shanghai, China). $AgNO_3$ and other inspected species (including Ni^{2+}, Cu^{2+}, Cr^{3+}, K^+, Na^+, Fe^{3+}, Pb^{2+}, Co^{2+}, Mn^{2+}, Hg^{2+}, Zn^{2+}, Al^{3+}, Fe^{2+}, Mg^{2+}, Cl^-, SO_4^{2-}, NO_3^- HCO_3^- and PO_4^{3-}) were prepared with ultrapure water from a Millipore system (18.2 M resistivity). All the experiments were carried out in phosphate buffer saline (PBS) buffer (0.1 mM PBS, 50 mM $NaNO_3$, 10 μM EDTA [29], pH 8.00).

2.2. Instrumentation

Bulk MoS_2 material was characterized by a scanning electron microscope (SEM). The morphology of single layer MoS_2 was characterized by a JEM-2100 transmission electron microscope (TEM) operated at 200 kV. Subsequently, a confocal laser micro-Raman spectrometer (HR800UV, JOBIN YVON) was used to obtain the Raman spectra of single layer MoS_2 with excitation wavelength being set at 633 nm. Finally, a fluorescence spectrometer (F-4600, Hitachi Co. Ltd., Japan) with a Xenon lamp excitation source was employed to record fluorescence spectra. The excitation was set at 490 nm and the emission was monitored at 518 nm.

2.3. Preparation of single layer MoS_2

Single-molecular-layer MoS_2 was prepared by exfoliation of lithium-intercalated MoS_2 powder in water with some modifications [30–32]. 0.35 g of layered bulk MoS_2 materials were mixed with 100 mL 1 M of *n*-butyl lithium in hexane solution, then the mixtures were stirred and allowed to react in nitrogen environment for 48 h at room temperature. After the mixture was filtrated, washed with hexane several times and dried, the lithium-intercalated MoS_2 powder obtained was exfoliated under ultrasonication for over 0.5 h (120 W) in 100 mL ultrapure water. During the whole experimental process, the lithium ions fulfill several important functions. First, the Li ions are inserted into the interlayer space of the layered bulk MoS_2 material, which expands the interlayer distance and weakens the van der Waals interactions between the layers. Second, the inserted Li^+ ions are subsequently reduced to Li^0 by accepting electrons during the discharge process. The metallic lithium can react with water to form LiOH and produce hydrogen gas. The generated hydrogen gas pushes the layers further apart [33]. Finally, the obtained stable MoS_2 dispersion was centrifuged to remove the unexfoliated monolayer MoS_2 and get the homogeneous single layer MoS_2 suspension (1.0 mg/mL).

2.4. Fluorescence spectra measurements

2.4.1. Selection of optimal MoS_2 concentration

FITC-ssDNA solution (500 nM) was incubated for 5 min at 90 °C and then cooled down slowly to the room temperature. Single layer MoS_2 solution was diluted by PBS buffer (pH 8.00) to a final concentration of 0.05 mg/mL. Different volumes (0–300 μL) of single layer MoS_2 solution (0.05 mg/mL) were mixed with 10 μL 500 nM of FITC-ssDNA in 1.5 mL test tube, and different volumes of PBS buffer were added to make each solution 400 μL, then these mixtures were vibrated and allowed to react for 0.5 h at 30 °C. Finally the fluorescence measurements were done at room temperature. To save the cost and time, kinetic assay is necessary to find turning point that fluorescence quenching and fluorescence recovery. 200 μL of single layer MoS_2 solution (0.5 mg/mL) was mixed with 10 μL 500 nM of FITC-ssDNA in cuvette, after 15 min,

20 μL of 2 μM Ag^+ in aqueous buffer and 170 μL PBS buffer were added. The fluorescence spectra were measured at 30 °C.

2.4.2. Assay for Ag^+ in aqueous buffer

FITC-ssDNA solution (500 nM) was incubated for 5 min at 90 °C, then cooled down slowly to the room temperature. 200 μL of single layer MoS_2 solution (0.05 mg/mL) was mixed with 10 μL 500 nM of FITC-ssDNA in 1.5 mL test tube, then the mixed solution was stirred and allowed to react for 5 min at 30 °C, after that, different volumes of 2 μM Ag^+ in aqueous buffer (0–20 μL) were added; finally, appropriate aliquot of PBS buffer (pH 8.00) was introduced to make each reaction solution 400 μL and final Ag^+ concentration (0, 1, 2, 3, 4, 6, 8, 10, 20, 40, 60, 80, 100 nM). The final mixed solution was stirred and allowed to react for 15 min at 30 °C. The fluorescence spectra were measured at room temperature.

2.4.3. Selectivity assays

In order to ensure the selectivity of the method towards Ag^+, the other 14 common metal ions and 5 common anions in natural water instead of Ag^+ were used to react with the above system and performed in the same manner. 200 μL of single layer MoS_2 solution (0.05 mg/mL) was mixed with 10 μL, 500 nM of FITC-ssDNA in 1.5 mL test tube, then the mixed solution was stirred and allowed to react for 5 min at 30 °C; after that, different metal ions (20 μL, 2 μM) in aqueous buffer were added, and finally, appropriate aliquot of PBS buffer (pH 8.00) was introduced to make each reaction solution 400 μL. The final mixed solution was stirred and allowed to react for 15 min at 30 °C. All the above experiments were conducted in PBS buffer (10 mM, 50 mM $NaNO_3$, 10 μM EDTA, pH 8.00).

2.4.4. Detection of Ag^+ in real samples

Atomic absorption spectrometry (AAS) was applied to detect Ag^+ in East Lake water to verify feasibility of this new Ag^+ probe and obtain real concentration of Ag^+ in lake water. East Lake water was filtered by 0.22 μm microporous membrane.10 μL FITC-ssDNA (500 nM) was incubated with 10 μL single layer MoS_2 (1.0 mg/mL) for 10 min at 30 °C; later, 380 μL of East Lake water was mixed in the above solution. The final mixed solution was stirred and allowed to react for 30 min at 30 °C. Also, the detection of Ag^+ in tap water has been completed. 380 μL tape water was mixed with Ag^+ aqueous solution. Then PBS buffer was added into mixed solution and made up the final volume of 400 μL. Final Ag^+ concentration is (e–a) 0, 5.00, 10.00, 50.00 and 100.00 nM, respectively. And then fluorescence spectra were monitored at room temperature.

3. Results and discussion

3.1. Characterization of single layer MoS_2

According to the method described in literature [30] with some modifications, single layer MoS_2 was synthesized. To confirm the successful formation of 2D MoS_2 nanosheet, the as-prepared MoS_2 was characterized by high resolution transmission electron microscopy (HRTEM) and bulk MoS_2 was characterized by SEM (Fig. S1). As shown in Fig. 1A, the sheet width of single layer MoS_2 was approximately 10 nm exhibiting relatively narrow size distribution [34]. Raman spectrum was used to further confirm the single-layer MoS_2 due to line width and frequency difference of the E^1_{2g} and A_{1g} Raman modes, which confirmed the effective reduction of flake thicknesses from the bulk MoS_2 to the dispersions [21]. Results in Fig. 1B reflect the characteristics of single layer MoS_2. The two peaks at 384 and 409 cm^{-1} are attributed to the in-plane E^1_{2g} and out-of-plane A_{1g} vibrations of single-layer MoS_2, respectively [35]. As the Raman spectra were consistent with those in previously reported literatures [18,21,32,35,36], it was proved that we had successfully prepared single layer MoS_2 in this work.

3.2. FRET between FITC-tagged ssDNA and single layer MoS_2

Single-layered MoS_2 is a kind of two-dimensional surface nanomaterial with favorable water solubility. Charge transfer from the electron donor to single or fewer layer MoS_2 material is substantial and is partially associated with the p-type nature of ultrathin MoS_2 material [37]. FITC-labeled ssDNA was absorbed rapidly when approached the surface of ultrathin MoS_2 via the van der Waals force between nucleobases and the basal plane of MoS_2, and was then quenched owing to charge transfer. Therefore, the fluorescence of FITC was efficiently quenched due to FRET between FITC and single layer MoS_2. According to Scheme 1, a FITC-labeled Ag^+ specific oligonucleotide, rich in cytosine, was employed as the fluorescent probe in sensing targets. The conformation of the probe would be changed from random coil single stranded DNA (ssDNA) to straight stiff double stranded DNA (dsDNA) with "C–Ag^+–C" base pairs followed by the addition of Ag^+. When FITC-labeled DNA probe was in the state of random coil ssDNA, FRET from FITC-ssDNA to single layer MoS_2 occurred, because the distance from the energy donor FITC to the energy acceptor single layer MoS_2 was shortened by the special p-type nature of ultrathin MoS_2 material [37] and Van der Waals force between nucleotide bases and single layer MoS_2. However, when the DNA probe was in formation of dsDNA due to the addition of Ag^+, the energy donor FITC was far away from the surface of single layer MoS_2 and FRET was disappeared. Therefore, the introduction of enough amounts of Ag^+ led to a large degree of fluorescence recovery, and the degree of fluorescence quenching

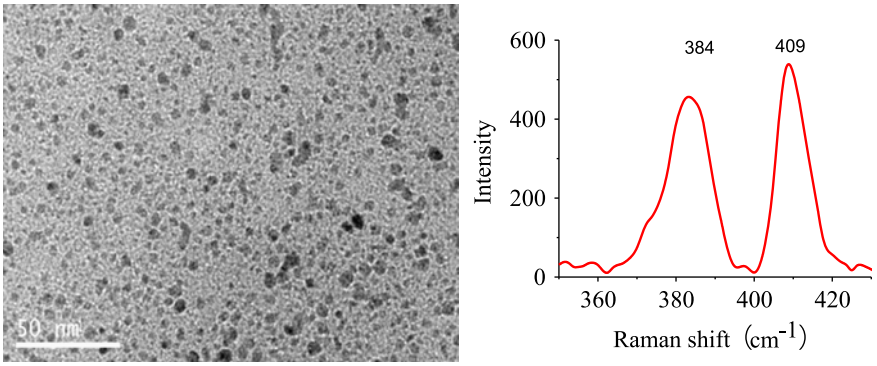

Fig. 1. High resolution transmission emission microscope (HRTEM) image of as-prepared single layer MoS_2 (A) and Raman spectra of single layer MoS_2 (B).

was closely related to the amount of added Ag^+ in certain linear range. The fluorescence of 12.5 nM FITC-ssDNA was effectively quenched by 25 μg/mL single layer MoS_2 (Fig. 2A, curve b), compared with the intensity without MoS_2 (Fig. 2A, curve a), indicating the strong quenching effect of single layer MoS_2 on the fluorescence of dye. The FITC-ssDNA rich in cytosine could capture Ag^+ by forming "C–Ag^+–C" base pairs. In the presence of Ag^+, the random coil ssDNA changed its conformation to rigid dsDNA, thus weakening the interactions between DNA nucleotide bases and single layer MoS_2 due to the hydrophilic force of the phosphoric skeleton in dsDNA, finally leading to the recovery of fluorescence (Fig. 2A, curve c). Results showed that the addition of Ag^+ induced the disappearance of FRET and the fluorescence recovery of FITC-ssDNA (Fig. 2B, curve b). Further, the fluorescence quenching kinetics was very fast, and highest fluorescence quenching efficiency was obtained within 5 min after FITC-ssDNA was mixed with the MoS_2 nanosheet solution. Meanwhile the fluorescence recovery kinetics was with up to best fluorescence recovery efficiency obtained within 15 min when Ag^+ was added into mixture solution (Fig. 3). This suggested that the designed Ag^+ probe system is successful and can be established with high performances.

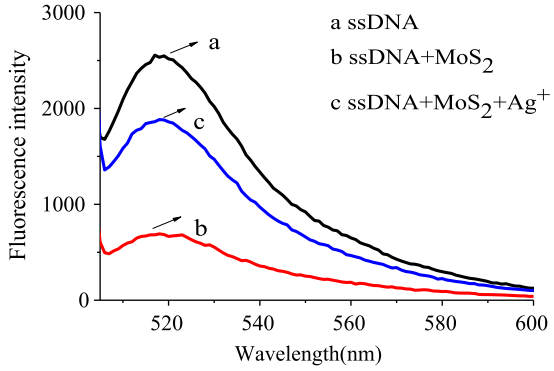

Fig. 2. Fluorescence spectra of before (curve a) and after (curve b) single layer MoS_2 (25 μg/mL) quenched 15 nM FAM-labeled ssDNA, and the change of fluorescence intensity after addition of Ag^+ (100 nM) (curve c). All these fluorescence spectra are carried out in PBS buffer at room temperature. The fluorescence is excited at 490 nm, and given in normalized form.

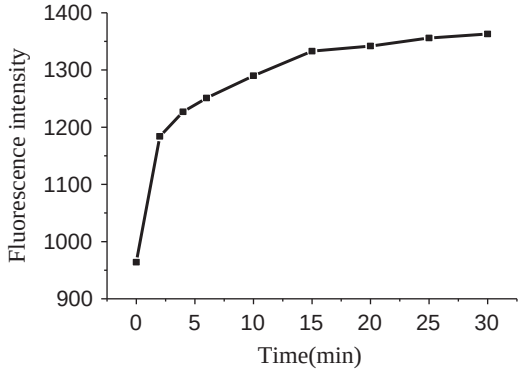

Fig. 3. Real-time fluorescence recovery records of mixtures with FITC-ssDNA (12.5 nM) and 25 μg/mL single layer MoS_2 upon additions of 100 nM Ag^+ (200 μL of single layer MoS_2 solution (0.5 mg/mL) are mixed with 10 μL 500 nM of FITC-ssDNA in cuvette, after 15 min, 20 μL of 2 μM Ag^+ in aqueous buffer and 170 μL PBS buffer is added. The fluorescence spectra are measured at 518 nm.).

3.3. Optimization of concentration of single layer MoS_2

Next, concentration of single layer MoS_2 was optimized as it is crucial in the detection of Ag^+ in aqueous buffer and complex water samples. As can be seen in Fig. 4A, the fluorescence intensity decreased gradually with the increasing concentration of single layer MoS_2, and a platform of fluorescence intensity was observed when the concentration of single layer MoS_2 reached 25 μg/mL (Fig. 4B). It indicated that too low concentration of single layer MoS_2 could lead to low fluorescence quenching efficiency and narrow detection range of Ag^+, while MoS_2 in high concentrations could have a poor effect on fluorescence recovery, and lower the sensitivity of Ag^+ determination. Therefore, an optimized concentration of 25 μg/mL single layer MoS_2 was chosen in the experiments.

3.4. Quantitative analysis of Ag^+ in aqueous buffer

As shown in Fig. 5, a new simple and sensitive assay for Ag^+ was successfully designed. The fluorescence intensity was dependent on the concentration of Ag^+ over a range of 1–100 nM when the concentration of single layer MoS_2 was 25 μg/mL. Fig. 5B shows that the fluorescence intensity increases rapidly as the concentration of Ag^+ increases from 1 nM to 6 nM ($R_1^2=0.996$). However, it exhibited another linear relationship ($R_2^2=0.995$) when the concentration of Ag^+ changed from 10 nM to 100 nM, where the fluorescence intensity increased more slowly as the Ag^+ concentration increased. The reason for this phenomenon was probably that FITC-labeled DNA in the state of random coil single strand was correspondingly abundant when Ag^+ was less than 6 nM in the system, and the plane structure of single layer MoS_2 could strongly adsorb these random coil single-strand

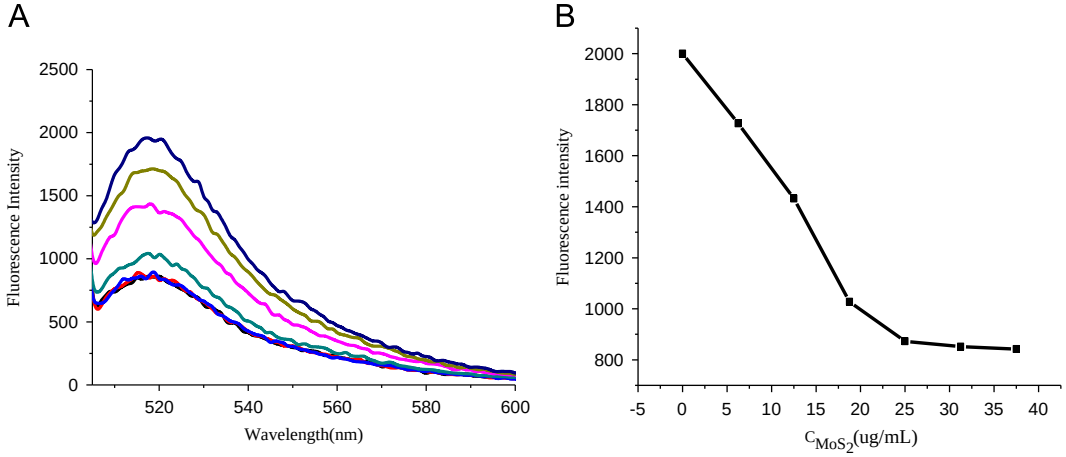

Fig. 4. (A) The fluorescence emission spectra of different concentrations of single layer MoS_2 (0, 6.25, 12.5, 18.75, 25, 31.25, 37.5 μg/mL) upon incubation with 12.5 nM FITC-ssDNA, then reacted with 100 nM Ag^+. (B) The fluorescence intensity at 518 nm changed against single layer MoS_2 concentration. The fluorescence spectra are excited at 490 nm. All experiments are in PBS buffer (10 mM, 50 mM $NaNO_3$, pH 7.4) at room temperature.

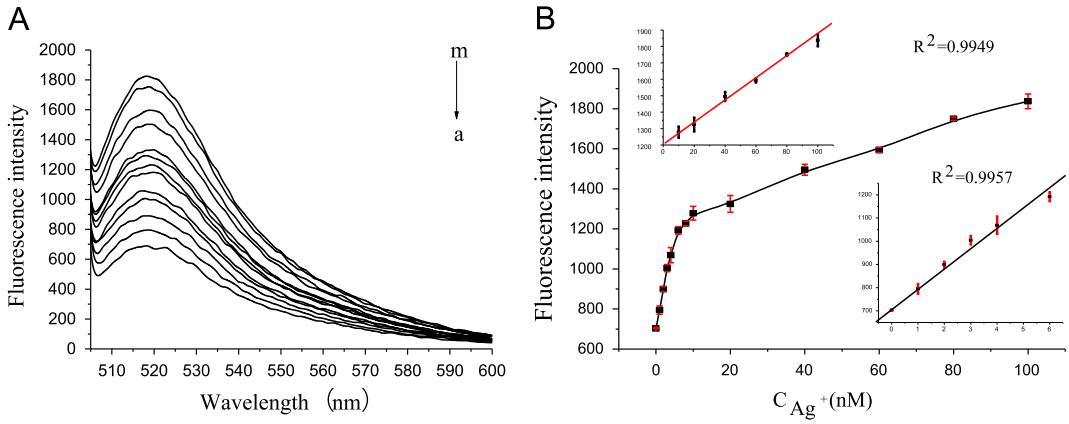

Fig. 5. (A) The normalized fluorescence spectra of 12.5 nM FITC-ssDNA upon incubation with 25 μg/mL single layer MoS_2, then reacted with a series of concentrations of Ag^+ (a–m: (0, 1, 2, 3, 4, 6, 8, 10, 20, 40, 60, 80, 100 nM)). (B) Calibration curve for Ag^+ detection in buffer, data are presented as average ± sd from three independent measurements. All these experiments are operated at room temperature and the fluorescence excitation and emission wavelengths are 490 nm and 518 nm, respectively.

Table 1
The precision of Ag^+ detection. The normalized fluorescence spectra of 12.5 nM FITC-ssDNA upon incubation with 25 μg/mL single layer MoS_2, then reacted with Ag^+ concentrations of 4.00 nM and 40.00 nM, respectively. All these experiments are operated at room temperature and the fluorescence excitation and emission wavelengths are 490 nm and 518 nm, respectively. Every experiment is repeated thrice.

$C(Ag^+)$ (nM)	Fluorescence intensity							RSD(%)
	0	6 h	12 h	24 h (1 d)	2 d	4 d	7 d	
4.00	1069.12	1072.34	1083.52	1104.64	1056.14	1047.87	1045.53	1.82
40.00	1495.41	1503.72	1431.35	1522.28	1436.62	1432.44	1468.36	2.38

Note: h is the abbreviation of the hour and d is the abbreviation of the day.

FITC-DNAs onto its surface, owing to the weak adsorption competition among the free FITC-ssDNA. When Ag^+ exceeded 6 nM in the system, free FITC-DNA in the state of random coil single strand became scarce. Adsorption competition among them became more intense, and so the fluorescence changed more slowly as the Ag^+ concentration increased. This method could be applied to detect as low as 1 nM (3 times the standard deviation rule) Ag^+ in aqueous buffer, and the detection range was wide, ranging from 1 nM to 100 nM. From this perspective, the proposed method towards Ag^+ has its own uniqueness, that is, the present method is much simpler and more effective to detect Ag^+ down to trace levels Table 1.

3.5. Selectivity of the method towards Ag^+

For determination of Ag^+ in natural water, the main interference includes other metal ions, such as Ca^{2+} and Mg^{2+}, because they always coexist with Ag^+. The results are demonstrated in Fig. 6, showing that no other metal ions interfered with the detection of Ag^+ in natural water. Furthermore, the effects of the other 12 common metal ions were taken into account. Typically, under optimum experimental conditions, the Ag^+ detection system was incubated respectively with 100 nM Ag^+ and 10 μM other 12 other metal ions in PBS buffer. As shown in Fig. 6, compared with the Ag^+ system, the existence of the other 12 commonly seen metal ions had almost no influence on detection of Ag^+. This suggested that the binding affinity of Ag^+ to a "C–C" mismatch site appeared to be much stronger than that to all metal ions except for Ag^+. The results clearly illustrated the specificity of the method for Ag^+.

3.6. Detection of Ag^+ in real samples

In order to further investigate the potential application of the sensor in the practical samples, the assay was used to detect Ag^+ in lake water and tap water. The concentration of Ag^+ in lake water

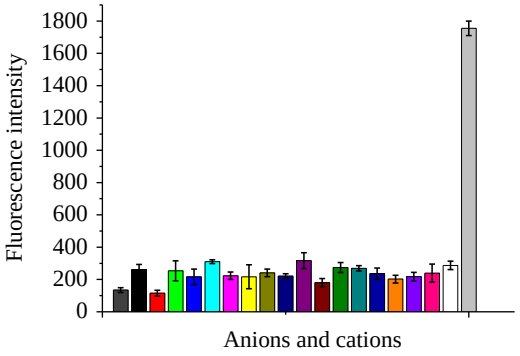

Fig. 6. Selectivity of single layer MoS_2-based method for Ag+. The other 14 common metal ions and 5 common anions in natural water instead of Ag^+ are used to react with above system and performed in the same way. The Ag^+ concentration of 100 nM is tested, while the concentration of other inspected species is 10 μM. All these experiments are operated at room temperature and the fluorescence excitation and emission wavelengths are 490 nm and 518 nm, respectively. Note: from left to right: Cl^-, SO_4^{2-}, NO_3^-, PO_4^{3-}, HCO_3^-, Ni^{2+}, Cu^{2+}, Cr^{3+}, K^+, Na^+, Fe^{3+}, Pb^{2+}, Co^{2+}, Mn^{2+}, Hg^{2+},Zn^{2+}, Al^{3+}, Fe^{2+}, Mg^{2+} and Ag^+.

from the East Lake of Wuhan, Hubei Province, China was chosen to detect Ag^+. To verify the feasibility of this new Ag^+ probe and obtain real concentration of Ag^+ in lake water, atomic absorption spectrometry (AAS) was applied to verify Ag^+ concentration in East Lake water compared with the Ag^+ probe in this work. Real concentration of Ag^+ detected by AAS in lake water is 1.039 nM (SD=0.002, n=3). As shown in Fig. 7, the concentration of detection of Ag^+ in the lake water (Fig. 7, curve b) was approximately equal to 1.04 nM Ag^+ in aqueous buffer (Fig. 7, curve a). It is probably that lake water contained many kinds of metal ions. These complicated materials in lake water could stabilize the fluorescence strength in some way and on the other hand, they might also participate in the nonspecific adsorption competition with each other onto the single

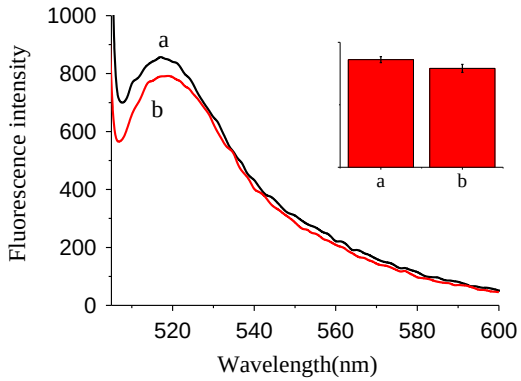

Fig. 7. Detection of Ag^+ in the East Lake water samples using fluorescence spectra of (a) single layer MoS_2+FITC-ssDNA+1 nmAg^+ aqueous buffer (b) single layer MoS_2+FITC-ssDNA+ lake water. Inset: corresponding histograms with error bar (standard deviation from the mean, $n=3$). Excitation wavelength is at 490 nm, and the emission intensity is monitored at 518 nm.

Table 2
Rate of recovery of Ag^+ 0.380 μL lake water mixed with Ag^+ aqueous solution, mixed solution final volume is 400 μL and final Ag^+ concentration are 4.00,8.00 and 12.00 nM, respectively. All these experiments are operated at room temperature and the fluorescence excitation and emission wavelengths are 490 nm and 518 nm, respectively.

Addition concentration of Ag^+ (nM)	Measured concentration of Ag^+ (nM)				Rate of standard addition recovery (%)			
–	$n=1$	$n=2$	$n=3$	Average	$n=1$	$n=2$	$n=3$	Average
0	1.02	0.98	1.04	1.01	–	–	–	–
4.00	4.64	4.62	4.73	4.66	90.75	90.25	93.00	91.33
8.00	8.75	8.31	8.64	8.57	96.75	91.25	95.38	94.46
12.00	12.36	12.44	12.71	12.50	94.58	95.25	97.50	95.78

layer MoS_2 surface. All these reasons led to the comprehensive result. Meanwhile, standard addition recovery experiment has been completed in our work. FromTable 2, good result (more than 90%) for rate of recovery of Ag^+ was obtained. Also, we have show an application of the proposed method in the tap water. According to our experimental data, no Ag^+ can be detected in tap water. So, low and certain concentrations of Ag^+ have been spiked into tap water. The result we detected for the concentrations of Ag^+ is closed to the theoretical concentration (see Fig. S2 in the Supporting information). In addition, the toxic levels for Ag^+ in drinking water are defined by the United States Environmental Protection Agency (USEPA) to be 10 nM [38]. The detection limit of this assay for Ag^+ (1 nM) was lower than the maximum limitation guided by the United States Environmental Protection Agency (EPA) as well as that permitted by the World Health Organization (WHO). Therefore, this sensor demonstrated great potential in practical applications.

4. Conclusion

In summary, a simple and novel approach based on FRET between single layer MoS_2 and FITC-ssDNA for detection of Ag^+ was proposed for the first time in this work. The proposed method exhibits higher sensitivity and selectivity toward Ag^+ even in the presence of other competitive heavy metal ions. Importantly, Ag^+ ion detections in lake water samples are performed to demonstrate the capablility of the sensor in practical applications. The developed sensor with high sensitivity and selectivity may be an alternative method for Ag^+ ion detection in environmental, biomedical, and other applications. Furthermore, we expect that this strategy based on single layer MoS_2 as fluorescent quencher may offer a new approach in sensitive and selective detection of a wide spectrum of analytes, high-through put drug screening and other metal ions.

ABSTRACT

A multifunctional label-free biosensor for the detection of Hg^{2+}, adenosine triphosphate and thrombin has been developed based on the changing of the electrochemical impedance spectroscopy (EIS) from the modified electrodes when nucleic acid subunits interacting with different targets. The modified electrode consists of three interaction sections, including DNA with T–T mismatch recognizing Hg^{2+} to form T–Hg^{2+}–T complex, split DNA chip against ATP, and DNA domin against thrombin to form G-quadruplex. Upon DNA interaction with thrombin or ATP, an increased charge transfer resistance (R_{ct}) had been detected. However, a decreased R_{ct} against Hg^{2+} was obtained. The R_{ct} difference (ΔR_{ct}) has relationship with the concentration of the different targets, Hg^{2+}, ATP and thrombin can be selectively detected with the detection limit of 0.03, 0.25, and 0.20 nmol L^{-1}, respectively. To separately detect the three analytes existing in the same sample, ATP aptamer, G-rich DNA strands and EDTA were applied to mask ATP, Hg^{2+} or thrombin separately.

1. Introduction

The development of biosensors for specific detection of bioanalyte has attracted particular attention due to their essential roles in clinical diagnostics [1], drug discovery [2] and environmental monitoring [3]. Among various biosensors, DNA-based ones are particularly interesting because of their high sensitivity [4], specificity [5] and easy regeneration capabilities [6]. The structural switching properties of DNA allow the biosensors to mediate target-responsive signal transduction. Over these years, great progresses have been made in developing DNA biosensors for the detection of small molecules [7,8] (e.g. cocaine or adenosine), proteins [9,10] (e.g. thrombin or lysozyme), or metal ions [11,12]. Although most of the biosensors are focused on monitoring single target analyte, many efforts have been taken to develop multifunctional DNA biosensors for the parallel detection of multiple target analytes [13]. For example, Du et al. [14] proposed a electrochemical impedance biosensor based on the integrated aptamer consisting of the adenosine triphosphate aptamer and the thrombin aptamer for the parallel detection of adenosine triphosphate (ATP) and thrombin with the detection limits of 1×10^{-8} and 1×10^{-11} mol L^{-1}, respectively. Deng et al. [15] adopted gold nanoparticles (AuNPs) as the signal amplifier and fabricated a sensitive bifunctional electrochemical biosensor for small molecule and protein. Lin et al. [16] designed a novel DNA-based electrochemical biosensor for the detection of three metal ions based on DNA interaction with Pb^{2+}, Ag^{+} and Hg^{2+}. These biosensors had been applied in real samples detection with satisfied results. However, to the best of our knowledge, no literature about simultaneous detection of metal ions, small molecules and proteins had been reported.

Electrochemical impedance spectroscopy (EIS) is one of the most generally used electrochemical techniques to monitor the properties of electrode surfaces. Any tiny changes on the electrode surfaces can be captured by impedimetric spectroscopy [17–19], which is widely employed in biosensors for monitoring bimolecular interactions or conformational changes. In this work, a sensitive multifunctional label-free electrochemical impedance biosensor is developed for the parallel detection of metal ion, small molecule and protein, and Hg^{2+}, ATP and thrombin were chosen as the example of metal ion, small molecule and protein. The targets could be captured onto the electrodes upon interaction with the sensing elements, in the present of Hg^{2+}, Hg^{2+} can insert into two DNA T–T mismatches, which leads to the formation of a T–Hg^{2+}–T pair, which elimination of the block of the electron-transfer reaction of the redox probe, however when the thrombin and ATP was introduced, the electrode surface formed an analogous insulating layer which retarded the interfacial electron transfer reaction of the redox probe, which further induces the changes of charge-transfer

resistance (ΔR_{ct}). As a result, three different analytes coexisting in a sample could be detected separately by a single biosensor.

2. Experimental

2.1. Materials and reagents

All oligonucletides were synthesized and purchased from Sangon Biotechnology Co. Ltd. (Shanghai, China). The sequences of oligonucleotides used in this study are list as follow:

Capture probe DNA (S1): 5′SH-TCAGACTTTTTTTTACCTGGGG-GAG TATGGTTGGTGTGGTTGGACG-3′.

Detection probe DNA (S2): 3′AGTCTGTTTTTTTTTGGAAGGAGG CGT GGTTGGTGTGGTTGGACG5′.

Linker Probe DNA (S3): 5′CCTGCTTTCGTCC3′.

G-rich DNA: 5′GGTTGGTGTGGTTGG3′.

ATP aptamer DNA: 5′ACCTGGGGGAGTATTGCGGAGGAAGGT3′

The sequences of split DNA against ATP and thrombin aptamer were labeled by wave line and straight line, separately.

6-Mercaptohexano (MCH), cysteine, adenosine triphosphate (ATP), cytidine triphosphate (CTP), guanosine triphosphate (GTP), anduridine triphosphate (UTP), bovine serum albumin (BSA), bovine Hemoglobin (BHb) and immunoglobulin G (IgG) were purchased from Sigma (St. Louis, MO) and used as received. The human serum had been got from the Hospital of Fuzhou University. Other chemicals were of analytical reagent grade and were used directly without further purification. Deionized water from a Millipore Milli-Q system was used throughout this work.

2.2. Sensor preparation

The Au electrodes (2 mm in diameter) were pretreated according to previous procedures [20]. Briefly, they were polished with various particle sizes (1.0 and 0.05 μm) of alumina slurry (Al_2O_3) and sonicated with pure water for 5 min and dried in a nitrogen stream to obtain clean gold electrode surfaces. They were electrochemically activated by consecutive potential scanning between −0.3–1.6 V in a fresh 0.5 mol $L^{-1}H_2SO_4$ solution under until stable cyclic voltammogram were obtained. Finally, they were rinsed with pure water and dried with nitrogen before modification. Capture DNA (S1) (10 μL) was dropped on surface of gold electrodes in a closed container at 37 °C for 2 h to form self-assemble monolayer, then the modified electrode was incubated into detection DNA (S2) (10 μL) at 37 °C for 2 h, and finally the electrodes was incubated into the buffer solution of linker DNA DNA (S3) (10 μL) for another 2 h before next experiment, and the final DNA concentration was 3.33 μmol L^{-1}. during the process, the capture DNA was modified onto the electrode surface first through thiol–Au interaction, then capture DNA was hybridized with detection DNA to form partially hybridized DNA (S1+S2), which was further hybridized with linker DNA (S3), finally the film of DNA (S1+S2+S3) was formed and modified to the electrode surface, then the electrode was incubated in 1 mM 6-mercaptohexanol (MCH) solution for 1 h to remove nonspecific DNA adsorption on the gold surface. The modified electrodes were finally incubated with different concentrations of Hg^{2+}, ATP and thrombin for 1, 2 and 1 h, respectively. For each step of immobilization, the EIS of the modified electrode was recorded while $[Fe(CN)_6]^{3-/4-}$ was used as redox probe. All experiments were carried out at laboratory ambient temperature.

2.3. Measurement

All electrochemical measurements were performed on a CHI Model 660D electrochemical analyzer (Chenhua Instruments, Shanghai, China) with a conventional three-electrode system. Au electrode, Ag/AgCl electrode and Pt wire were used as working electrode, reference electrode and counter electrode, respectively. EIS studies were performed in 5 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ solution containing 0.1 mol L^{-1} KCl. The AC (alternating current) voltage amplitude was 5 mV, and the voltage frequency was from 100 kHz to 100 mHz. The applied potential was 250 mV vs Ag/AgCl. A Randles equivalent circuit was used to fit the obtained impedance spectra.

3. Results and discussion

3.1. The principle of the biosensor

The protocol of the proposed biosensor is shown in Fig. 1. The capture probe with an alkanethiol moiety at the 5-terminus covalently immobilized on a gold electrode through Au–S bond, then detection DNA was partly hybridized with the capture probe through the linker DNA, result in the formation of the film of DNA (S1+S2+S3) onto the electrode surface. Both the capture and the detection probes consist of DNA fragments that serve as the sensing elements, in which T-rich DNA sequence, aptamer domain and split ATP aptamer recognize Hg^{2+}, thrombin and ATP, respectively. On the one hand, DNA S1 and S2 can bind with Hg^{2+} to form T–Hg^{2+}–T structure and the formed duplex-like DNA can promote the electron transfer, which results in the reduce of the charge transfer resistance R_{ct}. On the other hand, the addition of ATP can induce recombination of DNA S1 and S2 since both of which contain the sequence of split ATP aptamer fragments, this make the enhancement of the rigid structure of DNA S1+S2+S3, thus resulting in an increase of R_{ct}. In addition, DNA S1 and S2 which contain thrombin aptamer could also specifically recognize thrombin. The hybridized parts among DNA strands S1, S2 and S3 are dehybridized to form thrombin-stabilized G-quadruplex. Although DNA strand S3 is free released from the electrode and may provide an easier penetration channel for the redox probe, the macromolecular protein thrombin can be captured on the electrode surface to increase film thickness, thus resulting in a significant enhancement of R_{ct}.

Simple experiments had been performed to verify the feasibility of the proposed biosensor. Fig. 2 shows the EIS at different conditions. The equivalent circuit (Fig. 2, inset) as the model of the working electrode was applied to fit the EIS data [21], where R_s, Z_w and C_d are

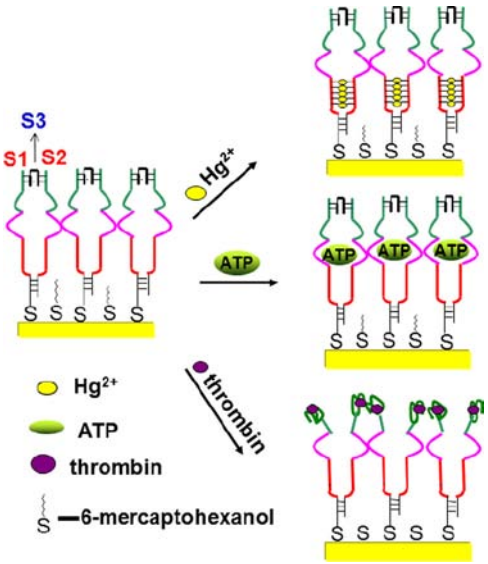

Fig. 1. Principle of the DNA-based EIS biosensor in response to Hg^{2+}, ATP and thrombin.

the electrolyte solution resistance, the Warburg impedance and the double layer capacitance, respectively. The most important parameter is R_{ct}, which reflects the electron transfer kinetics in the surfaces of the different electrodes. As shown in Fig. 2, curve *a* depicts the Nyquist diagram of the DNA S1+S2+S3 film modified gold electrode without analytes with R_{ct} of 2905 Ω. In the presence of Hg^{2+}, R_{ct} decreases to a smaller value (curve *b*, 1405 Ω) due to Hg^{2+} inserting into two DNA T–T mismatch and the formation of DNA(S1)/Hg/DNA (S2) complex as duplex DNA, thus enhancing the electron transfer ability of the redox probe on the electrode surface. Since ATP can induce the association of split aptamer fragments and the formation of DNA(S1)/ATP/DNA(S2) complex, the addition of ATP stabilizes the associated complex so that R_{ct} increases greatly (curve *c*, 5613 Ω). When thrombin is captured on the surface of Au electrode, R_{ct} increases significantly also (curve *d*, 4882 Ω) due to the bind of thrombin to the electrode surface, thus increasing the film thickness.

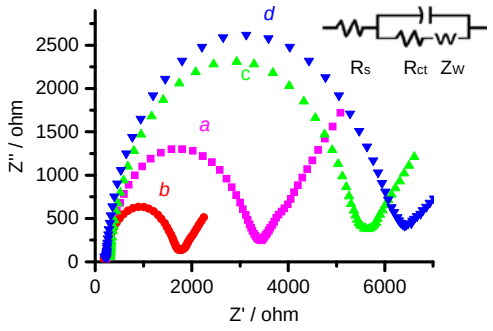

Fig. 2. Representative impedance spectra for the DNA biosensor before (a) and after incubating with 1 μmol L^{-1} Hg^{2+} (b); 1 μmol L^{-1} thrombin (c); 1 μmol L^{-1} ATP (d), respectively. The inset represent the equivalent circuit employed to fit the EIS measured data with 5 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ as redox probe.

3.2. Performance of the biosensor

In order to further investigate the analytical application, the biosensor was employed to detect Hg^{2+}, ATP and thrombin with various concentrations, respectively. As shown in Fig. 3A and Table 1, ΔR_{ct} decreased with increasing the concentration of Hg^{2+}, in which the ΔR_{ct} exhibited a linear relationship with the logarithm of Hg^{2+} concentration in the range from 5×10^{-7} to 1×10^{-10} mol L^{-1}. On the other hand, with the increase of the concentration of ATP, the formed DNA(S1)/ATP/DNA(S2) complex is progressively increased (Fig. 3B), which resulted in increased ΔR_{ct}. The linear responses of ΔR_{ct} against the logarithm of ATP concentration is from 1×10^{-6} to 1×10^{-9} mol L^{-1}. For thrombin, as shown in Fig. 3C, the increase of thrombin concentration caused the increase of ΔR_{ct}, until no distinct change in ΔR_{ct} was observed when the concentration of thrombin was decreased to 1 nmol L^{-1}. The ΔR_{ct} increased in line with the logarithm of thrombin concentration within a range from 1×10^{-6} to 1×10^{-9} mol L^{-1}. By the application of the R_{ct} difference (ΔR_{ct}), Hg^{2+}, ATP and thrombin were selectively detected with the detection limit of 0.03, 0.25 and 0.20 nmol L^{-1}, respectively, which was lower than the previous reported EIS sensor for Hg^{2+} [11], ATP [14] and thrombin [22]. The reproducibility of the electrochemical sensor

Table 1
The linear relationship between ΔR_{ct} and the logarithm of the concentrations of Hg^{2+}, ATP or thrombin.

	Linear regression equation (ΔR_{ct})	Regression coefficient (R)	Detection limit (mol L^{-1})
Hg^{2+}	303.78log$C$(Hg^{2+})+ 3208.16	−0.9918	3.0×10^{-11}
ATP	785.73log$C$(ATP)+ 7247.91	−0.9928	2.5×10^{-10}
Thrombin	531.46log$C$(thrombin)+ 5202.32	−0.9854	2.0×10^{-10}

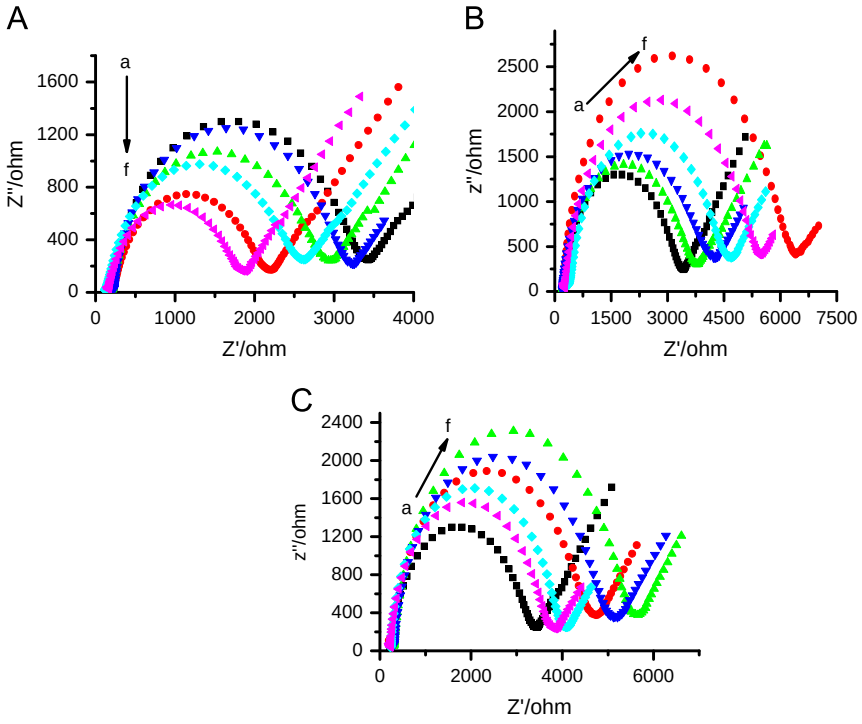

Fig. 3. Impendence spectra upon incubation with various concentrations of Hg^{2+}, ATP and thrombin at ambient temperature, (A) Hg^{2+} (a: 1×10^{-10} mol L^{-1}; b: 1×10^{-9} mol L^{-1}; c: 1×10^{-8} mol $^{-1}$; d: 1×10^{-7} mol $^{-1}$; e: 5×10^{-7} mol $^{-1}$; f: 0 mol L^{-1}); (B) ATP (a: 0 mol L^{-1}; b: 1×10^{-9} mol $^{-1}$; c: 5×10^{-9} mol $^{-1}$; d: 1×10^{-8} mol $^{-1}$; e: 1×10^{-7} mol $^{-1}$; f: 1×10^{-6} mol $^{-1}$); (C) thrombin (a: 0 mol $^{-1}$; b: 1×10^{-9} mol $^{-1}$; c: 5×10^{-9} mol $^{-1}$; d: 1×10^{-8} mol $^{-1}$; e: 1×10^{-7} mol $^{-1}$; f: 1×10^{-6} mol $^{-1}$).

was also investigated. Every five freshly modified electrodes were tested for the targets, respectively. All electrodes showed nearly similar electrochemical response, in which the relative standard deviation is 3.8% for Hg^{2+}, 3.0% for ATP and 4.8% for thrombin detection. The sensor still retained bioactivity after being stored at 4 °C for four weeks and impedance signal reduced less than 5%. These results suggest that the biosensor exhibits good reproducibility.

3.3. Separately detection of analytes

The introduced label-free multifunctional electrochemical biosensor could separately detect three different analytes. As mentioned above, in contrast with a decreased R_{ct} in response to Hg^{2+}, ATP and thrombin could induce an increased R_{ct}. When the signal is reduced upon the addition of the sample, we could first suppose that the sample contains Hg^{2+}, but it is still unable to determine whether the sample is a mixture. In order to exclusively detect Hg^{2+}, ATP or thrombin, masking agents was used to differentiate the electrochemical signals due to different analytes. EDTA, ATP aptamer and G-rich DNA were thus used for masking Hg^{2+}, ATP and thrombin, respectively. The mixture of EDTA and ATP aptamer successfully mask Hg^{2+} and ATP for the detection of thrombin. The mixture of EDTA and G-rich DNA was used for masking Hg^{2+} and thrombin for the detection of ATP, whereas the mixture of G-rich DNA and ATP aptamer was used for masking thrombin and ATP for the detection of Hg^{2+}. As shown in Fig. 4, it is demonstrated that the exclusive detection of Hg^{2+}, ATP and thrombin existing in the buffer solution could be achieved, respectively.

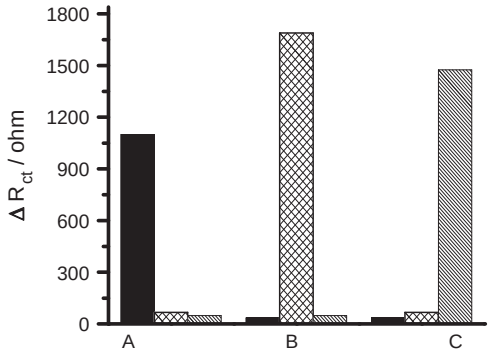

Fig. 4. (A) Specific detection of Hg^{2+}, ATP and thrombin existing in the buffer solution. (A) In the presence of ATP aptamer and G-rich DNA for Hg^{2+} determination; (B) in the presence of G-rich DNA and EDTA for ATP determination; (C) in the presence of ATP aptamer and EDTA for thrombin determination. The concentrations of masking reagents were both 10 μmol L^{-1}, and the targets were 100 nmol L^{-1}.

3.4. Interference study and sample detection

In order to explore the application of this biosensor in practical detection, the specificity of the multifunctional biosensor was also investigated. The interfering experiments were made when the analyte and the interfering species present in the same system. Other metal ions including Mg^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Cu^{2+}, Ca^{2+}, Fe^{3+}, Ag^{+} and Pb^{2+} were used as the interferents. It was revealed that only Hg^{2+} caused a considerable decrease of the R_{ct} (Fig. 5A). This is due to these metal ions could not insert into a T–T base pair to form a stable structure such as T–Hg^{2+}–T, and T–T base pair is only selective to Hg^{2+}. On the other hand, cytidine triphosphate (CTP), guanidine triphosphate (GTP) and anduridine triphosphate (UTP) were used in the control experiments to assess the specificity of the biosensor for the detection of ATP. As shown in Fig. 5B, significant changes in the EIS response were unobserved in presence of other triphosphates, implying that other nontarget molecules do not interact with the biosensor and thus not interfere with the detection of ATP. As for the detection of thrombin, bovine serum albumin (BSA), bovine hemoglobin (BHb) and immunoglobulin G (IgG) were used as the interferents to examine the selectivity of the sensor (Fig. 5C). It was found that the EIS response in the present of other interferents protein, the EIS response for thrombin was not found significant change. These results demonstrate that this biosensor displays a sufficient

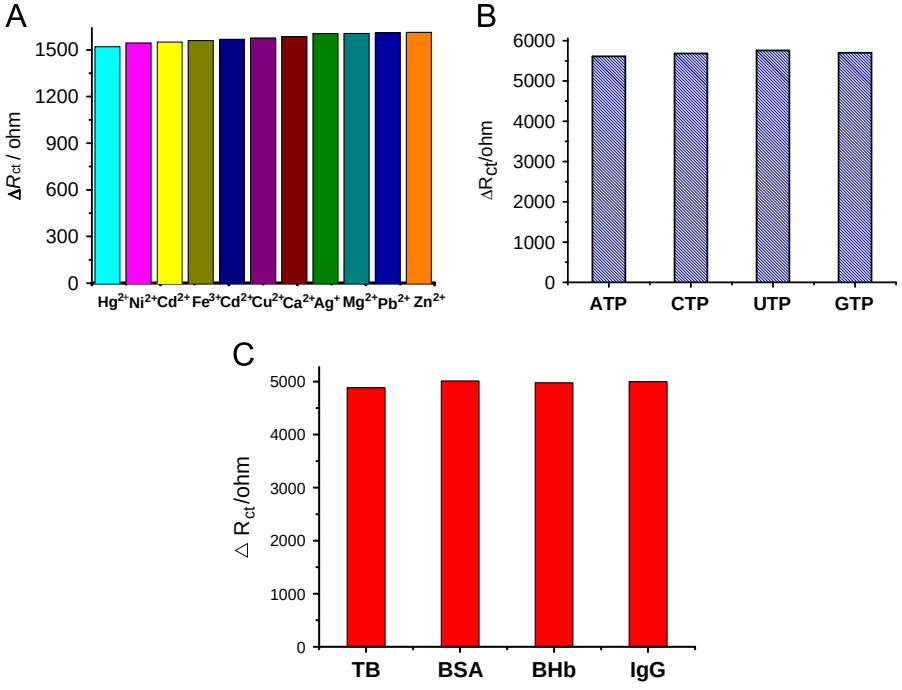

Fig. 5. Selectivity of the electrochemical biosensor. (A) Selectivity of the biosensor toward Mg^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Cu^{2+}, Ca^{2+}, Fe^{3+}, Ag^{+} and Pb^{2+} in the present of ATP and ATP. (B) EIS response for cytidine triphosphate (CTP), guanosine triphosphate (GTP) and uridine triphosphate (UTP) in the present of ATP and ATP. (C) EIS response for bovine serum albumin (BSA), bovine Hemoglobin (BHb) and immunoglobulin G (IgG) in the present of thrombin and thrombin. All the concentrations of tested molecules were used at 10^{-6} mol $^{-1}$.

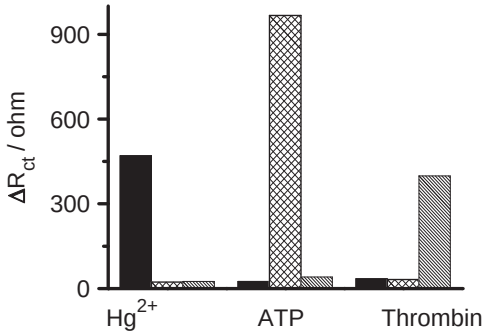

Fig. 6. Specific detection of Hg^{2+}, ATP and thrombin in the human serum in the presence of masking reagents, the concentrations of masking reagents were both 10 μmol L^{-1}, 10^{-8} mol L^{-1} Hg^{2+}, 10^{-8} mol L^{-1}ATP and 10^{-9} mol L^{-1} thrombin.

specificity for the exclusive detection of Hg^{2+}, ATP and thrombin, respectively.

To validate the possibility of the proposed biosensor in a real application, the human serum samples were spiked with different concentrations of Hg, ATP and thrombin, the concentration of Hg^{2+} is 1.5 mg/100 mL (75 nmol L^{-1}) which is defined by American Conference of Governmental Industrial Hygienists (ACGIH). Therefore, the concentrations in human serum were chosen to contain 1×10^{-8} mol L^{-1} Hg^{2+}, 1×10^{-8} mol L^{-1} ATP, and 1×10^{-9} mol L^{-1} thrombin, respectively. As shown in Fig. 6, simultaneous detection of three targets with masking reagents in the human serum was achieved. The results indicated that the biosensor has great potential for practical application.

4. Conclusions

An efficient, label-free DNA-based electrochemical impedance biosensor has been developed for the detection of Hg^{2+}, ATP and thrombin by taking advantage of the unique properties of split DNA fragment/target interaction and the specific aptamer target recognition. Hg^{2+} could interact with T–T mismatch even in the presence of other competitive metal ions to form T–Hg^{2+}–T so that the electron transfer is highly enhanced and the sensor showed high specificity for mercury(II). ATP could bind to partially split aptamer fragment and thrombin interacts with G-rich DNA strands to be preferentially adsorbed on the DNA modified Au electrode, both of which weakens the electron transfer. Based on this principle, we have successfully detected Hg^{2+}, ATP and thrombin at a concentration down to 0.03, 0.25 and 0.2 nmol L^{-1}, respectively. This electrochemical biosensor exhibits obvious advantages over the conventional methods. First, by combining of the unique properties of split aptamer fragment/target interaction and the specific aptamer-target recognition, label-free detection has been developed which makes the fabricating process simple and convenient, it took only 1, 2 and 1 h for the further detection Hg^{2+}, ATP, thrombin, respectively. Second, DNA could be prepared easily at low cost to afford a cheap biosensor. The multifunctional DNA-based biosensor shows good selectivity, reproducibility, and the useful life could retained for weeks for detection, which provides a promising platform for the electrochemical parallel detection of metal ions, small molecules and proteins, respectively. Moreover, the biosensor was applied to analyze targets in human serum with satisfactory results, which provide it could be used in the analysis of targets in complex samples.

ABSTRACT

A new pH sensing poly(vinyl chloride) (PVC) membrane electrode was developed by using recently synthesized 5,17-bis(4-benzylpiperidine-1-yl)methyl-25,26,27,28-tetrahydroxy calix[4]arene as an ionophore. The effects of membrane composition, inner filling solution and conditioning solution on the potential response of the proposed pH sensing membrane electrode were investigated. An optimum membrane composition of 3% ionophore, 67% *o*-nitrophenyl octyl ether (*o*-NPOE) as plasticizer, 30% PVC was found. The electrode exhibited a near-Nernstian slope of 58.7 ± 1.1 mV pH^{-1} in the pH range 1.9–12.7 at 20 ± 1 °C. It showed good selectivity for H^+ ions in the presence of some cations and anions and a longer lifetime of at least 12 months when compared with the other PVC membrane pH electrodes reported in the literature. Having a wide working pH range, it was not only applied as a potentiometric indicator electrode in various acid–base titrations, but also successfully employed in different real samples. It has good reproducibility and repeatability with a response time of 6–7 s. Compared to traditional glass pH electrode, it exhibited excellent potentiometric response after being used in fluoride-containing media.

1. Introduction

Accurate and reliable measurement of the pH in chemical, biological, clinical, industrial and environmental samples is always important [1–3]. The pH measurements are generally carried out by use of glass electrodes. They have become very popular due to their selectivity, reliability and dynamic pH range. Although pH-sensitive glass electrode has distinguished response characteristics and has been in use for such a long period, it has certain setbacks such as its high resistance, fragility, its instability in hydrofluoric acid or fluoride solutions, alkaline and acid errors and its unsuitability to serve as a microelectrode for biological applications [4,5]. Accordingly, the studies to develop non-glass pH-sensitive electrodes such as solid contact electrodes (SCE's) [1,6–13], coated wire electrodes (CWE's) [13,14], field effect transistors (FET's) [15,16], nanorod based electrodes [17,18] and polymeric membrane electrodes [19–33] have gained interest. Among these, PVC membrane electrodes are the preferred ones due to their low electrical resistance and ease of construction [31,32]. In addition, with the membrane supported by a tough material, they are solid and not easily fragile. These properties are critical, especially for in-vivo and in-vitro pH measurements. pH-sensitive membrane electrodes based on PVC are also considered for clinical applications and they are currently under investigation [8,10,22,34].

Many authors have focused on the design of new carriers for hydrogen ions to use as ionophores in the construction of pH sensing membrane electrodes. Among these carriers, hexafluorophosphate [1], diazacyclooctadecane [4], decamethylcyclopentasiloxane [6], hexabutyl-tri-amidophosphate [19], hex-3-ene [20], azole [21], phenoxazine derivatives (chromoionophores) [10,27,28], amines [11–13,22–25], pillar[5]arene [29] and calix[4]arenes [30–33] appear to be promising. Calixarenes are very popular as attractive and excellent ionophores due to their host–guest chemistry and ion-recognition properties [35,36]. It is stated in the literature that some specially designed calixarenes could successfully be used for the construction of pH electrodes [30–33].

Therefore, in this work, we focused on the possibility of us ing recently synthesized 5,17-bis(4-benzylpiperidine-1-yl)methyl-25,26,27,28-tetrahydroxy calix[4]arene (Fig. 1) as ionophore in the construction of a new pH sensing membrane electrode. It is known that calix[4]arene derivatives bearing amine or amide functions were capable of interacting with anions by hydrogen bonds.

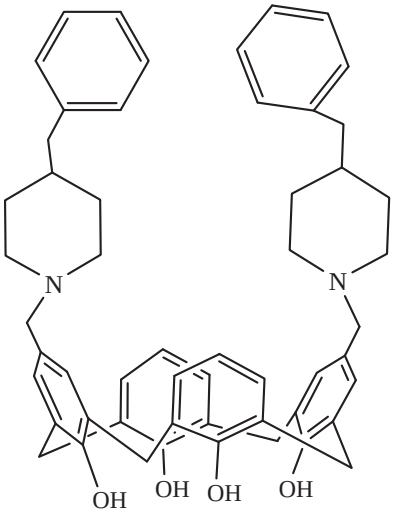

Fig. 1. The structure of 5,17-bis(4-benzylpiperidine-1-yl)methyl-25,26,27,28-tetrahydroxy calix[4]arene.

The studies regarding the removal of arsenate and dichromate ions from the aqueous solutions by using the calix[4]arene studied in liquid–liquid extraction indicated that it was protonated at proton-switchable binding sites in acidic conditions [37]. Hence, facilitating binding of anions at low pH is resulted from electrostatic interactions as well as hydrogen bonding via N atoms in upper piperidine rim and –OH groups in lower rim of the calix[4]arene derivative used in this study. It was considered that the calix[4]arene derivative could be used as suitable ionophore for hydrogen ion due to its possible reversible interaction with piperidine nitrogen or –OH groups of this compound. For this purpose, membranes with various combinations were prepared by changing the ratio of ionophore, PVC, plasticizer and lipophilic additive in order to determine the optimum membrane composition. The selectivity against some anions and cations, response time, lifetime, working range and other performance characteristics of the proposed electrode were investigated. The developed pH sensing membrane electrode worked well under laboratory conditions to determine titratable acidity and pH in real samples.

2. Experimental

2.1. Reagents and solutions

All chemical substances used were of reagent grade and were used without further purification.

High molecular weight poly(vinyl chloride), PVC, *o*-nitrophenyl octyl ether, *o*-NPOE, dibutyl phtalate, DBP, bis-(2-ethylhexylsebacate), BEHS, potassium tetrakis(*p*-chlorophenyl)borate, KT*p*ClPB, sodium tetraphenylborate, NaTPB, cesium tetrakis(3-methylphenyl)borate, CsT(3-Me)PB, and tetrahydrofurane, THF, were obtained from Sigma-Aldrich/Fluka in selectophore purity.

Britton–Robinson, BR, buffer solutions were used to investigate the performance of the pH sensing membrane electrode. BR buffer solutions were prepared by mixing appropriate amounts of boric acid, acetic acid and phosphoric acid; and the pH of these solutions were adjusted with the addition of diluted sodium hydroxide or hydrochloric acid solutions to the stock buffer solutions by the use of a combined glass pH-electrode.

The working solutions were obtained by dilution of 0.1 M stock solutions of ions with deionized water which was supplied from ELGA Purelab Classic Ultrapure Water System.

5,17-Bis-[(4-benzylpiperidine)methyl]-25,26,27,28-tetrahydroxycalix[4]arene was synthesized at the Department of Organic Chemistry of Selçuk University by procedures given in the literature [37].

2.2. Preparation of the electrode

The pH-sensing membrane electrode was prepared as follows: 0.0128 g of ionophore and 0.2851 g of *o*-NPOE were dissolved in 5 mL THF. 0.1276 g of PVC was slowly added to this mixture. The homogenous mixture formed was poured onto a glass disc with a diameter of 3.5 cm attached to a glass plate and was kept at room temperature for 24 h for the evaporation of THF. The 0.7 cm diameter disc of the polymer membrane was cut and fixed to the end of a glass tube with a diameter of 0.5 cm and a length of 10 cm.

An internal filling solution containing 1.0×10^{-3} M $CaCl_2$ was put into this glass tube and an AgCl-coated silver wire was placed into it. The prepared electrode was conditioned in deionized water for 12 h before each use.

2.3. Potential measurements

All potentiometric measurements were performed at 20 ± 1 °C by using the following cell assembly:

Ag/AgCl reference electrode | analyte solution | membrane | 1.0×10^{-3} M $CaCl_2$ | AgCl | Ag.

The potential measurements were made by the use of Mettler-Toledo SevenMulti pH–Ionmeter with Rondolino Sample Changer. The reference electrode was Ag/AgCl electrode (Mettler-Toledo Inlab Reference, catalogue no: 51343190). The pH measurements were carried out with Mettler-Toledo Inlab Routine Pro pH electrode (catalogue no: 51343055). The test solutions were stirred and the potentials were recorded after the equilibrium potentials had been reached.

The potentiometric titrations of hydrochloric, hydrofluoric and phosphoric acids were carried out with automatic titrater, Orion 940 expandable ion analyzer *S*/*N* 5816. The proposed electrode was employed in real samples such as vinegar, red wine, beer, fizzy drinks and fruit juices to demonstrate its applicability.

All electrochemical measurements were carried out with CHI660D Electrochemical Workstation and the experimental data taken under open circuit potential was recorded with three electrode cell in which Ag/AgCl/KCl, 3 M was the reference electrode. The electrode under study was the working electrode and the auxiliary electrode was platinum wire (BASi MW-1032). The impedance spectra were recorded in solutions of acetate buffer and BR buffer containing sodium chloride within the frequency range of 100 kHz to 0.01 Hz at 0.2 V and the amplitude for the sinusoidal excitation signal was 0.05 mV.

3. Results and discussion

3.1. The determination of the membrane composition

In the field of ion-selective electrodes (ISE), the common range of membrane composition was determined as 1–7% ionophore, 28–33% PVC (internal matrix), 60–69% plasticizer (solvent) and 0.03–2% lipophilic anion [38]. Herein, the optimum membrane composition for the proposed pH-sensing membrane electrode was found as 3% ionophore, 67% plasticizer and 30% PVC. The results obtained from the electrodes prepared with different membrane compositions are summarized in Table 1. The SEM images for the membrane of the proposed electrode with and without ionophore were shown in Fig. 2. The surface of both

Table 1
Effect of the membrane composition on the potentiometric response of new calix[4]arene based pH-sensing membrane electrode (Plasticizer/PVC=2.2).

Electrode number	Membrane composition (wt%) (m_T: 425.5 mg)				Slope $\pm tS/\sqrt{N}$ (mV pH^{-1})		Linear pH range

[a] Lipophilic additives were 70% mole ratio relative to the ionophore.

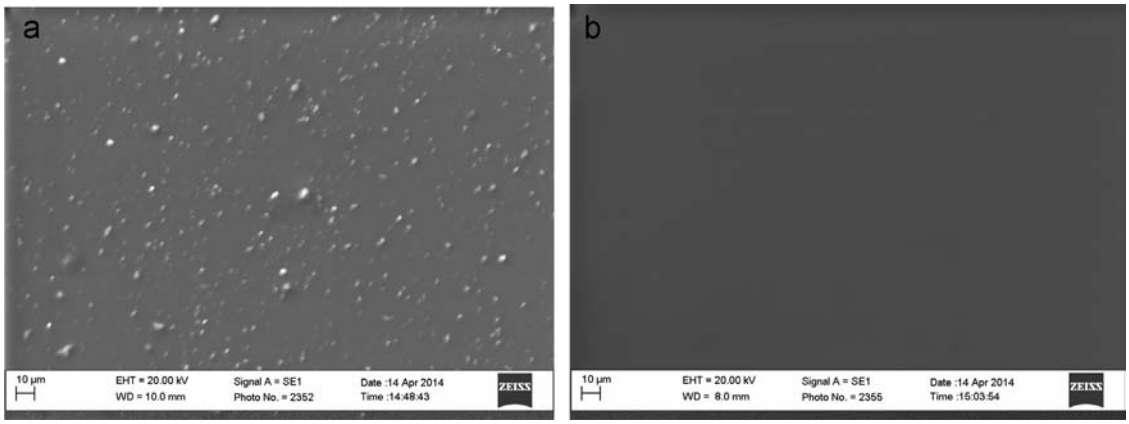

Fig. 2. SEM images of the PVC membranes containing 67 % *o*-NPOE and 30 % PVC (a) with 3% ionophore (b) without ionophore.

membranes was uniform and there were no defect. It can be seen that white spots in Fig. 2a referred as ionophore, which enhanced the sensitivity of H^+ ions of the membrane, was distributed hom ogeneously.

Concerning the effect of concentration of the macrocyclic compounds introduced into the membrane upon the selectivity, working range and the slope of the electrode, it is reported that the interaction between the macrocyclic compound and the species to be determined has a notable influence on these features [38]. Therefore, the preliminary studies were carried out by the membranes prepared by keeping the plasticizer/PVC ratio at 2.2 and changing the ratio of ionophore in the range 1–3%. As can be seen in Table 1, the electrode prepared with polymeric membrane containing 1% ionophore (electrode 2) and without ionophore (electrode 1) showed sub-Nernstian slopes in the linear working range of pH 1.9–10.7 and pH 3.2–10.7, respectively. It is stated in the literature that the complex stoichiometry between the macrocyclic compound and the analyte ion is of great importance regarding the selectivity and the slope of the electrode [38,39].

Therefore, the percentage of the ionophore in the membrane was increased up to 2 and 3% in order to investigate the effect of the ionophore concentration upon the performance. Not only the slopes of electrode 3 (53.3 ± 1.4 mV pH^{-1}) and electrode 4 (58.7 ± 1.1 mV pH^{-1}) were improved but also the linear working ranges were observed to be better than those containing 1% ionophore. We concluded that increasing the ionophore ratio upto 3% provided better response characteristics and the studies related to optimization of the membrane composition were continued by keeping the ionophore ratio at 3%.

Due to the fact that the plasticizers change the dielectric constant of the membrane phase, the type of the plasticizer has a remarkable effect upon the selectivity and the performance characteristics of the ISE membranes [40–42]. Therefore, DBP, BEHS and *o*-NPOE were used to investigate the effect of the plasticizer. It is clear in Table 1 that the electrode containing *o*-NPOE (electrode 4) exhibited higher slope and wider linear working range than that of the electrodes prepared with DBP (electrode 5) and BEHS (electrode 6). This led us to conclude that *o*-NPOE was the best membrane plasticizer for the proposed pH-sensing membrane electrode. That was why all the studies to determine the performance of the electrode and all the analytical applications relating to it were performed by the use of this electrode.

It is well-known that the addition of a lipophilic anion to neutral carrier membranes improved almost all of the electrode characteristics, since it stabilizes the membrane operating conditions, decreases the membrane resistance and significantly reduces the response times [39,43,44]. In our study, the electrodes were prepared by using KT*p*ClPB (electrode 7), NaTPB (electrode 8), and CsT*p* (3-Me)PB (electrode 9) as lipophilic additives. These electrodes showed weaker H^+ selectivity with sub-Nernstian slopes and narrower pH ranges. This is not in accordance with the literature, since it is claimed that the addition of lipophilic sites to the membrane phase improves the performance of the electrodes. It may be attributed to the fact that sodium, potassium and cesium ions which form ion-pairs with tetraphenylborate and tetrakis(*p*-chlorophenyl)borate, settle in the cavity of the calix[4] arene and decrease the number of active sites in the membrane. The adverse effect in our case can also be the result of the nature of the ionophore.

Taking into account both the slopes and the linear pH range of the electrodes, the electrode prepared with the membrane containing 3% ionophore, 67% *o*-NPOE and 30% PVC demonstrated the best Nernstian slope of 58.7 ± 1.1 mV pH^{-1} in the widest pH range

1.9–12.7 (electrode 4). Hence, further studies were performed with the electrode 4.

3.2. The effect of conditioning and inner filling solution

The effect of the conditioning upon the performance of the electrode was investigated by the use of two electrodes with the same membrane composition and 1.0×10^{-3} M $CaCl_2$ as inner filling solution. The electrodes were kept in 1.0×10^{-3} M HCl and in deionized water for 12 h, separately. The results obtained revealed that the performance and the lifetime of the electrode conditioned in deionized water were higher than that of the electrode conditioned in acid solution. Therefore, the electrodes were kept in deionized water prior to each experiment.

The composition and the concentration of the inner filling solution were found to have a significant effect on the potentiometric response of the PVC membrane electrodes by means of changing its selectivity and working range [45]. Either the chloride salts of inert electrolyte or the chloride salt of analyte ion with lower concentration were commonly used as internal solutions [46,47]. For this purpose, the electrode prepared with the membrane containing 3% ionophore, 67% *o*-NPOE and 30% PVC was filled with 1.0×10^{-3} M HCl and 1.0×10^{-3} M $CaCl_2$. From the view point of linear working range, it was determined that the most appropriate inner filling solution was 1.0×10^{-3} M $CaCl_2$. This application also confirmed that inner filling solutions prepared with inert salts have great effect on the working range of the electrodes [47].

3.3. Working range and the slope of the electrode

In order to investigate the working range and the slope of the electrode under study, two different types of calibration graphs were plotted (Fig. 3). The potentials measured were plotted against the pH values to obtain the first calibration curve (Fig. 3a) by using series of buffer solutions in the range of pH 1.9–12.9. The second calibration curve (Fig. 3b) was performed by recording the time elapsed to reach a stable potential value after the addition of diluted NaOH to access the appropriate pH (see Fig. 4). The proposed electrode was found much more suitable than many of the other alternatives given in the literature as regard to the linear working range and slope [1,6–14,16,18–20,22–25,30,32,33]. The comparison of response characteristics of some different type of pH sensing electrodes together with the proposed electrode are given in Table 2.

In this study, the impedance measurements were evaluated in two different buffer solutions containing sodium chloride. Fig. 5 (A) displays the impedance plots of the proposed pH sensing membrane and the same membrane without ionophore immersed into acetic acid/acetate buffer-NaCl solution (pH: 4). This type of spectra shows the behaviour of the membranes in the electrodes. As it can be seen, at high frequencies, the signal is mainly dominated by the electrical resistance and the geometric capacitance in parallel with the membrane which showed well defined semi-cyclic impedances [1,7]. The electrical resistance for the ionophore free membrane (electrode 1) was much lower than the resistance for the ionophore-containing membrane (electrode 4). On the contrary, it was stated in literature that the addition of neutral carriers such as alkyldibenzylamines had no effect on the electrical resistance of the membrane electrodes [24]. This behaviour may be attributed to the introduction of a huge neutral macrocyclic compound as calix[4]arene derivative to the membrane. On the other hand, there is a diffusional component ($\sim45^\circ$ line) at low frequencies which clearly indicates the reversible diffusion of the hydrogen ion from the solution into the proposed electrode membrane [7].

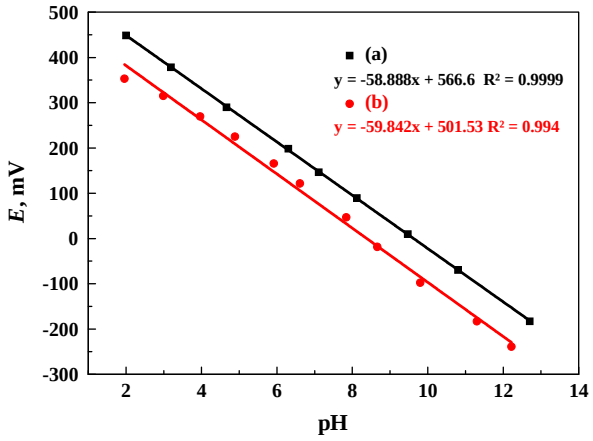

Fig. 3. Typical calibration graphs of the proposed pH sensing membrane electrode (electrode 4) plotted by the data obtained from (a) pH-ion meter and (b) potential-time graph.

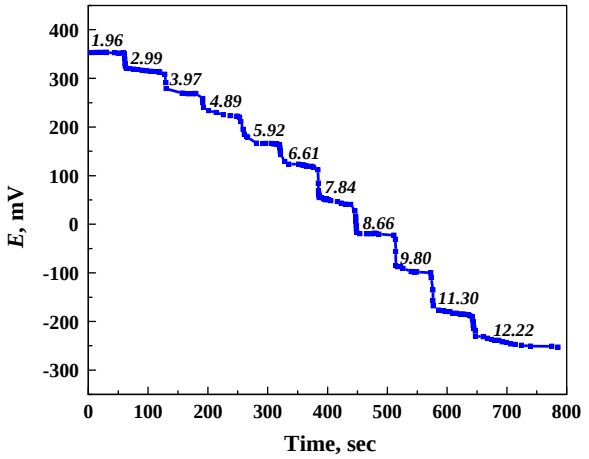

Fig. 4. Dynamic response of the proposed electrode for step changes in pH (electrode 4).

The impedance behavior of the proposed electrode in different pH buffered solutions (pH 3, pH 5 and pH 7) was presented in Fig. 5(B). The electrode displayed nearly the same semi-cyclic impedances at high frequencies. However, the bulk resistance increased with increasing pH values. This phenomenon was related to the transfer of hydrogen ion from solution to the calix [4]arene derivative in polymer layer. Hence, it is in accordance with the literature proposing that the energy of transfer of the hydrogen ion across the polymer membrane increased with increasing pH values [12,13].

3.4. Response time and lifetime of the electrode

The response time of an ion-selective electrode is an important factor for any analytical application. Therefore, the response time required for the electrode to reach 95% of equilibrium mV values after successful immersion in a series of solution each having a 10-fold difference in hydrogen ion concentration was measured. The static response time thus obtained was 6–7 s over the entire pH range (1.9–12.7) and no change was observed in 10 min. This was also confirmed from the potential-time graph in Fig. 4. The response times are comparable to, or even shorter than those reported in literature, that were found to give linear response in the same or narrower working ranges [6–12,30–34].

The lifetime of the electrode was determined by reading its potentials and plotting the calibration curves for a period of 12

PME	Calix[4]arene derivative	1.9–12.7	58.7 ± 1.1	6–7 s	This work

RSE redox system based electrode; SCE solid contact electrode; CWE coated wire electrode; FET field effect transistor; MOE metal oxide electrode; PME polymeric membrane electrode.

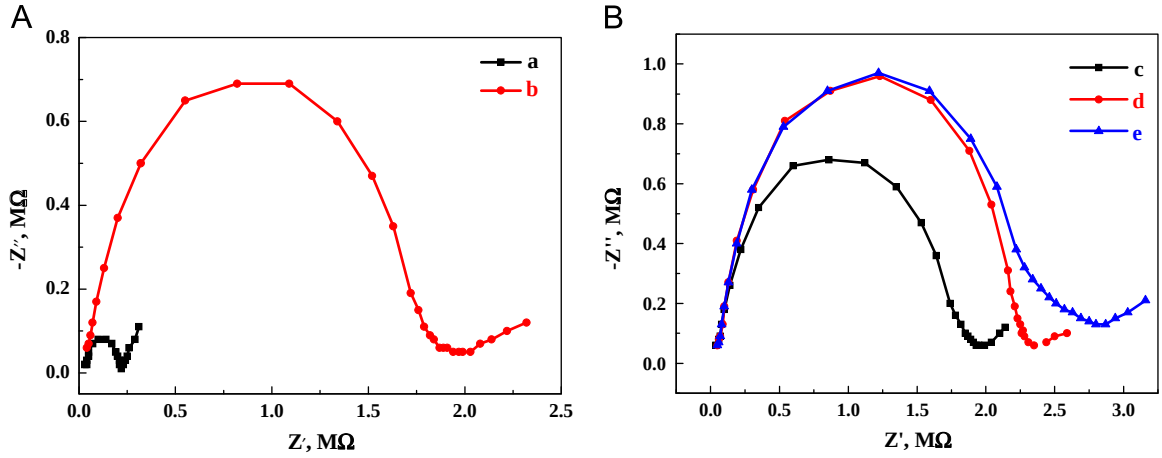

Fig. 5. Typical impedance plots of the membranes containing *o*-NPOE and PVC (A) in acetic acid/acetate buffer–NaCl solution (pH: 4): (a) without ionophore, electrode 1, (b) with 3% ionophore, electrode 4; (B) in BR buffer-NaCl solutions at: (c) pH: 3, (d) pH: 5, (e) pH: 7 for electrode 4.

months. The slope of the electrode was observed to show no significant change even after this period. This shows that the lifetime of the electrode prepared by the use of 5,17-bis(4-benzylpiperidine-1-yl)methyl-25,26,27,28-tetrahydroxy calix[4]arene was longer than the PVC membrane and other non-glass pH electrodes reported in literature with good repeatability and reproducibility [12,20,22,30–32].

3.5. The selectivity of the electrode

It is reported in literature that the working range of macrocyclic compounds-based electrodes was adversely affected by the anions and the cations. It is known that cations decrease the lower detection limit (at high pH) and anions decrease the upper detection limit (at low pH) of the pH electrodes [23,33]. In short, many ionic impurities are expected to narrow the working range of the electrode [13,43]. The interferences of cations such as Na^+, K^+, Li^+, NH_4^+, Mg^{2+}, Ca^{2+} (0.1 M) and anions such as bromide, iodide, chloride, nitrate, thiocyanate, perchlorate (1.0×10^{-3} M) were evaluated by the use of the fixed interference method (FIM).

The effect of the above mentioned anions on the pH response of the electrode was demonstrated in Fig. 6a. Tentatively notwithstanding, in the presence of higher anion concentrations at low pH values, anions form ion pair with hydrogen ions which are bonded to calix[4]arene thereby making the ionophore irresponsible, for the protons, to penetrate into and the system behaves insensitive to hydrogen ions. In this case, the potential is independent of the pH and is a function of the concentration of anions in the solution [31,32]. As it can be seen in Fig. 6a, the anions except from universal impurity chloride affected the working range of the proposed pH sensing membrane electrode. The following sequence of anion interference was observed: $ClO_4^- > SCN^- > I^- > NO_3^- > Br^-$.

Cation interference was also investigated in the region of high pH, where the hydrogen ion concentration is very low, but the above mentioned cation concentration is high, that causes alkaline error in case of some glass pH electrodes. The potentiometric response of the electrode in the presence of these cations indicated that the working range and the Nernstian slope were not changed (Fig. 6b). These results indicated that the corresponding cations would not cause any significant interference unless they present in concentrations > 0.1 M. These results are comparable to and even better than some of the data given for other PVC-based membrane electrodes in the literature [6,14,31–33]. Therefore, this electrode can conveniently be used for pH measurements in the media containing these ions.

3.6. The analytical applications of the electrode

The electrode was used in the titrations of hydrochloric, hydrofluoric and phosphoric acids with standardized sodium hydroxide. The titration curves were plotted in order to elucidate whether the prepared pH sensing membrane electrode can be employed as an indicator electrode in acid–base titrations. The same titrations were also carried out by the use of a commercial combined glass pH electrode. The expected end-points were observed identical for the proposed electrode and combined glass pH electrode. An example of each titration curves is given as supplementary material (Fig. 7). Furthermore, no erosion effect of hydrofluoric acid was observed on the prepared membrane. After a measurement with this electrode in hydrofluoric acid, the working range and the Nernstian slope remained the same. It can be concluded that the electrode prepared could be successfully employed in acid–base titrations and in fluoride containing media.

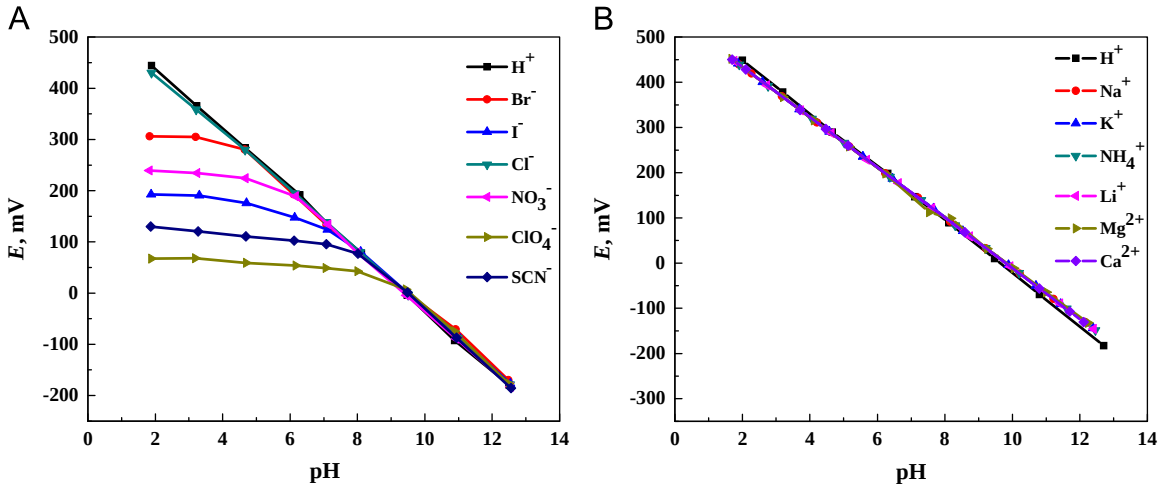

Fig. 6. Potentiometric response of the proposed electrode in the presence of (a) anions ($C=1.0\times10^{-3}$ M), (b) cations ($C=0.1$ M).

Table 3
The titratable total acidity of beverages found with the proposed electrode and commercial combined glass pH electrode (95% CL, $N=5$, $t_{crit}=2.78$, $F_{crit}=6.39$).[a]

Beverages	Glass pH electrode	Proposed electrode	t_{exp}	F_{exp}
Orange juice	13.3 ± 0.6	13.3 ± 0.6	0.1	1.0
Apple juice	9.8 ± 0.3	9.8 ± 0.1	0.4	0.2
Fizzy drink	0.6 ± 0.0	0.7 ± 0.0	2.3	0.2
Beer	0.6 ± 0.0	0.6 ± 0.0	0.1	1.0
Red wine	8.4 ± 0.2	8.1 ± 0.2	2.1	0.4
Vinegar	85.3 ± 4.3	83.6 ± 1.9	0.9	0.2

[a] The results were rounded as one digit beyond the decimal point.

The feasibility of the proposed electrode for the determination of the titratable acidity of some commercial beverages was also investigated [48]. Packaged of beverages were obtained from a local market (Ankara, Turkey). The analytical results obtained by this pH electrode were compared with those obtained by commercial combined glass pH electrode (Table 3). From Table 3, the critical value of t is 2.78 for the 95% confidence level and 4 degree of freedom. Since $t > t_{exp}$, no significant differences between the results obtained with the proposed pH sensing PVC membrane electrode and the commercial combined glass pH electrode was detected. Furthermore, since critical value of $F(6.39) > F_{exp}$, we concluded that the results obtained from the proposed electrode appear to give better precision than those from combined glass pH electrode at the 95% confidence level. It can be suggested that the developed calix[4]arene based PVC membrane electrode could be an effective tool for potentiometric determination of the titratable acidity in real samples.

4. Conclusions

5,17-Bis(4-benzylpiperidine-1-yl)methyl-25,26,27,28-tetrahydroxy calix[4]arene can be successfully used as an ionophore in pH-sensing membrane electrode. The proposed electrode can be a good alternative for a glass electrode. It showed good selectivity for H^+ ions in the presence of some cations and anions and a longer lifetime of at least 12 months. This electrode was also found much more suitable when compared with the other PVC membrane pH electrodes reported in the literature as regard to the linear working range and slope. Due to the fact that the electrode had a wide working pH range, it can be not only employed as an indicator electrode in acid–base titrations, but also can be used for the titratable acidity in different real samples. It was also successfully utilized in fluoride-containing media. The advantages of this electrode are its simplicity of preparation, low-cost, fast response time and long lifetime. Furhermore, it can be possible to prepare a PVC micro-pH electrode using the new calix[4]arene derivative to perform in-vivo pH measurements. We predicted that the proposed electrode could also be used as an anion-selective electrode for some anions due to the ability of protonated calix[4]arene binding anions reversibly to the polymer membrane by hydrogen bonds [49].

Fluorescent antibodies

ABSTRACT

Osteocalcin (bone gamma-carboxyglutamate protein; BGLAP) is a highly conserved molecule associated with mineralization of bone matrix. It regulates the dynamics of new bone formation and bone resorption. The synthesis of osteocalcin by osteoblasts is regulated by the active form of vitamin D. In this paper, we report the use of two fluorescent-based assays, one bead-based and a second involving an amino-silane surface pre-treatment, to obtain binding constants of $3.53 \times 10^6\ M^{-1}$ and $3.19 \times 10^6\ M^{-1}$, respectively, for the binding of BGLAP to fluorescently labeled monoclonal-anti BGLAP-clone 2D5. These simple microfluidic techniques demonstrate the feasibility of developing microsphere-based and surface electrostatically-attached binding assays to study peptide–antibody interactions. Both techniques utilize sub-microliter volumes of material an important consideration when studying bone turnover markers (BTMs) like BGLAP.

1. Introduction

The bone is a metabolically dynamic tissue that undergoes continuous remodeling throughout its lifetime. Bone remodeling serves to adjust bone architecture to meet changing mechanical needs and it helps to repair micro-damages in bone matrix preventing the accumulation of old bone [1]. Imbalances between osteoclast-mediated bone resorption and new bone formation causes metabolic bone disorders such as postmenopausal osteoporosis and osteopetrosis [2,3]. In osteoporosis, bone resorption outpaces bone formation resulting in ever porous bones. It is often treated by inhibition of bone resorption; however, bone formation is unfortunately also suppressed by this type of treatment illustrating the tightly coupled processes involved in bone remodeling. In osteopetrosis, the bones become denser due to an imbalance of bone formation over bone resorption [4]. The ability to detect and monitor the enzymes and proteins called bone turnover markers (BTMs), excreted biochemical products formed during bone metabolism would allow better understanding and earlier diagnosis of bone remodeling imbalance [5–7].

Osteocalcin, also known as bone gamma-carboxyglutamate (gla) protein (BGLAP), is a BTM produced primarily by osteoblasts during bone formation [8]. Because it is the most abundant of the non-collagenous proteins in bone it is widely studied as information can be garnered regarding bone formation and resorption. While BGLAP can be measured by a number of immunoassays they are hampered by the minute quantities of the protein in serum, lack of experimental protocols, and degradation in serum limiting analytical approaches to its study [9,10].

There are a myriad of studies espousing the use of bead-based techniques to probe the chemistry of biological systems [11–14]. Specifically, microsphere-based analyses enable facile separation of bound complexes from unbound species without the use of complex techniques and instrumentation. The limits of detection (LOD) are naturally decreased since the use of microspheres increases the surface area-to-volume ratio of the medium allowing for sample concentration. The plethora of microspheres commercially available come in a variety of diameters and surface termini thereby allowing for a paucity of chemistries to be conducted and heretofore immobilization of a wide range of biological species.

Poly(dimethylsiloxane) (PDMS) has for years been the material of choice in many microfluidic applications due to its elastomeric properties, ease of use and cost just to name a few reasons [15]. Unfortunately, unmodified PDMS is hydrophobic and is difficult to wet with aqueous solvents hindering many biochemical applications. In the important area of cell adhesion research, the use of amino-silane and homobifunctional aldehyde reagents has allowed for the covalent modification of PDMS and subsequent immobilization of proteins, antibodies, and other biological species.

In this paper we report the development of two fluorescence-based techniques to analyze the binding of BGLAP to fluorescently

labeled monoclonal-anti BGLAP-clone 2D5. In the first assay, BGLAP was covalently attached to magnetic beads and samples were incubated with increasing concentrations of fluorescently labeled anti-BGLAP clone 2D5 antibodies. The supernatant was extracted and injected into microchannels and the fluorescence measured to assess the extent of binding. In the second assay, 3-aminopropyltriethoxysilane (APTES) was used to modify the microchannel walls converting the –OH termini of the PDMS surface to an amine terminus. Injection of BGLAP into the microchannel caused it to electrostatically attach to the microchannel wall. Subsequent injection of bovine serum albumin to reduce non-specific binding, followed by fluorescently labeled antibody proved quantitatively the effectiveness of the assay. The use of these techniques demonstrate the ease of examining BTMs in a microfluidic platform and provide options to scientists to examine biological interactions where only minute quantities of expensive material may be available.

2. Experimental

2.1. Chemicals and materials

Osteocalcin Fragment 1-49 Human and Mix-n-stain Antibody labeling kit was obtained from Sigma-Aldrich Inc. (St. Louis, MO). Monoclonal Anti-BGLAP clone 2D5 antibodies and APTES were obtained from Sigma-Aldrich Inc. (St. Louis, MO). Negative photoresist SU-8-2025 and SU-8 developer were obtained from Microchem (Newton, MA). PDMS and Sylgard 184 silicone elastomer curing agent were purchased from Dow Corning (Midland, MI). Dynabeads M-270 carboxylic acid terminated magnetic beads were purchased from Invitrogen (Grand Island, NY).

2.2. Microchip fabrication

The master mold was created using the SU-8-2025 negative photoresist poured directly onto a 4 in. silicon wafer and was spun on a spin coater in order to achieve a uniform thickness of approximately 75 μM. A mask-aligner was used with a high-resolution transparency mask to create the channels on the wafer and the master mold. The PDMS and the curing agent were mixed at a ratio of 10:1, degassed, and poured directly onto the master mold. The microchip was cured at 75 °C for 2 h. This resulted in a chip with channels of the following dimensions: 100 μM width × 75 μM depth × 2 cm length. The inlet and outlet to the 10-channel chip were 25 μm in diameter and were made using a manual hole punch (Technical Innovations, Inc., Brazoria, TX). The microchips were then irreversibly sealed to a glass slide using plasma oxidation; the chip and the glass slide are cleaned using ethanol and are exposed to plasma oxidation.

2.3. Surface modification of microchannels

Six microchannels were incubated for 30 min with a 10% APTES in ethanol mixture to allow for silanization. At the conclusion of the incubation time the channels were washed with ethanol in deionized water, which was followed by incubation of osteocalcin in sodium bicarbonate at 1 mg/mL for 30 min. After incubation the channels were washed with deionized water and incubated with bovine serum albumin (BSA) at a concentration of 50 μM in PBS for 30 min. The microchannels were then washed with phosphate buffered solution (PBS) at a pH of 7.4 and channels 2–6 were incubated with fluorescently labeled antibodies ranging in concentration from 0.0 to 1.65 μM for 25 min. Channel 1 was used as a control and was not incubated with antibody. Once the incubation is complete all the channels were washed with PBS and the chips were ready for imaging.

2.4. Derivitization of magnetic beads

100 μL of carboxylic acid terminated magnetic beads was obtained from a stock solution consisting of 2×10^9 beads/mL. The beads were washed (5 ×) with 100 μL of 2-(*N*-morpholino) ethanesulfonic acid (MES) buffer (25 mM, pH 5.0). An external magnet was used at the end of each wash in order to separate the beads from solution and the supernatant was discarded. After the final wash, 200 μL of osteocalcin (1 mg/mL) in MES was added to the beads along with 100 μL of N-(3-Dimethylaminopropyl)-N′-ethyl-carbodiimide hydrochloride EDC (100 mg/mL) in MES and vortexed overnight. After 24 h of incubation the supernatant was removed from the bead solution. The beads were then washed with 100 μL of Tris buffer (50 mM, pH 7.4). Following the addition of Tris buffer, the beads were washed five times with PBS (100 mM, pH 7.4) in 1% BSA to block nonspecific binding. Lastly, the beads were washed once in PBS (100 mM, pH 7.4) and resuspended in PBS buffer. The bead solution was split into five aliquots of 20 μL and the supernatant was extracted. Different concentrations of fluorescently labeled anti-BGLAP clone 2D5 antibodies were made at concentrations of 0.0–1.65 μM and 20 μL of each was incubated with the functionalized beads for 30 min. After incubation the supernatant at each concentration was extracted and injected into channels 2–6 of a PDMS chip. Fluorescence measurements were taken of each channel.

2.5. Fluorescence microscopy and image processing

Fluorescence images were taken with a fluorescence microscope (Nikon Eclipse-2000U) equipped with a CCD camera (IN1820, SPOT Imaging Solutions, Sterling Heights, MI). A 20 × objective lens was used to focus the excitation and emission light. SPOT software was used to control the CCD camera and capture the images at an exposure rate of 105 ms and a gain of 4. ImageJ software was then used to analyze the images to extract intensity data. The background was subtracted from the intensity data for each concentration and plotted against the concentration. The binding isotherms were fitted using nonlinear regression with GraphPad Prism 5.0 (GraphPad Software, Inc., La Jolla, CA) to the Langmuir isotherm to determine the binding constants.

3. Results and discussion

In this work two different types of experiments were conducted to assess the binding of BGLAP to fluorescent antibodies. In the first series of experiments, BGLAP was covalently attached to magnetic beads and increasing concentrations (0.0–1.65 μM) of fluorescently labeled anti-BGLAP clone 2D5 antibodies were added into separate vials of solutions containing the derivatized beads. The supernatant was extracted after incubation for 24 h and injected into microchannels and the fluorescence was measured (Fig. 1). An increased fluorescence intensity is observed in the series of microchannels on increasing the concentration of fluorescent antibody. Subsequently, original antibody solutions were separately injected into a PDMS chip and their fluorescence also measured. The binding isotherm (Fig. 2) was obtained by extracting fluorescence intensity data from images of antibody solutions at different concentrations. The fluorescence intensity of free fluorescently labeled anti-BGLAP clone 2D5 antibody is an indirect method of measuring the amount of antibody bound to BGLAP. The binding constant was determined to be $3.53 \times 10^6 \pm 6.15 \times 10^5\ M^{-1}$ at the 95% confidence level.

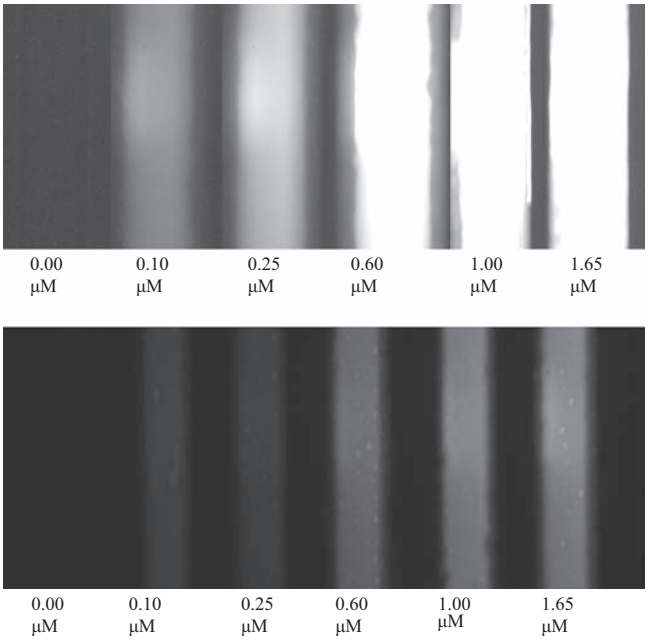

Fig. 1. Fluorescence inside microfluidic device for low to high concentrations of fluorescently labeled anti-BGLAP clone 2D5 antibody (magnetic bead method top image and APTES method bottom image). The images were taken at an exposure rate of 105 ms to avoid photobleaching and then analyzed to determine fluorescence intensity at each concentration.

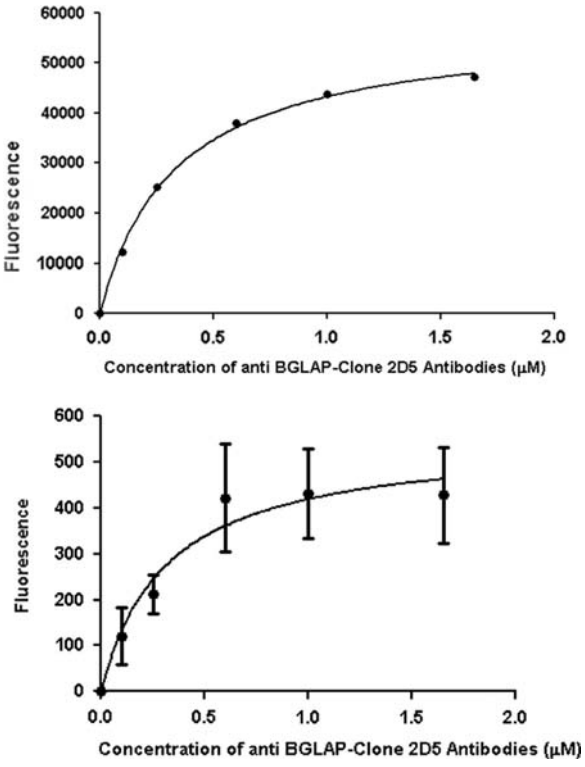

Fig. 2. Binding isotherms for fluorescently labeled anti-BGLAP clone 2D5 antibody from fluorescence microscopy using a bead-based assay (top) and surface modification assay (bottom).

In a second series of experiments, we used a similar surface modification we employed in the analysis of the glycopeptide antibiotics teicoplanin from *Actinoplanes teicomyceticus* and vancomycin from *Streptomyces orientalis* to 5-carboxyfluorescein-D-Ala-D-Ala-D-Ala (FAM-(D-Ala)$_3$ [16]. Here, 3-aminopropyltriethoxysilane (APTES) was used to modify the surfaces of a series of microchannels and each channel was subsequently exposed to a solution of BGLAP for a 25 min followed by washing and addition of BSA to reduce non-specific binding. There is no need for a pre-calibration of the amount of BGLAP electrostatically attached to the functionalized surface based on our earlier work with the glycopeptide antibiotics [16]. The microchannels are subjected to increasing concentrations of fluorescently labeled anti-BGLAP clone 2D5 antibody at room temperature followed by a wash with PBS. As shown in Fig. 1, the microchannels, with immobilized BGLAP, showed fluorescence after incubation with antibody. We speculate that the immobilization of BGLAP onto the microchannel surface results from the electrostatic attraction between the positively charged amine group on the microchannel surface and the negatively charged carboxyl groups on the BGLAP protein. The binding isotherm (Fig. 2) was obtained by extracting fluorescence intensity data from images of the microchannels with BGLAP incubated with antibody at different concentrations ranging from 0.0 to 1.65 µM. The binding constant was determined to be $3.19 \times 10^6 \pm 1.86 \times 10^6\ M^{-1}$ at the 95% confidence level.

Based on the two methods presented, a similarity in binding constants was obtained in both cases. To confirm this, a two-sample independent student *t*-test was utilized in order to determine if there was any statistical difference between the binding constants. When analyzed, it was determined that there was no statistical difference ($p > 0.05$) in the binding constants obtained using magnetic beads and APTES.

While a number of enzyme-linked immunoadsorbent assays (ELISAs) have been reported to detect BGLAP, we believe this report to be the first to actually quantify the binding of BGLAP to an antibody [17–19]. It is important to note, that this type of measurement is not unique in microfluidics as there is much precedent in the literature detailing both study and quantification of affinity constants between ligands and antibodies [20–22]. For example, Holden and Cremer provide a nice review on recent biophysical experiments to obtain mechanistic details of biomacromolecule interactions in microfluidic devices utilizing only nanoliters of analyte [23]. Because BGLAP is found in such small quantities in the body, techniques that offer high sensitivity and requiring minute sample volumes with short measurement times are at a premium.

4. Conclusions

In this study we have examined the binding constants of a fluorescent antibody to osteocalcin via two distinct techniques. The first assay involved the use of magnetic beads derivatized with osteocalcin that were subjected to increasing concentrations of fluorescently labeled anti-BGLAP clone 2D5 antibodies. The supernatant (free-antibody) was examined microscopically in a microchip and its extent of fluorescence could be used to assess the extent of binding between osteocalcin and antibody realizing a binding constant ($3.53 \times 10^6 \pm 6.15 \times 10^5\ M^{-1}$). The second assay first required the application of APTES to the microchannel wall to form a positively charged surface which upon addition of BGLAP electrostatically attached to the wall. Addition of increasing concentrations of fluorescently labeled antibody realized a binding constant $3.19 \times 10^6 \pm 1.86 \times 10^6\ M^{-1}$. The inherent ease of the assays detailed herein demonstrates the future potential of microfluidic-based assays of these types. Given the need for techniques that require minute quantities of materials and that are accurate, simple, inexpensive, and rapid, the development of fluorescent-based methods to analyze interactions like the one described herein are warranted. Future work will focus on expanding the range of interactions to be studied as well as integrating other microfluidic components to the devices.

Interference

ABSTRACT

Selectivity is extremely important in analytical chemistry but its definition is elusive despite continued efforts by professional organizations and individual scientists. This paper shows that the existing selectivity concepts for univariate analytical methods broadly fall in two classes: selectivity concepts based on measurement error and concepts based on response surfaces (the response surface being the 3D plot of the univariate signal as a function of analyte and interferent concentration, respectively). The strengths and weaknesses of the different definitions are analyzed and contradictions between them unveiled. The error based selectivity is very general and very safe but its application to a range of samples (as opposed to a single sample) requires the knowledge of some constraint about the possible sample compositions. The selectivity concepts based on the response surface are easily applied to linear response surfaces but may lead to difficulties and counterintuitive results when applied to nonlinear response surfaces. A particular advantage of this class of selectivity is that with linear response surfaces it can provide a concentration independent measure of selectivity. In contrast, the error based selectivity concept allows only yes/no type decision about selectivity.

1. Introduction

Selectivity is one of the most important features of any analytical measurement. Without selectivity, i.e., if the measuring system responded to every substance in exactly the same way both qualitatively and quantitatively, it would not be possible to determine the concentration of any particular substance in a mixture. It is therefore logical to expect that analytical chemists have a widely accepted definition of selectivity of analytical methods. One would also expect that selectivity can be quantitated in a meaningful way, so that one could compare methods or method variants according to their selectivities.

1.1. Lack of a general definition and of a measure of selectivity

Surprisingly, there is no generally accepted definition of selectivity in analytical chemistry, as shown by a recent review [1] and opinions diverge on its measurability. Some notable sources on the subject may be mentioned here. IUPAC has issued two recommendations and a technical report about the selectivity of general analytical methods [2–4]. It has also published selectivity definitions for particular methods, like potentiometry [5]. Guidelines for good laboratory practice require selectivity tests as part of method validation [6]. Metrological organizations define selectivity of measurements, including chemical ones [7,8]. Clinical chemists appear to avoid the term selectivity and discuss interferences instead [9]. Textbooks of analytical chemistry usually devote very little space to selectivity and either redefine it in an approximate fashion or cite an IUPAC definition as it has been shown in a review [1]. No two of the mentioned sources define selectivity in exactly the same way, and none of them quantitates selectivity (except for some special techniques, like potentiometry).

The common denominator of some of the more recent recommendations by the mentioned professional organizations is that they consider an analytical method selective only if interferences do not influence the measurement result at all or at least not significantly [1]. This is a very strict and therefore quite safe definition but it has some disadvantages. Analytical chemists often develop methods which need to work reliably with a large variety of samples. The question is then how one can prove that a method will be selective (in the above very strict sense) in any future samples to be investigated. Thus the recommendations shift the burden to the analytical chemist who should define the range of future samples which can be selectively analyzed with a particular method. Recommendations for solving this task have been

published in clinical chemistry [9], where the possible range of samples is more or less known, but similar recommendations are unlikely to be available or even possible for many other analytical problems.

The other disadvantage of the above mentioned definitions of selectivity is that while they may be satisfactory to characterize a fully developed method, they do not provide any quantitative measure of selectivity, not even an approximate one, which could guide the analytical chemist during method development in assessing and improving selectivity.

1.2. Narrowing of the problem

Interferences to an analytical method can be of many different types. One may have sample matrix effects, analytical reagents may undergo side reactions with some sample components, etc. In a frequently encountered type of interference some components of the sample may influence the measured signal in the same way as the analyte. This is a typical problem with sensors, but spectral overlaps are of the same type, and in immunoassays we also have cross sensitivities. Even if we reduce the selectivity problem to such cases (as will be done in this paper), there is no general definition and measure of selectivity available. In individual analytical techniques, though, measures of selectivity have been defined for this type of interference. In absorption spectroscopy at a single wavelength, when the Lambert Beer law is valid for mixtures, the ratio of the respective molar absorbances of the analyte and the interferent, respectively, is an obvious measure of selectivity (see below). In ion selective electrode potentiometry selectivity coefficients have been widely used. Such selectivity concepts are typically based on the response characteristics of a technique or a device in mixed solutions of the analyte and the interferent(s).

This paper investigates if the common selectivity concepts used in analytical chemistry are meaningful, i.e. free of internal contradictions and mutually compatible. This work appears to be the first one to carry out such analysis. It is based among others on our experience with selectivity problems of ion selective electrodes [10–13], numerous method validations following guidelines for Good Laboratory Practice (GLP) [14,15] and investigations about the selectivity of molecularly imprinted polymers [16,17]. An impulse to this work has been given by important recent recognitions about the selectivity of ion selective electrodes [18–21] supported by a large body of experimental data. This study was also motivated by the work of M. Valcarcel and coworkers, who have also recognized the lack of general approaches to analytical selectivity and contributed to the clarification of the term selectivity [22].

2. Selectivity concepts and their properties in the univariate case

The problem discussed here is defined as follows. An analytical output quantity (a signal or an estimate of the analyte concentration, in either case a scalar quantity) is influenced by two components' concentration (Fig. 1). One of these components is considered the analyte, the other the interferent. It is assumed that the response to the analyte alone is a strictly monotonous function of the analyte concentration. The interferent is supposed to affect the measurement in a similar manner to the analyte. This means here that the interferent alone would also give a monotonous calibration line with the same direction as the analyte. For simplicity we shall assume that the calibration lines are both monotonously increasing. It is also assumed that the addition of any of the two components to any mixture of them will increase the output value. All these assumptions are satisfied by many analytical methods.

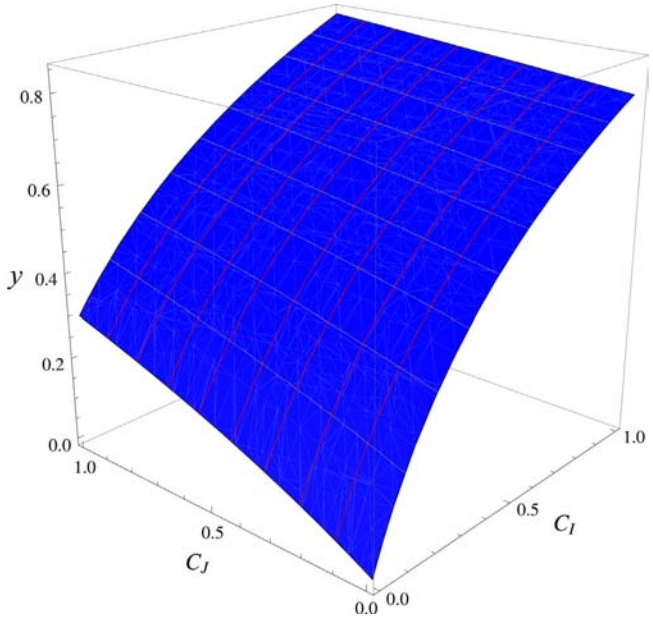

Fig. 1. A general response surface (y: measured signal, c_I: analyte concentration, c_J: interferent concentration).

The main ideas of the paper will be introduced by discussing first the simplest possible case, i.e., that of linear response in both concentration variables.

2.1. Linear response function

Let the measured signal, y, be a homogeneous linear function of the two concentrations, i.e.,

$$y = f(c_I, c_J) = k_I c_I + k_J c_J \tag{1}$$

here I denotes the analyte, J the interferent, c with a subscript stands for the respective concentration. The k-s are constants. (The equation might also include an additive constant. This would, however, not influence the final result.) The analyst wants to estimate the concentration of the analyte from the measured signal, y. Without having any further information, this is not possible, because there are two unknown concentrations but only one equation. As additional information the analyst may know, for example, that the ratio of interferent to analyte concentration is less than a certain value in all future samples. In another scenario the analyst may ascertain by a quick test or by sample preparation that the interferent concentration is less than a certain value. In either case a rational approach is to consider at first the total signal to be due to the analyte alone. By this procedure one obtains the highest possible value of the analyte concentration (because of the monotonicity criteria made above) which is in accordance with the measured signal value and the additional condition at the same time. This estimate of the analyte concentration may be in error, but as will be shown immediately, the maximum of this error may be estimated and compared with the required tolerance level.

The biased estimate, $\hat{c}_I$, of the analyte concentration is calculated, as proposed above, by dividing the signal, y, by k_I, which is the slope of the calibration line in pure I solutions:

$$\hat{c}_I = \frac{y}{k_I} = \frac{k_I c_I + k_J c_J}{k_I} = c_I + \frac{k_J}{k_I} c_J \tag{2}$$

This equation shows that the estimate is biased, it is higher than the true c_I. The relative error of the estimate is:

$$\frac{\hat{c}_I - c_I}{c_I} = k_{IJ}\frac{c_J}{c_I} \tag{3}$$

where

$$k_{IJ} = \frac{k_J}{k_I} \tag{4}$$

The maximum committed relative error can be estimated now from the maximal ratio of the two concentrations if this was the additional information. If this error is higher than the maximum allowed error, the method needs improvement. For example the interferent concentration may be reduced by sample pretreatment. Alternatively, the analytical device may be improved. If in the end the error of the method is less than the predefined error limit, then one may say that the method is selective for I compared to J, at least as long as the additional information about the samples is valid.

Analytical chemists have also other approaches to define selectivity. This is easily discussed for linear response functions [23]. One compares the values of k_I and k_J with each other. The method is considered selective for I if $k_I > k_J$ (which is equivalent to $k_{IJ} < 1$) and selective for J if $k_I < k_J$. If $k_I = k_J$ the method is not selective. These criteria are very reasonable. The relationship between the two constants shows to which compound is the method more sensitive. This type of selectivity may be simply characterized by k_{IJ}, which may therefore be called a selectivity coefficient. One should note that this second type of selectivity depends only on the response surface (which in the linear case is a plane), and does not depend on additional information about the samples.

The two selectivity concepts discussed here, i.e. the one based on error considerations and the one based on sensitivities, are not very simply related to each other. This is immediately seen if one considers the following example. Let there be a linear response surface with $k_{IJ} = 1$. In a particular sample the ratio of the concentrations, c_J/c_I, should be 0.01. The relative error of the c_I measurement is then 1% as predicted by Eq. (3). If this error level is tolerable, then the method will be considered selective (at least in the case of this sample and for any other samples where $c_J/c_I < 0.01$), because the effect of the interferent on the measurement result is negligible. But according to the other, sensitivity based definition of selectivity, the method is not selective at all, since $k_{IJ} = 1$, i.e., $k_I = k_J$.

The conclusion from these considerations is that two commonly used and apparently meaningful selectivity concepts are in conflict with each other even for the simplest possible response surface. This ambiguity may have contributed to the confusion about selectivity definitions.

Another conclusion is that the error based selectivity definition is only meaningful if we apply it either to a single sample instead of a method (which is not very practical in analytical chemistry), or if we make some tacit assumption about the composition of all future samples. Such assumptions may be difficult to check unless the composition of the samples is very restricted. In bioanalysis such restriction often exists for endogenous interferents which have a relatively narrow natural concentration range.

The selectivity concept based on the response surface parameter k_{IJ} has a great advantage: it provides a meaningful measure of selectivity for linear response surfaces in the form of k_{IJ}. It is also independent of assumptions about the sample composition. But it has also some disadvantages. Most importantly it cannot be transferred in a unique way to nonlinear response surfaces. This is so because k_{IJ} of a linear response surface can be interpreted in many different ways, which give the same result for a linear surface but usually different results for a nonlinear one. To give just two examples k_{IJ} can be interpreted as the ratio of the slopes of the separate calibration lines for I and J, respectively, or as the ratio of the two partial derivatives of y with respect to I and J, respectively.

A third approach to selectivity which is also intuitively appealing, consists of comparing the pure I and pure J concentrations, respectively, which belong to the same signal value. From Eq. (1) these are easily obtained for linear response surfaces:

$$c_I = \frac{y}{k_I} \tag{5}$$

and

$$c_J = \frac{y}{k_J} \tag{6}$$

If $c_I < c_J$ then the measurement may be regarded selective for I, since the same signal is caused by a smaller concentration of I than of J (and as assumed above the signal increases with concentration). From Eqs. (5) and (6) this type of selectivity for I occurs if $k_{IJ} < 1$, just like before. However, for nonlinear response surfaces this selectivity definition may have a complex relationship with the others.

2.2. General response function

In case of a more or less general response function (which still maintains monotonicity and smoothness as in Fig. 1) the problems of defining selectivity and of estimating the measurement error become worse. Sensitivity, i.e., the partial derivative of the signal with respect to either concentration, is no more a constant as it was in the form of k_I and k_J, respectively, in the linear case. The ratio of sensitivities for I and J, respectively, is only a local quantity (changing with both c_I and c_J) and not a universal constant.

Nonlinear response surfaces may complicate any statement about method selectivity. It is possible (as has been found, for example, in potentiometry [21]) that in certain ranges of c_I and c_J the method is selective for I and in other ranges for J. Thus one cannot always say that the method is selective for I or J, even if we consider only the response surface.

With some nonlinear surfaces a further type of selectivity has been defined, e.g., in potentiometry [18], which is conceptually different from those discussed so far. An interesting property of such surfaces is that given the parameters of the calibration line for the pure analyte I, the whole response surface (including the response to pure J) can be described by a single additional parameter. In potentiometry this parameter is the difference between the standard potentials measured in I and J solutions, respectively. This parameter (divided by a constant factor) has been called selectivity coefficient, although it does not describe selectivity in any of the above mentioned ways. However, it can be used to calculate any of those measures because it describes (together with the calibration parameters for I) the whole response surface.

2.3. Pseudo linear response functions

Since interpretation of selectivity becomes so difficult with nonlinear response surfaces, it is natural to ask if there are any practically existing nonlinear response surfaces which retain the simple properties of linear ones, with respect to selectivity. Interestingly, such surfaces exist. The Nicholsky equation in potentiometry (Eq. (7)) describes, for example, such a response surface if it is applied to two ions of identical charge.

$$E = E_I^0 + \frac{RT}{z_I F}\ln(a_I + k_{IJ}a_J^{z_I/z_J}) \tag{7}$$

(The notation is well known, only k is not in capital letter as in potentiometry.) It will be shown now that this equation is just one

representative of a special class of functions well-behaved in matters of selectivity.

Let us recall that for linear response surfaces the relative error was expressed by Eq. (3).

After simple rearrangement:

$$\hat{c}_I = c_I + k_{IJ} c_J \tag{8}$$

Similarly to the linear case, even if the response function is nonlinear, the biased estimate for the analyte concentration should be calculated from the measured signal by assuming that the concentration of the interferent is zero. Let us consider now only such response functions where for any (c_I, c_J) pair which gives the same signal y the relationship of Eq. (8) is valid. Then:

$$y = f(c_I, c_J) = f(\hat{c}_I, 0) = f(c_I + k_{IJ} c_J, 0) \tag{9}$$

here f means a general bivariate function. The right hand side of Eq. (9) describes a bivariate response surface which need not be linear. It is special, however, because it is an apparently univariate function of the variable

$$c_I + k_{IJ} c_J \tag{10}$$

with k_{IJ} being a constant. Due to Eq. (9) the error formula of Eq. (3) will be valid for such functions. As a practical example the Nicholsky equation for two ions of equal valency z satisfies this criterion:

$$E = E_I^0 + \frac{RT}{zF} \ln(a_I + k_{IJ} a_J) \tag{11}$$

As immediately seen, for a constant value of E the value of $a_I + k_{IJ} a_J$ is also constant. Note also that this equation is nonlinear.

One may call the response surfaces which satisfy Eq. (9) pseudo-linear surfaces. If a method has such a response surface then it can be characterized by a concentration independent selectivity coefficient. The measurement error is also easily calculated in this case, just like with linear response functions.

If the general condition of Eq. (9) is not satisfied, one can in many practical applications limit the allowed range of the variables c_I and c_J so that in the limited range Eq. (9) is valid, at least approximately. In certain analytical problems the analyte concentration can only move in a narrow range, so that the condition of Eq. (8)

$$\hat{c}_I = c_I + k_{IJ} c_J$$

needs to be satisfied with a k_{IJ} that is not an overall constant but can be considered constant in a narrow range of the analyte concentration. In this range it must be then independent of the interferent concentration.

2.4. The measure of selectivity

The previous discussion has shown that with certain response functions a constant and meaningful selectivity factor can be used. The constant k_{IJ} has been used here for easy comparison with the potentiometric selectivity coefficient. But k_{IJ} has a large value (i.e., much larger than 1) when the effect of the interferent on the signal is larger than that of the analyte. It would be therefore more appropriate to use the reciprocal of k_{IJ} to measure selectivity. In this paper we have used k_{IJ} for easy comparison with the Nicholsky equation (Eq. (11)).

3. Conclusion

Selectivity is an extremely important property of any analytical method but its definition and quantitation have still remained open questions. Many definitions of selectivity are possible and have indeed been used. They have been divided in this paper into two classes: definitions based on measurement error and definitions based on the response surface. Both types have their respective merits and problems. The error based selectivity is very general and very safe but its application to a range of samples (as opposed to a single sample) requires the knowledge of some constraint about the possible sample compositions. The selectivity concepts based on the response surface are easily applied to linear response surfaces but may lead to difficulties and counterintuitive results when applied to nonlinear response surfaces. A particular advantage of this class of selectivity is that with linear response surfaces it can provide a concentration independent measure of selectivity. In contrast, the error based selectivity concept allows only yes/no type decision about selectivity.

The relationship between the two classes of selectivity definitions has been derived for linear response surfaces (and with the necessary assumptions about the constraints of sample composition). It has been shown that the error based selectivity and the response surface based selectivity may be contradicting, i.e., a measurement classified as nonselective by using one definition may be perfectly selective according to the other definition.

If the response surface is nonlinear the selectivity concepts based on the response surface diverge and comparison with the error based selectivity becomes difficult. It has been shown here, however, that a practically relevant class of nonlinear response functions show in this respect the same behavior as the linear response functions. Therefore this type of nonlinear response function allows the use of a simply interpreted concentration-independent selectivity measure. Moreover it follows from our derivations that this is the only kind of nonlinear function making such simple interpretation possible.

Future research should investigate the response function of common analytical techniques and find the typical additional constraints used to limit the uncertainty of the result. From these one should derive, wherever possible, simple relationships between the parameters of the response function and the maximum error of the result. Notably such work has already been very successfully done in ion-selective potentiometry [18]. Interference by more than a single compound needs to be addressed, too. The uncertainty arising from interference should also be related to the uncertainty due to limited precision in measuring the signal and the limited precision of the calibration. One should also clarify the relations to multivariate concepts of selectivity.

Whole cows' milk

ABSTRACT

New rapid method of lateral flow enzyme immunoassay (LFEIA) for progesterone detection in whole cows' milk was developed. The test system utilized horseradish peroxidase as a label along with the substrate solution containing 3,3',5,5'-tetramethylbenzidine and dextran sulfate to obtain an insoluble blue colored product of the enzyme reaction on a surface of analytical membrane (test and control lines). Several aspects of LFEIA were optimized: time of the signal detection, membrane materials and assay conditions. Resulting competitive LFEIA can be performed within 15 minutes with the limit of progesterone detection of 0.8 ng/ml. Progesterone concentration in whole milk samples was determined by LFEIA and enzyme-linked immunosorbent assay (ELISA). The results obtained were in good correlation (R=0.97, n=46). Thus new sensitive LFEIA can be successfully used for on-site monitoring of oestrus status of cows' reproductive system and for early none-pregnancy detection. The method is fast, easy to perform and needs no preliminary sample preparation.

1. Introduction

Nowadays lateral flow immunoassay (LFIA) is a convenient method for semi-quantitative and quantitative detection of important biologically active substances performed on-site, point-of-care places or for personal testing [1]. The approach is widespread in medical and veterinary diagnostics, food control and many other areas due to short time of analysis (10–15 min) and easy procedure. LFIA test strips contain all necessary reagents in dry form; so to perform a test it is sufficient to add a liquid sample (extract) which migrates along overlying membranes and results in the formation of specific immunocomplexes in different areas of a test strip. The result of analysis is usually presented in a form of colored lines in the test and control zones of analytical membrane. A range of labels is used in LFIA including colloidal gold, latex particles, enzymes, quantum dots etc. [1–3]. It was reported that enzyme labels provided up to 10–30 times higher assay sensitivity compared to conventional LFIA labels such as colloidal gold [3–6]. Enzyme immunochromatography as a form of quantitative immunoassay was pioneered by Zuk et al. in 1985 [7]. The authors used paper test strip totally covered by specific antibodies and the assay was based on the measurement of the height of colored bars formed on strips as a result of immunoreaction with the following enzyme substrate saturation. Later enzyme immunoassay was realized in conventional LFIA format with specific reagents immobilized in a form of narrow bands [8]. In enzyme LFIA the most often used label is horse radish peroxidase (HRP) [3–6], however alkaline phosphatase [8,9] and cholinesterase [10] were also employed. As far as HRP is concerned, colorimetric [3–6], chemiluminescent [11,12] and electrochemical [13] detection modes were reported. Substrate solution contained 3,3',5,5'-tetramethylbenzidine (TMB) was predominantly employed for colorimetric detection in HRP-based LFIA [4,6], however 4-chloro-1-naphthol was also used in few studies [5,7].

In veterinary practice one of important biomarkers which should be checked on-site is sex hormone progesterone (P4). Thus P4 concentration in cows' milk is used to monitor cyclicity and confirm oestrus behavior as well as to perform non-pregnancy diagnosis on day 19–21 after artificial insemination [14,15]. Milk sampling is a convenient way of sample collection because probes are readily available. Moreover P4 concentration in milk is few times higher than in blood and they are closely correlated [16,17]. On day 19–21 (end of the oestrus cycle) P4 level in milk of non-pregnant cow is low (around 1–2 ng/ml) whereas for pregnant cow it is high (> 7 ng/ml) and remains high throughout gestation. Milk P4 test is the earliest proven method of identification of non-pregnant cows with high sensitivity [15].

Despite the fact that a variety of LFIA–based test systems is in use for a range of applications worldwide the practically important lateral flow immunoassay to measure the level of cows' milk P4 within the required concentration range hasn't been developed yet. Just a few attempts were taken to develop rapid LFIA for P4 [18–21]. The first paper established LFIA for a hapten where P4 was used as a model antigen was published in 1996 [18]. Finnish researchers showed that P4 can be detected with the plain LFIA test strip prepared of nitrocellulose membrane. A sample (milk) was first added and soaked into the membrane followed by the colloidal gold-labeled P4-protein conjugate. The detection limit was from 5 ng/ml (visual detection) to 2 ng/ml (photometric analysis). Later the influence of some LFIA parameters on the performance characteristics was investigated but sensitivity and variability of the method remained a problem [19]. Another LFIA system with an enzyme label was just able to detect mean differences between 5 and 50 ng/ml of P4 but due to large variability the limit of detection could not be determined [20]. A colloidal carbon was also used as a label in another modification of LFIA for P4 [21]. To increase the sensitivity of the assay high coating concentration of a P4-protein conjugate in combination with low concentration of specific antibody was used. As a result an IC_{50} equal to 0.6 μg/l P4 was achieved. However the assay was developed in buffer and did not work in whole cows' milk.

In our previous work the main approaches to a new P4 test based of lateral flow principle and utilized an enzyme as a label were established [22]. The objective of the present study was to develop quick and sensitive lateral flow enzyme immunoassay (LFEIA) for P4 determination in whole cows' milk without preliminary sample preparation.

2. Material and methods

Dextran sulfate MW 8000 (w/v) and P4 were purchased from «Sigma» (USA). Inorganic salts, acids and organic solvents were obtained from «Chimmed» (Russia). Tween 20 was from «MP Biomedicals» (France). Ready-to-use substrate solution containing TMB and H_2O_2 was supplied by "Immunoved" (Russia).

The following buffers were used: 0.01 M K-phosphate (K_2HPO_4-KH_2PO_4), 0.15 M NaCl, pH 7.4 (PBS) and 0.01 M K-phosphate (K_2HPO_4-KH_2PO_4), 0.15 M NaCl, 0.05% Tween 20, pH 7.4 (PBST).

P4 standard solutions were prepared by dilution of the stock solution (1 mg/ml in ethanol) with PBST.

Polyclonal rabbit antiserum obtained against 11α-hydroxy-progesterone hemisuccinate and the synthesis of a conjugate of 3-O-carboxymethyl oxime progesterone (3-CMO-P4) with HRP were described elsewhere [22].

The following membrane materials were used to prepare LFEIA test strips: analytical nitrocellulose membranes CNPC (15 μm), 150CNPH, CNPF (10, 8 and 5 μm) (MDI, India); absorbent pad AP045 (MDI, India) and sample pads MAPDS-0300 (Arista Biologicals, USA), FR1 (0,35; 0,6), R4, R7 and WF1 (MDI, India).

Whole cows' milk samples were kindly provided by SE «Ermolino» (Kaluga region, Russia) and stored at 4 °C.

2.1. Preparation of LFEIA test strips

Test strips (75*4 mm) were assembled according to the scheme shown in Fig. 1. Sample pad and absorbent pad were 27 mm long and overlain the analytical membrane by 2 mm. The specific antibody solution in PBS as test capture reagent was dispensed on the analytical membrane using BioJet Quanti 3000 and BioDot XYZ- 3050 dispensing platform (USA). To form a control zone, the antibodies against HRP were dispensed onto the strip at a distance of 5 mm from the test zone. The following parameters of the pump were applied: droplet size – 30 nl, step – 0.3 mm, speed – 50 mm/s. The strips were dried for 24 hours at 37 °C.

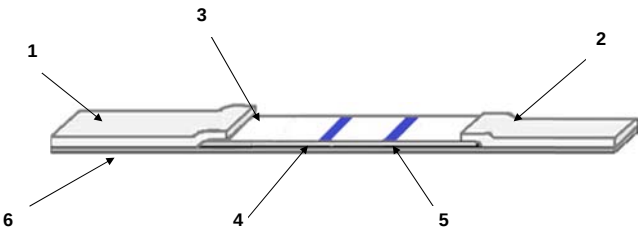

Fig. 1. Construction of LFEIA test strip. 1–sample pad; 2–absorbent pad; 3–analytical membrane; 4–test line; 5–control line; 6–plastic base.

2.2. Sample preparation

Whole milk samples were incubated for 30 min at 37 °C and vortexed before use.

2.3. ELISA procedure

"ELISA-progesterone-milk" kit (Immunoved, Russia) was used to perform P4 measurement in whole cows' milk samples. Briefly, aliquots of 10 μl P4 standard solutions/samples were added to wells of a mictotiter plate followed by 100 μl enzyme tracer (P4-HRP). After incubation and plate washing the substrate solution (100 μl) was added to each well. The color reaction was stopped after 10–15 min with 100 μl stop solution. Result of the reaction was evaluated on spectrophotometer at 450–620 nm ("Molecular Devices", USA). The values of optical densities were converted to $\%B/B_0$ values according to the formula: $B/B_0=(I/I_0) * 100\%$, where I is a value of optical density for a sample, I_0 is the value of optical density for 'zero' standard.

2.4. LFEIA procedure

A test strip was placed on a horizontal surface. The mixture of 10 μl 3-CMO-P4-HRP and 120 μl standard solution or sample was added onto the sample pad, and the solution migrated toward the absorbent pad. In 10 min the test strips were placed into tubes containing 2 ml of substrate solution supplied with 10% dextran sulfate and incubated for 5 minutes while stirring. After staining test strips were dried for 15 minutes at room temperature. Dried strips were scanned (Epson Perfection V700 Photo, Seiko-Epson, Japan) with a resolution of 600 dpi in 24-bit color (RGB). Analysis of the digital images and quantification of color intensity of test and control lines was performed using Scion Image software. Line intensity was corrected by the background subtraction and converted to $\%B/B_0$ mode as described earlier.

3. Results and discussion

In present work HRP with colorimetric detection of an analytical signal was used. As it was shown in our previous article colloidal gold label in LFIA of P4 did not provide required assay sensitivity [22]. So the approach called LFEIA (lateral flow enzyme immunoassay) consisting of the combination of the sensitivity of enzyme immunoassay with the rapidity of lateral flow assay was proposed. Enzyme-based lateral flow immunoassay with visual generation of results in test and control zones requires an additional procedure – coloring of a test strip by substrate solution. In our study to visualize the result of immunoreaction in LFEIA HRP was used in combination with the substrate solution contained

TMB and dextran sulfate. It was found earlier that dextran sulfate dramatically lowers the solubility of the TMB oxidation product which concentrated in the membrane zone where an enzyme conjugate bounded and that allows to develop highly sensitive technique for the detection of HRP [3,23]. TMB coloring can face a problem of background noise and line diffusion [6]. It was reported that after a completion of immunoreaction by vertical flow the best way to pass TMB substrate solution over the test strip in terms of uniformity of signal color and the background noise is the horizontal direction of substrate solution flow [4,6]. For this approach special substrate pads were applied to provide flow across analytical membrane. In our study P4 conjugated to HRP was mixed with a sample (standard solution) and the resulting mixture was applied onto a sample pad and migrated along the test strip (Fig. 1). To perform staining the test strip was immersed in a tube containing a HRP coloring precipitating substrate solution (TMB). This simple approach provided uniform coloring pattern and reduced diffusion of test and control lines. In this case the visual detection can be carried out in 5 minutes.

To develop accurate LFIA for P4 with HRP as a label the color intensity of the precipitating product of TMB oxidation should be proportional to the amount of the enzyme within immunocomplexes concentrated in the test line of analytical membrane, moreover the measured signal (end-point measurement) should be stable during time. Considering these conditions the dependence of the color intensity formed on the surface of analytical membrane during substrate reaction at different concentrations of HRP was studied. The experiment was conducted as follows: HRP solution was spotted on a surface of analytical membrane; after drying a piece of membrane was incubated in TMB solution for 5 minutes then the membrane was taken from substrate solution and quantification of colorimetric analytical signal was carried out by a scanner within 60 min (Fig. 2). The results have shown that the analytical signal (color intensity) remains stable for at least an hour after staining (Fig. 2A). The signal was also proportional to the concentration of HRP absorbed on the membrane in a form of saturation curve (Fig. 2B). Some reduction of signal intensity during initial 15–20 min after staining could be attributed to a membrane drying and to the fact that the background signal increased within the first 10–15 minutes (data not shown). Therefore, visual detection of LFEIA results can be performed immediately after staining and further instrumental detection – in 15 minutes after staining.

In current work direct competitive format of LFEIA was employed where specific antibodies were immobilized on a surface of analytical membrane. Sensitivity of the competitive immunoassay strongly depends on the label concentration, sensitivity of signal registration and antibodies affinity. The next step of the work was the selection of optimal membrane components and reagents concentration for sensitive competitive LFEIA. Five types of commercial analytical membranes with different pore size (15, 10, 8, 5 μm) and capability to bind proteins (CNPF – lower, CNPC – higher and CNPH – the highest protein binding) were considered. A range of lateral flow assay characteristics (assay time, sensitivity etc.) depends on the pore size of analytical membrane used. For example, while the pore size increase the sensitivity of the assay decrease, however the analysis time significantly reduces. Also the visual form of the stained line on the analytical membrane looks different. As shown in Fig. 3 for membranes with larger pore size the test line became less clear and diffused that can complicate visual detection of the results. It was also found that the membrane with a smaller pore size required 3 times less amount of P4 labeled with HRP to produce a line color of the same intensity, thus LFEIA sensitivity can be increased and background signal reduced. On the basis of the above characteristics a membrane with pore size of 8–10 μm was considered as optimal.

To develop lateral flow immunoassay in whole cows' milk a few aspects should be addressed – assay should detect P4 in the required concentration range (1–10 ng/ml) and can be applicable to such complicated matrix as undiluted whole milk. Few sample pads were checked in a combination with analytical membranes to fabricate a test strip. The LFEIA sensitivity (Fig. 4A) and the ability of whole cows' milk to migrate along a test strip were considered (Fig. 4B). As shown on Fig. 4, assay sensitivity was affected by a type of a sample pad used. For example, percent of signal inhibition at P4 concentration equal to 10 ng/ml varied from 80% to 20%. This could be attributed to different components which are used by membrane material producers for the pretreatment of sample pads and quite often are unknown. Among them are detergents, wicking agents etc. The zone of a test strip reached by the front of a whole milk sample also depended on a particular combination of membranes (Fig. 4B). Our aim was to find such combination which allows milk sample to flow up to absorbent

pad and at the same time provides necessary LFEIA sensitivity. On the base of above factors an optimal combination of the sample pad and analytical membrane was chosen for sensitive LFEIA of P4 in whole milk.

As a result of above study rapid LFEIA was designed and carried out as follows: aliquots of standard solution/sample and HRP-labeled P4 were mixed and applied onto the sample pad. When the solution was absorbed, the membrane was immersed in a test

tube with substrate solution and incubated for 5 minutes. Then the strip was taken out and visual result was registered. The instrumental detection was carried out in 15 min. An example of calibration curve and visual appearance of test and control lines are presented on Fig. 5. The detection limit of LFIA P4 was 0.8 ng/ml. Variation of results did not exceed 10%. It could be seen that concentration of P4 about 7–10 ng/ml and higher caused significant color change of a test line and its almost full disappearance.

To evaluate the applicability of this method for whole cows' milk, 46 samples from pregnant cows as well as from non-pregnant animals taken on different days of oestrus cycle were analyzed by the developed LFEIA and ELISA. The results were in good correlation ($R=0.97$) (Fig. 6). Moreover analysis of whole milk samples taken from pregnant cows caused almost complete disappearance of a test line whereas milk samples from non-pregnant cows taken at the beginning or end of oestrus cycle were identified as non-pregnant by visual and quantitative detection. Thus, this method can be used to quantify the level of P4 in whole cows' milk and can be applied for early determination of cows' non-pregnancy on a dairy farm without any special equipment. Quantitative detection of P4 with the help of an available portable device can give valuable information about status of a cow's reproductive system.

4. Conclusions

Here the applicability of LFEIA approach to P4 detection in particular concentration range in such complicated matrix as whole cows' milk was demonstrated. The pretreatment-free test can be used for rapid P4 detection while monitoring status of cows' reproductive system and for early non-pregnancy diagnosis on day 19–21 after artificial insemination. Development of rapid P4 milk test for on-farm use was a complicated task for years [14,21] and LFIA-based test was just recently commercialized. Using enzyme labels in LFIA is new and to some extent underestimated direction of research. "Enzyme immunochromatographic assay", "enzyme-based dry-reagent strip biosensor", "ELISA-on-a-chip", "enzyme-linked immuno-strip biosensor", "lateral flow immunosensor" – these are all names of the same assay principle which combines sensitivity of the enzyme immunoassay with advantages of lateral flow immunoassay (rapidity, low-cost and disposability) [4–6,9,13]. The approach can be considered as rapid ELISA performed in the form of lateral flow format or as an LFIA utilizing an enzyme label. This approach could be a potential substituent of a conventional ELISA as soon as it will be realized in rapid form with minimal manipulation required, particularly in cases when the sensitive on-site detection of a target analyte is needed. For instance, a delayed-release effect of an enzyme substrate by the asymmetric polysulfone membrane described recently by Joung et al. [12] provided one-step mode of chemiluminescent enzyme LFIA. Rapid and sensitive colorimetric, chemiluminescent or electrochemical detection of enzyme labels in visual or quantitative mode with the help of portable devices can be applied for a wide range of enzyme flow immunoassay applications in different areas.

Acknowledgments

The authors gratefully acknowledge dairy farm SE "Ermolino" (Kaluga region) for providing whole milk samples.

ABSTRACT

An automated method for analyzing free non-cholesterol sterols in human serum using online solid phase extraction–liquid chromatography–mass spectrometry is proposed herein. The method allows the determination of three phytosterols (sitosterol, stigmasterol and campesterol) and two cholesterol precursors (desmosterol and lanosterol). The analysis of sterols in human serum is critical in the study of cholesterol-related disorders, such as inherited familial hypercholesterolemias. Special effort was made to isolate the analytes from the serum lipoproteins, their natural conveyance through the bloodstream. The sample treatment consisted of a Bligh–Dyer extraction followed by dilution of the extract. This treatment allowed the sample to be injected into the online system and ensured the correct detection of the analytes, while avoiding the matrix effects commonly related to serum samples.

The analytical performance showed linear ranges that covered two orders of magnitude, with correlation coefficients above 0.99. Limits of detection and quantification ranged from 0.2 ng/mL to 13 ng/mL and from 1.0 ng/mL to 43 ng/mL, respectively. Recovery when spiking serum with a half or a tenth of the average concentration reported in human serum ranged from 99% to 111% and from 102% to 120%, respectively. Intra-day precision and inter-day precision were below 20%.

1. Introduction

Sterols are metabolites related to cholesterol metabolism. The analysis of these compounds in human serum is an essential step in the diagnosis of cholesterol-related disorders, such as inherited familial hypercholesterolemias, cerebrotendinous xanthomatosis and sitosterolemia [1]. Cholesterol and related sterols are regulated in the human body *via* a complex set of mechanisms. Cholesterol can be absorbed through diet at intestinal level [2]. The rate of cholesterol consumption can be inferred from the presence of phytosterols such as sitosterol, stigmasterol and campesterol in human serum, since they undergo the same absorption and secretion processes [3]. Cholesterol is also endogenously produced and regulated in the liver. Some sterols such as desmosterol and lanosterol are intermediate products (precursors) in this reaction mechanism. Since these compounds leak into the bloodstream at a rate proportional to their formation in the cholesterol synthetic pathway, the circulating levels of these endogenous precursors reflect the rate of cholesterol synthesis [4,5].

Sterols have a non-polar structure and are carried through the circulatory system by lipoproteins. Lipoproteins are aggregates of lipids surrounded by a 2-nm amphiphilic layer composed of phospholipids, apoproteins and free cholesterol [6]. Therefore, the analysis of sterols involves the breakage of these aggregates.

The extraction of sterols has been typically performed using the Bligh–Dyer method [7,8], where a mixture of chloroform and methanol solubilizes the lipids from the lipoproteins, allowing the apoproteins to be separated. Sterols have been traditionally analyzed using gas chromatography, *via* a time-consuming derivatization step [4,9–11]. Liquid chromatography (LC) coupled to mass spectrometry (MS) avoids this derivatization step, diminishing the sample processing time [8,12]. However, the sample cleanup prior to LC–MS analysis is still strongly recommended and a solid phase extraction (SPE) step is generally performed [8,13].

An interesting choice is the use of hyphenated techniques that couple SPE to LC–MS using a switching valve, which is common in the analysis of biological samples and enables rapid and reliable sample preparation [14–17]. Several publications dealing with online systems are focused on determining drugs in plasma or urine; but scarce literature has been found related to the determination of endogenous metabolites [18,19]. A previous work of the authors aimed at the reduction of the sample processing time for determining free and bonded sterols in human serum [20,21] and another contribution demonstrated the capacity of coupling a Restricted Access Material (RAM) cartridge to LC–MS for determining bile acids

in human serum [22]. To the best of our knowledge, there is not such a system to determine sterols in human serum, so the present contribution aims at the routine analysis of sterols in a faster way by using an online system.

2. Materials and methods

2.1. Chemicals and reagents

The sterols under study (Fig. 1) were provided by Sigma-Aldrich (Madrid, Spain): desmosterol (purity 85%, Chemical Abstract Service identification number: 303-04-2), campesterol (65%, 474-62-4), stigmasterol (95%, 83-48-7), lanosterol (97%, 79-63-0), sitosterol (95%, 83-46-5), and cholesterol-26,26,26,27,27,27-D6 (internal standard, IS, 97%, 60816-17-3). The solvents used were methanol (supragradient LC–MS grade, 67-56-1), 2-propanol (LC–MS grade, 67-63-0), and chloroform (HPLC grade, 67-66-3). The solvents were supplied by Sharlab (Barcelona, Spain). Water was obtained from a Milli-Q Plus 186 device from Millipore (Billerica, MS, USA).

Stock solutions of 1000 mg/L in methanol were prepared for each analyte. A stock solution of the IS at 100 mg/L was prepared in 2-propanol. A working solution with all of the sterols in methanol, at a concentration of approximately 10 mg/L, was prepared and stored in the dark at 4 °C.

2.2. Pooled serum

The pool of serum was obtained by mixing individual serum samples from 150–200 informed healthy volunteers. The pool was provided by the Lipids Unit of the Aragon Institute of Health Sciences (Zaragoza, Spain), and stored in the dark at −80 °C prior to the analysis.

2.3. Sample preparation

The sample was prepared using the following method: 300 μL of serum were extracted through a modification of the Bligh–Dyer method [23]. A volume of 1 mL of chloroform–methanol (1:2, v/v) was mixed with 30 μL of the IS solution and then added to the serum. The mixture was then centrifuged at 9000 rpm (7500*g*) for 10 min in a Microfuge® 18 Centrifuge, Beckman Coulter™ (Brea, CA, USA). The lower organic phase was recovered using a glass Pasteur pipet and transferred to a 2-mL vial. The extract was then accurately weighed, and 1 mL of methanol was added. The resulting extract was filtered using a 0.22-μm Nylon syringe filter. After this sample treatment, the final serum sample extract was ready to be injected into the online system described below.

2.4. Online system setup

Fig. 2 illustrates the online system. The mobile phases were delivered using three pumps; a 600E Controler Multisolvent Delivery System (pump 1) with a 717 plus Autosampler (Waters, Milford, MS, USA), a Kontron 322 System auxiliary binary pump (Kontron Instruments, Neufahrn, Germany) (pump 2) and an Alliance® 2795 Separations Module (Waters) (pump 3). The fluidic paths were controlled using a Cheminert C72 × 1690ED 10-port valve controlled by microelectric actuators, purchased from VICI® Valco Instruments (Houston, TX, USA). The analytes were detected using a Quattro micro™ API Mass Spectrometer (Waters). All these instruments were connected to operate simultaneously. This is explained in detail in the Supplementary information section S1.

Table 1 shows the steps of the online method, flow rate and composition of pumps 1 and 3, as well as the valve position program. The online method comprises four steps: loading, washing, eluting and detection.

2.4.1. Loading

For loading, 300 μL of the treated serum were injected using the 717 plus Autosampler and transferred to a 20 × 4 mm BioTrap 500C18 cartridge, supplied by ChromTech Ltd. (Cheshire, UK) at a 2.0 mL/min flow of 60% methanol and 40% water. A 2-μm filter was included before the cartridge to prevent clogging. This step lasted 4 min.

2.4.2. Washing

The washing step consisted of a 2.0 mL/min flow of water. The elution of large, non-retained molecules was monitored at 220 nm using a 2487 dual λ absorbance detector (Waters). Their elimination was considered to be complete when the UV signal had fallen below 0.05 absorbance units. Then, the valve was automatically switched to the eluting position.

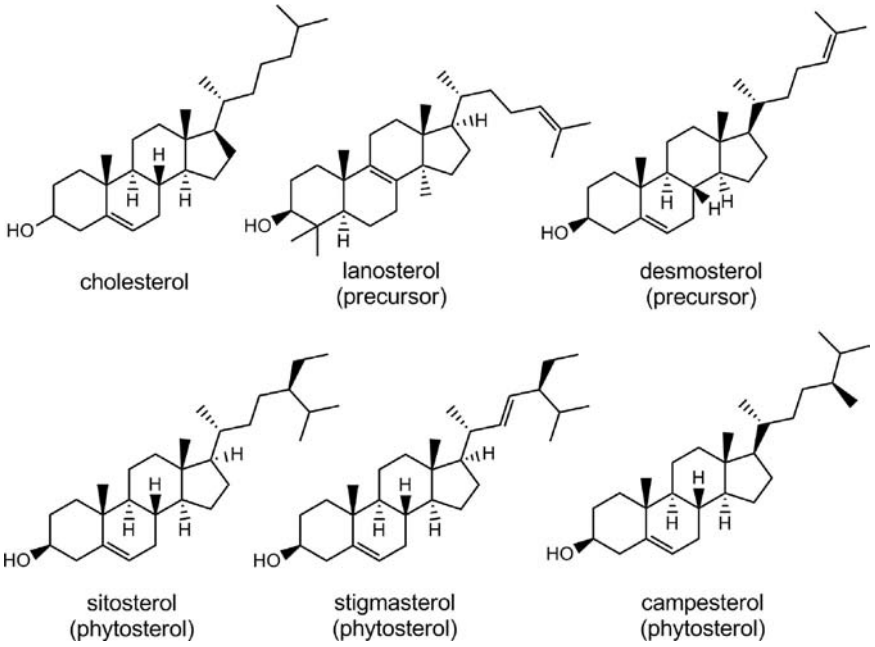

Fig. 1. Chemical structures of the sterols under study and cholesterol.

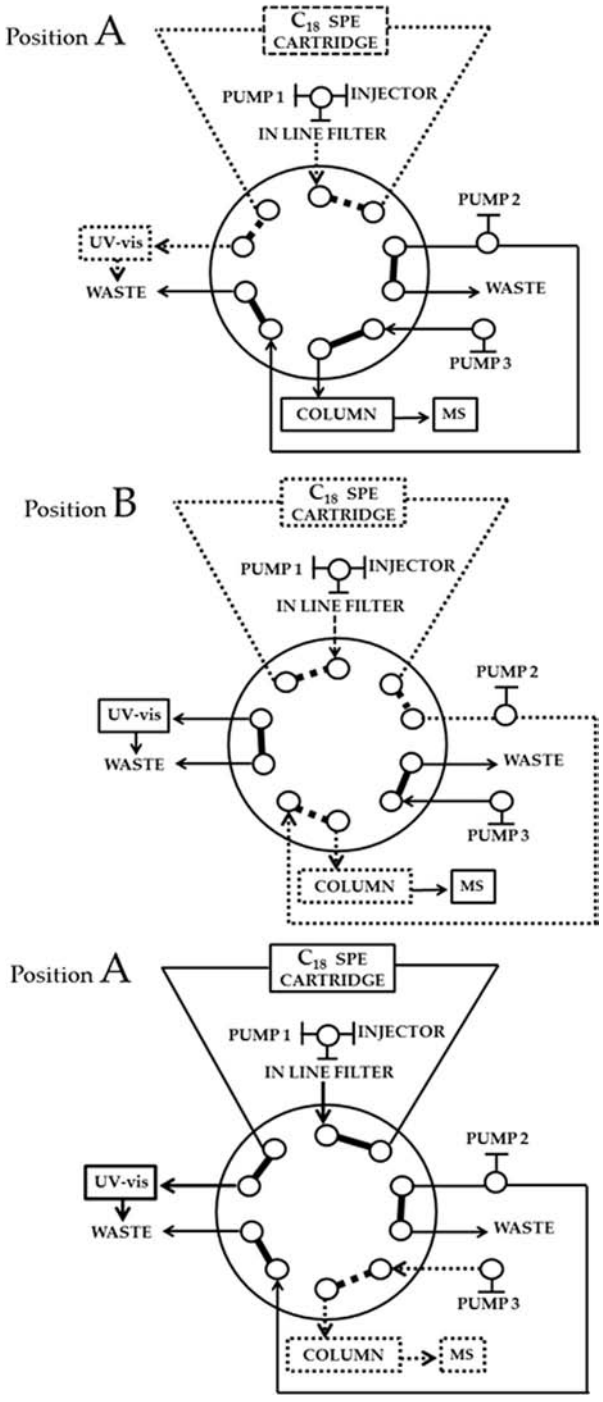

Fig. 2. SPE–LC–MS flowchart scheme. (A) Loading and detection steps. (B) Eluting step.

2.4.3. Elution

From min 9 to 35, the retained compounds were backflushed from the cartridge using 2-propanol at a flow rate of 0.4 mL/min. Before entering the analytical column, a water cross-flow of 0.6 mL/min was added (pump 2), leading to a total flow of 1 mL/min of 60% water and 40% 2-propanol. This flow composition ensured that the sterols were retained at the head of the analytical column.

2.4.4. Detection

The analytes were separated using an XTerra® MS C18 column (4.6 × 100 mm and 3.5 μm particle size, Waters). A guard column of the same stationary phase material and 5 μm particle size was used to protect the analytical column. The column temperature was set at 60 °C. The analytical gradient started at 35 min, using an 85% methanol and 15% water, at a flow rate of 0.7 mL/min. Then, the gradient was increased in 9 min to 100% methanol, where it was held for 5 min. The last compound (sitosterol) was eluted after 13.8 min of chromatography.

The compounds of interest were determined using atmospheric pressure chemical ionization (APCI) detecting in positive mode. The detection parameters were as follows: corona current, 10 μA; source temperature, 130 °C; desolvation temperature, 600 °C and desolvation nitrogen flow, 600 L/h. The optimized cone voltage was +20 V for all the compounds. The chromatograms were registered in selected ion monitoring (SIM) mode. The protonated molecules (m/z) of the target analytes are listed in Table 2. MassLynx v4.1 software from Waters was used to acquire and process the generated data.

Complementary information dealing with the steps of the online system can be found in the Supplementary information, section S2.

2.5. Evaluation of the method performance

The following analytical parameters were studied: calibration curve, limits of detection (LODs) and quantification (LOQs), linear dynamic range, recovery and reproducibility. The linear dynamic range was determined from the response of nine standard solutions spiked with the IS (30 μL of a 100 mg/L 2-propanol solution). The calibration curve was prepared in a 1:2 (v/v) chloroform: methanol solution, coinciding with the composition of the resulting mixture after the sample treatment. These solutions were injected into the system in triplicate. The LOD and LOQ were calculated as three and ten times the standard deviation of the area of the peaks detected, respectively, when processing blank samples (chloroform–methanol, 1:2 v/v). The determination of the intra-day precision ($n=5$), the inter-day precision ($n=3$) and the recovery was carried out by analyzing serum spiked at two concentration levels: half and a tenth of the average concentration of sterols according to the Human Metabolome Database [24].

Matrix effects were investigated by a post-extraction addition experiment, as explained by Trufelli et al. [25]. Four sets of samples were analyzed: a standard solution with a known concentration of the analytes (set A), serum samples spiked with the same amount of analytes after the sample treatment (set B), serum samples spiked with the same amount of analytes before the sample treatment (set C) and serum samples non-spiked (set D) to subtract the endogenous concentration levels. The response of the analytes was used in the following equations to quantify the matrix effects (Eq. (1)), the extraction recovery (Eq. (2)) and the process efficiency (Eq. (3)).

$$\text{Matrix effects}(\%) = \frac{100 \times (B-D)}{A} \quad (1)$$

$$\text{Extraction recovery}(\%) = \frac{100 \times (C-D)}{(B-D)} \quad (2)$$

$$\text{Process efficiency}(\%) = \frac{100 \times (C-D)}{A} \quad (3)$$

3. Results and discussion

3.1. Sample treatment

The Bligh–Dyer method [26] is commonly used with human serum samples to extract the lipids and remove the protein fraction due to sterols are carried through the bloodstream by lipoproteins [7,8]. For this reason, protein precipitation approach,

Table 2
Detection parameters, linear dynamic range and limits of detection and quantification of the analysis of sterols by the proposed online SPE–LC–MS method.

Sterol	CAS number[a]	Retention time (min)	*m/z*	Linear dynamic range (μg/mL)	Correlation coefficient	LOD (ng/mL)	LOQ (ng/mL)	Concentration in pooled serum (μg/mL)
Desmosterol	303-04-2	11.2	367.5	0.017–2.70	0.991	5.0	17	0.83 ± 0.23
Lanosterol	79-63-0	12.9	409.5	0.001–0.527	0.999	0.2	1.0	0.17 ± 0.04
Stigmasterol	83-48-7	13.0	395.5	0.025–5.22	0.994	7.5	25	1.35 ± 0.42
Campesterol	474-62-4	13.1	383.5	0.025–9.27	0.990	7.5	25	1.49 ± 0.26
Sitosterol	83-46-5	13.8	397.5	0.043–7.03	0.999	13	43	1.28 ± 0.07

[a] Chemical Abstract Service identification number.

results in the undesirable precipitation of the lipoproteins and the subsequent loss of the analytes (Fig. S3). Thus, a lipid extraction step is essential to determine sterols even when using an online system.

The composition of the final organic phase is mainly chloroform, which is not miscible with water and is not suitable for direct injection in reversed-phase liquid chromatography. Thus, the extract needs to be dried and reconstituted in a compatible solvent [8]. The aim of the sample treatment was to obtain a final extract suitable to be directly injected into the system. Herein, we took advantage of the miscibility properties of the water–methanol–chloroform tertiary system (as the Bligh–Dyer method does). First, the composition of the initial mobile phase in the online system was adjusted by increasing the proportion of methanol to the maximum that still allows the analytes to be retained in the C18 SPE cartridge, which is 60% methanol and 40% water. Next, the extract was diluted using methanol in such a way that the mixture with the initial composition of the mobile phase gives a single liquid phase. Fig. S4 shows the composition of the extract along the sample treatment in a ternary diagram for methanol–water–chloroform mixtures.

3.2. Online system setup

3.2.1. Loading and washing steps

In the loading step, the analytes were injected and taken to a C18 SPE cartridge. The strong non-polar properties of sterols permitted the use of C18 cartridges to concentrate them, while other less non-polar compounds (even lipids) were eluted to waste.

The solvent used in the washing step was water. This solvent showed satisfactory results removing interferences in a previous work [20].

3.2.2. Elution step and water cross-flow

Preliminary tests showed that 2-propanol was a powerful solvent for recovering the sterols from a C18 SPE cartridge. The elution profile was determined by collecting 0.4-mL fractions from the SPE cartridge in backflush mode every minute for 40 min. The fractions were later analyzed by direct flow-MS (*i.e.* without using the analytical column) in full-scan mode from 340 to 400 Da. In this way, each fraction appeared as a single peak (Fig. S5). As can be seen, 10 mL (25 fractions × 0.4 mL/fraction) of 2-propanol quantitatively recovered the analytes from the cartridge. Thus, the eluting stage lasted from 9 min to 35 min.

Because the cartridge and the analytical column were C18, the designed system did not have truly orthogonal features. This means that the eluting strength of 2-propanol would prevent the retention of the analytes in the head of the analytical column, compromising the chromatographic step. This problem was overcome by adding water to the 2-propanol eluent after the cartridge. To find out the necessary amount of water required to reduce the eluotropic strength of the flow, the following experiment was carried out. A standard solution of 1 μg/mL of sterols was prepared in 2-propanol. Increasing volumes of water were added to 1 mL of the standard solution and the resulting solutions were manually injected into the LC–MS, using an auxiliary sample loop and the MS divert valve. Fig. 3 shows how the added water reduced the eluotropic strength of the solution, enabling the chromatographic process. From these results, it was concluded that the flow composition entering the column should contain at least 60% (v/v) water.

A flow of 40% 2-propanol and 60% water (v/v) produced high backpressure in the analytical column. Hence, the total flow rate entering the column was cut back to 1.0 mL/min (working backpressure of 200 bar), 0.4 mL/min of 2-propanol were used to backflush the analytes from the cartridge and 0.6 mL/min water cross flow was added to reduce the eluotropic strength of the eluent.

3.3. Detection step

Sterols were detected in SIM mode as $[M+H-H_2O]^+$, which corresponds to the loss of the hydroxy group as a molecule of water (Table 2). This is commonly observed in the chemical ionization of alcohols [27]. Sterols crashed into several daughter

ions when the Multiple Reaction Monitoring (MRM) detection mode was selected (even when using soft collision voltages). The signal/noise values obtained in SIR mode were much higher than those of the MRM mode. In this case, the selectivity provided by the MRM mode was not enough to make up for the loss of sensitivity.

3.4. Cross contamination

The Bligh–Dyer extraction method is intended for removing proteins and simultaneously extracting lipids from blood and other tissues, so it is not sterol-selective. During the development of the method, cross-contamination was detected (blank injections with ghost peaks). Phospholipids and triacylglycerols usually build up in analytical or guard columns, especially when using aqueous mobile phases [28]. This problem was solved by extending the chromatographic gradient for 5 min after the elution of the last compound. Fig. S6 shows the improvement when a column cleaning step with 2-propanol was included. This is consistent with Ismaiel et al., who found that 35% of 2-propanol in the mobile phase was essential to elute lipids from the C18 guard column [28].

3.5. Evaluation of the method performance

One of the major drawbacks in biological analysis is the presence of matrix effects, which affect the recoveries, quantitative performance and the efficiency of the analytical process [15,25,29]. Hence, verifying the absence of matrix effects is advisable. In accordance with Trufelli et al. [25], post-extraction addition experiments were performed to evaluate matrix effects, extraction recovery and process efficiency.

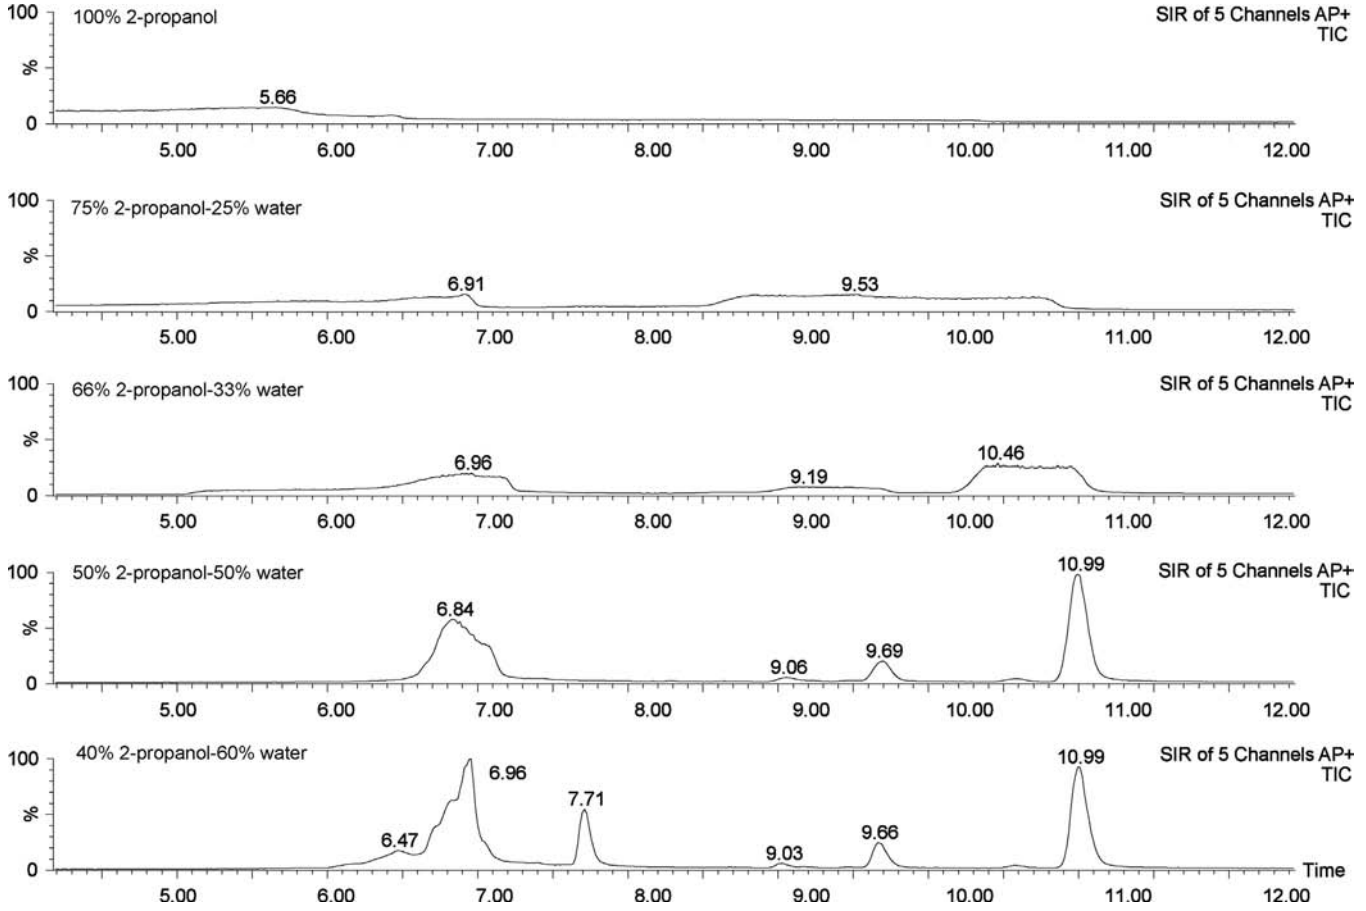

Fig. 3. Study of the eluotropic strength of the flow to be transferred to the LC analytical column. Increasing the ratio 2-propanol/water led to a weaker initial mobile phase. The chromatographic process was possible with at least 1.5 times more of water than 2-propanol.

Table 3
Recovery, intra- and inter-day precision of the analysis of sterols by the proposed online SPE–LC–MS method.

Sterol	Spiked concentration (ng/mL)	Calculated concentration (mean ± std deviation, ng/mL)	Recovery (%)	Intra-day precision (RSD %, $n=5$)	Inter-day precision (RSD %, $n=3$)
Desmosterol	205	210 ± 12	102	6	12
	42	47 ± 5	112	10	18
Lanosterol	38	42 ± 6	111	10	16
	10	12 ± 3	120	15	20
Stigmasterol	398	403 ± 12	101	7	10
	76	80 ± 9	105	11	14
Campesterol	736	730 ± 7	99	5	13
	154	157 ± 9	102	12	19
Sitosterol	440	448 ± 10	102	4	15
	87	92 ± 6	106	11	17

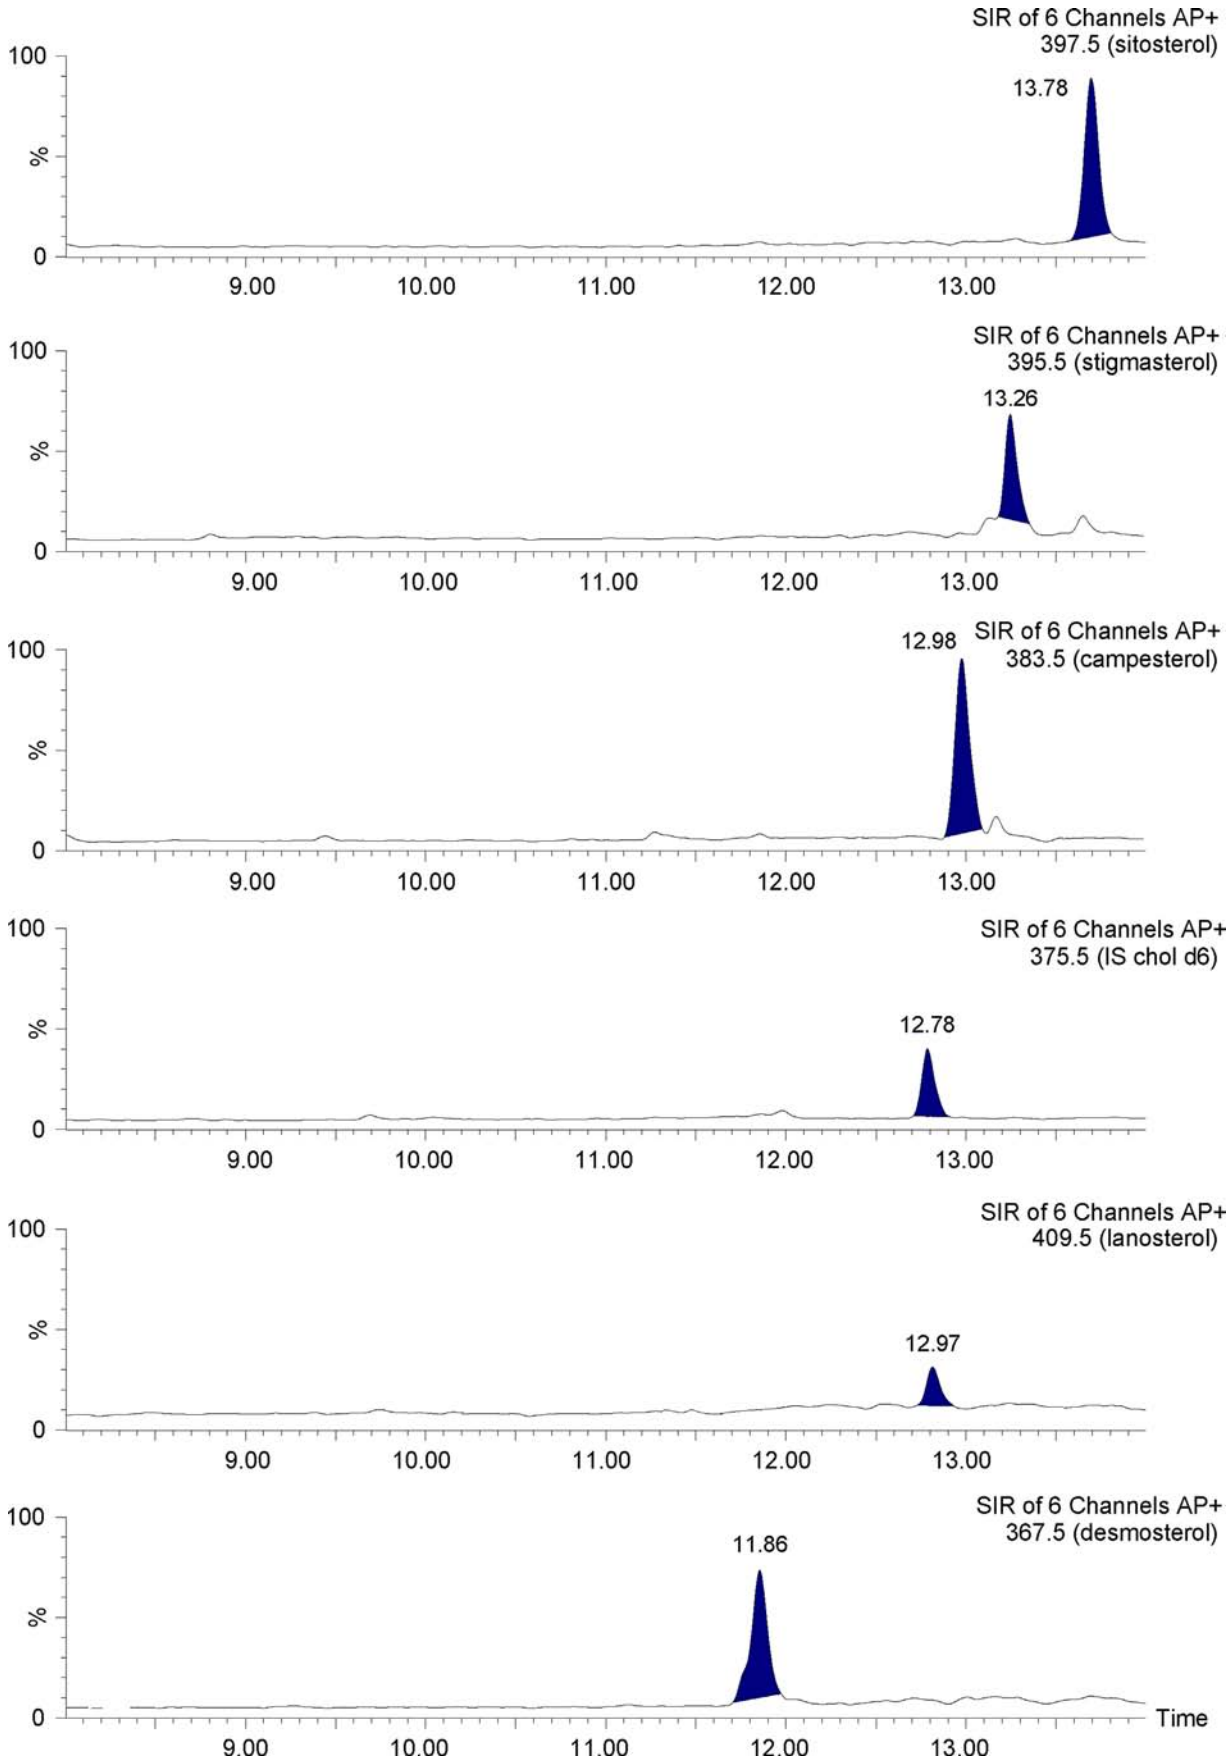

Fig. 4. Chromatograms of the studied sterols obtained after processing pooled serum.

Matrix effects ranged from 89% (stigmasterol) to 106% (lanosterol). This means that the signals observed were slightly affected by other compounds coming from the sample. Thus, there were almost no losses during the sample treatment. Finally, the process efficiency was also determined. The values obtained ranged from 90% (stigmasterol and campesterol) to 99% (desmosterol or lanosterol). These results showed that matrix effects do not hinder the determination of sterols *via* the proposed method. Since the response of the spiked samples was similar to the response of the sterol standard solution, an external calibration could be performed without applying a matrix matched calibration or standard additions.

3.6. Analytical features

The following analytical parameters were determined: linear dynamic range, LODs and LOQs, recovery, intra-day precision and inter-day precision. The results related to the linear dynamic range, limits of detection and quantification are listed in Table 2. Calibration was performed by plotting the ratio of the signal of the analyte and the deuterated IS versus the ratio of \the concentrations. The calibration curves were linear to two orders of magnitude with correlation coefficients that ranged from 0.990 (campesterol) to 0.999 (sitosterol or lanosterol). The LOD ranged from 0.2 ng/mL (lanosterol) to 13 ng/mL (sitosterol), and the LOQ ranged from 1.0 ng/mL (lanosterol) to 43 ng/mL (sitosterol). All of them were low enough to analyze the sterols in human serum.

Recovery and reproducibility (intra-day precision and inter-day precision) were evaluated by spiking the serum samples with standard solutions as it is described in Section 2.5. The results are summarized in Table 3. Recovery of the analytes at two levels of concentration was consistent and reproducible. The values obtained ranged from 99% to 111% when spiking with half of the average concentration in serum, and ranged from 102% to 120% when spiking with one tenth of the average concentration in serum. The results of intra-day precision ($n=5$) and inter-day precision ($n=3$) range from 4 to 20%. These results showed that the method meets the standards required for the study of hypercholesterolemia diseases.

