ABSTRACT

In order to assess the utility of a recently developed capillary electrophoresis–mass spectrometry (CE–MS) method for the study of anionic metabolites in urine, a comparison was made with hydrophilic interaction chromatography–MS (HILIC–MS) using negative electrospray ionization. After optimization of the HILIC conditions, a gradient employing 10 mM ammonium acetate (pH 6.8) in acetonitrile–water (5 min 90% acetonitrile followed by 90%–50% acetonitrile in 10 min) was selected, providing baseline separation of five representative anionic test metabolites. Relative standard deviations (RSDs) for HILIC retention times and peak areas were below 0.2% and 7.7%, respectively, and detection limits were in the range 0.04–2.21 μM. Metabolites in rat urine could also be analysed in a reproducible way with retention time and peak area RSDs below 0.6% and 13.6%, respectively. The CE–MS and HILIC–MS methods were compared in terms of reproducibility, sensitivity, selectivity and coverage of the anionic urinary metabolome. In general, peak area RSDs were similar whereas HILIC–MS yielded better retention-time repeatability and up to 80 times lower detection limits (expressed in injected concentration) for test metabolites as compared to CE–MS. Rat urine analysis by HILIC–MS provided detection of 1360 molecular features compared to 347 molecular features revealed with CE–MS. Of these, a number of 144 molecular features were found with both HILIC–MS and CE–MS, which showed on average 10 times higher peak areas in HILIC–MS. The HILIC retention and CE migration times of the common features were clearly not correlated. The HILIC and CE behavior of the test metabolites and 16 putatively identified common features were evaluated involving their physicochemical properties, indicating a markedly different separation selectivity, and thus significant degree of orthogonality of HILIC and CE.

1. Introduction

Elucidation and understanding of biochemical pathways require accurate and specific determination of metabolite levels in biofluids and tissues. Metabolites may exhibit very diverse physicochemical properties and can be present in a wide range of concentrations [1]. Capillary electrophoresis (CE) coupled to mass spectrometry (MS) is particularly suitable for the direct profiling of highly polar and charged metabolites as predominantly present in urine. CE can provide efficient separation of metabolites based on their charge-to-size ratios without the need for analyte derivatization [2]. Recently, we have developed a CE–MS method for the profiling of anionic metabolites applying triethylamine in the background electrolyte (BGE) and sheath liquid [3]. This new method provided significantly higher signal intensities as compared to other CE–MS methods in negative ionization mode. Urine samples from antibiotic-treated rats and control rats could be distinguished, and potential biomarkers were revealed [4]. Having this new method available, the question arises to what extent CE–MS can provide complementary information on the anionic metabolome with respect to more common liquid chromatographic (LC) techniques for metabolic profiling.

LC–MS can provide information on the quantity of low-abundant metabolites without the need for analyte derivatization. Common reversed-phase (RP) LC, however, is less suited for the analysis of highly polar compounds, and for small charged

compounds, ion-pairing agents are frequently used to increase their retention [5]. Unfortunately, ion-pairing agents can cause substantial ionization suppression of compounds in MS and source contamination. Hydrophilic interaction chromatography (HILIC) allows profiling of polar compounds, providing complementary information to RPLC, as has been demonstrated by numerous metabolomics studies [6–19]. HILIC utilizes a highly organic mobile phase (often acetonitrile) containing water in combination with a polar stationary phase. Analyte separation is based on partitioning between the mobile phase and a layer of adsorbed water molecules on the stationary phase as well as electrostatic interactions with polar groups on the stationary phase [20–22]. Hence, in order to appreciate the utility of CE–MS for profiling of anionic metabolites, comparison with HILIC–MS seems indicated.

So far, only a few studies have been conducted in which both CE–MS and HILIC–MS were used for comparative and comprehensive profiling [17,23–26]. Sugimoto *et al.* applied HILIC–MS and CE–MS to analyse edamame and Japanese sake [23,24]. However, as HILIC–MS was used to profile sugars only, no conclusions could be drawn on the complementarity of HILIC–MS and CE–MS for untargeted metabolite profiling. Büscher and colleagues extensively compared CE, LC and gas chromatography (GC) methodologies, all in combination with MS [25]. Metabolites were analysed with GC–MS after two different derivatization procedures. Ion-pair RPLC and HILIC were used as LC separation modes and two CE–MS methods were employed for the analysis of cationic and anionic metabolites. A mixture of 91 test metabolites representing central carbon and energy metabolism was used for comparison. Of these test metabolites, 33 compounds could be detected by all three platforms. CE and LC showed the greatest overlap in metabolite coverage (26 compounds) and each analytical technique was capable to measure two compounds which could not be detected with the two other methodologies. The CE–MS, LC–MS and GC–MS methodologies were considered in general, that is, GC, HILIC, ion-pair RPLC and cationic and anionic CE methods were not individually compared. Moreover, the evaluation of the complementarity of the techniques for metabolic profiling was limited since it was based on a confined number of test metabolites in standard solutions [25]. Ibáñez and coworkers studied the effect of dietary polyphenols on the proliferation of colon cancer cells with CE–MS, HILIC–MS and RPLC–MS [26]. Saric *et al.* used the same techniques to analyse the metabolome of the *Fasciola hepatica* worm [17]. In both studies, a small part of the detected metabolite features was identified. There was no or a limited overlap of identified metabolites detected by CE–MS, HILIC–MS and RPLC–MS, indicating the potential complementarity of the analytical techniques [17,26]. It should be noted, however, that Ibáñez *et al.* as well as Saric *et al.* employed positive electrospray ionization (ESI) for HILIC–MS and/or CE–MS, and thus could only compare the methodologies based on detected cationogenic compounds. Still, a significant number of urinary metabolites is acidic and can only be detected using negative ESI. Therefore, in order to achieve comprehensive profiling and to evaluate the complementarity of HILIC–MS and CE–MS, particular attention should also be paid to anionic metabolites.

In the present study, we compared a previously optimized CE–MS method with HILIC–MS for anionic metabolic profiling of urine samples. We first optimized a HILIC–MS method by carrying out infusion experiments to determine and evaluate the effect of different HILIC mobile phase compositions on the signal intensities of representative anionic test metabolites. An efficient gradient HILIC–MS method applying an acetonitrile–water mobile phase containing ammonium acetate was developed and the performance was assessed in terms of sensitivity, linearity and repeatabilities of peak area and retention time. Furthermore, HILIC–MS was applied to urine analysis and the number of detected molecular features of urine components was determined. Outcomes were extensively compared with results obtained with the earlier developed CE–MS method for anionic urinary profiling [3,4]. Numbers of common and unique urinary molecular features were considered and MS responses of common features were compared. Moreover, differences in separation selectivity of CE–MS and HILIC–MS were assessed by comparing migration and retention times of test metabolites as well as putatively identified common features.

2. Materials and methods

2.1. Chemicals

Acetic acid, ammonium formate, ammonium hydroxide (25% solution), acetonitrile, formic acid, methanol, glutaric acid, hippuric acid, DL-pyroglutamic acid and uridine were obtained from Fluka (Steinheim, Germany). Sodium hydroxide and L-proline were purchased from Sigma Aldrich (Steinheim, Germany). Triethylamine was from Fisher Scientific (Loughborough, UK), piperidine was from Alfa Aesar (Karlsruhe, Germany) and ammonium acetate was supplied by Merck (Darmstadt, Germany). Water was deionized and purified with a Milli-Q purification system (Millipore, Bedford, USA) prior to use.

2.2. Test mixture and rat urine sample

Stock solutions (50 mM) of the metabolites glutaric acid, hippuric acid, proline, pyroglutamic acid and uridine were prepared in deionized water. Stock solutions of the metabolites were mixed and diluted to obtain a test mixture in which each metabolite was present at the appropriate concentration (0.25–80 μM). Test metabolite mixtures were prepared in water–acetonitrile (1:4, v/v) and water for HILIC–MS and CE–MS analyses, respectively.

A mixture of aliquots of rat urine samples provided by AstraZeneca (Department of Drug Metabolism and Pharmacokinetics, Macclesfield, UK) [27] was prepared and stored at −80 °C. Prior to analysis, the urine sample was thawed. For HILIC–MS, urine was diluted with acetonitrile in a proportion of 1:4 (v/v) and centrifuged at 10,000 rcf for 10 min in order to attain proper metabolite peak shapes (see Section 3.1). When analysed with CE–MS, dilution of urine with BGE in a proportion of 1:1 (v/v) was sufficient to achieve good CE performance [3,4].

2.3. HILIC–MS

All samples were analysed on an LC system (Shimadzu, Kyoto, Japan) coupled online via an electrospray interface to a time-of-flight (TOF) mass spectrometer (micrOTOF, Bruker Daltonics, Bremen, Germany) using a Waters XBridge™ Amide column (3.5 μm, 3.0 × 100 mm).

In the optimized HILIC–MS method, the test metabolite mixture and urine sample (5 μL; approximately 1.5% of column volume) were injected and analysed under gradient elution with mixing solvent A (10 mM ammonium acetate in water–acetonitrile (1:1, v/v)) and solvent B (10 mM ammonium acetate in water–acetonitrile (1:9, v/v)) in varying ratios at an overall flow rate of 0.5 mL/min. The gradient scheme was as follows: 0.0–5.0 min, 100% B; 5.0–15.0 min, from 100% B to 100% A; 15.0–20.0 min, 100% A; 20.1–30.0 min, 100% B. Column temperature was 45 °C during separation.

Optimal signal intensities for test metabolites were obtained using the following interface conditions: dry gas temperature, 180 °C; dry gas flow, 4 L/min, nebulizer pressure, 50 psi; ESI voltage, 2 kV. Data were acquired in negative ionization mode in the mass range *m/z* 50–800 with a repetition rate of 1 Hz.

Recorded mass spectra were internally calibrated using sodium acetate clusters which were detected within every run.

2.4. CE–MS

The CE–MS experiments were performed and described before [3,4]. Briefly, CE–MS was carried out on a Beckman P/ACE MDQ instrument (Beckman Coulter, Fullerton, USA) coupled to a micrOTOF mass spectrometer using a sheath-liquid electrospray interface from Agilent Technologies (Waldbronn, Germany). A BGE of 25 mM triethylamine (pH 11.7) and a sheath liquid of 5 mM triethylamine in water–methanol (1:1, v/v) were used. Fused-silica capillaries (Polymicro Technologies, Phoenix, USA) had a total length of 100 cm and an internal diameter of 50 μm. Hydrodynamic injections were performed using a pressure of 0.5 psi for 30 s (16 nL; approximately 0.8% of capillary volume). The separation voltage was 30 kV and the capillary temperature was set at 20 °C. The sheath liquid was delivered with a flow rate of 5 μL/min by a 10 mL gas-tight syringe of Hamilton (Reno, USA) using a syringe pump (KD Scientific, Holliston, USA). The following optimized CE–MS interface conditions were applied: dry gas temperature, 180 °C; dry gas flow, 4 L/min; nebulizer pressure, 10 psi; ESI voltage, 4 kV. The negative ionization mode was used and data were acquired in the mass range 50–800 *m/z* with a rate of 1 Hz. Sodium formate clusters were used for internal calibration.

2.5. Data analysis

Data were processed using the DataAnalysis software of Bruker Daltonics. Using the 'Find Molecular Features' function of this software, the number of molecular features obtained during urine analysis was determined. A molecular feature was defined as the unique combination of an *m/z* value and retention time (HILIC–MS) or migration time (CE–MS), present in ten consecutive MS spectra with a signal-to-noise ratio of at least three. Peak areas and peak heights of metabolites were assessed using extracted-ion chromatograms (HILIC–MS) or electropherograms (CE–MS).