3.7. Analysis of pooled serum

The chromatograms of the analytes in pooled serum are showed in Fig. 4. The concentration of sterols in the pool of serum was also determined (Table 2). It can be seen that the concentrations obtained were in agreement with the values found in literature [2,7]. As said before, serum levels of cholesterol precursors are related to liver cholesterol synthesis and they were found in much less concentration than cholesterol in human serum. The concentration of desmosterol and lanosterol resulted in 0.83 ± 0.23 μg/mL and 0.17 ± 0.04 μg/mL (Table 2), similar to the concentration values reported by McDonald et al. (0.71 μg/mL and 0.20 μg/mL, respectively) [7]. The content of phytosterols is typically higher than the content of cholesterol precursors, and it is more sample-dependant. The concentration of stigmasterol (1.35 ± 0.42 μg/mL), campesterol (1.49 ± 0.26 μg/mL) and sitosterol (1.28 ± 0.07 μg/mL) (Table 2) fall within the ranges reported in the Human Metabolome Database [24]. Due to the association between non-cholesterol sterols with cholesterol absorption, synthesis and metabolism, the determination of these compounds is a useful tool to explore their behavior in the human body.

4. Conclusions

An online SPE–LC–MS system to determine non-cholesterol sterols in human serum has been developed and described herein. The method allows the determination of two cholesterol precursors, desmosterol and lanosterol, and three phytosterols, stigmasterol, campesterol and sitosterol.

This protocol substantially reduces the sample treatment, avoiding the time-consuming evaporation and reconstitution steps. The lipoproteins were extracted using the well-established Bligh–Dyer method, and the losses associated to a protein precipitation step with methanol or acetonitrile were eluded. This was achieved thanks to the careful selection of both the final extract and the initial mobile phase solvent compositions.

Two LC instruments have been coupled to operate simultaneously by using event analog signals. As a consequence, no additional tasks have to be executed by the analyst to run the online system. The use of the C18 cartridge combined with C18 LC was not a problem thanks to a water cross-flow added between both stationary phases. This can be performed by using a 10-port switching valve instead of an ordinary 6-port valve. Matrix effects were thoroughly studied and reduced to an extent that external standard calibration could be used.

All this work led to a sample treatment time reduction of 75%; that is to say, using this protocol, 25 samples can be handled in only 2 h. In previous works, the authors needed a working day (8 h) to handle these samples, using the alternative Bligh–Dyer, evaporation, reconstitution and SPE clean-up protocol based on the work of McDonald et al. [8].

The significant reduction in the analysis time would help in the research of cholesterol related diseases, which demands the processing of high number of samples to infer reliable conclusions.

Gold nanoparticles (GNPs)
Photon burst counting
Homogeneous sandwich immunoassay
Prostate specific antigen (PSA)

ABSTRACT

In this paper, we reported a sensitive single particle method by combining the photon burst counting technique with gold nanoparticles (GNPs) as labeling probes. The photon bursting of single GNPs will be generated in a highly focused laser beam (less than 1 fL) due to the plasmon resonance scattering and Brownian motion of GNPs. We observed an excellent linear relationship between the photon burst counts and the number of particles in GNPs solution. We investigated the statistical behaviors of background noise and photon burst signal of GNPs, and proposed the data processing method based on Gaussian distribution of the background noise. A new homogeneous sandwich immunoassay was developed by using this single particle method. We evaluated the performance of this method by using prostate-specific antigen (PSA) as a model. The linear range of PSA was 1–1000 pmol/L and the detection limit was 0.8 pmol/L. This novel method was successfully used for the direct detection of cancer biomarker PSA in human serum samples. Our results were in good agreement with conventional ELISA assays.

1. Introduction

The principle of immunoassay is on the basis of the specific reaction of antibody and antigen, and this analytical method is widely used in the fields of medical diagnostics, drug discovery, environmental monitoring, and food safety [1–3]. In current immunoassay, heterogeneous format such as ELISA is widely applied since this format usually has high sensitivity, wide dynamic ranges, and good specificity [4]. However, heterogeneous format relies on physical separation of binding and unbinding species before quantification, which results in nonuniform antibody-binding properties, reduced antibody activity, and makes this assay format laborious and time-consuming [5–7]. By contrast, the single-step and washing-free homogeneous format has attracted considerable interest [8–11]. The key issue in homogeneous immunoassay is how to quantitatively and sensitively distinguish antibodies (or antigens) and antibody–antigen complexes in the reaction solution [12,13]. Various strategies have been reported for this purpose based on different signal-transducer principles, such as colorimetric [14,15], fluorescence [16,17], electrochemistry [18], and chemiluminescence [19]. However, these detection methods still provide unsatisfactory sensitivity, therefore, to develop a sensitive and selective detection technique becomes critical in homogeneous immunoassay.

Single molecule methods provide alternative detection techniques for heterogeneous and homogeneous immunoassays. With the great progress on photoelectric conversion technology, it has been no longer a problem for single molecule detection by using the photon burst method [20,21]. Hirschfeld's group [22] for the first time reported the detection of the photon burst from a single molecule in solution. In their work, a single protein molecule was labeled with 80–100 fluorescent dyes, and the single molecule photon burst phenomenon was observed in solution. Dovichi's group [23–28] did some prospective studies on the photon counting technique, and they used the sheath flow cuvette to form the basis of a detector with a photomultiplier tube for counting the scattering photoelectrons bursts of individual particles eluted from a capillary. These methods provided good sensitivity for single particle detection. Recently, Zhang and co-workers [29,30] did some great works on single molecule detection by photon burst counting technique. They significantly improved the sensitivity and selectivity of the detection method using fluorescent quantum dots as probes and two-color labeling technique. This method has been successfully used in the detection of DNA [31], Micro-RNA [32], protein [33], virus and so on.

Compared to fluorescent dyes and semiconductor quantum dots, GNPs show unique chemical and optical properties such as

strong light absorption and scattering effect, high photothermal conversion rate, excellent photostability, noncytotoxicity and excellent biocompatibility. Up to now, GNPs are widely applied in certain biological fields, such as DNA hybridization detection, immunoassay, bioimaging, single particle tracking, drug delivery, and cancer diagnostics and therapy. Zhang [34–36] proposed a novel single nanoparticle method by the mass spectrometer, and they used the method to detect special sequence DNA and biomarkers targets in one-step homogeneous hybridization solutions. Yan [37–40] developed a single nanoparticle detection method by using a sensitive flow cytometer. The method can quantitatively detect nanoparticles, biomolecules or cells of different sizes by counting the fluorescence or scattering photon bursts of the analytes.

In resonance light scattering correlation spectroscopy (RLSCS), which is similar to fluorescence correlation spectroscopy (FCS), we observed the strong photon bursting phenomenon of single gold nanoparticles due to plasmon resonance scattering and Brownian motion of single GNPs in a highly focused detection volume. In this paper, we described a novel single particle method by using photon burst counting technique of plasmon resonance scattering. The photon burst counts and the number of particles in GNPs solution showed a good linear relationship. We investigated the statistical behaviors of noise and photon burst signal of GNPs and observed that the background noise of photon burst shows Gaussian distribution. Based on the behaviors of noise and photon burst signal of GNPs, we established a method for data processing of the photon burst counting. Based on this single particle method, new homogeneous immunoassays were developed. In the immunoassay, the sandwich strategy was used, and antibody or antigen was covalently conjugated to GNPs surfaces, respectively. The quantitative analysis is based on the linear relationship between the photon burst counts and log antigen concentration. This novel technique was successfully used for the detection of cancer biomarker prostate specific antigen (PSA) in serum samples. Our results obtained were in good agreement with conventional ELISA assays.

2. Experimental

2.1. Chemicals and materials

Mouse monoclonal anti-human PSA antibodies (ab10185 and ab10186), PSA protein (ab119154) were purchased from Abcam (Hong Kong) Ltd (Hong Kong, China). ELISA kits for human PSA were purchased from Beijing North Institute of Biological Technology (Beijing, China). Bovine serum albumin (BSA) and 4, 7, 10, 13, 16, 19, 22, 25, 32, 35, 38, 41, 44, 47, 50, 53-hexadecaoxa-28, 29-dithiahexapentacontanedioic acid di-*N*-succinimidyl ester (NHS-PEG disulfide) were obtained from Sigma-Aldrich Chemical Co. (Milwaukee, U.S.A.). Sodium citrate, disodium hydrogen phosphate, sodium dihydrogen phosphate and hydrogen tetrachloroaurate(III) hydrate ($HAuCl_4$) were purchased from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China). Alexa 647 fluorescent dye was purchased from Invitrogen Co. (California, U.S.A.). Ultrapure water (18.2 MΩ) was obtained from the Millipore Simplicity System (Bedford, MA, U.S.A.). All other reagents were products of Sigma-Aldrich Chemical Co. (Milwaukee, U.S.A.).

Prostate cancer patient serum samples and healthy human serum samples were provided by Shanghai Jiao Tong University Affiliated Shanghai First People's Hospital. Serum samples were clotted for 30 min at room temperature and centrifuged (Beckman Coulter, U.S.A.) at 2500 rpm for 10 min, and the serum samples were stored at 4 °C for further use. All experiments were performed in compliance with the relevant laws and institutional guidelines.

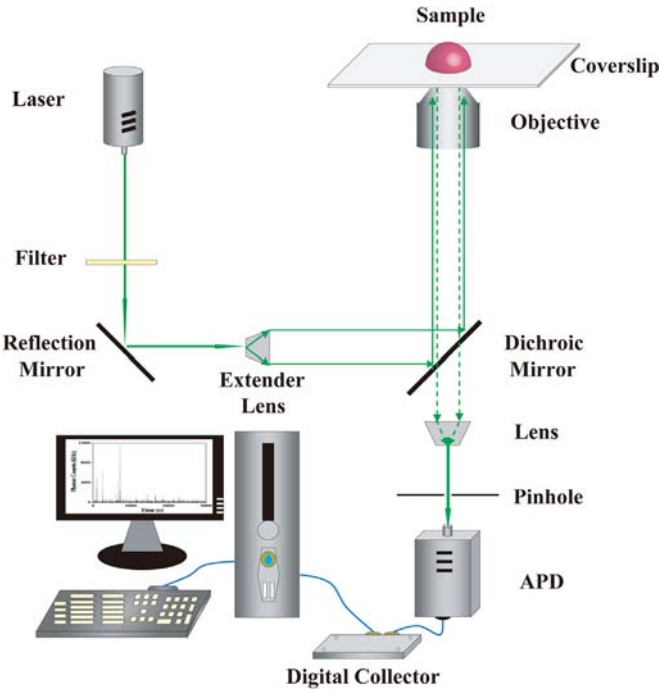

Fig. 1. Schematic diagram of photon burst counting system.

2.2. Instrumentations

The setup of photon burst counting system is similar to resonance light scattering correlation spectroscopy (RLSCS), and is shown in Fig. 1, which is based on an inverted Olympus IX 71 microscope (Japan). The exciting radiation provided by a 532 nm laser beam from an argon ion laser (ILT Technology, Shanghai, China) was attenuated to 20 μW by a neutral density filter. The sample was placed on a cover-slip (thickness: 0.13–0.17 mm), and the laser line was focused on the sample solution by a water immersion objective (UplanApo, 60 × NA1.2, Olympus). The scattering light was collected by the same objective. Then the light passed through the dichroic mirror (505DRLP, Omega Optical, U.S.A.) and the 35 μm pinhole into an avalanche photodiode (SPCM-AQR14, Perkin-Elmer EG&G, Canada). The signals obtained were recorded by a real time digital correlator (Flex02-12D/C, Correlator.com, U.S.A.). The measurement time per sample was 300 s and the time interval was 1 ms.

2.3. Synthesis of GNPs

GNPs were synthesized by reduction of the $HAuCl_4$ solution with sodium citrate according to the method described in the reference [41] with a minor modification, and the synthesis procedure was described in Supporting information.

2.4. Conjugation of antibodies to GNPs

In the conjugation of GNPs with antibodies, anti-human PSA antibodies were first modified with NHS-PEG disulfide through the reaction between the succinimidyl ester and amino group of antibodies, and then linked to the surface of GNPs through the covalent interactions between the disulfide and GNPs, respectively. The procedure was described in Fig. S-1.

Disulfide-functionalized antibodies were prepared by adding 10 μL antibody solution (1 mg/mL antibody) and 40 μL NHS-PEG disulfide solution (0.005 mol/L) into 50 μL 0.01 mol/L PB buffer (pH7.4). The resultant mixture was allowed to react for 8 h at room temperature. To remove excess NHS-PEG disulfide, the disulfide-

functionalized antibodies were purified and washed by ultrafiltration (Millipore ultrafiltration tube, cutoff of 50 kDa) 3 times with the 0.01 mol/L PB buffer. The products were redispersed in the 0.01 mol/L PB buffer and were stored at 4 °C for further use.

Antibody-functionalized GNPs were prepared by adding 5 μL 0.1 M NaOH and 20 μL 134 nmol/L disulfide-functionalized antibody into 300 μL 1.36 nmol/L 20 nm GNPs solution, and the solution were incubated for 8 h at 4 °C. In order to remove excess antibody, the GNP@antibody conjugates were purified and washed by centrifugation at 14,000 rpm for 5 min twice. The centrifuged conjugates were redispersed in 300 μL water for the first time, and 300 μL 0.01 mol/L PBS buffer (containing 0.1% BSA, pH 7.4) for the second time. Then the centrifuged conjugates were stored at 4 °C for further use.

2.5. Homogeneous sandwich immunoassay procedures

In the sandwich immunoassay of PSA, 20 μL of 1.36 nmol/L GNP-antibody-1 solution, 20 μL of 1.36 nmol/L GNP-antibody-2 solution were added into a 200 μL sterilized polypropylene tube respectively, and mixed well. To each mixed solution, 20 μL of standard antigen solution with different concentrations, or human sera, which was first 10 times diluted for sera samples by PBS buffer (containing 0.1% BSA, 10 mmol/L, pH 7.4) are added, and then incubated at 37 °C for 60 min. Finally, the dilution of serum samples was 40 times. The measurements of sample solutions were carried out by a home-built photon burst counting system. The recording time per sample was 300 s, and the assay of each sample repeated three times.

2.6. ELISA method (control experiments)

The ELISA procedures for assays of PSA were described in Supporting information.

2.7. Data processing and analysis

All data files for each measurement were exported as hexadecimal ASCII files. The hexadecimal ASCII files should be changed into decimalized ones by the detection software, and these decimalized files could be calculated and plotted with Origin (OriginLab Corp., MA, U.S.A.) software. The photon burst counts could be obtained by the Pick Peak tools in Origin software. The calibration curve was processed by plotting the photon burst counts against antigen concentrations.

3. Results and discussion

3.1. Photon burst counting detection system

Fig. 1 shows the schematics of photon burst counting system based on the resonance light scattering of noble metal nanoparticles, which is similar to the fluorescence correlation spectroscopy (FCS) system. As shown in Fig. 1, the scattering light intensities can be real time monitored by an avalanche photodiode when single nanoparticles (such as GNPs) diffuse into or out of the highly focused illumination volume due to Brownian motion.

In this study, 40 nm GNPs are used as model samples and their typical photon burst spectrum is displayed in Fig. 2.

As shown in Fig. 2, the strong photon burst of single GNPs is observed due to Brownian motion of single GNPs. However, the differences in the photon burst signal of single GNPs are relatively large, which are within the range of 0–12,000 kHz. This phenomenon mainly attributes to two reasons: the size distribution of nanoparticles and the non-uniform distribution of the focused laser beam. In order to study the effects of GNP sizes on the photon burst signal, variable sizes of GNPs (55 nm, 40 nm, 30 nm, 20 nm) were prepared. The photon burst traces and TEM images of different GNPs are shown in Fig. S-2 (Supporting information). As GNPs used in this study has a good monodispersity, which can be seen from Fig. S-2, the size distribution of GNPs provides a tiny contribution to the differences of photon burst intensity. The confocal configuration of laser beam is the main contributor to the differences in the photon burst. Due to the Gaussian distribution of the focused laser beam intensity, the intensity in the center of the focused laser beam is the strongest. The strong photon burst is generated when a GNPs passes through the center of the focused laser beam, and the weaker photon burst is observed when a GNPs passes through the edge of the focused laser beam.

3.2. The statistical characteristics of photon burst counts

As shown in Fig. 2, the marked differences in the photon burst signal of single GNPs probably result in the difficulty in the data

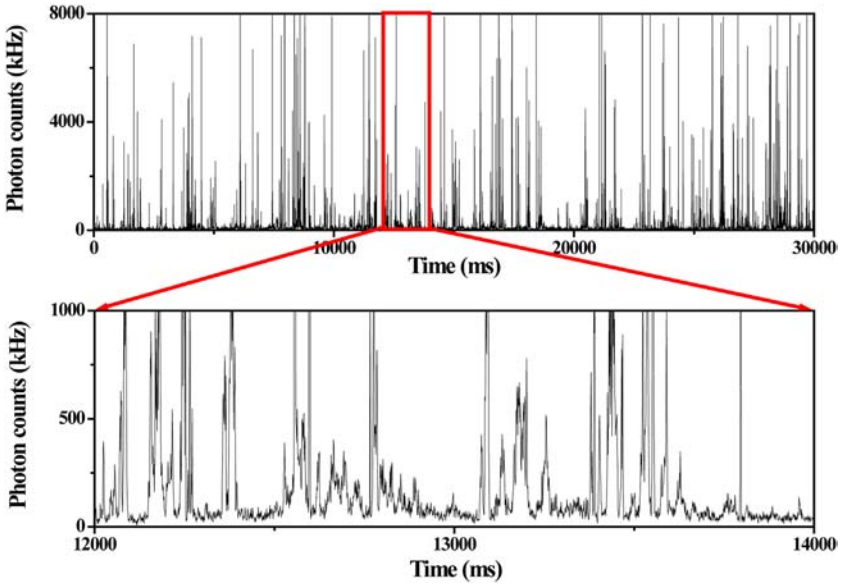

Fig. 2. Typical photon burst spectrum of GNPs. GNPs used was 40 ± 4 nm, the concentration of GNPs was 340 pmol/L, the sampling time was 30 s, and the bin time was 1 ms.

processing. In fact, the signal of photon burst includes two parts, the burst signal of GNPs and background noise. We need to develop a reliable method for efficiently distinguishing the signal and noise in a photon burst spectrum. In fluorescent photon burst counting technique, Christina and Nie [42,43] observed that the relation between the signal intensity and the photon burst counts of corresponding intensity satisfied the Poisson distribution. In order to obtain the relationship between the signal intensities and the numbers of photon burst peaks of the corresponding intensity, we investigated the photon burst of ultra-pure water as a background. As shown in Fig. 3A, the photon burst intensity of water varies around 0–45 kHz with tiny changes, which indicates that the background signal is weak and the detection system is stable.

The relationship between the photon burst intensity and the photon burst counts of corresponding intensity of water were fitted by using Gaussian and Poisson distribution models, respectively, and the results of two fitting methods were compared in Fig. 3B. The curve between the photon burst intensity and the photon burst counts of corresponding intensity is preferably fitted by Gaussian distribution model, and the correlation coefficient is up to 0.992. But, the Poisson model is unsuitable for fitting the data of background signal and the correlation coefficient obtained is only 0.838. Therefore, in the case, we think that the relationship between the intensity and the photon burst counts satisfies Gaussian distribution.

Fig. 4A shows the curve between the photon burst intensity and the photon burst counts of 40 nm GNPs according to the data of Fig. 2. The results show that the distribution between the intensity and the photon burst counts has a certain tailing. Since the noise zone must be a symmetric distribution, as displayed a symmetrical Gaussian distribution from the background of water, the noise zone of GNPs is considered to be a symmetrical profile. Thus the left part of noise distribution from GNPs was symmetrically operated, and the noise of the GNPs was extracted from the photon burst spectrum of GNPs. The noise zone was fitted by both Gaussian and Poisson distribution, and the results of two fitting methods were compared in Fig. 4B. The green line is the Gaussian fitting curve, and the blue one is the Poisson fitting curve. The result is similar to the background of water, and the noise zone of GNPs preferably meets Gaussian fitting and does not fit Poisson distribution. This result demonstrates that Gaussian model is suitable for fitting the noise zone of photon burst.

The photon burst spectrum of silver nanoparticles (SNPs) also can be observed by the same system, and the photon burst spectrum of a 20 nm SNPs and the fitting results of its noise zone were shown in Fig. S-3. In the figure, we found the Gaussian distribution was also suitable for fitting the photon burst noise zone of SNPs. So the introduced photon burst counting technique in this manuscript is also available for SNPs.

3.3. Principle of photon burst counting technique

To separate the signal of GNPs from the background noise in the photon burst spectrum of GNPs, a key parameter called the threshold is introduced. In the processing of data, all of the photon burst peaks, which intensities are above the threshold, are considered to be the signal of GNPs, and the peaks which the peak intensity is below the threshold are treated as the background noise. The photon burst counts can be calculated by using the Pick Peaks tool in Origin 6.1.

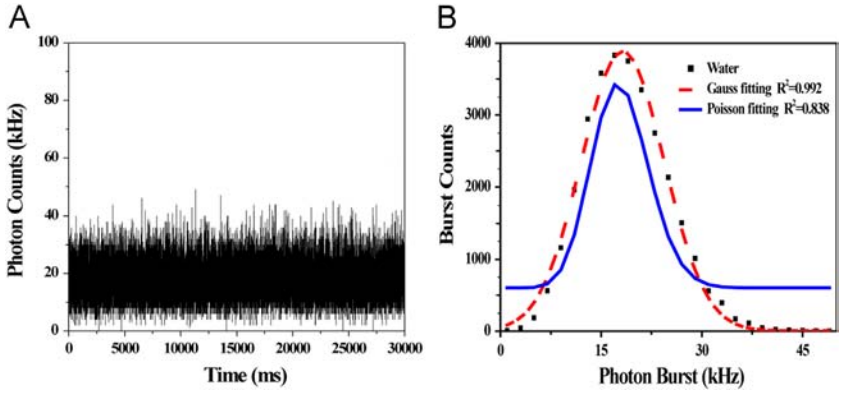

Fig. 3. Photon burst spectrum (A) and the noise distribution spectrum (B) of ultra-pure water. The resistivity of the water was 18 MΩ/cm. The sampling time was 30 s, and the bin time was 1 ms.

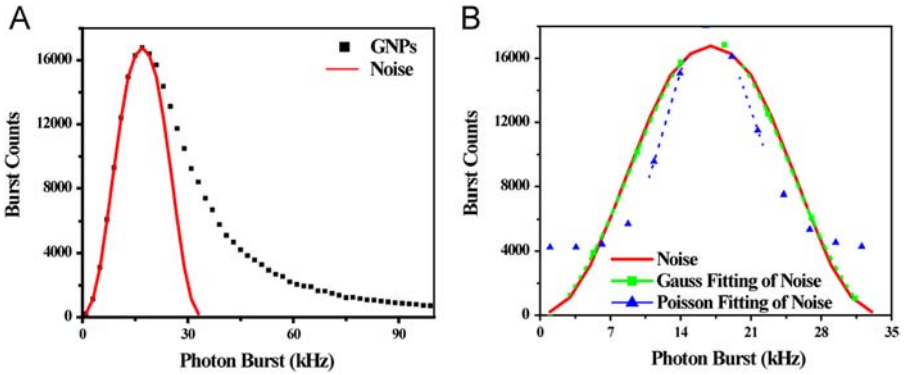

Fig. 4. (A) Photon burst signal distribution of 40 nm GNPs, and (B) the fitting curves of the noise zone. The GNPs used was 40 ± 2 nm, the concentration of GNPs was 340 pmol/L, the measurement time was 30 s, and the bin time was 1 ms. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

The threshold value (T) can be described as follows,

$$T = B + K \times F \quad (1)$$

where B is the baseline value, F is the fluctuation value of the baseline (or noise) and K is the coefficient. We can obtain the baseline value and the fluctuation value according to the Gaussian distribution of the background noise mentioned above.

In a Gaussian distribution curve, the mathematical function $f(x)$ was expressed as follows,

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma}\exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \quad (2)$$

where μ is the mathematical expectation of the distribution, and σ represents the standard deviation. In the photon burst distribution of GNPs, the mathematical expectation of the fitting curve reflects the most frequently occurring photon burst intensity, which can be considered as the baseline values (B) in this case. When x falls around $\mu+2\times\sigma$ and $\mu-2\times\sigma$, the confidence level is about 95.45%, that is, there are 95.45% of the data falls in the zone. In this case, the fluctuation value can be chosen as 4σ.

Based on the theory above, the threshold value and the fluctuation value were obtained. We first extract the noise zone of samples, and then fit the noise zone with Gaussian distribution to get the baseline value μ and fluctuation value 4σ of the noise zone. The threshold was defined as $\mu+K\times 4\sigma$.

K is one of the critical parameters in the detection method, and is related to the sensitivity and reproducibility of the method. The photon burst data of 40 nm GNPs with the concentration of 340 pmol/L, 170 pmol/L, 68 pmol/L, 34 pmol/L and 17 pmol/L are recorded in Fig. S-4. The photon burst counts reduce with the decrease in GNPs concentration. The different K values were putted into the threshold Eq. (1), and different thresholds were obtained. Fig. 5 displays the relationship between the concentration of GNPs and the photon burst counts of GNPs, respectively. As shown in Fig. 5, the slopes of the curve gradually reduced with the increase of K, which illustrated the reduction in the sensitivity. But the error becomes larger in the case of low K, because certain noises in the data are not completely eliminated. Under the consideration of both sensitivity and reproducibility, we selected 2 as the value of K, and the threshold were set as $\mu+8\times\sigma$ for the subsequent experiments. As shown in Fig. 5, the errors of each point are very small, which demonstrates that the method has a good reproducibility.

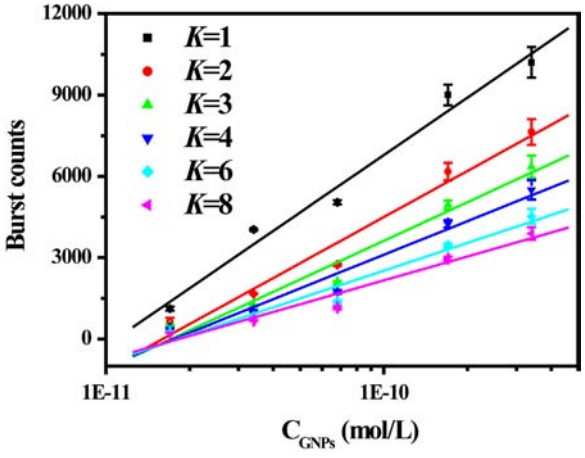

Fig. 5. Linear relationships between the concentration and the photon burst counting of GNPs. The K was 1, 2, 3, 4, 6, and 8, respectively. The GNPs used was 40 nm, the concentrations of GNPs were 340 pmol/L, 170 pmol/L, 68 pmol/L, 34 pmol/L, 17 pmol/L, and the sampling time was 30 s.

The reproducibility of photon burst counting method was investigated. In the intra-day study, the 40 nm GNPs was used as samples, each sample was detected seven times, and the measurement time was 300 s. In the inter-day study, the 40 nm GNPs was also used as samples, each sample was detected three times in the subsequent five days, and the measurement time was 300 s. The photon burst counts was calculated by Origin 6.1. The results are shown in Table S-1. The RSDs of the intra-day and the inter-day are 1.7% and 2.2%, respectively. The results further illustrate that the method described in this study shows a good reproducibility.

In order to obtain the accurate photon burst counts of gold nanoparticles, first the curve between the photon burst intensity and the photon burst counts of the GNPs is obtained based on a photon burst spectrum of GNPs, and the left part of this curve is symmetrically operated to generate the noise distribution curve of GNPs. And then, the mathematical expectation μ and the standard deviation σ of this noise zone can be acquired by fitting this curve with a Gaussian distribution. Finally, the threshold of this spectrum is set as $\mu+8\times\sigma$, the number of peaks which are beyond this threshold is calculated by the Pick Peak tools of Origin software, this number is considered to be the photon burst counts of a GNPs.

3.4. Homogeneous sandwich immunoassay by photon burst counting method

Prostate specific antigen (PSA) is a member of the kallikrein-related peptidase family and is secreted by the epithelial cells of the prostate gland [44,45]. PSA is present in small quantities in the sera of men with healthy prostates, but is often elevated in the presence of prostate cancer or other prostate disorders [46–48].

Fig. 6 illustrates the principle of homogeneous sandwich immunoassay on the basis of photon burst counting technique. As shown in Fig. 6, when GNPs labeled with two different antibodies are mixed in a sample containing antigens, the binding of antigens will cause GNPs to form dimers (or oligomers), which leads to the significant reduction in the number of nanoparticles. To further confirm the successful immunoreactions between the antibodies conjugated GNPs and antigen, TEM images of GNPs before and after the immunoassay were shown in Fig. S-5. In the study, the GNPs was 20 nm, the concentration of GNPs@Ab was 680 pmol/L, a 1:1 mixture solution of the two nanoprobes, GNP@Ab1:GNP@Ab2, was added into the solution of PSA with a concentration of 1 nmol/L. The mixed solution was incubated for 1 h at 37 °C, then drop on a copper grid and examined by TEM. In , few GNPs dimmer in the red circle can be found which may be caused by the aggregation of GNPs themselves. But in Fig S-5B, the increased GNPs dimmers can be seen, which were believed to be formed by the sandwich immunoreactions between antibodies and antigen.

Photon burst counting method can sensitively detect the changes in the photon burst counts of GNPs before and after immune reactions. We reason that the photon burst counts of GNPs reduces with an increase of antigens in solution due to the formation of immunocomplexes. The relationship between the photon burst counts of GNPs and antigen concentration may be used for quantification of antigen level. In this study, the sandwich immune reaction of PSA was used as models to construct homogeneous sandwich immunoassay platforms based on photon burst counting method.

We first investigated the effect of GNPs sizes on sandwich immunoassay of PSA. As we know, the large-sized GNPs are not stable in biological samples, and they are easy to form aggregates, which will affect the accuracy of analytical results. Therefore, the sizes of GNPs used in the assay were 20 nm and 40 nm, respectively. In the assay, the concentration of 20 nm GNPs was 680 pmol/L, and the concentration of 40 nm GNPs was 170 pmol/L. As shown in Fig. S-6A,

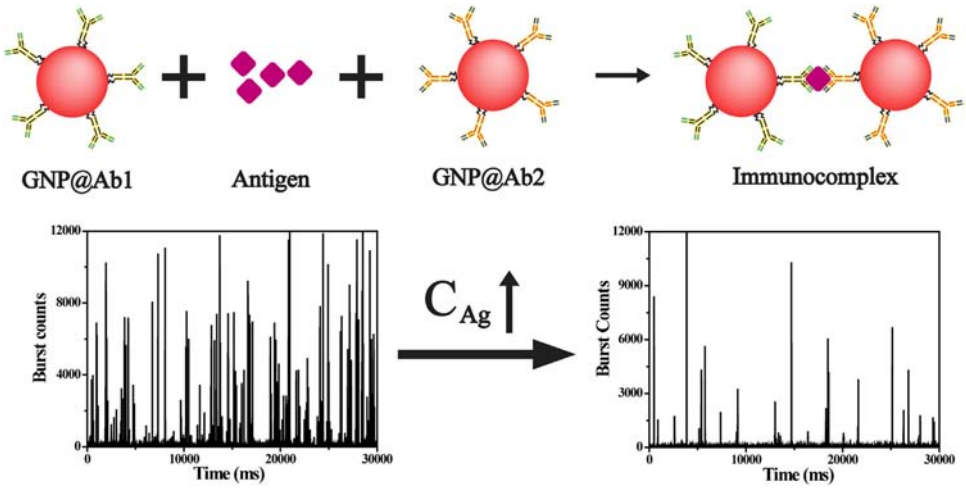

Fig. 6. Principle of homogeneous sandwich immunoassay based on photon burst counting method. GNP@Ab1 and GNP@Ab2 represent the antibodies labeled gold nanoparticles. C_{Ag} means the concentration of antigen.

the photon burst counts reduced with an increase of the probe sizes. The probe size of GNPs provides an obvious effect on the sensitivity and linear range of the sandwich immunoassay of PSA. When the small sized GNPs are used, the linear range is one order of magnitude wider than big sized GNPs, and the slope of the calibration curve is larger, which represents more sensitive in this case. Therefore, the probes size used in the subsequent sandwich immunoassay of PSA was 20 nm.

We also investigated the effects of GNPs concentration on sandwich immunoassay of PSA. The 20 nm GNPs were used in the assay, and their concentrations were 2.72 nmol/L, 1.36 nmol/L and 680 pmol/L, respectively. As shown in Fig. S-6B, the linear range increases with the increase in the concentration of GNPs. When the concentration of GNPs is 2.72 nmol/L, the linear range only has two orders of magnitude. But when the concentration of GNPs reduces to 680 pmol/L, the linear range reaches to three orders of magnitude. In the following research of sandwich immunoassay, the concentration of GNPs we used is 680 pmol/L.

We used the photon burst counting technique to construct a homogeneous sandwich immunoassay for PSA antigens. Under the optimal consideration, a good linear relationship between the photon burst counts and the log PSA concentration was obtained, which was shown in Fig. 7. The calibration curve of PSA has a wide linear range over three orders of magnitude (from 1 pmol/L to 1 nmol/L), and the detection limit is 0.8 pmol/L for PSA.

The method was successfully applied for the direct detection of the PSA level in serum samples from normal subjects and cancer patients. In the sandwich immunoassay measurements, all serum samples were diluted 10 times with a buffer (0.1% BSA/PBS). The photon burst spectrum of a prostate cancer patient serum sample is shown in Fig. S-7. In Fig. S-7, very few peaks are found, which doesn't affect the accuracy of the results. The results of PSA levels in serum samples are shown in Table 1, we observed that the PSA levels in cancer patients were more than one order of magnitude higher than those in healthy subjects. The contrast experiments were performed with ELISA. As shown in Table 1, the RSDs were less than 7%, and this result illustrated that the present method has a good reproducibility. The results obtained from the photon burst counting method were in good agreement with ELISA assays.

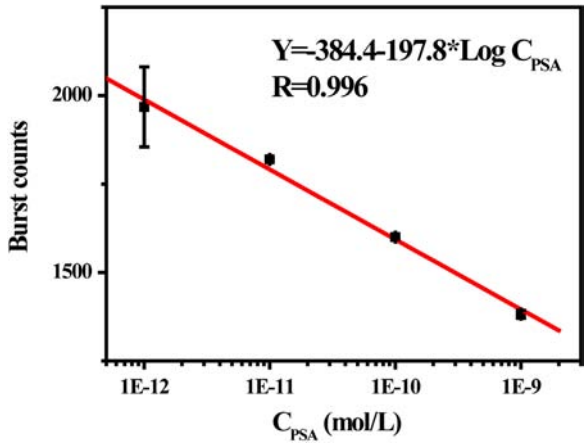

Fig. 7. The linear relationship between the photon burst counts and the concentration of PSA by homogeneous sandwich immunoassay based on the photon burst counting method. In the sandwich immunoassay of PSA, the size of GNPs used was 20 nm, and the concentration of GNPs was 680 pmol/L.

Table 1
The PSA levels in serum samples measured by sandwich immunoassay based on photon burst counting technique and ELISA.

Samples	Photon burst		ELISA (mol/L)
	Concentration (mol/L)	RSD (%)	
Normal 1	4.07×10^{-11}	1.4	3.40×10^{-11}
Normal 2	1.22×10^{-11}	6.5	1.70×10^{-11}
Cancer 1	1.45×10^{-10}	1.5	1.16×10^{-10}
Cancer 2	2.48×10^{-10}	5.9	1.06×10^{-10}

4. Conclusions

In this work, we described a novel photon burst counting method based on the resonance light scattering and Brownian motion of GNPs in a highly focused laser beam. The data processing method was proposed in the photon burst counting technique. This single particle technique was applied to develop homogeneous immunoassays. In the immunoassay, the sandwich strategy was used and the experimental conditions were investigated. This technique was successfully used for the direct detection of biomarker PSA in serum samples, and the results obtained were in good agreement with conventional ELISA assays. Compared with current methods, this method can be characterized as good reproducibility, high sensitivity, and a short analysis time, and it exhibits promising potential applications in clinical diagnosis, environmental and food safety analysis.

Staphylococcus epidermidis biofilms

ABSTRACT

Staphylococcus epidermidis is an important nosocomial agent among carriers of indwelling medical devices, due to its strong ability to form biofilms on inert surfaces. Contrary to some advances made in the transcriptomic field, proteome characterization of *S. epidermidis* biofilms is less developed. To highlight the relation between transcripts and proteins of *S. epidermidis* biofilms, we analyzed the proteomic profile obtained by two mechanical lysis methods (sonication and bead beating), associated with two distinct detergent extraction buffers, namely SDS and CHAPS. Based on gel electrophoresis-LC–MS/MS, we identified a total of 453 proteins. While lysis with glass beads provided greater amounts of protein, CHAPS extraction buffer allowed identification of a higher number of proteins compared to SDS. Our data shows the impact of different protein isolation methods in the characterization of the *S. epidermidis* biofilm proteome. Furthermore, the correlation between proteomic and transcriptomic profiles was evaluated. The results confirmed that proteomic and transcriptomic data should be analyzed simultaneously in order to have a comprehensive understanding of a specific microbiological condition.

1. Introduction

When *Staphylococcus epidermidis* establishes biofilms on indwelling medical devices, this may cause an early removal of the implant due to the lack of effective antibiotic therapeutics and risk of eventual systemic infection [1,2]. *S. epidermidis* biofilms grown in glucose-enriched medium were previously associated with an increased proportion of dormant cells within a biofilm [3]. Dormancy is a clinically relevant physiological state, since it has been associated with long-term bacterial survival, increased cellular tolerance to antibiotics [4–6] and evasion of the host immune system [3,7].

The availability of the complete genome of *S. epidermidis* strains RP62A (ATCC 35984) [8] and ATCC 12228 [9] has led to the development of proteomic studies, since it has been suggested that the genome sequence is not sufficient to elucidate the biological functions of an organism [10]. Although there have been major advances in the molecular characterization of the pathogenic mechanisms of *S. epidermidis* biofilms [1], much less is known regarding the proteome. A few proteomic studies, however, have been performed with some *Staphylococcus* spp. in order to identify specific features associated with the pathogenicity and physiology of these microorganisms [11–18]. In *S. epidermidis*, 2-Dimensional Electrophoresis (2-DE) analysis of proteomic patterns showed several differentially expressed proteins when comparing commensal and invasive strains [12]. To ensure high quality and reliable proteomic results, an appropriate sample preparation is fundamental [19,20]. Due to the complex structure of biofilms [21], it is necessary to develop an effective lysis method in order to obtain maximum coverage of the biofilm proteome and minimal protein losses, similar to the approach optimized for total RNA extraction from *S. epidermidis* biofilms [22]. Different protein extraction methods, including enzymatic, chemical, mechanical and other methods available via commercial extraction kits have been tested to obtain the highest number of proteins in *Staphylococcus* spp. [11,14]. Although the majority of these studies were performed with cell suspensions, relatively harsh techniques have been shown to be rapid and efficient to disrupt and lyse biofilms of Gram-positive bacteria, such as mechanical methods like bead beating with glass beads (FastPrep) or sonication [14,23,24]. Often, to optimize protein recovery, enzymes and detergents may be used in conjugation with mechanical lysis. Since lysostaphin efficiently cleaves staphylococcal cell wall peptidoglycan [25,26], it may

be used to disrupt staphylococcal biofilms [27]. However, due to high costs of lysostaphin, detergents are frequently used to enhance protein isolation and solubilisation [28].

In an attempt to determine the relation between protein and mRNA levels, several studies have shown that often the correlation is surprisingly low, and differs widely among organisms [29]. Correlation coefficients were found to vary from 0.09 to 0.46 in multi-cellular organisms, from 0.34 to 0.87 in yeasts, whereas in bacteria the correlations ranged from 0.20 to 0.47 (reviewed in [30]). Up to now, no correlation analysis between the transcriptome and proteome of *S. epidermidis* biofilms has been conducted.

Hence, herein, since distinct lysis and extraction methods may yield different protein recoveries, we assessed different lysis methods to obtain proteins from *S. epidermidis* biofilms grown in glucose-enriched medium. Then, we compared the proteomic profile with the gene expression profile obtained by RNA sequencing (RNA-seq) technology., We undertook a gel-based method to determine protein isolation efficiency, using total protein extracted with a detergent-based extraction (SDS or CHAPS) coupled with mechanical lysis (sonication or bead beating). A detailed analysis of proteomic data was performed in each condition. Label-free relative protein abundance index (emPAI) was used for the relative quantitation of the proteome and was compared to transcriptomic profile. The overall goal was to characterize and correlate both proteomic and transcriptomic profiles of *S. epidermidis* biofilm-grown cells.

2. Materials and methods

2.1. Growth conditions

Biofilm forming *S. epidermidis* 9142 strain was used as a model [31]. One colony was inoculated into 1 mL of Tryptic Soy Broth (TSB) (Liofilchem, Roseto degli Abruzzi, Italy) and incubated at 37 °C at 120 rpm for 18 h. The overnight culture was adjusted to an optical density at 640 nm of 0.250 (± 0.05) with TSB and 10 μL of the suspension was transferred into a 24-well plate (Thermo Fisher Scientific, Waltham, MA, USA) containing 1 mL of TSB supplemented with 0.4% glucose (v/v) (TSB 0.4% G) (Thermo Fisher Scientific). The culture plate was then incubated at 37 °C at 120 rpm for 24 h. After this period, the culture medium covering the biofilm was removed and replaced by fresh TSB supplemented with 1% glucose (v/v) (TSB 1% G). Biofilms were allowed to grow in these same conditions for 24 additional hours. Thereafter, biofilm culture medium was removed and biofilms were washed twice with phosphate buffered saline (PBS).

2.2. Protein preparation

The same number of biofilms (12 biofilms for each condition) were directly scraped and suspended in detergent extraction buffers: 25 mM Tris–HCl (pH=7.2) (Pharmacia Biotech, Uppsala, Sweden), 10 mM CHAPS (Sigma-Aldrich, St. Louis, MO, USA, 0.5 M NaCl (VWR, Radnor, PA, USA), 5% glycerol (Sigma-Aldrich) and 1 mM PMSF (Sigma-Aldrich) or 60 mM Tris–HCl (pH=6.8), 10% glycerol, 5% SDS (USB Corporation, Cleveland, OH, USA) and 1 mM PMSF. Mechanical lyses were performed in a sonicator (Cole-Parmer® 750-Watt Ultrasonic Homogenizer, Cole Parmer, Vernon Hills, IL, USA) (10 min, 30 s running, 10 s pause, 40% amplitude) or by bead beating, using glass beads of 0.1 mm (Sigma-Aldrich) in a FastPrep® cell disruptor (BIO 101, ThermoElectron Corporation, Thermo Fisher Scientific) (3 cycles of 30 s and 6.5 m/s). After lyses, cell debris were removed by centrifugation (15,000g for 15 min at 4 °C) and proteins precipitated with cold acetone [32]. Then, protein quantification was performed using the RC-DC assay (Bio-Rad, Hercules, CA, USA), following the manufacturer's instructions.

2.3. One-dimensional gel electrophoresis (SDS-PAGE) in gel protein digestion and protein identification

Forty μg of protein were incubated with SDS 10% (w/v), 0.5 M Tris–HCl (pH 6.8), glycerol, mercaptoethanol and bromophenol blue (w/v) for 5 min at 100 °C. Then, samples were loaded on Novex NuPAGE® 4–12% Bis-Tris gel (Life Tecnologies, Grand Island, NY, USA) and proteins were separated at a constant voltage (200 V). The gel was stained with colloidal Coomassie G-250 and all the lanes were manually excised into 16 gel slices for in-gel digestion with trypsin TPCK (AB Sciex, Framingham, MA, USA). Peptide extraction was made with 10% formic acid/ 50% acetonitrile. Dried peptides were dissolved in 5% acetonitrile (VWR), 0.1% formic acid (Sigma-Aldrich) and 0.1% trifluoroacetic acid (Sigma-Aldrich). Separation of tryptic peptides by nano-HPLC was performed on the module separation Ultimate 3000 (Dionex, Thermo Fisher Scientific) using a capillary column (Pepmap100 C18; 3 μm particle size, 0.75 μm internal diameter, 15 cm in length). A gradient of solvent A, (water/acetonitrile/trifluoroacetic acid (98:2:0.05, v/v/v)) to solvent B (water/acetonitrile/trifluoroacetic acid (10:90:0.045, v/v/v)) was used. The separation of 2 μg/μL sample was performed using a linear gradient (5–50 % B for 30 min, 50–70% B for 10 min and 70–5% A for 5 min) with a flow rate of 0.3 μL/min. The eluted peptides were mixed with a continuous flow of CHCA matrix solution (270 nL/min, 2 mg/mL in 70% ACN/0.1% TFA and internal standard Glu-Fib at 15 ftmol) and applied directly on a MALDI plate in 20 s fractions using an automatic fraction collector Probot (Dionex, Thermo Fisher Scientific). Mass spectra were obtained on a matrix assisted laser desorption/ionization–time of flight MALDI-TOF/TOF mass spectrometer (4800 Proteomics Analyzer, Applied Biosystems, Foster City, CA, USA) in the positive ion reflector mode and obtained over the mass range from 700 to 4500 Da with 900 laser shots. A fragmentation voltage of 2 kV was used throughout the automated runs. The spectra were processed and analyzed by the T2S (v1.0, Matrix Science Ltd, London, U.K) and submitted in Mascot software (v.2.3.0.2, Matrix Science Ltd) for protein/ peptide identification based on MS/MS data using the following criteria: trypsin as enzyme; a maximum of two missed cleavages; mass tolerances of 40 ppm for peptide precursors, mass tolerance of 0.6 Da was set for fragment ions. Simultaneously, phosphorylation of threonine (T), serine (S) and tyrosine (Y) were searched as variable modifications. The local false discovery rate (FDR) was calculated by searching the spectra against SwissProt (Firmicutes, release date 06022013) decoy (random) database. Protein identification was considered reliable when the individual ion score for each peptide had a minimum individual score of 95% and a minimum sequence tag of four aminoacids. Relative quantitation was performed using emPAI. Gene ontology [33] analysis was performed with proteins identified in each extraction condition using STRING database (Search Tool for the Retrieval of Interacting Genes/Proteins) (version 9.1) [34] (statistically significant specific GO terms, FDR adjust $p < 0.05$). Two independent experiments were performed with pools of *S. epidermidis* biofilms.

2.4. RNA sequencing

RNA extraction from *S. epidermidis* biofilms, cDNA library preparation and RNA-seq, were performed as previously described, with some modifications [35]. Briefly, total RNA was extracted using the RNeasy Mini kit (Qiagen, Valencia, CA, USA). To remove genomic DNA, Ambion® TURBO DNA-free™ kit (Life Technologies) was used followed by acid–phenol:chloroform precipitation (Ambion®, Life

Tecnhologies), both following the manufacturer's instructions. RNA integrity was determined using the Bioanalyzer 2100 (Agilent Technologies, Santa Clara, CA, USA), and samples with RNA Integrity Number (RIN) above 8 were selected for complementary DNA (cDNA) library preparation. Ribosomal RNA was depleted from total RNA samples using the Ribo-Zero™ Magnetic kit for Gram-Positive bacteria (Epicentre, Madison, WI, USA), following the manufacturer's specifications. The Illumina® TruSeq™ RNA Sample Preparation kit (Illumina, San Diego, CA, USA) was used with the already purified mRNA, following the manufacturer's protocol. The construction of the libraries was rigorously validated by quantitative PCR and Hi-Sensitivity D1K TapeStation (Agilent 2200 TapeStation). Sequencing data were generated from paired-end reads (2×150 bp) on a MiSeq® system (Illumina) using a RNA-seq library of 10 nM. The mapping to reference genome and normalization of gene expression was performed using CLC Genomics Workbench software (V.5.5.1, CLC Bio.). RNA-seq reads were aligned to the reference genome of *S. epidermidis* strain RP62A (GenBank accession number NC_002976). Gene expression was normalized by calculating Reads per Kilobase per Million Mapped Reads (RPKM) using the methods described by Mortazavi and colleagues [36], in which normalization is adjusted by the counts of reads per kilobase per million mapped and gene length. All genes with RPKM value under 1.00 were not considered for analysis. Three independent experiments, each one from a pool of four biofilms, were performed.

3. Results and discussion

3.1. Proteomic characterization

In the present study, a proteomic and transcriptomic analysis of *S. epidermidis* biofilms grown in glucose-enriched medium was performed using gel-based proteomic separation and LC–MS/MS analysis along with RNA-seq technology, respectively. The proteomic profile obtained is highly dependent on the extraction procedure used, with quickness, handling and robustness of protein extraction methodologies being important criteria [11,37–39]. Before protein concentration, we used SDS-PAGE to compare the lysis efficiency of sonication and glass bead disruption of *S. epidermidis* biofilm cells (Fig. 1). Cellular lysis by the glass bead disruption method produced a higher protein yield compared to the performed sonication cycle. Due to sample and protein properties, precipitation may be required as a treatment to reduce or eliminate substances which could interfere with protein identification, as well as to concentrate proteins [40].

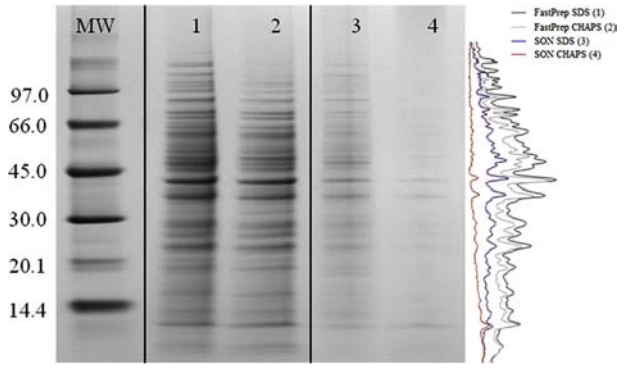

Fig. 1. SDS-PAGE before protein concentration and respective optical density traces. 1—Protein profile obtained with FastPrep and SDS buffer extraction; 2—protein profile obtained with FastPrep and CHAPS buffer extraction; 3—protein profile obtained with sonication and SDS buffer extraction; 4—protein profile obtained with sonication and CHAPS buffer extraction. *MW*—molecular weight (KDa).

However, it is known that protein precipitation leads to specific changes in the protein composition of proteomic samples. These modifications depend, mainly, on the specific structure of the protein rather than the precipitating agent used [41]. Nevertheless, proteins recovered in each extraction method were precipitated, solubilised and quantified, followed by SDS-PAGE (Supplementary Fig. S1) and LC–MS/MS analysis.

A total of 453 *S. epidermidis* proteins were identified, which corresponds to 17.96% of the predicted proteome (total of 2522 for *S. epidermidis* RP62A strain in UniProtKB database, at 29112013) with an increased confidence (FDR was below 5.5% among replicates). Venn diagram [42] demonstrated that 158 proteins were common to all extraction conditions (Supplementary Fig. S2). A total of 361 proteins were identified in FastPrep lysates with SDS, 391 in FastPrep with CHAPS, 359 in sonication lyses with SDS and 175 proteins after sonication in the CHAPS extraction buffer. The FastPrep protocol seemed to be the most efficient to lyse cells within *S. epidermidis* biofilms. Additionally, the CHAPS extraction buffer resulted in the identification of a higher number of proteins, compared to the SDS extraction buffer. Interestingly, this last finding, diverges from the work described by Encheva and colleagues [43], where it was shown that SDS gave a higher protein yield as compared to CHAPS, in an analysis of the *Streptococcus pneumoniae* proteome. SDS is an anionic detergent, used as a surfactant in protein denaturation, breaking lipid–lipid interactions and lipid–protein interactions rather than protein–protein interactions [44]. SDS is known to be very effective at solubilising almost all proteins [45,46]. However, it denatures them, causing loss of their native conformations and functions [47]. Alternatively, zwitterionic detergents such as CHAPS minimize protein–protein interactions [28,48]. Differences in extraction efficiency support the importance of extraction buffer to optimize protein yield or to increase yields of groups of proteins.

Next, Gene Ontology (GO) annotation, incorporating molecular function (Supplementary Table 1), biological processes (Supplementary Table 2) and cellular component (Supplementary Table 3) of proteins recovered from each extraction condition was analyzed. The main differences were observed in molecular function enriched categories (Fig. 2). The GO terms adenyl nucleotide binding (GO:0030554) and nucleic acid binding (GO:0003676) were only found in protein extraction performed with FastPrep lysis. Similarly, the GO terms for metal ion binding (GO:0046872), cation binding (GO:0043169) and ion binding (GO:0043167) were only found enriched in extractions performed with SDS buffer. These findings may be explained by the interaction established by SDS and cationic metal ions, due to the anionic head group of SDS [49]. While some studies showed that mechanical disruption of bacterial cells enhances the identification of cytoplasmic proteins [50,51], a number of cell membrane, secreted and cell surface proteins were also identified here. Membrane proteins are hydrophobic and they are present in low levels, since they are unstable and often aggregate, causing problems in analyzing membrane protein extractions [52]. However, within a heterogeneous protein properties set, it is difficult to find the conditions which will solubilise all proteins, including most membrane proteins, since not all are equally hydrophobic [53].

In an attempt to search for a methodological impact in the intrinsic properties of identified proteins, GRAVY score (grand average of hydropathy), molecular weight and p*I* were analyzed (Fig. 3). Overall, p*I*, protein molecular weight and GRAVY score presented a similar tendency, among the tested conditions, with a few exceptions. Most of the identified proteins had a GRAVY score between -0.5 and -0.25 (Fig. 3A). CHAPS extraction buffer allowed separation of a higher number of hydrophilic proteins (GRAVY score lower than -1.00) compared to SDS extraction buffer. Although gel-based approaches, e.g. SDS-PAGE, may allow

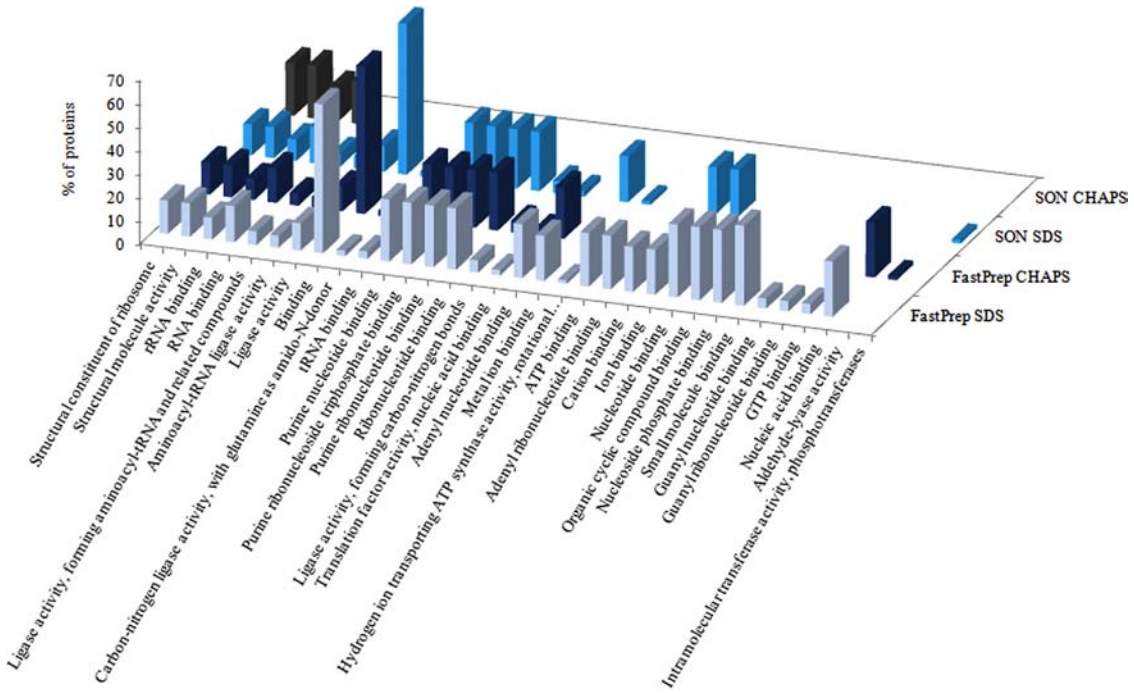

Fig. 2. GO classification. Molecular function specific terms with statistically significant enrichment ($p < 0.05$, FDR-corrected).

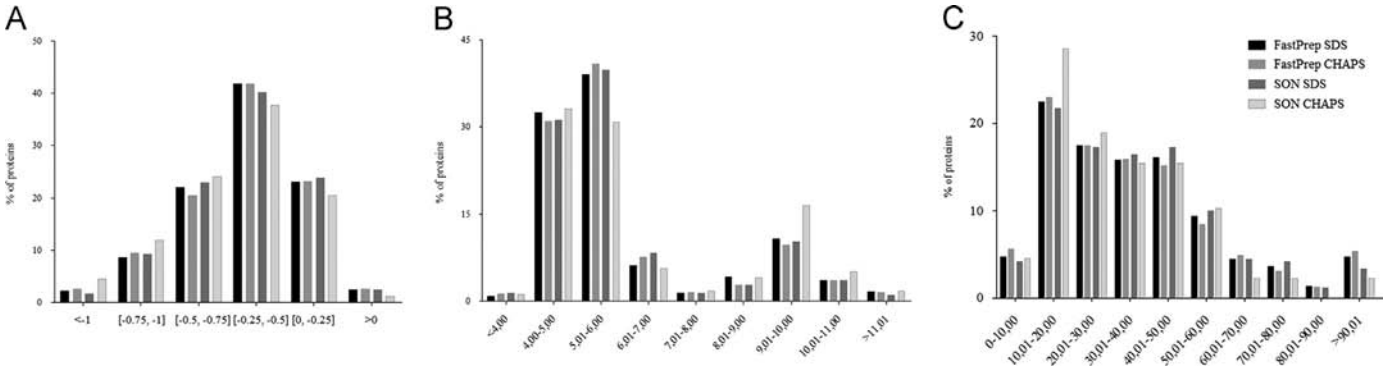

Fig. 3. Intrinsic properties of proteins. GRAVY (A), p*I* (B) and molecular weight (C) for each condition.

recovery of a significantly higher number of hydrophobic proteins, these extraction methods seemed to be less efficient at isolating hydrophobic proteins (positive GRAVY score). However, a few cell membrane proteins were identified, despite having high hydrophobicity. Our approach allowed us to identify only 3.3% of hydrophobic proteins. In proteins inferred from homology or with evidence at protein level (total of 997 proteins in UniProtKB/Swiss-Prot at 29112013), the number of hydrophobic proteins corresponds to 13.04%. Concerning p*I*, most of the isolated proteins showed a value between 4–6 or 9–10, similar to proteins inferred from homology or with evidence at protein level. More than 60% of proteins had a p*I* between 4 and 6 (Fig. 3B). Gumber et al. [54] showed that non-ionic detergents, such as Tween20 and Triton X-100 were more efficient at extracting proteins with high p*I*. Conversely, CHAPS associated with urea was shown to extract more proteins with low p*I* [54]. Regarding molecular weight, most of the proteins presented a mass between 10 and 50 kDa (Fig. 3C), which is also the most common range among the proteins inferred from homology or with evidence at the protein level. The FastPrep protocol allowed separation of higher numbers of proteins with more than 90 kDa compared to sonication. Moreover, the CHAPS extraction buffer combined with FastPrep seemed to be more efficient than SDS in obtaining proteins of less than 10 kDa. Independent of the methodological approach, a predominance of hydrophilic proteins, with 10–50 kDa and a p*I* between 4 and 6 was observed. Overall, major differences were not clearly found in molecular weight, GRAVY and p*I*, and only the GO analysis showed evident differences between SDS and CHAPS detergent extraction buffers.

3.2. Transcriptomic characterization

Whole transcriptomic profile of *S. epidermidis* biofilm cells was obtained by RNA-seq. This methodology represents a valuable method to measure mRNA expression levels, since RPKM normalization allows comparison of transcript levels among and within samples [36]. A total of 2069 genes were found with a RPKM value above 1.00, which corresponds to 77.72% of the *S. epidermidis* genome (total of 2662 for RP62A strain in GenBank). More than 50% of transcripts presented RPKM values up to 250. The most represented GO slim terms in each RPKM group (RPKM < 150, 151 > RPKM < 250 and RPKM > 250) are represented in Fig. 4. Additionally to common GO terms, RPKM values above 250 showed a predominance of catabolic (GO:0009056) and carbohydrate metabolic processes (GO:0005975) within the biological process GO category (Fig. 4A). In contrast, transcripts with RPKM lower than

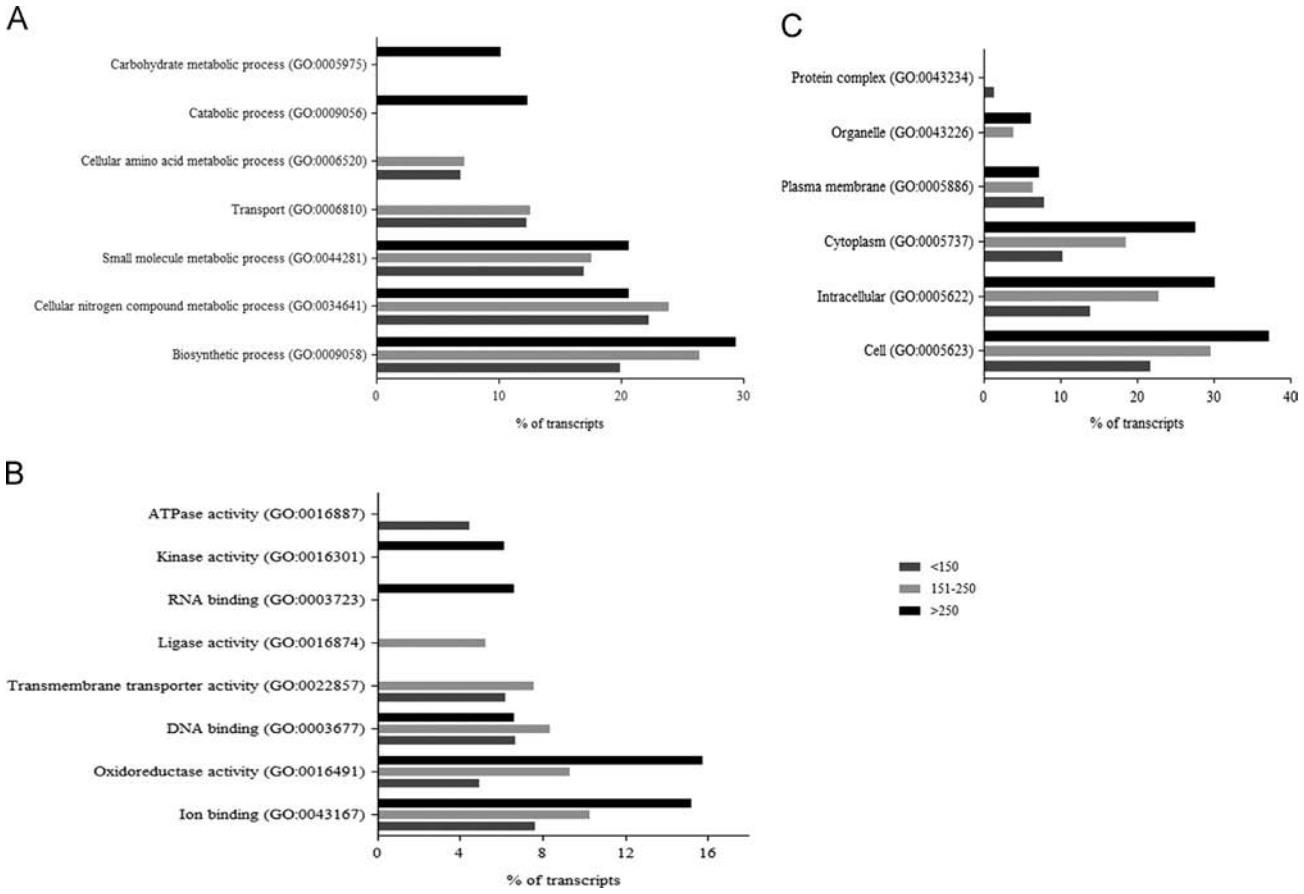

Fig. 4. GO classification of RNA-seq data. Five most represented GO slim terms of biological processes (A), molecular functions (B) and cellular components (C).

Table 1
List of the 10 genes with higher RPKM values found in transcriptomic analysis and respective function.

Gene	RPKM	Gene function
*SERP_SeSRP*1	299,510.4	Non-coding RNA involved in protein export
*SERP_SetmRNA*1	372,738.7	Transfer-messenger RNA
*SERP*1273	28,468.9	Universal stress protein
*SERP*2379	27,311.7	Diacetyl reductase [(S)-acetoin forming] which catalyzes the irreversible reduction of 2,3-butanediol to (S)-acetoin in the presence of NADH
*asp*23	24,019.2	Alkaline shock protein 23 which may play a key role in alkaline pH tolerance
arcC	11,927.2	Carbamate kinase
*SERP*2220	13,204.3	Universal stress protein
*SERP_SernpB*1	15,829.8	Non-coding RNA
spoVG	13,016.0	Septation protein
*SERP*2343	11,865.1	Uncharacterized protein

250 were associated with transport (GO:0006810) and cellular amino acid metabolic processes (GO:0006520), in addition to common GO terms. Molecular functions related to RNA binding (GO:0003723) and kinase activity (GO:0016301) were only found in transcripts with RPKM higher than 250 (Fig. 4B). Regarding cellular components (Fig. 4C), protein complex category (GO:0043234) was amongst the most represented transcripts with RPKM lower than 150. Amongst the 10 most expressed transcripts are genes involved in response to stimulus, translation, catabolic processes and non-coding RNAs (Table 1). These were expected results since during growth, bacteria need to obtain energy. Moreover, increased expression of certain classes of genes may be related to an adaptive response [55–59]. It is well known that glucose has a key role in biofilm physiology since is generally used to promote biofilm growth *in vitro* [7,31]. However, high concentrations of glucose affect biofilm gene expression [31].

3.3. Comparative proteomic and transcriptomic analysis

In order to compare proteomic and transcriptomic profiles, mass spectrometry and RNA-seq data were compared. Large scale proteomic experiments have been conducted using emPAI to determine, in a single LC–MS/MS experiment, the relative quantitation of proteins based on protein coverage by the peptide matches in a database search result [60–62]. Since the emPAI value has a linear correlation with protein concentration, it allows a more accurate estimation of protein abundance, as compared to simple peptide or spectral count [62,63]. In order to obtain an estimation of protein abundance, two independent experiments were performed. Then, emPAI values were compared within each condition (Supplementary Fig. S3). Importantly, emPAI presented the same tendency among proteins found in each extraction condition. Furthermore, reproducibility of experiments was also high, as indicated by Pearson correlation (Pearson's *r*

correlation), which varied between 0.81 and 0.99. Based on these results, we chose to calculate the emPAI average for further analysis. Extremely abundant proteins may affect the efficiency of protein identification because of ionization suppression and detector saturation as well as the limited loading capacity of LC columns [62]. We observed that bead beating lysis led to a lower percentage of identified proteins with low emPAI (0–0.20) compared to those identified following sonication (Supplementary Fig. S4). Moreover, a combination of bead beating and CHAPS extraction buffer showed more proteins with higher emPAI values (>5.00). Protein separation by SDS-PAGE and in-gel digestion decreased sample complexity and, consequently, contributed to avoiding suppression by extremely abundant proteins. Since proteins with similar abundances may functionally be correlated, proteins common to all conditions were further analyzed using CLUSTER 3.0 [64] (Fig. 5). We found four main clusters which resulted from the hierarchical clustering (two main biological processes are represented in Fig. 5). Proteins with lower emPAI tended to be involved in biosynthetic and cellular nitrogen compound metabolic processes (cluster A and D). Clusters B and C include mainly proteins with higher emPAI values. Protein cluster B is mainly related to biosynthetic processes and translation. Protein cluster C is related to biosynthetic and catabolic processes. Catabolic process was also found as one of the most prevalent GO term in transcripts with higher RPKM (Fig. 4A). Interestingly, proteins with the highest emPAI values presented translation among the main biological processes. In accordance, molecular functions, such as structural constituent of ribosome and RNA binding, were found among these proteins. However, these biological functions were not evidenced in transcripts with the highest RPKM. More precisely, instead of translation, response to stress was a biological process found significant in these transcripts, among others. In relation to molecular functions, only oxidoreductase activity was a significant class. Despite a biological condition is not characterized by the most expressed transcripts or proteins, it is of utmost importance to undertake a whole bacteriome analysis using multi-approaches. RPKM obtained by RNA-seq was next compared to emPAI values obtained from protein extraction experiments performed with FastPrep and sonication (Fig. 6). Correlations between mRNA transcripts and protein abundance obtained with FastPrep lyses were 0.37 and 0.36 (Pearson coefficient) in SDS and CHAPS extraction buffer, respectively. A somewhat smaller correlation coefficient was observed in sonication lyses with SDS ($r=0.30$) and CHAPS extraction buffer ($r=0.22$). Although this is not a strong correlation, our results are in agreement with correlation data previously described in bacteria (reviewed by [30]). When we zoomed Fig. 6A and B, we found that several proteins did not correlate with mRNA expression level. The main biological processes of these proteins are translation (when emPAI is higher than RPKM) and response to stress (when emPAI is lower than RPKM). Interestingly, dormancy is associated with low metabolic activity, leading to a decrease expression of transcripts involved in translation [65]. This suggests that these biological processes, in particular, may contribute to a lower correlation between transcriptomic and proteomic data. In almost every organism, transcript abundances only partially predict protein abundances, which suggests that other modes of regulation must be involved to explain how the levels of proteins are set within cells [29]. Also, the localization of proteins may display different correlations when compared to global correlation [66]. Despite direct correlation between proteins and mRNA is lower than 0.50, besides noise and experimental errors [67], several levels of regulation of transcripts and proteins may cause variability, such as transcription, post-transcription and post-translation regulation. Protein folding and post-translational modifications as phosphorylation, glycosylation, acetylation, proteolysis, methylation, lipidation, among others, are the most significant modifications [68–71]. Phosphorylation, such as found in LRTQKIVFS(Phospho)IGLCYSILMALSR peptide (Q5HLC3),

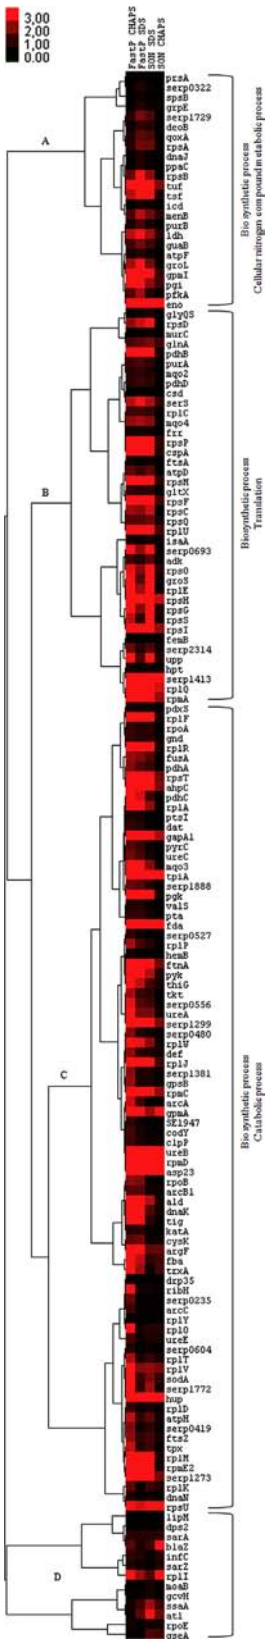

Fig. 5. emPAI hierarchical clustering. Clusters and two most represented biological function of the common proteins in each of the tested conditions generated in CLUSTER 3.0 and based on emPAI average from replicates (Slim terms).

corroborate that protein modifications increase phenotypic variability. These regulation mechanisms may explain why transcripts and proteins levels have a low correlation, among bacteria. Previously, it

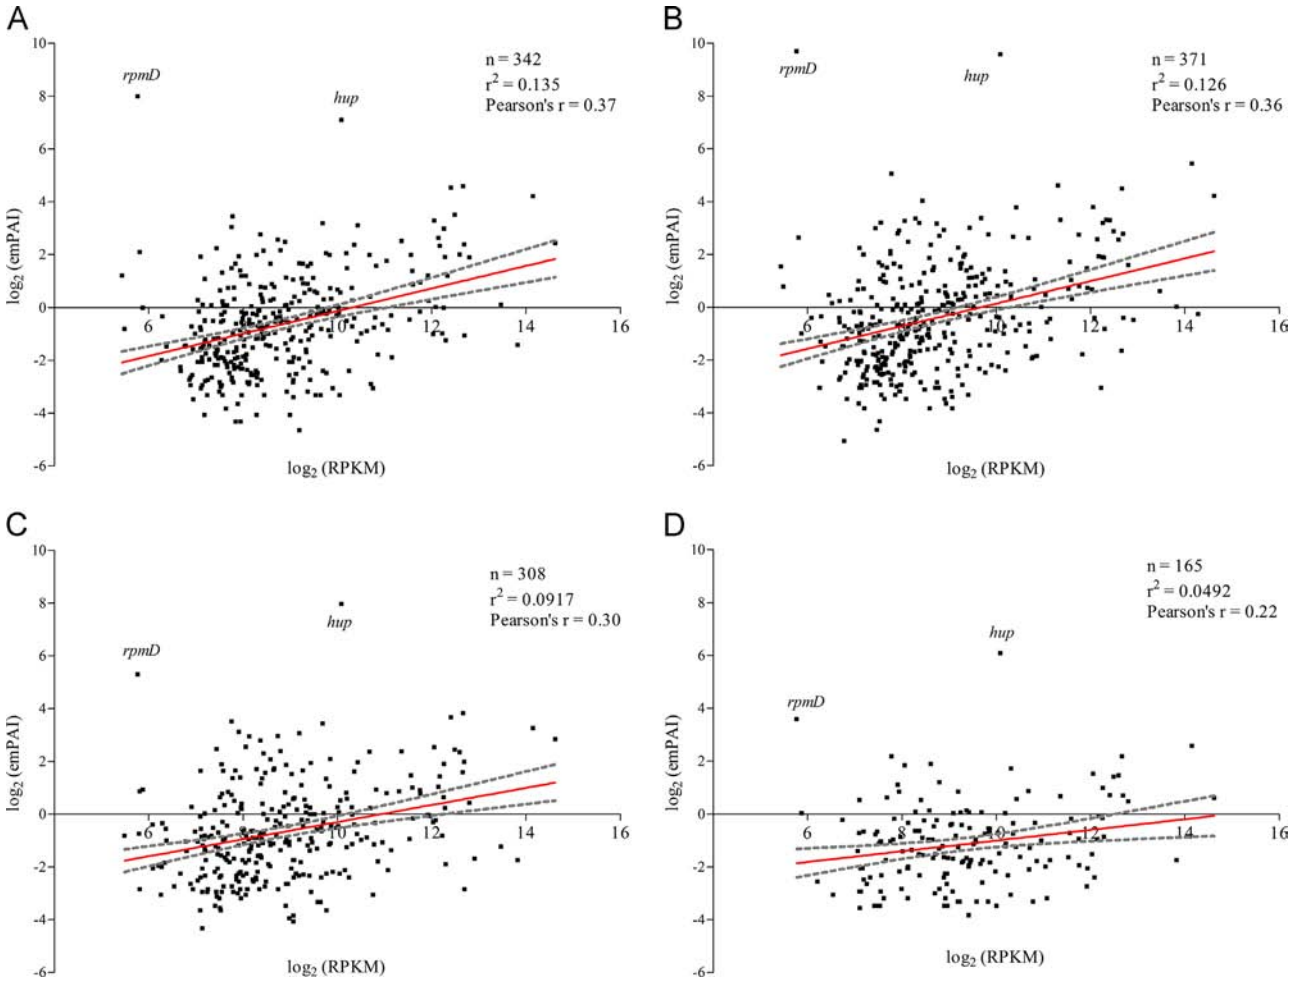

Fig. 6. Protein and transcript correlation in *S. epidermidis* biofilms grown in glucose enriched medium. FastPrep SDS (A), FastPrep CHAPS (B), SON SDS (C), SON CHAPS (D). Linear regression ($R2$), Pearson correlation (Pearson's r) and a number of proteins (n) are shown. The 95% confidence interval is shown is each condition, represented in grey dashed line. All correlations were significant ($p < 0.01$). SON—sonication.

was shown that, in *Staphylococcus aureus*, serine and threonine phosphorylations was associated with metabolic activity, virulence and translation [72]. This addresses the biological importance of regulation processes and modifications over proteins.

4. Conclusion

Similar to other studies, we demonstrated that protein extraction methods affect the proteome characterization of *S. epidermidis* biofilms. It is assumed that an efficient protein extraction method is crucial to ensure successful proteome analysis. A combination of mechanical and chemical lyses or enzymatic lysis provides a better methodology to extract proteins from *S. epidermidis* biofilms. The ideal choice of a detergent is still empirical, although, optimization of sample preparation is fundamental to correctly analyze the cell proteome. Our data suggest that a higher number of total proteins from *S. epidermidis* biofilm can be extracted and recovered by a combination of glass beads mechanical lysis with CHAPS extraction buffer. However, only mildly hydrophobic proteins can be solubilised with SDS or CHAPS. Also, the use of SDS extraction buffer led to an enhancement of metal ion binding proteins. A few lyse buffers have been used to enhance protein extraction, but one buffer is not sufficient for all purposes. This study emphasizes the need for a detailed study over extraction buffers that should be used for each experiment in order to identify the most efficient extraction methodology.

More important, we provide evidences that transcriptomic and proteomic data present a similar correlation to other bacteria, despite the detergent extraction buffer used. Interestingly, proteins involved in translation or response to stress appear to be those which less correlate with the correspondent transcript. Several "omics" may provide useful information instead of individual transcriptome or proteome analysis, since it gives an integrative view of a specific physiological state.

Dispersive solid-phase extraction (DSPE)
Toner samples

ABSTRACT

Metal-organic frameworks (MOFs) have been paid widespread attention in the field of adsorption and separation materials due to its porosity, large specific surface area, unsaturated metal-ligand sites and structural diversity. In this study, the green powder MIL-101 was synthesized and used for the extraction of benzophenone, 2,4-dihydroxybenzophenone and 2-hydroxy-4-methoxy-benzophenone from toner samples for the first time. The synthesized MIL-101 was characterized by X-ray diffraction, scanning electron microscopy, thermogravimetry and nitrogen adsorption porosimetry. The MIL-101 was applied as the dispersive solid phase extraction (DSPE) adsorbent for the extraction and preconcentration of benzophenone, 2,4-dihydroxybenzophenone and 2-hydroxy-4-methoxy-benzophenone from toner samples. The extraction conditions were investigated. Under the optimized conditions, a DSPE-HPLC method for the determination of benzophenone, 2,4-dihydroxybenzophenone and 2-hydroxy-4-methoxy-benzophenone was developed. The method yielded a linear calibration curve in the concentration ranges from 4.0 to 3500 μg L^{-1} for the three analytes in toner samples with regression coefficients (r^2) of 0.9992, 0.9999 and 0.9990, respectively. Limits of detection were 1.2, 1.2 and 0.9 μg L^{-1}, respectively. Both the intra-day and inter-day precisions (RSDs) were $<10\%$.

1. Introduction

The daily exposure to sunlight has harmful health effects. So, the use of personal care products containing ultraviolet (UV) filters steadily increased. In general, UV filters are divided in two categories: organic and inorganic filters, and are used in single or combination of both in cosmertics and sunscreens, to protect from UV light. The organic UV filters posses single or multiple aromatic structures, commonly conjugated with different chemical groups, which are able to absorb UV solar radiation and protect human skin from direct exposure. These compounds are used extensively in sunscreens, cosmetic products such as facial day creams, after-shave products, makeup formulations, lipsticks, shampoos, and in plastic based packaging materials.

There are 12 well-known BP-UV filters, namely benzophenone (BP), 2,4-dihydroxybenzophenone (benzophenone-1, BP-1) and 2-hydroxy-4-methoxy- benzophenon (benzophenone-3, BP-3), as well as other less usual compounds as 2-hydroxybenzophenone (2-OH-BP) or 4-hydroxybenzophenone (4-OH-BP). There are increasing evidences that BP-UV filters are able to interfere with the endocrine system. In vitro studies have shown that BPs stimulate the proliferation of the breast cancer cellline MCF-7 due to their estrogenic activity, and that these compounds have antiandrogenic activity too [1-3]. So, in European Union and China, the maximum content of BPs in cosmetics is regulated by the actual legislations, at a usual concentration between 0.1% and 10% (w/w). Therefore, monitoring of BPs in cosmetics samples is important for the quality control of sunscreen products.

Up to now, the main approaches for the detection of BPs included thin layer chromatography (TLC) [4], gas chromatography (GC) [5], high performance liquid chromatography (HPLC) [6,7], gas chromatography–mass spectrometry (GC–MS) [8,9] and liquid chromatography–mass spectrometry (LC–MS) [10]. All of the above reported methods are accurate but somewhat expensive and time consuming or requires complex sample preparation prior to analysis. In these methods, HPLC is a common and useful method for trace determination of analytes in complex samples. Sample preparation techniques, such as liquid–liquid extraction (LLE) [11–14], solid phase extraction (SPE) [15] and solid-phase microextraction (SPME) [16], can enhance the sensitivity and selectivity of HPLC. Compared with LLE and LPME, SPE has the

advantages of simplicity, rapidity and less consumption of organic solvents. SPE has become a routine sample preparation technique for extracting analytes from water samples. Dispersive solid-phase extraction (DSPE) is a procedure which involves single extraction of sample with solid adsorbent and followed by a rapid clean-up process [17]. The advantages of the preparation method are simplicity of operation, efficient, less consumption of organic solvents. So, DSPE is previously used for the determination of pesticides, herbicides, environmental pollutants and veterinary drug residues.

Metal-organic frameworks (MOFs) are a new class of hybrid inorganic-organic microporous crystalline materials self-assembled straightforwardly from metal ions with organic linkers through coordination bonds. The availability of various building blocks of metal ions organic linkers makes it possible to prepare an infinite number of new MOFs with diverse structures, topologies, and porosity, which bear multiple complexing functions [18–21]. The particular interest in MOFs is due to the easy tunability of their pore size and shape from a microporous to a mesoporous scale by changing the connectivity of the inorganic moiety and the nature of organic linkers. Compared with conventional adsorbents, MOFs have diverse compositions and structure types, tunable pore size, large surface area, and coordinative unsaturated or saturated metal sites to regulate the adsorption ability. MOFs have shown great potential in sorption-related fields [22–33]. Recently, researches on the liquid phase adsorption on MOFs have attracted great interests. Unfortunately, to the best of our knowledge, MOFs have not been applied for the DSPE and determination of small molecule drugs in complex matrices.

MIL-101, $Cr_3O(F/OH)(H_2O)_2[C_6H_4(CO_2)_2]_3$, is one of the most widely studied MOFs which has a cubic structure, a huge pore volume and pore sizes. MIL-101 is built up from carboxylate moieties (terephthalic acid PTA) and chromium trimeric octahedral clusters and offers a unique high surface area, large pore windows (12 to 16 Å) and mesoporous pores (29 to 34 Å), and excellent chemical and solvent stability which are very suitable for liquid phase adsorption [34,35].

In this work, MIL-101 was synthesized using the hydrothermal synthesis method, and a novel DSPE method for the extraction and concentration of three commonly used BP-UV filters (benzophenone, 2,4-dihydroxybenzophenone, 2-hydroxy-4-methoxy-benzophenone) in toner samples was developed using MIL-101 as the adsorbent for the first time. The adsorption mechanism of analytes on MIL-101 was discussed. Some important extraction parameters affecting the performance, such as the amount of MIL-101, extraction time, extraction solvent, the solution pH and salt effect were investigated.

2. Experimental

2.1. Reagents and standards

Terephthalic acid (99%, TPA), chromium (III) nitrate $Cr(NO_3)_3 \cdot 9H_2O$ (98%) and hydrofluoric acid (HF) (40.0%) (Aladdin Chemistry Co. Ltd., Shanghai, China) were used to prepare MIL-101. N,N-dimethylformamide (99.5%, DMF) and ethanol (99.7%) (Sinopharm Chemical Reagent Co. Ltd., Shanghai, China) were used as the solvents. Benzophenone (99.5%, BP), 2,4-dihydroxybenzophenone (99.5%, BP1) and 2-hydroxy-4-methoxy-benzophenon (99.5%, BP3) were purchased from Aladdin (Aladdin Chemistry Co. Ltd., Shanghai, China). Methanol and acetonitrile (HPLC grade) were obtained from Tedia Company Inc. (Ohio, USA). Other reagents used were of analytical grade. Ultrapure water was obtained on an Ultrapure Water System (Beijing, China). *Caution: Care should be taken to avoid direct contact with hydrofluoric acid because of its high toxicity and to prepare all the solutions in a well-ventilated hood!*

The stock standard solutions of BP, BP1 and BP3 were prepared in methanol at a concentration of 1.0 mg mL^{-1} and stored at −4 °C in refrigerator. Working standard solutions of BP, BP1 and BP3 were prepared by appropriate dilution of the stock solutions using ultrapure water.

2.2. Apparatus and HPLC conditions

The chromatographic analysis was carried out on a Dionex Summit U3000 HPLC system equipped with a manual injector and a Photodiode Detector Array (PDA) (DionexTechnologies, USA). A personal computer equipped with a Chromeleon Chem-Station program for LC was used to process chromatographic data. An amethyst-C18 column (4.6 mm × 250 mm, 5 μm) from Sepax Technologies Inc. (Newark, USA) was connected with a guard column (cartridge 2.1 mm × 12.5 mm, 5 μm, Agilent Technologies, Palo Alto, CA, USA) filled with the same packing material. The mobile phase was a mixture of methanol-0.04% phosphoric acid solution (80:20, v/v) and the flow rate was 1.0 mL min^{-1}. The column temperature was set at 30 °C by a temperature controller (Nuohai Technologies, China). The UV detector was set at wavelengths of 256 nm (BP), 290 nm (BP1 and BP3) for analytes. All injections were performed manually with a 20.0 μL sample loop. 0.22 μm membrane was obtained from Xingya Scavenging Material Company (Shanghai, China).

The X-ray diffraction (XRD) patterns were recorded with a D/max-2500 diffractometer (Rigaku, Japan) using Cu K_α radiation ($\lambda = 1.5418$ Å) over the angular range from 2° to 50°. The microscopic morphology of the material was examined by a Model X-650 scanning electron microscope (Hitachi, Tokyo, Japan). The TGA experiments were performed on a PTC-10A thermal gravimetric analyzer (Hitachi, Tokyo, Japan) from room temperature to 800 °C at a ramp rate of 10 °C min^{-1}. The surface area, pore volume, and pore size distributions of adsorbents were measured on a NOVA 2000e surface area and pore size analyzer (Quantachrome, Florida, FL, USA) at 77 K in the range $0.02 \le P/P_0 \le 0.20$. The Barrett–Joyner–Halenda (BJH) method was used to calculate the mesopore distribution for the adsorbents.

2.3. Synthesis of MIL-101(Cr)

MIL-101 was synthesized according to Férey et al. [34] with small modifications. Typically, $Cr(NO_3)_3 \bullet 9H_2O$ (1601.1 mg, 4.0 mmol), terephthalic acid (665.2 mg, 4.0 mmol), and hydrofluoric acid (0.2 mL, 1.0 mmol) were mixed with 19.2 mL of ultrapure water in a teflon-lined stainless steel autoclave, sealed, heated to 220 °C for 8 h, and then were cooled down rapidly to 150 °C within 1 h. It was cooled down slowly to room temperature within 12 h. The resultant green crystalline solid was washed thoroughly with DMF and ethanol by Soxhlet extraction. The procedure was repeated at least 4 h to remove the unreacted terephthalic acid and ethanol from MIL-101 pores. The green solid was then evacuated in vacuum at 150 °C for 12 h to form dehydrated MIL-101, which was characterized by X-ray diffraction (XRD) spectrometry, thermogravimetric analysis (TGA), scanning electron microscopy (SEM) and nitrogen adsorption porosimetry.

2.4. Extraction procedure

The MIL-101 was dried overnight at 150 °C before use. Then, 12 mg of MIL-101 was dispersed into sample solution (20 mL) in a 50 mL centrifuge tube. The mixture was vortexed for 40 min. Subsequently, MIL-101 was isolated from the solution by centrifugation at 10000 rpm for 5 min. The supernatant was discarded. 1.0 mL of methanol with acetonitrile (3:7, v/v) was added. The analytes were desorbed under ultrasonication for 5 min (120 W, 100 kHz). The mixture was centrifuged at 10000 rpm for 5 min. The collected eluate was dried with a gentle stream of nitrogen at

30 °C and dissolved in 0.1 mL of methanol and filtered through 0.22 μm membrane for HPLC analysis.

2.5. Sample preparation

Three different toner samples were purchased from a local store. The toner samples were filtered through 0.22 μm millipore cellulose membrane, then, diluted for 10 times using ultrapure water and stored in clean glass containers at 4 °C in darkness before use.

3. Results and discussion

3.1. Characterization of the prepared MIL-101

The prepared MIL-101 was characterized by XRD, TGA, SEM and N_2 adsorption–desorption experiment (Fig. 1). The experimental XRD pattern of the synthesized MIL-101 crystals was in good agreement with the simulated one, showing the successful preparation of MIL-101. The TGA data revealed that the MIL-101 was stable up to 330 °C. The SEM image exhibited cubic shaped crystals

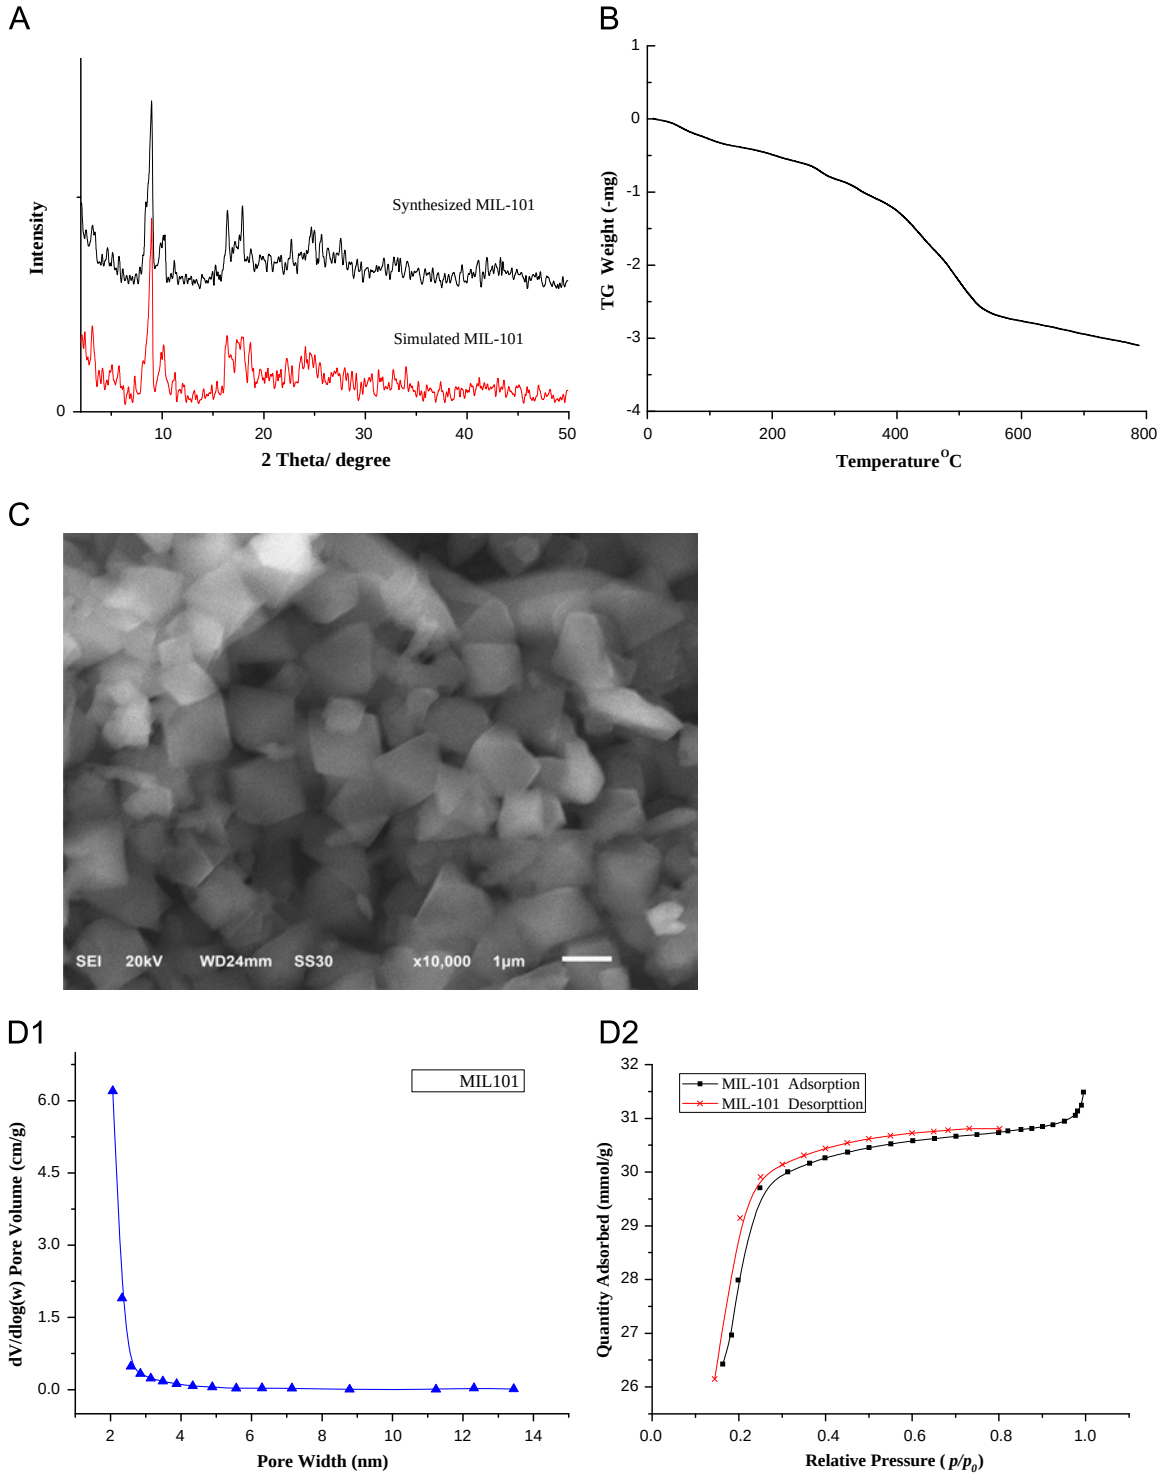

Fig. 1. XRD pattern (A), TGA curve (B), SEM image (C), nitrogen adsorption–desorption isotherms and the pore size distribution (D) of synthesized MIL-101.

of MIL-101 with an average size of 1 μm. The prepared MIL-101 was characterized by surface area and pore size analyzer and gave a BET surface area of 2295 m^2 g^{-1} with a pore volume of 0.53 cm^3 g^{-1}.

3.2. Optimization of the DSPE conditions

In order to optimize the DSPE conditions, several extraction parameters including the amount of MIL-101, desorption solvent, the adsorption time, solution pH and the ionic strength were investigated. Sample solutions (20 mL) were spiked with analytes at 100 μg L^{-1} to perform the experiments.

3.2.1. Effect of the amount of MIL-101

The amount of MIL-101 has a significant effect on the recoveries of target analytes. So, the amounts of MIL-101 were tested from 2.0 mg to 15.0 mg. The experimental results showed that the recoveries of analytes increased with the increase of MIL-101. When 12 mg of MIL-101 was used, the recoveries of BP, BP1 and BP3 were in the range of 80–100%. Subsequently, obtained analyte recoveries remained almost unchanged while increasing the amount of MIL-101. Therefore, 12 mg of MIL-101 was chosen as the final amount.

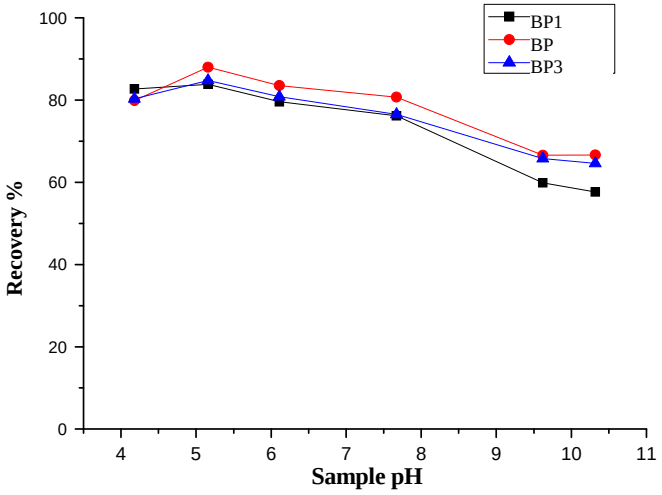

Fig. 2. The effect of solution pH. Other conditions: MIL-101, 12 mg; concentration of BP, BP1 and BP3, 100 μg L^{-1}; extraction time, 50 min; desorption solvent, 1 mL methanol with acetonitrile (3:7, v/v); 0% (w/v) NaCl.

3.2.2. Effect of desorption solvent

Different desorption solvents including methanol, methanol with acetonitrile (7:3, v/v), methanol with acetonitrile (5:5, v/v), methanol with acetonitrile (3:7, v/v) and acetonitrile were tested, respectively. The experimental data indicated that methanol with acetonitrile (3:7, v/v) provided the best desorption efficiency due to its strongest dissolving ability toward analytes. Ultrasonic irradiation enhanced the desorption of the analytes from MIL-101. The experimental results indicated that the 1.0 mL mixture of methanol with acetonitrile (3:7, v/v) as the eluent under ultrasonic irradiation offered the higher recoveries of analytes.

3.2.3. Effect of the adsorption time

The adsorption time had an obvious effect on the recoveries of target analytes. It was necessary to select an exposure time that guarantees the equilibrium between aqueous phase and sorbent. So, the adsorption times were varied from 20 min to 60 min. The experimental results showed that the highest recoveries of these analytes were obtained when the adsorption time was at 50 min. After 50 min, the recoveries of these analytes decreased slightly. Therefore, the adsorption time of 50 min was chosen for further studies.

3.2.4. Effect of solution pH

The sample pH is another important factor that affects the extraction of analytes. The sample pH not only influences the molecular existing form of analytes but also closely affects the charge species and density on the sorbent surface. The effect of solution pH on the recoveries of BP, BP1 and BP3 was investigated in a range of 4.0 to 10.5. As illustrated in Fig. 2, the recoveries of analytes increased slightly when the solution pH increased from 4.0 to 5.0, then further increase of pH from 5.0 to 10.5 led to a

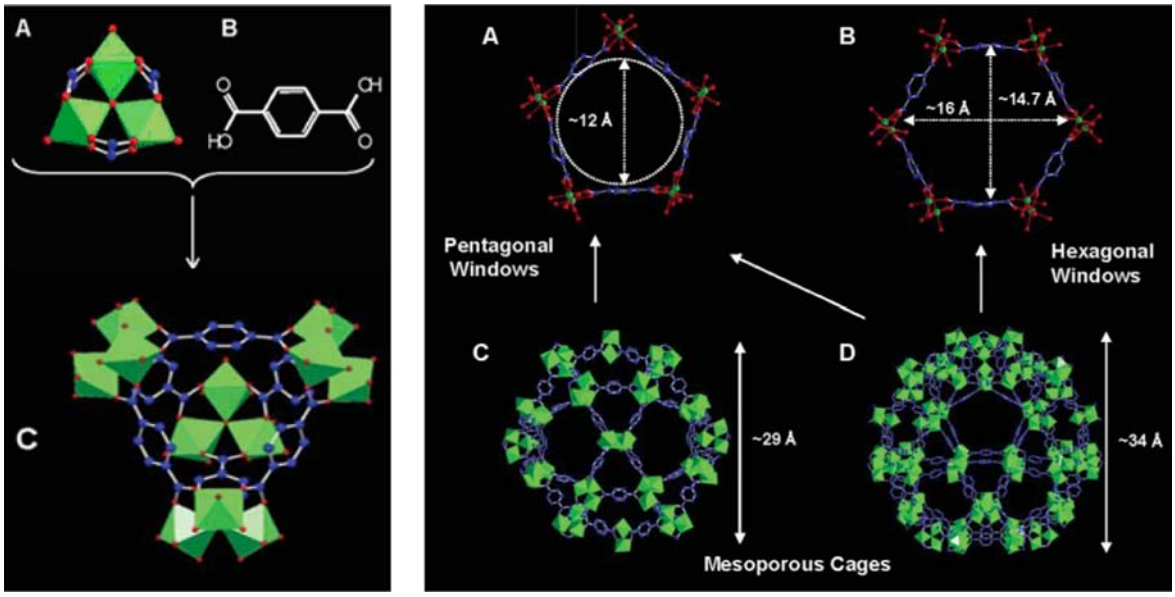

Fig. 3. Structure of MIL-101. Adapted and reproduced with permission from Ref. [33] Copyright 2005 American Association for the Advancement of Science; Left (A) The computationally designed trimeric building block chelated by three carboxylic functions. The ST was constructed with (B) terephthalic acid, which lies (C) on the edges of the ST. Right (A and B) Ball-and-stick view and free dimensions (A°) of the pentagonal and hexagonal windows. (C and D) Ball-and-stick view of the two cages.

decrease of the recoveries. Thus, pH 5.0 was chosen as the optimum sample pH.

Generally, when the solution pH value is higher than pKa of the analyte, the analyte is mostly in an ionic form due to the deprotonation. The dissociation constants (pKa) of BP, BP1 and BP3 are all bigger than 7.5, respectively. As the solution pH $\leq$ 5.0, the three ananlytes were mainly in the forms of molecule state. A significant decrease of the adsorption capacity of MIL-101 for BP, BP1 and BP3 with the pH increased from 5.0 to 10.5 might be resulted from the increase of negative charges on the surface of MIL-101[36]. As revealed in Fig. 3, Cr^{3+} exists in octahedral environment, each of the octahedral is coordinated by one chromium ion and four carboxyl ligand from terephthalic acid. The π-π interaction between the benzene rings in analytes and MIL-101 may also play important role for the extraction. BP, BP1 and BP3 with delocalized π electrons allowed π-π interaction with the terephthalic acid molecules in the framework of MIL-101, and the π-complexation between the π-electrons of benzene rings and Lewis acid sites in the pores of MIL-101. Besides, the molecules of the target analytes can enter the pores of MIL-101 for the kinetic dynamic diameters of BP, BP1 and BP3 are smaller than the pores (29 Å and 34 Å) and their windows (12 Å and 16 Å × 14.5 Å) of MIL-101 [34]. And, large octanol-water partitioning coefficients of the analytes enhance their hydrophobic interaction with the hydrophobic MIL-101 framework. The results showed that the interaction between MIL-101 and the analytes made a principal contribution to extraction.

3.2.5. *Effect of ionic strength*

Addition of salt into the sample solutions could decrease the solubility of organic compounds in the aqueous solution and lead to the salting-out effect. In the extraction procedure, the effect of ionic strength of the sample solution was evaluated by adding 0–25% (w/v) of sodium chloride into the samples. The experimental results showed that the salt concentration have not influence on the extraction efficiency. So, no NaCl was added in the subsequent experiments.

3.3. *Analytical approach*

Under the optimized conditions, the linearity of the calibraton curves was in the range of 4.0–3500 μg L^{-1} for three analytes in toner samples. Satisfactory determination coefficients (r^2) (>0.9990) for analytes were obtained. The limits of detection (LODs, S/N=3) and limits of quantification (LOQs, S/N=10) were found to be 0.9–1.2 μg L^{-1} and 3.1–4.0 μg L^{-1}, respectively (Table 1), which were lower than the maximum possible magnitude of three analytes in toner.

Table 1
Linearity and sensitivity characteristics of the MIL-101-DSPE-HPLC method for BP, BP1 and BP3.

Matrix	Analyte	Regression equation	R^2	LOD (μg L^{-1})	LOQ (μg L^{-1})
Toner	BP	$Y=0.0143X+0.4942$	0.9992	1.2	3.9
	BP1	$Y=0.0132X-0.0644$	0.9999	1.2	4.0
	BP3	$Y=0.0191X-0.4691$	0.9990	0.9	3.1

3.4. *Sample analysis*

The development method was applied to the determination of analytes in toner samples. Three toner samples were purchased from local supermarket. The results showed that these samples were free of BP, BP1 and BP3.

To validate the established method in real samples, the blank toner samples were spiked BP, BP1 and BP3 at three levels of 10, 1000 and 3500 μg L^{-1}, respectively. The recoveries were 93.7–104.8%, as shown in Table 2.

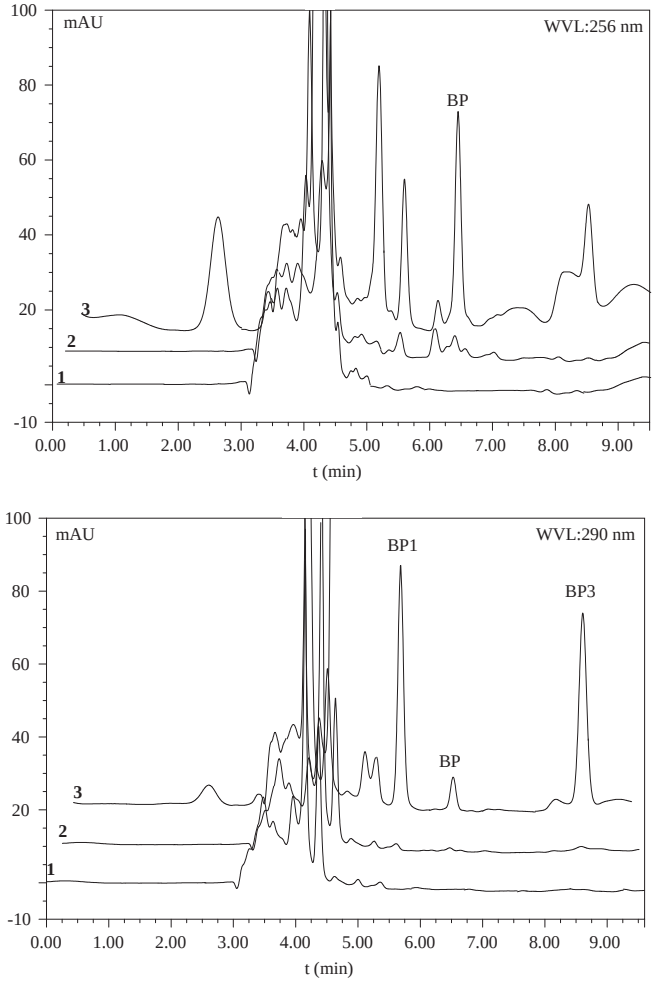

Fig. 4. HPLC chromatograms of BP, BP1 and BP3 in toner. (1) real toner sample; (2) spiked toner at 500 μg L^{-1}; (3) spiked toner at 500 μg L^{-1} after MIL-101.

[a] Liquid-liquid extraction.
[b] Solid-phase microextraction.
[c] Dispersive lquid-liquid microextraction.

The intra- and inter-day reproducibilities (RSDs) were calculated with BP, BP1 and BP3 spiked at 10, 1000 and 3500 μg L^{-1} in toner. Five parallel extractions of a sample solution over a day gave the intra-day RSDs, and the inter-day RSDs were determined by extracting sample solutions that had been independently prepared for contiguous days. The intra- and inter-day RSDs were in the range of 1.5–7.4% and 2.5–8.9%, respectively, which indicated the acceptable reproducibility.

Chromatograms of real toner sample, spiked toner at 500 μg L^{-1} and spiked toner at 500 μg L^{-1} after MIL-101 were shown in Fig. 4. It can be seen that a dramatic enrichment of the peak height was observed.

Compared with other analytical techniques for the determination of BPs (Table 3), the limit of detection of the MIL-101-DSPE-HPLC for BPs was obviously lower than SPME-GC–MS. And, the sensitivity of the method for BPs was similar to LLE-LC-MS/MS and DLLME-LC-MS/MS. The result revealed that the MIL-101-DSPE-HPLC is a sensitive, rapid, low cost and reproducible technique. The method can be used for selective extraction and sensitive determination of analytes in complex samples.

4. Conclusions

In this work, MIL-101 was synthesized using a hydrothermal synthesis method. The material was characterizated and successfully applied for the dispersive solid-phase extraction of BP, BP1 and BP3 in toner samples. The developed approach offered wide linear range, and good reproducibility. Owing to the diverse structures and unique characteristic, MOFs possesses great potential in the preconcentration and analysis of trace compounds in real aqueous samples.

Keywords:
CuO@Cu nanowires array
Electrodeposition
Glucose
Non-enzymatic sensor

ABSTRACT

Vertically aligned cable-like CuO@Cu nanowires array was synthesized using a template-directed electrodeposition strategy. The morphology, crystal structure, and surface property of nanowires array were investigated by SEM, HRTEM, XRD, and XPS, respectively. It is found that the free standing namowires are highly dense, and possess about 20 μm in length and 200 nm in diameter. The bulk Cu nanowires are assembled by a number of single crystalline Cu nanoparticles and surface is wrapped by a thin layer of amorphous CuO with size of 2.5 nm. Electrocatalytic activity of the nanowires array towards glucose oxidation was investigated by cyclic voltammetry and amperometry in alkaline media. The nanowires array with 3×3 mm^2 was then used to fabricate a non-enzymatic glucose sensor. The sensor exhibits a wide concentration range of 1×10^{-6} M–1×10^{-2} M for glucose, with an ultra-high sensitivity of 1250.8 μA mM^{-1} cm^{-2} and excellent anti-interference ability. The good sensing performances could be attributed to the integration of the superior electrocatalysis of high density of Cu nanowires array and the outer shell of negatively charged CuO against interferences.

1. Introduction

In the past few years, one-dimensional (1-D) nanostructures have attracted a considerable amount of attention, because of their potential utilization in electronic, magnetic, optical, energy and chemical sensors [1–6]. As important 1-D nanostructures, nanowires array commonly assembled by numbers of nanowires, possess a high surface area-to-volume ratio, rendering them extremely sensitive to species adsorbed on surfaces and resulting in excellent sensitivity and activity [7].

The ability to precisely prepare nanowires array on a large scale with tailored morphology and geometry is an important goal of the material science. In the last decade, various methods have been developed to prepare high-density and well-aligned nanowires array. The conventional techniques used to fabricate nanowires array include sol–gel method, chemical vapor deposition, direct electrodeposition and so forth [8–11]. Among these methods, template-assisted electrodeposition has been established to be an attractive route for the synthesis of nanowire arrays because of its simplicity, cost-effectiveness, low temperature fabrication, etc [12]. Also, the morphology, nanostructure, and composition of nanowires array could be tuned through selectively controlling deposition parameters. To date, the templates used in the most work were generally entailed to two types of nanoporous template, polycarbonate template and porous anodic aluminum oxide template. For polycarbonate template, it usually contains randomly distribution cylindrical pores with poor density and there are numbers of pores intersect within the template. As a consequence, the nanowires array obtained within polycarbonate template usually suffer from some drawbacks, such as less uniformity and low density of nanowires [13,14]. Anodic aluminum oxide is another type of template which has advantages over polycarbonate template such as high density, highly ordered pore channels and uniform pore size. Thus the nanowires can be well confined in the uniform and parallel hexagonally porous structure of the anodic aluminum oxide membrane. After the post-treatment in phosphoric acid solution or NaOH solution, the nanowires achieved normally possess ordered morphology and high-density (channel density of template is in the range of 10^{10}–10^{12} cm^{-2}). More recently, a lot of works tend to electrodeposition of nanowires array in anodic aluminum oxide template for virous applications. Glennon et al. deposited Au nanowires array in anodic aluminum oxide membrane and utilized this ordered nanowires array as a matrix to immobilize horseradish peroxidase for the biosensing of hydrogen peroxide [15]. Liang and co-workers fabricated Cu nanowire arrays and employed them as effective current collectors in lithium-ion batteries [16]. Jiang et al. introduced the highly ordered Pd nanowire arrays as effective catalysts

for ethanol oxidation in direct alcohol fuel cells [17]. Cheng et al. applied the Pd nanowires array to the detection of formaldehyde in environmental pollution [18].

In the family of one-dimensional metallic nanomaterials, considerable attention has been focused on the Cu nanowires, due to its low cost, excellent electrical conductivity and easy availability. Cu based nanomaterials exhibit the direct electrooxidation to some small molecular organic compounds [19–22]. This will provide a chance for construction of non-enzymatic glucose sensor. Non-enzymatic glucose biosensors are based on the glucose oxidation catalyzed by a variety of electrocatalysts, including metals (Au, Pt, Pd), metal oxides (Co_3O_4, CuO, NiO), alloys (PtPb, PtRu) [23,24]. Non-enzymatic glucose biosensors have alleviated the problems of enzyme-based biosensors such as insufficient stability, lower reproducibility, thermal and chemical instability, sensitivity to temperature, pH, and humidity [25,26]. Hence it will probably become the fourth generation glucose sensors for the future analytical applications.

In the case of sensor device, the well-aligned nanowires array is attractive than those randomly scattered nanowires usually prepared by a wet-chemistry method. The array acts as an excellent current collector to improve the signal-to-noise and mechanical stability is enhanced as well. Besides, nanowires array is easily tailored to various geometry and size for further device fabrication.

In this work, the highly ordered cable-like CuO@Cu nanowires array was synthesized by electrodeposition within anodic aluminum oxide template. The nanowires array with different lengths from 20 μm to 90 μm was obtained. The bulk Cu nanowires are assembled by a number of single crystalline Cu nanoparticles and surfaces are wrapped by a thin layer of amorphous CuO with thickness of 2.5 nm. The nanowires array shows the excellent electrocatalytic activities to glucose oxidation in alkaline media. An enzyme-free glucose sensor based on the cable-like CuO@Cu nanowires array was developed for detection of glucose. The sensor exhibits a wide concentration range of 1×10^{-6} M–1×10^{-2} M for glucose, with an ultra-high sensitivity of 1250.8 μA mM^{-1} cm^{-2} and excellent anti-interference ability.

2. Experimental

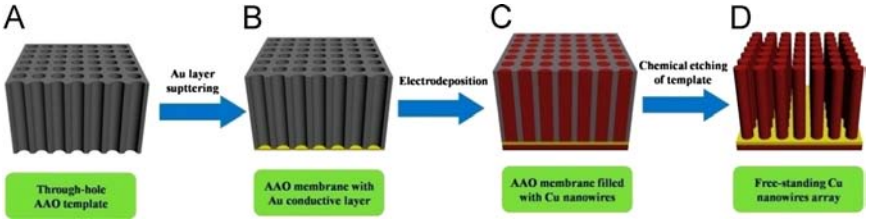
2.1. Reagents and materials

H_2SO_4, $CuSO_4\cdot5H_2O$, NaCl and NaOH were purchased commercially from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China) and used without further purification. L-Ascorbic acid (AA), dopamine (DA), uric acid (UA) and d-(+)-glucose were purchased from Sigma-Aldrich. All the other chemicals used were of analytical grade and all solutions were diluted with doubly distilled water. The porous anodic aluminum oxide (AAO) templates with a nominal pore size of 200 nm were obtained from Whatman Inc.

2.2. Instruments

The electrochemical experiments were performed using an electrochemical workstation (Chenhua, Shanghai, China). Scanning electron microscopy (SEM) (JSM-6700F), transmission electron microscope (TEM) (JSM-200CX) and high-resolution transmission electron microscope (HRTEM) (JEM-2010F) were utilized for the investigation of the morphology and structural properties of the deposited nanowires. The crystal phase, chemical composition and surface property of the prepared nanowires were determined by X-ray diffractometer (XRD) (Bruker AXS) with Cu Ka radiation at 40 kV and 40 mA. X-ray photoelectron spectra (XPS) was conducted on ESCALAB 250Xi using monochromatic Al Ka radiation as the exciting source. The peak at 284.6 eV attributed to the C–C band in the C1s spectrum was used for binding energy reference.

2.3. Synthesis of nanowire array



Vertically standing Cu nanowires array were fabricated using a template electrodeposition technique and the experimental procedures used for the preparation of the Cu nanowires array are presented in Scheme 1. Typically a thin layer of Au was first sputtered onto one side of the AAO template which served as the working electrode during the electrodeposition. Electrodeposition of copper nanowires was carried out at a constant current density of 1.0 mA cm^{-2} for 8 h in a copper bath that consisted of 0.5 M $CuSO_4$ and 0.1 M H_2SO_4. Finally, the templates were dissolved with a 5% H_3PO_4 solution for 6 h and carefully rinsed away with deionized water to remove any remaining H_3PO_4. Subsequently, the free-standing Cu nanowires array with an orange–red color was obtained and stored in N_2 atmosphere when not used. It is noteworthy that along with the growth of Cu nanowires array, a thin film of Cu (about 10 μm) was simultaneously deposited onto the back side of the Au layer (Scheme 1C). This back layer is very favorable to prevent the nanowires from collapsing after removal of the templates, which could provide a powerful support for the subsequent preparation of the sensors.

2.4. Sensor fabrication

Firstly nanowires array was rinsed in deionized water and punctured to a size of 3×3 mm^2 of slice. Then the tailored slice was pasted to the surface of 5 mm glassy carbon electrode (GCE) with very small amount of conductive silver paste and left it dry a few of hours before use. Finally the epoxy resin was used to seal the edges of array and the resulting electrode was denoted as NAS (nanowires array sensor).

2.5. Electrochemical experiments

All of the electrochemical experiments were carried out at room temperature in a standard three-electrode system. Before each experiment, the solution was purged by N_2 gas for 20 min and a nitrogen atmosphere was then kept over the solution during measurements. The NAS was evaluated as a glucose sensor in 0.1 M NaOH solution. The cyclic voltammetry (CV) was carried out in the potential range of 0.2–1.0 V vs. Ag/AgCl (3 M KCl). The amperometric curves were recorded by adding the desired amount of glucose into NaOH solution under stirring condition.

Scheme 1. The Schematic diagram of the fabrication of Cu nanowires array.

3. Results and discussion

3.1. Characterization of nanowires array

Fig. 1 records the SEM images of the prepared nanowires array after carefully etching away the AAO template. The plane views of the nanowires array in Fig. 1A and B clearly show that most of the nanowires are running along the pores of the template. The nanowires array is free standing and highly uniform, not lodging or curved to form bundles. The cross-section images (Fig. 1C and D) show that the nanowires are about 20 μm in length and 200 nm in diameter, which is consistent with the channel diameter of AAO template. The length of nanowires can be controlled by varying the deposition time. Fig. S1 shows the SEM images of the nanowires array deposited for 20 min (Fig. S1A) and 24 h (Fig. S1B–D) respectively. When the electrodeposition time was shortened to 20 min, the length of nanowires was 0.5 μm (Fig. S1A). While the nanowires array with a uniform length of approximately 90 μm can be achieved by prolonging the deposition time to 24 h (Fig. S1B–C). Unfortunately, it can be clearly seen that the longer nanowires tend to aggregate into bundles on a large scale after removing of the AAO template (Fig. S1D).

The microstructures of the nanowires array were further investigated by TEM and selected area electron diffraction. Fig. 2A and B shows the TEM images of the discrete nanowires. The morphology and size of nanowires are in accordance with the observation in SEM images. Moreover, the high magnification TEM image of a single nanowire in Fig. 2B clearly shows that the electrodeposited Cu nanowires are assembled by lots of nanoparticles. The corresponding electron diffraction pattern taken from a single nanowire is displayed in Fig. 2C. The continuous bright rings can be indexed as face-centered cubic polycrystalline Cu structure. Additionally, the selected-area electron diffraction pattern (in Fig. 2D) reveals that the nanoparticles near the edge of nanowire exhibit the characteristic single crystalline Cu structure nature, which is useful for biosensing behavior. Therefore, it can be concluded that the bulk Cu nanowires are aggregated of a numbers of single crystalline Cu nanoparticles.

XRD profile of Cu nanowires array is shown in Fig. 3A. The peaks positioned at 43.30°, 50.43°, 74.13°, 89.93°, and 95.14° perfectly match the {111}, {200}, {220}, {311}, and {222} crystalline planes of the face-centered cubic metal Cu (JCPDS 04-0836), respectively. Those results are consistent with the electron diffraction pattern taken from the Cu nanowires in Fig. 2C. No extra peaks of other oxides such as Cu_2O or CuO are visible, suggesting the high purity of Cu nanowires. An obvious peak observed at $2\theta = 38.18°$ was attributed to Au (111) (JCPDS 004-0874).

XPS is a powerful tool for the surface structural analysis. The XPS profile of Cu nanowires array is shown in Fig. 3B. It is found that four main bands are centered at 932.3 eV, 952.4 eV, 934.8 eV and 954.5 eV, which are corresponding to binding energy of Cu $2P_{3/2}$, Cu $2P_{1/2}$, CuO $2P_{3/2}$ and CuO $2P_{1/2}$, respectively (NIST X-ray Photoelectron Spectroscopy Database). XPS results imply the presence of a small amount of CuO. It is generally believed that the copper nanomaterials could be oxidized easily in air due to the high surface energy. Although the characterization of XRD proves the metallic nature of bulk Cu nanowires array, the result of XPS reveals that there is a small amount of CuO existed on the surface of Cu nanowires actually, whose quantity is too small to be quantified by bulk characterization techniques such as XRD. In addition, the HRTEM image in Fig. 3C further confirms that the outer surface of Cu nanowires array is wrapped by a thin shell of amorphous CuO layer. The thickness of CuO shell can also be distinguished to be ~2.5 nm. Moreover, rows of lattice fringes with a space of 0.127 nm are clearly visible, which matches well with the crystal plane {220} of metallic Cu structure. This kind of array with the nanocable-like structure is interesting and has not been reported till now in the open literatures. Even though the shell of CuO is very thin and amorphous, it would make a significant effect on the performance of biosensor and effectively improve the anti-interference ability of NAS.

3.2. Electro-oxidation of glucose on NAS

In order to evaluate the analytical applicability of NAS, the electrocatalytic performance of NAS towards the glucose was

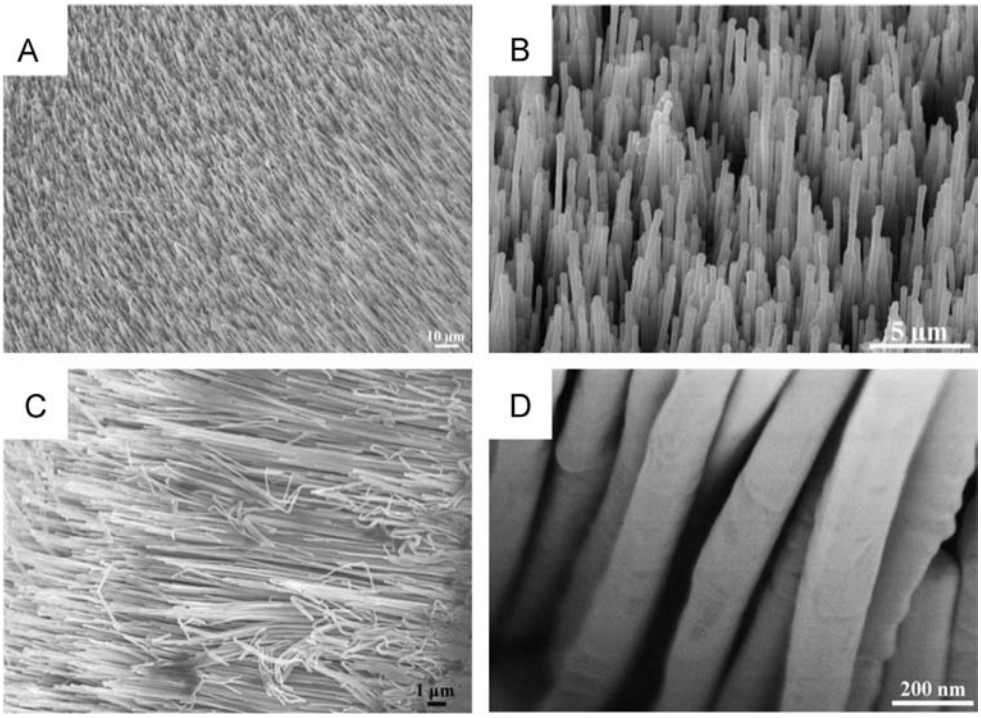


Fig. 1. SEM images of nanowires array after completely dissolving the AAO template.

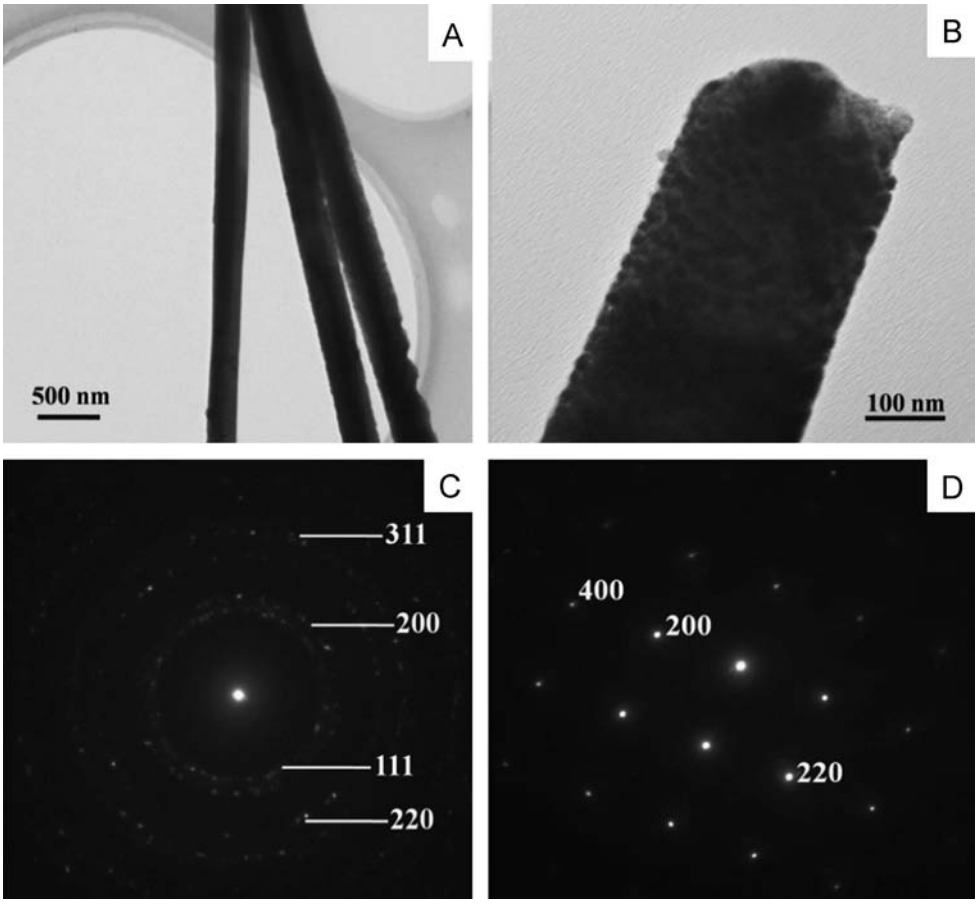

Fig. 2. TEM images of the prepared nanowires after thoroughly remove of template: (A) Low magnification TEM image; (B) High magnification TEM image of a single nanowire; (C) Electron diffraction pattern of a single nanowire; (D) Electron diffraction pattern of the nanoparticles near the edge of nanowire.

investigated extensively in alkaline solution. Fig. 4A shows the cyclic voltammograms of NAS in the presence and absence of the glucose in the potential range of −1.0 to 1.0 V. Some redox transitions appeared and were indicated by peaks I–IV. In the absence of glucose, the peak I and peak II are due to the transition Cu (0) to Cu (I) and Cu (0) to Cu (II), respectively [22,27,28]. The wave at about 0.25 V (peak III) is associated with the formation of soluble species, such as $HCuO_2^-$, from the oxidation of Cu [27]. It is generally thought that the presence of Cu (III) species is crucial to electrocatalytic oxidation of glucose. Unfortunately, this species is rather unstable. The formation of Cu (III) species has been previously reported at about 0.60 V [28], but it is not easily distinguished in Fig. 4A and could only be observed in highly alkaline electrolytes. The reverse scan reveals that the symmetric cathodic peaks of peak IV, peak V and peak VI are assigned to the reduction of Cu (III) to Cu (II), Cu (II) to Cu (I) and Cu (I) to Cu (0), respectively.

Therefore, the electrochemical reaction which occurs on the surface of the Cu nanowires can be described as follow:

$$Cu + OH^- \rightarrow CuOH + e^-$$

$$Cu + 2OH^- \rightarrow Cu(OH)_2 + 2e^-$$

$$Cu + 3OH^- \rightarrow HCuO_2^- + H_2O + 2e^-$$

$$Cu(OH)_2 \rightarrow Cu\ (III)$$

In the presence of the glucose, the peak I and peak II became weaker and even invisible, indicating the interaction between the Cu species and glucose [27]. Moreover, the disappearance of the peak III may be due to the adsorption of glucose on the surface of Cu catalyst to form a passivation film, which blocks the contact of Cu substrate and OH^- [29]. During the cathodic potential sweep, the missing of the peak IV supports the evidence that Cu (III) has been consumed in the electrooxidation of the glucose. Additional, the other peaks of Vand VI diminished proportionally, possibly as a result of the interaction between Cu (I) and glucose [29]. So the electrocatalytic oxidation of glucose to glucolactone in the alkaline solution at NAS can be summarized as:

$$Cu\ (III) + glucose \rightarrow Cu\ (II) + glucolactone$$

In order to investigate the applicability of NAS in non-enzymatic glucose sensing, CVs (Fig. 4B) were recorded in the different concentrations of glucose under the potential range of 0.2–1.0 V. It can be noticed that the oxidation peak currents increase accordingly with the increase of glucose concentration in the potential range of 0.50 V–0.75 V, presenting a pronounced electrocatalytic behavior of Cu catalyst to the oxidation of glucose.

3.3. Optimization for glucose sensing on NAS

To find the optimal conditions for the amperometric sensing of glucose, various factors influencing the response of the sensor were investigated.

The effect of the concentration of NaOH on the response current of the sensor is illustrated in Fig. S2A. With the concentrations of NaOH solution are increased from 10 to 100 mM, the responses to glucose are improved accordingly since glucose is oxidized more easily at higher pH. However, when the concentration of NaOH is above 100 mM, the response current is reduced, and meanwhile,

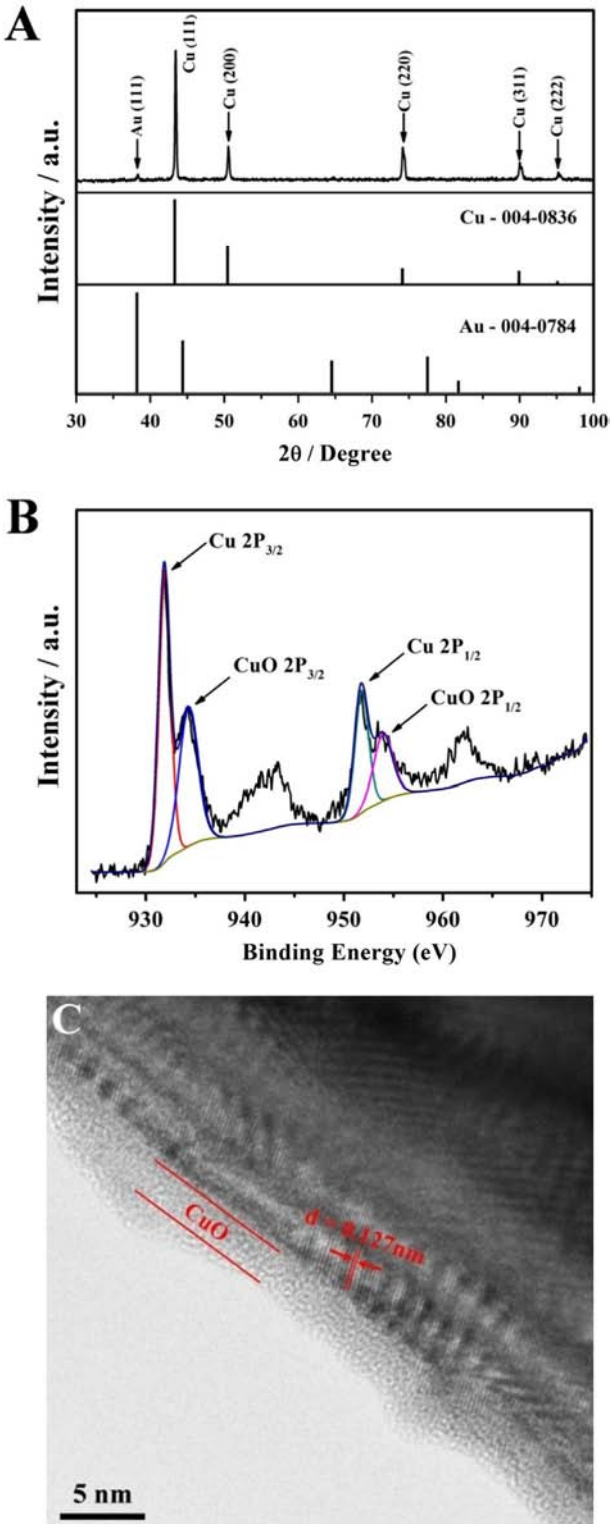

Fig. 3. (A) XRD patterns of the nanowires array; (B) XPS spectra of nanowires array; (C) HRTEM image of a single nanowire.

the noise signal is raised as a result of an increase of background reactions.

Fig. S2B showed the amperometric responses of the NAS to 0.2 mM glucose under different potentials from 0.55 V to 0.7 V in 100 mM NaOH. In the range of 0.55 V–0.65 V, the oxidation currents of glucose increase gradually with increasing potential. The maximum response current is observed at 0.65 V and a good signal/noise ratio can also be offered. While, further increasing the

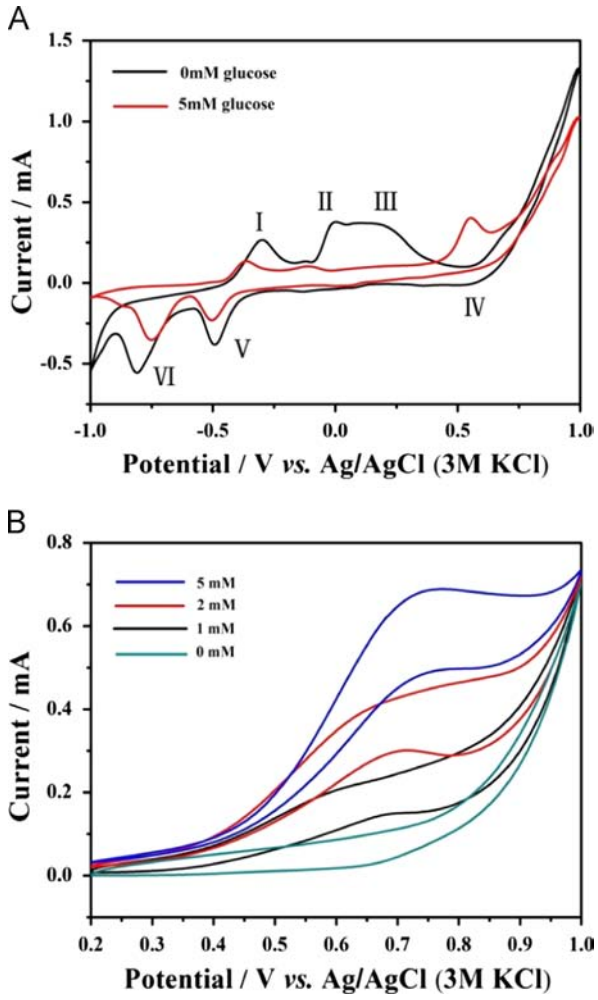

Fig. 4. (A) Cyclic voltammograms of the NAS in the presence and absence of 5 mM glucose in 100 mM NaOH and scan rate at 5 mV/s. (B) CV obtained for the increment of glucose (0 mM to 5 mM) on NAS in 100 mM NaOH and scan rate at 5 mV/s.

potential, the side reactions would take place on the electrode surface, resulting in the increase of the background current. Besides, under the high potential, some interfering species (such as ascorbic acid, uric acid and dopamine) would be oxidized and generate some intermediate products that would probably hinder glucose oxidation. Therefore, an applied potential of 0.65 V and a medium of 100 mM NaOH solution are chosen for subsequent experiments.

Fig. S2C presents the responses of Cu nanowires array with different lengths to glucose. One can observe that the response current of nanowires array with length of 20 μm is higher than that one with 90 μm. This result could be attributed to the less void space between the longer nanowires, which blocking the diffusion of glucose molecules from the bulk solution to the active sites of nanowires surface.

3.4. Analytical application of NAS

NAS were evaluated by measuring the response to glucose under the optimal conditions.

Fig. 5A illustrates the typical amperometric responses to successive increments of glucose concentration at the NAS. It is found that the response currents increase with successive additions of glucose. And the current value achieves 95% of the steady-state current within 5 s. The currents are linear with the concentration of glucose

in the range of 1×10^{-6} M–1×10^{-2} M with the linear equation: I (μA) = 112.57 C_{glu} (mM) + 16.02 and a correlation coefficient of 0.997. The sensitivity of NAS sensor is 1250.8 μA mM^{-1} cm^{-2} and the detection limit is estimated to be 6.9×10^{-7} M ($S/N=3$). This ultra-high sensitivity of NAE sensor is prominent and striking.

The comparison of NAS with different non-enzymatic glucose sensors based on Cu nanomaterial or other metal based on array strategy are summarized in Table 1. As can be seen that the CuO@Cu nanowires array exhibits excellent performance in terms of wide linear range, high sensitivity and low detection limit in contrast with the previous works.

NAS was also used to detect glucose in human serum samples using standard additions method. A rapid and stable amperometric response is obtained when the addition of 25 μL the diluted human serum samples into 25 ml 100 mM NaOH. The amount of glucose in human serum is calculated to be 4.05 mM from calibration curve (average for $n=3$), which is close to 4.2 mM given by a local hospital.

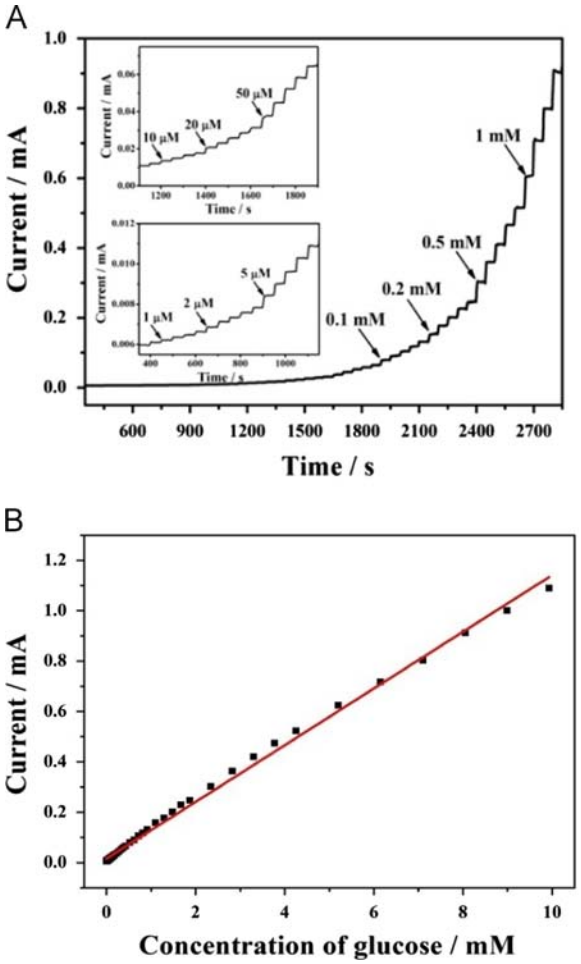

Fig. 5. (A) Typical amperometric responses of the NAS to the successive addition of different amounts of glucose in 0.1M NaOH at applied potential of 0.65V; (B) The corresponding calibration curve.

3.5. Anti-interference study of the NAS

One of the major challenges in non-enzymatic glucose sensor is some electrochemically active interferences (such as ascorbic acid (AA), dopamine (DA) and uric acid (UA)) which generate electrochemical signals at the same potential as glucose. Ordinary, the normal physiological level of glucose is about 3–8 mM in human serum, while those of ascorbic acid, dopamine and uric acid are about 0.1 mM [41]. The interference experiments (Fig. 6A) were carried out by adding 0.01 mM interfering species in 100 mM NaOH.

Compared to glucose, the interfering species of 0.01 mM AA, DA and UA yield current response of ~2.68 %, ~1.26 % and ~0.14 % respectively, indicating the good selectivity of NAS against these interferences. Additionally, chloride ion is also one of the important interferences in human serum. It has been reported that the electrochemical glucose sensors based on Cu electrodes could easily lose their activity due to the chloride poisoning effect. Therefore, the anti-interference performance of the NAS against chloride ion was examined (Fig. 6B). The change of amperometric response is negligible in the presence of 2 mM chloride ion, demonstrating the tolerance of the NAS to the chloride ion. All these excellent anti-interference ability of the NAS could be attributed to the existence of a thin shell of CuO layer on the outer surface of Cu nanowires. Usually, the isoelectric point of CuO is 9.5 [22]. So, the CuO layer on the surface of Cu nanowires could carry a certain amount of negative charge in 100 mM NaOH medium (pH = 13). As a result, those negatively charged species could be excluded out of the negatively charged Cu nanowires surface.

Furthermore, the other saccharide such as fructose and sucrose may also interfere with the accurate determination of glucose. Considering their relatively low concentration in physiological samples [42], Fig. 6C shows that the current responses are 2.79% and 4.47% for 8.1 μM fructose and 10 μM sucrose in contrast to glucose, respectively.

3.6. Reproducibility and stability of NAS

The reproducibility and stability of NAS were also evaluated. The current responses of five newly prepared NAS to 0.2 mM glucose

Experimental conditions: in 100 mM NaOH medium and at the applied potential of 0.65 V.

were measured (Fig. S3A) and the relative standard deviation (RSD) was 5.3%. The current responses of 10 successive measurements to 0.2 mM glucose at one chosen NAS yielded a RSD of 3.1%, demonstrating that the NAS was stable and suitable for repeated detection of glucose (Fig. S3B). The long term stability was investigated by measuring the responses of glucose over 20 days. Fig. S3C shows the variation of current during the investigated period. For convenience, the response on the first day was set to 100%. The results demonstrated that the responses were almost unchanged over the entire investigated period and the NAS was found to retain 94% of its initial activity within 20 days, implying that the NAS can be used in long term routine applications.

4. Conclusion

In this paper, we constructed the mechanically stable and easily handling cable-like CuO@Cu nanowires array for glucose electrooxidation and further fabricated a non-enzymatic glucose sensor with ultra-high sensitivity.

SEM images reveal that Cu nanowires array is highly dense, thus providing the more active sites for glucose electrocatalytic oxidation. The bulk Cu nanowires are found to have a polycrystalline structure and are assembled by a lot of single crystalline Cu nanoparticles. XPS combined with HRTEM confirm that there is a thin layer of CuO wrapped on the outer surface of Cu nanowires, which could repulse some negatively charged species such as UA, DA, AA, Cl^- in alkaline medium, implying the excellent anti-inference ability. Moreover, metallic Cu nanowires array possesses the excellent unidirectional conductivity along 1-D direction and therefore facilitating the electron transfer of redox reaction. Based on these merits, Cu nanowires array is developed for a non-enzymatic glucose sensor. And it exhibits excellent sensing performances such as a wide linear range, ultra-high sensitivity and selectivity. Besides that, it is also successfully applied to detect glucose in serum samples with good accuracy.

ABSTRACT

A novel highly selective and sensitive fluorescent probe (NJ1) had been designed and synthesized for Cu^{2+} detection by fluorescence quenching mechanism, and then the enhancement of fluorescence intensity with the addition of hydrogen sulfide in complex NJ1Cu aqueous solution at physiological conditions were described. This "on–off–on" type fluorescence recognition system was a reversible process, which could be utilized to monitor copper ion and hydrogen sulfide based on a complex NJ1Cu formation–Cu^{2+} displacement approach. Importantly, this real-time recognition process of Cu^{2+} and hydrogen sulfide exhibited excellent anti-interference ability. In addition, this new fluorescent probe also has potential utility for Cu^{2+} and hydrogen sulfide detection in living cells, providing a potential tool for investigating copper ion and hydrogen sulfide in living systems or environment.

1. Introduction

Developing a sensitive, reliable and selective detection technique for various chemically and biologically pertinent metal cations and anions has attracted many research interests [1]. As the third most abundant transition metal in the human body, copper plays an important role in various physiological processes of organism [2]. However, the excessive exposure to these Cu^{2+} sources could cause imbalance in cellular processes, resulting in various diseases such as Alzheimer's disease and Parkinson's disease [3]. Additionally, copper has also been widely used in the industrial process, which is potentially toxic to environment. Therefore, there is an increasing need to monitor the existence of Cu^{2+} in the live biological samples or aquatic environment [4]. Fluorescent probes have become an important diagnostic tool for biological and environmental concern considering their sensitivity, special selectivity, and real-time monitoring with fast response time [5]. Owning to the notorious paramagnetic nature of Cu^{2+}, it usually leads to fluorescence quenching effect of the bound fluorophore [6]. More interestingly, this Cu^{2+} complex would also be potentially applied to monitor other substances, such as sulfide anion [7].

Hydrogen sulfide (H_2S) is a toxic gas best known for its rotten egg smell. It is slightly soluble in water, giving the hydrosulfide anion HS^- ($pK_a = 6.9$) and the sulfide dianion S^{2-} ($pK_a > 14$). H_2S has been utilized as a reactant or produced as a by-product in industrial process, which is widely spread in the environment. However, the role of H_2S in living organisms has recently received increasing attention. It has been suggested as the third signaling gasotransmitter, along with nitric oxide and carbon monoxide [8]. It is shown to act as a vascular relaxant, an energy regulator, and to be associated with cardiovascular regulation and the inflammation response [9]. Altering the level of hydrogen sulfide in human body or exposure to high-level sulfide can cause various physiological and biochemical problems. Therefore, the detection of hydrogen sulfide in industry, environment, and biological samples has attracted great attention. Several conventional detection strategies have been developed for hydrogen sulfide [10], such as electrochemical methods and ion chromatography. However, these analytic methods usually need complicated equipment and trou blesome sample pretreatment that are unsuitable for the analysis of sulfide in real time. For this reason, more convenient detection tools, such as fluorescent probes, have received significant attention as their easy operability and high sensitivity. To the best of our knowledge, several hydrogen sulfide selective probes based on copper ion displacement approach have been reported [7]. However, most of these probes have some limitations such as poor water solubility, complicated synthesis, poor membrane permeability, and detection systems required much organic co-solvents [7c], which would significantly restrict their practical applications in physiological condition. So far, real-time sulfide selective probes that are applicable in aqueous solution are still limited. It is thus desirable to develop simple and effective fluorescent probes for detection of sulfide in aqueous media that displays high sensitivity and selectivity as well as enables easier accessibility.

Scheme 1. Synthesis of NJ1 and the proposed mechanism of the monitoring system.

With this in mind, we designed and synthesized a novel small fluorescent probe NJ1 (Scheme 1). NJ1 demonstrated obvious fluorescence quenching after the addition of copper ion to form new complex NJ1Cu. This new complex displayed high specificity for hydrogen sulfide that induced copper ion to be released from the dye in the aqueous media, resulting in fluorescence enhancement. Herein, we reported the synthesis, photophysical characterization of NJ1 that was highly sensitive and selective for Cu^{2+}. The subsequent complex NJ1Cu could be developed as a platform for hydrogen sulfide real-time detection that could be potentially utilized in industry, environment, or biological requirements. Furthermore, the imaging of copper ion and hydrogen sulfide in living cells were also successfully developed.

2. Experimental

2.1. Materials and instrumentations

All chemicals were purchased from commercial suppliers and used without further purification. Chromatographic purification of products was accomplished by using forced-flow chromatography on silica gel (300–400 mesh). Thin layer chromatography was performed on EM Science silica gel 60 F254 plates (250 μm). Visualization of the developed chromatogram was accomplished using UV lamp. Nuclear magnetic resonance (NMR) spectra were acquired on Bruker DRX-400 operating at 100 MHz for ^{1}H NMR and ^{13}C NMR; residual protio solvent signals were used as internal standards for calibration purposes. Data for ^{1}H NMR are reported as follows: chemical shift (ppm), multiplicity (s, singlet; d, doublet; t, triplet; q, quartet; and m, multiplet), integration, coupling constant (Hz). TOF EI mass was performed by Mass Spectrometry Facility at Nanjing University. All fluorescence measurements were recorded on a Varian Cary Eclipse Fluorescence Spectrophotometer and Hitachi Fluorescence Spectrophotometer F-7000. The pH measurements were carried out on a HI 2221 calibration check pH/ORP meter.

2.2. General procedure for analysis

Stock solution of metal ions and other anions were prepared in ultrapure H_2O, stock solution of NJ1 (1 mM) were prepared in DMSO, which was diluted to the required concentration for measurement. All fluorescence measurements were carried out at room temperature on a Hitachi Fluorescence Spectrophotometer F-7000. The samples were excited at 360 nm; the emission spectrum was scanned from 425 nm to 650 nm at 1200 nm/min.

2.3. Cell culture and fluorescence imaging

HeLa cells were grown up in DMEM medium with 10% fetal bovine serum/penicillin/streptomycin in a 5% CO_2 atmosphere at 37 °C. Cells were then seeded on Coverglass-Bottom confocaldish and continuously incubated at 37 °C in a 5% CO_2 atmosphere for 24 h. After cells were incubated with 1 μL, 10 mM NJ1(final concentration: 10 μM) for 30 min at 37 °C, media was removed, and cells were washed with HEPES buffer three times again to remove any probe left in solution to optimize the background signal. Then, cells were added to fresh media and incubated with Cu^{2+} (0 μM, 10 μM) for another 20 min at 37 °C before imaging; or NaHS (10 μM) was added into the cells with NJ1 (10 μM) and Cu (10 μM) for another 20 min at 37 °C before imaging. All imaging experiments were performed on a fixed cell DSU spinning confocal microscope (Olympus), excitation at 405 nm. Imaging was performed using X40 objective and captured using Slidebook software. For all experiments, solution of NJ1 was prepared in DMSO (10 mM) and diluted into DMEM to the desired working concentration (10 μM). Cu^{2+}, and NaHS were diluted into ddH_2O to the desired working concentrations (10 μM) from a 10-mM stock solution.

2.4. Synthesis of probe NJ1

2.4.1. (E)-7-(dimethylamino)-3-((2-(pyridine-2-yl)hydrazono) methyl)naphthalene-2-ol

To a mixture compounds 3- (645 mg, 3 mmol) and 2-hydrazinylpyridine (360 mg, 3.3 mmol) was added ethanol under argon. The mixture was stirred at 80 °C for 1 h. The solvent was then evaporated under reduced pressure and the obtained residue was purified by silica gel column chromatography (eluent: 30 ethyl acetate/petroleum ether). (E)-7-(dimethylamino)-3-((2-(pyridine-2-yl)hydrazono)methyl)naphthalene-2-ol (NJ1) was obtained as a brown solid (421 mg, 46). ^{1}H NMR (400 MHz, DMSO-d_6): δ 10.76 (s, 1 H), 9.72 (s, 1 H), 8.54 (s, 1 H), 8.49 (d, J=2.3 Hz, 1 H), 8.12 (d, J=3.8 Hz, 1 H), 7.73 (d, J=8.8 Hz, 1 H), 7.69 (d, J=8.8 Hz, 1 H), 7.73 (d, J=7.4 Hz, 1 H), 7.30 (d, J=8.4 Hz, 1 H), 7.20 (d, J=8.8 Hz, 1 H), 6.96–6.99 (m, 2 H), 2.80 (s, 6 H).^{13}C NMR (100 MHz, DMSO-d_6): δ 157.8, 157.2, 152.7, 148.2, 140.8, 138.3, 133.1, 130.24, 130.22, 125.0, 119.2, 116.9 115.6, 114.8, 107.8, 106.9, 45.6; Ms (TOF MS EI$^+$): (m/z): 304.2.

3. Results and discussion

3.1. Synthesis

The preparation of the fluorescent probe (NJ1) and the possible reaction mechanism of NJ1 toward Cu^{2+} to form NJ1Cu complex, which could be utilized to monitor hydrogen sulfide, are shown in Scheme 1. The synthesis is quite straightforward through a three-step route with 2, 7-dihydroxynaphthalene (1) as the starting material. 7-(Dimethylamino)naphthalen-2-ol (2) was then synthesized by a Bucherer reaction using dimethylamine. The formylation of compound 2 was achieved using $POCl_3$/DMF reaction to afford aldehyde 3 in 83% yields. Finally, the target compound NJ1 was obtained by refluxing with 2-hydrazinylpyridine in EtOH. The final probe was characterized using NMR spectroscopy and mass spectrometry (see the supporting information).

3.2. Effects of the absorption and emission spectroscopic properties of NJ1

With this novel probe in hand, we first investigated its absorption and emission spectra in 20 mM HEPES buffer (pH 7.4, 0.5% DMSO, 25 °C), which could be utilized for studying the binding mechanism of NJ1 with Cu^{2+}. As described in Fig. 1, upon the addition of Cu^{2+} into the solution of NJ1, the absorption bands at 250 and 350 nm decreased, and new absorption bands at 300 and 450 nm emerged simultaneously.

We then evaluated the change of fluorescence emission spectra after the addition of Cu^{2+} into the solution of NJ1. The free probe displayed a strong fluorescence emission at physiological pH. The introduction of Cu^{2+} (1.0 equiv.) to the solution of NJ1 would lead to almost complete fluorescence quenching, revealing that NJ1 could be recognized Cu^{2+} through fluorescence "on–off" behavior. The pH effect studies suggested that the significant fluorescent signals could be observed at the physiological pH (Fig. S1).

We next evaluated the sensitivity of NJ1 for Cu^{2+} through varying concentrations of Cu^{2+} (0–10 μM) (Fig. 2a). The continuous addition of Cu^{2+} resulted in a gradual decrease of fluorescence intensity at 492 nm, and reached the saturation state when 1.0 equiv. of Cu^{2+} was added into NJ1 solution; the detection limit was found to be 0.5 μM. The effective fluorescence quenching of NJ1 was attributed to the coordination to a paramagnetic copper ion to form NJ1–Cu complex. The linear relationship of the fluorescence titration displayed that NJ1 responded to copper ion in 1:1 stoichiometry (Fig. 2b). This result had also been confirmed using TOF EI-MS (see the supporting information).

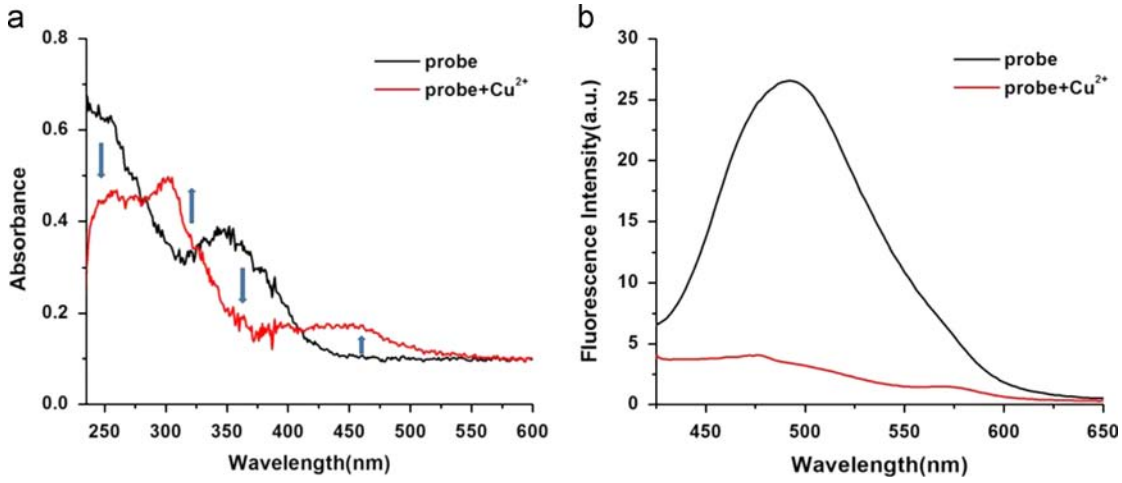

Fig. 1. (a) Absorption spectra of NJ1 (5 μM) in the absence and presence of Cu^{2+} (5 μM) in 20 mM HEPES buffer (pH 7.4, 0.5% DMSO) at 25 °C. (b) Fluorescence spectra of NJ1 (5 μM) in the absence and presence of Cu^{2+} (5 μM) at 25 °C. Excitation wavelength=360 nm. The data represent the average of three independent experiments.

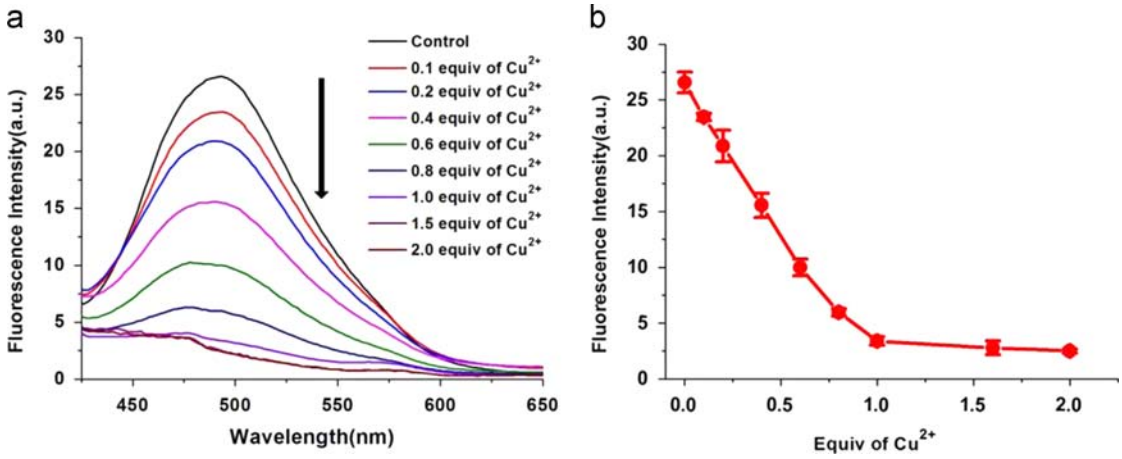

Fig. 2. (a) The fluorescence spectra of NJ1 (5 μM) incubated with different concentrations of Cu^{2+} (0.5–10 μM) in 20 mM HEPES buffer (pH 7.4, 0.5% DMSO) at 25 °C. (b) The fluorescence intensity of NJ1 at 492 nm versus different concentrations of Cu^{2+} (0.5–10 μM). Excitation: 360 nm, emission: 425–650 nm. The data represent the average of three independent experiments.

Then, the specificity of NJ1 toward Cu^{2+} was investigated by monitoring the change of the emission signal of NJ1 upon addition of other metal ions (represented by K^+, Na^+, Ag^+, Cu^+, Pb^{2+}, Pd^{2+}, Zn^{2+}, Mg^{2+}, Mn^{2+}, Fe^{2+}, Cd^{2+}, Al^{3+}, Cr^{3+}, Fe^{3+}, Cu^{2+}). All other metal ions had little quenching effect on the fluorescence spectra of NJ1, which did not induce significant fluorescence spectral changes. Only Cu^{2+} could cause a remarkable fluorescence quenching of NJ1, which demonstrated that NJ1 have high selectivity toward Cu^{2+} ions. To examine the intereference of different metal ions on the Cu^{2+} recognition of NJ1, antiinterference of NJ1 was also carried out. As displayed in Fig. 3, in the absence of Cu^{2+}, other potential competitive metal ions failed to cause significantly fluorescent quenching of NJ1, whereas it would be dramatically quenched after addition of Cu^{2+} ions. Taken together, all these results showed that NJ1 possessed high selectivity toward Cu^{2+}; the other coexiting metal ions could not lead to significant intereference on Cu^{2+} recognition.

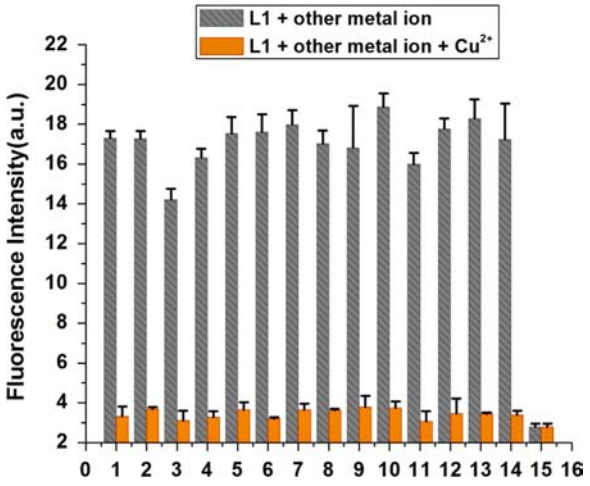

Fig. 3. Fluorescence emission spectra of NJ1 (5 μM) and different metal ions (5 μM) in the absence (gray bar) and presence (orange bar) of Cu^{2+} (5 μM) in 20 mM HEPES buffer (pH 7.4, 0.5% DMSO) at 25 °C. (1) K^+, (2)Na^+, (3) Ag^+, (4) Cu^+, (5) Pb^{2+}, (6) Pd^{2+}, (7) Zn^{2+}, (8) Mg^{2+}, (9) Mn^{2+}, (10) Fe^{2+}, (11) Cd^{2+}, (12) Al^{3+}, (13) Cr^{3+}, (14) Fe^{3+}, (15) Cu^{2+}. All the data represent the fluorescence intensity at 492 nm, excitation: 360 nm. The data represent the average of three independent experiments.

Subsequently, the "off–on" property of NJ1Cu toward H_2S was investigated. As H_2S is a small gas molecule and has a pK_a of around 6.9, we chose NaHS as the sulfide sources. The fluorescence recovered quickly upon the addition of NaHS to the solution of NJ1Cu, so this probe was potentially suitable for real-time monitoring of hydrogen sulfide levels in biological samples. The high selectivity was an important quality for an excellent fluorescent sensor; then selective fluorescence response of NJ1Cu to various anions or sulfur species had also been investigated in physiological conditions. Interestingly, NJ1 could only be regenerated by adding hydrogen sulfide to the NJ1Cu solution. Other anions or sulfur species, such as Cl^-, Br^-, I^-, HSO_3^-, HSO_4^-, $S_2O_5^-$, SO_4^{2-}, SO_3^{2-}, lys, cys, could not result in the significant change of the fluorescence intensity and corresponding fluorescence regeneration. The competitive experiment of NJ1Cu system was also carried out for the selectivity of NJ1Cu toward hydrogen sulfide in the presence of other anions. As shown is Fig. 4a, there were nearly no difference in the absence and presence of other anions; this system indicated remarkably selective "turn on" behavior toward H_2S. Furthermore, an excellent linear response of NJ1Cu versus the concentration of NaHS in the low concentration region (varying between 0 and 5 μM) was observed (Fig. 4b). Thus, the above results strongly proved that NJ1Cu system was a selective and sensitive detection method toward hydrogen sulfide that could not be significantly interfered by the commonly coexistent anions.

3.3. Cellular imaging experiment

We further investigated the potential application of NJ1 in living cells. Hela cells were incubated with 10 μM NJ1 in culture medium for 30 min at 37 °C; then live-cell imaging of the cells were carried out using confocal fluorescence microscopy. As shown in Fig. 5, strong fluorescence in the cells was observed after the cells were incubated with this developed probe. Next, the cells were added to 10 μM Cu^{2+} and further incubated for another 20 min, the fluorescence of the cells was quickly quenched and showed almost no fluorescence. However, the fluorescence of cells could be quickly recovered after incubation with 10 μM NaHS for 20 min at 37 °C. Therefore, these results revealed that NJ1 has the potential to use for the detection of copper ion in living cells and their complex NJ1Cu would also be an excellent monitoring system to visualize sulfide in living cells.

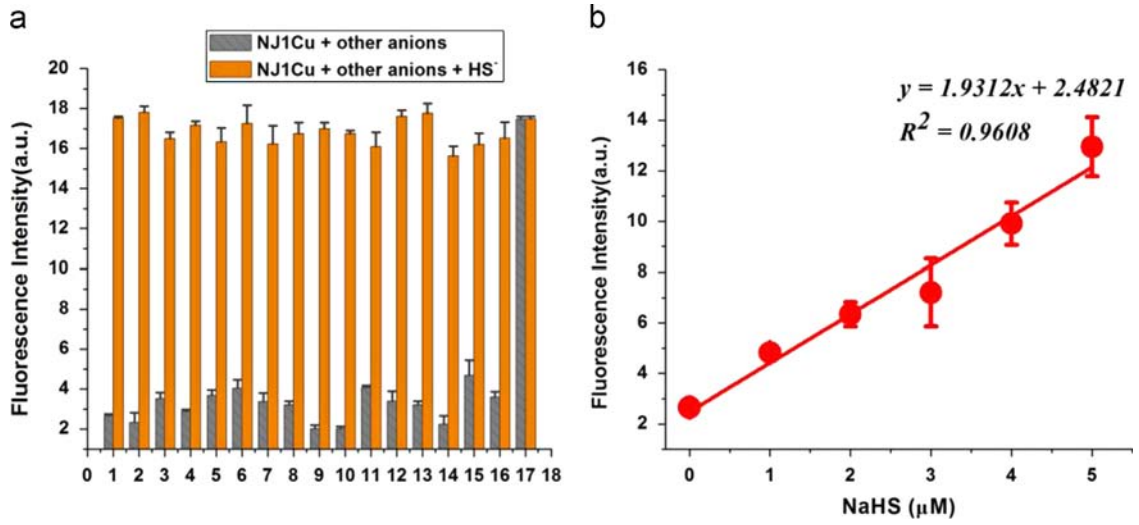

Fig. 4. (a) Fluorescence spectra of NJ1Cu (5 μM) upon addition of different anions (5 μM) in 20 mM HEPES buffer (pH 7.4, 0.5% DMSO) at 25 °C. The gray bars represent the fluorescence intensity of NJ1Cu in the presence of 5 μM anions; the orange bars represent the fluorescence intensity of the above solution on further addition of 5 μM NaHS. (1) Cl^-, (2) Br^-, (3) I^-, (4) $HClO_4^-$, (5) CH_3COO^-, (6) HPO_4^{2-}, (7) HSO_3^-, (8) HSO_4^-, (9) NO_2^-, (10) NO_3^-, (11) OCN^-, (12) $S_2O_5^-$, (13) SO_4^{2-}, (14) SO_3^{2-}, (15) lys, (16) cys, (17) HS^-. (b) Fluorescence spectra of NJ1Cu (5 μM) upon addition of different amounts of HS^- ions (0–5 μM). All the data represent the fluorescence intensity at 492 nm, excitation: 360 nm. The data represent the average of three independent experiments.

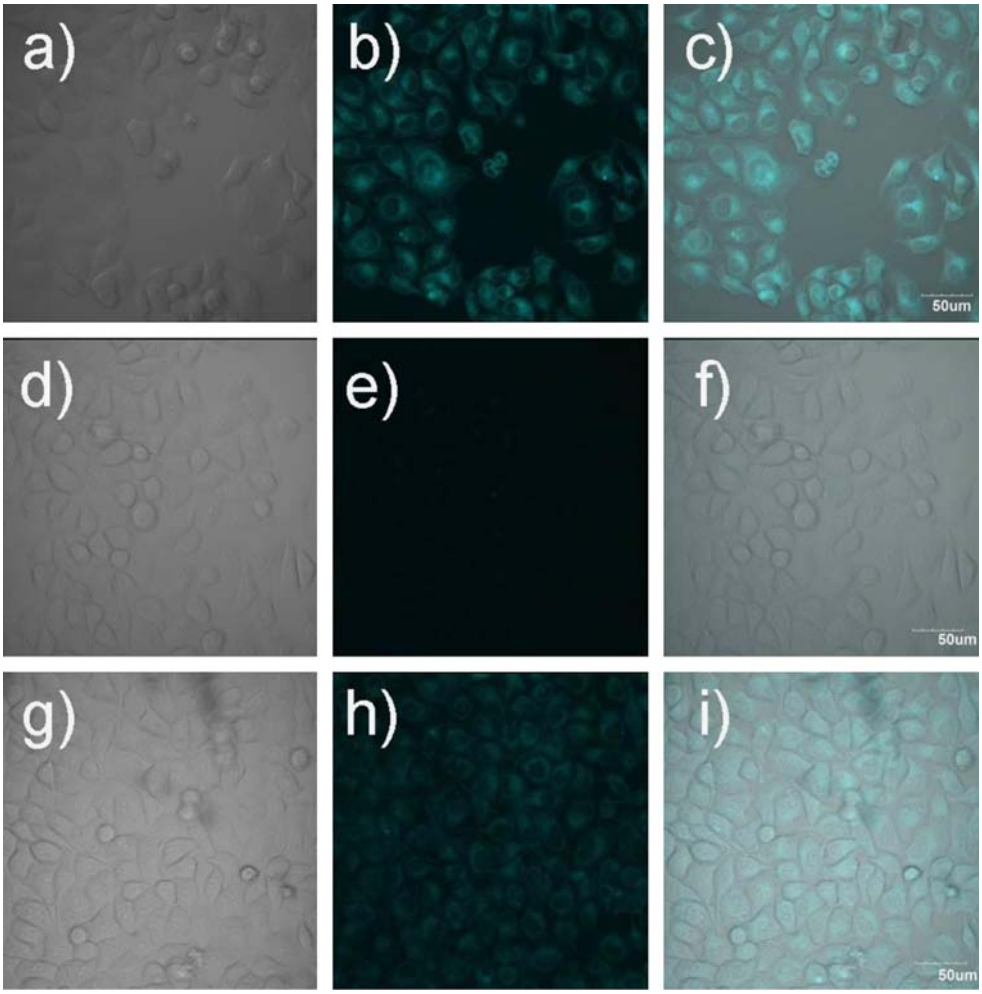

Fig. 5. Confocal fluorescent images of HeLa cells: Cells incubated with NJ1 (10 μM) for 30 min (a–c); Cells incubated with NJ1 (10 μM) for 30 min and subsequent treatment of the cells with Cu^{2+} (10 μM) for 20 min (e–f); Cells incubated with NJ1 (10 μM), Cu^{2+} (10 μM) for 30 min and subsequent treatment of the cells with NaHS (10 μM) for another 20 min (g–i). (a, d, and g) Bright-field images; (b, e, and h) fluorescent images; (c, f, and i) merged images. λ_{ex}=405 nm, scare bar=50 μM.

4. Conclusions

In summary, we have designed and synthesized a novel highly selective and sensitive fluorescent probe NJ1 for Cu^{2+} detection by fluorescence quenching mechanism. The enhancement of fluorescence intensity with the addition of hydrogen sulfide by Cu^{2+} released from the core of the complex NJ1Cu in aqueous solution at physiological conditions were also described. This "on–off–on" type fluorescence recognition system was a reversible process, which could be utilized to detect copper ion and hydrogen sulfide based on a complex NJ1Cu formation–Cu^{2+} displacement approach. More importantly, this real-time recognition process of Cu^{2+} and hydrogen sulfide exhibited excellent antiinterference ability. Furthermore, Preliminary imaging experiments demonstrated that NJ1 also had the potential to be used for imaging in living cells. Therefore, this new, simple, sensitive, and selective fluorescent probe has potential application in biological or environment systems for Cu^{2+} and hydrogen sulfide detection. The development of more specific fluorescent probes for optical imaging in living cells, tissues, and animals is our current interest and ongoing in our laboratory.

ABSTRACT

This work reports the development of a novel extraction method for total Hg determination in oil samples. After extracting Hg from samples it was quantified in the extracts by cold vapor atomic absorption spectrometry (CV-AAS), employing a laboratory-made gas–liquid separator (GLS) and $NaBH_4$ as reducing agent. The extraction of Hg from samples was carried out by extraction induced by emulsion breaking (EIEB), which is based on the formation and breaking of water-in-oil emulsion between the oil samples and an extractant solution containing an emulsifying agent (surfactant) and nitric acid. Operational parameters of the GLS were evaluated in order to set the best performance of the measurement system. In these studies it was proven that the volume of sample and the concentration of HCl added to the sample extracts had significant influence on Hg response. The best conditions were achieved by adding 0.5 mL of a 0.3 mol L^{-1} HCl solution on 1 mL of sample extract. The extraction conditions were also optimized. The highest efficiency was observed when 4 mL of a solution containing 2.5% triton X-100 and 15% v/v HNO_3 were employed for the extraction of Hg contained in 20 mL of sample. Emulsion breaking was performed by heating at 80 °C and took approximately 20 min. The limit of quantification of the method was 1.9 μg L^{-1} and recovery percentages between 80% and 103% were observed when spiked samples (2 and 10 μg L^{-1}) of diesel oil, biodiesel and mineral oil were analyzed.

1. Introduction

Nowadays, the determination of trace elements in organic liquids is one of the most challenging tasks in the field of analytical chemistry. The high complexity of samples, that present high carbon content, makes these procedures very laborious and subjected to contamination and losses of analytes during sample preparation. Atomic spectrometric techniques are very popular for the elemental analysis of organic liquids (such as oils), especially because of their high selectivity and suitable sensitivity and precision [1–3]. Besides, atomic spectrometric techniques are well-established and present in the majority of analytical laboratories. Despite these advantages, most times, the use of atomic spectrometric techniques requires a careful preparation of samples in order to avoid or minimize possible interferences.

Different strategies have been employed for sample preparation in the elemental analysis of organic liquids by spectrometric techniques. Total decomposition of samples [4–8] and their introduction in the equipment in the form of emulsions or microemulsions [9–12] are very popular, despite some problems verified in their application. Extraction methods are also available for the determination of trace elements in organic liquids [13–16]. They present some advantages over the other methods, since they make possible the separation of the organic matrix. Besides, in most cases, the calibration can be performed with aqueous standard solutions, thus avoiding the use of unstable and high-cost oil-based standards.

Mercury is one of the metallic elements that arouses the greatest interest in the scientific community, probably due to its toxicity and particular chemistry [17,18]. It is prone to accumulation in biota and represents a serious problem when released to the environment, being recognized as a large scale global pollutant [19,20]. Undoubtedly, the natural occurrence of Hg in crude oil and its presence in fuels [21,22] contribute significantly to the input of this pollutant to the environment. Some spectrometric techniques, such as cold vapor atomic absorption spectrometry (CV-AAS) [23], electrothermal atomic absorption spectrometry (ETAAS) [24], atomic fluorescence spectrometry (AFS) [25], inductively coupled plasma mass spectrometry (ICP-MS) [26] and electrothermal vaporization coupled to ICP-MS (ETV-ICP-MS) [27] were already employed for total Hg determination in oil samples.

A few extraction methods were already proposed for total Hg determination in organic liquids. Liang et al. [28] reported the

development of a method for extraction of total Hg from gasoline and other petroleum-derived products followed by the determination of Hg in the aqueous extracts by cold vapor AFS. The extraction was performed with a mixture of BrCl/HCl. The same mixture was employed by Uddin et al. [29] in the determination of total Hg in crude oils by cold vapor AFS. Nevertheless, in this case, the samples were firstly diluted in toluene in order to decrease their viscosity and allow a convenient shaking with the aqueous extractant solution. Bromine water was employed by Heyward et al. [30] for the oxidation and extraction of Hg from liquid hydrocarbons. In this work, Hg determination in the extracts was carried out by CV-AAS.

The goal of this work was to develop and propose a novel simple approach for the determination of total Hg in different types of oils without using either bromine or any organic solvent. The method employed the extraction induced by emulsion breaking (EIEB) [31–34], which is based on the formation and breaking of detergent emulsions prepared with the samples and an extractant solution (containing triton X-100 and nitric acid only), to enhance the extraction process. The developed method was applied in the determination of trace concentrations of Hg in diesel, biodiesel and mineral oil samples.

2. Experimental

2.1. Apparatus

Absorbance measurements were performed with a Varian AA240FS atomic absorption spectrometer (Mulgrave, Australia) equipped with a hollow cathode lamp of Hg operated at 5 mA. The measurements were made at 253.4 nm wavelength using a 1 nm slit width.

A laboratory-made gas-liquid separator (GLS) was employed for Hg cold vapor generation. The GLS was constructed with a capped 50 mL polyethylene tube and PEEK connections. A scheme of the GLS used in this work is depicted in Fig. 1. Ultrapure Argon (99.99%, Linde Gases, Macaé, Brazil) was employed to transport Hg vapor from GLS to the measurement cell.

Emulsion breaking was carried out by heating the flasks in a water bath maintained at 80 ± 2 °C). A water bath supplied by Nova Técnica (São Paulo, Brazil), model NT-247, was employed for this purpose.

2.2. Reagents and solutions

The water used in this work was deionized in a Direct-Q 3 system from Millipore (Milford, MA, USA). It always had resistivity equal to or higher than 18.2 MΩ cm. All reagents were of analytical grade and used without further purification.

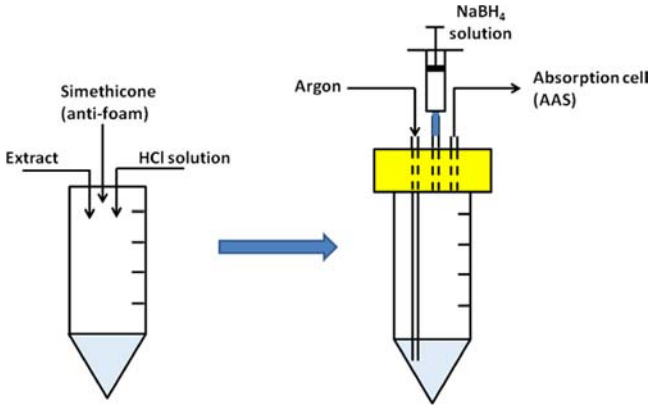

Fig. 1. Gas–liquid separator (GLS) employed in this work.

A 1000 μg mL^{-1} stock solution of Hg(II), supplied by Spex (Metuchen, NJ, USA), was employed for the preparation of aqueous diluted standard solutions of Hg(II). They were prepared from suitable dilution of the stock solution with deionized water just before their use.

The oil-based stock solution of Hg(II) with 100 μg g^{-1} concentration was supplied by Conostan (Bale, Canada). Diluted oil-based solutions employed for spiking the samples in the recovery test were prepared from adequate dilution of the stock solution with HPLC grade hexane (Tedia, Fairfield, OH, USA).

Concentrated nitric and hydrochloric acids from Tedia (Fairfield, OH, USA) were employed to prepare diluted solutions of these acids. Dilution was performed in a volumetric flask with deionized water.

A 0.5% m/v $NaBH_4$ solution was prepared by dissolving 0.5 g of the reagent (Vetec, Rio de Janeiro, Brazil) in approximately 80 mL of a 0.05% m/v NaOH solution. Afterwards, the obtained solution was transferred to a 100 mL volumetric flask and the volume was made up to the mark with the same 0.05% m/v NaOH solution. The $NaBH_4$ solution was prepared daily just before its use.

The 75 mg mL^{-1} simethicone solution employed as antifoam was purchased from the drugstores of the city of Niterói in the form of commercial pharmaceutical formulation.

2.3. General extraction and measurement procedure

Mercury extraction from oil samples was achieved by employing extraction induced by the emulsion breaking technique, which is based on the formation and breaking of water-in-oil emulsions. Emulsions were prepared by vigorous mixing of 20 mL of each oil with 4 mL of a solution containing 2.5% m/v triton X-100 and 15% v/v HNO_3 in a 50 mL capped polyethylene flask. Then the flask containing the emulsion was put on a horizontal mixer, where it was agitated for 30 min at 100 rpm. After the extraction time needed to promote quantitative transference of Hg from the oil to the aqueous dispersed phase the flask containing the emulsion was immersed into the water bath at a temperature of 80 ± 2 °C, where it was maintained until the emulsion breaking was observed, which took approximately 20 min. Emulsion breaking resulted in the formation of two well-defined phases: (i) the upper oil phase and (ii) the lower aqueous acid phase, containing Hg extracted from oil. The oil was removed with the aid of a pipette, and the lower phase (extract) was collected for Hg quantification.

The determination of Hg in the extracts was performed by CV-AAS, using the GLS constructed for this purpose. The main advantages of this GLS were the possibility to use discrete portions of the extracts for analysis and the use of different flasks for the determination of Hg in each aliquot of the extract, which avoided cross contamination. The measurement of Hg in the extracts was performed by transferring 1.0 mL of the extract, 0.5 mL of a 0.3 mol L^{-1} HCl solution and 2 drops of a 75 mg mL^{-1} simethicone solution to the GLS flask, which was adapted to the GLS cap. Then, 0.1 mL of a 0.5% m/v $NaBH_4$ solution was added through the hole in the cap using a syringe. The Hg vapor formed was transported to the spectrometer by the Ar that flowed through the GLS, yielding a transient signal. Peak height was employed as a quantitative variable.

3. Results and discussion

3.1. Optimization of the operational conditions for Hg measurement by CV-AAS

The first step of this work was to evaluate the viability of the use of the laboratory-made GLS (Fig. 1) assembled for Hg vapor generation, aiming its measurement by atomic absorption spectrometry. The main characteristic of the GLS employed in this work

was that it made possible introducing discrete portions of the extracts into the system. The generation of Hg cold vapor was performed through the addition of a given volume of $NaBH_4$ (reducing agent) solution on the mixture of the sample (or standard solution) with HCl solution. Argon was bubbled in the mixture in order to provide Hg vapor release from solution and its transportation to the measurement cell. In order to achieve maximum sensitivity, the influences of chemical variables such as HCl and $NaBH_4$ concentrations and the sample volume introduced into the GLS were investigated. Some parameters such as the volumes of HCl solution mixed with the sample and $NaBH_4$ solution added to the GLS were maintained constant at 0.5 and 0.1 mL, respectively. The carrier gas (Ar) flow rate was also maintained constant at 1000 mL min^{-1}.

The generation of Hg cold vapor depends on the addition of a suitable amount of reducing agent, since mercury is found in solution in the form of Hg(II) ions and needs to be reduced to gaseous elemental Hg. Sodium borohydride was employed for this purpose. As mentioned previously, the volume of $NaBH_4$ solution added was always 0.1 mL and the concentration of the reagent was varied in the range of 0.01–0.2% m/v. All $NaBH_4$ solutions were prepared in the presence of 0.5% m/v NaOH. The highest Hg response was observed when the $NaBH_4$ concentration was 0.1% or 0.2% m/v. Therefore, a 0.1% m/v $NaBH_4$ solution was employed in all further experiments.

The vapor generation of Hg also depends on the acidity of the medium since the decomposition of $NaBH_4$ into hydroboron intermediates, which are responsible for the reduction of Hg(II) ions, is accelerated in acidic medium [35]. Hence, to keep the medium acid sufficient for promoting suitable Hg vapor evolution, HCl solution was added to the sample extract (or standard solution) before addition of $NaBH_4$ solution. As mentioned previously, the volume of HCl solution added to the flask was always 0.5 mL and the concentration of HCl in this solution was varied from 0 to 6 mol L^{-1}. The results obtained in this experiment (Fig. 2) showed that the highest response could be achieved when HCl concentration was in the range of 0.10–0.3 mol L^{-1}. When the HCl concentration was higher than this value, a decrease of Hg signals was verified. In view of these results, a 0.3 mol L^{-1} HCl solution was selected for the method.

The volume of sample added to the GLS controlled the amount of Hg introduced into the measurement system. Theoretically, the increase of the mass of Hg added to the flask would lead to the increase of signals. On the other hand, the magnitude of Hg signals could be limited by the amount of reducing agent added, which could not be enough to promote the evolution of all Hg present in the solution, and also by kinetic effects. Then, an experiment was performed to evaluate the influence of the sample volume employed on Hg measurement. A 50 μg L^{-1} Hg(II) solution was used and the other conditions were those optimized in the previous experiments. The sample volume was varied from 0.5 to 5 mL.

As can be seen in Fig. 3, the Hg response increased linearly with the increase of sample volume. This behavior was already expected, since the increase of the sample volume also increased the amount of Hg inserted into the system for atomization. The signals are registered in terms of peak height and peak area (Fig. 3) and no significant differences are observed in their behavior with the variation of volume, indicating that the release of Hg vapor from aqueous medium is fast and does not suffer from kinetic interferences. Evidently, the increase of volume caused some broadening of the peaks, which must be associated to the higher amount of Hg that must be atomized. As the volume of extract recovered in the extraction induced by emulsion breaking was limited to not more than 4 mL, all further experiments were conducted with 1 mL of solution (extract or standard solution) in order to allow that measurements could be made in triplicate.

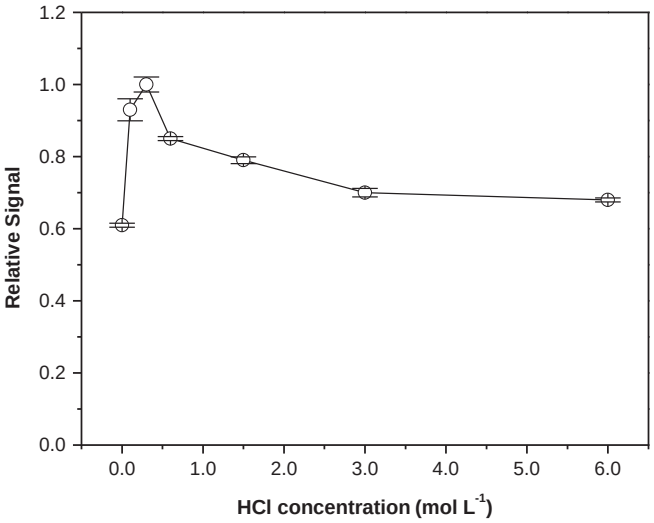

Fig. 2. Effect of HCl concentration in the solution mixed with the extract (or satndard solution) for Hg measurement by CV-AAS. Volume of sample =1 mL and volume of HCl solution =0.5 mL.

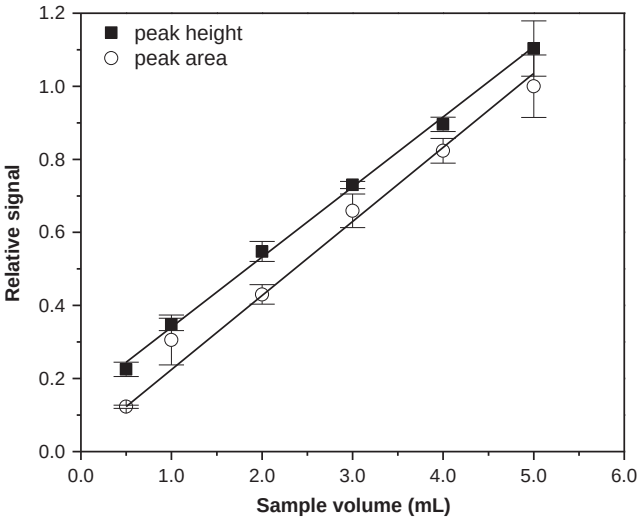

Fig. 3. Effect of sample volume employed for Hg measurement by CV-AAS. Volume of HCl solution =0.5 mL and concentration of HCl in the solution =0.3 mol L^{-1}.

The final conditions used in the measurement of Hg employing the proposed GLS are summarized in Table 1. Mercury signals obtained in the construction of a typical calibration curve are shown in Fig. 4.

3.2. Optimization of extraction induced by emulsion breaking conditions

After establishing suitable conditions for Hg measurement by CV-AAS using the GLS device proposed in this work, the extraction induced by emulsion breaking was optimized. As well known, extraction induced by emulsion breaking is based on the formation and breaking of detergent emulsions. The extraction of the analytes occurs during phases separation (emulsion breaking) due to the stronger affinity of metallic cations by the acid aqueous medium than oil one. In the present work, the extraction conditions were optimized using a diesel oil sample spiked with 10 μg L^{-1} of Hg in organometallic form (oil-based standard). The parameters evaluated were concentration and type of surfactant (triton X-100 and triton X-114), concentration of HNO_3 in the extractant solution, and extraction time.

Table 1
Operational parameters of the GLS employed in the measurement of Hg by CV-AAS.

Parameter	Condition
Sample volume	1 mL
HCl solution concentration	0.3 mol L^{-1}
HCl solution volume	0.5 mL
$NaBH_4$ solution concentration[a]	0.5% m/v
$NaBH_4$ solution volume	0.1 mL
Carrier gas (Ar) flow rate	300 mL min^{-1}

[a] Solution prepared in 0.05% m/v NaOH.

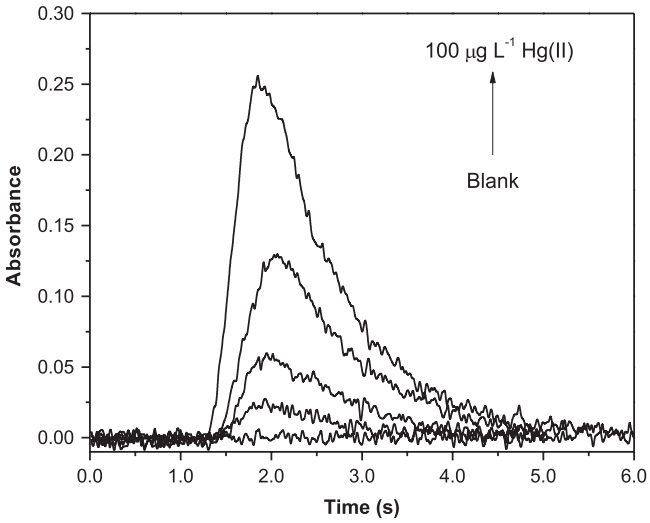

Fig. 4. Hg signals obtained with the GLS constructed in this work at optimized conditions.

The first parameters evaluated were the type and concentration of surfactant in the extractant solution. Both triton X-100 and triton X-114 were tested as emulsifier agents in different ranges of concentrations. Triton X-100 was tested in the range of 0.5–7% m/v, whereas triton X-114 was tested in the range of 0.5–15% m/v. These ranges were chosen taking into account the ability of each surfactant to promote adequate emulsification of the system. The HNO_3 concentration in the extractant solution, in this experiment, was always 15% v/v. Results obtained (Fig. 5) showed that surfactant concentration played an important role on the extraction efficiency of Hg from oil. In both cases, at low concentrations of surfactant, Hg response was low, indicating that the analyte was not satisfactorily extracted from oil. This poor extraction occurred possibly due to the inefficient dispersion of the aqueous phase through the oil. The increase of surfactant concentration resulted in the increase of Hg signals probably because of the formation of emulsions with very small droplets, which increased the contact between the extractant solution and the sample. The highest signals were obtained at 2.5% m/v triton X-100 concentration and 12.5% m/v triton X-114 concentration.

Another aspect considered in this study was the time required to break the emulsions. In general, triton X-114 emulsions are broken in a shorter time than triton X-100 emulsions when the surfactants are present in the same concentration. This difference occurs due to higher stability of triton X-100 emulsions when compared with triton X-114 ones. Nevertheless, when considering optimized concentrations, a 2.5% m/v triton X-100 solution was selected for the method because it was broken in approximately 20 min while the 12.5% m/v triton X-114 emulsion took approximately 35 min to be broken. The presence of triton X-100 in the

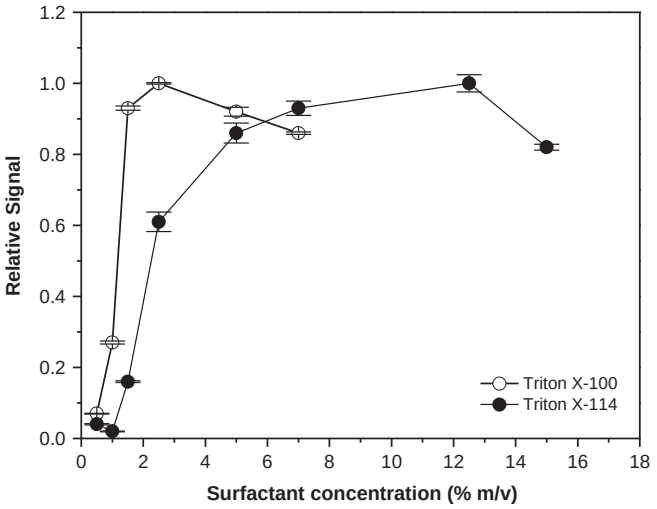

Fig. 5. Effect of surfactant type and concentration in the extractant solution on the extraction of Hg from the diesel oil employed in the optimization studies. HNO_3 concentration = 15% v/v.

extracts from EIEB resulted in the formation of an excessive amount of foam inside the GLS system during Hg measurement. This drawback was overcome by the addition of two drops (approximately 100 μL) of a 75 mg mL^{-1} simethicone solution, which acted as an antifoam agent.

The concentration of HNO_3 in the extractant solution also played fundamental role in the extraction process. According to data obtained in previous works [31–34], the extraction process is enhanced in the presence of mineral acids because H^+ ions compete with metallic cations for the basic sites present in the organic molecules that form the oil sample. Also, nitric acid is able to break covalent bonds between metals and organic structures (oxidation), allowing the release of metals to the medium in the form of free ions. In the present work, the influence of HNO_3 concentration in the extractant solution was investigated in the range of 5–30% v/v. It is important to remember that this solution also contained 2.5% m/v triton X-100, employed as an emulsifier agent. Maximum signals were observed at 15% v/v HNO_3. In concentrations below this value, the amount of acid was not enough to displace Hg from organic structures. At HNO_3 concentrations higher than 15% v/v, the signals decreased probably due to the influence of some substances co-extracted from sample, since this same behavior was not noted when standard solutions of Hg(II) were tested to evaluate the influence of HNO_3 concentration (Fig. 6). Therefore, a 15% v/v HNO_3 concentration was chosen for extracting Hg from samples in the method.

Finally, the last parameter evaluated is the extraction time, which is the time lapse between emulsion formation and breaking. Although the formation of emulsions already enhances the extraction process, since it increases the contact between the oil sample and the aqueous extractant solution, sometimes extraction efficiency can be limited by the time required for displacing metals from organic molecules and achieving satisfactory transference of the analyte from the organic to the aqueous phase.

The influence of extraction time was tested in the range of 0 (emulsion breaking just after its formation)–60 min. The extraction process was carried out maintaining the emulsions under continuous agitation with a horizontal shaking. This agitation was performed to avoid phases separation (emulsion breaking) and allowed aqueous droplets of extractant solution to move through the continuous phase, represented by the oil, thus improving extraction efficiency. The concentrations of HNO_3 and triton X-100 in the emulsifier solutions were those optimized in the previous

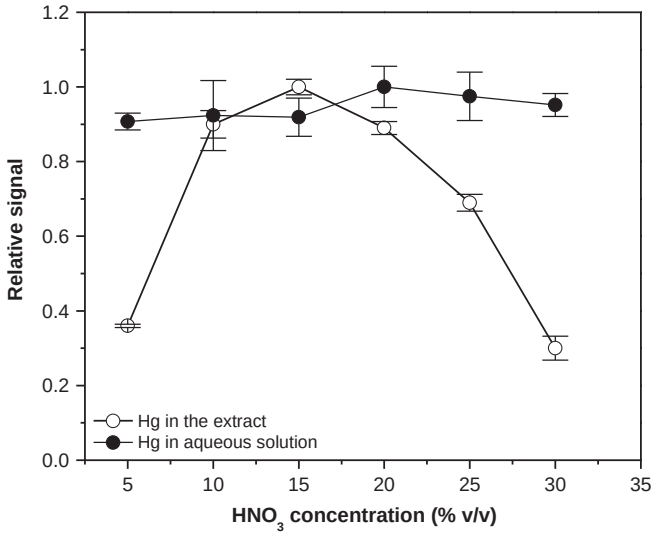

Fig. 6. Effect of HNO_3 concentration in the extractant solution on the extraction of Hg from the diesel oil employed in the optimization studies. Triton X-100 concentration =2.5% m/v.

experiments. The maximum Hg response was observed by agitating the emulsions for 30 min, at least, before emulsion breaking. Therefore, this extraction time was used in the preparation of samples for analysis employing the proposed method.

3.3. Analytical features of the method

The proposed method yielded linear calibration curves in the range of 10–100 $\mu g\,L^{-1}$, with the typical equation $A=0.0014[Hg(\mu g\,L^{-1})]+0.0007$ ($r^2=0.9985$). The limits of detection and quantification of the proposed method were calculated from the calibration graph and took into account the preconcentration factor obtained with the extraction procedure, which was 5 (quantitative extraction of the analyte from 20 mL of sample to 4 mL of extract). The limit of detection (3σ criterion) was 0.6 $\mu g\,L^{-1}$, whereas the limit of quantification (10σ criterion) was 1.9 $\mu g\,L^{-1}$. They were estimated from 10 repetitive measurements of the blank obtained from extraction. The precision of the method was satisfactory for this kind of procedure, being situated in the range of 3.5–5.6% (2 and 10 $\mu g\,L^{-1}$ concentration levels) for within-run analysis and 5.0–11.7% for between-run analysis (2 and 10 $\mu g\,L^{-1}$ concentration levels).

The enhancement factor (EF) was also calculated. It is defined as the ratio of the slope of the standard addition curve obtained when EIEB is applied to a spiked sample to the slope of the calibration curve obtained by direct introduction of the aqueous standards in the system. The derived EF is 5.1, very close to the expected value of 5, which represents the volume ratio of the organic to the aqueous phases. This result confirms that the method is virtually free of non-specific interferences, in relation to Hg measurement in the extracts, and that the analyte is quantitatively extracted from oils.

3.4. Evaluation of calibration strategy and application of the propose method

The application of EIEB to oil analysis resulted in the formation of aqueous extracts with specific characteristics. They contained minor amounts of organic matter extracted from the samples and significant concentrations of HNO_3 and surfactant, which were originally present in the extractant solution composition. The presence of these substances could cause some non-specific interferences on Hg measurement by changing the kinetics and/or efficiency of Hg reduction. In order to verify the possible occurrence of non-interferences on Hg measurement, calibration curves prepared in water were compared with standard addition curves prepared in the extracts obtained from diesel oil, biodiesel and mineral oil samples free of Hg (S_1, S_4 and S_5). The curves were prepared in the range of concentrations of 10–100 $\mu g\,L^{-1}$. As can be seen in Table 2 there were no significant differences between the slopes of the calibrations curves and standard addition curves, indicating that at optimized conditions the method is actually free of non-specific interferences and it is possible to quantify Hg in the extracts obtained from different oil samples by external calibration approach.

Once the calibration strategy was established, the proposed method was applied in the determination of total Hg in five samples of different types of oils. Samples of biodiesel, diesel oil and mineral oil were analyzed. A recovery test was performed to evaluate the accuracy of the method. In a such test, samples were spiked with 2 and 10 $\mu g\,L^{-1}$ of Hg, in the form of organometallic compound, and the EIEB procedure was applied in the optimized conditions. The difference between the Hg concentrations found in non-spiked and spiked samples was employed to estimate recovery rates. Recovery rates between 80% and 103% were achieved (Table 3), indicating that the proposed method is really able to extract and quantify total Hg in oil samples of different origins.

Table 2
Typical calibration curves obtained in the comparison of external calibration and standard addition approaches.

Calibration mode	Equation	Sample type
Calibration curve	$A=0.0014[Hg(\mu g\,L^{-1})]+0.0007$, $r^2=0.996$	
Standard addition curve	$A=0.0014[Hg(\mu g\,L^{-1})]+0.0012$, $r^2=0.998$	Diesel oil
	$A=0.0014[Hg(\mu g\,L^{-1})]+0.0019$, $r^2=0.998$	Biodiesel
	$A=0.0016[Hg(\mu g\,L^{-1})]+0.0006$, $r^2=0.993$	Mineral oil

Table 3
Results obtained in the determination of total Hg in oil samples by the proposed method. Results are expressed as mean ± standard deviation ($n=3$).

Sample	Oil	Hg added ($\mu g\,L^{-1}$)	Hg found ($\mu g\,L^{-1}$)	Recovery (%)
S_1	Diesel	0	< LOD	–
		2.0	2.0 ± 0.1	100
		10	12.0 ± 1.1	100

		2.0	1.6 ± 0.1	80
		10	9.6 ± 0.7	96

4. Conclusions

The method proposed (and optimized) in this work was shown to be a good alternative to total digestion for the determination of total Hg in oil samples. It presented remarkable advantages over regular methods based on Hg extraction from organic liquid samples such as the preconcentration of the analyte in the

aqueous phase and the possibility of using aqueous standards in the methodological calibration procedure, instead of high-cost and unstable oil-based standards. Besides, possible interferences due to the high content of carbon in the samples were not seen, which permitted external calibration to be employed in the quantification of Hg in the extracts.

The laboratory-made GLS device proposed in this work was suitable for Hg vapor generation from the extracts. It is easy to construct and can be employed in other applications for Hg determination in different types of samples. Additionally the GLS worked in a way that avoided cross contamination, since different flasks were used in the measurement of Hg in different solutions.

Different types of oils could be analyzed with the developed method, independently of the particular characteristics of the samples tested. This fact shows the versatility of the extraction procedure in relation to Hg extraction and can open new possibilities for the use of EIEB in the analysis of other organic samples.

ABSTRACT

Green analytical chemistry is an aspect of green chemistry which introduced in the late nineties. The main objectives of green analytical chemistry are to obtain new analytical technologies or to modify an old method to incorporate procedures that use less hazardous chemicals. There are several approaches to achieve this goal such as using environmentally benign solvents and reagents, reducing the chromatographic separation times and miniaturization of analytical devices. Traditional methods used for the analysis of pharmaceutically active compounds require large volumes of organic solvents and generate large amounts of waste. Most of them are volatile and harmful to the environment. With the awareness about the environment, the development of green technologies has been receiving increasing attention aiming at eliminating or reducing the amount of organic solvents consumed everyday worldwide without loss in chromatographic performance.

This review provides the state of the art of green analytical methodologies for environmental analysis of pharmaceutically active compounds in the aquatic environment with special emphasis on strategies for greening liquid chromatography (LC). The current trends of fast LC applied to environmental analysis, including elevated mobile phase temperature, as well as different column technologies such as monolithic columns, fully porous sub-2 μm and superficially porous particles are presented. In addition, green aspects of gas chromatography (GC) and supercritical fluid chromatography (SFC) will be discussed. We pay special attention to new green approaches such as automation, miniaturization, direct analysis and the possibility of locating the chromatograph on-line or at-line as a step forward in reducing the environmental impact of chromatographic analyses.

1. Introduction

The concept of green chemistry was introduced in the nineties with the aim of minimizing the environmental impact of chemical activities [1]. Green analytical chemistry is an aspect of green chemistry with the aim of minimizing hazardous waste and to use solvents friendly to the environment [2]. Recently, green chemistry has gained increasing attention from many researchers in both industry and academia and the need to make analytical chemistry greener is becoming more widely accepted. The main objectives of green analytical chemistry are to develop new analytical method or to modify an old one to incorporate procedures that need less hazardous chemicals [3]. The crisis of the shortage of acetonitrile (2008–2009) encouraged many chromatographers to develop new analytical methods aiming at reducing the use of acetonitrile as an organic modifier for RP–LC or replacing it with other alternatives. The driving force for decreasing acetonitrile usage at that time was cost rather than the desire to develop green methodologies [4].

In traditional LC, little attention has been given to green aspects of the separation. Traditional LC methods using standard column dimensions and conventional stationary phases require large amounts of organic solvents and generate large volumes of waste. For instance, traditional LC instruments operated with a column of standard internal diameter (4.6 mm) and 25 cm length at a mobile phase flow rate of about 1–1.5 mL min^{-1} generate more than 1L of effluent daily, and this waste has to be disposed of [5]. Common solvents used in LC are volatile organic compounds that can easily disperse in the environment, many of them exhibiting both acute and chronic toxicity; therefore green aspects should be taken into consideration when new analytical method has to be developed.

Chromatographic techniques have the potential to be greener at all steps of the analysis, from sample collection to separation and final determination. Because sample preparation prior to chromatographic analysis cannot be avoided in most case, solventless or miniaturized sample preparation techniques should be used whenever possible. Currently, greening of sample preparation methods has been receiving greater attention aiming at minimizing or eliminating the solvent usage [4]. Green sample preparation techniques include solventless solid phase microextraction (SPME), supercritical fluid extraction (SFE, when only pure carbon dioxide is used), and solid phase extraction (SPE) where a small volume of organic solvent is used [1,6]. The most widespread clean-up method used for the analysis of pharmaceuticals is SPE. It provides many advantages in the green point of view such as low organic solvent consumption, short sample preparation time and the possibility of automation [7]. SFE is also an environmentally-friendly analytical methodology that can be automated easily and completely [1]. Because greening of sample preparation techniques is beyond the scope of this review, readers are advised to refer to other articles for more details e.g. [1,8–10]. The main directions currently explored for transforming chromatography in a green approach are reduction of solvent consumption through reducing columns internal diameters and particle sizes (from 5 to sub-2 μm), replacement of acetonitrile and/or methanol in the mobile phases by less harmful and environmental friendly alternatives such as water, ethanol and carbon dioxide (either in sub-critical or supercritical states) and miniaturization [1,11].

The growing demand for development of environmentally friendly analytical protocols usually results with miniaturization of the existing and well established methods [12]. Miniaturized separation systems offer many advantages such as consuming fewer consumables, producing less waste, minimizing energy consumption and allowing on-line or at-line analysis. All of these advantages make the chromatographic analysis green. For the analysis of pharmaceuticals in environmental samples, very sensitive and highly efficient methods are highly required, especially for wastewater. Because of the polarity of pharmaceuticals, the technique of choice for their analysis is LC, which remains the main tool for the analysis of pharmaceuticals in most commercial and research laboratories. Therefore, recent developments in green LC methodologies will be discussed in this review[1].

2. Recent trends in green liquid chromatography

The direct way to minimize the solvent consumption of an HPLC separation is to reduce the analysis time (without increasing flow rate of the mobile phase) [5]. For a given separation, the volume of the mobile phase consumed (V) can be calculated from the following equation [5]:

$$V = F \times t \quad (1)$$

where F is the volumetric flow rate and t is the analysis time.

However many approaches can be used to achieve fast separations, including the use of monolithic columns, fully porous sub-2-μm particles with UPLC systems, superficially porous particles and elevated mobile phase temperatures, not all of these strategies are considered green separations. The advantages and disadvantages of these approaches will be discussed in details in the following sections.

Another way of reducing the use of solvent in liquid chromatography is to decrease the column volume by shortening its length and/or decreasing the internal diameter [5]. Also, in recent years miniaturization of HPLC systems and columns has gained interest. The use of micro-flow and capillary columns could effectively reduce solvent consumption; however, dedicated systems are highly needed. In addition to solvent reduction strategies, replacing traditional solvents with more benign alternatives such as ethanol, carbon dioxide and pure water has received great attention.

Other chromatographic systems such as GC and SFC are considered green approaches because GC is a solvent-free technique, and SFC is based mainly on using environmentally friendly carbon dioxide, which minimizes the use of toxic organic solvents and additives. This review focuses mainly on liquid chromatographic separations.

2.1. Reduction in solvent consumption

2.1.1. Fast chromatography

High-speed HPLC analysis is highly required in many analytical fields, such as clinical, forensic, toxicological, environmental and pharmaceutical analysis [13]. Speeding up LC method using fast analysis results in reducing the overall solvent consumption and costs. These improvements provide benefits for laboratories in terms of productivity enhancement and economic savings. Recently; new stationary phases, new column geometries and new instruments are introduced in order

[1] Some parts are based on Ref. 11.

to decrease analysis times while maintaining high resolution and efficiency. Various analytical approaches have been proposed to speed up the analysis. These approaches usually include the following strategies, applied individually or in combination(s): reducing the column length, increasing the mobile phase flow rate, decreasing packing particle size, increasing pressure or increasing temperature. In fast LC method development, all factors are usually not changed simultaneously, but step-by-step to optimize the separation and reduce the analysis time without losing resolution.

Gritti and Guiochon proposed different approaches to achieve rapid LC separations without loss in resolution and efficiency [14]. The first strategy is to increase the mobile phase linear velocity, which can be achieved either by operating the column under a higher inlet pressure or by decreasing the solvent viscosity. The eluent viscosity can be reduced by elevating the column temperature, so the diffusion coefficients of the solutes increase, leading to faster mass transfer [14]. Another strategy aiming at increasing the velocity of the mobile phase is to increase the column permeability which allows higher flow rates to be used with the same inlet pressure. This could be accomplished by using monolithic columns. An alternative approach to decrease the analysis time while maintaining efficiency is to reduce the column length while decreasing the plate height, which can be done by using smaller particle size packing (e.g. sub-2 μm). However, in this case column permeability is decreased and very high pressures are mandatory. Finally, analysis time can be shortened by combining the increase in column permeability with an increase in efficiency, which could be achieved by using sub-3 μm superficially porous particles [14]. These different strategies and their application to the analysis of pharmaceuticals in the environmental water samples will be discussed in more details in the following section.

2.1.1.1. Monolithic columns. Monolithic supports consist of a single rod of porous material with unique features in terms of permeability and efficiency. These supports were originally introduced during the 1990s [15]. Different kinds of monoliths can be prepared, both inorganic (silica, zirconia, carbon and titania) and organic (polymethacrylate, polystyrene-divinylbenzene and polyacrylamide). However, the only commercially available kinds are polymethacrylate, polystyrene-divinylbenzene and silica-based monolithic columns [15]. Silica-based monolithic supports are most widely used in HPLC and have been commercially available since 2000 from Merck and Phenomenex under the trademarks Chromolith and Onyx, respectively [15].

Monolithic columns provide many advantages. One of them is their high external porosity due to the relatively large thorough-pores, which imparts high column permeability. Consequently, chromatographic separations can be performed at lower backpressures than with conventional fully porous particle-packed columns [16,17]. Another advantage is the possibility of using high flow rates (up to 10 mL min^{-1}), due to low flow resistance, leading to fast separations using conventional LC systems [18]. Although high speed analysis using monolithic columns is quite common, the amount of waste generated is the same as or greater than with conventional HPLC columns of comparable dimensions [5]. Monolithic columns are used mainly for speeding up the analysis and this approach is not considered a powerful option for greening the analysis, especially that small internal diameter column, e.g. 2.0 or 3.0 mm, are not commercially available in all common column lengths [13]. In addition, the wide use of monolithic columns in the environmental analysis is not common due to the limited commercial availability of different stationary phases [18]. Another drawback of monolithic supports is poor efficiency due to radial heterogeneity of monolithic silica rods, as their external porosity is smaller in the center than close to the wall [19]. In addition, silica-based monoliths have limited chemical stability (pH range) [20]. All these drawbacks limit their applications in environmental analysis.

For environmental analysis, commercial Chromolith columns of 100 mm × 4.6 mm I.D. are typically used. These columns have been reported in the analysis of three fluoroquinolone antibiotics in river water samples using fluorescence detection with analysis time of 14 min [21]. In this study, the mobile phase consumption was quite large because of using high mobile phase flow rate (2.5 mL min^{-1}). The use of coupled monolithic columns was also proposed to increase peak capacity and resolution; however, this increased the analysis time significantly [22]. In this study, two coupled monolithic columns were used to separate 21 pharmaceutical residues in 70 min with Ultra-Violet (UV) detection.

Because of the use of high mobile phase flow rates with monoliths, their use with mass spectrometric detection is limited and few LC–MS methods using monolithic columns were developed for environmental analysis [23]. Green liquid chromatography can sometimes benefit from the use of monolithic stationary phases because these columns offer the possibility of using mobile phases of higher viscosity, for example ethanol/water mixtures [24]. Also, monolithic columns allow the use of high mobile phase flow rates leading to shorter analysis times. However, unless the column diameter is reduced, this does not result in solvent savings [24]. Since large volumes of organic solvents are consumed due to the usage of high mobile phase flow rates, alternatives have been developed aiming at speeding up the analysis but with lower solvent consumption.

2.1.1.2. Fully porous sub-2 μm particles and ultrahigh pressure liquid chromatography (UPLC). The development of fully porous sub-2 μm particles is considered a second leap forward in column technology. Columns packed with these small particles were commercially available since 2004. Fully porous sub-2 μm particles could improve efficiency, optimal velocity and mass transfer compared to conventional particle sizes [25,26]. These particles can be used to decrease the analysis time since the optimal flow rate is inversely proportional to particle diameter according to the equation [27]:

$$\mu = \nu D_m / d_p \quad (2)$$

where ν is the reduced mobile phase velocity, (d_p) is the particle diameter, μ is the optimal velocity and D_m the diffusion coefficient of the solute in the mobile phase. Reducing the particle size allows the use of high flow rates resulting in decreasing the analysis time without loss of resolution and efficiency. Also, the A and C terms of Van Deemter equation can both be decreased by using smaller particle size columns, which leads to a reduction in the plate height and a corresponding increase in efficiency for a given column length. The A term represents the dispersive contribution from the flow profile (eddy diffusion, $A = 2\lambda d_p$) where λ is particle shape with regard to the packing and the C terms are mass transfer terms in mobile and stationary phases [28]. The use of small particle size packing (sub-2 μm) improves the chromatographic performance as these particles provide minimum plate heights nearly four times smaller than those observed with conventional columns packed with 5 μm particles or with monolithic columns [13]. However, the main limitation of using sub-2 μm particles is the induction of high column backpressure. According to Darcy's law, the pressure is inversely proportional to the particle size at the optimum linear velocity [20]:

$$\Delta P = \mu L \eta \phi / d_p^2 \quad (3)$$

where ΔP is the pressure drop, L is column length, η is the viscosity of the solvent and is the flow resistance. The high backpressure generated by these particles prevents these particles to be used with standard HPLC hardware. To overcome this problem, some improvements to the chromatographic systems have been made. In recent years, instruments that can produce pressure above 400 bar

have been commercialized and are known as UHPLC systems. The term UHPLC is used to define the use of columns packed with sub-2 μm particles at pressures exceeding 400 bar [15]. The first commercially available UHPLC system was introduced by Waters Corporation in 2004. Several instruments were also developed by other manufactures and can withstand pressures ranging from 600 to 1200 bar [29]. These systems can speed up LC separations compared with conventional HPLC while maintaining identical performance [20,30]. Liquid chromatographic separations performed in less than 10 min are considered fast, and separations performed in less than 1 min are known as ultrafast [13]. Sub-2 μm particles can provide flat Van Deemter curves which allows high flow rates to be used leading to decreased analysis time even further; however, the mobile phase consumption might be increased and in this case solvent savings might be an issue. Therefore, speeding up the analysis simultaneously with reducing solvent consumption could be achieved by using small particle size particles in a combination with short columns, generating the same number of theoretical plates as with conventional columns, but with shorter analysis time and lower solvent consumption. For example, a 5 cm column packed with sub-2 μm particles is sufficient to obtain approximately the same number of plates as a 15 cm column packed with 5 μm particles according to equation [31]:

$$N \sim L/2d_p \quad (4)$$

When small particles are packed in columns with small diameter, savings in solvent consumption are more obvious than when standard column diameter (4.6 mm) is used. In addition, using small diameter columns could reduce frictional heating which might contribute to efficiency losses [20]. However, it should be mentioned that UHPLC systems are sometimes used with conventional particles (3–5 μm) leading to large solvent consumption, therefore not all

Table 1
Applications of columns packed with sub-2 μm particles in the analysis of pharmaceuticals in environmental water samples.

Analytes	Sample	Stationary phase	Detection	Flow rate	Analysis time	Reference
7 Antidepressants	Wastewater Surface water	Acquity UPLC BEH C18 (50 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.4 mL min^{-1}	7.5 min	[33]
74 Pharmaceutically active compounds	Wastewater Surface water Ground water	Acquity UPLC BEH C18 (100 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.4 mL min^{-1}	8 min	[34]
28 Basic/neutral pharmaceuticals	Surface water	Acquity UPLC BEH C18 (100 mm × 1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.07 mL min^{-1}	15.5 min	[35]
9 Pharmaceuticals	Surface water	Acquity UPLC HSS T3 (100 mm × 2.1 mm, 1.8 μm)	MS-Triple Q mass analyzer	0.5 mL min^{-1}	9.6 min	[36]
15 Steroidal oral contraceptives	Surface water	Acquity UPLC BEH C18 (50 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.1 mL min^{-1}	8.5 min	[37]
10 Pharmaceuticals	Wastewater	Acquity UPLC BEH C18 (100 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.35 mL min^{-1}	7.2 min	[38]
36 Endocrine disrupting chemicals	River water	Acquity UPLC HSS T3 (100 mm × 2.1 mm, 1.8 μm)	MS-Q-TOF mass analyzer	0.5 mL min^{-1}	9.5 min	[39]
11 Illicit drugs	Wastewater Surface water	Acquity UPLC BEH C18 (50 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.3 mL min^{-1}	6 min	[40]
65 Illicit drugs	Wastewater Surface water	Acquity UPLC BEH C18 (150 mm × 1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.04 mL min^{-1}	23.1 min	[41]
160 Pharmaceutical metabolites	Wastewater	Acquity UPLC BEH C18 (100 mm × 2.1 mm, 1.7 μm)	MS-Q-TOF mass analyzer	0.3 mL min^{-1}		[42]
47 Pharmaceuticals	Wastewater	Acquity UPLC HSS T3 (100 mm × 2.1 mm, 1.8 μm)	MS-Triple Q mass analyzer	0.3 mL min^{-1}	10 min	[43]
76 Illicit drugs and metabolites	Wastewater	Acquity UPLC BEH C18 (150 mm × 2.1 mm, 1.7 μm)	MS-Q-TOF mass analyzer	0.3 mL min^{-1}		[44]
20 Pharmaceuticals	Wastewater Surface water	Acquity UPLC BEH C18 (50 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.3 mL min^{-1}	9 min	[45]
7 Estrogens	Wastewater Surface water Ground water	Acquity UPLC BEH C18 (50 mm × 2.1 mm, 1.7 μm)	MS-Q-TOF mass analyzer	0.4 mL min^{-1}	13 min	[46]
16 Sulfonamides and trimethoprim	Wastewater Surface water	Acquity UPLC BEH C18 (100 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.3 mL min^{-1}	> 6.5 min	[32]
9 Sulfonamides	Wastewater Surface water	Zorbax SB C18 columns (150 mm × 4.6 mm, 1.8 μm)	UV λ=272	1.5 mL min^{-1}	3 min	[47]
9 Pharmaceuticals	Wastewater Surface water	Zorbax SB-AQ column (30 mm × 2.1 mm, 1.8 μm)	UV λ=272, 247	1 mL min^{-1}	1 min	[48]
81 Pharmaceutical residues	Surface and treated waters	Acquity BEH C18 column (50 mm × 2.1 mm, 1.7 μm)	MS-Q-IT mass analyzer	0.5 mL min^{-1}		[49]
27 Pharmaceuticals	Drinking or waste water	Acquity BEH C18 column (100 mm × 2.1mm, 1.7μm)	MS-Triple Q mass analyzer	400 μL min^{-1}.	12 min	[50]
81 Pharmaceuticals	Waste, surface, underground, and drinking water	Acquity HSS T3 column (50 mm × 2.1 mm, 1.8 μm)	MS-Triple Q-LIT mass analyzer	0.5 mL min^{-1}		[51]
10 Anticancer drugs	Hospital and urban wastewaters	Acquity HSS T3 column (50 mm × 2.1 mm, 1.7 μm)	MS-Triple Q-LIT mass analyzer	0.4 mL min^{-1}		[52]
69 Multiclass pharmaceuticals	Surface water	Acquity HSS T3 column (150 mm × 2.1 mm, 1.8 μm)	MS-Q-TOF mass analyzer		19 min	[53]
21 Pharmaceuticals and 6 personal care products	Drinking-water sludge	Acquity BEH C18 column (50 mm × 2.1 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.225 mL min^{-1}		[54]
48 Pharmaceuticals and 6 metabolites	Wastewater and surface water	Acquity BEH C18 column (100 mm × 1.0 mm, 1.7 μm)	MS-Triple Q mass analyzer	100 μL min^{-1}	15 min	[55]
25 Acidic/neutral pharmaceuticals and personal care products	Surface water	Acquity BEH C18 column (100 mm × 1.0 mm, 1.7 μm)	MS-Triple Q mass analyzer	0.05 mL min^{-1}		[56]

UHPLC analytical methods published in the literature are considered green separations. Overall, though, using sub-2 μm particles packed in short narrow bore columns with UHPLC could significantly lower the consumption of the mobile phase compared to using conventional particle sizes with standard HPLC systems [5].

Several recent applications of UPLC–UV, UPLC–MS [Quadrople (Q), time-of-flight (TOF), linear ion trap (LIT) mass analyzer] methods using sub-2 QUOTE μm particle size packed columns in environmental analysis are summarized in Table 1. Most of these applications are based on reversed-phase separations using the Acquity UPLC BEH C18 columns of 1.7 μm particle size with different columns lengths. Other C18 reversed-phase columns such as Zorbax SB C18 (1.8 μm particle size) have also been used.

As an example, Chang et al. reported an UPLC-MS/MS method for the analysis of 16 sulphonamides and trimethoprim antibiotics in influent and effluent wastewater and river water using Acquity UPLC BEH C18 column (100 mm × 2.1 mm, 1.7 μm) [32]. The analytes could be separated in less than 6.5 min at a flow rate of 0.3 mL min^{-1} (Fig. 1). As can be seen in the figure, very sharp peaks were obtained with peak widths of 5–10 s at the base, and the 17 analytes were eluted in less than 6.5 min providing short analysis time and high sample throughput. The method detection limits for the 17 analytes were 20–200 pg L^{-1} for the influent, 16–120 pg L^{-1} for the effluent and 8.0–60 pg L^{-1} for the river water.

2.1.1.3. Superficially porous particles. Superficially porous particles, also known as fused-core particles were originally developed in the 1990s by Kirkland. In 2006, sub-3 μm superficially porous particles became commercially available which is considered a major breakthrough in column technology [57]. Introducing superficially porous particles to the markets has provided an attractive alternative option for high speed analysis using conventional LC systems. The use of columns packed with these particles is another approach aiming at shortening the analysis time. Fused core particles could reduce the analysis times while maintaining column efficiencies with relatively low pressures [58,59]. Typical sub-3 μm superficially porous particles consist of a 1.7 μm solid core surrounded by 0.5 μm layer of porous silica, giving a total particle diameter of 2.7 μm. Columns packed with this kind of particles are available under different brand names, such as Halo (Advanced Materials Technology), Ascentis (Sigma-Aldrich) and Poroshell (Agilent). Also, fused core particles with a 1.9 μm fused core and 0.35 μm layer of porous silica coating (i.e. 2.6 μm diameter) are offered under different brand names such as Kinetex (Phenomenex) and Accucore (Thermo Fisher Scientific) [13]. In addition to sub-3 μm fused core particles, superficially porous sub-2 μm particles are becoming available from an increasing number of manufacturers.

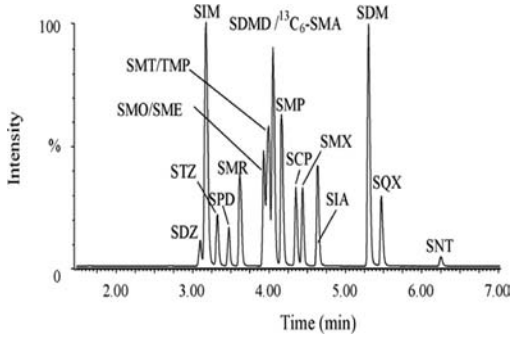

Fig. 1. Chromatogram of 17 analytes separated by LC–MS/MS [32]. Chromatographic conditions: Acquity UPLC BEH C18 column (100 mm × 2.1 mm, 1.7 μm) with a flow rate of 0.3 mL min^{-1}. Peak identification: (sulfamethoxypyridazine (SMP), sulfamoxol (SMO), sulfaquinoxaline (SQX), sulfanitran (SNT), sulfisomidine (SIM), sulfamethoxazole (SMX), sulfamerazine (SMR), sulfathiazole (STZ), sulfadiazine (SDZ), sulfamethizol (SMT), sulfadimidine (SDMD), sulfadimethoxine (SDM), sulfapyridine (SPD), sulfisoxazole (SIA), sulfachloropyridiazine (SCP), sulfameter (SME) and trimethoprim (TMP).

Researchers have conducted many studies aiming at comparing the performance of superficially porous particles to that of fully porous sub-2 μm particles e.g. [18,29,60–62]. From these studies, it can be shown that the use of fused-core silica particles could improve chromatographic column efficiency over fully porous particles. These particles exhibit efficiencies that are comparable to sub-2 μm porous particles, but with lower backpressures. Enhanced efficiency with these particles is due to narrower particle size distribution leading to improvements in the eddy diffusion term. Also, the thin porous shell on fused-core particles allows solutes to diffuse more quickly in and out of the porous structure for interaction with the stationary phase resulting in reduced resistance to mass transfer (the C-term in the van Deemter equation) and allowing operation at higher flow rates without a significant loss in efficiency [60]. Using this kind of column packing in the analysis of pharmaceuticals is limited to food analysis [63–66] and biological fluids [67,68]. Also, several papers describing the use of columns packed with these particles in environmental analysis have been published [69–71]. As an example, Tarcomnicu et al. reported a UHPLC–MS/MS method for the analysis of 15 top-prescribed pharmaceuticals and their metabolites in influent wastewater using a Kinetex C18 column (100 mm × 2.1 mm, 2.6 μm particle size) [69]. By working at a mobile phase flow rate of 0.2 mL min^{-1} under gradient elution, a fast chromatographic separation in 9 min was achieved. In another study, Pedrouzo et al. could separate 10 drugs of abuse and their metabolites in waste and surface waters in 13 min [70]. The analysis was performed on fused-core Ascentis Express C18 column (50 mm × 4.6 mm × 2.6 μm) using a flow rate of 0.4 mL min^{-1}. Bratkowska et al. could separate seven polar pharmaceuticals in wastewater and surface water in less than 13 min using C18 Kinetex column (100 mm × 4.6 mm × 2.6 μm) at a flow rate of 0.6 mL min^{-1}. However, all these studies were limited to few compound classes and/or small numbers of analytes. The use of columns packed with fused core particles was also extended to cover a larger number of pharmaceuticals from a wide range of classes. As an example, Shaaban and Górecki [72] reported a UPLC–UV method for the analysis of 25 emerging contaminants including veterinary antibiotics, CNS stimulants, non-steroidal anti-inflammatory drugs, steroids and preservatives from personal care products in wastewater and surface water in only 10 min (Fig. 2). In this study, all the studied analytes could be fully separated using a C18 Kinetex column (150 mm × 4.6 mm × 2.6 μm) at a flow rate of 1 mL min^{-1}. Achieving the analysis in a short time with low flow rate resulted in solvent savings, making the analysis green. Compared to separations performed on conventional stationary phases, using superficially porous particles can be considered a powerful approach to achieving fast green separations on conventional LC systems.

2.1.1.4. High temperature liquid chromatography. One of the ways to reduce the analysis time when conventional RP–LC systems are used is increasing flow rates while using ambient operating temperatures. Working at high temperature is a promising approach to increase the analysis speed. Elevated column temperature can be used as a tool to overcome the flow rate problem associated with high back pressure, allowing the use of flow rates that otherwise could not be applied [73].

In 1969, the term high temperature liquid chromatography (HTLC) was introduced [74]. HTLC is LC analysis performed at temperatures above ambient and below supercritical [75]. By increasing temperatures, the analysis conditions could be improved because some physical parameters playing an important role in HPLC, such as viscosity, mobile phase polarity or diffusivity depend strongly on temperature [76]. Antia and Horvath showed that increasing the separation temperature is a very efficient tool for large molecule separation [77]. Later on, in 1995, Chen and Horvath presented an extremely high speed separation of four proteins at 120 °C in less than 10 s [78].

Using high temperatures in HPLC offers many significant advantages. By increasing the temperature, the viscosity of the mobile phase will be decreased resulting in reduced backpressure. This allows the use of small particle size packing, long columns and increasing the column length through coupling. Elevating the temperature from ambient (20 °C) to about 50 °C causes a decrease in solvent viscosity by ~50% [79]. Consequently, it becomes possible to double the column length at the same linear velocity to double the efficiency, or to operate the same column at an approximately twice faster flow rate to provide about twice faster analysis with nearly the same efficiency [14]. Also, increasing the temperature leads to an increase in the optimal mobile phase linear velocity. Under the maximum operating pressure, the main benefit of an increase in the temperature is a reduction in the analysis time. In addition to decreasing the analysis time, reduction in mobile phase consumption could also be achieved leading to greener analysis.

Another benefit of using high mobile phase temperature is that the change in the dielectric constant of water makes it less polar and allows reducing the percentage of organic solvent in the mobile phase [75]. Also, by increasing temperature the partition coefficients of the analytes between the mobile phase and the stationary phase is decreased leading to a reduction in the organic solvent percentage in the mobile phase in order to maintain the same retention otherwise, the analytes would elute earlier (but at lower resolution). Both these phenomena make HPLC analysis at elevated temperatures greener than at room temperature. Also, operation at high temperature could enhance the mass transfer of the solutes in the mobile phase due to the increase in the diffusion coefficients of the molecules in the solvent. According to the Wilke–Chang equation, the diffusion coefficient is directly proportional to temperature and inversely proportional to viscosity. Consequently, by increasing the temperature, diffusion of the analytes in the mobile and stationary phases increases, and the minimum plate height (H) in the van Deemter curve shifts to higher linear velocities allowing the use of higher flow rates without compromising the efficiency [75,80]. Other advantages of using high temperature in LC separations are discussed elsewhere [81,82]. On the other hand, using high temperature in LC has some limitations. For example, the availability of packing materials stable at temperatures higher than 80 °C is very limited. Also, potential degradation of thermolabile analytes and the need to have constant temperature along the chromatographic system is of great concern [74]. To successfully implement HTLC, a special instrumentation is required including a mobile phase preheater, column heater and post column effluent cooling system. The use of a specially designed heating system allows the benefits of high eluent temperatures to be accomplished. The instrumental design used for HTLC should minimize both thermal mismatch and extra-column band broadening. Thermal mismatch results from insufficient mobile phase preheating and viscous heat dissipation across the column length, leading to thermal gradients both longitudinally and radially. While radial thermal gradients decrease efficiency, longitudinal thermal gradients affect solute retention factors. Also, in order to minimize extra-column band broadening, the system used should have low dead volume [73].

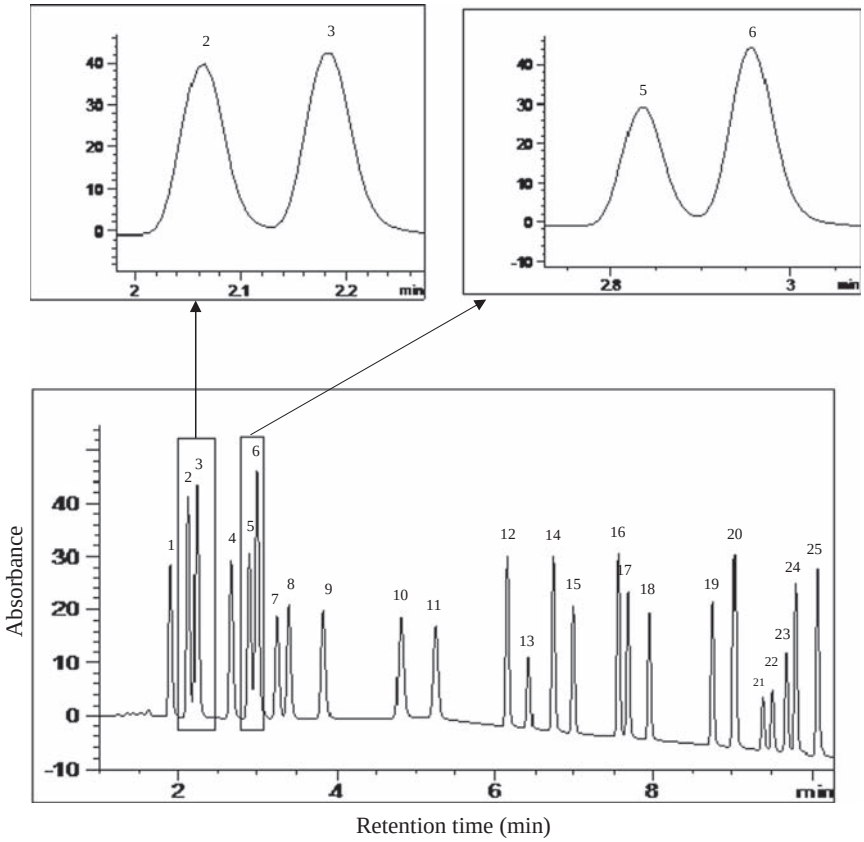

Fig. 2. Chromatogram of analytes separated on a column packed with fused-core particles [72]. Chromatographic conditions: Zorbax Stable Bond C18 columns (150 mm × 4.6 mm × 1.8 μm) at 30 °C using gradient elution. The gradient used for the analysis was 0 min, 15% acetonitrile and flow rate 1 mL min^{-1}; 3 min, 15% acetonitrile and flow rate 1.3 mL min^{-1} then increasing to 82% acetonitrile at 10 min with flow rate 1.3 mL min^{-1}. The equilibrium time was set to 5 min. Peak identification: 1—sulphanilamide, 2—theophylline, 3—acetaminophen, 4—sulfacetamide, 5—caffeine, 6—sulfadiazine, 7—sulfathiazole, 8—sulfapyridine, 9—sulfamerazine, 10—sulfamethazine, 11—sulfamethoxypyridazine, 12—sulfamonomethoxine, 13—acetyl salicylic acid, 14—sulfamethoxazole, 15—methylparaben, 16—sulfadimethoxine, 17—sulfaphenazole, 18—ethylparaben, 19—propylparaben, 20—ketoprofen, 21—17 α-ethinyl estradiol, 22—estrone, 23—fenoprofen, 24—flurbiprofen and 25—diclofenac. The inset shows baseline separation of peaks 2, 3 and 5, 6.

However using elevated mobile phase temperatures provide many advantages, the technique is not routinely used in environmental analysis and its applications have been typically limited to temperatures not exceeding 60–80 °C with conventional solvents. Until now, the approach of using a high mobile phase temperature in pharmaceutical industry is not common in everyday routine analysis. Due to the low availability of packing materials stable at high temperatures and the thermal instability of some analytes, the use of high temperature LC separations in the environmental area is limited. However, some environmental applications at high temperature are described in the literature. For example, an UPLC–UV method for the analysis of nine sulfonamides in surface water and wastewater at elevated temperature was reported [47]. In this study, nine sulfonamides could be fully separated on a single Zorbax SB C18 column (150 mm × 4.6 mm, 1.8 μm particle size) at 60 °C in only 3 min using a flow rate of 1.5 mL min^{-1} (Fig. 3). By increasing temperature to 60 °C, the percentage of the acetonitrile as an organic modifier could be reduced to 20% resulting in reducing solvent consumption and making the analysis green. Also, extending column length through coupling at elevated temperature and its use for the analysis of pharmaceuticals in wastewater has also been reported in the literature. Eight sulfonamides were determined in wastewater samples at 80 °C with very high efficiency in less than 16 min using isocratic elution on three coupled columns (3 × 150 mm × 4.6 mm, 1.8 μm particle size) [83]. Also, coupled columns have been used in a gradient mode of separation for the analysis of a large number of pharmaceuticals. For example, Shaaban & Górecki separated 24 pharmaceuticals (sulfonamides and non-steroidal anti-inflammatory drugs) in a wastewater sample in less than 27 min with very high efficiency using this technique [84].

The use of high mobile phase temperature in combination with ultra-high pressure liquid chromatography is a promising approach aiming at increasing the analysis speed without compromising efficiency and minimizing the organic solvents consumption. To the best of our knowledge the use of temperatures higher than 80 °C for the analysis of pharmaceuticals in aquatic environmental samples has not been reported thus far. Several environmental applications of HT–UPLC with separations performed at temperatures above 100 °C have been described in the literature. As an example, Thomas described the analysis of triazine herbicides in surface, ground and municipal drinking water by UPLC at 160 °C [85]. In this study, 12 herbicides was separated in less than 2.5 min with a flow rate of 0.5 mL min^{-1} using a Hypercarb porous graphitic carbon column (100 mm × 1 mm, 3 μm particle size) (Fig. 4). Only 20% acetonitrile was used as an organic modifier at high temperature (160 °C) leading to a reduction in the consumption of organic solvents. The use of pure water as an eluent for the environmental analysis of pharmaceuticals in water compartments has not been reported in the literature. Development of packing materials stable at very high temperature is highly needed in the near future to enable exploring high temperature liquid chromatography applications in environmental analysis.

2.1.2. Reduction in system dimension

As discussed before, the consumption of organic solvents can be reduced by speeding up the analysis via using monolithic columns, fully porous sub-2 μm particles with very high pressure systems, superficially porous particles and high mobile phase temperatures. However, not all these fast chromatographic approaches allow reduction in solvent use. Other ways to reduce solvent consumption is to decrease the column volume via shortening its length or reducing its internal diameter, and to miniaturize the whole chromatographic system.

2.1.2.1. Reduced column length and diameter. Because of the high cost of UPLC systems, their availability in many laboratories is not common. Therefore, using conventional HPLC systems with reduced column dimensions is another alternative to reduce the solvent consumption. A direct way to shorten the analysis time is decreasing the column length [13]. However, using short columns has some drawbacks such as loss of resolution. In order to compensate for the loss in efficiency resulted from using shorter column lengths, a simultaneous reduction in particle size is necessary.

To obtain the maximum number of plates at the optimal velocity (u_{opt}) when the internal diameter of the column is reduced, the flow rate has to be reduced by a factor (F) according to the following equation [31]:

$$F_2 = F_1 \times \frac{r_2}{r_1} \quad (5)$$

where F_2 and r_2 are the flow rate and the radius for the smaller diameter column, and F_1 and r_1 are the flow rate and the radius for the larger diameter column.

Upon reducing the column diameter from 4.6 to 3 mm, the flow rate has to be reduced by a factor of 0.43 resulting in a 57% reduction in solvent consumption and waste generation [5]. Upon switching from a standard 4.6 mm I.D. column to a narrow bore 2.1 mm I.D. column, F equals 4.8. When a 4.6 mm column is

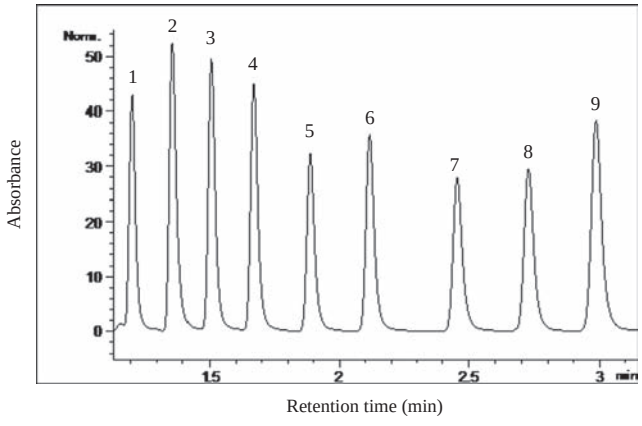

Fig. 3. Chromatogram of separation of the studied sulfonamides [47]. Chromatographic conditions: acetonitrile:water containing 0.5% acetic acid (20:80 v/v) at 60 °C and a flow rate of 1.5 mL min^{-1} with UV detection at 272 nm. Peak identification: 1—sulfanilamide, 2—sulfisomidine, 3—sulfacetamide, 4—sulfadiazine, 5—sulfapyridine, 6—sulfamerazine, 7—sulfamethoxypyridazine, 8—sulfamethazine, 9—sulfamonomethoxine.

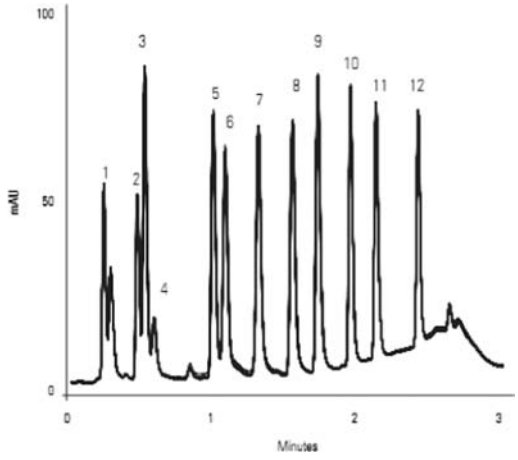

Fig. 4. Chromatogram of separation of 12 triazine herbicides [85]. Chromatographic conditions: a Hypercarb graphitic carbon column (100 mm, 1 mm, 3 μm particle size) at 160 °C. Peak identification: 1. melamine, 2. unknown, 3. deisopropylatrazine, 4. desethylatrazine, 5. cyanazine, 6. propazine, 7. prometryn, 8. atrazine, 9. ametryn, 10. simazine, 11. simetryn, 12. propanil.

operated at 1 mL min^{-1}, the 2.1 mm column should be operated at 0.21 mL min^{-1} [31]. Thus, a narrow bore column of 2 mm I.D. uses approximately one-fifth of the solvent that a wide bore column of 4.6 mm uses when run at the same mobile phase linear velocity; a 1.0 mm microbore column uses 1/20 of the solvent consumed with a 4.6 mm i.d. column [4].

In addition to a reduction in solvent consumption, small diameter columns could increase sensitivity due to the reduction in dilution of the solutes in the mobile phase and the appearance of more concentrated bands at the detector [31]. Another advantage of using narrow bore columns is faster heat dissipation compared to standard columns, so the use of narrow bore columns is highly preferred when very high pressure is used [13].

UPLC fast analysis technologies using short columns with smaller diameter packed with smaller particles and operated at high pressures offer a greener alternative to conventional HPLC. Chen and Kord demonstrated that a UPLC system with a narrow bore column (2.1 mm) offers ~80% solvent savings compared to conventional HPLC [86]. Using narrow bore columns (2 or 2.1 mm) with standard particle size packing (2.5–5 μm) for the pharmaceutical analysis in the aquatic media is well documented in the literature [82,87–95]. The use of UHPLC systems with narrow bore columns packed with small particles (sub-2-μm) has also reported (see Table 1). Because of its high selectivity and sensitivity, MS becomes the technique of choice for detecting pharmaceuticals in environmental samples. Using MS as a detection method provide many advantages such as the confirmation of the identity of the studied compounds, especially when complex matrices such as environmental samples are used. In addition, MS is a greener technique than using UV detection because when MS is used, smaller internal diameter columns ($\leq$2 mm) are preferred due to the increased sensitivity of the instrument and inability to cope with the larger amounts of solvent vapour from larger internal diameter columns ($\geq$4.6 mm) [4]. Among different kinds of mass analyzers, triple quadrupole is the most commonly used mass analyzer in the analysis of pharmaceuticals in the aquatic environment (Table 1). Other MS analyzers such as quadrupole-linear ion traps have also been used for UPLC applications (Table 1). High resolution MS using e.g. hybrid Q-TOF analyzers has also been proposed for the analysis of pharmaceuticals in environmental water samples [42,44,46,67,96,97].

UV detection has also been reported for the analysis of pharmaceuticals in the environmental water samples. For example, the analysis of nine pharmaceuticals in surface water and wastewater using UPLC–UV method in only one minute was reported [48]. In this study, nine pharmaceuticals (sulfonamides, NSAIDs and CNS stimulants) could be fully separated on a short narrow bore Zorbax SB-AQ column (30 mm × 2.1 mm, 1.8 μm particle size) in only 1 min using a flow rate of 1 mL min^{-1} (Fig. 5a). The real chromatogram of waste water sample showing acetaminophen separated from other interferences is presented (Fig. 5b). Unlike LC–MS, LC–UV detection lacks the ability to provide compound confirmation. Therefore in this study the specificity and the selectivity of the method were evaluated by studying the peak purity index values including purity factor (similarity factor), threshold limit, and purity ratio (similarity ratio) for each analyte. Similarity ratio values below unity indicate spectrally pure peaks, while values above unity indicate spectrally impure peaks. For all the studied analytes, similarity ratios were below unity indicating that no significant differences between the spectra could be observed. Consequently, the peaks were considered pure, with no coelution [48]. In this method, a significant reduction in solvent consumption was achieved, as the volume of the mobile phase consumed in each run was only 1 mL. Achieving the LC separation in less than 1 min is widely known as ultrafast analysis [13]. The method could be used as an alternative to traditional approaches, making the analysis of pharmaceuticals greener.

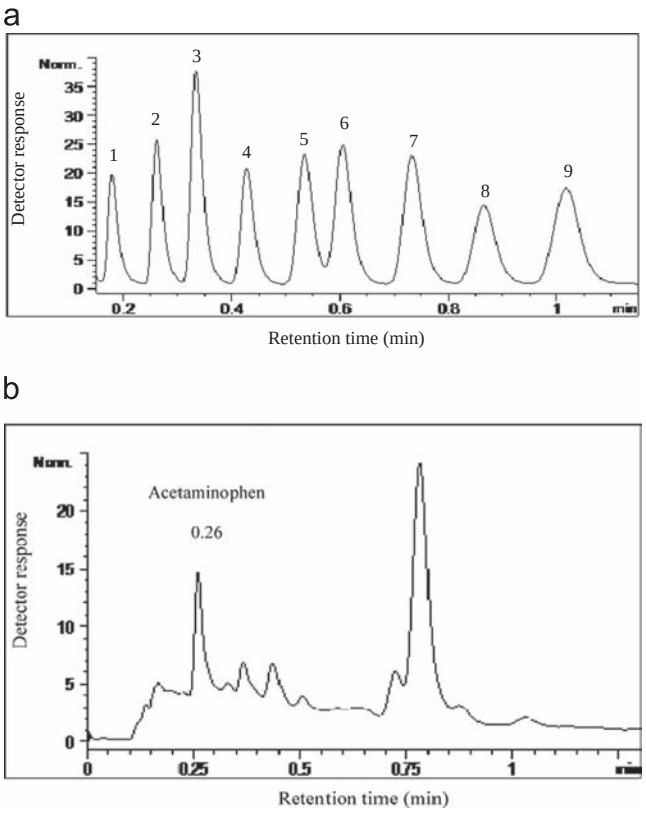

Fig. 5. (a) Chromatogram of separation of the studied pharmaceuticals with UV detection at 272 nm and (b) chromatogram of wastewater sample extract showing detection of AMPH at a detection wavelength of 247 nm [48]. Chromatographic conditions: acetonitrile:water containing 0.5% acetic acid (85:15 *v*/*v*) at 30 °C and a flow rate of 1 mL min^{-1}. Peak identification: 1—sulfanilamide, 2—acetaminophen, 3—theobromine, 4—theophylline, 5—sulfathiazole, 6—sulfamerazine, 7—caffeine, 8—sulfamethoxypyridazine, 9—sulfamethoxazole.

Table 2
classification of LC techniques according to the internal diameter and the impact on the flow rate [31].

LC techniques	Column diameter (mm)	Flow rate (μL min^{-1})
Conventional LC	4.6	1000
	4.0	750
	3.0	430
Narrow-bore LC	2.1	210
	2.0	100
Micro-LC	1.0	47
Capillary LC	0.5	11
Nano-LC	0.1	0.5

2.1.2.2. Micro-flow and capillary HPLC. The substitution of all toxic reagents employed in chemical analysis is not easy, so reduction of the amounts employed should be also considered [1]. Min iaturization is considered a promising approach in solvent savings. Recently, using microflow chromatography to reduce the use of organic solvents has gained great interest [5]. This approach focuses on reducing the overall scale of the analytical instrument. Table 2 shows the classification of LC techniques according to the internal diameter, flow rate and sensitivity [31]. Using microflow chromatography provides many advantages. For example, microflow LC systems allow the use of flow rates of microliters rather than milliliters per minute used with conventional instruments, leading to great reduction in solvent consumption and waste generation. These instruments can be operated automatically resulting in less than 10 mL of waste during 24 h of analysis [5]. Another advantage of

using microflow chromatography is that a small fraction of the chromatographic stationary phase is needed for column packing [5]. Also, micro-LC is preferred when MS is used for the detection. Fast analysis using microflow chromatography with low solvent consumption is well documented in the literature [5] (Fig. 6). In this example, only 39 μL of solvent was used to separate the analyte mixture on a 300 μm I.D. column, whereas 12 mL of solvent per analysis were needed when a standard column of 4.6 mm I.D. was used. While solvent savings of microscale LC has been demonstrated theoretically and experimentally, there are also some drawbacks relates to sensitivity such as lower limit of detection arising from UV-detector limitations [5]. Because of relatively small volumes of injected sample in the ranges of 10–60 nL and 1–50 μL (nano-LC and CLC, respectively), the sensitivity with these techniques can be questionable for the analysis of real samples [98]. It is more problematic for the low level quantitation required in metabolite and trace impurity studies [5]. Several studies have been carried out to solve this problem by using more sensitive detectors such as MS and/or applying sample pre-concentration (off- and on-column) [98].

However micro-LC columns allow great reduction in solvent use, their application in routine analysis is very limited because of the difficulty in column packing, instrumental requirements, and lower plate numbers compared with similar columns in terms of length and particle size [31]. Using columns of 1 mm I.D. in environmental analysis is not widely common. Only few studies were reported for the analysis of pharmaceuticals in the aquatic environment. As an example, Kasprzyk-Hordern et al. could separate 28 pharmaceuticals and illicit drugs in surface water using micro-LC column of 1 mm internal diameter in 15.5 min with a flow rate of 70 μL min^{-1} and resulted in solvent consumption of less than 1.1 mL run^{-1} [35]. In another study, the same author separated 65 stimulants in wastewater and surface water in 23.1 min on a micro-LC column with a flow rate of 40 μL min^{-1} and resulted in the use of ~0.9 mL of solvent per run [41]. Also, using a column of 0.5 mm I.D. with a flow rate of 20 μL min^{-1} is reported for the determination of vitamin E in cosmetic products [99]. Miniaturization to nano-columns and using LC-chip columns have also been reported [4]. These columns can interface directly

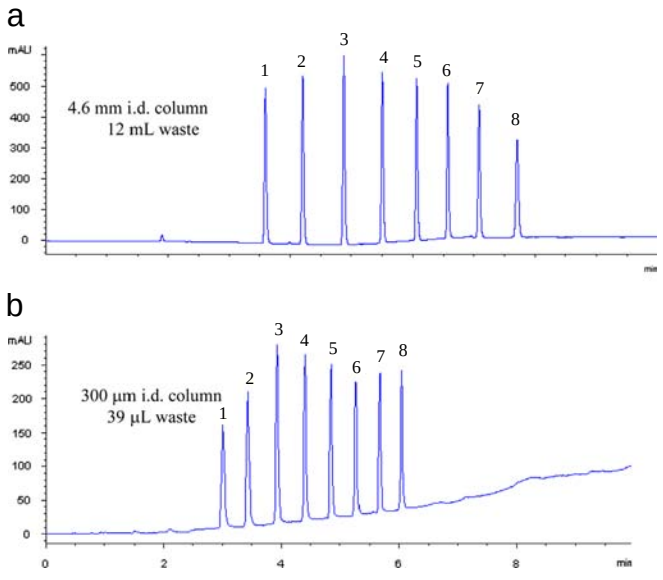

Fig. 6. Chromatogram of separation of an alkyl benzene mixture separated [5] on (a) conventional HPLC using 4.6 mm i.d. column at 1.5 mL min^{-1} requiring 12 mL of solvent per analysis; and (b) microscale HPLC using 0.3 mm i.d. column at 6 μL min^{-1} requiring only 39 μL of solvent per analysis. Chromatographic conditions: Gradient elution 50–95% acetonitrile in water over 5 min, then 95% in 1 min using Agilent SB-18, 150 mm, 3.5 μm particles and UV detection at 220 nm.

to a nanospray LC–MS system. Nano-LC instruments using a few hundred nanoliters of the mobile phase per minute are now commercially available [4]. Capillary and nano-LC columns have been applied mainly to proteomics and food analysis [100]; they found limited applications in environmental analysis. Using nano-LC systems as "green" techniques requires instrument adjustments, including minimizing extra-column volumes through decreasing pump, injector and detector cell volumes, as well as the volumes of all connections between the injector and the detector [4].

2.2. Replacement of existing solvents with green alternatives

Replacing toxic solvents with greener alternatives is another strategy aiming at reducing the solvent consumption. The most commonly used solvent in LC separations is acetonitrile. Because of its unique characteristics, such as the ability to dissolve a wide range of solutes, low acidity, minimal chemical reactivity, low UV cut-off and low viscosity [31], it is considered the solvent of choice for RP–LC separations [101]. Even though the unique characteristics of acetonitrile, it is less preferred as a green solvent because of its flammability, volatility and toxicity. Consequently, HPLC wastes containing acetonitrile must be properly disposed of, which is costly and might be harmful to the environment [5]. Green alternatives such as water, acetone, ethanol and carbon dioxide are environmentally friendly and can replace acetonitrile in some LC applications [31].

2.2.1. Use of ethanol in RP–HPLC

Ethanol has characteristics similar to acetonitrile but with less toxicity, lower disposal costs and less volatility, allowing higher stability of the mobile phase composition upon long [31]. However, the use of ethanol with conventional LC systems (400 bar) is hindered because of its high viscosity. With the development of UPLC instrumentation providing pressures $\geq$1000 bar, the viscosity is no longer considered a critical problem. Replacement of acetonitrile with ethanol as an organic modifier is a new approach aiming at greening the RP–LC analysis where ethanol/water is used as the mobile phase. In this case, all incoming solvents and outgoing waste are compatible with the environment. The tendency to use ethanol in place of acetonitrile or methanol in LC separations has been evidenced by the gradually increasing number of publications [102–108]. Also, substitution of acetonitrile as organic modifier by mixtures of propylene carbonate and ethanol may be considered a greener approach for pharmaceutical applications [109]. Propylene carbonate (R,S-4-methyl-1,3-dioxolan-2-one) is a carbonate ester derived from propylene glycol, synthesized by means of more or less green processes, often used as a polar aprotic solvent in analytical chemistry and organic synthesis. Such a replacement is achievable without any major compromise in terms of elution order, chromatographic retention, efficiency and peak symmetry [109]. Considered in both analytical and sustainable viewpoints, the mixture of ethanol and water is an effective alternative mobile phase for RP–LC methods.

2.2.2. Replacement of organic modifiers with pure water (superheated water chromatography)

Greening the analysis by replacing traditional solvents with green alternatives can also be achieved by replacing the organic modifier with pure hot water. In recent years, the use of pure water as an eluent has been received a great interest and studied by a number of researchers. This approach is known as "Superheated Water Chromatography" (SHWC), "Subcritical Water Chromatography" or "Chromatography in Very Hot Water" [110]. SHWC is a green alternative for conventional RP–LC separations where

the mobile phase used is a mixture of water with acetonitrile or methanol [5].

At elevated temperatures, dielectric constant of water decreases and water becomes a stronger solvent resulting in increasing the solvent strength. Therefore pure water can be used as an eluent in RP–LC [75]. For example, at 150 °C, the dielectric constant of water is reduced to that comparable of a mixture of 50:50 *v*/*v* methanol–water at ambient temperature. Elimination of organic modifier allows LC separations to be completely "green" [111]. Using water as an eluent provides attractive advantages such as non-toxicity and wide availability. In addition, waster is inexpensive, non-flammable and environmentally friendly [5]. Also, using pure water as a solvent allows the possibility of hyphenation with non-conventional detectors, e.g. flame ionization detector (FID), which is desirable for UV-transparent compounds [110]. Furthermore, using pure water allows UV detection to be carried out at very short wavelengths (~190 nm), allowing the detection of many analytes that do not absorb at longer wavelengths [110]. Besides, the compatibility of heated effluents with MS detectors has been shown to increase the ionization efficiency and signal to noise ratio (S/N) for some compounds [75].

To implement SHWC, special instrumentation is required as described before. However, alkyl silane-bonded phases are the most popular in RP–LC; they show thermal and chemical instability [112]. Conventional alkyl silane-bonded silica phases are typically unstable at temperatures above 50 °C since higher temperature accelerates the dissolution of silica in aqueous solutions. At temperatures above 100 °C, silica-based C18 phases are rapidly degraded with water as the mobile phase [113]. Another drawback of these stationary phases is the degradation at pH outside the range of 2.5–8. To overcome the problem of thermal and chemical instability of alkyl silane-bonded silica phases, different approaches have been developed such as grafting an organic protective layer on the silica surface, modifying silica with bonding and endcapping technologies and synthesizing hybrid particles resulting in organic groups incorporated into the silica matrix [110]. Also, alternative packing materials have been developed to withstand high temperatures, including metal oxide-based columns, porous graphitic carbon and organic polymers such as polystyrene-divinylbenzene (PS–DVB). However SHWC has attractive features, this technique has some limitations such as potential on-column degradation of thermally labile compounds and insolubility of hydrophobic compounds in water [5].

Pharmaceutical analysis is an area of particular interest for SHWC. The use of pure water as a mobile phase in pharmaceutical analysis is reported in the literature [114–118]. For example, six anticancer drugs were separated on a polystyrenedivinylbenzene (PS–DVB) column with buffered superheated water as a mobile phase using temperature range from ambient temperature up to 160 °C [114]. Good separation for all analytes is achieved. The use of SHWC in analysis of environmental pollutants is also reported [119–122]. In environmental analysis, analyte stability is important and before any quantitative work is carried out it is necessary to check recoveries and ensure that the high temperatures don't result in artefact peak formation [123].

2.2.3. Replacement with carbon dioxide

Another approach in greening LC separations is the use of carbon dioxide either in a liquid state, or as a supercritical fluid. In supercritical fluid chromatography (SFC), the chromatographic eluent is usually the pressurized carbon dioxide in the supercritical state with a polar modifier, such as methanol or ethanol, and very small amounts of acid or base as additives to improve the peak shapes of the analytes [124,125]. Pressure must be controlled to keep carbon dioxide in the supercritical form. Upon depressurization, carbon dioxide returns to gas phase allowing the recovery of non-volatile analytes [5]. Carbon dioxide provides many advantages as a green alternative such as it is non-toxic and environmentally friendly. Also, in the supercritical state it has low viscosity allowing high flow rates to be used leading to faster separations. The optimal linear velocity for SFC is approximately three times greater than for HPLC [126]. With SFC, the consumption of organic solvent can be reduced to 88–98% compared to normal-phase HPLC [5]. Also, using carbon dioxide provides high diffusivity and highly efficient separations [101].

Recently, SFC popularity has increased because of its greener character and wider availability of commercial instrumentation, including accessories that can convert a conventional HPLC system to one with SFC capability. SFC is regarded as a separation technique for non-polar substances and also can be applied to polar and chiral compounds, as well as to drugs and proteins. The application of SFC for separation of pharmaceuticals is also reported [127,128]. SFC is used increasingly for analytical, semi-preparative and preparative scale purification of chiral compounds, including production of enantiomers [24,129]. SFC can be used as an alternative to LC for many drug substances, so it is gaining popularity in the pharmaceutical industry. Because of its high speed, short analysis time, limited environmental impact, low organic solvent consumption, SFC fulfills all the requirements of green analytical chemistry approaches [128]. The use of SFC in the environmental analysis of organic contaminants is reported [130–132].

In addition to using carbon dioxide as a supercritical fluid, it can also be used in the liquid state under appropriate pressure and temperature as a component of the mobile phase providing fast and efficient separations. The technique is known as enhanced fluidity chromatography [101].

Nowadays, the interest in hydrophilic interaction chromatography (HILIC) has been increasing and at present it is considered the preferred LC mode for the separation of polar and ionizable compounds such as pharmaceuticals. In HILIC, separation is achieved by partitioning between a water-enriched layer on the surface of a polar stationary phase and a mobile phase that contains a high percentage of an organic solvent such as acetonitrile. Using HILIC in the environmental analysis of pharmaceuticals is well documented in the literature [69,133–138]. Because using a high percentage of acetonitrile in HILIC is not a green approach, Pereira et al. proposed the use of enhanced-fluidity liquid (EFL) in HILIC by adding liquid carbon dioxide to the mobile phase composed of ethanol–water [139]. Using enhanced fluidity mode (water/ethanol/CO_2) allows HILIC separations to be performed in a greener fashion with the same performance as when using water/acetonitrile [139]. The application of EFL mobile phases in HILIC mode for the analysis of nucleosides and nucleotides is reported in the literature [140,141]. Nucleosides and nucleotides are compounds of interest for pharmaceutical chemistry. To the best of our knowledge, EFL mobile phases in HILIC mode have not been used in environmental analysis. In the near future, this trend is likely to receive more attention by researchers aiming at greening HILIC separations.

Ionic liquids are also considered as green solvents. Recently, ionic liquids have been used as additives in LC to improve the peak shape by pairing ion mechanism [142]. For green solvent selection, an ionic liquid could be a potential candidate for LC. The use of ionic liquids has attracted considerable interest because of their unique properties (e.g. electric conductivity, low volatility, thermostability) and an increasing number of publications focus on their use in preparing stationary phases of LC [143].

More recently, the use of micellar mobile phases containing nonionic surfactants has been explored as a green approach aiming at eluting compounds without the need of adding an organic solvent. The application of micellar mobile phase with LC for separation of pharmaceuticals is reported [144,145]. Also, the use of two-dimensional LC (2DLC) for the analysis of pharmaceuticals in

complex matrices has gained more interest such as [146]. Fast separations can be achieved in the second dimension by using high temperature LC, which is a green approach, and/or using short columns. On-line 2DLC may be considered a green technique because it allows reduction in solvent consumption and waste generation, prevention of sample contamination or sample loss, possibility of automation and shorter analysis time compared to off-line mode [24].

3. Green aspects of gas chromatography

GC is a separation technique that does not use solvents but relies on the separation of the analytes in the gas phase. It is used mainly for the analysis of semi-volatile and volatile compounds. GC is considered a green approach because its eluents are usually helium and hydrogen, which are gases harmless to the atmosphere. However helium is the most commonly used carrier gas in GC because of its high optimum linear velocity, non-toxicity, non-flammability and inertness, helium is a non-renewable resource [24]. With the awareness about the run out of this precious gas, hydrogen seems to be the best alternative as a carrier gas in GC. Its van Deemter curve is very flat which allows separations to be conducted at higher flow rates with little loss in efficiency leading to short analysis time. One approach to make GC greener is the reduction of the analysis time leading to increased sample throughput which is commonly referred as fast capillary GC. This may be achieved by using shorter columns with small internal diameter without sacrificing separation and resolution. Fast GC reduces overall analysis time leading to significant savings in time and energy [147]. Fast chromatography can be especially attractive for laboratories where many routine samples are analyzed every day. It can also be advantageous when quick results are needed. Increasing column temperature during GC analysis is referred to temperature-programmed GC (TPGC). The use of temperature programming in GC is an important parameter which provides many benefits such as better separation for solutes with a wide boiling points range, improved peak symmetry and improved detection limits [24]. The use of programmed temperature vaporizers for environmental analysis is well documented in the literature such as [148–154]. To achieve ultrafast temperature programming, low thermal mass technology (LTM) which introduced in 2001 [24]. LTMGC is considered a green technique aiming at greening GC separations because resistive heating of a GC column can reduce the power consumption by approximately a factor of 200, and increase the column heating speed (up to 1800 $^{\circ}$C min^{-1}; achievable rates depend on column mass, configuration and column void times), which can potentially reduce the analysis time [24]. Another technology introduced to make GC greener is the resistively heated nickel-clad fused silica columns [155]. This technology is considered green because it allows rapid heating and cooling with low power consumption making it suitable for fast GC analysis and for portable instruments [24]. However the main tool for the analysis of pharmaceuticals in most studies is LC due to the polarity of pharmaceuticals, many analytical methods based on GC–MS have been developed to determine various pharmaceuticals in different environmental samples such as [156–165].

4. Application of direct chromatographic techniques

The application of direct chromatographic techniques is a step forward in reducing the environmental impact of chromatographic analyses. Direct chromatographic analysis allows the determination of analytes in a sample without any pre-treatment or sample preparation which is the most polluting step in the entire chromatographic analysis [166]. The use of direct methodologies is limited only to samples with relatively clean matrices [24], otherwise the chromatographic columns might quickly deteriorate due to deposition of sample components that do not elute from the column. GC methods are usually more readily adaptable to the elimination of sample preparation step than LC. The early work on direct GC methods was focused on the development of on-column injection. The application of on-column GC for the environmental analysis in water is documented in the literature such as [167–173]. Another approach of using direct GC is to prevent the solvent from reaching the column by using a liner filled with sorbent [174]. The use of GC with sorbent-packed liner for the analysis of environmental pollutants is reported [175,176].

LC methods are less amenable to eliminating sample pre-treatment as it requires the injected sample to be absolutely clean, so there are hardly any absolutely direct LC methods. However, there are some successful applications of direct LC methods in environmental analysis such as [177–183]. Application of direct chromatographic methodologies is considered a green approach aiming at greening the analysis because it provides reduction of analysis time and elimination of sample preparation step which allows placing the chromatograph at-line or on-line, which may further reduce the analysis time. These benefits lead to minimizing environmental impact of chemical processes through real-time monitoring.

5. Placing the chromatograph with respect to the investigated medium

The traditional approach of chromatographic analysis involves collection of the sample, sample pre-treatment followed by final analysis. All of these activities generate negative environmental impact. Therefore, locating the chromatograph on-line or at-line may reduce the analysis time and minimize the consumption of reagents. The shorter time of analysis and the possibility of locating the chromatograph on-line or at-line is a step towards fulfilling the need for the real-time monitoring of chemical processes. On-line chromatography is achieved when the analytical device is located near the investigated medium. In this case, sample is collected and analyzed periodically and automatically and on-line sample preparation is usually applied [2]. The advantage of using on-line chromatography is minimal loss of sample representativity because sample is directly analyzed without being transported nor stored. Application of on-line chromatographic techniques in environmental analysis is documented in the literature [184–187]. In addition to on-line mode, at-line is also known where the analytical device is brought to the investigated medium by the analyst. In this case, sample is analyzed at the site of collection. Environmental analysis using at-line chromatographic techniques is also documented [188–191].

6. Green aspects of biological techniques

Biological methods are used for screening and diagnosis of organic compounds in environmental samples of water, sludge and sediments. The most relevant biological techniques or bio-detectors applied to environmental analysis can be classified according to their technical principles into (bioassays, immunoassays and biosensors) or the type of measurement (screening method and specific measurement) [192]. Immunoassays are based on the reversible binding of antibodies with antigens. The binding properties of an antibody to an antigen have been used for the development of a wide variety of analytical techniques applicable in environmental monitoring [193–196].

Immunoassays are considered as green techniques because they provide rapid analysis, simple sample pre-treatment, low volumes of sample required and low use of solvents, reduced energy consumption and possibility of in situ analysis [3]. The main drawbacks of these techniques are poor thermal and chemical stability of immune-reagents, cross reactivity between structurally-related compounds, and possible matrix effects. At present, most immunochemical advances in environmental analysis have been carried out using enzyme-linked immunosorbent assays (ELISAs). Several methods have been used for the environmental analysis of emerging pollutants using ELISAs [46,197–202]. Biosensors are also considered green because of its capabilities of automation, miniaturization, on-line and at-site analysis, with minimal waste production and energy cost. Biosensors are chemical sensors that use active, biologically derived components integrated with a suitable transducer [3]. It is capable of providing specific quantitative or semi-quantitative analytical information. Several reviews on biosensors and biological techniques for environmental analysis have been published in recent years [203,204].

7. Conclusions

Chromatographic techniques have the potential to be greener at all steps of the analysis. Greening LC separations becomes the main goal for many researchers aiming at reducing solvent usage and protecting the environment from hazardous effect of organic solvents. Traditional methods used for the analysis of pharmaceuticals require large volumes of organic solvents with large volumes of waste production. So developing green methods is highly demanded aiming at eliminating or reducing the amount of organic solvents consumed while maintaining the chromatographic performance. In this review, recent trends for greening LC analysis have been discussed. Many strategies have been developed to save solvent consumption such as shortening the analysis time or replacing the traditional organic modifiers used in RP–LC with safe alternatives. These options offer many benefits both environmentally and economically. Fast green separations can be achieved by using high mobile phase temperature, fully porous sub-2 μm with UPLC systems and superficially porous particles. GC is a relatively green separation method because its eluents are usually helium and hydrogen, which are gases harmless to the atmosphere. Faster GC separation can be achieved by reducing the inner diameter and the length of the capillary columns, working above optimal carrier gas velocities and using fast temperature programming. SFC is also considered as green technique because it fulfills all the requirements of green analytical chemistry approaches. Carbon dioxide is non-toxic and environmentally friendly with low viscosity allowing high flow rates to be used leading to faster separations. Miniaturization is also considered a promising approach in solvent savings. Another approach aiming at greening chromatographic analysis is locating the chromatograph on-line or at-line which is considered a step towards fulfilling the need for the real-time monitoring of chemical processes. Greening biological techniques is gained great interest. Immunoassays and biosensors are generally greener techniques because they provide rapid analysis, simple sample pre-treatment, low volumes of sample required and low use of solvents, reduced energy consumption and possibility of in situ analysis.

ABSTRACT

Magnetic graphene @hydrophilic polydopamine composites were successfully fabricated via a simple solvothermal reaction and self-polymerization of dopamine. Benefit from the excellent characteristics of strong magnetic responsivity, super-hydrophilicity and abundant π-electron system, the prepared material showed great potential as a magnetic solid phase extraction (MSPE) sorbent. In this work, six kinds of phthalates (PAEs) were selected as the target analytes to evaluate the extraction ability of the adsorbents combined with MSPE-GC–MS. And various extraction parameters were optimized by selecting the pH value of samples, the amount of sorbents, adsorption and desorption time, the type and volume of eluting solution. Meanwhile, the whole extraction process could be finished in 30 min. Under the optimized conditions, validations of the method were evaluated as well. And the results presented excellent linearity with a wide range of 50–20,000 μg/L ($R^2 > 0.9991$). The detection of limits were in the range from 0.05–5 μg/L ($S/N=3$). Therefore, the novel magnetic graphene@polydopamine composites were successfully used as the sorbents for the enrichment and analysis of PAEs in real water samples. This proposed method provided a simple, efficient and sensitive approach for the determination of aromatic compounds in real environmental samples.

1. Introduction

Recently, magnetic materials have been exploited in many fields, such as catalysis [1], biomedicine [2], cell imaging [3], and separation science [4]. These materials are superparamagnetic, and usually possess large surface area, high adsorption capacity [5]. In separation science, they are always combined with solid phase extraction (SPE) to help analyze small molecules in real samples and it has been developed as a new method called magnetic solid phase extraction (MSPE) [6–8]. In MSPE, the magnetic materials and sample solution could be easily separated with an external magnetic field without the need of centrifugation or filtration. Among the magnetic materials, iron oxides such as magnetite (Fe_3O_4) are widely used in MSPE [9–11]. Since the simple iron oxides have little selectivity and sometimes can form large aggregates, lots of functionalized materials have been developed.

Among the variety of functionalized magnetic materials, graphene-based materials have attracted great attention with its excellent characteristics of large surface area (2630 m^2/g), good thermal stability and easy modification on the surface [12,13]. Moreover, benefit from delocalized π-electron system from graphene sheets, the material could extract benzene series compounds via π–π interaction [14,15]. And in order to simplify the preconcentration procedure, it is widely used to combine graphene with Fe_3O_4 microspheres to separate sorbents from matrix via an external magnetic field [16,17]. However, with the hydrophobicity of graphene, the materials could not well disperse in aqueous samples, which would affect the extraction efficiency sometimes. So, it requires chemical modification to improve the property.

Dopamine, which is widely known as a neurotransmitter, has attracted much interest in different fields since 2007 [18], such as in drug delivery, biosensing and interfacing with cells [19]. It could spontaneous polymerize in weak alkaline solution at room temperature. Besides, the generated polydopamine was successfully coated on metal oxides [20,21], polymers [22], carbon nanotubes [23]. And polydopamine has good biocompatibility, great environmental stability and excellent dispersibility in water [24]. Moreover, it has π electrons that could help absorb aromatic compounds via π–π interaction [25]. Inspired by these wonderful characteristics, we designed and synthesized the hybrid magnetic material combined graphene with polydopamine.

In this work, we synthesized magnetic graphene coated with polydopamine (mag-graphene@PDA) via a solvothermal reaction

and self-polymerization of dopamine. The prepared material has super-hydrophilicity and strong magnetic responsivity. To evaluate the extraction performance of the materials as the MSPE sorbents, six kinds of phthalates were selected as the target analytes. It is well known that phthalates (PAEs) are hazardous to human health [26–28]. And some compounds may cause hormone disrupting effects and malformation [29,30]. But PAEs have been widely used as polymer additives in industries of plastics and they can migrate into environment. So, the analysis of PAEs from environmental matrix becomes a meaningful task. Herein, the prepared composites were successfully developed as the sorbents for the enrichment and analysis of PAEs in environmental water samples.

2. Experimental

2.1. Reagents and materials

A mixture of phthalate standards containing dimethyl phthalate (DMP), diethyl phthalate (DEP), butyl benzyl phthalate (BBP), di-n-butyl phthalate (DBP), bis-2-ethylhexyl phthalate (DEHP) and di-n-octyl phthalate (DNOP) was purchased from Sigma-Aldrich Chemical Company (Shanghai, China). Graphene was acquired from J&K Chemical Corporation (Beijing, China). Dopamine hydrochloride was bought from Alfa Aesar (Tianjin, China). All other chemical and reagents were of the highest grade commercially available. Distilled water was purified by a Milli-Q system (Milford, MA, USA).

The working standard solution of PAEs was prepared by dissolving PAEs in methanol at a concentration of 100 μg/mL and was stored at 4 °C for the following usage. Pond water samples were obtained from Xiyuan in Shanghai, China, and analyzed within one day.

2.2. Preparation of mag-graphene@PDA composites

The synthetic route of the mag-graphene@PDA composites was presented in Fig. 1. And the magnetic graphene was synthesized via a solvothermal reaction in our previous work [31]. Briefly, graphene (400 mg) was dispersed into 50 mL concentration nitric acid with magnetic stirring for 8 h. Then, the dispersion was centrifuged, washed with distilled water for several times until it turned neutral and dried in vacuum at 50 °C. And in the solvothermal reaction, the magnetic graphene was fabricated according to the previous study with a little modification [32]. $FeCl_3 \cdot 6H_2O$ (200 mg) was dispersed into 40 mL ethylene glycol solution and the dried acid-treated graphene (150 mg) was added under magnetic stirring for 1 h. Then 150 mg trisodium citrate, 1.8 g sodium acetate and 1.0 g poly (ethylene glycol) (PEG-20000) were added into the solution and stirred for 0.5 h. The mixture was transferred into the airtight steel container and heated in an oven at 200 °C for 12 h. The products were collected by magnetic separation, washed with ethanol and dried in vacuum at 50 °C.

For synthesis of the mag-graphene@PDA composites, 400 mg of dopamine hydrochloride was dissolved in 400 mL of Tris buffer (10 mM). Then 100 mg of mag-graphene was added and mechanically stirred for 16 h at room temperature. The prepared mag-graphene@PDA was collected by magnetic separation and washed with ethanol for several times. The mag-graphene@PDA composites were dried in vacuum at 50 °C before use.

2.3. Instrument and analytical conditions

Fourier transform infrared spectra (FT-IR) were collected on Nicolet Fourier spectrophotometer using KBr pellets (USA). Transmission electron microscopy (TEM) images were taken on a JEOL 2011 microscope (Japan) operated at 200 kV. Sample was dispersed in ethanol and dried on a holey carbon film copper grid for analysis. Scanning electronic microscopy (SEM) images were recorded on a Philips XL30 electron microscope (Netherland) operating at 20 kV. A thin gold film was sprayed on the sample before characterization. Powder X-ray diffraction (XRD) patterns were recorded on a Bruker D4 X-ray diffractometer with Ni-filtered Cu K_α radiation (40 kV, 40 mA).

The GC–MS instrument was Thermo Focus DSQ. The extracted compounds were separated using a HP-5MS capillary column (30 m × 0.25 mm, 0.25 μm). The injection temperature was set to 250 °C and the sample was injected at a splitless mode. Helium

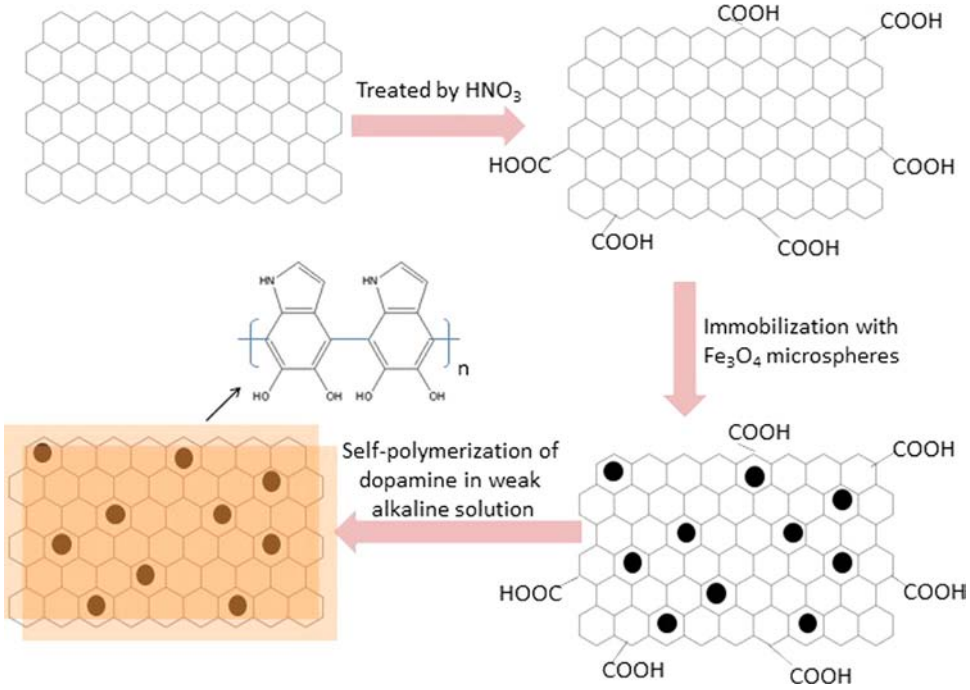

Fig. 1. Synthetic route of mag-graphene@PDA composites.

(99.999%) was used as carrier gas at a flow rate of 1.0 mL/min. The oven temperature program was held for 2 min at 100 °C, raised to 300 °C at a rate of 30 °C/min and held for 6 min. The quantitative analysis was performed in the selected ion monitoring (SIM) mode. And the ion source and transfer line temperature were both maintained at 250 °C. The ionization energy was 70 eV.

2.4. Procedure of MSPE

10 mL distilled water containing 500 μg/L phthalates standard was added in a vial with PTFE-silicone septum. And 15 mg mag-graphene@PDA composites were put into the vial to extract the analytes by vortex for 10 min. Then a magnet bar was used to isolate the materials and the sample solution was removed. 0.5 mL of dichloromethane was introduced to the vial to elute the analytes under vibration for 10 min. The magnet bar was placed beside the vial and the eluting solution was collected. 3, 4, 5-Tribromobiphenyl was selected as the internal standard (I. S.). The appropriate amount (20 μg/ml) of I.S. was added to water samples for the method validation. Finally, 1.0 μL of the obtained solution was injected into the GC–MS for analysis.

2.5. Method validation

The calibration curves were evaluated by analyzing a series of phthalates of the concentration range (50–20,000 μg/L). The limits of detection ($S/N=3$) were calculated by the analysis of the water sample with a low concentration, which ranged from 0.05–5 μg/L. And they were examined by three replicate analytes. The limits of quantification were estimated on the basis of $S/N=10$. The method precision was investigated by five replicate analytes of phthalates in water with the concentration (500 μg/L) under the optimized conditions, and was calculated with the relative standard deviations (RSD). In addition, accuracy was evaluated with the recovery rate of the target analytes. And it was investigated by preconcentrating the standard-spiked water samples (500 μg/L) with the optimized procedure, and determined by comparing real values with the calculated values.

2.6. Sample collection and analysis

In order to evaluate the extraction performance of the proposed method in real samples, pond water samples were analyzed as the environmental water samples. And pond water samples were collected from Xiyuan, Shanghai, China, which were stored at 4 °C until use. In contrast, 500 μg/L of phthalates standard was added in real water samples. The extraction procedure was performed under the optimal conditions.

3. Results and discussion

3.1. Characterization of mag-graphene@PDA composites

In this work, the mag-graphene composites were synthesized via a solvothermal reaction. Then dopamine was polymerized on the mag-graphene composites in alkaline buffer. The polymerization procedure was fast and simple.

The size and morphology of the mag-graphene@PDA composites were characterized by SEM and TEM. The SEM images (Fig. 2(a) and (b)) showed the magnetic particles were well dispersed on the surface of graphene sheets and the diameter of the Fe_3O_4 microsphere was about 200 nm. The TEM images (Figs. 2(c) and 2(d)) suggested that the polydopamine layer was successfully coated on the mag-graphene composites and the coating layer was about 70 nm. The characteristic diffraction peaks of Fe_3O_4 microspheres around 30°, 35°, 43°, 53°, 57° and 62° were obtained from the XRD pattern (Fig. 3). And the strong peak at 26° indicated the graphitic layers were observed

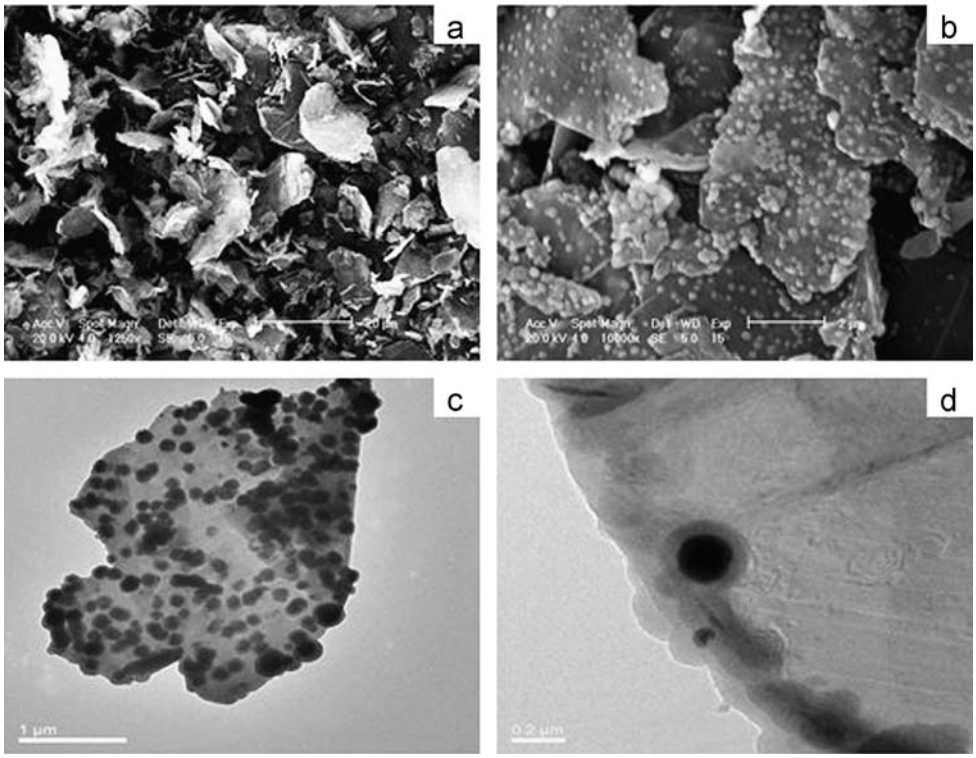

Fig. 2. SEM images (a) and (b) and TEM images (c) and (d) of mag-graphene@PDA.

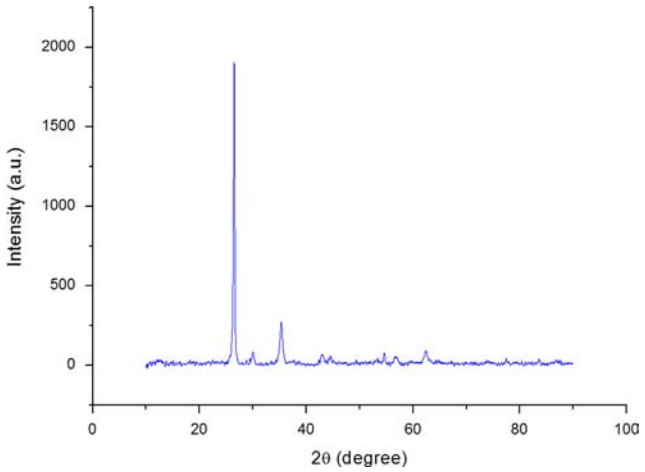

Fig. 3. XRD patterns of mag-graphene@PDA.

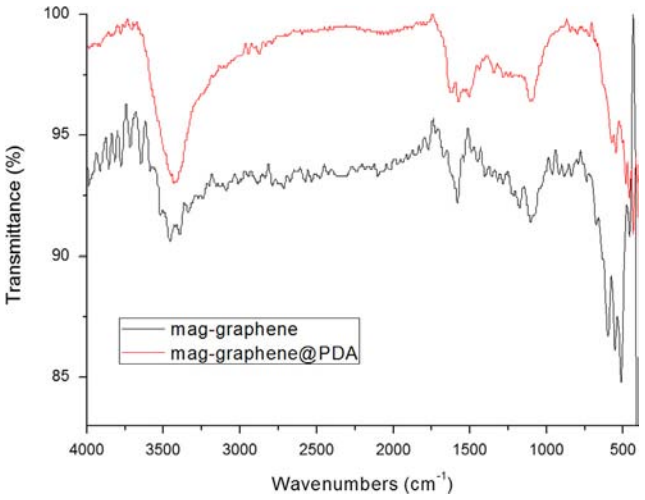

Fig. 4. The FT-IR spectra of mag-graphene and mag-graphene@PDA.

simultaneously. The result was in accordance with the previous reports [33,34].

FT-IR spectra (Fig. 4) demonstrated the successful polymerization of dopamine coated on the surface of mag-graphene. The signal at 548 cm^{-1} and 3429 cm^{-1} belonged to Fe–O–Fe stretching of Fe_3O_4 and O–H vibration of the hydroxyl groups on the surface. And the peak at 1109 cm^{-1} was assigned to C–N stretching vibration. The adsorption peak at 1616 cm^{-1} and 1344 cm^{-1} were ascribed to the C=O stretching carboxylic groups and C=C vibration of graphene framework. The adsorption band at 1574 cm^{-1} and 1508 cm^{-1} originated from the aromatic C=C vibration. All the results indicated that mag-graphene was successfully coated by polydopamine.

3.2. Optimization of the extraction process

The mag-garphene@PDA composites have benzene rings from dopamine, so it is easy to adsorb aromatic compounds via π–π interaction. Meanwhile, hydroxyl group contained on dopamine makes it shows excellent dispersibility in water, which can ensure an effective contact with the target anayltes in aqueous phase. In order to improve the extraction efficiency of this method, variety of extraction parameters were studied, including pH of the sample solution, amount of adsorbents, adsorption and desorption time, type and volume of eluting solution.

The pH value of the sample solution plays an important part for the adsorption process because it could affect the ionization form of the target analytes and the surface charge of the adsorbents. The pH values (5, 7, 9) of the sample solutions were adjusted by the addition of hydrochloric acid or sodium hydroxide solution. The results showed in Fig. 5(a) revealed that the extraction efficiency reduced obviously with the pH value of 9. And there was no clear difference between the pH value of 5 and 7. Therefore, it was not necessary to adjust the pH value before the analysis of general water samples. To ensure the maximum recovery of the analytes, the amount of sorbents was studied in the range from 0.5 mg/mL to 2.0 mg/mL. Based on the results (Fig. 5(b)), when the amount of mag-graphene@PDA reached 1.5 mg/mL, it was enough for most of the PAEs and there was no significant difference between 1.5 mg/mL and 2.0 mg/mL. Thus, 1.5 mg/mL was considered to be the optimized amount of sorbent. Next, adsorption time was an essential condition to assure the sufficient contact between the sorbents and the target analytes. Fig. 5(c) showed the influence of adsorption time in the range of 5–30 min. Due to the excellent hydrophilicity of dopamine, the sorbents could well disperse in water samples. And extend the time to 10 min, there was no significant difference. As a result, 10 min was selected as the best adsorption time.

During the desorption process, there were three parameters that should be optimized. Elution solvent was an important role for the desorption process. In this work, four different kinds of solvents were experimented, including methanol, acetone, isopropanol and dichloromethane. According to the results showed in Fig. 5(d), dichloromethane revealed the best eluting performance, while methanol, acetone and isopropanol had relative low desorption ability for the PAEs. Since the solvent of dichloromethane had a similar polarity with the target analytes and possessed the characteristic of hydrophobicity which could interact with PAEs, it was not difficult to explain the good eluting efficiency of dichloromethane. Thus, dichloromethane was used as the desorption solvent in the following work. And desorption time was also another important factor. Variety of desorption time (in range from 5–20 min) was studied in this work. As the results showed in Fig. 5(e), there was no obvious difference when the desorption time extended to 10 min. And it showed the system had reached the desorption balance after 10 min. So, 10 min was selected as the optimal condition. Another experimental parameter was the volume of desorption solvent. In order to obtain the maximum eluting performance, 0.3, 0.5 and 0.8 mL of dichloromethane were chosen in this work. Fig. 5(f) showed that when the volume was 0.5 mL, the eluting efficiency was best. Therefore, 0.5 ml of dichloromethane was chosen for further analysis.

3.3. Adsorption capacity

In order to investigate the adsorption capacity of mag-graphene@PDA, DBP was selected as a model analyte. And the adsorption capacity was evaluated with a series of standard solutions in the range of 2–14 mg/L under the optimized extraction procedure. After the preconcentration, mag-graphene@PDA was separated from the solvent, and the concentration of DBP in the elution solvent was analyzed. When the concentration of the standard solution was up to 10 mg/L, the extraction yield became stable and the adsorption capacity reached the maximum. Finally, the adsorption capacity of mag-graphene@PDA was investigated to be 4.9 mg/g.

3.4. Validation of the method

Under the optimized conditions, a series of method validation were studied, such as the limit of detection (LOD), recovery, precision and linearity. All the results were listed in Table 1. In this work, linearity of the calibration curves were obtained in a

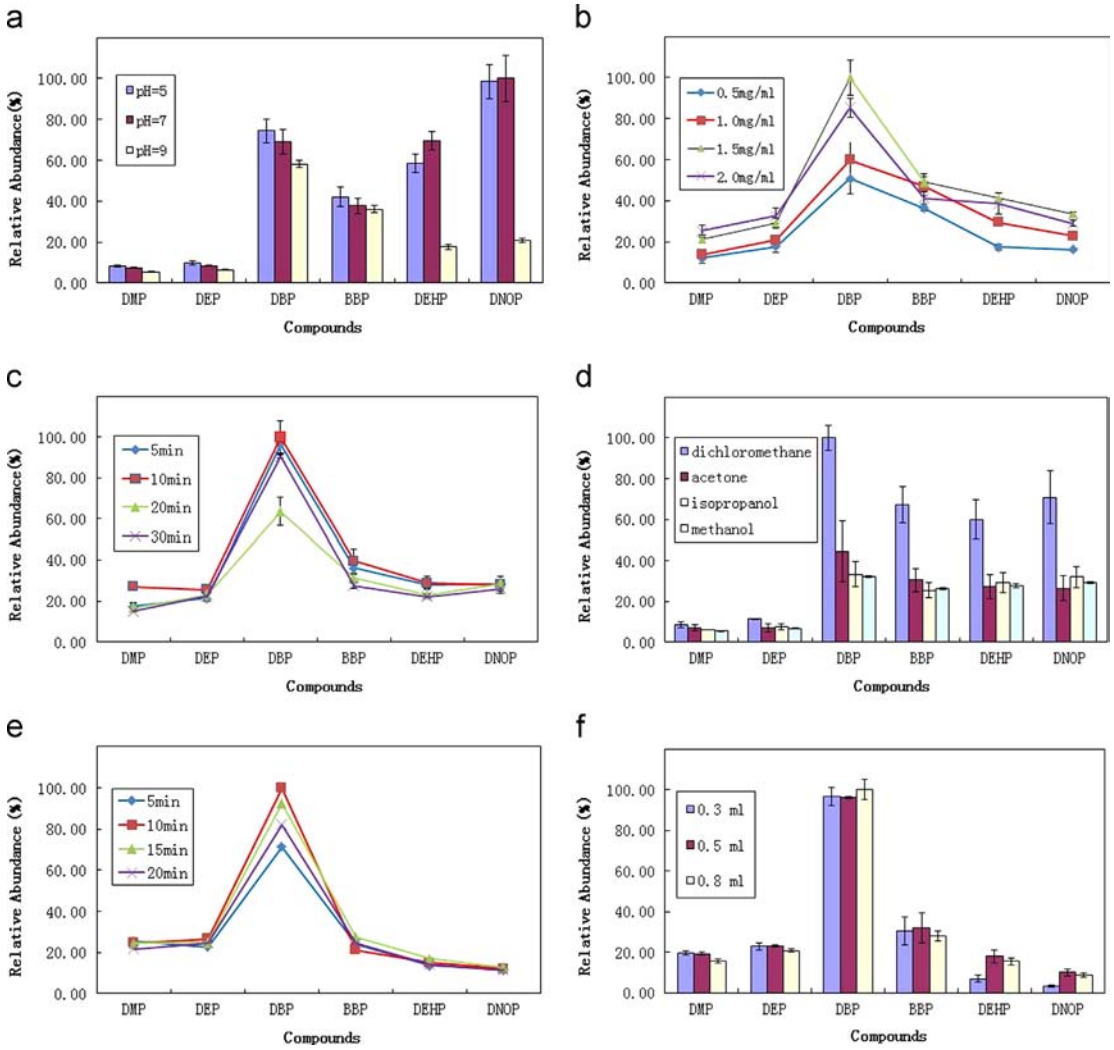

Fig. 5. Optimization of the extraction process (a) pH values (5, 7 and 9) of water samples; (b) the adsorbent amounts (0.5, 1.0, 1.5 and 2.0 mg/ml); (c) adsorption time (5, 10, 20 and 30 min); (d) species of desorption solutions (dichloromethane, acetone, isopropanol, methanol); (e) desorption time (5, 10, 15 and 20 min); and (f) volumes of desorption solutions (0.3, 0.5 and 0.8 mL) ($n=3$).

Table 1
Validation of mag-graphene@PDA based on SPE-GC–MS procedure.

Analytes	Confirmation ions (m/z)	Linear range (μg/L)	R^2	LOD (μg/L)	LOQ (μg/L)	Intra-day RSD (%)	Recovery (%)
DMP	163,194	50–20,000	0.9996	5	16.67	5.05	43.0
DEP	149,167,177	50–20,000	0.9991	5	16.67	3.80	47.3
DBP	149,223	50–20,000	0.9997	0.05	0.17	6.21	94.9
BBP	149,223	50–20,000	0.9996	5	16.67	6.87	96.5
DEHP	149,167	50–20,000	0.9998	0.5	1.67	6.88	79.6
DNOP	149,223	50–20,000	0.9995	5	16.67	8.31	84.7

wide range from 50–20,000 μg/L. And the corresponding values (R^2) were more than 0.9991. The LOD values varied from 0.05–5 μg/L on the basis of $S/N=3$. And on the basis of $S/N=10$, the LOQ values were evaluated ranging from 0.17–16.67 μg/L. Precision values of the method was investigated by the intra-day RSDs ($n=5$) and the values were less than 8.31%. The recovery of the analytes ranged from 79.6–96.5%, except the relative lower values of 43.0% for DMP and 47.3% for DEP. And it could be interpreted that the two targets had shorter ester chains, which resulted in a relatively weak hydrophobicity. As a result, it was not so favorable for the extraction from aqueous samples. But all these validation results have demonstrated that the method based on MSPE technique was reliable and the proposed method could be used to analyze environmental water samples.

3.5. Analysis of the environmental water sample

To investigate the applicability of the proposed method, mag-graphene@PDA was used to extract the target analytes in pond water samples. Under the optimized conditions, water samples were analyzed by the method in this work. Fig. 6(a) showed the GC–MS chromatogram, and the chromatogram of the PAEs spiked pond water was showed in Fig. 6(b), respectively. As a result, DMP, DBP and DEHP were detected in water samples and the concentration of DBP was 8.01 μg/L. The contents of DMP and DEHP were below LOQ, while DEP, BBP and DNOP were not observed. The extraction factor of PAEs was 20.

Compared with the previous work focused on analyzing phthalates in water samples (Table 2), the proposed method in this work had comparable LOD values and wider linear range. Benefit from the excellent magnetic responsivity of mag-graphene@PDA, the materials could be separated from the solvent in 20 s with a magnetic bar and the extraction time in this method was similar

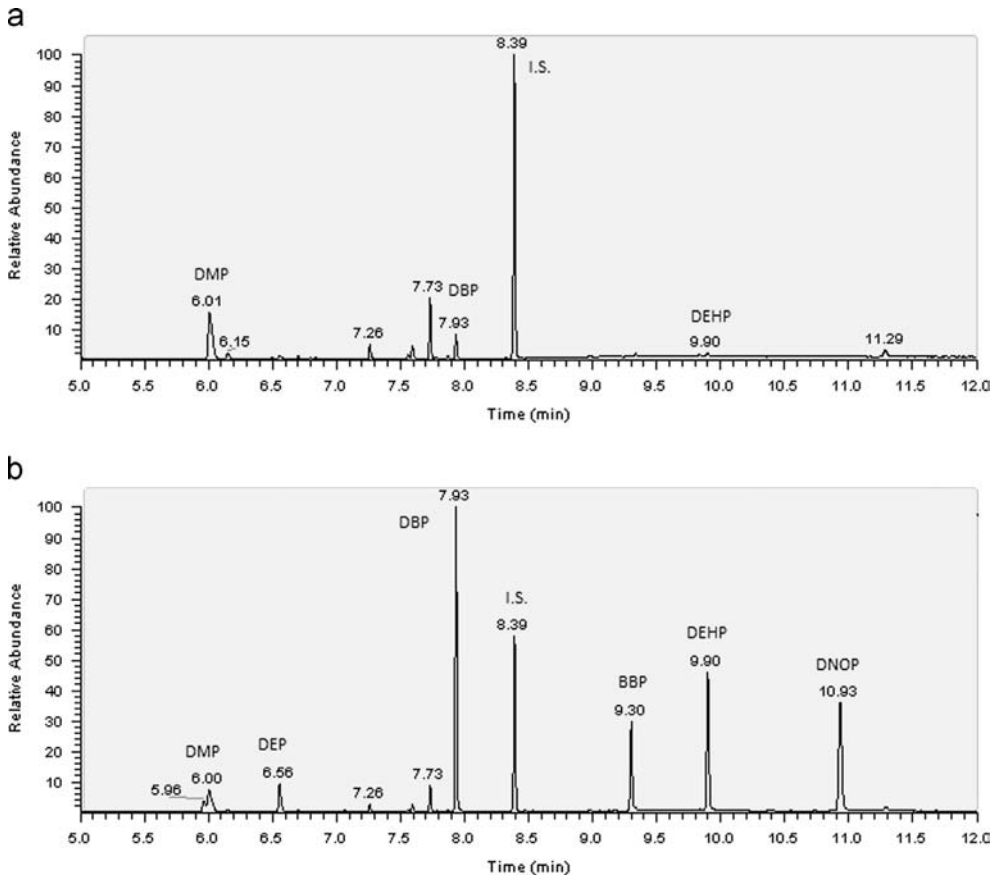

Fig. 6. The GC–MS chromatograms of (a) pond water samples and (b) 500 μg/L PAEs-spiked pond water samples by the proposed method.

Table 2
Comparison of mag-graphene@PDA-SPE with previous analytical methods for the determination of phthalates.

Methods	Matrix	Absorbent	Linear range (μg/L)	LOD (μg/L)	Adsorption time	Ref.
SPE-GC–MS	Saliva	Poly (EGDMA-MATrp)	100–2000	3–10	90	[35]
SPE-GC–MS	Serum	Water Oasis MAX SPE cartridge	2–1000	0.7–4.5	–	[36]
LPME-HPLC/UV	Landfill leachates	Carbon tetrachloride	5–50,000	1.2–2.2	40	[37]
SPE-GC–MS	Water	C18-Fe3O4@mSiO2	50–3000	25–77	10	[38]
SPE-GC–MS	Water	mag-MCNTs	50–10,000	0.08–0.47	10	[39]
SPE-GC–MS	Water	mag–graphene@polydopamine	50–20,000	0.05–5	10	This work

or even shorter than other works. All these results demonstrated that the method was applicable for analysis of PAEs in water samples.

4. Conclusions

In this work, a facile synthesis of mag-graphene@PDA composites was introduced via a simple polymerization of dopamine coating method. Due to the excellent characteristics of hydrophilicity and magnetic responsivity, the sorbents could easily disperse into aqueous samples and the whole extraction procedure required only 30 min. Meanwhile, the proposed method combined with GC–MS exhibited good linearity and high selectivity for the extraction of PAEs from water samples. Finally, the magnetic-graphene@PDA composites were successfully used as the sorbents for the enrichment of PAEs in real water samples. Based on the results, the MSPE method combined with GC–MS technique was established. And magnetic-graphene@PDA composites are recommendable as the promising sorbents for further environmental analysis.

ABSTRACT

This paper concerns a time lapse spectroelectrochemical study of the growth of lead dodecanoate layers on a lead substrate in an aqueous solution using cyclic voltammetry. In-situ synchrotron radiation X-ray diffraction measurements were carried out on station BM26A (DUBBLE) at the European Synchrotron Radiation Facility (ESRF) in France. The diffraction pattern images were taken using a two-dimensional Mar CCD camera. After deposition of the coating, a spectroelectrochemical study of a linear sweep voltammetry experiment using an acetic acid electrolyte, simulating 'active' lead corrosion, was carried out on both a bare and lead dodecanoate coated sample. The results show that the coating inhibits the formation of new lead corrosion products.

1. Introduction

Many ancient lead based artifacts suffer severe corrosion in wooden (such as oak) display cases which are used for storage or exhibition purposes in museums worldwide [1]. The increase of relative humidity and temperature create an acidic microclimate in the wooden cases. The production of these organic acids is a consequence of hydrolysis of acetyl groups of hemicellulose in the wood [2]. Other sources for the formation of organic acids are the presence of plastics, glues, human bodies, varnishes, formaldehyde, etc. [3–5]. Corrosion studies, conducted in Europe, have demonstrated that the emission of formic and acetic acid are the primary responsible compounds for the irreversible damage of the artifacts [6–9].

Potential countermeasures against the corrosion of these historical lead, lead-tin and other lead alloy artifacts are commonly based on two strategies: either the change of the nearby environment and/or the development and application of a protective coating [10]. In this paper, we focus on the latter approach. A successful coating should have following characteristics: stable, reversible, cheap and aesthetically justified [11].

An interesting candidate for a protective coating on lead has been found in the deposition of saturated linear monocarboxylates of the type $CH_3(CH_2)_{n-2}COONa$ ($n=7$–11), hereafter called NaC_n. Initial studies by Rocca et al. [12–14] show that the immersion of lead and copper metal objects in NaC_n results in their protection due to the growth of a layer consisting of a crystalline metal monocarboxylate complex $(CH_3(CH_2)_{n-2}COO)_2M$, hereafter called $M(C_n)_2$. When a clean lead surface is immersed in a sodium carboxylate solution, a layer of the corresponding lead carboxylate is formed. A higher chain length of the saturated carbon chain of the monocarboxylate commonly provides a higher inhibition and protection efficiency [15,16]. The formed layers are hydrophobic, and practically invisible for thicknesses on the micron scale [17]. These coatings may provide long-term protection through the exclusion of water and/or air and therefore become a suitable candidate for the protection of the extensive amounts of lead in museum objects, pipe organs, and other heritage-related artifacts.

In this work, we perform an in-situ spectroelectrochemical study of the deposition process of a lead dodecanoate coating using cyclic voltammetry. The spectroelectrochemical insight allows us to study the growth of the lead dodecanoate layer as a function of time. Furthermore, we try to look at the influence of

the cyclic voltammetry procedure on the growth of the coating. Using the Beer–Lambert law, hypothetical calculations are added to predict the thickness of the coating layer as a function of time. After the electrochemical growth, the air-dried coating has been tested in-situ for its corrosion inhibitive properties using a standard corrosion testing procedure in an aqueous acetic acid solution. The in-situ XRD data gives us information about the inhibition time, the corrosion products and the decomposition of the coating.

2. Experimental section

2.1. Materials

A 0.05 mol L^{-1} inhibitor solution was prepared by dissolving 1.252 g of dodecanoic acid (98%, Sigma-Aldrich, USA) in 250 mL deionized water and by subsequently neutralizing the obtained suspension with a standardized 0.25 mol L^{-1} NaOH solution. The addition of NaOH helps the dissolution of the dodecanoic acid, HC_{12}, which is only slightly soluble in water. NaOH is added up to reach a pH value of approximately 9 (just before the equivalence point) [25]. The initially turbid solution was heated to 25–30 °C and stirred during 1 h to neutralize all the acid and to obtain a clear and transparent sodium dodecanoate, NaC_{12}, solution.

Experiments were carried out on coupons made from 99.99% pure lead (Goodfellow, Cambridge, Ltd., UK). The coupons were pressed from a lead metal sheet and their edges machined so as to seal into the holder in the exposure cell (Fig. 1). These are 2 mm thick, and 12.6 mm in diameter (A_s = 1.2469 cm^2). All coupons were pre-treated by mechanical polishing. They were first roughly ground on a wetted silicon carbide paper of grit P600, subsequently grit P1200. Thereafter, the surface was fine-polished during 15 min using a polishing cloth (12″ micro cloth PSA 10/PK, Buehler, USA) with diamond polish dissolved in oil with a particle size of 6 μm and subsequently 1 μm (MetaDi Diamond Suspension, Buehler). To remove as much diamond as possible from the polished lead surface, the coupon was rinsed with isopropanol (99.5%, reagent grade) and cleaned in an ultrasonic bath for 30 s. Some of the polishing particles will, however, always remain stuck into the lead matrix because of its soft nature. The last step of the procedure consisted of polishing the cleaned coupons by pressing them firmly on a bare micro cloth. At the end, a shiny blue–white surface was obtained.

2.2. Deposition and corrosion testing procedure

The growth of the lead dodecanoate coating was carried out by immersing the lead coupons in the NaC_{12} solution described above, and performing 10 consecutive cyclic voltammetric scans between −1.3 and 1.5 V vs. SCE at a scan rate of 20 mV s^{-1} [16]. After the deposition and upon drying the coupons to air, the lead dodecanoate coated samples were corroded using linear sweep voltammetry (LSV) in a 5 μg L^{-1} acetic acid solution with a potential range from −1 V to 1.5 V and a scan rate of 1 mV s^{-1} ('corrosion test' procedure). The electrochemical measurements were done using a PalmSens handheld potenstiostat/galvanostat controlled by the PalmSensPC software package (PalmSens, The Netherlands).

2.3. Synchrotron measurements

Both the growth of the coating as well as its corrosion inhibition was studied using in-situ synchrotron radiation X-ray diffraction measurements (SR-XRD). All experiments were performed at DUBBLE (station BM26A) at the ESRF in France [18]. An X-ray beam with a wavelength of 1.5498 Å (8 keV) and with dimensions of 1 mm × 200 μm was used to bombard the sample surface. A Mar CCD 165 detector (Mar USA Inc., Evanston, IL, USA), consisting of 2048 × 2048 individual elements with a pixel size of 79 μm, was used to record the two-dimensional diffraction patterns of the deposited layers. X-rays were incident at 10°. The axis of the CCD camera was at 40.5° to the incident beam, and the face was 130 mm from the intersection between the beam axis and the surface. A fast shutter was used to shield the sample from X-ray damage between exposures.

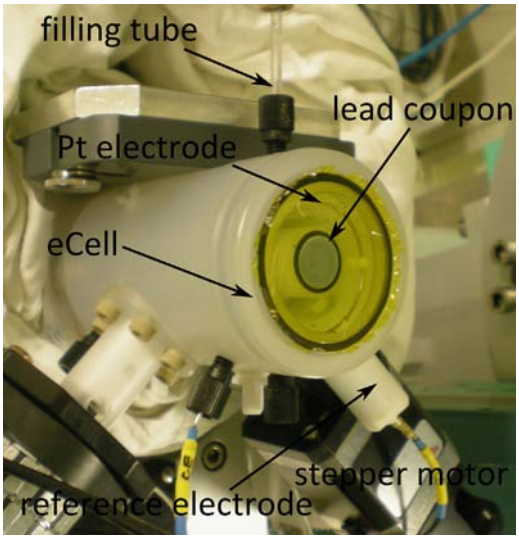

Fig. 1. The set-up on the DUBBLE beamline for time-lapse SR-XRD – the eCell Mk IV is shown here with a Kapton window. The lead coupon is fitted into a dedicated holder to be placed in the middle of the eCell (is used as a working electrode).

For the experiments the eCell Mk IV (see Fig. 1) was used, of which the prototype has been published by Dowsett and Adriaens [19]. The eCell is an electrochemical/environmental cell consisting of a 40 mL polychlorotrifluoroethylene (PCTFE) cup, with inner and outer diameters of 30 and 44 mm, respectively, configured to take electrodes or coupons with a diameter of 12.6 mm in a holder from which they can easily be demounted. The cell is used for a particular (electro)chemical treatment (in this case the electrochemical treatment of the lead sample in the NaC_{12} solution), while at the same time the metal surface is analyzed through a thin electrolyte layer using the XRD spectroscopic technique. The piston is driven by a variable-speed motor (type BLDC 58, McLennan Servo Supplies, Ltd., UK), using remote control from outside the X-ray hutch. A sequence of surface powder diffraction images was recorded through a 6 μm Kapton window and approximately 100 μm of the electrolyte solution. In Fig. 1, the Ag/AgCl reference and counter electrode are indicated. During the growth sequence (ca.1 h), the sample was automatically moved between the analysis position (close to the window) and deeper (1 cm down) in the solution by the eCell control system. Data collection was synchronized with this movement: actual collection time was 5 s per image, time in between images was 35 s. For the corrosion test experiment a collection time of 10 s per image and the time between the images was 50 s.

2.4. Spectral processing

All diffraction patterns were processed using the esaProject 2012 software [20–21]. It is analytical software, which handles both two dimensional XRD powder diffractograms from devices such as the Mar CCD 165, as well as a huge range of spectra, all in native format, and provides an acquisition to publishing capability for XRD, X-ray absorption spectroscopy (XAS), X-ray emitted optical luminescence (XEOL), and other spectroscopic data with a rapidly developing image

stack and spectrum data mining capability. For the growth of the lead dodecanoate layer and the corrosion test experiment a sequence of around 100 Mar CCD images was taken. The images were batch processed using esaProject through the reprojection algorithm. The one-dimensional diffraction patterns from DUBBLE are simply integrated out of the reprojected image, by summing image rows.

The peaks present in the diffraction pattern are a consequence of constructive interference following Bragg's law [22]:

$$n\lambda = 2d \sin\theta \quad (1)$$

where n is an integer, d is the interplanar distance, λ is the wavelength of the incident wave and θ is the angle between the incident ray and the scattering planes.

For the ease of comparison, the abscissae of all diffraction patterns are given as intensity vs. wave number q [23]:

$$q = \frac{2\pi}{d} = \frac{4\pi \sin\theta}{\lambda} \quad (2)$$

This formula ensures that the peaks are compared on a common scale. The growth process images were made by assembling a plot of all the extracted one-dimensional spectra as a function of time [24]. The colors in the pattern set image represent the intensities of the corresponding 2θ angle.

3. Results and discussion

3.1. Growth of a coating on lead using cyclic voltammetry with a scan rate of 20 mV s^{-1}

The lead coupons are immersed in a NaC_{12} solution (see Section 2.1). Afterwards, 10 consecutive cyclic voltammetric scans are carried out in-situ between −1.3 and 1.5 V vs. SCE at a scan rate of 20 mV s^{-1} to produce the coating. During the electrochemical treatment, XRD spectra are taken.

Fig. 2A shows a reprojected Mar diffractogram from a lead dodecanoate coated coupon acquired on DUBBLE. The acquisition time was 10 s. The two bottom rings in the images refer to $q = 1.5514$ Å^{-1} and 1.7262 Å^{-1} from the lead dodecanoate coating (pattern reference number 00-009-0712 for lead dodecanoate in the ICDD database). The coarse polycrystallinity of the lead substrate is demonstrated by the streaky nature of the lead rings. On the other hand, the evenly spaced rings which represent the lead dodecanoate are smooth and homogeneous. This tells us that the coating is formed from small and random poly crystals [21]. The lead dodecanoate rings demonstrate the c-axis alignment of the coating from the localization of the intensity to the center of the image. By integrating the different image rows as a function of the diffraction angle θ, a one-dimensional pattern is constructed as shown in Fig. 2B. The 1D diffraction pattern shows us clearly the diffraction peaks of the formed lead dodecanoate coating between 1.5 Å^{-1} and 2.0 Å^{-1}. The (111) and (200) lead diffraction peaks, however, form an intense narrow peak at higher q-space values around 2.1907 Å^{-1} and 2.5305 Å^{-1} (pattern reference number 03-065-2873 in the PDF-2 ICDD database (2012)). Due to atmospheric corrosion and electrochemical oxidation of the lead substrate, lead(II)oxide is detected. At 2.0435 Å^{-1}, a small (101) lead (II)oxide diffraction peak is detected (pattern reference number 03-065-1471 in the PDF-2 ICDD database (2012)). This is in agreement with previous findings in our research group [25–26]. The presence of small concentrations of OH^--ions in the aqueous solution ensures the formation of PbO (litharge) [27,28]:

$$Pb\,(s) + 2\,OH^-(aq) \rightleftharpoons PbO(s) + H_2O + 2\,e^- \quad E_0 = -0.002V \text{ vs. SCE} \quad (3)$$

In addition to the formation of lead(II)oxide, due the high oxidation potentials, lead(IV)oxide (PbO_2, plattnerite) is produced. The (110), (101) and (200) plattnerite diffraction peaks at 1.7952 Å^{-1}, 2.2234 Å^{-1} and 2.5398 Å^{-1} are clearly detected (pattern reference number 00-025-0447 in the PDF-2 ICDD database (2012)). The first oxidative scan to 1.5 V provides together with the presence of OH^--ions an ideal environment for the production of

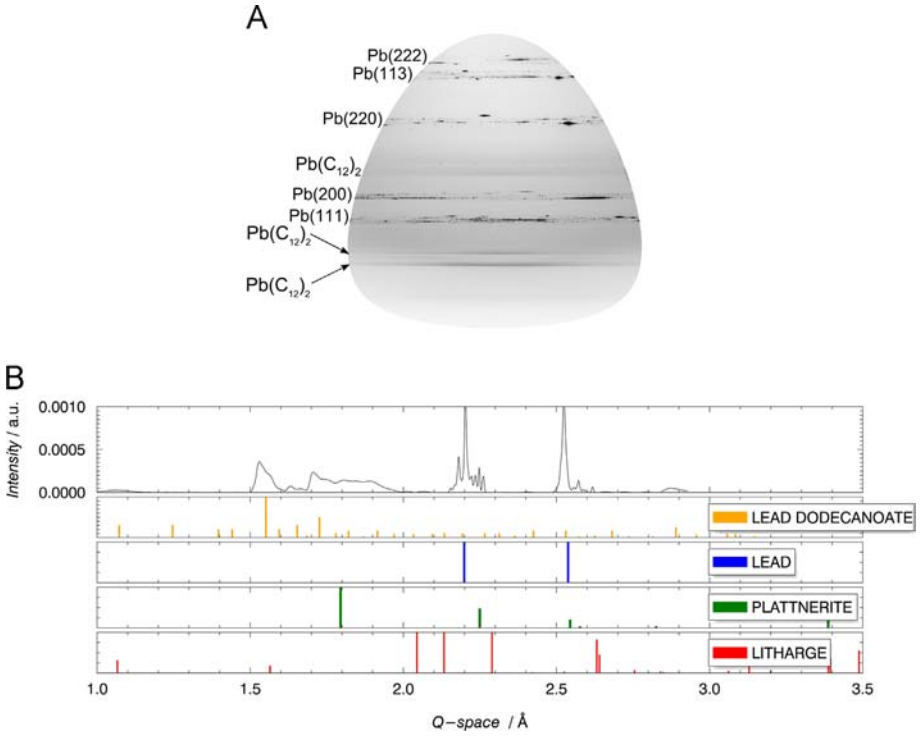

Fig. 2. (A) Reprojected image of a Mar SR-XRD diffraction pattern from a lead dodecanoate coated lead coupon acquired on the DUBBLE beamline at the ESRF. The acquisition time was 10 s. (B) The XRD pattern of the lead dodecanoate coated lead sample calculated using integration.

PbO_2 [28,29]:

$$PbO(s)+2\,OH^-(aq)\rightleftharpoons PbO_2(s)+H_2O+2\,e^-$$
$$E_0=+0.86\ \text{V vs. SCE} \quad (4)$$

Fig. 3 shows the first voltammetric scan of the deposition of the lead dodecanoate coating with a scan rate of 20 mV s^{-1} using the eCell system. This voltammetric scan explains the formation of all the products mentioned in Fig. 2B. The anodic peak (A_1) is characteristic for a passivation process, because the current drops to a low value corresponding to the passive state. This process can be explained using two consecutive steps. At the start, lead dissolves and forms a soluble lead salt with dodecanoate as anion explained by a series of adsorption reactions [16]:

$$Pb+C^-_{12(ads)}\rightleftharpoons PbC_{12(ads)}+e^- \quad (5)$$

$$PbC_{12(ads)}+C^-_{12}\rightleftharpoons Pb(C_{12})_{2(ads)}+e^- \quad (6)$$

$$Pb(C_{12})_{2(ads)}\rightleftharpoons Pb(C_{12})_{2(aq)} \quad (7)$$

After that, there is a precipitation of a crystalline salt film Pb $(C_{12})_2$ (s) on the electrode surface when the solubility product of the salt is exceeded. The formation is described by the dissolution-precipitation mechanism [16]. After precipitation the film, as a consequence of crystallization, stays on top of the surface without dissolving during the cathodic process. After the third scan, only lead dodecanoate compounds present in the solution are reduced and oxidized. This oxidation process ensures the lead dodecanoate coating is formed rapidly. Above 0.5 V, the current forms a peak (A_2) which represents the production of lead(IV) oxides. This initially formed oxidative layer is then partly reduced in two steps (R_2 and R_1) to form lead metal. Table 1 shows the calculation of the potential of the peaks measured in the cylic voltammogram based on the Pourbaix diagram of lead-water and the solubility product of lead dodecanoate.

Fig. 4 shows the pattern set image of all diffraction patterns recorded during the progressive growth process of the lead dodecanoate coating on a bare lead coupon using cyclic voltammetry with a scan rate of 20 mV s^{-1} in a 0.05 mol L^{-1} aqueous NaC_{12} solution as a function of time. The total length of the experiment is 46 min. In addition, the relevant diffraction lines are indicated, obtained from the reference spectra present in the ICCD database. All diffraction peaks of the lead dodecanoate coating clearly increase during the cyclic voltammetric measurement up to a maximum intensity due to complete coverage of the lead substrate surface. The reduction of the surface during the reverse scan in the cyclic voltammetric procedure stimulates the formation of metallic lead, which allows the intensity of the lead diffraction peaks to range around a stable value. All the q-values of the lead diffraction peaks seem to be shifted to a more positive value (+ 0.077 $Å^{-1}$). A possible explanation is the strain in the upper lead crystal structure due to the fast oxidation processes. The diffraction peaks of the lead(IV)oxide show an increase after the start of the time lapse measurement, but stabilize very quickly to a maximum value.

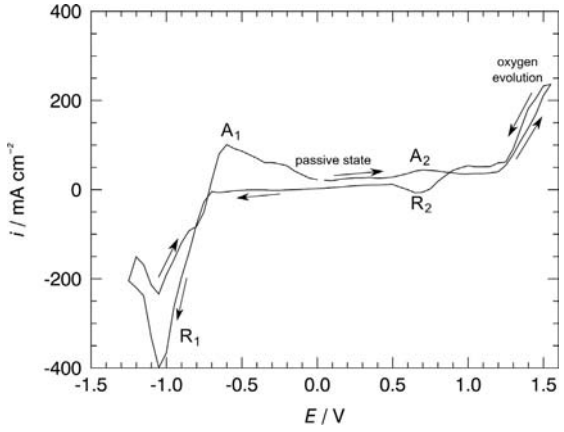

Fig. 3. The first voltammetric scan of the cyclic voltammetric deposition of the lead dodecanoate coating with a scan rate of 20 mV s^{-1}.

Fig. 5 shows the peak areas extracted from the diffraction patterns of the change in surface composition in real time using 10 consecutive cyclic voltammetric scans with a potential range from −1.3 V to 1.5 V and a scan rate of 20 mV s^{-1}. Fig. 5A shows the peak area of the lead dodecanoate peaks at 1.5514 $Å^{-1}$, 1.7262 $Å^{-1}$ and 2.8902 $Å^{-1}$ extracted from a stack of recorded two-dimensional SR-XRD patterns. The observed growth in peak area of all three curves is due to the progressive formation of the lead dodecanoate coating during the different voltammetric scans. The experimental graphs for all peak areas calculated at three different q-space values are fitted to an exponential growth curve based on the following equation:

$$I=I_m\left(1-e^{-\frac{t}{\tau}}\right) \quad (8)$$

with τ is the time constant and I_m is the intensity for $t\rightarrow\infty$.

The fitted values are presented in Table 2. The fitted time constant τ, in seconds, gives some idea as to the relative speed of the lead dodecanoate coating growth. The low time constant given by the exponential fit of the peak area of the diffraction peak at 1.5514 $Å^{-1}$, indicates a fast growth of this peak due the growth of the lead dodecanoate layer. After 10 consecutive cycles, a steady state value is measured, because of the saturation of all binding sites on the lead substrate.

Fig. 5B shows the small change of the (101) peak area of lead(II) oxide over time. The lead(II)oxide growth results from the direct contact of the lead surface with the NaC_{12} solution. For the fitting of the lead(II)oxide signal, however, the fact of a native oxide layer due to atmospheric corrosion should be taken into account using the following equation:

$$I=I_0+I_m(1-e^{-\frac{t}{\tau}}) \quad (9)$$

with I_0 the peak area of the diffraction peak at the start of the exponential growth.

The diffraction peak of lead(II)oxide keeps growing very slowly, which is due to the oxidative treatment and the presence of OH^--ions in the NaC_{12} inhibitor solution (Eq. 3). In Fig. 5B, the peak area of the diffraction peak of lead(II)oxide seems to change continuously, which

Table 2
List of the values of the exponential fit of the growth process of the lead dodecanoate coating using cyclic voltammetry with a scan rate of 20 mV s^{-1}.

	$Q(Å^{-1})$	I_m(a.u.)	τ(s)	I_0(a.u.)
$Pb(CH_3(CH_2)_{10}COO)_2$	1.5514	$3.13 \times 10^{-5} \pm 0.5\%$	$630 \pm 2.5\%$	–
	1.7262	$6.9 \times 10^{-6} \pm 6\%$	$1700 \pm 15\%$	–
	2.8902	$2.83 \times 10^{-6} \pm 0.9\%$	$1110 \pm 2.9\%$	–
PbO	2.0435	$2.6 \times 10^{-7} \pm 13.9\%$	$1800 \pm 45\%$	$2.5 \times 10^{-7} \pm 4.9\%$
PbO_2	1.7926	$2.0 \times 10^{-6} \pm 12.9\%$	$390 \pm 21.7\%$	$8.9 \times 10^{-8} \pm 10.5\%$
	2.5398	$8.2 \times 10^{-6} \pm 2.0\%$	$780 \pm 4.7\%$	$9.5 \times 10^{-6} \pm 2.0\%$
Pb	2.2681	$1.93 \times 10^{-5} \pm 3.1\%$	$570 \pm 9.2\%$	$2.69 \times 10^{-5} \pm 1.0\%$
	2.6079	$8.7 \times 10^{-6} \pm 3.8\%$	$220 \pm 7.4\%$	$1.90 \times 10^{-6} \pm 2.8\%$

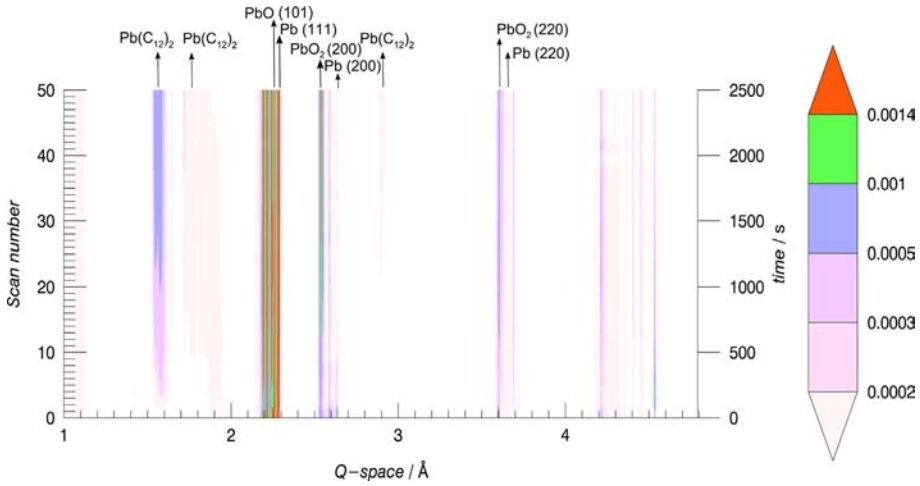

Fig. 4. A pattern set image of all diffraction patterns recorded during the growth process of the lead dodecanoate coating on a bare lead coupon using cyclic voltammetry with a scan rate of 20 mV s^{-1} in a 0.05 M aqueous sodium dodecanoate solution (as a function of time).

can be explained by the quick change of oxidation and reduction processes (due to the CV procedure) taking place at the lead surface.

Fig. 5C shows the area of the (110) and (200) plattnerite diffraction peaks at 1.7926 $Å^{-1}$ and 2.5398 $Å^{-1}$. The lead(IV)oxide growth results from the direct contact with OH^--ions in the inhibitor solution and the presence of a lead(II)oxide corrosion layer (Eq. 4). The most sensitive diffraction peak at 2.5398 $Å^{-1}$ shows small fluctuations in the calculated peak area, which are related to the alternating oxidation and reduction process due to the cyclic voltammetric deposition procedure (see second *x*-axis representing the number of CV cycles). At the start, lead(IV)oxide grows very fast due to the high vertex potential (1.5 V). The peak area reaches a maximum due to saturation of the surface.

Fig. 5D shows the peak area of the (111) and (200) lead peaks at 2.2681 $Å^{-1}$ and 2.6079 $Å^{-1}$ (taking into account the 0.077 shift of the peaks) extracted from the consecutive diffraction patterns. The observed decrease in peak area is due to surface coverage by the lead dodecanoate coating or by some corrosion products, which reduces the interaction of X-rays with the lead bulk metal. The formation of this coating layer reduces the peak area of the lead diffraction peaks. This information proves that a layer is continuously covering the lead surface of the substrate. The intensity of the lead characteristic peaks drops rapidly at the starting point and stagnates after the first two scans, which demonstrates the formation of a lead dodecanoate coating layer during the first voltammetric scan. An explanation of the changing of the peak shapes could be the reorientation of the lead crystals. The exponential fit of the lead peak is given by:

$$I = I_0 + I_m e^{-\frac{t}{\tau}} \tag{10}$$

The small oscillations in the calculated peak area of the peak at 2.2681 $Å^{-1}$ are related to the alternating oxidative and reductive process due to the cyclic voltammetric deposition procedure. All above-mentioned products have been identified using XPS, as reported in a previous communication of our group [31]. Furthermore, a hypothetical scheme is drafted for the lead dodecanoate growth on a lead sample (see Fig. S1).

Using the decay of the peak area of the most intense (111) lead peak, we can calculate the lead dodecanoate coating thickness. Consider we have a coating of thickness d on the surface of the lead substrate, the incoming X-ray beam will be attenuated on its way through the surface, and then the fraction scattered into the peak will be attenuated some more on the way out. The total attenuation of the lead peak will therefore depend on the total path length on the coating as a function of time following the Beer–Lambert law [32]:

$$\ln\left(\frac{A_k(t)}{A_0}\right) = -\left(\frac{\mu}{\rho}\right) d(t) \tag{11}$$

where A_k (t) is the peak area of the lead (111) peak at immersion time k (time dependent), A_0 is the peak area of the lead peak for no attenuation, d (t) is the mean mass thickness (mass per unit area or g cm^{-2}) of the lead dodecanoate layer and (μ/ρ) is the mean mass attenuation coefficient for the lead dodecanoate layer at 8 keV ($=122.3$ cm^2 g^{-1} (see NIST database)) [33]. This quantification gives us information on the thickness of the lead dodecanoate layer by simply dividing the mass thickness results by the density of lead acetate (comparable for lead dodecanoate), 3.25 g cm^{-3}.

This total path length is written as a function of the thickness of the coating. If we consider a X-ray beam incident at θ_i to the

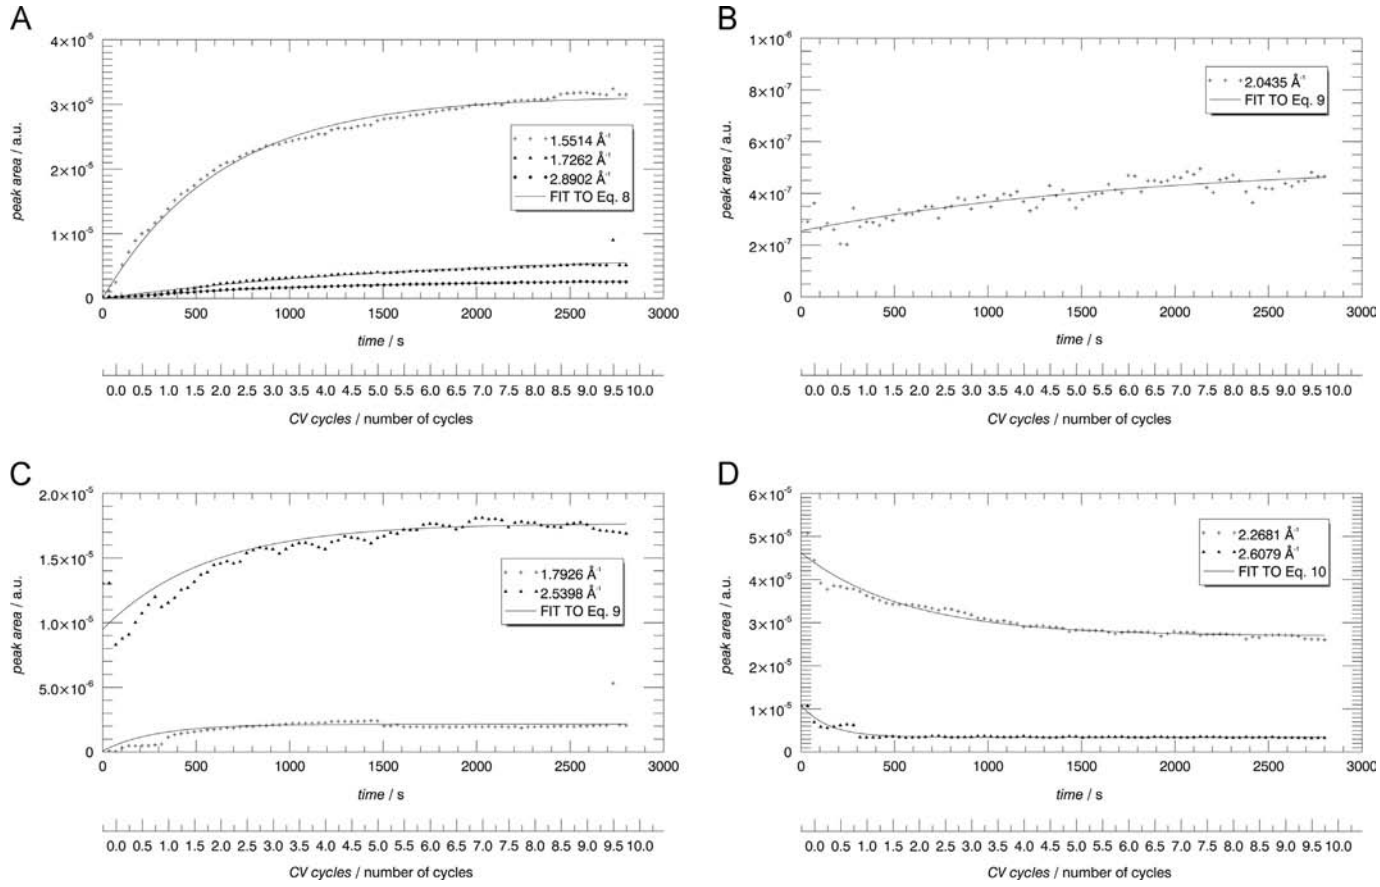

Fig. 5. The peak areas extracted from the diffraction patterns of the growth of the lead dodecanoate coating in real time using 10 consecutive cyclic voltammetric scans with a range from −1.3 V to 1.5 V and a scan rate of 20 mV s^{-1}. The peak areas were extracted from (A) lead dodecanoate at 1.5514 $Å^{-1}$, 1.7262 $Å^{-1}$ and 2.8902 $Å^{-1}$, (B) litharge at 2.0435 $Å^{-1}$, (C) plattnerite at 1.7926 $Å^{-1}$ and 2.5398 $Å^{-1}$ and (D) lead at 2.2681 $Å^{-1}$ and 2.6079 $Å^{-1}$ (taking into account the 0.077 shift of the peaks).

surface and scattered at $2\theta_s$ into the diffraction peak, the length of the inward path will be $d/\sin(\theta_i)$and the length of the outgoing path $d/\sin(2\theta_s-\theta_i)$. The total path length t will therefore be [32]:

$$t = d\left[\frac{1}{\sin(\theta_i)}+\frac{1}{\sin(2\theta_s-\theta_i)}\right] \quad (12)$$

To calculate the thickness d from the total path length, the equation is rewritten as follows:

$$d = t\left[\frac{\sin(\theta_i)\sin(2\theta_s-\theta_i)}{\sin(\theta_i)+\sin(2\theta_s-\theta_i)}\right] \quad (13)$$

where θ_i is the incident angle ($=10^\circ$) and $2\theta_s$ is the two-theta angle for the Pb(111) peak.

Fig. 6 shows the calculated thickness of the lead dodecanoate coating as a function of immersion time. The error lines are based on the fitting error on the measured peak areas of the lead (111) peak. After 1 h, the thickness of the lead dodecanoate layer is around 1.5 μm. The fast deposition is related to the fast oxidation of the lead metal in the solution due to the use of cyclic voltammetry. The reduction processes in the backward scan do not allow the lead dodecanoate film to form a thick layer. As predicted by the graph in Fig. 6, the thickness of the lead dodecanoate layer tends towards asymptotic behavior due to the passivation of the surface and adsorption of the incoming X-rays by the protective layer.

Table 2 shows statistically different time constants from the fitting implying different growth rates for the different compounds. The different τ values for the lead dodecanoate show that one peak grows faster than the other. This suggests an anisotropic growth of the lead dodecanoate crystal structure from a sodium dodecanoate aqueous solution. Probably due to the fact of the lamellar structure of the crystal, one layer is formed faster than another in the crystal [34]. Another explanation is the anisotropic formation of a lower temperature mesophase involving increased lateral disorder [35].

3.2. Corrosion test of the lead dodecanoate coated lead coupon

After the deposition, the coupons are dried in the air. Then, the coated samples are corroded using linear sweep voltammetry (LSV) in a 5 μg L^{-1} acetic acid solution with a potential range from −1 V to 1.5 V and a scan rate of 1 mV s^{-1}. During the electrochemical treatment again XRD spectra are taken.

Fig. 7 shows the peak areas extracted from the corrosion of the lead dodecanoate coated lead sample in real time using a LSV scan with a potential range from −1 V to 1.5 V and a scan rate of 1 mV s^{-1} in an acetic acid solution. The total length of the experiment is 41 min. The relevant q-space values of the most important corrosion products are shown (see also Fig. S2), obtained from the reference spectra present in the ICCD database. The initial coated sample shows diffraction lines between a q-value of 1 and 2 $Å^{-1}$. These peaks originate from the well-ordered lamellar lead dodecanoate crystals as described by Lacoutre et al. [36]. Drying the sample in air ensures that the formed complexes reorganize and form less distorted lamellar crystal structures. The most important corrosion product that could be identified in the first diffractogram is a lead carbonate compound (plumbonacrite), but still there is overlap with the lead dodecanoate diffraction peaks (see also Fig. S3). Due to presence of CO_2 in the ambient air during drying, hydrogen carbonate is formed in the aqueous solution, which reacts with the

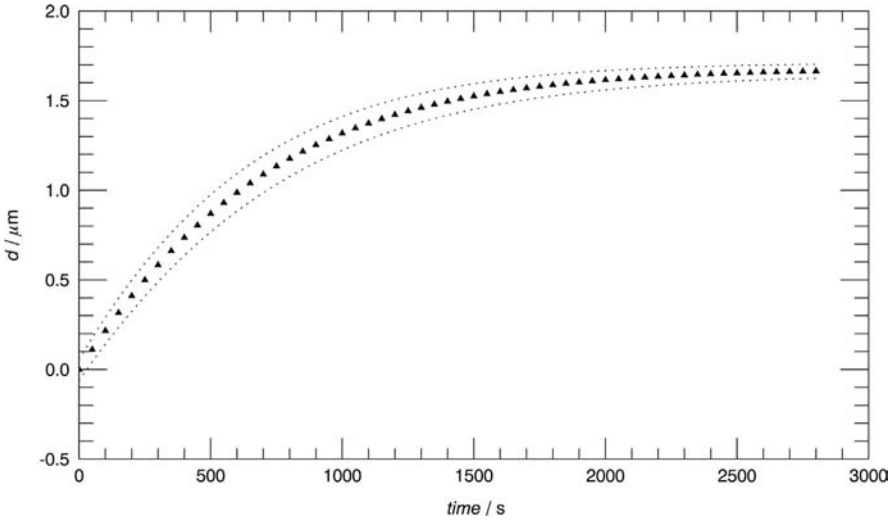

Fig. 6. The calculated thickness (d) of the lead dodecanoate coating as a function of immersion time.

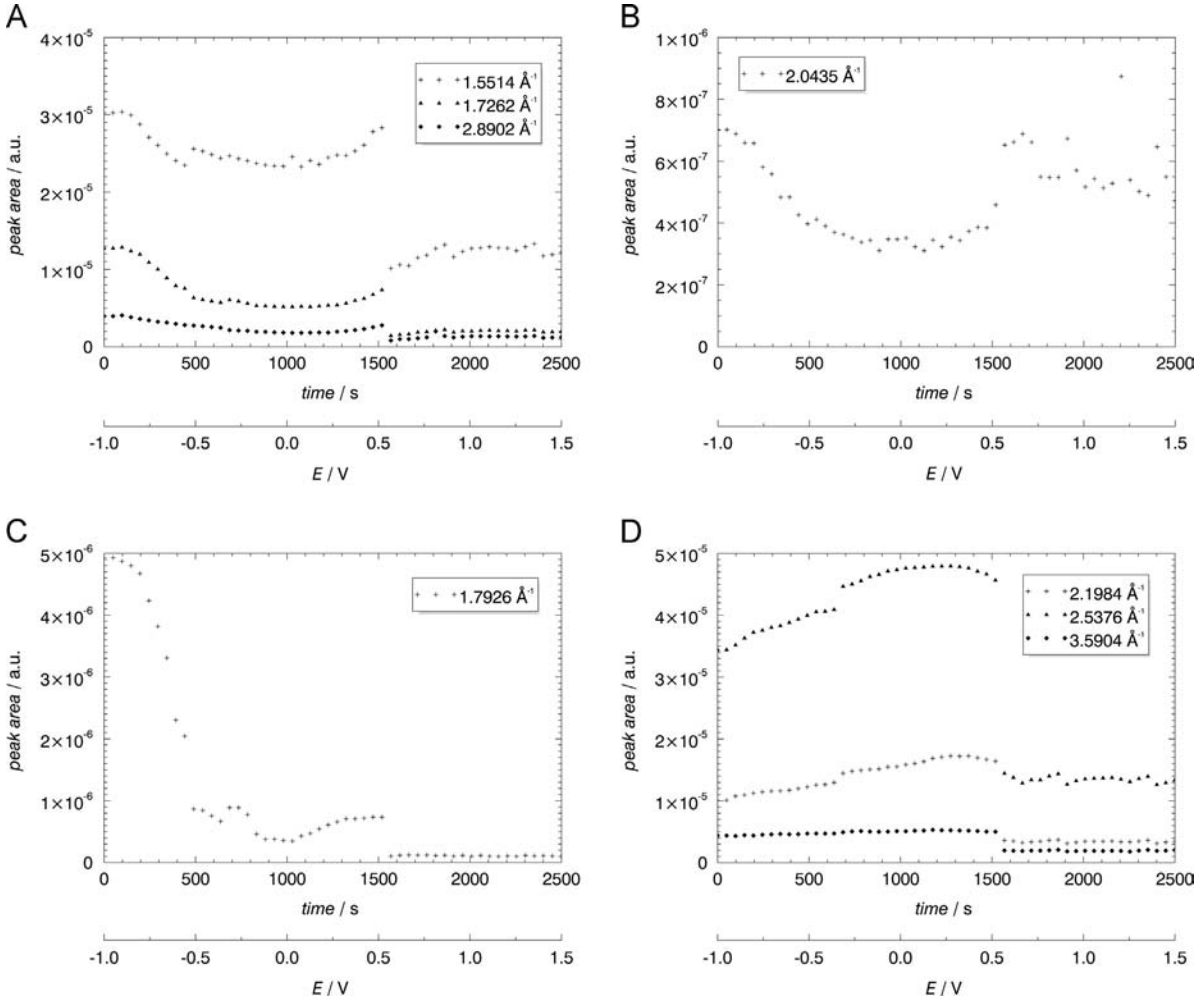

Fig. 7. The peak areas extracted from the diffraction patterns of the corrosion test of the lead dodecanoate coated lead sample in real time using a LSV scan with a range from −1 V to 1.5 V and a scan rate of 1 mV s^{-1}: (A) lead dodecanoate at 1.5514 $Å^{-1}$, 1.7262 $Å^{-1}$ and 2.8902 $Å^{-1}$, (B) litharge at 2.0435 $Å^{-1}$, (C) plattnerite at 1.7926 $Å^{-1}$ and (D) lead at 2.1984 $Å^{-1}$, 2.5376 $Å^{-1}$and 3.5904 $Å^{-1}$.