3. Results and discussion

3.1. HILIC–MS method

For the optimization of the HILIC–MS method for anionic metabolic profiling, the composition of the mobile phase was studied. Ammonium acetate, sometimes in combination with acetic or formic acid, is often used as mobile phase additive in HILIC–MS for urinary metabolic profiling studies [28]. In a previous CE–MS study, we found triethylamine and piperidine to be more favourable salts with respect to attainable signal intensities for anionic metabolites [3]. Infusion experiments were performed to study the influence of several mobile phase additives on signal intensities of the test metabolites glutaric acid, hippuric acid, proline, pyroglutamic acid and uridine. These metabolites represent the diverse compound classes present in urine. The metabolites (100 μM each) were dissolved in acetonitrile–water (1:1, v/v) with and without 10 mM ammonium acetate, 10 mM ammonium formate, 0.1% formic acid, 0.1% triethylamine or 0.1% piperidine. Using ammonium formate and formic acid, test metabolite signals were lower as obtained with ammonium acetate. With triethylamine, the signal intensities of the tested metabolites were on average 6.5 times higher compared to ammonium acetate. Similar results were obtained using piperidine with 6.3 times higher signals. However, the use of triethylamine and piperidine as mobile phase additives in HILIC–MS resulted in reduced retention times (too fast elution) and broad and asymmetric peaks. Overall this led to reduced plate numbers and poor metabolite resolution. Furthermore, proline and pyroglutamic acid could not be detected. Therefore, ammonium acetate was selected and the influence of its concentration (0–10 mM) in a mobile phase of acetonitrile–water was further evaluated. The separation, peak shapes and signal intensities of the five test metabolites obtained with HILIC–MS were taken into consideration. A concentration of 10 mM ammonium acetate in the eluent yielded more symmetric and narrow peaks as compared to 0 and 5 mM ammonium acetate. This was especially apparent for the compounds uridine and hippuric acid of which the peak widths were about 40% smaller at 10 mM ammonium acetate. Furthermore, only at 10 mM ammonium acetate, baseline separation of proline and pyroglutamic acid was achieved. Still, the increase of ammonium acetate concentration from 0 to 10 mM resulted in up to 59% lower signal intensities, except for proline which showed a remarkable signal increase of 67%. Adjusting the pH of the mobile phase to 9.0 with ammonium hydroxide did not affect the separation of the test metabolites, but decreased their signal intensities up to 60% as compared to pH 6.8 (not adjusted) due to ion suppression.

The acetonitrile–water gradient of the mobile phase containing 10 mM ammonium acetate (pH 6.8) was optimized to obtain a large separation window without deteriorating the peak shape and detection limits (LODs) of metabolites. A high percentage of acetonitrile in the mobile phase at the start of the analysis is desirable in order to maximize the separation of metabolites. Therefore, the start of the gradient was set at 90% acetonitrile and held at 90% for 5 min to enhance the separation of metabolites eluting in the beginning of the chromatogram. Then, the percentage acetonitrile was gradually decreased to 50% and different slopes of the gradient were tested to maximize peak separation and minimize the peak widths. A gradient of 4% acetonitrile per min appeared to be optimum by providing the best resolution of metabolite peaks within a relatively short analysis time. The mobile phase was held at 50% acetonitrile for another 5 min in order to elute all compounds from the column. Thereafter, the percentage acetonitrile in the mobile phase was switched back to 90% and hold for 10 min to allow reequilibration of the HILIC–MS system.

Because of the high percentage of acetonitrile at the start of the gradient, the sample injection solvent had to contain a large amount of acetonitrile to prevent peak splitting and to achieve narrow and symmetric peaks. The maximum allowable acetonitrile percentage in the sample is, however, limited by the solubility of polar and charged compounds. More than 80% acetonitrile in the sample solvent resulted in precipitation of metabolites. Moreover, dilution of the sample with acetonitrile will reduce the concentration sensitivity. Using a sample injection volume of 5 μL containing 80% acetonitrile in combination with a gradient starting at 90% acetonitrile resulted in narrow and symmetric peaks. Injection volumes of 7.5 μL and larger, or a gradient starting at 95% acetonitrile, gave deformed and splitted peaks.

The optimized HILIC-MS method comprised gradient elution employing 10 mM ammonium acetate (pH 6.8) in acetonitrile–water, an injection solvent containing 80% acetonitrile and an injection volume of 5 μL.

3.2. Comparison of CE–MS and HILIC–MS

3.2.1. Reproducibility, sensitivity and metabolite coverage

Using the optimized HILIC–MS method, the test metabolites were baseline separated with retention times ranging from 3.1 to 13.5 min (Fig. 1). The retention times were highly reproducible for all metabolites with relative standard deviations (RSDs) below 0.2%. Also peak area repeatability was acceptable with RSD values below 8% for ten consecutive measurements (Table 1). Mixtures of

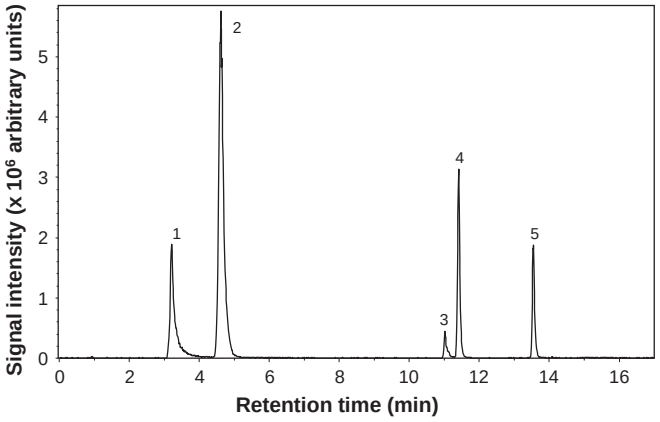

Fig. 1. Multiple extracted-ion chromatogram obtained during HILIC–MS of a test metabolite mixture (50 μM each). Metabolites: 1. uridine (*m/z* 243.06); 2. hippuric acid (*m/z* 178.05); 3. proline (*m/z* 114.06); 4. pyroglutamic acid (*m/z* 128.04); 5. glutaric acid (*m/z* 131.04). Gradient elution with (a) 10 mM ammonium acetate in water–acetonitrile (1:1, v/v) and (b) 10 mM ammonium acetate in water–acetonitrile (1:9, v/v): 0–5 min, 100% b; 5–15 min, from 100% b to 100% a; 15–20 min, 100% a. See Section 2 for other experimental conditions.

Table 1
Retention/migration time and peak area repeatability (RSD (%), n = 10) for five test metabolites analysed using HILIC–MS and CE–MS.

Compound	Retention/migration time		Peak area	
	HILIC–MS	*CE–MS*	*HILIC–MS*	*CE–MS*
Glutaric acid	0.03	0.33	7.70	10.83
Hippuric acid	0.13	0.38	5.26	6.57
Proline	0.03	0.34	2.42	6.08
Pyroglutamic acid	0.04	0.42	6.14	7.25
Uridine	0.16	0.36	4.56	3.97

the five test metabolites in the concentration range 0.25–80 μM were analysed to determine the linearity of the method. For all compounds, a good linearity was observed with coefficients of determination (R^2) above 0.99. LODs (signal-to-noise ratio of 3) for the test metabolites were in the range 0.04–2.21 μM (Table 2).

The anionic test metabolites have previously been analysed with an optimized CE–MS method employing a triethylamine-containing BGE and sheath liquid [3]. In CE–MS, all metabolites were baseline separated with migration times from 7.0 to 17.5 min. RSDs for elution/migration time of the test compounds were lower with HILIC–MS, but repeatability for peak areas was similar for most metabolites (Table 1). Using CE–MS, detection limits for the five test metabolites ranged from 0.92 to 9.08 μM [3]. Thus, the LODs obtained with HILIC–MS were up to 80 times lower for these compounds (Table 2). Most likely, this can be explained by the larger sample injection volume employed in HILIC (5 μL) as compared to CE (16 nL). The injection volumes relative to capillary and column volume are approximately 0.8% and 1.5%, respectively. Notably, the sensitivity difference is not as severe as supposed from the difference in injection volume (factor 300) only. Furthermore, the ionization efficiencies of the test metabolites may be relatively higher under the applied CE–MS conditions. The observed difference in signal-to-noise ratios between HILIC–MS and CE–MS was not the same in magnitude for each test metabolite. Noise levels varied extensively throughout the HILIC chromatograms and CE electropherograms. Furthermore, ionization conditions in HILIC–MS vary due to the gradient elution leading to different ionization efficiencies.

In order to examine the applicability of the optimized HILIC–MS and CE–MS method for the analysis of biological samples, a rat urine sample was repetitively analysed. Notably, in CE–MS urine samples were diluted with BGE in a proportion of 1:1 (v/v), whereas for HILIC–MS a dilution of 1:4 (v/v) with acetonitrile was required for proper HILIC separation. Based on the analysis of rat urine, the CE–MS and the HILIC–MS method were compared in terms of number of observed molecular features, analyte elution/migration order and repeatability. The base-peak chromatograms and electropherograms obtained with the optimum HILIC–MS and CE–MS method showed large numbers of peaks, which were widely spread over the elution/migration time window (Figs. 2A and C). Overall, the absolute signal intensities were higher with HILIC–MS. HILIC–MS provided almost four times more molecular features than CE–MS (1360 vs. 347 features). Five molecular features, which were detected with both systems (same *m/z* value) and which were spread over the elution/migration window (Figs. 2B and 2D), were selected to assess repeatability. Ten consecutive measurements of the urine sample showed that the elution time repeatabilities of these urine metabolites were better for HILIC–MS (0.17-0.55%) with respect to CE–MS (5.93–11.8%), whereas peak area repeatabilities were similar (Table 3). As demonstrated before [4], CE–MS migration time repeatability for the rat urine components could be reduced to $< 0.4\%$ by applying a proper alignment procedure.

Table 2
Limits of detection (μM) for five test metabolites applying HILIC–MS and CE–MS.

Compound	HILIC–MS	CE–MS[a]	Factor difference
Glutaric acid	0.75	9.08	12.1
Hippuric acid	0.05	0.92	18.4
Proline	2.21	3.99	1.8
Pyroglutamic acid	0.04	3.21	80.3
Uridine	0.06	1.61	26.8

Test metabolites were dissolved in acetonitrile-water (4:1, v/v) and water using HILIC–MS and CE–MS, respectively

[a] Previously reported by Kok *et al.* [3].

Taken all molecular features into account, proportionately more molecular features with *m/z* values below 200 were detected with CE–MS, whereas the relative number of features with *m/z* values above 400 was higher in HILIC–MS (Fig. 3). To compare the two analytical methodologies more extensively, molecular features which were detected with both CE–MS and HILIC–MS (common molecular features) were determined. Molecular features were considered to be common if the difference of the respective *m/z* values was less than 10 mDa. An *m/z* value only detected with one of the two methods was regarded as a unique molecular feature for the respective method. Based on these criteria, HILIC–MS and CE–MS revealed 1216 and 203 unique features, respectively, and 144 common molecular features were found with *m/z* values ranging from 108 to 503 of which most had *m/z* values below 300. There were 28 isobaric compounds among the 144 common molecular features. These features could not be assigned unambiguously based on mass only and were therefore dismissed during further evaluation. The ratios of peak areas and peak heights of the remaining 116 common molecular features were calculated to compare the signal intensities obtained with HILIC–MS and CE–MS (Fig. 4). The ratios of peak area and height ranged from 0.20–63.9 and 0.59–130.5, and were on average 10.1 and 16.3, respectively. For 11 compounds, peak abundances in CE–MS were even higher than obtained with HILIC–MS. The large variance in intensity ratio between HILIC–MS and CE–MS might be caused by varying degrees of ionization suppression. As the separation principles of HILIC and CE are so manifestly different, the co-migration of urinary compounds and thus ionization conditions may vary strongly along the elution/migration window.