PbO at the surface to form carbonates [5]:

$$CO_2(g)+H_2O(aq)\rightleftharpoons HCO_3^-(aq)+H^+(aq) \quad (14)$$

$$6\,HCO_3^-(aq)+10\,PbO(s)+6\,H^+(aq)\rightleftharpoons Pb_{10}O(OH)_6(CO_3)_6(s)+3\,H_2O(aq) \quad (15)$$

Next to the lead dodecanoate coating and plumbonacrite, lead(II) oxide and lead(IV)oxide are present due to the high oxidation potential during deposition. During the cathodic polarization (up to −0.5 V), the lead dodecanoate complexes and lead(II)oxide corrosion products

seem to be reduced to form metallic lead (Fig. 7A and B). The lead(IV) oxide is clearly reduced at a higher rate (Fig. 7C). The cathodic current ensures a big loss of lead corrosion products, but does not destroy the deposited lead dodecanoate coating. Due to these reduction reactions, metallic lead is formed as seen in the first part of the peak area plot extracted from the (200) lead diffraction peak at 2.5376 $Å^{-1}$ (Fig. 7D).

After −0.5 V, the anodic polarization starts. It is noticeable that peak areas of all compounds shown in Fig. 7 stagnate from −0.5 V to 0.5 V. This is explained by supposing a protective region (and corrosion inhibition) for the lead dodecanoate coating present on the lead sample. In this region, no corrosion takes place due to the fact that no extra crystalline corrosion products are being formed. The SR-XRD patterns recorded at these potentials do not change as a function of time.

Around the potential of 0.5 V, major changes occur on top of the coated lead sample. A sudden drop in the peak area of the lead dodecanoate diffraction peaks explains the cracking and destruction of the lead dodecanoate coating so that the acetic acid starts to attack the lead sample (Fig. 7A). This implies that a small amount of acetic acid in the aqueous solution attacks and decomposes the hydrophobic lead dodecanoate crystal layer due to its acidic character. The presence of acetic acid ensures the start of a very fast 'active' corrosion process forming new lead acetate complexes starting with the acidification of the surface resulting in lead(II)oxide dissolution [37].

Fig. 7B shows that higher potentials induce the production of lead(II)oxide. Due to the reaction with acetic acid, these water soluble lead acetate complexes will associate with these formed lead(II)oxides present on the surface as follows [38]:

$$2\ PbO\ (s) + Pb^{2+}(aq) + 2\ CH_3COO^-(aq) + H_2O \rightleftharpoons Pb(CH_3COO)_2.2\ PbO \cdot H_2O(s) \quad (16)$$

The formed water insoluble lead acetate oxide hydrate cannot be identified due to the fact that the range of our measurements did not extend to 0–0.5 A^{-1}. The main lead acetate peak appears around 0.3 A^{-1}.

The formation of lead(IV) species, however, is unlikely at these lower oxidative potentials and without the presence of basic hydroxide species (see Fig. 7C). The peak area of the diffraction peak of lead drops suddenly together with the accumulation of corrosion products on the lead surface (see Fig. 7D). Next to the production of lead hydroxy carbonates and lead acetate oxide hydrate, the formation of dodecanoic acid on the surface explains the decrease of the lead peak area. Acids (Eq. 17) attack the hydrophobic lead dodecanoate coating re-converting the lead complexes into lead ions and dodecanoic acid [12]:

$$Pb(C_{12})_2 + 2\ H^+ \rightleftharpoons Pb^{2+} + 2\ HC_{12} \quad (17)$$

The formation of dodecanoic acid could not be confirmed using XRD, as it is no crystalline compound (could be verified using Raman spectroscopy) under these circumstances. In any case, the scattering from the hydrocarbon chain is very weak in comparison with that from the lead planes in the lead dodecanoate. One must keep in mind that this corrosion process is enormously accelerated due to the use of LSV. Real time corrosion processes would proceed much more slowly. Furthermore, a hypothetical scheme is drafted for the corrosion test measurement of a lead dodecanoate coated lead sample based on the SR-XRD patterns (see Fig. S4).

To be able to compare a reference on the acetic acid corrosion on lead, the same corrosion test procedure was applied on a bare lead coupon during 41 min. During the measurement, the only visible diffraction peaks are the ones of the bare lead substrate. Afterwards, the coupon was dried in air and a diffraction pattern was recorded (see Fig. S5). Most of the formed lead corrosion products are soluble in the acidic water making it impossible to detect them during the in-situ growth [39]. First of all, the (111) and (200) lead diffraction lines form intense narrow peaks. Close to the lead diffraction lines, the (110), (101) and (200) plattnerite diffraction peaks are detected. The low intensity peaks between q-space values of 1–1.5 $Å^{-1}$ evidence the presence of a lead carboxylate complex. The presence of acetic acid in the corrosive solution results in the formation of insoluble lead acetate oxide hydrate using reaction (Eq. (16)). The lead acetate complexes can be converted to lead hydroxy carbonates [9]. The formation of lead hydroxy carbonates is confirmed by the presence of the (115) plumbonacrite diffraction peak. Compared to the protected sample, the bare sample starts to corrode at lower potentials, which explains the higher relative intensities of these diffraction peaks associated with the active acetic acid corrosion. The lower relative intensities of the diffraction peaks predict a protective behavior of the lead dodecanoate coating on the lead samples.

4. Conclusions

In-situ spectroelectrochemical measurements have demonstrated that a crystalline lead dodecanoate coating immediately forms at the start of the experiment using cyclic voltammetry. Later on, during the drying process the formed complexes reorganize and lead hydroxy carbonates are formed. In addition to the lead dodecanoate coating, small quantities of other lead corrosion products are detected, which are explained by the oxidation of the surface and atmospheric corrosion. During the reductive scan, these lead corrosion products are reduced to form lead metal. The consecutive cyclic voltammetry scans ensure the formation of a lead dodecanoate coating up to the saturation of the surface. The fast and thin layer deposition, however, is related to the oxidation of the lead metal using cyclic voltammetry. The reduction processes do not allow the lead dodecanoate film to form a thick layer.

An accelerated 'active' corrosion test in acetic acid has been conducted on a bare and a lead dodecanoate coated lead coupon. In both cases, lead acetate oxide hydrate is formed due to the formation of lead oxides and lead acetates in the aqueous corrosive acetic acid solution. The bare sample formed much more corrosion products compared to the coated sample, which indicates the inhibitive properties of the coating.

Not only is the electrochemical coating method in an aqueous solvent quick and inexpensive (the materials are all cheap substances mass produced for industrial applications), but the deposited layers of lead dodecanoate are considerably hydrophobic and therefore potentially more protective. The method may be extended to using cotton drenched or a spray can filled with the inhibitor solution to apply the lead dodecanoate coating, increasing the range of possible applications in archeaometry and conservation.

ABSTRACT

A simple and rapid microextraction method, vortex-assisted low density solvent liquid–liquid microextraction and salt-induced demulsification (VLLME–SID) coupled to high performance liquid chromatography (HPLC) was developed for the determination of organophosphorus pesticide (OPP) residues in fruits. The studied OPPs were azinphos-methyl, parathion-methyl, fenitrothion, diazinon and chlorpyrifos. For VLLME–SID, a mixture of low density solvents (1-dodecanol and hexane) was used as the extraction solvent under vortex agitation for enhancing dispersion. After complete dispersion, the emulsion was formed and the OPPs were extracted into extraction solvent droplets. Then, the emulsion was quickly broken up into two clear phases after the addition of $AlCl_3$ as a demulsifier. Centrifugation was not required in this procedure. Under the optimal conditions, high enrichment factors (180–282), low limit of detections (LODs) (0.05–1 ng mL^{-1}) and good precision (RSD $\leq$ 7% for retention time and peak area) were obtained. The proposed method was successfully applied to the analysis of OPP residues in fruit samples (watermelon, grape, and cantaloupe). The LODs for samples were in the range 0.0006–0.0015 mg kg^{-1} which are below the established EU-MRLs (0.01–0.3 mg kg^{-1}). Good recoveries were also obtained (80–104%).

1. Introduction

Pesticides are extensively used to control pests and prevent diseases in various crops, such as fruits, vegetables and cereals. Organophosphorus pesticides (OPPs) are used instead of banned organochlorine compounds, because of their efficient control of pests and lower persistence in the environment. OPPs affect the enzyme acetyl-cholinesterase which controls nerve function not only in insects but also animals and humans [1]. Because of their persistence, water solubility, bioaccumulation and potential toxicity, OPPs may be present in a wide range of fruits, vegetables, foodstuff and agricultural runoff [2]. Therefore, it is necessary to develop analytical methods with high sensitivity, selectivity and simplicity for the determination of OPP residues in various samples to ensure health safety and international trade [3,4].

Chromatographic methods including gas chromatography (GC) and high-performance liquid chromatography (HPLC) have been widely used for the separation and quantification of OPP residues in various samples such as water [1], soil [5], fruit [6–8], tea [9], milk [10] and biological samples [11]. Since OPPs are mostly present in complex sample matrices, they cannot be injected directly into chromatographic systems. Therefore, an appropriate sample-preparation step is necessary before instrumental analysis. Good sample preparation can not only eliminate interferences but can also increase the concentration of the analytes, thus enhancing the apparent sensitivity of the analytical method.

Dispersive liquid–liquid microextraction (DLLME) has been recognized as an effective preconcentration method for various target compounds [12,13]. DLLME is based on a ternary solvent system including an aqueous solution, a water immiscible solvent (extraction solvent) and a water miscible solvent (dispersive solvent). The dispersion (cloudy solution) and very fine droplets occur immediately, just after the rapid injection of the mixture solution of extraction and dispersive solvents into aqueous solution. During this step, the analytes enter the extraction phase

and are concentrated. Subsequently, the extraction solvents with higher density than water are separated from aqueous phase by centrifugation. DLLME provides many advantages such as simplicity, high enrichment factors, and rapid extraction times [14].

However, there are some limitations in DLLME mostly arising from the solvents used in this technique. These include (i) the use of hazardous chlorinated solvents having density higher than water [15], and (ii) the use of dispersive solvents, resulting in decreased partition coefficients of analytes into the extraction solvent [16]. Another limitation of DLLME is the extra time required for the centrifugation step.

Several strategies have been attempted to address these limitations and also to achieve high extraction efficiency using more "green" extraction methods. The first efforts use extraction solvents having densities lower than water and/or the solidification of floated organic solvents [17,18]. However, for this approach, special homemade narrow-necked devices are required. Other strategies involve the use of surfactants instead of water miscible dispersive solvents [19]. In addition, vortex agitation or application of ultrasound energy have been employed in dispersion process [16,20,21].

Recently, demulsified DLLME has been introduced with its advantages of simplicity and fast extraction [15,22–24]. In demulsified DLLME, the demulsifier is added to facilitate the phase separation of the aqueous phase and the organic extraction phase, thus the centrifugation step is omitted. The demulsifiers used are water miscible organic solvents which are mostly used as the dispersive solvent. This approach still suffers from the decreased partition coefficients of analytes into the extraction solvent [15,22–24].

Therefore, it is a challenge to develop demulsified DLLME with new demulsifiers. As an alternative demulsifiers, electrolytes, or salts, can reduce the zeta potential, hence decrease the stability of hydrophobic colloids (an emulsion solution) and increase the ionic strength of solution, leading to flocculation and coalescence of fine droplets of the extraction solvent [25–27]. Thus, the separation of two phases is expected from the addition of electrolyte into emulsion.

In the present work, vortex-assisted low density solvent liquid–liquid microextraction and salt-induced demulsification (VLLME–SID) preconcentration of OPPs residues prior to analysis by high performance liquid chromatography have been developed. For the VLLME–SID, the solvent having a density lower than water was used as extraction solvent. A vortex agitator was used for dispersion (without the addition of dispersive solvent). Salts were investigated as a new demulsifier to address the large volume problem of the conventional solvent-demulsified DLLME. In addition, the extraction can be performed using a 10-mL narrow-necked volumetric flask and common laboratory glassware. A modified QuEChERS (Quick, Easy, Cheap, Effective, Rugged, and Safe) method [28] was used for fruit samples preparation before VLLME–SID and analysis by HPLC.

2. Experimental

2.1. Chemicals and reagents

All chemicals were of at least analytical reagent grade. The analytical standards of organophosphorus pesticides (OPPs) were obtained from Dr. Ehrenstorfer GmbH (Germany), including azinphos-methyl, parathion-methyl, fenitrothion, diazinon and chlorpyrifos. The stock solutions of each pesticide were prepared at 1000 mg L^{-1} by dissolving an appropriate amount in methanol (MeOH). 1-undecanol, 1-dodecanol and 2-dodecanol were purchased from Sigma-Aldrich (USA). 1-Octanol was obtained from Panreac (Spain). n-Hexane was obtained from Lab-Scan Analytical Sciences (Ireland). Methanol (HPLC grade) was obtained from RCI Labscan Ltd. (Thailand) and acetonitrile (HPLC grade) was obtained from Merck (Germany). Sodium chloride (APS, Australia), magnesium sulfate anhydrous (Panreac, Spain), magnesium chloride (Carlo Erba, France), sodium acetate (Carlo Erba, France), acetic acid (Carlo Erba, France), aluminum chloride anhydrous (Ajax Finechem Pty Ltd, New Zealand) and aluminum sulfate hexahydrate (Fluka, Switzerland) were utilized. All solutions were prepared in deionized water with the resistivity of 18.2 MΩ cm from RiO_s™ Type I Simplicity 185 (Millipore Waters, USA).

2.2. Instruments

The HPLC system (Waters, Massachusetts, USA) consisted of an in-line degasser, a 600E quaternary pump, and a Waters 2996 photodiode array detector (DAD). Empower software was used to control the system and for the acquisition and analysis of data. The separation of the studied pesticides was carried out on a Chromolith RP-18e (2 mm × 50 mm, 1.5 μm) column (MERCK, Germany). A vortex mixer (50 Hz) from Scientific Industries, INC (USA) was used. Other equipments including a thermostatted water bath (ISOTEMP 228, Thermo Fisher Scientific, Massachusetts, USA), a Rotavapor R-200 (Buchi Labortechnik AG, Switzerland) and automatic shaker (SSeriker, Vision Scientific, Korea) were also used.

2.3. Sample preparation

Fruit samples including cantaloupe, watermelon (yellow pulp and red pulp) and grape were randomly purchased from local markets at Khon Kaen province in Northeast Thailand. Peels of the fruit samples (except grape) were removed. The edible parts of samples (500 g) were cut and blended using a commercial food mixer. A modified QuEChERS method [28] was applied for sample preparation of the studied fruit samples. Briefly, a precisely weighed representative sample portion (about 10 g) was placed in a 50 mL centrifugation tube and mixed with 20 mL of 1% (v/v) acetic acid in ACN. Then the mixture was shaken at 300 rpm for 5 min using automatic shaker. After that, anhydrous $MgSO_4$ (15 g) and sodium acetate (1 g) were added and the mixture was immediately shaken manually. The solution was then centrifuged at 3000 rpm for 5 min. The supernatant was subsequently evaporated to dryness using a rotary evaporator (40 °C water bath). The resulting residue was re-dissolved with 10.00 mL of water before extraction by VLLME–SID.

2.4. VLLME–SID procedure

A 10 mL aliquot of a standard solution of the OPP mixture or sample solution was placed in a 10 mL volumetric flask. A mixture of 15 μL hexane and 15 μL 1-dodecanol was added into the sample solution. The solution was then vortexed at 1800 rpm for 1 min, forming a cloudy solution. After the addition of 1% (w/v) of $AlCl_3$, the solution was clear and quickly separated into two phases and the extraction phase floated on the surface of the solution. The floated extraction phase was collected using a micro-syringe and then injected into the HPLC for analysis.

2.5. HPLC conditions

The separation of OPPs was performed on a Chromolith RP-18e (2 mm × 50 mm, 1.5 μm) column with gradient elution using ACN and water, at a flow rate of 1.0 mL min^{-1} and detection at 210 nm. The injection volume was 10 μL. The gradient elution profile of ACN and water (%v/v) was programmed as follows: 35% (v/v) ACN (0–1.5 min), followed by an increase to 70% (v/v) ACN (1.5–2 min) and then held at 70% (v/v) ACN until 8 min. After that, the composition of mobile phase was returned to the initial value of

35% (v/v) ACN in order to equilibrate the column for the next run. Using the above mentioned conditions, the separation of five OPPs was successfully obtained within 6 min with the resolution greater than 2.2.

3. Results and discussion

3.1. Type of the extraction solvent

A choice of extraction solvent is a key parameter for high extraction efficiency of DLLME. The extraction solvent is considered based on a high extraction capability for the target analytes and compatibility with HPLC chromatographic separation. In this study, the immiscible solvents having density lower than water were investigated, including hexane, 1-octanol, 1-undecanol, 1-dodecanol and 2-dodecanol. The extraction efficiency was evaluated by enrichment factor (EF). The EF was calculated based on the analyte concentration in the floated phase ($C_{floated}$) divided by the initial analyte concentration in the aqueous samples (C_0) [18]. Fig. 1 shows the effect of extraction on EF. It is clearly seen that types of extraction solvent affect the extraction efficiency for both a number of the analytes extracted and the EF. The differences in the extraction efficiencies of solvents may be discussed in terms of polarity (log K_{ow}) [29] and water solubility of solvents [30]. Among the solvents investigated, the most polar solvent, 1-octanol (log K_{ow}=3.15), could not extract any analytes studied. This may due to the high water solubility of 1-octanol (water solubility ~814 mg/L). Three OPPS (azinphos-methyl, parathion-methyl and fenitrothion) were extracted by 1-undecanol, while, four OPPS (azinphos-methyl, parathion-methyl, fenitrothion and diazinon), were extracted by both 1-dodecanol and 2-dodecanol. Although, 1-dodecanol and 2-dodecanol could extract four OPPs (the same OPPs), 1-dodecanol provided higher EF than 2-dodecanol. This may be explained by the lower polarity of 1-dodecanol compare to 2-dodecanol and 1-undecanol. The water solubilities of these alcoholic solvents are in the order: 6.9 mg/L (1-dodecanol), 16.2 mg/L (2-dodecanol), and 43.0 mg/L (1-undecanol) which also agree well with their log K_{ow} as follow: 1-dodecanol (5.13), 1-undecanol (4.72) and 2-dodecanol (4.70). The non-polar solvent, hexane, could extract four OPPS (azinphos-methyl, parathion-methyl, fenitrothion and chlorpyrifos). It was found that the least polar analyte, chlorpyrifos (log K_{ow}=4.66), was extracted only by hexane. As these results show, a single extraction solvent could not extract all targeted OPPs in this study.

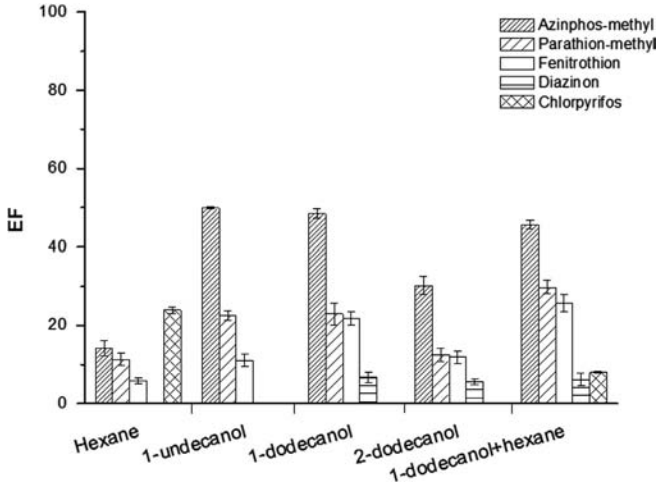

Fig. 1. The effect of extraction solvent on EF of OPPs. Extraction conditions: water sample volume (10.00 mL), extraction solvent volume (100 μL), vortex time (20 s at 1800 rpm), 0.5 g of $Al_2(SO_4)_3$ and 0.05 mg L^{-1}OPPs (each).

A combination of extraction solvents was then used to test the feasibility for extracting and preconcentrating OPPs. The mixture of 1-dodecanol and hexane (1:1, v/v) was investigated. As the result show, the mixture of extraction solvent of 1-dodecanol and hexane was effective for extraction of all target OPPs. Consequently, 1-dodecanol mixed with hexane at 1% (v/v) was chosen for further studies.

3.2. Effect of the extraction solvent volume

The extraction solvent volume influences directly the extraction efficiency. Enough extraction solvent is required for quantitative extraction. On the other hand, a large volume of extraction solvent results in dilution of the extraction phase [22]. As a compromise between high extraction efficiency and minimizing the dilution effect, the volume of 1-dodecanol and hexane (1:1 (v/v)) was investigated from 20 μL to 90 μL. The volume of extraction solvent lower than 30 μL was difficult to handle when collecting the extract phase. The highest EF was obtained at 30 μL and then decreased dramatically with increasing extraction solvent volume from 40 μL due to the dilution effect. Therefore, 30 μL of a mixture of 1-dodecanol and hexane was chosen (Fig. 2).

3.3. Effect of vortex extraction time

Without dispersive solvents, a vortex agitation is a simple alternative way to enhance extraction efficiency in a short time. A vortex mixer facilitates the dispersion of the extraction solvent into the aqueous solution resulting in enhancement of extraction efficiency [20]. In this study, a 10-mL narrow-necked volumetric flask was used as a simple and convenient extraction device. The vortex rotational speed was fixed at 1800 rpm and different vortex times were investigated, from 0.5 to 5 min. It is clearly seen that the extraction equilibrium could reach within a short time (1 min) and also providing high EF for all target analytes. After 1 min, the EF of all target analytes was constant. Based on these results, the use of vortex agitation for 1 min at 1800 rpm was chosen.

3.4. Effect of salt demulsifier

In general, the addition of salt decreases the solubility of analytes in aqueous solution, due to salting-out effect [16]. Thus, analytes transfer efficiently to the extraction (organic) phase. It has been reported that strong electrolyte salts can be used as demulsifier to break-up the emulsion [25,26,31]. After the water immiscible extraction solvent and aqueous solution were mixed using a

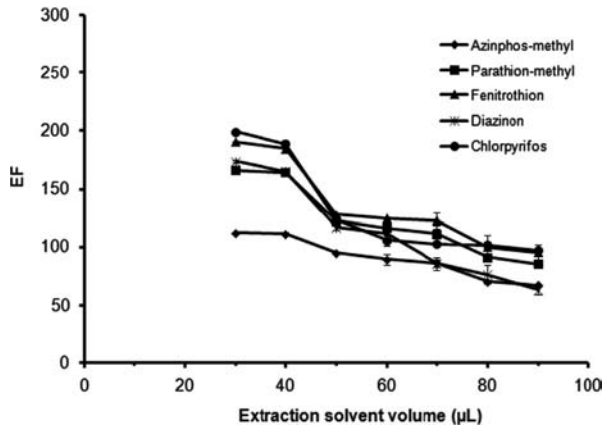

Fig. 2. The effect of extraction solvent volume on the EF. Extraction conditions: water sample volume (10.00 mL), 1-dodecanol: hexane (1:1, v/v) as extraction solvent, vortex time (20 s at 1800 rpm), 0.5 g of $AlCl_3$ and 0.05 mg L^{-1}OPPs (each).

vortex mixer, an emulsion was formed. The addition of electrolytes into solution may reduce zeta potential and the stability, particularly of hydrophobic colloids. Thus, the repulsion of the droplets of extraction solvent in the solution was decreased [27], resulting in agglomeration of fine droplets of extraction solvent and finally the phase separation was easily obtained. Various salts were studied at 1.0%, w/v, such as sodium chloride (NaCl), sodium sulfate (Na_2SO_4), magnesium sulfate ($MgSO_4$), magnesium chloride ($MgCl_2$), aluminum chloride ($AlCl_3$) and aluminum sulfate ($Al_2(SO_4)_3$). It is clearly seen (Fig. 3) that $AlCl_3$ provided the highest efficiency. This may due to the stronger interaction between the larger charge of the salt and the emulsion. $AlCl_3$ was chosen for further studies because it is the most effective demulsifier. Notice that increasing the % w/v of $Al_2(SO_4)_3$ to obtain the same amount (mole) as $AlCl_3$, the obtained EFs were not significantly different.

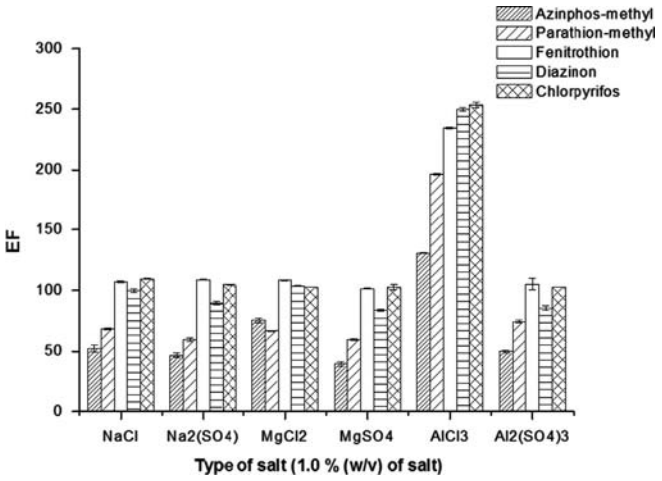

Fig. 3. The effect of type of salt as demulsifier on the EF. Extraction conditions: water sample volume (10.00 mL), 30 μL of 1-dodecanol: hexane (1:1, v/v) as extraction solvent, vortex time (1 min at 1800 rpm), 1.0% w/v of salt and 0.05 mg L^{-1}OPPs (each).

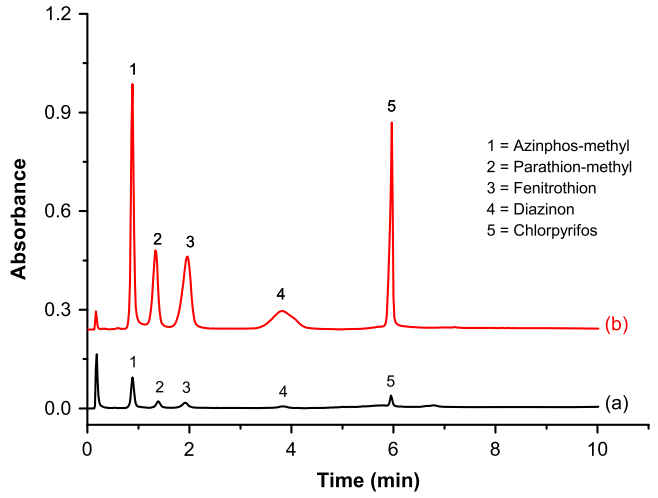

Fig. 4. Chromatograms of the studied OPPs obtained using on a Chromolith RP-18e (2 mm × 50 mm, 1.5 μm) column and injection volume as 10 μL, (a) direct analysis without preconcentration (5 mg L^{-1} of each OPP) and (b) using VLLME–SID conditions: 15 μL of 1-dodecanol mixed with 15 μL of hexane as extraction solvent, vortex 1 min at 1800 rpm, 1.0% (w/v) of $AlCl_3$ as demulsifier and 0.5 mg L^{-1} of each OPP.

The amount of $AlCl_3$ was then investigated from 0.5–10% (w/v). The results indicated that 1.0% (w/v) gave the highest EF, after that the EF was constant over the studied range. It was found that the amount of $AlCl_3$ affected directly on the phase separation. For lower amounts of $AlCl_3$ (less than 1.0% (w/v)), the extraction phase and the aqueous phase were not clearly separated. Thus, 1.0% (w/v) $AlCl_3$ was chosen as the optimum demulsifier concentration.

3.5. Quantitative analysis and method validation

A typical chromatogram obtained from the VLLME–SID method compared to direct injection analysis (before preconcentration) under the optimum conditions is shown in Fig. 4. The analytical performance and validation parameters, including linear ranges, limits of detection (LODs), precisions (intra-day and inter-day) and enrichment factors (EF), were evaluated. The results are listed in Table 1. Good linearity was observed in the range 0.5–500 ng mL^{-1} with a coefficient of determination (r^2) higher than 0.9998. The obtained LODs were from 0.05 to 1 ng mL^{-1}. The intra-day (repeatability) and inter-day (reproducibility) precisions of the developed method are expressed as the relative standard deviations (RSD) of several measurements ($n=5$) of the standard mixture (at 10 ng mL^{-1} each) in a day and three executive days, respectively. High precision was obtained with RSDs of retention time less than 2.7%, while RSDs of peak area were below 6.7%. High EF ranging from 180 to 282 were obtained.

3.6. Fruit analysis

The matrix-match calibration was constructed to eliminate matrix interference in samples. The solutions of fruit extracts after QuEChERS were spiked with the target OPPs at five concentration levels in the range of 0.001–0.5 mg kg^{-1} before VLLME–SID and analysis. Calibration curves show good linearity over the studied concentration ranges with the coefficient of determination (r^2) greater than 0.995. LODs of the target analytes in samples were also investigated using 3.3 × (SD *y*-Intercept/Average Slope) and limits of quantitation (LOQs) were statistically determined using 10 × (SD *y*-Intercept/Average Slope) [32]. The obtained LODs are in the range of 0.0006–0.0015 mg $kg^{-1}$for all the studied OPPs in the fruit samples. These are below the established EU-MRLs (0.01–0.3 mg kg^{-1}). LOQs were in the range of 0.0020–0.0055 mg kg^{-1}. The identification and

Analytical performance of the proposed method for the studied OPPs standard solution.

Pesticide	Linear equation	Linearity (ng mL^{-1})	r^2	LOD (ng mL^{-1})	EF	Intra-day ($n=5$), %RSD		Inter-day ($n=5\times3$ days), %RSD	
						t_R	area	t_R	area
Azinphos-methyl	$Y=8{,}490{,}908X+9597$ ($Y=55{,}369X-8478$)[a]	0.5 – 500	0.9999	0.05 (50)	197	2.0	3.5	2.6	6.7
Parathion-methyl	$Y=5{,}296{,}248X-3996$ ($Y=26{,}518X-5834$)	1.0 – 500	0.9999	0.3 (100)	222	1.5	2.5	2.4	6.0
Fenitrothion	$Y=6{,}837{,}688X+2940$ ($Y=24{,}235X-7162$)	1.0 – 500	0.9998	0.3 (100)	282	1.5	4.2	2.4	5.6
Diazinon	$Y=4{,}212{,}274X-21{,}268$ ($Y=13{,}872X-6472$)	5.0 – 500	0.9999	1.0 (500)	180	2.2	2.9	2.7	3.5
Chlorpyrifos	$Y=6{,}261{,}339X-8403$ ($Y=25{,}417X-16{,}328$)	0.5 – 500	0.9999	0.05 (100)	232	0.6	1.4	0.6	3.7

[a] Values reported in parentheses are obtained from without preconcentration method (direct injection).

confirmation of peaks were performed using three criteria: (1) comparison of retention times to those of the standard, (2) addition of known amounts of the expected OPPs and observation of the increase in peak area, (3) comparison of absorption spectra with the standards using a photodiode array detector. For this analysis, no contamination by OPPs was detected in cantaloupe and watermelon, but azinphos-methyl and parathion-methyl were found in grape sample at concentration of 0.0054 ± 0.0010 mg kg^{-1} and 0.0087 ± 0.0013 mg kg^{-1}, respectively. To test the accuracy of the proposed method, recovery was investigated by spiking known concentrations (0.0075, 0.010 and 0.025 mg kg^{-1}) of mixed standard OPPs into samples before QuEChERS and VLLME–SID. All experiments were performed in triplicate. Fig. 5 shows the chromatograms of a grape sample (blank) and grape with mixed OPPs (0.025 mg kg^{-1} each). The results (Table 2) indicate good analytical performance of the proposed method with average recoveries of all the studied OPPs ranged from 80% to 104% and good precision with relative standard deviation (RSD) less than 12%.

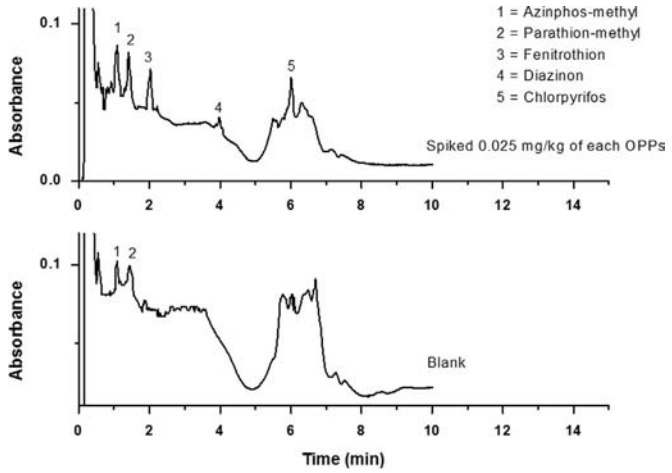

Fig. 5. Chromatograms of grape sample (blank) and grape sample spiked with 0.025 mg kg^{-1} of each OPP extracted using QuEChERS and VLLME–SID. The VLLME–SID conditions: 15 μL of 1-dodecanol mixed with 15 μL of hexane as extraction solvent, vortex 1 min at 1800 rpm and 1.0 (% w/v) of $AlCl_3$ as demulsifier.

3.7. Comparison to the other sample preconcentration methods for OPPs in fruit samples

The extraction efficiency of the proposed VLLME–SID method was compared to the other sample preconcentration techniques for the determination of OPP residues in fruits in terms of LOD, recovery, RSD, extraction time, EF and solvent volume (Table 3). The analytical features in terms of accuracy and precision obtained from the proposed method were comparable to those from the other methods. LODs of the proposed method are lower than the others. In addition, the proposed method is superior to the others in term of using small amounts of organic solvents, short extraction times and simple procedures. Therefore, it can be used as an alternative technique to the conventional DLLME and the other complicated extraction methods for analysis OPP residues in fruit samples.

4. Conclusions

A new demulsified DLLME method for the preconcentration of OPP residues including azinphos-methyl, parathion-methyl, fenitrothion, diazinon and chlorpyrifos in fruit samples using VLLME–SID method and analysis by HPLC–DAD has been successfully developed. The chromatographic analysis was performed on a short Chromolith RP-18e column (2 mm × 50 mm, 1.5 μm) with gradient elution using ACN and water, at a flow rate of 1.0 mL min^{-1}, and detection at 210 nm. The injection volume was 10 μL. The separation of five OPPs was successfully obtained within 6 min with the resolution greater than 2.2. The VLLME–SID used extraction solvent (1:1 (v/v) of 1-dodecanol and hexane) without dispersive solvent and in the presence of salt (as demulsifier) under vortex agitation. The method is easy, rapid, and uses less organic solvent; therefore it is environmental friendly and does not require any special

homemade devices. High enrichment factors (180–282), low LODs (0.05 to 1 ng mL^{-1}) and good repeatability (RSD ≤ 7%) were obtained. Overall, VLLME–SID is an excellent approach to the determination of studied OPPs in fruit samples (watermelon, grape and cantaloupe). Azinphos-methyl and parathion-methyl were found in grape at concentrations of 0.0054 ± 0.0010 mg kg^{-1} and 0.0087 ± 0.0013 mg kg^{-1}, respectively, however, they are lower than the regulatory limit for pesticides residues.

ABSTRACT

A LC–MSMS method for the simultaneous determination of tamoxifen, *N*-desmethyltamoxifen, 4-hydroxytamoxifen and endoxifen in dried blood spots samples was developed and validated. The method employs an ultrasound-assisted liquid extraction and a reversed phase separation in an Acquity® C18 column (150 × 2.1 mm, 1.7 μm). Mobile phase was a mixture of formic acid 0.1% (v/v) pH 2.7 and acetonitrile (gradient from 60:40 to 50:50, v/v). Total analytical run time was 8 min. Precision assays showed CV % lower than 10.75% and accuracy in the range 94.5 to 110.3%. Mean analytes recoveries from DBS ranged from 40% to 92%. The method was successfully applied to 91 paired clinical DBS and plasma samples. Dried blood spots concentrations were highly correlated to plasma, with $rs > 0.83$ ($P < 0.01$). Median estimated plasma concentrations after hematocrit and partition factor adjustment were: TAM 123.3 ng mL^{-1}; NDT 267.9 ng mL^{-1}, EDF 10.0 ng mL^{-1} and HTF 1.3 ng mL^{-1}, representing in average 98 to 104% of the actually measured concentrations. The DBS method was able to identify 96% of patients with plasma EDF concentrations below the clinical threshold related to better prognosis (5.9 ng mL^{-1}). The procedure has adequate analytical performance and can be an efficient tool to optimize adjuvant breast cancer treatment, especially in resource limited settings.

1. Introduction

Tamoxifen (TAM) [*trans*-1-(4-β-dimethylaminoethoxyphenyl)-1,2-diphenyl-1-butene] has been the mainstay hormonal treatment for breast cancer for more than 30 years, with significant impact on the survival rates of patients. However, besides the therapeutic benefits of TAM in the general population, 30 to 50% of patients under TAM pharmacotherapy have tumor recidives or present resistance to the treatment [1].

The usual presentation of TAM is TAM citrate tablets, containing 10 or 20 mg of the pure *trans* isomer, with the recommended posology of 20 mg per day. TAM pharmacologic activity is dependent of its bioativation by cytochrome P 450 enzymes [2,3]. CYP3A4 and 3A5 convert TAM to *N*-desmethyltamoxifen (NDT), this being the largest primary metabolic route. NDT undergoes 4-hydroxylation via CYP2D6, being biotransformed into 4-hydroxy-*N*-desmethyltamoxifen or (Z)-endoxifen (EDF). CYP2D6 also catalyzes the metabolism of TAM to 4-hydroxy-TAM (HTF) [4]. The antiestrogenic activity of TAM is mainly due to EDF, which, as HTF, is up to 100 times more potent to inhibit the proliferation of

estrogen-dependent cells, and usually have plasma concentrations up to 6 times higher than HTF [5].

EDF plasma concentrations were widely variable among patients, what could be explained by polymorphisms in the gene encoding CYP2D6 and by interactions with enzyme modulating agents, leading to insufficient plasma EDF levels in many individuals [6]. Along CYP2D6, CYP3A and CYP2C9 enzymes were related to EDF formation, but to a lesser extend [2]. Recently, Teft et al. [7] described reduced EDF plasma concentrations during the winter months, which was associated to low plasma 25-hydroxyvitamin D levels. These authors suggested that CYP3A4 activity together with sunlight exposure is an underscored factor in the evaluation of the therapeutic efficacy of TAM.

In a recent clinical study, Madlensky et al. [8] exploited the relation between the clinical outcome of hormonal therapy and serum concentrations of TAM and its metabolites, suggesting that adequate therapeutic outcome is dependent to the achievement of a threshold EDF concentration. Patients presenting trough EDF plasma levels above 5.9 ng mL^{-1} had a 26% reduction of recurrences comparing with patients with EDF concentrations below this threshold. These findings, along with the increasing knowledge about TAM metabolism modulating agents, encouraged studies with individualized dose adjustments, with increased doses for patients with impaired EDF formation (30 or 40 mg day^{-1}) [9–11]. Moreover, the metabolic ratio [NDF]/[EDF] has been described as an appropriate surrogate of CYP2D6 activity, rendering useful clinical information about TAM metabolism [5]. Considering the available evidence, therapeutic drug monitoring of TAM and its main metabolites during hormonal therapy of breast cancer could be an important tool to obtain optimal pharmacological response, recognizing patients eligible to higher TAM doses or alternative pharmacotherapy.

Several methods for the measurement of TAM and metabolites in serum or plasma samples were described [6,12–14]. To obtain these conventional samples, it is necessary to perform a phlebotomy in a proper facility, also considering pharmacokinetically appropriated collection times. A novel option for therapeutic drug monitoring that has been emerging recently is testing in dried blood spots on paper (DBS), collected by finger prick [15–17], mainly due to the stabilization of the analytes by drying and the possibility of postal transportation, once DBS samples are usually non-bio hazardous. Also, this novel matrix allows the possibility of training patients to take their own samples and flexible collection times, more adequate to their personal posology [18].

The use of DBS for TAM and metabolites measurements could be a very useful strategy to optimize the use of this drug in breast cancer, potentially allowing continuous monitoring of EDF levels during a long-time treatment, without requiring patients to come to a specialized center. However, considering the small blood volume present in a DBS obtained after a finger prick and the low concentrations of TAM and metabolites, especially EDF, this application requires highly sensitive analytical methods. In view of the above, the objective of this study was to develop and validate a method for determination of TAM and its metabolites NDT, EDF e HTF in DBS using ultra performance liquid chromatography-positive electrospray ionization tandem mass spectrometry and evaluate its performance in clinical samples of breast cancer patients.

2. Experimental

2.1. Reagents, materials and reference standard samples

Tamoxifen, 4-hydroxy tamoxifen e clomifen citrate (E/Z) were acquired from Sigma (Saint Louis, USA). *N*-desmethyl tamoxifen chloridrate and *N*-desmethyl-4-hidroxy tamoxifen (E/Z) were obtained from Toronto Research Chemicals (North York, Canada). Tris(hidroxymethyl)aminomethane was obtained from Nuclear (Diadema, Brazil). Formic acid, metanol, acetonitrile, *n*-propanol and hexane (60% *n*-hexane) were bought from Merck (Darmstadt, Germany). Purified water was obtained from an Elga Purelab Ultra® system from Veolia Labwater (High Wycombe, UK). Whatman 903 paper was obtained from GE Healthcare (Westborough, USA).Finger prick blood samples were collected using Medlance® Plus Special lancets (0.8 mm blade) from Medlance Plus Special (Marietta, USA).

2.2. Preparation of solutions and standards

TAM, NDT and EDF (E/Z) stock solutions were prepared in methanol to obtain a concentration of 1 mg mL^{-1}. The stock solution of HTF was prepared in methanol to obtain a concentration of 0.1 mg mL^{-1}. Stock was diluted with methanol to obtain intermediate solutions of EDF and HTF at 20 μg mL^{-1} and intermediate solutions of TAM, NDT e EDF at 40 μg mL^{-1} (20 μg mL^{-1} of the Z-fraction of EDF). Working solutions were prepared by dilution of the intermediate solution with methanol. Calibration samples were prepared in whole blood diluting working solutions at 1:20 with whole blood free from the analytes, as described in the *linearity* section. Clomifene citrate stock (internal standard, IS) solution was prepared in methanol at 1 mg mL^{-1} concentration. Intermediate clomifene solutions were prepared by dilution of the stock with methanol (10.0 μg mL^{-1}) and further diluted to 0.1 μg mL^{-1}. DBS extraction solution was prepared by dilution of the clomifene intermediate (0.1 μg mL^{-1}) with methanol to obtain a concentration of 0.1 ng mL^{-1}.

2.3. Sample preparation

Quality control and calibration samples were prepared by pipetting 60 μL aliquots of spiked blood onto Whatman 903 paper and leaving them to dry at room temperature for 3 h before processing. DBS discs were obtained by perforation, using a 10 mm punch cutter, and two discs were used for extraction. Discs were cut in half, transferred to polypropylene microtubes and 1000 μL of extraction solution was added (clomifene 0.1 ng mL^{-1} in methanol), followed by 1 min vortexing. After 45 min h in an ultrasonic bath, 850 μL of extract was transferred to a clean polypropylene microtube and dried at 55 °C under a gentle stream of air. The dried extract was recovered with 100 μL of mobile phase, transferred to an autosampler vial and a 25 μL aliquot was injected into the LC–MS/MS system.

2.4. UHPLC–MS–MS equipment and conditions

Samples were analyzed using a TSQ Quantum Access triple quadrupole mass spectrometer with an electrospray source, coupled to an Ultimate 3000 XRS UHPLC system, controlled by the Xcalibur software, all from Thermo Scientific (San Jose, USA). Separation was performed in an Acquity C18 column (150 × 2.6 mm, p.d. 1.7 μm) from Waters (Milford, USA), maintained at 50 °C and eluted at a mobile phase flow rate of 0.4 mL min^{-1}. The mobile phase consisted of formic acid 0.1% pH 2.7 (eluent A) and acetonitrile plus 0.1% formic acid (eluent B). Initial eluent composition was 60% A, maintained for 3 min, and followed by a linear 1 min ramp to 50%, which was maintained for until 5.5 min. The mobile composition returned to 60% A at 6 min. Equilibration time was 2 min. Injection volume was 25 μL. The MS conditions were as follows: electrospray ionization (ESI), positive mode, capillary voltage of 4 kV; sheath gas, nitrogen at a flow rate of 50 arbitrary units; auxiliary gas, nitrogen at flow rate of ten arbitrary units; collision

gas, argon; vaporizer temperature, 400 °C; and ion transfer capillary temperature, 220 °C. The scan time was set at 0.3 s per transition. The following transitions were used for MRM acquisition: TAM *m/z* 372→72 (quantitation) and *m/z* 372→70 and 372→129 (qualification); NDT *m/z* 358→58 (quantitation) and *m/z* 358→129 and 358→178 (qualification); EDF *m/z* 374→58 (quantitation), *m/z* 374→152 and 374→223 (qualification); HTF *m/z* 388→72 (quantitation) and *m/z* 388→129 and 388→223 (qualification); IS (clomifene) *m/z* 406→100 (quantitation) and *m/z* 406→72 and 406→58 (qualification). Collision energies were 23, 19, 19, 24 and 24 eV for TAM, NDT, EDF, HTF and IS, respectively.

2.5. Selectivity

Blank DBS samples obtained from 6 different human sources were prepared as described above to check for the presence of chromatographic peaks that might interfere with detection of analytes or IS.

2.6. Benchtop stability

For estimation of stability of processed samples under the conditions of analysis, control DBS samples were extracted as described above, in sextuplicate. Quality control low (QCL) samples had TAM, NDT, EDF e HTF at 21.0; 45.0; 3.0 and 1.8 ng mL^{-1}, respectively. Quality control high (QCL) samples had TAM, NDT, EDF and HTF at 210.0; 450.0; 30.0 and 10.8 ng mL^{-1}, respectively. The extracts obtained at each concentration were pooled. Aliquots of these pooled extracts at each concentration were transferred to autosampler vials and injected under the conditions of a regular analytical run at time intervals of 1 h, during 12 h. Stability of analytes was tested by regression analysis plotting absolute peak areas corresponding to each compound at each concentration *vs.* injection time. Using the obtained linear regression, the concentration after 12 h was calculated. A decrease or increase of up to 10% in the measured peak areas was considered as acceptable.

2.7. Stability of analytes in DBS at varying temperatures

For evaluation of thermal stability of TAM and metabolites in DBS samples, quality control DBS samples (QCL and QCH), previously described, were maintained at −20 °C, 25 °C e 45 °C and analyzed (triplicate) on days 2, 6, 8, 10, 13, 15, 17 e 20 after spotting in the paper. Stability was considered acceptable if all results were within the range of 85–115% of the concentrations measured at the beginning of the series.

2.8. Linearity

Aliquots of 950 μL blank blood (Hct 35%), were enriched with 50 μL of the corresponding stock solutions to obtain seven calibration levels of samples containing TAM (300, 225, 150, 75, 30, 15, 7.5 ng mL^{-1}), NDT (600, 450, 300, 150, 60, 30, 15 ng mL^{-1}), EDF (40, 30, 20, 10, 4, 2, 1 ng mL^{-1}) and HTF (50, 15, 10, 5, 2, 1, 0.5 ng mL^{-1}). Calibration samples were applied to Whatman 903 paper (12 × 60 μL for each level), dried at room temperature and analyzed within 24 h. Replicates ($n=6$) at each concentration were analyzed as described at item 2.5. Calibration curves were calculated relating the area ratios from TAM, NDT, EDF and HTF peaks to the IS peak and with the nominal concentrations of the calibration samples. Homoscedasticity of calibration data was evaluated with *F*-test at the confidence level of 95%. Curves were fitted using least-squares linear regression using several weighting factors ($1/x$, $1/x^2$, $1/y$, $1/y^2$). Calibration models were assessed using coefficients of correlation (r) and cumulative percentage relative error ($\sum$%RE) [19]. Daily calibration curves using the same concentrations (single measurement at each concentration level) were analyzed with each batch of validation and clinical samples.

2.9. Precision and accuracy

Aliquots of blank blood were enriched with methanolic solutions and applied to paper to obtain quality control DBS samples containing TAM, NDT, EDF and HTF at concentrations of 21.0; 45.0; 3.0 and 1.8 ng mL^{-1}, respectively (quality control low, QCL), 70.0; 150.0; 10.0 and 6.0 ng mL^{-1}, respectively (quality control medium, QCM) and 210.0; 450.0; 30.0 and 18.0 ng mL^{-1}, respectively (quality control high, QCH). Control samples were maintained at room temperature and analyzed within 24 h as item 2.5. The quality control samples were analyzed as described above in triplicate on each of 5 days. Within-assay precision and between-day precision were calculated by one-way ANOVA with the grouping variable "day" and were expressed as CV%. Accuracy was defined as the percentage of the nominal concentration represented by the concentration estimated with the calibration curve. The acceptance criteria for accuracy were mean values within ±15% of the theoretical value and for precision a maximum CV of 15% was accepted [20].

2.10. Lower limit of quantification

An independent DBS quality control sample at the lowest point of the calibration curve at concentrations of 7.5; 15.0; 1.0; 0.5 ng mL^{-1} for TAM, NDT, EDF and HTF, respectively, was included in the accuracy and precision experiments (quality control at the limit of quantitation, QCLOQ) and was tested in triplicate in three different days. The acceptance criteria established for the limit of quantification was accuracy within 100 ± 20% of the nominal value and an imprecision with of maximum 20% [20].

2.11. Influence of hematocrit on analytes concentrations assayed in DBS samples

Aliquots of blood containing different Hct% (25, 30, 35, 40, 45 and 50%) were prepared by centrifuging EDTA whole blood and then combined with appropriate volumes of cells and plasma. TAM and metabolites were added to these aliquots of blood to achieve concentrations of QCL: 21.0; 45.0; 3.0 and 1.8 ng mL^{-1} and QCH: 210.0; 450.0; 30.0 and 18.0 ng mL^{-1} for TAM, NDT, EDF and HTF, respectively, which were then pipetted onto Whatman 903 paper, followed by drying at room temperature for 3 h. The DBS obtained were analyzed in triplicate for each concentration and Hct% as described in item 2.5. The influence of the Hct% on TAM and metabolites measurements was determined as the percentages of nominal concentrations that were actually measured in the DBS.

2.12. Matrix effect and extraction yield

Matrix effect was evaluated by a post-extraction spike method. Three series of quality control samples (QCL, QCM and QCH) were prepared in order to assess extraction yield and matrix effect on ionization as follows: (A) solutions of TAM, metabolites and IS prepared in mobile phase solutions in order to obtain final concentrations equivalent to 100% extraction yield and directly injected onto column. (B) DBS extracts samples from 5 different sources (mixed before application on paper), post-extraction spiked with TAM, metabolites in mobile phase containing IS. (C) DBS extracts samples from 5 different sources (mixed before application on paper) enriched with TAM and metabolites before extraction. Each quality control sample was analyzed in quintuplicate. Matrix effect (ME) on ionization was estimated as the percentages of reduction or increase of TAM, NDT, EDF, HTF and IS areas on post-extraction spiked (B), comparing to directly injection of

solutions (B), calculated as ME=[100%−(B/A%)]. Extraction yields (EY) were calculated comparing the analyte/IS area ratio before extraction (C) and after extraction (B), using the formula EY=C/B%.

2.13. Application of the method

The study was conducted in accordance with the Declaration of Helsinki and was approved by the Research Ethics Committee at the Hospital de Clínicas de Porto Alegre. A total of 91 patients on adjuvant hormonal treatment with tamoxifen (20 mg day^{-1}) for at least 4 months were enrolled in the study with informed consent. Data on age, weight, body mass index (BMI), race, compliance (obtained from the number of TAM tablets taken monthly) and menopause status were recorded, in addition to the duration of TAM therapy and any concomitant therapies considered as CYP2D6 inhibitors. Blood samples were taken 18–24 h after the last TAM intake, patients being fasten for 4 h. Capillary blood was collected after finger prick using a 2.0 mm penetration, 0.8 mm blade contact-activating lancet (Medlance®). Blood spots were collected on 2 circles of the Whatman 903 DBS card and allowed to dry for at least 3 h at room temperature.

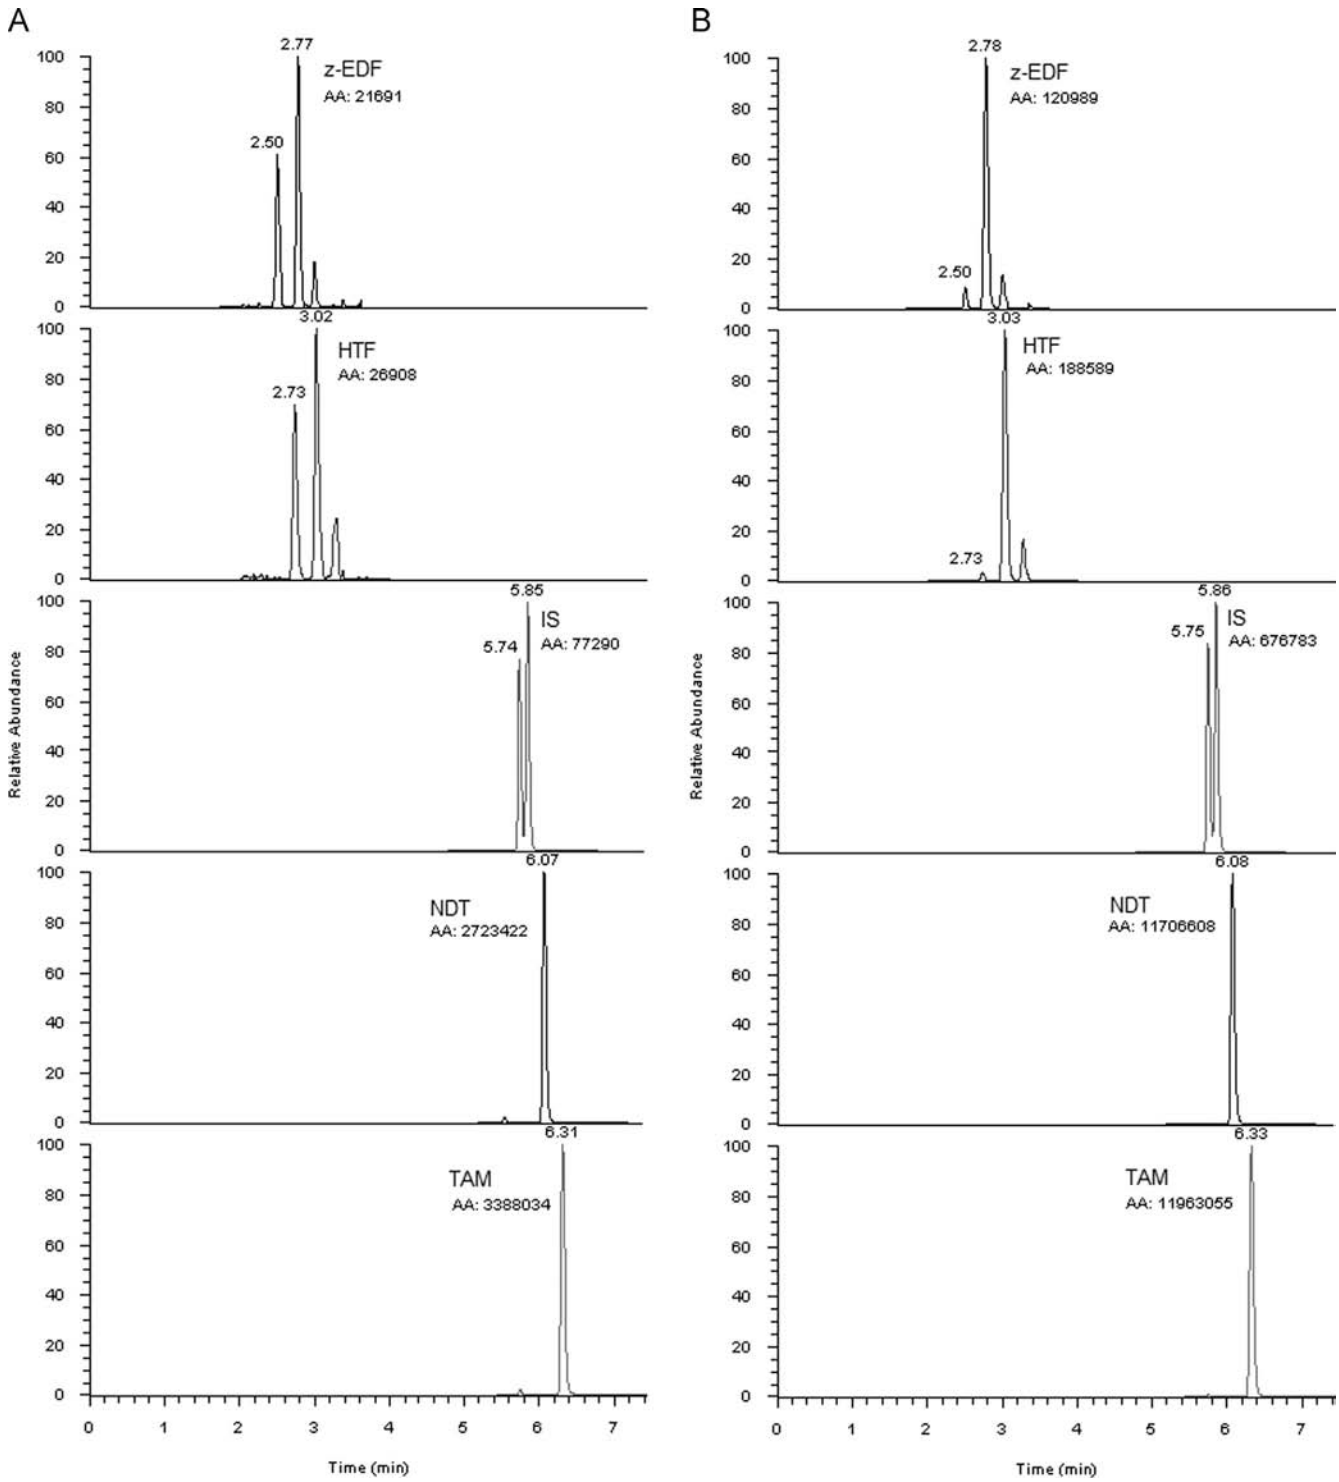

Fig. 1. Chromatograms obtained from DBS and plasma analyses. (A) Plasma EDF 9.9, HTF 1.5, NDT, 188.3, TAM 111.8 (ng mL^{-1}); (B) dried blood spot EDF 4.8, HTF 1.2, NDT, 166.0, TAM 100.0 (ng mL^{-1}). Transitions: EDF 374→58 (*m*/*z*), HTF 388→72 (*m*/*z*), IS 406→100 (*m*/*z*), NDT 358→58 (*m*/*z*) TAM 372→72 (*m*/*z*).

Analyses were performed within 3 days. Venous blood was simultaneously collected within an interval of ± 15 min by venipuncture into two EDTA tubes. One tube was used for Hct% determination, the other was immediately centrifuged and plasma was transferred to polypropylene tubes, stored at −70 °C until analysis within one month. Concentrations of TAM, NDT, EDF and HTF were measured through daily calibration curves and estimated plasma concentrations (EPC) were obtained after adjustment of DBS concentrations by patients Hct % and use of a correction factor, as follows:

$$EPC = [(\text{DBS concentration})/(1-\text{Hct})] \times \text{correction factor}$$

Correction factors were estimated so that the ratio of mean DBS to mean plasma levels would be equal to 1.

2.14. Determination of TAM and metabolites in plasma

A 0.2 mL aliquot of plasma was transferred to screw cap glass tube and 0.1 mL of the IS solution (clomiphene 0.01 μg mL^{-1}), 0.1 mL of Tris buffer pH 10 and 2 mL of extraction solvent (hexane: *n*-propanol 95:5, v/v). After homogenization for 30 min and centrifugation at 3000*g* for 10 min, a 1.6 mL aliquot of the supernatant was transferred to a polypropylene microtube and dried at 55 °C for 15 min under air stream. The extract was resuspended with 0.15 mL of mobile phase and a 25 μL aliquot was injected into the LC–M/MS system. The chromatographic conditions and mass detector parameters were the same as those used for the DBS samples. Concentrations were calculated with daily calibration curves. The method was linear from 0.5 to 600 ng mL^{-1} with LLOQ of 7.5 ng mL^{-1} for TAM, 15 ng mL^{-1} for NDT, 1 ng mL^{-1} for EDF and 0.5 ng mL^{-1} for HTF. Accuracy and imprecision were acceptable with accuracy of 90.7–107.5%, and percent coefficient of variation within and between assay in the range of 4.8–13.4.

2.15. Statistical analysis

Initially, a descriptive analysis of the study variables was conducted. The precision validation parameters were evaluated using ANOVA. Medians and 25% and 75% percentiles for TAM, NDT, EDF, HTF levels and metabolic ratio [NDT]/[EDF] were determined. Analytes in DBS (y) *vs* measured plasma concentrations (x), as well as estimated plasma (y) *vs* measured plasma concentrations (x) were assessed by Passing–Bablok regression [21] and Spearman correlation. The presence of outliers and tendencies were evaluated using Bland Altman plots [22] of estimated plasma concentrations *vs* measured plasma concentrations as well as DBS *vs* measured plasma concentrations. Acceptation criteria for the agreement between estimated and measured plasma concentrations were based on the guideline on Bioanalytical Method Validation of the EMA, the difference in concentration should be within ± 20% of their mean for at least 67% of the samples [23].

The effect of concomitant CYP2D6 inhibitors was tested for TAM, NDT, EDF, HTF and metabolic ratio [NDT]/[EDF] from measured and estimated plasma data obtained from patients stratified in 2 cohorts based on the use or not of CYP2D6 inhibitors by Mann–Whitney test. DBS levels of EDF and the DBS metabolic ratio [NDT]/[EDF] were further compared between these 2 cohorts with plasma EDF above or below the threshold of efficacy of 5.9 ng mL^{-1} by Mann–Whitney test. Analyses were conducted using SPSS version 17.0 and MedCalc version 12.3, $P < 0.05$ was considered statistically significant.

3. Results and discussion

3.1. Chromatography and preparation of samples

The LC–MS/MS system proved to be an appropriate system for determination of TAM and its main metabolites in DBS samples. TAM, NDT, HTF and EDF are structurally very similar, with demethylation and/or hydroxylation, resulting in slight differences of polarity. Reversed phase C18 columns appeared appropriate to separate TAM metabolites [24]. In this study an Acquity® C18 column (150 × 2.1 mm, 1.7 μm) was used, separating TAM and the 3 metabolites in a 8 min run, with reduced mobile phase consumption of 3.2 mL per analysis. Retention times were 2.77 min for EDF, 3.02 min for HTF, 5.85 min for IS, 6.07 min for NDT and

6.31 min for TAM. Fig. 1 illustrates chromatograms from DBS and plasma samples.

No interfering compounds were identified in the 6 DBS samples processed free from TAM and analytes. Additionally, the tandem mass spectrometry results in inherent specificity analysis, in which chromatograms are monitored through the transition of molecular ion to three products (1 quantifying and 2 confirmatory ions).

Sample preparation was simple, based on ultrasound-assisted liquid extraction of analytes from paper punches containing approximately 90 μL of blood. Extraction yield was higher for the least polar compounds, with average of 91.5% for TAM and 84.8% for NDT, comparing to 47.5% for (Z)–(Z)–EDF and 39.6% for HTF. Besides the lower extraction recoveries of EDF and HTF, the method presented satisfactory sensitivity considering the extent of concentrations found in clinical samples, with LLOQ of 1.0 ng mL^{-1} for EDF and 0.5 ng mL^{-1} for HTF [25,14,11,26].

3.2. Method validation

Extracts from DBS containing TAM and metabolites at QCL and QCH concentrations were stable during the 12 h bench stability test, with maximum variation in analytical response of 9.2%, indicating that large batches can be analyzed without taking special measures to preserve extracts. Calibration data exhibited significant heteroscedasticity, with F_{exp} ranging from 495.1 to 1237.0 ($F_{tab\ (6;\ 5;\ 0.95)}=4.95$). The regression using a weighting factor of $1/x$ offered the best ∑%RE of the models tested, with values below 1×10^{-9} and this weighting factor was used for all subsequent validation tests and for analysis of the clinical samples. The coefficients of correlation were above 0.99 for all weighting factors. The results of the precision and accuracy experiments, assessed by analyzing low, medium and high concentration quality control samples, were satisfactory, as shown in Table 1. Intra-assay imprecision were in the range of 5.13 to 12.30% and inter-assay imprecision was 5.10 to 11.54%, demonstrating that the method is adequately repeatable. Accuracy was estimated at 94.6 to 110.3%, which is also within the limits of acceptance for bioanalytical methods recommended by Shah et al. [20]. The quality control samples at the lower limit of quantification (LLOQ) of 7.5; 15; 1.0; 0.5 ng mL^{-1} for TAM, NDT, EDF and HTF presented acceptable imprecision (from 7.01 to 12.07%) and accuracy (90.6 to 97.5%).

Due to its high specificity and sensitivity LC–MS/MS is considered as the method of choice for quantitative analysis of compounds in biological matrices. However molecules originating from the sample matrix that coelute with the compounds of interest can interfere with the ionization process, causing ion suppression or enhancement [27]. Post-extraction spiked method analysis showed (Z)–EDF and HTF ionization suppression within 12% and IS ionization enhancement effect of 8%, indicating that co-eluting matrix components appear to have a minimal effect on the considered analytes. TAM and NDT demonstrated to be more affected by matrix effect with average suppression of 22.9 and 34.7% respectively. Similar observation was pointed out on a previously described LC–MS/MS method [28], where matrix ionization suppression (plasma samples) was larger for NDT (38% area reduction) comparing to other TAM metabolites.

As reported above, matrix components do influence to some extent TAM and NDT ionization and consequently the overall process efficiency, requiring therefore the preparation of calibration and control samples in a DBS matrix reflecting at best the composition of the samples to be analyzed. More important that the absolute matrix effect, no significant variability among concentrations and samples was observed in our method. Additionally, TAM and NDT presented high extraction yields (>81%), allowing analysis with satisfactory sensitivity and linearity range comprising clinical samples concentrations after a 20 mg/daily intake of TAM [25,11,26].

Thermal stability was also tested in DBS samples at the concentrations of QCL and QCH after storage at −20 °C, 25 °C and 45 °C up to 20 days. These temperatures were selected to simulate conditions that samples sent by regular mail could potentially be exposed. No changes were observed neither for TAM nor for NDT on DBS stored over a period of 20 days at the tested temperatures (maximum variance of 14%). However, (Z)–EDF and HTF were stable at −20 and 25 °C (maximum variance of 15%) but not at 45 °C, with an increase on concentrations, which ranged from 38% at day 2, to 47% after 20 days. In absence of any data in the literature regarding TAM and metabolites stability on DBS samples, we assumed that increase of metabolite concentrations at higher temperature could be the consequence of TAM and NDT degradation. Tested EDF and HTF levels were approximately 10 fold lower than TAM and NDT, therefore more likely affected by any minor changes in TAM and NDT concentrations. Another possible explanation for this finding could be the production of isobaric interfering compounds on DBS samples under high temperatures. Both hypotheses should be further tested.

Information about the thermal, light, and chemical stability of the analytes in DBS matrix must be available in order to explore its logistic advantages. When using transport by regular mail it is important to be aware that the inner temperature of mailboxes in full sun exposure can reach about 60 °C in summer months [29]. Up to now there is no data in the literature regarding the stability of EDF and HTF in DBS samples. Considering our findings on EDF and HTF stability and the high temperatures during summer time, it is reasonable to recommend that temperature during transport and storage of DBS cards for TAM and metabolites measurement should be controlled and not exceed 25 °C.

Alopecia	68/23
Thrombosis	87/4

3.3. Impact of hematocrit on determination of TAM and metabolites

The impact of different Hct% levels on calculated concentrations of TAM and metabolites during analysis of DBS samples was tested at concentrations of QCL and QCH prepared in blank blood with Hct% ranging from 25 to 50 and quantified by analytical curves prepared using blood with Hct% of 35. Variation from nominal concentrations found in control samples were within ± 13% for Hct 25%, ± 10% for Hct 30%, ± 10% for Hct 35%, ± 8% for Hct 40%, ± 16% for Hct 45% and ± 20% for Hct 50%. Highest variations from target were found at Hct 45% and 50% and were above 15% which was the cutoff for acceptability. This is probably due to increased viscosity of the blood and hence reduced dispersion through the paper. In contrast, DBS prepared with blood with Hct percentages ranging from 25 to 40 presented results within the range of acceptability (87–108%). On this basis, analytical curves prepared using blood with Hct% of 35 are applicable to samples from patients with Hct% within 25–40, covering most of patients Hct% range (30.6 to 43.6, mean 36). Seven patients had Hct% above 40, where calculated concentrations have to be corrected accordingly.

Besides DBS samples being obtained from capillary blood, venous blood was used to determine the patient Hct%, considering the absence of difference between capillary and venous Hct% [29]. Yang et al. [30] also found no difference between Hct% measured in venous and capillary blood.

3.4. Clinical application and method comparison

A total of 91 patients on adjuvant hormonal treatment with tamoxifen (20 mg day^{-1}) were enrolled in this study. Patient's demographic and clinical data are presented in Table 2. All patients were classified as adherent to TAM, with reported use of 30 tablets monthly. The patient population displayed a mean age of 56.3 years, mean BMI of 27.0 kg m^{-2} and mean Hct% of 36.0 (range 30.6–43.5), 75 patients were Caucasian and 16 were brown (*parda*-a Brazilian national census classification) or black. Hot flashes were the major adverse effect (51.6%). Eighteen patients (19.8%) reported concomitant use of CYP2D6 inhibitors drugs: 11 on weak inhibitors (*e.g.* venlafaxine, citalopram and haloperidol) and 7 on strong inhibitors (*e.g.* fluoxetine and bupropion).

The developed method was used to analyze DBS concentrations of TAM and its metabolites, paired with plasma analyses. Analytes concentrations were highly variable in both matrices, as presented in Table 3. Median DBS levels in the whole cohort were: TAM 100.0 ng mL^{-1}; NDT 202.0 ng mL^{-1}, (Z)–EDF 5.9 ng mL^{-1} and HTF 0.9 ng mL^{-1} and median plasma concentrations were: TAM 123.2 ng mL^{-1}; NDT 263.5 ng mL^{-1}, EDF 9.1 ng mL^{-1} and HTF 1.4 ng mL^{-1}. Plasma trough concentrations were consistent with those previously reported in the literature [25,11,26]. EDF levels were 6.5-fold higher than HTF concentrations, with the 5.7-fold [14] and 6.8-fold [31] previously reported, confirming the predominance of EDF over HTF.

Tamoxifen, NDT, EDF and HTF concentrations in DBS were in average 80%, 77%, 59% and 72% of those measured in plasma. EPC were calculated from DBS concentrations after adjustment by patients Hct% and using the correction factors of 0.84; 0.78; 1.12; 0.87 for TAM, NDT, EDF and HTF respectively. After Hct% and factor correction, median estimated plasma levels were: TAM 123.3 ng mL^{-1}; NDT 267.9 ng mL^{-1}, EDF 10.0 ng mL^{-1} and HTF 1.3 ng mL^{-1}, thus estimated levels represented in average 98 to 104% of the actually measured plasma concentrations. The differences between EPC and

Table 3
Patients median, percentiles, range and correlations of TAM, NDT, EDF, HTF, and metabolic ratio [NDT]/[EDF] concentrations in plasma, dried blood spot and estimated plasma ($N=91$).

Analyte	Sample	Median (P25–P75) (ng mL^{-1})	Range (ng mL^{-1})	Mean ± SD relation to measured plasma (%)	Passing Bablok regression to measured plasma	Spearman correlation to measured plasma (*rs*)
Tamoxifen	Measured plasma	123.2 (101.5–165.5)	52.6–307.8	–	–	–

NDT: *N*-desmethyltamoxifen; EDF: endoxifen; P25: percentile 25; P75: percentile 75, *rs*: spearman correlation coefficient.
P value as Cusum test for linearity.

** $P<0.01$ Spearman correlation.

measured plasma concentrations were within ±20% for most samples, 87 (97%) TAM, 86 (95%) NDT, 73 (80%) EDF and 80 (88%) HTF, being in accordance with the EMA acceptation criteria for the agreement between methods [23].

DBS concentrations and EPC were highly correlated to measured plasma concentrations with $rs > 0.83$ ($P < 0.01$) for all associations. Passing–Bablok regressions were performed in order to evaluate the existence of constant and/or proportional errors. Comparison of DBS (y) and measured plasma (x) concentrations returned in intercept 95% confidence intervals of −0.6472 to 10.0400 for TAM, −9.1216 to 28.0722 for NDT, −0.5097 to 0.4635 for EDF, −0.09409 to 0.09373 for HTF and −5.9314 to 0.3608 for the ratio [NDT]/[EDF] indicating no constant error. However, slope 95% confidence intervals showed the presence of proportional difference between methods: 0.6086 to 0.7879 for TAM, 0.6577 to 0.8289 for NDT, 0.4979 to 0.6402 for EDF, 0.6598 to 0.8512 for HTF and 1.3389 to 1.6789 for the ratio [NDT]/[EDF]. When EPC (y) and measured plasma levels (x) were compared, intercept 95% confidence intervals were −11.8954 to 17.8583 for TAM, −30.1816 to 26.4940 for NDT, −1.0641 to 0.7439 for EDF and 0.1460 to 0.1349 for HTF, indicating no constant error. At this evaluation, slope 95% confidence intervals showed to have no proportional differences: 0.8343 to 1.1120 for TAM, 0.9113 to 1.1465 for NDT, 0.9205 to 1.1744 for EDF, and 0.9289 to 1.1778 for HTF, indicating that when the effect of Hct% and multiplication factor are taken into account, methods are comparable. Cusum test P values were all > 0.05, indicating no significant difference from linearity.

Estimated plasma concentrations (EPC) of TAM and metabolites were also compared to measured plasma concentrations (MPC) by Bland–Altman plots (Fig. 2). The mean difference of the concentrations in plasma and estimated plasma concentrations using individual Hct% were 4.0 ng mL^{-1} for TAM, −0.7 ng mL^{-1} for NDT, 0.0 for EDF and 0.06 ng mL^{-1} for HTF, with only 4, 5 and 3 values (out of 91) outside the ±1.96 standard deviation range for TAM and NDT, EDF and HTF, respectively. Moreover, differences were also distributed randomly around the mean, indicating the absence of systematic errors which were proportional to TAM and metabolites levels.

Our data showed a wide range of EDF plasma concentrations among patients, with a 16.8 fold difference between the lowest (2.4 ng mL^{-1}) and the highest (40.3 ng mL^{-1}) measurement. The amplitude of concentrations may be attributed to the interindividual pharmacokinetic variability, including polymorphisms of CYP2D6 and CYP3A4 and drugs interactions [1,2,4–7]. Thus, we evaluated the impact of CYP2D6 inhibitors on EDF levels and [NDT]/[EDF] metabolic ratio in both matrices and found reduced metabolites concentrations in patients under concomitant use of CYP2D6 inhibitors drug inhibitors (Table 4) as compared to the group without use of drug inhibitors, as follows: median DBS

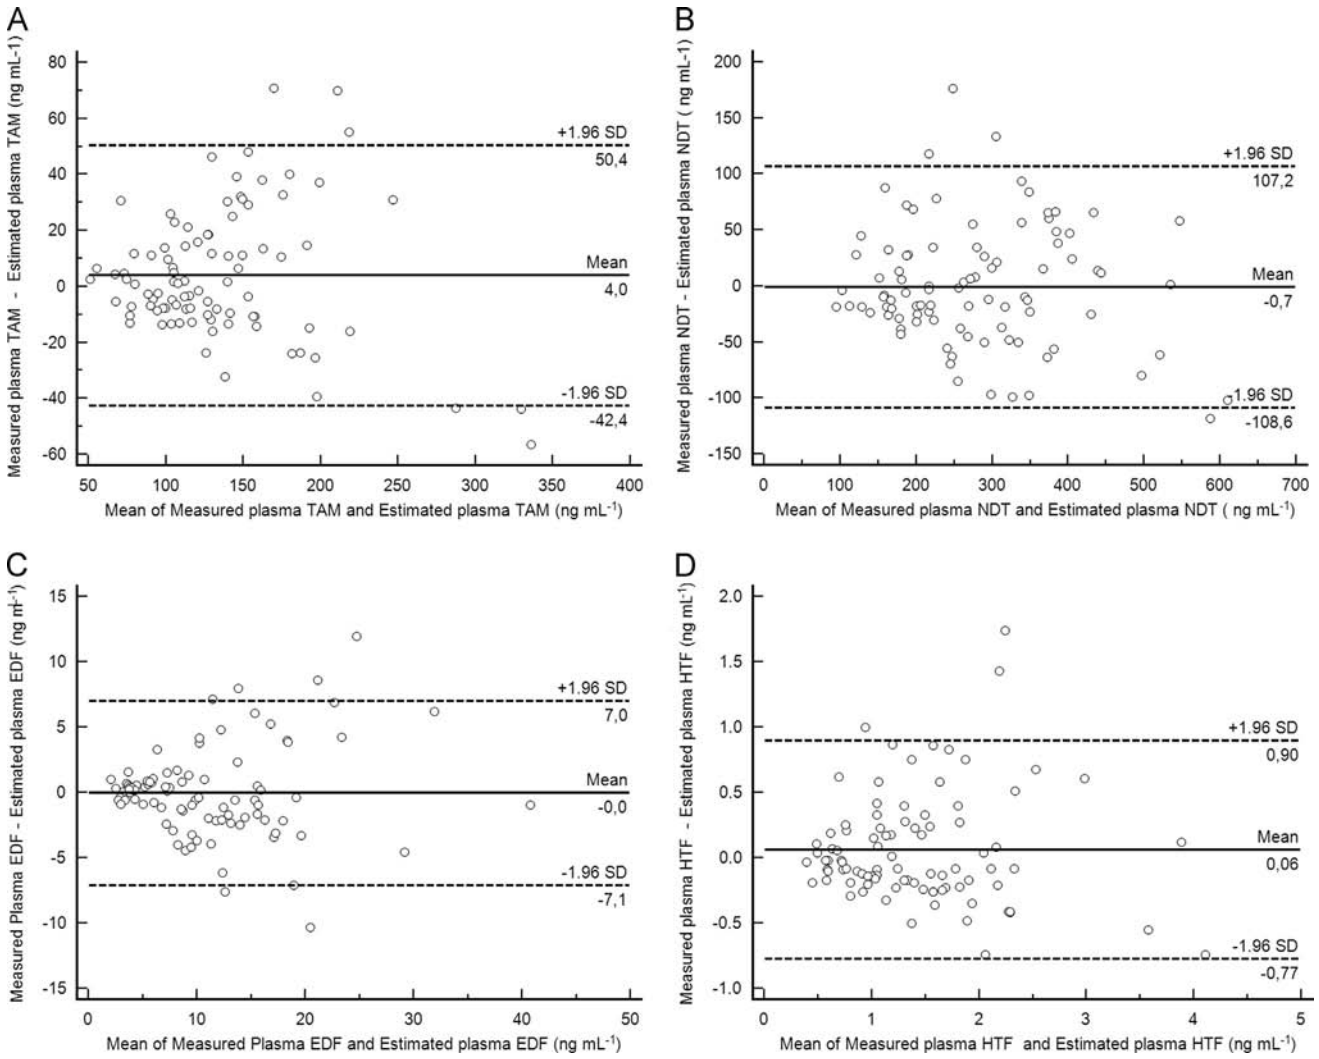

Fig. 2. Method comparison, Bland Altman plot of estimated plasma *vs* measured plasma concentrations of TAM (A), NDT (B), EDF (C) and HTF (D) in clinical samples ($N = 91$).

3.5 ng mL^{-1} *vs* 5.8 ng mL^{-1}, EPC 6.1 ng mL^{-1} *vs* 10.2 ng mL^{-1} and measured plasma 5.5 ng mL^{-1} *vs* 10.1 ng mL^{-1} ($P<0.05$ in DBS and EPC, and $P<0.01$ in measured plasma). Moreover, the frequency of patients with EDF levels below the threshold of optimal clinical activity (5.9 ng mL^{-1}) was higher in patients taking CYP2D6 inhibitor drug, 50% (9 of 18), compared to patients without CYP2D6 inhibitors, 20.5% (15 of 73) (Fisher Exact test, $P<0.05$).

The metabolic ratio [NDT]/[EDF], depending on CYP2D6 metabolism, was also affected by the use of drug inhibitors, as observed in both matrices: median DBS 40.5 *vs* 32.0, EPC 24.0 *vs* 40.5 and measured plasma 20.8 *vs* 53.3 for patients taking or not inhibitors respectively ($P<0.05$ in DBS and EPC, and $P<0.01$ in measured plasma). Thus, DBS based monitoring method showed to have equivalent capacity to identify differences on EDF levels and metabolic ratio between CYP2D6 metabolism affected or not by drug interactions as does the usual plasma measurement.

Based on these findings, it was interesting to evaluate if it was possible to identify, through DBS samples, patients with EDF plasma levels below 5.9 ng mL^{-1}. Overall, 24 patients (26.4%) had EDF measured plasma concentrations <5.9 ng mL^{-1}, of these 23 (96%) also presented estimated plasma concentrations below the threshold. Only 4 patients with estimated plasma concentrations <5.9 ng mL^{-1} had measured plasma concentrations above it (6.07 ng mL^{-1}, 6.18 ng mL^{-1}, 6.48 ng mL^{-1} and 7.94 ng mL^{-1}), but still close to the threshold. Thereafter, using Passing–Bablok regression equation, we extrapolated the plasma EDF threshold to DBS concentration and found a proposed DBS threshold of 3.3 ng mL^{-1} (Fig. 3). Using the DBS proposed threshold, as previously observed on estimated plasma results, we were able to identify 23 of 24 samples with measured plasma concentrations <5.9 ng mL^{-1}. The high prevalence of patients with low EDF levels could be related to the high frequency of use of inhibitor drugs (20%) and other factors such as genetic polymorphisms of CYP2D6 and/or other enzymes to be further evaluated.

Additionally we compared DBS and estimated plasma EDF concentrations between groups of measured EDF above or below 5.9 ng mL^{-1} and found reduced levels at the last group as well: median EDF DBS 2.0 ng mL^{-1} *vs* 7.0 ng mL^{-1} and 3.6 ng mL^{-1} *vs* 12.5 ng mL^{-1} ($P<0.01$), for DBS and estimated plasma respectively. Similarly DBS and estimated plasma [NDT]/[EDF] metabolic ratio were also significantly different between groups of EDF plasma levels

Table 4
Endoxifen levels and metabolic ratio of [NDT]/[EDF] in patients taking or not CYP2D6 inhibitor drugs and according to EDF plasma threshold 5.9 ng mL^{-1} ($N=91$).

Patients	*n*	Endoxifen DBS (ng mL^{-1})	Estimated plasma Endoxifen (ng mL^{-1})	Measured plasma Endoxifen (ng mL^{-1})	DBS [NDT]/[EDF]	Measured plasma [NDT]/[EDF]	Estimated plasma [NDT]/[EDF]

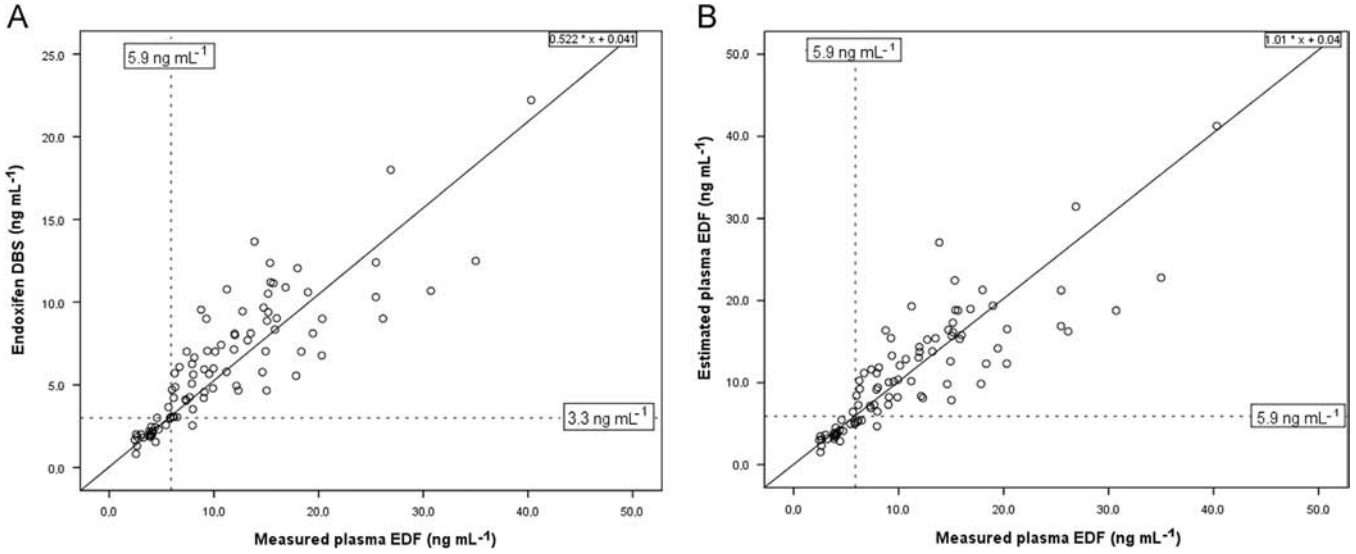

Fig. 3. Correlation of EDF concentrations in DBS and plasma (A); correlation of estimated plasma EDF concentration and EDF measured plasma concentration (B) ($N=91$). Dashed lines indicate EDF minimum therapeutic threshold concentration in plasma (5.9 ng mL^{-1}) [8] and proposed EDF concentration threshold in DBS, extrapolated from plasma concentrations (3.3 ng mL^{-1}).

(Table 4). In summary, the DBS method was able to identify with high accuracy (96%) patients with plasma EDF levels below the clinical threshold related to better prognosis as well as impaired CYP2D6 metabolism through [NDT]/[EDF] metabolic ratio.

4. Conclusions

A method for determination of TAM and its major metabolites in DBS using LC–MS/MS was developed and validated. Transport and storage of DBS samples require special attention, since EDF and HTF concentrations in control samples increased after storage at 45 °C. TAM, NDT, EDF, HTF concentrations in DBS and estimated plasma were highly correlated to measured plasma concentrations. We found a high prevalence of patients with EDF level below the clinical threshold of 5.9 ng mL^{-1} which were effectively identified through DBS samples. These findings suggest that DBS based therapeutic monitoring of TAM can be an efficient tool to optimize adjuvant breast cancer treatment, allowing patients to collect blood samples at their home within the appropriate time to obtain trough samples, facility transport conditions and handling safety. In addition, our results also offer insight into the effects of CYP2D6 inhibitors on TAM metabolism to EDF.

ABSTRACT

This paper presents the use of polymer coated microelectrodes for the realtime conductivity monitoring in a microchannel photoablated through the polymer without contact. Based on this strategy, a small conductometry sensor has been developed to record in time conductivity variation when an enzymatic reaction occurs through the channel. The rate constant determination, k_2, for the dephosphorylation of organic phosphate–alkaline phosphatase–superparamagnetic beads complex using chemically different substrates such as adenosine monoesterphosphate, adenosine diphosphate and adenosine triphosphate was taken as an example to demonstrate selectivity and sensivity of the detection scheme. The k_2 value measured for each adenosine phosphate decreases from 39 to 30 s^{-1} in proportion with the number (3, 2 and 1) of attached phosphate moiety, thus emphasizing the steric hindrance effect on kinetics.

1. Introduction

In the recent years, the growing development of microfluidic systems for ultrasensitive medical diagnostics on chip has been integrated as new module for smartphone application [1–3]. For this challenge, electrical transduction methods are more suitable for the detection of ionic species (oxidable or reducable) because of their high sensitivity and no need labelling step is required [4–6]. The relevance of electrochemical detection on microchips with improvement of micro nanoelectrode fabrication [7–12] has been widely proven, including the application of amperometric detection [13–16], and potentiometric [17–19]. However, contactless to the microelectrodes as electrical detection scheme with the electrolyte is the most promising [20–23]. Indeed, the non contact measurement scheme with two microelectrodes galvanically isolated has several advantages conversely to the contact mode. For instance, in the microelectrophoresis field [23–25], some drawbacks due to interference associated with the contacting electrode and the electrolyte, such as non specific adsorption, degradation or electrode corrosion, bubbles formation due to the water electrolysis, are suppressed by measuring the contactless conductivity of the electrolyte in the separation channel. Moreover, this configuration enables an electronic decoupling as the detector for measuring conductivity is effectively isolated from the high voltage applied in the same channel for the separation and ions migration. Another significant advantage is that the networking and alignment of the detector are simplified making it possible electrode positioning anywhere in the separation channel.

A new strategy for microelectrode without contact with the streaming electrolyte in the microchannel has been developed in the recent years [26–28]. It differs from the previous strategies by the use of microelectrodes that are embedded in an insulating dielectric polymer (PET) thanks to laser photoablation process. Indeed, the laser permits a close positioning of the microchannel with a near distance to the fluidic channel bottom equals to 2–5 μm. In this work the capacitive effect originates from coupling between the electronic charges (two planar microband electrodes) on one side of the dielectric PET layer and the ionic charges (streaming electrolyte in microchannel) in contact with the other side of the dielectric PET layer [26]. A detailed methodology for non contact impedance in dielectric microdevice was published and a procedure was proposed to eliminate the contribution of the surronding PET layer comprised between the two embedded microelectrodes [29,30]. This procedure enables a clear enhancement of the microchannel impedance contribution from the microchip global impedance. The non-contact geometry was previously tested for adsorption monitoring of BSA protein on photoablated PET [31] and for testing the biomolecular recognition

between two proteic ligands i.e. BSA adsorbed on PET and the corresponding antibodies Ab-BSA [32].

However, in this paper the reaction takes place not on the PET substrate but on superparamagnetic beads immobilised in the detection zone [33]. Conversely to previous work [34] where microchannel impedance variation was monitored during enzymatic conversion of an enzymatic substrate, the present paper concerns the calibration of the detection scheme by using the microchannel conductivity which is determined through the cell constant accurately determined for this goal. The biological model proposed is the determination of dephosphorylation rate constant of the complexes enzyme-beads-organic phosphate measured using three adenosine phosphate biomolecules such as adenosine monoesterphosphate (AMP), adenosine diphosphate (ADP), adenosine triphosphate (ATP) that occurs on alkaline–phosphatase-linked superparamagnetic-beads in polymer microchannel. Indeed, the possibility to distinguish between the dephosphorylation rate constants for these enzyme phosphate complexes having close molecular structures is also evidenced.

2. Experimental

2.1. Chemicals

Adenosine monophosphate (AMP), adenosine diphosphate (ADP) and adenosine triphosphate (ATP) were purchased from Sigma Aldrich; 2-methylaminoethanol (MAE) was from Fluka Analytical. Magnesium chloride, sodium chloride, Tris(hydroxymethyl)aminomethane (Tris) were purchased from Sigma Aldrich. The washing buffer was made of 100 mM Tris supplemented with 500 mM NaCl. The substrate buffer was 100 mM 2-methylaminoethanol with 2 mM $MgCl_2$. Washing and substrate buffers were adjusted to pH 9 with HCl and NaOH. The organic phosphates were diluted in the substrate buffer: 16.1 mM AMP, 10.6 mM ADP, 11.7 mM ATP. Deionized water was used as regeneration solution. Alkaline Phosphatase at 3 mg mL^{-1} was from intestine of veal (Boehringer, Mannhein). Microbeads 1.8 μm (Dynabeads) were purchased from Invitrogen France. The microbeads concentration was equal to 10 mg mL^{-1} with 4×10^8 microbeads per milliliter in phosphate buffer saline (PBS), pH 7.4, containing 0.1% BSA and 0.02% NaN_3.

2.2. Microchannel networks

The non contact microchip device used in this work was described elsewhere [20,35]. Briefly, admittance measurements were carried out through a polyethylene terephthalate (PET) microchannel photoablated having a cross-section shape with a depth of 50 μm, a top width of 100 μm and a length of 1.4 cm. The distance separation between both microelectrodes is 120 μm edge to edge. The electrode fabrication is achieved using a carbon ink loaded with gold nanoparticles, thermally sealed by a polyethylene (10 μm)/polyethylene terephthalate (25 μm) (PE/PET) layer with a total thickness of 35 μm. The distance separation in the PET band between the two planar microelectrodes and the main microchannel is equal to 5 μm and the detection surface area per microelectrode is 8.8×10^{-4} cm^2.

2.3. Microchannel admittance measurement protocol

The current measured is related to the total admittance of the microdevice. Measurements were performed using a frequency response analyzer (FRA 1255B, Solartron U.K.) associated with a dielectric interface 1296 (Solartron, U.K.) which extends the frequency range from 1 Hz to 10 MHz. Experiments were performed using the company-made software SMaRT. Electric admittance spectroscopy measurements have been performed by applying a 3 V ac voltage amplitude through the microelectrodes at 1 MHz fixed frequency. To analyze these results, a physical model displayed on Fig. 1 is used as described previously [29].

3. Results and discussion

3.1. Microchannel conductivity without direct electrical contact

The characteristics of this kind of interface with an insulated layer sandwiched between two galvanic isolated microelectrodes can be represented as a dielectric system with, on the one part of the thin polymer layer, electronic charges on microelectrodes and, on the other part, ionic charges in the microchannel. An electrical equivalent circuit can be drafted, considering admittances for each part of the microdevice as displayed in Fig. 1. The global admittance, Y_G, through the microdevice using free contact microelectrodes configuration, is given by the sum:

$$Y_G(\omega)=Y_1(\omega)+Y_2(\omega) \quad (1)$$

wherein ω is the angular frequency (rad s^{-1}), defined by $\omega=2\pi f$, where f is the frequency (Hz).

The detailled admittances Y_1 and Y_2 in Eqs. (2) and (3) can be decomposed for each branch i.e. through the microchannel and through the direct coupling between the two embedded microelectrodes, respectively.

$$Y_1(\omega)=\frac{1}{\frac{2}{j\omega C_{PET,5\ \mu m}}+\frac{2}{(j\omega)^{a_{int}}Q_{int}}+\frac{R_S}{1+j\omega C_C R_S}} \quad (2)$$

and

$$Y_2(\omega)=j\omega C_{PET,120\ \mu m} \quad (3)$$

The 5 μm thickness of the PET layer isolated microelectrodes from the small channel makes it to behave as a capacitor $C_{PET,1}$ and was equal to 14×10^{-11} F. The 120 μm thickness of the PET layer separated the two microelectrodes also behaves as a capacitor $C_{PET,2}$ and was equal to 8×10^{-13} F. The PET/microchannel interface is represented by a non ideal capacitor which is defined by

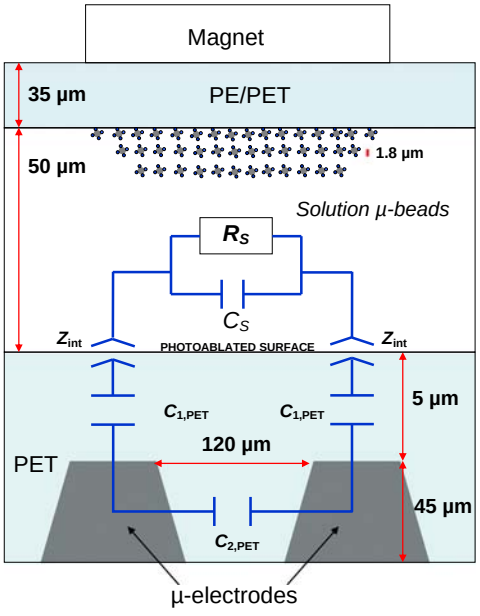

Fig. 1. Schematic description of the small conductometric sensor in PET microchip through the dielectric microelectodes/PET/microchannel interfaces with an superimposed equivalent electrical circuit.

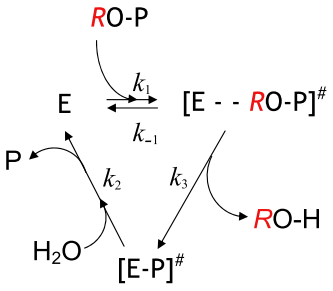
a constant phase element CPE with Q_{int} and α_{int} being the CPE element and the CPE exponent, respectively. The CPE exponent α_{int} takes into account the role of the photoablated PET surface at the microchannel bottom. In previous work alpha α_{int} was found equal to 0.5 and $Q_{int}=4.7\times10^{-8}\,\Omega^{-1}\,s^{-\alpha}$ [29]. The change on the interfacial CPE parameter is neglected to the aim of this paper as the organic phosphate dephosphorylation occurs on Alcaline Phosphatase linked beads and not on the PET photoablated surface [31,32,36].

In the microchannel, the admittance Y_{CH} is represented by a parallel association $R_S//C_C$ circuit. The resistance, R_S, is characteristic to the electrolyte resistance while C_C is an intrinsic parameter linked to the cell geometry named the cell capacitance. This latter was estimated to $C_C=3\times10^{-13}$ F [29,32]. As mentioned previously, the target application is the real-time monitoring of the microchannel conductivity that is given through the relative variation of the conductance (Y_1 real admittance part, $\Delta\Re e\,(Y_1)$). Indeed, the derivative expression of Eq. (2) leads to Eq. (4), in which conductance is conversely proportional to the microchannel resistance at fixed frequency.

$$\Delta\Re e(Y_1)=\Delta\left[\frac{1}{R_S}\right] \tag{4}$$

This can finally lead to an analytical expression for determining the microchannel conductivity variation at fixed frequency taking into account the cell constant, K, as follows:

$$\Delta\sigma=K\Delta\Re e(Y_1) \tag{5}$$



where K is the cell constant equals to $5\times10^{3}\,m^{-1}$ and $\Delta\sigma$ expressed in $S\,m^{-1}$.

3.2. Kinetics of enzymatic conversion of organic phosphate

Scheme 1 presents in brief the catalytic hydrolysis mechanism for organic phosphate involving intermediate phosphorylation of ALP enzyme, E, where $[E\text{-ROP}]^{\#}$ and $[E\text{-Pi}]^{\#}$ are the Michaelis complex and the phosphoryl enzyme, respectively. The reaction products RO-H and Pi are the corresponding alcohol (from substrates which are chemically different via R in RO-P) and the released inorganic phosphate, respectively. As displayed in Scheme 1, the ratio of two kinetic constants k_1/k_{-1} is an equilibrium constant because k_1 is known as a diffusion-controlled rate (10^9–$10^{10}\,M^{-1}\,s^{-1}$) [37]. The last step constitutes the rate-determining enzymatic step as expressed in the following Eq. (6) since hydrolysis of the phosphoryl enzyme is the rate determining step.

$$v=\frac{d[\mathrm{Pi}]}{dt}=\frac{k_2k_3}{k_2+k_3}[E-\mathrm{RO}-P]^{\neq} \tag{6}$$

where k_3 and k_2 are the constants of the phosphorylation and dephosphorylation rates, respectively.

Scheme 1. Simplified mechanism of alkaline phosphatase ALP (E) for catalytic hydrolysis of organic phosphate compounds (RO-P) involving intermediate phosphorylation of E, where $[E\text{-ROP}]^{\#}$ and $[E\text{-Pi}]^{\#}$ are the Michaelis complex and the phosphoryl enzyme, respectively.

In order to determine the dephosphorylation rate with the following organic phosphate biomolecules: AMP, ADP, ATP the procedure described below was followed for various concentrations of ALP. The experimental data consist, for each organic phosphate concentration, in a set of conductivity experimental curves that were recorded as a function of the measurement time, t. Samples were introduced by capillarity in the PET microchannel with a total volume of 80 nL. The detection procedure of the microchannel conductivity was preferred at 1 MHz fixed frequency (fast acquisition) with time until a baseline between each step. As displayed in Fig. 1, a permanent magnet located above the conductometry sensor was switched on the position ON [33]. The procedure for monitoring experiments of ALP catalyzing dephosphorylation was divided in three steps (see Fig. 2). The step one consisted in measuring the conductance for microchannel filled with substrate buffer (100 mM MAE and 0.2 mM $MgCl_2$). Then, in step two, the microchannel was filled with beads linked ALP enzyme. For instance, an ALP-μbeads sample (see Table S1 in Supplementary material) was introduced on the channel and the measurement protocol described above was followed until a baseline was reached. The step three consisted in loading the channel with organic phosphate sample as illustrated with ADP in Fig. 2. Magnification of step 3 as it appears on Fig. 3 highlights the net increase of the measured conductance with time. A normalization step was performed by subtracting the background conductivity σ_0 at t_0. For that purpose, $\Delta\sigma$ variation against time during catalytic dephosphorylation of ADP is plotted from typical $\Delta\sigma=f(t)$. At the end, the initial rate, ν_i-slope, of $\Delta\sigma$ variation in time (see Eq. (7) and Fig. 3) gives information about the conversion kinetics of phosphate biomolecule.

$$\nu_i=\frac{d\Delta\sigma}{dt} \tag{7}$$

where the unit is in $S\,m^{-1}\,s^{-1}$.

Obviously, the conductivity variation in presence of ALP-μbead is due to the ionic charge increase in microchannel solution when the catalytic hydrolysis starts. In fact, when the phosphoryl complex is hydrolysed, the substrate (ADP) level decays and product amounts (AMP and phosphate ion) increase (see Scheme 1 and Fig. 3). The experimental protocol described in Fig. 2 and Fig. 3 was performed for the three organic phosphate biomolecules in presence of various concentration for ALP-μbeads (see Table S1 in Supplementary material). All data rates obtained,

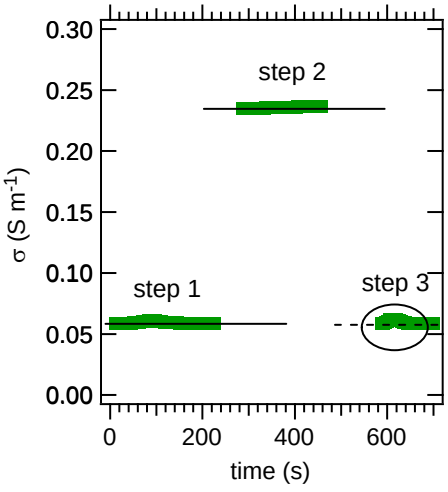


Fig. 2. Measurement protocol for catalytic ADP dephosphorylation. In step 1: Conductivity level for microchannel filled with substrate buffer. In step 2: Conductivity level for microchannel filled with ALP-linked beads (0.045 pM ALP-μbeads, see Table S1 in Supplementary material). In step 3: Conductivity level for microchannel filled with 16.1 mM ADP as organic phosphate.

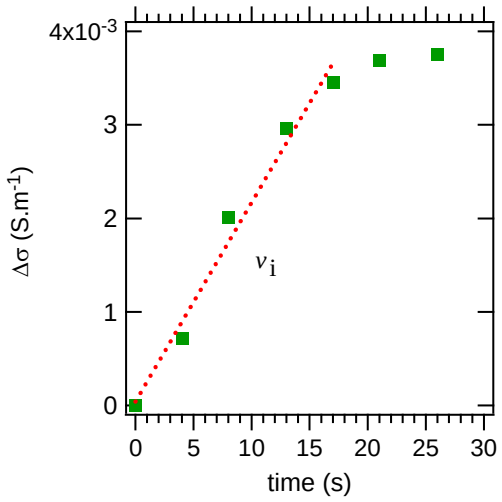

Fig. 3. Magnification of step 3 where the microchannel conductivity was normalized with σ_0 (background conductivity) at t_0 (reaction starts) when 16.1 mM ADP concentration was in presence of 0.045 pM ALP-μbeads.

including standard deviations, are listed in Table S1 in Supplementary material. The mean values of dephosphorylation kinetics rate for each used organic phosphate was obtained through the ν_i-slope listed in Table 1.

The dephosphorylation rate constant, k_2, is obtained by plotting the initial rate (ν_i-slope in Table 1) against the total enzyme concentration. As displayed in Fig. 4, a pseudo-first-order kinetic behaviour can be observed due to the low enzyme concentration that is negligible in comparison with the high organic phosphate concentration (see Table 1). The linear fits obtained using Eq. (8) have a slope which corresponds to the dephosphorylation rate constant, k_2, and k_0 without enzyme.

$$\nu = k_2[\mathrm{ALP}] + k_0 \tag{8}$$

with k_2 in S m^{-1} (pM s)$^{-1}$ and k_0 in S m^{-1} s^{-1}.

The obtained values for k_2 and k_0 listed in Table 2 have been converted using the method sensitivity (1 μS m^{-1} pM^{-1}) in order to compare these values with standard units i.e. in s^{-1} and pM^{-1} s^{-1}, respectively. The obtained values are in agreement with those published and obtained with optical methods [38,39]. Assuming that k_2 is negligible in comparison with k_3 (see Eq. (6)), k_2 becomes equivalent to the hydrolysis catalytic constant, k_{cat}. The means values of $k_{2,\ AMP}$ (39.4 s^{-1}) > $k_{2,\ ADP}$, > (32.8 s^{-1}) > $k_{2,\ ATP}$, (30.2 s^{-1}) are close in the adenosine series and show steric hindrance effect according to the number phosphate groups (1, 2 and 3), respectively.

4. Conclusions

Microchannel conductivity detection using electric admittance on polymer coated microelectrodes in microchip is a very sensitive method for monitoring chemical reaction such as dephosphorylation of organic phosphate in low volume reagent. This has been illustrated with a presented methodology for monitoring enzyme kinetics with ultralow (45 fM) concentration of ALP enzyme added in the microchannel. Detection through this microdevice permits small consumption of reagents in comparison with other assays. Measurement of kinetic rates can be measured after a few seconds for an assay in comparison with the traditional ELISA microtitration plates where the data processing is long. Furthermore, this detection scheme could be extended for any enzymatic substrates since the detected product does not need to be a chromophoric or electroactive species. The different dephosphorylation kinetics rate obtained with adenosine phosphate substrates on alcaline phosphatase-linked beads underline sensitivity and selectivity of the method. This opens a new way for fast medical diagnostics in low volume reagent or for biological screening of ligands of interest such as natural phosphoproteins having no chromogenic or electrochemical property [40].

Table 1
The obtained ν_i-slopes according to the fit using Eq. (7) (see Table S1 in Supplementary material for more details).

ν_i, initial rate $\times 10^{-5}$ (S m^{-1} s^{-1})			ALP enzyme concentration ($\times 10^{-12}$ M)			
			1.21	0.405	0.135	0.045
Organic phosphate ($\times 10^{-3}$ M)	16.1	AMP	4.58	3.24	2.96	2.28
	10.6	ADP	3.87	2.48	2.26	1.83
	11.7	ATP	3.65	2.36	2.07	1.86

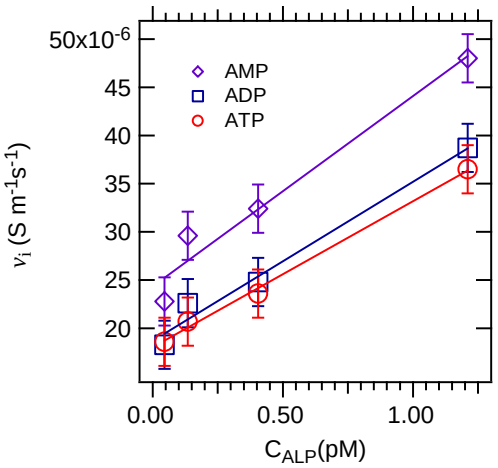

Fig. 4. Calibration curves of dephosphorylation rate of ALP-μbeads for AMP, ADP, ATP substrates. The maximum rate, ν_i-slope, is plotted against ALP concentration with a fixed organic phosphate concentration. Each point represents the mean of experiments with ALP concentrations (from 0.045 pM to 1.21 pM). The linear fits (solid lines) are performed using Eq. (8) (in the text).

Table 2
The obtained values for k_2 and k_0 according to the fit using Eq. (8).

Kinetic constants of enzymatic conversion	k_2 (s^{-1})	k_0 (M^{-1} s^{-1})
AMP	39.4	48.6
ADP	32.8	37.4
ATP	30.2	36.2

ABSTRACT

Bovine serum albumin stabilized Au nanoclusters (BSA–AuNCs) were demonstrated as a novel fluorescence probe for sensitive and selective detection of free chlorine in drinking water. The fluorescence of BSA–AuNCs was found to be quenched effectively by the free chlorine, and the decrease in fluorescence intensity of BSA–AuNCs allowed the sensitive detection of free chlorine in the range of 0.8–800 μM. The detection limit is 0.50 μM at a signal-to-noise ratio of 3. The present fluorescent assay for free chlorine possesses low detection limit, wide linear range and good selectivity. Real tap water samples were analyzed with satisfactory results, which suggested its potential for water quality analysis.

1. Introduction

Liquid chlorine, sodium hypochlorite and bleaching powder are adopted by more than 80% of waterworks as disinfectants in water treatment process to remove pathogenic bacteria, viruses, and microorganisms, as well as organic and inorganic chemicals. As a result, a certain amount of residual chlorine in municipal tap water is essential to prevent breeding of bacteria and germs. The residual free chlorine mainly includes dissolved chlorine (Cl_2), hypochlorous acid (HClO), and hypochlorite (ClO^-) [1], which are strictly regulated to ensure water quality. If the chlorine content exceeds the standard, it will pose a threat to life in many ways. Firstly the redundant free chlorine possesses a pungent odor, and is harmful to the respiratory system. Secondly it is very easily and rapidly absorbed into the human body by any pore, such as skin, nostril and oral cavity, causing a variety of bodily diseases [2]. Furthermore, immoderate chlorine reacts with organic matter existing in the water to generate various carcinogens, such as trihalomethanes (THMs) [3–5]. Therefore, it is necessary to monitor the concentration of residual free chlorine in water.

Currently, the determination of free chlorine has been conducted by several analytical methods including colorimetric methods, [6–8], fluorescence methods [9], chemiluminescence methods [10,11] and electrochemical methods [12,13]. Among these methods, N-N-diethyl-p-phenylenediamine (DPD) colorimetric method is the most commonly and widely one to be used [6]. The use of toxic reagents and complicated instrumentation limit the scope of their practical applications and necessitates an interest in the development of efficient measurement techniques with simplicity, high sensitivity, cost effectiveness and selectivity to determine free chlorine in water.

As an emerging fluorescent nanomaterial, bovine serum albumin (BSA) stabilized gold nanoclusters (BSA–AuNCs) have recently been paid intense attention because of their simple and green synthesis and red emission as well as photostability and biocompatibility [14]. BSA–AuNCs have been applied in the label-free determination of metal ions such as Hg^{2+} and Cu^{2+}, biological molecules like cysteine and dopamine, and nitrites [15–19]. Herein we found that the free chlorine could quench the fluorescence of BSA–AuNCs, and decrease in fluorescent intensities was correlated linearly to the concentration of free chlorine. Based on these phenomena, the use of the BSA–AuNCs as a selective fluorescence probe for detection of free chlorine was investigated.

2. Experimental

2.1. Materials

Bovine serum albumin (BSA) was purchased from Shanghai Sangon Biotechnology Co., Ltd. (Shanghai, China). Tetrachloroauric (III) acid trihydrate ($HAuCl_4 \cdot 3H_2O$) and sodium hypochlorite

(NaClO) were obtained from Sinopharm Chemical Reagent Co., Ltd (Shanghai, China). All other reagents used in this work were of analytical grade and were used without further purification. Water was purified with a Milli-Q plus 185 equipment from Millipore (Bedford, MA, USA) and used throughout the work.

2.2. Apparatus

Fluorescence spectra were measureed on an LS-55 fluorescence spectrometer (Perkin-Elmer, USA) equipped with a 10 mm quartz cuvette. The emission spectra were recorded in the wavelength range of 550–700 nm upon excitation at 365 nm. Slits for both the excitation and the emission were 15 nm. UV–vis absorption spectra were measured with a Cary UV–vis spectrophotometer (Agilent Technologies, United Kingdom).

2.3. Synthesis of fluorescent BSA–AuNCs

BSA–AuNCs using BSA as "biological templates" were synthesized in aqueous solution following a previous method with a slight modification [14]. All glasswares used in the experiment were cleaned with freshly prepared aqua regia, and rinsed with ethanol and superpure water thoroughly prior to use. 15.0 mL of 10.0 mM $HAuCl_4$ solution was added to 15.0 mL of 50.0 mg/mL BSA solution under vigorous stirring at 37 °C. After 2 min, 1.5 mL of 1.0 M NaOH solution was introduced to adjust the pH value and the mixture was incubated at 37 °C for 12 h. The color of the solution changed from light yellow to light brown, and then to deep brown. The obtained AuNCs were further purified by ultrafiltration and dialysis [20]. The first step was carried out on a 30,000 MW filter and centrifuged at 3000 rpm for 15 min at 4 °C to remove unreacted BSA. The obtained solution was then dialyzed in superpure water for 48 h to remove unreacted $HAuCl_4$ and NaOH, and the final solution was stored at 4 °C in a refrigerator for use. The concentration of the AuNCs in the following experiments was approximately evaluated based on the measured BSA concentration.

2.4. Detection procedure of free chlorine

For free chlorine determination 30 μL of prepared BSA–AuNCs solution was diluted with phosphate buffer solution (20 mM, pH 5.0), and 12 μL of different concentrations of sodium hypochlorite was added. Then, the solution of reaction volume 120 μL was mixed thoroughly on a vortex mixer. After 20 min reaction, the absorption spectra and fluorescence emission spectra of BSA–AuNCs in the presence of free chlorine were measured. All measurements were carried out at room temperature. To study the usefulness of this method for free chlorine detection in real samples, the relevant metal ions and non-metallic ion were used for the interference experiments.

2.5. Determination of free chlorine in tap water

For the analysis of the real samples, the tap waters collected freshly from various locations were not subjected to any pretreatment in this experiment. Water samples should be determined immediately after sampling, which should avoid light, stirring and heating. To validate the assay, a standard addition method was applied by spiking different concentrations of hypochlorite solutions to water. The procedure was the same as above, except that the standard hypochlorite solution was replaced by the sample.

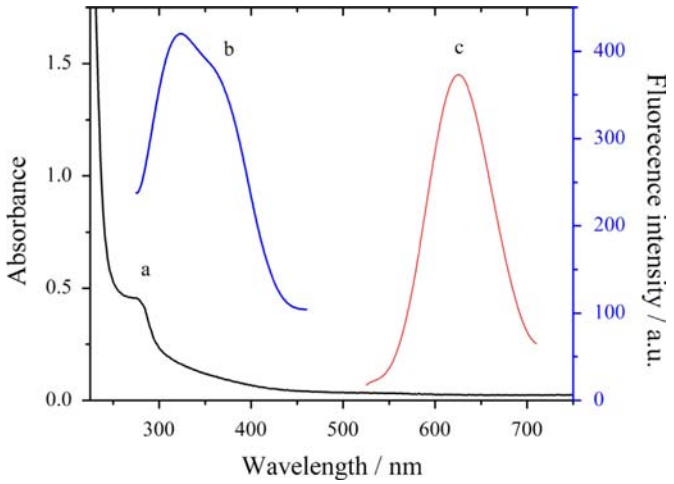

Fig. 1. The UV–vis absorption (a), the fluorescence excitation (b) and fluorescence emission (c) spectra of BSA–AuNCs solution.

3. Result and discussion

3.1. Characteristics of BSA–AuNCs

BSA–AuNCs were prepared according to a method described previously [14]. The optical properties of BSA–AuNCs were detected by UV–vis absorption and fluorescence spectra. As shown in Fig. 1, the absorption spectrum of BSA–AuNCs appeared as a strong absorption band at 278 nm [21]. On the basis of the previous studies, pure BSA exhibited an absorption maximum at 278 nm and this peak remained almost unchanged after the conjugation with AuNCs [22]. Moreover, the absorption spectrum misses the characteristic surface plasmon resonance peak of Au nanoparticles (NPs), indicating the formation of the nanoclusters rather than the nanoparticles [23]. The fluorescence excitation and emission spectra of prepared BSA–AuNCs are shown in Fig. 1. Upon being excited at 365 nm, the BSA–AuNCs showed an emission band centered at 630 nm. The character of the spectra was consistent with the literature [14,24,25], which suggested the successful preparation of BSA–AuNCs.

The aqueous solution of BSA–AuNCs was deep brown in color (Fig. 2a) and exhibited a red fluorescence (Fig. 2c) under UV light. After addition of free chlorine the original deep-brown color of BSA–AuNCs became yellow (Fig. 2b), and a very-weak blue fluorescence was observed under UV light (Fig. 2d).

3.2. Fluorescence response of BSA–AuNCs to free chlorine

The effect of free chlorine on the fluorescence emission was investigated. As indicated in Fig. 3, upon the addition of free chlorine to a solution of BSA–AuNCs, the red fluorescence of BSA–AuNCs became very-weak fluorescence (Fig. 3b), and the fluorescence intensity of BSA–AuNCs was effectively quenched by free chlorine. The fluorescence quenching effect may be attributable to oxidation of Au atoms in the AuNCs by free chlorine [26–29]. To prove this hypothesis, the effect of a commonly used oxidant on the fluorescence emission was investigated. Experimental results show that oxidants with stronger oxidation capability than that of free chlorine (such as $KMnO_4$) can also quench the fluorescence of BSA–AuNCs. In addition, because the fluorescence emission was originated from intra-band transitions of free electrons of the AuNCs, charge transfer behavior may cause the fluorescence quenching. As can be seen from Fig. 2 the original deep-brown color of the AuNCs became dark, and very-weak blue fluorescence was observed in 365 nm light. The very-weak blue fluorescence is a characteristic of the aromatic side groups

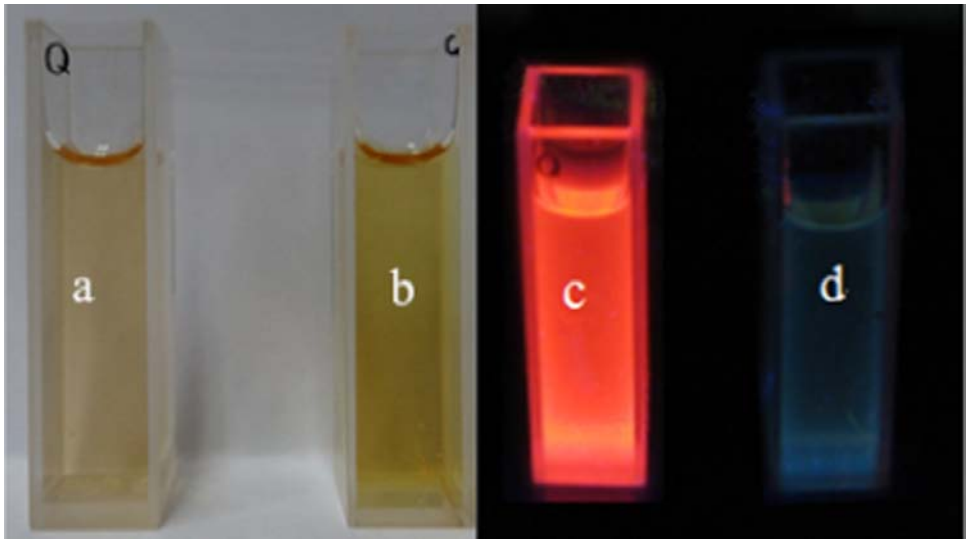

Fig. 2. Photographs of BSA–AuNCs solution in the absence (a, c) and presence (b, d) of free chlorine with natural light (left) and UV (right) irradiation. (For interpretation of the references to color in this figure, the reader is referred to the web version of this article.)

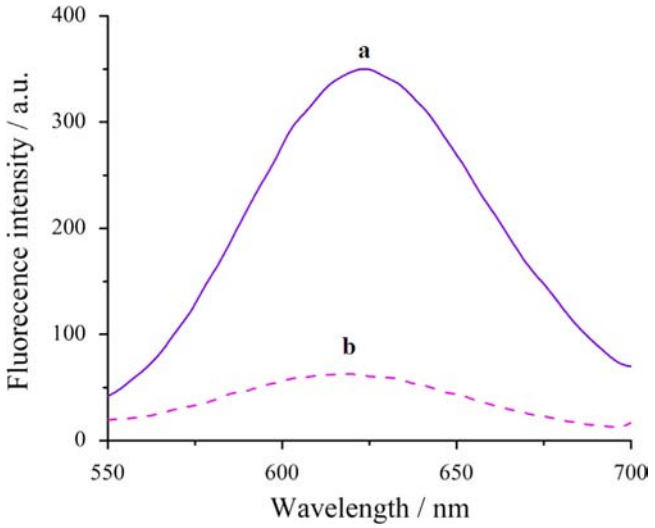

Fig. 3. Fluorescence response of BSA–AuNCs to free chlorine. (a) Fluorescence spectrum of BSA–AuNCs and (b) fluorescence spectrum of BSA–AuNCs in the presence of free chlorine. The pH of solution was 5.0. The concentration of BSA–AuNCs was 6 mg/mL. Reaction time was 20 min at room temperature.

in the amino acid residues of the BSA protein (tryptophan, tyrosine and phenylalanine) [14,22,27]. Based on these findings, we concluded that the mechanism for the fluorescence quenching behavior was more likely due to the oxidation state change of AuNCs during the course of the reaction period.

3.3. Optimization of the sensing system

Prior to the application of proposed fluorescent method for the detection of free chlorine in water some key factors, including the concentration of BSA–AuNCs, the pH value of reaction solution, reaction temperature and time, need to be further optimized.

3.3.1. Concentration of BSA–AuNCs

The concentration of BSA–AuNCs plays a key role in this sensing system. With the increase of BSA–AuNCs concentration from 2 mg/mL to 25 mg/mL, the fluorescence intensity also increased (Fig. 4A). Free chlorine can result in the fluorescence quenching of BSA–AuNCs solution. The fluorescence quenching efficiency increased with increasing of BSA–AuNCs concentration and reached the maximum when 6.0 mg/mL BSA–AuNCs was used, whereas it tended to decrease with further increase of BSA–AuNCs (Fig. 4B). In order to obtain the best signal-to-noise ratio, 6.0 mg/mL of BSA–AuNCs was chosen for this study.

3.3.2. Reaction temperature and time

The purpose of this method is to determine free chlorine in tap water; therefore room temperature was selected as the reaction temperature. To understand the response rate of the fluorescence signal of BSA–AuNCs to free chlorine, time-dependent fluorescence change upon addition of 400 μM free chlorine was monitored. As shown in Fig. 5 the fluorescence intensity of BSA–AuNCs solution decreased rapidly with reaction time up to 1 min, and changed slowly during 2 h reaction subsequently. Taking the reduced fluorescence of BSA–AuNCs with time into account, the experimental procedure was carried out at room temperature for 20 min.

3.3.3. The pH of reaction solution

In order to achieve sensitive detection of free chlorine, the effect of reaction solution pH on the fluorescence of BSA–AuNCs was investigated. Fig. 6 reveals that upon adding the material the fluorescence quenching efficiency changs apparently in weakly acidic, neutral and weakly alkaline solutions, while fluorescence intensity changes are relatively stable from pH 4.0 to 6.0. The largest signal–noise ratio can be obtained at pH 5.0. Free chlorine exists mainly as hypochloric acid (HClO) in acidic, neutral and weakly alkaline solutions, and as hypochlorite anion (ClO^-) in strongly alkaline solutions. The ClO^- exhibits weaker oxidation capability than the HClO [1,30]. Therefore, a comparatively weak acidic environment at pH 5.0 (phosphate buffer, 20 mM) was chosen for optimal sensing system.

3.4. Sensitivity of the sensing system

Under the optimal experimental conditions, the capability of this sensing system was evaluated for quantitative detection of free chlorine. Fig. 7 displays the fluorescence spectra of BSA–AuNCs solution in the presence of various concentrations free chlorine. As shown in Fig.7 the fluorescence intensity of BSA–

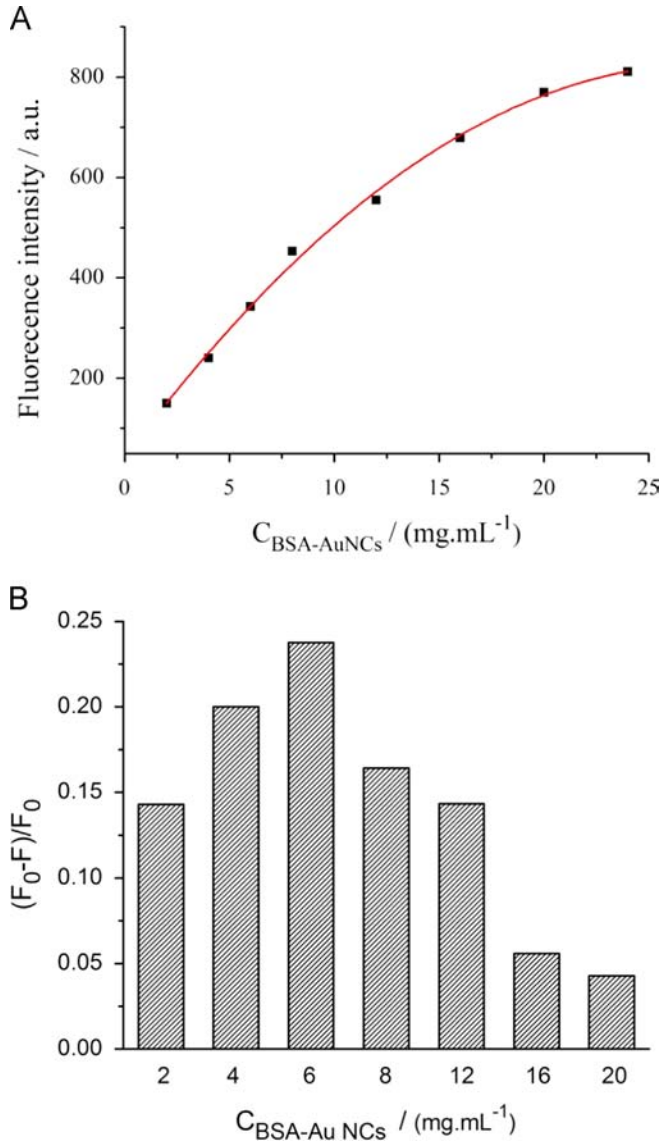

Fig. 4. Concentration-dependent fluorescence of BSA–AuNCs solution (A) and concentration-dependent fluorescence quenching efficiency of BSA–AuNCs to 200 μM free chlorine. Other experiment conditions were as in Fig. 3.

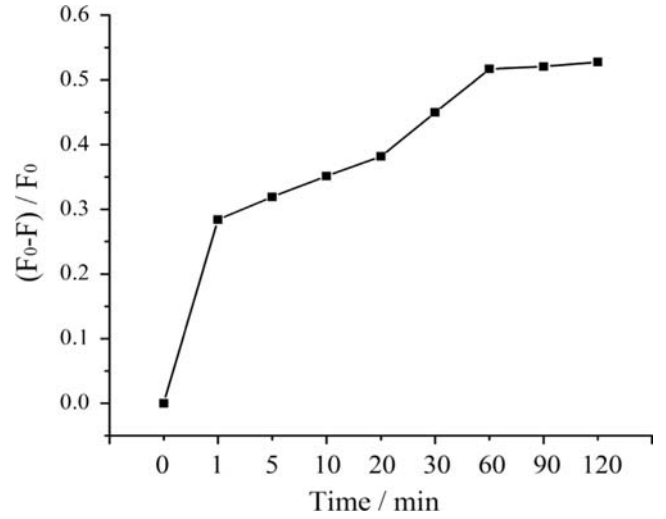

Fig. 5. Time-dependent fluorescence quenching efficiency of BSA–AuNCs to 400 μM free chlorine. Experimental conditions were as in Fig. 3.

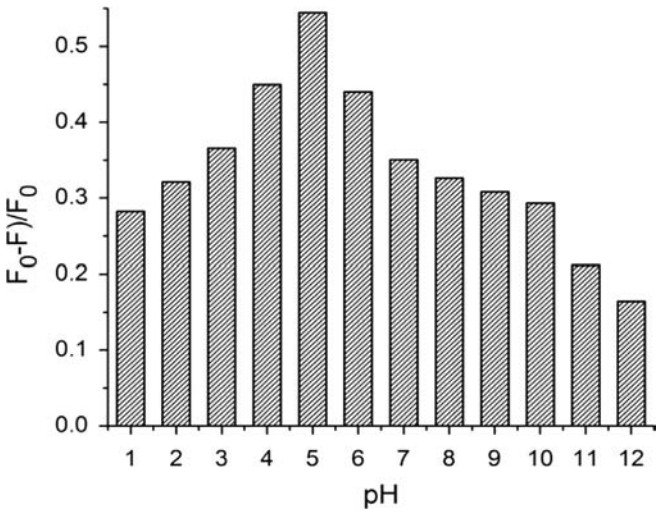

Fig. 6. The fluorescence quenching efficiency of BSA–AuNCs to 700 μM free chlorine at different pH values. Other experiment conditions were as in Fig. 3.

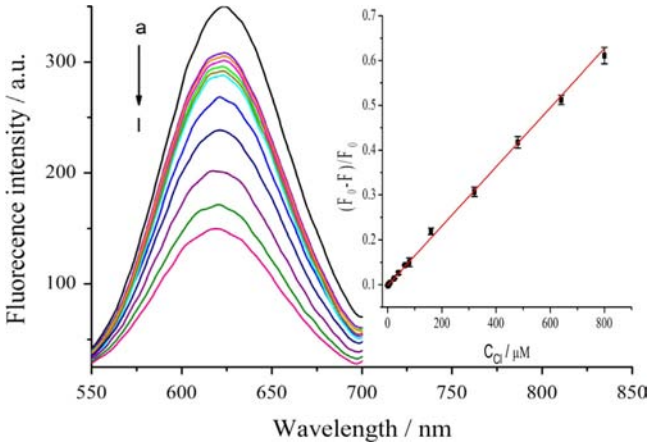

Fig. 7. The fluorescence response of BSA–AuNCs upon addition of various concentrations free chlorine (from a to l: 0, 0.8, 4.0, 8.0, 24, 40, 64, 80, 160, 320, 480, 640 and 800 μM). Inset: plot of the fluorescence quenching efficiency versus free chlorine concentration. Experiment conditions were as in Fig. 3.

Table 1
Comparison of analytical methods for the free chlorine quantification.

Method	Linear range (μM))	Limit of detection (μM))	References
Colorimetric (DPD)	0.67–56	0.67	[31]
Electrochemistry	1.0–932	1.0	[32]
Chemiluminescence	2.0–1000	2.0	[33]
Colorimetric	0–90	2.0	[34]
Fluorescence	0.5–5.0	0.5	[35]
Fluorescence	0.8–800	0.5	This work

AuNCs at 630 nm decreases gradually with increasing of concentration of free chlorine, indicating that the addition of analyte can effectively oxidize the BSA–AuNCs and lead to fluorescence quenching. The calibration curve for free chlorine was established according to the fluorescence quenching efficiency $(F_0-F)/F_0$ (Fig. 7 inset). The regression equation is $(F_0-F)/F_0=6.6034\times 10^{-4}C+0.0985$ with a linear range from 0.8 to 800 μM ($R^2=0.9975$) and the limit of detection (LOD) at 3σ ($\sigma=S_0/S$; S_0, standard deviation of blank sample; S, slope of the calibration curve) is 0.5 μM, which implies more sensitive than those of many of the free chlorine assays ever reported (Table 1). The reproducibility of the sensing system was investigated by

operating six repeated measurements of 30 μM free chlorine, and the relative standard deviation (RSD) was found to be 4.2%.

3.5. Specificity of the sensing system

To detect free chlorine in real samples such as tap water, the selectivity of proposed sensing system was evaluated. As mentioned above for the fluorescence quenching mechanism, only oxidants of oxidation capability more than that of free chlorine would quench the fluorescence of BSA–AuNCs. However, most of the natural water does not contain strong oxidizing agents. Therefore, the proposed sensing system was tested with a variety of environmentally relevant cations (Ca^{2+}, Mg^{2+}, Fe^{3+}, Cu^{2+}, Cd^{2+}, Ag^{+}, Pb^{2+}, Co^{2+}, NH_4^+) and anions (Br^-, F^-, NO_3^-, $CH_3CO_2^-$, SO_4^{2-}, SO_3^{2-}, PO_4^{2-}, CO_3^{2-}, HCO_3^-) (each 1 mM) to evaluate the selectivity under optimal conditions with 700 μM free chlorine. The results are shown in Fig. 8. As can be seen, the fluorescence intensity of BSA–AuNCs is almost same without and with ion target except Cu^{2+}, whereas a significant fluorescence decrease was observed in the presence of free chlorine. And the interference from Cu^{2+} can be eliminated by triethanolamine. These features contributed to the excellent selectivity toward free chlorine, rendering the BSA–AuNCs highly suitable for the analysis of environmental samples.

3.6. Application in tap water sample

From above described results, the applicability of proposed BSA–AuNCs fluorescence probe for detection of free chlorine in tap water was carried out. A standard addition method was used for evaluation of the accuracy and credibility of proposed method. Tap water samples are analyzed by the proposed procedures and the results are presented in Table 1. It can be seen that the concentrations of free chlorine in these tap water samples are found to be in the range of 15.95–26.45 μM, and the recoveries are found to be in the range of 94.8–105.3%. The assay precision was examined by repeatedly analyzing each tap water sample five times within a working day. The RSDs were between 1.8% and 5.6%. Table 2.

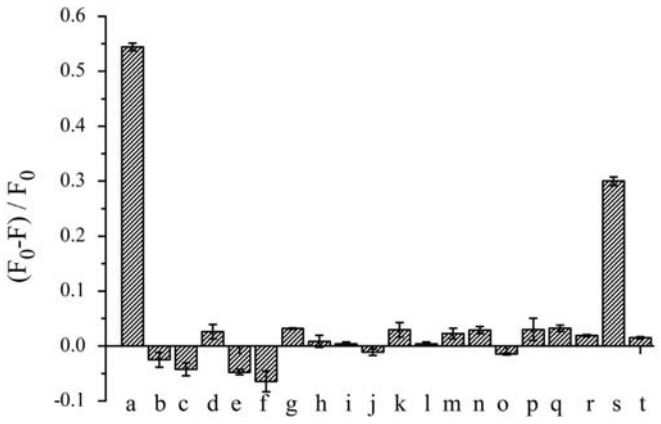

Fig. 8. Selectivity of fluorescence probe for free chlorine over other ions. The concentration of free chlorine was 700 μM; the concentrations of other common ions were all 1.0 mM (a: Cl, b: Ca^{2+}, c: Mg^{2+}, d: Fe^{3+}, e: Cd^{2+}, f: Ag^{+}, g: Pb^{2+}, h: Co^{2+}, i: NH^{4+}, j: Br^-, k: F^-, l: NO^{3-}, m: CH_3CO^{2-}, n: SO_4^{2-}, o- SO_3^{2-}, p: PO_4^{2-}, q: CO_3^{2-}, r: HCO_3^- s: Cu^{2+}, t: Cu^{2+} + triethanolamine. Experimental conditions were as in Fig. 3.

Table 2
Determination of free chlorine in drinking water.

Sample	Found (μM)	Added (μM)	Total found (μM)	Recovery (%)	RSD (%, $n=5$)
Tap water 1	15.95	10.00	26.08	101.3	4.2
		20.00	34.91	94.8	3.4
		30.00	44.98	96.8	2.2
Tap water 2	26.45	10.00	36.63	101.8	2.7
		20.00	46.93	102.4	3.7
		30.00	58.04	105.3	1.8

		20.00	41.86	100.7	5.6
		30.00	52.77	103.5	3.7

4. Conclusion

A novel and facile fluorescent assay has been developed for sensitive detection of free chlorine in drinking water using BSA–AuNCs as the fluorescence probe. The detection mechanism was based on the oxidation of BSA–AuNCs by free chlorine, which resulted in the decrease of BSA–AuNCs fluorescence intensity. This method required no complicated preparation procedure and also exhibited an environmentally friendly feature with high sensitivity and good selectivity. The developed method has been applied for detection of free chlorine in tap water, which presages more opportunities for studying the environmental systems in future applications.

ABSTRACT

Due to industrialization and the use of chemical products in everyday life, various types of drugs and pesticides are present in our environment, which threaten and cause negative impacts on aquatic ecosystems. The consequences of these pollutants are gradually becoming visible. Recent evidence confirms that long term exposure to environmental pharmaceutical concentrations can induce adverse effects in aquatic vertebrates and invertebrates such as reproductive impairments and collapse wild populations. Consequently, one of the challenges of environmental science is to evaluate the associated risks.

In this context, a new methodology has been developed using nano-LC-nano-ESI MS/MS to quantify traces of two pharmaceuticals (a neuropharmaceutical drug, fluoxetine, and an anticonvulsant drug, carbamazepine) in two molluscs, *Potamopyrgus antipodarum* and *Valvata piscinalis*, which are both prosobranch gastropods. A simple and quick extraction method was developed based on a modified and miniaturized version of the QuEChERS method. The procedure involves the extraction of approximately 10 mg of wet mollusc tissue by 500 μL of a mixture of acetonitrile/water/hexane (50/20/30) and 100 mg of buffer salt. Thus, the extraction step was carried out on an individual scale.

The sensitivity of this method allowed for the detection of levels as low as 18 ng/g and 128 ng/g for carbamazepine and fluoxetine, respectively, with recoveries of greater than 85% for the two targeted compounds. This method was then applied to both gastropod species exposed to fluoxetine under laboratory conditions. The results provide evidence of bioaccumulation in both *P. antipodarum* and *V. piscinalis* and reveal the inter-species differences.

1. Introduction

In addition to the classical priority pollutants (pesticides, polychlorinated biphenyls, polycyclic aromatic hydrocarbons), the non-regulated so-called emerging contaminants have become an important topic of research interest, especially with regard to their environmental occurrence. These chemicals are produced on a large scale worldwide, are used in a wide range of applications and have become indispensable to our modern society. Among them, pharmaceuticals are a large and diverse group of compounds that are used in significant quantities worldwide to prevent, cure and treat diseases. These ubiquitous environmental pollutants can enter the aquatic ecosystem via wastewater treatment plant discharges or direct industrial waste, and tend to deposit and accumulate in sediments, soils and biota because of their physical and chemical properties [1]. The occurrence of pharmaceuticals in the aquatic environment has been reported over the past decade or so, with over 80 human drugs detected at low μg/L concentrations in wastewater treatment plant effluents, surface water, groundwater, soils, and aquatic organism tissues worldwide [2–5].

Molluscs are well known as filtering organisms which have been previously used in persistent organic pollutant (POP) monitoring programmes due to their high bioaccumulation capacity, their fixed location and their high population density [6–9]. Moreover, the analysis of these organisms may provide information about the fraction of environmental pollution that is bioavailable to aquatic organisms [8]. In any case, pollutants present in aquatic biota can affect all of the trophic levels by means of their

bioaccumulation along the food chain [10,11]. For all of these reasons, the development of analytical tools for the quantification of traces of micropollutants in biotic environmental matrices such as benthic invertebrates is required.

In this study, two compounds of interest, namely fluoxetine and carbamazepine, have been chosen. Fluoxetine is a widely used antidepressant, frequently found in aquatic ecosystems and in the environment [12,13] at concentrations of up to μg/L. Carbamazepine is also ubiquitous in aquatic ecosystems [7,14]. Moreover, it has been highlighted that they both exhibit dissimilar effects on the reproduction of two gastropod species, *Potamopyrgus antipodarum* and *Valvata piscinalis* [15].

For the analysis of pharmaceuticals in biotic samples, extraction techniques such as soxhlet extraction, sonication [16], microwave assisted extraction (MAE) [17] and pressurized liquid extraction (PLE) [18,19] have been employed. However, the disadvantages of these sample preparation methods include the use of large amounts of organic solvent and the time required for the preparation of each sample. Furthermore, an efficient clean-up to remove interferences was mandatory to prevent the presence of interfering substances, particularly lipids, which can affect the sensitivity of the method and reduce the LC column life. Solid-phase extraction (SPE) [17,18,20] and gel permeation chromatography (GPC) [19,21] have been the most commonly used purification techniques.

In 2003, a new extraction procedure called QuEChERS (Quick, Easy, Cheap, Effective, Rugged and Safe) was developed by Anastassiade et al. [22] and was first used to extract pesticides from food matrices such as fruits and vegetables. This method is based on a salting out extraction with a solvent (mainly acetonitrile) followed by a dispersive solid-phase extraction (dSPE). Since 2003, the two steps of this method have been optimized and adjusted several times. Moreover, two different standards for the first step have been developed: the American standard (AOAC), which involves the use of acetate salts in order to buffer the liquid–liquid extraction and avoid the degradation of base-sensitive pesticide [23], and the European standard EN 15662, which involves the use of citrate buffer [24]. In 2008, Przbylski et al. optimised a previously developed method for high fat content matrices by adding a small fraction of hexane in acetonitrile to remove lipids from the extract [25]. Regarding the second step (clean-up), it initially consisted of dSPE based on primary and secondary amine bonded silica (PSA). However, in 2006, Leandro et al. used PSA and octadecyl bonded silica (PSA/C18) to eliminate apolar interferences [26]. One of the advantages of the QuEChERS method is that it requires low solvent consumption. Therefore, this technology is of great interest because of its favourable toxicological, environmental and economic aspects. It has recently been used for the extraction of various compounds (veterinary drugs, pesticides, pharmaceuticals) in different complex matrices such as animal tissues [27], soil [28,29] or honeybees [30].

The last step in the analytical process is the identification and the quantification of pharmaceuticals. This step is usually based on liquid chromatography (LC) [17,18,31] or gas chromatography (GC) [32] coupled with mass spectrometry (MS) detection because it provides the high selectivity, specificity and sensitivity required for these types of studies.

In the last decade, great attention has been paid to developing miniaturized analytical systems that can offer reliable separations and higher sensitivity with the use of smaller volumes of both the solvent and sample [33]. Nano-liquid chromatography (Nano-LC) introduced in 1988 by Karlsson and Novotny [34] is a chromatographic technique that uses capillary columns with an internal diameter (ID) of less than 100 μm. In fact, the sensitivity can be increased by reducing the ID of the column and keeping constant all other experimental parameters. Downscaling from conventional LC columns of 4.6 mm ID to 100 μm ID results in a sensitivity gain of nearly 2000 [35], which can be ascribed to both a reduction of analyte dilution [36] and an increase in efficiency [37]. Conversely, the injected volume sample is limited to < 10 nL because of the low column volumes (due to the small ID), which counterbalances the theoretical improvement in sensitivity to a large extent [38]. Consequently, large volume injection methods have been successfully investigated and applied. Both on-column focusing [39,40] and the use of trapping columns [41,42] have been described for the effective preconcentration of a wide range of analytes. The coupling of a nano-LC system with mass spectrometry can also be used to increase the sensitivity. For example, using an electrospray ionisation interface as a continuous flow ionisation technique enhances the ionisation process because the number of ions increases in the gas phase, thereby improving the sensitivity [43]. The largest application for nano-LC is proteomic analysis [44–46]; however, it has not been as widely applied in other important fields such as environmental analysis. Consequently, it is necessary to explore the potential of nano-LC in environmental field analysis.

To this end, the aim of this study was to establish an analytical strategy consisting of one single extraction for fluoxetine and carbamazepine based on a modified and miniaturized QuEChERS method, followed by analysis using nano-LC–MSMS. Indeed, nano-chromatography coupled with mass spectrometry (nano-LC-nano-ESI MS/MS) increases the detection sensitivity, reduces the amount of sample required and is shown to be a good tool to investigate the bioaccumulation potential of pharmaceuticals in gastropods.

2. Materials and method

2.1. Materials

Both target compound standards and isotopically labelled standards (carbamazepine-d10 and fluoxetine-d5) were obtained from Sigma-Aldrich (Saint-Quentin Fallavier, France) with purity higher than or equal to 97%. Individual stock solutions of each compound were prepared at concentrations of 1000 mg/L in acetonitrile (ACN) and stored at -20 °C. Working solutions were prepared by the adequate mixture and dilution of the stock solutions in ACN. For the *ex-situ* exposure experiments, fluoxetine (98%, purity) from Interchim (Montluçon, France) was used.

LC–MS grade ACN, hexane and formic acid were obtained from Fluka (Sigma-Aldrich, St-Quentin Fallavier, France). Pure water (18.2 MΩ cm) was obtained from our MilliQ device manufactured by Millipore (Saint Quentin en Yvelines, France). “Citrate QuEChERS kits” were obtained from Agilent Technologies (Massy, France), in which salts were packaged separately and consisted of 4 g of anhydrous $MgSO_4$, 1 g of sodium chloride, 1 g of sodium citrate dihydrate and 500 mg of disodium citrate sesquihydrate. 15 mL centrifuge tubes for PSA/Cl8 dispersive SPE were purchased from Carlo-Erba (Val de Reuil, France). The PSA/C18 tubes contain 900 mg of anhydrous $MgSO_4$, 150 mg of PSA bonded silica and 150 mg of C18 bonded silica.

2.2. Sample collection

P. antipodarum and *V. piscinalis* were obtained from long term cultures established in IRSTEA (National Research Institute of Science and Technology for Environment and Agriculture, Lyon, France). These cultures were initiated with snails that originated from natural populations collected in the Rhône River. The snails were kept 6 weeks at 21 ± 1 °C in 20 L stainless aquaria filled with reconstituted water (mixture of natural spring water and deionized water)and fed with Tetramin® fish food (Tetrawerke, Melle, Germany) as previously described by Gust et al. [15] before experiments. These snails were used as blank matrix or for the development step.

Fluoxetine exposures on both *P. antipodarum* and *V. piscinalis* were performed simultaneously according to a procedure which was previously published by Gust et al. [15]. Briefly, snails from each species were placed in the same test beakers filled with 0.5 L to avoid any differences in the exposure conditions. The beakers were set at 21 ± 1 °C with a 16:8 h light:dark photoperiod. A flow-through system was used which consisted of beakers filled with continuously renewed test water (four renewals a day) and a continuous pumping system. For each tested concentration, it consisted of clean water and a fluoxetine-spiked solution allowing the required exposure concentrations to be obtained after mixing. The fluoxetine-spiked stock solution was renewed every three days and kept at an ambient temperature (18 °C) and in darkness, based on its stability under these conditions [47]. The nominal exposure concentrations included 11.1, 33.3 μg/L and a control for both species. They were chosen in accordance with the biological effects previously observed in these species [15]. Adult snails, with a size of approximately 4.3 mm (±0.2) and 4.0 mm (±0.2) for *P. antipodarum* and *V. piscinalis,* respectively, were used at the start of the experiment.

Six replicates per concentration and three replicates of solvent control were prepared and exposed for 7 (*V. piscinalis*) and 14 days (*P. antipodarum*). Each replicate contained 25 organisms of *P. antipodarum* and 17 of *V. piscinalis*.The specific conductivity, temperature and pH of the water were monitored daily. The snails were fed with 1.5 mg/individual Tetramin® fish food (Tetrawerke, Melle, Germany) per working day, corresponding to the *ad libitum* conditions.

2.3. Sample preparation

One gastropod was weighed in a 1.5 mL centrifuge tube and ground with a pestle. A volume of 250 μL of ACN, 100 μL of water, 150 μL of hexane, 50 μL of ISTD working solution at 50 μg/L and 100 mg of "citrate QuEChERS" salts were then added to the centrifuge tube. The tube was then immediately shaken by hand, vortexed for 10 s and centrifuged for 2 min at 5000 rpm. Afterwards, an aliquot of 150 μL of supernatant was sampled in a 1.5 mL eppendorf tube. The extract was then diluted in ACN/H_2O (50:50) for nano-LC injection.

2.4. LC–MS/MS

The system used for LC–MS/MS was a nanoliquid chromatography Ultimate3000 (Thermo Fisher®, Villebon sur Yvette, France) coupled to a triple quadrupole mass spectrometer Qtrap3200 from ABSciex® (Darmstadt, Germany) equipped with a Nanospray® II interface (ESI) (AB Sciex®, Darmstadt, Germany). The data were processed using the Analyst 1.5 software package.

Chromatographic separation was performed in two steps: a preconcentration step on a C18 pre-column (5 μm, 300 Å, Thermo Fisher®, Villebon sur Yvette, France) followed by separation on a Pepmap C18 column (C18 3 μm × 75 μm × 100 Å, Thermo Fisher®, Villebon sur Yvette, France). The capillary column was directly connected to a ten-port valve to minimize the dead volume and dispersion of injected plug sample. Both ends of pre-column were also connected to the ten-port valve.

In the final optimised configuration, the column oven temperature was set at 30 °C and an injection volume of 1 μL (in μL pickup mode) of the sample was loaded for 4.5 min onto the pre-column at a flow rate of 20 μL/min using a loading solvent consisting of pure water and ACN (98/2) with 0.1% (v/v) formic acid. Once the compounds were trapped (loading step), the valve position was changed to connect the pre-column with the analytical column.

Next, the analytes were back flushed with the mobile phase delivered by the nano-pump into the reversed phase column at a flow rate of 0.3 μL/min. The targeted compounds were separated using (A) H20:ACN (98:2) with 0.1% of formic acid and (B) ACN: H20 (80:20) with 0.1% of formic acid. The following elution program was used: from 40% to 100% (B) in 5 min and 100% (B) for 15 min. The column was re-equilibrated for 20 min at the initial composition of the gradient between runs.

MS/MS detection was performed in multiple reaction monitoring (MRM) mode using the NanoSpray® II source in positive ion mode. For each compound, the declustering potential (DP), energy potential (EP), collision energies (CE) of two MRM transitions were optimised from a continuous flow of a standard injection (1 mg/L solution in 50/50 (A) and (B) at 10 μL/min) to obtain the maximum signal intensities. One MS/MS transition (MRM 1) was used for the quantification, and a second MS/MS transition (MRM 2) was selected for confirmation for each targeted compound. The selected parent and fragment ions, MS/MS conditions and retention times are listed in Table 1.

2.5. Method performance and validation

The development method combining the sample preparation and the LC–MS/MS analysis was validated following the International Conference on Harmonization (ICH) guidelines [48]. The limit of detection (LOD) was determined as the analyte concentration that produced a peak signal of three times larger than the background noise from the chromatogram using MRM 2. The limit of quantification (LOQ) was determined as the analyte concentration that produced a peak signal of ten times larger than the background noise from the chromatogram using MRM 1. Each value of the estimated detection and quantification limits was checked by extracting and analysing samples of blank matrix spiked before extraction at different concentrations. The validation strategy is outlined in Fig. 1. It was performed on three days with concentrations ranging between LOQ and 50LOQ. More precisely, on each day, six samples of blank matrix spiked with six levels of concentration (C1=5LOQ, C2=10LOQ, C3=20LQ, C4=30LOQ, C5=40LOQ and C6=50LOQ) were extracted to examine the linearity. Linearity was considered to be validated if the correlation coefficient measured in this concentration range was found to be greater than 0.99.

The repeatability and recoveries were evaluated for three levels of concentration: C2, C4 and C6. For each day, two additional samples of blank matrix spiked with a particular concentration level (first day C2, second day C4 and third day C6) were extracted to determine the repeatability. The repeatability is associated with the intra-day precision, which is expressed as the relative standard deviation (RSD) of a series of measurements carried out under the same conditions by the same manipulator and on the same day. Each day, three samples of blank matrix were spiked at the same concentration before the extraction. The signals of these samples ($S_{\text{spiked before extraction}}$) were compared with those of samples spiked at C2, C4 or C6 after extraction ($S_{\text{spiked after extraction}}$) in order to

Table 1
Retention time (*Rt*), MS/MS parameters: quantitation transitions, precursor product ions, desclustering potential (DP), energy potential (EP), collision energies (CE), and transition ratio.

Analytes	*Rt* (min)	Precursor ion (*m/z*)	Product ion (*m/z*)	DP (V)	EP (V)	CE (V)	Transition ratio
Carbamazepine	18.7	237.2	194.2	61	10	27	10
		237.2	179.2	61	10	47	
Carbamazepine-d10	18.6	247.2	204.3	46	4	29	–
Fluoxetine	16.9	310.2	148.3	41	5.5	13	30
		310.2	91.1	41	5.5	27	
Fluoxetine-d5	16.9	315.2	153.2	36	4	14	–

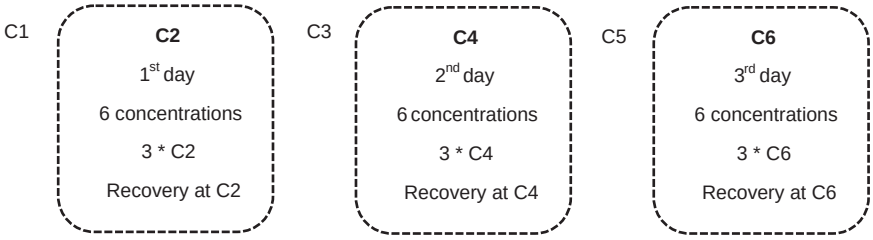

Fig. 1. Validation plan on three days.

determine recoveries. Consequently, three replicates per day of validation were used to evaluate recoveries and repeatability.

Intermediate precision, also named inter-day precision, was also evaluated at the same levels of concentration as those used for the repeatability measurements. The intermediate precision can be determined by introducing variations in the process, such as different conditions, different manipulators or different days. In our case, the procedures were performed over a period of three days and different bottles of solvents were used. For the LC–MS/MS analysis, due to a matrix effect the signals of samples spiked before extraction had to be corrected using the signals of the isotopically labelled compounds carbamazepine-d10 and fluoxetine-d5 (S_{IsoLab}). The intermediate precision was expressed as the RSD of the ratio $S_{spiked\ before\ extraction}/S_{IsoLab}$ as a percentage. For each validated concentration level, five replicates were used to determine the intermediate precision.

As recommended in ICH guidelines [48], with respect to the repeatability, all the RSDs should be less than or equal to 20%. Additionally, for the intermediate precision, the RSDs should be below 30%.

2.6. Quantification

Matrix-matched calibration was used for quantification. In each batch, 6 calibration points prepared as described in Section 2 with concentration ranges between LOQ and 50LOQ were injected. The quantification was carried out by two replicate injections. The instrumental performance was checked using the injection of Quality Control samples which corresponded to a standard solution of targeted compounds at 50 ng/mL. The extraction performance was checked using the signal peak areas of carbamazepine-d10 and fluoxetine-d5. Fluoxetine and carbamazepine were identified by their retention times, the two MRM transitions and the specific ratios of the responses of the transitions with deviations $<20\%$ with respect to the ratios of the analytical standards.

3. Results and discussion

3.1. Method development

3.1.1. Sample extraction

The QuEChERS extraction method consisted of two major steps: a liquid/liquid buffered extraction followed by a dispersive SPE clean up. In the first step, an organic phase allows the extraction of the analytes from the matrix. Several organic solvents such as acetone, ethyl acetate or acetonitrile can be used; however, the efficiency of extraction solvent depends on specific matrix and targeted compounds. Nevertheless, acetonitrile has already been used for the extraction of pharmaceuticals and various compounds in mollusc tissues [49,50]. Because water and acetonitrile are miscible, a buffered mixture of salts and $MgSO_4$ must also be added in order to induce phase separation. This procedure increases the passage of the target compounds into the organic phase and improves the pH-dependent stability of the substances, resulting in increased recovery of the analytes [51]. Due to a limited number of available biotic organisms, some of the extraction parameters were fixed: the quantity of added salts (100 mg), the quantity of water added (100 μL), the type of buffered salts (chosen according to the standard Method EN 15662 [24]) and the type extraction solvent (acetonitrile). The type of liquid/liquid extraction is chosen based on the affinity of the analytes for each phase. This affinity is dependent first on the compound, second on the nature of the solvents and finally on the volume of solvents used for extraction. Thus, the volume of acetonitrile was optimized first in order to carry out an efficient extraction.

To determine the influence of the volume of ACN used in the first step of the extraction, the signal of each molecule was compared after extraction with different quantities of acetonitrile in the range of 50 to 250 μL. The results obtained with three replicate measurements for each experiments were normalized with respect to the maximum response and are presented in Fig. 2. For both compounds the highest signal intensity was reached for 250 μL of ACN. Consequently, this volume was used for all subsequent extractions of target analytes from biotic organisms.

In the QuEChERS method, the clean-up step is performed using dispersive SPE [22]. The dSPE sorbent should retain the matrix co-extractants but not the target analytes. To selectively trap the matrix impurities, different dSPE sorbents such as PSA, PSA/C18, and graphite carbon black are available. PSA is used to eliminate polar organic acids, sugars and lipids, whereas PSA/C18 removes also non polar compounds. For our application we used PSA/C18 to evaluate the efficiency of the dSPE clean-up. The choice of this sorbent was justified by the high concentration of lipids contained in the extracts from the biotic matrices. PSA/C18 is also recommended by the European standard [24] for the clean-up of highly fatty matrices such as meats or cereals. In addition, one sample was extracted without the clean-up step.

Fig. 3 presents the recoveries of the two molecules in the presence and absence of the dSPE phase. Three replicate measurements were carried out for each experiment. The results show no significant difference in the case of carbamazepine, whereas the recoveries are better without dSPE in the case of fluoxetine. Indeed, the use of PSA/C18 decreased the recovery of fluoxetine by a factor of 6. These results can be explained by the relative hydrophobicity of fluoxetine, which has a logP value of 4.05, while logP of carbamazepine is approximately 2.45.

This test revealed that the PSA/C18 sorbent is not suitable for the dispersive SPE clean-up step proposed in the original QuEChERS method. Because the dSPE clean-up retains fluoxetine, this step was omitted and replaced by an addition of hexane. Indeed, it has been shown that this solvent allows for the elimination of non-polar and fatty compounds [25]. Thus, to investigate the impact of hexane on biotic matrix samples, 100 μL of this solvent were added during the extraction step. The benefit of adding hexane could be immediately observed during the experiment: the samples cleaned with hexane appeared clearer and less viscous. This solvent efficiently eliminated lipids and ensured the defatting of the sample. Moreover, when the volume of hexane was lower than 100 μL, the partition between ACN and hexane phases was not clearly visible. Consequently, the

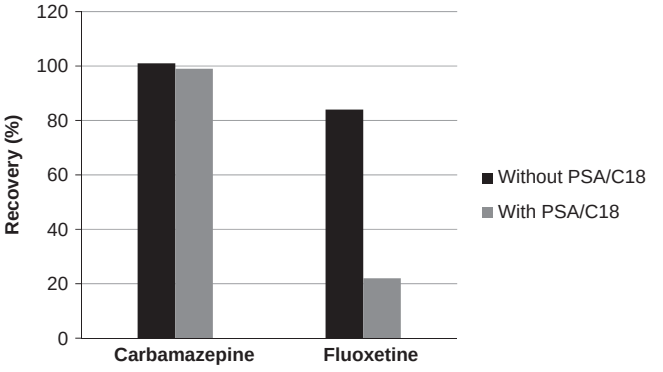

Fig. 3. Recoveries of target compounds obtained (at 300 ng/g wet weight) using PSA/C18 dSPE and without dSPE (replicate measurements, $n=3$).

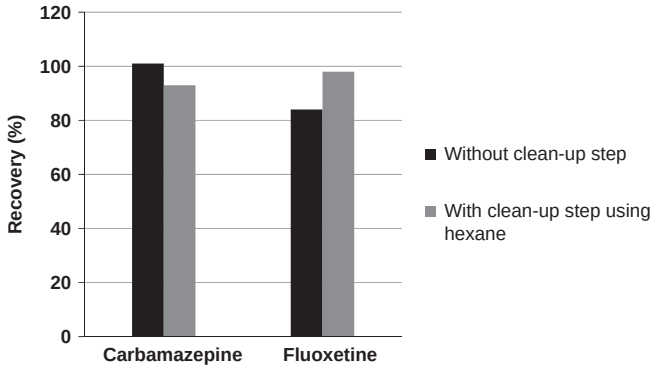

Fig. 4. Recoveries of target compounds (at 300 ng/g wet weight) obtained using hexane clean-up and without clean-up step (replicate measurements, $n=3$).

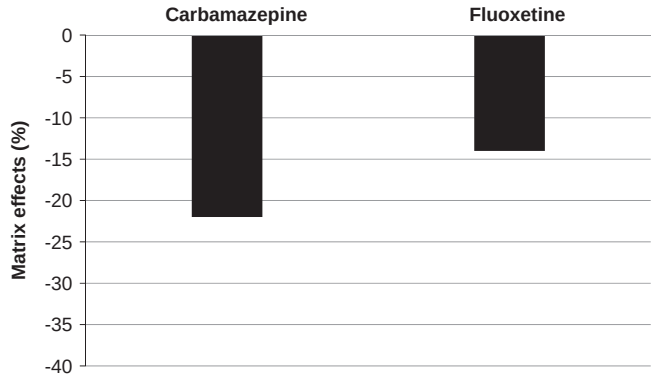

Fig. 5. Matrix effects of the target compounds (at 300 ng/g wet weight) obtained with optimized method (replicate measurements, $n=3$).

recovery of the cleaned extract was poorly repeatable. For these reasons, the addition of 100 µL of hexane was chosen for the clean-up step as a dSPE replacement. The recoveries of each target compound obtained with the optimized method including the extraction and purification steps are presented in Fig. 4 and are compared with those obtained without the purification step.

3.1.2. *Matrix effects*

Matrix effects that can cause the enhancement or suppression of the analytical signals are frequently observed in the chemical analysis field. This phenomenon is due to matrix compounds that are eluted with the same retention time as the target compounds [52]. Matrix effects depend on the nature of the matrix and the efficiency of the sample preparation step. Therefore, the sample preparation step should eliminate interfering compounds while retaining the target analytes. To thoroughly study this phenomenon, the biotic samples were spiked after the extraction, and the corresponding signals ($S_{\text{spiked matrix}}$) were compared with those of the standard (S_{solvent}) with the same concentration. The matrix effects for our application were determined with the following equation:

$$\text{Matrix effect}\ (\%) = \left(\frac{S_{\text{spiked matrix}}}{S_{\text{solvent}}} - 1\right) \times 100$$

and the results are presented in Fig. 5.

The results indicate that ion suppression was observed for both targeted compounds, with the maximum ion suppression of 22% found for carbamazepine. Applying an external calibration to complex matrices such as biotic matrices would certainly lead to errors in quantification. Therefore, three calibration strategies can be employed in this study: an internal standard, standard addition and matrix-matched calibrations. Internal standard calibration is an efficient method to correct matrix effects. For example, in order to correct for the ion suppression, deuterated internal standards of compounds can be used. The internal standard undergoes the same interferences as that of the analyte; thus, the phenomenon of ion suppression is similar for the analyte and the internal standard. Standard addition is also an interesting but very time-consuming method, especially when a large number of samples have to be analysed. Finally, matrix-matched calibration is a useful method to correct matrix effects, however only if a blank matrix is available and if the ion suppression/enhancement matrix effects used for the calibration are the same as those for the samples analysed. One of the objectives of this study was to apply the analytical method to a large number of samples to obtain an overview of environmental contamination, so standard addition calibration could not be used. Finally, because a blank matrix (see Section 2.2) was available, matrix-matched calibration was chosen. To make sure that the ion suppression/enhancement matrix effects were the same for the calibration and the analytes, the extraction performance was checked using the signal areas of fluoxetine-d5 and carbamazepine-d10.

3.2. *Nano-LC–MS/MS*

The optimization of the ESI–MS/MS parameters was performed by direct infusion into the electrospray source (Table 1). Two MRM transitions were monitored for each compound: the more sensitive ion was used for the quantification and the second for confirmation. Both positive and negative ionisation modes were tested. The better choice will provide the best selectivity of the transitions and the smallest noise for the product ions. For both target compounds, positive ionisation mode was selected. Another approach for increasing the MS/MS sensitivity is improvement in the ionisation

efficiency of the analyte undergoing quantification. The ionisation efficiency of a target compound can be increased by the use of mobile phase additives such as formic acid or ammonium acetate. These modifiers are often commonly used in bioanalysis [53]. Both of the selected analytes showed more efficient ionisation when using formic acid as an additive.

Optimising the nanochromatographic conditions of small molecule analysis is challenging because of the technology used: nanochromatography is a relatively recent development in chromatography driven by advances in proteomics. Nanochromatography columns are adapted for peptide separation, which means that they are designed for molecules with molecular weights of up to 3000 Da. In contrast, the two molecules of interest in this study weighed 237 g/mol (carbamazepine) and 310 g/mol (fluoxetine). Nevertheless, the advantage of using a nano-LC system, which is a miniaturization of a chromatographic system and electrospray source, is that it improves the analytical performance. Therefore, the system enables handling small volumes, working with a limited matrix quantity and increasing of the sensitivity. From a detailed examination of the current literature it is clear that the selected pharmaceuticals have never been analysed by nano-LC. To develop the nano-LC separation, a capillary column with 75 μm ID was used with a silica-based C18 stationary phase ;(3-μm particle size) with virtually zero silanophilic activity. The choice of this column was based on the results of several reports that used the C18 stationary phase for the separation of pharmaceuticals by HPLC [17–19]. To increase the sensitivity of the method, an on-line preconcentration procedure using a trapping μ-pre-column (C18 300 μm × 5 mm × 100 Å, Dionex®) was applied because it previously provided higher sensitivities in several nano-LC applications [41,42].

Regarding the pre-concentration step, the key factor for obtaining good sensitivity is the loading time (or switching time), which can be defined as the time that the mobile phase is pumped into the μ pre-column once the sample has been loaded. To obtain the best sensitivity, various loading times were compared. Fig. 6 presents the normalized response of the two target compounds for loading times of 4 min, 4.5 min and 5 min on the cartridge. The best loading time was determined to 4.5 min because a shorter time was not able to elute the pre-column to a sufficient extent and a longer loading time produced lower efficiency. Indeed, the most polar compound, carbamazepine in this case, was desorbed and directed into the waste.

With this column, different isocratic and gradient elution programs were tested. Complete separation with good efficiency was achieved using a mobile phase (A) of water and ACN (98/2) with 0.1% of formic acid and a mobile phase (B) of ACN and water (80/20) with 0.01% of formic acid. The separation of the two target compounds under these conditions was achieved in less than 20 min, and the column was re-equilibrated for 20 min between runs.

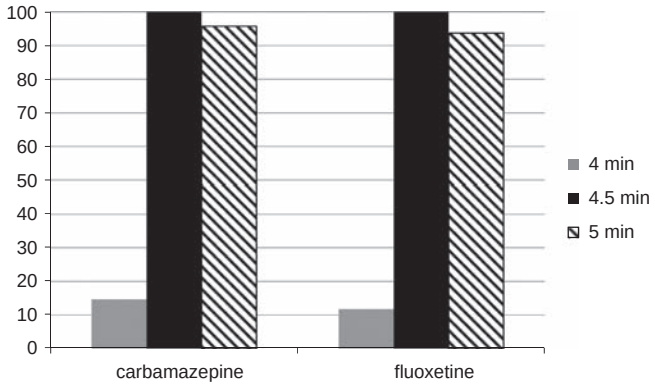

Fig. 6. Normalized responses of the target compounds with different loading times (replicate measurements, $n=3$).

3.3. Method validation and performance

Method validation is an important requirement in the practice of chemical analysis. This step is crucial in order to prove the repeatability of the developed QuEChERS-LC–MS/MS method with respect to the actual validation criteria [54]. The criteria used for the validation method were the limit of quantification, linearity, recovery, inter-day precision and intra-day precision.

Satisfactory recoveries (> 85%) were obtained for both compounds. The intra- and inter-day precisions were measured to be less than 15% and 20%, respectively, for the compounds of interest. The correlation coefficients of the performed regressions were greater than 0.99. The limits of detection were found to be in the range of environmental contaminant concentrations, which is between 16 and 127 ng/g for carbamazepine and fluoxetine, respectively. The limits of quantification were measured to be 48 and 343 ng/g for carbamazepine and fluoxetine, respectively.

If we compare the instrumental detection limits for the two studied compounds obtained with nano-LC-nano-ESI–MS/MS to those obtained with LC–ESI–MS/MS from a previous study with the same detector, we find a 50-fold and 125-fold increase in the sensitivities for carbamazepine and fluoxetine, respectively. Such sensitivities allow for the study of a unique gastropod.

3.4. Application to ex situ experiments

After a short exposure (7 and 14 days) at different concentrations (11 and 33 μg/L), the quantification of fluoxetine in both *P. antipodarum* and *V. piscinalis* was carried out (Table 2) using triplicate measurements. Fluoxetine was quantified for both sentinel species; however, no significant differences were noted between the fluoxetine concentrations in *P. antipodarum* after 7 or 14 days, suggesting that the bioconcentration steady state had already been achieved by 7 days of exposure in this species. A previous study reports that in the Japanese medaka, the bioconcentration steady state was achieved after only 3 days of exposure. Therefore, it was estimated that the fluoxetine steady state was also reached in *V. piscinalis*, even though measurements were only performed on day 7.

Concentrations of fluoxetine in *P. antipodarum* were significantly higher than in *V. piscinalis*, implying a higher bioconcentration of the parent compound in *P. antipodarum* after 7 days of exposure. These results reveal an inter-species difference in the accumulation of fluoxetine. As this method was carried out on one gastropod, a metabonomics approach could be possible to characterize biological responses.

4. Conclusion

Using a combination of a single and quick extraction and nanoliquid chromatography coupled to tandem mass spectrometry analysis, the developed nano-LC-nano-ESI–MS/MS method offers

Table 2
Concentrationof fluoxetine in *P. antipodarum* and *V. piscinalis* after a short exposure (7 and 14 days) at different doping concentrations (11 and 33 μg/L) (average of three replicates measurements per experiments).

Fluoxetine (μg/L)			Control	11 μg/L	33 μg/L
Fluoxetine (μg/g ww)	*P. antipodarum*	J0	< LD	–	–
		J7	< LD	1.2 ± 0.2	5.5 ± 0.2
		J14	< LD	1.8 ± 0.3	6.3 ± 0.5
	V. piscinalis	J0	< LD	–	–
		J7	< LD	< LD	2.8 ± 1.1

the sensitivity and selectivity necessary for the detection of the target analytes in the ng/g range.

Moreover, this analytical method combines extraction and purification of the extracts in a single step in order to comply with the principles of Green Chemistry, to simplify the experimental procedure and to better avoid sources of contamination. The method was successfully applied to the analysis of two gastropod species, *V. piscinalis* and *P. antipodarum*, exposed to various levels of fluoxetine concentration.

This study has investigated the accumulation of pharmaceuticals in gastropod molluscs for the first time. The results indicate an inter-species difference in the amount of bioaccumulation between the two molluscs. The success of this method allows us to foresee one possible outlook for future studies: as this study was carried out on one gastropod, a metabolomics approach may be possible to characterize the biological responses in order to better understand the diversity of responses between both molluscs. Additionally, as there is little quantification data for fluoxetine detected in the different mollusk species in the literature, the developed method can be used to extend knowledge about pharmaceutical bioaccumulation mechanisms, thus improving understanding of biological effects.

Squamous cell carcinoma antigen

ABSTRACT

Sodium montmorillonites (Na-Mont), which could be transformed from nano-montmorillonites, have large surface area, chemical stability, nontoxicity, high cation exchange property and superior adsorption ability. In this paper, Na-Mont were used as a support of polyaniline (PANI) and gold nanoparticles (AuNPs) via the interaction of aniline and $HAuCl_4$ solution. A sandwich-type electrochemical immunosensor was developed to detect squamous cell carcinoma antigen (SCC-Ag). It used nitrogen-doped graphene sheets (N-GS) for the immobilization of primary anti-SCC antibodies (Ab_1) and the combined Na-Mont-PANI-AuNPs nanocomposites as labels. Na-Mont-PANI-AuNPs have excellent catalytic ability towards the reduction of H_2O_2, thus enhance the sensitivity of the immunosensor. The immunosensor exhibits a wide linear range (1 pg/mL–5 ng/mL), a low detection limit (0.3 pg/mL), good reproducibility, selectivity and stability. This new type of immunosensor with Na-Mont-PANI-AuNPs as labels may provide potential application for the detection of SCC-Ag.

1. Introduction

Squamous cell carcinoma antigen (SCC-Ag), a glycoprotein with isoforms ranging from 45 to 55 kDa, is a subtype of TA-4 and belongs to the ovalbumin family of serine proteinase inhibitors [1–3]. There is a close relationship between high level of SCC-Ag in human serum and cervical cancer, squamous cell carcinoma of the lungs, esophageal cancer, and so on [4]. The serum level of SCC-Ag would increase in parallel to the growth of the tumor size or the recurrence of the disease [5]. Recently, radioimmunoassay [6], enzyme-linked immunosorbent assay [7] and chemiluminescence enzyme immunoassay [8] have been used to detect SCC-Ag in serum. Although these methods are widely used, there is still a highly demand for developing a sensitive, simple and low-cost method for the early detection of SCC-Ag. Electrochemical immunosensor is a miniaturized analytical device. Due to its many merits such as high sensitivity, precise current measurement and the cost-effectiveness, it has attracted much attention in analytical chemistry. To aim at this demand, herein, we had developed a convenient sandwich-type immunosensor based on Na-montmorillonite-polyaniline-gold nanoparticles (Na-Mont-PANI-AuNPs) and nitrogen doped graphene sheets (N-GS) for the sensitive detection of SCC-Ag. There are two basic issues for increasing the sensitivity of the immunosensor, one is the capture of primary antibody (Ab_1) onto electrode surface, and the other is the signal amplification strategy.

In recent years, many kinds of nanomaterials, such as silica nanoparticles, carbon nanotubes, titanium dioxide nanoparticles and nano-montmorillonites have been used as labels for signal amplification in electrochemical immunosensors [9–12]. Nano-montmorillonites belong to aluminosilicate clay minerals that could be converted to sodium montmorillonites (Na-Mont) by reacting with NaCl solution [13]. Na-Mont which consisted of layered structures have proved to be an ideal host due to their inherent advantages, such as large surface area, high cation exchange capacity, superior adsorption ability, nontoxicity and chemical stability and so on [14–18]. Based on the cation exchange ability of Na-Mont, many organic molecules with polar functional groups and ions can be intercalated into the interlayer space of montmorillonites [15]. Polyaniline (PANI) have aroused extensive attention in the application of electrochemical immunosensor due to their interesting conductivity, electronic and catalytic characteristics [19,20]. Gold nanoparticles (AuNPs) also have many advantages including its good catalytic performances, easy preparation, good biocompatibility and strong bonding ability [21–23]. Usually, aniline would exist in the form of cations in acidic solution, so it can insert into Na-Mont and react with the added $HAuCl_4$ solution. Due to the large surface and cation exchange ability of Na-Mont [24,25], AuNPs and PANI could form largely in the interlayer structures based on the

reaction of $HAuCl_4$ and aniline. The secondary anti-SCC antibodies (Ab_2) can be adsorbed onto the Na-Mont surface based on its excellent adsorption ability and the Ab_1 could be immobilized by N-GS due to its excellent electronic conductivity, large surface areas and amounts of edge sites [26–28].

Hence, we proposed a new type electrochemical immunosensor for the sensitive detection of SCC-Ag by using Na-Mont-PANI-AuNPs nanostructures as labels. To the best of our knowledge, this is the first time that Na-Mont-PANI-AuNPs nanostructures have been prepared through intercalation strategy and used as labels for electrochemical immunosensor construction.

2. Materials and methods

2.1. Apparatus and reagents

The montmorillonites were purchased from the Fangzi Bentonite Plant (Weifang, Shandong Province, China). Bovine serum albumin (BSA, 96–99%) was purchased from Sigma. The SCC-Ag, Ab_1 and Ab_2 were purchased from Beijing Kwinbon Biotechnology Co., Ltd. (Beijing, China). Aniline, $HAuCl_4 \cdot 4H_2O$, chitosan and $K_3[Fe(CN)_6]$ were obtained from Sinopharm Chemical Reagent Shanghai Co., Ltd., China (Beijing, China). KH_2PO_4 and Na_2HPO_4 were of analytical reagents grade and used without further purification. Phosphate buffered solutions (PBS) were prepared using 0.067 mol/L Na_2HPO_4 and 0.067 mol/L KH_2PO_4 stock solution. All other chemicals and solvents were of analytical grade. Ultrapure water was used throughout the experiment.

All electrochemical measurements were performed on a CHI760D electrochemical workstation (Chenhua Instrument Shanghai Co., Ltd., China). Scanning electron microscope (SEM) images were recorded using field emission SEM (ZEISS, Germany). Transmission electron microscope (TEM) images were obtained from a Hitachi H-800 microscope (Japan). Conventional three-electrode system was used for all electrochemical measurements: a glassy carbon electrode (GCE, 4 mm in diameter) as working electrode, a platinum wire electrode as the counter electrode and a saturated calomel electrode (SCE) as the reference electrode.

2.2. Synthesis of nitrogen-doped graphene sheets (N-GS)

N-GS were synthesized through thermal annealing of graphite oxide in ammonia [29]. Graphite oxides (GO) were prepared from graphite powder by a modified Hummers' method [30]. In brief, a 9:1 (v:v) mixture of 36 mL H_2SO_4 and 4 mL H_3PO_4 solution were added

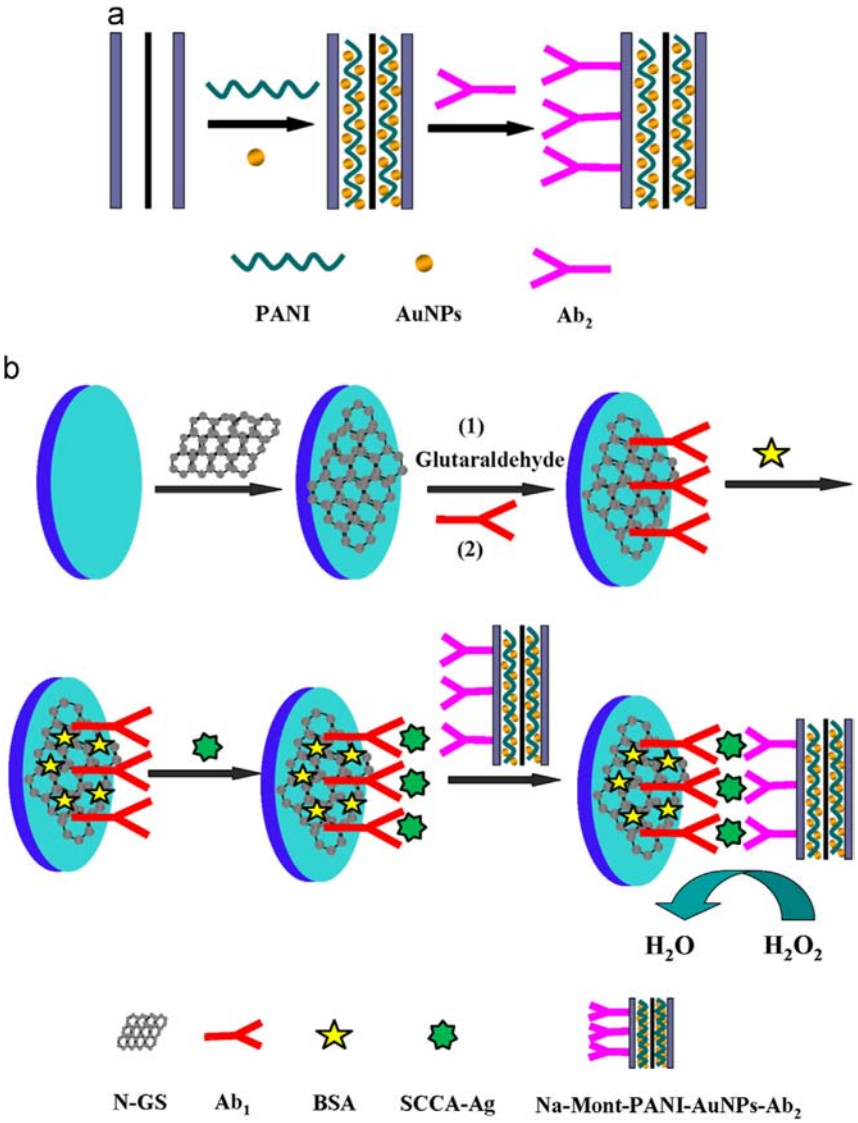

Fig. 1. Schematic representation of the preparation of the Na-Mont-PANI-AuNPs-Ab_2 (a) and the fabrication processes of the immunosensor (b).

into the mixture of 1.8 g $KMnO_4$ and 0.3 g graphite flakes and the reaction was under 50 °C for 12 h in a three flask. Then 30 μL H_2O_2 was added into the solution after stirring for 0.5 h and the products were washed by hydrochloric acid (0.2 M) and ethyl alcohol by drying after reaction. The synthesized GO (50 mg) were dispersed in 25 mL ultrapure water with a concentration of 2 mg/mL, then the pH of the solution was raised up to 10 by the addition of 30% $NH_3 \cdot H_2O$. After stirring for 10 min, 100 mL *N*,*N*-dimethyl formamide was added to the mixture and they were reacted at 153 °C for 1 h. Finally, the black sediment was filtered and washed with ultrapure water to neutral. The solids were dried to gain N-GS and the obtained N-GS were then dispersed in chitosan (0.5 wt%) until used.

2.3. Synthesis of sodium montmorillonites (Na-Mont)

According to Yan's report [31], 25.0 g natural montmorillonites with 29.3 g NaCl powder were dispersed in 0.5 L ultrapure water. The solution was shaken for 12 h. After that, the remaining solids were washed with ultrapure water repeatedly until no free of chloride ions were detected by $AgNO_3$ solution. The products were dried at 85 °C for 24 h. They were ground in an agate mortar and then kept in a sealed bottle.

2.4. Synthesis of Na-Mont-PANI-AuNPs

About 10.0 μL aniline were added into 50.0 mL ultrapure water to form 0.0022 M aniline solution, then they were added into 100 mL 0.2 M sulphuric acid solution for the protonation of aniline. Next, 1.06 g Na-Mont was dispersed in the acidic solution along with shaking uniformly for 3 h. In this process, the protonated aniline would insert into the interlayer of Na-Mont. 300 μL 1% $HAuCl_4$ solution was added into above mixture with gently stirring, it can be observed that the solution color changed from yellow to light green and then to dark green. After discarding the supernatant, the Na-Mont-PANI-AuNPs nanocomposites were obtained.

2.5. Preparation of Na-Mont-PANI-AuNPs-Ab_2 labels

Fig. 1a showed the schematic illustration for the preparation of Na-Mont-PANI-AuNPs-Ab_2 labels. Typically, 0.25 mL of 10 μg/mL Ab_2 was added into the Na-Mont-PANI-AuNPs solution and the mixture were placed at 4 °C under shaking for 12 h. Ab_2 could be loaded into channels of the Na-Mont-PANI-AuNPs. The obtained Na-Mont-PANI-AuNPs-Ab_2 was washed with PBS (pH 7.4). The resulting bioconjugates were redispersed in 1 mL of PBS at 4 °C until used.

2.6. Fabrication of the immunosensor

Fig. 1b showed the preparation process of the immunosensor. A GCE with 4 mm diameter was polished with 1.0, 0.3 and 0.05 μm alumina powder and thoroughly cleaned with ultrapure water before use. First, 6.0 μL of N-GS solution (2 mg/mL) which was dispersed in chitosan (0.5 wt%) was modified onto the electrode. After drying, the electrode was thoroughly cleaned with PBS to remove unbounded N-GS. Then 3 μL of glutaraldehyde (2.5%) was dropped onto the electrode surface to immobilize the Ab_1 and incubated for 1 h. Next, 6.0 μL of Ab_1 (10 μg/mL) solution was added onto electrode surface and incubated for another 1 h. The excess Ab_1 was washed by PBS. The modified electrode was then incubated with 1 wt% BSA solution to block nonspecific binding sites. Subsequently, different concentrations of SCC-Ag solution were added to the electrode surface and incubated for another 1 h.

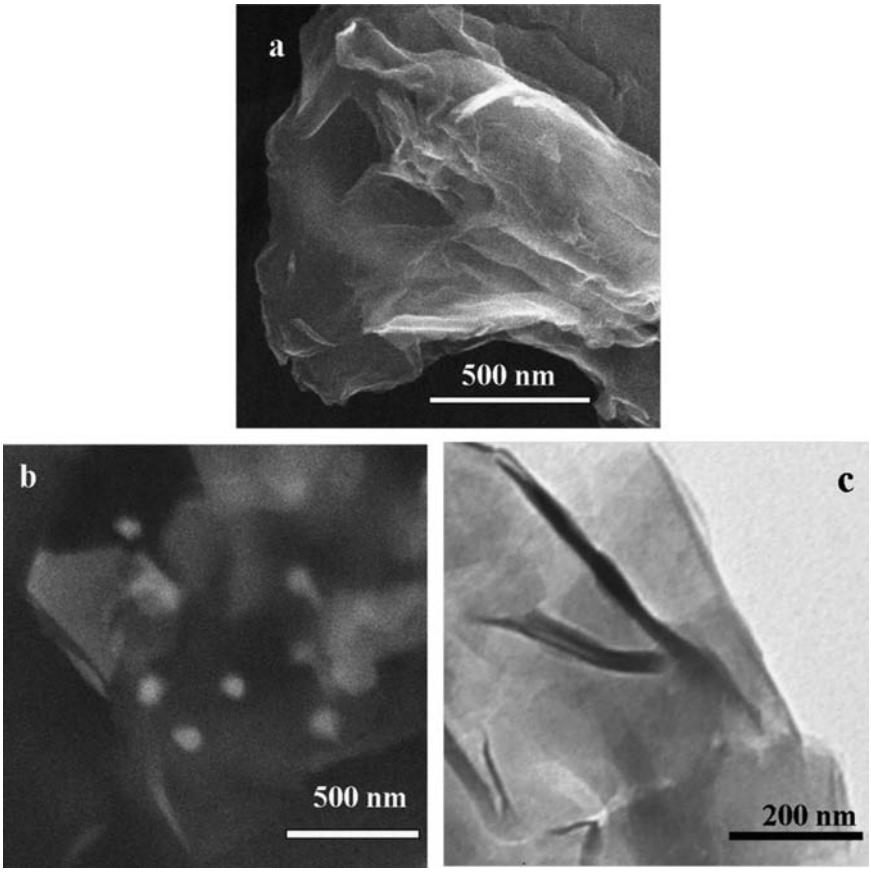

Fig. 2. SEM images of N-GS (a) Na-Mont-PANI-AuNPs (b) and TEM image of Na-Mont (c).

Finally, the prepared Na-Mont-PANI-AuNPs-Ab_2 solution was dropped onto electrode surface and incubated for another 1 h via specific antibody-antigen interaction. The modified electrode was washed three times to remove unbound Na-Mont-PANI-AuNPs-Ab_2. The well-prepared electrode was stored at 4 °C prior to use.

2.7. Detection of SCC-Ag

Electrochemical characteristics of modified electrode were measured by amperometric measurements in PBS (pH 6.4). A detection potential of −0.4 V was selected for amperometric measurement. After the background current was stabilized, 5 mM H_2O_2 was added into PBS and the changed current was recorded. All electrochemical measurements were conducted in a harmony electrochemical condition at 25 °C.

3. Results and discussion

3.1. Characterization of N-GS and Na-Mont-PANI-AuNPs nanostructures

In this study, SEM and TEM were used to characterize N-GS and Na-Mont-PANI-AuNPs nanostructures. N-GS were used to increase Ab_1 loading because of its large surface area. Fig. 2a shows the SEM image of a wrinkle paper-like structure of N-GS. Na-Mont-PANI-AuNPs were used to incubate Ab_2 and Fig. 2b displays the SEM image of Na-Mont-PANI-AuNPs. It can be seen that the layered wrinkle structured Na-Mont and AuNPs were dispersed evenly in the interlamination of Na-Mont. From the TEM image of Na-Mont (Fig. 2c), it could be concluded that the layered structure with large specific surface area can immobilize more Ab_2 and improve the sensitivity of immunosensor.

3.2. Characterization of the immunosensor fabrication

Electrochemical impedance spectroscopy (EIS) has been employed to be a powerful tool to characterize the interface properties of surface-modified immunosensor during the process of fabrication and assembly. It is well known that the changes in electrochemical impedance show the chemical obstruction occurring in the electrochemical sensors [32]. The impedance spectra consist of a semicircle portion and a linear portion. The semicircle portion at higher frequencies indicates the electron-transfer limited process and the linear portion at low frequencies represents the diffusion-limited process. The semicircle diameter corresponds to the electron-transfer resistance (R_{et}). As shown in the Nyquist curves (Fig. 3), both GCE (curve *a*) and N-GS modified electrode (curve *b*) appear to be a very small semicircle domain nearly linear, which implies of a diffusion-limiting step in the electron-transfer process. Subsequently, for Ab_1 modified electrode (curve *c*), the larger semicircle indicated that Ab_1 was immobilized onto the electrode and the hydrophobic

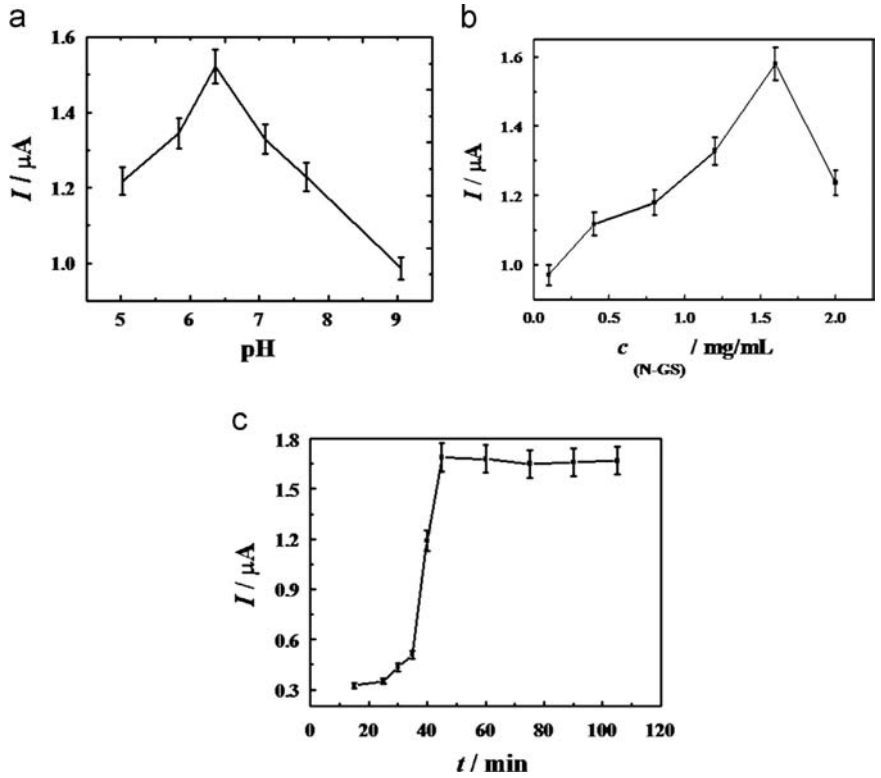

Fig. 4. Effect of pH (a), the concentration of N-GS (b), and incubation time (c) on the response of the immunosensor to 0.5 ng/mL SCC-Ag.

layer of protein was insulated the conductive support, thus hindering interfacial electron transfer. The R_{et} of the electrode further increased after modification of BSA, which indicated the successful immobilization of BSA. Additionally, after successful incubation of SCC-Ag and Na-Mont-PANI-AuNPs-Ab_2, the R_{et} elevated again (curves *e* and *f*). EIS Nyquist plots demonstrated that the immunosensor had been fabricated successfully and could be used for the detection of SCC-Ag.

3.3. Optimization of experimental conditions

The immunosensor was fabricated based on the chemical reaction of Na-Mont-PANI-AuNPs labels towards H_2O_2 reduction. The injected H_2O_2 solution in the electrolyte would result in saltation of current response, then SCC-Ag could be quantified based on specific recognized immunoreaction between antibody and antigen.

In order to obtain the best electrochemical signal responses, the experimental conditions were optimized. For the immunosensor with the same concentration of SCC-Ag (0.5 ng/mL), the pH value of working solution plays an important role in the current response. As shown in Fig. 4a, it could be found that the amperometric responses increased with the increase of pH values from 5.0 to 6.4 and then decreased from 6.4 to 9.0. These results indicated that Na-Mont-PANI-AuNPs displayed best catalytic performance towards H_2O_2 reduction at pH 6.4, then pH 6.4 PBS was used as the optimal electrolyte solution in the following experiments.

In addition, the amount of N-GS has a great effect on the electrochemical behavior of immunosensor. N-GS influenced the electrochemical signals of both the coated electrode and the loaded of Ab_1. As seen in Fig. 4b, with the increased concentration of N-GS, the current response increased and then decreased. Therefore, the optimal concentration of N-GS was 1.5 mg/mL.

Furthermore, incubation time has a great influence on the sensitivity of the immunosensor. In the fabricating process of the immunosensor, after adding SCC-Ag onto electrode surface, various incubation times were investigated for the detection of 0.5 ng/mL SCC-Ag. As shown in Fig. 4c, the current response increased with the incubation time increasing initially, but further increasing incubation time did not significantly change the signal. Hence, 45 min was selected for the optimal antigen-antibody interaction time.

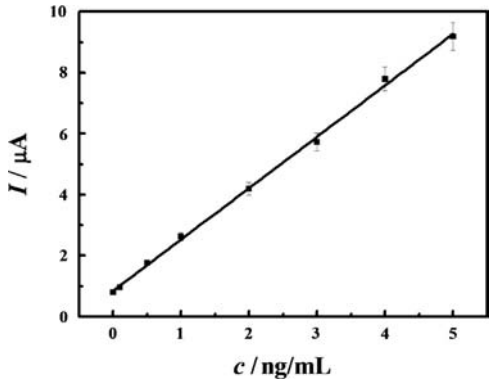

Fig. 5. Calibration curve of the immunosensor toward different concentrations of SCC-Ag, errorbar=RSD (n=5).

Under the optimal conditions, the immunosensor using Na-Mont-PANI-AuNPs as labels was used to detect different concentrations of SCC-Ag. The relationship between the current responses and different concentrations of SCC-Ag towards 5 mM H_2O_2 by reduction in pH 6.4 PBS at −0.4 V was shown in Fig. 5. The current responses increased linearly with the increasing of SCC-Ag concentrations in the range from 1 pg/mL to 5 ng/mL. The equation of the calibration curve was I (μA)=0.8432+1.686 $c_{\text{SCC-Ag}}$ (ng/mL) (r=0.998) with a detection limit of 0.3 pg/mL. The sensitivity of our immunosensor is favorable in detecting cancer marker compared with previous reports [33–37] in Table 1. The low detection limit may be attributed to three factors: (1) N-GS could greatly increase the loading number of Ab_1 and facilitate electron transfer due to its good biocompatibility and high conductivity; (2) as discussed above, Na-Mont-PANI-AuNPs with large surface area could immobilize amounts of Ab_2, which greatly increases the sensitivity of the immunosensor; (3) PANI and AuNPs with good electrochemical conductivity could accelerate electron transfer and possess good catalytic performance towards H_2O_2 reduction.

3.4. Reproducibility, stability and selectivity of the immunosensor

In order to evaluate the reproducibility of immunosensor, five immunosensors were prepared to detect 0.5 ng/mL SCC-Ag under the same conditions. The relative standard deviation (RSD) achieved from these five measurements was 3.18%. The result suggested the precision and reproducibility of the proposed immunosensor were both good.

The study on the stability of immunosensor was measured by periodically checking current response. When the immunosensor was not in use, it was stored in a refrigerator at 4 °C. The current response of the immunosensor still retained 94% and 85% of the initial value after one week and three weeks, respectively. The slow decrease in the current response may be due to the gradual denature of SCC-Ag and anti-SCC antibody.

The selectivity of the immunosensor was tested for its important role in analyzing biological samples. The effect of possible inhibitors that might interfere with the response of immunosensor had been investigated. SCC-Ag (0.5 ng/mL) solution containing 100 ng/mL of interfering substances (BSA, glucose, vitamin C and AFP) was measured by immunosensor. As a result, the current variation due to the interfering substances was less than 5% of that without interferences. These results indicated the selectivity of the immunosensor was acceptable.

3.5. Real sample analysis

In order to evaluate the feasibility of the electrochemical immunosensor for practical application, the detection of SCC-Ag in human serum samples was evaluated using standard addition methods. 1.00 ng/mL, 2.00 ng/mL and 4.00 ng/mL of SCC-Ag solutions were added into serum samples and analyzed by the proposed immunosensor. The results are shown in Table 2. It can be seen that the RSD

Table 2
Results for determination of SCC-Ag in human serum samples.

Initial SCC-Ag concentration in sample (ng/mL)	Added SCC-Ag concentration (ng/mL)	The detection content (ng/mL)	RSD (%, $n=5$)	Recovery (%)
	1.00	1.77, 1.79, 1.82, 1.83, 1.76	1.70	99.7
0.800	2.00	2.83, 2.86, 2.84, 2.78, 2.79	1.20	101
	4.00	4.62, 4.71, 4.81, 4.89, 4.75	2.14	99.1
	1.00	1.48, 1.54, 1.53, 1.44, 1.47	2.82	99.5
0.500	2.00	2.54, 2.50, 2.56, 2.66, 2.59	3.30	102
	4.00	4.47, 4.42, 4.53, 4.59, 4.35	2.08	99.3

was from 1.20% to 3.30% and the recoveries were between 99.0% and 102%. Thus, the presented method could meet the demand for clinical determination of SCC-Ag in serum samples.

4. Conclusions

In this work, a novel sandwich-type immunosensor for the det ection of SCC-Ag had been developed. The immunosensor was fabricated by immobilizing Ab_1 onto N-GS and using Na-Mont-PANI-AuNPs as labels. N-GS with large surface area enhanced the amount of Ab_1 immobilized onto electrode surface and the Na-Mont-PANI-AuNPs showed excellent catalytic performance towards H_2O_2 reduction. Then the proposed immunosensor showed low detection limit for the detection of SCC-Ag. The simplicity, good sensitivity and reproducibility of the immunosensing platform may be quite promising in clinical application for the detection of SCC-Ag.

Exponential amplified analysis

ABSTRACT

A novel strategy of cleaved DNAzyme substrate induced enzymatic cascade has been devised for the exponential amplified detection of L-histidine. The enzyme strand carries out hydrolytic cleavage of the substrate strand in the presence of L-histidine. The cleaved DNAzyme substrates introduce the polymerase/endonuclease reaction cycles as primers. The L-histidine acts as the activator for enzymatic cascade amplification generating a distinguishable fluorescence enhancement. A good nonlinear correlation (R=0.9994) between fluorescence intensity and the logarithm of the L-histidine concentration is obtained over the range from 50 nM to 1.0 mM. The detection limit was estimated as 30 nM. This efficient amplification of the fluorescence signal is attributed to the L-histidine induced cooperation of Klenow Fragment polymerase (exo$^-$) and Nb.BbvCI endonuclease reaction. The activation of such enzymatic cascades through analyte-DNAzyme interactions has a substantial impact on the development of exponential amplified DNAzyme sensors.

1. Introduction

The enzymatic cascade reaction induced by target recognition event has become a core technology in medical diagnostics [1–3]. In the nucleic acid–based enzymatic cascade assays, the exponential isothermal amplification of DNA often employs a strand displacement polymerase and a single-strand nicking enzyme to continuously replicate one strand of a DNA duplex under a constant temperature [4–8]. Since the target can activate circular polymerization reactions, enzymatic cascade mediated strategy offers a versatile method with high sensitivity and specificity. Liu et al. [9] presented a sensitive MicroRNA amplified detection based enzymatic cascade. Tian et al. [10] described a novel exponential isothermal amplification of telomere repeat assay for measuring telomerase activity in cell extracts. Li et al. [11] reported proximity-dependent isothermal cycle amplification strategy in aptamer–cocaine complexes coupled with surface enhanced Raman scattering. Among these sensing systems, the enzymatic cascade assay has distinct advantages of ultra-high amplification efficiency and great potential for target testing. So far as we know, enzymatic cascade has rarely been implemented for the development of DNAzyme sensor studies perhaps due to the difficult control of flexible joint in variable structure of cleavage responsible DNAzyme.

Elevated levels of serum histidine are characteristic of histidinemia [12], which is one of the inborn errors of amino acid metabolism that increases person's chances of developing intellectual disability, behavioral problems, or learning disorders [13]. The recognition and quantification of histidine for diagnosis of histidinemia has emerged as one of the fastest growing areas in clinical chemistry [14–16]. The L-histidine-dependent DNAzyme [17,18] possessing a specific catalytic activity has shown a great potential in diagnosis application [19–21]. Willner's group evaluated L-histidine-dependent DNAzymes to yield the horseradish peroxidase-mimicking catalytic nucleic acids, which enable a simple and effective detection of L-histidine [22]. Enzyme mediate signal amplification offers an efficient way to improve the sensitivity. Kong and co-workers employed an endonuclease based enzymatic recycling cleavage strategy in the design of DNAzyme-based sensors [23]. This assay is sensitive and specific, but the drawbacks of requirement of doubly-labeled molecular beacon are limited to a laboratory setting and a practice complexity. However, an even higher sensitivity is desired if these sensors are to be used in complex cellular or environmental samples to ensure large signal-to-noise ratios. We intend to devise a cleaved DNAzyme

Scheme 1. Schematic representation of the cleaved DNAzyme substrate induced enzymatic cascade strategy for the amplified detection of L-histidine.

substrate induced enzymatic cascade strategy for isothermal amplified determination of L-histidine using cleaved substrate as the replication trigger. The combination of the DNAzyme and the polymerase/endonuclease reaction cycles leads to the direct activation of enzymatic cascade amplification. It would be of great interest to develop DNAzyme-based sensors with exponential amplification for the output signal.

2. Experimental section

2.1. Materials and reagents

L-histidine cofactor-dependent nucleic acid cleaving DNAzyme was applied for L-histidine determination. Oligonucleotides were customer-designed and supplied by Sangon Biotechnology Co. Ltd. (Shanghai, China), as shown in Scheme 1. The substrate strand contains a single, sessile ribo-adenine (rA) indicated as an italic nucleotide. The deoxynucleotide triphosphates (dNTPs) and exo$^-$-Klenow Fragment polymerase (KF (exo$^-$)) were obtained from Sangon Biotechnology Co. Ltd. Nicking endonuclease Nb.BbvCI (Nb.BbvCI), exo$^-$-vent DNA polymerase (Vent (exo$^-$)) and Taq DNA polymerase were purchased from New England Biolabs Ltd (USA). L-histidine was obtained from Sigma-Aldrich Inc. DNA stock solutions and L-histidine solution were prepared in NEBuffer 2 (1 × concentrate). SYBR Green I (SG, 20 × concentrate) was supplied by Generay Biotech. Co., Ltd (Shanghai, China). Ultrapure water was obtained through a laboratory ultrapure water system series (Kertone water treatment Co., Changsha, China) with an electrical resistance larger than 18.25 MΩ. All solutions were sterilized throughout the experiments.

2.2. Apparatus and fluorescence measurements

Fluorescence emission spectra were performed on Hitachi F-7000 fluorescence spectrometer (Japan) linked to a personal computer. Excitation and emission slits were all set for 10.0 nm band-pass. The SG fluorophore was excited at 495 nm, and the emission spectra were collected from 508 to 618 nm. The fluorescence intensity at 523 nm was used to evaluate the performance of the proposed assay. Fluorescence spectra were collected using 0.2 × 1 cm^2 quartz cuvettes containing 100 μL of solution. All measurements were carried out at room temperature unless stated otherwise.

2.3. Enzymatic cascade amplification and L-histidine detection

The working solution including 100 nM of the enzyme strand, 20 nM of the substrate strand was incubated with L-histidine at required concentration for 30 min. Then 300 nM of the template strand was added into the mixture and kept for 10 min. The result solution was subjected to an enzymatic cascade step. The replication solution containing 5 U KF (exo$^-$), 10 U Nb.BbvCI and 2.5 mM dNTPs was introduced into the system, and incubated at 37 °C for 30 min. After the injection of SG, the system solution were diluted to 100 μL, and then performed to estimate the fluorescence performances.

2.4. Agarose gel electrophoresis

Analysis by electrophoresis was carried out under nondenaturing conditions on 3% agarose gels with GoldView (Dingguo Biotechnology, Beijing, China) staining, cast and run in 0.5 × TBE buffer (pH 7.9). The enzymatic cascade amplification reaction was set in a volume of 12 μL containing 10 μM enzyme strand, 2 μM substrate strand, 5.0 mM L-histidine, 30 μM template strand, 2.5 mM dNTPs, 5 U KF (exo$^-$) and 10 U Nb.BbvCI. Electrophoresis was performed at a constant potential of 100 V for 60 min with loading of 10 μL of each samples into the centermost lanes. The resulting gel was excited and imaged using a Tanon MP device (Shanghai, China).

3. Results and discussion

3.1. Design strategy of cleaved DNAzyme substrate induced enzymatic cascade assay

Scheme 1 depicts schematically the assay protocol of the cleaved DNAzyme substrate induced enzymatic cascade for the amplified detection of L-histidine. The DNAzyme is composed of a 41-mer enzyme strand (in black) and a 23-mer substrate strand (in orange). The enzyme strand is designed to hybridize to the two

ends of the substrate strand. In the middle of the substrate strand, a ribo-adenosine (rA in blue) was introduced as the cleavage site. When the DNAzyme is incubated with solutions containing L-histidine, the enzyme strand carries out catalytic reactions to hydrolytic cleavage of the substrate strand at the scissile rA [18]. Then the substrate is broken into two pieces and dissociated from the enzyme strand. The released enzyme strand could then hybridize to another substrate strand and initiated another cycle of cleavage with the released L-histidine (Scheme 1A). The cleaved 13-mer strand with the rA designed to hybridize with 48-mer template strand (in grey) triggers the enzymatic cascade amplification cycles. With the KF (exo$^-$), the replication of template domain induces the primer extension to form a full-length double strand DNA (dsDNA) containing a recognition site (in pink) for the Nb.BbvCI (Scheme 1B). Nb.BbvCI recognizes the double-stranded 5′-CCTCAGC-3′/5′-GCTGAGG-3′ site and cuts the GCTGAGG strand at the second nucleotide downstream from the site [24]. The cleavage opens a new site for a new replication. The 3′ end of the nicked DNA fragments is extended by KF (exo$^-$) and displaces the previously synthesized strand, which is designed to hybridize to a new template strand. The enzymatic cascade based polymerization regenerates the completely dsDNA to initiate another cycle of nicking, polymerization and displacement (Scheme 1C). Finally the fluorescence dye, SYBR Green I (SG), inserts into the DNA double helix to generate a distinguishable fluorescence enhancement. Thus the amount of replicated products corresponds to the amount of the cleaved strand and indirectly reflects the amount of L-histidine. In the absence of L-histidine, the DNAzyme is so stable to assemble that the cleavage activity is dramatically reduced. Therefore, since L-histidine could displace the primer and trigger the enzymatic cascade polymerization circularly, exponential fluorescence enhancement could be observed even with a trace amount of the L-histidine. Hence the presented method not only shows the high sensitivity in comparison with the traditional methods, but also provides the great potential in the early clinic diagnosis.

3.2. Target induced enzymatic cascade amplification of the L-histidine detection

Our results, as shown in Fig. 1, demonstrated that the enzymatic cascade probes have excellent sensitivity. The DNAzyme only has a very low fluorescence intensity of intercalated SG (~160.0, curve *a*). After introducing L-histidine into DNAzyme solution, the SG emission is even feeble due to weak interaction between SG and single-strand hydrolytic fragments (curve *a*′). This result suggested that the substrate is cut into two overhangs and released from the DNAzyme under the experimental conditions. But a reversed trend is observed for the other three systems. The fluorescence intensity of SG for the DNAzyme/template solution after addition of L-histidine (curve *b*′) is more intense as compared to that from the DNAzyme/template solution (curve *b*), owning to the high-affinity hybridization between the template and released 13-mer strand. As a controlled experiment, the SG emission intensity of KF (exo$^-$) polymerization products of DNAzyme/template solution in the absence (curve *c*) or presence (curve *c*′) of L-histidine were studied to fully characterize the proposed system. The response of analytes was represented by relative fluorescence intensity (RFI), an initial ratio of fluorescence enhancement (F–F_0) to the fluorescence background (F_0). KF (exo$^-$) involved assay in L-histidine solution shows a clear increase signal (RFI=0.33) in causing KF (exo$^-$) replication triggered by the cleaved strand. A fluorescent background (curve *d*) is observed when delivered enzymatic cascade assay cooperating KF (exo$^-$) and Nb.BbvCI. This phenomenon is most likely the result of nonspecific hydrolytic reaction of the substrate strand and initiating partial replication. The enzymatic cascade assay shows an extraordinary increase (RFI=0.62) in fluorescence upon addition of 50 μM L-histidine (curve *d*′), indicating the enormous efficiency of enzymatic cascade amplification as compared with KF (exo$^-$)-amplified assay. As expected, the enzymatic cascade amplification was not limited to one round of cycling. In fact, the proposed strategy was regarded as a chain reaction since there were cross-replications between the sense and antisense structures. It can be seen that the fluorescence signal increases exponentially when the number of replication cycles is increased.

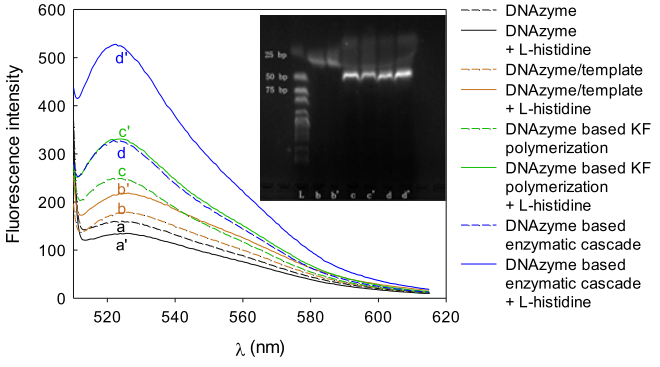

Fig. 1. Fluorescence spectra of the DNAzyme based assays for L-histidine determination. In fluorescence experiments: [enzyme strand]=10 nM; [substrate strand]=2.0 nM; [L-histidine]=50 μM; [template]=30 nM; [KF (exo$^-$)]=5.0 U; [Nb.BbvCI]=10 U; [dNTP]=250 μM; [SG]=1 × concentration. The inset shows the gold view stained agarose gel (3.0%) analysis of different assays. In electrophoresis experiments: [enzyme strand]=10 μM; [substrate strand]=2.0 μM; [L-histidine]=5.0 mM; [template]=30 μM; [KF (exo$^-$)]=5.0 U; [Nb.BbvCI]=10 U; [dNTP]=2.5 mM.

3.3. Electrophoresis characterization

As a further support for this novel DNAzyme based enzymatic cascade assay, the amplification products were characterized by 3.0% agarose gel electrophoresis (Fig. 1, inset). The mixture of DNAzyme and temperate strands in the absence (lane b) and presence (lane *b*′) of L-histidine produce fast migration bands due to small molecules and stem helix of DNAzyme. A slower migration band without L-histidine appears in the lane *c*. This band revealed a fraction of KF (exo$^-$) products triggered by nonspecific hydrolysis of the substrate. The replication is carried out when DNAzyme was added into the mixture containing template and L-histidine during the KF (exo$^-$) polymerization (lane *c*′). An observable fluorescent band is also at the same migration position in the lane d, indicating that the nonspecific hydrolyzed substrate could trigger the polymerase/endonuclease reaction. The enzymatic cascade assay with L-histidine provides a significant product band (lane *d*′), suggesting the existence of amounts of nicked strands produced by the polymerase/endonuclease replication cycles. These results were consistent with the fluorescence emission spectra in the main figure.

3.4. Optimization of experimental condition

Fig. 2 shows the time courses of incubating KF (exo$^-$) and Nb.BbvCI with different L-histidine concentrations. The target of 1.0 mM, which is barely detectible by the proposed assay, induces quick increase in fluorescence intensity in the enzymatic cascade amplification step. The increase in fluorescence intensity indicated continuous synthesis of the double strand DNA. The signal plateaus in about 30 min because the cleaved primers are used up. The increase in fluorescence intensity slows down with the dilution of the L-histidine. Taking the 50 μM time course as an example, the fluorescence intensity increases almost linearly with

time until it reaches a plateau over 60 min (data not shown). The signal trend is the same when the target concentration dropped to 500 nM. The background (0 nM sample) keeps at a low level before 30 min, indicating that the substrate strand without L-histidine is hard to initiate the replication in 30 min due to its binding affinity in DNAzyme structure. The false positive signal occurs after 30 min because of the nonspecific hydrolyzation of rA contained substrate. After repeating the time courses for three times each, 30 min was set as the optimized incubating time at the enzymatic cascade amplification step.

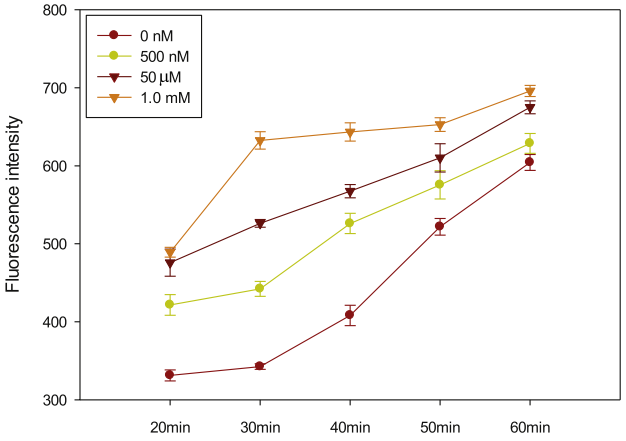

Fig. 2. Time course of incubating KF (exo$^-$) and Nb.BbvCI at various L-histidine concentrations (0 nM, 500 nM, 50 μM, 1 mM). The experimental conditions were the same as those for fluorescence experiments in Fig. 1. All experiments were prepared in NEBuffer 2, pH=7.5. The error bars represent to standard deviation with n=3.

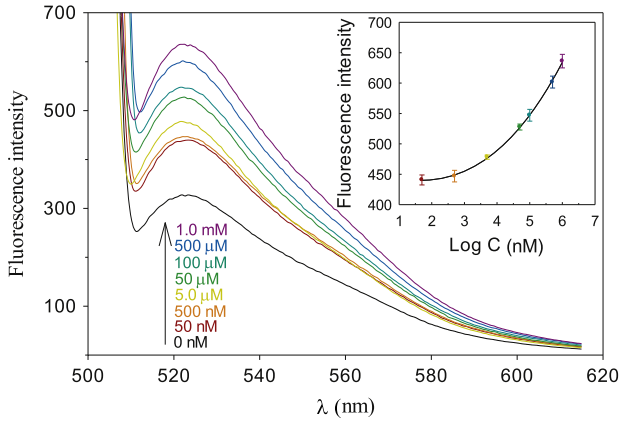

Fig. 3. Fluorescence spectra of the cleaved DNAzyme substrate induced enzymatic cascade assay upon incubation with different L-histidine concentrations (0 nM–1.0 mM). Inset: curve describing the exponential relationship between the fluorescence enhancement and the logarithm of the concentrations of L-histidine. The experimental conditions were the same as those for fluorescence experiments in Fig. 1. Each data point was performed in triplicate.

3.5. Quantification of L-histidine by cleaved DNAzyme substrate induced enzymatic cascade assay

Fig. 3 presents the fluorescence intensity as a function of the L-histidine concentration. In the absence of L-histidine, the DNAzyme keeps its stable stem-loop structure and results in the lowest fluorescence response (F=331.0). After the addition of 50 nM L-histidine, the intensity shift resulting from the replication products increases (F=443.3) because parts of DNAzyme react with L-histidine and release strands, which initiate the enzymatic cascade reaction. It demonstrated that an enzymatic cascade assay can recognize specifically its target to produce ordinary DNA duplex in the nanomole range. The 20,000-fold serial dilutions, in the range of 50 nM–1.0 mM, of L-histidine were used to generate a standard curve for enzymatic cascade assay. The inset demonstrates the cubic logarithm of the L-histidine concentration dependence of fluorescence intensity. The standard nonlinear curve is described using the equation (R=0.9994), $F=0.6800(\mathrm{LgC})^3+3.942(\mathrm{LogC})^2-18.65\mathrm{LogC}+457.1$, where F is the value of fluorescence intensity, Log$C$ is the logarithm of the L-histidine concentration. This nonlinear response phenomenon could be attributed to the release of cleaved strand from DNAzyme. These strands worked as primers, which induced the cooperation of enzyme network and thus resulted in an efficient increase of the effective fluorescence signal. The detection limit was estimated as 30 nM from three times the standard deviation corresponding to the blank sample detection. The detection results for analyzing the concentration of L-histidine were comparable with otheroptical DNAzyme probes [25] or even superior to the previously reported L-histidine assays listed in Table 1, indicating high sensitivity of the designed method for detection of its targets.

3.6. Selectivity of the enzymatic cascade assay and the application in serum samples

The selectivity of the sensing system is another important parameter for a biosensor. We chose four kinds of natural amino acids (L-alanine, L-arginine, L-cysteine, and L-leucine), which have a structure

similar to that of L-histidine. As shown in Fig. 4, the enzymatic cascade assay displays a specific response to the L-histidine at 50 μM concentrations. But nearly negligible RFI change are observed after the enzymatic cascade assay reacting with 100 μM L-alanine, L-arginine, L-cysteine, and L-leucine. The specificity can be well addressed when the target L-histidine is present in low concentrations compared to nontarget amino acids. These results confirmed that the developed strategy has sufficient specificity and L-histidine can be identified with high selectivity. To investigate the application of the assay, 50-fold diluted serum samples were tested to obtain calibration curves at different L-histidine concentrations (Fig. 5). Since L-histidine concentration in normal human plasma ranges from 1.998 μM to 169.8 μM [26], the human serum samples were diluted 50 times with NEBuffer 2. The L-histidine -spiked serum samples were prepared by adding L-histidine in 50-fold diluted serum samples. Then blind tests were conducted using the calibration curves to evaluate the reliability of the method. An exponential plot ($R=0.9958$) of the RFI against the logarithm of concentration of L-histidine (50 nM–1.0 mM) is expressed as: $RFI=1.322\times10^{-3}(LogC)^3+2.213\times10^{-2}(LogC)^2-9.512\times10^{-2}LogC+0.4339$. On the basis of real sample test (solid circles), the results are in good agreement with those obtained in NEBuffer (open circles).

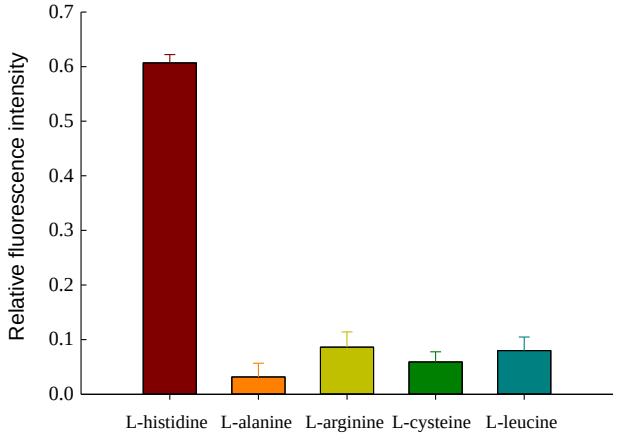

Fig. 4. Selectivity of enzymatic cascade reaction for L-histidine (50 μM) over other common natural amino acids (100 μM). The experimental conditions were the same as those for fluorescence experiments in Fig. 1. Each data point was performed in triplicate.

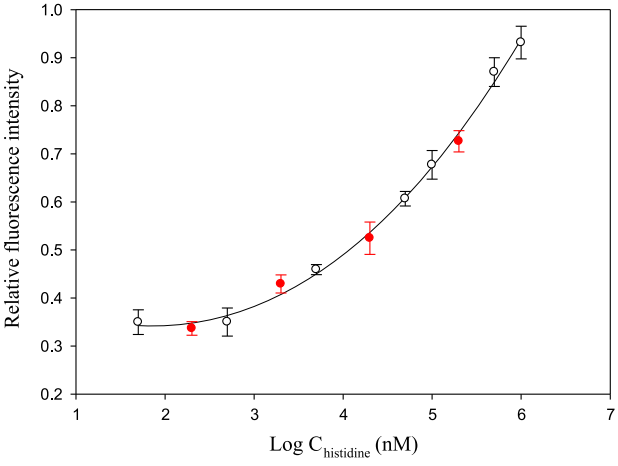

Fig. 5. Exponential response of the RFI of the assay after the standard addition of L-histidine into 50-fold diluted serum samples (solid plots) and the NEBuffer (open circles). The experimental conditions were the same as those for fluorescence experiments in Fig. 1. Error bars indicate standard error of triplicate tests.

These results revealed that the cleaved DNAzyme substrate induced enzymatic cascade assay has a promise in practical application with great accuracy and reliability for L-histidine detection.

4. Conclusion

In summary, the present study has combined an L-histidine cofactor-dependent DNAzyme and the polymerase/endonuclease reaction cycles for amplified fluorescent analysis. The L-histidine acted as the activator for enzymatic cascade amplification generating multiple duplex structures. The efficiency of the enzymatic cascade depended on the concentration of its analyte, which produced primers in closed replication system. Our novel method was able to quantify target levels as low as nanomolar sensitivity. This cleaved DNAzyme substrate induced enzymatic cascade strategy showed great potential for future use in clinical tests owing to its sensitive, isothermal, and cost-efficient features. The activation of such enzymatic cascades through analyte-DNAzyme interactions was not only valuable to activate the cooperation of muti-enzyme networks, but also had a substantial impact on the development of amplified DNAzyme sensors.

Review

ABSTRACT

Chromium holds a special position among living organisms because depending on its species it can be either essential or toxic. Cr(VI) even at very low concentrations is harmful and carcinogenic, while Cr(III) is a necessary microelement for cellular metabolism. Therefore, a simple analysis of Cr concentration in collected samples will not be able to distinguish these differences effectively: for a proper chemical analysis we need to perform a reliable detection and quantification of Cr species. Separation and detection of chromium can be accomplished with high performance liquid chromatography hyphenated to inductively coupled plasma mass spectrometry (HPLC/ICP-MS) in a one-step. Our review assembles articles published since 2000 regarding chromium speciation in water samples with the use of HPLC/ICP-MS. It addresses the following issues: chromium chemistry, the possibilities of dealing with interferences, metrological aspects, analytical performance and speciated isotope dilution mass spectrometry (SIDMS) which is a definitive measurement method. The authors would like to advocate this hyphenated advanced technique as well as the metrological approach in speciation analysis of chromium.

1. Introduction

1.1. Cr(III) vs. Cr(VI): the good and the evil twin

Element toxicity, bioavailability and transport properties depend on the specific form in which element is present in the environment rather than its total amount. Along with an improvement of analytical methods, speciation analysis has attracted more attention [1]. A lot of research focus on chromium, as it is widely used in industrial processes, including: metallurgy (production of stainless steel, ferro- and nonferrous alloys), refractory industry (high temperature-resistant materials used as linings for furnaces) and chemical manufacturing (textile dyes, pigments, electroplating, leather tanning and wood preservatives). Large quantities of chromium compounds are released into the environment which has an adverse effect on the ecosystem [2–5]. Additionally, dissolved species of chromium in relatively high concentrations can occur naturally [6,7].

Chromium is an extraordinary example of an element which different species show opposite types of behavior. This phenomenon occurs in the case of some other metals but not to such an extent. The two most widespread oxidation states of chromium: Cr(III) and Cr(VI) differ with respect to their mobility and bioavailability. In general, Cr(III) compounds are relatively immobile and poorly soluble compared to highly mobile, soluble and, consequently, more bioavailable Cr(VI) compounds [8–10]. These differences extend to the chemical and biochemical reactivity of both species. Cr(III) in trace amounts is an essential nutrient for the human body: it is involved in carbohydrate, lipid and protein metabolism [11–13]. Nevertheless, it appears that the free ion of Cr(III) has no biological activity unless bound to a suitable organic ligand. Its properties are not unequivocally established. Additionally, it has also been reported that Cr(III) picolinate, which may be used as a micronutrient and dietary supplement, can cause harmful effects on human cells, although in very rare cases [5]. By contrast, Cr(VI) is explicitly toxic because of its high oxidation potential and ability to penetrate biological membranes. The ability of Cr(VI) (or actually the CrO_4^{2-} ion) to diffuse freely through cell membranes is possible due to its structural similarity to anions such as SO_4^{2-} or PO_4^{3-}, which are transported by suitable anion exchange channels. The reduced form of chromium is practically unable to enter the cell by the same ion channels, thus Cr(VI) compounds are recognized as 1000 times more cytotoxic. However, intracellular Cr(III), which is the terminal product of the Cr (VI)-reduction, can also exhibit toxic effects e.g., by suppressing the activity of some metallo-enzymes or reaction with macromolecules (including DNA) [14].

Since 1990, the International Agency on Research Cancer (IARC) has classified Cr(VI) compounds to Group 1, known as human carcinogens. The US Environmental Protection Agency (USEPA) has also considered this chromium species as a mutagenic and carcinogenic agent. Epidemiological studies have shown that exposure to Cr(VI) can induce a variety of clinical problems among which are an increased incidence of cancer and dermal disease [5].

1.2. Determination of chromium species

Due to significant differences in the biochemical properties of both Cr species there is an obvious need for their accurate quantification. In consequence, speciation analysis takes an important role in an environmental monitoring. Numerous papers concerning analytical methods for chromium speciation in water samples have been published during recent years. Among these approaches, HPLC/ICP-MS has proved to be a powerful analytical tool. The high diversity of chromatographic separation mechanisms determines various applications of the HPLC technique. The ICP-MS is a preferred detector in elemental speciation analysis owing to its unique analytical capabilities. Currently, as one of the most robust commercially available instruments, ICP-MS presents many advantages that include elemental specificity, multi-isotope detection and extremely low detection limits [15,16]. Furthermore, it offers high sensitivity of measurements along with a wide linear dynamic range. In addition, ICP-MS can be easily coupled online with HPLC [17].

1.3. Legal norms concerning the concentration of chromium in drinking water

The World Health Organization (WHO) has recommended that the concentration of Cr in drinking water should be 0.05 mg L^{-1} or less [18]; a similar value has also been published by the Council of the European Union [19]. However, according to the drinking water standards laid down by the Environmental Protection Agency (EPA), in the United States the permissible level of chromium is 0.10 mg L^{-1} [20]. However, the recommended values of Cr concentration in drinking water do not take into consideration particular species of this element. They provide just a temporary solution implemented because no routine or reliable method exists for the determination of low concentrations of chromium in water.

The number of articles concerning elemental speciation has increased appreciably over the last two decades, particularly since 1995 [21,22] and many different analytical strategies have been developed to deal with quantification of Cr forms existing in the nature. The papers (also overview articles) have covered various topics such as environmental occurrence [2,23,24], risk assessment, health effects [5,25–29] and analytical approaches (including offline and online methods) [3,21,30–41]. In a recently published comprehensive overview the application of the isotope dilution technique, which provides the highest quality of metrological traceability in chromium speciation analysis in different matrices, was widely described [41].

In this review we present a new perspective for the determination of chromium chemical forms in water. We focus on the problems connected with obtaining reliable and competent results,

which are basic requirements for any projected legislation concerning chromium species determination in water. Unlike other reviews, besides presenting several issues related to chromium occurrence in water environments, determination of chromium species by the HPLC/ICP-MS method and accompanying problems, this work raises an important issue regarding the quality assurance of obtained analytical results: method validation, the traceability and uncertainty of the measured results.

2. Environmental occurrence of chromium

2.1. Chromium chemistry

Cr can exist in several oxidation states from 0 to VI. The two forms of chromium commonly found in the environment are Cr (III) and Cr(VI). The intermediate states: Cr(II), Cr(IV), Cr(V) are unstable products in oxidation and reduction reactions of trivalent and hexavalent chromium, respectively [2,8,11]. The prevalent forms of chromium might undergo a series of transformations, changing from one into another under the influence of various physicochemical processes. In many cases, disruption of the chemical balance between particular species strongly depends on pH value. Additionally, redox reaction, precipitation/dissolution and adsorption/desorption can cause Cr conversions. Some of these aspects are discussed below [9,10,12,24].

2.1.1. pH value

In aqueous solution (assuming the absence of other complexing agents besides H_2O or OH^-), Cr(III) exists as a hexa-aqua complex $Cr(H_2O)_3^{3+}$ (abbreviated as Cr^{3+}) which has hydrolysis products as demonstrated by equations (Eqs. 1–3).

$$Cr(H_2O)_3^{3+} + H_2O \leftrightarrow Cr(OH)(H_2O)_5^{2+} + H_3O^+ \quad (1)$$

$$Cr(OH)(H_2O)_5^{2+} + H_2O \leftrightarrow Cr(OH)_2(H_2O)_4^{3+} + H_3O^+ \quad (2)$$

$$Cr(OH)_2(H_2O)_4^{+} + H_2O \leftrightarrow Cr(OH)_3^0 + H_3O^+ \quad (3)$$

The deprotonated forms of hexaaquachromium(3+) can be simply abbreviated to $Cr(OH)^{2+}$, $Cr(OH)_2{}^+$ and $Cr(OH)_3{}^0$. The presence of these hydroxo species in the environment is closely related to pH. In more acidic solutions ($pH \approx 4$), Cr^{3+} is the predominant species of Cr(III). Under slightly acidic conditions its hydrolysis generates $Cr(OH)^{2+}$ and $Cr(OH)_2{}^+$. Within a pH range from neutral up to alkaline Cr(III) tends to precipitate as a virtually insoluble $Cr(OH)_{3\,(s)}$, which is transformed into soluble $Cr(OH)_4^-$ in more basic solutions ($pH > 12$), because of its amphoteric properties. As a consequence, in a pH range typical for natural waters (approximately 4–9), $Cr(OH)^{2+}$ and $Cr(OH)_3{}^0$ are the prevalent aqueous forms of Cr(III).

In the case of Cr(VI), pH-value and its total concentration determine the relative fractions of these species occurring in a solution. H_2CrO_4 belongs to the strong acids and is only observed below pH 1. As a result of its dissociation the following products are formed: $HCrO_4^-$ at a pH from about 1–6.5 and at a Cr(VI) concentration below 0.01 mol L^{-1}, whereas $Cr_2O_7{}^{2-}$ is prevalent in more concentrated solutions ($c > 0.01$ mol L^{-1}) and $CrO_4{}^{2-}$ at pH-value higher than 6.5 over the entire concentration range. All of the above-mentioned Cr(VI) oxyanions are present in a pH range of natural waters [2,8,9].

2.1.2. Oxidation/reduction reactions

Redox potential (Eh) and pH play a crucial role in the interconversion of both stable states of chromium. To understand the behavior of Cr(III) and Cr(VI), please refer to the Eh–pH diagram for chromium species in aquatic environments presented in Fig. 1. Under acidic conditions, Cr(VI) exhibits a high positive Eh value, which means it is a strong oxidizing agent and is easily reduced by electron donors such as organic matter or appropriate inorganic compounds widespread in water systems. At neutral pH, the Cr(III)–Cr(VI) proportion is related to the oxygenation of solution. By contrast, in more alkaline media, the oxidizing character of hexavalent chromium is much less effective and thus it has a tendency to remain in this state rather than be reduced [2,9].

The concentration of reducers and oxidation mediators also regulates the redox behavior of chromium. Even though the Eh value of the Cr(VI)/Cr(III) couple is high there are several oxidants in the natural aquatic environment that can oxidize Cr(III) into Cr(VI) but only a few of them are found at sufficient levels. Dissolved oxygen does not affect the oxidation of Cr(III) if additional compounds are absent. Only in the presence of manganese oxides Cr(III) can be readily converted to Cr(VI). Although hexavalent Cr reduction is less privileged thermodynamically, this process can be carried out because the concentrations of reductants are high enough. Consequently, the major factors in the water body taking part in the transformation of Cr(VI) into Cr(III) are: Fe^{2+}, S^{2-}, dissolved organic matter (e.g., humic acid), as well as the activity of microorganisms [7,10,13,42,43].

Sunlight also plays an essential role in the regulation of chromium chemistry in surface water. It has been proven that photochemical generation of Cr(III) and Cr(VI) is possible. The sunlight contributes to the reduction of iron which affects the formation of hydrogen peroxide and both of these reducing agents favor the reduction of Cr(VI). Additionally, sunlight influences the oxidation of manganese (which determines Cr(III) formation), breaks organic bindings of chromium and thereby releases its inorganic species [7]. However, the problem of Cr(III) oxidation to more toxic Cr(VI) may be intensified owing to the anthropogenic contamination of water and an application of ozone in water treatment systems.

2.1.3. Precipitation/dissolution reactions

Precipitation and dissolution are other important aspects that influence the distribution of Cr species in the environment. They are ruled by the solubility of the chromium compounds, which varies between individual Cr species [7]. Under conditions prevalent in surface waters, Cr(III) solubility is limited by the formation of insoluble chromium hydroxides, including mixed ones (e.g., $(Cr, Fe)(OH)_3$). The amount of soluble Cr(III) is extensively regulated by the precipitation of these hydroxides, especially mixed iron–chromium that have even lower solubility than $Cr(OH)_3$ [24,42]. However, trivalent chromium exhibits a tendency to form various complexes with naturally

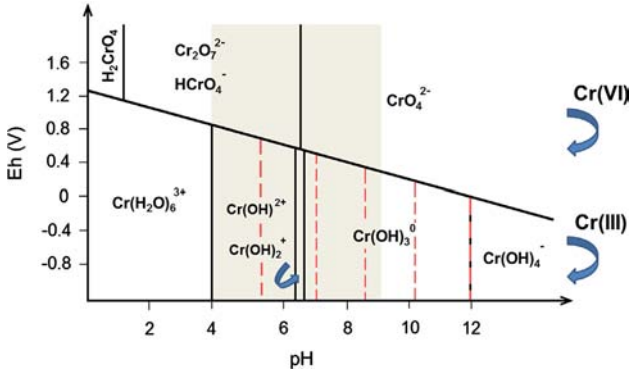

Fig. 1. Trivalent and hexavalent species of chromium in water environments as a function of Eh vs. pH; assuming the presence of H_2O, OH^- only and the concentration of total $Cr = 10^{-6}$ mol L^{-1}. The dotted lines demonstrate precipitated Cr(III) as $Cr(OH)_{3\,(s)}$, and the gray zone illustrates the typical range for pH in natural waters [2,9,10].

occurring macromolecular substances such as fulvic or humic acids. This complexation reduces the efficiency of Cr(III) precipitation and affects the mobility of organic ligands. If humic compounds are bound to sediment or soil, we observe the removal of Cr(III) from aquatic environments due to formation of its stationary complexes.

A large number of Cr(VI) compounds (chromates and dichromates) are water-soluble at wide range of pH. However, they can also exist as solid minerals containing different divalent cations (e.g., Ba^{2+}, Sr^{2+}, Pb^{2+}, Ca^{2+}). The solubilities of CrO_4^{2-}, $Cr_2O_7^{2-}$ and above mentioned cations are governed by pH, and it has been shown that the dichromates are, in principle, highly soluble as opposed to the chromates [7,8,44]. Therefore, the mobility of hexavalent anionic forms is relatively greater than trivalent chromium, which causes the first ones to be more available for living organisms in soil-water systems [9,42,45].

2.1.4. Adsorption/desorption reactions

The concentration of chromium in natural aquatic systems is also controlled by adsorption and desorption reactions. Sorption causes the migration of Cr from the aqueous phase to the surface of suspended and settled sediments. The equilibrium of this process depends on complex environmental conditions such as pH, surface area or density of active sites [43]. Hexavalent chromium can be adsorbed on particle surfaces (which have protruding –OH groups), including iron and aluminum oxides as well as kaolinite. Iron oxides are the dominant adsorbents in acidic to neutral oxidized soils and ground water. The sorption of dissolved Cr(VI) is higher at lower pH values. However, Cr(VI) anions are generally weakly adsorbed on minerals due to their being repelled by the negative charge of soil particles [13]. On the other hand, Cr(III) species are attracted to partially negatively charged surfaces such as silicates, and organically-bound Cr(III) can also adsorb on or desorb from the organic substances [2,7,8,45].

2.2. Chromium in water systems

Chromium and its compounds present in water come mostly from anthropogenic sources but natural Cr release cannot be neglected. In combination with other elements, Cr naturally occurs in the environment mainly as an ore mineral – chromite ($FeCr_2O_4$). The primary natural sources of this element, contributing to an increase of its concentration in aquatic systems, are: weathering of rocks, wet precipitation and dry fallout from the atmosphere (e.g., volcanic dust, forest wildfires), as well as run-off from terrestrial areas. As mentioned earlier, Cr contamination of water and soil is caused by intensive industrial activities to a much greater extent than natural release. However, elevated levels of naturally occurring Cr(VI) in ground and surface waters (exceeding the value of total Cr for drinking water recommended by the WHO) have been observed. This is a consequence of a release of Cr(III) to solution from rocks (e.g., ultramafic) and then its oxidation by commonly found MnO_2 [6]. The introduction of sewage, which is rich in chromium, into waters (mostly surface waters) has become a serious problem and may be a result of the discharge of industrial waste (e.g., from metallurgical and electroplating plants, tanneries or from dyeing and other chemical factories) as well as sanitary landfill leaching [45,46]. The industrial use of Cr is associated with chromite mining. In 2011 its total world mine output was approximately $24\,000 \times 10^3$ metric tons. Large reserves of this ore exist in Kazakhstan, South Africa, India and the United States [10]. The majority of chrome ore production (90%) is consumed by metallurgical industries, while chemical and refractory industries equally account for 5%. Chemical processes in which chromium is used influence the quantity and species of Cr later released in sewage outflows. The above mentioned activities employ an oxidized form of Cr [2,7,12,24].

Typically, lakes are characterized by high levels of biological activity and high ratios of sediment-to-water surface area that control transport of metals. Significant amounts of organic matter, which are responsible for establishing reductive and complexing conditions, favor reduction of Cr(VI). Subsequently, the fate of chromium depends on the various processes discussed above. Chromium enters the ocean in two ways: by rivers or atmospheric fallout. In the ocean waters an equilibrium exists between dissolved and precipitated Cr. The most prevalent form of chromium in seawater is found in chromates (besides estuaries), as a result of the oxidizing character of these waters and the low concentration of suspended solids.

When examining the distribution of chromium species in ground water, we should take into account their solubility and ability to be

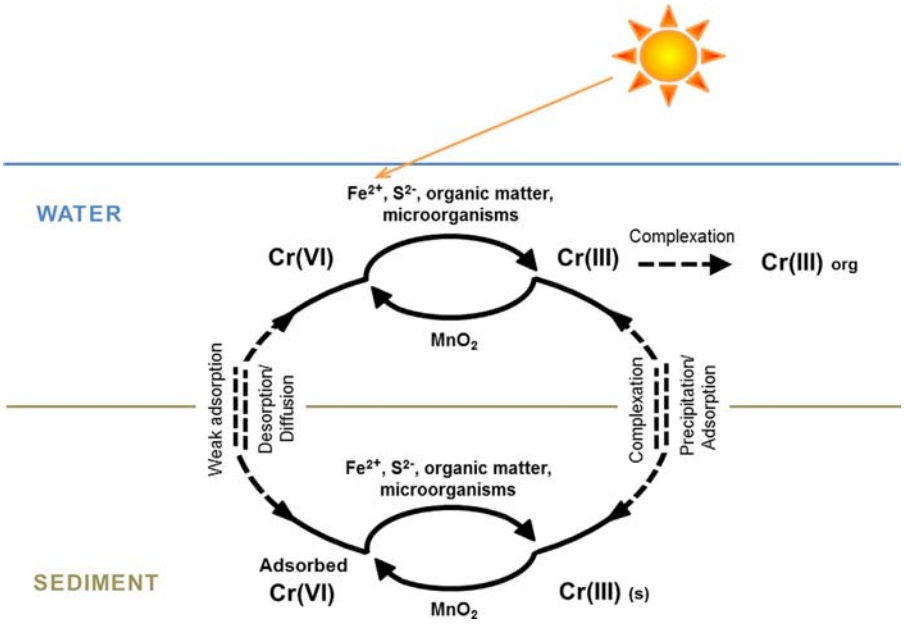

Fig. 2. The chromium cycle in the water-sediment system [2,9,23].

sorbed by soil or aquifer materials. These factors are governed by the chemistry of this type of water and the properties of soil or aquifer material. In general, Cr(III) is immobile in most ground waters due to the formation of poorly soluble compounds (in neutral to alkaline pH values). Hexavalent chromium, in turn, tends to be the most mobile form of Cr in shallow ground water. Chromium species behave similarly in surface waters [7]. The transformations and movement of chromium species in the environment are illustrated in Fig. 2.

Natural concentrations of total chromium in surface waters (except regions with substantial chromium deposits) are very low, normally between 1 and 10 $\mu g\,L^{-1}$, and in lake water do not exceed 5 $\mu g\,L^{-1}$ [47]. Total Cr concentration in surface waters in Europe ranges from $< 0.01\ \mu g\,L^{-1}$ to 43.3 $\mu g\,L^{-1}$, with a median value of 0.38 $\mu g\,L^{-1}$ [13]. Chromium concentration in sea water is one order of magnitude lower than in rivers and freshwater lakes, most of the samples contain 0.1 $\mu g\,L^{-1}$–0.5 $\mu g\,L^{-1}$ of Cr. In ground water the content of chromium is comparable to the typical amount of this element found in surface waters [45,48]. Total Cr level in drinking waters is predominantly less than 2 $\mu g\,L^{-1}$, however, a higher concentration of chromium (120 $\mu g\,L^{-1}$) has also been noted [18]. Concentrations of specific species of Cr in various water samples, which have been analyzed using HPLC/ICP-MS, are summarized in Table 1.

3. Analytical problems in quantification by ICP-MS and their manners of reduction

3.1. Interferences

Elemental speciation, as previously discussed, involves the coupling of two analytical tools: a highly selective separation technique with a sensitive detection. Among numerous methods described in the literature concerning the quantification of chromium species, most of the recent ones are based on the ICP-MS as a detector. The ICP-MS instrument provides many advantages, however, it also presents some pronounced difficulties such as spectral and non-spectral interferences, in particular quadruple ICP-MS (qICP-MS).

3.1.1. Spectral interferences

Spectral interferences occur mainly due to polyatomic and isobaric ions, which have the same mass-to-charge ratios (m/z^+) as the analyte of interest. For the determination of chromium by ICP-MS, four Cr isotopes with natural abundances between 2.4% and 83.8% are available. Nevertheless, all of these isotopes are affected by numerous polyatomic species, which are formed by interaction between constituents of gaseous plasma (Ar), reagents and sample matrix (O, H and less often C, N, Cl, S, P) [49]. The polyatomic interferences on $^{52}Cr^+$, including $^{40}Ar^{12}C^+$ and $^{35}Cl^{16}O^1H^+$ are the most frequent ones for ICP-MS detection of Cr. Despite the fact that determination of chromium has some difficulties, ^{52}Cr is preferred by researchers because it is the most abundant isotope (83.8%) [12,28,32,50,51]. Additionally, isobaric interferences are caused by isotopes of other elements that overlap ions at the masses of interest, but doubly charged ions derive only from elements with a low second ionization energy, therefore their formation depends on the ionization source [49]. Spectral interferences associated with the measurement of chromium ions using ICP-MS are listed in Table 2.

A variety of approaches can be applied to effectively overcome interferences caused by the limited resolving power of qICP-MS. In order to eliminate isobaric and doubly charged ions, the usage of alternative isotopes of the analyte is recommended. Moreover, mathematical correction (also as an option in the software of contemporary ICP-MS) can be used for isobaric interferences, while the optimization of operational conditions of the instrument is suitable for doubly charged forms [49,52]. In turn, the application of multipole collision (hexapole or octapole) or reaction cells (in upgraded qICP-MS), mathematical correction, cool plasma conditions, high resolution ICP mass spectrometer or optimization of the chromatographic separation reduces the level of polyatomic interferences to a great extent [17,37,44,53–55].

[a] Abundance of naturally occurring chromium isotope recommended by IUPAC.

3.1.2. Non-spectral interferences

Non-spectral interferences called matrix-effects are induced by the sample matrix or mobile phases when organic compounds as well as inorganic salts are contained. They contribute to clogging the nebulizer, the sampling and skimmer ICP-MS cones, they can also accumulate on the torch and the ion lens, causing distortions by increasing or decreasing signal intensities. Incorrect measurements stemming from non-spectral interferences are usually overcome with the use of appropriate calibration procedures e.g., standard addition method or internal standardization [49,52].

3.2. Reaction/collision cells

Among currently available approaches to cope with the problem of spectral interferences, dynamic reaction cells (DRC) as well as multipole collision cells (MCC) are one of the most effective. The DRC is a rf/DC quadrupole placed inside the enclosed reaction chamber which is positioned between the single lens ion optics and the mass filter. The DRC is pressurized with a reactive gas in order to carry out ion-molecule reactions intended to suppress plasma-based polyatomic interferences [56]. The bandpass of the DRC is selected in a manner so as to control the generation of new interfering species within the reaction cell. Removal or reduction of polyatomic interferences has been achieved by different processes including neutralization or exchange reaction between interference ions and gaseous molecules pressurizing the cell. Products of these reactions are swept from the chamber with a continuous fresh reaction gas stream [57–61]. As a consequence of these interactions, the obtained chemical forms are characterized by another m/z^+ than the analyzed ion or they are converted into neutral species which cannot be recognized by the detector. Preferred reaction gases as well as the mixtures (e.g., with argon) used in the DRC are: ammonia, methane, hydrogen or oxygen [62,63]. The selection of gas depends on its ability to undergo a gas phase chemical reaction with the polyatomic species and to remove them. An exemplary interaction between NH_3, as an extensively employed reaction gas, and argon plasma ion was demonstrated as follows [56]:

$$Ar^+ + NH_3 \rightarrow NH_3{}^+ + Ar \text{ (neutralization)}$$

According to scheme presented above, the major interference $^{40}Ar^{12}C^+$, which occurs at the same m/z^+ as $^{52}Cr^+$, can also be transformed into neutral species by ammonia [58]:

$$^{40}Ar^{12}C^+ + NH_3 \rightarrow NH_3{}^+ + {}^{40}Ar + {}^{12}C$$

Carbon-based interferences react much faster with NH_3 than chromium, and thus the interfering ions will be effectively reduced. As can be seen, the ionization energy of Cr (6.8 eV) is lower than NH_3 (10.2 eV), therefore, the electron transfer from ammonia to chromium ion is endothermic and the reaction is not observed to proceed [64].

MCC similar to the DRC employ rf to focus the ion beam instead of separating ions according to their m/z^+ like a typical mass analyzer. However, in the case of collision technology, non-reactive gases (e.g., He, H_2, Xe) are introduced into the cell and they can attenuate or even eliminate polyatomic interferences by an ion–molecule collision mechanism. In order to separate the collision product from the analyte, kinetic energy discrimination (KED) is used. Particular ions will be distinguished, while the analyte ions will have higher energy than the interfering ions [62,65,66].

In the reviewed articles the application of DRC/MCC technology was one of the most frequently adopted approaches used to overcome spectral interferences. Sakai et al. used H_2 as a collision cell gas for attenuating $^{40}Ar^{12}C^+$ and $^{35}Cl^{16}O^1H^+$, primary based-matrix interferences at m/z^+ 52 [67]. Chen et al. reported that an octopole reaction system can be used for determination of $^{52}Cr^+$ in the presence of chloride, using either an He or H_2 mode [53]. However, the authors also recommended H_2 cell gas to efficiently remove polyatomic spectral interferences. By contrast, Wang et al. suppressed polyatomic interferences from chlorine and carbon by application of a mixture of 7.28% H_2/He, while McSheehy et al. utilized a mixture of 8% H_2/He as the collision cell gas for preventing $^{40}Ar^{12}C^+$ [28,68]. An alternative approach to the above mentioned system was collision/reaction interface (CRI), where a collision/reaction gas had been introduced through the sampler or skimmer cones [69]. The use of H_2 CRI gas at 70 mL min^{-1} appreciably eliminated the problem of chlorine-based and carbon-based interferences and so enabled a reliable determination of $^{52}Cr^+$. Bednar et al. employed methane as a reaction gas in DRC for attenuating $^{40}Ar^{12}C^+$ interferences at m/z^+ 52 and 53 [44]. Tsoi and Leung applied DRC technology to overcome polyatomic ions in multi-elemental speciation analysis of seven forms of arsenic, chromium, and selenium altogether [70]. They tested the efficiency of the interference reduction by optimizing the following DRC conditions: gas flow rate and rejection parameter q (Rpq) using various reaction gases including NH_3, CH_4 and O_2. The experiments revealed that the preferable gas for determination of all seven analytes of interest is CH_4. Its capability of dealing with the problem of chloride interferences, under the optimal conditions of the reaction cell, was demonstrated by the analysis of 250 mg L^{-1} NaCl solution. However, Neubauer et al. suppressed interferences encountered during trace element speciation of arsenic and chromium, using O_2, which reduces the $^{40}Ar^{12}C^+$ ions on $^{52}Cr^+$ and forms a new species $^{75}As^{16}O^+$ free from interfering ions [71]. Other authors selected NH_3 as the DRC gas to remove a great part of the chlorine-based and carbon-based polyatomic interferences, predominantly occurring in chromium determination. [50,72,73]. They studied influential operating parameters for the DRC system (gas flow rate and Rpq) to achieve the optimal signal to noise (S/N) ratio. In particular Chang et al. and Wolf et al. effectively reduced the interfering background peaks at m/z^+ 52 as well as 53 (under the optimized DRC conditions) by three or even four orders of magnitude [3,12].

3.3. Other approaches to dealing with interferences

An alternative approach to resolve the problem of spectral interferences is the use of mathematical correction [49,52,55]. As previously mentioned (Section 3.1.1), corrections may be applied for evaluating the formation of $^{40}Ar^{12}C^+$ and $^{35}Cl^{16}O^1H^+$, being the

most common interferences in total chromium determination at m/z^+ 52 by ICP-MS. Even though it is cost-effective, taking into consideration all the interfering ions is not an easy task, especially in complicated matrices [69]. This is probably the reason why mathematical equations were less popular as solutions in the reviewed papers.

Another way to avoid polyatomic interferences is the optimization of chromatographic separations, especially in the case of ion exchange chromatography because it enables interfering ions to be isolated from chromium species. Chlorides were not applied as components of mobile phases in order to reduce chlorine-based spectral interferences. Different solutions with high ionic strength such as NH_4NO_3, $NH_4H_2PO_4$ and EDTA were often used for the Cr(III) and Cr(VI) elution [53,74,75]. However, the presence of the above-mentioned reagents in mobile phases causes an instrumental instability of ICP-MS which can be decreased by using diluted HNO_3 [4]. Additionally, Gürleyük and Wallschläger as well as Séby et al. reported that a separation between the chromium species and carbon- or sulfur-based polyatomic interferences is achievable [4,74]. Effective elimination of $^{40}Ar^{12}C^+$, which co-elutes with Cr (VI), was also performed under cool plasma conditions. In contrast, the $^{35}Cl^{16}O^1H^+$, which interferes with the determination of Cr(III), was not reduced [54]. However, those spectral interferences generated by carbonate and chloride ions were separated with a high resolution ICP-MS instrument; unfortunately, its main disadvantage is a significant loss in sensitivity [54,52,76,77].

4. Speciation analysis of chromium by HPLC/ICP-MS

HPLC/ICP-MS technique enables speciation analysis of chromium at very low concentration levels. It may be achieved by involving the DRC mode, which significantly decreases the background signal. The quality of separation is provided by selection of the mobile and stationary phase. Using HPLC/ICP-MS online system chromium speciation analysis takes only several minutes. Additionally, the measurement consumes very little sample volume and usually requires minimal sample pretreatment. More detailed information about this online method applied for chromium speciation is given in Table 3, which contains data from papers concerning Cr speciation in water samples published since 2000. The data include: (i) type of sample, its storage and preservation conditions; (ii) parameters of the separation process; (iii) HPLC operation conditions and (iv) figures of merit.

5. Metrological approach to measurement

The authors would like to emphasize the importance of chemical metrology in the analytical process. The metrological approach has been introduced by international organizations such as the ISO or BIPM through numerous documents, standards and guidelines describing the analytical processes in detail and providing an opportunity to compare measurement results worldwide. Three main concepts need to be taken into consideration while discussing the metrological approach, namely: (i) analytical validation; (ii) metrological traceability and (iii) uncertainty of the measurement result. Unfortunately, the above mentioned aspects are not always presented in all of the papers. The last column in Table 3 contains the validation parameters from articles regarding Cr speciation, namely the limit of detection (*LOD*), precision and recovery. The validity of methods and procedures used for Cr speciation in water samples, industrial processes brines, waste waters and human urine has been tested by various authors.

A description and commentary of method validation (linearity, *LOD*, limit of quantification (*LOQ*), precision and trueness), traceability and uncertainty of measurement result is presented below.

5.1. Method validation

5.1.1. Linearity

Linear range is a range of concentrations in which the output signal from the detector is linearly correlated with the concentration of the analyte in standard solutions. The HPLC/ICP-MS technique allows a wide range of linearity to be achieved. The presented papers show the linear calibration range up to 4 or 5 orders of magnitude: 1 $\mu g\,L^{-1}$–1000 $\mu g\,L^{-1}$ and 0.1 $\mu g\,L^{-1}$–1000 $\mu g\,L^{-1}$, respectively [32,78]. The lowest concentrations were chosen by Sakai et al., (0.05 $\mu g\,L^{-1}$–1.0 $\mu g\,L^{-1}$), Chang and Jiang as well as Neubauer et al. (0.1 $\mu g\,L^{-1}$–10 $\mu g\,L^{-1}$) and Tsoi and Leung (0.1 $\mu g\,L^{-1}$–100 $\mu g\,L^{-1}$), in contrast, the highest were chosen by Gürleyük and Wallschläger (50 $\mu g\,L^{-1}$–5000 $\mu g\,L^{-1}$) and Chen et al., (1 $\mu g\,L^{-1}$–1000 $\mu g\,L^{-1}$) [3,32,67,70,71,74]. For the majority of calibration graphs the correlation coefficients were very good, usually up to 0.999 and higher.

5.1.2. LOD and LOQ

One of the most important parameters in the speciation analysis is *LOD*. It is defined as the concentration or amount of analyte which can be reliably determined with a given level of confidence. In general, the most popular method of *LOD* estimation is 3 times standard deviation (*SD*) of a certain analytical response, specifically: (i) 3 times *SD* of blank [68,78], (ii) 3 times *S/N* ratio [32,53,67,71,75], 3 times *SD* of the background signal [3,54,74] and 3 times *SD* of a low level analyte sample [70]. Barałkiewicz et al. presented three approaches to *LOD* estimation which are: the modified blank determination method, the graphical method and linear regression method [72]. The above methods; 3 times *SD*, 3 times *S/N* and 3 times of the background signal; do not take into consideration the influence of the parameters of the calibration curve, namely the slope, interception and their errors. Also, usually little is known about the number of replicates of samples or blank used for estimating *LOD*. A knowledge of these factors is important for the selection of an appropriate *LOD* estimation approach. Methods relying on 3 times *SD* of blank or *S/N* determine the ability of the apparatus or detector to recognize the analyte on the lowest possible level. Measurements are usually carried out using blank samples or calibration standards without matrix. The *LOD* estimated by such methods is called the instrumental detection limit. Another type of *LOD* is the method detection limit where the lowest analyte level is determined in real samples and includes the possible effects caused by matrix and interferences, besides instrumental noise. It is crucial to remember to always present the *LOD* value with a description of method and numbers of replicates used for its estimation in order to compare it with different research [79].

The *LOD* values presented in the reviewed papers vary to a great extent in the range 0.005 $\mu g\,L^{-1}$–1.5 $\mu g\,L^{-1}$ with the most common values being around 0.04 $\mu g\,L^{-1}$–0.4 $\mu g\,L^{-1}$. Vanhaecke et al. calculated *LOD* for different detector conditions [54]. The application of cool plasma conditions or increasing resolution to $R=3000$ cause the *LOD* at m/z^+ 52 to decrease slightly and at m/z^+ 53 cause a slight increase. The authors of the papers presented in Table 3 obtained higher *LOD* values at m/z^+ 53 than at m/z^+ 52 due to much lower ^{53}Cr isotope abundance [3,4,44,54,74]. A smaller volume of injected sample generates higher *LOD*, a similar effect is observed in precision values [68]. Application of DRC/MCC technology enables the background count rate to decrease significantly, which translates to the lower *LOD* values [12,70].

The *LOQ* is usually omitted in papers, however, several authors have presented it as either an *LOQ* or a practical quantification limit (*PQL*). McSheehy et al. and Burbridge et al. calculated *LOQ* as 10 times the *SD* of the blank while Barałkiewicz et al. used 3 times the *LOD* [68,72,78]. To calculate *PQL*, Wolf et al. measured several samples with low concentrations until the result was within the $\pm$ 20% of the true concentration value [12].

5.1.3. Precision

Precision is a parameter describing the spread of values obtained by performing repeated analysis of a sample. Depending on the time period that separates subsequent analysis, there is repeatability, an analysis performed during one day and intermediate precision, one over the course of several days or longer. Precision is usually presented as *SD* or relative standard deviation (*RSD*). The values of *RSD* for both Cr species ranged from 0.6% to 12% with the most frequent values lying between 1.5% and 3.6% in the papers presented in Table 3. Precision should be stated with the number of replicates, which was not always the case in the reviewed articles. Several authors have evaluated the intermediate precision by analyzing samples over three different days which resulted in a more than two-fold higher long-time precision value compared to short-time precision [72,75]. Chang and Jiang have shown that there is no significant difference in the precision between the standard and DRC mode [3]. It is also noticeable that higher concentrations of analyte contribute to better precision values [75].

5.1.4. Trueness

To confirm if the obtained result is in accordance with the true value the trueness is determined. In the reviewed papers this was achieved by calculating recoveries of real samples spiked with a known amount of analyte. The lowest and highest recoveries for all Cr species are 0% and 180%. Such extremely low and high values are considered unacceptable and are probably due to interconversions of Cr species in the presence of Mn, Fe, sulfides or organic carbon such as humic substances, plant exudates as well as heat treatment of the samples [12,78]. Most of the recoveries fall within the range of 90%–110% which is generally considered as very good, as presented in Table 3. The values that are usually acceptable are 75%–125% [72]. By assessing the recoveries one can determine whether the sample matrix, container material or eluent could cause conversions of Cr species in the sample. Seby et al. has noticed that low recoveries of Cr(III) can be explained by its precipitation as $Cr(OH)_3$ in an alkaline medium [4].

5.2. Traceability of measurement result

Traceability is a property of a measurement result whereby the result of the measurement can be related to a reference through a documented unbroken chain of calibrations, each contributing to the measurement uncertainty [80]. One of the best ways to establish traceability is to apply CRM. Unfortunately, there are no appropriate CRMs that possess the specified species concentration that would match the matrix of the samples. Usually CRMs are certified for total chromium concentration without distinguishing for Cr(III) and Cr(VI). BCR CRM 544 was one of the few CRMs with certified Cr(III) and Cr(VI) content available in the past and applied for Cr speciation in surface waters [4,68,81]. Currently no CRM with certified concentration values of Cr(III) and Cr(VI) forms is available due to difficulties with maintaining the stability of Cr species, which is the most important property of CRMs.

One way to overcome the lack of CRMs is to spike the real samples with a known amount of Cr species. This method is widely applied in speciation analysis [53,82–84]. The result is then compared to the unspiked sample value and presented as the recovery. One must keep in mind that standard spiking is not a fully metrologically accepted method of establishing traceability in measurements. SIDMS has been

effectively used for Cr speciation. As a definitive measurement method, the SIDMS provides the highest quality of metrological traceability. This issue is described more extensively in Section 6.

5.3. Estimation of uncertainty budget

Uncertainty is one of the most important parameters to prove the usefulness and reliability of the analytical method. It is defined by the limits around the obtained analytical result where the true value can be found with a given level of confidence. Depending on the method, uncertainty is calculated using numerous components of the analytical process, parameters connected with preparation of the sample and the measurement itself. There are several approaches to assess uncertainty, two of them are applied by Barałkiewicz et al. [72], namely, the modeling approach and the single-laboratory validation approach. The uncertainties presented in papers from Table 3 are based only on standard deviation of repeated measurements of sample, which is called instrumental uncertainty [3,4,12,32,53,67,74,75,78].

6. Speciated isotope dilution ICP-MS as a definitive method for determining chromium species

The combination of two analytical tools: HPLC with ICP-MS in recent years has played an important role in the characterization of element species. These techniques working as an online coupled system enable the isotope dilution technique to be applied. SIDMS allows a highly accurate and precise determination of numerous elemental forms including Cr species in various sample matrices [37,39,41,84,86]. For IDMS analysis, accurate and precise results can be obtained by using the isotope ratio of the isotope-diluted sample for determining the analyte concentration, rather than the absolute intensity measurement [87]. The principle of this method relies on the alteration of natural isotopic abundances of an endogenous form of an analyte by the addition of an accurately known amount of an enriched isotopic spike [76,88–90]. According to data from the literature, the optimum performance of the IDMS analysis is usually achieved by using the isotope ratio of the isotope-diluted sample in a range of 0.1–10 [85,89]. However, it is

recommended that the isotope ratio of added enriched spike to the reference isotope (analyte naturally occurring in the sample) should be 1:1 [88,91,92]. Considering that IDMS determinations are based on an isotope ratio measurement, at least two isotopes must remain free from spectral interferences. Therefore, particular care should be taken with regard to the ICP-IDMS analysis because, as mentioned previously, the problem of interferences is present and thus they might disturb the obtained results [85,90]. In order to obtain unbiased chromium isotope ratio measurements in water samples DRC technology was used (Table 4). Additionally, optimization of a detector dead time and mass discrimination factors have to be performed to get accurate and precise results.

The application of multiple spiking procedures enables detection of the species transformations that may occur at every step of the analytical process, during sampling, storage, sample preparation and measurement. This means that the original concentrations of different species in a sample can be accurately determined, which cannot be achieved by any other analytical method [64,91]. Species interconversions in environmental matrices commonly found during sample pretreatment are a large problem in trace and ultra-trace element speciation. For this reason, the isotope-dilution step should take place before Cr(III)–Cr(VI) transformations, so potential loss of part of an analyte of the isotope-diluted sample will not have any influence on the final result because the isotope ratio of the sample will remain constant [87,89,90].

The prerequisite for accurate results using IDMS is to achieve effective equilibrium between the added enriched isotopic spike and the natural abundant species in the sample [92]. In the case of total element analysis, fulfillment of the foregoing condition is easier as only the equilibration of the spike with all determined species of the analyte is necessary, whereas in element speciation performed by SIDMS it is required that no species interconversion occurs prior to their complete separation [85].

Comparing quantification strategies including the isotope dilution technique, external calibration or standard additions, it can be observed that only the first takes no account of instrumental sensitivity. Consequently, the isotope ratio measurement is largely unaffected by instrumental instabilities such as signal drift or matrix effects and therefore the instabilities will have no impact on the species concentration in a sample [87,88]. The basis of the isotope dilution technique and general equations for determination of the species concentration are detailed in overall reviews as well as in the US EPA method 6800 [85,90,93].

In world literature, there are relatively few articles concerning SIDMS of chromium in water samples [64,91,94]. The first work to consider SIDMS in application to chromium species determination was published in 1998 [91]. The authors described the first standard method for environmental measurements and outlined the general procedures for SIDMS application in an analysis of drinking water, river water and deionized water samples. Simultaneously, they indicated the potential that SIDMS could offer as a diagnostic tool for the validation of other methods of speciation analysis. The second group took on similar research determined chromium species in ground and surface waters in the vicinity of chromite ore processing residue disposal sites [94]. The results obtained by those authors showed that Cr was present predominantly ($>90\%$) in a hexavalent form as CrO_4^{2-}. In turn, Ma and Tanner developed an IDMS method for determining Cr(III) and Cr(VI) in natural waters (local nullah spiked water samples) [64]. They described an approach that, allowed chromium species to be determined without any need for a separation instrument connected to an ICP-MS spectrometer. In this work DRC, with ammonia as a reaction gas, was involved in the elimination of interferences. The applications of SIDMS for determining chromium species in water matrices are presented in Table 4 together with details concerning isotopic spikes, their preparation, analytical techniques used, optimization of ICP-MS parameters for ID measurements, determined concentration levels and figures of merit.

At this point the significance of the adequate preparation of Cr isotopic spike solutions must be emphasized. It should be remembered that a thorough preparation process is the most important step in the analytical procedure. Different approaches to isotopic spike solution preparation were widely commented by Novotnik et al. [95]. The authors pointed out the risk, which in the previously reported procedures may arise depending on the excess of H_2O_2 remains. The pe-pH relationships of $CrO_4^{2-}/Cr(OH)_3$ and O_2/H_2O_2 couples show that H_2O_2 is an oxidant of Cr(III) at $pH > 7.5$; while, at lower pH values, it becomes a reductant and in this condition its strength as a reductant strongly increases [96]. Hence, H_2O_2 is used as an oxidizing and/or reducing agent in the preparation process of chromium spike solutions. However, if H_2O_2 residues are still present in the solution it can cause artefacts in chromium speciation [95]. In order to be sure that no excess of the reducing oxidizing agents remain in the prepared solution, Novotnik et al. developed a new procedure involving alkaline melting of $^{50}Cr(III)$ enriched oxide for the preparation of pure $^{50}Cr(VI)$ spike solution. No other oxidizing agents except air oxygen were used for quantitative oxidation of Cr(III)–Cr(VI). Cr(III) was quantitatively oxidized to Cr(VI) with air oxygen without applying any other oxidizing agents. Furthermore, the authors suggested that a microwave assisted digestion procedure of ^{53}Cr enriched oxide could be used in order to prepare $^{53}Cr(III)$ spike solution without any need for reducing agents. FPLC coupled with ICP-MS was used to examine the purity of $^{50}Cr(VI)$ and $^{53}Cr(III)$ spike solutions [95].

Therefore, in spite of difficulties with spectral interferences affecting the measured Cr isotopes as well as those connected with the preparation of isotopic spike solutions, SIDMS offers the highest accuracy and precision, hence it can be considered as a reference or the highly qualified definitive method for element speciation analysis [86].

7. Conclusion

How is the issue of chromium speciation presented in the literature published since 2000?

Trace speciation of chromium is a topic of considerable importance due to great differences in the biochemical behavior of its single chemical forms. Chromium is an excellent example of an element whose species present opposite effects: Cr(III) is essential for living organisms, while Cr(VI) is considered toxic. To date researchers have described many analytical aspects concerning the speciation analysis of chromium in water matrices by HPLC/ICP-MS, especially in terms of the development of new procedures, improving existing ones as well as dealing with the problem of eliminating the interferences accompanying chromium species determination.

What are the outlooks?

Currently, we have to provide mathematically proven competent results of chromium species determination. Such results are essential in health protection and doping control, radiochemistry, trace analysis of toxic elements in the environment, food and materials, as well as in verification of the purity of products. We have no other alternative than to introduce metrology rules into chemical measurements, thus solving problems related to insufficient knowledge of the three basic metrological principles: validation of measurement procedure, establishing traceability and uncertainty of measurement results.

Nowadays the online HPLC/ICP-MS system has become commercially available and its purchase should be perceived as an investment. Additionally, using this hyphenated technique in combination with SIDMS offers a huge potential to establish the highest quality of metrological traceability. Such an attitude to scientific research on

speciation analysis, especially in chromium species determination in water, will broaden our knowledge, alter our points of view and show a new direction. Most of all, it will prove efficient in practice.

ABSTRACT

Extra virgin olive oils produced from three cultivars on different maturation stages were characterized using Raman spectroscopy. Chemometric methods (principal component analysis, discriminant analysis, principal component regression and partial least squares regression) applied to Raman spectral data were utilized to evaluate and quantify the statistical differences between cultivars and their ripening process.

The models for predicting the peroxide value and free acidity of olive oils showed good calibration and prediction values and presented high coefficients of determination (>0.933). Both the R^2, and the correlation equations between the measured chemical parameters, and the values predicted by each approach are presented; these comprehend both PCR and PLS, used to assess SNV normalized Raman data, as well as first and second derivative of the spectra.

This study demonstrates that a combination of Raman spectroscopy with multivariate analysis methods can be useful to predict rapidly olive oil chemical characteristics during the maturation process.

1. Introduction

The quality of olive oil is influenced by a great number of factors, namely the nature of the cultivar and geographic origin [1], the fruit ripening degree [2,3], where important chemical changes occur, the irrigation regimes [2], the oil extraction technology and the storage of the oil [4] and agricultural practices [5]. Nutritional and sensory properties of extra virgin olive oils (EVOO) were also affected by these factors. Thus, the European Community (EC) Council of Regulation established standards on olive oil production regarding labeling giving the origin for virgin and extra virgin olive oils to avoid consumers being misled about their true characteristics and origin [6]. Some of the important quality parameters consist on peroxide value (PV) and free acidity (FA) determination [7]. However, these conventional measurements are time consuming and require large amounts of reagents and solvents, which are often toxic, besides being very expensive.

Infrared (IR), mainly Fourier Transform Infrared (FTIR), and Raman, are vibrational spectroscopic techniques widely used for food and feed analysis [8,9]. These optical spectroscopic methods provide information about the chemical composition of various food and biological materials, and molecular structure, without requiring large amount of samples or sample preparation and pre-treatments [10]. Furthermore, these techniques have a great potential due to their simplicity, rapidity, low-cost and reproducibility, besides being non-destructive [11].

Both techniques assess the same physical property – molecular vibrations – but present different selection rules. In one hand, the vibrational modes corresponding to a change in polarizability, such as the symmetrical vibrations of covalent bonds in the non-polar groups, (*e.g.* C=C bond stretching), give rise to intense Raman bands. While in the other hand, IR absorption is related to a change in the electrical dipole moment as the molecules vibrate, with the vibrational modes involving polar groups, such as C=O and O-H, showing intense infrared absorption bands [12]. Therefore, one of the major advantages of Raman spectroscopy is

the almost negligible influence of water and carbon dioxide on Raman spectra, as opposed to IR absorption spectroscopy [13]. Additionally, as the infrared peaks are often broad, they tend to overlap, being rather difficult to found isolated or well-defined peaks, and these might be also influenced from the aforementioned atmospheric components, which display also broad peaks. This problem is overcome in Raman, where a spectrum is normally composed of isolated bands, besides the previously mentioned advantage of the insignificant contributions from atmospheric gases and water in the Raman spectra.

Furthermore, in Raman, if the excitation wavelength matches the electronic absorbance of a chemical system, its Raman signal will be enhanced by resonance, making this technique suitable for monitoring particular compounds, or properties related to specific constituents of a sample. Thus, Raman spectroscopy can provide useful qualitative and quantitative information on chemical composition of olive oils. For instance, El-Abassy et al. (2009) took advantage of the resonance phenomenon in carotenoids at 514.5 nm excitation, and their correlation with free fatty acid (FFA) content, to assess the FFA percent values in distinct EVOO´s using Raman spectroscopy. Actually, the concentrations of both FFA, and carotenoids, change during the ripening process, with an inversely proportional trend, therefore, the changes occurring in those bands corresponding to carotenoids, can be (indirectly) related to the variations in the FFA content [14].

In fact, in the last years, Raman spectroscopy combined with chemometric data analysis methods allowed researchers to determine the total unsaturation in oils [15], the FFA contents [14,16], to discriminate and classify oils [17], to detect oil adulteration [18], and to distinguish the ripening stages of olive fruit [19]. Additionally, the rapid spreading, and developments occurred, concerning portable Raman devices, which are nowadays available with a variety of excitation wavelengths (*e.g.* 1064, 785, 671 and 532 nm), widen the potential of this technique, that can be now used *In situ*, a major advantage regarding this kind of work.

However, to the best of our knowledge, no comprehensive study has been undertaken involving chemometric analyses of the Raman spectra, combined with analytical parameters (peroxide value and free acidity), to discriminate varietal origin of olive oil and different maturation stages of cultivars 'Cobrançosa', 'Galega' and 'Picual' growing in Alentejo region.

Moreover, the vast majority of the aforementioned works have been undertaken with resort to excitation wavelengths within the NIR range (mainly the 1064 radiation from the Nd:YAG), while some authors have more recently used excitation wavelengths within the visible range for the study of olive oils, with optimal performance [14,20]. Therefore, the aim of this study was to use short wavelength Raman spectroscopy (488 nm excitation) associated with chemometrics in order to differentiate EVOO's produced with olives from three cultivars on three different maturation stages. Discrimination was achieved using an unsupervised method, principal component analysis (PCA).

Furthermore, quantitative models for the rapid prediction of the peroxide value and acidity of EVOO's based on Raman spectral data and on its 1st and 2nd derivatives were developed using the principal component regression (PCR) and the partial least square regression (PLS-R) methods.

2. Material and methods

2.1. Sampling

The present work was carried on monovarietal extra virgin olive oils from three cultivars (cv. 'Cobrançosa', 'Galega' and 'Picual'). The olive fruits were obtained from a certified olive orchard, at the National Plant Breeding Station, at Elvas (Portugal) during the crop season 2012/2013.

Only healthy olive fruits, without any kind of infection or physical damage, were collected from ten different trees of comparable age and vigor and located in distinct points of the same growing area. Thus, differences in climate conditions, agricultural practices and geographical were excluded. Olives were handpicked at three ripening stages, except Picual cultivar olives that were picked during two harvesting periods. The harvesting dates are presented in Table 1. For the classification of the maturity index, the olives were evaluated according to their skin and pulp color [21]. The ripeness index (RI) values range from 0 (100% intense green skin) to 7 (100% purple flesh and black skin).

After harvesting, the olive fruits were immediately transported to the laboratory mill where they were processed within 24 h. For the production of each olive oil, three kilos of fresh olive fruits were used using an Abencor system (INIA I.P., Elvas, Portugal) where olives were crushed with a hammer crusher and the past mixed at 25 °C for 30 min, centrifuged without addition of warm water and then filtered and transferred into dark glass bottles without headspace and stored in the dark at 4 °C until analysis. All samples were classified as extra virgin olive oils according to the EU regulations [7].

2.2. Quality chemical indices determination

For all the samples, the determination of the physicochemical quality indexes, free acidity (expressed as % of oleic acid) and peroxide value (expressed as meq O_2/kg), were performed according to the official method described in the EEC Reg. No. 2568/91 and subsequent amendments, which focus on the characteristics of olive oil and olive-residue oil and on relevant methods of analysis [7].

2.3. Raman spectra measurement

The Raman spectra were collected in the 250–3050 cm^{-1} spectral range, at room temperature, with a T64000 Jobin-Yvon triple spectrometer, coupled to a liquid-nitrogen-cooled CCD detector. The excitation line was the 488 nm of an Ar laser, and the incident laser power was kept below 100 mW on the sample, to avoid self-heating. A confocal Olympus microscope equipped with a 100X objective (NA=0.95) was used to focus the laser radiation on the sample and for collecting the Raman scattered signal in a back-scattering geometry. Under these conditions, which were maintained for all experiments, the spectral slit width was about 2.0 cm^{-1}. A substrate of crystalline silicon was used under the same conditions as an external standard for calibration, by recording the position of its well-defined Raman band at 520.0 cm^{-1}.

For the measurement, a drop of olive oil was placed directly on a special microscope slide with a small concavity by pipetting a

Table 1
Description of olive fruits at each sampling date.

Cultivar	Maturity stage	Sample code	Harvest date	RI[a]
Cobrançosa	Green	Cob G	02/10/2012	0.4
	Semi-ripe	Cob SR	12/10/2012	2.1

[a] Ripening Index.

few drops. The integration time was set to 20 s and each recorded Raman spectrum is the average of five accumulations. The time necessary for acquire one spectrum was about 4 minutes. For each olive oil sample, four replicates were measured in identical conditions, for each one the microscope was focused on two different points and the corresponding Raman spectra recorded, therefore, retrieving eight spectra for each sample.

2.4. Mathematical treatment of data set

The Raman spectral data can be considered as a multidimensional set of variables where each spectrum consists of hundreds of variables, corresponding to the Raman intensities (counts) recorded at the different Raman shifts (cm^{-1}). These data sets were then analyzed by a multivariate analysis method as described below.

A principal component analysis (PCA) was applied to inspect differences between samples. The PCA transforms a large number of potentially correlated factors into a smaller number of uncorrelated factors (principal components, PCs), and thus reduces the size of the data set.

For qualitative analysis, principal components contributing to the variance of the data set were subjected to discriminant analysis (DA) in an attempt to predict the likelihood of a sample belonging to a previously defined group. Since the raw spectral data could not be used because of the strong correlation between the wavenumbers, uncorrelated PCs resulting from PCA were employed. DA is a statistical method used to find a linear combination of structures, which characterizes or separates classes of objects or observations. The resulting arrangement may be used as a linear classifier or dimensionality reduction priori to classification.

Both PCR and PLS regression methods are utilized to model a response variable when a biological system is analyzed through a large number of predictor variables that are highly correlated or even collinear [22]. Both methods give rise to new predictor variables, usually known as principal components (PC) or latent variables that are linear combinations of the original predictor variables. Those components are calculated in different ways, PCR creates PC's to explain the observed variability in the predictor variables, without considering the response variable. In PLS-R the response variable is taken into account and, consequently, leads to models that can fit the response variable with fewer factors [23]. Whether or not it ultimately translates into a useful model depends on the specific biological system.

2.5. Treatment of spectral data

Pre-treatment of the raw spectral data included several steps. To subtract the fluorescence background the baseline of each spectrum was approximated by a fourth-order polynomial. After smoothing the spectra were normalized using the standard normal variate (SNV) method [24,25]. First and 2^{nd} derivatives were determined by the Savitzky–Golay method [26].

The Raman spectra were collected in the 250–3050 cm^{-1} spectral range. However, it was found that well-defined Raman bands associated with free fatty acids and with changes due to oxidation could be observed in specific regions. The most relevant spectral region that can be linked to free acidity and to the peroxide value is the region between 950–1800 cm^{-1}, in accordance with El-Abassy et al. (2009) [14]. The inclusion of irrelevant spectral information in the Chemometrics procedures yields an over-fitting model.

2.6. Model selection

For quantitative analysis of chemical parameters of olive oil samples, factors considerably contributing to the variance of the data set were regressed using principal component regression (PCR) and partial least squares regression (PLS-R) onto the referred variables. This multivariate calibration technique, sometimes called factor analysis, transform the original variables (Raman spectra) into the new ones (known as factors), which are linear combination of original variable.

The method relied on two steps, so-called calibration and validation. In the calibration step, a mathematical model was built to establish a correlation between the matrix of Raman spectra (predictor variables) and the concentration of analytes of interest (response variables) used a set of observations usually named calibration set. In the validation step, the developed calibration model was used to calculate the concentration of samples not used to set-up the model [26].

The quality of the fitting was scrutinized by the root mean square error of calibration (RMSEC), multiple coefficient of determination or regression coefficient (R^2, where R is the correlation factor) and by the root mean square error of cross validation (RMSECV). The optimum number of factors either for PLS-R or PCR models was determined using Leave-One-Out (LOO) cross-validation method. The optimal number of factors is the one that minimizes the RMSECV.

PCA, DA, PCR and PLS-R calculations were performed using the XLSTAT-v2006.06 package (Addinsoft, Inc).

3. Results and discussion

3.1. Chemical analysis

The regulated quality indices studied in this work (free acidity and peroxide value) are displayed in Table 2. In all samples of cv Cobrançosa, Galega and Picual olive oils, analytical parameters were widely within the limits established in the European Legislation for EVOO [27].

The PV is useful once it's an indicator of the initial stage of oxidation, where the primary oxidation products are measured. As can be seen, PV decreased as the maturation stage increased and were significantly lower in Galega and Picual olive oils in the first and latest ripening stage than in Cobrançosa olive oils. This behavior can be explained by a decrease in the activity of lipoxygenase enzyme [28]. Furthermore, for each cultivar studied,

Table 2
Means and standard deviations for peroxide value and free acidity of olive oil samples from cv's Cobrançosa, Galega and Picual in three maturation stages, for four replicates ($n=4$).

Cultivar		Peroxide value (meq O_2/kg)	Free acidity (% oleic acid)
Cobrançosa	Green	$8.33^{aA} \pm 0.42$	$0.29^{aA} \pm 0.01$
	Semi-ripe	$6.69^{bA} \pm 0.42$	$0.24^{bA} \pm 0.01$
	Ripe	$4.97^{cA} \pm 0.25$	$0.31^{aA} \pm 0.02$
	p	< 0.001	< 0.001

	Ripe	$3.33^{bB} \pm 0.17$	$0.17^{bC} \pm 0.01$
	p	< 0.001	< 0.001

For each cultivar, means with different lower case letters differ significantly. For each maturation stage, means with different capital letters differ significantly.

significant differences of PV were evident during the maturation process.

Regarding free acidity, this percentage didn't show a trend during fruit ripening of cultivars studied. For Cobrançosa and Galega samples, free acidity decreased from the first to the second maturation stage and then increased in the ripe stage. However, olive oil samples from Picual cultivar presented free acidity values ranged between 0.31 ± 0.02 to $0.17 \pm 0.01\%$ in green and ripe stages, respectively. Usually, olives at a later stage of ripening originate oils with higher levels of acidity due to a progressive enzymatic activity, especially by lipolytic enzymes, and are more sensitive to pathogenic infections and mechanical damage [28]. This increase has been observed for Cobrançosa and Galega cultivars, but not for Picual olive oils that revealed a significant decrease of free fatty acids during maturation, in agreement with previously reported data by Garcia et al. (1996) [29].

3.2. Raman spectra of olive oil

Representative Raman spectral data in the range of 950 and 1800 cm^{-1} together with its 1st and 2nd derivatives are shown in Fig. 1 for EVOO from cv Cobrançosa in three maturation stages.

The Raman spectrum includes bands that can provide information on biochemical changes occurring during the maturation of olives used to produce the olive oils [19]. Some of these bands are displayed in the aforementioned region and correspond to the peaks: at 1749 cm^{-1}, associated to the ester stretching mode υ (C=O), at 1651 cm^{-1}, due to stretching mode υ (C=C) of the cis double bond, at 1439 cm^{-1} and 1303 cm^{-1}, assigned to the methylene (CH_2) scissoring and twisting deformations, respectively, and at around 1267 cm^{-1}, related to the scissoring deformation in the cis unsaturated moiety δ (=C-H) [30]. These bands are assigned to fatty acids, both free and in triacylglycerols, therefore, being directly related to the fatty acid content of each sample. It must be mentioned that the band at 1267 cm^{-1} is very week under 488 nm excitation. This band has been pointed out by Baeten [30], and more recently by Machado [31], which related its intensity loss to the degradation of the *cis*-unsaturated moiety, occurring during the peroxidation process, therefore, being proposed for monitoring the oxidation status.

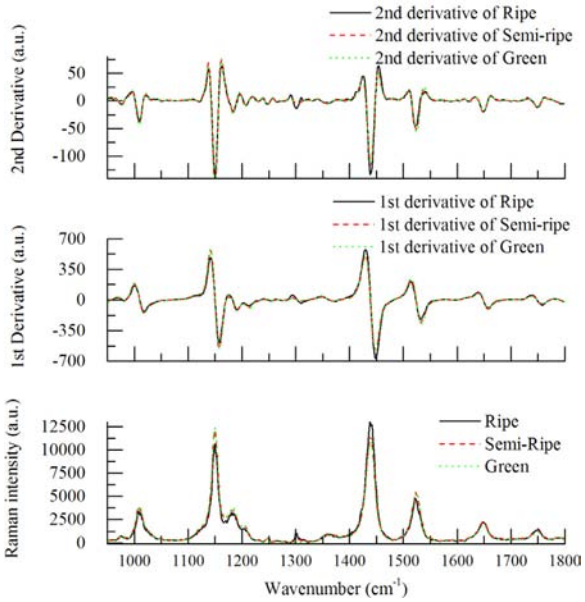

Fig. 1. Raman spectra between 950 and 1800 cm^{-1} of extra virgin olive oil from cv Cobrançosa in three maturation stages together with its 1st and 2nd derivatives.

Regarding the spectral changes due to compositional differences, there are three more bands to be pointed at around 1009 cm^{-1}, 1150 cm^{-1} and 1523 cm^{-1}, attributed to carotenoids, and assigned to the (C-CH_3) deformation, υ (C-C) and υ (C=C) mode, respectively [32]. These compounds are natural antioxidants, responsible for different characteristics of distinct EVOO's, and their quantity changes during the maturation process [19]. Their bands are not observed in investigations using laser excitation wavelengths within the Infrared range (*e.g.* 785, 1064 nm), however, they became visible under shorter excitation wavelengths, such as the 488 nm laser line presently used. Therefore, short wavelength excitation improves differentiation between olive oils produced using distinct cultivars, in different maturation stages. Similar results were reported in El-Abassy et al. (2009) using 514.5 nm excitation [14].

3.3. Supervised olive oil maturation monitoring using Raman spectral data

3.3.1. Preliminary analysis of the spectral data set

Standardized (SNV) Raman spectral data collected between 950 and 1800 cm^{-1} of the 64 spectra (8 spectra for each maturation stage, resulting in 24 spectra from Olive cv Cobrançosa and Galega, in three maturation stages, and 16 from Picual cv in two maturation stages) were subjected to PCA. It was found that the variance of the data set, based in 425 original variables (wavenumbers), is described by 47 principal components but 95% of the total variance is explained by the first 11 principal components.

In statistics, communality is defined as the sum of the squared factor loadings for all factors for a given original variable. It is the variance in that variable accounted for by all the factors. In other words, the communality measures the percentage of variance in a given variable explained by all the factors jointly and may be interpreted as the consistency of the indicator [33]. By definition, the initial value of the communality in PCA is 1. Small communalities values after extraction indicate variables that do not fit well the factor solution and should be dropped from the analysis [34]. According to Stevens (2002), a lower limit of 0.6 should be used [35].

Wavenumbers (variables) for which the communality value of each principal components out of the eleven was higher or equal to 0.6 were considered as meaningfully explaining the variance of the spectral data set and then were considered as prospective wavenumbers associated with the biochemical changes happening during maturation of olives used to produce the olive oil samples. These wavenumbers are in agreement with the above mentioned bands related to compositional differences, and belong to the following intervals: 997 to 1023 cm^{-1}, 1139 to 1161 cm^{-1}, 1295 to 1309 cm^{-1}, 1425 to 1455 cm^{-1}, 1511 to 1537 cm^{-1}, 1631 to 1665 cm^{-1} and 1737 to 1761 cm^{-1}. This new set of 86 variables, each one corresponding to a Raman intensity, collected from the above-mentioned intervals (one registered for each 2 cm^{-1}), was then selected for additional analyses. The band at 1267 cm^{-1}, used by other authors, has been left out after this selection procedure of intervals for DA. This is probably due to the low intensity of this band, under the presently used excitation of 488 nm, which led its variation to be insignificant for this analysis.

A new PCA performed on this reduced spectral data set showed that 89% of the variance could be explained by five principal components. These variables were then subjected to a discriminant analysis based on the known membership (maturation stage) of each sample analyzed, constituting the dependent variable.

The observation diagram represented in 2 is defined by discriminant factors F1 and F2, which explained the total variance. The cultivars of green ripening stage are in the lower left side of the plot, with exception of Picual, placed near the center. EVOO's

of Cobrançosa and Galega cultivars in semi-ripe stage are mostly located in positive part of F2 axis and negative part of F1 axis. EVOO' samples in ripe stage are located in the right side of the F1/F2 plane. The classification in Table 3, resulting from the discriminant analysis, provided 96.5% correct classification for the calibration set and 81.9% correct classification when cross-validated. A high degree of correct classification (91.7%) is achieved for ripe EVOO, as opposed to the semi-ripe group that has 25% probability of being classified as green. Thus, though not being suitable for the discrimination between green and semi-ripe EVOO's, discriminant analysis allows the possibility to distinguish EVOO samples obtained from ripe fruits.

3.3.2. PCR and PLS-R models for prediction of peroxide value and free acidity

PLS-R and PCR calibration models were carried out in order to determine a relationship between predictor variables (Raman scattering intensities) and the chemical characteristics of olive oils referred above. Specifically, the main goal was to develop a model able to predict the peroxide value and free acidity, considering the high relevance these parameters for consumers of EVOO.

Actually, as the olive oil Raman spectrum contains contributions from different species, each observable band might either correspond to a specific component, or to a sum of different contributions (bands) arising from distinct chemical systems. Thus, Raman is suitable for the assessment of these chemical parameters – peroxide value and free acidity – due to the different contributions of the samples' constituents, which vary, and also to the chemical modifications related to these parameters, which are reflected in the behavior of certain bands. For instance, some Raman signs are specifically related to the peroxide value, such as the vibrational modes due to the conjugated (C=C-C=C) system formed due to the peroxidation process (stretching ~1660 cm^{-1}),

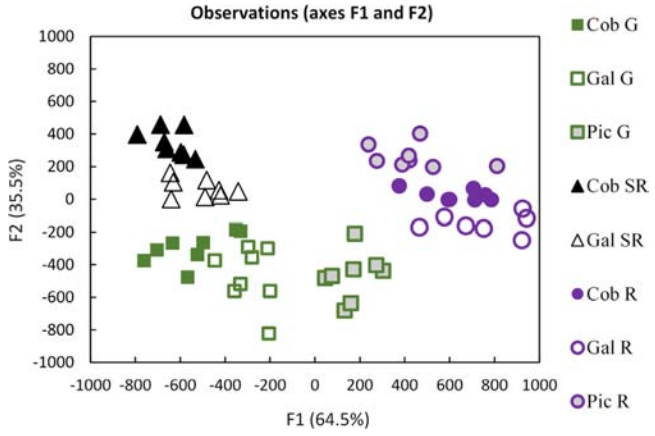

Fig. 2. Observations diagram from a principal component analysis of extra virgin olive oil samples from cv's Cobrançosa, Galega and Picual in three maturation stages, using the normalized (SNV) Raman spectral data.

or the loss of intensity in bands corresponding to the intact fatty acids, such as the band at 1267 cm^{-1} [30,31].

Furthermore, triacylglycerides represent different chemical systems, respecting free fatty acids or glycerol molecules. For example, the band at 1749 cm^{-1}, is raised by the carbonyl ν (C=O) mode, either from the free fatty acids (carboxylic group), or from the triglyceride bonded fatty acids (ester group), displaying slightly different frequencies. Thus, the shape of this band, and Raman features on the corresponding interval (1737–1761 cm^{-1}), retrieve information on the free acidity. Moreover, fatty acids might undergo structural changes when inserted in a triglyceride, these conformational changes are reflected in the frequency of the ν(C=C) mode [36]. Therefore, the band at 1651 cm^{-1}, corresponding to the ν(C=C) modes of the fatty acids, arises as meaningful for the assessment of free acidity. Additionally, in our case, the three bands of carotenoids (1009, 1150 and 1523 cm^{-1}), whose intensities are known to be inversely proportional to the FFA content [14], can be detected. Therefore, there is a rational relationship between Raman obtained data, and these chemical parameters, both free acidity and peroxide value, thus, this spectroscopic technique displays the potential for their assessment.

PLS regression method is able to collect information from large spectral intervals, correlating changes therein to the concentration of specific constituents, and concomitantly consider other possible contributions to these changes not related to the sample constitution [37]. On the other way, in PCR method the spectral and concentration information are incorporated into the model in one step [38].

The results achieved for the PLS-R and PCR calibrations of peroxide value and free acidity in terms of R^2, RMSEC and RMSECV, either for normal spectra, from 950 to 1800 cm^{-1}, and its 1st and 2nd derivatives are presented in Table 4. The high value of R^2 and the lowest of RMSEC and RMSECV indicate the good performance and precision of the models. Furthermore, to obtain a good calibration model, the number of regression factors used should be the lowest as possible [39]. The plot of the measured concentrations of the chemical parameters against the predicted values based on Raman scattering intensities reveals the quality of the models. To illustrate the quality of the models established in this work, PLS-R calibrations are presented in Fig. 3a) and b).

Moreover, though some authors undertook previous works resorting to spectral intervals bellow 1600 cm^{-1} [14], the usefulness of the bands in the 1600–1800 cm^{-1} interval, which reached a relative intensity high enough for its variations to be considered in the model, has been observed in the present study, also Korifi has previously considered these bands, in a study conducted with the 532 nm excitation [20] Therefore, it can be elated that, besides the enhanced intensity of these bands, the improved sensitivity due to the use of a lower excitation wavelength, allows the retrieval of useful information from the shape of these bands, which are raised by contributions from different chemical systems.

For both chemical parameters under analysis, the multivariate calibrations showed, in general, the highest value of R^2 and the lowest of RMSECV when using the 1st derivative of the spectral

Table 3

RMSE of Peroxide value in meq O_2/kg; RMSE value of Acidity in %.

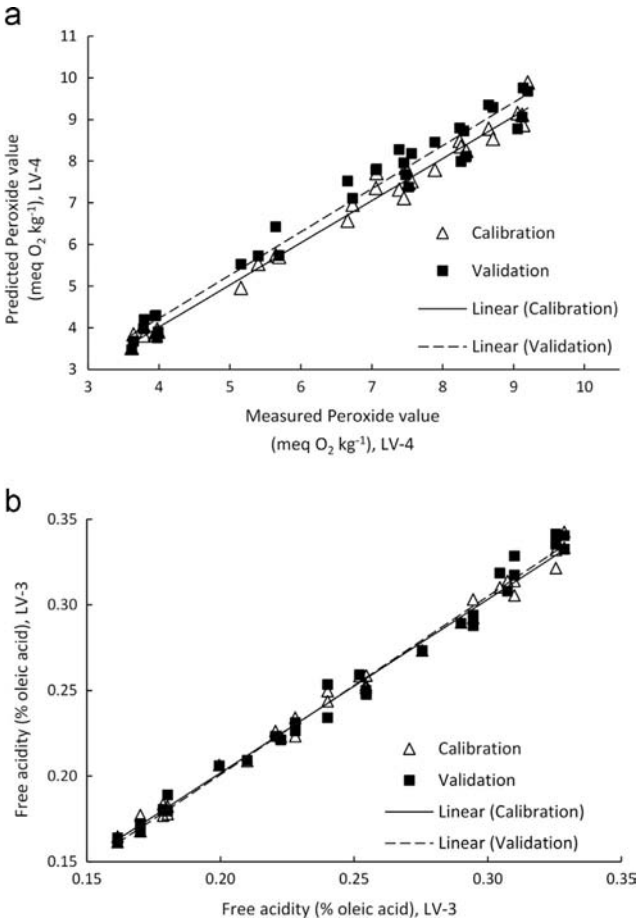

Fig. 3. PLS-R calibration models for the relationship between measured values and Raman predicted values of: a) peroxide values and of b) free acidity of olive oil.

data. In general, PLS-R offers enhanced results compared to others regression methods, such as PCR [40] or multiple linear regression (MLR) for quantitative analysis of chemical parameters [23]. In our study, despite both calibration models presented good prediction values, it was also PLS-R method that showed the best results, displaying good performances for both the prediction of peroxide value, and free acidity.

The relationship between measured values of the chemical parameters predicted values based on Raman scattering intensities showed R^2 values ranging from 0.937 to 0.994 using the calibration set and from 0.933 to 0.990 when cross validated. The RMSECV were as low as 0.72 meq O_2/kg for the peroxide value, when using the 1st derivative and a PLS model with 4 factors. However, a slightly higher value of 0.77 meq O_2/kg was attained for a simpler 3 factor PCR model. For the free acidity the lowest RMSECV value was 0.02% attained for both PCR and PLS-R models, the latter being simpler (3 factors) than the former.

4. Conclusion

In the present work, Raman spectroscopy, alongside with multivariate analysis methods, has been successfully used, in order to monitor free acidity and peroxide values in EVOO's, as well as to distinguish ripe from non-ripe oils. Since each Raman spectrum is constituted of several different contributions, arising from distinct constituents, these unique Raman features, corresponding to each species, render a possibility to the assessment of the samples' content through this methodology.

Furthermore, the use of a short wavelength excitation, 488 nm, allowed, not only, to observe bands due to carotenoids, which are important for these assessments, but also to register good quality spectra, so as to retrieve information from bands raised by distinct constituents.

In order to correlate the Raman spectra with the quality parameters assessed, as well as to evaluate the best approach to do so, the present work has been conducted with resort to two distinct approaches, PCR and PLS-R. Both have shown good results, and best performance when applied to the first derivative of the spectra, for the prediction of either peroxide value, or free acidity. In the latter case both approaches, PCR and PLS-R, retrieve similar results, presenting R^2 values of 0.990 and 0.988, respectively, and equal errors for cross-validation. In the case of peroxide value, PLS-R displays somewhat lower errors of validation in comparison to PCR (0.72 *vs* 0.77 meq O_2/kg) therefore, the former being proposed as the most suitable for these determinations.

Additionally, Raman shows some advantages over Infrared technique, which are exploited by the advent of the Raman portable devices, bringing the hot prospect of the *in situ* monitoring of these quality parameters. Therefore, this methodology represents an important trend, respecting the assessment of these quality parameters in field.

ABSTRACT

A new innovative analytical method combining ultra-fast analysis time with high resolution/accurate mass detection was developed to eliminate the misidentification of anatoxin-a (ANA-a), a cyanobacterial toxin, from the natural amino acid phenylalanine (PHE). This was achieved by using the laser diode thermal desorption–atmospheric pressure chemical ionization (LDTD–APCI) coupled to the Q-Exactive, a high resolution/accurate mass spectrometer (HRMS). This novel combination, the LDTD–APCI–HRMS, allowed for an ultra-fast analysis time (< 15 s/sample). A comparison of two different acquisition modes (full scan and targeted ion fragmentation) was made to determine the most rigorous analytical method using the LDTD–APCI interface. Method development focused toward selectivity and sensitivity improvement to reduce the possibility of false positives and to lower detection limits. The Q-Exactive mass spectrometer operates with resolving powers between 17 500 and 140 000 FWHM (m/z 200). Nevertheless, a resolution of 17 500 FWHM is enough to dissociate ANA-a and PHE signals. Mass accuracy was satisfactory with values below 1 ppm reaching precision to the fourth decimal. Internal calibration with standard addition was achieved with the isotopically-labeled (D_5) phenylalanine with good linearity ($R^2 > 0.999$). Enhancement of signal to noise ratios relative to a standard triple-quadrupole method was demonstrated with lower detection and quantification limit values of 0.2 and 0.6 μg/L using the Q-Exactive. Accuracy and interday/intraday relative standard deviations were below 15%. The new method was applied to 8 different lake water samples with signs of cyanobacterial blooms. This work demonstrates the possibility of using an ultra-fast LDTD–APCI sample introduction system with an HRMS hybrid instrument for quantitative purposes with high selectivity in complex environmental matrices.

1. Introduction

Cyanotoxins are produced by cyanobacteria, commonly known as blue–green algae. They are naturally encountered in natural waters after the proliferation of a cyanobacterial bloom favored in eutrophic and hypertrophic water [1,2]. The principal families, with their most studied toxins, are the hepatotoxins (microcystins, nodularins, cylindrospermopsin), the neurotoxins (anatoxin-a, anatoxin-a(s), homoanatoxin-a, saxitoxins, BMAA), the cytotoxins (aplysiatoxin, debromoaplysiatoxin, lyngbyatoxin, cylindrospermopsin) and the endotoxins (lipopolysaccharides) [3,4]. Among the neurotoxins, anatoxin-a (ANA-a) has a vast distribution with 10 cyanobacteria genera responsible for their production—*Anabaena*, *Aphanizomenon*, *Arthrospira*, *Cylindrospermum*, *Microcystis*, *Nostoc*, *Planktothrix* (*Oscillatoria*), *Phormidium* and *Raphidiopsis* [1]. Our main target cyanotoxin, ANA-a, is an alkaloid compound (p*K*a 9.4, M.W. = 165.24 g/mol), stable under acidic conditions (pH = 2) but degradable under natural conditions at high pH and in contact with sunlight. Degradation products include the non-toxic metabolites dihydroanatoxin-a and epoxyanatoxin-a [2,5]. ANA-a is a potent neuromuscular blocking agent with a high toxicity (LD_{50}) of 200–250 μg/kg for mouse, causing irreversible inhibition of the acetylcholinesterase activity and accumulation of acetylcholine in

the neuromuscular junctions. High doses of ingested ANA-a can cause continuous stimulation of the respiratory muscles, leading to asphyxiation [6]. Several animal mortality have been regularly attributed to ANA-a for cattle, wildlife, and pets, and some documented confirmations have also been published [7,8]. Although the World Health Organisation (WHO) has not established guidelines for ANA-a concentrations in drinking and recreational waters, several jurisdictions have implemented such guidelines into their risk management of this neurotoxin. To date, Canada and New Zealand tolerate concentrations below 3.7 μg/L and 6 μg/L respectively in drinking water. In addition, three U.S. states, California, Oregon and Washington, tolerate concentrations from 1 μg/L for drinking water and as high as 100 μg/L for recreational waters [9]. Lower amount of ANA-a are produced in natural blooms compared to other cyanotoxins (e.g. microcystins), but due its non-negligible toxicity, it is important to assess the presence of the toxin in drinking and recreational waters for public and animal safety [4,10].

Most of the techniques developed for the detection of ANA-a are based on liquid chromatography coupled with tandem mass spectrometry (LC–MS/MS) [4,10–12]. Spectroscopic detection methods are avoided mainly for the lack of sensitivity due to the instability of ANA-a in contact with UV light and the impossibility to detect the degradation products [11–14]. Therefore, mass spectrometric detection following a chromatographic separation gives higher accuracy, sensitivity as well as selectivity. Unfortunately, phenylalanine (PHE), an essential amino acid present in natural waters, is an isobaric interference of ANA-a and they cannot be resolved by using a triple-quadrupole mass spectrometer [15]. Indeed, given their similar molecular masses and identical fragmentation prior to mass spectrometric detection, their similar liquid chromatography (LC) retention time can potentially lead to the misidentification of ANA-a. Different LC strategies have been proposed to achieve sufficient separation of ANA-a and PHE, but further work is needed since the required analyses are long and costly [13,16–18]. The use of high resolution mass spectrometry (HRMS) for cyanotoxins was presented for the first time by James et al. [19]. with the study of the fragmentation pathways of ANA-a, using a hybrid quadrupole time-of-flight mass spectrometer (QqTOF-MS) and a quadrupole ion-trap mass spectrometer (QIT-MS). According to the mass difference of ANA-a and PHE, a resolution of 4500 FWHM (full width at half maximum) is needed to achieve a mass separation to 10% valley. These instruments have sufficient resolving power to distinguish the signals compared to the minimal resolution needed [20]. Given the different MS instruments and hybrids, the use of HRMS becomes interesting to reduce the presence of false positives due to isobaric interferences and improve the selectivity of ANA-a detection.

Previously, a technique was proposed using laser diode thermal desorption–atmospheric pressure chemical ionization-tandem mass spectrometry (LDTD–APCI-MS/MS) for the analysis of ANA-a in natural waters [21]. The LDTD is a sample introduction apparatus using thermal desorption prior to atmospheric pressure ionization that significantly reduces the analysis time by eliminating the liquid chromatography step. The analytical approach requires a simple sample preparation method by eliminating the time consuming extraction procedures normally required for ANA-a and it is combined with the LDTD–APCI prior to MS detection allowing for an analysis time of 15 s/sample [1,22]. This analytical pathway gave a robust alternative for the high throughput analysis of ANA-a in water containing cyanobacterial blooms. However, the isobaric interference, PHE, was an issue since there is no chromatographic separation before ionization. The problem was solved by the use of a pseudo-separation of both compounds using the LDTD laser power, given that the desorption of ANA-a takes place at a temperature lower than PHE [21].

In order to resolve the PHE interference, a new approach is proposed, the LDTD–APCI–HRMS. It couples the LDTD interface with a high-resolution and accurate-mass (HR/AM) detection using a benchtop Orbitrap mass spectrometer, the Q-Exactive. The Orbitrap is combined to a high-performance quadrupole precursor selection and a higher energy collisional dissociation (HCD) cell, thereby giving a powerful tool for the screening of various compounds in environmental matrices. Moreover, the use of an S-lens increases the ion flux through the quadrupole, improving sensitivity and signal intensity [23]. Various HRMS mass spectrometers are known to be alternatives to triple quadrupole instruments with slightly higher instrument costs [20]. Time of flight (TOF) and QTOF have similar resolving power, up to 40 000 FWHM offering a mass accuracy lower than 5 ppm. On the other hand, Orbitrap and LTQ-Orbitrap instruments have better performances with resolving power up to 70 000 FWHM with mass accuracy lower than 2 ppm [20,24–26]. Compared to other Orbitrap mass spectrometers, the performances of the Q-Exactive are slightly better with resolving power up to 140 000 FWHM and mass accuracy <3 ppm with external mass calibration and <1 ppm with internal mass calibration (use of a lock mass) [27]. Furthermore, the main advantage of the Q-Exactive hybrid resides in the quadrupole mass filter combined with a HCD cell offering the possibility of precursor ion fragmentations analogous to an MS/MS mass spectrometer, thus giving a high specificity in ion selection [28]. The Q-Exactive was previously used for peptides sequencing, metabolomics and relatively few studies explored the possibility of quantifying small molecules in environmental matrices [28–30]. The aim of this study was to develop and validate a new analytical method for the ANA-a detection in lake water using a novel instrument combination, the LDTD–APCI–HRMS, in order to resolve the isobaric interference from phenylalanine. The possibility to couple the LDTD as a sample introduction prior to detection with the Q-Exactive instrument for higher sensitivity and selectivity is demonstrated. The sensitivity and selectivity of two different detection modes, full scan (FS) and targeted ion fragmentation (t-MS^2) are evaluated with the use of LDTD–APCI for an environmental water matrix. Several HRMS parameters were optimized to enhance mass resolution and accuracy, duty cycle and signal intensity. The method validation is done with the use of deuterated phenylalanine (PHE-D_5) as an internal standard. Under these conditions, the method detection limit and quantification limit (MDL and MQL), linear dynamic range, accuracy, precision and matrix effect were determined. The method was applied to real freshwater samples with cyanobacterial blooms and proved to be suitable for ANA-a detection in presence of PHE with a lower MDL relative to the previously developed analytical method using a triple-quadrupole MS instrument [21].

2. Materials and methods

2.1. Chemicals and reagents

(±)-Anatoxin-a/furamate salt standard, 99%, was purchased from Abcam Biochemicals (Cambridge, MA, USA). DL-Phenylalanine standard, 99%, was obtained from Sigma-Aldrich Chemical Co. (Oakville, ON, Canada). DL-Phenylalanine (Ring-D_5) standard, 98%, was obtained from Cambridge Isotope Laboratories, Inc. (Andover, MA, USA). Sodium hydroxide, 97%, and formic acid, 95%, were purchased from Sigma-Aldrich Chemical Co. (Oakville, ON, Canada). Methanol (MeOH) was of analytical grade purity from Fisher Scientific (Whitby, ON, Canada). Deionized/distilled water (dd-H_2O) was used for dilution. Compressed air (Ultra Zero Certified grade; ≤ 2 ppm water) used as carrier gas was purchased from MEGS Specialty Gases, Inc. (St-Laurent, QC, Canada).

2.2. Stock solution and cyanobacterial bloom samples

The solutions were prepared and stored according to previous protocol with modifications [21]. Stock standard solutions of ANA-a/furamate salt (100 mg/L) were prepared with acidified water (0.1 M formic acid, pH~2) and were stored at −20 °C for a maximum of 4 months. A 100 mg/L stock solution of DL-PHE was prepared daily in dd-H_2O. The DL-PHE-D_5 (100 mg/L) stock solution was prepared in dd-H_2O and was stored at −20 °C for a maximum of one month [17]. All working solutions were prepared daily in dd-H_2O with pH adjusted to 2 with formic acid and diluted in MeOH (50:50 v/v). Environmental samples were provided by the monitoring program realized by the *Ministère du Développement Durable, de l'Environnement, et de lutte aux changements climatiques,* (MDDELCC—The province of Quebec Ministry of the Environment) (Québec, Canada). All targeted lakes were chosen for their high occurrence of cyanobacterial blooms in different regions from the province of Québec, Canada. ANA-a was previously quantified by LC–MS/MS by the Centre d'Expertise en Analyse Environnementale du Québec (CEAEQ), the analytical services of the MDDELCC. The samples were acidified for preservation (0.1 M formic acid, pH~2) and then submitted to a freeze-thaw lysis three times to break the cells walls and leach the toxin, followed by a filtration using 0.45 μm nitrocellulose membrane obtained from Whatman (Florham Park, NJ, USA). The solutions were then prepared the same way as for the working solutions.

2.3. LDTD–APCI parameters

The desorption and ionisation of ANA-a, PHE and PHE-D_5 were performed using the T-960 LDTD–APCI ionization interface model and the instrument was controlled by LazSoft 4.0 software (Phytronix Technologies, Québec, QC, Canada) integrated with the Excalibur 2.2 Software (Thermo Fisher Scientific, Waltham, MA, USA). The LDTD apparatus was described in previous work [21,22,31,35]. Briefly, 2 μL of sample is spotted into a LazWell 96-well sample metal plate. After complete solvent drying at 40 °C (about 5 min), the back of the sample well is heated by an infrared laser (980 nm, 20 W, continuous) in the LDTD instrument. After the sample desorption, a carrier gas flow (2 L/min), set at 50 °C to avoid temperature variation, transfers the gas phase molecules to positive APCI ionisation followed by the MS detection. In previous work, we used lower laser power for a pseudo-separation of ANA-a and PHE since the amino acid desorption is substantially decreased with a lower temperature compared to the targeted toxin [21]. In this study, a higher temperature is needed to desorb both compounds since the internal standard is the amino acid PHE labeled with deuterium (PHE-D_5). In this manner, tests of different laser powers, from 10 to 60%, were performed by spiking 250 μg/L of ANA-a and 200 μg/L of PHE-D_5 in blank water matrix from a lake sample ($n=6$). The laser pattern was optimized to the following settings: 2 s at 0%, 1 s ramping from 0% to 45%, 2 s hold at 45%, 0.1 s from 45% to 0% and 2 s hold at 0%, with a total desorption time of 7 s/sample. APCI ionization in positive mode is within these parameters: ion sweep gas 0.3, sheath gas, auxiliary gas and skimmer offset are set to 0 (all arbitrary values), vaporizer temperature 0 °C and capillary temperature 350 °C.

3. HRMS parameters

Detection of compounds was performed using a Q-Exactive mass spectrometer controlled by the Excalibur 2.2 Software (Thermo Fisher Scientific, Waltham, MA, USA). Instrument calibration in positive mode was done within 24 h to avoid mass shifts in detection with a direct infusion of a LTQ Velos ESI Positive Ion Calibration Solution (Pierce Biotechnology Inc. Rockford, IL, USA.). All the Q-Exactive parameters were optimized toward mass resolution and accuracy for better quantification, sensitivity and selectivity. The different optimization tests were performed by spiking 250 μg/L of ANA-a and 200 μg/L of PHE-D_5 in blank water matrix from a lake sample ($n=6$). Full scan (FS) and targeted MS/MS (t-MS^2) modes were optimized and compared to determine which was best suited for LDTD analysis in environmental water matrices. A lock mass (m/z 155.1185—$C_8H_{14}N_2O$) was chosen from matrix background as internal standard for mass accuracy enhancement during spectral data acquisition. The mass range of FS mode was within m/z 100–200. The data were acquired at a resolving power of 35 000 FWHM at m/z 200. The automatic gain control (AGC) target for a maximum capacity in C-trap was set at 3×10^6 ions for a maximum injection time of 100 ms. As for t-MS^2, a mass inclusion list has to be used including the precursor ion masses and their expected retention time and a time of 0.2 min was set as the total analysis time. The precursor ions are filtered by the quadrupole which operates at an isolation width of 0.4 amu. A resolving power of 17 500 FWHM at m/z 200 was used. The AGC target was set at 10^5 ions for a maximum injection time of 50 ms. All optimized collision energies, precursor ions and fragment ions are shown in Table 1.

3.1. Data analysis and method validation

All data treatment was performed using the Excalibur 2.2 Software (Thermo Fisher Scientific, Waltham, MA, USA). The method validation was done according to the recommendation of validation protocol for environmental chemistry analysis from the Québec's MDDELCC guidelines [32]. The second most abundant observed ion was used as confirmation ion for each target compounds in both

Table 1
Parameters of HRMS detection.

detection modes (FS and t-MS^2) and the isotopic ratio was confirmed with $<10\%$ of intensity variations (Table 1). Two fragment ions, with the highest signal intensity, were selected as quantification and confirmation ions (Table 1) and the relative intensities of their ratios were used for confirmation of the targeted compounds and to avoid false positives. The quantification ion, with the highest signal intensity, was used to establish the limits of detection and quantification. Mass scale stability was assessed by measuring the mass measurement accuracy of each ion (precursors and fragments) for each concentration level of the linear dynamic range of the calibration. Mass accuracy stability of measurements over time was evaluated in FS mode for ANA-a (250 μg/L) over a month for a total of 120 acquisitions. Selectivity was improved with the optimization of the extracted masses from acquisition data, and the mass tolerance was set to 5 ppm ($\pm$2.5 ppm). The masses were selected at three points of a LDTD peak for a target compound, two at the extremities and one at the top. Each concentration level of the internal calibration was analyzed in triplicates using standard addition (ranging from 0.5 to 1000 μg/L). Seven-point calibration curves were prepared with blank bloom water matrices for validation. The concentration of internal standard PHE-D_5, (200 μg/L), was selected for its capacity to correct the signal variation of ANA-a with three different concentrations on the calibration curve, 1, 50 and 750 μg/L (data not shown). Method detection limit (MDL) and method quantification limit (MQL) were established by calculating 3 and 10 times respectively the standard deviation of the mean value of 6 spiked blank matrix samples ($n=6$) containing approximately 5 times the estimated concentration for detection limit (1 μg/L). Accuracy, interday/intraday variations, and matrix effects were determined with three different concentrations on the linearity range (1, 50 and 750 μg/L, $n=6$) in blank relevant matrix. Intraday repeatability was estimated over six weeks. Accuracy values were determined by the relative error (%) and precision values were defined as the relative standard deviation (%). The matrix effect was determined by comparing spiked blank relevant matrix with spiked pure solvent samples and the ratios gave the signal recovery and were expressed as percentage.

All validation parameters were determined for both scan modes (FS and t-MS^2) for performance comparison. Statistical comparison was used when needed with the Statistical Package for Social Science (SPSS 21.0, Chicago, IL) for Windows. ANOVA test and Tukey's post hoc tests were used with statistical significance defined as $P<0.05$.

4. Results and discussion

4.1. Solutions pH and LDTD laser pattern optimization

The pH of the working solutions was optimized to consider the presence of PHE-D_5 with ANA-a in the samples and therefore increase signal intensity. The p*K*a of ANA-a is 9.4 and the p*K*a's of PHE, are 2.18 and 9.09 [33,34]. The effect of the pH on signal intensity was studied between pH 2 and 13. As shown in Supplementary materials Fig. A-1, it is found that above neutral pH, signal intensities decrease. First, for ANA-a, it is known that it is unstable in alkaline conditions and degrades into its metabolites [2]. Also, with a pH lower than 9.4, the global charge state is positive, which improves ionization stability and reproducibility prior to MS detection. As for PHE-D_5, considering both p*K*a values, its global charge becomes negative in alkaline conditions with pH higher than 9.1. Finally, the pH in the working solutions was adjusted to 2, for higher stability and to improve the storage conditions of ANA-a.

The LDTD parameters were previously optimized and discussed for ANA-a, including deposition solvent, carrier gas flow and laser pattern including laser power [21,22,35]. However, the LDTD laser power was selected in order to have a minimum desorption of PHE without affecting ANA-a. In the proposed method, there is no need to separate the two compounds with laser desorption since the isobaric masses are distinguished through high resolution mass detection. Furthermore, the internal standard PHE-D_5, has to be desorbed with the same amount of energy as PHE. Fig. 1 presents the new condition results with the same correlation of signal intensity with the laser power (%) of ANA-a and PHE compared to the first optimization [21]. For optimal desorption of both compounds, laser power was set at 45% since PHE-D_5 signal does not significantly increase above a laser power of 40% ($P>0.05$), but ANA-a signal significantly decreases for a laser power above 45% ($P<0.05$). The parameters were optimized to the following settings: 2 s at 0%, 1s ramping from 0% to 45%, 2 s hold at 45%, 0.1 s from 45% to 0% and 2 s hold at 0%, for a total desorption time of 7 s.

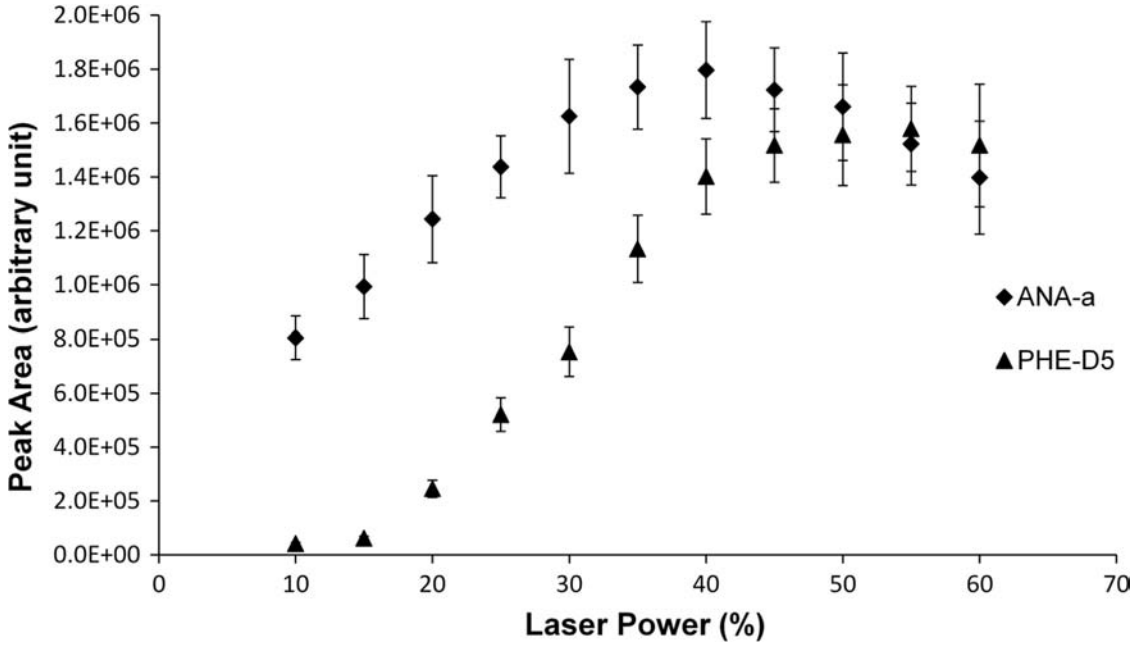

Fig. 1. Effect of LDTD laser power on average peak area of the target compound, ANA-a and PHE-D_5. Vertical error bars represent standard deviations from the mean ($n=6$).

A slightly shorter pattern was used for analysis without affecting the desorption step.

4.2. LDTD–APCI–HRMS parameters optimization

Signal intensity and selectivity are two major parameters when optimizing an analytical method in complex matrices with low concentrations of target analytes (μg/L to low ng/L). According to the European Commission, the confirmation criteria for MS/MS detection consists of using two different transitions for a precursor ion. For HRMS detection operated in full scan mode at a resolution higher than 10 000 FWHM, the second-most abundant ion in isotopic pattern must be distinctive with 10% of peak height [36]. The Q-Exactive is a two dimensional Orbitrap and it can thus enhance selectivity using both criteria, thereby reducing the possibility of false positives in complex analytical conditions [37]. The LDTD is a sample introduction technique which eliminates the separation step prior to detection in order to increase sample analysis time as well as sample throughput and there is no criteria given using this apparatus for analysis confirmation with a hybrid HRMS detector. Considering these, the following optimization of different HRMS parameters are presented in both FS and t-MS^2 scan modes to determine the optimal detection method using the LDTD–APCI coupled with the Q-Exactive mass spectrometer.

A lock mass is used in HRMS detection, for internal mass correction of the measured accurate mass. According to the manufacturer recommendations, external and internal mass calibrations (with and without lock mass) give mass accuracies of <1 ppm and <3 ppm, respectively, under defined conditions [27]. A lock mass is selected for its constant presence in samples and its signal must be stable throughout the analysis. Fig. A-2 presents the different lock masses used for mass correction and they were selected according to their detection in empty LDTD plate wells, pure solvent blanks and in the bloom water sample matrix background in FS mode (m/z 50–300), depending on their abundance and recurrence. The results show the distribution of mass shifts ($n=12$) of the precursor ion of ANA-a (m/z 166.1232) in FS mode including the maxima, minima, quartiles and median corrected with different lock mass target. Each exact masses used are presented with their corresponding molecular formula. Without the use of a lock mass in complex matrix, the mass shift of the target ion is higher than 3 ppm, however, m/z 131.1184, 155.1184 and 195.1487 make a significant correction to the accurate measured mass with mass shift lower than 3 ppm. The selected mass was m/z 155.1184 according to its capability to permit significant mass correction with mass shift lower than 1 ppm and with less mass variation (RSD $<15\%$) ($P<0.05$).

The Q-Exactive has the ability to temporarily trap the ions in the detector, unlike a triple quadrupole mass spectrometer which operates with a continuous path to the detection. For Orbitrap analyzers, the automatic gain control (AGC) is the total ion population injected and it has to be pre-defined as the AGC target. The injection time (IT) of the population to the detector will vary depending on the number of ions introduced to the mass analyzer. Therefore, the AGC target is selected to have a maximum of target ions travelling to the detector and which compete with the background molecules. Moreover, injection time will affect the duty cycle of the detection, which establishes the number of measurements essential for accurate quantification. A compromise between signal intensity and repeatability is made under specific conditions. For a FS scan, large amounts of background ions are analyzed with targeted compounds so the AGC target should be high enough to "trap" these ions and increase their signal intensity. As for the t-MS^2 scans, much fewer ions are transferred to the Orbitrap analyzer, since only targeted precursors are transferred to the C-trap and then fragmented [23,30]. Fig. A-3 presents the variation of signal intensity of ANA-a and PHE-D_5 for different AGC targets with different maximum ion time injections of both FS and t-MS^2 scan modes. The selected AGC targets were 3×10^6 ions for a maximum of 100 ms and 10^5 ions for a maximum of 50 ms, respectively. These results were selected in accordance with the previous explanations.

The main novelty of the Q-Exactive mass spectrometer compared to other Orbitrap analyzers is the use of a high-performance quadrupole precursor selection and a HCD cell which enables SIM and MS/MS experiments. The use of a precursor mass filter and fragmentation leads to great improvements of selectivity in complex matrices for a HRMS instrument. As for triple quadrupole mass analysis, two fragments were selected, one for quantification and one for confirmation. The optimized energies with their respective fragments are presented in Table 1.

The selectivity of HRMS analysis is principally determined by the resolving power (RP) and the mass tolerance (MT) [30,37]. First, using higher RP enables a better mass accuracy, thus a higher selectivity. Yet, increasing the RP decrease the number of acquisitions for an analysis due to duty cycles [37]. For quantitative measurements with acceptable RSDs, it is generally agreed that a LC peak must count at least seven acquisition points [23]. This notion is also considered for a LDTD acquisition peak. The LDTD desorption is faster than a usual elution time for a LC peak for a target compound. Therefore, the number of acquisition points in relation with RP was studied to yield the best compromise between selectivity and repeatability. The tested RP were between 17 500 and 140 000 FWHM (m/z 200) for both FS and t-MS^2 scan modes with results shown in Fig. 2. As previously explained, the number of acquisition points decreases with the increase of RP for both scan modes. Accordingly, due to a decrease of duty cycle for t-MS^2 analysis, less data is acquisitioned. With these criteria, the selected RP for FS scans was 35 000 FWHM (m/z 200) and 17 500 FWHM (m/z 200) for t-MS^2. Second, by narrowing the mass tolerance of a monitored ion in a mass extraction window, selectivity is greatly enhanced by reducing the presence of false positives. However, mass tolerance must consider the accuracy of a target mass given that minimizing a mass tolerance window can eliminate the presence of masses outside the established range. Fig. 3 presents the optimization of the mass tolerance for the mass extraction of the ANA-a quantification fragment in t-MS^2 mode. An adequate mass tolerance was chosen to be 5 ppm (±2.5 ppm), by comparing mass tolerances between 1 and 10 ppm. With mass windows smaller than 5 ppm, there is a mass distortion and there is no difference on the signal with a larger window. According to Kaufmann et al. [37], with FS scans using an Exactive mass spectrometer, the resolving power must be higher than 50 000 (m/z 200) with a MT of maximum 5 ppm for a comparable selectivity with conventional MS/MS experiments with SRM acquisitions. Unfortunately, the FS mode using the LDTD–APCI interface, in this case, does not permit quantitative analysis with resolving power higher than 35 000 FWHM (m/z 200) because of the limited amount of data points during the acquisition (the peak width is approximately 0.5 s). On the other hand, considering that the t-MS^2 scan mode can be compared to a traditional SRM experiment for its levels of ion selection, the use of a resolving power of 17 500 FWHM (m/z 200) with a MT of 5 ppm is more selective than FS acquisitions and should be more selective than a common SRM experiment considering the high mass discrimination.

4.3. Data analysis and method validation

To confirm the signal resolution of ANA-a and PHE, a FS data acquisition was recorded at 17 500 FWHM (m/z 200). The respective signal of ANA-a and PHE are presented at the left of the mass spectrum (Fig. 4) and they are complete separated. This is in accordance with the resolution needed (>4500 FWHM) to dissociate the two signals considering their difference in mass values.

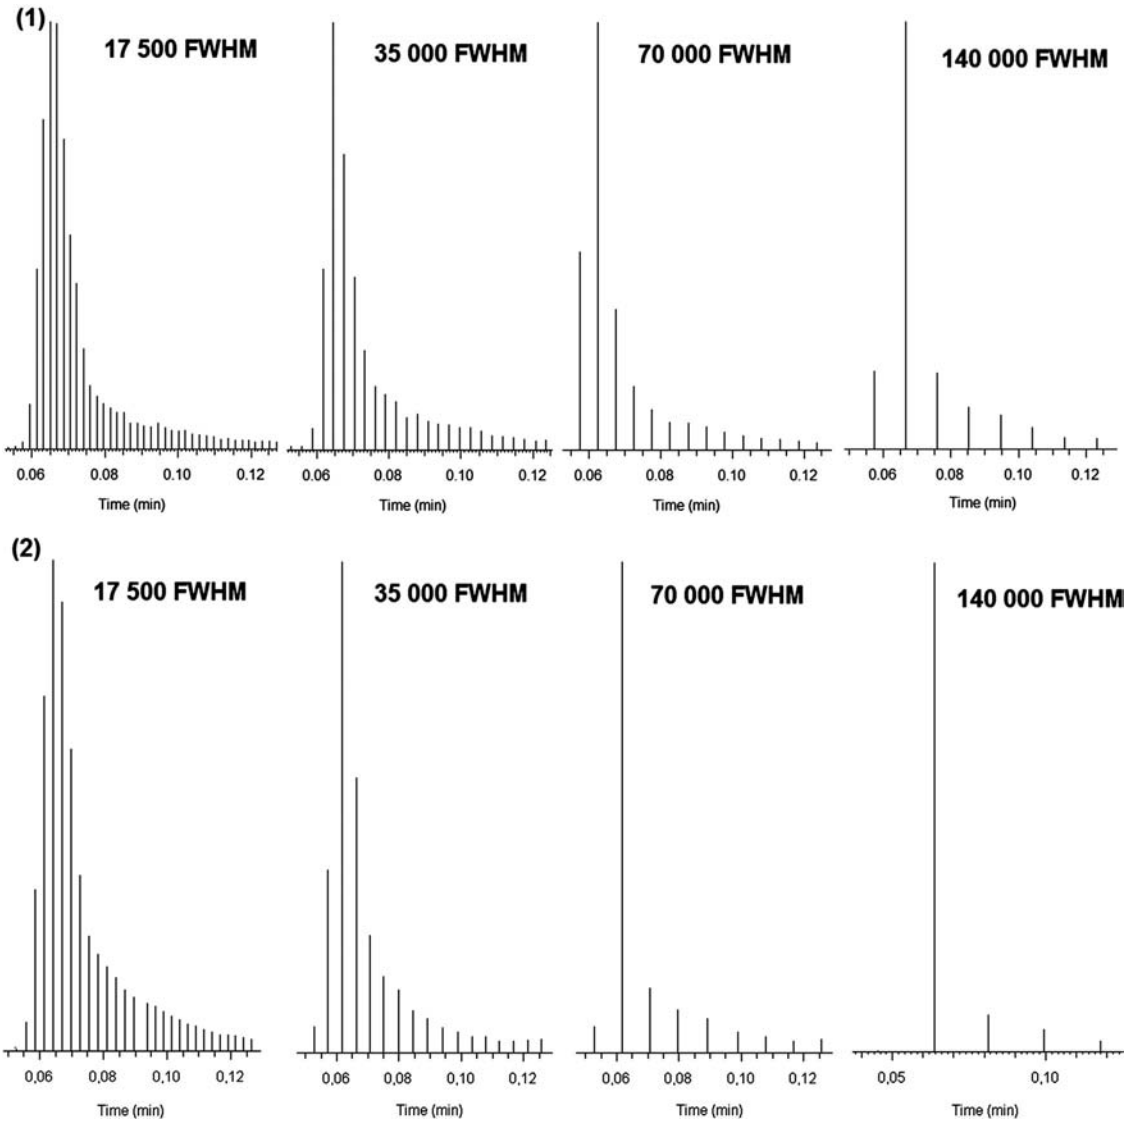

Fig. 2. Examples of the number of data acquisition for a LDTD peak of ANA-a with the different resolving powers scanned by (1) FS mode and (2) t-MS^2 mode.

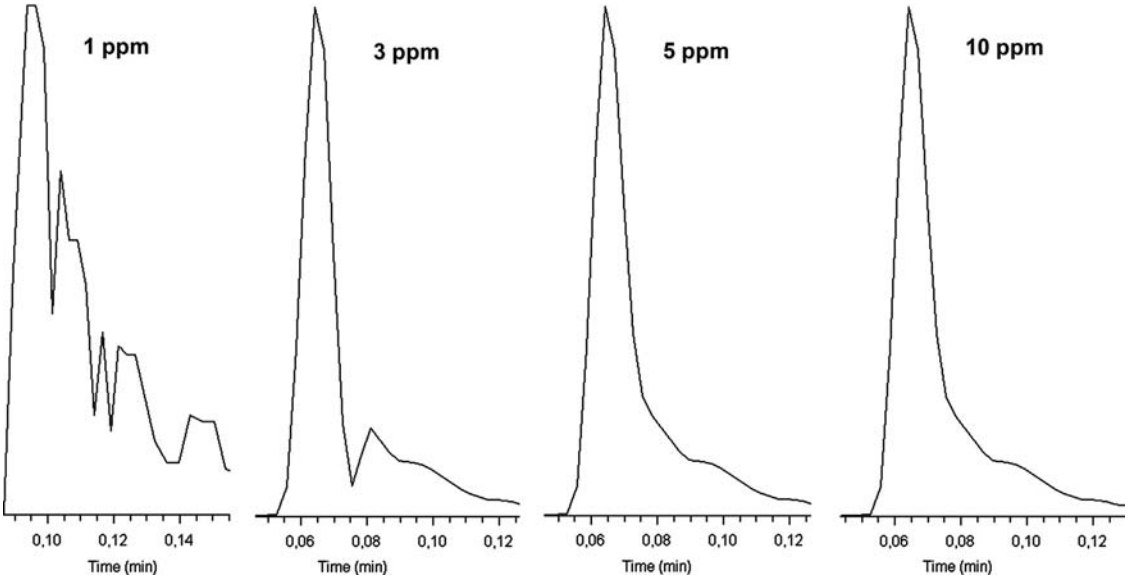

Fig. 3. Effect of different mass tolerances from the mass extraction of the ANA-a quantification fragment (m/z 149.0965) by t-MS^2 mode and impact on the LDTD peak shape distortion.

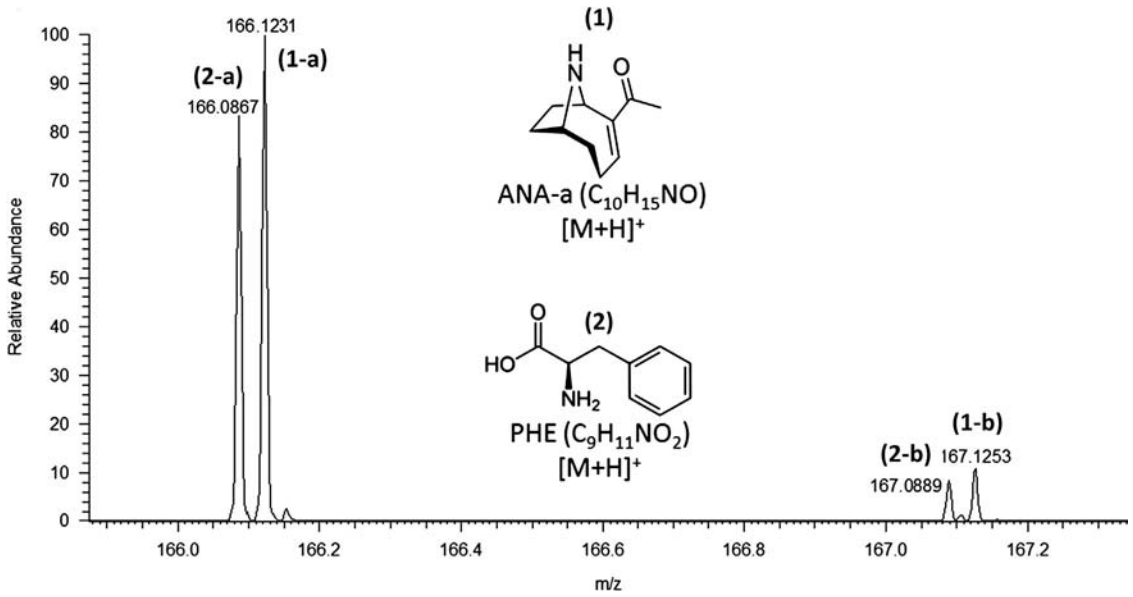

Fig. 4. Mass spectrum of (1) ANA-a and (2) PHE acquisitioned in FS scan mode with a resolving power of 17 500 FWHM (*m*/*z* 200). (1-a) and (2-a) are the resolved signals and (1-b) and (2-b) are the signals of the first characteristic isotopes of both compounds.

Table 2
Comparison of method validation parameters for experience modes (FS and t-MS^2).

Experience mode	R^2	Linearity range (μg/L)	MDL (μg/L)	MQL (μg/L)	Standard avg. RSD (%)
FS	0.998	1.5–1000	0.5	1.5	10
t-MS^2	0.999	0.5–1000	0.2	0.6	5

To the right, the characteristic isotopes of the two compounds appear with relative heights of approximately 10%. The use of isotopically-labeled phenylalanine (PHE-D_5) as internal standard was justified by the unavailability of isotopically-labeled ANA-a and by its structural analogy. Moreover, PHE-D_5 has also been successfully used as internal standard in previous work [17]. We used a seven-point internal calibration curve based on a standard addition by spiking ANA-a in blank relevant matrix with a linear dynamic range between 0.5 and 1000 μg/L analyzed in triplicates. The concentration of PHE-D_5 used in every measure is 200 μg/L and was optimised considering the lowest variability of signal ratio (ANA-a/ PHE-D_5) throughout the calibration curve (data not shown). Table 2 summarizes the validation parameters for the two experience modes. With the Q-Exactive operating in t-MS^2 (targeted ion fragmentation), the MDL and MQL (n=6) were lower than for the FS (full scan) mode with values of 0.2 and 0.6 μg/L compared to 0.5 and 1.5 μg/L. Overall, these results are an improvement compared to previous values obtained using a triple quadrupole mass spectrometer which ranged from 1 to 4 μg/L [21]. Accuracy, expressed as relative errors (RE—%), intraday/interday precisions, expressed as relative standard deviations (RSD—%) and matrix effect expressed as the percentage of signal recovery of replicate measurements (n=6), are summarized in Table 3 and were evaluated with three concentration levels from the calibration curve, 1, 50 and 750 μg/L in blank relevant matrix. Overall, the data showed similar accuracy for both scan modes at higher concentrations with ≤15% RE. However, at the lowest concentration, FS mode showed lower accuracy with >15% RE. The t-MS^2 experiment offered less measurement variability (≤10% RSD) compared to FS experiment (≤15% RSD). As for the signal recovery of ANA-a for FS mode at higher concentrations and for t-MS^2 mode for all concentrations, results showed no significant matrix effect in the analysis with values ranging from 96 to 108% with a precision <15%. However, at

Table 3
Parameters for FS and t-MS^2 detection by LDTD–APCI–HR/MS in positive ionization mode (PI)→$[M+H]^+$.

Experience mode	QC concentrations (μg/L)	Accuracy (RE %)	Intraday (RSD %)	Interday (RSD %)	Signal recovery from matrix effect (%)
FS	1	17	12	15	172
	50	13	10	12	108
	750	11	11	13	98
t-MS^2	1	9	9	8	102
	50	6	10	9	96
	750	8	8	7	98

the lowest concentration for FS mode, the signal recovery was 172% with a precision of 16% showing that significant signal enhancement due to matrix effect occurs at low concentrations with this scan mode. Two fragments ions of ANA-a were selected and their second most abundant isotope was monitored for ion confirmation to avoid false positives for HRMS analysis (Table 1). The mass accuracy for all ions monitored in HRMS is shown in Table 1 and the values were deemed acceptable (0.65–0.76 ppm) compared to instrument standard values for internal calibration with lock mass (<1 ppm). Mass scale stability is shown in Fig. A-4 and mass accuracy variation is stable with average mass accuracies of <0.8 ppm and RSD variation of <10%. The assessment of mass accuracy stability of measurements over time is shown on Fig. A-5 with 120 acquisitions. An average mass accuracy of <0.8 ppm with RSD variation of <15% over 4 weeks of analysis shows an acceptable stability of exact mass measurements. Finally, the developed method was tested on positive cyanobacterial bloom samples of 8 different lakes around the province of Québec, Canada, obtained during the proliferation season. The detection was done with the two optimized scan modes and the selectivity was evaluated by comparing the new quantification approaches with a parallel certified standard LC–MS/MS analysis performed by the CEAEQ (Table 4). Except for sample no 5, all concentrations were reported below our determined limits of detection (<0.1–0.01 μg/L). For the t-MS^2 analytical method, the only positive sample was no 5, with a concentration of 0.21 μg/L, which is similar to the value reported by the CEAEQ (<0.2 μg/L). Inversely, the FS method gives considerably higher concentration of ANA-a for samples no 1, 2,

5 and 7 with values ranging from 1.1 and 2.5 μg/L and these samples had the characteristic of being highly charged in green algae. The presented results clearly show the presence of false positives in the FS scan analysis and the lack of selectivity of the analytical method. Furthermore, the validation was done with only one sample from the lot. Normally, reported concentrations are very low, around the concentrations of our tested samples. This is in agreement with the low occurrence of ANA-a production in cyanobacterial blooms [1,4]. Nonetheless, the evaluated MDL and MQL of the present developed method are substantially lower than the pertinent guidelines in Canada (3.7 μg/L) making it a valid approach for the screening ANA-a for risk management purposes. Globally, an analytical pathway using precursor selection and fragmentation is the method of choice for a quantitative detection using the LDTD–APCI–HRMS with the Q-Exactive mass spectrometer instrument with confirmed selectivity and sensitivity. Moreover, high resolution mass spectrometry is a method of choice for the resolution of isobaric interferences as demonstrated with the signal separation of ANA-a and the amino acid phenylalanine.

5. Conclusion

A new analytical method was explored, the LDTD–APCI–HRMS, using a mass spectrometric hybrid, the Q-Exactive. This method was successfully used to resolve the misidentification of the cyanobacterial toxin, anatoxin-a, from the essential amino acid, phenylalanine. Two scan modes were explored (FS and t-MS^2) to determine the best detection method for selective, sensitive and quantitative analysis. FS mode did not show good results in terms of selectivity given an important presence of false positives in charged complex matrices. On the other hand, the use of t-MS^2 greatly increases the selectivity of compound detection. An internal calibration with standard addition was also validated with the isotopically-labeled phenylalanine (PHE-D_5) as internal standard. The method was validated and deemed linear with correlation coefficients (R^2) above 0.999. MDL and MQL ranged from 0.2 to 1.5 μg/L, and with better sensitivity compared to the previous study of ANA-a analysis using the LDTD–APCI-MS/MS. Accuracy and precision values were below 15% and the signal recovery showed no significant matrix effect with values ranging from 96 to 108% except for FS detection at the lowest concentration which showed a precision higher than 15% and a signal enhancement with a recovery of 172%. With the use of a lock mass, mass accuracy was below 1 ppm with low variation (< 15%). The LDTD–APCI–HRMS is a powerful tool for the screening of anatoxin-a at lower concentrations than established guidelines (3.7 μg/L) in natural and recreational water with simple sample preparation, fast quantification responses (< 15 s/samples), high-throughput analysis and high selectivity. Compared to traditional MS/MS and HRMS detection, the Q-Exactive has the advantage of combining high-performance precursor selection with a high resolution and accurate mass detection. It would be possible, for future work, to adapt this analytical technique for the detection of ANA-a in different matrices such as plant extract and animal tissues given that such performances are attractive for fast trace level detection of contaminants in complex environmental matrices.