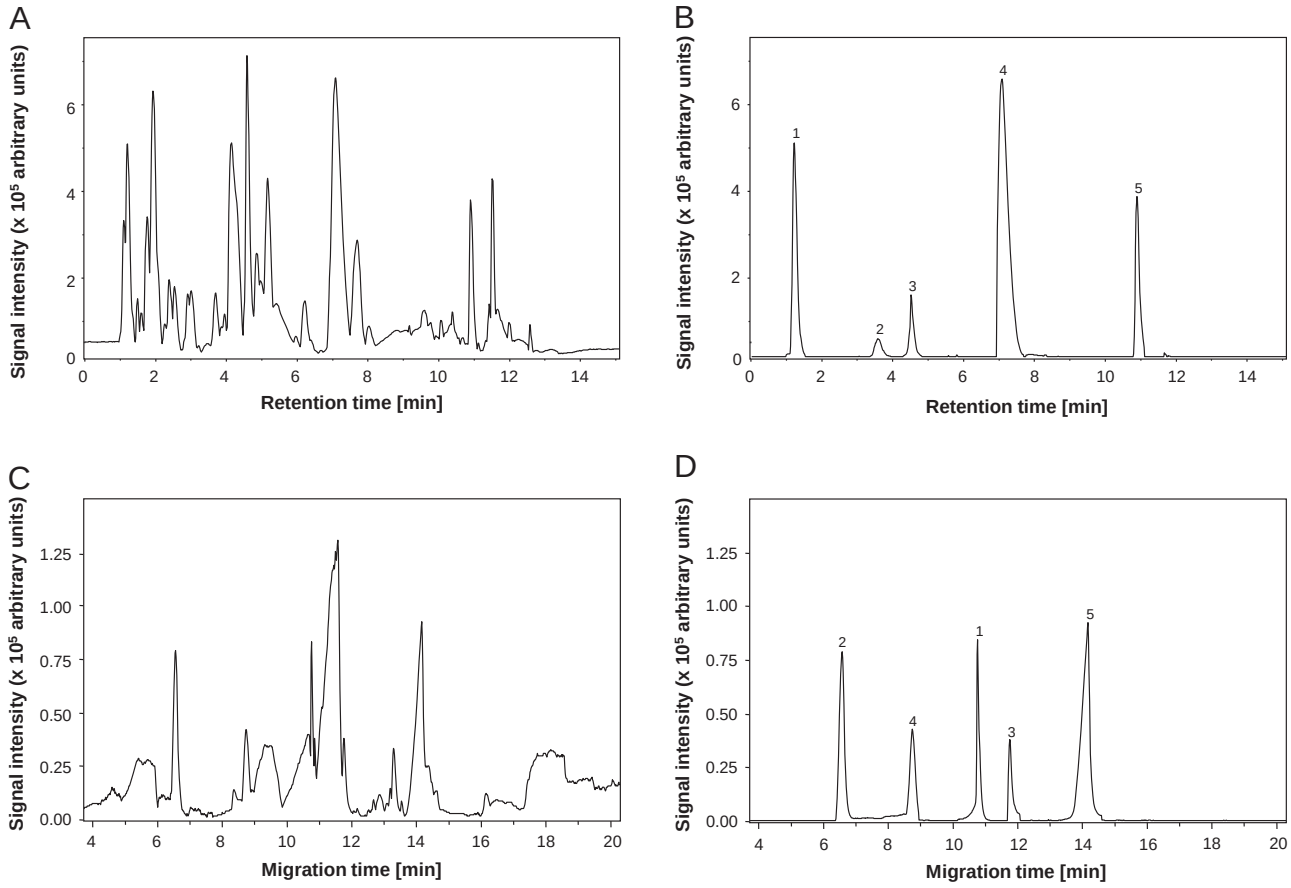

Fig. 2. Base-peak and multiple extracted-ion chromatograms and electropherograms obtained when analysing a rat urine sample by HILIC–MS (A, B) and CE–MS (C, D). Peaks: 1. *m/z* 212.00; 2. *m/z* 112.05; 3. *m/z* 124.99; 4. *m/z* 243.06; 5. *m/z* 167.02. HILIC–MS conditions: gradient elution with (a) 10 mM ammonium acetate in water–acetonitrile (1:1, v/v) and (b) 10 mM ammonium acetate in water–acetonitrile (1:9, v/v): 0–5 min, 100% b; 5–15 min, from 100% b to 100% a; 15–20 min, 100% a. CE–MS conditions: BGE, 25 mM triethylamine (pH 11.7); sheath liquid, 5 mM triethylamine in water–methanol (1:1, v/v). See Section 2 for other experimental conditions.

Table 3
Retention/migration time and peak area repeatability (RSD (%), n=10) for five metabolites in rat urine detected with HILIC–MS and CE–MS.

m/z value	Retention/migration time		Peak area	
	HILIC–MS	*CE–MS*[a]	*HILIC–MS*	*CE–MS*[a]
212.00	0.17	10.8	7.89	13.3
112.05	0.29	5.93	11.6	8.58
124.99	0.55	10.8	13.6	13.2

167.02	0.23	11.8	7.68	7.85

[a] Previously reported by Kok *et al.* [4].

3.2.2. Separation selectivity

In order to appreciate the observed differences in selectivity between CE–MS and HILIC–MS, the elution and migration behavior of the test metabolites and common features in rat urine were evaluated, involving – when possible – the molecular structure of the compounds. The observed elution order of the test metabolites in HILIC roughly follows compound polarity (Fig. 1). Uridine is the only test metabolite that is uncharged at the applied pH of 6.8, which may explain its fast elution. The aromatic ring of hippuric acid reduces its overall polarity leading to modest retention in HILIC. Proline and pyroglutamic acid have a rather polar structure providing significant retention. The dicarboxylic glutaric acid is highly polar and strongly retained in HILIC. In CE–MS, proline migrated first, followed by successively uridine, hippuric acid, pyroglutamic acid and glutaric acid [3], exhibiting a different order than observed during HILIC–MS. The CE migration order largely follows the overall negative charge of the compounds at pH 11.7. The amino group of proline is partly protonated, whereas glutaric acid is doubly charged at pH 11.7.

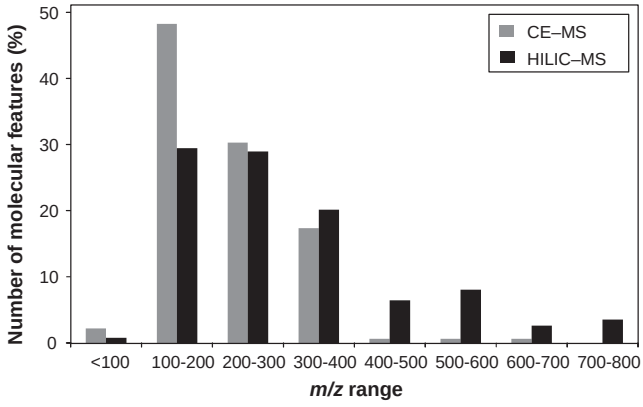

Fig. 3. Distribution of *m/z* values of molecular features detected during CE–MS and HILIC–MS of a rat urine sample. The relative number of features (%) in the various *m/z* ranges is depicted taking the total number of molecular features detected with the respective analytical method as 100%.

The distinctive separation selectivity of CE and HILIC was strongly underlined by plotting the CE–MS migration times and the HILIC–MS retention times of the 116 common features observed during the analysis of rat urine (Fig. 5). Compounds are

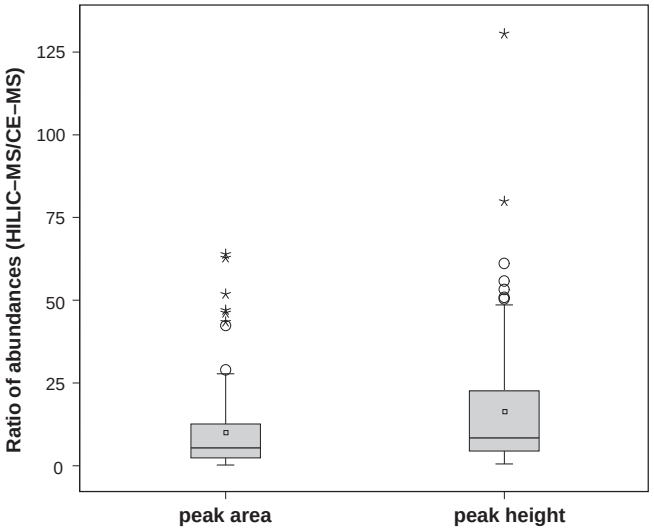

Fig. 4. Box plot of the ratio of peak areas and peak heights of 116 common molecular features in a rat urine sample detected with both HILIC–MS and CE–MS. The 25th percentile, median and 75th percentile are represented by the boxes. The whiskers indicate the 5th and 95th percentile and the squares represent the average ratio of the peak areas and peak heights, respectively. Circles indicate ratios higher than 95% of the observed ratios and asterisks symbolize outliers.

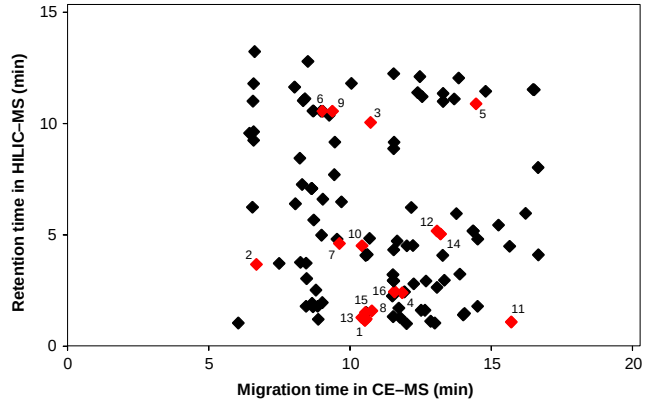

Fig. 5. Relation between migration times and retention times of common molecular features obtained during CE–MS and HILIC–MS of a rat urine sample. The red diamonds with numbers represent metabolites which were putatively identified based on accurate mass. The identities together with the corresponding numbers are given in Table 4.

scattered over the entire plot, indicating a clear lack of correlation between CE migration and HILIC retention. To explore the observed differences in separation selectivity of CE and HILIC in more molecular detail, the *m/z* values of the common features were searched against metabolomics databases [29–31]. This way, 16 molecular features could be assigned based on accurate mass. These features included typical urinary compounds, such as allantoin, glucuronic acid, hippuric acid, indoxyl sulfate, phenol and uric acid (Table 4 and red diamonds in Fig. 5). As can be expected, all identified compounds, except creatinine, have an acidic group allowing their negative ionization.

The CE and HILIC migration and retention data of the identified metabolites in Table 4 confirm the different selectivity of the methods. For example, the sulfonic acids cresol sulfate, benzenediol sulfate, methoxycatechol sulfate and indoxyl sulfate were hardly retained and not separated in HILIC–MS, whereas in CE–MS these compounds showed considerable migration times. Moreover, benzenediol sulfate could be separated from the other sulfonic acids in CE, most probably because it carries relatively more negative charge due to deprotonation of its phenol group. In

Table 4
Retention (RT) and migration times (MT) of putatively identified urinary metabolites detected with both HILIC–MS and CE–MS.

#	*m/z* Value	RT ($_{min}$) HILIC–MS	MT ($_{min}$) CE–MS	Putative identity
1	93.03	1.14	10.67	Phenol
2	112.05	3.59	6.51	Creatinine
3	124.01	10.05	10.73	Taurine
4	157.09	2.39	11.86	Allantoin
5	167.02	10.89	14.47	Uric acid
6	168.08	10.55	8.99	Methylhistidine
7	178.05	4.61	9.64	Hippuric acid
8	187.01	1.48	10.78	Cresol sulfate
9	187.07	10.55	9.38	Glycylhydroxyproline
10	188.03	4.50	10.43	Kynurenic acid
11	188.99	1.08	15.72	Benzenediol sulfate
12	193.05	5.17	13.09	Glucuronic acid
13	203.00	1.20	10.67	Methoxycatechol sulfate
14	204.03	5.03	13.21	Xanthurenic acid
15	212.00	1.23	10.70	Indoxyl sulfate
16	276.14	2.43	11.58	Methionine–lysine

contrast, taurine, also comprising a sulfonic acid group, could only be separated from the other sulfonic acids in HILIC. In CE–MS, uric acid (diprotic) and its oxidation product allantoin (monoprotic) were separated based on their charge-to-size ratios. For these compounds, a large difference in retention times was observed in HILIC–MS, although the molecular structures of allantoin and uric acid are highly similar. Another example is the separation of compounds having a carboxylic group. Methylhistidine, hippuric acid, glycylhydroxyproline, kynurenic acid, glucuronic acid, xanthurenic acid and methionine–lysine had retention times between 2.43 and 10.55 min, and migration times ranged from 8.99 to 13.21 min. The elution order of these metabolites in the CE system differed completely from their elution order in HILIC. Furthermore, despite the apparent larger separation window in the optimized HILIC method, methylhistidine and glycylhydroxyproline coeluted, whereas separation of these compounds was achieved in CE.

4. Concluding remarks

In order to assess the added value of CE–MS for anionic metabolic profiling of urine, a previously developed CE–MS method was compared to an optimized HILIC–MS method using ammonium acetate as mobile phase additive. In general, higher signal intensities were obtained with HILIC–MS compared to CE–MS. This is mainly due to the considerably larger injection volume applied in HILIC–MS. Still, the average difference in analyte response between CE–MS and HILIC–MS is much less than estimated from injection volume only, indicating overall higher absolute sensitivity in CE–MS. Notably, CE–MS can be particularly useful when volume-limited samples have to be analysed. The separation selectivities of CE–MS and HILIC–MS appeared to be considerably different, as demonstrated by the low correlation between CE migration and HILIC retention of urinary metabolites. The unique detection of 203 and 1216 molecular features in rat urine by CE–MS and HILIC-MS, respectively, further demonstrated the different selectivity of the methods. Hence, although HILIC–MS revealed significantly more molecular features than CE–MS, there is a clear added value for CE–MS. In metabolomics studies, CE–MS could aid in finding discriminatory compounds (e.g. potential biomarkers) and help to elucidate metabolic pathways.