Fluorescence quenching

ABSTRACT

Fluorescent water soluble carbon nanoparticles, in short carbon dots (CDs), was synthesized from lactose by microwave assisted hydrochloric acid method. Characterized by TEM and DLS to obtain the morphology shape (average 10 nm in size), with a higher negative surface charge supported by the composition was obtained by XPS spectroscopy. The maximum of the emission was centered at 450 nm with a lifetime of 2.1 ns. Without further functionalization of the CDs a nanosensor was obtained that responded exponentially to HAAs in the 0.35–0.45 mg L^{-1} concentration range by fluorescence static quenching, demonstrated by the lifetime analysis of the CDs in presence of HAAs. Some amino compounds were selected as model for interferences to evaluate the selectivity of this method, showing a notorious added value, with recoveries around 98%. The accuracy of the method was in terms of RSD about 2.5%. The results suggest their promising applications in chemical sensing.

1. Introduction

The International Agency for Research on Cancer (IARC) regards some of the heterocyclic aromatic amines (HAAs) as possible human carcinogens such as (2-amino-3,4-dimethyl-imidazo [4,5-f]-quinoline, 2-amino-3,8-dimethyl-imidazo [4,5-f] quinoxaline and 2-amino-3,4,8-trimethylimidazo [4,5-f]-quinoxaline, 2-amino-3,7,8-trimethyl-imidazo [4,5-f]-quinoxaline (class 2B) and 2-amino-3-methylimidazo [4,5-f]-quinoline (class 2A) [1–3]. Therefore, an important issue in Analytical Chemistry as the main source is the cooked food when the proteins are converted at high temperatures due to the incomplete their combustion process.

Chromatographic methods are the most widely used when analyzed grilled, barbecued or fried meat and fish and urine samples, being HPLC–MS the main analytical technique used previous microextraction procedure [4–13]. HPLC with different detection systems such as UV [14–16] and fluorescence [17,18]; GC–MS [19–23] and by electrophoresis capillary (CE) [24–28], an extensive revision of all this techniques and compared can be found in literature [29]. Very few references to other techniques have been found in the literature for the analysis of these harmful metabolites, except for improvements in the processes of extraction prior to chromatographic analysis such as the used of supercritical fluids [27] and ionic liquids [30], making interesting the development of new alternatives as the sensitive luminescent techniques for their analysis is an important and interesting challenge in the analysis of HAAs [31].

Nanotechnology offers the best alternative, which combines the easiest design of nanoparticles with their cheap cost and luminescent properties, being the emerging system based in carbon dots (CDs) the best candidates to be applied as a detection system of any analyte to study due to its application in many other areas of analysis. These systems are the one of the lasts discover where heavily functionalized carbon networks are involved, which were firstly discovered by simple purification of carbon nanotubes and nowadays can be obtained by means a great variety of simple process [32–37].

This work shows the photoluminescent characteristics of CDs prepared from lactose using microwave process. The advantages of this treatment include faster preparation method, good fluorescence efficiency, reproducibility and stability of the obtained nanoparticles. Furthermore, the exploitation of the sensorial ability of these CDs gives rise to an excellent tool for the quantification, and without any further functionalization, of four different HAAs, by the quenching effect on the fluorescence of CDs.

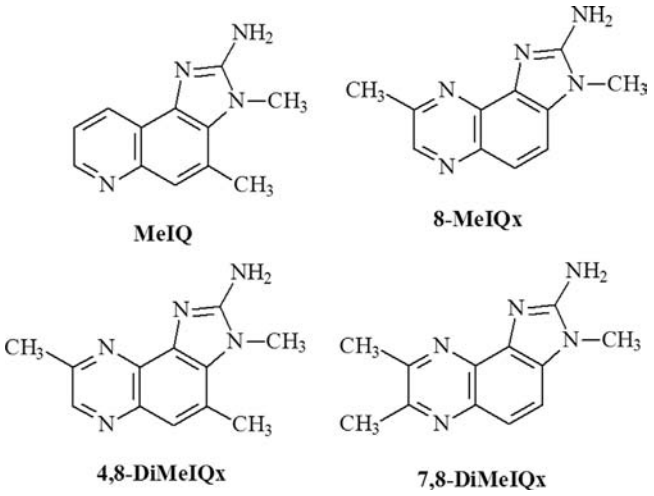

Fig. 1. Chemical structures of the heterocyclic aromatic amines: 2-amino-3,4-dimethyl-imidazo (MeIQ); 2-amino-3,8-dimethyl-imidazo [4,5-f]-quinoxaline (8-MeIQx); 2-amino-3,4,8-trimethylimidazo [4,5-f]-quinoxaline (4,8-DiMeIQx) and 2-amino-3,7,8-trimethyl-imidazo [4,5-f]-quinoxaline (7,8-DiMeIQx).

2. Experimental

2.1. Chemicals

Lactose monohydrate (99%) and hydrochloric (37%) were purchased from Panreac S.A.U. (Barcelona, Spain), 2-amino-3,4-dimethyl-imidazo [4,5-f]-quinoline (MeIQ), 2-amino-3,8-dimethyl-imidazo [4,5-f]-quinoxaline(8-MeIQx), 2-amino-3,4,8-trimethylimidazo [4,5-f]-quinoxaline (4,8-DiMeIQx), 2-amino-3,7,8-trimethyl-imidazo [4,5-f]-quinoxaline (7,8-DiMeIQx), 2-Amino-1-methyl-6-phenyilimidazo [4,5-b]-pyridine (PhIP) and 2-amino-1-methyl-imidazo [4,5-f]-quinoline (iso-IQ) (Fig. 1), were supplied from Toronto Research Chemicals Inc. (North York, ON, Canada). Ethylamine, trimethylamine, lysine, arginine and tyrosine were purchased from Sigma-Aldrich. Ultrapure water used throughout all experiments was purified through a Millipore system. All reagents were used as received without further purification.

2.2. Synthesis of CDs

With ultrasounds, CDs were prepared by mixing a solution of lactose 1 M (50 mL) with concentrated HCl (50 mL). The mixture

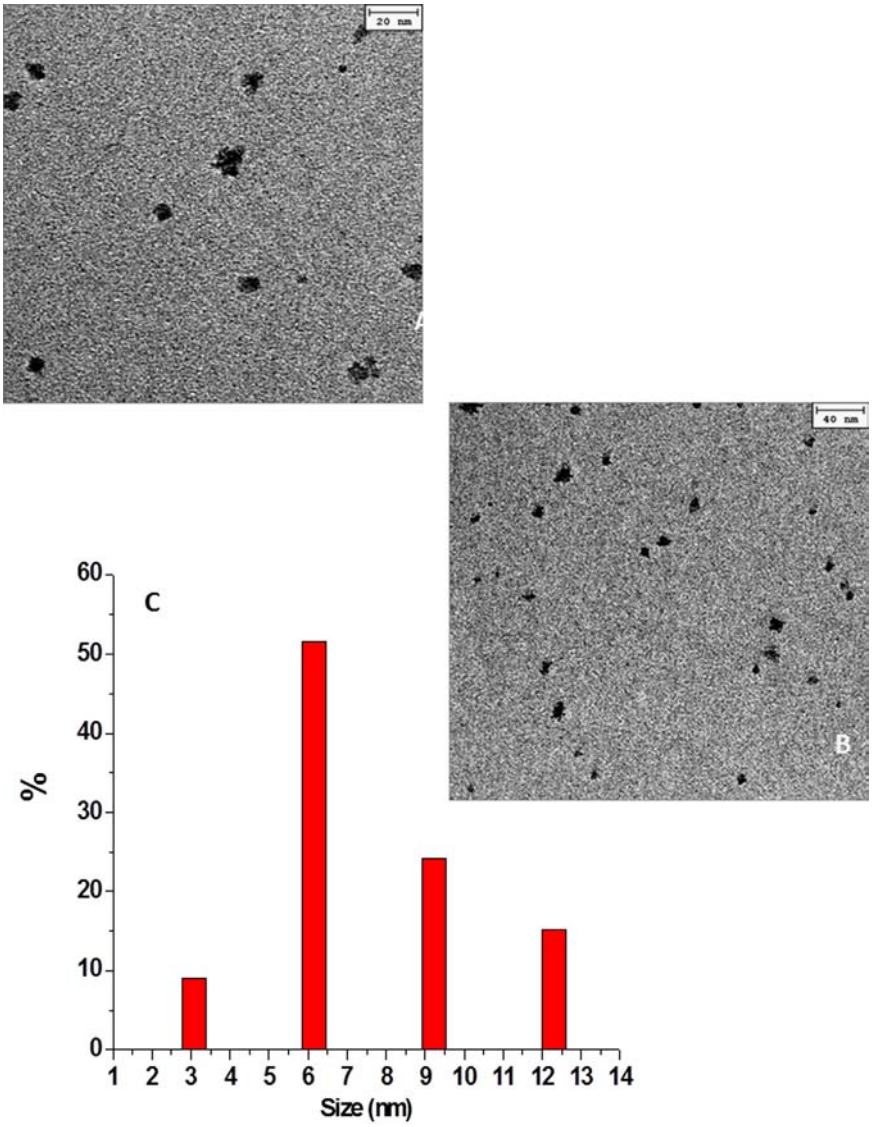

Fig. 2. (A and B) Typical TEM images of CDs thus synthesized at different magnification by assisted microwave procedure at 160 °C, and (C) The corresponding CDs size distribution histogram.

was transferred into a 100 mL Teflon vessel and submitted to a hydrothermal microwave treatment at 160 °C for 15 min (ANTON Microwave 3000 at 20 bar and 750 W), obtaining a brown colour product. The sample was cooled down naturally and the resulted solution was centrifuged, filtered, neutralized to pH 7, centrifuged again and lyophilized to afford the fluorescent CDs for further characterization and use.

2.3. Characterization of CDs and data analysis

PhotonTechnology International (PTI) Inc. Quanta Master 40 spectrofluorometer that was equipped with a 75 W continuous Xenon arc lamp. An ASOC-10 USB interface FeliX GX software was used for fluorescence data acquisition and also controlled the hardware for all system configurations. The slits width for excitation and emission widths were both 2 nm. All optical measurements were performed in 10 mm quartz cell at room temperature. Fluorescence lifetime analysis was done using an Edinburgh Instruments FLS920, equipped with a Xe lamp (450 W) as excitation source for steady state fluorescence measurements and monochromatic LEDs (PicoQuant PLS), controlled by a PDL 880-B system. Fluorescence decays were interpreted in terms of a multi-exponential: $I(t)=A+\Sigma B_i \exp^{-t/\tau i}$, where A and B_i are the pre-exponential factors and τ_i the decay times. Transmission Electron Microscopy (TEM) analysis was carried out with a Philips CM-200. The size and zeta potential (ζ) of CDs were determined using a Zetasizer Nano ZS (Malvern Instruments, U.K.) equipped with a 4 mW HeNe laser operating at $\lambda=633$ nm. Size measurements were recorded with dynamic light scattering (DLS), at 25 °C in a polystyrene cell (ZEN0040) at a scattering angle of 173° and were average of three tests. The ζ measurements were also performed at 25 °C in polycarbonate folded capillary cells, incorporated with gold plated electrodes (DTS1061) and deionized H_2O was the dispersion medium. Both, size and ζ were automatically obtained by the software, using the Stokes–Einstein and the Henry equation, with the Smoluchowski approximation. X-ray photoelectron spectroscopic (XPS) studies were performed on a Physical Electronic PHI 5700 spectrometer using non-monochromatic Mg-*K*a radiation (300 W, 15 kV, 1253.6 eV) for analyzing the core-level signals of the elements of interest with a hemispherical multichannel detector. The spectra of powdered samples were recorded with a constant pass energy value at 29.35 eV, using a 720 μm diameter circular analysis area. The X-ray photoelectron spectra obtained were analyzed using PHI ACESS ESCA-V6.0F software and processed using Multipak 8.2B package. The binding energy values were referenced to adventitious carbon C 1s signal (284.8 eV). Shirley-type background and Gauss–Lorentz curves were used to determine the binding energy.

2.4. Procedure

For the evaluation of HAAs as possible quenchers of the CDs fluorescence in solution, microliters of stock solutions (1000 mg L^{-1}) of chosen analytes were added to 50 μL of CDs keeping constant the final volume to 5 mL. The concentrations ranging upward from 0.5 to 10 mg L^{-1} were measured to obtain the Stern–Volmer plot.

3. Results and discussion

An easiest, rapid and hydrothermal procedure, assisted by microwave treatment, previous purification process, was chosen to obtain CDs from lactose which exhibited a strong emission. The most attractive feature of this method is that the surface passivation step is not necessary, since the starting material. Fig. 2A and B shows the TEM images of CDs at different magnifications revealing, that the synthesis procedure without any modification, could easily disperse in water with a narrow size distribution showing a mean diameter around 10.99 ± 3.97 nm (Fig. 2C). The zeta potential (ζ) of the CDs synthesized by this procedure afforded high negative charge (-29.1 ± 1.46 mV), in accordance with previous results when carbohydrates are used as CDs precursors, where a high density of susceptible functional groups to be in the surface [35], the XPS analysis supported this hypothesis due to synthesis procedure carried out.

The surface composition and elemental analysis for the resultant CDs were characterized by XPS technique. The XPS results indicate that these CDs are composed, in atomic concentration %, of C: 79.99%; O: 14.06%, Na: 3.59; Cl: 2.36%. The C 1s spectrum of CDs (Fig. 3A) is

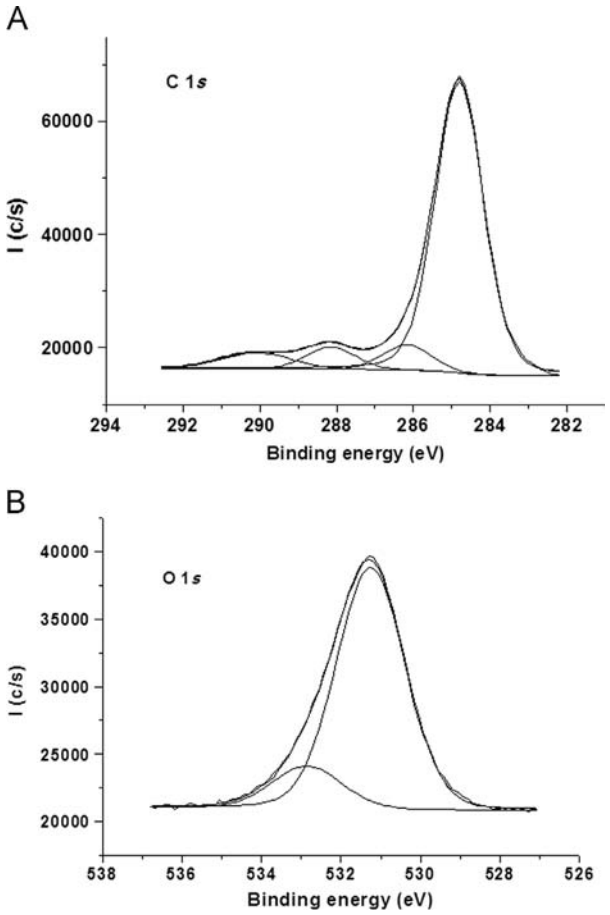

Fig. 3. (A) C 1s and (B) O 1s cores level spectra for CDs.

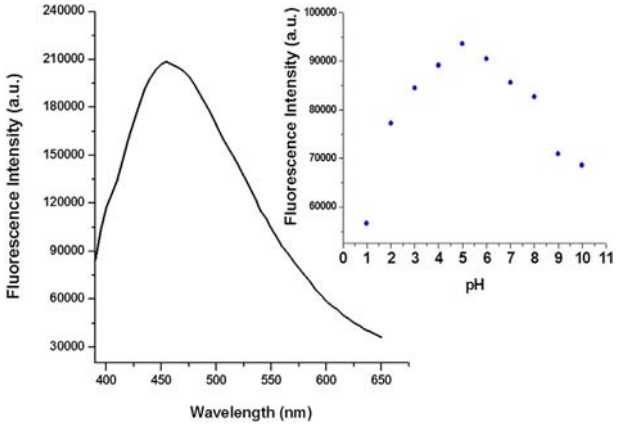

Fig. 4. Fluorescence spectra of CDs obtained from lactose after microwave treatment ($\lambda_{exc}=350$ nm; slit widths: 5.5 nm). Inset: the influence of pH on the intensity of CDs at 450 nm.

composed of four contributions at 284.8 (81%), 286.3 (7%), 288.2 (6%) and 290.1 eV (6%). The first and main contribution at 284.8 eV is assigned to graphitic carbon plus adventitious carbon. The second one at 286.3 eV to carbonyl groups and the contributions at higher binding energy (288.2 and 290.1 eV) to carboxylic and carbonate groups, respectively. The O 1s core level spectrum shows and asymmetric signal that can be decomposed in two contribution at 531.3 eV (85%) and 532.9 eV (15%) assigned to oxygen of carbonyl and carboxylate groups (Fig. 3B). The Cl $2p_{3/2}$ signal appears at 199.1 eV, typically of chlorine covalently bonded to carbon (Cl–C). Finally, the Na 1s signal is symmetric and centred at 1071.2 eV, being assigned to Na^+ as counter ion of the carboxylic group. To further elucidate the surface features of the CDs, various spectroscopic analyses were used, the ATR spectra two prominent bands are observed at 3240 and 1644 cm^{-1}, which correspond to the stretching of –OH and C=O bonds, respectively. The Raman spectrum of the as-prepared CDs was also measured which, in addition to the IR features, revealed distinct peaks: (i) at 1610 cm^{-1} due to the carbonyl groups attached to the CDs, which are bonded to donor groups (ii) a weak band at 1345 cm^{-1} typical of carbon nanostructures in this case due to the CDs core vibrations, i.e.: carbonaceous structure and (iii) at 1078 cm^{-1} likely arising from the C–C and C–O bending modes. Both together, the IR and Raman spectra provide spectroscopic evidences of the composition of the CD dots complementary to that of XPS in this study (Supplementary material).

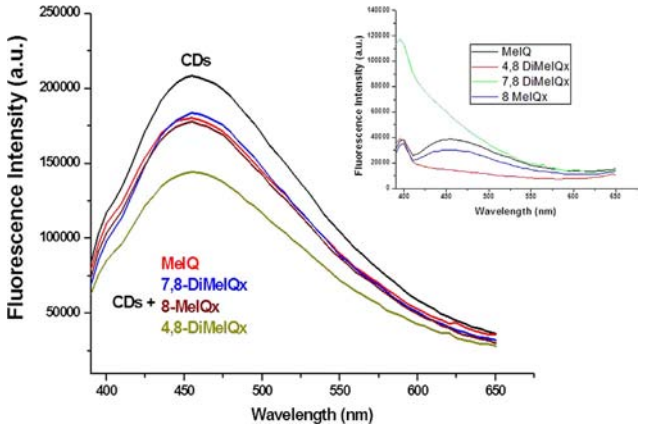

Fig. 5. Influence of HAAs on the fluorescence intensity of synthesized CDs when excited at 350 nm. (Inset the fluorescence of the four HAAs studied).

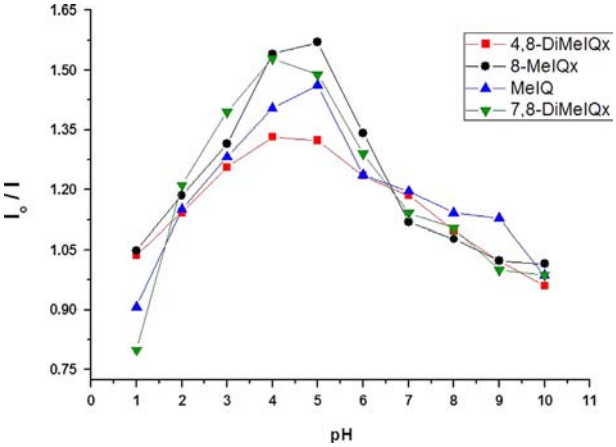

Fig. 6. Influence of the pH on the quenching effect of HAAs at 450 nm.

The influence of the thermal effect was studied over the CDs, and was observed that after the synthesis of CDs by the proposed method, when heated until 100 °C, only an increasing on the fluorescence intensity was observed, around 13% (Supplementary material).

Fig. 4 shows the fluorescence spectra of CDs with a maximum of emission at 450 nm (λ_{exc}=350 nm), showing a full width at half maximum (FWHM) of 152 nm, relative high value, indicating their great size distribution dependence. The stability of CDs was investigated under three different conditions sunlight exposure, ambient light and dark. For this purpose, aliquots of 100-fold dilutions of CDs were prepared and exposed under these conditions during several intervals of times. In all cases the fluorescence intensity at 450 nm were recorded. In general, CDs remain stable for long periods (three months). In addition, CDs are photo-stable when they remain under continuous irradiation. No abnormalities in their fluorescence because of sunlight exposition were observed either.

The influence of pH on the fluorescence activity of CDs was also studied. Inset Fig. 4 shows the pH-response of photoluminescence behavior of the different water-soluble CDs, in which the fluorescence generally tends to increase when increasing the pH of the medium in the range between 1 and 5, and decrease when the pH is high tan 5. It is noticeable than this synthesis procedure increases the fluorescence intensity when increases the pH until 5. No aggregation neither variation in the maximum emission wavelength was observed with the pH 5 for CDs. The analysis of the fluorescence decays shows that the lifetimes, calculated with a three component decay time model was:

$$\mathbf{I}(t) = 1.501 \times 10^2 + 1.057 \times 10^3 e^{(-t/\tau_1)} + 3.019 \times 10^2 e^{t/\tau_2} (\chi = 1.155)$$

with τ_1=2.41 and τ_2=7.84 ns, respectively, showing a higher goodness of the fitting (χ). Luminescence decays showed that CDs produced by assisted microwave HCl treatment method have the presence of different emissive sites, at 450 nm of emission (λ_{exc}=350 nm), as supported by the presence of different functional groups supported by XPS analysis [38].

The dilution of CDs effects on the fluorescence intensity. Five dilutions of CDs in proportions 1:10, 1:20, 1:50, 1:100 and 1:200 with ultra-pure water and PBS solution were investigated. In both cases, optimized dilutions of 100-fold for CDs were observed and considered as stock solutions for their higher fluorescence intensity. The study of the interaction of different chemical species with the surface of CDs is widely reported in the literature [33–35]. It has revealed that the luminescence properties of these nanomaterials strongly depend on their surface atoms and their environment [39,40]. This work is focused in the interaction established between the different surface functional groups of the synthesized CDs with four HAAs (MeIQ, 8-MeIQx, 4,8-DiMeIQx and 2,7,8-DiMeIQx), which affect on the fluorescence intensity of the CDs (Fig. 5). For understanding the possible influence of these HAAs on the luminescence intensity of

Table 1
Interferences of other related amines on the determination of the selected HAAs, expressed in recoveries (%).

Interferent	Tolerance ratio (m m^{-1})	MeIQ Recovery (%)	8-MeIQx Recovery (%)	4,8-DiMeIQx Recovery (%)	7,8-DiMeIQx Recovery (%)
Aliphatic amines: ethylamine and trimethylamine	1000	100	100	100	100
Aminoacids: lysine, arginine and tyrosine	900	95–99	98–101	97–99	95–97
Others heterocyclic amines: PhIP and Iso-IQ	250	100	99, 102	94, 97	96, 98

CDs, the fluorescence emission spectrum of each HAAs (λ_{ex}=350 nm) was observed. Any significant emission was observed at the 400–650 nm range (inset in Fig. 5). When each HAAs was added to the CDs aqueous solution, a quenching effect on the CDs emission band (λ_{em}=450 nm) was observed. Previously to the determination of the selected HAAs, were carried out the pH study, MeIQ, 8-MeIQx, 4,8-DiMeIQx and 7,8-DiMeIQx, with a p*K*a 5.95, 5.86, 5.56 and 5.65, respectively, have their N atom in the 3 position of imidazole ring as their most basic centre [41]. These analytes, protonated at pH < 5, interact with a negative charged surface of CDs by hydrogen bonded of amine groups of HAAs and carboxylic groups of CDs, causing maximum quenching of fluorescence at pH 5 (Fig. 6). At pH > 5 a quenching decrease since the negative charged amino groups of HAAs.

In order to assess the feasibility of the proposed analytical method, the effect of other group of amines on the fluorescence signal of CDs was also checked. This study included aliphatic amines (ethylamine and trimethylamine), aminoacids (lysine, arginine and tyrosine), and others HAAs such as (2-Amino-1-methyl-6-phenyilimidazo[4,5-b]-pyridine (PhIP) and 2-amino-1-methyl-imidazo [4,5-f]-quinoline (iso-IQ), that were added over the CDs ten levels of concentrations (10, 50, 100, 250, 400, 500, 600, 800, 900 and 1000 mg L^{-1}). The results obtained indicated that these amines did not produce any noticeable effect in the fluorescence signal of the CDs with 1 mg L^{-1} of HAAs.

The results of including significant levels of possible interferents are presented in Table 1. The results indicated that the aliphatic amines and amino acids did not quench CDs fluorescence emissions with each HAAs which in turn would give rise to erroneous HAAs levels being determined (tolerance ratio of 1000 m m^{-1}). In the case of others HAAs such as PhIP and iso-IQ, the tolerance ratio was 250. The dependence of the measured luminescence intensity signal with increasing concentrations of HAAs was observed to follow the well-known Stern–Volmer equation ($I_0/I=1+K_{sv}$ [Q]), where I_0 is the luminescence signal at 450 nm of CDs in absence of HAAs and I is the same signal in the presence of increasing concentration of HAAs. Hence, (I_0/I) were plotted versus each HAA concentration. It is interesting to remark that this plot did not fit a conventional linear equation. An upward curvature was observed, typical behavior of charged quenchers Fig. 7 shows the logarithmic known Stern–Volmer plots and calibration equations of MeIQ, 8-MeIQx, 4,8-DiMeIQx and 7,8-DiMeIQx. These molecules do not contact at all in the surface of the CDs, only a partial amount of molecules of HAAs, indicating that both dynamic and static quenching seem to act together, here suggesting a more complex quenching model [42,43]. However, when $\ln(I_0/I)$ was plotted versus the concentration of each HAAs a good linear relationship ($r^2 > 0.995$) was obtained, in other words the quenching of the fluorescence of CDs has an exponential relationship with the concentration of HAAs ($I_0/I=e^{\alpha[HAAs]}$), where α represents the constant associated to the quenching effect.

Therefore, this signal could be used to develop a HAAs determination method based on luminescence quenching of CDs by DiMeIQx at optimum conditions. The precision in terms of relative standard deviation (RSD) was 0.25, 0.35, 0.57 and 0.75% for MeIQ, 8-MeIQx, 4,8-DiMeIQx and 7,8-DiMeIQx, respectively; being the reproducibility (for 1 mg L^{-1} of each HAA, n=5) of RSD value less than of 2.5% in all cases. The limit of quantification, were 0.35, 0.41, 0.45 and 0.36 mg L^{-1} for MeIQ, 8-MeIQx, 4,8-DiMeIQx and 7,8-DiMeIQx, respectively. To check this effect, the analysis of the fluorescence decays shows that the lifetimes of the components (Table 2), calculated with a component decay time model for CDs, in the presence of increasing concentration of 4,8-DiMeIQx is not particularly sensitive to the presence of the quencher. They do not depend of the HAA concentration, demonstrating the static quenching effect over CDs linked to the formation of a stable complex between the fluorophore and 4,8-DiMeIQx in this case. Fig. 8 shows the lifetime decay curves of the fluorescence emission, which can be fitted to four components.

Ethiofencarb
Voltammetry
Multivariate curve resolution
Differential pulsed voltammetry
Unfolded partial least squares regression followed by residual bilinearization

ABSTRACT

This work presents the development of a method based on a voltammetric determination coupled to second-order data modeling with multivariate curve resolution-alternating least-square (MCR-ALS) and unfolded partial least squares regression followed by residual bilinearization (U-PLS/RBL) for the quantitation of the pesticide ethiofencarb in the presence of interferences in tap water.

The determination of ethiofencarb by voltammetry is possible on the basis that this pesticide is hydrolysed in alkaline media giving rise to a compound which shows an oxidation peak at Ep=0.80 V. But some other pesticides belonging to the same family can be considered as interferences due to the high overlapping in their signals. The two such interferences are fenobucarb and bendiocarb, which have not been included in the calibration step.

The possibility of second-order multivariate calibration was studied by using the hydrolysis time as the third variable, and MCR-ALS and U-PLS/RBL. Good results were obtained in this determination in spite of the high overlapping in voltammetric signals.

1. Introduction

Ethiofencarb [(2-ethylthiomethyl-phenyl)-N-methyl carbamate] is a systemic insecticide widely used in agriculture, which acts as a cholinesterase inhibitor. The World Health Organization lists ethiofencarb as “highly hazardous” and it is considered by the European Union's Nordic Council of Ministers as “dangerous for the environment” [1]. For these reasons, a wide range of analytical techniques has been developed for its identification and determination at trace levels.

A literature search reveals that the quantitation of the product or its residues is performed mainly by using separative techniques. Gas chromatography–mass spectrometric (GC–MS) methods with various derivatization reagents have been used [2]. High performance liquid chromatography (HPLC) is the most common technique used to analyze this pesticide [3] using reverse phase equipped with different detectors. Tandem mass spectrometry (MS/MS) has been used for sensitive quantitation. Although these methods have high selectivity and sensitivity, they inherently rely on expensive instruments. Consequently, it is attractive to develop simple and cheap methods for the quantitation of ethiofencarb.

As regards the use of voltammetric techniques for the latter analysis, only one paper has been reported [4]. Barroso et al. performed a basic study on the voltammetric behavior of ethiofencarb at a glassy carbon electrode and at a hanging mercury electrode by using cyclic voltammetry and square wave voltammetry. Finally, they applied the electrochemical study of the reaction product of alkaline ethiofencarb hydrolysis in the development of a FIA system with amperometric detection.

The determination of ethiofencarb by voltammetry is possible on the basis that this pesticide is hydrolysed in alkaline media giving rise to a compound which shows an oxidation peak at Ep=0.80 V at the glassy carbon electrode, which corresponds to the phenol derivative product. But some other pesticides belonging to the same family can be considered as interferences due to the high overlapping in their signals [5,6].

Usually, as voltammetry is not a separative technique, full selectivity cannot be obtained with it because by using any kind of working electrode (mercury, carbon etc.) different types of analytes can show overlapped signals. However, this problem can be overcome by using chemometric tools. When this occurs

generating second-order data and its proper modeling with multiway algorithms can guarantee selectivity by mathematical means, allowing resolution and quantitation of analytes with overlapped signals [7,8]. This is possible because the information provided by second-order data if adequately decomposed by suitable algorithms can be uniquely ascribed to the analyte of interest, even in the presence of unexpected components not considered in the calibration stage. This property has been called "the second-order advantage" and avoids the requirement of physically removing interferences [9]. There are three well-known second-order algorithms able to handle third-order data arrays deviating from trilinearity, as is expected to occur with second-order voltammetric data: multivariate curve resolution-alternating least-squares (MCR-ALS) [10], parallel factor analysis 2 (PARAFAC2) [11] and unfolded partial least squares followed by residual bilinearization [12]. They are able to take into account changes in signal shape of components from sample to sample. When MCR-ALS is performed in the so-called extended mode, the challenge is overcome by building an augmented data matrix by appending calibration and test data matrices in the time direction. In this way the rows represent in this case voltammograms and the columns time profiles, alleviating the problems associated with sample-to-sample differences in this dimension [13].

A large number of works have been published concerning the chemometric modeling of second-order data generated by different techniques. As an example, a search in Scopus using "HPLC" and "second-order data" as keys revealed that 132 papers were published since 1985 to date, MCR-ALS being the algorithm of choice to solve most of the analytical problems at hand [8,14]. However, to the best of our knowledge, a reduced number of papers have been published regarding the development of analytical methodologies based on second-order voltammetric data, most of them using MCR-ALS [15–17]. In the present work the development of a method for the determination of ethiofencarb in the presence of two other insecticides (fenobucarb and bendiocarb) of the same family, which have not been included in the calibration step, was attempted. The possibility of exploiting the second-order advantage by implementing three-way calibration was studied by using the hydrolysis time as the second mode and applying a well-established algorithm: MCR-ALS. In addition, unfolded partial least squares regression followed by residual bilinearization (U-PLS/RBL) [18] was implemented considering the possibility of a better performance owing to non-linearities usually present in electrochemical data [19,20]. To the best of our knowledge this latter algorithm was used for first time for modeling second-order voltammetric-hydrolisis time data, and as will be shown performs better than MCR-ALS for the kind of data analyzed in the present report.

2. Experimental

2.1. Apparatus and software

All experiments were performed using an Autolab AUT 12.v PSTAT10 (Ecochemie, The Netherlands) in combination with a Metrohm VA-663 stand, with a tree electrode system: working electrode of glassy carbon (GCE), an Ag/AgCl saturated KCl reference electrode and a Pt wire auxiliary electrode. The system is monitored by the general purpose electrochemical system version 4.0 (GPES4) software package (Ecochemie, Ultrecht, The Netherlands).

The GCE was polished at the start of the work, with aqueous slurry of 0.5 μm alumina powder. For electrode regeneration between measurements, it was polished for one minute in a cotton disk soaked in dimethylformamide and for another minute in a cotton disk soaked in water.

All the algorithms were implemented in MATLAB 7.10 [21]. Those for applying MCR-ALS are available in the internet at http://www.mcrals.info/. U-PLS/RBL was implemented with an integrated chemometric toolbox (MVC2) available in the literature [22]

2.2. Chemicals and reagents

Ehiofencarb (97.5%) was obtained from Dr. Ehrenstorfer (Augsburg, Germany); bendiocarb (99%) and fenobucarb (98%) were obtained from Riedel-de Haën (Seelze, Germany). They were used without further purification, and their solutions of them in ultrapure water (40 μg mL^{-1}) were prepared and stored in the dark at 4 °C.

HPLC-grade water was obtained from a Milli-Q system (Millipore, Bedford, MA., USA). All other chemicals were of analytical reagent grade.

2.3. Preparation of standard solutions and samples for the validation study

The calibration data sets were built by using only pure standard solutions of ethiofencarb under the above selected conditions. This was done in order to prove that the second-order advantage is exploited when analyzing validation mixture samples of three compounds. Solutions for calibration were randomly prepared, by convenient dilutions of stock solution in order to obtain the necessary concentrations. The range of concentration was between 2.5 and 10.0×10^{-6} mol L^{-1}.

The samples for the validation set were mixtures of ethiofencarb, endiocarb and fenobucarb prepared in tap water. The specific validation concentrations of the nine samples are provided in Table 1. An inter-day precision study was performed analyzing sample number 1 during three consecutive days in triplicate and then performing an ANOVA test.

2.4. Sample preparation

The calibration and validation samples were prepared as follows. In a 25.0 mL volumetric flask a suitable volume of the pesticide(s) was taken; 5 mL of $NaClO_4$ 0.5 mol L^{-1}, 1 mL of NaOH 0.2 mol L^{-1} and pure (standards) or tap (validation samples) water to a volume near 20 mL were added, after shaking for a few seconds, and allowed to stand for t min (hydrolysis time). Then, 0.2 mL of glacial acetic acid was added and the solution was diluted to the mark with pure/tap water. The obtained solution was transferred to the electrochemical cell and the differential pulse voltammogram (DPV) in the range +0.4–1.0 V was registered at the following instrumental conditions: scan rate 15 mV s^{-1} and pulse amplitude 50 mV.

Table 1
Composition of the nine samples validation set.

Sample	Ethiofencarb (μmol L^{-1})	Fenobucarb (μmol L^{-1})	Bendiocarb (μmol L^{-1})
1	9.50	7.50	9.00
2	6.25	9.50	6.00
3	8.55	6.09	6.00
4	3.00	7.50	9.00
5	8.55	8.91	3.00
6	3.95	8.91	6.00
7	3.95	6.09	9.00
8	6.25	5.50	3.00
9	6.25	7.50	3.00

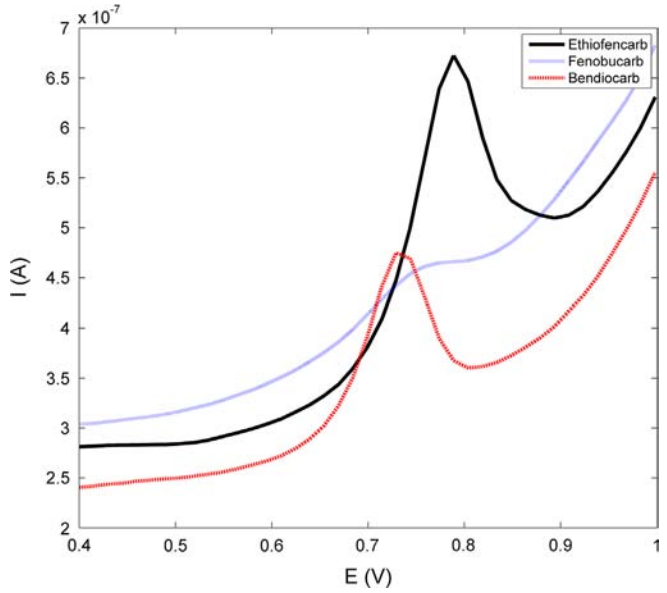

Fig. 1. Voltammograms at hydrolysis time =4 min, corresponding to pure standard solutions of ethiofencarb 6.25 μmol L^{-1}, fenobucarb 10.00 μmol L^{-1} and 6.00 μmol L^{-1} of bendiocarb.

3. Results and discussion

3.1. General considerations

The determination of ethiofencarb by voltammetry is possible on the basis that this pesticide is hydrolysed in alkaline media giving rise to a compound which shows an oxidation peak at around Ep=0.80 V. But some other pesticides belonging to the same family can be considered as interferences due to the high overlapping in their signals. The two interferences selected for this study are fenobucarb and bendiocarb. Voltammograms at hydrolysis time of 4 min corresponding to pure standard solutions of ethiofencarb 6.25×10^{-6} mol L^{-1}, fenobucarb 10.00×10^{-6} mol L^{-1} and 6.00×10^{-6} mol L^{-1} of bendiocarb are showed in Fig. 1.

In order to study the possibility of determining ethiofencarb in the presence of interferences, second-order data and chemometric algorithms were studied. The calibration data sets were built by using only pure standard solutions of ethiofencarb and the samples for the validation set were mixtures of ethiofencarb, bendiocarb and fenobucarb prepared in tap water.

Second-order data were obtained by recording the voltammograms of each sample at different hydrolysis times as the third variable. The hydrolysis time employed were 1, 2, 3 and 4 min. There were 41 points in each voltammogram obtained, taking into account the scan potential interval employed and the experimental conditions. Then for each sample a matrix of 41×4 was recorded.

3.2. Asymmetric least squares (ALS) background correction adapted to second-order data

A background matrix **F** ($J\times K$) is estimated from the data matrix **M** ($J\times K$), where J and K are the number of digitized potentials and the hydrolysis time, respectively. With this purpose, a $\mathbf{B}_1$ ($L\times J$) spline basis matrix along the rows of the **M** matrix and a $\mathbf{B}_2$ ($M\times K$) spline basis matrix along the columns of the **M** matrix are used along with a compromise of 3 basis functions [23], i.e., $L=M=3$. **F** can be represented as

$$f_{j,k}=\sum_{L,M} b1_{LJ}\, b2_{MK}\, a_{LM} \tag{1}$$

where a_{LM} is the (L,M) element of an **A** matrix containing the regression coefficients, which can be calculated by minimizing the following cost function:

$$Q=\sum_{L,M}\nu_{JK}(y_{JK}-f_{JK})^2+p. \tag{2}$$

In Eq. (2), y is the experimental signal, f is a smooth trend (the baseline approximation), and ν is the prior weights. The elements of ν should have large values in the parts of the signal where it is allowed to affect the estimation of the baseline. Considering the choice of the following asymmetric weights: $\nu_{JK}=p$ if $\nu_{JK}>f_{JK}$ and $\nu_{JK}=1-p$ if $\nu_{JK}\le f_{JK}$ with $0<p<1$, positive deviations from the trend will result in weights different from negative residuals. Experience shows that starting from $\nu\cong1$, and iterating between the two computations, quickly and reliably leads to a solution in about 10 iterations. The penalty term in Eq. (2) is defined as follows:

$$p=\left[\sum_{L}(\Delta_1^{d}\mathbf{a}_{\cdot L})^2+\sum_{L}(\Delta_2^{d}\mathbf{a}_{\cdot M})^2\right] \tag{3}$$

where Δ_1 and Δ_2 are differences of order d calculated for each column ($\mathbf{a}_{\cdot L}$) and row ($\mathbf{a}_{\cdot M}$) of **A**, respectively. If different values are used for the regularization parameter Δ, the penalty may have different influences for vertical and horizontal directions.

Fig. 2 depicts a plot of the four voltamograms recorded at different hydrolysis times (see above) for a water sample previously spiked with the three studied analytes. The four voltammograms correspond to a data matrix **M** (41×4). The background estimation **F** depicted as individual voltammograms (41×4) obtained via ALS is also shown in Fig. 2, and, as can be seen, the background contribution is significant within the entire range. The estimated matrix was obtained by setting L and M to a value of 3 and the asymmetry parameter (p) in Eq. (2) to 0.005. The subtraction of the **F** matrix from the **M** matrix provides the background corrected voltammograms shown in Fig. 2. All further experimental data were background subtracted, generating an ALS matrix within the ranges of interest. Fig. 3 shows the landscape obtained after background correction of data corresponding to Fig. 2.

3.3. MCR-ALS analysis

MCR-ALS is an algorithm capable of handling data sets deviating from trilinearity, i.e., data in which kinetic time shifts or signal

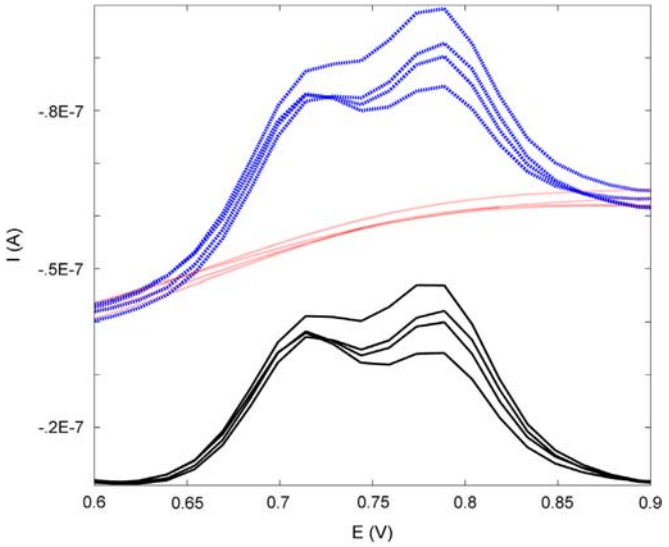

Fig. 2. Voltammograms corresponding to validation sample number 1, before and after background correction.

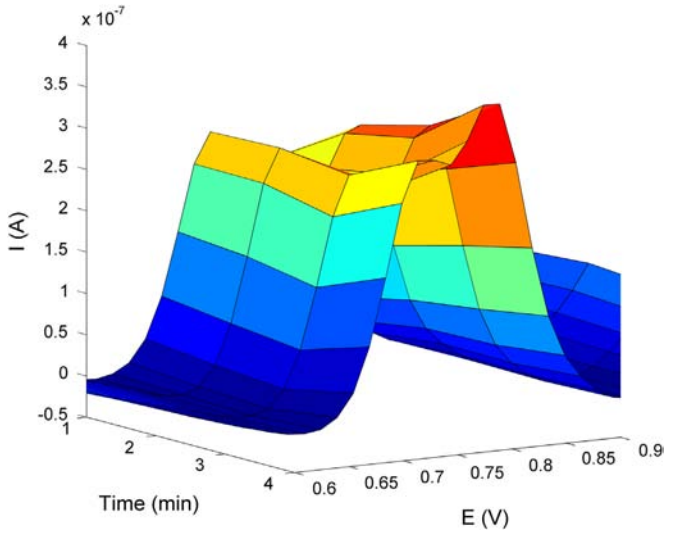

Fig. 3. Landscape plotted for validation sample number 1 after background correction.

shape changes occur for analytes from sample to sample [8]. With this purpose, the strategy of augmenting matrices along the mode which is suspected of breaking the trilinear structure is implemented. Thus, if matrix-to-matrix variation of profiles occurs along the column direction, a column-wise augmented matrix is created. The bilinear decomposition of the augmented matrix **D** is performed according to the expression

$$\mathbf{D}_{\text{aug}} = \mathbf{C}_{\text{aug}}\mathbf{S}^{\text{T}} + \mathbf{E}_{\text{aug}} \quad (4)$$

in which the rows of $\mathbf{D}_{\text{aug}}$ contain the voltammograms (K sensors) as a function of time of hydrolysis (J times), the columns of $\mathbf{C}_{\text{aug}}$ contain the time profiles of the N compounds involved in the process, the columns of **S** their related voltammograms, and $\mathbf{E}_{\text{aug}}$ is a matrix of residuals not fitted by the model. Decomposition of $\mathbf{D}_{\text{aug}}$ is achieved by iterative least-square minimization of $\|\mathbf{E}_{\text{aug}}\|$, under suitable constraining conditions. In this work the implemented constrains were non-negativity in the spectral profiles, unimodality and non-negativity in the time profiles, and correspondence among species and samples in the case of samples containing uncalibrated interferents. $\mathbf{D}_{\text{aug}}$ is built by placing one on top of another the calibration sub-matrices and each of the test data sub-matrices. Thus, while the pure voltammogram of each compound should be the same in all experiments and this mode must be selective, the temporal profiles in the different $\mathbf{C}_{\text{aug}}$ sub-matrices need not share a common shape.

The first modeling step consisted in building an augmented data matrix $\mathbf{D}_{\text{aug}}$ in the temporal mode of $\{[(I+1)\times 4]\times 41\}$ by stacking the data matrices corresponding to each test sample followed by those of the standard samples for the analyte ethiofencarb (I).

This algorithm needs initialization with system parameters as close as possible to the final results. Therefore, analyte and interference voltammograms are required as the resolution is based on the selectivity in the latter mode. In this work, the selection of the purest voltammogram for the interferents was made based using homemade routines based on SIMPLISMA (simple interactive self-modeling mixture analysis) [24]. The number of contributing species in the system under study when applying singular value decomposition (SVD) was always equal to the real number of components, i.e. three when analyzing test samples.

Fig. 4A shows the voltammograms retrieved for all the three mentioned components in validation sample number 1. As can be

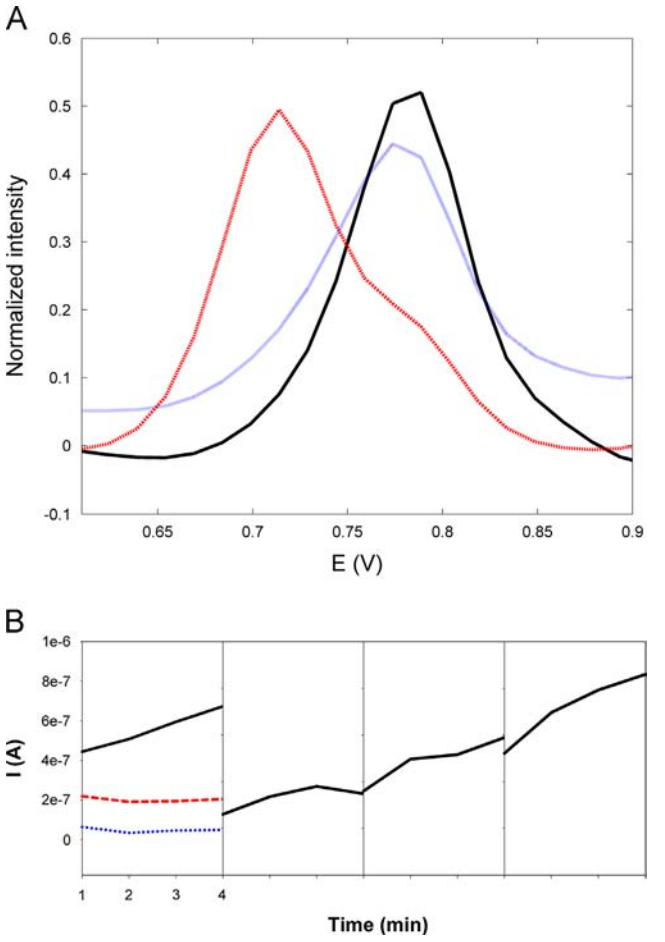

Fig. 4. (A) Voltammogram profiles retrieved with MCR-ALS for validation sample number 1 and (B) time profiles retrieved with MCR-ALS when analyzing validation sample number 1 and three pure standard solutions of ethiofencarb at 3.60, 6.25 and 10.00 μmol L^{-1}.

appreciated there exists a high degree of overlapping among analyte and interferents signals but the profile corresponding to the analyte (in black) has a peak at 0.79 V, which agrees well with the peak that presents this compounds (see Fig. 1). In addition, Fig. 4B shows the corresponding time evolution profiles in this particular sample and the ones retrieved for three ethiofencarb standard samples at 3.60×10^{-6}, 6.25×10^{-6} and 10.00×10^{-6} mol L^{-1}. As was mentioned before, the areas under the kinetic profiles were used to build a calibration curve that allowed us to obtain the concentration of ethiofencarb in the validation samples.

3.4. U-PLS/RBL modeling

The U-PLS method has already been described in detail [25], as well as the U-PLS/RBL combination [26]. The first step in the application of U-PLS/RBL was the assessment of the optimum number of calibration factors (A). This was done by resorting to the leave-one-out cross-validation procedure, which computes the ratios $F(A)=\text{PRESS}(A<A^*)/\text{PRESS}(A)$, where PRESS is the predicted error sum of squares, defined as $\text{PRESS}=\sum(\text{ci, act}-\text{ci, pred})^2$, A is a trial number of factors and A^* corresponds to the minimum PRESS. The number of optimum factors was selected as the one leading to a probability of less than 75% and $F>1$. Since the present study was carried out with pure standards of ethiofencarb, and because the blank signal was eliminated by the pre-treatment procedure, it was expected that the parameter A is equal to 1.

Table 2
Predictions on validation samples containing two interferents by MCR-ALS and UPLS/RBL.

Sample	Ethiofencarb (μmol L^{-1})				
	Nominal	MCR-ALS		U-PLS/RBL	
		Prediction	Recovery (%)	Prediction	Recovery (%)
1	9.50	9.30	97.9	9.35	98.4
2	6.25	6.40	102.4	6.30	100.8
3	8.55	7.80	91.2	8.65	101.2
4	3.00	3.50	116.7	3.28	109.3
5	8.55	8.70	101.8	8.69	101.6
6	3.95	4.30	108.9	4.15	105.1
7	3.95	4.30	108.9	4.12	104.3
8	6.25	6.00	96.0	6.10	97.6
9	6.25	6.30	100.8	6.30	100.8
REP (%)	–	5.86	–	2.54	–

However, two additional latent variables were necessary to model the variability of the data by U-PLS. This fact would allow inference about the presence of non-linearities, which are usually found in electrochemical data [19]. On the other hand, this would allow explaining the better performance of this algorithm compared with MCR-ALS (see below).

The next step was to estimate the number of unexpected components in validation samples via the post-calibration RBL procedure. This was done by considering the variation of the residual as a function of the trial number of unexpected components [26]. The stabilization of the residual around the instrumental noise ($\sim 5 \times 10^{-8}$ A) suggested two unexpected components. The good agreement that exists among the predicted and the nominal concentrations of ethiofencarb (see Table 2) demonstrates the success of RBL in extracting the spectral contributions of both unknown components from the sample. This ability, which refers to the second-order advantage with the U-PLS/RBL algorithm, makes prediction possible with no potential interference from the sample.

The predictive ability of both algorithms was compared through the elliptic joint confidence region (EJCR) test [27]. In this case, it should be remarked that both ellipses contain the theoretically predicted value of the slope (1) and the intercept (0) (Fig. 5B). On the other hand, a better performance in term of precision can be observed for the U-PLS/RBL algorithm. This fact could be explained based on a better ability to compensate the non-linearities which are usually present in electrochemical data, as was commented above. Nevertheless, it can be concluded that both methods reach accurate predictions.

In addition repeatability (or intra-assay) and intermediate variations (or inter-assay) were studied, performing analyte determinations with the U-PLS/RBL algorithm in validation sample number 1, during three consecutive days. The obtained values (average and standard deviation) are the following (in μmol L^{-1}): 9.33 (0.09_7), 9.28 (0.08_8) and 9.37 (0.09_5), respectively. On the other hand, in order to further evaluate the inter-assay precision, an analysis of variance was performed for the recoveries obtained for each concentration level during the three days, in such a way that both within-condition and between-condition variances were taken into account. The *p*-values obtained, which are greater than 0.05, allowed us to conclude that there are no significant differences between the mean recoveries for each level in the three different days studied with a confidence level of 0.05. From this study, it can be concluded that the developed method presents acceptable precision.

Finally it should be commented that PARAFAC was also implemented but, as was expected, worse results than those obtained with MCR-ALS were obtained. This fact can be due to the characteristics of the data under study in the present report: non-trilinearity of the three-way array and non-linearity between signal and concentration.

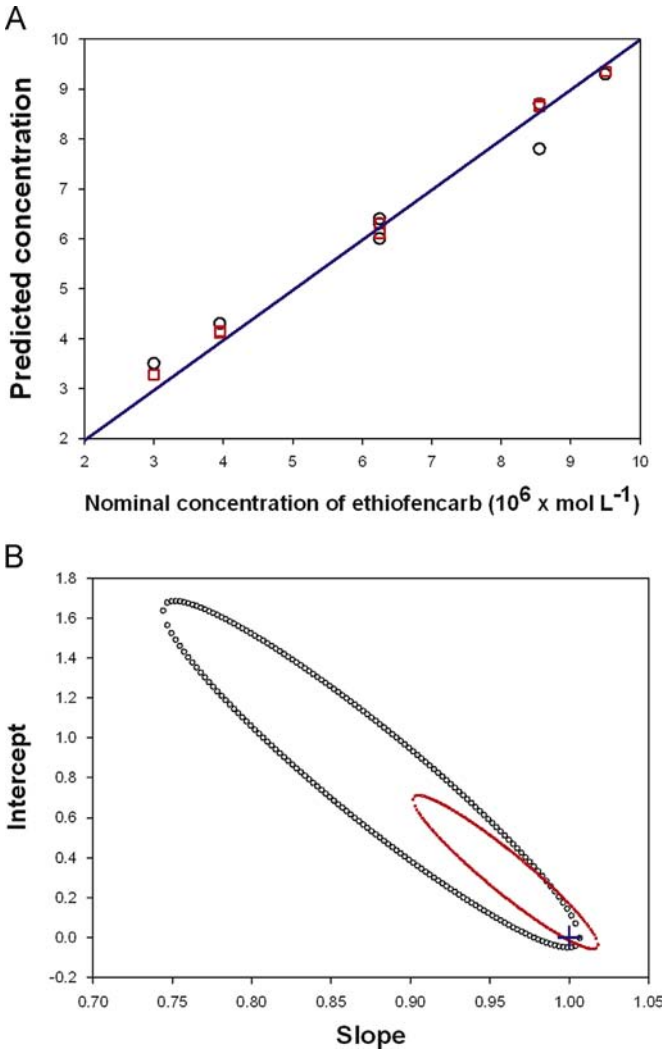

Fig. 5. (A) Predicted against nominal ethiofencarb concentrations in validation samples by MCR-ALS (black circles) and UPLS (red squares). (B) Elliptic joint confidence regions for predictions by MCR-ALS (black circles) and UPLS (red squares). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

4. Conclusions

The applicability of voltammogram evolution as a function of hydrolysis time in alkaline media accomplished through second-order multivariate calibration methodology has been demonstrated for the first time. The extreme overlap between the electroanalytical first-order signal shown by the target analyte and the interferences can be evaded by incorporation of the second-order signals using the kinetic hydrolysis time differences of the three components. Consequently, the feasibility of using second-order voltammetric data modeled with multivariate curve resolution-alternating least-square (MCR-ALS) and unfolded partial least squares regression followed by residual bilinearization (U-PLS/RBL) for the quantitation of the pesticide ethiofencarb was demonstrated in the presence of interferences in tap water. Considering the complexity of the data at hand, U-PLS/RBL (which was implemented for first time for voltammetric data) showed

a better performance than MCR-ALS in terms of predictive ability. Nevertheless, both algorithms reach reasonably good results.

It should be remarked that although more research and experimental work is necessary, this strategy show promise for quantitation of ethiofencarb at a lower cost than using more sophisticated techniques like HPLC–MS for example.

ABSTRACT

A polyethyleneimine (PEI)–iron phosphate ($FePO_4$) nanocomposite is prepared by immobilization of PEI onto the surface of $FePO_4$ nanoparticles via electrostatic interaction. The obtained PEI–$FePO_4$ nanocomposites are spherical with a size centered in ca. 100 nm. They provide a novel adsorbent for the solid-phase extraction of DNA from complex sample matrices. At pH 4, 50 μg mL^{-1} of DNA (salmon sperm DNA sodium salt) in 1.0 mL aqueous solution are quantitatively adsorbed (100%) by 2 mg of the PEI–$FePO_4$ nanocomposites, and meanwhile the coexisting albumin at a same concentration level is not retained, demonstrating the favorable selectivity of the nanocomposites to DNA against proteins. The adsorption behaviors of DNA onto the PEI–$FePO_4$ nanocomposites fit *Langmuir* model, corresponding to an adsorption capacity of 61.88 mg g^{-1}. The adsorbed DNA could be readily recovered by using a 0.04 mol L^{-1} Britton–Robinson (BR) buffer at pH 10, resulting in a recovery of 85%. The nanocomposites have been further used for the isolation of DNA from a series of real sample matrices, including synthetic λ-DNA sample, human whole blood and *Escherichia coli* cell lysate. The extraction efficiency and the purity of the recovered DNA are at least comparable to those achieved by using the reported sorbent materials or commercial kits. In addition, the DNAs isolated from human whole blood and *E. coli* cell lysate are of high quality, which have been further demonstrated by using them as templates for successful PCR amplifications.

1. Introduction

DNA-based assays are fundamental tasks in molecular biology and life science studies. In biological samples, DNA concentration is generally very low in comparison with those of coexisting proteins, e.g., ng level of DNA versus mg level of proteins in μL volume of whole blood in addition to even high concentrations of other sample matrix components [1]. In this respect, the isolation and purification of DNA from complex biological sample matrices is a critical issue and it is mandatory in forensic, clinic analysis and molecular biochemistry applications, with the aim to obtain qualified templates for the subsequent downstream processes including polymerase chain reaction, cloning, sequencing and hybridization [2–4]. Among the various methodologies for DNA extraction/purification, solid-phase extraction (SPE) is the most popular approach which is able to provide rapid and efficient isolation/purification of DNA along with certain extent of preconcentration. Further, the use of volatile and harmful organic solvents is generally avoided. Conventionally, silica has been one of the most useful sorbent material for the adsorption/purification of DNA, due to its ease of surface modification and favorable biocompatibility [5,6]. DNA could be efficiently adsorbed onto positively charged surface of amino-modified silica nanoparticles without any extra binding agents and the adsorbed DNA is protected from enzymatic cleavage [7]. Aqueous media of high ionic strength are usually necessary to promote the adsorption of DNA on silica as a result of a series of interactions [8]. In aqueous medium, DNA exists as a large negatively charged polyanion with phosphate groups on the nucleic acid backbone, thus it could be readily captured on positively charged sorbent materials [9]. This offers an effective strategy for DNA extraction/purification based on ionic interactions with cationic moieties [10]. Immobilization of silane moieties on the surface of various solid supports has been demonstrated to be an effective way to introduce positive charge for facilitating ionic interaction with DNAs [11,12].

Some other sorbent materials have recently been reported for the adsorption of DNAs. The superparamagnetic iron oxide is found to be able to adsorb DNA [13]. In practical applications, magnetic particles with size of <30 nm are preferential which are well dispersed without aggregation [14]. DNA extraction has been performed by using 3-[2-(2-aminoethyl)-ethylamino]-propyltrimethoxysilane and hyper-branched polyamidoamine dendrimer modified bacterial magnetic particles as adsorbents [15], and an

improvement on DNA adsorption efficiency is observed with the presence of a large number of amino groups [16]. Polyethylenimine (PEI) is a multivalent cationic agent with abundant amino groups. PEI-modified magnetic Fe_3O_4 nanobeads have been used as a medium for the purification of plasmid DNA from bacterial cell lysates [17]. The obtained plasmid DNA is of good quality and free of other contaminant molecules in the culture medium.

Iron phosphate ($FePO_4$) nanoparticles provide a biocompatible medium and it has gained interest in various fields including gas storage and adsorption [18]. The potentials for the use of fluoridized iron phosphate in the selective adsorption of protein species of interest have been previously reported [19]. It is expected to provide special selectivity for DNA adsorption with iron phosphate by combining the features of amino groups in PEI. Therefore, in the present study $FePO_4$ nanoparticles are used as solid support for the immobilization of PEI, and the obtained PEI–$FePO_4$ nanocomposite is used as a powerful adsorbent for the selective extraction of DNA. DNA is selectively adsorbed on the PEI–$FePO_4$ nanocomposites at pH 4 via electrostatic interaction, and the adsorption equilibrium is reached within a very short time, i.e., 30 s. The adsorbed DNA could be recovered by using Britton–Robinson (BR) buffer at pH 10. The developed extraction protocol is applied to the extraction of DNAs from different matrices including synthetic λ-DNA samples, human whole blood and *Escherichia coli* cell lysate. The DNAs recovered are demonstrated to be high purity and suitable for downstream PCR amplification.

2. Experimental

2.1. Materials

Branched polyethyleneimine (Mw ≈ 25 kDa) was received from Aldrich (Milwaukee, MI, USA). Bovine serum albumin (BSA) and salmon sperm DNA sodium salt were purchased from Sigma (St. Louis, MO) and used as received. DL2000 DNA Marker and λ-DNA were from Takara Biotechnology (Dalian, China). 2 × Power Taq PCR MasterMix, Proteinase K and whole blood genomic DNA extraction kit (Spin-Column) were obtained from BioTeke Corporation (Beijing, China). AxyPrep plasmid Miniprep kit was the product of Axygen Biotechnology Co. Ltd. (Hangzhou, China). Primers for 500 bp fragment of λ-DNA, 580 bp fragment of human P53 gene and 700 bp fragment of GFP gene were provided by Sangon Biotech (Shanghai, China). Cetyltrimethyl Ammonium Bromide (CTAB), $(NH4)_2Fe(SO_4)_2 \cdot 6H_2O$, HCl, H_3PO_4, HAc, H_3BO_3, NaCl, urea, EDTA and Triton X-100 were purchased from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China). Agarose was the product of Hispanagar Company (Spain).

All the reagents used were at least of analytical reagent grade unless specified. 18 MΩ cm deionized water was used throughout.

Human whole blood samples from healthy volunteers were provided by the Hospital of Northeastern University (China). After adding appropriate amount of anticoagulant, the blood samples were stored in a refrigerator at −20 °C for future use.

2.2. Preparation of $FePO_4$ nanoparticles

$FePO_4$ nanoparticles were prepared in a microwave system based on a literature protocol with minor modifications [20]. Shortly, 1.2 g of urea and 0.1 g of CTAB were dissolved in 40 mL of $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ solution (0.1 mmol). Then 0.1 mmol of H_3PO_4 was added. The mixture was vigorously stirred until a homogeneous solution was obtained. The homogeneous reaction mixture was afterwards transferred into a 300 mL round-bottom flask and placed in an UWave-1000 Microwave · Uv · Us Synthesis/Extraction Reactor (Sino Microwave Chemistry Technology Co. Ltd, Shanghai, China) for carrying out the reaction at 80 °C for 15 min. The product was eventually cooled down to room temperature.

2.3. Immobilization of PEI onto $FePO_4$ nanoparticles and characterizations of the PEI–$FePO_4$ nanocomposites

400 mL of the above mentioned $FePO_4$ solution and 10 mL of PEI solution (5 mg mL^{-1}) were mixed together, and the mixture was then sonicated for 2 h under ultrasound irradiation to facilitate the immobilization of PEI onto the surface of $FePO_4$ nanoparticles. After centrifugation at 10,000 rpm for 3 min, the supernatant was discarded and the residue was collected and washed with double-distilled water for three times. The final product was dried at 50 °C for 6 h for future use.

The morphologies of the obtained PEI–$FePO_4$ nanocomposites were monitored by a Superscan SSX-550 Scanning Electron Microscope (Shimadzu, Japan) at 200 kV. FT-IR spectra was recorded with a Nicolet 6700 spectrometer (Thermo Electron, USA) from 400 cm^{-1} to 4000 cm^{-1} with a resolution of 2.0 cm^{-1}. The surface charge properties of the PEI–$FePO_4$ nanocomposites were investigated by measuring the Zeta potential with a ZEN3600 Nano Zetasizer (Malvern, England). Absorption spectra were recorded on a U-3900 UV–vis spectrophotometer (Hitachi, Japan) with a 1.0 cm quartz cell.

2.4. DNA adsorption on PEI–$FePO_4$ nanocomposites

The dependence of DNA adsorption on the variation of pH value was investigated within a range of pH 2–12. 2 mg of the PEI–$FePO_4$ nanocomposites were added into 1.0 mL of DNA aqueous solution (50 μg mL^{-1}), and the mixture was then shaken vigorously for 30 s to facilitate the adsorption of DNA. After phase separation by centrifugation at 8000 rpm for 3 min, the supernatant was collected to quantify the DNA content remained in the original aqueous solution by monitoring the soret band of DNA at 260 nm.

For the recovery of the adsorbed DNA, the PEI–$FePO_4$ nanocomposites were prewashed with ethanol (70%, v/v) to remove the loosely retained matrix components via physical adsorption. 1.0 mL of Britton–Robinson (BR) buffer solution at pH 10 (0.04 mol L^{-1}) was then added as a stripping reagent. The mixture was oscillated for 5 min to facilitate the stripping of the retained DNA from the PEI–$FePO_4$ nanocomposites. After centrifugation at 8000 rpm for 3 min, the supernatant with the recovered DNA was collected for the ensuing investigations.

2.5. Sample preparation

A 200 μL aliquot of synthetic sample consisting of 3.5 mg L^{-1} λ-DNA, 0.1 g L^{-1} BSA and 0.3 mol L^{-1} $MgCl_2$ was diluted to 1000 μL by using a 0.01 mol L^{-1} BR buffer at pH 4.

A 250 μL aliquot of human whole blood sample was mixed with 20 μL of proteinase K (20 μg μL^{-1}). After incubating at room temperature for 15 min, the mixture was put into a water bath of 56 °C for further incubating for 10 min, and the lysate was then diluted to 1000 μL by using a 0.01 mol L^{-1} BR buffer at pH 4.

E. coli DH-5a cells containing PEGFP-C1 plasmid were cultured overnight in a shaker flask at 37 °C in 100 mL of LB medium containing 50 mg L^{-1} Kanamycin. 1.5 mL of *E. coli* cell cultures were pelleted at 8000 rpm for 3 min by centrifugation. The cells were then mixed with a 100 μL of 10% Triton-X solution containing 400 μg proteinase K. After incubating at room temperature for 15 min, the mixture was put into a water bath of 56 °C for 10 min, and the lysate was then diluted to 1000 μL by using a 0.01 mol L^{-1} BR buffer at pH 4.

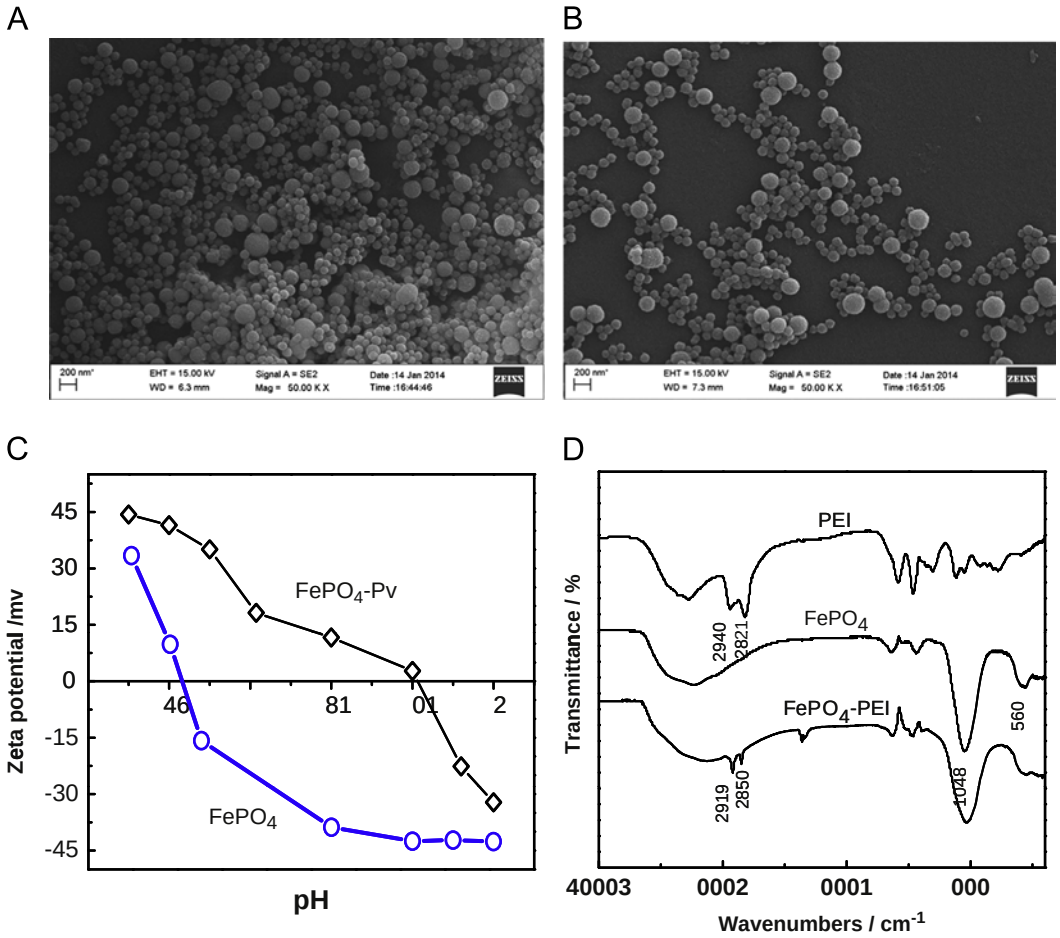

Fig. 1. SEM images of (A) bare $FePO_4$ and (B) PEI–$FePO_4$ nanocomposites. (C) Zeta potential of the bare $FePO_4$ and PEI–$FePO_4$ nanocomposites. (D) FT-IR spectra of PEI, bare $FePO_4$ and PEI–$FePO_4$ nanocomposites.

3. Results and discussion

3.1. Characterization of the PEI–$FePO_4$ nanocomposites

The SEM images of bare $FePO_4$ and the PEI–$FePO_4$ nanocomposites are illustrated in Fig. 1A and B, where microspheres with sizes of 90–200 nm (centered in ca. 100 nm) are observed for both $FePO_4$ and PEI–$FePO_4$ nanocomposites. It seems that the immobilization of PEI onto $FePO_4$ surface poses virtually no change on the morphology and size distribution of the nanoparticles. However, the obtained PEI–$FePO_4$ nanocomposites are well dispersed with much less aggregation with respect to that observed for the bare $FePO_4$ nanoparticles. The improvement on dispersion is favorable for DNA adsorption as more interaction sites should be provided in an aqueous medium.

This immobilization of PEI onto the surface of $FePO_4$ nanoparticles is most probably facilitated by the electrostatic interaction between them. As illustrated clearly that the surface of bare $FePO_4$ nanoparticles is negatively charged with a ζ potential of ca. -18 mV within a range of pH 4–12. After modification with PEI, a positively charged surface is achieved for the PEI–$FePO_4$ nanocomposites within pH 3–10. At a higher pH value, i.e., pH > 10, the surface of PEI–$FePO_4$ nanocomposites turns to negatively charged. These results might be ascribed to the abundant amino groups in the structure of PEI. The decrease of pH value, i.e., the increase of $[H^+]$, results in protonatation of the amino groups, which contributes to a higher ζ potential [21]. The surface charge property of the PEI–$FePO_4$ nanocomposites is obviously favorable for the adsorption of DNA within a neutral medium and followed by desorption of DNA in a medium at pH > 10.

FT-IR spectra of PEI, bare $FePO_4$ and PEI–$FePO_4$ nanocomposites are shown in Fig. 1D. The absorption bands at 560 cm^{-1} and 1048 cm^{-1} in the spectrum of $FePO_4$ nanoparticle are attributed to the asymmetric vibrations of O–P–O [22] and Fe–O–P bond [23]. These bands are also clearly identified in the spectrum of PEI–$FePO_4$ nanocomposites. After the modification of PEI, the absorption bands at 3300–3600 cm^{-1}, 2850 cm^{-1} and 2919 cm^{-1}, which are the characteristic stretching vibrations of N–H, vibration of $-CH_3$ and $-CH_2$ of PEI, are all observed in the spectrum of PEI–$FePO_4$ nanocomposites [24]. These observations well suggest the successful immobilization of PEI onto the $FePO_4$ nanoparticles.

3.2. Selective adsorption of DNA on PEI–$FePO_4$ nanocomposites

The pH-dependent adsorption behaviors of DNA onto the PEI–$FePO_4$ nanocomposites are investigated and the results are shown in Fig. 2A. It is obvious that favorable adsorption of DNA, i.e., ca. 100% adsorption efficiency, is achieved at pH 2–5. At pH > 5, a significant drop of the adsorption efficiency is encountered, and the adsorption of DNA becomes marginal at pH > 10. These observations could be well explained by the electrostatic interaction between DNA moiety and the PEI–$FePO_4$ nanocomposites. As illustrated in Fig. 1C that at pH 2–10, the surface of PEI–$FePO_4$ nanocomposites is positively charged with the ζ potential ranges from 45 mV to 3 mV, while the polyanionic DNA moiety is negatively charged within the same pH range. Therefore, at a lower pH value the strong electrostatic attraction between polyanionic DNA moiety and the PEI–$FePO_4$ nanocomposites facilities the adsorption of DNA and eventually results in a favorable adsorption efficiency.

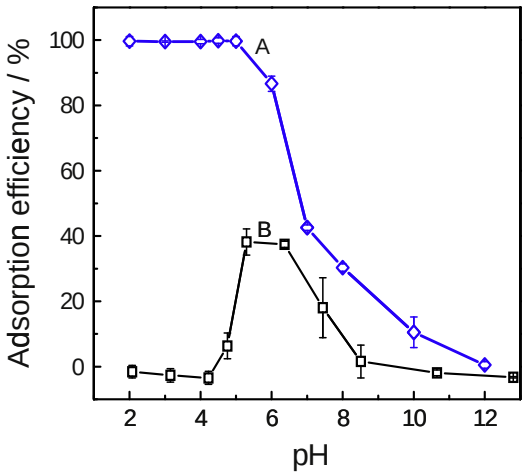

Fig. 2. pH-Dependent adsorption efficiency of (A) DNA and (B) BSA. The amount of PEI–$FePO_4$ nanocomposites: 2 mg; DNA concentration: 50 μg mL^{-1}; BSA concentration: 50 μg mL^{-1}; adsorption time: 30 s.

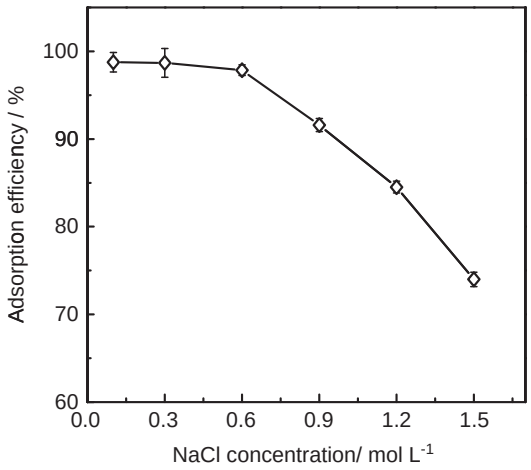

Fig. 3. The effect of ionic strength on the adsorption of DNA. The amount of PEI–$FePO_4$ nanocomposites: 2 mg; DNA concentration: 50 μg mL^{-1}; pH: 4; adsorption time: 30 s.

The increase of pH value gives rise to a decrease of positive surface charge of the PEI–$FePO_4$ nanocomposites, which leads to a decrement of electrostatic attraction between DNA and the PEI–$FePO_4$ nanocomposites. This causes a gradual drop of the adsorption efficiency. At pH > 10, the surface of the PEI–$FePO_4$ nanocomposites turns to negatively charged and thus the electrostatic repulsion deteriorates the adsorption of DNA.

In the adsorption of DNA from biological samples, the potential interference from coexisting proteins is a critical issue. In this respect, the adsorption of protein by the PEI–$FePO_4$ nanocomposites is investigated with BSA as a model. As shown in Fig. 2B a maximum adsorption of BSA is achieved at a pH value close to its isoelectric point, i.e., pI ~4.8, while virtually no adsorption on BSA is observed at pH < 4 or pH > 8. It is known that BSA is positively charged at a pH value of lower than its isoelectric point, i.e., pH < pI, thus its adsorption is prohibited at pH < 4 due to the electrostatic repulsion between the BSA and the positively charged PEI–$FePO_4$ nanocomposites. With the increase of pH value to exceed the isoelectric point, BSA turns to neutral and then to negatively charged, the electrostatic attraction with the positively charged PEI–$FePO_4$ nanocomposites facilitates its adsorption. By further increasing the pH value a decrease of BSA adsorption is encountered similar to that described for the case of DNA adsorption. In practical applications, the adsorption of DNA is conducted at pH 4, where the adsorption of protein is avoided at same experimental conditions. On the other hand, further experiments have indicated that at pH 4 the presence of protein, i.e., BSA at a same concentration level, causes no effect on the adsorption of 50 μg mL^{-1} DNA.

Generally, the ionic strength exhibits significant effect on the adsorption behaviors of biomacromolecules on solid materials in which electrostatic interaction plays a governing role on the adsorption process [25]. In the present case, the effect of ionic strength is investigated by introducing certain amount of NaCl (0–1.5 mol L^{-1}) into the DNA sample solution. The experimental results illustrated a substantial decrease on the adsorption efficiency of DNA with the increase of the ionic strength (Fig. 3). This observation further indicates that the adsorption of DNA onto the PEI–$FePO_4$ nanocomposites is mainly governed by electrostatic interaction [26].

As mentioned previously that selective adsorption of DNA onto the surface of the PEI–$FePO_4$ nanocomposites is achieved at pH 4 with coexisting proteins. It has been further demonstrated that the adsorption of DNA is a fast process and the adsorption equilibrium is reached within 30 s. The dynamic adsorption isotherm at room temperature within a DNA concentration range

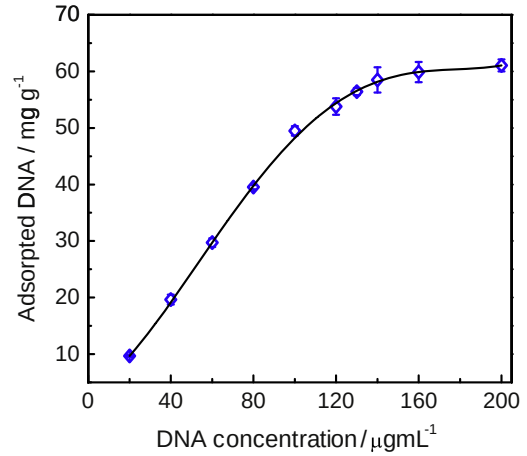

Fig. 4. Adsorption isotherm of DNA onto the PEI–$FePO_4$ nanocomposites recorded at pH 4 by using 2 mg of the PEI–$FePO_4$ nanocomposites with an adsorption time of 30 s.

of 20–200 mg L^{-1} is illustrated in Fig. 4. The experimental data fit *Langmuir* theoretical adsorption model as expressed in the following:

$$Q^* = \frac{Q_m \times C^*}{K_d + C^*}$$

C^* is the DNA concentration in aqueous solution, Q^* denotes the amount of DNA retained by the PEI–$FePO_4$ nanocomposites. Q_m represents the maximum adsorption capacity and K_d is the dissociation constant. An adsorption capacity of 61.88 mg g^{-1} is derived by fitting the experimental data. Table 1 compares the maximum DNA sorption capacity of the present nanocomposite with those of other materials reported in the literatures. It is obvious that the PEI–$FePO_4$ nanocomposite offers a relatively higher sorption capacity for DNA.

3.3. DNA recovery from the PEI–$FePO_4$ nanocomposites

As discussed in the previous section that electrostatic interaction is the major driving force for the adsorption of DNA onto the PEI–$FePO_4$ nanocomposites. The adsorption of DNA is strongly dependent on the variation of pH value and ionic strength of the sample solution. Therefore, the recovery of the adsorbed DNA from the surface of PEI–$FePO_4$ nanocomposites could be facilitated by

Table 1
The maximum adsorption capacities of DNA by various adsorbents.

Adsorbent	Sorption capacity ($mg\ g^{-1}$)
Ionic liquid-modified Fe_3O_4 nanoparticles [27]	19.8
Fe_3O_4@SiO_2-NH magnetic nanoparticles [28]	27.9
Aminosilane-modified bacterial magnetic particles [11]	60
PEI-modified Fe_3O_4 nanoparticles [14]	70
PEI–$FePO_4$ nanocomposites (this work)	61.88

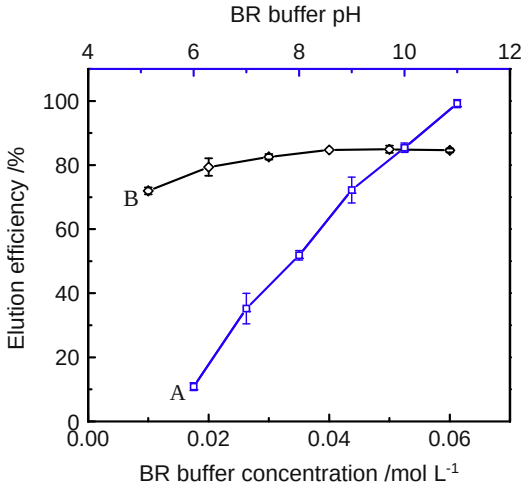

Fig. 5. (A) pH-Dependent recovery of DNA from the surface of PEI–$FePO_4$ nanocomposites. 2 mg PEI–$FePO_4$ nanocomposites; DNA concentration: 50 μg mL^{-1}; adsorption time: 30 s; stripping time: 5 min. (B) The variation of DNA recovery with ionic strength of the stripping reagent. 2 mg PEI–$FePO_4$ nanocomposites; DNA concentration: 50 μg mL^{-1}; pH 10; adsorption time: 30 s; stripping time: 5 min.

regulating either the pH value or the concentration of electrolyte in the stripping reagent or eluent. Taking into consideration that the collected DNA should fulfill the requirement for further biological investigations, e.g., PCR amplification, a BR buffer solution is preferential for this purpose. Fig. 5A illustrates the pH-dependent recovery of DNA within a range of pH 6–11. It is obvious that an increase of the pH value results in a significant improvement on the recovery of DNA, and at pH 11, ca. 100% recovery is achieved. Considering that a too strong alkali medium tends to cause conformational change on the DNA moiety, a BR buffer solution at pH 10 is adopted.

The ionic strength of the stripping reagent is controlled by regulating the concentration of the BR buffer solution, and the dependence of DNA recovery on the ionic strength is shown in Fig. 5B. An improvement of DNA recovery from ca. 70% to 85% is achieved by increasing the BR buffer concentration from 0.01 mol L^{-1} to 0.04 mol L^{-1}, and the recovery remains virtually unchanged by further increasing the BR buffer concentration up to 0.06 mol L^{-1}. The increase of BR buffer concentration, i.e., the ionic strength, shields the electrostatic interaction between DNAs and the PEI–$FePO_4$ nanocomposites. Therefore, for the ensuing experiments, a BR buffer concentration of 0.04 mol L^{-1} is adopted for DNA stripping, giving rise to a recovery of 85%.

3.4. DNA isolation from synthetic sample, human whole blood and E. coli cell lysate

The PEI–$FePO_4$ nanocomposites have been applied for the isolation of DNA from various real sample matrices, including synthetic λ-DNA sample, human whole blood and *E. coli* cell lysate. The DNAs recovered from these samples are then used as templates for PCR-amplification by a MyCycler™ thermal cycler (Bio-Rad Laboratories, USA).

For the synthetic λ-DNA sample, a 500 bp DNA fragment was amplified using the forward primer 5′-GATGAGTTCGTGTCCGTACAACTGG-3′ and the reverse primer 5′-GGTTATCGAAATCAGCCACAGCGCC-3′. The PCR cocktail consists of 4 μL of the recovered λ-DNA, 2 μL of forward/reverse primer (10 μmol L^{-1}) and 25 μL of 2 × Power Taq PCR Master Mix in a final volume of 50 μL. The PCR temperature program is 95 °C for 5 min, 35 cycles at 95 °C for 30 s, 68 °C for 1 min, and 72 °C for 1 min, with a final extension at 72 °C for 10 min.

For the human whole blood sample, a 543 bp P53 gene fragment was amplified using the forward primer 5′-CCACCATCCACTACAACTACAT-3′ and the reverse primer 5′-GCTTGCTTACCTCGCTTAG-3′. The PCR cocktail consists of 2 μL of the recovered λ-DNA, 1 μL of forward/reverse primer (10 μmol L^{-1}), 13 μL of 2 × Power Taq PCR Master Mix in a final volume of 25 μL. The PCR temperature program is 95 °C for 5 min, 35 cycles at 95 °C for 30 s, 57 °C for 30 s, and 72 °C for 1 min, with a final extension at 72 °C for 5 min.

For the *E. coli* cell lysate, 2 μL (10 mg mL^{-1}) RNase was added to eliminate the interference from RNA, and then a 700 bp EGFP gene fragment was amplified using the forward primer 5′-CCTG GATCCATGGTGAGCAAGGGCGAGGAG-3′ and the reverse primer 5′-GCGCTCGAGTTACTTGTACAGCTCGTCCATG-3′. The PCR cocktail consists of 2 μL of the recovered λ-DNA, 2 μL forward/reverse primer (10 μmol L^{-1}), 25 μL of 2 × Power Taq PCR Master Mix in a final volume of 50 μL. The PCR temperature program is 94 °C for 5 min, 35 cycles at 94 °C for 60 s, 56 °C for 30 s, and 72 °C for 1 min, with a final extension at 72 °C for 10 min.

The quantity and quality of the isolated DNAs from the above sample matrices are estimated by measuring the absorbance at 260 nm (A_{260}) and the absorbance ratio at 260 nm/280 nm (A_{260}/A_{280}), respectively. In the present study, the concentration of the isolated DNAs can be read directly from the Synergy H1 hybrid multi-mode microplate reader by measuring its UV absorbance at 260 nm. Consequently, the quantity of isolated DNAs is calculated according to its concentration and the eluent volume.

By using the PEI–$FePO_4$ nanocomposites as adsorbent for DNA extraction, 4.6 μg of human genomic DNA and 19.1 μg plasmid DNA are isolated from 200 μL of human whole blood and 1.5 mL of *E. coli* cell culture. The yields for DNA extraction by using the PEI–$FePO_4$ nanocomposites as adsorbent are comparable to those obtained by previously reported adsorbents as shown in Table 2. The A_{260}/A_{280} ratio for the recovered DNA from human whole blood and *E. coli* cell lysate are ca. 1.88 and 1.90, respectively, indicating that the extracted DNA templates are of high purity with negligible protein contamination. Especially, extraction of DNAs with PEI–$FePO_4$ nanocomposites exhibits a few distinct advantages, including (1) PEI–$FePO_4$ nanocomposites are readily available with low cost; (2) they entail a fast equilibrium within 30 s; (3) they avoid the use of chaotropic reagents and eliminate potential contamination of the recovered DNA sample which generally tends to inhibit PCR amplification; (4) a simple manipulation of the pH value facilitates flexible recovery of DNA with a favorable efficiency of 85%.

Fig. 6 illustrates the electrophoretograms for the PCR products. It can be seen that the 500 bp, 543 bp and 700 bp amplified products from λ-DNA, human whole blood gene and *E. coli* cell lysate are clearly identified (as illustrated in the lanes 2,3 in Fig. 6A–C). It is noticeable that comparable results are observed for the DNAs isolated from the corresponding sample matrices by using the PEI–$FePO_4$ nanocomposites as adsorbent with respect to those obtained by using the commercial DNA extraction kits. It is worthy to notice that no PCR amplified products are observed when directly using the synthetic λ-DNA sample, human blood and *E. coli*

Table 2
Yields of DNAs from human whole blood and *E. coli* cell culture with extraction by various adsorbents.

Adsorbent	DNA yields (human whole blood, μg/200 μL)	Adsorbent	DNA yields (*E. coli* cell culture, μg/1.5 mL)

cell lysate as templates. The successful PCR amplifications further demonstrate that the DNAs isolated from human whole blood and *E. coli* cell lysate are of high purity, indicating the favorable efficiency of PEI–$FePO_4$ nanocomposites for DNA adsorption.

4. Conclusions

Polyethyleneimine (PEI) is immobilized on the surface of $FePO_4$ nanoparticles via electrostatic interactions. The obtained PEI–$FePO_4$ nanocomposites exhibit favorable selectivity for the adsorption of DNAs with high efficiency in biological samples at pH 4 driven by the electrostatic interaction between the negatively charged poly-anionic DNA moiety and the positively charged amino groups on the surface of the PEI–$FePO_4$ nanocomposites. The retained DNAs can be readily recovered by simply manipulating the pH value. The PEI–$FePO_4$ nanocomposites have been demonstrated for the isolation of DNAs from a series of real sample matrices, including synthetic λ-DNA sample, human whole blood and *E. coli* cell lysate. The DNAs isolated by using the PEI–$FePO_4$ nanocomposites as adsorbent are well suitable for PCR amplifications.

ABSTRACT

A π-conjugated cyanostilbene derivative of (Z)-2-(4-nitrophenyl)-3-(4-(vinyloxy)phenyl)acrylonitrile (**CN-vinyl**) had been designed, synthesized and confirmed by the standard spectroscopic analyses. **CN-vinyl** possesses an unusual high emissive aggregation-induced emission (AIE) feature in a tetrahydrofuran/water mixture (2:8, v/v). The fluorescence intensity of **CN-vinyl** can be quenched linearly with the addition of Hg^{2+} in a range of 0–50 μM with a correlation coefficient of $R^2=0.9957$. The detection limit of Hg^{2+} is 37 nM. The mechanism for Hg^{2+}-mediated optical properties of **CN-vinyl** is due to the selective cleavage of vinyl group by Hg^{2+}. Accuracy of the proposed methodology was evaluated by means of the recovery study in real samples and the analyzing certified reference material of the standard solution of Hg^{2+}. By this novel strategy, **CN-vinyl** can be used for quantitative detection of Hg^{2+} as well as the presence of other physiological relevant metal ions.

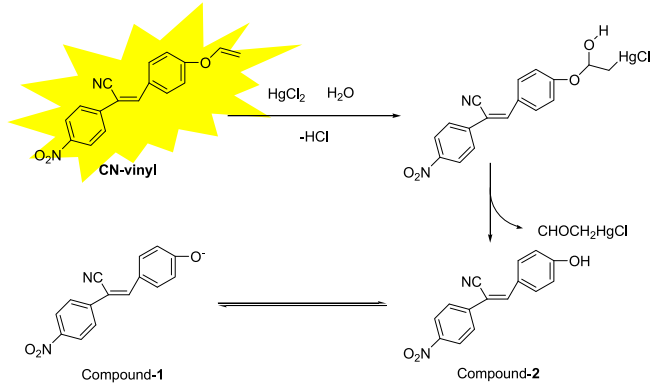
1. Introduction

Mercury, a class of heavy metal distributed throughout the environment by both natural processes and human activities, has long been identified as one of the most toxic heavy metals and a kind of persistent contaminant [1,2]. It can first be transformed into organic mercury after being absorbed from the environment by organisms, and then accumulated highly in trophic animals through the food chain [3,4]. According to recent reports, the toxicity of Hg^{2+} can induce a variety of syndromes and harmful effects [5], such as damage DNA, disable normal functions of liver and kidney, disrupt the immune system homeostasis [6–9] etc. Therefore, efficient monitoring the trace amount of Hg^{2+} with highly selective and sensitive is remarkably important for human health. Conventional analytical techniques include spectrophotometry, atomic absorption spectrometry, inductively coupled plasma–mass spectroscopy (ICP–MS), cold-vapor atomic fluorescence spectrometry (CV-AFS), ultraviolet–visible spectrometry, and X-ray absorption spectroscopy [10–15]. Whereas, these methods require expensive intricate instrumentation and complicated sample preparation processes. Moreover, the complexity makes them unsuitable for using in on-site Hg^{2+} analyses. Different from the traditional Hg^{2+} analyses, fluorescence probe offers several advantages for Hg^{2+} measurements because of its high sensitivity, lower detection limit, non-sample destructing and simple operation. In consequence, these unique characteristics make it favorable for both detection and imaging of Hg^{2+} in biological samples [16]. Many Hg^{2+} chemosensors with fluorescence response have been reported, such as, proteins conjugated polymer and diblock copolymer fluorescence sensors, biomolecules fluorescence sensors, foldamer-based fluorescence sensors, inorganic gold nanoparticles and CdS nanoparticles, and small organic molecule fluorescence probes [9,17–20]. However, luminescence of these conventional fluorophores often becomes weakened or quenched at high concentration or solid state due to the thermodynamically favorable process under the driving forces of intermolecular π–π stacking interaction of aggregation. The outcome of this effect is the sacrifice of the fluorescence emission efficiency and reduction of sensing performance.



Fortunately, in 2001, Tang and co-workers first observed an intriguing phenomenon [21] that is the exact opposite of the aggregation-caused quenching (ACQ). Some practically non-luminescent in the solution state but become strongly emissive when aggregated or in the solid state due to suppression of nonradiative deactivation associated with restriction of intramolecular rotations (RIR). Then a large number of so called "aggregation-induced emission (AIE)" active molecules have since been developed, example of which including siloles, 1-cyano-trans-1, 2-bis-(4′-methylbiphenyl) ethylene (CN-MBE), 2, 5-diphenyl-1, 4-distyrylbenzene (DPDSB) derivatives, fluorenonearylamine derivatives, diphenyldibenzofulevne (DPDBF) derivatives, conjugated polymers, and so on [22–29]. Most of them can be employed as optical devices or bioprobes.

Scheme 1. Synthesis of CN-vinyl.

Scheme 2. The reaction mechanism of CN-vinyl with Hg^{2+}.

Zhu et al. have demonstrated that the vinyl group is useful to design Hg^{2+} probe [30]. Inspired by their works, a novel fluorescence turn-off probe **CN-vinyl** ((*Z*)-2-(4-nitrophenyl)-3-(4-(vinyloxy)phenyl) acrylonitrile) toward Hg^{2+} was designed and synthesized (as shown in Scheme 1). **CN-vinyl** is a potential AIE cyanostilbene derivatives based on π-conjugated fluorophore, and the vinyl group as a recognition site with unique and high reactivity toward Hg^{2+}. We hypothesized that the reaction of CN-vinyl with Hg^{2+} would result in the cleavage of the vinyl group and the recognition mechanism is shown in Scheme 2. In addition, compound-**2** (*Z*)-3-(4-hydroxyphenyl)-2-(4-nitr-ophenyl)acrylonitrile was also synthesized as a contrast of CN-vinyl and the synthetic route is shown in Fig. S1.

2. Experimental section

2.1. Reagents and apparatus

All reagents and solvents were commercially available and were used without further purification unless otherwise stated. The water used for investigating was distilled prior to use. 4-nitrobenzylcyanide and p-hydroxybenzaldehyde were purchased from Alfa Aesar. MeHgCl was purchased from Dr. Ehrenstorfer Germany. The certified reference material of the standard solution of Hg^{2+} was purchased from General Research Institute for Nonferrous Metals, China and the certificate information is shown in Table S1. Stock solutions of metal ions (2.5 mM, Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Al^{3+}, Fe^{2+}, Fe^{3+}, Mn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+}, Sn^{2+}, Ag^+, Cd^{2+}, Ba^{2+}, Cr^{3+}, $MeHg^+$, Hg^{2+}) were prepared in deionized water. Stock solution of **CN-vinyl** (2.5 mM) was prepared by dissolving 18.2 mg **CN-vinyl** in 25 ml THF. Phosphate buffer solutions (PBS) were prepared by combining proper amounts of NaH_2PO_4 and NaOH and adjusted by a pH meter. Purification of reaction products was carried out by flash chromatography using silica gel (300–400 mesh, Branch of Qingdao Haiyang Chemical Co., Ltd.).

Infrared spectra were recorded on a Shimadzu IR-8400S spectrophotometer. ^1H NMR and ^{13}C NMR spectra were recorded at 400 MHz on a Varian Gemin-400 respectively. ESI-MS spectra were obtained on Bruker spectrometers. All absorption and fluorescence spectra in this work were recorded in Pgeneral TU-1901 and Hitachi F-4500 fluorescence spectrometers. All pH values were measured with a Model pHS-3C pH meter (Shanghai, China). Analytical TLC was carried out on silica gel plates (HSGF254, 0.2 mm, Yantai Chemical Industry Research Institute). Melting points were measured with RD-II melting point apparatus (uncorrected, Tainjin Xintianguang Instrument Company).

2.2. Synthesis

2.2.1. Synthesis of 4-(2-bromoethoxy)benzaldehyde (compound-**3**)

A similar method was adopted to synthesize the titled compound according to literature [31]. To a solution of p-hydroxybenzaldehyde (1.22 g, 0.01 mol) and anhydrous K_2CO_3 (4.14 g, 0.03 mol) in 20 ml DMF, requisite linear chain aliphatic dibromoethane (9.35 g, 0.05 mol) was added and then stirred at 80 °C for 1 h. After the reaction was finished (controlled by TLC), the reaction mixture was cooled to 0 °C and quenched with 1 M HCl. The mixture was then extracted with $CHCl_3$ and the organic layer was washed with water, dried over anhydrous Na_2SO_4, and then filtered out. Excess solvent was evaporated under reduced pressure and the resultant solid left was purified by column chromatography (EtOAc/petroleum ether=1:5 as eluent) to afford compound-**3** (1.63 g, 72% yield). mp 52–54 °C. IR (KBr) *ν*: 1685, 1602, 1577, 1506, 1253, 1163, 831 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) *δ*: 9.88 (s, 1H), 7.83 (d, *J*=8.8 Hz, 2H), 7.00 (d, *J*=8.8 Hz, 2H), 4.36 (t, *J*=6.4 Hz, 2H), 3.65 (t, *J*=6.4 Hz, 2H).

2.2.2. Synthesis of 4-(vinyloxy)benzaldehyde (compound-**4**)

A similar method was adopted to synthesize the titled compound according to the literature [32]. To a solution of compound-**3** (0.227 g, 0.001 mol) in DMSO (10 mL), t-BuOK (0.224 g, 0.002 mol) was added. The reaction mixture was stirred at 25 °C for 4 h, after which it was diluted with EtOAc (20 mL), washed with H_2O (3 × 10 mL) and then brine (20 mL). The organic layer was dried, filtered, and concentrated. The crude product was purified by column chromatography (EtOAc/petroleum ether=1:5 as eluent) to afford compound-**4** as a colorless oil (0.082 g, 56% yield). IR (KBr) *ν*: 1697, 1645, 1598, 1504, 1299, 1249, 1161, 958, 833 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) *δ* (ppm): 9.90 (s, 1H), 7.85 (d, *J*=8.8 Hz, 2H), 7.09 (d, *J*=8.8 Hz, 2H), 6.67 (dd, *J*=6.0 Hz, 13.6 Hz, 1H), 4.92 (dd, *J*=2.0 Hz, 13.6 Hz, 1H), 4.61 (dd, *J*=1.6 Hz, 6.0 Hz, 1H).

2.2.3. Synthesis of (*Z*)-2-(4-nitrophenyl)-3-(4-(vinyloxy)phenyl) acrylonitrile (***CN-vinyl***)

To a mixture of compound-**4** (0.148 g, 0.001 mol) and 4-nitrobenzylcyanide (0.162 g, 0.001 mol) in absolute EtOH (5 mL), piperidine (0.255 g, 0.003 mol) was added with dropwise. After the reaction mixture was stirred at room temperature for 3 h, the obtained precipitated was filtered, washed with EtOH, dried and purified by column chromatography (CH_2Cl_2/petroleum=1:2 as eluent), a yellow solid was obtained. (0.233 g, 79% yield). mp 175–177 °C. IR (KBr) *ν*: 2212, 1643, 1596, 1579, 1508, 1336, 1257, 1180, 848 cm^{-1}. ^1H NMR (400 MHz, DMSO-d) *δ* (ppm): 8.34 (d, *J*=8.8 Hz, 2H), 8.28 (s, 1H), 8.06–8.00 (m, 4H), 7.27 (d, *J*=8.8 Hz, 2H), 7.03 (dd, *J*=6.0 Hz, 13.6 Hz, 1H), 4.89 (dd, *J*=1.6 Hz, 13.6 Hz, 1H), 4.62 (dd, *J*=1.6 Hz, 6.0 Hz, 1H). ^{13}C NMR (DMSO) *δ* (ppm): 158.9, 147.6, 147.3, 146.06, 140.7, 132.5, 132.3, 130.6, 128.3, 127.2, 124.8, 118.0, 117.1, 116.7, 106.7, 97.4, 97.3. ESI-MS (*m/z*): calcd for: $C_{17}H_{12}N_2O_3$ $[M+Cl]^-$ 327.05, found 327.1. Anal. calcd for: $C_{17}H_{12}N_2O_3$, C, 69.86; H, 4.14; N, 9.58; found: C, 70.55; H, 4.07; N, 9.56.

2.3. Analytical procedure

To characterize the AIE property of **CN-vinyl**, 100 μL stock solution of **CN-vinyl** (25 mM) was added to 10 mL THF/water (10:0, 4:6, 3:7, 2:8, 1:9, v/v, containing 50 mM NaH_2PO_4–NaOH). As shown in Fig. S10, the effect of water volume fraction on the pH was measured in THF/water containing 50 mM PBS. When THF and PBS was mixed well, the acidity of the solution decreased slightly (pH=7.21–7.94) compared with PBS (pH=7.0). It is probably due to the restricting ionization of acid induced by THF. Then, the mixed solution was incubated at room temperature for 15 min and was transferred to a 1 cm quartz cell for absorption spectra and fluorescence spectra.

In a standard detection method of Hg^{2+}, the test solution was prepared by placing 100 μL stock solution of **CN-vinyl** and 1.9 ml THF into a test tube, diluted to 10 mL with 50 mM PBS at pH=7.0, added appropriate amount of Hg^{2+} ions, incubate at room temperature for 15 min, and then record the fluorescence spectra.

To evaluate any possible facts which may affect the response of the fluorescence intensity caused by interfering ions, three sequences of addition were attempted. (1) The interfering metal ions were added to the test solution, and then Hg^{2+} was added to explore whether the reaction of **CN-vinyl** with Hg^{2+} ions was affected by the interfering metal ions; (2) Hg^{2+} ions were added to the test tube ahead, and then other interfering metal ions were added to explore whether the fluorescence intensity of reaction product was effected by interfering metal ions; (3) Hg^{2+} ions and interfering metal ions were added to the test tubes at the same time to simulate the application in real sample analysis. All of them were allowed to incubate at room temperature for 15 min following to record the fluorescence spectra.

For application in real sample analysis, the concentration of Hg^{2+} in real samples was detected by the standard addition method. $HgCl_2$ (4.1 mg) was added to 500 ml volumetric flask and diluted to metered volume with three real water samples which contain 50 mM PBS at pH=7.0 respectively, and gave 30 μM real sample solutions of Hg^{2+}. Moreover, the certified standard solution of Hg^{2+} (2.5 ml) was transferred to a 500 ml volumetric flask and diluted with PBS (50 mM, pH=7.0) to the metered volume, and give a 25 μM standard solution of Hg^{2+}. Subsequently, 100 μL stock solutions of **CN-vinyl** and 1.9 ml THF were placed into test tubes and diluted to 10 mL with the three real samples and the standard solution of Hg^{2+} respectively, and gave the test solutions. Finally, the fluorescence emission spectra were recorded.

All fluorescence spectra were recorded in the range from 480 nm to 650 nm using a 456 nm excitation wavelength. The excitation and emission bandwidths were set to 5 nm and 10 nm respectively.

3. Results and discussion

3.1. Aggregation-induced emission characteristics of CN-vinyl

We first studied the optical properties of **CN-vinyl** and compound-**2**. As shown in Fig. S11, both the absorption spectra of **CN-vinyl** and compound-**2** in THF solution exhibited three absorption bands at 245.0, 291.5, 365.5 nm and 249, 293.5, 368 nm respectively. Although **CN-vinyl** has a longer π-conjugated unit, it showed a blue-shift spectrum due to a more twisted conformation caused by the cyano and vinyl group. This process had been supported by the theoretical calculations which was performed at B3LYP/6–31G (d) basis in the Gaussian 09 package. The optimized molecular structures and HOMO and LUMO energy levels of **CN-vinyl** and compound-**2** are shown in Fig. S12. Obviously, both of them have strong intramolecular charge transfer (ICT) effect from the electron cloud distribution. The calculated energy band gap for **CN-vinyl** is 3.456 eV, which is wider than that of compound-**2** (3.392 eV). Hence, the results of theoretical studies are consistent with the absorption spectra.

The characteristics of **CN-vinyl** were investigated in THF/water (from 10:0 to 1:9, v/v) phosphate buffer solution (PBS, 50 mM, pH=7.0) and the results are shown in Figs. 1 and 2. As expected, there was a structured absorption spectra and almost no fluorescence emission could be detected in dilute THF solution, suggesting that **CN-vinyl** is non-fluorescence when dispersed in its "solution" state. However, its fluorescence spectra in a THF/water mixture with a high water fraction (80%) had an intensive band at 537 nm, and showed a leveling-off in the ultraviolet region of the absorption spectra (commonly observed in nanoaggregates suspension). The fluorescence increased by 79 times compared with that in pure THF and a lower THF volume fraction was found to enhance the AIE fluorescence intensity. These results correlated well with the fact that more aggregates were formed in poorer solvents. On the other hand, the maximum peak in the absorption spectra of the nanoparticle suspension of **CN-vinyl** had a clearly red-shift (12 nm) compared with that of dilute solution (as shown in Fig. 2). This result implied that there is an extension of the effective conjugation length which was caused by the planarization of twist molecular in nanoparticles. The new shoulder band (the arrow) observed around 450 nm should be resulted from the

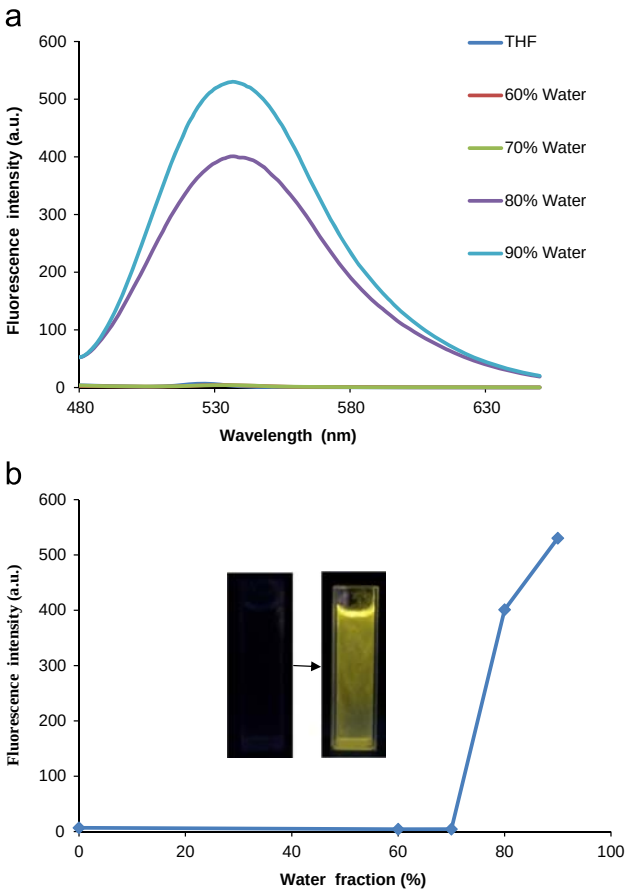

Fig. 1. (a) Fluorescent spectra of **CN-vinyl** (25 μM) in a THF/water mixture (excitation wavelength was 456 nm) (b) Effect of water volume fraction on the emission intensity of **CN-vinyl** (25 μM) in THF/water containing 50 mM PBS at pH 7.0. Inset show photographs of **CN-vinyl** (25 μM) in dilute THF solution and a THF/water mixture with a high water fraction under a UV lamp (365 nm). Excitation and emission was at 456 nm/537 nm respectively.

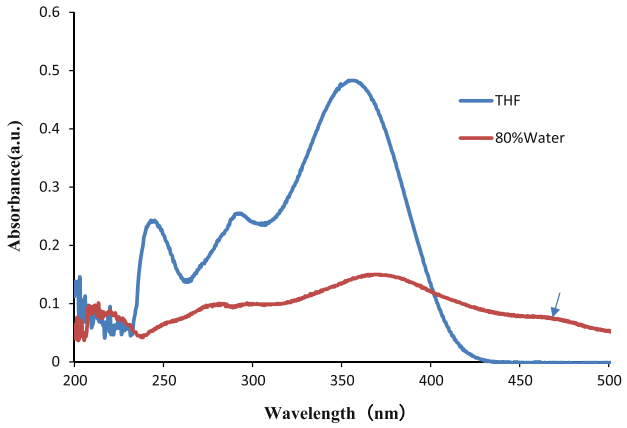

Fig. 2. Absorption spectra of **CN-vinyl** (25 μM) in a THF/water mixture.

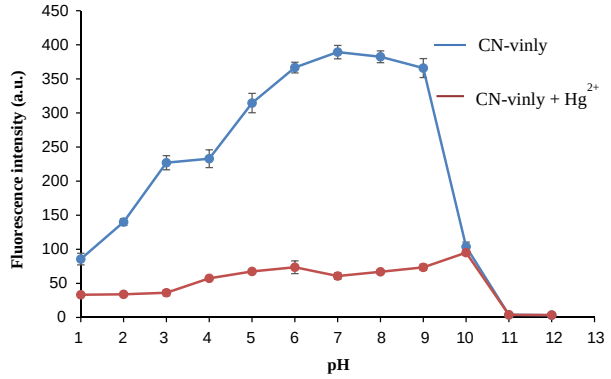

Fig. 3. Effect of pH on the emission intensity of probe **CN-vinly** (25 μM) at 537 nm in the absence and presence of 50 μM of Hg^{2+}. All measurements were taken in PBS (50 mM, pH=7.0) at25 °C. Excitation and emission were at 456 nm/537 nm respectively.

J-type aggregation. These date clearly indicated that **CN-vinyl** exhibits a significant feature of AIE.

3.2. Optimization of the analytical condition

The reaction conditions, such as pH, incubation time and buffer capacity of PBS, play an important role in the sensing process. The effects of pH value on the fluorescence intensity of **CN-vinyl** (25 μM), and the mixture of **CN-vinyl** (25 μM) with Hg^{2+} (50 μM) in THF/water (2:8, v/v) were investigated at first. As shown in Fig. 3, the fluorescence intensity of **CN-vinyl** decreased gradually with the rising of pH from 7.0 to 1.0 due to the formation of oxonium ion. However, when pH increased up to 10, there was almost no fluorescence because of the 1, 4-addition reaction of OH^- to α, β-unsaturated cyano compound, which lead to destruction of the conjugate structure. As **CN-vinyl** displayed a strong fluorescence changes in the pH range of 6–9 upon the addition of Hg^{2+}, and considering the application of samples in physiological or environmental, pH=7.0 was thus chosen as the experiment condition. In addition, the results of time-dependent fluorescence measurement of **CN-vinyl** (25 μM) and Hg^{2+} (50 μM) in THF/water (2:8, v/v, PBS, pH=7.0) is displayed in Fig. S13, of which would be quenched completely after 15 min. So, all the results of the assay were tested at the time of 15 min after the **CN-vinyl** was mixed with the Hg^{2+}. Finally, the buffer capacity of PBS (pH=7.0) was explored. As shown in Figs. S14 and 15, we could see that pH present a relatively stable value even if the concentration of Hg^{2+} ions or other interfering metal ions reach its maximum (50 μM) in 50 mM PBS.

3.3. Fluorescence detection of Hg^{2+} based on **CN-vinyl**

The fluorescence spectra of **CN-vinyl** upon titration with Hg^{2+} was recorded in THF/water (2:8, v/v) buffered by 50 mM PBS at pH=7.0 to investigated the quenching behavior of Hg^{2+} ion. As shown in Fig. 4, **CN-vinyl** itself showed a very strong emission. However, the fluorescence of **CN-vinyl** (25 μM) at 537 nm was dramatically decreased upon the addition of Hg^{2+} and followed a slight red-shift. Simultaneously, a perceived fluorescence color change of **CN-vinyl** was observed from yellow to colorless (Fig. 4, insert). It was plausible to suppose that a water-soluble species (should be compound-**2**) increased and the formation of aggregation of **CN-vinyl** decreased with the cleavage of the vinyl group upon the addition of Hg^{2+} to **CN-vinyl**. The quenching of photoluminescence is observed at a lower concentration of Hg^{2+}. The change of emission intensity became constant and caused 7-fold decrease when the addition of Hg^{2+} added to 2.0 equiv. (50 μM). There was an approximately linear relationship (R^2=0.9957) between fluorescence intensity at 537 nm and Hg^{2+} concentration in the range of 0 to 50 μM (Fig. 5). The detection limit was found to be 37 nM on the basis of the equation $L_{OD}=3\delta/m$ (δ was the standard deviation of the blank solution and m is the absolute value of the slope between fluorescence intensity and Hg^{2+} concentration) (Fig. S16). Above results demonstrated that our

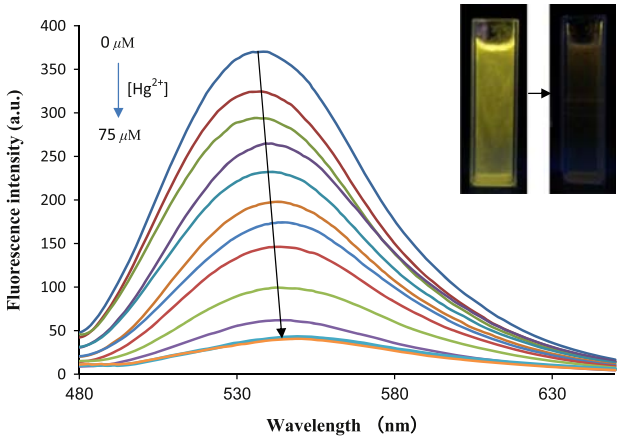

Fig. 4. Fluorescence spectra of **CN-vinyl** (25 μM) in the presence of different concentrations of Hg^{2+} ion at a THF/water mixture (2:8, v/v); Inset: fluorescence color change of **CN-vinyl** (25 μM) in the absence and presence of Hg^{2+} (2.0 equiv.). All measurements were taken in PBS (50 mM, pH 7.0) at 25 °C. Excitation wavelength was 456 nm.

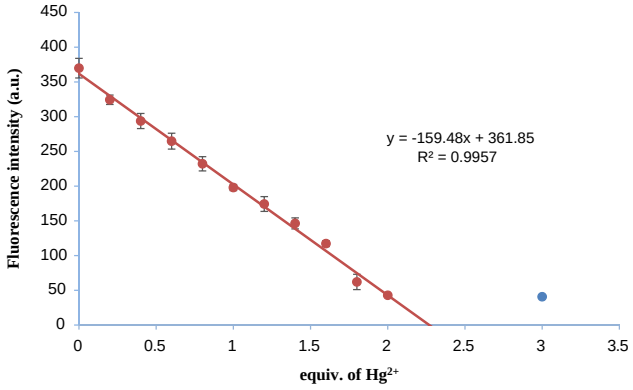

Fig. 5. The relationship between fluorescence intensity and Hg^{2+} concentration. Plots of the fluorescence intensity obtained from the reaction of **CN-vinyl** (25 μM) with Hg^{2+} (0–2.0 equiv.).All measurements were taken in PBS (50 mM, pH 7.0) at 25 °C. Excitation and emission were at 456 nm/537 nm respectively.

proposed **CN-vinyl** could detect Hg^{2+} in quantitative and with excellent sensitivity by the fluorescence spectrometry method.

3.4. Reaction mechanism

It has been reported that Hg^{2+} could selectively cleave the vinyl group by the oxymercuration reaction [33]. To verify our design principle of **CN-vinyl** for Hg^{2+}, the reaction mechanism was studied by ^1H NMR and mass spectra. Compound-**2** was isolated from the reacting system to confirm that the breakage action of **CN-vinyl** with Hg^{2+} had indeed produced after Hg^{2+} was added to **CN-vinyl**. ^1H NMR spectra of **CN-vinyl**, the isolated reaction product of compound-**2** and the synthesized compound-**2** were shown in Fig. 6A–C. Upon the addition of Hg^{2+}, three protons of **CN-vinyl** corresponding to the protons of vinyl group around 7.03, 4.94 and 4.62 ppm dramatically disappeared. Meanwhile, a new peak at 10.46 ppm which assigned to the released phenolic hydroxyl group emerged from the concomitant reaction. About the mass spectra, a same peak of $[M-H]^-$ (265.1*m/z*) for the isolated reaction product of compound-**2** and the synthesized compound-**2** were also found respectively. Especially, the isolated product of compound-**2** displayed a same absorption (Fig. S17) and fluorescence spectrum (Fig. S18) with the synthesized compound-**2.** All these experimental facts support the proposed oxymercuration reaction and the breakage reaction of **CN-vinyl** with Hg^{2+}.

3.5. Selectivity of *CN-vinyl* to Hg^{2+} over other metal ions

Selectivity is a very important parameter for evaluating the performance of a chemosensor. Twenty-one kinds of metal ions (2.0 equiv., 50 μM), such as Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Al^{3+}, Fe^{2+}, Fe^{3+}, Mn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+}, Sn^{2+}, Ag^+, Cd^{2+}, Ba^{2+}, Cr^{3+}, $MeHg^+$, Hg^{2+} (50 μM) were investigated by fluorescent spectra in THF/water (2:8, v/v, PBS, pH=7.0) solution at λ_{ex}=456 nm (Fig. 7). We can see that only Hg^{2+} (50 μM) could cause a significant fluorescent decrease emission of **CN-vinyl**. Especially, $MeHg^+$, a specific organic interferent, has no obvious fluorescence response change to **CN-vinyl** due to its more weak electrophilic to vinyl group compared to Hg^{2+}. Then, the interference of other metal ions was explored with three different sequences of addition of interfering ions and Hg^{2+}. The process was described in detail in analytical procedure and no remarkable

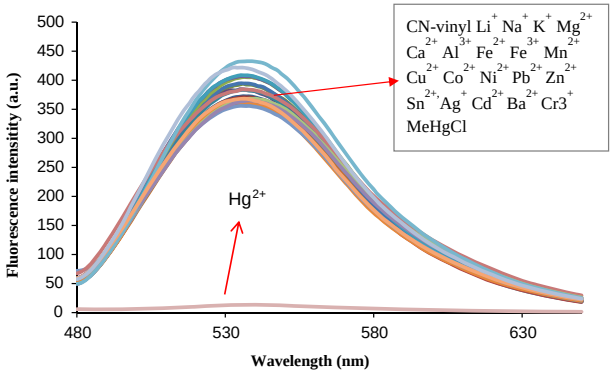

Fig. 7. Fluorescent spectra of **CN-vinyl** (25 μM) in the presence of various metal ions (50 μM) in THF/water (2:8, v/v); All measurements were taken in a pH 7.0 PBS (50 mM) at 25 °C, Excitation wavelength was 456 nm.

Detection of Hg^{2+} in real samples.

Sample	Added (μM)	Detected (μM)	Recovery (%)	RSD (%)
Tap water	0	Not detected	–	–
	30	30.82	102.73	2.91
Qinghe river	0	Not detected	–	–
	30	30.74	102.49	3.29
Weiming lake	0	Not detected	–	–
	30	30.38	101.27	1.91

Table 2
Detection in certified reference material of standard solution of Hg^{2+}.

Sample	Diluted concentration (μM)	Detected (μM)	Recovery (%)	RSD (%)
Standard solution of Hg^{2+}	25	25.32	101.28	2.80

changes were detected with the three assay ways in the presence of coexisting metal ions including organic mercury as shown in Fig. 8 and Figs. S19, S20. All these results showed that **CN-vinyl** has remarkable sensing selectivity to Hg^{2+}, which made it suitable for practical Hg^{2+} detection.

4. Analysis of Hg^{2+} in real sample

Three water samples were collected from Qinghe River in Beijing (sample 1), Weiming Lake in Beijing (sample 2) and tap water (sample 3). The results for the determination of Hg^{2+} were shown in Table 1 and no Hg^{2+} was detected in the three blank samples. When Hg^{2+} was added to them, the recovery was determined three times by the standard addition method and in range of 100–103%. These results demonstrate that the proposed assay strategy is successful in the detection of Hg^{2+} in real sample. In order to further demonstrate the accuracy of this method, the detection in certified reference material of standard solution of Hg^{2+} was carried out according to the analytical procedure. The results are summarized in Table 2 and it shows good agreement between the expected and found values. All these data above indicate the proposed method can be used to analyze Hg^{2+} accurately.

5. Conclusions

In summary, we have designed and synthesized a "turn off" quantitative fluorescence probe **CN-vinyl** and confirmed by the standard spectroscopic analyses. **CN-vinyl** possesses unusual AIE characteristic, and interestingly, has remarkable sensing selectivity to Hg^{2+}, which weaken with the increase of Hg^{2+} and showed a good linear relation (R^2=0.9957) with Hg^{2+} concentration in the range of 0 to 50 μM. There was no interference of coexist metal ions to Hg^{2+} with this assay and it could be used to detect Hg^{2+} with a low concentration limit of 37 nM. By means of NMR and MS analyses, the mechanism for Hg^{2+}-mediated optical properties of **CN-vinyl** is depicted. It has a potential to be used to detect Hg^{2+} ion in river, lake or tap water. The present study provides valuable information for designing fluorescent probes for Hg^{2+} by taking advantage of the selective cleavage of vinyl group by Hg^{2+}.

ABSTRACT

A new strategy for the assembly of graphene-like C_3N_4 on graphene is reported. Transmission electron microscopy (TEM), thermogravimetric analysis (TGA), Raman spectroscopy, Fourier transform infrared spectroscopy (FTIR), X-ray diffraction (XRD), and X-ray photoelectron spectroscopy (XPS) clearly demonstrated that g-C_3N_4 was successful in the reduction of GO and the immobilization of g-C_3N_4 on the graphene surface. Investigation of their electrochemical behaviour for several redox systems was conducted, which indicated the unique electron structure endows the G–g-C_3N_4 with faster transfer and proper amount of g-C_3N_4 could make G–g-C_3N_4 advantageous in terms of improving the redox current and promoting electron transfer. Finally, several electroactive biomolecules, such as uric acid (UA), norepinephrine (NE), tyrosine (Tyr), tryptophan (Trp), acetaminophen (APAP) and rutin, were used to probe the biosensing capacity of G–g-C_3N_4 films by using the cyclic voltammetric method.

1. Introduction

The development of nanoscience and nanotechnology has inspired scientists to continuously explore new electrode materials for constructing an enhanced electrochemical platform. Exploring materials combining good characteristics of electrochemistry (e.g., high sensitivity, low cost, and good compatibility) with unique properties of nanomaterials (e.g., electronic, optical, magnetic, mechanical, and catalytic) has become one of the most exciting topics [1]. Recently, metal-free graphene-like carbon nitride polymer, referred to as g-C_3N_4, is a rising star in the areas of photocatalytic hydrogen production [2,3], metal-free heterogeneous catalysis in various organic systems [4], and oxygen reduction for fuel cells [5], due to its peculiar thermal stability, appropriate electronic structure and low cost of preparation [6,7]. However, reports of study on its electrochemical performance are rare. Based on previous theory [8,9] a relatively high nitrogen doping can enhance the electron-donor property of the carbon matrix, which greatly improves the interaction between carbon and guest molecules, thus resulting in high and stable catalytic activity. g-C_3N_4, because of its high nitrogen content and facile synthesis procedure, may provide relatively significant catalytic activity.

Nevertheless, the poor conductivity of g-C_3N_4 is a serious problem strongly restricting the electron transportation and limiting the electrocatalytic activity [10]. Graphene, a two dimensional JI carbon structure material with unique electronic properties, large theoretical specific surface area and environmental benignity, has been recognized as a superior candidate for the construction of catalysts [11,12]. Therefore, we incorporated the g-C_3N_4 onto the surface of graphene as G–g-C_3N_4 to promote the electron transfer ability of g-C_3N_4 and increase the active sites of graphene [13]. Here, we took a facile step-by-step metal-free casting method. In brief, after impregnating graphene oxide with the liquid precursor (cyanamide, $CN–NH_2$) 1–3 times, the resulting composites were calcined at 823 K in an inert Ar atmosphere for 4 h to synthesize g-C_3N_4 in situ on the surface of graphene oxide. Consequently, the obtained G–g-C_3N_4@1#, G–g-C_3N_4@2#, and G–g-C_3N_4@3# showed good electrochemical performance as expected. The synthesis route for the development of promising electrocatalysts proposed here is facile, of low cost and environment friendly.

2. Materials and methods

2.1. Chemicals

Dopamine (DA), uric acid (UA), norepinephrine (NE), Hexaammineruthenium (III) chloride ($Ru(NH_3)_6Cl_3$) and cyanamide solution (50 wt%) were all purchased from Sigma Co. L-tryptophan (Trp), L-tyrosine (Tyr), rutin trihydrate (RT), and acetaminophen (APAP) were all purchased from Sinopharm Chemical Reagent Co. Ltd. $(NH_4)_2FeSO_4$,

and $K_3Fe(CN)_6$ were purchased from Shanghai Chemical Reagent Company (Shanghai, China). H_2O_2 (30 wt%) was from Beijing Chemical Co. (Beijing, China). The supporting electrolyte was 0.1 M phosphate buffer solution (PBS) prepared with 0.1 M Na_2HPO_4 and 0.1 M KH_2PO_4 and the pH value was adjusted to 7.4 with NaOH. Double-distilled water was used for preparation of all solutions and for washing.

2.2. Synthesis of G–g-C_3N_4 and TGO

Graphene oxide was synthesized from graphite by a modified Hummers method [14,15]. 0.25 mL cyanamide solution (50 wt%) and 0.25 mL H_2O were added into 50 mg fresh graphene oxide. After ultrasonicating for 30 min, the mixture was stirred overnight and dried statically at 40 °C in air for 12 h. The same impregnation procedure was repeated once, twice, and three times in order to increase the loading of precursors on the graphene oxide. The dried powder was calcined at 550 °C for 4 h in Ar atmosphere and a heating rate of 2.3 °C/min to get the final G–g-C_3N_4 product. Additionally, the preparation of the thermal treatment graphene oxide (TGO) was similar to that of G–g-C_3N_4 nanosheets except that there was no addition of cyanamide solution.

2.3. Synthesis of g-C_3N_4

g-C_3N_4 was synthesized according to a procedure described in a previous literature [16]. In detail, dicyandiamide was heated at 550 °C for 4 h in static air at a ramp rate of 2.3 °C/min; the cooling rate was kept at around 1 °C/min. The resultant yellow agglomerates were milled into powder in a mortar. The nanosheets were prepared by thermal oxidation etching of the bulk g-C_3N_4 obtained as above in static air as follows: 400 mg of the bulk g-C_3N_4 was placed in an open ceramic container and was heated at 550 °C for 2 h at a ramp rate of 5 °C/min. A light yellow powder of g-C_3N_4 nanosheets was finally obtained with a yield of about 5.6%.

2.4. Preparation of G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, g-C_3N_4 and TGO+g-C_3N_4 electrodes

Prior to modification, the glassy carbon (GC) electrode (2 × 1.5 cm^2) used in the electrochemical experiments was polished with alumina paste (0.05 μm) on a micro-cloth and subsequently ultrasonically cleaned thoroughly with acetone, NaOH (1:1), HNO_3 (1:1) and doubly distilled water and then dried at room temperature. The G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, g-C_3N_4 and TGO+g-C_3N_4 electrodes were obtained by casting 3 μL of 1 mg/mL G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, g-C_3N_4 and TGO+g-C_3N_4 suspension, respectively, on the surface of a well-polished GC electrode and dried in air. Finally, the modified electrodes were activated by 20 successive scans at a scan rate of 50 mV/s in phosphate buffer solution (pH 7.4) until a steady voltammogram was obtained.

3. Results and discussion

3.1. Characteristics of G–g-C_3N_4, g-C_3N_4

The weight contents of g-C_3N_4 in G–g-C_3N_4@1#, G–g-C_3N_4@2#, and G–g-C_3N_4@3# composites were tested to be about 37.4, 53.7, and 74.7 wt%, respectively, by thermogravimetric analysis (TGA) under flowing N_2 atmosphere (see Fig. 1a). Here we selected

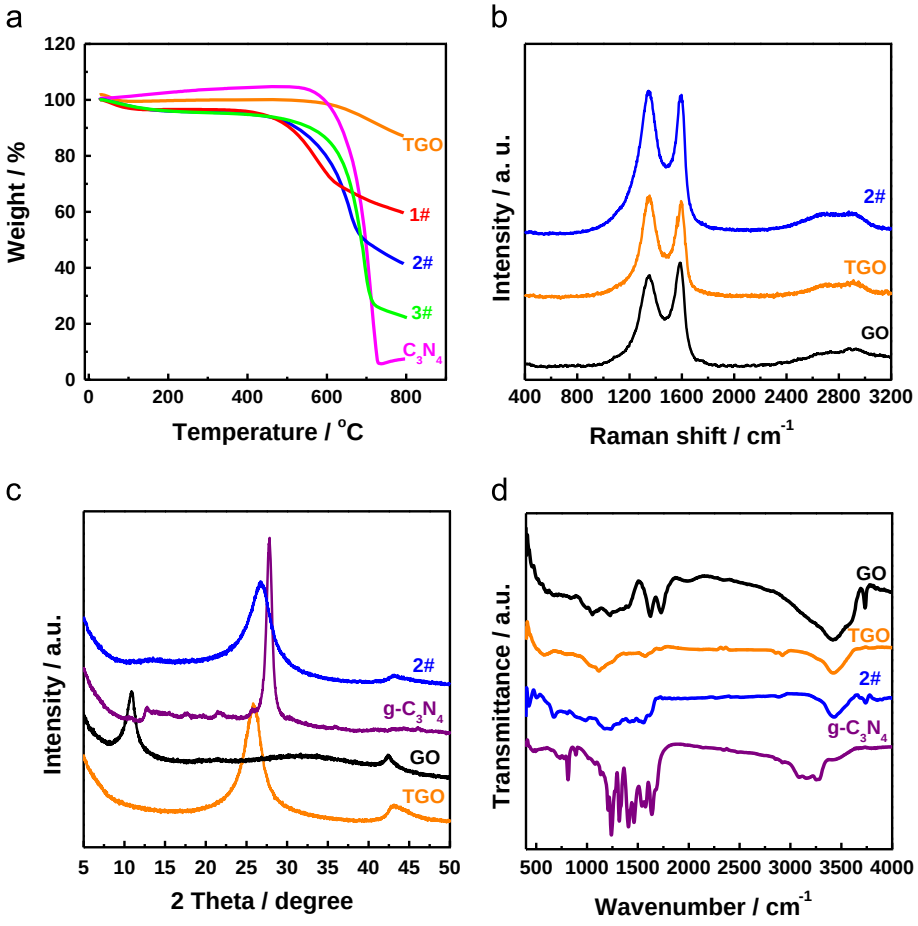

Fig. 1. (a) TGA curves of TGO, G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3# and g-C_3N_4; (b) representative Raman spectra of GO, TGO and G–g-C_3N_4@2#; (c) typical XRD patterns of GO, TGO, G–g-C_3N_4@2# and g-C_3N_4 and (d) FTIR spectra of GO, TGO, G–g-C_3N_4@2# and g-C_3N_4.

G–g-C_3N_4@2# obtained by two times precursor impregnation as an example. For better understanding of the structure and properties of the as-prepared G–g-C_3N_4, TGO and g-C_3N_4 were taken as references. From the Raman spectra (see Fig. 1b) the D band (1351 cm^{-1}) corresponding to defects in the curved graphene sheets, the staging disorder, and the G band (1597 cm^{-1}) related to the sp^2 hybridized carbon of graphene were observed for both samples. In agreement with previous reports for chemically reduced GO [17,18] the *D*/*G* intensity ratio increased from 0.92 (GO) to 1.07 (TGO) and 1.02 (G–g-C_3N_4@2#), which illustrated the good reduction of TGO and G–g-C_3N_4 from GO. The results also indicate more disorder of the TGO than G–g-C_3N_4@2#, which may be due to the CN–NH_2 creates a layered g-C_3N_4 template for better reduction of GO [19]. From the X-ray diffraction (XRD) patterns (see Fig. 1c) the interplanar distance of G–g-C_3N_4@2#, based on the diffraction peak, is between those of TGO and g-C_3N_4, indicating that crystalline g-C_3N_4 layers were separated by graphene sheets [20]. The typical Fourier transform infrared spectroscopy (FTIR) spectrum (see Fig. 1d) also implied the successful immobilization of g-C_3N_4 on the graphene surface [21] and XPS examinations confirmed this result as well (see ESI, Fig. S1†).

Fig. 2 gives representative transmission electron microscopy (TEM) overviews of these samples. TGO displays crumpled multilayer sheets and the g-C_3N_4 on graphene obtains a layered film G–g-C_3N_4 which is relatively flat. From G–g-C_3N_4@1#, we can also clearly identify the crumpled curve from graphene. To clearly confirm the layer structure, high magnification TEM of TGO, G–g-C_3N_4@1#, G–g-C_3N_4@2#, and G–g-C_3N_4@3# was further examined (see ESI, Fig. S2†). With another one or two more casting procedures, the transparency decreases obviously because of the g-C_3N_4 films covered on graphene.

3.2. Electrochemical behaviour for different redox species of G–g-C_3N_4

Several redox systems with different electrode kinetics were selected to firstly study the electrochemical properties of G–g-C_3N_4. The cyclic voltammograms (CVs) of various redox species of $Fe(CN)_6^{3-/4-}$, $Ru(NH_3)_6^{3+/2+}$, $Fe^{2+/3+}$, and dopamine at diverse modified electrodes are illustrated in Fig. 3 and their cyclic voltammetric data and electroactive surface areas are summarized in Table S1. All the CVs data were obtained out and recorded for 5 scans and the reported CVs here are for the third scan, which is rather stable and more or less of the same CVs pattern as that of the later scans. $Ru(NH_3)_6^{3+/2+}$, involving simple electron transfer on most electrodes including diamond and sp^2 carbon, is relatively insensitive to surface microstructure, surface oxides and adsorbed monolayers on sp^2 carbon electrodes [22]. Therefore, we took this redox system as an example. G–g-C_3N_4 composites, showing enhanced peak currents and relatively lower ΔE_p values, displayed faster and more reversible behaviour of the $Ru(NH_3)_6^{3+/2+}$ couple. Moreover, we found that the CVs were rather stable, and the repeatability and long-term cyclic voltammograms (CVs) of the above six compounds at G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, and mixed TGO stability were also quite good (data not shown) even 1 or 2 years later. Considering the reversible redox reaction of $Ru(NH_3)_6^{3+/2+}$ on the G–g-C_3N_4 electrodes, the density of the electronic states should be sufficient to support the rapid electron transfer of $Ru(NH_3)_6^{3+/2+}$. This redox system also selected for further investigation on the effect of scan rate on the peak current (see ESI, Fig. S3†). For scan rates in the range from 0.02 to 0.35 mV/s, the oxidative and reduction peak currents of the G–g-C_3N_4@1# electrode increase linearly with the

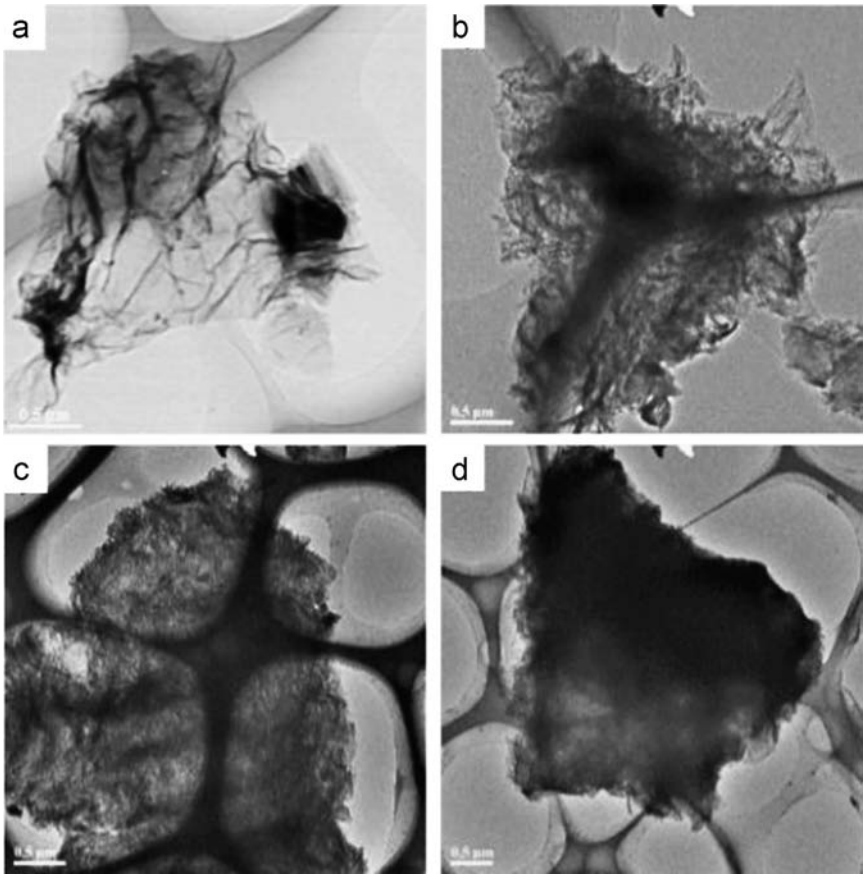

Fig. 2. Typical TEM images of (a) TGO, (b) G–g-C_3N_4@1#, (c) G–g-C_3N_4@2#, and (d) G–g-C_3N_4@3#.

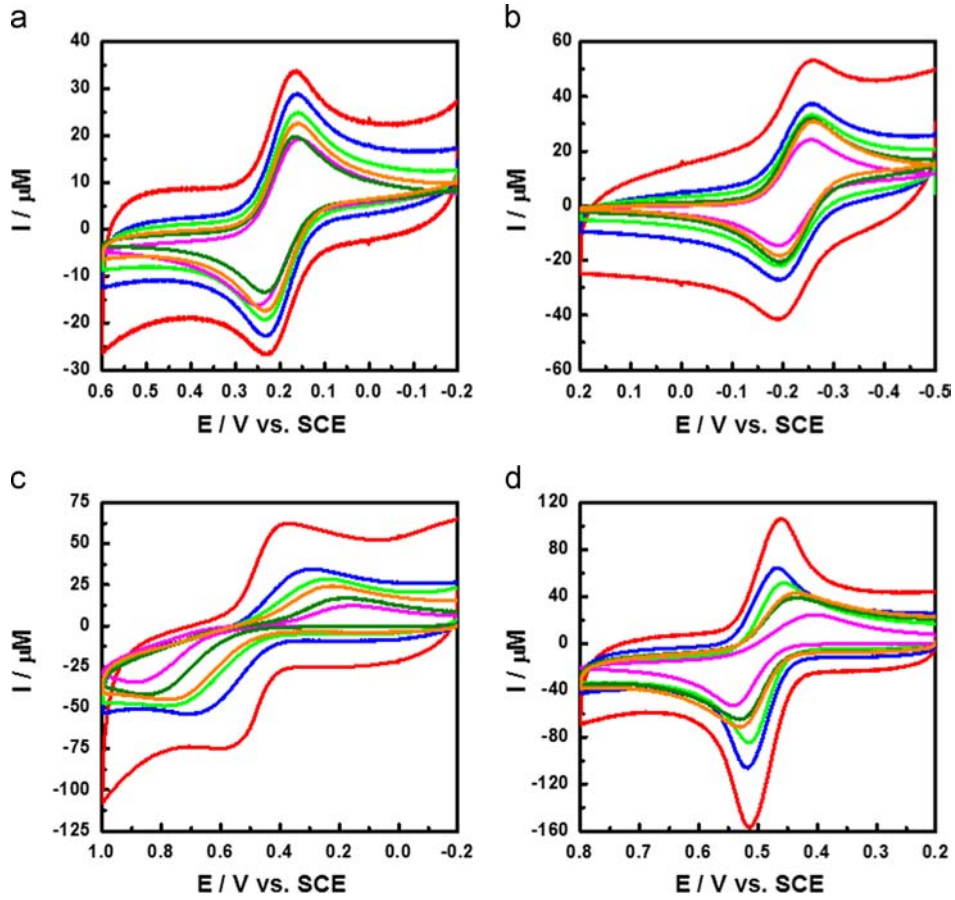

Fig. 3. Cyclic voltammograms for four kinds of redox systems at G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, mixed TGO+g-C_3N_4, and g-C_3N_4 (up to down) electrodes deoxygenated with N_2: (a) 1.0 mM $Fe(CN)_6^{3-/4-}$ in 0.2 mM KCl, (b) 1.0 mM $Ru(NH_3)_6^{3+/2+}$ in 0.2 mM KCl, (c) 1.0 mM $Fe^{2+/3+}$ in 0.1 M $HClO_4$ and (d) 1.0 mM dopamine in 0.1 M $HClO_4$. Data shown are for the third scan. Scan rate 100 mV s^{-1}.

square root of the scan rate, implying that the reaction is controlled by semi-infinite linear diffusion. Furthermore, the specific electroactive surface areas for these electrodes are calculated in the ESI according to the Randless–Sevcik equation [23,24] and summarized in Table S1. Compared with other materials, the G–g-C_3N_4 composites displayed remarkably higher electroactive surface areas. In the four different redox systems the results shown in Table S1 are in keeping with each other, which suggests that the unique electron structure endows the G–g-C_3N_4 with faster transfer. Especially G–g-C_3N_4@1# shows the highest peak current and largest electroactive surface area, indicating that too much g-C_3N_4 on graphene could make them disadvantageous in terms of improving the redox current and promoting electron transfer. Nevertheless, impregnating graphene oxide with less CN–NH_2 cannot produce g-C_3N_4, thus restricting obtaining of good composites.

3.3. *Electrochemical behaviour for different electroactive biomolecules of G–g-C_3N_4*

The important characteristics described above enable G–g-C_3N_4 to be a good material for electrochemical sensing and biosensing. Here the electrochemical behaviours of two biomolecules [uric acid (UA) and norepinephrine (NE)], two amino acids [tyrosine (Tyr), tryptophan (Trp)] and two drugs [acetaminophen (APAP), rutin], which are all electroactive, were investigated. Fig. 4 shows cyclic voltammograms (CVs) of the above six compounds at G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, mixed TGO+g-C_3N_4, and g-C_3N_4 electrodes. We used bare GC electrode to compare the electrochemical performance here. All the oxidation peak currents of these six compounds are increased at G–g-C_3N_4 electrodes relative to the currents at TGO, mixed TGO+g-C_3N_4, and g-C_3N_4 electrodes, indicating a favourable catalytic activity of G–g-C_3N_4 toward the oxidation of the compounds. At the G–g-C_3N_4@1# electrode, all show a remarkable increase in the peak currents relative to that at the other five electrodes. This illustrates that appropriate amount of g-C_3N_4 on graphene not only can optimize the structure of the graphene but can also have a synergic effect on each other, which can further enhance electrochemical reactivity of G–g-C_3N_4@1# electrode. The great electrochemical performance of the G–g-C_3N_4@1# electrode toward H_2O_2 and O_2 serves as a further verification of the above results (see Fig. 5). As the G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, mixed TGO+g-C_3N_4, g-C_3N_4 and GC electrodes can produce different background currents in blank solution, the background current is deducted from the linear sweep voltammetry (LSV). Upon G–g-C_3N_4@1#, G–g-C_3N_4@2#, and G–g-C_3N_4@3# electrodes, both on-set potential and peak potential of the reduction reaction shift to more positive positions with a concomitant increase in the peak currents density than those of mixed TGO+g-C_3N_4, TGO, and g-C_3N_4 electrodes (Table 1). However, because of the poor conductivity of g-C_3N_4, the on-set potential and peak potential of the reduction reaction were just slightly negative to g-C_3N_4 electrode. Such results clearly indicate a significant improvement in the catalytic activity when g-C_3N_4 is incorporated onto the graphene due to the enhanced electron transfer efficiency. Much higher current and lower overpotential are found on G–g-C_3N_4@1# electrode in comparison with other electrodes, which further reveals that G–g-C_3N_4@1# is an excellent material for

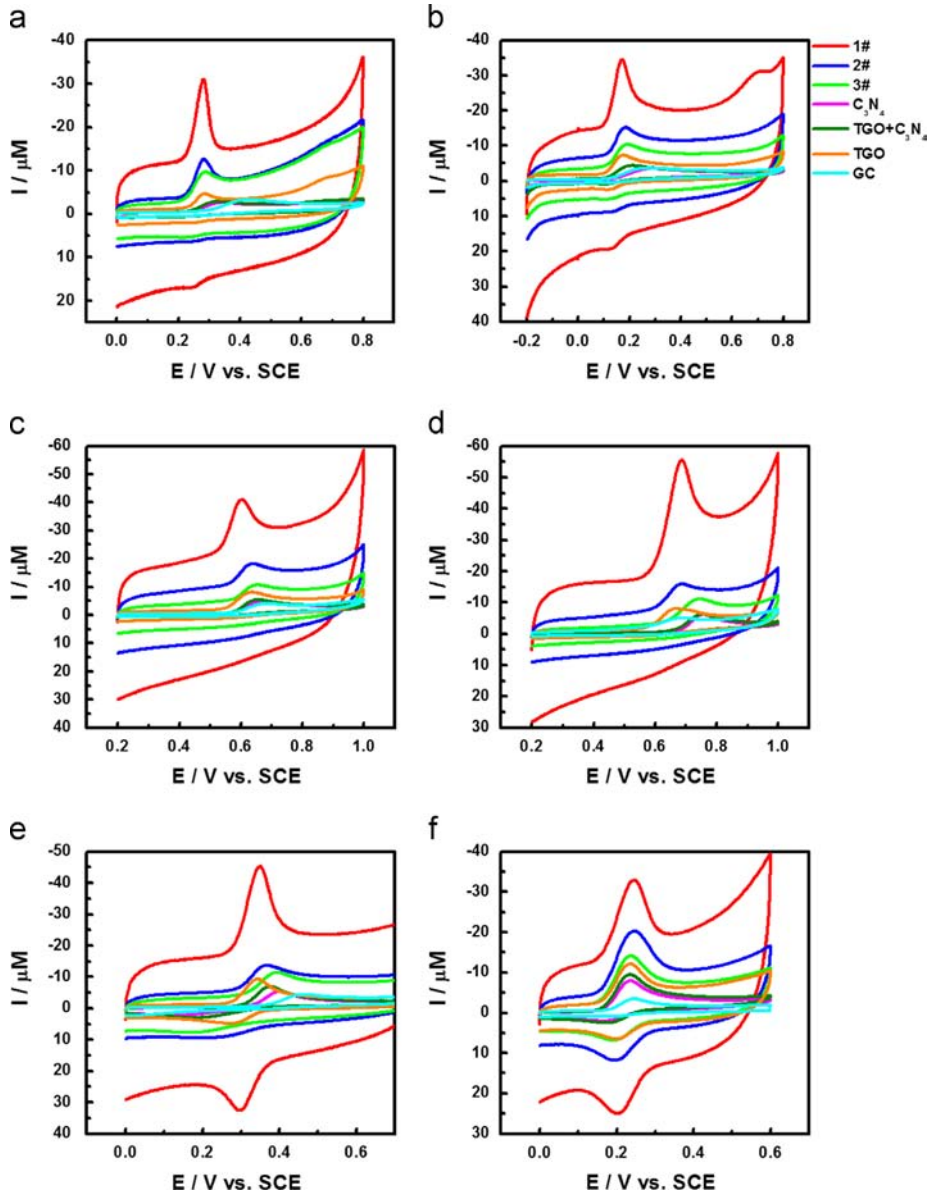

Fig. 4. CVs of 50 μM (a) UA, (b) NE, (c) Tyr, (d) Trp, (e) APAP, and (f) rutin at G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, mixed TGO + g-C_3N_4, g-C_3N_4 and GC electrodes in 0.2 M phosphate buffer (pH 7.4). Scan rate 100 mV s^{-1}.

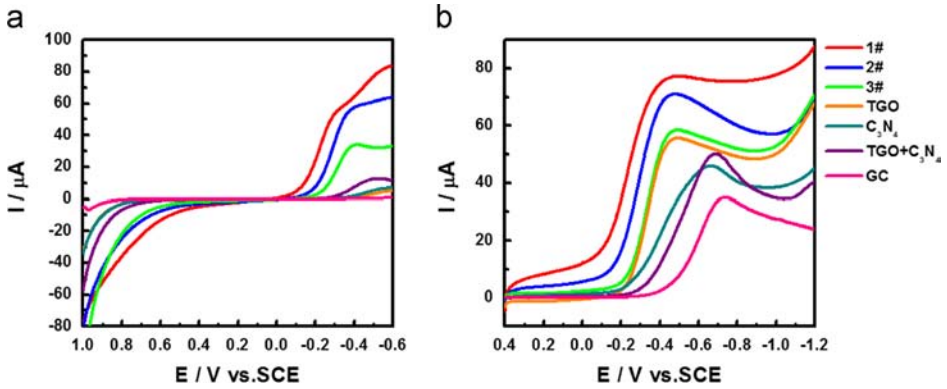

Fig. 5. Background deducted LSV responses of G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, mixed TGO + g-C_3N_4, TGO, g-C_3N_4 and GC electrodes in 0.2 M phosphate buffer (pH 7.4) (a) containing 5 mM H_2O_2 and (b) saturated with O_2.

Table 1
Summary of reduction performances on G–g-C_3N_4@1#, G–g-C_3N_4@2#, G–g-C_3N_4@3#, TGO, mixed TGO+g-C_3N_4, g-C_3N_4 and GC electrodes in 0.2 M phosphate buffer (pH 7.4) containing 5 mM H_2O_2 or saturated with O_2.

		On-set potential (V)	Peak potential (V)	Peak current response (μA)

electrochemical sensing. Additionally, excellent reproducibility and its great long-term stability was also tested using G–g-C_3N_4@1# electrode for these compounds after 1 or 2 years resulting in a relative standard deviation of 2.5% (data not shown here).

4. Conclusion

In conclusion, layered G–g-C_3N_4 composites were synthesized through a facile step-by-step casting route and electrocatalytically investigated. Compared with the TGO, mixed TGO+g-C_3N_4 and g-C_3N_4, G–g-C_3N_4 exhibited much higher electrochemical performance. Furthermore, we found a proper amount of g-C_3N_4 on graphene which could improve the electrocatalytic activities for redox reaction. We believe that the results could bring important applications in sensors.

ABSTRACT

Analysis of organic ligands such as ethylenediaminetetraacetic acid (EDTA) is today an important challenge due to their ability to increase the mobility of radionuclides and metals. Reactive desorption electrospray ionization mass spectrometry (reactive-DESI-MS) was used for direct analysis of EDTA on concrete samples. EDTA forms complexes and those with Fe^{III} ions are among the most thermodynamically favored. This complexing capacity was used to improve the specific detection of EDTA directly on a concrete matrix by doping the solvent spray of DESI with a solution of $FeCl_3$ to selectively create the complex between EDTA and Fe^{III}. Thus, EDTA sensitivity was largely improved by two orders of magnitude with reactive-DESI-MS experiments thanks to the specific detection of EDTA as a $[EDTA\text{-}4H+Fe^{III}]^-$ complex. The proof of principle that reactive DESI can be applied to concrete samples to detect EDTA has been demonstrated. Its capacity for semi-quantitative determination and localization of EDTA under ambient conditions and with very little sample preparation, minimizing sample manipulations and solvent volumes, two important conditions for the development of new methodologies in the field of analytical chemistry, has been shown.

1. Introduction

Organic complexing molecules are widespread both in the environment and in industrial processes. In the nuclear industry, these molecules can be used at different stages of the fuel cycle as radionuclide-chelating agents. In decontamination processes, various ligands are used, and in particular aminopolycarboxylic acids, due to their ability to form strong complexes with radionuclides in solution [1,2].

One of the most used aminopolycarboxylic agents is ethylenediaminetetraacetic acid (EDTA). The control of its presence in nuclear waste is important in the management of intermediate and low-level waste (ILLW) and its maximum concentration is now restricted. EDTA is able to chelate not only actinides but also most alkaline earth and heavy metals ions, which can increase the mobility of radionuclides and heavy metals after leaching processes [3].

Several analytical tools have already been developed for the detection and/or quantification of aminopolycarboxylic acids. These include gas chromatography [4–6], liquid or gas chromatography coupled with mass spectrometry [1,7–12], capillary electrophoresis [13,14], or direct analysis by mass spectrometry [15]. However, all these techniques are time-consuming and require the analytes to be in solution. Several steps are also usually required prior to analysis such as extraction, desalting, derivatization, pretreatment or clean-up protocols. Thus, the development of an analytical method for EDTA detection and quantification directly in a concrete, matrix used for ILLW, without any solubilization step or extraction of the molecule constitutes a great advantage.

With the recent development of ambient mass spectrometry (AMS) and the introduction of desorption electrospray ionization (DESI) [16] and direct analysis in real time (DART) [17], the acquisition of mass spectra under atmospheric conditions is now available directly at the surface of samples with little or no sample preparation [18]. DESI-MS enables the analysis of a large range of compounds, including volatile or semi-volatile molecules [19,20], non-polar [21], or polar compounds [22], inorganic ions or proteins [23]. Moreover, a wide variety of surfaces can be used, including conductive or non-conductive surfaces (e.g., glass, paper, metal, plastic, thin-layer chromatography, porous silicon, nano-porous aluminium).

Many applications over large areas can be explored [23–32], permitting high-throughput analysis [33,34], and qualitative or

quantitative detection [21,34,35]. Finally, chemical imaging is also possible under ambient pressure and without surface pretreatment, which is an important advantage over usual mass spectrometry imaging (MSI) techniques such as matrix-assisted laser desorption ionization (MALDI) [36] and secondary ion mass spectrometry (SIMS) [37].

Even though the mechanism of the DESI process is not yet completely elucidated, it is suggested that the solubility of the analyte in the spray solution is an important factor in the desorption/ionization process [38,39]. Moreover, it has been shown that ion/molecule reactions can occur at the interface between the charged microdroplets of the solvent and the solid sample [40]. Thus, if the spray solvent is correctly doped with a suitable compound, the analyte of interest forms a specific characteristic adduct [25]. This method known as reactive DESI enables to improve the selectivity and sensitivity of the produced complex [41].

The choice of the solvent is not the only critical parameter. The surface is also an important parameter. The chemical composition, porosity, texture, and electrical conductivity have been reported to affect desorption/ionization and analyte detection. It has been shown that surfaces of high conductivity reduce responses whereas inert and hydrophobic surfaces increase them [30,42]. Hence the surface properties play a significant role in the charge transfer process [42].

Concrete analysis by ambient mass spectrometry has already been performed by DART [17]. In this work, we have chosen DESI-MS to take advantage of reactive-DESI experiments and thereby increase the chemical selectivity of EDTA in DESI ionization. This article presents a feasibility study of reactive-DESI-MS experiments for semi-quantitative analysis and imaging of EDTA on concrete under ambient conditions without sample preparation.

2. Material and methods

2.1. Chemicals and reagent

All used chemicals used were analytical grade reagents. Ethylenediaminetetraacetic acid disodium salt dihydrate (EDTA.$Na_2 \cdot 2H_2O$) and iron (III) chloride hexahydrate ($FeCl_3 \cdot 6H_2O$) were purchased from Sigma-Aldrich (Saint-Quentin Fallavier, France). Methanol and acetonitrile were of HPLC reagent grade (J.T. Baker). Deionized water at 18.2 MΩ was prepared by a Milli-Q purification system (Millipore).

2.2. Instrumentation

DESI-MS experiments were carried out using an LCT XE Premier (Waters, Manchester, UK) equipped with the DESI ion source Omnispray from Prosolia (Indianapolis, IN). The DESI spectra were recorded in negative mode. The distance between the mass spectrometer inlet orifice and the cone entrance was 8 cm (due to the Z-spray design), connected by a stainless steel line. The spray needle voltage was initially set to 3.5 kV and nitrogen operating at 100 psi was employed as both the drying and the nebulizing gas. The infusion syringe pump delivered the solvent at 5 μL/min. The source temperature was initially set to 150 °C and the sample cone voltage was tuned at 30 V.

Due to the low mass-to-charge ratio of the studied molecules, the desorption angle was 55° and the sample distance was around 2 mm. Others source geometries were optimized for each sample in order to obtain the best ionization efficiency. Different spray solvents such as methanol and acetonitrile were tested. This optimization of the DESI conditions is presented in Section 3. For the reactive-DESI experiments, a solution at 40 μM of $FeCl_3 \cdot 6H_2O$ in methanol was utilized as the spray solvent. Spectra were acquired at 1 scan/s over a mass range of m/z 50 to 1000 with an acquisition time of 2 min.

2.3. Sample preparation

Several surfaces were considered: Omni Slides™ Hydrophobic Arrays (Prosolia Inc.) and concrete samples. For analysis on hydrophobic spots 1 μL of EDTA solutions diluted in methanol at the appropriate concentration was spotted at the surface and allowed to dry as possible before analysis. The spread of solution on each spot was estimated by dividing the number of moles deposited by the area over which the sample was distributed (r=1 mm). For the analyses on concrete, concrete samples that were 1 cm high and a few centimeters wide were cut with a mineral saw to obtain flat surfaces. The aim was to maintain the same capillary-to-surface distance during all DESI analyses. 10 μL of EDTA solution with an appropriate concentration in methanol were directly deposited at the concrete without further treatment. The spots were allowed to dry as possible before analysis.

2.4. Semi-quantitative analysis on concrete

Several concrete samples were prepared with approximately the same surface. A stock solution of EDTA in methanol at 10 mM was prepared. 10 μL of diluted solution of EDTA in methanol at known concentrations (0.1, 0.5, 1, and 5 mM) were then spotted onto the concrete surface. Due to the spread of the solution on the surface, absolute concentrations of EDTA were estimated by dividing the number of deposited moles by the area over which the sample was distributed (r=1.5 cm). The resultant concentration ranged from 5.65 to 565 pmol/mm². All samples were dried several hours at room temperature before analysis to be sure that concrete samples are as dried as possible.

To control for the possible uneven distribution of the compound on the concrete slice, several spectra were collected at different points of the concrete sample. The final intensity of the characteristic EDTA ion was taken as the average of all intensities of this ion on the various sample surface points. Mass spectra were acquired at 1 s/scan over a mass range of m/z 50 to 1000 for 2 min. Concentrations were then plotted as a function of the intensity of the targeted ion. Each data point of the calibration curve represented an average of the data obtained from three different concrete samples spotted with the same concentration of EDTA.

2.5. Image acquisition

1 mL of EDTA solution in methanol was spotted at the center of a concrete sample and allowed to dry as possible at room temperature before analysis. The final concentration on the concrete after the drying step was 650 pmol/mm². A step of 500 μm in the y-direction and a velocity of 500 μm/s in the x-direction were employed. One mass spectrum was collected every second over a mass range m/z 100–1000. The time to record an image depended on the sample size and ranged from 1 to 2 h. The data was then converted using the Firefly™ conversion software (Prosolia Inc., Indianapolis, IN, USA) and ionic images were generated with the BioMap software (www.maldi-msi.org).

3. Results and discussion

3.1. Optimization of DESI conditions

The aim of this work was to demonstrate the feasibility of EDTA detection directly in its environment. In a first step, the DESI conditions (ionization mode and solvents choice) were optimized to enable the EDTA detection.

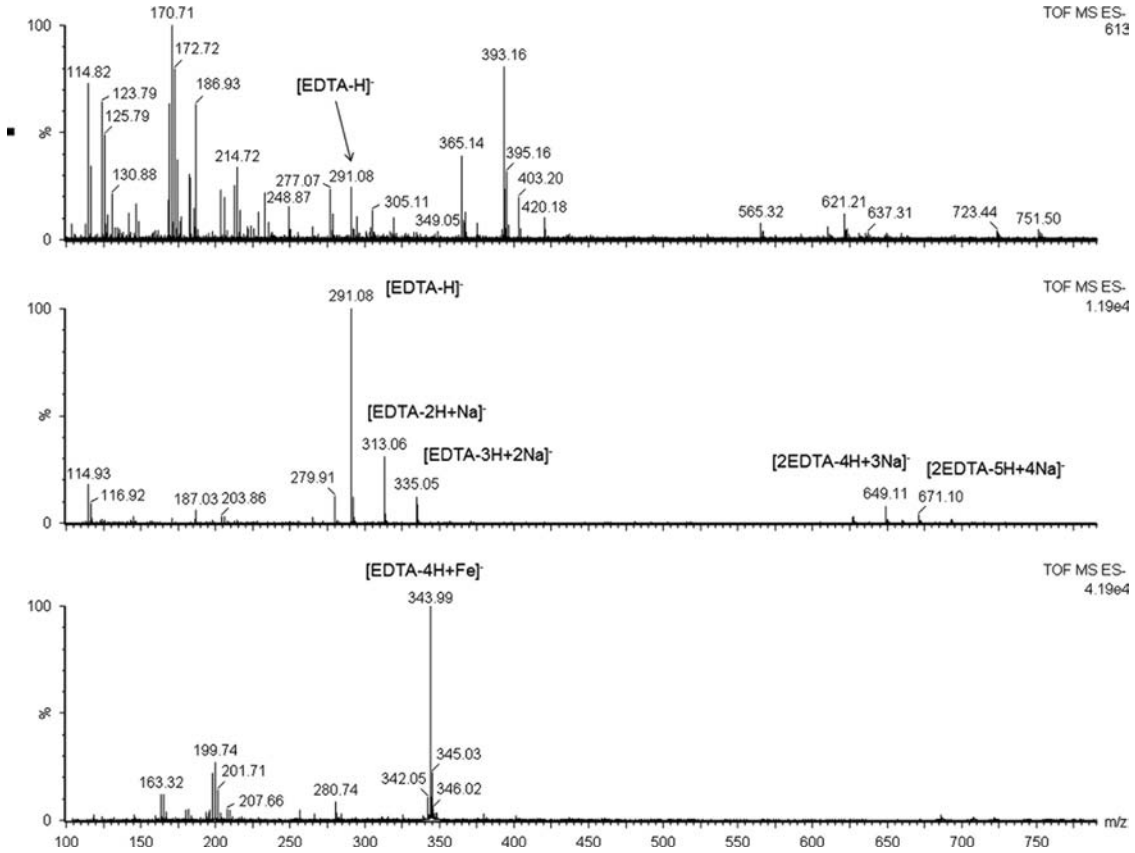

Fig. 1. Solvent comparison for EDTA analysis on Omni Slides Hydrophobic Arrays by DESI. Spray solvents used are (a) ACN, (b) MeOH and (c) 40 μM of FeCl3 in MeOH. EDTA concentration was 3 nmol/mm² for all DESI spectra.

3.1.1. Ionization conditions

EDTA is an organic complexant with four acidic functions. Thus, this molecule possesses four mobile hydrogens, and is therefore easily detected in negative mode after deprotonation of acidic functions. To reach the best sensitivity, experimental conditions were first optimized on a model surface, the Omni Slides™ Hydrophobic Arrays from Prosolia Inc. To obtain the best sensitivity in all cases, the choice of the solvent is an important parameter in the method development [43]. As with electrospray, two widely used solvents, methanol (MeOH) and acetonitrile (ACN) were tested in DESI.

Fig. 1a and Fig. 1b show DESI spectra of 3 nmol/mm² of EDTA detected with respectively ACN and MeOH. Changing the organic solvent from ACN to MeOH had a significant effect on the sensitivity. When ACN was used as the spray solvent (Fig. 1a), a large number of peaks were observed but only one EDTA ion corresponding to the deprotonated molecule $[EDTA\text{-}H]^-$ at *m/z* 291 was detected. This peak presented a low signal-to-noise ratio and was not the most intense peak. All other peaks were believed to come from the surface or solvent contamination.

When MeOH was used as the spray solvent (Fig. 1b), and with the same EDTA concentration, the molecular ion $[EDTA\text{-}H]^-$ (*m/z* 291) was the major peak. Adducts and aggregates of the molecule were also detected: $[EDTA\text{-}2H+Na]^-$ at *m/z* 313, $[EDTA\text{-}3H+2Na]^-$ at *m/z* 335, $[2EDTA\text{-}3H+2Na]^-$ at *m/z* 627, $[2EDTA\text{-}4H+3Na]^-$ at *m/z* 649 and $[2EDTA\text{-}5H+4Na]^-$ at *m/z* 671. Peaks coming from the environment, as those observed with ACN, could here be suppressed due to the better signal-to noise ratio of the EDTA peak.

The intensity of the molecular ion $[EDTA\text{-}H]^-$ was also improved by two orders of magnitude by using methanol as the spray solvent. The choice of the solvent is known to be an important parameter in the DESI process, and Badu-Tawiah et al. have shown that the solubility of the analyte in the solvent is crucial for the desorption process [38]. Since the analyte is solubilized in the spray solvent, highly hydrophobic compounds are better ionized with hydrophobic solvents, whereas hydrophilic molecules are better ionized with polar solvent. Since EDTA is a hydrophilic molecule, it seemed reasonable that it was better detected with a protic solvent such as methanol.

3.1.2. Limit of detection and reactive-DESI

In the next step, the limit of detection (LOD) was investigated. Dilutions of the EDTA stock solution from 10 to 0.001 mM were prepared. If we consider the spread of the solution on the spot, the concentrations ranged from 3 nmol/mm² to 0.3 pmol/mm². These concentrations were chosen according to the estimated EDTA concentration in disposal areas. Under the optimized experimental conditions described previously, the LOD of EDTA (a threshold cut-off of 3:1 signal-to-noise ratio (*S/N*) was chosen for the $[EDTA\text{-}H]^-$ ion at *m/z* 291) was determined to be 300 pmol/mm².

To improve this LOD, the reactive-DESI method was investigated and an appropriate reagent was added to the spray solvent. EDTA is known to create particularly stable 1:1 complexes with many metals. Among the possible metal ions, the Fe^{III} ion was chosen for two reasons. First, this transition metal presents one of the highest stability constants ($\log_{10}K = 25.1$) [44] with EDTA. Second, the use of ferric ions to increase the limit of detection of EDTA in solution has already been demonstrated in the literature, with several analytical methods, such as HPLC [45] or LC-ESI–MS [46], thanks to the formation of a negative charged complex $[EDTA\text{-}4H+Fe^{III}]^-$ in aqueous solution. The spray solvent was doped with a solution of $FeCl_3$. Bergers et al. have shown that a large excess of ferric ions enables to obtain an enhanced limit of detection [45].

Fig. 1c presents a DESI spectrum of 3 nmol/mm² of EDTA detected by reactive-DESI using a spray solvent of 40 μM of $FeCl_3$ in MeOH. EDTA was detected at *m*/*z* 344 as $[EDTA\text{-}4H+Fe^{III}]^-$. This ion was the only form of EDTA observed in this DESI spectrum. No free form of EDTA or different adducts or aggregates of EDTA were detected. Only two forms of iron chloride ions $[Fe^{II}Cl_3]^-$ and $[Fe^{III}Cl_4]^-$, respectively, at *m*/*z* 161 and 196, were observed. It was deduced that the total amount of EDTA has been converted into an $[EDTA\text{-}4H+Fe^{III}]^-$ complex. This result confirms that the Fe^{3+} ion reacts rapidly and selectively with EDTA.

The limit of detection using the reactive-DESI method was then studied. The same range of concentration as when determining the LOD by DESI was used (from 3 nmol/mm² to 0.3 pmol/mm²). By reactive-DESI, the LOD ($S/N=3$ for $[EDTA\text{-}4H+Fe^{III}]^-$ ion at *m*/*z* 344) was determined at 3 pmol/mm², i.e., two orders of magnitude lower than the LOD obtained under classic DESI conditions. The reactive-DESI experiment enabled to attain an LOD lower than the estimated concentration of EDTA in concrete disposal. In the next step, this method of detection of EDTA by reactive-DESI directly on concrete was now investigated.

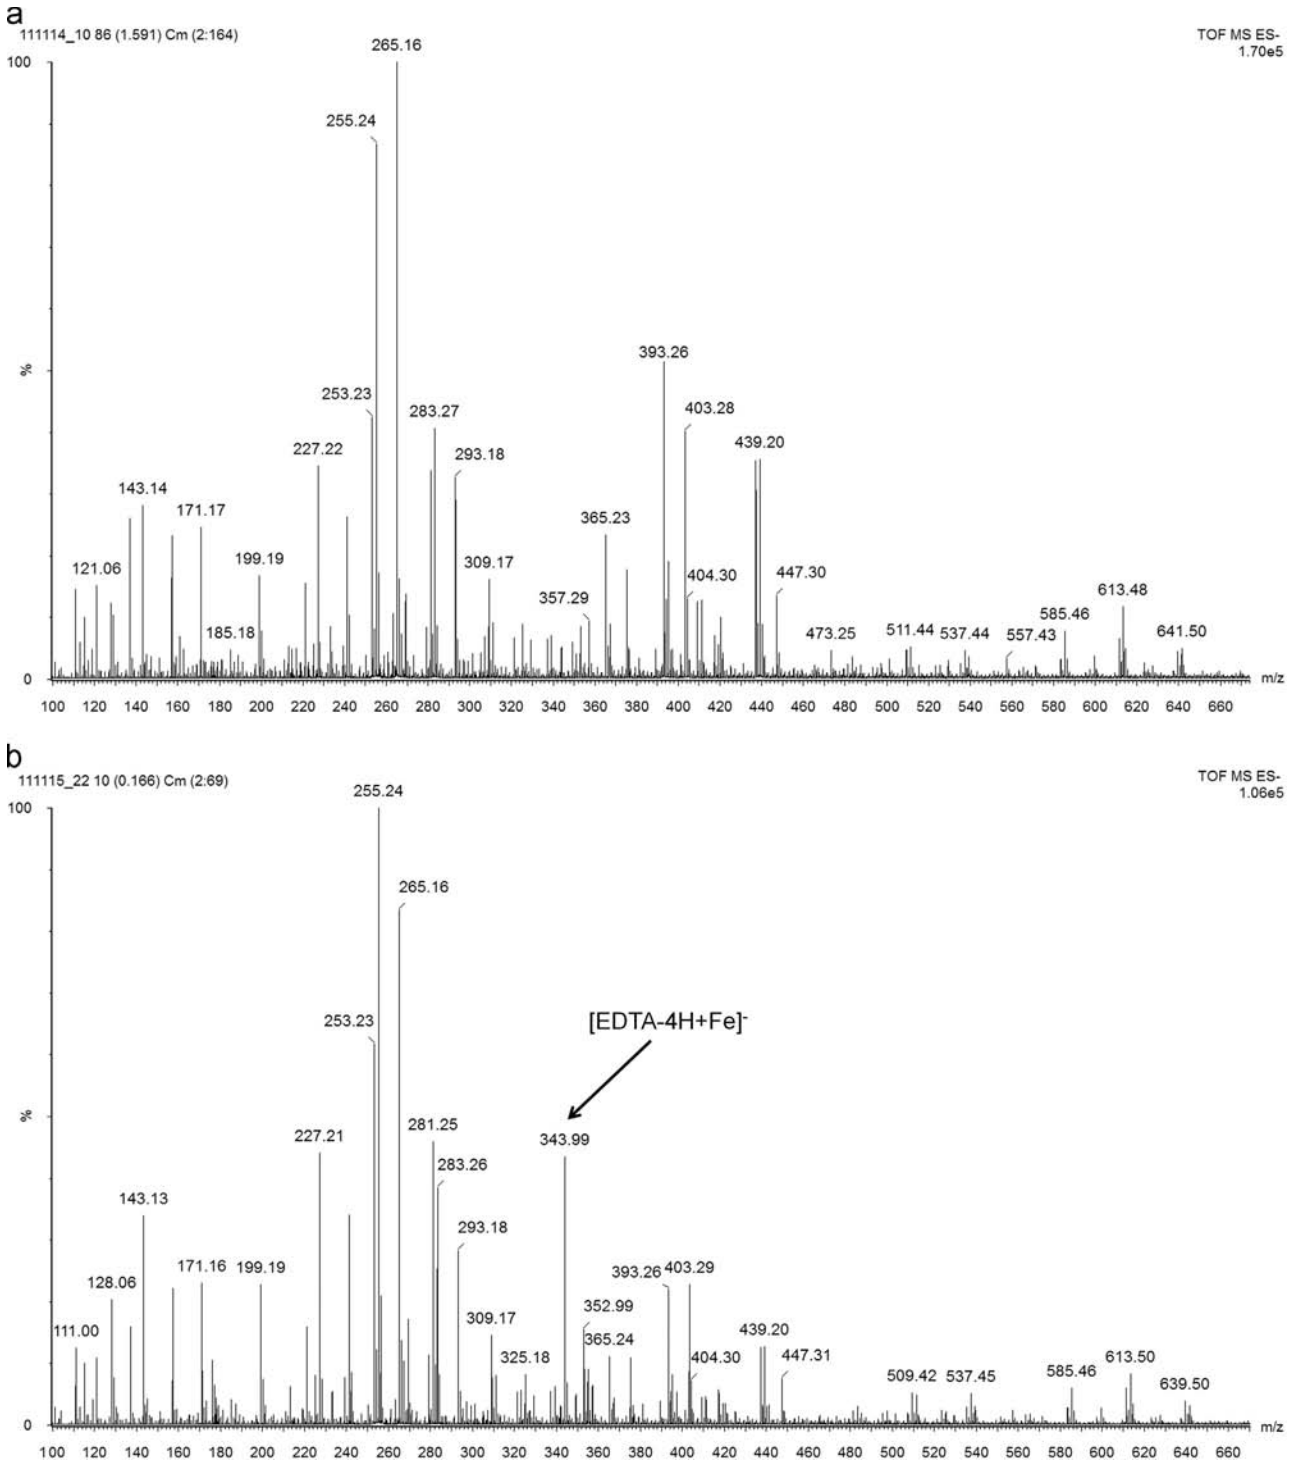

Fig. 2. DESI spectra of EDTA on concrete sample obtained with (a) MeOH as the spray solvent and (b) $FeCl_3$ solution in MeOH as the spray solvent.

3.2. EDTA detection on concrete surface

3.2.1. EDTA detection on concrete by reactive-DESI

First, the DESI spectrum of a concrete sample surface was studied. Fig. 2a presents the DESI spectrum obtained with MeOH as the spray solvent. A large number of peaks was detected since concrete is a very complex matrix containing both organic and inorganic compounds such as oxides, polyols, carboxylic acids, polymers, etc …. However, none of the observed peaks from the matrix was detected in the mass range of any expected EDTA ions, i.e., deprotonated EDTA (*m*/*z* 291) or the EDTA complex with iron (*m*/*z* 344). In a case where EDTA is present at a surface, it is important that its attribution be unambiguous.

The detection of EDTA at the concrete surface with only MeOH as the spray solvent was not possible. This can be explained by the significant porosity of the concrete matrix. The spray solvent was found to be rapidly absorbed by the matrix and the charged microdroplets of the solvent had no time to interact with the solid sample. To allow the spray solvent time to react with the analyte, different optimizations were realized by increasing or decreasing the solvent flow rate. Takats et al. have shown that increasing the nebulizing gas flow rate yielded smaller sizes of the spray droplets and increased their velocity [32]. In these conditions, the desolvation efficiency and the production of secondary droplets under impact were enhanced. However, no signal corresponding to EDTA ions could be observed, regardless of whether the nebulizing gas flow rate was increased or decreased. This result can be explained both by the diffusion capacity into the concrete surface and by the DESI mechanism. At a low gas flow rate, the droplets velocity was too low and did not produce secondary droplets because of the concrete absorbing the solvent. At a high gas flow rate, the initial droplet size was too small and the droplets evaporated before reaching the sample surface.

Reactive-DESI experiment was thus tested with the aim to selectively extract the targeted molecule of the complex matrix thanks to the fast reaction between iron and EDTA. As in the previous experiment on hydrophobic spots, the spray solvent used was doped with a solution of $FeCl_3$ at 40 μM in methanol. Fig. 2b shows a DESI spectrum of EDTA at 200 pmol/mm² on the concrete surface obtained by reactive DESI. The identified ions of EDTA were the same as those observed after deposit on hydrophobic spots. The peak of the complex $[EDTA\text{-}4H+Fe^{III}]^-$ at *m*/*z* 344 was consistently detected as the more intense peak of the EDTA ions, and no other EDTA ions, such as free EDTA ions or adducts or aggregates, were identified. This result also indicates that the chelation of iron by EDTA was fast enough and that the 'droplet pick up' DESI mechanism has time to occur before that concrete absorb the solvent. Fe(III) ions had time to interact with the EDTA at the surface, demonstrating the possibility to directly detect EDTA at a concrete surface by reactive-DESI.

In concrete matrices, various metal species are present, e.g., Ca (II), Mg(II), K^+, Na^+, Al(III). However, all these cations have a lower $\log_{10}K$ value than the Fe(III) ion, which is also present in cement pastes but to a lesser extent. This explains why it is not possible to observe chelating EDTA with these other ions. Moreover, Bradbury and Sarott have demonstrated that the complexing power of an organic ligand can be significantly reduced on cement because of the competition between chelating molecules and inorganic complexing ions like hydoxy ions, which can be found in very high concentration in concrete interstitial water [47]. This explains why only Fe(III) was chelated by the targeted molecule independently of the other cations present in the matrix.

The speciation of EDTA with Fe^{III} also depends on the pH. Serne et al. have shown that with the exception of divalent transition metals complexes, EDTA-metal complexes appear to be readily dissociated at alkaline pH [48]. Moreover, EDTA is weakly sorbed onto cement pastes, i.e., at high pH value [49,50]. Thus, the EDTA present at the surface is prone to react with Fe(III) ions from the spray solvent. Reactive-DESI is thus a fast enough reaction, since ferric ions can react with EDTA, and the DESI process takes place before diffusion of the spray solvent into concrete. The concrete matrix with all its significant chemical or physical features, e.g., highly alkaline pH or high concentrations of salts, thus does not seem to hinder the detection of $[EDTA\text{-}4H+Fe^{III}]^-$ complex. We have demonstrated the feasibility to selectively detect EDTA, in its chelated form with Fe(III), at the surface of a concrete sample without any surface pretreatment thanks to reactive-DESI.

3.2.2. Semi-quantitative analysis of EDTA on concrete samples

Each concrete samples was spotted with EDTA solution at different concentrations (from 565 to 5.65 pmol/mm²). The relationship between the EDTA concentrations on the concrete surface and the MS response (absolute peak height for the corresponding ion) were verified and each point of the calibration curve was the result of an average of 3 replicates. After reactive-DESI analysis, the intensity of the $[EDTA\text{-}4H+Fe^{III}]^-$ ion at *m*/*z* 344 was plotted against the concentration in pmol/mm². The points obtained were satisfactorily represented by a linear regression with a determination coefficient of 0.9985 as shown in Fig. 3. The linearity was assessed by the method of least squares. The relative standard deviation between each measured peak height was better than 25%. It is worth noting that at a concentration higher than 1000 pmol/mm^2 the linearity of the relationship was no longer assured. This loss of linearity was believed to be due to an effect of ion suppression as shown by Takats et al. [32] or to the too high EDTA concentration compared with that of iron. There was no free iron available to induce more [EDTA/Fe] complexes.

Under these experimental conditions, the LOD was determined to be 5.65 pmol/mm² (*S*/*N*=3 for $[EDTA\text{-}4H+Fe^{III}]^-$ ion at *m*/*z* 344) and the limit of quantification was 14 pmol/mm² (*S*/*N*=10 for $[EDTA\text{-}4H+Fe^{III}]^-$ ion at *m*/*z* 344). The limit of detection of EDTA on concrete was close to the limit of detection of the EDTA deposited on the hydrophobic spots and analyzed by reactive-DESI. This confirms, as discussed in the previous section, that the matrix, i.e., concrete, did not seem to interfere with the detection of the $[(EDTA\text{-}4H+Fe^{III}]^-$ complex in MeOH spray. These limits of detection and quantification were estimated by dividing the number of deposited moles by the area over which the solution had spread in the *x*- and *y*-directions. Nevertheless, a solution on concrete sample also diffuses in the *z*-direction. The amount of EDTA that diffused into the concrete matrix when the MeOH solution was spotted was difficult to evaluate. In this case, the

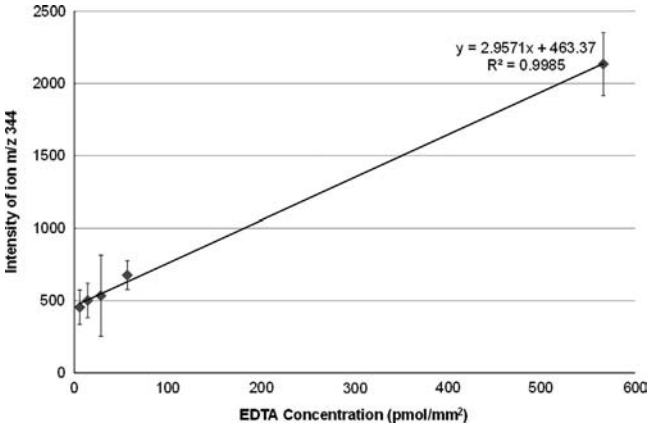

Fig. 3. Calibration curve obtained from 5 samples with different EDTA concentrations (in pmol/mm²) on a concrete surface obtained by plotting the peak height of ion *m*/*z* 344 against the EDTA concentration.

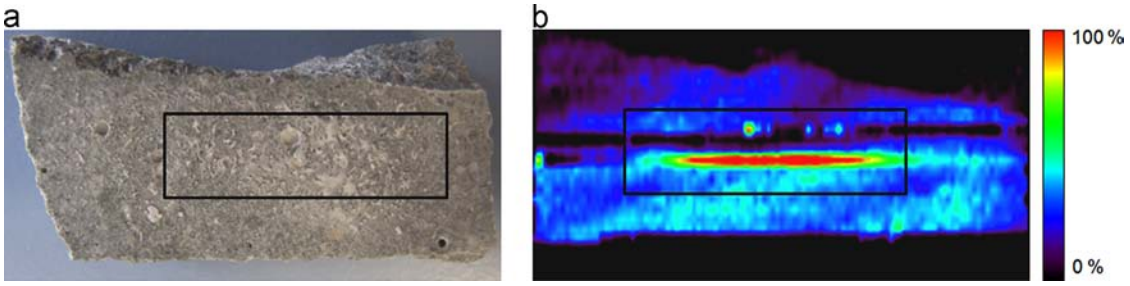

Fig. 4. (a) Optical image of a concrete sample and (b) ionic image of the complex [EDTA-4H+Fe] (m/z 343.9).

limits of detection and quantification that have been determined may be even better than those given above. We conclude that the reactive-DESI can be favorably used to analyze and quantify EDTA on samples coming from a concrete canister.

3.2.3. DESI imaging

This analytical method for detection of EDTA on concrete surfaces by reactive-DESI was developed to control the presence of the substance on a concrete canister, for example before its disposal. In this context, a representative sample can be scanned to evaluate the distribution of EDTA at its surface. To realize this work, imaging analysis using mass spectrometry has been developed and is now presented to show the spatial distribution of EDTA at the sample's surface. Fig. 4a displays the optical image of a concrete sample doped with EDTA, and the ion image of the peak at m/z 344 identified as the complex $[EDTA\text{-}4H+Fe^{III}]^-$ is shown in Fig. 4b. Thus, there was a good correlation between the EDTA distribution at the surface and the ion image of the EDTA complex.

It is concluded here that using reactive-DESI for imaging analysis of a sample of concrete doped with EDTA is possible under ambient conditions and without sample preparation. It has to be noted that the ionic image of the complex ion presented an elongated distribution and not the expected circular one. This could be explained by the strong diffusing power of concrete. The EDTA is mainly diffusing on the y-direction.

Albeit imperfect, this method brings some advantages in comparison with other imaging techniques using mass spectrometry such as SIMS or MALDI, and can even be complementary to these two methods. MALDI and SIMS techniques require a sample preparation with matrix or metal deposition [51] which can produce a high background signal below m/z values of 300 and may thus limit the ability to detect low-mass signals such as EDTA. Moreover, the DESI ionization is soft enough to keep all non-covalent complexes and allow the formation of specific ions.

4. Conclusions

This study has demonstrated the feasibility of EDTA detection on concrete surfaces without sample preparation using reactive DESI. An MSI analysis has also shown that a distribution of the complexing agent on the concrete is possible. The selective and strong chelation of iron by EDTA allows the selective detection, localization and quantification of this molecule in a complex matrix. Thus, a complete analysis of a specific organic compound in conventional and imaging mode proved to be possible using the methodology described in this article. The huge advantage in these reactive-DESI experiments is the very limited sample preparation, reducing sample manipulations and quantities of used solvent used - two important conditions in the development of methodologies in the context of nuclear facilities.

Nevertheless, several limitations of this method should also be reported. First, the time for the analysis of this surface of approximately 7 cm² was quite long (approximately 50 min). To reduce this analysis time the large-area DESI-MS technique may be an option [52]. This modified DESI source is able to scan larger surfaces than the conventional DESI sources, thanks to its 200-times larger desorption/ionization area. With this source, the total scanning time is reduced, however the spatial resolution may also be lowered.

The second limitation of our analytical method is that the analyzed sample should be as flat as possible to keep the same capillary-to-surface distance during all DESI analyses. When quantification or imaging experiments are required, this limitation cannot be solved.

One of the important challenges that needs to be solved in DESI analysis is the low spatial resolution. In this experiment the spatial resolution was estimated to approximately 500 μm because of the strong absorbing power of the concrete and its high capacity of diffusion. It is thus not yet possible to precisely observe EDTA molecules which are localized in the pores of the concrete matrix (from 0.5 nm to 5 μm) [53] or outside the pores. Moreover, due to the inherent diffusion tacking place at the surface of the porous concrete examined by DESI, it is unlikely that this resolution will ever be attained. However, the aim of this method was the demonstration that chelating molecules as EDTA can be detected via DESI-MS analysis, and this was proven here. This analytical approach can now be applied to other aminopolycarboxylic agents.

Ammonium determination

ABSTRACT

A mobile drop based approach was utilized for the conductometric determination of aqueous ammonium ion. A liquid drop was manipulated by gravity to remain or move out of a conductivity measurement zone located on a hydrophobic path. A dilute sulfuric acid drop functioned as a micro gas absorber. Gaseous NH_3 was liberated from a sample containing NH_4^+ by adding NaOH and purged to flow over the absorber drop. As H^+ in the absorber drop was converted to NH_4^+, the conductivity decreased. The rate of the conductivity decrease thus ultimately depended on the NH_4^+ concentration in the sample. While the sample could be complex, the liberation of NH_3 gas essentially freed the analyte of interest from the matrix and allowed the use of an otherwise nonselective detector. The system was applied to the determination of NH_4^+ in some natural waters without prior filtration; the results agreed well with those from a manual indophenol blue method. The approach exhibited a limit of detection (LOD) of 5 μM and a relative standard deviation (RSD) of < 5%. The mobile drop gave a constant volume of the gas absorbing solution and provided a cost-effective and simple analytical platform.

1. Introduction

Ammonium (NH_4^+) is a globally important micronutrient. High NH_4^+ levels in natural waters indicate deteriorated water quality, generally from anthropogenic sources. Analyses for NH_4^+ are routine in agriculture, soil science and environmental studies. The most widely used method for NH_3/NH_4^+ determination is the spectrophotometric indophenol blue method [1], based on the Berthelot reaction.

One successful approach to NH_4^+ determination has been to convert aqueous NH_4^+ to gaseous NH_3 by adding base and collecting the produced gas for quantitation; this has the further virtue of removing matrix interferences. In flow analysis systems, NH_4^+ has been commonly converted inline to unionized NH_3 in the donor stream and letting the NH_3 thus formed diffuse through a gas diffusion unit (GDU) into an acceptor stream for measurement. The GDU may be fabricated with or without a membrane. Different detectors have been used with a GDU in a flow system for NH_4^+ determination. Frenzel et al. used flow injection (FI) with a GDU prior to potentiometric measurement of NH_4^+ [2–4]. Conductometry, normally a nonselective technique, has been used with a FI-GDU system for measuring Kjeldahl Nitrogen in milk and chicken digests [5]. Contactless conductometry works particularly well with small bore tubing; this has also been used for NH_4^+ determination with a FI-GDU system [6]. Other automated flow methods, e.g., sequential injection [7], multi syringe FI [8,9], and multi-commutation FI [10,11] have all been used with a GDU and spectrophotometric NH_4^+ determination. Fluorometric detection, a more sensitive technique has also been similarly used, for both sea water [12] and fresh water [13].

The conversion of an aqueous analyte species of interest to the gaseous state (and thus liberating it from a matrix potentially containing interferents) is not unique to the NH_4^+/NH_3 system, the same principle is used in hydride generation atomic spectroscopy. Hydride generation coupled with chemiluminescence detection (HG-CL) permitted a portable sensitive system for measuring arsenic in drinking water [14]. Generation of H_2S from an aqueous sample and measurement with a micro gas analysis system was used for the determination of sulfide in natural waters [15]. Cyanide in a blood sample was converted to gaseous HCN and collected in a porous membrane containing a chromogenic reagent to permit measurement using disposable platforms [16]. A membraneless setup avoids membrane fouling problems [17,18]. The flow analysis coupled with membraneless format has been developed [17–19]. Air segmentation in such systems can have advantages [20]; this has been applied to ethanol determination [21].

A liquid drop represents a small volume that has no membranes and a large surface/volume ratio, well suited for gas sampling without involving any membranes. A soluble gas can be scavenged by a drop and the product concentration can accumulate rapidly. The product can then be measured in-situ, often with a short overall analytical

cycle. Liquid drops are easily manipulated, represent very low reagent consumption and waste generation and provide for low-cost methods [22]. Liquid drops/films have been extensively used for gas collection and analysis, e.g., for many different gases at a time with a capillary electrophoresis (CE) system [23–25], or by simple LED-based photometry for NO_2 [26], NH_3 [27], H_2S [28], SO_2 [29], etc. Although conductometry is non-selective, it can provide highly sensitive measurements with simple instrumentation. Toda et al. [30] used a renewable hemispherical drop of dilute acid atop the tip of an annular tubular electrode assembly that monitored the conductivity of the drop. As breath ammonia flowed over the drop it reduced the conductance by neutralizing the acid; the rate of conductivity decrease was a direct measure of the breath ammonia concentration. Although a liquid film/bubble [31] can provide an even greater surface/volume ratio than a drop, a liquid drop based system is simpler to set up.

Drops moving by gravity have the added advantage of incorporating both flow and transient examination capabilities. An inclined platform on which a drop falls and moves is particularly conducive to this; Liu and Dasgupta [32] introduced transient electrokinetic injection in CE based on this principle. Recently, we have refined the ability to control drop movement by using a hydrophobic inclined path for drop movement and a suspended probe with a hydrophilic exterior in the transit path to stop the drop by adhesion, and then allow it to move down again by allowing additional drop(*s*) to merge whence the gravitational force overcomes adhesion forces [33]. The use of this system was then demonstrated for microcoulometric titrations of analytes in the drop.

In this paper we demonstrate another application of this inexpensive versatile platform using the moving drop for (NH_3) gas collection, quantitating the collected gas conductometrically by momentarily stopping the drop at a measurement probe and then transmitting all to waste by sending a merging wash drop. Ammonia gas was liberated from a NH_4^+-containing solution by alkalinization and purging and directed to the drop. Results from real samples are compared with spectrophotometric determination by the indophenol blue method, which often requires sample pretreatment [34].

2. Experimental

2.1. Reagents and solution

All reagents were of analytical reagent grade. Sulfuric acid (0.1 M) was used as the gas absorbing liquid drop; this was prepared by dilution from 98% H_2SO_4. The NH_4^+ stock standard solution (10 mM) was freshly prepared by dissolving 0.1593 g of NH_4Cl (www.merck-millipore.com) in 0.1 M H_2SO_4 and adjusting the volume to 100.00 mL with 0.1 M H_2SO_4. Diluted standards were prepared daily using 0.1 M H_2SO_4. Because the H_2SO_4 may itself contain traces of NH_4^+, the exact concentration of NH_4^+ in the standards were determined by the Indophenol Blue method [34], the requisite reagents were prepared as instructed therein. For liberating gaseous NH_3 from NH_4^+ bearing samples, 4 M NaOH was prepared by dissolved 24 g NaOH in 150 mL deionized water.

Water samples for analysis consisted of surface water from the Ping River and local ponds in the Chiang Mai area, Thailand. Sulfuric acid (2 mL 98% acid per 500 mL Sample) was added to the samples before storage at 4 °C in the dark in polyethylene bottles [2].

2.2. Experimental setup

The system is schematically depicted in Fig. 1. A polymethylmethacrylate (PMMA) tube (2.0 cm i.d., 2.4 cm o.d., 20.0 cm length), equipped with end-caps, is used as the incline; normal inclination angle was ~23° from the horizontal plane. The bottom cap was connected by a drain tube to a waste container. A length of Polytetrafluoroethylene (PTFE) tape (plumber's tape) was placed lengthwise inside the PMMA tube to provide a hydrophobic path. A PEEK tube segment (0.5 × 1.6 × 10.0 mm i.d. × o.d. × length, www.upchurch.com) was affixed through a hole in the PMMA tube as shown and functioned as the drop head. A second drop head was similarly located, ~2 cm behind the first one. Disposable syringes were employed for manually dispensing H_2SO_4 and deionized water through the first and second drop heads, respectively. The drop size largely depends on both the i.d. and o.d. of the drop head terminus and the material. For the present case, drop volume was ~25 μL [33]. The liquid drop moves by gravity and is stopped through adhesion at the conductivity probe. In this position the drop is exposed to the gas generated from the sample. After the gas exposure and conductivity measurement step, a drop of DI water is dispensed on the path, merges with the extant drop and together flows down to waste. Relatively little residual liquid adheres to the conductivity probe. Because this becomes part of the measurement and calibration process and there is no residual free NH_3 in this liquid and the measurement is based on the rate of conductivity decrease and not absolute values, the residual adherence causes no perceptible error.

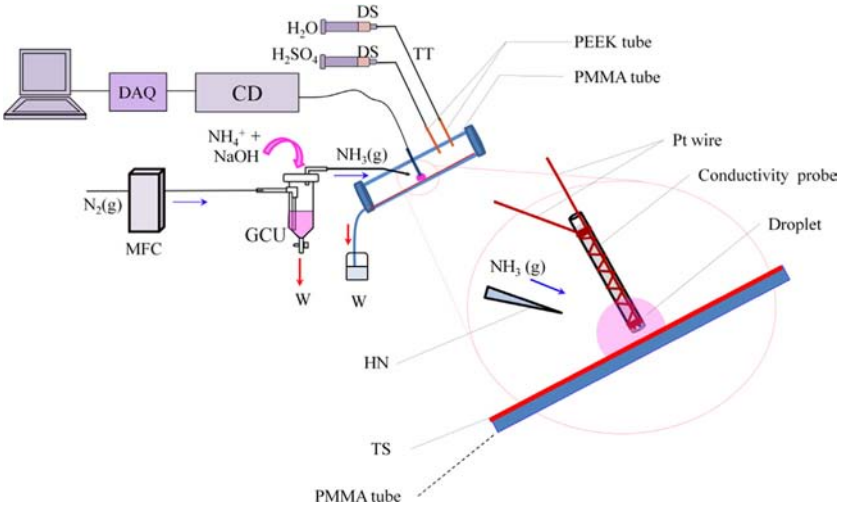

Fig. 1. The experimental setup: the mobile drop on the hydrophobic path with conductivity measurement for NH_4^+/NH_3 determination, MFC=Mass flow controller, GCU=Gas Conversion Unit, HN=hypodermic needle, CD=conductivity detector, DAQ=Data acquisition, TS=Teflon sheet, DS=Disposable syringe, TT=Teflon tube, *W*=waste.

The conductivity probe was made from a glass tube (1 × 1.5 × 65 mm i.d. × o.d. × length). One platinum wire (0.3 mm dia.) was inserted through the tube and affixed centrally at the mouth of the tube and the other was wrapped around the tube and fixed in place with epoxy adhesive. Only a small length at the end was left uncoated at the terminus for liquid contact. The wire termini were ~1 mm apart. The cell constant was ~33.0 cm^{-1}. The conductivity cell entered the PMMA tube wall in a perpendicular fashion and affixed thereto with hot-melt adhesive such that the tip was ~1.0 mm above the PTFE path. The conductance was measured by a commercial instrument (model 712 conductometer, www.metrohm.com). The instrument analog output was acquired at 5 Hz by a 22-bit A/D card (Emant300, www.emant.com). Custom software was written in-house in Visual Basic for data acquisition.

The gas conversion unit (GCU) was fabricated from a 50 mL polypropylene centrifuge tube (www.corning.com) as depicted in Fig. 1. A rubber cap was placed on top to seal the unit and also to function as a septum for reagent injection. The bottom of the chamber was connected with an on/off valve to drain out the solution to waste after the experiment. Nitrogen gas, flow controlled by a digital mass flow controller (0–2.0 L/min, Model MQ0002B/C, www.azbil.com) at 200 mL/min (ambient temperature) was used to bubble through the solution in the GCU: the gas entered through an elbow connector and used a 0.2 mm i.d. tube for bubbling.

The effluent gas traveled through a polycarbonate tube and terminated in a 21 ga. hypodermic needle that was affixed through the PMMA tube at an angle, the needle tip being ~1 cm from the liquid drop and directed at it. The gas flow creates circulating mixing, at least in the outer layer of the drop [27].

2.3. Experimental procedure

Ammonium bearing standards or samples in 0.1 M H_2SO_4 (5.00 mL) were transferred into the GCU by a transfer pipette. The H_2SO_4 absorber drop was manually dispensed and allowed to stop at the conductivity probe. The 4 M NaOH solution (5 mL) was then manually delivered to the GCU. The solution needs to be strongly alkaline for ammonia to be fully released and this is accomplished by the significant amount of NaOH added. Next the MFC was activated to begin purging of the GCU; this led to both mixing of the solution and transport of the evolved NH_3 out of the GCU. As NH_3 reacted with H^+ in the drop, the conductivity decreased; this was recorded for 200 s. The rate of decrease of the conductivity (RDC) was calculated. The RDC for a blank was similarly measured. The net RDC for various NH_4^+ samples were plotted against the known concentrations. The indophenol blue method was used for comparative measurements [28]; the absorbance due to the blue product was measured at 630 nm spectrophotometrically (CE1010, www.cecilinstruments.com).

3. Result and discussion

3.1. Fraction of ammonium volatilized

It is difficult to estimate how long it will require a solution of to be a purged of a volatile dissolved gas as this depends on many factors such as bubble size, gas flow rate and the operative Henry's law constant (K_H). For gases with a high K_H, such as NH_3, quantitative purging (> 99%) requires a time too long to be practical for analysis. Measurement of residual NH_3/NH_4^+ in the GCU solution after 200 s of bubbling under the stated conditions suggested that ~15% at room temperature (28 °C) on average is removed and this provides satisfactory results under the proposed procedure.

3.2. Analytical signal profile

As high mobility H^+ (λ_{H+} 349.8 S cm^{-2} $equiv^{-1}$) is converted to much lower mobility NH_4^+ (λ_{NH4+} 73.5 S cm^{-2} $equiv^{-1}$), the conductivity will decreases. The initial signal decrease is linear with time (Fig. 2a) and the slope (RDC) was linearly related to the NH_4^+ concentration (Fig. 2b). The relationship between the RDC and the ammonium concentration in the range 5–100 μM is linear and described by an equation

$$\mathrm{RDC}\ (\mu S/\mathrm{cm\ s}) = 0.0913\left[\mathrm{NH_4^+}\ (\mu M)\right] + 0.2725, \quad r^2 = 0.9957 \qquad (1)$$

The temporal profile of the conductance also reaches a minimum at the point the free acid is completely neutralized (hereinafter called time for lowest conductivity, TLC). Following the minimum, the excess ammonia leads to the formation of NH_4^+ and OH^- and increases the conductivity again [30]. The TLC, predictably, changes with varying sample [NH_4^+] concentration as shown in Fig. 2. Regardless of the concentration TLC has a finite

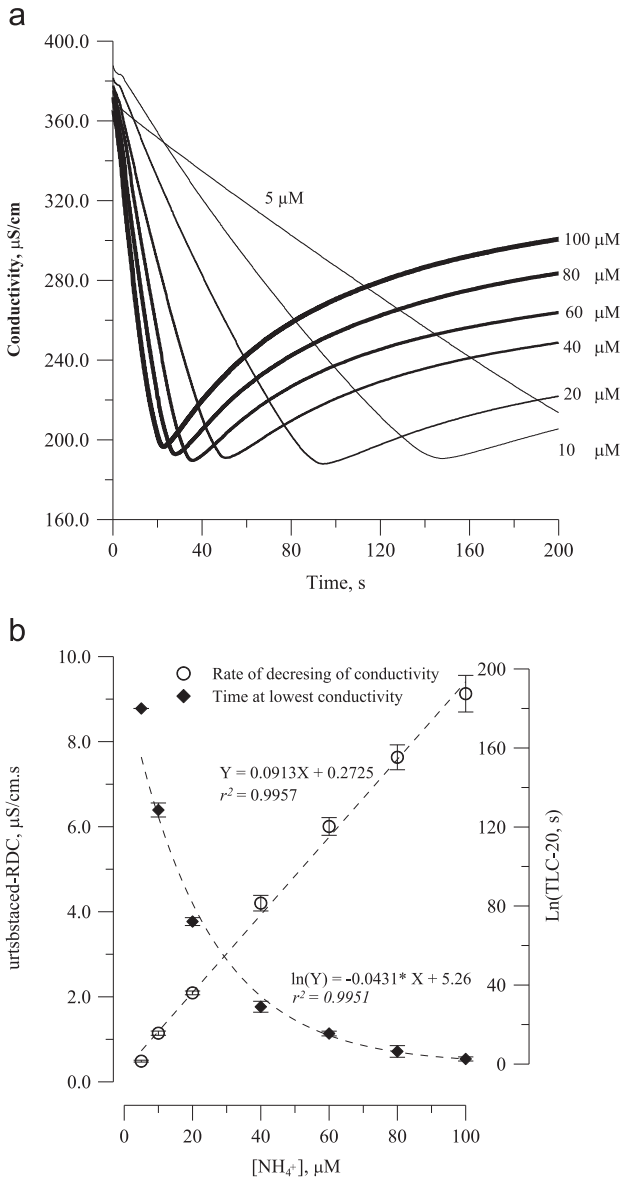

Fig. 2. (a) Typical temporal profile of conductivity signals (50 μM H_2SO_4) which decrease due to 5–100 μM NH_4^+. 4 M NaOH and N_2 flow rate 200 ml/min were employed to convert NH_4^+ /NH_3. (b) Relationship of subtracted rate of decreasing of conductivity and ln(TLC-20) vs NH_4^+ concentration.

minimum value (~20 s) as a finite time is required for the gas to be liberated, transported, absorbed, and the droplet sufficiently mixed for the conductance minimum to be registered. Once this finite value is subtracted from the apparent TLC value, the logarithm of this value also bears a relationship with the analyte concentration, at least up to 100 μM:

$$\ln(\mathrm{TLC, s} - 20) = -0.431 \times \left[NH_4^+, \mu M\right] + 5.26, r^2 = 0.9951$$

Using 50 μM H_2SO_4, the interday operations (4 day study) were observed to give slopes of calibrations (RDC vs $[NH_4^+]$) (5–100 μM NH_4^+) which differed by no more than 10%.

3.2.1. Parametric effects

Parameters that affect the performance of this analytical system include drop volume, gas flow rate, added NaOH amount, sample volume, as well as electrode alignment and liquid drop delivery and removal.

3.2.2. Drop volume

The PEEK drop head as listed provided a drop volume of 25 ± 1 μL ($n = 10$) as determined gravimetrically. Deliberately changing the volume of the liquid drop (by 3 drops, ~75 μL) required that the incline be changed to ensure drop adherence. Increasing the drop volume makes a little change of slope of calibration graph (RDC vs $[NH_4^+]$). From the base case of a single drop taken as unity, the slope decreases to 0.9 and 0.8, respectively, for 2 and 3 delivered drops. As the delivery of drops significantly less than 25 μL in volume was difficult to achieve reproducibly, this was not pursued. A single 25 μL drop also centers itself well on the present probe.

3.2.3. Gas flow rate

The N_2 purge gas not only carries the liberated NH_3 to the measurement drop absorber, but also helps the mixing of the GCU content. The gas flow rate affects the exit humidity (very slow flow rates can lead to moisture supersaturation of the exit humidity, potential condensation on exit tube walls and wall losses) and collection efficiency by the drop [35] (at very high gas flow rates, not only the collection efficiency will be poor, the drop shape is distorted and in an extreme case can be dislodged from the electrode. We studied gas flow rates in the 50–600 mL/min range; at 50 mL/min, the observed signals from samples were barely discernible from that of a blank. At the other extreme, at 600 mL/min, the drop became so skewed and unstable, no meaningful measurement was possible. Fig. 3 shows results for 100, 200 and 500 mL/min gas flow rates: although 500 mL/min provided the highest sensitivity, at high flow rates, the GCU solution was nebulized and contamination of the drop by the aerosol made for a high and poorly reproducible blank. In contrast, at 200 mL/min, the RDC of a blank was indistinguishable from that obtained after adding 1 M NaCl, indicating nebulization did not occur.

3.2.4. NaOH concentration

In principle, an NaOH concentration just over 0.2 M is sufficient to neutralize an equal volume of a sample containing 0.1 M H_2SO_4. But the pH needs to be high enough (≥ 11) where the concentration of NH_4^+ is negligible compared to that of NH_3. We investigated 0.2–6 M NaOH for this purpose and 4 M NaOH provided the highest calibration slope (RDC). This concentration is high enough to deal with highly acidic samples such as those encountered with Kjeldahl digests [5].

3.2.5. Sample volume

We studied sample volume effects only over a small range (4.80–5.20 mL), over this range, the RDC signal was not perceptibly affected. Note that it is the concentration of NH_3 in the solution in the GCU rather than its amount that will be the primary determinant of the gas concentration. The tolerance to a modest amount of volume uncertainty suggests that a 5 mL disposable syringe, rather than a volumetric pipette, should be sufficient for sample transfer.

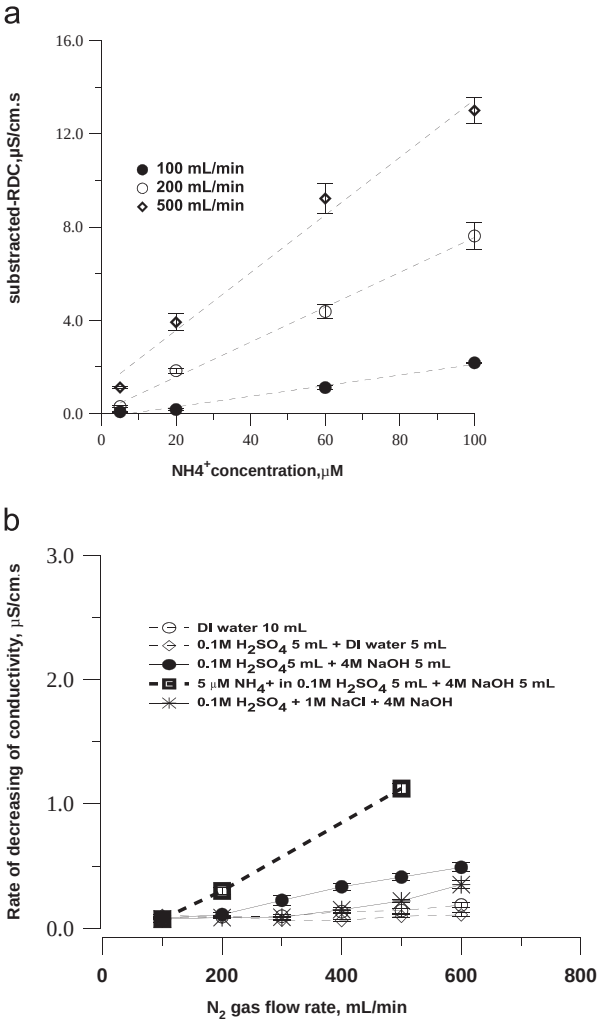

Fig. 3. Effect of N_2 gas flow rate to the subtracted rate of decreasing of conductivity of 50 μM H_2SO_4 at Pt electrode: (a) RDC vs NH_4^+ 5–100 μM with using N_2 flow rate 100, 200 and 500 mL/min, (b) RDC vs N_2 Flow rate of various sets of solution in GCU (DI water, 0.1 M H_2SO_4+DI water, 0.1 M H_2SO_4+4 M NaOH, 5 μM NH_4^+ in 0.1 M $H_2SO_4^+$ 4 M NaOH, 0.1 M H_2SO_4+1 M NaCl+4 M NaOH).

3.3. Extending the operational range to desired analyte concentrations through choice of absorber acid concentration

The absorber acid concentration can influence the linear range of calibration graph. We investigated various H_2SO_4 concentrations (5, 50, 200, 500, and 1000 μM) for this purpose. It was found that using a lower acid concentration will obviously be better to improve the lower working range of this method. Data from a sulfuric acid concentration of 5 μM was difficult to reproduce. Regarding, possibility on that a lower concentration of H_2SO_4 could be interfered by CO_2 in air as in the studies on breath NH_3 by Toda et al. that 5%v/v of CO_2 can affect measurements with a 50 μM H_2SO_4 absorber [30]. In the present application, as long as the stock absorber is protected from CO_2 absorption, the drop is really exposed primarily to a water and ammonium bearing N_2 atmosphere during measurement. We conservatively judge, for example with 50 μM H_2SO_4, the limit of detection (LOD), was ~5 μM NH_4^+ as the lowest concentration in linear calibration curve of RDC vs $[NH_4^+]$. The absorber acid concentration should be

Table 1
Determination of NH_4^+ in water by using proposed method (50 μM H_2SO_4 with Cu-electrode, 4 M NaOH, and N_2 flow rate 200 mL/min) and indophenols blue method.

Triplicate results: mean ± SD.

chosen based on the anticipated analyte concentration; for a high concentration sample such as those in Kjeldahl digests [5], a high acid concentration needs to be chosen.

3.4. Choice of electrode materials

Low cost materials, such as copper wire that can easily be taken from normal electrical cable, were employed as an alternative to platinum [5].

3.5. Interferences

As demonstrated by the lack of any response to the incorporation of 1 M NaCl in the GCU solution, nonvolatile materials do not interfere. Heavy metals that cause problems in the indophenol blue method by forming precipitates are automatically separated by matrix isolation. Only possible interferents in this approach would be low molecular weight volatile amines. It is well known that the volatile amine concentrations in natural waters are far lower compared to that of NH_4^+ [10]. We nevertheless tested the response of the system to ethylamine and diethylamine; at the 5 μM level (this would be unacceptable based on odor) these changed the RDC of 50 μM NH_4^+ by ~5%.

3.6. Natural samples

Results for several natural water samples are reported in Table 1. The results agree well with that of the indolphenol blue method, $y=0.9809+0.462$, $r=0.9987$. We did observe some carry-over; for best results repeat runs were made and data from the first run for each sample was discarded. In replicate measurements ($n=3$), the typical variance was ~ < 5%.

4. Conclusion

This work aims to develop a cost-effective procedure for the determination of ammonia/ammonium ion, by employing a mobile drop system that is simple and requires no conventional pumps and injection valves. The components used are inexpensive. The mobile drop platform serves for facile manipulation of solutions.

Here, a drop defines a measured volume of solutions and moving of the drops offer enables handling of solutions without using conventional tools such as pipette, beakers, etc. It is cost effective and down scaling chemical analysis. This would be useful for some places where budget is limited. The designed GCU can handle a solid sample without extraction. Application for the determination of soil NH_3-N is in progress. Application to other analytes such as carbonate or sulfite will further be developed as an extension of some previous works [36,37].

Isomeric amines

ABSTRACT

Eight selected isomeric amines were ionized using atmospheric pressure chemical ionization and atmospheric pressure photoionization producing a protonated molecule $[M+H]^+$ for each amine. The mobility of these ions was measured by ion mobility spectrometry. The amine compound class was shown to have an important role in mobility separation of the amines. 2,4,6-collidine, *N*,*N*-dimethylaniline and *N*-methyl-*o*-toluidine with highest observed mobilities have a *N*-heterocyclic aromatic ring, or are tertiary or secondary amines, respectively, whereas the rest of the compounds with lower mobilities were primary amines. It is suggested that the protonated $-NH_2$ group ($-NH_3^+$) interacts more with the drift gas, and therefore the primary amines have lower mobilities. The effect of the drift gas was tested by mixing argon or helium with the nitrogen drift gas. The presence of argon shifted the mobilities towards lower values, while with helium the mobility shifted towards higher values. However, in neither case did this result in better separation of the unresolved compounds.

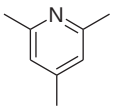
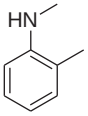
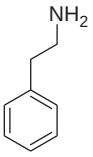
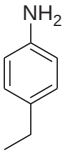
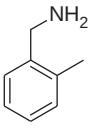
1. Introduction

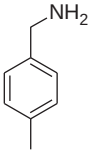


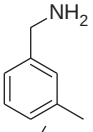


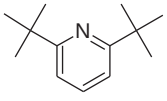












In ion mobility spectrometry (IMS) the analyte ions travel through a counter-flow drift gas in an electric field. The ions interact with the drift gas, which results in specific drift times for different ions. The analysis is commonly conducted at ambient pressure, which allows the construction of small portable IMS devices, which are widely used in field applications, for example, to detect explosives and warfare agents [1,2]. In the laboratory the IMS drift tube can be attached to a mass spectrometer (MS) [3,4]. This combination allows simultaneous access to mass and mobility data, for example to study different ionic structures of the same molecule [5,6], separating isomers of di-*tert*-butylphenol [7] or ovalbumin *N*-linked glycans [8] or distinguishing between different conformations of peptides [9].

Here, the main aim was to study the separation of isomeric amines ($M_r = 121$, $C_8H_{11}N$, Table 1) with IMS in order to understand better how compound structure affects separation. In addition, it was investigated how the addition of helium and argon to the nitrogen drift gas affects the separation of these amines. This report completes the preliminary presentation of the results [10]. Some of the amines in our study, namely 4-ethylaniline [11], *N*,*N*-dimethylaniline [12,13] and 2,4,6-collidine [13–15], have been studied before with IMS, but the whole set of isomeric amines used in this study was not included to the compounds studied. The drift gas has a significant role in separating ions, and changes in drift gas polarizability and radius will result in different interaction with analyte ions, and can thus produce different drift times [14,16–18]. For the compounds studied here, the effect of the drift gas on the mobility has been studied earlier for 2,4,6-collidine by using nitrogen, air, helium, argon, carbon dioxide and sulfur hexafluoride as drift gases [14]. The drift gas studies include also for example the use of drift gases, such as nitrogen, helium, argon, and carbon dioxide for amines other than those studied here [14,17], as well as peptides [17], and cocaine and its metabolites, amphetamines and benzodiazepines [18]. Here, our aim was to investigate how the addition of different proportions of helium and argon to the nitrogen drift gas affects the separation of the model amines.

Table 1
Summary of the reduced mobility K_0 ($cm^2\ V^{-1}\ s^{-1}$) values for the isomeric amines ($M_r = 121$) and 2,6-di-tert-butylpyridine ($M_r = 191$) measured with an IMS-FP instrument using nitrogen as the drift gas. Mobility values are not normalized with the mobility of 2,6-DtBPyr (average of eight measurements). The mobility values of amines are the average of four measurements; two within one day, which were then repeated on the second day.

Compound	Abbreviation	Structure	K_0 ($cm^2\ V^{-1}\ s^{-1}$) APCI	K_0 ($cm^2\ V^{-1}\ s^{-1}$) APPI
2,4,6-collidine[a]	2,4,6-Col		1.80	1.81
N,*N*-dimethylaniline[a]	*N*,*N*-DMA		1.75	1.75
N-methyl-*o*-toluidine[a]	*n*-M-*o*-T		1.70	1.69
2-phenethylamine[b]	PEA		1.62	1.62

2,6-di-*tert*-butylpyridine[d]	2,6-DtBPyr		1.47	

[a] Measured from Mix A.
[b] Measured from Mix B.
[c] Measured individually.
[d] Measured from Mix B and Mix C.

2. Experimental section

2.1. Chemicals

The amines *N*-methyl-*o*-toluidine (> 95%), 2-methylbenzylamine (> 96%), 4-methylbenzylamine (> 97%), 3-methylbenzylamine and 4-ethylaniline (> 98%), 2-phenethylamine (> 99%), *N*,*N*-dimethylaniline (> 99.5%) and 2,6-di-*tert*-butylpyridine (> 97%) were purchased from Sigma-Aldrich (Steinheim, Germany) and 2,4,6-collidine (> 99%) from Merck (Darmstadt, Germany). Stock solutions (5 mM) were prepared in methanol (HPLC, Lab-scan, Dublin, Ireland) and diluted further with methanol:toluene (95:5%) (HPLC, Baker, Deventer, Holland) to give 50 and 100 μM solutions.

2.2. Instrumentation

The mobility distributions were recorded using a custom-made drift tube ion mobility spectrometer equipped by a Faraday plate detector (IMS-FP) [19] and the mass spectrometric data were recorded using an ion mobility spectrometer-mass spectrometer (IMS-MS) [3]. In the IMS-FP the length of the drift region was 13.85 cm. The instrument was operated using a Bradbury–Nielsen (B–N) type ion gate with a 200 μs gate opening time. The drift gas flow was set to 1.9–2.5 L min^{-1} and measurements were conducted at room temperature (294–297 K). Nitrogen, and mixtures of nitrogen and argon or helium were used as drift gases. The desolvation and drift fields were both set to 316 V cm^{-1}.

A custom-made program was used to operate the instrument. During the total measurement time of 25 s 500 drift time transients were summed up to achieve drift time distribution. The obtained data were processed by a ChemStation 10.02 program code (Agilent Technologies, Inc., PaloAlto, CA, USA), with custom-made macros to calculate reduced mobilities of the ions detected. The IMS-MS was operated in continuous ion flow mode (both B–N gates open) to record the mass spectra [3]. The desolvation and drift fields were set to 304 and 316 V cm^{-1}, respectively. The nitrogen drift gas flow was ~2.4 L min^{-1}. The mass spectrometer was a triple–quadrupole mass spectrometer API-300 (SCIEX Applied Biosystems, Toronto, ON, Canada) operated in positive ion mode with a declustering potential of 5 V, and a mass range of m/z 30–300. The data were collected by Analyst 1.4.1 program code (Applied Biosystems/MDS SCIEX, Concord, ON, Canada).

2.3. Gases

Nitrogen for the drift and nebulizer gases was produced from compressed air with a heatless dryer Dominic Hunter Pneudri MiDAS 4 (Parker Hannifin Ltd., Gateshead, England) and a NGLCMS20 (Labgas Instrument Co., Espoo, Finland) or N2-MISTRAL-0 (LNI Schmidlin AG, Neuheim, Switzerland) nitrogen generator. The N_2 gas was further purified using a hydrocarbon and moisture trap. The level of humidity was measured using a humidity gauge (Vaisala DMT242; Helsinki, Finland) downstream from the drift tube. The bottled gases were purchased from AGA (Espoo, Finland) with a 99.999% purity for argon and 99.996% for helium. The drift gas mixtures were produced using two EL-Flow mass flow controllers (Bronkhorst, Ruurlo, the Netherlands).

2.4. Ionization

The samples were delivered to the ionization region using a custom-made heated nebulizer [19], which was heated up to 423 K. The samples were delivered with a PHD 2000 Advanced Syringe Pump (Harvard Apparatus GmbH, Hugstetten, Germany) into a nebulizer (the injection speed was 180 μL h^{-1}), where the nitrogen gas flow at 1.6-1.8 L min^{-1} carried the sample vapor to the ionization region. Two different ionization methods were used in this study: (1) atmospheric pressure chemical ionization (APCI) was conducted using an acupuncture needle (the corona needle potential was 2.0–2.2 kV), and (2) atmospheric pressure photoionization (APPI), using a krypton discharge lamp (PKS-100, Cathodeon, Ltd., Cambridge, England) with 10 and 10.6 eV photons.

3. Results and discussion

3.1. Ionization

Most of the experiments were conducted with an IMS-FP instrument operated in positive ion APCI or APPI mode. Mass spectra measured with the IMS-MS instrument confirmed that all the amines produced protonated molecules $[M+H]^+$ with positive APCI and APPI. Furthermore, both ionization methods resulted in a reaction ion peak (RIP).

3.2. Mobilities

All the reduced mobilities for isomeric amines were recorded with IMS-FP using APCI or APPI, and are summarized in Table 1. The mobility measurements were mainly done using three different mixtures of the analytes: Mix A (2,4,6-Col, *N*,*N*-DMA, *n*-M-*o*-T and 2-MBA), Mix B (PEA, 4-EA and 2,6-DtBPyr) and Mix C (2-, 3- and 4-MBA, and 2,6-DtBPyr). The mobility order was confirmed by measuring the amines individually. As an example of the reproducibility of the measurements the reduced mobility of 2,6-DtBPyr $K_0 = 1.47$ cm^2 V^{-1} s^{-1} with the relative standard deviation of 0.3% ($n=8$, on two different days) measured using APCI is reported. 2,6-DtBPyr is nowadays a commonly used IMS standard [19–22]. However, in this study reduced mobility values were not normalized with the reduced mobility of 2,6-DtBPyr.

Due to the different experimental conditions it is difficult to compare the reduced mobility values obtained in this study to the ones previously published [11–15]. However, the reduced mobility values in Ref [13] for 2,4,6-Col (1.83 cm^2 V^{-1} s^{-1}) and N,N-DMA (1.81 cm^2 V^{-1} s^{-1}) measured at 150 °C and using air as the drift gas are close to the values reported in Table 1, showing the same mobility order, but smaller differences in mobilities. Interestingly, Karpas et al. have reported that anilines typically form two mobility peaks, one for nitrogen-protonated, and one for ring-protonated species [12,13]. Later, this has been proven by mobility separation of different forms of protonated aniline molecules formed by electrospray ionization, and interpreting the subsequently measured collision induced dissociation (CID) mass spectra of the mobility separated protonated molecules [6]. It was observed that the nitrogen-protonated ions had longer drift time than the ring-protonated ions due to stronger interaction with the drift gas. However, in our study photoionization and corona discharge ionization produced only one mobility peak for each amine meaning that only one protonation site (most likely nitrogen) was preferable.

Based on the reduced mobility values presented in Table 1 and Fig. 1, two different amine groups can be separated. The first group contains the amines 2,4,6-Col, *N*,*N*-DMA and *n*-M-*o*-T, which contain a *N*-heterocyclic aromatic ring, or a tertiary or secondary amino group, respectively. These amines have clearly faster mobilities than the second group containing primary NH_2-groups (PEA, 4-EA, and 2-, 3- and 4-MBA). From Fig. 1A and Table 1 it can be seen that the amines in the first group can be separated from each other, and they have clearly different mobility values. Fig. 1A shows also that the first group of amines can be easily separated from a second group amine 2-MBA. Reduced mobilities of the amines in the second group are very close to each other. PEA and 4-EA could be separated from each other (Fig. 1B), but the mixture of 2-, 3- and 4-MBA produced a single mobility peak (Fig. 1C).

The clear separation of isomeric amines 2,4,6-Col, *N*,*N*-DMA and *n*-M-*o*-T could be explained by the varying number of carbon containing groups attached to the nitrogen atom, or by the aromatic nitrogen being surrounded by two methyl groups in *ortho* position, i.e. the charge in the *N*-protonated molecule is shielded by the alkyl groups, resulting in decreased interaction of the protonated molecule with the drift gas, and therefore higher mobility. Because of a similar shielding effect of the charged site, some molecules, such as 2,6-DtBPyr [20,21] and tetraalkylammonium halides [23], have been found suitable as IMS instrumental standards, and their reduced mobilities have been observed to be minimally affected by e.g. impurities of the drift gas. Interestingly, PEA was separated from 4-EA, even though both compounds have $-NH_2$ groups (Fig. 1B). The reason for this might be that the protonated PEA forms a "loop" via $-NH_3^+$ interaction with the benzene ring, resulting in a more closely-packed shape. Therefore protonated PEA is likely to interact less with the drift gas than the protonated 4-EA, which cannot form a similar "loop". This is also supported by the slightly higher mobility of PEA (Table 1, Fig. 1B). Similar loop formation has been reported in an IMS study for protonated diamines and polyamines [24]. In addition, very recently it has been shown by infrared multiple-photon dissociation spectroscopy that for the protonated phenylalkylamines, $C_6H_5(CH_2)_nNH_3^+$ ($n=2$–4), the most stable ion geometry has

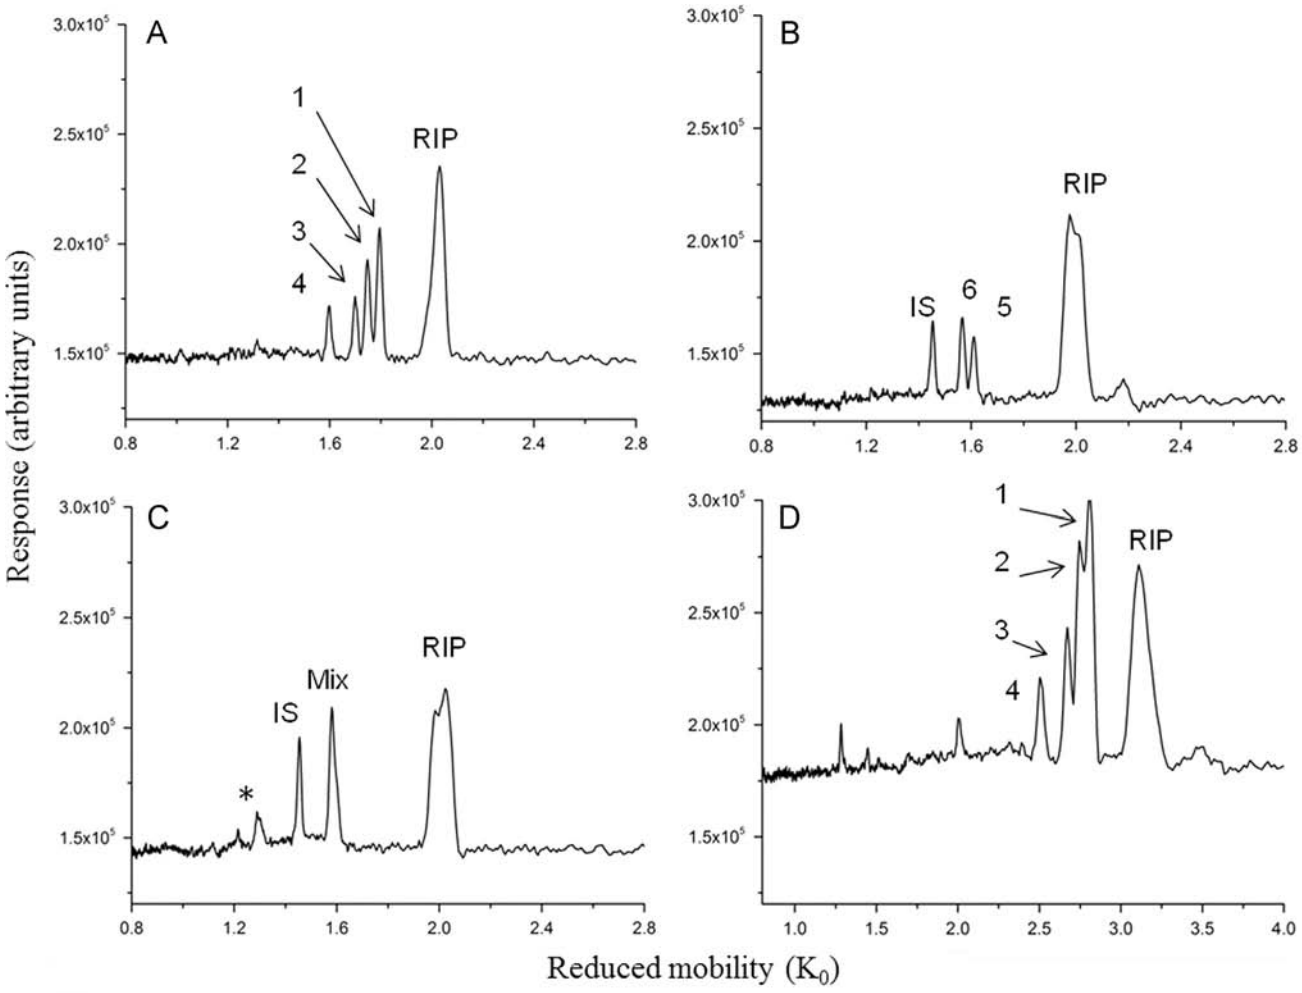

Fig. 1. Positive APCI ion mobility spectra of mixtures of isomeric amines measured with IMS-FP instrument (A and D) 1=2,4,6-Col, 2=*N*,*N*-DMA, 3=*n*-M-*o*-T and 4=2-MBA, (B) 5=PEA and 6=4-EA, and (C) Mix=2-, 3-, and 4-MBA. In Fig. (A)–(C) the drift gas was nitrogen and in Fig. (D) the drift gas mixture was 33% helium and 67% nitrogen. RIP=reaction ion peak, IS=2,6-DtBPyr and the asterisk indicates possible amine cluster ions.

interactions between the aromatic ring and the $-NH_3^+$ group causing folding of the side chain [25].

The effect of drift gas composition was studied using positive APCI–IMS–FP, sample mixture A, and a varying amount of helium or argon in the nitrogen drift gas. The addition of helium shifted all the peaks towards higher mobility (Fig. 2A), and separation of the amines was deteriorated at higher helium concentrations (Fig. 1D vs. 1A). On the contrary, the addition of argon to the nitrogen drift gas shifted all the peaks towards lower mobility (Fig. 2B), but the reduced mobility of the reaction ion peak (RIP) stayed more or less constant after the first argon addition. In addition, it was observed that peak heights of the analytes increased as the amount of helium in the drift gas increased, but with increasing amount of argon in the drift gas the peak heights were observed to decrease. These results are in good agreement with literature, where it has been reported for many compounds that reduced mobilities increase, when helium is used as the drift gas instead of nitrogen, and decrease, when argon is used as the drift gas [14,18]. Of the compounds used here, for 2,4,6-collidine clearly higher mobility in helium than in argon has been reported [14]. The observed changes in the peak height, and the effect of helium on resolution are also in good agreement with literature. It has been reported that helium provides clearly better sensitivity and argon lower, when compared to the use of nitrogen as drift gas [17]. In the same study it was hypothesized that the sensitivity changes are due to increased amount of reactions in the drift tube, since longer drift times allow more reactions, and the presence of different gases may cause differences in ionization efficiency in the electrospray process. In the same study it was also reported that shorter drift times in helium drift gas provide lower resolving power. Comparison of Fig. 1A and D confirms this observation.

4. Conclusions

The selected isomeric amines produced $[M+H]^+$ ions with APCI and APPI. Both ionization methods produced a single mobility peak for each amine. Two subgroups from the model compounds could be identified based on reduced mobility. Compounds with *N*-heterocyclic aromatic ring, tertiary or secondary amino groups (2,4,6-collidine, *N*,*N*-dimethylaniline and *N*-methyl-*o*-toluidine, respectively) had clearly higher reduced mobilities than the rest of the amines, which had a primary $-NH_2$ group (2-phenethylamine, 4-ethylaniline, and 2-,3- and 4-methylbenzylamine). 2,4,6-Col, *N*,*N*-DMA and *n*-M-*o*-T could also be separated from each other, while the primary amines had mobility values very close to each other. However, PEA could be separated from 4-EA. The extent of how much the adjacent groups are shielding the protonated nitrogen is expected to be the major explanation for the different reduced mobilities. In other words: the more protected the charge, the less the ionized analyte can interact with the drift gas, and therefore it can move faster through the drift tube.

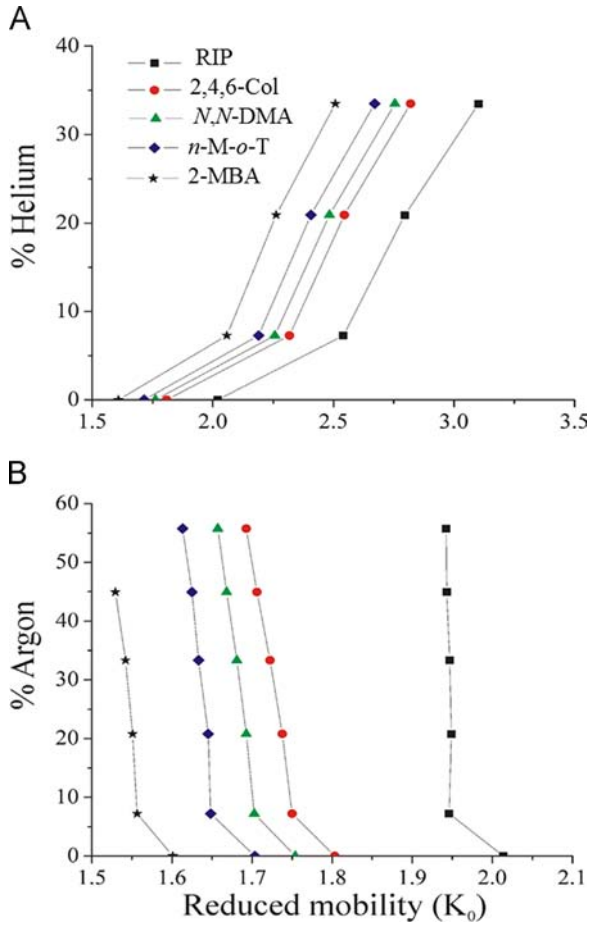

Fig. 2. Reduced mobility values of isomeric amines measured with a positive APCI–IMS–FP instrument. Helium (A) or argon (B) mixed in the nitrogen drift gas.

When argon was mixed with nitrogen drift gas all the peaks shifted towards lower reduced mobility, and a reduction in the peak height was observed, whereas the opposite behavior was observed with helium, which shifted all the peaks towards higher reduced mobility and increased peak height.

Acknowledgments

The project was supported by the Academy of Finland (Project nos.: 114132, 122018, 125758 and 255559). Docent Elina Kalenius and Jyrki Viidanoja are thanked for stimulating conversations. Prof. Herbert H. Hill, Jr. is acknowledged for a conversation regarding the structures of protonated amines.

Bovine serum albumin
Fluorescein isothiocyanate
Competitive binding study

ABSTRACT

The fundamental studies for the binding events of protein and its partner are crucial in drug development. In this study, a novel technology named microscale thermophoresis (MST) was applied in the investigation of molecular interaction between an organic dye fluorescein isothiocyanate (FITC) and bovine serum albumin (BSA), and the results were compared with those obtained from conventional fluorescence spectroscopy. The MST data demonstrated that with a short interaction time, FITC showed a high binding affinity for BSA by weak interaction instead of labeling the protein. By using competitive strategies in which warfarin and ibuprofen acted as the site markers of BSA, FITC was proven to mainly bind to the hydrophobic pocket of site II of BSA compared to site I of BSA. Except for the binding affinity, MST also provided additional information with respect to the aggregation of BSA and the binding of FITC to BSA aggregates, which is unobtainable by fluorescence spectroscopy. This work proves that MST as a new approach is powerful and reliable for investigation of protein–small molecule interaction.

1. Introduction

In vivo, cellular signaling involves a series of recognition events, leading from an external stimulus to a cellular response. Each recognition event is the binding between a protein and a partner that ranges from a small-molecule ligand to a macromolecular compound, which is the center of biological and biochemical processes in living organisms [1–3]. Notably, the interactions between biomolecules such as protein-protein and protein–small molecule with a wide range of affinities, have generated great interests for fundamental investigations in vivo and the development of targets for drugs [4–6]. Moreover investigation on these recognition events helps elucidate the structural nature of bioaffinity of drugs and their binding sites. Equilibrium binding experiments are extensively applied in the investigation of binding and competitive binding events in biological systems [7]. Recently, competitive binding behaviors have aroused more concerns to investigate the interactions between proteins and their ligands.

Up to present, a variety of powerful tools have been developed to study biomolecular interactions, such as absorption spectroscopy, circulardichroism [8], fluorescence spectroscopy [9], isothermal titration calorimetry (ITC) [10,11], fluorescence polarization (FP) [12,13], surface plasmon resonance (SPR) [14,15], dynamic light scattering (DLS) [16] and so on. These approaches are useful and convenient for investigating biomolecular interaction, but also have some disadvantages. For instance, fluorescence quenching or fluorescence correlation spectroscopy can be applied to analyze equilibrium constants of the interactions. However, these methods are only suited for a few interactions, as they crucially rely on molecular size and size-change upon binding parameters, the relative position of fluorophores to each other [17], and consumption larger quantities of sample or require extensive data analysis [18].

Although ITC is the most common nonfluorescent method that can monitor and record a biological binding process by microcalorimetry, obtaining the complete thermodynamic data requires long acquisition times and a relatively large amount of sample to obtain an adequately heat signal [19,20]. FP is a fully automated high-throughput analysis, but the limited lifetimes of the fluorescent dyes and the molecular weight change on binding hinder its applicability and sensitivity.

Although SPR is based on the changes of the physical optics of bound molecules and has relatively high sensitivity, it is not applicable in free solution because it relies on immobilizing one of the binding partners onto a thin noble metal film. Nonspecific binding of sample components onto the metal film may also interfere with the measurement. DLS is a label-free analytical

technology, using the relationship of time-dependent fluctuations of light scattered by molecules in solution, applied in free solution binding investigations. However, this approach requires an obvious difference in the dynamic radius (r_H) of the unbound partners relative to the complex. Considering r_H scales with the cube root of the molecular volume, the sensitivity of large particles is higher than that of smaller particles [21,22].

Recently, a new method microscale thermophoresis (MST) technology has emerged, monitoring the directed movement of fluorescently labeled molecules through temperature gradients. Distinguished from the other binding measurements, MST is a highly sensitive probe for many kinds of binding-induced interactions such as molecular size, charge, hydration shell or conformation [37]. Typically, the size, charge, and hydration entropy obtained by the thermophoresis of the fluorescently labeled molecules do not differ from those obtained from the unlabeled complexes. Furthemore, MST possesses several advantages including easy implementation, faster speeds (about 1 min), and lower sample requirements (e.g., microliter volumes). In addition, a wide variety of buffer solutions can be used and there is no practical limitation on molecular size or weight for the binding partners.

In this study, the interaction between fluorescein isothiocyanate (FITC) and albumin bovine serum (BSA) was investigated by using MST, which provides a new method for biomolecular interaction and proves the feasibility of MST for biomolecular interaction studies. FITC is currently the most widely used fluorescein dye for protein labeling, imaging and so forth. In the biological pharmacology field, serum albumin (SA) protein is the most abundant soluble protein found in blood plasma [23], which can combine with many kinds of endogenous or exogenous compounds such as amino acids, fatty acids, drugs, and many other small molecules [24,25]. BSA is an SA protein often used in biological investigations because it has a 76% sequence homology with human serum albumin.

The binding regions of BSA have been previously indentified by crystallography [26,27], which contain three structurally similar domains (I, II, and III) with each domain including two sub-domains. Sudlow's sites I and II are known as the common high affinity regions. The two tryptophan residues Trp-134 and Try-212 of BSA are located in sites I and II, respectively [28,29]. An anticoagulant drug warfarin and an anti-inflammatory drug ibuprofen have been demonstrated as stereotypical marker ligands for sites I and II, respectively [30]. Therefore by using binding studies, it is possible to identify the location of BSA that binds FITC. In this study, MST is demonstrated as a new approach for biomolecular interaction and the results are compared with those from conventional fluorescence spectroscopy.

2. Experimental

2.1. Apparatus

Fluorescence spectra were recorded on 970CRT spectrofluorometer (Shanghai, China). The width of the excitation and emission slits were 5.0 nm and 10.0 nm, respectively. The sensitivity was 3.

The binding affinity study was investigated on the microscale thermophoresis instrument (NanoTemper Tchnologies GmbH, Munich, Germany). The value of K_d was calculated by NT ANALYSIS SOFTWARE provided by NanoTemper Technologies GmbH. All the pH values were measured with a PHS-3C precision pH meter (Leici Devices Factory of Shanghai, China), which was calibrated with standard buffer solutions each day.

2.2. Materials and reagents

BSA was purchased from Roche Pharmaceuticals, Ltd. (Shanghai). Warfarin and ibuprofen were purchased from the National Institute for the Control of Pharmaceutical and Logical Products (China). FITC was purchased from Aladdin Reagent (Shanghai). Phosphate buffer solution (PBS) was prepared at a pH of 7.4 and a concentration of 10 mmol L^{-1} and was used in all experiments. All chemicals and reagents were of analytical grade and used without further purification.

2.3. Labeling procedure

BSA was dissolved in PBS (pH 7.4, 0.01 mol L^{-1}) with a concentration of 20 mg mL^{-1}, and FITC was dissolved in dimethyl sulfoxide (DMSO) with a concentration of 1 mg mL^{-1}. BSA was titrated by FITC slowly with a final mass ratio of 1:0.15 (BSA: FITC). The mixture of BSA and FITC was incubated at 277 K for 8 h in darkness. Subsequently, 30 μL of NH_4Cl (5.0 mol L^{-1}) was added to the mixture with a final concentration of 50 mmol L^{-1} to quench the reaction. Unreacted FITC and the FITC-labeled BSA were separated on a G-50 Sephadex column with 0.01 mol L^{-1} PBS eluent. Finally, the concentration of FITC-labeled BSA was determined as 0.9 μmol L^{-1} with a UV–vis spectrophotometer.

2.4. Theoretical background of MST

MST is a method based on micro-thermal effect of mobility. The directional movements of molecules on a microscopic scale are highly sensitive to many kinds of binding-induced interaction such as molecular size, charge, hydration shell or conformation (The details were reported by Seidel et al. [31]). When the liquid is heated locally, the molecules begin to move along the temperature gradient from high temperature to low temperature. As the movement reaches an equilibrium state, the spatial concentration distribution of the liquid can be expressed by the equation:

$$\frac{c_{hot}}{c_{cold}} = \exp[-S_T(T-T_0)] = \exp(-S_T\Delta T) \approx 1 - S_T\Delta T \quad (1)$$

for which c_{hot} is molecular concentration in the hot area; c_{cold} is molecular concentration in the cold area; S_T is the Soret coefficient; T_0 is the initial temperature; T is the elevated temperature. Although the theory of thermophoresis is nascent, most theories consider that various parameters may influence S_T, such as size, charge, hydration layer and solvation entropy. The Soret coefficient may be expressed by the following equation:

$$S_T = \frac{A}{kT}\left(-\Delta s_{hyd}(T) + \frac{\beta\sigma_{eff}^2}{4\varepsilon\varepsilon_0 T} \times \lambda_{DH}\right) \quad (2)$$

for which A represents the molecule's surface area, σ_{eff} is the effective charge, Δs_{hyd} is the hydration entropy of the molecule-solution interface, λ_{DH} is the Debye-Hüeckel screening length, ε is the dielectric constant, and β is temperature derivative of ε.

Fig. 1 is a schematic of the MST instrument for signal acquisition for a single capillary that contains the fluorescent species and its binding partner. An infrared (IR) laser is coupled into the light path of fluorescence excitation and emission, is focused on the sample to the exact spot where fluorescence emission is detected. The fluorescence within the capillary is excited and measured through the same optical elements. Initially, the infrared laser is off and there is no temperature gradient in the solution. Therefore the fluorescent species is homogenously distributed and a steady fluorescence signal is acquired. Once the infrared (IR) laser is switched on, the focused spot is heated immediately. The increase of temperature leads to a strong decrease in fluorescence due to the sensitivity of fluorescence quantum yield with respect to temperature, which creates an observable temperature jump. Due to thermophoretic molecular motion, the fluorescence decreases slowly until reaching a steady state when the thermophoretic motion is counterbalanced by the mass diffusion. Because of the short timescale of the temperature

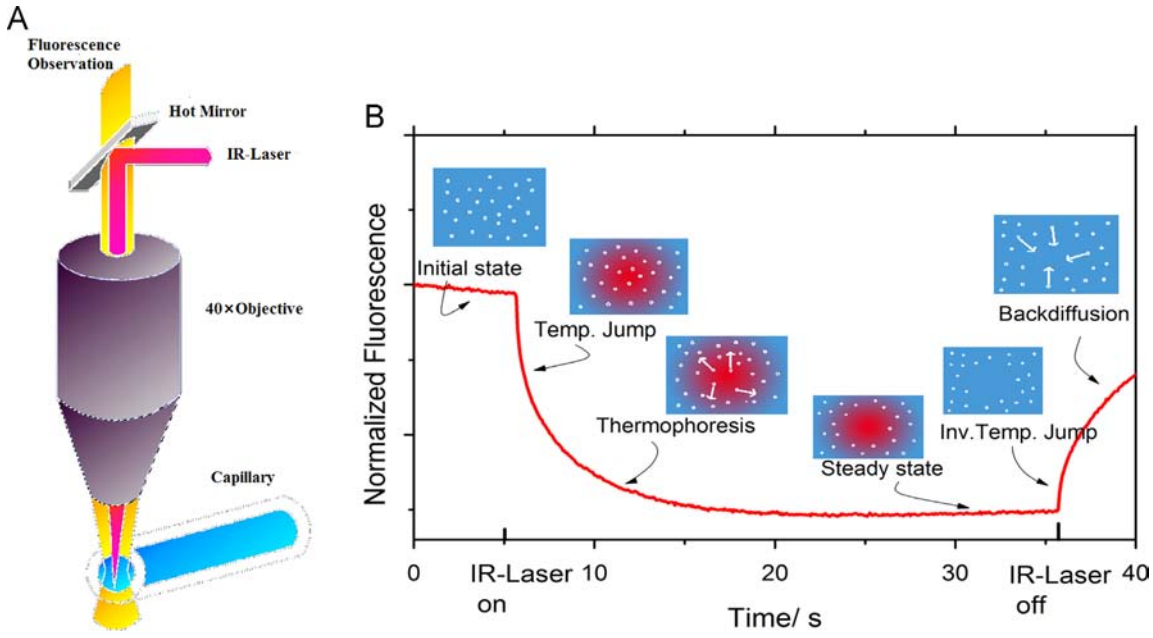

Fig. 1. A displays the experimental instrument of MST. The measurements are investigated in capillary. An infrared laser coupled into the light path of fluorescence excitation and emission is focused on the sample to exact spot where fluorescence intensity is measured. B is a typical MST signal for a given capillary. [36].

jump process (about 100 ms), it can be consequently distinguished from the following slower thermophoretic process. When the IR-laser is switched off, the fluorescence increases suddenly because of the decrease in local temperature, which results in a reversed temperature jump. After a short time of fluorescence recovery, the fluorescence increases gradually until achieving a steady state due to back-diffusion.

The dissociation constant K_d quantifies the binding affinity by analyzing the change in F_{norm}, which is the relative fluorescence (normalized fluorescence). F_{norm} is used for quantifying the concentration of fluorescent molecules and is defined by the following equation, including both the temperature jump process and the thermophoresis process.

$$F_{norm} = \frac{F_{hot}}{F_{cold}} = 1 + \left(\frac{\delta F}{\delta T} - S_T\right)\Delta T = \frac{c_{hot}}{c_{cold}} + \frac{\delta F}{\delta T}\Delta T \tag{3}$$

In the above equation, F_{hot} is the fluorescence in the hot area and the F_{cold} is the fluorescence in the cold area, both of which are the results from all fluorescent species in solution. When a fluorescent species binds to a non-fluorescent ligand and forms a fluorescent complex, the thermonphoretic signals of the bound species and unbound species are linearly superposed and described by the following equation

$$F_{norm} = (1-x)F_{norm,unbound} + xF_{norm,bound} \tag{4}$$

for which the F_{norm} is the total normalized fluorescence, $F_{\mathrm{norm,\ unbound}}$ is the normalized fluorescence of the unbound fluorescent species, $F_{\mathrm{norm,\ bound}}$ is the normalized fluorescence of the bound fluorescent complex and x is the fraction of the bound fluorescent species. By titrating a fluorescent species with a fixed concentration of a non-fluorescent ligand with varying concentrations and recording, F_{norm} is recorded versus different concentrations of the non-fluorescent ligand and the data are fitted according to different mathematical models.

Applying the law of mass action, the binding behavior of molecules can be described by a variety of models. The simplest binding model is the partner bound with its ligand at ratio of 1:1, which can be expressed as

$$AL \Leftrightarrow A + L \tag{5}$$

for which A is the binding partner; L is the titrating ligand; AL is the bound complex of A and L. Subsequently, the dissociation constant K_d can be defined as

$$K_d = \frac{[A][L]}{[AL]} \tag{6}$$

for which [A] is the equilibrium concentration of the free partner; [L] is the concentration of the free titrating ligand; [AL] is the concentration of bound complex of A and L. As the free equilibrium concentrations of A and L are not easily known, the analytical concentrations of A and L are used instead, which are expressed as:

$$c_A = [A] + [AL] \tag{7}$$

$$c_L = [L] + [AL] \tag{8}$$

for which c_A is the analytical concentration of A and c_L is the analytical concentration of L. Combining the above Eqs. (6)–(8), the dissociation constant K_d may be expressed as

$$K_d = \frac{(c_A - [AL])(c_L - [AL])}{[AL]} \tag{9}$$

Typically, the binding behavior of A and L is investigated by titration in microscale thermophoretic experiments. A is a fluorescent substance with a fixed concentration and L is the titrating ligand which is increased in concentration. Hence, the fraction bound of A can be described as:

$$x = \frac{[AL]}{c_A} = \frac{c_A + c_L + K_d - \sqrt{(c_A + c_L + K_d)^2 - 4c_A c_L}}{2c_A} \tag{10}$$

Combining the Eqs. (4) and (10), the value of K_d can be calculated by NT ANALYSIS SOFTWARE provided by NanoTemper Tchnologies GmbH.

2.5. MST experiments

The concentration of FITC stock solution was 0.4 μmol L^{-1} prepared in PBS (0.01 mol L^{-1}, pH of 7.4) and FITC also acted as a means of monitoring thermophoretic movement due to its fluorescence. A serial dilution of BSA (0.02 μmol L^{-1} to 2.0 mmol L^{-1}) in the same buffer (PBS pH 7.4) was prepared and mixed with the

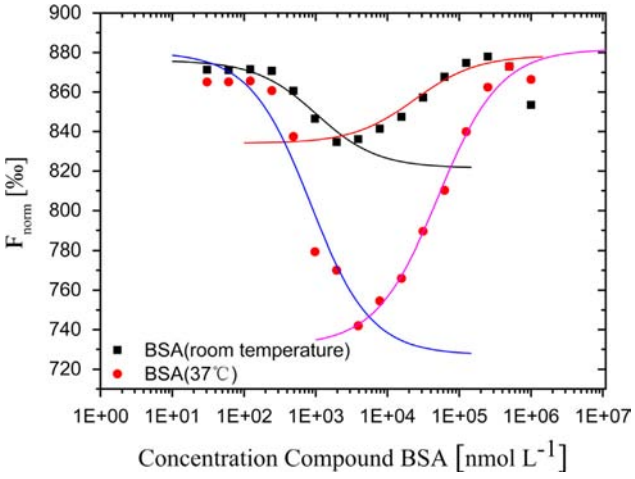

Fig. 2. The binding curves of FITC with BSA obtained from MST. FITC was titrated by BSA at room temperature (black dots) and 37 °C (red dots). The signal indicated the binding behavior between BSA and FITC is a biphasic event. The FITC concentration was kept constant at 0.2 μmol L^{-1}. The BSA concentration was ranging from 1.0 mmol L^{-1}. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

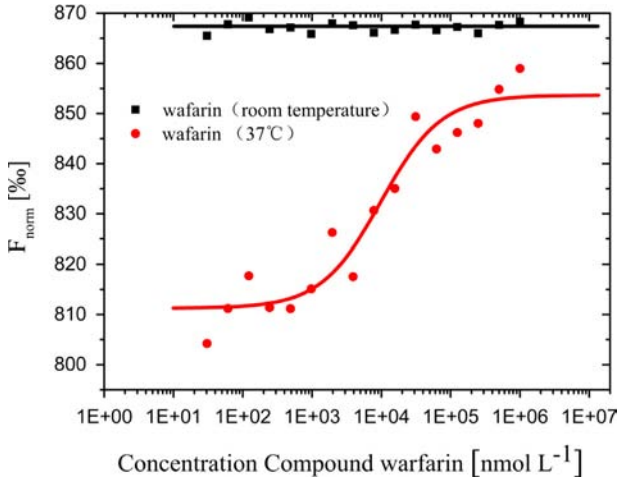

Fig. 3. Competitive experiments by MST. The binding of warfarin to a constant amount of FITC-BSA was quantified at room temperature (black dots) and 37 °C (red dots). Because of the binding in a competitive experiment with two ligands present, the fitting curves are just a guide to the eyes. The amplitude of F_{norm} signal indicates the degree of competition. The final concentration of FITC and BSA were fixed as 0.2 μmol L^{-1} and 0.6 μmol L^{-1}, respectively, and warfarin with varying concentrations was added. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

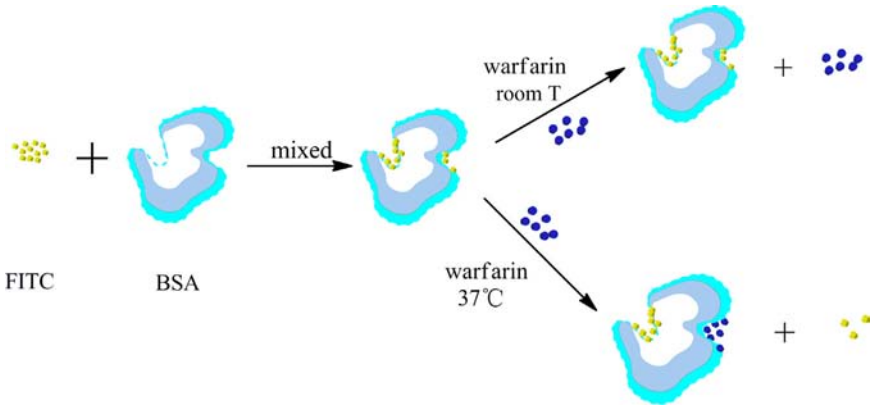
above FITC stock solution with the volume ratio of 1:1. In the first competitive binding study, the concentrations of FITC and BSA were fixed as 0.4 μmol L^{-1} and 1.2 μmol L^{-1}, respectively. After FITC was fully mixed with BSA (regarded as FITC-BSA), a serial dilution of warfarin (or ibuprofen) was added starting at 1 mmol L^{-1}. In the second competitive binding study, the BSA was pre-saturated with warfarin (or ibuprofen), and then the FITC with a fixed concentration of 0.4 μmol L^{-1} was mixed with a series of warfarin (or ibuprofen) saturated BSA. For the BSA aggregation investigation, the FITC labeled-BSA at the fixed concentration of 0.9 μmol L^{-1} were mixed with a series of unlabeled BSA at varying concentrations. All the solutions were filled in the standard glass capillaries after the sample mixing and immediately measured by MST. Data analyses and curve fitting were carried out using the Nanotemper Analysis software. All the experimental parameters used by the MST instrument were fixed with a LED power of 20% and a laser power of 80%.



2.6. Fluorescence spectroscopy experiments

In fluorescence measurements, BSA was introduced in an amount such that its concentration was always constant at 0.02 mmol L^{-1} for each sample. FITC solution was pipetted into these samples so as to obtain a series of quenching curves from 0–0.14 mmol L^{-1}, yielding 12 samples. The second series of solutions with the mixture of BSA and warfarin or ibuprofen (their concentration ratio was fixed as 1:1) was prepared as above and FITC was added to give different concentrations that ranged from 0–0.036 mmol L^{-1}, yielding 8 samples for the mixture of BSA and warfarin. The third series FITC was added to yield a range of concentrations from 0–0.028 mmol L^{-1} and 7 samples for the mixture of BSA and ibuprofen. All of these solutions were scanned on the fluorophotometer in the range of 300–450 nm with the excitation wavelength of 280 nm at 298 K.

3. Results and discussion

3.1. Interaction between FITC and BSA by MST

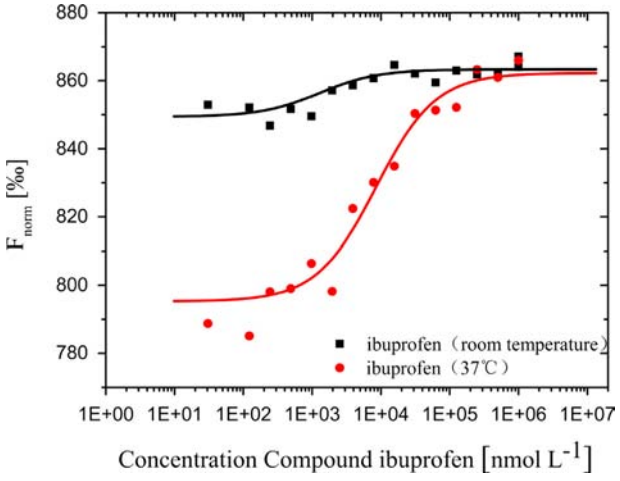
The interaction between FITC and BSA was investigated at room temperature and 37 °C with MST. During the experiment, the final FITC concentration was fixed at 0.2 μmol L^{-1}. By titrating FITC with an increasing concentration of BSA, the binding curves were obtained, which are given in Fig. 2. At the initial three points, due to the low concentration of BSA compared to FITC, only a small amount of FITC was bound to BSA, which resulted that the F_{norm}, an indicator of thermophoretic property of binding partners, was

Scheme 1. Depiction of the competitive interaction between FITC-BSA and warfarin at room T or 37 °C.

dominated by free FITC with its value about 860–870 units. As the BSA concentration increased, the F_{norm} decreased first, indicating a binding process between FITC and BSA, and then recovered to almost the same level at both room temperature and 37 °C, which suggests a biphasic binding pattern. At room temperature, FITC had a higher binding affinity for BSA with a K_d of 0.963 μmol L^{-1} (black) and a lower binding affinity with K_d of 23.8 μmol L^{-1} (red). At 37 °C, similar results were obtained with K_d of 0.783 μmol L^{-1} (blue) and 50.1 μmol L^{-1} (pink) for high and low binding affinities, respectively.

3.2. Competitive interaction study by MST

Sudlow's sites I and II are high affinity regions of BSA for a variety of molecules, such as dyes, drugs and small molecules. To locate the binding region of BSA upon binding with FITC, warfarin and ibuprofen were used as marker ligands for site I and II, respectively. A competitive strategy was applied to locate the FITC when binding to BSA. The final concentrations of FITC and BSA were fixed at 0.2 μmol L^{-1} and 0.6 μmol L^{-1}, respectively. After FITC was fully mixed with BSA (regarded as FITC-BSA), a serial dilution of warfarin was added starting at 1 mmol L^{-1}. These samples were measured by MST at both room temperature and 37 °C, and the results are given in Fig. 3. At room temperature, the value of F_{norm} was constant at 860 units with the increasing concentration of warfarin (0.01 μmol L^{-1} to 1 mmol L^{-1}), which value was consistent with that of FITC-BSA's at the same concentration in Fig. 2. This result implies that warfarin is not the competitor for the binding site between FITC and BSA, and FITC does not locate at site I. However, at 37 °C, the F_{norm} value changed from about 800 units to 860 with the increasing concentration of warfarin. In Fig. 2, when the concentration of FITC and BSA were 0.2 μmol L^{-1} and 0.6 μmol L^{-1}, respectively, the F_{norm} value was 800 units at 37 °C. Therefore the F_{norm} recovery from 800 to 860 units in Fig. 3 was probably due to the replacement of FITC with warfarin and the release of free FITC. This result suggests that FITC might interact with BSA at site I to some extent at elevated temperatures. At the higher temperatures site I may open up to permit some FITC binding. This interaction process is depicted in Scheme 1.



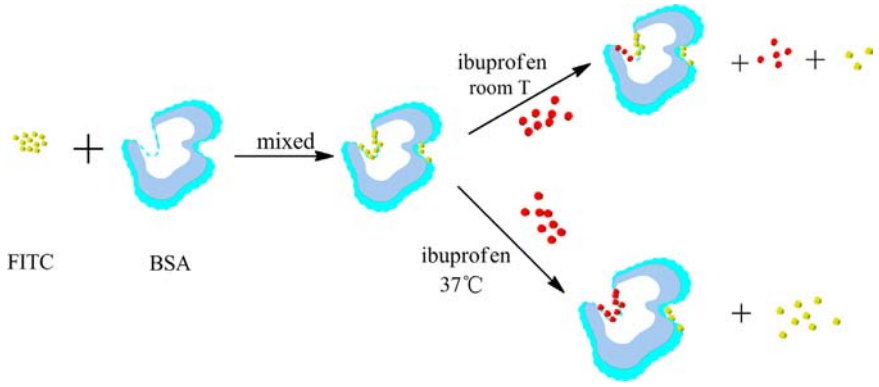


Fig. 4. Competitive experiments by MST. The binding of ibuprofen to a constant amount of FITC-BSA was quantified at room temperature (black dots) and 37 °C (red dots). Due to the presence of two ligands, the fitting curves are just a guide to the eyes. The final concentration of FITC and BSA were fixed as 0.2 μmol L^{-1} and 0.6 μmol L^{-1}, respectively, and ibuprofen with varying concentrations was added. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Subsequently, ibuprofen which has high affinity for the site II of BSA was chosen as the competitor and added to the mixture of FITC-BSA. The final concentration of FITC and BSA were still fixed as 0.2 μmol L^{-1} and 0.6 μmol L^{-1}, respectively, and mixed thoroughly. With the increasing addition of ibuprofen (0.01 μmol L^{-1} to 1.0 mmol L^{-1}), the F_{norm} signal increased slightly from about 840 to 860 units at room temperature, which is indicative of substitution of ibuprofen for FITC (Fig. 4). The released free FITC led to a recovery of F_{norm} to 860 units. When the temperature was increased to 37 °C, similar results were obtained. The F_{norm} value started at 800 units, which is exactly the signal level for FITC-BSA thermophoresis, and finished at with about 860 units, in accordance with the signal level of free FITC. From these results, it is deduced that ibuprofen has partly displaced FITC by binding at site II. The competitive process is described in Scheme 2. Because the replacement of FITC by ibuprofen happened at both room temperature and 37 °C, FITC is most likely more inclined to bind at site II of BSA.

FITC is a frequently used organic dye to label proteins by forming covalent bonds with lysine or arginine in most common labeling method [32]. Usually in the most protocols, the labeling process requires several hours, but in this study, FITC only mixed with BSA for several minutes. Whether this short incubation time will lead to labeling process is unknown. Therefore it is necessary to distinguish whether the interaction between FITC and BSA in this study is a labeling process or weak interaction due to electrostatic interaction, hydrophobic interaction, etc. Another competitive strategy was used to make a distinction between these two possible processes. Because warfarin and ibuprofen specifically bind to sites I and II of BSA, respectively, the BSA which was saturated beforehand by warfarin or ibuprofen was subjected to the FITC-BSA interaction study. When BSA is saturated with warfarin or ibuprofen, either site I or site II are completely

Scheme 2. Depiction of the competitive interaction between FITC-BSA and ibuprofen at room T or 37 °C.

occupied, which might lead to a weaker or unchanged interactions with FITC depending on the different processes of binding.

A fluorescence quenching experiment was performed to determine the minimum amount of warfarin and ibuprofen at which BSA is saturated by achieving the maximum fluorescence quenching. According to the results, the fluorescence quenching effect was maximized when the concentrations of warfarin and ibuprofen were 50 and 300 times as much as that of BSA, respectively.

Subsequently, the final FITC concentration was fixed at 0.2 μmol L^{-1} and mixed with a serial dilution of the mixture of BSA and warfarin or ibuprofen (the concentration ratio was fixed as 1:50 for BSA and warfarin, and the ratio was fixed as 1:300 for BSA and ibuprofen) starting at BSA concentration of 8.0 μmol L^{-1} at room temperature (Fig. 5). After data fitting, the K_d of FITC binding to warfarin-saturated BSA was 1.24 μmol L^{-1} and the K_d of FITC binding to ibuprofen-saturated BSA could not be calculated accurately because the signals never reached a stable value. The difference between these two curves excluded the possibility of the FITC labeling process, because if FITC had formed covalent interactions with BSA, the dissociation constant would remain constant regardless of the presence of warfarin or ibuprofen. However, the K_d of FITC binding to ibuprofen-saturated BSA could not be obtained and differed from the K_d of FITC binding to BSA, and thus FITC interacts with BSA by a weak interaction instead of a labeling process. The K_d of FITC binding to warfarin-saturated BSA is approximately equal to that of FITC binding to free BSA, which demonstrates that thermophoretic movement is not affected by excess amount of warfarin. This result indicates that FITC is more inclined to have a higher affinity for site II of BSA, which is displayed in Scheme 3. When FITC added to the ibuprofen-saturated BSA, because site II was occupied by ibuprofen, a lower binding affinity was achieved, confirming that FITC binds biphasically, FITC tends to interact with site II of BSA to a large extent, and with site I to a lesser degree.

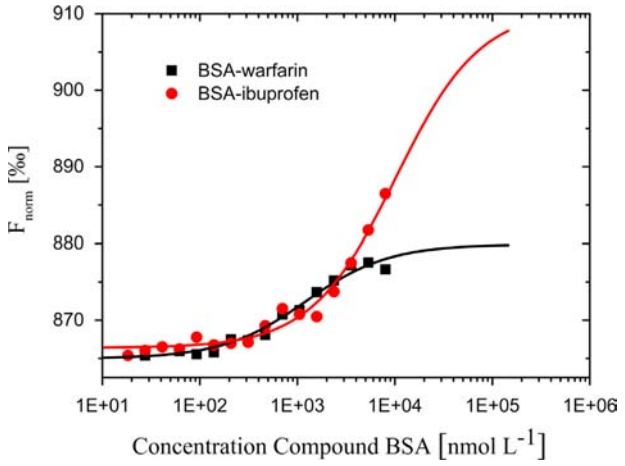

Fig. 5. The binding curves of FITC with warfarin-saturated BSA or ibuprofen-saturated BSA. The signal of black dots showed a constant amount of FITC (0.2 μmol L^{-1}) was titrated by warfarin-saturated BSA (the concentration ratio of BSA and warfarin was 1:50). The signal of red dots showed a constant amount of FITC (0.2 μmol L^{-1}) was titrated by ibuprofen-saturated BSA (the concentration ratio of BSA and ibuprofen is 1:300). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

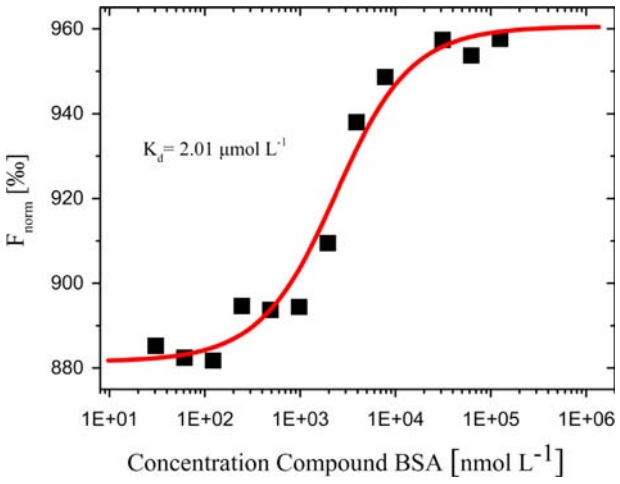
3.3. Property of BSA in solution

In Fig. 2, a biphasic binding pattern was observed, which indicates two forms of BSA binding to FITC. To elucidate the reason for the increase of F_{norm} with respect to BSA concentration, a serial dilution of BSA was added into FITC-labeled BSA. The FITC-labeled BSA was fixed at 0.9 μmol L^{-1}. With the increasing addition of free BSA, a binding curve was obtained with the K_d of 2.01 μmol L^{-1}, which indicates that BSA tends to aggregate at this concentration (Fig. 6). The value of K_d is almost in line with the concentration (about 2.0–4.0 μmol L^{-1}) corresponding to the



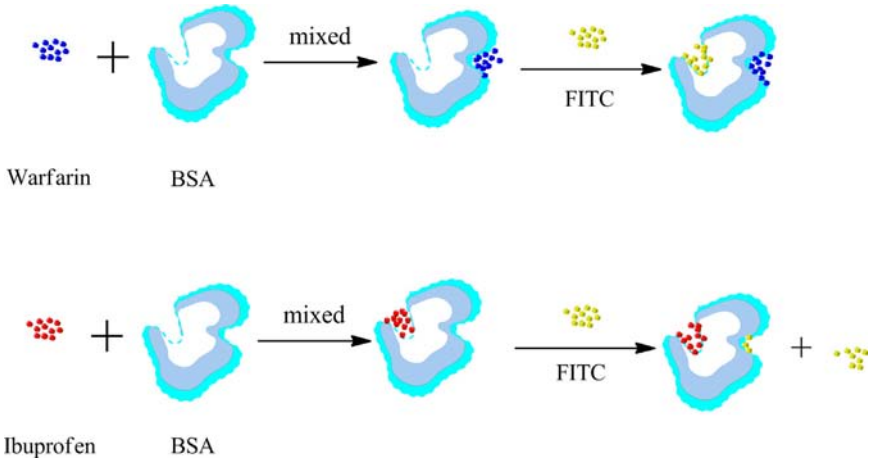


Fig. 6. MST quantified aggregation of BSA. A constant amount of labeled BSA–FITC (9.0 μmol L^{-1}) was titrated by unlabeled BSA. The value of K_d was corresponding to the lowest value of F_{norm} from the interaction between FITC and BSA.

Scheme 3. Depiction of FITC interacting with BSA in the presence of site markers-saturated.

lowest value of F_{norm} in Fig. 2, confirming that FITC binds to the aggregate of BSA which results in a second binding process.

3.4. Fluorescence measurements

MST is a new method for biomolecular interaction investigation, and thus conventional fluorescence spectroscopy method was applied to verify the results obtained from MST. Warfarin and ibuprofen were still selected respectively as the marker of site I or site II for the competitive study.

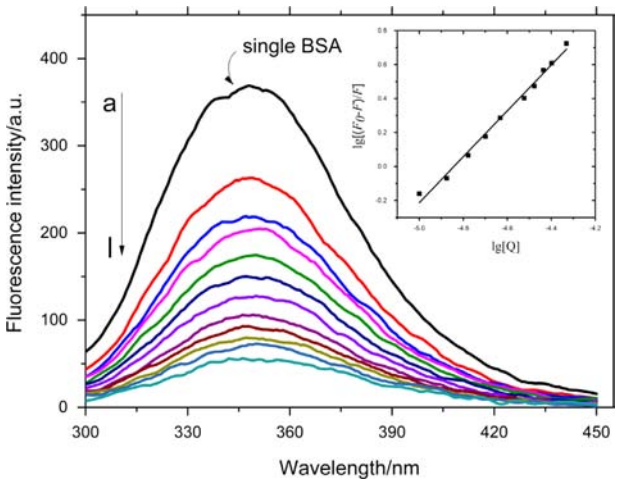

Fig. 7. Fluorescence emission spectra of BSA (0.02 mmol L^{-1}) in the presence of FITC with different concentrations (0–0.14 mmol L^{-1}). λ_{ex}=280 nm. Inset: the linear relationship for quenching BSA by FITC.

BSA shows intrinsic fluorescence mainly due to the two tryptophan residues [33], which are strongly affected by the interaction between BSA and molecules. When the increasing amounts of FITC were added to a BSA solution of constant concentration, the fluorescence of tryptophan at 340 nm decreased gradually without obvious shift in emission wavelength (As can be seen in Fig. 7). The fluorescence intensity decrease is probably attributed to dynamic quenching, static quenching or both of the two. To clarify the mechanism, the quenching process was first assessed by the Stern-Volmer equation [34] assuming a dynamic quenching:

$$F_0/F = 1 + K_q\tau_0[Q] = 1 + K_{SV}[Q]$$

In the above equation, F_0 and F are the fluorescence intensities of the protein before and after the addition of quencher (in this case, FITC), respectively; K_q is the quenching rate constant of the biomolecule; τ_0 is the average lifetime of the protein without the quencher, and generally taken as 10^{-8} s; [Q] is the concentration of the quencher, and K_{SV} is the dynamic quenching constant. The Stern–Volmer plots for the interaction of FITC and BSA were calculated to be in accordance with linear model. The value of K_{SV} was 3.1×10^5 L mol^{-1} (with a correlation coefficient r of 0.9987) and the corresponding K_q was calculated as about 3.1×10^{13} L mol^{-1} s^{-1}, which was much larger than the maximum scatter collision quenching constant (2.0×10^{10} L mol^{-1} s^{-1}) for biomolecules. Therefore, the interaction between FITC and BSA is possibly a process of static quenching rather than dynamic quenching.

Due to the deduction that the binding of FITC to BSA is a static fluorescence quenching process, which results in the formation of non-fluorescent compound, the fluorescence intensity could be described by the Scatchard equation [35]

$$\lg[(F_0 - F)/F] = \lg K_a + n \lg[Q]$$

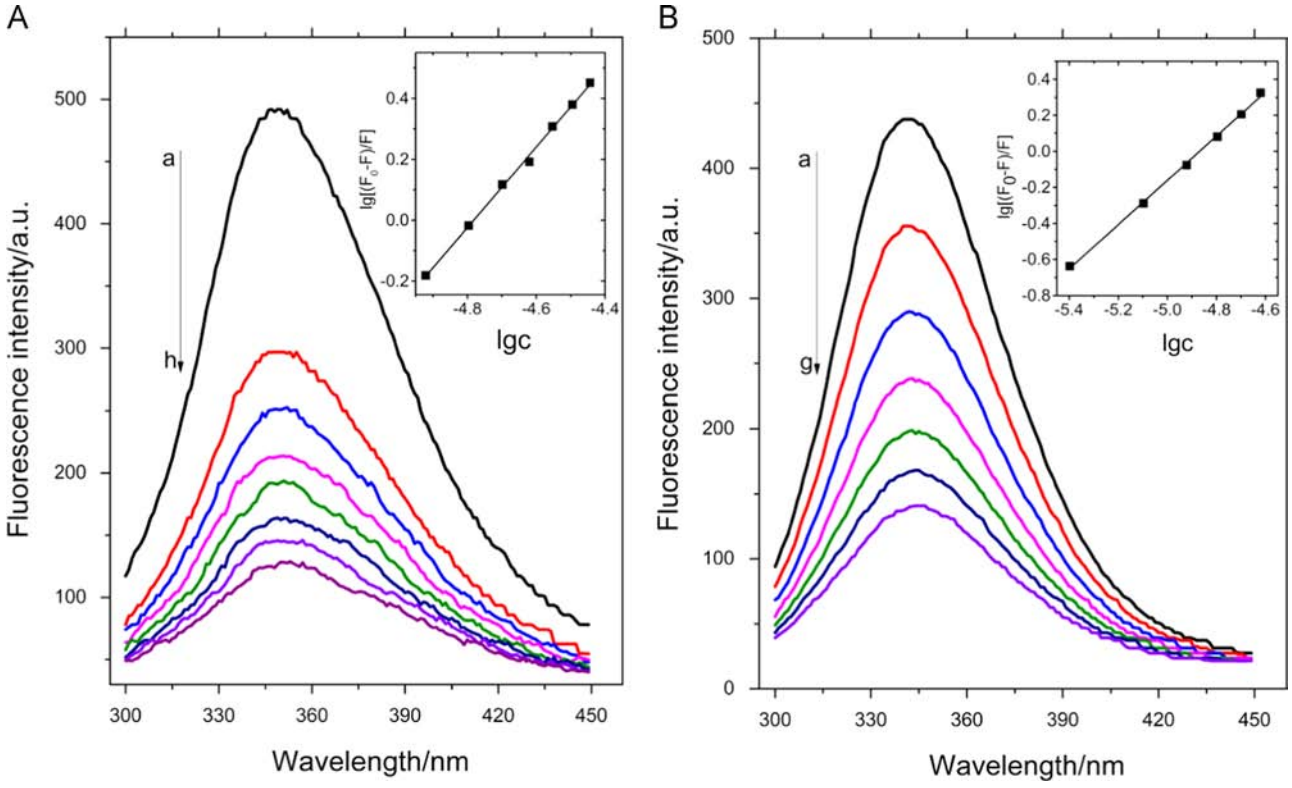

Fig. 8. (A) Fluorescence emission spectra of BSA-warfarin (0.02 mmol L^{-1}) (their concentration ratio was fixed as 1:1) in the presence of FITC with different concentrations (from a to h: 0.000, 0.012, 0.016, 0.020, 0.024, 0.028, 0.032 and 0.036 mmol L^{-1}). (B) Fluorescence emission spectra of BSA-ibuprofen (0.02 mmol L^{-1}) (their concentration ratio was fixed as 1:1) in the presence of FITC with different concentrations (from a to h: 0.000, 0.004, 0.008, 0.012, 0.016, 0.020 and 0.024 mmol L^{-1}).λ_{ex}=280 nm. Inset: the linear relationship for quenching.

Table 1
Binding constants of FITC-BSA system in the absence and presence of site markers at 298 K.

Site marker	Scatchard equation	r	$K_a/10^6$ L mol^{-1}
Without markers	$Y=(1.36)X+6.55$	0.9957	3.47
Warfarin	$Y=1.32X+6.32$	0.9993	2.09
Ibuprofen	$Y=1.23X+5.97$	0.9990	0.93

for which K_a is the binding constant, implicating the degree of interaction between BSA and FITC, and n is the number of binding sites. Depending on the linear relationship between $\lg[(F_0-F)/F]$ and lg[Q], K_a was calculated to be 3.47×10^6 L mol^{-1}. The reciprocal of this K_a value (2.88×10^{-7} mol L^{-1}) is on the same order of magnitude as the dissociation constant K_d obtained by MST, which suggests that MST provides reliable results. For comparison, the influence of warfarin or ibuprofen on the binding of FITC to BSA was investigated by titrating the pre-mixed 1:1 BSA-warfarin (or ibuprofen) solution with a series concentration of FITC (as given in Fig. 8A and B). The increasing amount of FITC produced a gradual decrease in fluorescence intensity of BSA-warfarin (or BSA-ibuprofen) mixture and the corresponding K_a was calculated, which are listed in Table 1. The binding constants changed from 3.47×10^6 L mol^{-1} to 2.09×10^6 L mol^{-1} and 0.93×10^6 L mol^{-1} in the presence of warfarin and ibuprofen, respectively. Accordingly, the decrease of K_a in the presence of ibuprofen was much larger than that in the presence of warfarin, which also indicates that FITC mainly tends to bind with the site II of BSA, and with the site I of BSA to a smaller extent. These results are consistent with those from MST.

4. Conclusions

In this study, a novel approach microscale thermophoresis was applied to investigate the interaction between BSA and a small organic dye FITC. FITC exhibits a strong binding affinity for BSA. FITC is mainly prone to interacting with the hydrophobic pocket of site II of BSA, while it also binds to site I of BSA to a lesser degree. These results from MST were in accordance with those from fluorescence spectroscopy, indicating the feasibility and reliability of MST in the application of protein–small molecule interaction. In addition, MST also demonstrated that FITC not only binds to BSA, but also binds to BSA aggregates, providing some detailed information about the BSA aggregation which was not obtained by fluorescence spectroscopy. Therefore MST is a powerful and reliable approach for protein–small molecule interaction. Combined with other advantages of MST, such as the low sample consumption which only needs several microlitres and nano molarity level, the simplicity of mixing, the fast measurement, the diversity of analytical solution especially in native environment and so on, MST is notably suitable in the application involved precious and expensive sample analysis.

ABSTRACT

Techniques, such as Diffusive Gradients in Thin-films (DGT), which either minimally disturb the soil or perturb it in a controlled way are most likely to provide information relevant to toxicity. Herein, we report the first use of DGT for organics (o-DGT) in soil systems to gain insight into the mobility and lability of four antibiotics—sulfamethoxazole (SMX), sulfamethazine (SMZ), and sulfadimethoxine (SDM), trimethoprim (TMP) in soil. In experiments where the same known amount of antibiotics were spiked into the soil, which was then further modified with NaOH, NaCl or dissolved organic matter, directly measured soil solution concentrations (C_{soln}) of these antibiotics were in the order: SMX > SMZ ≈ SDM > TMP. The *R* values (ratio of concentrations measured by o-DGT and directly in solution) were 0.56, 0.41, 0.40 and 0.28, respectively, indicating that the removal of these antibiotics from the solution can be to some extent resupplied by release from the solid phase. The nonlinearity of the relationship between o-DGT fluxes and the reciprocal of diffusive layer thickness (Δg) also suggested that soil solution concentrations were only partially sustained by the solid phase. The potential fluxes of these antibiotics in this soil were 5.4, 3.6, 2.4, and 1.2 pg/cm^2/s for SMX, SMZ, SDM, and TMP, respectively. o-DGT is a promising tool for understanding the fate and behaviour of polar organic chemicals in soil, and it potentially provides an *in situ* approach for assessing their bioavailability.

1. Introduction

Antibiotics are one of the most important classes of pharmaceuticals, widely used in our daily life, for human and veterinary purposes to cure or prevent some bacteria associated diseases. As some of the dose of antibiotics administered to animals or humans is not metabolized, it is excreted and enters effluent streams and reaches the environment [1]. Antibiotics are incompletely removed by wastewater treatment plants (WWTPs) [2], and discharged as parent compounds or easily re-transferable metabolites. Their adverse effects, particularly promotion of antibiotic resistance [3], has raised their profile within environmental science and ecology as a problem contaminant [4]. Antibiotics could enter the soil system through sludge/manure application or effluent irrigation. However, although these rather polar organic compounds have been in use for over half a century, knowledge of their fate and behaviour in soil systems is still not fully understood [5,6].

Understanding the interactions between contaminants and soils is essential for their risk assessment. Currently, there is a lack of understanding of both chemical speciation in soil solution and the kinetics of exchange between solution and solid phase. Most of the current knowledge on the environmental behaviour of antibiotics in soils has been gained by batch [6–13] or dynamic column [14,15] studies. While the information provided by such procedures is useful, information it does not relate directly to the *in situ* transfer of antibiotics between solids and solution, even though it is this *in situ* information which is essential for understanding their bioavailability/mobility and developing predictive models. Traditional approaches such as chemical extraction disrupt chemical equilibria, which may affect the distribution of species in solution, while dynamic column techniques also change soil conditions from the natural *in situ* situation. *In situ* chemical measurements which either minimize disturbance or perturb the solution in a controlled way [16] offer an alternative approach.

Recently we developed a novel passive kinetic sampler—Diffusive Gradients in Thin-films for organics (o-DGT) to measure antibiotics in solutions *in situ* [17]. It has been successfully employed to measure the concentrations of antibiotics in WWTP [18]. The DGT technique has been successfully and widely used to assess the availability, toxicity and lability of inorganic chemicals in soils and sediments [19,20]. In the present study, availability

refers to all the fraction of chemicals that can be accumulated by o-DGT, while lability particularly is used in reference to the susceptibility of a compound to desorption from soil particles. Most studies using passive equilibrium samplers to investigate availability/toxicity [21,22] in soil/sediment have been focused on persistent organic pollutants (POPs), with little work on polar organic chemicals (POCs). To start to fill this knowledge gap, we applied the o-DGT technique to soils and present the first measurements by o-DGT of antibiotics in a soil system. This study was performed on soils in which sodium azide (NaN_3) was added to inhibit the microbial activity [23], to facilitate investigation of physico-chemical processes.

2. Theory of o-DGT

The DGT technique is based on Fick's first law of diffusion [24]. A resin layer is separated from bulk solution (with a concentration C) by an analyte-permeable diffusion layer of thickness Δg, comprising an agarose or polyacrylamide hydrogel, known as the diffusive gel, plus a filter membrane (Fig. 1). Analyte diffuses through the diffusion layer (with a diffusion coefficient D) and is rapidly bound by the resin in the binding gel. For well stirred solutions or a hypothetical fully sustained sediment/soil (see fully supplied case (i) later), C is constant outside the o-DGT unit and a constant concentration gradient is maintained in the diffusion layer during the deployment time (t) (case (i) in Fig. 1). The flux (F) of analyte diffusing through the diffusion layer is determined by Eq. (1):

$$F = \frac{DC}{\Delta g} \quad (1)$$

In practice, the flux of an analyte from soil to an o-DGT device can be calculated from the measured mass (M) accumulated during the deployment time through a well-defined exposure area (A) (Eq. (2)). This assumption of a steady state flux requires that capacity of the binding layer is not approached. A high capacity that fulfils this condition has been established [17]:

$$F = \frac{M}{At} \quad (2)$$

In soil systems, the flux from the solid phase to solution, F_{ss}, induced by o-DGT may not be the same as the potential maximum flux from the solid phase to solution, F_m. Depending on the characteristics of the o-DGT device and the soil properties, F_{ss} will be a fraction of F_m and is therefore regarded as a partial flux. The directly measured o-DGT flux (F_{DGT}) of analyte from the solid phase to solution and its relationship to F_{ss} and F_m can be considered for three possible conditions [16] (Fig. 1).

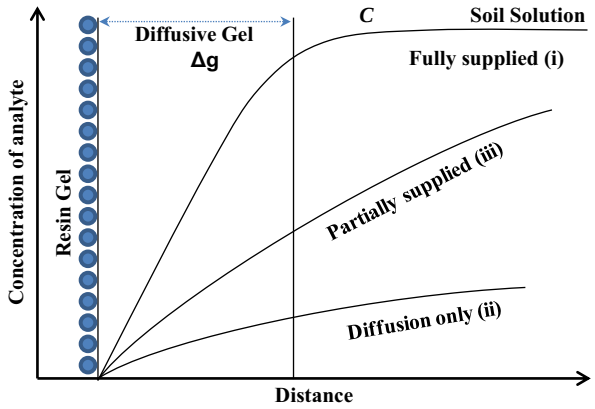

Fig. 1. Schematic of concentration gradients in o-DGT and soil.

2.1. Fully supplied

This is typically the case in well stirred solutions where C is independent of the distance from the membrane. In soils or sediments, analyte taken up from the pore water by the o-DGT is rapidly resupplied from the solid phase provided there is a labile pool size, which results in an effective buffer to maintain a constant concentration in the pore water. In this case, the concentration in soil solution or pore water can be calculated by Eq. (3):

$$C = \frac{M\Delta g}{DAt} \quad (3)$$

The F_{DGT} can be calculated by Eq. (2). It is likely to be less than F_m as the flux could be higher if an o-DGT device with a different geometry and higher demand for the analyte was used.

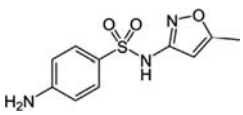
2.2. Diffusion only

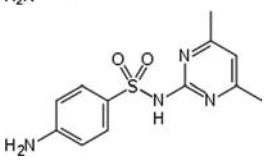
There is no resupply from the solid phase to the soil solution *i.e.* $F_{ss} \approx 0$. The only supply of analyte to a DGT device is diffusion. The concentration in the soil solution at the surface of the device will gradually decline, with this depletion in concentration progressively extending further into the soil away from the surface of the o-DGT device, resulting in a concentration gradient in the soil. Consequently F_{DGT} declines with deployment time.

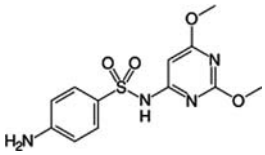
2.3. Partially supplied

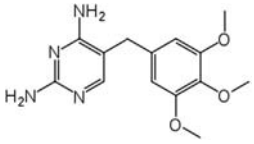
There is some re-supply of analyte from the solid phase to solution, but it is insufficient to sustain the initial concentration in the soil solution and to satisfy the DGT demand. In this case, $F_{ss} \approx F_{DGT} \approx F_m$.

In general, case (iii) is the most likely and expected phenomena, particularly for organic chemicals, which may be supplied from the solid phase to solution by breaking the forces of various interactions, including electrostatic, surface complexation and hydrogen bonding [25]. Case (i) and (ii) are two extremes for soils and sediments, but they may be approached.









The ratio (R) of o-DGT measured concentration (C_{DGT}) to the independently measured soil solution concentration (C_{soln}) is an indicator of the extent of depletion of solution concentrations at the DGT interface (Eq. (4)) [26]:

$$R = \frac{C_{DGT}}{C_{soln}} \quad (4)$$

R can help identify the different cases mentioned above. If $R=1$ (in practice, $R \geq 0.95$), then the analyte in the soil solution is fully supplied by the solid phase. If $0.1 < R < 0.95$, then it is partially supplied. If $R < 0.1$, it would be seen as diffusion only case, with no resupply from the solid phase to the solution. Generally higher R values indicate that the labile pool size of the analyte is large and/or a fast resupply rate.

The above mentioned cases can also be identified using approaches that do not rely on the measurement of R. Deployment of o-DGT devices with various thicknesses of diffusive layers (different Δg) for the same time can provide plots of fluxes against $1/\Delta g$, while deployments with a constant Δg for different times provide plots of fluxes versus time. In both cases the lines increase linearly with $1/\Delta g$ or time for the fully supplied case, but are curved for the partially supplied or diffusion only cases (Fig. S1).

3. Methods and materials

3.1. Chemicals

Four antibiotics—sulfamethoxazole (SMX, purity > 98%), sulfamethazine (SMZ, purity > 99%), sulfadimethoxine (SDM, purity > 98.5%), trimethoprim (TMP, purity > 99%) and ^{13}C-Caffeine (^{13}C-CAF as the internal standard [27], purity > 99%) were supplied by Sigma-Aldrich (Poole, UK). Their physiochemical properties are given in Table 1.

Antibiotic stock solutions were dissolved in pure methanol. Acetonitrile (ACN) and methanol (MeOH) were purchased from Fisher (Poole, UK). Humic acid (used as the dissolved organic matter—DOM) was obtained from the International Humic Substances Society.

3.2. Soil sample and treatments

The soil was collected from near Preston, Lancashire, U.K. The physico-chemical properties of this soil are: texture clay loam, maximum water holding capacity (MWHC) 46%, pH 6.5 (dH_2O), sand 56%, silt 25%, clay 19% and soil organic matter (SOM) 4.8% [29]. The soil was air dried and passed through a 2 mm sieve to remove roots and stones prior to experiments.

The soil was spiked with antibiotic solutions. Spiking solutions were prepared in methanol and added to soils, to deliver individual antibiotic concentration of 2.5 mg/kg in order to be detected in the solution. NaN_3 (10 mM) was added to inhibit the microbial activity [23]. To minimise solvent effects, the antibiotic solutions were first added to 25% of the soil and allowed to vent totally (to avoid potential effect of MeOH) before mixing well with the remaining soil (*i.e.* 75% of the soil) following the procedure in previous study [30]. Blank soil that was not augmented with antibiotics, but treated with the same amount of pure MeOH, was also prepared following the same procedure. The soils were then wetted to 50% MWHC by adding appropriate amounts of MQ water (high purity water, Milli-Q water system, UK), mixed well and left to equilibrate at room temperature. After 1, 2, 4, 7, 10, 15, and 19 days, soil was wetted to 100% MWHC 24 h before o-DGT deployment, and mixed well to obtain a soil slurry [16]. This pre-test established the time for reaching equilibrium and further experiments were conducted after 15 days equilibration. Soils were also modified using NaOH, NaCl and DOM to produce soils with different pH, ionic strength and organic matter for investigating their effects on fluxes from the solid phase to solution. In summary, six treatments were carried out. A, soil spiked with antibiotics; B, soil A mixed with blank soil (1:1) to produce soils with different antibiotic concentration; C, soil A further spiked with 0.01 M NaOH; D, soil A further spiked with 0.1 M NaOH; E, soil A further spiked with 0.1 M NaCl; F soil A further spiked 1.1% DOM. The resulting pH and SOM are given in Table 2.

3.3. o-DGT preparation and deployment

Standard o-DGT devices with 0.5 mm XAD18 resin gels, 0.8 mm agarose diffusive gels and polyethersulfone (PES) filter membranes were prepared as in our previous study [17]. o-DGT units were also made with different thicknesses of diffusive gels. The diffusive layer thickness including the PES filter ranged from 0.14 to 2.14 mm.

Deployment in the soil followed the standard procedures for using DGT in soils [16]. Briefly, a small amount of soil paste was applied gently onto the filter surface of the o-DGT devices and then pushed gently onto the soil surface with a slight twisting movement, enabling good contact between the soil and the device. All o-DGT devices were deployed for 24 h at room temperature (18 ± 3 °C). Photographs of laboratory deployment are provided in Fig. S2.

3.4. o-DGT retrieval and soil sampling

After deployment, o-DGT devices were retrieved. Soil particles were jet washed away with MQ water, the binding gel was removed (Fig. S2) and put into amber glass vials. An appropriate amount of internal standard was added. To extract the target chemicals 5 mL of MeOH was added into the vial followed by 20 min ultrasonication and the process repeated with a further 5 mL of MeOH. As recovery of all analytes was > 95%, 100% recovery was assumed in calculations [17].

[b] Dry weight based.

The pooled extract was blown down to dryness with a gentle N_2 flow, reconstructed in 1 mL of MeOH, and filtered through 0.2 μm PP syringe filters (Pall, UK) into a 2 mL GC vial.

About 5 g of the soil slurry was sampled and centrifuged at 3000 rpm for 30 min to obtain soil solution. The solution was filtered (with 0.2 μm PP syringe filters, Pall, UK) into 1 mL glass vials. The rest of the soil was extracted twice with 10 mL acetonitrile (ACN) [10]. All the samples were reconstructed in initial mobile phases before being injected into the HPLC.

3.5. Chemical analysis

A Thermo Finnigan HPLC coupled with a photodiode array detector was employed to analyze the antibiotics by UV absorbance at 265 nm. A Varian Pursuit C18 LC column (150 × 2.1 mm, 3 μm) was used to separate antibiotics. The mobile phase used was: 0.2% formic acid in MQ water (A) and acetonitrile (B). The gradient procedure was optimised at: 0–1 min, 10% B, then increase to 70% B within 11 min, followed by increasing to 100% B in 1 min, hold for 5 min, after that decrease to the initial condition within 1 min. Finally, 10 min of post run ensured re-equilibration of the column before the next injection. The injection volume was 10 μL and the column temperature was set at 30 °C. The quantification of antibiotics was based on an internal standard method following a previous study [27], and the instrument detection limits were 1–5 ng/mL.

3.6. Quality assurance/control (QA/QC)

Blank soils without spiking antibiotics were analyzed and no target compounds were detected (Table 2). The caffeine (which might interfere with the internal standard analysis) was not detectable. Every batch of samples was analyzed in parallel with a standard solution and blank (initial mobile phase) to check the instrument performance. Values within 5% of the previous measurements were considered acceptable.

4. Results and discussion

4.1. Concentrations in soil solution

In a pilot experiment with sterile soils, soil solution concentrations (C_{soln}) decreased over the first 7 days after spiking, but changed insignificantly (ANOVA, $p > 0.05$, SPSS, IBM Statistics 20) after 7 days (Table S1). This indicates the added chemicals have reached equilibrium with the soils. Subsequent studies were conducted with soils allowed to equilibrate for 15 days.

Although the 4 antibiotics were spiked to the same concentration (*i.e.* 2.5 mg/kg), the C_{soln} varied between compounds (Table 2), with SMX the highest, followed by SDM, SMZ and TMP. C_{soln} for TMP was much lower than that for the three sulphonamides. Different from traditional soil-solution partition coefficient (K_d) which refers to the total solid phase concentration, this study uses labile soild phase-solution phase partition coefficient (K_{dl}) since the labile fraction in the soil particles was refered here, estimated by the ACN extraction. TMP has a higher K_{dl} than SMX, SMZ and SDM, and SMX has the lowest value, which is consistent with previous studies of K_d [10,31]. C_{soln} for SMZ was comparable to or slightly higher than for SDM, even though they have different logK_{ow} values of 0.89 and 1.63, respectively. These results suggested that chemical structure is an important factor affecting the fate of antibiotics in soil, different chemical structure results in different steric hindrance, p*K*a, etc. K_{ow} is not the only key parameter to contol the fate of these polar organic chemicals [25]. Mass balance estimates showed that nonextractable (ACN) fractions are (69 ± 8)%, (76 ± 8)%, (67 ± 9)%, and (60 ± 8)% for TMP, SMZ, SMX, and SDM, respectively.

4.2. Concentrations measured by o-DGT

The *D* values for these antibiotics, taken from a previous study [18], are 4.19E−06, 3.29E−06, 3.15E−06, and 3.11E−06 cm^2/s at 18 °C for SMX, SMZ, SDM, and TMP, respectively. The appropriate values were used in Eq. (3) in calculating concentrations measured by o-DGT (C_{DGT}). Like directly measured pore water concentrations they declined with aging time. *R* values for each antibiotic were obtained using Eq. (4).

For the aged soils, concentrations calculated from o-DGT correlated well with independently measured C_{soln} (Fig. 2). This results in averaged *R* values of 0.56, 0.41, 0.40, and 0.28 for TMP, SMZ, SDM, and SMX, respectively. The higher *R* value of TMP than the other three antibiotics at a given time indicates that it can be resupplied more quickly by the solid phase than SDM, SMZ and SMX and/or it has a larger labile reservoir.

A lower o-DGT concentration than that measured directly in soil solution indicates that the solution concentrations of these

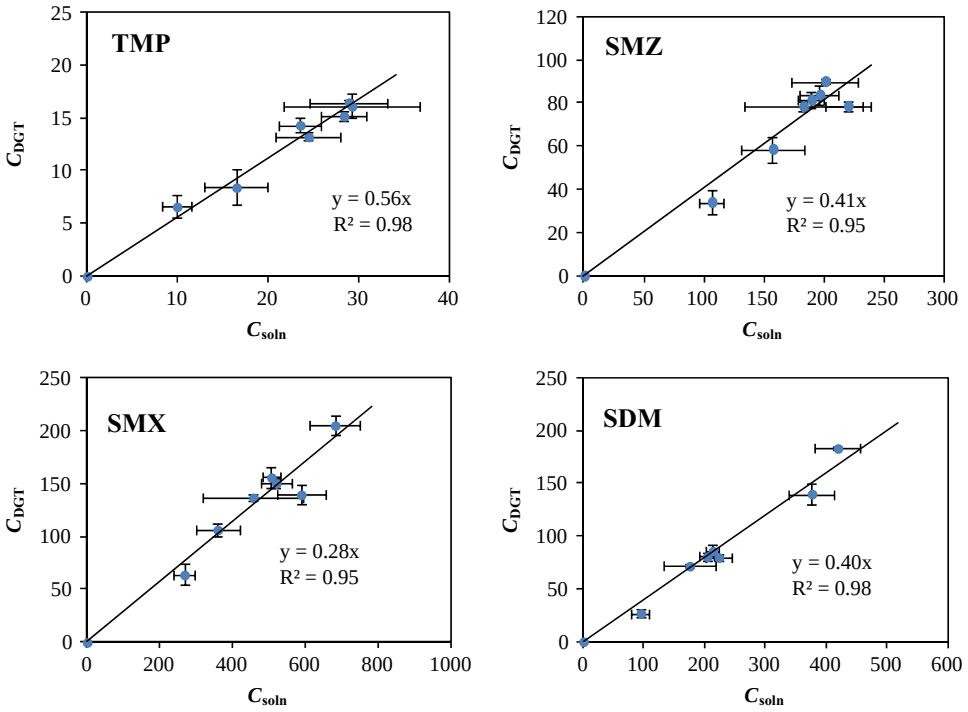

Fig. 2. Relationships between o-DGT measurement (C_{DGT}, ng/mL) and directly measured soil solution concentrations (C_{soln}, ng/mL) of 4 antibiotics in soils (error bars: SD for triplicate measurements).

antibiotics were only partially sustained by the solid phase [16]. The lower C_{DGT} than C_{soln} could be due to: (1) some species in the solution being unavailable to the o-DGT and/or (2) kinetic limitation of the resupply from the solid phase to soil solution. During deployment, the antibiotics at the surface of o-DGT devices were consumed, resulting in a decrease in the soil solution concentration at the interface. The removal of antibiotics in the solution at this interface could not be sufficiently rapidly resupplied by desorption from the solid phase. Consequently the concentration was depleted and the flux to the o-DGT device was less than the maximum possible flux, and the mean concentration measured by o-DGT, C_{DGT}, was lower than the initial solution concentrations, C_{soln}.

The acetonitrile extractable fraction was used here to estimate the labile solid phase concentrations in soil, and then K_{dl} could be derived. They were constant for each of the 4 antibiotics in the variously modified soil except for SDM in the soil at pH 7.6, for which the obtained K_{dl} (5.0) was only about half of the value obtained (10.6) for lower pH soils. As R was the same (0.40) for this higher pH soil, the desorption rate, k, must be larger. It appears that the desorption rate constant (and K_{dl}) is only sensitive to pH for SDM, whereas for TMP, SMZ and SMX it is independent of pH.

4.3. Fluxes from solid phase to solution

As discussed above, in most cases, these antibiotics in this soil solution are partially sustained by resupply from the solid phase. Therefore, the o-DGT results should be interpreted as fluxes rather than concentrations. The calculated, time-averaged, fluxes to o-DGT (F_{DGT}) are approximately equal to the average fluxes from solid phase to solution induced by o-DGT (F_{ss}) (given in Table 2).

Environmental changes (such as irrigation and application of manure or sludge) in the soil system will change soil properties (*e.g.* pH, cation exchange capacity—CEC and soil organic matter—SOM) which will consequently lead to different flux responses of these antibiotics from soil particles to soil solution. Fig. 3 shows the effect of soil pH on the fluxes of these 4 antibiotics from solid phase to solution. Good correlations were observed between the fluxes and soil pH (6.3–7.6). Less sensitivity of the fluxes for TMP and SMZ to pH might be due to the pH values studied being within (nearly all for SMZ and partly for TMP) the range of pKa_1 to pKa_2 (Table 1), where there are no big changes in the speciation. Increasing pH appears to facilitate the fluxes from solid phase to solution, which is consistent with previous studies [6,7,25]. At higher pH there is a greater proportion of anionic species, resulting in higher electrostatic repulsion between anionic sulphonamides and the negatively charged soil surface. Increasing soil pH leads to remobilizing the antibiotics, raising the risks of these antibiotics in terms of exposure to microorganisms or contamination of ground water.

Ionic strength and SOM affect sulphonamides and TMP differently. Both increasing of the ionic strength and SOM enhanced ($p < 0.05$) fluxes of TMP from the solid phase to the solution (Table 2). This could be due to the decreasing thickness of the electrical double layer of the charged surface [6] and competition between SOM and TMP [32]. However, it seems that both ionic strength and SOM suppressed slightly the fluxes of sulphonamides (SMZ, SMX and SDM) from soil particles, although not significantly for the SOM effect. The ionic strength effect in this study for SAs is inconsistent with a study by Białk-Bielińska and co-workers [6], where they found increasing ionic strength decreased the K_d of SAs. This might be attributed to the different composition of the exchangeable cations [7,32].

Deployment of o-DGT with different thicknesses of diffusive gel layers can help to characterize the transport of antibiotics from soil solids to solutions. For example, o-DGT with 0.8 mm and 0.5 mm diffusive gels were deployed in the soils for the same time. If concentration measured by o-DGT with 0.8 mm gel was higher than that by o-DGT with the 0.5 mm gel, it indicates the antibiotic in the soil solution was partially supplied by the solid phase. Obtaining lower C_{DGT} with thinner gels (0.5 mm) than thicker ones (0.8 mm) implies resupply from the solid phase cannot satisfy the demand of the uptake of o-DGT with a 0.5 mm gel, hence the solution is only partially resupplied due to limited labile pool or/and kinetic limitation. This is consistent with the observations made by comparing C_{DGT} with C_{soln} (R values).

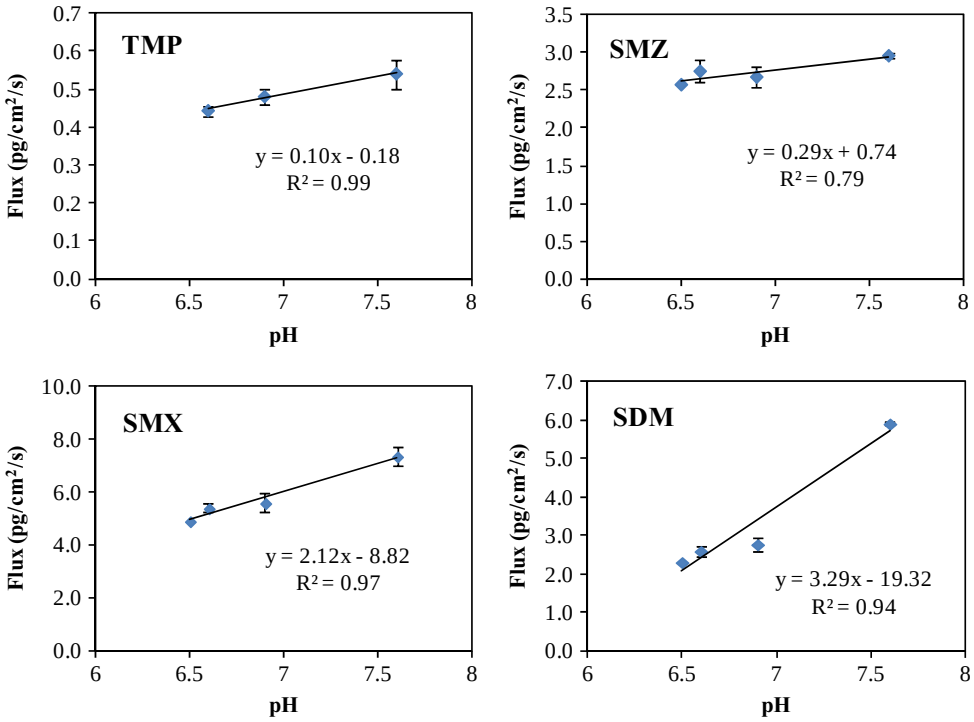

Fig. 3. Relationships between fluxes of antibiotics from solid phase to solution and soil pH (error bars: SD for triplicate measurements).

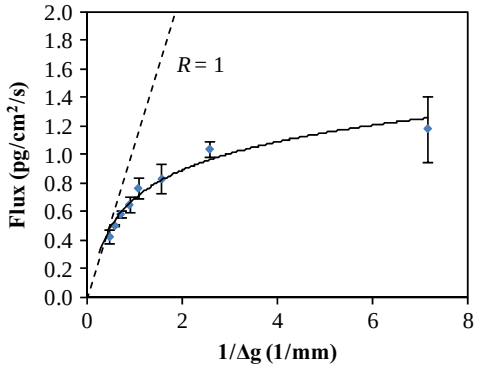

Fig. 4. o-DGT Fluxes of TMP *vs* reciprocal of diffusive layer thickness in the clay loam soil (dash line represents theoretical line according to Eq. (1) where $R=1$; error bars: SD for duplicate measurements).

Deployment of o-DGT with various thicknesses of diffusive gel layers can offer further information (Fig. 4). A nonlinearity of the plot of flux against the $1/\Delta g$ again suggests the concentrations of these antibiotics in the soil solution were partially supplied by desorption from the soil particles. A straight line interpretable with a slope of *DC* would only be expected if there was full supply from the solid phase (no kinetic limitation), where *R* should be 1 (shown in Fig. 4, TMP as an example). Although the demand for the o-DGT with thicker diffusion layers was smaller, it could not be satisfied by the resupply from the solid phase, as shown by the data points being lower than the $R=1$ line. Lower values than the theoretical slope and the apparent approach to a plateau suggest a kinetic limitation on the supply from solid phase to solution.

Deployments of o-DGT with thicker diffusion layers than those used here might enable accurate measurement of slope, *DC*, and derivation of the solution concentration, facilitating quantitative comparison with *R*. Fluxes of o-DGT with the thinnest diffusive layer are limited by the supply from soil to solution and so give potential fluxes of these antibiotics from this soil. The values were 5.4, 3.6, 2.4, and 1.2 pg/cm^2/s for SMX, SMZ, SDM and TMP, respectively. The fluxes measured using the standard o-DGT (0.8 mm diffusion gel) are about 60% for TMP and 80% for sulphonamides of the potential fluxes.

5. Conclusions and environmental implications

An important finding of this work is that when antibiotics are removed from solution, as they might be by biota, they are to an extent rapidly supplied by the solid phase. This resupply is most significant for SMX and least for TMP. Values obtained for the potential maximum supply fluxes of each antibiotic from soil to solution have the potential to be used in models of biological uptake. They could be used to estimate maximum possible uptake, as limited by transport form the soil.

This work has demonstrated that o-DGT is an *in situ* technique, which can provide quantitative measurements of antibiotic remobilization fluxes from soil to soil solution, and this might be linked to their bioavailability. DGT measured fluxes of metals have proved to be a good surrogate for plant uptake [19]. There is an urgent need to establish whether the bioavailability of antibiotics in soil/sediment can be predicted by o-DGT measurements. o-DGT opens up the possibilities of both directly obtaining kinetic information of polar organic chemicals such as antibiotics in natural or contaminated soil/sediment systems and providing an *in situ* measurement of bioavailability. In doing so it is likely in the future to enhance our understanding of the behaviour of these organic chemicals in the environment and improve risk assessment and associated models.

ABSTRACT

A new direct laser photo-induced fluorescence high performance liquid chromatography (DL-PIF–HPLC) method is developed for the simultaneous determination of three anilide pesticides, namely carboxin, monalide and propanil. DL-PIF–HPLC uses a tunable Nd:YAG-OPO laser to obtain fluorescent photoproduct(s) and to simultaneously analyze their fluorescence in a short acquisition time with an intensified CCD camera, which improves the selectivity (by choosing the suitable excitation wavelength), increases the sensitivity (due to the high energy of the laser beam) and reduces the time of analysis, relative to the classical PIF methods. However, one of the main drawbacks of PIF methods is the presence of interferences with other compounds, such as other pesticides from the same group yielding similar fluorescent photoproducts, which reduces their selectivity. The analytical interest of DL-PIF–HPLC to avoid these interferences is demonstrated. The DL-PIF spectra, chromatographic conditions and analytical performances of DL-PIF–HPLC are presented for the simultaneous determination of three anilide pesticides. The calibration curves are linear over one order of magnitude and the limits of detection are in the ng mL^{-1} range. The new DL-PIF–HPLC system has the advantage to combine the performances of both techniques, DL-PIF and liquid chromatography, and to improve the analysis selectivity.

1. Introduction

Pesticides are widely used in agriculture to improve productivity and, consequently, they can produce residues in crops, soils and surface water. Their persistence is an important matter of concern due to their toxicity and possible carcinogenicity. The presence of pesticides could affect the ground water quality, and/or disrupt water treatment plants. Therefore, it is important to develop sensitive and selective analytical methods for determining pesticides in surface water or seawater. Monitoring pesticides at low concentrations is usually performed by chromatographic techniques preceded by a preconcentration step, such as solid-phase extraction (SPE) or solid-phase micro-extraction (SPME). Many pesticides thermally unstable or non-volatile are difficult or impossible to analyze using gas chromatography. Therefore, high performance liquid chromatography (HPLC) is usually preferred. HPLC coupled to tandem mass spectrometry (MS/MS) offers a powerful tool for multiresidue pesticide determination [1,2]. Nonetheless, fluorimetric detection has the advantage of being more sensitive than classical UV absorption and less expensive than MS detection.

Many pesticides are naturally non-fluorescent, but they can be photolysed into rapidly-formed strongly fluorescent photoproducts upon UV irradiation. PIF conversion has been widely applied to the determination of pesticides for stationary media [3,4] as well as in flow injection analysis [5,6]. As an alternative to classical PIF, we have recently developed a different method based on direct laser photo-induced fluorescence (DL-PIF) [7,8]. This method uses a tunable Nd:YAG-OPO laser to obtain fluorescent photoproduct(s) and to simultaneously analyze their fluorescence in a short acquisition time with an intensified CCD camera. Compared to classical PIF, the use of a tunable laser improves the sensitivity (due to the high energy of the laser beam) and also the selectivity because the suitable wavelength can be chosen to excite and form only the PIF compounds of a given pesticide. However, as in classical PIF, several pesticides from the same

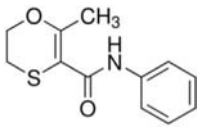
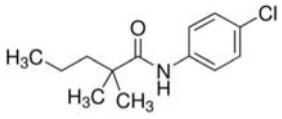
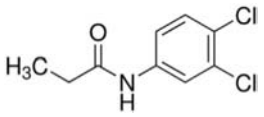
family cannot be analysed simultaneously if they have similar photoreactivity and form the same PIF compounds. PIF methods are then considered as broad specific routine methods useful to monitor the total amount of pesticides of a given family [3,5]. To overcome this problem, and to improve the selectivity of the method, it is necessary to couple chromatography to PIF.







Chromatography has been already coupled to classical PIF for the determination of pesticides. A post-column photoreactor is used to irradiate the non-fluorescent pesticides with an UV lamp and to transform them into strongly fluorescent photo-products that are subsequently detected with a fluorimetric detector [9–11]. In this way, the problem of selectivity of classical PIF is improved thanks to the chromatography separation. Following this strategy, we have coupled for the first time chromatography to DL-PIF in order to improve the sensitivity of the chromatographic method. The aim of this paper is to develop and optimize a new DL-PIF method, based on the on-line coupling between high performance liquid chromatography (HPLC) and DL-PIF detection. As an example, we investigated the application of the DL-PIF–HPLC method to three anilide pesticides namely carboxin, monalide and propanil (Table 1), and we reported the analytical performances of this method.

2. Material and methods

2.1. HPLC–DL-PIF system

Liquid chromatography was performed with a C18 column ($150 \times 3.9\ mm^2$, 5 µm particle size). The system was equipped with a "Milton Roy" pump and a manual injector valve with a 200 µL sample loop. The post-column photochemical derivatization of the pesticides was carried out in a 450 µL flow cell (quartz Suprasil, Hellma) that was irradiated with a Nd:YAG tunable laser in order to simultaneously form the photoinduced compounds and measure their fluorescence [18]. The laser source was a Powerlite Precision 9010 (Continuum, Santa Clara, USA) pulsed Nd:YAG pump laser beam at a 10 Hz repetition rate, with a Sunlite EX Optical Parametric Oscillator (OPO) and FX-1 UV frequency extension system from Continuum, which permits continuous

wavelength scanning from 225 to 1750 nm (LYOPO program). The available energy in the UV domain ranges from 2 mJ at 225 nm to 10 mJ per pulse at 275 nm [12,13]. The PIF fluorescence was collected at 90° angle from the excitation beam and focussed with a *f*/8 cm lens to the spectrometer entrance slit. The SpectraPro-550i spectrometer (Acton Research Corporation, Acton, MA, USA) has a 550 mm focal length and is equipped with a triple grating turret. The fluorescence was measured with an ICCD-MAX intensified CCD Camera (Princeton instruments, Trenton, NJ, USA) with a 512 × 512 pixel array optimized for the UV–visible domain. The camera is operated with a ST-133 controller (RS Princeton Instruments, Trenton, NJ, USA) for data acquisition. Timing control is achieved with a DG 535 digital delay/pulse generator (Stanford Research System Inc, Sunnywale, CA, USA). The WINSPEC 32-bit Windows software package (Roper Scientific Inc, Trenton, NJ, USA) provides acquisition, display and processing functions. Fig. 1 shows a schema of the whole system.

2.2. Absorption and fluorescence spectrophotometer

UV–visible absorption spectra were recorded on an Eclipse UV–visible spectrophotometer (Varian) and excitation fluorescence spectra with a Cary Eclipse fluorescence spectrophotometer (Varian).

2.3. Reagents

Carboxin, monalide and propanil were purchased from Sigma-Aldrich. Methanol was obtained from Sigma. All the reagents were of analytical reagent grade. Ultrapure water (Millipore Mro-MQ System) was used for the experimental work.

Stock standard solutions of the pesticides (200 mg/mL) were prepared by dissolving the compounds in methanol. An ultrasonic bath was used to obtain complete dissolution; then, solutions were stored in the dark. Serial dilutions were performed to obtain the working standard solutions. The working solutions were prepared in 60:40 (v/v) methanol–water mixture.

2.4. Sample preparation and chromatographic conditions

The water samples analysed were from the Senegal River, from the Atlantic Ocean of the Dakar seaside (Senegal) and from Penmarc'h seaside (France). The samples were filtered through a filter disk (45 μm) in order to eliminate the suspended organic matter and collected in 0.5 L amber glass bottles samples. The filtered samples were spiked with the anilide pesticides at two concentration levels (0.05 and 0.20 μg mL^{-1}).

A SPE C18 cartridge (LiChrolut RP-18E 200 mg 40–63 μm) was preconditioned with 2 mL of methanol followed by 5 mL of ultrapure water. 50 mL of the spiked water samples were passed through the cartridge. After elution of the polar compounds by 5 mL of pure water, the pesticides were eluted, leading to a 10-times pre-concentration factor. The samples were analysed in isocratic conditions with a methanol–water mixture (60:40 v/v). The flow rate was of 0.8 mL min^{-1}.

2.5. Statistical calculations

Statgraphics software (Statpoint Technologies), was used for statistical computation.

3. Results and discussion

3.1. Photo-induced fluorescence properties

Carboxin, monalide and propanil exhibited no native fluorescence, while UV irradiation yielded the formation of strongly fluorescent photoproducts. Fig. 2 compares the absorbance spectra of each pesticide with the excitation and emission fluorescence spectra of their photo-induced compounds (PIF) formed after 1 min of laser irradiation in a 3 mL fluorescence cell. The main absorption bands for carboxin, monalide and propanil were respectively 251, 247 and 251 nm (Table 2). One can see that carboxin formed two PIF compounds whereas monalide and propanil formed only one. For carboxin, the excitation emission couple (EEC) of its PIF compounds was of 230/370 nm (PIF 1) and 242/430 nm (PIF 2). The EEC of the photo-induced compoundsof monalide and propanil were,

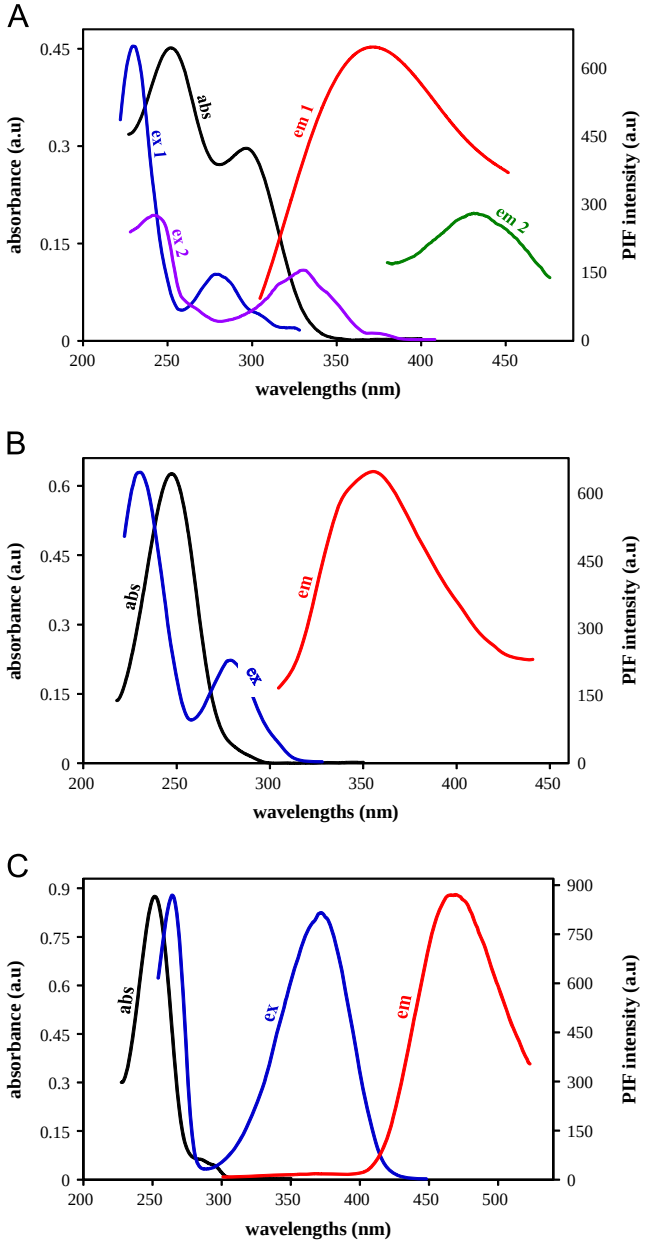

Fig. 2. Comparison of the UV–absorption spectra of the pesticides under study with the fluorescence excitation and emission spectra of the photo-induced compounds formed after 1 min of laser irradiation of the pesticides at 1 μg mL^{-1} in methanol–water mixture (60:40 v/v). (A) Carboxin; (B) monalide; and (C) propalil.

Table 2
UV absorption of monalide, carboxin and propanil and fluorescence properties of their photoproducts in methanol–water mixture 60:40 (v/v).

Pesticide		Absorbance λ_{max} (nm)	Fluorescence	
			λ_{EX} (nm)	λ_{EM} (nm)
Carboxin		251/296		
	PIF 1		230/280	370
	PIF 2		242/330	430
Monalide		247		
	PIF 1		230/280	354
Propanil		251		
	PIF 1		264/370	464

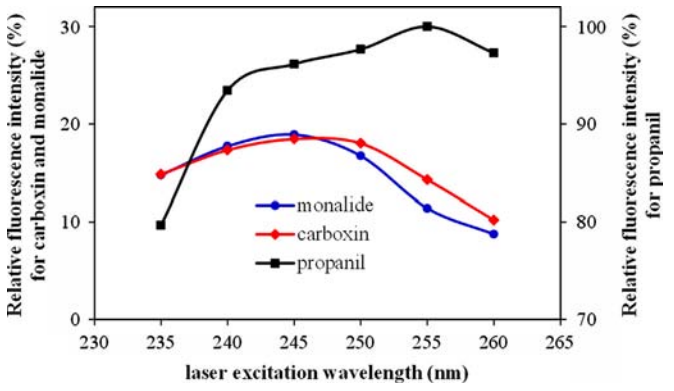

Fig. 3. Optimization of the laser excitation wavelength for carboxin, monalide and propanil. The fluorescence emission of carboxin, monalide (left axis) and propanil (right axis) are measured at 370, 354 and 464 respectively.

respectively, 230/354 nm and 264/464 nm (Table 2). Fig. 2 shows that the photo-induced compounds of carboxin and monalide have very similar fluorescence properties, while the photo-induced fluorescence of propanil is significantly red shifted.

3.2. HPLC–direct laser photo-induced fluorescence analysis

One of the limitations of classical PIF methods is the matrix effects due to the presence of interfering fluorescent compounds such as humic and fulvic acids. Even if the photo-induced fluorescence can be corrected by the fluorescence background of the interfering compounds, the measurement of a small change of fluorescence due to the target pesticide (with a very low concentration) on top of high native background fluorescence can reduce the sensitivity of the method and lead to systematic errors. Moreover the presence of other organic compounds, intrinsically fluorescent or not, can induce fluorescence quenching and reduce the fluorescent quantum yield of the PIF compounds leading to an error in the pesticide determination.

More problematic are the interferences with other compounds producing under UV irradiation PIF photoproduct(s). This is the case of pesticides from several chemical families, i.e. pyrethroids [5], chlorophenoxyacids [6], phenylureas [9], benzoylureas [10], sulfonylureas [14], etc. The worst interference problem is occurring when the pesticides under study belong to the same chemical class, and forms photo-products with very similar fluorescent behaviour. This is the case for monalide and carboxine. These pesticides cannot be individually analysed by classical PIF or DL-PIF methods when the samples contain simultaneously both pesticides. To overcome the limitations of classical PIF and DL-PIF, we have coupled HPLC to DL-PIF (Fig. 1). In this way, the problem of selectivity and matrix effects is improved thanks to the chromatographic separation.

To maximize the sensitivity of the HPLC–DL-PIF method, the formation of the photo-products has to be maximized (i.e. the wavelength should be set at the maximum UV absorption of the pesticide) but, at the same time, the photo-products have to be excited at their maximum excitation wavelength in order to maximize their fluorescence. However, the maximum absorption of the pesticide has seldom the same wavelength as the maximum excitation wavelength of its photo-induced compounds. Ideally, two wavelengths should then be used: one to form the photo-products and another to measure their fluorescence. Since the Nd:YAG laser can be tuned only at one wavelength at a time, we had to find a compromise between both wavelengths. For this purpose, we have compared for each pesticide the absorption spectrum and the emission spectrum of its PIF compounds (Fig. 2). In this way, we can see that the laser wavelength should be set approximately at 260 nm for propanil and at 240 nm for monalide and carboxin. Nonetheless, the energy of the laser is maximum at 275 nm and diminishes for lower wavelengths. Since the formation of the photo-products diminishes when the laser energy diminishes; we have studied the laser induced photo-induced fluorescence as a function of the laser wavelength. Fig. 3 shows that the maximum florescence intensity is obtained at 255 nm for propanil, and at 245 nm for monalide and carboxin.

We have obtained a good chromatographic separation of the three pesticides (Fig. 4). To maximize sensitivity, the laser was tuned during the chromatographic analysis. As carboxin is the first pesticide eluted at 5.4 min, the laser is set at 245 nm from the start to 7.0 min. To analyse propanil the second pesticide eluted at 10.2 min the laser then is tune to 255 nm (at the speed of

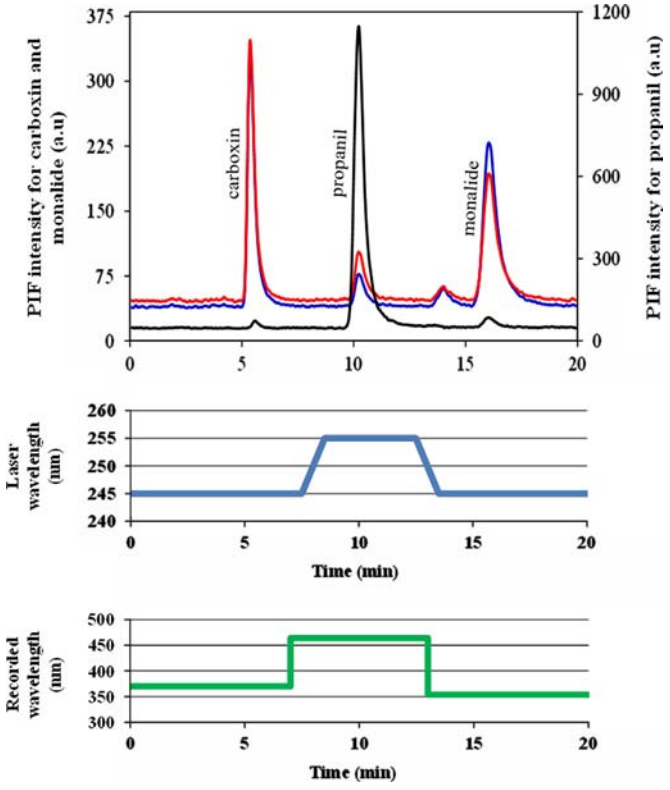

Fig. 4. Upper panel: chromatographic separation of carboxin, monalide and propanil. Laser irradiation is set at 245 nm for carboxin and monalide and 255 nm for propanil, PIF fluorescence detection is set at 370 nm for carboxin, 354 nm for monalide, and 464 nm for propanil. Middle panel: evolution of the laser excitation wavelength versus the time. Lower panel: evolution detected wavelength versus the time.

10 mn min^{-1}). At the end, to detect monalide eluted at 16.1 min the laser is tuned again to 245 nm. At this last wavelength the laser is ready for the next analysis. The "time line" of the laser wavelength is shown in Fig. 4 below the chromatogram.

At the same time the chromatograms are recorded at three emission wavelengths, firstly at 354 nm to detect monalide, then 464 nm for propanil and at last at 370 nm for carboxin. The time line of the recorded wavelength is shown at the bottom of the Fig. 4.

We have then validated the method following the standard ISO 8466-2 [15]. We have first conduct the statistical evaluation of the linear calibration function, followed by the evaluations of the detection and quantification limits.

The calibrations have been calculated with 7 different pesticides concentration from 0.01 to 5 μg mL^{-1} and 2 or 3 duplication per value. The results obtained are presented in Fig. 5 and Table 3 shows the performance parameters of the HPLC–DL-PIF methods. The propanil give the most sensitive result with a slope of 133.87 au mL μg^{-1}, while monalide and carboxin are less sensitive with a slope of 28.97 and 30.47 au mL μg^{-1} respectively. For the three pesticides the intercept are not significantly different from zero with p value for carboxin, monalide and propanil of 0.36, 0.12 and 0.08 respectively.

The linear function has been tested by variance analysis (Table 4), for each pesticide, at 5% confidence level. In all cases the regression variance of the linear model is found significantly greater than the residual variance (p value < 0.01 in all cases). Moreover, the lack of fit variance is not significantly greater than the pure error variance (p value for carboxin, monalide and propanil of 0.30, 0.09 and 0.91 respectively). Consequently the linear range could be validated from 0.01 to 5 μg mL^{-1}.

The instrumental detection limits (without pre-concentration) obtained for carboxin, monalide and propanil are respectively 3.2, 3.6 and 0.5 ng mL^{-1}. We can notice a great improvement of the analytical performance of our method compared to other results obtained by classical HPLC PIF. For example, the detection limits were 70 ng mL^{-1} for propanil, about 200 ng mL^{-1} for phenylureas pesticides [16] and about 15 ng mL^{-1} for pyrethroids [17] and benzoylureas [10].

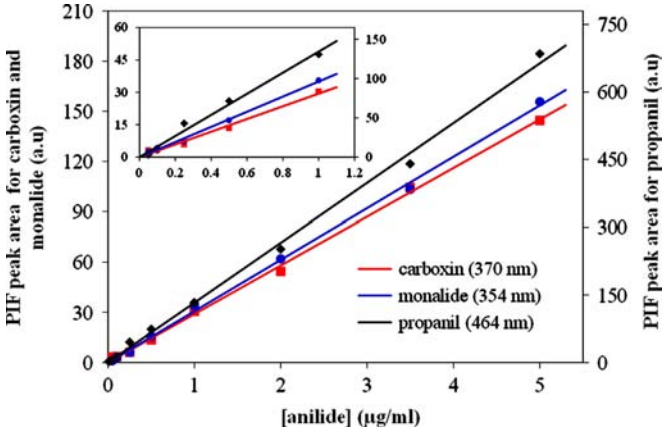

Fig. 5. Calibration curves of carboxin, monalide and propanil. Laser irradiation is set at 245 nm for carboxin and monalide and 255 nm for propanil, PIF fluorescence detection is set at 370 nm for carboxin, 354 nm for monalide, and 464 nm for propanil.

3.3. HPLC DL PIF analytical applications

The usefulness of the method was tested with recovery studies carried out in samples from Senegal River water which irrigates one of the most important agricultural areas of Senegal and can be submitted to some pesticide pollution. As river effluents can transfer the pesticide residue to seawater and induce fish contamination studies have been also carried out on sea water samples from Dakar seaside and Penmarc'h seaside.

The water samples were spiked with 0.05 and 0.2 μg mL^{-1}, extracted by SPE, and analysed by HPLC–DL-PIF as described in Section 2.4. The recoveries obtained can be observed in Table 5. The recovery values were very close to 100%, ranging from 89.5% to 115.9%. The relative standard deviation of the concentration found ranged from 1.2% to 7.2%. The HPLC–DL-PIF method is then suitable to determine anilide pesticides in river and sea water samples. Since the anilide pesticides were 10-fold pre-concentrated, the instrumental detection and quantification limits (Table 2) diminished also 10 times when the water samples are analysed by HPLC–DL-PIF. Thanks to SPE and also to the high sensitivity of the DL-PIF detection, it was then possible to detect and quantify the anilide pesticides of water samples in the order of ppb (ng mL^{-1}).

4. Conclusion

We have shown in former papers that the DL-PIF method has better analytical performances and shorter times of analysis than classical PIF. However, the main drawbacks of classical and DL-PIF methods are the matrix effects due to fluorescent compounds or to other pesticides that form also under UV irradiation photo-products with very similar fluorescence behaviour. To solve these problems, the coupling of HPLC with DL-PIF detection allows one to combine the advantages of both techniques. The chromatographic separation significantly improves the selectivity of the DL-PIF method, and pesticides belonging to the same family, such as carboxin and monalide, yielding similar photoproducts, can be simultaneously analysed. At the same time, the DL-PIF determination of the compounds at the specific excitation wavelength can improve the selectivity of the method in case of insufficient chromatographic resolution.

ABSTRACT

An environmentally friendly and sensitive method for determination of blockers and agonists was described in this paper. The method is based on a homemade sol–gel solid-phase microextraction (SPME) coating with simultaneous on-fiber derivatization and subsequent gas chromatography mass spectrometry (GC/MS) analysis. The influences of the main factors on the type and thickness of the homemade fiber coatings, conditions of the derivatization, extraction and desorption of SPME were investigated in detail. The proposed procedure showed limits of detection lower than 0.2 ng mL^{-1}. The linearity was in the 0.5–150 ng mL^{-1} for clenbuterol and 1.0–100 ng mL^{-1} for metoprolol and propranolol. The variation in measurements (repeatability) was below 8.7% ($n=6$) and the degree of difference between (reproducibility) was below 11.4% ($n=3$). In the application, spiked human saliva samples and real human saliva samples were analyzed, it was found that saliva would affect the detection of propranolol when it was a very low content. The established method can be feasible in practical application and helpful for agonists and blockers preliminary screening during the competition.

1. Introduction

Clenbuterol is one of the most widely used β2-adrenoceptor agonists, while metoprolol and propranolol are the most common β-antagonists (β-blockers). They both work on the body's β-adrenergic receptors with contrary effects and they are structural related amino alcohols. So they can be manipulated and analyzed together with similar detection procedures. The mainstream methods for determination of blockers and agonists include GC–MS [1,2], liquid chromatography [3,4], Capillary electrophoresis mass spectrometry (CE-MS) [5,6] and liquid chromatography–tandem mass spectrometry (LC–MS/MS) [7–9]. The involved biological samples include hair [10], whole blood [11], serum [12], plasma [13,14] and urine [5]. In the Medical Commission of the International Olympic Committee, the β2-agonists and β-blockers have been forbidden, and the official detection requirement is concentration of 0.5 μg mL^{-1} in urine by GC–MS after derivatization.

In fact, no matter what kind of biological sample analysis, the pretreatment and concentration is essential. And the new sample preparation method solid-phase microextraction (SPME) integrated sampling, extraction, concentration and sample introduction into one step, it has been considered as a very powerful sample preparation tool [15]. While introducing derivatization in SPME-GC/MS can further expand the application areas of SPME-GC/MS and bring lower limits of detection (LODs), there have been some researches and several reviews on this topic [16–20]. In brief, achieve derivatization operation during SPME-GC/MS process have three modes: in the gas chromatography injector port [21], in the sample matrix [22–24] and on the fiber coating after SPME sampling [25,26]. The injection-derivatization method is the inchoate derivatization approach of SPME-GC/MS which might lead to incomplete derivatization reaction and possible damage to the capillary column because of the excessive derivative agent. Derivatization reaction in the sample matrix with SPME sampling simultaneously is the simplest mode but with some limitations. While the derivatization occurs on the SPME fiber coating, the fiber is not only a separation/extraction device but also being turned into a reaction vessel. It makes the whole process simple and fast.

Until now, GC–MS is the major detection technique for beta2-agonists and beta-antagonists, and analysis of β2-agonists and

β-blockers in saliva is a great choice because of its noninvasive, easy to collect and less confidential in comparison with blood and urine. In this paper, homemade sol–gel SPME coatings were prepared and contrasted for on-fiber derivatization and SPME operation; an entire GC–MS determination method for blockers and agonists was trying to establish and the application in positive saliva samples were realized so as to the unlimited and sensitive preliminary screening of clenbuterol, metoprolol and propranolol in competitions.

2. Experimental procedures

2.1. Chemicals and reagents

Silylating reagents of N-methy-N-(trimethylsilyl) trifluoroacetamide (MSTFA) was obtained from Sigma (SIGMA, St. Louis, MO, USA). Clenbuterol, metoprolol and propranolol (Fig. 1) were from national institute for the control of pharmaceutical and biological products (Beijing, China). Methyl methacrylate (MMA), benzoyl peroxide (BPO), tetramethyl orthosilicate (TMOS), trifluoroacetic acid (TFA) and polyethylene glycol 20 000 (PEG 20 000) were from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). Hydroxy-terminated silicone oil (OH-TSO) and poly methyl hydrogen siloxane (PMHS) were purchased from Santai Organic Silica Material Factory (Zhejiang, China). Divinylbenzene (DVB) was obtained from Shengzhong Fine Chemical Co. Ltd. (Shanghai, China).

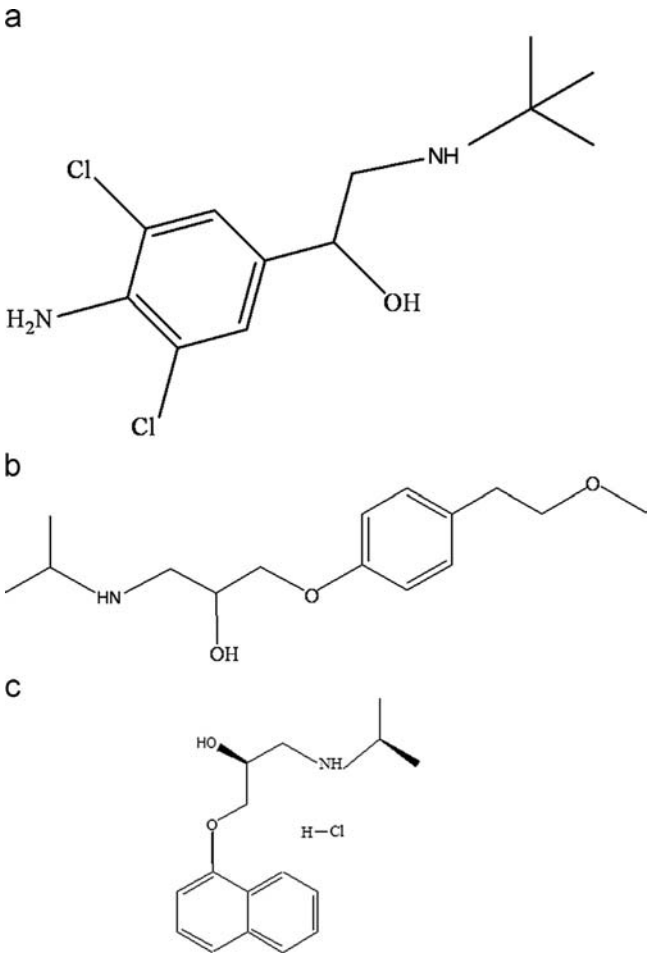

Fig. 1. Structures of the studied molecules.

A stock standard mixture containing clenbuterol, metoprolol and propranolol (1.00 mg mL^{-1}, respectively) was prepared in methanol and stored at 4 °C.

Working standard solutions were prepared by diluting with methanol and renewed every week. Spiked water samples were prepared weekly by adding the appropriate volume of the working standards solution to the 20 mL water sample. Milli-Q ultrapure water (Millipore, Bedford, USA) was used throughout the experiments and the resistivity was about 18 MΩ cm (25 °C).

2.2. Instrumentation and operating conditions

All the gas chromatographic experiments were performed on an Agilent 6890N-5973I GC-MSD (Hewlett-Packard, Palo Alto, CA, USA). A HP-5MS GC column (0.25 μm film thickness, 0.25 mm × 30 m, Agilent Technologies) was used for separation.

The SPME device for manual extraction was consisted in a homemade holder assembly and several replaceable homemade fiber assemblies, which were prepared as described in reference [27]. The thickness of the homemade SPME fiber coating was monitored by environmental scanning electron microscope (XL30 ESEM, Philips).

The injector temperature was maintained at 270 °C. Splitless injection was employed and the injection volume was 1.0 μL. The oven temperature was set at 80 °C for 1 min, and then increased to 260 °C at 25 °C min^{-1} and held for 1 min, and then heated at 15 °C min^{-1} to 300 °C. Carrier gas was helium (Purity > 99.999%) and the flow rate was set at 1.2 mL min^{-1}. The electron impact (EI) ion source, quadrupole mass analyzer, and the interface temperature were maintained at 230, 150 and 300 °C, respectively. Electron impact ionization (70 eV) was utilized. *m*/*z* range was 50–550, and solvent delay was 7 min. Positive mode was used for detection. Selected ion monitoring (SIM) was employed for quantitative measurement. For clenbuterol, the qualitative ions were 57, 73, 86 and 262 (*m*/*z*), and the quantitative ion was 86 (*m*/*z*); for metoprolol, the qualitative ions were 72, 101, 223 and 324 (*m*/*z*), and the quantitative ion was 72 (*m*/*z*); for propranolol, the qualitative ions were 72, 115, 144 and 215 (*m*/*z*), and the quantitative ion was 72 (*m*/*z*).