Concentration effect

ABSTRACT

We have developed a technique for the rapid, precise and accurate determination of sulfur isotopes ($\delta^{34}S$) by MC–ICP–MS applicable to a range of sulfur-bearing solutions of different sulfur content. The 10 ppm Alfa-S solution (ammonium sulfate solution, working standard of the lab of the authors) was used to bracket other Alfa-S solutions of different concentrations and the measured $\delta^{34}S_{V-CDT}$ values of Alfa-S solutions deviate from the reference value to varying degrees (concentration effect). The stability of concentration effect has been verified and a correction curve has been constructed based on Alfa-S solutions to correct measured $\delta^{34}S_{V-CDT}$ values. The curve has been applied to AS solutions (dissolved ammonium sulfate from the lab of the authors) and pore water samples successfully, validating the reliability of our analytical method. This method also enables us to measure the sulfur concentration simultaneously when analyzing the sulfur isotope composition. There is a strong linear correlation ($R^2 > 0.999$) between the sulfur concentrations and the intensity ratios of samples and the standard. We have constructed a regression curve based on Alfa-S solutions and this curve has been successfully used to determine sulfur concentrations of AS solutions and pore water samples. The analytical technique presented here enable rapid, precise and accurate S isotope measurement for a wide range of sulfur-bearing solutions – in particular for pore water samples with complex matrix and varying sulfur concentrations. Also, simultaneous measurement of sulfur concentrations is available.

1. Introduction

Sulfur is a relatively active chemical element and it occurs in various oxidation states, such as sulfate, elemental sulfur and metal sulfides. Various biological and geochemical processes result in variations in sulfur oxidation states and impart sulfur isotope fractionations. Therefore, sulfur isotopes have diverse applications in geological science and variations in sulfur isotopic compositions act as useful tracers of the sources and cycling of sulfur species in biological and geochemical processes [1–4].

Sulfur isotope ratio measurements are conventionally performed by gas source isotope ratio mass spectrometry (GS-IRMS) in which S is measured as SO_2 or SF_6 [1,5–7]. Compared with SO_2, SF_6 is preferable for high-precision sulfur isotope analysis because it has no spectral interferences from oxygen species [7] while the corrections for the oxygen isotopic contributions are necessary when using SO_2 as the analyte [8]. For GS-IRMS, however, the sample preparation method is complex. In the case of water samples (e.g., pore water), the sulfate is precipitated as $BaSO_4$ first and then reduced to hydrogen sulfide, and then converted to metal sulfide (Ag_2S) for combustion to generate SO_2. Furthermore, the complicated and time-consuming sample preparation methods may lead to additional sulfur isotopic fractionation or contamination from the reagents employed. Moreover, different $\delta^{34}S$ values for the same material are obtained depending on which species (SO_2 or SF_6) is introduced into the GS-IRMS [9]. Continuous flow isotope ratio mass spectrometry (CF-IRMS) has been widely used for sulfur isotope analysis in which sulfur is introduced as SO_2 [10–12]. The generation and purification procedures for the SO_2 gas source are automated and rapid sulfur isotope analyses (< 15 min per sample) are realized. However, poor reproducibility of oxygen isotope variations in SO_2 results in calculated $\delta^{34}S$ values in error by up to 1–3‰ [13].

There are other alternative methods for sulfur isotope analysis such as multiple-collector thermal ionization mass spectrometry (MC–TIMS) and secondary ion mass spectrometry (SIMS). For MC–TIMS, S is measured as AsS^+ at masses 107 and 109 and a very small sample mass (<2 μg S) is needed [14,15]. However, the sample preparation method is also complex and time-consuming. The ion microprobe (SIMS) enables in situ measurement of S isotopes at high spatial resolution (8–25 μm). However, it is subject to shortcomings including spectral interference and matrix effects and is not suitable for water samples.

Multiple-collector inductively coupled plasma mass spectrometry (MC–ICP–MS) has been widely applied to sulfur isotope ratio measurement [16–18]. Compared with single-collector ICP–MS, whose precision is limited because data are acquired sequentially and variability of plasma conditions are not accounted for, multi-collector ICP–MS enables precise measurement of isotope ratios with instrumental precision between 0.1% and $<0.005\%$ [19] due to its ability to measure multiple isotopes simultaneously. Another advantage of MC–ICP–MS is its compatibility with diverse sample introduction schemes, enabling both bulk solution analysis and in situ laser-ablation analysis.

When applying MC–ICP–MS to measure the $\delta^{34}S$ values of sulfur-containing solutions, isobaric interferences and matrix effects have strong influences on the accuracy and the precision of $\delta^{34}S$ values. Isobaric interferences from oxygen species can be removed by using the medium-to-high mass resolution and the interference-free plateau is chosen to detect sulfur isotopes [20,21]. Conventionally, prior chemical purification is necessary to avoid matrix effects. For water samples, the ion exchange purification step is necessary which is complex, multistep and time-consuming. Moreover, quantitative recovery of sulfur is essential to avoid potential isotope fractionation [20].

Another method to correct matrix effects has been developed by using matrix-matched standards to bracket the samples such that they can be analyzed without chemical purification [21], which provides a method that significantly simplifies the analysis procedure. However, the sulfur concentrations of sample solutions need to be known in advance to prepare the corresponding standards, which is not always available. Furthermore, if the sulfur concentrations vary in a large range, for each sample the corresponding standard is needed to be prepared, which impairs the convenience of this method. Also, in this case, because the standard-sample bracketing (SSB) method is applied and different samples cannot share the same working standard, the corresponding working standard of each sample needs to be measured twice (before and after the sample) and the number of standards to be measured is almost twice as many as that of samples.

In this study, we did research on concentration effect, that is to say, we used the same standard to bracket sulfur-bearing solutions that have the same matrices as the standard while different sulfur concentrations from that. We have investigated how the concentration difference between samples and standards influence the measured $\delta^{34}S$ values and made an attempt to utilize the correction curve we constructed to correct the pore water samples and the results are satisfactory.

Sulfur concentrations of sediment pore water samples are variable and usually decrease with depth [22–24] and thus conventionally for each sample the corresponding standard is needed to be prepared. And in pore water research, it is quite common that dozens of samples need to be analyzed. Consequently, as discussed above, a large number of standards need to be measured. However, with the help of our technique, only one working standard needs to be prepared and can be shared by different samples, thus reducing the standard preparation time greatly. Moreover, because the same working standard is used to bracket different samples, the number of standards to be measured will be reduced significantly. Furthermore, the matrix-matched standard also enables samples to be measured directly without prior chemical purification. Therefore, the new analytical protocol is more rapid than other ones and our research will simplify the analysis procedure significantly and bring much convenience to the pore water research. Besides, not only is this technique applicable to pore water samples but also to other geological samples that vary in sulfur concentration. And we believe that this method provides an idea which could be transferred to other isotopic analysis and will arouse a lot of interest and concerns from other researchers.

2. Analytical methods

2.1. Preparation of standards and samples

The water used for dilutions and rinses was prepared using a Milli-Q system (Millipore, Billerica, MA, USA) operated at 18.2 MΩ cm. High-purity nitric acid (HNO_3) was prepared by sub-boiling distillation. All bottles and vials used for sample preparation and storage were cleaned for at least 24 h in 10% HNO_3 and rinsed three times with 18.2 MΩ cm Milli-Q water. All standard and sample solutions were prepared in a clean lab for analysis as matrix-matched solutions stabilized in 2% (w/w) HNO_3.

Four sediment pore water samples (DH-5, DH-12, DH-18, and DH-25) from the South China Sea were volumetrically diluted 100 times for sulfur isotopic determination. The $\delta^{34}S$ values of standard solutions (Alfa-S and AS) were first measured using the CF-IRMS method on a MAT 253 isotope ratio mass spectrometer (ThermoFisher, Bremen, Germany) at the Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, China (Table 1). Matrices of modern seawater are mainly composed of Cl^- (~19,344 ppm), Na^+ (~10,773 ppm) and sulfur (~907 ppm). Sediment pore water below the seafloor has almost the same matrices as seawater while the sulfur concentrations vary with depth. The water samples were volumetrically diluted 100 times and about 193 ppm Cl^-, 108 ppm Na^+ and 9.1 ppm sulfur can be estimated. Therefore, the matrix-matched working standard (discussed below) should contain 200 ppm Cl^- (added as NaCl) and 10 ppm sulfur.

Two standard solutions (Alfa-S and AS) were prepared as in-house standards. The Alfa-S solution was made by diluting an Alfa Aesar Specpure^{TM} 1000 μg mL^{-1} S stock (Alfa Aesar, Johnson Matthey Co., Ward Hill, MA, USA), and the AS solution by dissolving solid ammonium sulfate provided by the laboratory of the authors. We prepared a series of Alfa-S and AS solutions which contained different concentrations of sulfur to investigate the concentration effect during the MC–ICP–MS measurement. Specifically, the Alfa-S solutions contained 1 ppm, 3 ppm, 5 ppm, 7 ppm, 9 ppm, 10 ppm, 11 ppm, 15 ppm, and 20 ppm S respectively, and the AS solutions contained 2 ppm, 4 ppm, 5 ppm, 8 ppm and 15 ppm S respectively. In addition, all standard solutions were matrix-matched (contain 200 ppm Cl^-) to eliminate mass bias arising from matrix effects during the measurement of sediment pore water [21]. In this study, all the Alfa-S and AS solutions mentioned were matrix-matched.

2.2. Instrumentation and apparatus

The isotopic measurements were performed using a Neptune Plus MC–ICP–MS (ThermoFisher, Bremen, Germany) at the State Key Laboratory for Mineral Deposits Research, Nanjing University, Nanjing, China. The Neptune Plus is a double-focusing magnetic sector instrument with variable dispersion (17%) ion optics. It is equipped with one fixed central Faraday cup and eight motorized Faraday cups that locate on both sides of the center cup. Typical

Table 2
Operating conditions and data acquisition parameters for the MC–ICP–MS for sulfur isotopic measurements.

Mass spectrometer setup	
MC–ICP–MS	Thermo Electron NEPTUNE plus
Cooling gas flow rate	~15 L min^{-1}, Argon
Auxiliary gas flow rate	~1.30 L min^{-1}, Argon
Sample gas flow rate	~1.006 L min^{-1}, Argon
Extraction lens	~2000 V
Interface cones	Ni cones
Analyzer pressure	~10^{-9} Torr
RF forward power	~1162 W
RF reflect power	~4 W
Data acquisition parameters	
Mass resolution mode	Medium resolution ($m/\Delta m \approx 3000$)
Acquisition mode	Static
Detection system	Faraday cups
Cup configuration	^{32}S (C), ^{33}S (H2), ^{34}S (H3)
Wash-out time	2–3 min

operating parameters are summarized in Table 2. The solutions were aspirated using argon as the nebulizer gas.

2.3. Isotope measurement and data acquisition

Isotope ratio measurements are performed in medium-to-high mass resolution mode to remove the isobaric interferences resulting from oxygen species. Medium mass resolution ($m/\Delta m \sim 3000$) can separate the peaks of $^{16}O_2^+$ from $^{32}S^+$ efficiently [21]. Elemental sulfur species are lighter than molecular interferences from $^{16,17,18}O_2$, so isotopes of sulfur are determined on the interference-free plateau at lower mass to remove interferences from O_2^+ [20].

Standard-sample bracketing (SSB) was used to determine the δ^{34}S values of Alfa-S and AS solutions of different concentrations and pore water samples [25–27]. Specifically, for each sample, the standards were analyzed immediately before and after the sample analysis. And the true S isotope ratio is calculated by interpolating the mass bias of an unknown sample between the biases inferred from two neighboring standard analyses. In this study, the 10 ppm Alfa-S solution was used as standard whereas other Alfa-S and AS solutions were viewed as 'samples'. All the data for the sulfur isotope composition are reported as δ^{34}S values related to the Vienna-Cañon Diablo Troilite (V-CDT) scale [28] (Eq. 1):

$$\delta^{34}S_{V-CDT} = \left[\frac{\left(\frac{^{34}S}{^{32}S}\right)_{Samp}}{\left(\frac{^{34}S}{^{32}S}\right)_{V-CDT}} - 1\right] \times 1000 \quad (1)$$

In this research, we used the 10 ppm Alfa-S solution as the in-house working standard and δ^{34}S data for samples (including Alfa-S and AS solutions of different concentrations) are calculated according to the following equation:

$$\delta^{34}S_{V-CDTSamp} = \left[\frac{2 \times \left(\frac{^{34}S}{^{32}S}\right)_{Samp}}{\left(\frac{^{34}S}{^{32}S}\right)_{Alfa-1} + \left(\frac{^{34}S}{^{32}S}\right)_{Alfa-2}} - 1\right] \times 1000 + 1.90 \quad (2)$$

where $\left(\frac{^{34}S}{^{32}S}\right)_{Alfa-1}$ and $\left(\frac{^{34}S}{^{32}S}\right)_{Alfa-2}$ are sulfur isotope ratios of two neighboring working standards (10 ppm Alfa-S) of a sample. Constant value 1.90 is δ^{34}S value of working standard solution Alfa-S on the scale of V-CDT (measured on Thermo MAT 253 isotope ratio mass spectrometer).

Raw mass spectrometry data were reduced using the software Iolite [29]. The Data Reduction Scheme (DRS) file for sulfur isotope analysis was written by the authors. The $\delta^{34}S_{V-CDT}$ values of samples were calculated according to Eq. (2). Interpolation of the standards was achieved by choosing Iolite's 'Automatic' spline type option and the background signals (~3 mV ^{32}S intensity) were removed by on-peak zero subtraction. Errors given in Section 3 are standard errors (2σ) calculated by Iolite.

2.4. Instrument mass bias and matrix effects

In this study, we applied the standard-sample bracketing (SSB) method to correct instrumental mass discrimination. The matrix-matched 10 ppm Alfa-S solution was used as the bracketing standard and other matrix-matched Alfa-S and AS solutions were used as samples.

Instrumental mass bias within ICP–MS arising from so-called 'space-charge' and 'ion-diffusion' effects on the transmission of ionized particles [30–32] is sensitive to matrix composition (matrix effects) [33,34]. In this study, the sediment pore water samples used were prepared without chemical purification, so the matrix-matched Alfa-S solution was used to bracket water samples to correct matrix effects [21].

3. Results and discussion

3.1. Concentration effect of sulfur

In order to explore concentration effect, we prepared a set of Alfa-S solutions (matrix-matched) of different concentrations. The 10 ppm one was used as the standard and the SSB technique was applied to get the $\delta^{34}S_{V-CDT}$ values of other Alfa-S solutions. These solutions have identical isotopic composition and the difference between them is that they have different sulfur concentrations. However, as shown in Table 3 and Fig. 1, the measured $\delta^{34}S_{V-CDT}$ values of Alfa-S solutions of different concentrations all deviate from the reference value (1.90 ± 0.17‰). It shows that when the concentrations of samples are lower than that of the standard, the measured $\delta^{34}S_{V-CDT}$ values are smaller than the reference value

Table 3
Measured $\delta^{34}S_{V-CDT}$ values of Alfa-S solutions of different concentrations.

[a] The ^{32}S intensity ratios of samples and the standard. I_{sample} is the ^{32}S intensity of the sample and $I_{std\ 1}$ and $I_{std\ 2}$ are the ^{32}S intensities of the neighboring standards.
[b] The ^{32}S intensity ratios of the standard and samples. I_{sample}, $I_{std\ 1}$ and $I_{std\ 2}$ have the same meanings as above.
[c] The measured $\delta^{34}S_{V-CDT}$ values of Alfa-S solutions of different concentrations by MC–ICP–MS.
[d] The deviation values of measured $\delta^{34}S_{V-CDT}$ values from the reference value (1.90‰), i.e. $\Delta\delta^{34}S_{V-CDT} = \delta^{34}S_{V-CDT(measured)} - \delta^{34}S_{V-CDT(referencevalue)}$.

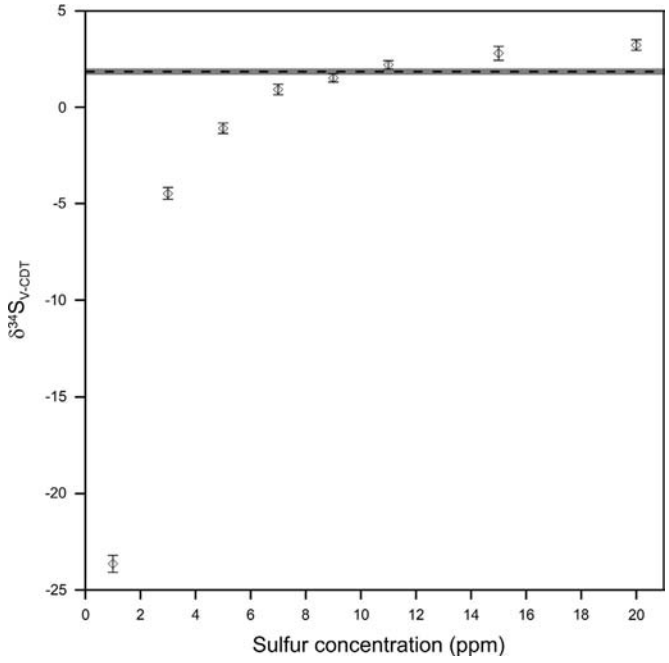

Fig. 1. The measured $\delta^{34}S_{V-CDT}$ values of Alfa-S solutions of different concentrations. All the measured values of Alfa-S solutions deviate from the reference value (gray bar) to different degrees according to their concentrations.

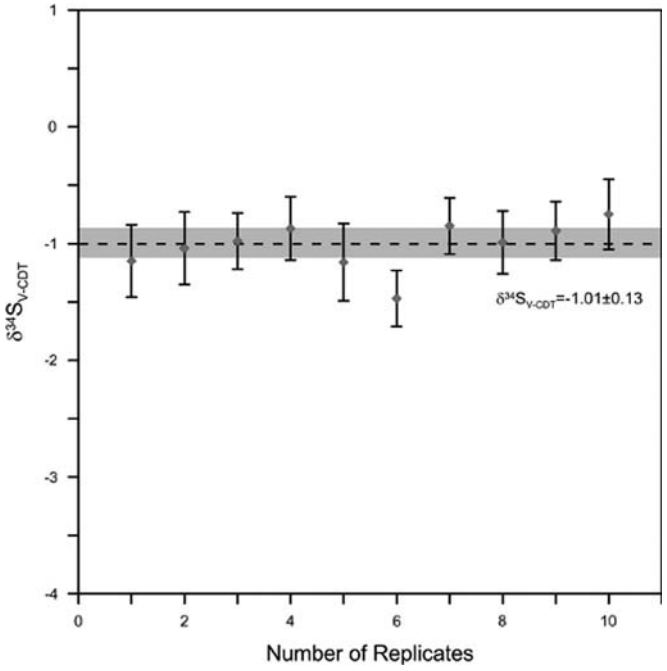

Fig. 2. Long-term reproducibility of S-isotope for 5 ppm Alfa-S solution over multiple, independent analytical sessions. Data are shown relative to the V-CDT scale. The estimated external uncertainty is ± 0.13‰ based on 10 replicates.

while when the concentrations of samples are higher than that of standard, the measured values are larger than the reference value. Besides, the difference between the reference value and the measured $\delta^{34}S_{V-CDT}$ values has relationships with the concentration difference of the standard and samples. The larger the concentration difference is, the more the measured $\delta^{34}S_{V-CDT}$ value deviates from the reference value. Because the difference between measured $\delta^{34}S_{V-CDT}$ values and the reference value is relatively large (the largest difference is −25.55‰), it is necessary to correct the measured values and the qualitative description above is not enough. In this study, the concentration range (1–20 ppm) is large enough for pore water research because in practice, pore water samples are volumetrically diluted 100 times and the sulfur concentrations of diluted water samples are usually lower than 10 ppm. For other geological samples that vary in sulfur concentration, the final sulfur-bearing solutions can be diluted to this concentration range. And we believe that this concentration range is sufficient for most samples because the maximum concentration (20 ppm) is 20 times as high as the minimum concentration (1 ppm).

Before we find out how to correct the measured values, we need to investigate the stability of concentration effect, i.e. whether the concentration effect varies with time during one experiment under the same instrumental operating conditions. Also, we want to replace sulfur concentrations with ^{32}S signal intensities because in practice sulfur concentrations of samples are usually unknown while ^{32}S intensities can be measured during the isotopic determination. These two questions are discussed in Section 3.2 and Section 3.3.

3.2. The stability of concentration effect

We used the 10 ppm Alfa-S solution as the working (in-house) standard to measure the 5 ppm Alfa-S solution over multiple, independent analytical sessions (Fig. 2) to test the stability of concentration effect. As shown in Fig. 2, we estimate an external precision of ± 0.13‰ (2σ) within 10 replicates. And the $\delta^{34}S_{V-CDT}$ value of the 5 ppm Alfa-S solution is stable within analytical uncertainty, which indicates that the concentration effect does not vary with time, thus we have verified the stability of concentration

effect. The external precision given here also describes the long-term stability and the precision of MC–ICP–MS method.

3.3. Sulfur concentration determination

Before we introduce the correction method, we introduce the sulfur concentration determination method first because here we present the relationships between sulfur concentrations and ^{32}S signal intensities and we replace S concentrations with ^{32}S intensity ratios in Section 3.4. So that in practice, it is not necessary to know sulfur concentrations of samples in advance to utilize the correction curve we constructed (discussed in Section 3.4).

During the exploration of concentration effect, we get the relationships between concentrations and intensities (Fig. 3). Alfa-S solutions of different concentrations were used to determine the concentration–intensity relationship (Table 3). We used $2I_{sample}/(I_{std\ 1}+I_{std\ 2})$ as the *X*-axis, where I_{sample} is the ^{32}S intensity of the sample and $I_{std\ 1}$ and $I_{std\ 2}$ are the ^{32}S intensities of the neighboring standards, and sulfur concentration as the *Y*-axis. We used the intensity ratio instead of absolute intensity value of ^{32}S as the *X*-axis to eliminate the instrumental intensity drift, which is similar to the SSB method.

As shown in Fig. 3, we constructed a regression curve which is based on best-fit linear function (through origin) to represent the relationships. The correlation coefficient is 0.9993, which indicates that concentrations and intensity ratios have a strong linear correlation.

We applied the constructed curve to AS solutions of different concentrations to test the validity of it (Table 4). We calculated the concentrations of AS solutions according to their intensity ratios and compared the results with the known concentrations. It shows that the calculated concentrations are consistent with the known ones (within 0.3 ppm) and thus indicates that the curve is also applicable to AS solutions.

Because our pore water samples were analyzed without chemical purification, there was no loss of sulfur content. We applied the regression curve to pore water samples (Table 4). The results are quite satisfactory: all the calculated sulfur concentrations of pore water samples are consistent with their concentrations measured by ion chromatography (within 0.1 ppm), which indicates that this technique can determine the sulfur concentration of pore water samples. Therefore, we can measure the sulfur concentration simultaneously when analyzing the sulfur isotope compositions.

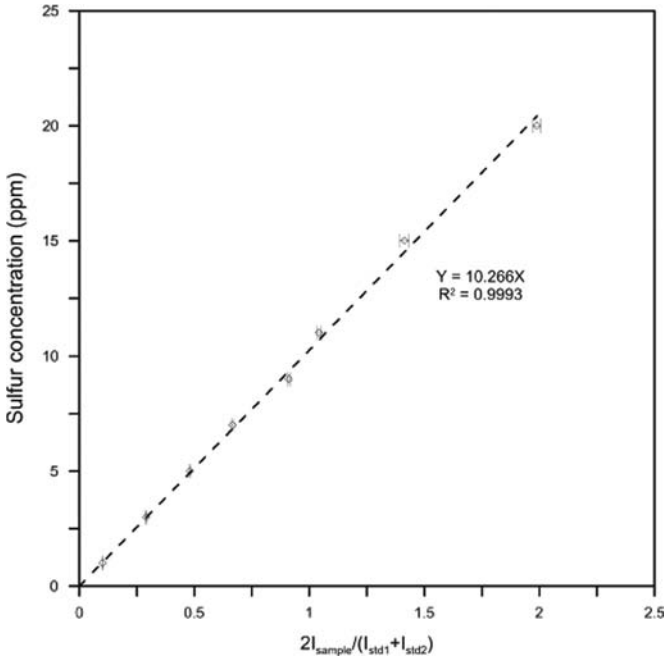

Fig. 3. The linear relationships between sulfur concentrations and intensity ratios. $Y=10.266X$, ($R^2=0.9993$), where *Y* is sulfur concentration (ppm) and *X* is $2I_{sample}/(I_{std\ 1}+I_{std\ 2})$.