2.3. Preparation of the homemade SPME fiber coatings

Before sol–gel coating, commercial silica fiber (Yongnian Optical Fiber Factory, Yongnian, Heibei Province, China) was immersed in acetone for 15 min to remove the polyimide on its surface, then rinsed with water and dried. After that, a rehydroxylation process was performed to maximize the number of silanol groups on the silica surface before the preparation of fiber coatings. At first, the fiber was immersed in 1.00 mol L^{-1} sodium hydroxide solution for 60 min to increase the number of silanol groups on fiber wall, then rinsed with water and dried. Finally, the fiber was immersed in 0.10 mol L^{-1} hydrochloric acid for 20 min to reestablishment of equilibrium, then rinsed with water again and dried. The procedure was repeated for 3 times.

Then, four different fibers coatings with different polarities – carbowax–divinylbenzene (CW–DVB), carbowax (CW), hydroxyl silicone oil–polymethylhydrosiloxane (OH-TSO–PMHS) and polyacrylate (PA) – were prepared according to the procedures in our previous work [27]. Briefly, for the preparation of OH/TSO–PMHS fiber coating, a volume of 600 μL of TMOS (precursor), 440 μL of OH-TSO (coating polymer), 60 μL of PMHS (deactivation reagent), and 400 μL of TFA (acid catalyst) were thoroughly shaken and degasification for 5 min by supersonic purifier. The mixture was then centrifuged at 4000 r min^{-1} for 5 min. The precipitate was removed and the top clear sol solution was used for fiber coating. For the preparation of CW fiber coating, 400 μL of TMOS, 200 μL of

OH-TSO, 50 μL of PMHS, 300 μL of 99% TFA, 200 mg of PEG-20,000 and 300 μL of acetone were mixed in a 2 mL tube. For CW/DVB fiber coating, 400 μL of TMOS, 200 μL of OH-TSO, 50 μL of PMHS, 300 μL of TFA, 200 μL of DVB, 200 mg of PEG-20,000 were mixed, and for PA fiber coating, 300 μL of TMOS, 220 μL of OH-TSO, 30 μL of PMHS and 200 μL of 99% TFA were mixed. When fibers were dipped vertically into a freshly prepared sol solution, it was held inside the sol solution for 20 min with sol–gel coating forming on the bare outer surface of the fiber end. For each fiber, this coating process was repeated for 3 times. Then it was placed in a desiccator at room temperature for 12 h.

2.4. SPME and derivatization procedure

The SPME fibers were conditioned on GC injection port at 250 °C for 2 h before use. A 20 mL of measured solution was placed in a 25 mL glass vial with a silicon-septum cap and spiked with analytes, and mixed with 4.5 g of NaCl adjusted pH to 11.00 with 1.0 mol L^{-1} NaOH. The vial was capped, and placed on a stirrer and heated to 30 °C with 650 r min^{-1} for 30 min. After extraction, the fiber was exposed in the headspace of a 2.0 mL sample vial containing 3.0 μL MSTFA at 40 °C for 10 min. Finally, the fiber was pulled out from the vial and immediately inserted into the GC injection port for thermal desorption with 270 °C and 4 min.

2.5. Sample preparation

Saliva samples were collected from three healthy male volunteers. All saliva samples were collected before or 2 h after eating 50.00 mg metoprolol. To obtain the mixed saliva samples, each volunteer was told not to swallow the saliva but to store it 6 min in their mouths when sampling. Then, saliva was collected in Eppendorf tubes and stored at −20 °C immediately. Every saliva sample was taken out of 200 μL in serum bottle, added 4.50 g NaCl for SPME extraction and diluted to 20.00 mL by deionized water then adjusted to pH 11.00 with 1.00 mol L^{-1} NaOH solution.

3. Results and discussion

Because clenbuterol, metoprolol and propranolol are polar materials and cannot respond in GC/MS without derivatization, they need to be derivatized to achieve good recoveries and precision. In this paper, based on the merits of on-fiber derivatization method introduced above, the typical derivatizing reagent for hydroxyl compounds (the silylating reagent of MSTFA with β-agonists and β-blockers) was chosen to be loaded on the fiber after analytes extraction [28,29]. In optimization experiments, every measuring datum was repeated three times, and an average was applied.

3.1. Selection of SPME fiber

Fiber coating is one of the key factors in the extraction efficiency to analytes. One objective of this study was to select the suitable SPME fiber coating for the extraction and derivatization of blockers and agonists from aqueous samples.

In this experiment, three types of homemade fiber coating were selected for investigation as strong polar coatings CW and CW–DVB, moderate polar coating PA and weak polar coating OH-TSO/PMHS. As the rule of "like dissolves like", it could be seen from Fig. 2 that CW–DVB fiber exhibited the best effect to all three analytes.

Fiber thickness, one of critical factors in the determination of the adsorption capacity of SPME fiber coating, is related to the number of coating times. Coating fiber of the CW–DVB column was executed from 2 to 5 layers, and the thickness of them were about 10, 21, 32 and 39 μm, mesured by ESEM. It was found that the adsorption amount of analytes reached maximum when 32 μm fiber coating was used.

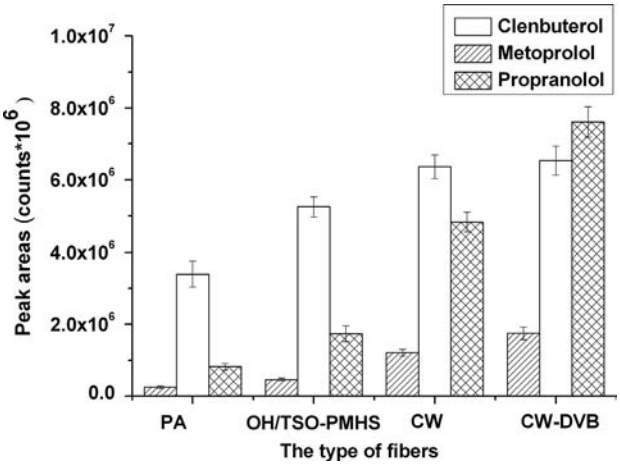

Fig. 2. Selection of SPME fiber coatings. SPME conditions: extraction temperature, 30 °C; extraction time, 30 min; stirring rate, 650 r min^{-1}; pH, 11.00; NaCl concentration, 0.225 g mL^{-1}; MSTFA, 3 μL; derivatization temperature, 40 °C; derivatization time, 10 min; desorption temperature, 270 °C; desorption time, 4 min. The concentrations of clenbuterol, metoprolol and propranolol were 2.0 ng mL^{-1}, respectively.

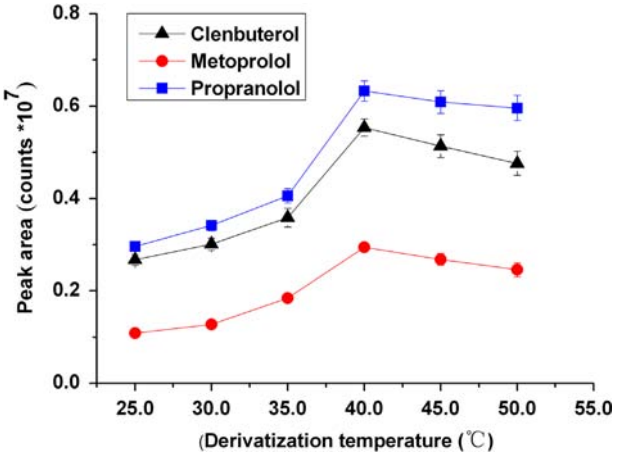

Fig. 3. Selection of derivatization temperature. CW–DVB fiber coating, other SPME conditions are as Fig. 2. The concentrations of clenbuterol, metoprolol and propranolol were 2.0 ng mL^{-1}, respectively.

3.2. Optimization of derivatization reactions

The derivatization reaction was affected by various parameters, including the reaction temperature, the derivatization time and the volume of the reagent. The derivatization conditions were optimized to achieve both high derivatization yield and high extraction efficiency.

First of all, the effect of the reaction temperatures was tested at 25 °C, 30 °C, 35 °C, 40 °C, 45 °C and 50 °C with 3 μL MSTFA to the analytes, respectively. When the temperature was lower than 40 °C, the extraction yields was positively correlated with the temperature; but when the temperature was higher than 40 °C, the correlation was reversed because of the side reactions of derivatization (Fig. 3). So, the derivatization temperature was chosen at 40 °C.

In order to examine the effect of the reaction time on the derivatization efficiency, experiments were performed at 5, 8, 10,

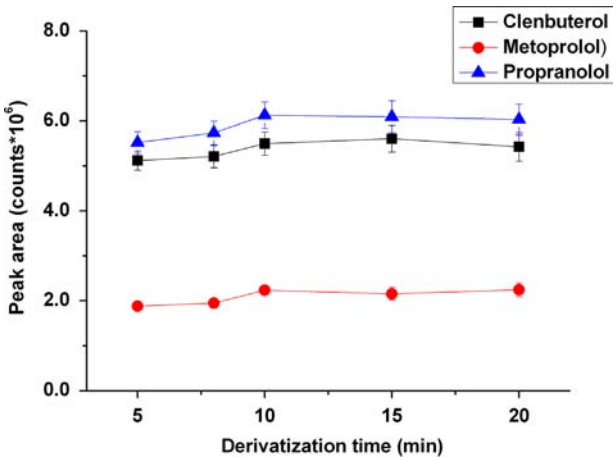

Fig. 4. Selection of derivatization time. CW–DVB fiber coating, other SPME conditions are as Fig. 2. The concentrations of clenbuterol, metoprolol and propranolol were 2.0 ng mL^{-1}, respectively.

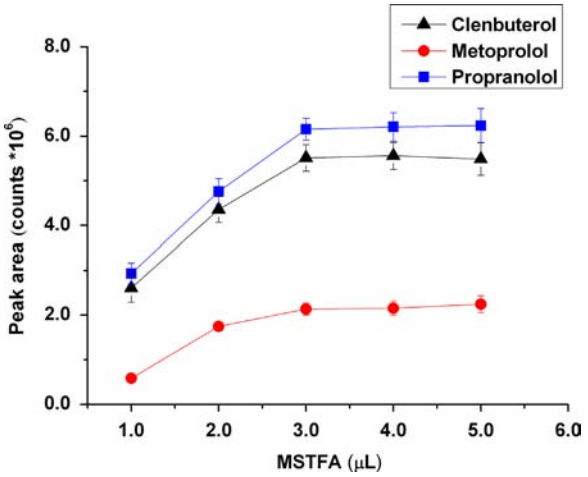

Fig. 5. The volume of MSTFA. CW–DVB fiber coating, other SPME conditions are as Fig. 2. The concentrations of clenbuterol, metoprolol and propranolol were 2.0 ng mL^{-1}, respectively.

15 and 20 min by using MSTFA at 40 °C. As shown in Fig. 4, the highest peak area for the derivatives of compounds was at 10 min and with no significant change until 20 min. As a result, subsequent experiments were carried out using a 10 min derivatization time.

Although the amount of derivatization reagents should be enough for the derivative reaction, immoderate excess of derivatization reagents is actually disadvantageous to the fiber coating lifetime. In this experiment, the effect of 1–5 μL of derivatization reagent MSTFA was compared with the same amount of analytes at 40 °C for 10 min. It can be seen from Fig. 5 that the peak areas of three TMS derivatives increased as the volume of MSTFA increased to a maximum of 3 μL. As a consequence, 3 μL of reagent was used to ensure that enough derivatizing reagent was present during the extraction process.

3.3. Optimization of SPME extraction conditions

Many factors, including extraction temperature, extraction time, stirring speed, pH of the solution and concentration of NaCl, can influence SPME extraction efficiency. These parameters were carefully optimized in this SPME study.

The effect of extraction temperature to the target compounds was examined from 20 to 60 °C and the results were illustrated in

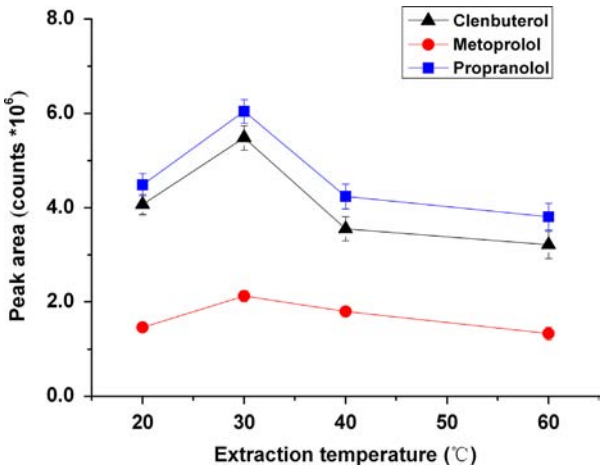

Fig. 6. Selection of extraction temperature. CW–DVB fiber coating, other SPME conditions are as Fig. 2. The concentrations of clenbuterol, metoprolol and propranolol were 2.0 ng mL^{-1}, respectively.

Fig. 6. Temperature affects both the kinetics and the thermodynamics of the extraction process of analytes. Higher temperature can accelerate the mass transference; at the same time, partition coefficients of the analytes between the fiber and the solution decrease with the increase of temperature. In conclusion, the effect of various temperatures on the response of metoprolol was insignificant, whereas the effects on propranolol and clenbuterol reached maximum at 30 °C; thus 30 °C was selected as the optimum value.

The duration of SPME extraction was also studied. SPME is an equilibrium-based technique, and the best extraction efficiency usually reached after equilibrium. To find the optimum extraction time, the samples were stirred at 30 °C with 650 r min^{-1} for 5–60 min. It was found that the responses of metoprolol and clenbuterol increased with increasing extraction time until 30 min and propranolol reached maximum at 45 min. Taking into account of the effect of extraction time to all three analytes, 30 min was selected as the extraction time.

The optimization of stirring speed was performed from 500 to 1100 r min^{-1}. The results indicated that increasing stirring speed to 650 r min^{-1} could markedly enhance the extraction amounts of compounds, especially propranolol. High stirring speed can accelerate the diffusion from the bulk of the sample solution to the coating surface and reduce the equilibrium time, while the frangible silicon dioxide fiber could be damaged with excessively high stirring speed. So, 650 r min^{-1} was selected.

One of the most important parameters in the extraction process is the pH. pH values influenced not only the dissociation of functional groups in analytes, but also the surface properties of the fiber. Generally, in order to increase the extraction efficiency of the target compounds in sample solution, appropriate pH should be chosen to keep these compounds as molecular form and prevent them from dissociating during the SPME process. The effect of the pH of the sample solution was examined by varying pH from 8.00 to 12.00 (adjusted by 1.0 mol/L HCl and 1.0 mol/L NaOH). At pH 11.00, all three analytes achieved maximum responses.

Increasing the ionic strength of the sample solution can reduce the solubility of analytes in water due to the formation of hydration spheres around the ionic salt molecules. However, the additional ions brought competitive adsorption with analytes and changed the surface properties of the fiber, which were unfavorable for the extraction. For investigating the effect of salt addition, various concentrations of NaCl in sample solutions (0, 0.075, 0.150, 0.225, 0.300 and 0.350 g mL^{-1}) were tested. Results showed that

0.225 g mL^{-1} NaCl yielded the most extracted amounts to all three target compounds; hence NaCl concentration of 0.225 g mL^{-1} was chosen for next experiments.

3.4. Optimization of desorption conditions

After SPME extraction and derivatization, the target compounds were desorpted using the GC injection port. With respect to the desorption conditions, both the desorption temperature and the desorption time were optimized.

For removing the extracted analytes from the fiber coating to the vaporizing chamber, the temperature of injection port, namely the desorption temperature, was optimized from 240 to 290 °C (Fig. 7). Optimal desorption temperatures were decided by the capabilities of the instrument, the properties of analytes and the specifications of the SPME fiber. The SPME fiber used in this method could endure 290 °C with gradually degradation and the inappropriate temperature would result in the coating bleed of the fiber and could be disadvantageous to the chromatographic column. Considering precision and recovery, 270 °C was chosen as suitable desorption temperature.

Then, for achieving the total desorption of analytes with no memory effects, desorption time was optimized and the optimal time for extracting maximal amounts of all compounds was 4 min.

To sum up, the optimal conditions of extraction, derivatization and desorption were as follows: in 20 mL spiked water solution, adjusting pH to 11.0, including 0.225 g mL^{-1} NaCl, using 32 μm homemade CW–DVB fiber coating extracted analytes for 30 min with 650 r min^{-1} stirring rate at 30 °C; then derivatization for 40 °C and 10 min with 3.0 μL MSTFA; desorption was performed in 270 °C for 4 min.

After choosing related influence factors, the typical total ion current (TIC) chromatograms and the extracted ion current (EIC) chromatograms of three analytes in blank water solution and spiked water solutions (2.0 ng mL^{-1} and 100 ng mL^{-1}) were given as Fig. 8a and b. It could be seen from Fig. 8a that, derivatization introduced some impurities to the SPME fiber in the TIC mode; but it did not affect the detection of extracted ions of clenbuterol (ion 86), metoprolol (ion 72) and propranolol (ion 72) (see Fig. 8b). It demonstrated that the water matrix and SPME fiber did not affect the detection of clenbuterol, metoprolol and propranolol.

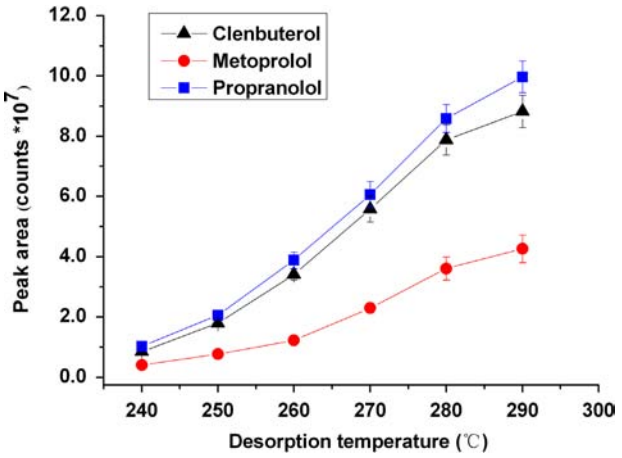

Fig. 7. Selection of the desorption temperature. CW–DVB fiber coating, other SPME conditions are as Fig. 2. The concentrations of clenbuterol, metoprolol and propranolol were 2.0 ng mL^{-1}, respectively.

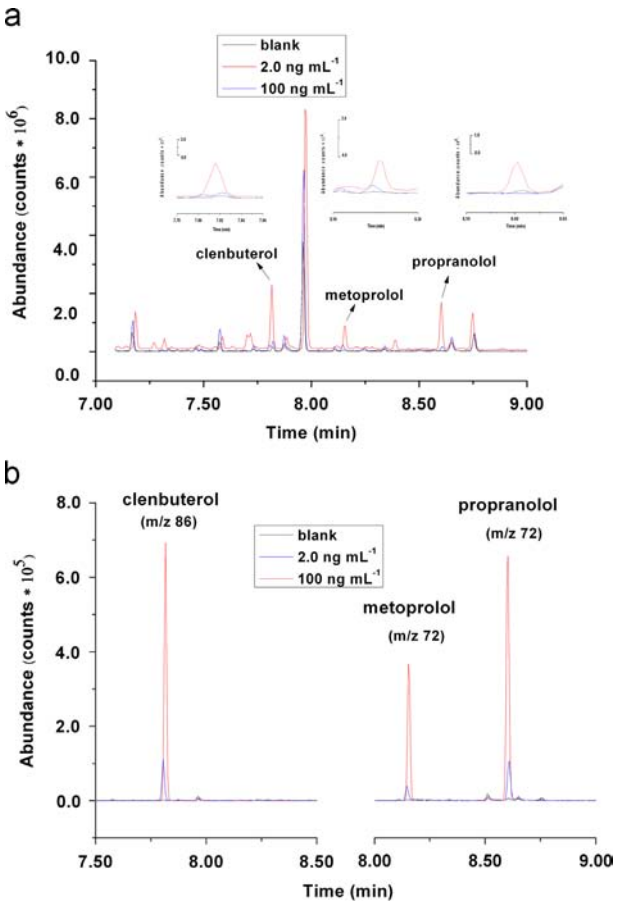

Fig. 8. The chromatograms of analystes with on-fiber derivatization after SPME. (a) TIC chromatogram, and (b) EIC chromatogram. CW–DVB fiber coating, SPME conditions are as Fig. 2.

3.5. Method performance

Calibration solutions with spiked deionized water samples were adsorbed, derivatizated, desorpted, analyzed with the optimized conditions and detected with GC–MS. The regression curves, correlation coefficients (R^2), linear ranges and limits of detection (LODs) of three targets were shown in Table 1. The linearity of this method was investigated over a concentration range of 0.5–150 ng mL^{-1} for clenbuterol and 1.0–100 ng mL^{-1} for metoprolol and propranolol. The linear relationship between peak areas and concentrations were observed with R^2 greater than 0.9933. This allowed the quantification of the compounds by the method of external standardization. The LODs for the analytes were estimated at S/N=3 under GC/MS conditions (SIM mode) by considering the lowest concentration of each of the analytes. The LODs were lower than 0.2 ng mL^{-1}.

Repeatability, expressed as the relative standard deviation of the analysis of seven samples spiked at 100 ng mL^{-1}, was below 8.7% (n=6). Reproducibility between days, expressed as the relative standard deviation of three samples spiked at 100 ng mL^{-1} and analyzed on three different days, was below 11.4% (n=3).

3.6. Method application

3.6.1. Spiked and real human saliva sample analysis

Each of the 200 μL blank saliva sample obtained from healthy people was added 4.50 g NaCl and diluted with deionized water to 20.00 mL. Then they were adjusted by 1.00 mol L^{-1} NaOH to pH

Table 1
The regression equations, linearity, correlation coefficients, LODs, repeatability and reproducibility of the method[a].

Analytes	Equation[b]	R^2	Linear range (ng mL^{-1})	LOD[c] (ng mL^{-1})	Repeatability[d] (%RSD, n=6)	Reproducibility[e] (%RSD, n=3)
Clenbuterol	y=298100x+10555	0.9977	0.5–150	0.2	7.2	10.6
Metoprolol	y=117237x+16144	0.9933	1.0–100	0.5	8.7	11.4
Propranolol	y=334490x+39156	0.9985	1.0–100	0.5	8.3	10.9

[a] Conditions as in Fig. 8.
[b] S/N=3.
[c] The parameters, x and y, refer to the concentration of the target compound (ng mL^{-1}) and the corresponding peak area.
[d] 100 ng mL^{-1}.
[e] 100 ng mL^{-1}.

Table 2
Extraction recoveries of spiked saliva samples by SPME with on-fiber derivatization[a].

Analytes	Recoveries (%RSD, n=3)		
	1.0 (ng mL^{-1})	5.0 (ng mL^{-1})	50 (ng mL^{-1})
Clenbuterol	109.7 (7.9)	112.7 (7.3)	106.1 (8.6)
Metoprolol	111.4 (9.0)	105.5 (8.2)	107.7 (7.4)
Propranolol	120.3 (13.1)	116.8 (11.7)	114.5 (12.0)

[a] Conditions as in Fig. 8.

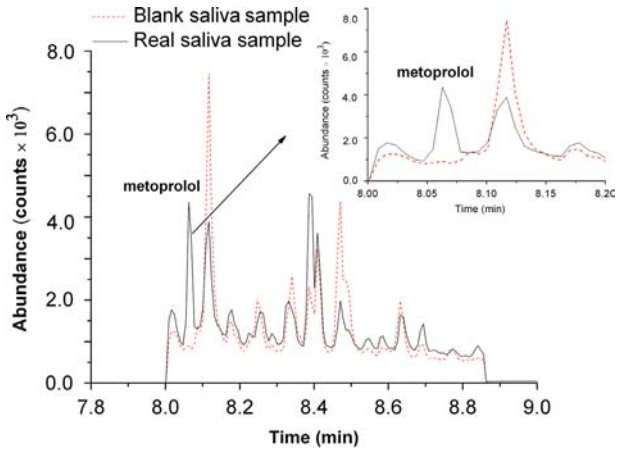

Fig. 9. The EIC chromatograms of blank and positive metoprolol saliva samples. SPME conditions are as Fig. 8.

11.00. After that, the diluted saliva solutions were spiked with analytes to 1.0, 5.0 and 50 ng mL^{-1}, respectively. Under the optimized conditions, the blank and spiked target compound solutions were detected three times, and the recoveries and precisions were given in Table 2.

As shown in the table, the recoveries of the target compounds were between 105.5% and 120.3%,, and the precisions were lower than 13.1%; so this method could be used for lightly determination of trace clenbuterol, metoprolol and propranolol in real saliva positive samples without more tedious additional disposals such as deproteinization.

3.6.2. Application to positive human saliva sample analysis

A male volunteer was treated with one pill of metoprolol tablet (~50 mg metoprolol) and the saliva was collected after 2 h. After pre-treatment with description in 2.3.6, the proposed method was applied to the detection of metoprolol in collected positive saliva samples under the optimal conditions. The EIC chromatograms (ion 72) of metoprolol positive saliva samples and blank saliva samples using optimized parameters were shown in Fig. 9.

It could be seen that there was an obvious chromatographic peak in positive saliva sample chromatogram at metoprolol's peak time which was significantly different from the blank sample chromatogram, and unfortunately, a small peak of blank saliva sample was found appearing at the position of propranolol in the EIC chromatogram for ion 72. It would affect the detection of extracted ion of propranolol when propranolol was a very low content.

4. Conclusion

A selective analytical method based on SPME followed by on-fiber derivatization with MSTFA coupled to GC–MS was used to determine clenbuterol, metoprolol and propranolol. The important parameters involved in the method such as appropriate polarity and thickness of fiber coating material with consistent extraction, derivatization and desorption parameters were evaluated. This method is timesaving and easy to perform as the total analytical time is less than 1 h; it is environmental friendly and avoids using toxic organic solvents and excess derivatization reagents. This method is fully validated and shown to be suitable for the simultaneous confirmation and quantitation of blockers and agonists with good LODs lower than 0.2 ng mL^{-1}. The repeatability was below 8.7% (n=6) and the reproducibility was lower than 11.4% (n=3). This simple and sensitive method has been applied to the measurement of clenbuterol, metoprolol and propranolol in human saliva. It showed that in saliva samples the performance of the method is still descent in presence of enzymes and proteins. The established method can offer a preliminary screening means for clenbuterol, metoprololand and propranolol. Since on the one side, large competitions have huge amount of samples need to screening and on the other side, confirmation of abuse drugs still using urine samples. This method was feasible in practical application and helpful for agonists and blockers control during the competition. It can provide an alternative option to extend the scope of doping monitoring and biological monitoring of blockers and agonists.

Polycyclic aromatic hydrocarbons

ABSTRACT

An easy preparation of g-C_3N_4/Fe_3O_4 nanocomposites by chemical co-precipitation has been demonstrated. The as-prepared materials were characterized by X-ray diffraction, transmission electron microscopy, Fourier transform infrared spectroscopy and thermogravimetric analysis. The high affinity of g-C_3N_4 toward polycyclic aromatic hydrocarbons and the magnetic behavior of Fe_3O_4 were combined to provide an efficient and simple magnetic solid phase extraction (MSPE). The adsorption and desorption of polycyclic aromatic hydrocarbons on g-C_3N_4/Fe_3O_4 were examined. Different factors affecting the magnetic solid phase extraction of polycyclic aromatic hydrocarbons were assessed in terms of adsorption, desorption, and recovery. Under the optimized conditions, the proposed method showed good limits of detection (LOD, S/N=3) in the range of 0.05–0.1 ng mL^{-1} and precision in the range of 1.8–5.3% (RSDs, n=3). This method was also successfully applied to the analysis of real water samples; good spiked recoveries over the range of 80.0–99.8% were obtained.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a widely distributed group of environmental persistent pollutants, which are ubiquitous in aquatic environments and suspected to be endocrine disrupters. They have aroused great attention to their influences on environment, especially aquatic environment. The Environmental Protection Agency (EPA) (e.g. maximum contaminant levels for benzo(a)pyrene and benz(a)anthracene in ambient water were 0.2 and 0.1 μg mL^{-1}, respectively) and European Union (EU) have taken some PAHs as priority pollutants for monitoring purposes [1,2]. Most PAHs do not dissolve easily in water (supplementary file). Due to their trace concentration and wide distribution in water environments, it is required and vital to develop efficient analytical techniques [3]. However, the direct determination of extremely low concentrations of analytes can be difficult, owing to matrix interferences or insufficient sensitivity of analytical techniques. Therefore, preliminary separation and preconcentration of trace analytes from matrices is usually required. Solid-phase extraction (SPE) and liquid-liquid extraction (LLE) are the most commonly used techniques for sample preconcentration. Of these methods, SPE has become a powerful tool in trace analysis [4], because of its high recoveries, enrichment factors, low consumption of organic solvents, and the possibility of combining with chromatography and spectroscopic techniques. On the other hand, a high recovery and enrichment factor can be obtained only if a suitable sorbent is used. In recent years, we have seen an intense growth of interest in materials with graphite-like structures, such as graphene (G) and graphene oxide (GO), owing to their large surface area and hexagonal array of carbon atoms in graphite sheets which are ideal for strong interactions with other molecules [5,6]. They were used as sorbent for the preconcentration of small molecules [7,8], and both sides of the planar sheets are available for molecule adsorption. As a novel two-dimensional graphite analogue, graphitic carbon nitride (g-C_3N_4) is emerging recently and may be a viable alternative to separation and preconcentration of organic compounds in solutions.

g-C_3N_4 has a stacked two-dimensional structure (2D sheets of tri-s-triazine connected via tertiary amines) and is made from simple precursors under ambient conditions at a low cost. Moreover, it is the most stable allotrope of carbon nitride [9,10]. Compared with other inorganic semiconductor counterparts, g-C_3N_4 is an eco-friendly organic material and exhibit great potential for energy conversion, storage, and environmental applications including direct methanol fuel cells, catalysis, photocatalysis, and CO_2 capture [11]. Above all, the dispersity of g-C_3N_4 in water is much better than that of G with strong affinity (π–π stacking and

hydrophobic interactions) for nonpolar carbon-based ring compounds [12]. These properties suggest the possibility of g-C_3N_4 as a novel sorbent for SPE and as a new material for the adsorption and preconcentration of organic analytes.

On the other hand, sufficient dispersity of nanomaterials usually creates difficulties in separating and recycling. As one of the most widely used magnetic materials, Fe_3O_4 nanoparticles, has good stability, easy synthesis, high surface area and good solubility in water. On the other hand, they aggregate easily and cannot adsorb analytes effectively because of the simplicity of its surface [13]. Therefore, immobilizing Fe_3O_4 particles on the surface of nanomaterials is an effective solution, as it can easily be separated from solution with an external magnet [14]. This approach can efficiently increase the recovery of nanoparticles and recycle time, and it is therefore our goal to design and prepare g-C_3N_4/Fe_3O_4 composite materials. Moreover, the application of this kind of magnetic material for SPE was defined as magnetic solid phase extraction (MSPE). MSPE technology exhibits significant advantages in separation science. The sorbent is dispersed in a sample solution instead of being packed into an SPE cartridge providing a sufficiently large contact area between sorbents and analytes, and can be rapidly separated from the matrix by an external magnetic field [15,16].

To examine the feasibility of this g-C_3N_4/Fe_3O_4 nanocomposite for MSPE, seven PAHs were selected as model compounds. Key factors, including concentration of PAHs, ionic strength, pH, eluent, amount of sorbent, time, etc., were systematically optimized to achieve excellent MSPE efficiency. Moreover, a quick, selective and sensitive method was established by combining MSPE with high performance liquid chromatography (HPLC) to analyze seven PAHs in real water samples.

2. Experimental

2.1. Chemicals

Melamine (>99.0%), naphthalene (Naph) (>99.5%), acenaphthylene (Acy) (>98.0%), phenanthrene (Ph) (>99.0%), anthracene (An) (>99.5%), fluoranthene (Flt) (>98.0%), pyrene (Pyr) (>98.0%) and benz[a]anthracene (BaA) (>98.0%) were purchased from Aladdin Industrial Inc. (Shanghai, China). Ferric chloride hexahydrate (>97.0%), ferrous chloride tetrahydrate (>98.0%), and ammonia water (25.0%) were obtained from Sinopharm Chemical Reagent CO., Ltd (Shanghai, China). Distilled water was filtered using a vacuum pump (Division of Millipore, USA) and filter (HA-0.45, Division of Millipore, USA) prior to use. All other solvents were of HPLC or analytical grade.

2.2. HPLC analysis and characterization

The HPLC system consisted of a Waters 1525 Binary HPLC Pump, a Waters 2707 Autosampler (20.0 μL sample loop) and a variable wavelength 2489 UV dual channel detector. Data processing was carried out using a Millennium 3.2 consisting of a HP Vectra 500PC. HPLC was performed by using a commercial C_{18} column (4.6 × 150 mm, 5.0 μm) purchased from Thermo Fisher Scientific Inc. The mobile phase was methanol/water (80/20, *v*/*v*) at a flow rate of 1.0 mL min^{-1}, and detection was performed at a UV wavelength of 254 nm.

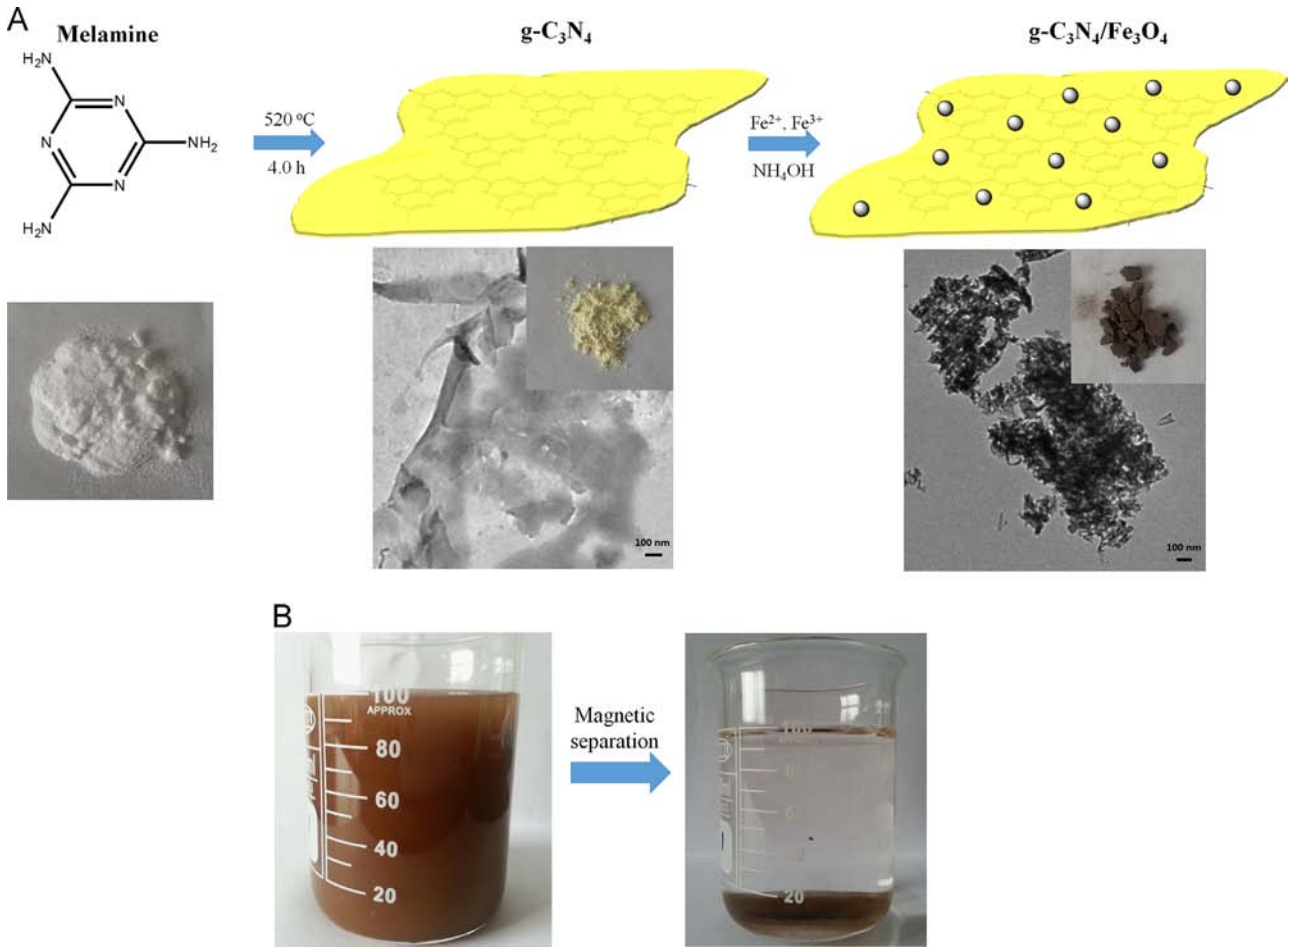

Fig. 1. Schematic representation of depositing Fe_3O_4 nanoparticles on a g-C_3N_4 with morphology exhibitions.

X-ray diffraction (XRD) studies were carried out on a Rigaku D/max 2500/PC instrument. Transmission electron microscopy (TEM) was executed on a Hitachi H-7650. Fourier transform infrared (FT-IR, Bruker Tensor 27) spectra were obtained between 400 and 4000 cm^{-1} at a scan rate of 20 scans min^{-1} using KBr pellets. Thermogravimetric measurements were performed on a NETZSCH STA 449 F3 Jupiter simultaneous thermal analyzer at a heating rate of 10 °C min^{-1} in air.

2.3. Preparation of g-C_3N_4/Fe_3O_4 nanoparticles

g-C_3N_4 was prepared by directly heating melamine to 520 °C for 4 h in a N_2 atmosphere [17]. The g-C_3N_4/Fe_3O_4 nanocomposites were obtained by chemical co-precipitation [18,19]. According to a typical procedure, g-C_3N_4 (70.0 mg) was dispersed in 250.0 mL of ethanol/water (1:2) and ultrasonicated for 6 h at room temperature. $FeCl_3 \cdot 6\,H_2O$ (0.92 g) and $FeCl_2 \cdot 4\,H_2O$ (0.45 g) at a molecular ratio of 2:3 were added to the suspension of g-C_3N_4 at 65 °C. Next, the ammonia solution was injected into the reaction mixture until the pH reached 10.0. The resulting mixture was stirred at 80 °C for another 30 min, after which the reaction mixture was cooled and washed several times with ethanol and double-distilled water. The as-prepared nanocomposite was named g-C_3N_4/Fe_3O_4-1 and was dried in air at 80 °C (Fig. 1).

Alternatively, another synthetic method was proposed and used to synthesize the g-C_3N_4/Fe_3O_4 composite. Fe_3O_4 nanoparticles were first synthesized using the same procedure without the addition of g-C_3N_4. The obtained nanoparticles were mixed with melamine in ethanol and dried in air. The mixture was then heated to 520 °C for 4 h. The obtained nanocomposite was named g-C_3N_4/Fe_3O_4-2.

2.4. Preparation of the standard stock solution

PAHs, including Naph, Acy, Ph, An, Flt, Pyr, and BaA were dissolved in methanol to obtain standard stock solutions at a concentration of 0.1 mg mL^{-1}. The stock solutions were stored at 4.0 °C. Working solutions were prepared daily by diluting the standard stock solutions with deionized (DI) water.

2.5. Multicomponent adsorption of PAHs on g-C_3N_4/Fe_3O_4

The sorbents (1.0 mg) were sonicated and vibrated with 1.0 mL of aqueous standard PAH solution (0.3 μg mL^{-1} PAHs mixture with adding a small amount of methanol) in vials at room temperature until the concentration of target compounds ceased decreasing and the equilibrium adsorption was obtained. The amounts of PAHs adsorbed on the sorbents were calculated by subtraction, and the adsorption percentage (%) was calculated by adsorbed amount/maximum theoretical adsorbed amount. The reproducibility was assessed over five tests.

2.6. Procedure of MSPE

g-C_3N_4/Fe_3O_4 (10.0 mg) was used to extract the analytes from 100.0 mL real water samples. The extraction was carried out for 10.0 min to ensure that most of the analytes were adsorbed on the solid phase. The magnetic adsorbents were separated from water by a magnetic field. To elute the adsorbed analytes, 1.0 mL (0.5 mL × 2 times) of a 1:1 mixture of methanol/acetonitrile was added and the vial was subsequently subjected to ultrasonic irradiation for 5 min. After elution, the solutions were collected and analyzed by HPLC.

3. Results and discussion

3.1. Characterization of g-C_3N_4/Fe_3O_4

First, the as-prepared g-C_3N_4/Fe_3O_4 samples were characterized by XRD [20]. As shown in Fig. 2, the XRD peaks of the pure Fe_3O_4 sample were in good agreement with the standard magnetite Fe_3O_4. For g-C_3N_4, a strong peak at 27.41 corresponded to the (0 0 2) crystal plane of g-C_3N_4. The diffraction peaks of g-C_3N_4 and Fe_3O_4 were observed in the XRD pattern of g-C_3N_4/Fe_3O_4-1, and were weaker than that of pure g-C_3N_4, indicating that g-C_3N_4/Fe_3O_4-1 was a two-phase composite composed of g-C_3N_4 and Fe_3O_4. In contrast, the characteristic diffraction peak of g-C_3N_4 disappeared in g-C_3N_4/Fe_3O_4-2, and the structure of Fe_3O_4 was different. These phenomena can be explained by the evaporation of melamine and oxidation of Fe_3O_4 at high temperatures under air.

In addition, FT-IR spectra of g-C_3N_4/Fe_3O_4-1 (Fig. 3) showed the successful formation of g-C_3N_4/Fe_3O_4 [21]. The most intense signal at 570 cm^{-1} was assigned to the Fe–O stretch of Fe_3O_4 [22]. The strong absorption band in the range of 1200–1650 cm^{-1} was assigned to the typical skeletal stretching vibrations of the s-triazine or tri-striazine and the sharp peak centered at 808 cm^{-1} was a characteristic breathing mode of the triazine unit. The broad adsorption band at 3100–3300 cm^{-1} corresponded to the stretching vibration modes of residual N–H components or O–H bands, associated with uncondensed amino groups and absorbed H_2O

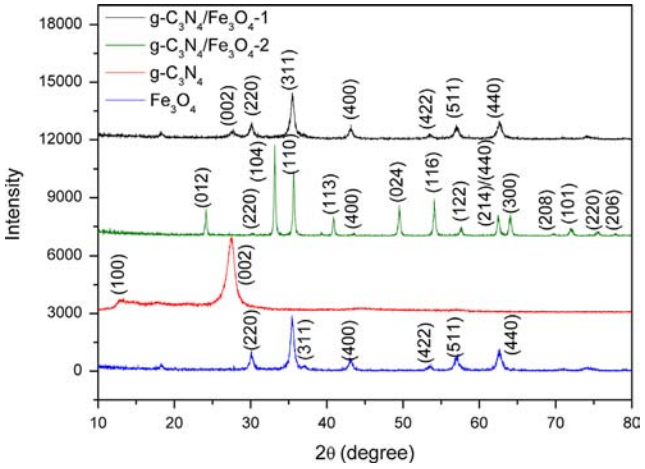

Fig. 2. XRD patterns of g-C_3N_4, Fe_3O_4 and g-C_3N_4/Fe_3O_4.

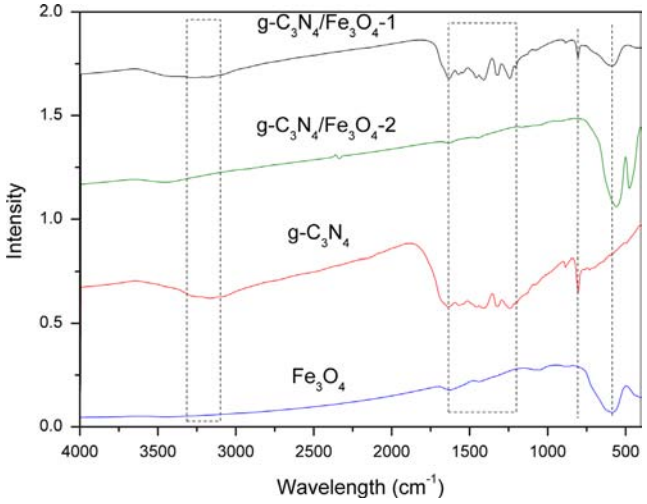

Fig. 3. FT-IR spectra of g-C_3N_4, Fe_3O_4 and g-C_3N_4/Fe_3O_4.

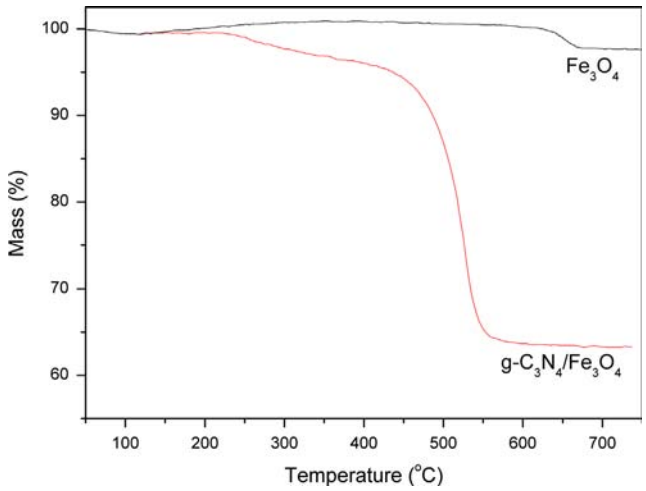

Fig. 4. TGA curves of Fe_3O_4 and g-C_3N_4/Fe_3O_4.

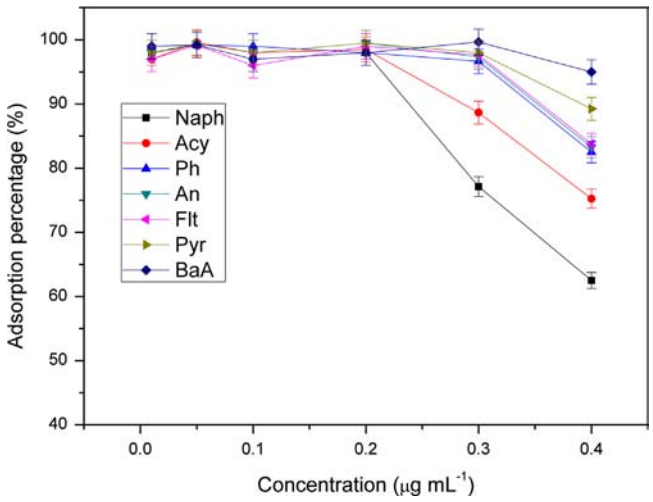

Fig. 5. Effect of initial concentration of PAHs on adsorbed amount of PAHs on g-C_3N_4/Fe_3O_4.

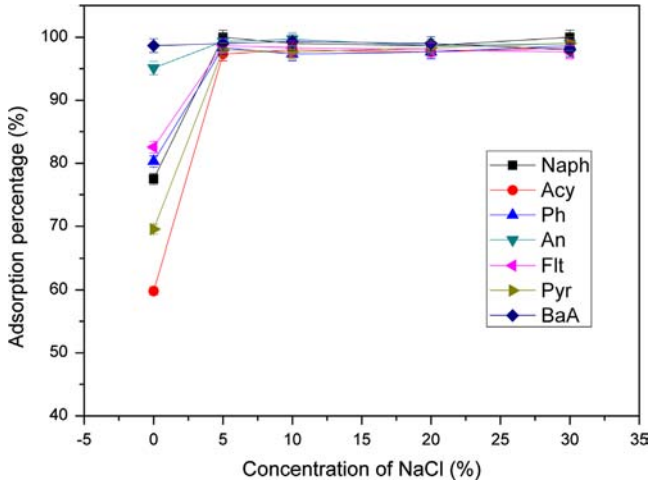

Fig. 6. Effect of NaCl% on adsorbed amount of PAHs on g-C_3N_4/Fe_3O_4.

molecules, respectively. Similarly, these peaks were not observed in the spectrogram of g-C_3N_4/Fe_3O_4-2.

Thermogravimetric analysis was used to determine the thermal stability of the g-C_3N_4/Fe_3O_4 nanocomposite, as the weight loss observed between 500 °C and 550 °C was associated with the loss of the g-C_3N_4. Fig. 4 shows the TGA curves for Fe_3O_4 and g-C_3N_4/Fe_3O_4-1. From 500 °C to 550 °C, approximately 2.61% and 36.26% mass loss was observed for Fe_3O_4 and g-C_3N_4/Fe_3O_4-1, respectively.

Fig. 1 shows the TEM images of pure g-C_3N_4 and g-C_3N_4/Fe_3O_4-1. Pure g-C_3N_4 consisted of a transparent sheet structure, whereas in g-C_3N_4/Fe_3O_4-1, dark Fe_3O_4 nanoparticles were deposited on the surface of g-C_3N_4. Overall, g-C_3N_4/Fe_3O_4-1 was successfully synthesized and could be used for further experiments of the MSPE of PAHs in this study.

3.2. Optimization of the MSPE procedure

Before applying the magnetic sorbent g-C_3N_4/Fe_3O_4 in the MSPE of real samples, factors that influence the adsorption and desorption of target analytes on g-C_3N_4/Fe_3O_4 nanocomposites should be investigated and optimized. Because MSPE was achieved by the adsorption and subsequent desorption of PAHs on the sorbents, the amounts adsorbed and desorbed indicate the performance of g-C_3N_4/Fe_3O_4. Meanwhile, ultrasonication was used to suspend the g-C_3N_4/Fe_3O_4 nanocomposite in water. The aggregated nanocomposite is disrupted by ultrasonic vibrations leading to an increase in the total solid surface which contacts water or target compounds.

3.2.1. Adsorption

The initial concentration of PAHs in water samples dictates the maximum amount that can be adsorbed theoretically, and can affect the actual adsorbed amount on the g-C_3N_4/Fe_3O_4 nanocomposite. High adsorption efficiencies of PAH compounds were observed at low concentrations such as 0.01–0.2 μg mL^{-1} (Fig. 5). The adsorption of seven PAHs nearly reached the maximum theoretical adsorption when the concentrations were below 0.2 μg mL^{-1}. The efficiencies decreased with further increase of the concentration, which was attributed to the limited adsorption capacity of g-C_3N_4/Fe_3O_4. To investigate other effects on the adsorption behavior and avoid errors in MSPE process, 0.3 μg mL^{-1} PAHs was selected.

The effect of the ionic strength was evaluated using sodium chloride as a model electrolyte within the concentration range of 0–30.0% (*w*/*v*) (Fig. 6). The adsorption of PAHs increased with increasing NaCl concentrations up to 5.0% due to a salting-out effect [23], and remained almost constant in this interval. The results indicated that the addition of NaCl had a negligible effect on the extraction recovery of the analytes when the concentration was higher than 5.0% (*w*/*v*). Hence, 5.0% NaCl was added to the all samples in subsequent experiments.

Generally, the pH of the solution is a crucial factor in the adsorption process, because pH not only changes the formation of the analytes but also alters the interaction between the sorbents and the analytes. Thus, it was necessary to investigate the effect of pH on adsorption efficiency by adding appropriate volumes of 1M NaOH or 1M HCl. As shown in Fig. 7, the adsorption efficiency of PAHs increased upon increasing the pH from 3.44 to 6.86. However, upon further increase of the pH value, the adsorption efficiency of BaA decreased. Although PAHs exist as neutral molecules under ordinary conditions and are unlikely to be influenced by a change in the solution pH, the pH of the solution may affect the g-C_3N_4/Fe_3O_4 formation and dispersity in water. Acidic conditions may cause some leaching of Fe_3O_4, thereby decreasing the adsorption of PAHs on the g-C_3N_4/Fe_3O_4 nanocomposite. Relatively basic conditions are conductive to g-C_3N_4/Fe_3O_4, but slightly decrease the dispersity of the sorbent in water by affecting the remaining amino groups and negative charge on

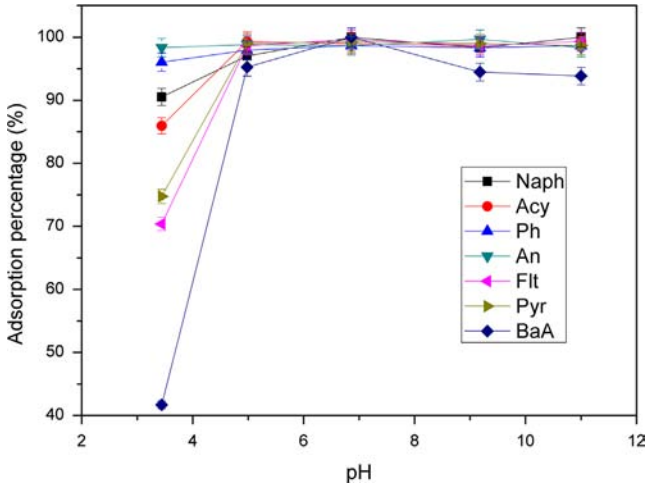

Fig. 7. Effect of pH values on adsorbed amount of PAHs on g-C_3N_4/Fe_3O_4.

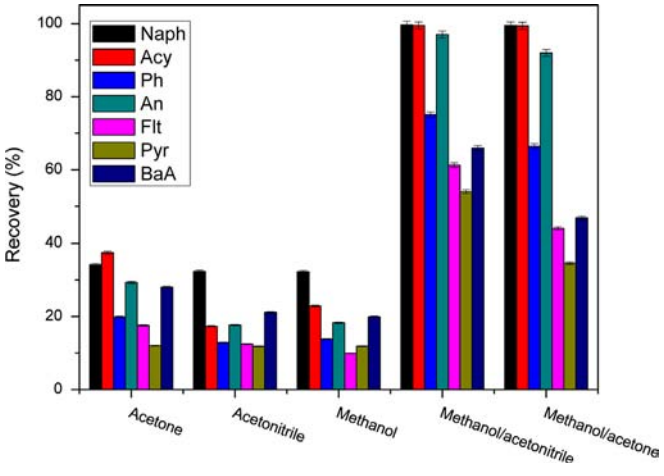

Fig. 8. Effect of type of solvents on recovery of PAHs.

g-C_3N_4. Therefore, the adsorption of BaA, the PAH with the largest molecular size, was decreased.

3.2.2. Desorption

The organic solvent is one of the most important factors that affect the MSPE procedure directly, and the extraction efficiency strongly relies on the properties of the eluent. Therefore, 10.0 mg of g-C_3N_4/Fe_3O_4 was used to extract the analytes from 10.0 mL of spiked water samples (concentration: 0.3 μg mL^{-1}). Considering that HPLC was used for the analysis of the PAHs and the remaining water on the surface of g-C_3N_4/Fe_3O_4 due to previous dispersion in water for adsorption, five organic solvents and mixtures (1.0 mL) including methanol, acetonitrile, acetone, methanol/acetone (1/1, *v*/*v*) and methanol/acetonitrile (1/1, *v*/*v*) were compared for their eluting efficiency. As shown in Fig. 8, the desorption efficiency was significantly affected by the eluent. Single solvent systems were not efficient for the elution of the condensed ring PAHs with good dispersity because of the relative hydrophilicity of g-C_3N_4/Fe_3O_4 and hydrophobicity of PAHs. Methanol/acetonitrile (1/1, *v*/*v*) provided the highest elution efficiency and was chosen as the eluent for MSPE.

3.2.3. Optimization of MSPE

Although a very small amount of sorbent was required in the adsorption of trace PAHs in water samples according to the theoretical adsorption capacity of g-C_3N_4/Fe_3O_4, a larger amount

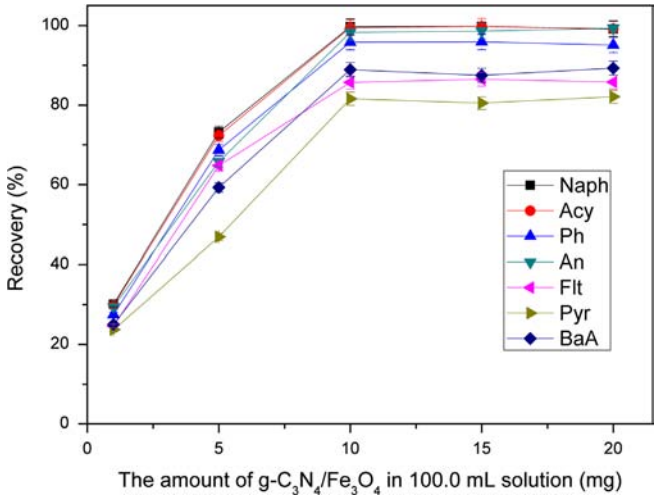

Fig. 9. Effect of g-C_3N_4/Fe_3O_4 amount on recovery of PAHs.

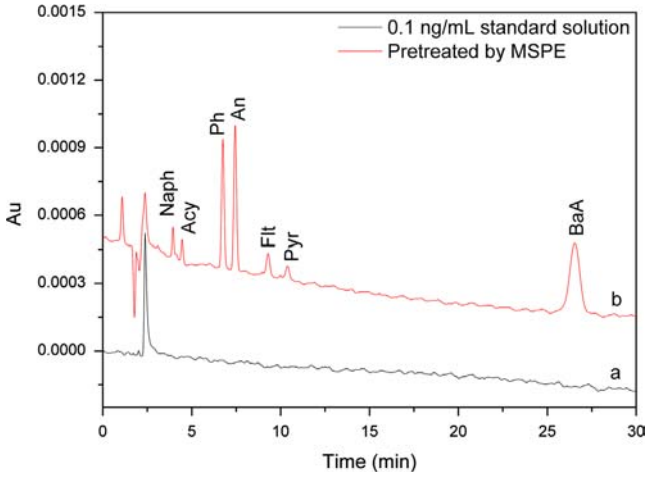

Fig. 10. Chromatogram of water samples with 0.1 ng mL^{-1} PAHs: (a) water sample without MSPE, (b) water sample after MSPE using g-C_3N_4/Fe_3O_4.

was needed to achieve facile phase separation and to obtain a higher recovery. To choose the optimum dosage of the sorbent (g-C_3N_4/Fe_3O_4) for the MSPE of PAHs from spiked aqueous samples (0.1 ng mL^{-1}), different amounts of sorbent were investigated in the range of 1.0 to 20.0 mg (Fig. 9). The recoveries increased with increasing sorbent from 1.0 to10.0 mg, and then stabilized with a further increase. This result indicated that 10.0 mg of the sorbent was sufficient to extract PAHs from 100.0 mL of aqueous sample.

The extraction time profiles were studied by varying the absorption time between 5 and 30 min. The recoveries reached a maximum at 10 min. Therefore, it can be concluded that extraction equilibrium between the aqueous phases and the sorbent was reached after 10 min.

The eluent volume was optimized because the amount of methanol/acetonitrile (1/1, *v*/*v*) can affect the elution efficiency. When the volume of the elution solvent was in the range of 0.5–1.0 mL, the recoveries increased with increasing eluent volume. On the other hand, the recoveries remained almost unchanged when the eluent volume was further increased. The highest recoveries were achieved when the volume of the eluent was 1.0 mL. Therefore, 1.0 mL (0.5 mL each time and washed two times) methanol/acetonitrile (1/1, *v*/*v*) was selected for elution. Under optimal conditions, 100.0 mL of spiked water samples (0.1 ng mL^{-1}) were

pretreated and analyzed by HPLC (Fig. 10). In comparison with the chromatogram of standard solution without MSPE (Fig. 10a), clear chromatographic peaks of PAHs were observed in Fig. 10b after preconcentration.

A:peak area C:concentration

3.3. Reusability of g-C_3N_4/Fe_3O_4

To investigate the recyclability of the sorbent, g-C_3N_4/Fe_3O_4 was reused in MSPE. After five times of recycling, there was no obvious decrease or increase in the analyte recoveries. The recoveries of PAHs were 97.8–99.6% for Naph, 98.2–99.4% for Acy, 93.4–95.1% for Ph, 97.1–98.6% for An, 84.9–86.5% for Flt, 80.0–81.8% for Pyr and 86.7–88.9% for BaA. The results indicate that g-C_3N_4/Fe_3O_4 is stable and no carryover of analytes occurred during MSPE procedure, indicating good reusability.

3.4. Analytical performance and application

A series of experiments were conducted to determine the linearity, reproducibility, and limit of detection (LOD) of the method. All parallel experiments were repeated three times and the results are listed in Table 1. The calibration plots were drawn by analyzing 100.0 mL of distilled water spiked with different analytes

in the range from 0.1 ng mL^{-1} to 20.0 ng mL^{-1}. The correlation (r^2) of these curves was above 0.997. The reproducibility of a spiked water sample (1.0 ng mL^{-1}) was evaluated, and the RSD values were 1.8–5.3%. The detection and quantification limits were calculated based on S/N=3 and S/N=10, with values from 0.05–0.1 ng mL^{-1} and 0.17–0.33 ng mL^{-1}. Overall, the method had a good linear range, low detection limit and high reproducibility. The method was then compared with other previous extraction methods that were used for the determination of PAHs in water samples [24–28], the results are summarized in Table 2. The present method required smaller amounts of the sorbent, or conveniently manipulation, but exhibited better or similar performance.

Finally, real water samples from a tap, Qixia Lake and Xuanwu Lake were collected and analyzed. None of the seven types of PAHs were detected in the non-spiked water samples except for the sample from Qixia Lake (1.37 ng mL^{-1} of Acy and 2.81 ng mL^{-1} of BaA). The results were proved by using Method 550, U.S. EPA., and 1.12 ng mL^{-1} of Acy and 3.05 ng mL^{-1} of BaA from water sample of Qixia Lake were detected. Spiked samples were analyzed to calculate the recoveries of the seven PAHs. Table 3 lists the concentrations of the detected analytes and their recoveries. All the recoveries were in the range of 80.0–99.8% with relative standard deviations (RSDs) of 1.6–5.5%. Therefore, g-C_3N_4/Fe_3O_4 has potential application in the analysis of nonpolar carbon-based ring compounds in water samples.

4. Conclusions

g-C_3N_4/Fe_3O_4 was synthesized by chemical co-precipitation and was evaluated in terms of the adsorption and desorption of seven PAHs. The MSPE conditions using magnetic nanocomposites were optimized and applied to the pre-treatment of PAHs from water samples prior to HPLC with UV detection. Low limits of detection, good linearity and recovery were obtained indicating that g-C_3N_4/Fe_3O_4 has potential application in the pretreatment of water samples and other environmental nonpolar pollutants containing carbon-based ring structures and in the removal of PAHs from water samples.

Phenolic compounds

ABSTRACT

A new method based on nano-liquid chromatography coupled to time-of-flight mass spectrometry (nano-LC–TOF–MS) using lock-mass calibration was developed to facilitate the accurate and routine characterization and quantification of phenolic compounds. Thus, it was applied to study cranberry syrups, in which, using negative ionization mode, a total of nine phenolic compounds were unequivocally identified using standards and 38 tentatively taking into account their retention time, accurate mass (errors < 5 ppm) data and isotope pattern, as well as literature. Among them, 13 compounds, belonging to flavonols and iridoids conjugated with phenolic acids, were reported for first time in cranberry or cranberry based-products. The analytical method was also validated using chlorogenic acid, *p*-coumaric acid, (+)-catechin, (−)-epicatechin, procyanidin A2, quercetin 3-*O*-glucoside, quercetin 3-*O*-rhamnoside, quercetin, and myricetin standards. In this way, the analytical method showed adequate linearity, with R^2 above 0.99, and acceptable values of intra- and inter-day repeatability of the retention time and peak area. The detection limits and quantification were between 1.0–15.6 ng mL^{-1} and 2.0–62.5 ng mL^{-1}, respectively. The method can be extended to characterize phenolic compounds in other food and plant matrices, and as well biological samples.

1. Introduction

The characterization of beneficial food constituents to formulate novel functional ingredients or pharmaceutical preparations continues to attract scientific and industrial attention, because these compounds may contribute in prevention and mitigation of diseases, promote health and wellbeing with a reduction of health care costs. As example, American cranberry (*Vaccinium macrocarpon*) (Ericaceae fam.) is a rich source of bioactive phenolic compounds with antiproliferative, antioxidant [1] anti-inflammatory and anticarcinogenic activities [2], as well as antimicrobial activity related to reduction of urinary-tract infections [3,4]. In fact, different sorts of pharmaceutical products containing cranberry have been launched in the market. Thus, robust, fast, and low-cost quantification methods, are required as quality control of phenolic compounds. In this sense, novel analytical methods to determine cranberry phenolics are based on the use of ultra-high-pressure-liquid chromatography (UHPLC), using sub-2 μm particles, coupled to UV, diode-array and fluorescence detectors and/or mass spectrometry (MS) [5–7].

Currently, other trends in modern analytical chemistry include the miniaturization of liquid chromatography (LC). Advances in this separation technology have enabled the development of nano-LC, which employs capillary columns with internal diameters (i.d.) ranging between 10 and 100 μm [8]. This column i.d. provides a good compromise between sensitivity, loadability, and robustness [9]. In the case of sensitivity, it is especially improved when nano-LC is coupled with MS. In this context, nano-LC has been recently coupled to UV and MS to analyze phenolic compounds in olive oil and other phytochemicals such as gibberellins, phytosterols and methylxantines in different food matrices [10–13]. However, this technique also presents several drawbacks often subjected to far more methodological problems than a conventional HPLC, such as presence of void volumes or easily generation of mixing chambers [14]. However, owing to the advantages that offer nano-LC, including sensitivity, lower cost effectiveness and to be an eco-friendly technique with low solvent demand, developing new methods to characterize phenolic compounds in both plant extracts/products and biological samples is imperative. In contrast, the applicability of

nano-LC in the proteomics field has grown faster than for the analysis of phytochemicals.

In the case of coupling nano-LC with high-resolution MS, calibration of the MS spectra is one of the most critical parameters to consider in the achievement of the accuracy that allows performing characterization studies with high reliability. In this sense, several strategies based on internal and external calibration could be found in literature. Our research group has previously employed both calibration modes [10,15]. However, in the first approach it required to use well-known phenols found in the studied matrix, that is not always possible, and in the second study a solution of sodium formate cluster was introduced externally using a pump before each run, but it could not be automated. Thus, in this study lock-mass calibration and nano-LC coupled to time-of-flight-MS were applied to assure the mass accuracy and the routine analysis of phenolic compounds in both negative and positive ionization modes. For this purpose, the method was applied to characterize cranberry syrups as example of plant product matrix and also validated for quantification. This study allows assuring the application of the method to characterize unknown phenolic compounds in other food and plant matrices as well as biological samples.

2. Material and methods

2.1. Chemicals

All chemicals were analytical MS reagent grade. Formic acid and acetonitrile used for preparing mobile phases were obtained from Fluka (Sigma-Aldrich, Steinheim, Germany) and Fisher Scientific (Loughborough, Leics, UK), respectively. A G560E Vortex-Genie 2 (Scientific Industries, Bohemia, NY, USA) was used for mixing and water was deionized by using a Milli-Q system (Millipore, Bedford, MA, USA).

2.2. Cranberry syrup

Commercial cranberry syrup (Urell®, Pharmatoka Lab., France) was purchased from a local pharmacy (syrup 1) and an experimental gamma-irradiated syrup, prepared with the same commercial extract of American cranberry, was also procured. The preparation was according to Iswaldi et al. [5]: 200 μL of cranberry syrup was dissolved at final volume of 4 mL in methanol, vortexed for 2 min and filtered with a polytetrafluoroethylene (PTFE) syringe filter (0.2 μm pore size). Afterwards, for the analysis by nano-LC–TOF–MS, samples were additionally diluted 1/40 in mobile phase A containing 10% of methanol (dilution solvent).

2.3. Preparation of standards

Standards of 7-hydroxycoumarin, *p*-coumaric acid, chlorogenic acid, (+)-catechin, (−)-epicatechin, myricetin, quercetin, and quercetin-3-*O*-glucoside were purchased from Sigma–Aldrich, whereas quercetin-3-*O*-rhamnoside (quercitrin) and procyanidin A2 were from Extrasynthese (Genay, France). Purity was at least higher than 96%. Stock solutions of each compound were prepared at 1 mg mL^{-1} in methanol and stored at −20 °C. Then, stock solutions were diluted to appropriate working concentrations with dilution solvent, ranging from 5 μg mL^{-1} to the detection limit.

2.4. Chromatographic and MS conditions

Analyses were made with a commercially available EASY-nLC™ (Bruker Corporation, Bremen, Germany), equipped with three pumps, three pressure sensors, four valves, two flow sensors, an autosampler, and a touchscreen (see schematic diagram in Supporting information, Fig. S1). Chromatographic separation was performed with a commercial C18 capillary column (360 μm o.d., 75 μm i.d., length 10.1 cm, 3 μm of particle size; NanoSeparations, Nieuwkoop, The Netherlands). An on-line short capillary pre-column (360 μm o.d., 100 μm i.d., length 20 mm, 5 μm of particle size, NanoSeparations) was used before the analytical column with the intention of trapping of the compounds and working with volumes in the order of μL (see "loading position" Fig. S1). Mobile phases consisted of 1% formic acid in water (phase A) and acetonitrile (phase B) at a constant flow rate of 0.3 μL min^{-1} using the following multi-step linear gradient: 0–2 min, from 5% B to 26% B; 2–14.5 min, from 26% B to 31% B; 14.5–21 min, from 31% B to 36% B; 21–23 min, from 36% B to 60% B; 23 to 25 min, from 60% B to 80% B; 25 to 26 min, 80% B; from 26 to 28 min, 80% B to 5% B. Finally, the initial conditions were maintained for 12 min (total run 40 min).

Before starting the analysis, the pre-column and column were re-equilibrated with phase A at 2.5 μL min^{-1} for 2 min and 0.3 μL min^{-1} for 8.3 min, respectively. The sample (1 μL) was loaded into the pre-column at 2.5 μL min^{-1} for 0.6 min. The flow rate used to elute the compounds in the analytical column was 0.3 μL min^{-1}. Samples were maintained at 15 °C in the autosampler.

The nano-LC instrument was coupled to a micrOTOF™ (Bruker Corporation). The C18-column was connected with a nano-spray interface presenting a tapered fused silica sprayer needle (outer tip, 300 μm) by a peek union. The spraying conditions were adjusted for the abovementioned flow rate (0.3 μL min^{-1}) to achieve stable spray across the entire gradient: nebuilizing gas pressure, 0.5 bar, drying gas temperature and flow 150 °C and 5.0 L min^{-1}, respectively. The selected parameters of MS analysis in negative ion mode were as follows: capillary voltage, 3.7 kV; end-plate offset, −500 V; capillary exit, −80 V; skimmer 1, −50 V; skimmer 2, −23 V; hexapole 1, −22 V; hexapole RF, 70 V; lens transfer time 50 μs; lens pre-pulse storage time, 3 μs; and spectra rate 2 Hz. In positive ion mode, the parameters were set at the same values as in the negative ion mode, but with the opposite polarity. All operations were controlled by HyStar software (Bruker Corporation) and data processing was performed with DataAnalysis 4.0 software (Bruker Corporation), which provided a list of possible elemental formulas by using the SmartFormula™ editor based on a CHNO algorithm. For the generated molecular formulas, it provides the deviation between the measured mass and theoretical mass (error) (Da and ppm) and the comparison of the theoretical with the measured isotope patterns (msigma value or $m\sigma$) for increasing the confidence in the suggested molecular formula. TargetAnalysis™ 1.2 (Bruker Corporation) was used for targeted screening.

2.5. Calibration of the spectra

All the spectra were calibrated prior to the compound identification by external calibration and/or lock-mass calibration function available in the software DataAnalysis 4.0. For external calibration, the calibrant was a sodium formate cluster containing 5 mM sodium hydroxide and 0.2% formic acid in water:isopropanol (1:1, v/v), injected at the end of each run with a 74900-00-05 Cole Palmer syringe pump (Vernon Hills, IL, USA). For this purpose, it was connected manually to the nano-spray interface, owing to, with the instrumentation used in this work, external calibration could not be performed automatically. For lock-mass calibration, hexakis (2,2-difluoroethoxy)phosphazine was dissolved at 2 mg mL^{-1} in 2-propanol. This calibrant solution was applied to an adsorber material, which was placed inside a reservoir from Bruker and then

mounted on top of the spray shield of the TOF (Fig. S1). The intensity was at least 2000 counts for each ion.

2.6. Validation of the analytical method

2.6.1. Limit of detection (LOD) and quantification (LOQ)

The limit of detection (LOD) was determined through successive dilutions of the standard mixture until peaks with a signal-to-noise ratio near three ($S/N \geq 3$) were reached [16,17]. The limit of quantification (LOQ) was also determined through successive dilutions, being defined as the concentration that resulted in peaks with a signal-to-noise ratio above 8 ($S/N \geq 8$) [16]. For this, to extract ion chromatograms and estimate the S/N ratio using DataAnalysis software, the mass window selected was 100 mDa.

2.6.2. Linearity

The calibration curves were plotted by determining the linear relationship between the concentration of 9 selected phenolic compounds standards vs. their peak area in the extracted ion chromatogram of the molecular ions ($[M-H]^-$). Three replicates and at least six different concentrations were used to build the curves. The estimation of the regression parameters was done by the ordinary least squares method. The assumption of linear regression was checked by ANOVA and lack-of-fit test using Statgraphics Centurion 16.2.04 software (StatPoint Technologies, Inc., Warrenton, VA, USA; www.statgraphics.com).

2.6.3. Intra- and inter-day repeatability

Intra-day repeatability was estimated by the relative standard deviation (RSD) of the peak areas and the retention time for six consecutive analyses of the cranberry syrup (syrup 1), and inter-day repeatability was estimated by the RSD of the areas and the retention time for 10 consecutive analyses of the syrup performed on two different days (separated by 1 week) [18].

2.6.4. Accuracy

Accuracy was evaluated accordingly [18,19] and calculated over the linear range. For this purpose, pure standard were prepared to reach a final concentration of 50 and 100 ng mL^{-1} in dilution solvent and a selected syrup (syrup 1) was prepared as for analysis, but spiked at the latter levels. The analyte concentrations were estimated and the accuracy was calculated by the ratio of this calculated concentration versus the theoretical (spiked) concentration. All samples were analyzed in triplicate.

3. Results and discussion

3.1. Selection of the analytical conditions

The mobile phases selected were according with Iswaldi et al. [5], but mobile phase A was 1% formic acid in water and without organic solvent to avoid the loss of more polar compounds during the load step in the trapping column. Preliminary studies (data not

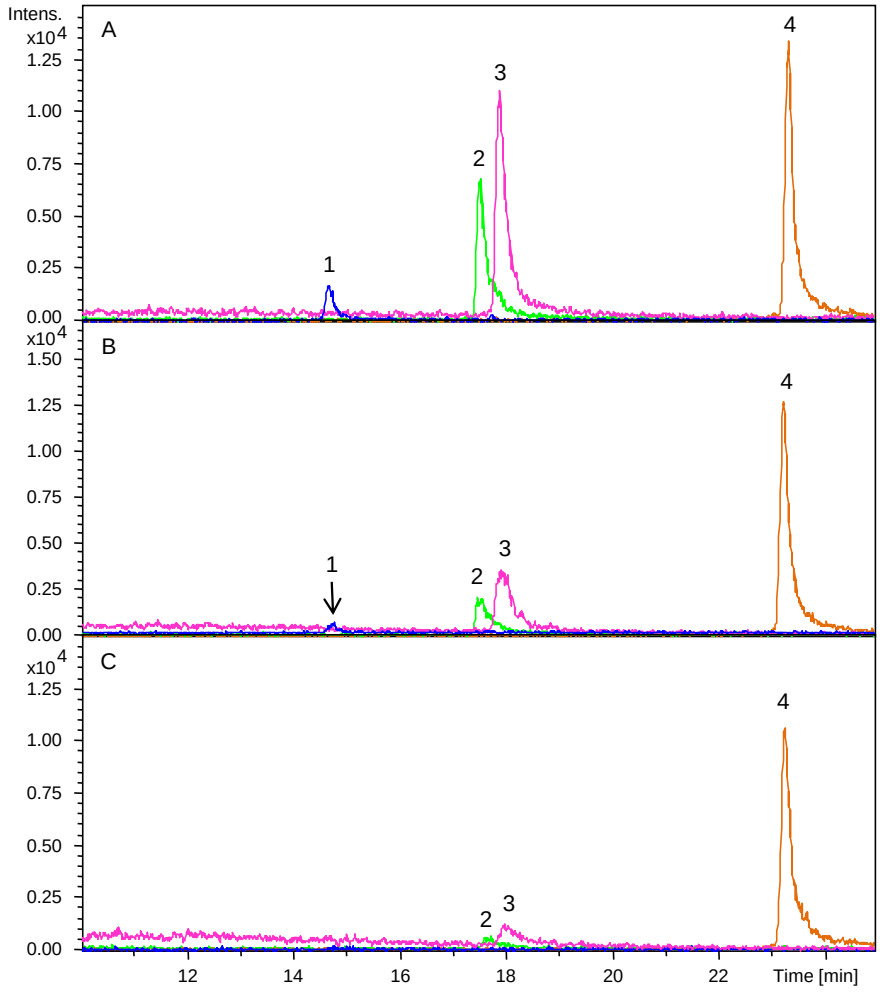

Fig. 1. Effect of the loading volume on the trapping of several phenolic compounds at 500 ng mL^{-1} using a C18 pre-column, an injection volume of 1 μL, and a load flow rate of 2.5 μL min^{-1}: (A) 1.5 μL, (B) 3.0 μL, and (C) 15.0 μL. Extracted ion chromatograms in negative ionization mode of compound 1: (+)-catechin; 2: *p*-coumaric acid; 3: 7-hydroxycoumarin; 4: quercetin.

shown) were made to assess the best way to equilibrate the pre-column and column. It implied the time for equilibration using an adequate flow to avoid higher system pressures and disturbing nebulization; for example, the maximum recommended flow in the used nano-ESI source is up to 0.5 μL min^{-1}. Thus, pre-column and column were equilibrated with the mobile phase A at 2.5 μL min^{-1} for 2 min and 0.3 μL min^{-1} for 8.3 min, respectively, the system pressure being lower than 120 bar.

Another important step using this instrument was to optimize the on-column trapping of the analytes of interest in the pre-column [10]. Therefore, using mobile phase A at 95% (gradient initial conditions), the appropriate sample-loading volume and speed during the loading/washing step (see Fig. S1) of the analysis were established using phenolic standards with different polarities and retention properties in C18 stationary phase. As an example, Fig. 1 shows the effect of different loading volumes; when the volume was too large, the most hydrophilic compounds, especially (+)-catechin (compound **1**), were displaced from the pre-column. Thus, for a injection volume of 1 μL, the best loading conditions were a load volume of 1.5 μL at 2.5 μL min^{-1}. This injection volume is also appropriate for future works with biological samples, where the sample volume/amounts could be limited. Moreover, the gradient was also modified to allow the better separation of the compounds. Fig. 2 shows the retention properties of phenolic compounds from commercial cranberry syrup by the optimized nano-LC–TOF–MS method in negative ionization mode.

3.2. Selection MS parameters

To optimize MS transfer, a methanolic solution composed by *p*-coumaric acid, 7-hydroxycoumarin, (+)-catechin and quercetin (500 ng mL^{-1}) was injected off-line in negative and positive ion modes. All ions were detected under the conditions tested, the MS signal being in general higher with the parameters set as indicated in Section 2 (for an example, see Fig. S2A of Supporting information). These results were also confirmed by on-line injection with the nano-LC instrument and the mobile phases selected (as example, see Fig. S2B, using negative ionization mode).

3.3. Lock-mass calibration

For high accuracy, the mass analyzer must be calibrated using known masses along the *m/z* range, and then applying a correction. In this work, the lock-mass calibration function was tested using hexakis(2,2-difluoroethoxy)phosphazine ($C_{12}H_{18}F_{12}N_3O_6P_3$), which is a common component of tuning mix (see Agilent brochure of G2431A/G2431-60001). This compound was selected because it is an artificial compound, presents an intermediate mass-to-charge ratio in the selected mass-range analysis, and it was detected in both negative (theorical monoisotopic *m/z* value of 601.9790) and positive (theorical monoisotopic *m/z* 622.0290) ion

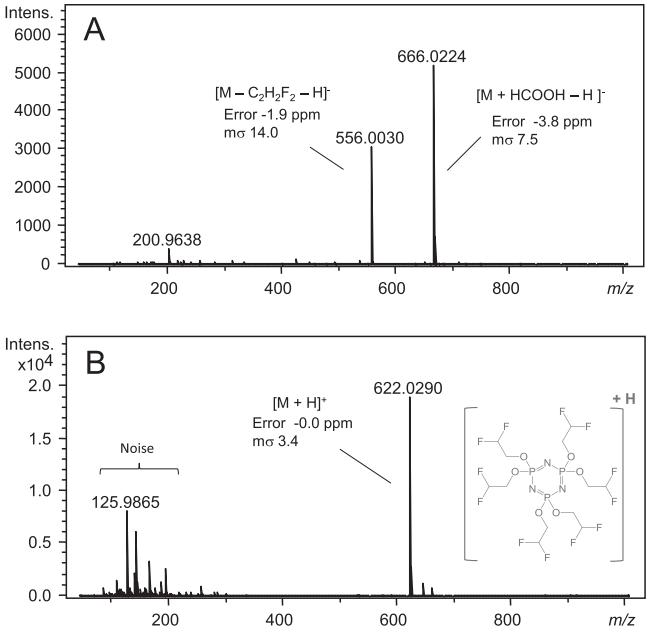

Fig. 3. MS spectra of hexakis(2,2-difluoroethoxy)phosphazine, which was used as lock-mass calibrant, in (A) negative and (B) positive ionization modes.

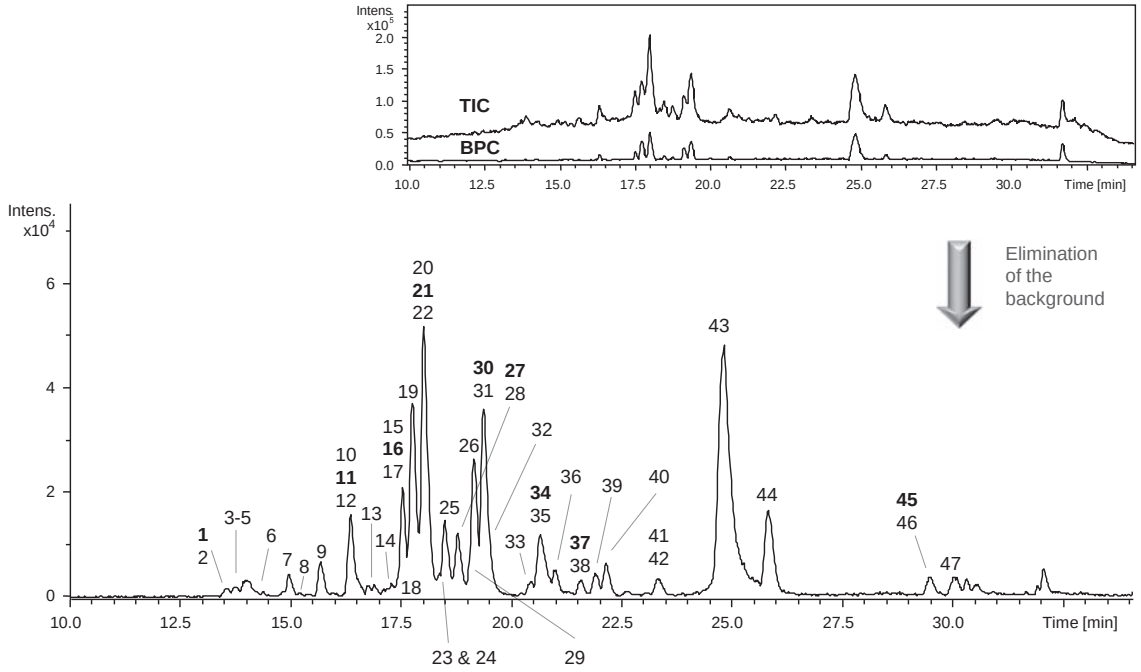

Fig. 2. Base peak chromatogram (BPC) in negative ionization mode after the elimination of the spectral background of a commercial cranberry syrup. Compounds are numbered according to Table 1 and the most abundant ones in each peak are given in bold. Superior panels show raw total ion chromatogram (TIC) and BPC.

Table 1
Phenolic compounds characterized in cranberry syrup by nano-LC–TOF–MS in negative and positive ionization modes and using external and lock-mass calibrations: class, retention time, molecular formula, theoretical *m/z*, msigma value, measured *m/z* and error.

No	Phenolic compounds	TR (min)	Molecular formula (M)	Negative ionization mode $[M-H]^-$						Positive ionization mode $[M+H]^+$

* Phenolic compounds verified with commercial standards.
[a] Compounds previously characterized by HPLC–DAD–TOF–MS, using C18 column (150 × 4.6 mm, 1.8 μm particle size) [5].
[b] Myricetin 3-*O*-arabinoside, myricetin 3-*O*-xyloside and quercetin 3-*O*-galactoside have been described in cranberry.
[c] Isorhamnetin 3-*O*-xyloside has only been described in *Vaccinium* L. spp.

modes with high relative abundance, when the tuning mix was injected off line (data not shown). With the analytical conditions, the formic adduct (theorical monoisotopic *m/z* value of 666.0199, $[C_{12}H_{18}F_{12}N_3O_6P_3+HCOOH-H]^-$) and the latter positive ion (*m/z* 622.0290) were detected in negative (Fig. 3A) and positive (Fig. 3B) ion modes, respectively, and so selected to apply the lock-mass calibration function. Afterwards, the recalibration of the MS spectra was successful, with *m/z* errors being lower than 5 ppm in both negative and positive ionization modes, which were similar to those measured using external calibration and a sodium formate cluster introduced with a pump at the end of the analysis (see Table 1).

For high-mass resolution, the calibrant can be included either within the sample itself (internal calibration) [10] or, alternatively, can be introduced externally (external calibration) [11,15]. However, in the first case, for example, it requires the application of a quality control (with several known compound standards) every two or three analyses to use their calibration parameters in the following samples. On the other hand, our system does not present a valve to select automatically the introduction of the flow from the nano-LC, the tuning solution for the primary daily calibration of the TOF or for recalibration of MS data. Thus, with the present instrumentation, external calibration is tedious since the analyst has to connect the calibrant pump to the nano-ESI source manually, and injections during night are limited. Remarkably, the applied mass corrections by lock-mass calibration enabled to maintain the mass error below 5 ppm even up to three weeks, without the requirement of that daily external calibration of the mass analyzer. This also implies to reduce the number of insertions and removals of the fingertight fitting, which connect the column with the interface, and could result in its damage, leading to wrong adjustments of the column tubing and so generating leaks which are difficult to detect or huge chambers of dead volumes where the separated compounds are mixed (see "the practical guide to nano-LC troubleshooting" by [14] and some of the difficulties that the analyst could find when working with this miniaturized technique instead an HPLC).

3.4. Identification of phenolic compounds in cranberry syrup

In general, phenolic compounds were tentatively identified based on the generated molecular formula using exact mass and isotope pattern data, retention time, fragmentation via in-source collision-induced dissociation (ISCID) together with literature concerning cranberry and Ericaceae family. When possible, phenolic compounds were studied in depth by matching with standards.

3.4.1. Negative ionization mode

Fig. 2 shows the base peak chromatogram (BPC) in negative ionization mode of commercial syrup sample after noise/background elimination and 47 compounds characterized by nano-LC–TOF–MS, whereas Table 1 shows their retention times, theoretical *m/z*, msigma values, and experimental *m/z* and error by both lock-mass and external calibration.

Thus, it was possible to characterize five phenolic acid derivatives, four flavanols (simple and low-mass oligomers), 10 flavonols, and an isoflavone, in common with our previous analysis by HPLC–DAD–TOF–MS [5]. Furthermore, the phenolic acid *p*-coumaric acid, the flavanol (−)-epicatechin, several isomers of flavonols, i.e. isorhamnetin (3′-methoxyquercetin) and isorhamnetin 3-*O*-galactoside, quercetin-3-(6″-coumaroyl)-β-galactoside, myricetin pentoside, kaempferol 3-*O*-glucoside, and methoxyquercetin derivatives were also detected. These compounds were previously described by several authors in cranberry fruit or cranberry-based products

Table 2
Analytical parameters for the nano-LC–TOF–MS method: linear range, regression coefficients for calibration curves ($y=a+bx$), R^2, limits of detection (LOD) and quantification (LOQ), relative standard deviation (%) obtained for intra- and inter-day repeatability of peak area and retention time, accuracy and lack-of-fit significance (p-value).

Selected phenolic compounds	Range (ng mL^{-1})	a	b	R^2	LOD (ng mL^{-1})	LOQ (ng mL^{-1})	Repeatability (peak area)		Repeatability (retention time)		Accuracy (%)	Lack-of-fit (p)

All regression coefficients (a, b) presented are significantly different from zero ($p<0.05$).

[1,6,7,20–23]. Quercetin hexoside (**32**) could be quercetin 3-*O*-galactoside, which was previously characterized in cranberry [1,21].

Notably, in our study, other phenolic compounds which were previously described in other *Vaccinium* spp. or the family Ericaceae were characterized for first time in cranberry, e.g. flavonols dihydromyricetin (ampelopsin) (**10**) [24], syringetin (3′,5′-*O*-dimethylmyricetin) 3-*O*-hexoside (**31**) and pentoside (**39**) [20,25,26], methoxyquercetin rhamnoside (**38**) [26], and three pentosides (**35**–**37**) [20,22], as well as kaempferol (**46**) [20,27], and the dihydrochalcone phloridzin (phlorizin) (**33**) [28,29]. The compound myricetin 3-*O*-(2″-*O*-*p*-hydroxybenzoyl)-α-rhamnopyranoside (**41**) was previously found in *Limonium sinense* (Plumbaginaceae fam.) [30].

Moreover, five iridoids conjugated with phenolic acids (**16**, **18**, **21**, **22** and **24**), also described in *Vaccinium* spp., were tentatively identified as 10-*p*-*trans*- and 10-*p*-*cis*-coumaroyl-1*S*-monotropein (vaccinoside/andromedoside) or 10-*p*-*trans*- and 10-*p*-*cis*-coumaroyl-1*S*-dihydromonotropein isomers [27,31]. The benzoyl iridoid derivative besperuloside (**45**) was also characterized for first time in cranberry and previously described in *Globularia* (Plantaginaceae fam.) [32].

3.4.2. Positive ionization mode

In positive ionization mode the background was higher than in negative ionization mode and, after the elimination of the spectral background, the chromatographic peaks could be clearly visualized in the BPC. Thus, the major part of the latter compounds (a total of 38), using either lock-mass calibration or external calibration, were also characterized in this mode (Table 1). In general, in positive ion mode and under our MS conditions, several of the *O*-glycosides compounds showed lower stability than in the negative ion mode and were partially fragmented. It bears noting that the characterization of these fragments enabled the confirmation of the structure of compounds with the same molecular formula, reaffirming the characterization in negative mode. For example, compounds **29** and **39** (Fig. S3, supporting information) with molecular formula $C_{22}H_{22}O_{12}$ were assigned to isorhamnetin 3-*O*-galactoside and syringetin pentoside, respectively.

However, the analytical conditions were not adequate to detect anthocyanins, which require more acidic conditions to improve their MS signal [5] even in positive ionization mode. On the other hand, more acid mobile phase A may also improve peak shape, resolution and analysis time of anthocyanins [33,34], but it requires further works.

3.5. Validation of the quantification by nano-LC–TOF–MS

Nano-LC–TOF–MS in negative ionization mode was selected for the simultaneous quantification of phenolic compounds in this syrup matrix, since a major number of compounds were characterized comparing with positive ionization mode. The validation parameters of sensibility, linearity, repeatability and accuracy are shown in Table 2. The LOD values ranged between 1.0 and 15.6 ng mL^{-1} and the LOQ values between 2.0 and 62.5 ng mL^{-1}. These data are lower than those reached by previous analytical methods used for the analysis of cranberry products using HPLC or UHPLC methods [5,7,16], and/or comparable to other nano-LC methods [10,12,33]. Therefore, this underscores the potential of the nano-LC–TOF–MS for future works studying phenolic compounds in biological matrices. On the other hand, the LOD and LOQ values were also examined in positive mode, being as low as in the negative ionization mode (Table S1, supporting information). The values for the coefficient of determination (R^2) were above 0.99, indicating that the fits were adequate. In all cases, the regression was significant ($p<0.05$) and lack-of-fit was not observed ($p>0.05$), confirming linearity in the studied concentration ranges.

Regarding the intra- and inter-day repeatability of the retention time, the RSD values were lower than 1% for all the compounds studied. The intra- and inter-day repeatability of the peak area depended on the compound considered, with values ranging between 4.0 and 14.7%, and being acceptable in comparison with other previously reported methods using nano-LC coupled to MS analyzing phytochemicals [10,11,33]. The accuracy of the method was also verified spiking craberry syrup 1 with standards at two levels (50 ng mL^{-1} and 150 ng mL^{-1}) under the linear range. In overall, the mean value for each compound ranged between 81.3 and 107.4% (Table 2). The worst value was observed for (+)-catechin (81.3%) when was analyzed in the first syrup matrix. In any case, the values met acceptance criteria [35].

As commented above, our system allows to perform on-column trapping step to introduce relative high volumes of sample (in this case 1 μL) and trap the analytes of interest. Although in this study concentration was not a critical problem, the objective was to optimize the method for further characterization works. In this sense, samples were highly diluted previously to perform the analysis (see Section 2), but residual sugars where detected along the MS spectrogram (Fig. S4), which could indicate that these highly polar components may remain into the system. Therefore,

our loading conditions were not enough to perform a large clean-up of the samples by washing these highly polar compounds from the pre-column with mobile phase A (at 95%), but with the compromise to retain more polar phenolic compounds (e.g. Fig. 1). Amongst the polar fraction, sugars are commonly present in phenolic extracts of plants [36] and so of interest as possible MS

interferents upon our analytical conditions due to their aforementioned behaviour. This a critical disadvantage compared when working in proteomics field, where the application of the nano-LC has spread widely. In these works a common strategy is to introduce a mix of peptides (protein hydrolysate) in the nano-LC system and the possible loss of amino acids or several polar peptides during the loading (normally, higher washing volumes are used) is not so relevant, whenever the characterized peptides may define the precursor protein (e.g. see applications in [37]). Although matrix compounds such as sugars might influence reproducibility and accuracy [38], remarkably, the estimated values for these parameters are acceptable as commented above.

3.6. Quantification and semi-quantification of phenolic compounds in cranberry syrups

The validated nano-LC–TOF–MS method was applied to estimate the quantities of phenolic compounds in both cranberry syrups with the use of the aforementioned calibration curves (Table 3). Thus, the MS response of the other phenolic compounds, which were not available as commercial standards, were calculated assuming similar responses for compounds of the same class/subclass and taking into account if they were glycosilated or aglycones when possible. For this purpose, a targeted analysis was performed using the software TargetAnalysis™ 1.2 [39], enabling the MS spectra to be automatically calibrated using lock-mass calibration, matching the phenolic compounds with previously characterized ones while taking into account retention time (error narrow range 0.2 min), accurate *m/z* (error narrow range < 5 ppm) and isotope pattern (msigma threshold 150), and determine the peak area. Successfully, the method enabled to detect the compounds in the samples in a faster way with high level of confidence taking into account the later parameters. Afterwards, the amounts of the detected phenolic compounds were estimated (Table 3). Among the phenolic families determined, the contents of flavonols and phenolic acid conjugated with iridoids were the highest in both syrups. In general, the individual values for each phenolic compound from commercial syrup were within the range of those previously determined in our previous works using HPLC–UV based-curves [5]. Other methods based on nano-LC characterized between 1 and 18 phenolic compounds in pollen, juice, olive oil, tea or honeysuckle, whereas quantified a lower number of them, ranging from **1** to **7** compounds [10,12,33,40,41]. Thus, our results remark that the application of our methodology to explore other vegetable matrices or biological samples is suitable.

4. Conclusion

In the present study, a nano-LC–TOF–MS using lock-mass calibration strategy with a single *m/z* ion, was successfully applied to make accurate mass measurements lower or close to 5 ppm, allowing the characterization of 47 (*m/z* ranging from 163.0398 to 863.1783) and 39 (*m/z* ranging from 165.0556 to 865.1994) phenolic compounds in negative and positive ionization mode, respectively. Several of these compounds were reported here for first time in cranberry. The method was also validated in negative ionization mode and showed adequate inter- and intra-day repeatability of retention time and peak area, and linearity. Thus, these results demonstrate that this miniaturized technique could be implemented for the characterization and simultaneous quantification of phenolic compounds in new plant matrices as well as biological matrices, with the advantage of using minimum volumes of mobile phases and sample, as well as achieving high sensitivity.

ζ-potential
UV–vis spectroscopy

ABSTRACT

In this study, 40 nm silver nanoparticles (AgNPs) were synthesized using the citrate reduction method and then the surface of AgNPs was modified by conjugating Cytochrome C (Cyto C) to improve stability and to enhance bioactivity and biocompatibility of AgNPs. It is known that Cyto C may undergo conformational changes under various conditions of pH, temperature, ionic strength, etc., resulting in aggregation of the particles. These parameters also affect the size and size distribution of Cyto C–conjugated AgNPs (Cyto C–AgNP). ζ-potential measurement revealed that the adsorption of Cyto C on the surface of AgNPs is saturated at the molar ratio [Cyto C]/[AgNPs] above about 300. Asymmetrical flow field-flow fractionation (AsFlFFF) analysis showed that hydrodynamic diameter of AgNPs increases by about 4 nm when the particle is saturated by Cyto C. The aggregation behavior of Cyto C–AgNP at various conditions of pH, temperature and ionic strength were investigated using AsFlFFF and UV–vis spectroscopy. It was found that the aggregation of Cyto C–AgNP increases with decreasing pH, increasing temperature and ionic strength due to denaturation of Cyto C on AgNPs and reduction in the thickness of electrostatic double layer on the surface of Cyto C–AgNP.

1. Introduction

Metallic nanoparticles are of interest in the field of life science due to their unique chemical, physical and biological properties [1]. Surface modification of metallic nanoparticles with polymer or protein is an approach to stabilize the nanoparticles. Surface modifications with a suitable agent such as organic molecules, surfactant, protein or polymer prevent aggregation, and improve biocompatibility and stability of the metallic nanoparticles in suspensions [2–4].

Among metallic nanoparticle, silver nanoparticles (AgNPs) are of particular interest because of their unique characteristics including antimicrobial activities, which often depend on their size and shape. They can be used as biosensor materials, fibers, superconducting materials, cosmetic products, and electronic components [5–8].

AgNPs are often coated with various types of anions, polymers or proteins to improve their biocompatibility and stability and also to control toxicity [9,10]. Cytochrome C (Cyto C) is a highly water soluble protein which is often used to coat nanoparticles to improve their biocompatibility. Sometimes Cyto C undergoes conformational changes as it becomes partially unfolded upon adsorption onto the surface of nanoparticles. The unfolded Cyto C adsorbed on a nanoparticle interacts with other Cyto C in suspension causing protein aggregation on nanoparticle surface, which results in nanoparticle aggregation [11,12]. The unfolding of Cyto C induced by presence of denatures or change in pH, temperature or ionic strength has been studied using light scattering [13]. It has been reported that aggregation of Cyto C–AgNP induces a coupling of the localized surface plasmon resonance of AgNPs, and may cause color change at various pH [12].

The effects of pH and ionic strength on aggregation behavior of nanoparticles in aqueous suspensions have been studied in terms of the change in the hydrodynamic diameter of particles [14,15]. It has been reported that the combined effect of pH, ionic strength, capping agent, ionic composition and other characteristics of the suspending liquid play a significant role in formation of aggregates or stability of the nanoparticles [16]. Appropriate analytical tool is thus required to detect and quantify aggregates.

Various analytical techniques such as light scattering, separation, spectroscopy and microscopy are employed to monitor aggregation of bioconjugated nanoparticles including dynamic light scattering (DLS) [17,18], size-exclusion chromatography (SEC) [19,20], UV-vis spectroscopy [21,22], electron microscopy (EM) [23,24]. Each technique has its own merits and limitations for characterization of bioconjugated nanoparticles. DLS provides hydrodynamic diameter and its distribution using the Stokes–Einstein equation, and is fast and simple to operate. However its

application to polydisperse samples or quantification of aggregates is often limited [25]. SEC provides size-based separation of particles, and yields useful information on size distribution of particles. However the resolution of SEC may be hampered by nonspecific interaction of the sample with stationary phase, and its application to larger particles is rather limited due to lower resolution. UV–vis spectroscopy provides information on aggregation in suspension, but requires fairly concentrated sample for measurement. EM allows one to view the size and shape of individual nanoparticles. During EM measurement, however, the sample suspension is dried and put on a high-vacuum, which may cause shrinkage and agglomeration of particles.

Field-flow fractionation (FFF) is a family of size-based separation techniques capable of providing separation and characterization of macromolecules or particles ranging in size from 1 nm up to about 100 μm [26]. Among the members of FFF family, asymmetrical flow field-flow fractionation (AsFlFFF) is particularly useful for separation and characterization of bioconjugated nanoparticle [27,28] and protein aggregates [28–31].

In this study, 40 nm AgNPs were synthesized using the citrate reduction method [32]. Then the surface of the nanoparticles were modified by conjugating Cyto C at various molar ratios of Cyto C to AgNPs, [Cyto C]/[AgNPs]. AsFlFFF was then used for separation and quantification of Cyto C–conjugated AgNPs (Cyto C–AgNP) obtained at various pH, temperature and ionic strengths. Also, the aggregation behavior of Cyto C–AgNP was studied using AsFlFFF and UV–vis spectroscopy. Aim of this study is to determine the size and size distribution of Cyto C–AgNP and to study stability of Cyto C–AgNP in suspension at various conditions.

2. Theory

In AsFlFFF, the hydrodynamic diameter (d_H) of a particle is related with its retention time (t_r) by [33]

$$d_H = \frac{2V^o kTt_r}{\pi\eta w^2 F_c t^o} \quad (1)$$

where V^o is the void volume of the AsFlFFF channel, k is the Boltzmann constant, T is the absolute temperature (k), η is the viscosity of the carrier liquid, w is the channel thickness, F_c is the volumetric cross-flow rate, and t^o is the void time (the elution time of the species that are not retained). Using Eq. (1), an AsFlFFF fractogram of the particles can be converted directly to a size distribution.

3. Experimental

3.1. Chemicals

Silver nitrate ($AgNO_3$), trisodium citrate, sodium azide and Cyto C were purchased from Sigma-Aldrich (St. Louis, MO, USA). Sodium phosphate buffer solution (PBS) was prepared by adjusting the concentrations of sodium dihydrogen phosphate and disodium hydrogen phosphate to achieve desired pH and ionic strength. Cyto C was prepared in 20 mM PBS at pH 7.2.

3.2. Synthesis of citrate–silver nanoparticles and preparation of Cyto C–AgNP

Silver nanoparticles were prepared by the citrate reduction of silver nitrate, first reported by Lee and Meisel with some modifications [32]. A 200 mL of 0.0001 M $AgNO_3$ solution was heated to boil at 100 °C. 7.5 mL of 1% (w/v) sodium citrate solution was then added and the solution was refluxed for 35 min. The temperature, stirring rates were held constant during preparation. In other to obtain the Cyto C–AgNP, pH of AgNPs suspension was adjusted to 11 by adding 0.1 M NaOH. The isoelectric point of Cyto C is near 10, and Cyto C is stable and no aggregation occurs at pH 11 [11]. At pH above the isoelectric point, Cyto C molecules become negatively charged, and produce Cyto C–AgNP via electrostatic interaction. Then, 0.01 mg/mL or 0.1 mg/mL solutions of Cyto C in PBS buffer was added at desired molar ratio of [Cyto C]/[AgNPs]. The suspension was kept at 4 °C for 1 day.

3.3. Determination of concentration of silver nanoparticles

The concentration of silver nanoparticles was determined by the method which has been previously reported by Liu et al. for gold nanoparticle analysis [34]. The average number of atoms per nanoparticle is defined as

$$N = \frac{\pi\rho d^3}{6M} N_A \quad (2)$$

where N is the number of atoms per nanoparticle, ρ is the density of silver (10.5 g/cm^3), d is the average diameter of nanoparticles, M is the atomic mass of silver (107.868 g), and N_A is the number of atoms per mole (Avogadro's number).

The molar concentration C of the nanoparticles in suspension was determined by

$$C = \frac{N_T}{NVN_A} \quad (3)$$

where N_T is the total number of silver atoms added as $AgNO_3$, N is the number of atoms per nanoparticle in Eq. (2), and V is the volume of the reaction solution. The concentration of silver nanoparticles synthesized in this study was calculated to be 4.55×10^{-11} mol/L from Eqs. (2) and (3).

3.4. Asymmetrical flow field-flow fractionation (AsFlFFF)

The AsFlFFF system used in this study was the Eclipse AF4 (Wyatt Tech., Europe GmbH, Dernbach, Germany) assembled with a 350 μm-thick Mylar spacer and a regenerated cellulose membrane (Millipore, Bedford, MA, USA) having the cut-off molecular weight of 10 kDa. The channel geometry was trapezoidal with the tip-to-tip length of 26.5 cm and breadths at the inlet and the outlet of 2.2 and 0.6 cm, respectively. To measure the channel thickness, 52 ± 2 nm polystyrene beads having a narrow size distribution were injected with the carrier solution of water containing 0.02% FL-70 and 0.02% NaN_3. The channel thickness determined from the retention time of 52 ± 2 nm polystyrene beads was 238 μm.

A HPLC pump (Futecs P-6000, Daejeon, Korea) was used to deliver the carrier liquid into the AsFlFFF channel. The channel and the cross-flow rates were measured using liquid flow meters (Optiflow 1000, Agilent Technologies, Palo Alto, CA, USA). Eluted particles were monitored using a Model-500 UV detector (Chrom tech Inc., MN, USA) with the wavelength set at 410 nm. The detector signal was collected by using FFF analyzer software supplied by Quantum Soft. (Daejeon, Korea). The 20 μL particle suspension was injected into the AsFlFFF channel using a 20 μL loop injector (Rheodyne, Cotati, CA, USA). A syringe pump (Model 100, KD Scientific, USA) was used to inject the sample suspension into the AsFlFFF channel at the flow rate of 0.2 mL/min for 60 s.

3.5. Other instruments

DLS and ζ-potential measurements were made at the scattering angle of 90° (for DLS measurement) and 17° (for ζ-potential measurement), respectively, with a Zetasizer Nano ZS90 (Malvern

instrument, Worcestershire, UK) equipped with a He–Ne laser (633 nm) as the light source. All measurements were repeated three times for a DLS analysis and ten times for a ζ-potential measurement, respectively. The results were presented as the mean size or ζ-potential ± one standard deviation. UV-3101-PC spectrophotometer (Shimadzu, Kyoto, Japan) was used for UV–vis spectroscopic analysis of AgNPs.

4. Results and discussion

4.1. Formation of Cyto C–AgNP

The ζ-potential measurement of nanomaterial provides not only information on the electrical potential on the surface ('surface charge'), yielding an insight into stability of nanometerials in suspension, but also the thickness of the electrical double layer on the surface of bioconjugated nanometerials [11,35]. As the amount of protein adsorbed on the nanoparticle increases, the surface charge varies, and eventually reaches a stable value, indicating the nanoparticle surface is saturated with the protein.

In order to obtain saturated Cyto C–AgNP, ζ-potential was measured by varying the molar ratio, [Cyto C]/[AgNPs], at pH 11. Fig. 1 shows ζ-potential measured for Cyto C–AgNP prepared at various molar ratios of [Cyto C]/[AgNPs] ranging from 0 up to 500. As shown in Fig. 1, ζ-potential of AgNPs increases as [Cyto C]/[AgNPs] increases at the beginning, which suggests that the surface charge of AgNPs is neutralized upon adsorption of Cyto C. ζ-potential of the bare AgNPs was -61 ± 4.5 mV and increases rather quickly with increasing [Cyto C]/[AgNPs] until the molar ratio reaches about 100. At [Cyto C]/[AgNPs] higher than about 100, ζ-potential still increases with [Cyto C]/[AgNPs], but at much slower rate. Further increase in [Cyto C]/[AgNPs] above about 300 did not lead to significant changes in ζ-potential. It seems that Cyto C–AgNP is formed by electrostatic attraction of the negatively charged carboxylate groups on AgNPs and the positively charged Cyto C.

4.2. Characterization of Cyto C–AgNP

In order to determine the size of Cyto C adsorbed on AgNPs, hydrodynamic diameter was determined using AsFlFFF and DLS. Fig. 2 shows AsFlFFF fractograms (Fig. 2(a)) and size distributions (Fig. 2(b)) of three types of AgNPs (bare AgNPs and Cyto C–AgNP obtained at [Cyto C]/[AgNPs] of 300 and 20,000). Both Cyto C–AgNP were prepared at pH 11. The AsFlFFF channel flow rate

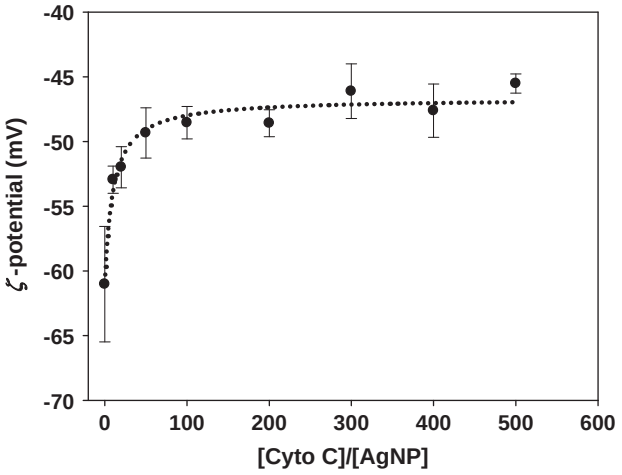

Fig. 1. Variation of ζ-potential of Cyto C–AgNPs with molar ratio of [Cyto C]/[AgNPs].

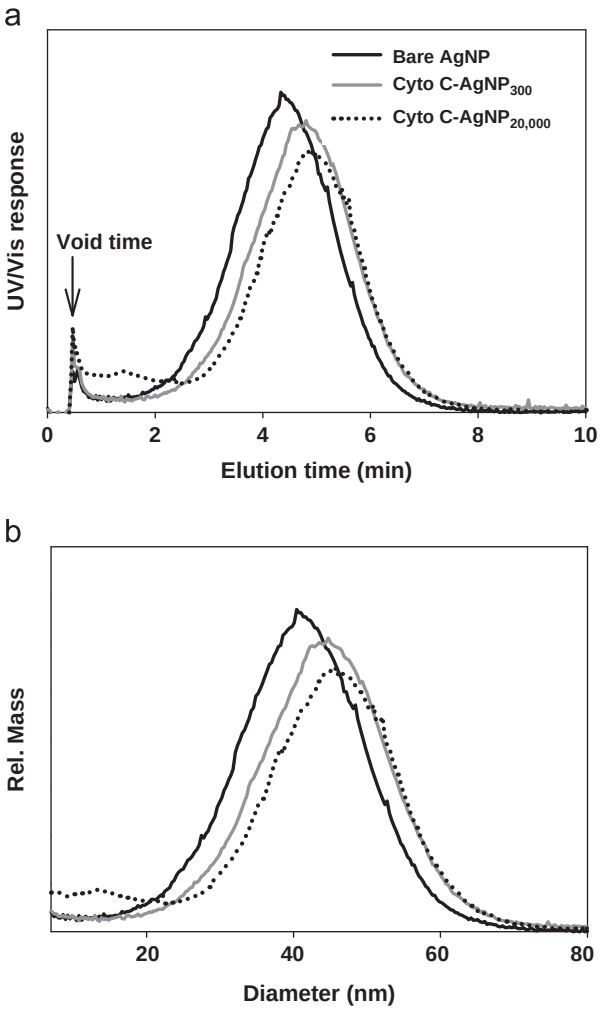

Fig. 2. AsFlFFF fractograms (a) and size distributions (b) of bare AgNPs and Cyto C–AgNP obtained at [Cyto C]/[AgNPs] of 300 and 20,000. The channel and cross-flow rate were 0.49 and 1.05 mL/min, respectively.

and the cross-flow rate were 0.49 and 1.05 mL/min, respectively. As shown in Fig. 2(a), the elution time of AgNPs at peak was increased by about 0.5 min when the particles were treated with Cyto C at [Cyto C]/[AgNPs] of 300 due to an increase in hydrodynamic diameter of the particles. This increase in the elution time of about 0.5 min is translated to an increase in the hydrodynamic diameter of about 4 nm (from 40.4 ± 0.4 to 44.5 ± 0.2 nm) as shown in Fig. 2(b). Each run was repeated 2 or more times.

The size increase of the Cyto C–AgNP was clearly supported by UV-vis spectroscopy, as shown in Fig. 3(a). The maximum absorbance of bare AgNPs appeared at 410 nm, and the full width at half maximum (FWHM) was 77 nm, indicating the particles have a narrow size distribution [36]. When AgNPs was conjugated with the Cyto C at [Cyto C]/[AgNPs] of 300, the UV-vis absorption band was red-shifted to 416 nm, and FWHM increases to 79 nm. It has been reported that the red shift is caused by alteration of the refractive index of AgNPs by the Cyto C layer, resulting particle size increase [11].

Fig. 3(b) shows size distributions of the same two AgNPs obtained from DLS. It can be seen that the hydrodynamic diameter of AgNPs was increased from 47 ± 0.5 to 55 ± 1.1 nm due to adsorption of Cyto C molecules on the AgNPs surface. It is seen that the hydrodynamic diameters from DLS (Fig. 3(b)) are somewhat larger than those from AsFlFFF (Fig. 2(b)) for the same

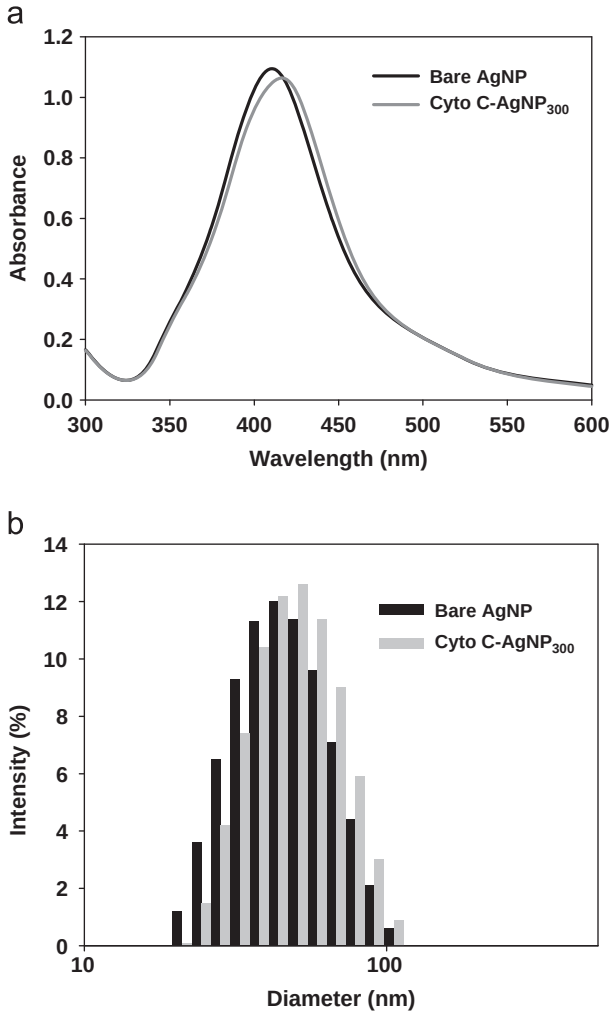

Fig. 3. UV-vis spectra (a) and DLS data (b) of bare AgNPs and Cyto C–AgNP obtained at [Cyto C]/[AgNPs] of 300.

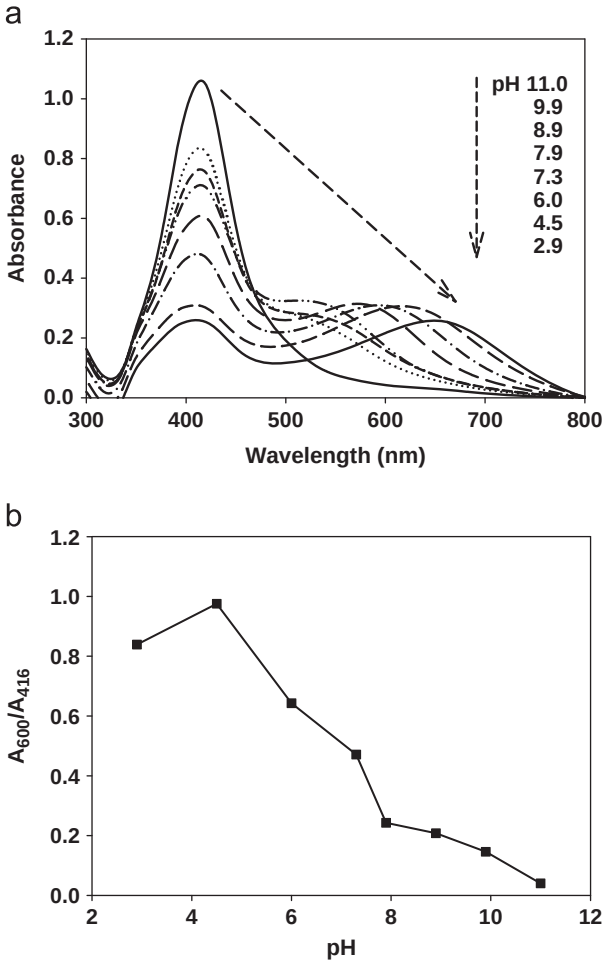

Fig. 4. Variation of UV-vis absorption spectra (a) and absorption ratio (b) of Cyto C–AgNP with pH.

sample. DLS measurements may have been overestimated due to bias toward large particles [37].

As shown in Fig. 2(b), addition of an excess of Cyto C ([Cyto C]/[AgNPs] of 20,000) did not change the particle size significantly as compared to that of Cyto C–AgNP obtained at the molar ratio of 300. This indicates the AgNPs particle surface is already saturated by Cyto C at the molar ratio of 300, and there will exist a large amount of free Cyto C in solution. The earlier eluting band that appears between the void time and about 2 min in Fig. 2(a) corresponds to those free Cyto C and their aggregates. When Cyto C was injected alone at the same condition, it was eluted together with the void peak as expected. At the molar ratio of 300, all (or most) of Cyto C molecules are adsorbed on AgNPs forming a uniform layer on the surface of the particles. On the other hand, at the molar ratio of 20,000, many of free Cyto C molecules are present between particles, resulting in reduction in repulsive force between particles. This may explain why the ζ-potential measured at the molar ratio of 20,000 (-23.6 ± 1.6 mV) was much lower than that measured at 300.

4.3. *Quantification of aggregates in Cyto C–AgNP suspension determined by UV–vis spectroscopy and AsFlFFF*

UV–vis spectroscopy can be employed to characterize bioconjugated nanoparticles in terms of the size, aggregation behavior and the change in refractive index [38]. Fig. 4(a) shows variation of UV–vis spectra of Cyto C–AgNP with pH. As pH decreases from 11.0 to 2.9, the absorbance of the first band (at 416 nm) gradually decreases, and the second band is red shifted from around 520–670 nm. The red shift was observed by the change in color of the suspension from yellow to red and then finally to a grey-blue as aggregation of Cyto C–AgNP proceeds as reported previously [12].

The ratio of the absorbance at 600 nm to that at 416 nm (A_{600}/A_{416}) can be used as a measure of particle aggregation as it will increase proportionally as aggregation increases [11,12]. Fig. 4(b) shows variation of A_{600}/A_{416} with pH, which shows gradual decrease of A_{600}/A_{416} with increasing pH. This indicates aggregation of AgNPs decreases as pH increases.

Fig. 5 shows variation of UV–vis spectra and AsFlFFF fractogram of Cyto C–AgNP with storage time at pH 10. As shown in Fig. 5(a), UV–vis absorbance of Cyto C–AgNP at 416 nm gradually decreases with storage time, while a new band at around 600 grows. This indicates aggregation of Cyto C–AgNP increases with increasing storage time. In order to quantify the aggregation behavior, the particles were analyzed by AsFlFFF as shown in Fig. 6(b). Experimental conditions were same as those in Fig. 2(a), except that the cross-flow was turned off after 10 min to allow complete elution of the aggregates. It can be seen that the area of first peak gradually decreases, while that of the second peak (which corresponds to aggregates) gradually increases with increasing storage time. It seems the Cyto C molecules adsorbed on AgNPs become increasingly unfolded and interact with Cyto C molecules on other

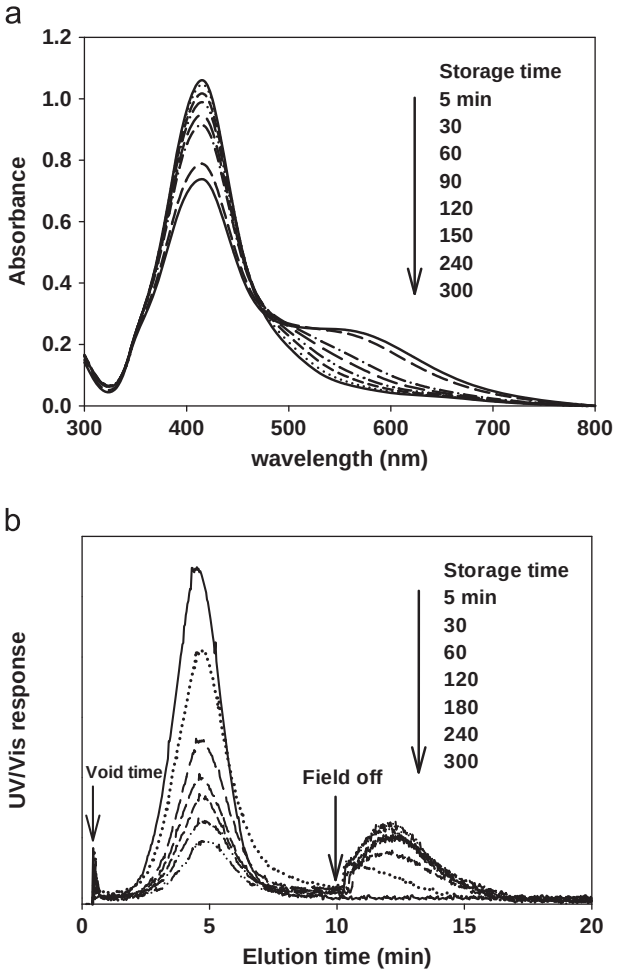

Fig. 5. Variation of UV-vis spectra (a) and AsFlFFF fractogram of Cyto C–AgNP with storage time at pH 10.

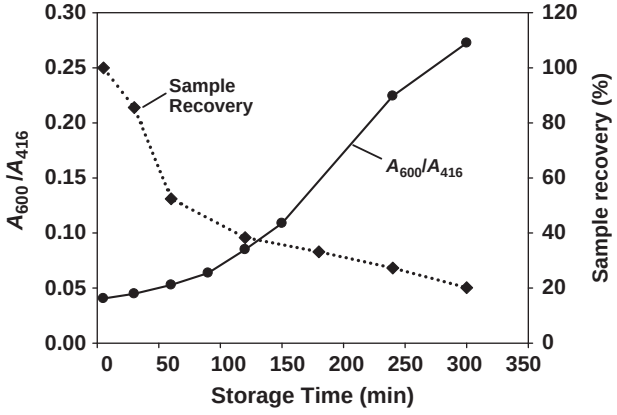

Fig. 6. Variation of UV-vis absorption ratio and sample recovery of Cyto C–AgNP with storage time.

particles that are protonated in the solution with increasing storage time [12,13,39].

Sample recovery R of Cyto C–AgNP in AsFlFFF can be determined by

$$R = \left(\frac{A}{A_o}\right) \times 100\% \quad (4)$$

where A and A_o are the AsFlFFF peak area of unaggregated Cyto C–AgNP in the elution time range of 0–10 min with and without the cross-flow, respectively. The peak area A decreases with increasing storage time, and thus R decreases.

Fig. 6 shows plots of A_{600}/A_{416} of Cyto C–AgNP and the sample recovery, R, in AsFlFFF as a function of storage time. It can be seen that the sample recovery in AsFlFFF decreases rapidly by about 50% after 60 min of storage, and then decreases slowly down by about 20% after 300 min. On the other hand, the absorption ratio slowly increases from about 0.04 to 0.085 after 120 min of storage, and then rapidly increases up to 0.27 after 300 min. It is noted that, while UV/vis spectroscopy provides qualitative information on the existence of aggregation of Cyto C–AgNP in suspension, AsFlFFF provides quantitative information from the sample recovery data.

4.4. Effect of temperature and ionic strength on stability of Cyto C–AgNP in solution

Fig. 7 shows variation of AsFlFFF fractogram of Cyto C–AgNP with storage temperature (Fig. 7(a)) and with the ionic strength of the suspending liquid (Fig. 7(b)) at pH 11. In both Fig. 7(a) and (b), the external field (cross-flow) was turned off after 10 min.

In Fig. 7(a), Cyto C–AgNP suspensions were stored at seven different temperatures of 25, 50, 55, 60, 65, 70, and 80 °C in preheated water bath for 1 h on a horizontal shaker (shaken at 200 cycles/min). At 25 °C, no elution was observed after the external field was turned off as shown in Fig. 7(a), and the sample recovery, R, was determined to be 100% from Eq. (4). As the storage

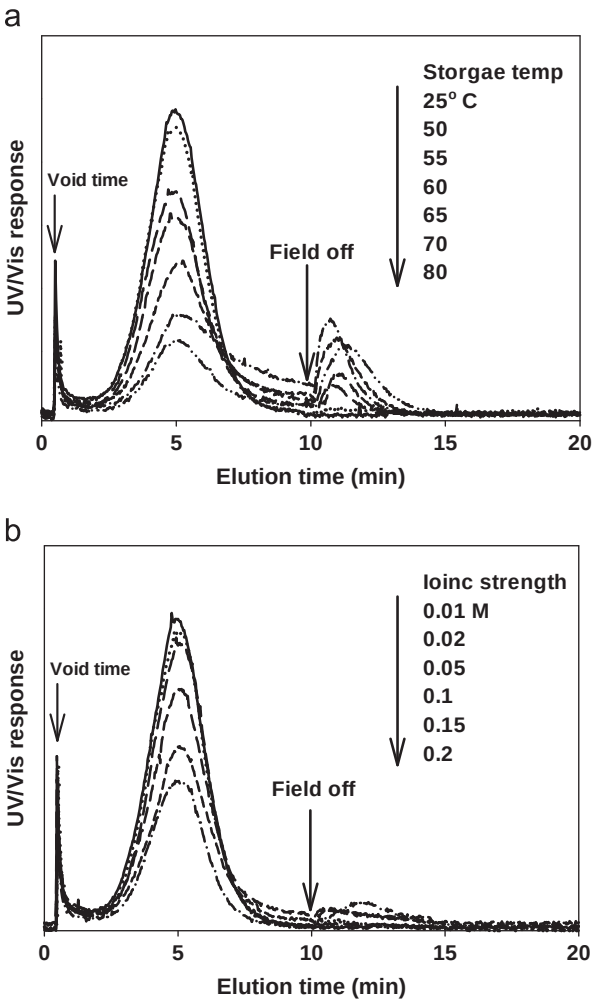

Fig. 7. Variation of AsFlFFF fractogram of Cyto C–AgNP with storage temperature (a) and ionic strength at pH 11.

temperature increases, the peak area decreases gradually, and, at the same time, the elution band area observed after 10 min gradually increases. As mentioned earlier, partially unfolded Cyto C molecules adsorbed on an AgNPs interacts with Cyto C on other AgNPs, and results in aggregation of the AgNPs. Results shown in Fig. 7(a) indicate that higher storage temperature promotes unfolding of Cyto C's, and causes more aggregation of Cyto C–AgNP.

In Fig. 7(b), Cyto C–AgNPs were stored at 25 °C for 1 h in suspension liquids of six different ionic strengths. The ionic strength was adjusted by adding appropriate amount of sodium chloride. It can be seen that, as the ionic strength of the suspension liquid increases, the peak area decreases gradually, and, at the same time, the elution band area observed after 10 min gradually increases. This suggests aggregation of Cyto C–AgNP increases with increasing ionic strength of the suspension liquid. It seems that, as the ionic strength increases, the thickness of the electrical double layer on the surface of the AgNPs decreases, and the electrostatic repulsion between particles decreases, promoting aggregation of the particles.

5. Conclusion

In this study, AsFlFFF was employed to determine the average size and size distribution of AgNPs, and to study the aggregation behavior of Cyto C–AgNP at various conditions of pH, temperature, ionic strength and storage time. Results showed that adsorption of Cyto C on the surface of AgNPs is saturated at the molar ratio ([Cyto C]/[AgNPs]) above about 300, and, from AsFlFFF analysis, the hydrodynamic diameter of the particles increases by about 4 nm.

Results suggest that AsFlFFF is a useful tool not only for the analysis of the size distribution of nanoparticles, but also for quantitative monitoring of aggregation behavior of bioconjugated nanoparticles.

ABSTRACT

Retention behavior of micron-sized particles in gravitational field-flow fractionation (GrFFF) was studied in this study. Effects of ionic strength and flow rate as well as the viscosity of the GrFFF carrier liquid was investigated on the size-based selectivity (S_d), retention ratio (R), and plate height (H) of micron-sized particles using polystyrene latex beads as model particles. It was found that the retention ratio of microparticles increases with increasing flow rate or the viscosity of the carrier liquid as the particles are forced away from the accumulation wall by increased hydrodynamic lift forces (HLF). On the other hand, the retention time increases (retention ratio decreases) with increasing ionic strength of the carrier liquid at the same flow rate, due to decreased repulsive interaction between the particles and the channel accumulation wall (glass in this study) allowing the particles approach closer to the wall. Results suggest the ionic strength of the carrier liquid plays a critical role in determining retention of microparticles in GrFFF as well as the viscosity or the flow rate of the carrier liquid. It was found that the resolution and the separation time could be improved by increasing the carrier viscosity and by carefully adjusting the ionic strength of the carrier liquid.

1. Introduction

Field-flow fractionation (FFF) is a family of elution-based separation techniques that utilize a thin flow channel, where an external field is applied vertically to the direction of the carrier flow [1–3]. The external field forces the particles move across the channel, impelling them to approach the channel accumulation wall [4]. Particles of different sizes are separated as they migrate down the channel at different rates by the channel flow having a parabolic profile [5–7]. FFF is capable of providing separation and characterization of macromolecules and particles which are in sizes from a few nanometers to a few tens of microns [8–10] including blood cells [11–13].

Gravitational field-flow fractionation (GrFFF) is a member of FFF family, and employs the Earth's gravity as the external field. GrFFF is usually applied for separation of micron-sized particles where larger particles are eluted earlier than smaller ones.

In GrFFF, particles are eluted by the "lift-hyperlayer" mode [13–21], where the particles are lifted up from the accumulation wall by the HLF, and, as a result, the particles are focused into a narrow zone ('hyperlayer') at a distance away from the accumulation wall. The hyperlayer is located at the position where the effective particle weight F_G equals HLF. The 'lift-hyperlayer' mode is also called 'focusing' mode.

Various ways of changing the external field force in GrFFF have been suggested [5], which includes changing of the channel angle [10,22], the density of the carrier liquid [6,23], and the carrier viscosity [4,22,23]. In our previous report [22], effect of the carrier viscosity and the channel angle on the retention behavior of microparticles in GrFFF was investigated. It has been reported that the retention in FFF may be affected by the particle-wall and particle-particle interactions (electrostatic repulsion and van der Waals attraction) depending upon the carrier composition (mainly the ionic strength) and experimental conditions (e.g., flow rate, field strength, and channel dimension) [24,25]. This work focuses on the effect of the ionic strength and the flow rate of the carrier liquid. Effect of the ionic strength and flow rate as well as the viscosity of the carrier liquid on various retention (and thus the resolution-related) parameters such as the retention ratio (R), plate height (H), distance of particles from the accumulation wall (δ), size-based selectivity (S_d), and resolution (R_s) was investigated using micron-sized polystyrene (PS) latex beads as model particles. Hydroxypropyl methyl cellulose (HPMC) was added to the carrier liquid to change the viscosity of the carrier liquid without affecting density as in our previous report [22].

2. Theory

2.1. Retention in GrFFF

In GrFFF theory, the retention ratio (R) is given by [7]

$$R = 3\gamma\frac{d}{w} \tag{1}$$

where d is the particle diameter and w is the channel thickness. The γ is the 'steric correction factor' that is known to vary with experimental conditions such as the field strength, carrier flow rate and the particle size [26–28]. As the carrier flow rate increases or the field strength decrease, γ increases [18,29]. Experimentally, R can be measured from

$$R = \frac{t^o}{t_r} \tag{2}$$

where t^o is the channel void time and t_r is the sample retention time. γ can thus be determined from Eq. (1) by measuring R of particles of known diameter using Eq. (2). As suggested by Eqs. (1) and (2), t_r increases as the particle size decreases in GrFFF, providing a size-based separation.

The size-based selectivity (S_d) is the absolute value of the slope of a GrFFF calibration plot ($\log t_r$ *vs.* $\log d$) and is given by [27,30,31]

$$S_d = \left|\frac{d\log t_r}{d\log d}\right| \tag{3}$$

2.2. Near-wall lift force (F_{NW})

The near-wall lift force F_{Nw} is the force exerted on particles in the region near the wall, and is given by [18,26,32]

$$F_{Nw} = 6C\eta u\frac{a^3}{w\delta} \tag{4}$$

where C is an empirical dimensionless coefficient, η is the viscosity of the carrier liquid, u is the average linear flow velocity of the carrier liquid, a is the particle radius, and δ is the closest distance between the particle surface and the channel bottom (accumulation wall). The F_{NW} plays an important role in determining the equilibrium position of a particle in a FFF channel [21]. It can be seen from Eq. (4) that F_{Nw} increases with particle size, flow rate, viscosity of carrier liquid, and with decreasing channel thickness [4,6,20].

At some point, the lift force in Eq. (4) becomes sufficient to counter the gravitational force and result in a particle equilibrium position established above the wall ($\delta > 0$). If the inertial contribution to lift force is negligible, then the net force F_{net} on a particle in the direction away from the wall is given by [22]

$$F_{net} = \frac{6Ca^3\eta\langle\nu\rangle}{w\delta} - F_G \tag{5}$$

where F_G is the force on the particle due to gravity (equal to (4/3) $a^3\Delta\rho G$, where $\Delta\rho$ is the difference between the particle density and fluid density and G is the acceleration due to gravity or 9.81 m/s^2). The particle equilibrium position is given when the net force becomes zero. Rearranging Eq. (5) with $F_{net}=0$ gives:

$$\delta_{eq} = \frac{9}{2}\frac{C\langle\nu\rangle\eta}{\pi w\Delta\rho G} \tag{6}$$

It is noted that that δ_{eq} is independent of the particle size.

Electrostatic repulsion between the negatively charged accumulation wall (glass) and negatively charged particles may also contribute to elevation of the particle zone [33]. Thus the difference between the retention behaviors of the particles in different carrier liquid compositions could be explained by a combination of the hydrodynamic lift forces (HLF) and the electrostatic force [6].

2.3. Plate height (H)

Plate height H is a measure of band broadening, and is usually consisted of several contributing factors including the non-equilibrium effect (H_n), instrumental effect (H_i), sample polydispersity (H_p) and the diffusion of particles (H_D). The total plate height H is thus given by $H = H_n + H_i + H_p + H_D$ [34]. In GrFFF, particles are eluted either by the steric or the lift-hyperlayer mode, and thus it can be assumed that H_n and H_i are similar for particles of different sizes. If the particle polydispersity (and thus H_p) remains same for all samples, the band broadening would be mainly caused by H_D, the diffusion of particles [34,35]. Diffusion increases with decreasing particle size, and thus H is expected to increases as the particle size decreases.

H can be measured from the well-known relationship, $H = L/N$, where L is the GrFFF channel length and N is the number of the theoretical plate that can be obtained from the half peak width ($w_{1/2}$) and the elution volume of the peak (A) by $N = 5.54(A/w_{1/2})^2$ [35].

2.4. Resolution

As a measure of resolution (R_s), a resolution factor R_s* was defined as [34]

$$R_s^* = \frac{S_d}{\sum H} \tag{7}$$

where $\sum H$ is sum of plate height of each particle sample.

3. Experimental

3.1. Materials

Polystyrene (PS) latex beads having nominal diameters of 6, 12, and 20 μm were obtained from Fluka AG (Steinheim, Germany), and 40 μm beads from Duke Scientific (Palo Alto, CA, USA). All PS beads have density of 1.05 g/mL. Two HPMC products (HPMC H-7509 and HPMC H-8384) were obtained from Sigma Aldrich (St. Louis, MO, USA). HPMC-7509 provides higher viscosity than HPMC-8384 at the same concentration. All chemicals were used without further purification. FL-70, a mixture of anionic and non-ionic compounds, was purchased from Fisher Scientific (Fair Lawn, NJ, USA), and sodium azide (NaN_3) were purchased from Sigma-Aldrich (St. Louis, MO, USA).

The PS latex bead samples were diluted with the GrFFF carrier liquid before being injected into the channel. The GrFFF carrier liquid was de-ionized and distilled water having various concentrations of FL-70, sodium azide, and hydroxyl propyl methyl cellulose (HPMC). HPMC was added to adjust the viscosity of the carrier liquid without affecting density of the liquid. Carrier liquids of seventeen different compositions (denoted 'A-1', 'A-2', 'A-3', 'A-4', 'B-1', etc.) were prepared in this study, and are listed in Table 1. The ionic strength is also shown for each carrier liquid. It can be seen that the ionic strengths of the carrier liquids with HPMC added (Carrier liquid-C's and D's) are in a relatively narrow range between 4.28 and 4.32. The viscosity of the carrier liquid was measured with a VIBRO SV-10 viscometer (A&D Company, Tokyo, Japan).

Table 1
GrFFF carrier liquids used in this study.

Carrier liquid	Composition	Viscosity[a] η (cP)	Ionic strength I (mM)
W	Water	1.000	0.0001
A-1	0.05% FL-70	1.023	0.600
A-2	0.1% FL-70	1.033	1.200
A-3	0.2% FL-70	1.027	2.400
A-4	0.3% FL-70	1.033	3.600
B-1	0.1% FL-70+0.01% NaN_3	1.047	2.738

[a] Viscosities of carrier liquids are averages of three measurements.

3.2. Gravitational field-flow fractionation (GrFFF)

The GrFFF channel was cut in a 200 μm-thick spacer. The dimensions of the channel were 2 and 50 cm in width and length, respectively. Particle suspensions were injected directly into the channel using a 50 μL syringe (Hamilton Co., Reno, NV, USA) through a rubber septum. After the injection, the particles were allowed to settle by stopping the channel flow for 3 minutes [4,36]. The sample would be eluted on resumption of the flow. The carrier liquid was pumped by a Young-Lin SP930D HPLC pump (Seoul, Korea). The elution of the particles was monitored by Young-Lin M720 UV detector at the operating wavelength of 254 nm.

4. Result and discussion

4.1. Effect of flow rate

As mentioned earlier, flow rate affects the hydrodynamic lift forces (HLF). GrFFF retention ratios of 40, 20, 12, and 6 μm PS latex beads obtained at various flow rates in carrier liquids of seventeen different compositions are shown in Fig. 1(a), (b), (c), and (d), respectively. As expected, for all samples, R generally increases with increasing flow rate. And R is always higher for larger particles at the same flow rate, showing GrFFF provides size-based separation of particles. Dotted lines in (Fig. 1) represent R values calculated from Eq. (1) with $\gamma = 1$. It can be seen that, as the

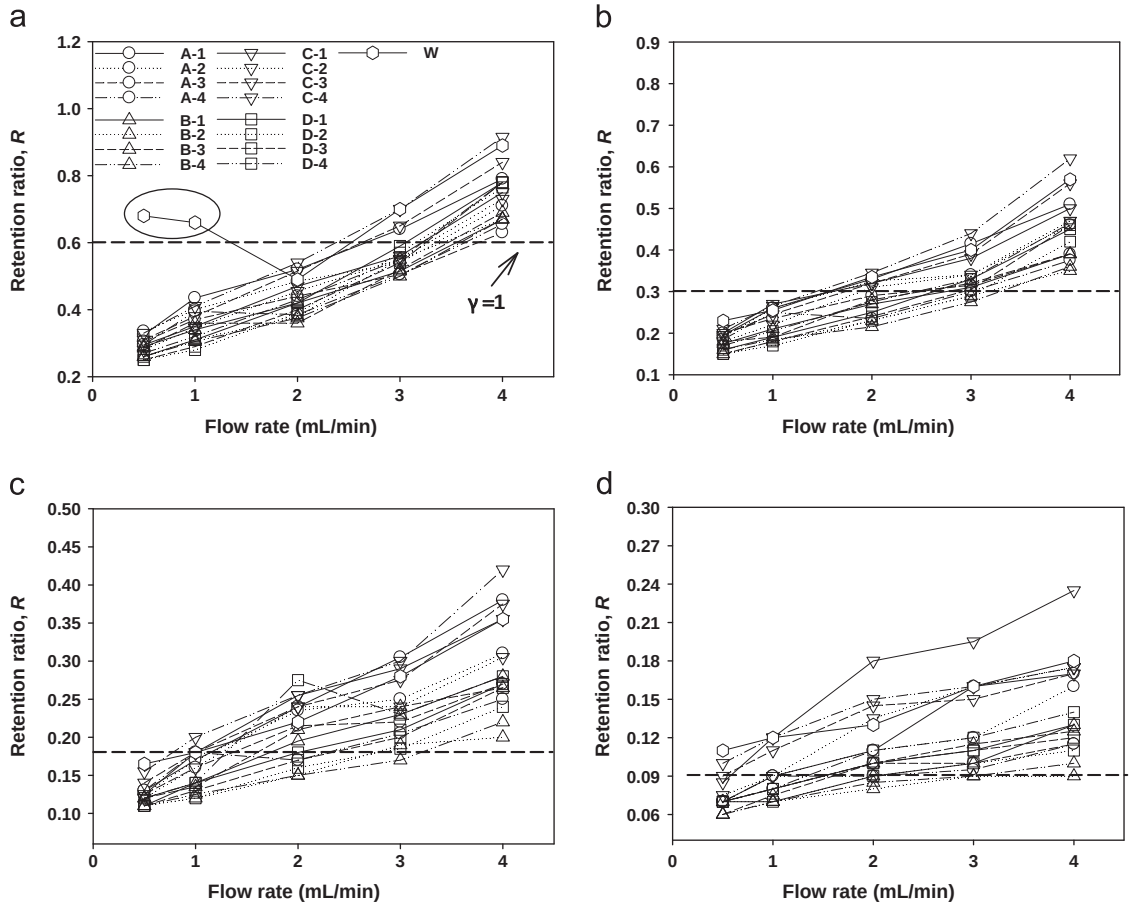

Fig. 1. Effect of flow rate on R of 40 (a), 20 (b), 12 (c) and 6 μm (d) PS beads in GrFFF with various carrier liquid compositions. Dotted lines are for cases of $\gamma = 1$.

Table 2
Effects of channel flow rate on size-based selectivity, S_d, in GrFFF.

Carrier liquid	S_d at flow rate (mL/min) of				
	0.5	1.0	2.0	3.0	4.0
C-1	0.703	0.678	0.629	0.655	0.771
C-2	0.685	0.568	0.505	0.553	0.615
C-3	0.660	0.630	0.670	0.764	0.824
C-4	0.645	0.632	0.685	0.773	0.863

D-2	0.697	0.704	0.772	0.936	1.021
D-3	0.697	0.707	0.758	0.858	0.982
D-4	0.698	0.718	0.682	0.811	0.926

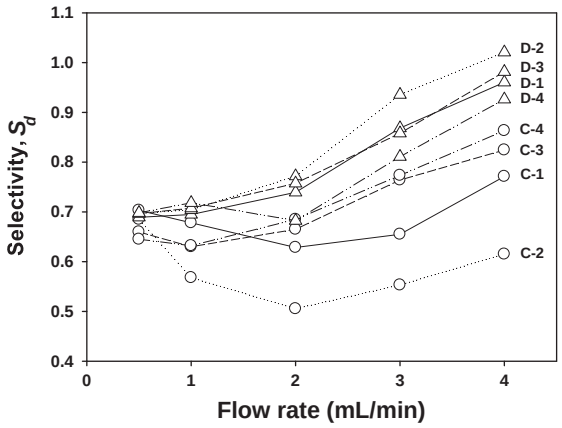

Fig. 2. Effect of flow rate on S_d in GrFFF with various carrier liquid compositions.

flow rate increases, the particles are forced away from the accumulation wall by increased HLF, resulting in a gradual increase in R with the flow rate.

It is noted that, for 40 μm particles with the carrier liquid of pure water (Fig. 1(a)), R does not follow the general trend at the flow rate lower than 2 mL/min (those in circled area), where the R values are much higher than those in other carrier compositions, and decreases as the flow rate increases. At the flow rate higher than 2 mL/min, R follows the general trend (increases with increasing flow rate) again. Those high R's are probably due to electrostatic repulsion between particles and the glass wall (used as the channel accumulation wall) at low ionic strengths. As the flow rate increases, particles are lifted up by stronger HLF, and effect of the electrostatic interaction becomes insignificant. This phenomenon was not observed for smaller particles, suggesting the electrostatic repulsion is insignificant for smaller particles at the same conditions.

The size-based selectivity S_d was determined at various channel flow rates using Eq. (3), and the results obtained with carrier liquids containing HPMC (carrier liquid C's and D's) are listed in Table 2 and Fig. 2. It can be seen that no general trend in S_d with flow rate was observed at the flow rate below about 2 mL/min. At the flow rate above about 2 mL/min, S_d tends to increase as the flow rate increases. It is seen that all S_d's in the carrier liquids with HPMC-7509 (Carrier C's) are lower than those in the carrier liquids with HPMC-8384 (Carrier D's). However no general trends in S_d with the carrier viscosity nor the ionic strength were observed, suggesting that S_d may be determined by a combination of some other factors as well as the carrier viscosity and ionic strength. It is interesting that the highest S_d was obtained with the carrier liquid 'B-2' (water with 0.1% FL-70 and 0.02% NaN_3), which is the carrier composition generally used in FFF.

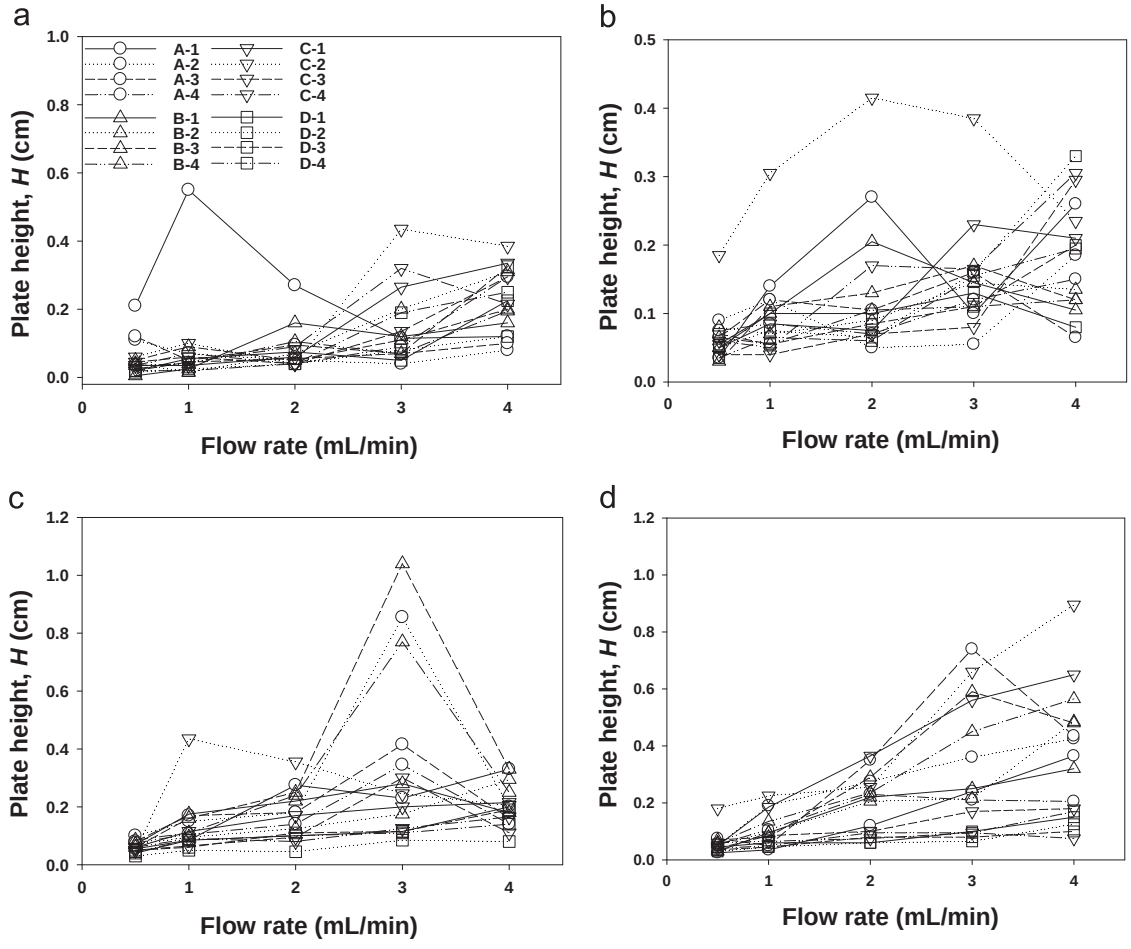

Fig. 3. Effect of flow rate on H for 40 (a), 20 (b), 12 (c) and 6 μm (d) PS beads in GrFFF with various carrier liquid compositions.

Table 3
Effects of ionic strength on retention time of PS latex beads in GrFFF.

Carrier liquid	t_r[a] (min) measured for PS beads having nominal diameter (μm) of			
	6	12	20	40
W	16.00	10.28	7.32	2.83
A-1	21.60	10.90	7.26	4.53

B-4	25.28	14.75	10.10	6.20

[a] Retention time t_r is average of two measurements made at flow rate of 1 mL/min.

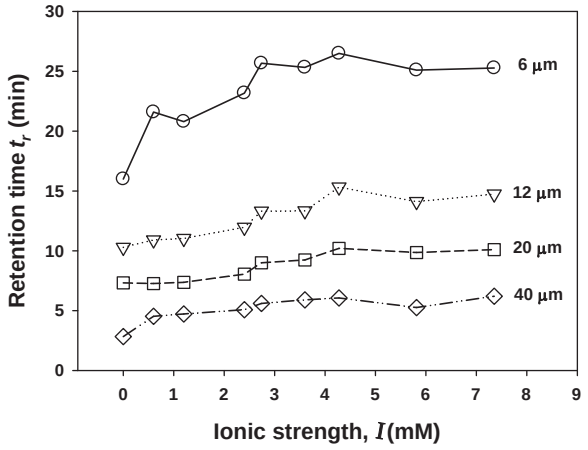

Fig. 4. Effect of ionic strength of carrier liquid on GrFFF retention of 6, 12, 20, and 40 μm latex beads in various carrier liquid compositions. Flow rate was fixed at 1 mL/min.

As shown in Eq. (3), only the retention time difference ($d \log t_r$) is taken into account in S_d calculation. If the degree of band broadening remains constant, higher S_d will result in higher resolution (R_s). Usually the band broadening is measured by the plate height H. Fig. 3 shows plate heights measured at various flow rates for 40, 20, 12 and 6 μm PS beads, respectively, in various carrier compositions. It can be seen that, for the same size particles, H tends to slowly increase as the flow rate increases, which agrees with the results reported previously [12,37].

4.2. Effect of ionic strength

Table 3 shows retention time t_r of PS latex beads measured at the flow rate of 1 mL/min with various carrier liquid compositions. t_r's in Table 3 are averages of two measurements. As shown in Table 3, at all conditions, t_r decreases with increasing diameter as expected (size-based separation). The data shown in Table 3 are plotted in Fig. 4. It can be seen in Fig. 4 that, for each PS bead sample, t_r increases with increasing ionic strength. As mentioned earlier, the retention behaviors of particles in various carrier liquid compositions could be explained by a combination of the lift force and the electrostatic force [6]. At a constant flow rate, the lift forces will be the same for particles for particles of the same size, and the difference in retention time shown in Fig. 4 can only be explained by the difference in the electrostatic interaction.

Effects of ionic strength in FFF have been extensively studied in previous reports [21,25,38]. Usually the repulsive interaction between particles and between particles and the channel wall is

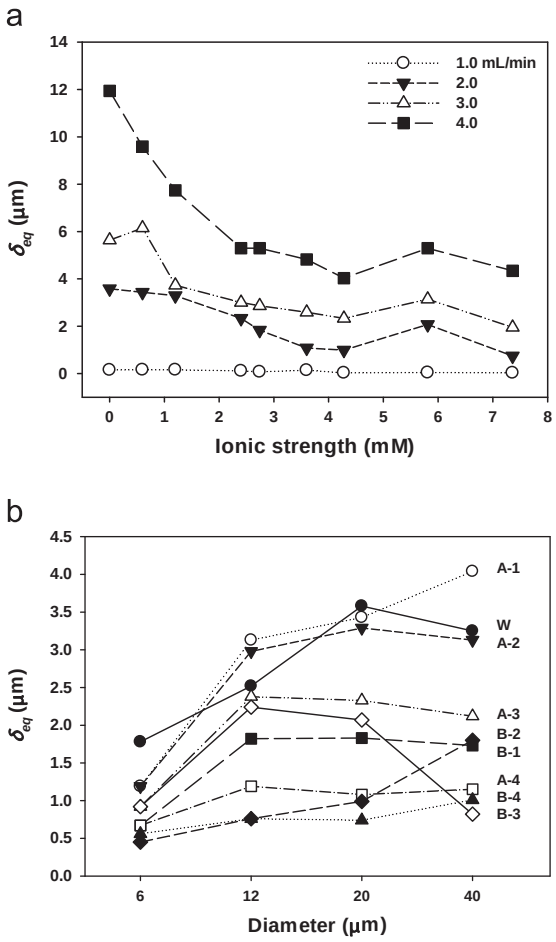

Fig. 5. Effect of ionic strength on δ_{eq} in GrFFF observed at various flow rates for 20 μm PS latex beads (a) and for PS beads of various sizes at 2 mL/min (b).

stronger in pure water than in a solution, and decreases as the ionic strength increases [38] allowing particles approach closer to the channel bottom, which results in increasing retention with increasing ionic strength as shown in Fig. 4. The retention time tends to level off after the ionic strength reaches about 4 mM, and the retention times obtained with the carrier liquids of B-2, 3, and 4 (last three data points for each particle size) are similar. This suggests water with 0.1% FL-70 and 0.02% NaN_3 (Carrier B-2) is appropriate as the carrier liquid for GrFFF separation of PS latex beads (or may be for many other types of particles).

The δ in Eq. (4) is the closest distance between the particle surface and the channel bottom (accumulation wall), and is zero

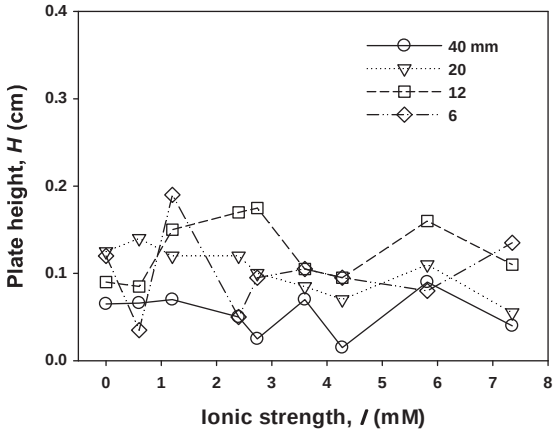

Fig. 6. Effect of ionic strength on plate height for PS latex beads in GrFFF at flow rate of 1 mL/min.

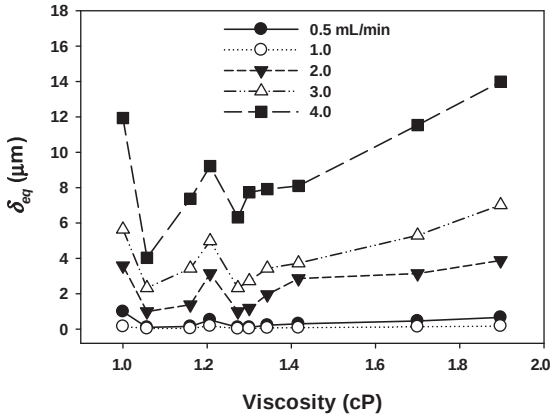

Fig. 8. Effect of viscosity on δ_{eq} of 20 μm PS latex beads in GrFFF at various flow rates.

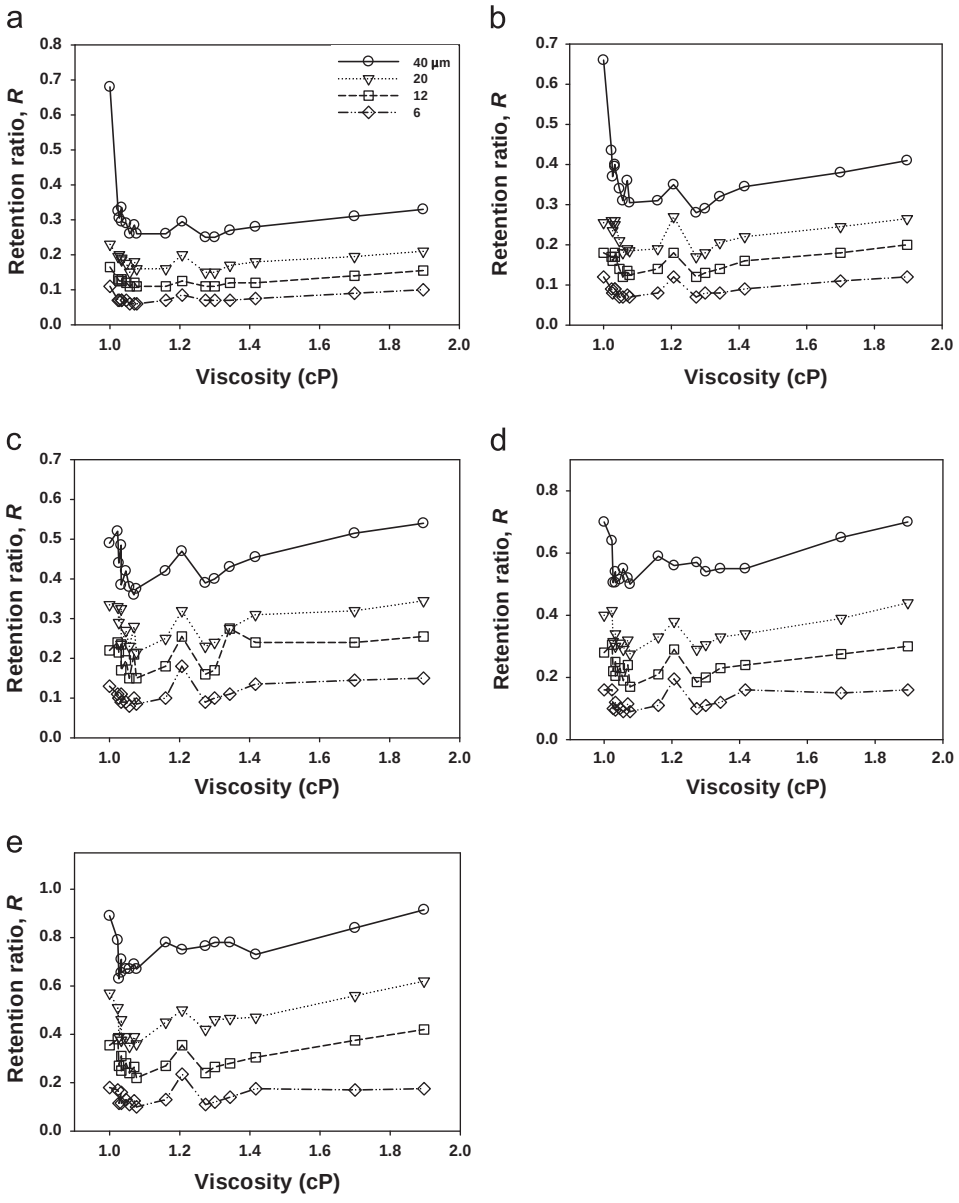

Fig. 7. Effect of viscosity of carrier liquid on retention ratio (R) of PS beads in GrFFF at flow rate of 0.5 (a), 1 (b), 2 (c), 3 (d) and 4 mL/min (e), respectively.

when the particle is on the channel bottom, and will increases as the particle is lifted away from the channel bottom. The δ_{eq} can be determined experimentally for each particle from its retention ratio R. The effect of the ionic strength on δ_{eq} is expected to be the same as that on R (shown in Fig. 4) as R is proportional to δ_{eq}. Fig. 5 (a) and (b) are plots of δ_{eq} vs. ionic strength obtained at various flow rates for 20 μm PS latex beads and for PS beads of various sizes at a fixed flow rate of 2 mL/min, respectively. In Fig. 5(a), at the same flow rate, δ_{eq} decreases as the ionic strength increases due to reduced repulsive interaction between particles and the channel bottom, and then levels off. It can be seen that, unlike at higher flow rates, the changes in δ_{eq} with ionic strength at lower flow rates (0.5 and 1 mL/min) are insignificant, and δ_{eq} stays close to 0, suggesting particles stay close to the channel bottom due to relatively lower (or insignificant) lift force. The lift force increases with increasing flow rate, and it seems higher lift force multiply the influence of the ionic strength on δ_{eq}. It can also be seen in Fig. 5(a) that, at the same ionic strength, δ_{eq} increases as the flow rate increases due to increased lift forces. In Fig. 5(b), δ_{eq} is plotted against particle diameter, and no general trend in δ_{eq} with particle diameter was observed as expected from Eq. (6).

Fig. 6 shows effect of ionic strength on plate height, H, for PS latex beads of various sizes. No general trend in H with ionic strength was observed. It seems there is no correlation between H and the ionic strength of the carrier liquid in the tested range.

4.3. Effect of viscosity

In accordance with Eq. (4), lift force increases with increasing viscosity of the carrier liquid, and thus the retention ratio is also expected to increases. Fig. 7 shows the effect of the carrier viscosity on retention ratio of PS latex beads at various flow rates. It can be seen that, at all flow rates, the retention ratio generally increases with increasing carrier viscosity, as expected. At the carrier viscosity near 1, retention ratios are high due to repulsive interaction between particles and the channel bottom as mentioned earlier. Fig. 8 shows δ_{eq} determined for 20 μm PS latex beads from the data in Fig. 7. As expected, δ_{eq} tends to increase with the carrier viscosity at relatively higher range of the carrier viscosity. Fig. 9 shows again that there is no general trend in H with the carrier viscosity.

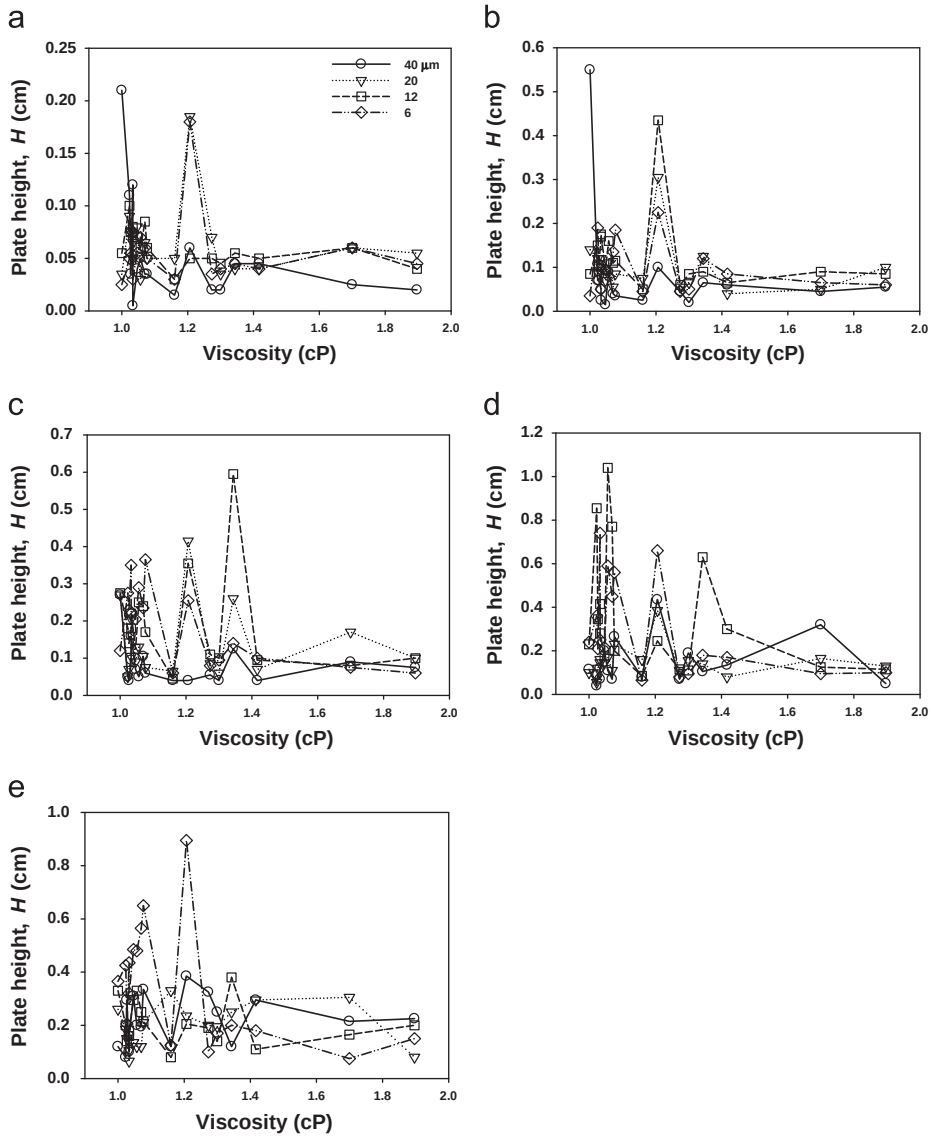

Fig. 9. Effect of viscosity of carrier liquid on plate height (H) of PS beads in GrFFF at flow rate of 0.5 (a), 1 (b), 2 (c), 3 (d) and 4 mL/min (e), respectively.

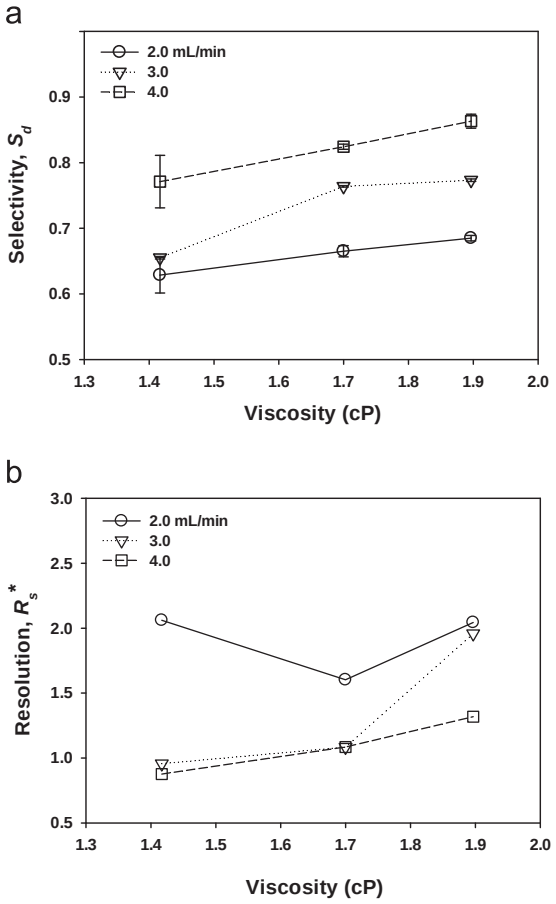

Fig. 10. Effect of viscosity on selectivity (S_d) and resolution (R_s^*) of PS latex beads in GrFFF observed at various flow rates.

Fig. 10(a) and (b) show effects of the carrier viscosity on selectivity (S_d) and resolution (R_s^*), respectively. As shown in Fig. 10(a), the selectivity increases with increasing viscosity of the carrier liquid in the flow rate range of 2–4 mL/min. At flow rates lower than 2 mL/min, the trend was not clear (data are not shown). In Fig. 10(b), the resolution (calculated from Eq. (7)) also increases with increasing carrier viscosity at relatively higher range of the carrier viscosity. From Figs. 9 and 10, it can be concluded that improved resolution with increasing viscosity observed in this study is caused mainly by the improvement in selectivity with the carrier viscosity (not by the plate height).

5. Conclusion

Retention behavior of microparticles in gravitational field-flow fractionation (GrFFF) was studied in this study. It seems the ionic strength of the carrier liquid plays a critical role in determining the size-based selectivity, retention ratio, and plate height, thus the resolution of microparticles in GrFFF as well as the viscosity or the flow rate of the carrier liquid. The repulsive interaction between particles and between particles and the channel wall decreases as the ionic strength increases, allowing particles approach closer to the channel bottom, which results in increasing retention with increasing ionic strength. Results suggest that the resolution and the separation time could be improved in GrFFF by increasing the viscosity and by carefully adjusting the ionic strength of the carrier liquid.

Talanta

The International Journal of Pure and Applied Analytical Chemistry

Aims & Scope

Talanta provides a forum for the publication of original research papers, preliminary communications, and critical reviews in all branches of pure and applied analytical chemistry. Papers are evaluated based on established guidelines, including the fundamental nature of the study, scientific novelty, substantial improvement or advantage over existing technology or methods, and demonstrated analytical applicability. Original research papers on fundamental studies, and novel sensor and instrumentation development, are especially encouraged. Novel or improved applications in areas such as clinical and biological chemistry, environmental analysis, geochemistry, and materials science and engineering are welcome.

Analytical performance of methods should be determined, including interference and matrix effects, and methods should be validated by comparison with a standard method, or analysis of a certified reference material. The developed method should especially comprise information on selectivity, sensitivity, detection limits, accuracy, and reliability. However, applying official validation or robustness studies to a routine method or technique does not necessarily constitute novelty. Proper statistical treatment of the data should be provided. Relevant literature should be cited, including related publications by the authors, and authors should discuss how their proposed methodology compares with previously reported methods.

Since classical spectrophotometric measurements and applications (including derivative spectrophometry), fluorimetry, solvent extraction, titrimetry, chemometrics, etc. are well established and are considered routine analytical methods, studies in such areas should demonstrate a unique and substantial advantage over presently known systems. New reagents or systems should demonstrate clear advantage, and their presentation should be comprehensive rather than generating a series of similar papers for several analytes or similar reagents. Modifications of reagents should demonstrate significant improvements. Obvious application of known chemistries or methods to established instrumental techniques are discouraged.

Application of established analytical approaches to relatively simple matrices having no major interferences, such as pharmaceutical preparations, are discouraged unless considerable improvements over other methods in the literature are demonstrated. Papers dealing with analytical data such as stability constants, pK_a values, etc. should be submitted to more specific journals, unless novel analytical methodology is demonstrated, or important analytical data are provided which could be useful in the development of analytical procedures.