3.4. Concentration effect correction

3.4.1. The construction of correction curve

In the previous discussion, we have verified the stability of concentration effect and the feasibility of replacing S concentrations with ^{32}S intensity ratios. Our following work is to correct the measured $\delta^{34}S$ values. During the exploration of concentration effect (Section 3.1), we found that the difference between measured $\delta^{34}S$ values and the reference value has relationships with the concentration ratios of the standard and samples. The larger $(I_{std\ 1}+I_{std\ 2})/2I_{sample}$ is, the smaller $\Delta\delta^{34}S_{V-CDT}$ is (Table 3). Here we use $(I_{std\ 1}+I_{std\ 2})/2I_{sample}$ to represent the concentration ratios of

Table 4
Calculated sulfur concentrations of AS solutions and pore water samples.

Sample ID	$2I_{sample}/(I_{std\ 1}+I_{std\ 2})$	Calculated sulfur concentration (ppm)	Sulfur concentration (ppm)

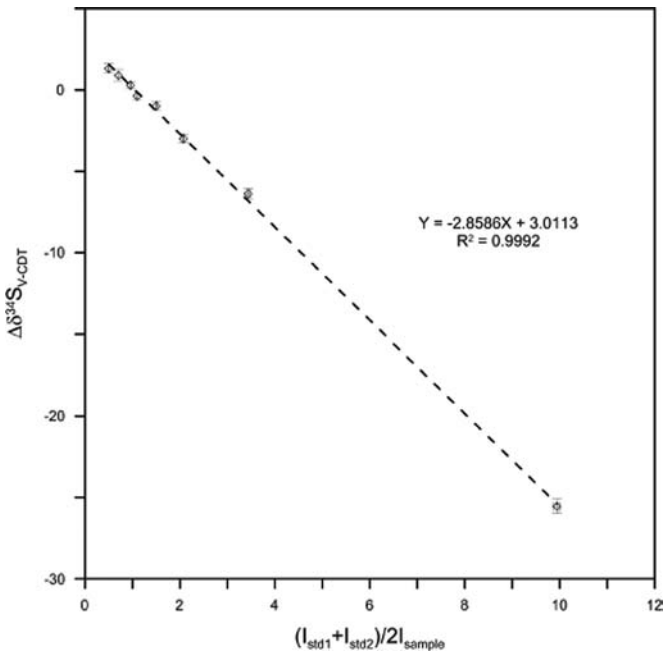

Fig. 4. The scatter plot of $(I_{std\ 1}+I_{std\ 2})/2I_{sample}$ and $\Delta\delta^{34}S_{V-CDT}$. The dash line is the linear regression curve that represents the relationships between $(I_{std\ 1}+I_{std\ 2})/2I_{sample}$ and $\Delta\delta^{34}S_{V-CDT}$. $Y=-2.8586X+3.0113$, ($R^2=0.9992$), where *Y* is $\Delta\delta^{34}S_{V-CDT}$, i.e. the difference between measured $\delta^{34}S_{V-CDT}$ values and the reference value and *X* is $(I_{std\ 1}+I_{std\ 2})/2I_{sample}$, i.e. the concentration ratios of the standard and samples.

the standard and samples, where $I_{std\ 1}$, $I_{std\ 2}$ and I_{sample} have the same meanings as in Section 3.3. Also, we define $\Delta\delta^{34}S_{V-CDT}$ as the difference between measured $\delta^{34}S_{V-CDT}$ values and the reference value ($\Delta\delta^{34}S_{V-CDT}=\delta^{34}S_{V-CDT(measured)}-\delta^{34}S_{V-CDT(referencevalue)}$).

We used $(I_{std\ 1}+I_{std\ 2})/2I_{sample}$ as the *X*-axis and $\Delta\delta^{34}S_{V-CDT}$ as the *Y*-axis to draw the scatter plot (Fig. 4). It seems that they have a linear correlation, so we constructed a regression curve based on best-fit linear function to represent the relationships. The correlation coefficient is 0.9992, which indicates that they have a strong linear correlation. Also, the function of this regression curve is $Y=-2.8586X+3.0113$, where Y is $\Delta\delta^{34}S_{V-CDT}$ and X is $(I_{std\ 1}+I_{std\ 2})/2I_{sample}$. When X is 1 (the standard and the sample have same sulfur concentration), the calculated Y is 0.1527, which is very close to the theoretical value (0, i.e. the measured value is same as the reference value). Therefore, the regression curve is very satisfactory.

This linear regression curve seems to provide a method of correcting the measured $\delta^{34}S_{V-CDT}$ values. We used the AS solutions of different concentrations to investigate whether this curve could be used to correct other standard solutions. SSB method was used to get the $\delta^{34}S_{V-CDT}$ values of AS solutions and the 10 ppm Alfa-S solution was used as the standard. As shown in Fig. 5 and Table 5, all the measured $\delta^{34}S_{V-CDT}$ values of AS solutions also deviate from the reference value ($-6.78\ \pm0.07$‰).

We used the correction curve to calculate the $\Delta\delta^{34}S_{V-CDT}$ values of AS solutions and the corrected $\delta^{34}S_{V-CDT}$ values of AS solutions are calculated by subtracting the $\Delta\delta^{34}S_{V-CDT}$ values from the measured $\delta^{34}S_{V-CDT}$ values. As shown in Fig. 5 and Table 5, the results are quite satisfactory. All the corrected $\delta^{34}S_{V-CDT}$ values of AS solutions are consistent with the reference value when considering the errors, which strongly indicates that the correction curve is applicable to AS solutions.

3.4.2. *Applications to pore water samples*

We have constructed a correction curve based on Alfa-S solutions of different concentrations and verified its applicability to AS solutions. Our following work is to investigate whether this correction curve is also applicable to water samples. We used the 10 ppm Alfa-S solution as the standard to bracket water samples, and the results are shown in Table 5. The standard solution has been matrix matched to remove matrix effects, but its sulfur

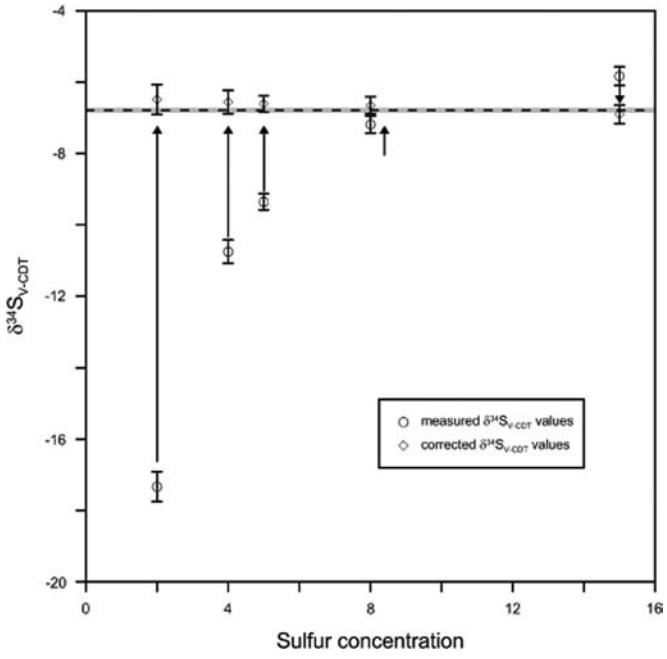

Fig. 5. The measured and corrected $\delta^{34}S_{V-CDT}$ values of AS solution. All the measured values (circle) of AS solutions deviate from the reference value (gray bar). And all the corrected values (diamond) are consistent with the reference value when considering the errors.

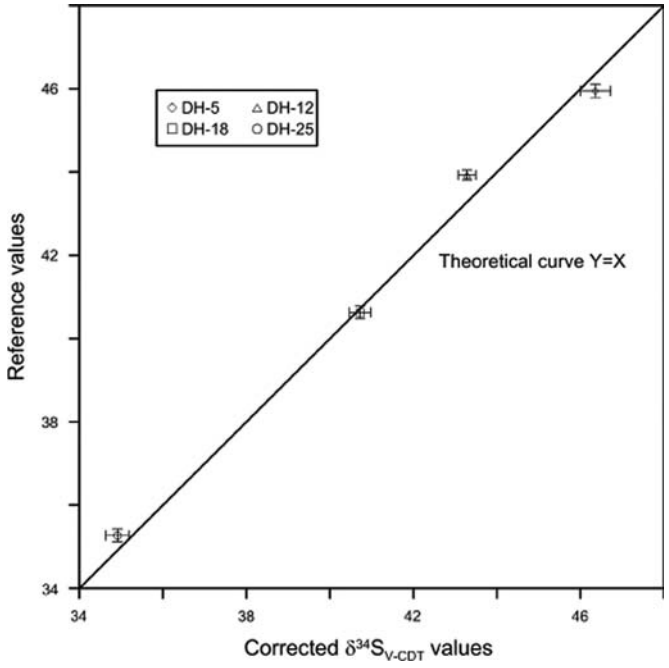

Fig. 6. The scatter plot of corrected and reference $\delta^{34}S_{V-CDT}$ values of pore water samples. The solid line is the theoretical curve ($Y=X$, where Y is reference values and X is corrected $\delta^{34}S_{V-CDT}$ values of pore water samples) that means corrected values are consistent with reference values. DH-12 point is very close to the theoretical curve and other points fall on the curve when considering the errors.

[a] The measured $\delta^{34}S_{V-CDT}$ values of AS solutions and pore water samples by MC–ICP–MS.
[b] The corrected $\delta^{34}S_{V-CDT}$ values of AS solutions and pore water samples, $\delta^{34}S_{V-CDT(corrected)}=\delta^{34}S_{V-CDT(measured)}-\Delta\delta^{34}S_{V-CDT}$.

concentration is different from that of the water samples, so the measured values also deviate from the 'true' values.

By strict matrix-matched, we can get the convincing $\delta^{34}S_{V-CDT}$ values of water samples [21]. We prepared four other matrix-matched Alfa-S solutions, which contain the same concentrations of sulfur as the pore water samples respectively, to bracket the pore water samples and the results (convincing values) are shown in Table 5. We used the correction curve to calculate the $\Delta\delta^{34}S_{V-CDT}$ values of pore water samples and then got the corrected $\delta^{34}S_{V-CDT}$ values of them.

When comparing the corrected $\delta^{34}S_{V-CDT}$ values of pore water samples with their reference values, we drew a scatter plot (Fig. 6). We used corrected $\delta^{34}S_{V-CDT}$ values as the *X*-axis and reference values as the *Y*-axis. As shown in Fig. 6, the points of DH-5, DH-18 and DH-25 all fall on the theoretical curve ($Y = X$) when considering the errors and the DH-12 point is very close to the theoretical curve. These results indicate that the corrected $\delta^{34}S_{V-CDT}$ values of pore water samples are consistent with their reference values and the correction curve can be used to correct pore water samples.

With the help of matrix match and the correction curve we constructed, we have developed a new analytical technique for sulfur isotope measurement which is rapid, precise and accurate.

4. Conclusions

We have developed a technique for the rapid, precise and accurate determination of S isotopes ($\delta^{34}S$) by MC–ICP–MS applicable to a range of sulfur-bearing solutions of different sulfur content. The major isobaric interferences from molecular $^{16}O_2^+$ on sulfur masses are removed in the medium resolution mode ($m/\Delta m \approx 3000$). Standard-sample bracketing (SSB) method is used to correct the instrument mass bias and matrix-matched standard solutions are used to eliminate the mass bias arising from the matrix effects. We have investigated the concentration effect and it shows that the measured $\delta^{34}S_{V-CDT}$ values of Alfa-S solutions of different concentrations deviate from the reference value to varying degrees. We have verified the stability of concentration effect and constructed a correction curve to correct measured $\delta^{34}S_{V-CDT}$ values. When applying the curve to correct AS solutions of different concentrations, the results are very satisfactory. We use the same method to correct the pore water samples and the corrected $\delta^{34}S_{V-CDT}$ values of them are consistent with the reference values, which validates the reliability of our analytical method.

This method also enables us to measure the sulfur concentration simultaneously when analyzing the sulfur isotope composition. There is a strong linear correlation between the sulfur concentrations and the intensity ratios. We have constructed a regression curve based on Alfa-S solutions and this curve is also applicable to AS solutions and pore water samples.

The analytical technique presented here enable rapid, precise and accurate S isotope measurement for a wide range of sulfur-bearing solutions – in particular for pore water samples with complex matrix and varying sulfur concentrations. Another advantage of this method is we can measure the sulfur concentrations simultaneously because the samples are analyzed without chemical purification, which will simplify the analysis procedure significantly.

Propranolol

ABSTRACT

An on-line solid-phase extraction (SPE) method coupled to gas chromatography–mass spectrometry (GC–MS) has been developed for the determination of atenolol (ATN) and propranolol (PRO) in human plasma. The hyphenation of SPE with multisyringe flow injection analysis (MSFIA) allows the simultaneous GC–MS determination of ATN and PRO with high selectivity and sensitivity. On-line preconcentration and derivatisation of the analytes were carried out by means of using restricted access materials (RAM) and microwave (MW) assisted derivatisation reactions with N-methyl-N-(trimethylsilyl) trifluoroacetamide (MSTFA)+1% trimethylchlorosilane (TMCS). Multivariate optimization was applied to optimize experimental conditions. The whole procedure comprising sample pretreatment and analyte determination took about 15 min. However, the overlap of the automatic sample treatment with the GC separation increased the frequency to 7 samples h^{-1}. The validated method was successfully applied to direct ATN and PRO determination in human plasma.

1. Introduction

Beta-blockers (BB), also called beta-adrenergic antagonists, constitute one of the most frequently prescribed drugs to treat heart rhythm disorders, angina pectoris, hypertension, tachycardia or acute myocardial infarction [1,2]. Atenolol and propranolol have been considered a first-line treatment for hypertension [1]. Due to its wide therapeutic range, these drugs require periodic monitoring for adjusting the corresponding dose [3]. For this purpose, sensitive and accurate analytical methodologies for quantification of these compounds in biological fluids are required.

Several methods have been described for the determination of ATN and PRO in human plasma using different techniques such as: immunoassays [4], spectrofluorimetry [5,6], electrochemistry [7] and liquid chromatography (LC) with photodiode array (UV), fluorescence detection (FLD) [8–11] and mass spectrometry (LC–MS) [12–15]. The latter have proved to be selective and sensitive methods for the simultaneous determination of BB in biological fluids. However, LC–MS is not as common as GC–MS in routine laboratories.

Gas chromatography with mass spectrometry detection (GC–MS) is an alternative to LC–MS systems that has also been used for the determination of ATN and PRO in different matrices, with successful results [16–19], providing extra technical advantages, such as good separation, high sensitivity, robustness, and the availability of large spectrum libraries for accurate analyte identification.

The very low concentration of ATN and PRO in biological samples and the complexity of these matrices make necessary a sample preparation step. Selective extraction of analytes from complex matrices is recognized as a very difficult task because these contain a large variety of compounds that may difficult the analysis, leading to a lengthy purification processes. Most of the drugs bind to proteins for circulation in the body. Therefore, for the quantitative determination of ATN and PRO, a deproteinizing process should be carried out, which not only releases the analytes of interest and increases the selectivity in the subsequent steps of sample treatment, but also prevents the appearance of unknown peaks in the chromatogram that can be generated due to contamination.

In this sense, generally determination of BB in biological samples requires conventional sample preparation procedures

prior to injection, such as: liquid–liquid extraction (LLE) and solid-phase extraction (SPE) [16–21], being latter the most used, since time consuming procedures, errors and the risk of low recoveries can be significantly reduced [16–19].

During the last years, special SPE supports have been developed to allow direct injection of plasma samples into on-line SPE liquid chromatography systems. These sorbents called restricted access materials (RAMs) [20,21], combine size exclusion of proteins without destructive accumulation, and other macromolecular matrix components with the simultaneous enrichment of low-molecular analytes, which can be retained and extracted selectively [22,23]. Low-molecular-mass analytes are retained by conventional retention mechanisms such as hydrophobic, ionic or affinity interactions at the inner surface of the sorbent particles. The access of proteins is prevented by a physical diffusion barrier or a chemical barrier. In the majority of the applications described in the literature, RAMs are used in on-line coupled-column SPE–LC systems. These systems require highly sophisticated apparatuses, high operating cost and expensive instrumentation (column switching system, programs equipment and two pumps). In the search of more affordable approaches, other methods exploiting flow-techniques (FT) with on-line column switching schemes have been described [24].

FT-based methods allow well-defined and precisely metered reagent and sample volumes handling, along with miniaturization and automation of SPE based sample processing, and its possible hyphenation with a plethora of instrumental techniques [25,26]. Multisyringe flow injection analysis (MSFIA) has played a major role in SPE automation, providing rapid procedures with low solvent/sample consumption and generation of waste [25]. Potentialities of this technique have been previously discussed in the literature [26].

It is well known that GC analysis is restricted to volatile compounds, so that, polar analytes such as BB, require a derivatisation reaction to achieve the most adequate conditions for GC separation and MS detection. Different derivatising reagents have been used with this purpose [16,27], including MSTFA, which through a silylation reaction produces volatile and thermally stable trimethylsilated (TMS) derivatives [17–19,28]. Reported standard conditions for these reactions are mainly represented by the use of temperatures between 30 and 60 °C with thermal heating and reaction times between 10 and 60 min [16,17,28]. In order to decrease derivatisation time, we propose employing microwave radiation (MW) instead of direct thermal heating [29], exploiting the advantages of MSFIA for coupling auxiliary microwave energy devices, allowing the automation of this step in the sample treatment.

Therefore, the objective of the present work was the development of a MSFIA-SPE-MW procedure coupled to GC–MS as an alternative to existing methods, for determination of ATN and PRO in human plasma samples. Main advantages of the developed method are simplicity, high automation degree and inexpensiveness, simplifying the hyphenation of plasma sample treatment with GC–MS.

2. Materials and methods

2.1. Reagents and standards

Reagents used were of analytical grade and solvents were of HPLC grade. Acetonitrile and methanol were supplied by JT Baker (Phillipsburg, NJ, USA). The derivatising reagent N-Methyl-N-trimethylsilyltrifluoroacetamide (MSTFA)+1% trimethylchlorosilane (TMCS), and USP atenolol were supplied by Sigma Chemical Co. (St. Louis, MO, USA). USP propranolol (available in the market as Propranolol Hydrochloride) was kindly provided by Inversiones Dayamar CA (Venezuela). Double deionized and distilled water was obtained with a Milli-Q water purification system (Millipore, Bedford, MA, USA).

Stock solutions of ATN and PRO (1000 mg L^{-1}) were prepared in acetonitrile and stored in amber bottles under refrigeration at 4 °C until use. Working solutions at different concentrations were prepared daily by dilution in acetonitrile and/or water:acetonitrile 98:2 v/v.

2.2. Plasma sample preparation

For the optimization and validation of the method, a pool of 30 mL of human plasma from healthy adult volunteers was used. All volunteer patients signed an informed consent to participate in the study.

Blood samples (10 mL) were drawn from a forearm vein into vacutainer® blood collection tubes with EDTA (as K_2EDTA). Subsequently, samples were centrifuged at 4800 rpm for 10 min. Finally, the plasma was isolated and kept frozen at −20 °C until analysis.

At the time of analysis, plasma samples were diluted 1:2 (v/v) in water/acetonitrile 98:2 v/v and centrifuged at 12000 rpm for 5 min. The supernatant was separated and filtered through 0.22 μm polyvinylidene difluoride (PVDF) syringe filters (Millipore). A volume of 0.200 mL of filtrate was then ready to be injected into the extraction precolumn for analysis. Samples were analysed within two days after being collected.

2.3. GC–MS system

Derivatised samples were analysed using a Varian 3800 Gas Chromatograph equipped with a Varian 8200 autosampler and Saturn 2000 ion trap mass spectrometer (IT-MS) detector (Varian, CA, USA). Data acquisition and analysis were performed using standard software supplied by the manufacturer (Varian Saturn 2000). Samples were injected under splitless mode and the injector temperature was set initially at 120 °C held for 2 min and then ramped at 200 °C min^{-1} up to 325 °C and held for 5 min. This temperature programme allowed the injection of at least 9 μL of sample into the GC inlet liner at a temperature below the boiling point of the solvent.

The analyte separation was achieved on a fused silica capillary column AV-5-MS (Varian-MS, 30 m length, 0.25 mm i.d. with 0.25 mm film thickness) with an oven temperature set at 120 °C during 3 min and then programmed to reach 290 °C at 35 °C min^{-1} and held 5 min. Helium was used as carrier gas at a flow rate of 1.0 mL/min.

The MS detector was operated in electron impact ionization mode at 70 eV and the temperatures of the ion trap, manifold and transfer line were set at 230, 40 and 280 °C respectively. Ions monitored, in SIM mode, were m/z 72, 188, 294 and 395 for ATN-diTMS and 72, 115 and 332 for PRO-TMS.

2.4. SPE-MSFIA-MW system

The MSFIA manifold devised for SPE and MW assisted derivatisation is shown in Fig. 1. The system is constituted by a multisyringe automatic burette (MicroBU Crison, Barcelona, Spain), equipped with four high-precision bidirectional syringes (S1–S4) (Hamilton, Bonaduz, Switzerland). Each syringe has a three-way commutation valve at the head (V1-V4) (N-Research, Caldwell, NJ, USA) which helps reducing reagent consumption. In the proposed system, only three syringes were used: S1 (10 mL), S2 (10 mL) and S3 (5 mL). Depending on the position of the solenoid valves, the fluids contained in the syringes were loaded (pickup) or dispensed to the flow network (ON) or to their reservoirs (OFF). Additionally

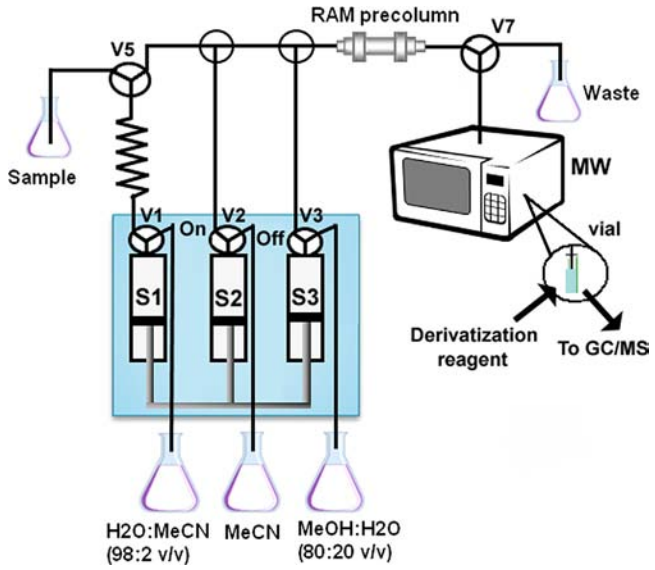

Fig. 1. Schematic illustration of the SPE-MSFIA-MW system. MeCN: acetonitrile, MW: microwave, GC/MS: gas chromatograph/mass spectrometer, S (1–3): syringes, V (1–7): valves, RAM: restricted access material.

two extra commutation valves (V5 and V7) (Takasago Electric, Nagoya, Japan) were connected to and controlled through the burette.

The automatic control of the flow system via PC was made through an RS232C interface [25]. The manifold was constructed with PTFE tubing of 0.8 mm i.d. and T connectors which were made from polytetrafluoroethylene, resisting organic solvents better than typical methacrylate connectors. The plasma sample treatment was performed in a LiChrospher RP-18 ADS precolumn with 25 mm × 4 mm i.d., 25 μm particle diameter (Merck, Darmstadt, Germany), which can be directly connected to the flow system without generating high back-pressure. To control the conditions of the derivatisation reaction a domestic microwave-oven (LG Intelowave, MS-0745 V with a nominal power of 750 W) was incorporated in the MSFIA system as shown in Fig. 1. The microwave oven used in the proposed system was modified by adding a cooling condenser to pass the PTFE tube to the vial. Before and after the modification, microwave power was calibrated. No significant loses of energy were denoted and the nominal power of the microwave (750 w) remained constant. System control was performed using the Autoanalysis 5.0 software package (Sciware Systems, Bunyola, Spain) [25].

2.5. MSFIA-SPE-MW procedure

The automated protocol of the developed MSFIA-SPE-MW is described in Table S1 of supplementary information and summarized as follows:

System initialization. With all valves in OFF position, syringes were filled from their respective reservoirs at a flow rate of 5.0 mL min^{-1}. S1 contained the extraction mobile-phase (water: acetonitrile 98:2 v/v), S2 the elution mobile-phase (acetonitrile) and S3 the mobile-phase for precolumn conditioning (methanol: water 80:20 v/v).

Conditioning step. ADS precolumn was conditioned with 5 mL of the mixture methanol:water (80:20 v/v) supplied by S3. Next, S1 dispensed a volume of 0.8 mL of H_2O:MeCN (98:2 v/v) through the precolumn to remove residual methanol which could be present in the dead volume, after the conditioning step.

Sample loading. S1 was connected to V5 in position OFF for sample loading into the 0.200 mL loop. The same syringe (S1) but with valve V5 in ON position, introduced the sample into the ADS precolumn to isolate the analytes from matrix constituents.

Clean-up. After analytes retention, the precolumn was rinsed with 2 mL of H_2O:MeCN (98:2 v/v) with the aim to remove the non-retained plasma matrix compounds, and therefore, to prevent interferences in the subsequent derivatisation reaction.

Elution. Firstly, S2 with the valve V7 in OFF position dispensed acetonitrile to the precolumn to remove any water present in the dead volume of the precolumn that could interfere during the derivatisation reaction. Thereafter, S2, with the valve V7 in ON position supplied the organic solvent to elute the analytes from the precolumn into the vial. Afterwards the derivatising reagent (MSTFA + 1% TMCS) was added to the vial and sealed. The vial was located in the microwave oven where derivatisation was carried out. Then, the determination of ATN and PRO was performed by GC–MS. The operational sequence was repeated three times for each sample. The entire procedure, i.e. SPE and derivatisation of the analytes, was done in 7.70 min.

2.6. Optimisation strategy

An on line procedure based on SPE with assisted microwave derivatisation was proposed. In this context, the analytical cycle involved four main steps: (1) loading the sample onto the precolumn and removing the proteinaceous ballast material, (2) washing the column and removing the more polar interfering substances, (3) elution of the analytes and (4) microwave assisted derivatisation.

The composition and volume of the extraction and elution phases were optimized using the MSFIA system with UV and fluorescence (FL) detection. Standard solutions of ATN and PRO (0.5 μg mL^{-1}) were used for all the experiments. On the one hand, SPE parameters were optimized using the OVAT method (one variable at time) aiming to extract the analytes with an effective removal of the proteinaceous matrix and other interfering components of the sample and to attain an efficient elution (quantitation) of the analytes.

On the other hand, factors corresponding to microwave assisted sylilation reaction with MSTFA + 1% TMCS were optimized using a factorial experimental design for screening the variables and a central composite design (CCD) to investigate the interactions among the principal affecting variables, and to obtain the critical values corresponding to the most favourable conditions, respectively. The experimental matrix design and data analysis were carried out by the software package STATISTICA 6.0 (Statsoft Inc. Tulsa, USA). Peak areas of ATN and PRO derivatives, as well as total peak area (average of ATN and PRO derivatives) were used as response variables in all multivariate experiments.

3. Results and discussion

3.1. Optimisation

3.1.1. MSFIA-SPE-MW system

The priority of our study was to optimise the composition of all the mobile phases (washing and elution) in order to obtain the maximum recovery in the shortest analysis time.

The washing mobile phase was proposed for propelling of the sample to the precolumn and proteins removal. The content of organic solvent is limited to avoid proteins denaturation and system clogging. However, addition of a small amount of organic solvent is recommended to achieve the release of the drug from the binding sites of plasma proteins enhancing the selectivity and sample clean up. In this sense acetonitrile:water (2:98 v/v) was employed as washing mobile phase with satisfactory results.

Flow rates in MSFIA are limited by back-pressure of the RAM column, and the viscosity of the plasma that restricted the use of high flow rates without increasing the back-pressure in the column during the elution process. This technique allows a maximum pressure of about 2.5 MPa [24]. For this reason, a flow rate of 0.6 mL min^{-1} was proposed for this step to prevent overloading of the syringe pump and to provide enough contact time between the analytes and the sorbent. The removal of the proteinaceous ballast was monitored by direct connection of the ADS precolumn to the diode array UV detector set at 254 nm and the fluorescence detector at $\lambda_{ex}=230$ nm, $\lambda_{em}=310$ nm.

For this purpose, 0.200 mL of a blank plasma sample and a plasma sample spiked with ATN and PRO were injected into the ADS precolumn. Quantitative recoveries of ATN and PRO were obtained with a washing time of 3 min. Recoveries were calculated by comparing the peak areas of each compound after extraction with those obtained by direct injection of the same amount of analyte in aqueous solution.

These results showed that this washing mobile phase provided a good reproducibility and selectivity in the subsequent derivatisation step. Moreover, the endogenous components from the plasma were completely removed from the precolumn while the analytes remained retained. Thus, this washing mobile phase was used for further analysis.

Once the clean up step was accomplished, it was necessary to optimise the composition of the eluting mobile phase to achieve convenient conditions for elution and derivatisation reaction. Acetonitrile provided best results, because of its stronger elution power, allowing analytes peak compression. Also this solvent has an acceptable dielectric constant ($\varepsilon'=37$) which gives a good sensitivity to microwave radiation [30–32]. Therefore, analytes were eluted from the ADS precolumn at a flow-rate of 0.6 mL min^{-1} during 0.8 min.

MSFIA is generally characterized by short analysis times and high sample throughput. However, in the proposed MSFIA-SPE-MW system, the analytical procedure is quite complex comprising sample pretreatment and derivatisation what leads to reduced sample throughput. Moreover, the flow rates used with this technique are limited by back-pressure of the RAM column especially when loading the viscous proteinaceous sample.

Different flow-rates of sample introduction within 0.4–0.8 mL min^{-1} were studied. 0.6 mL min^{-1} was chosen as an optimal value. Higher flow rates could cause back-pressure, worsening the repeatability of the signal.

Sample volumes were also tested in the range from 0.050 to 0.500 mL. Higher values of peak area of analytes were obtained by increasing sample volume. However, values above 0.500 mL affected RSD of the analysis measurements. In order to achieve a high sensitivity with a low relative standard deviation a volume of 0.200 mL was selected as a reasonable compromise.

3.1.2. Microwave assisted derivatisation

ATN and PRO, given their polarity, are not stable and decompose at high temperatures. For this reason, they were derivatised before GC–MS analysis using a silylation reaction. In this case, N-methyl-N-(trimethylsilyl) trifluoroacetamide (MSTFA) was used for this purpose, which is one of the most widely used for the identification and quantification of BB in biological samples [17,18,28]. MSTFA is an effective trimethylsilyl donor that replaces labile hydrogens atoms with this group on polar compounds such as ATN and PRO. Secondary amine (–NH) and hydroxy (–OH) groups present in the molecular structures of ATN and PRO, are converted to the corresponding (–N-TMS) and (–O-TMS) groups [27].

Previous studies describe derivatisation procedures prior to GC–MS analysis of ATN and PRO which are time-consuming, e.g. with conventional heating process. In our case, to shorten the sample preparation time, we used microwave radiation to supply high acceleration rates to the derivatisation reaction [29,30–33].

When microwave assisted derivatisation is employed, reaction solvent, microwave power and reaction time are important parameters that must be controlled. In contrast with conventional heating, the amount of heat transferred to the reaction mixture depends on the dielectric properties of the molecules [31,32]. Since polar molecules have a permanent dipole moment, they can absorb the microwave energy and convert it into heat. Methanol and acetonitrile have a high polarity, being very suitable for absorbing electromagnetic energy [31,32,34]. However, methanol has an hydroxyl group susceptible to be derivatised, therefore acetonitrile was selected.

To investigate the yield of the derivatisation reaction with microwave energy, a comparison using conventional heating was made. Two calibration curves were graphed by spiking 6 blanks of plasma with ATN and PRO at different concentration levels (0.006–2000 μg mL^{-1}). For assisted microwave derivatisation a reaction time of 90 s and a power of irradiation of 30% (250 W) were used, while for the conventional heating the conditions were 10 min at 30 °C. The equations of both calibration curves are showed in Supplementary Information (Fig. S2). As can be seen coefficients of correlation were higher than 99% in both cases. Results showed that, there were not significant differences between microwave heating and the classical method. Being both methods suitable for ATN and PRO determination.

After choosing the derivatisation reagent and the solvent, the remaining conditions were optimised using a multivariate design. These procedures provide relevant knowledge on the effect of variables within the entire selected experimental domain, and the variance of the estimate of the response in every point of the domain is better than that obtained by univariate methods [34]. Full factorial designs are the most popular first order designs owing to their simplicity and relatively low cost. They are very useful for preliminary studies or in initial optimisation steps. Full factorial designs at two levels are mainly used for screening, that is, to determine the influence of a number of effects on a response, and to discard those that are not significant [34].

Based on preliminary experiments, at least three factors might affect the experimental response (total peak area) in the present work: microwave irradiation power, reaction time and molar relation between the analyte and the sylilation reagent. Three levels were selected and a 2^3 factorial design with twelve experiments was carried out to optimise the analytical conditions that affect the analytes response signals (Table 1). The analysis of variance (ANOVA) results were evaluated to determine the significant effects (see supporting information Table S3). Normalized results of the experimental design were evaluated at a 5% of significance and analyzed by standardized Pareto chart (Fig. 2). The vertical line on the plot judges statistically significant effects, i.e. the bar extracting beyond the line corresponds to the effects that are statistically significant at the 95% confidence level [35]. Furthermore, the positive or negative sign also provides information about the effect of the variables upon the response signal.

Table 1
Factor codes, low, medium and high in 2^3 factorial design.

Factors	Levels		
	Low (−1)	Medium (0)	High (+1)
Reaction time (s)	20	55	90
Microwave irradiation power (%)	20	55	90
Molar relation (analyte:MSTFA) (v/v)	1:1	1:2	1:3

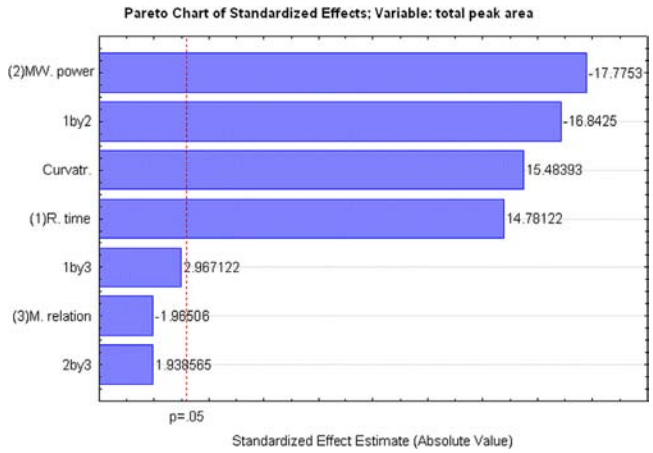

Fig. 2. Standarized main pareto chart for 2^3 factorial design. Vertical line in the chart defines 95% of confidence level.

According to Fig. 2, microwave power was the most significant factor having a negative effect on the peak area in this study. Reaction time has a positive significant effect, while molar relation showed a negative but non-significant effect on the peak area (taking into account the dilution effect). Molar relation was not a significant factor for the studied BB. For this reason, a 1:1 molar relation analyte: MSTFA volume was chosen as an adequate compromise between reactive amount and derivatisation yield.

In the next step, a central composite design (CCD) including quadratic terms was applied to optimise the two significant factors (microwave power and reaction time) according to the screening results (supplementary information Table S4).

In the central composite design levels varied from 20% to 90% for irradiation power and between 20 and 90 s for reaction time. The centre point was executed eight times resulting in a total of 16 experiments, which were made in random order.

The ANOVA table and the pareto chart (supplementary information Table S5 and Fig. S6, respectively) show that microwave irradiation power has the largest influence on the peak area and a negative effect upon the reaction yield. Results showed that at higher values of microwave irradiation power and reaction time the derivatisation efficiency increases up to 70%. However, microwave irradiation power higher than 70% had a negative effect on the reaction, because the effect called "bumping" occurred. Bumping is a sudden heating inhomogeneous in time, with high-energy radiation. This is due to physicochemical properties of acetonitrile, which has a large dielectric constant ($\varepsilon = 37.1$) and a boiling temperature close to 80 °C, thus, an abrupt behaviour can occur while irradiation power rises [36].

On the other hand, the reaction time has a significant positive effect upon the peak area. Nevertheless, its interaction with microwave irradiation power, produces a significant negative effect in the peak area of both analytes (see Fig. S6).

Response surface mapping was an effective way to find the optimum conditions. The design fitting a full quadratic model is provided below:

$$\text{Peak area} = 101499.087 + 3957.610x - 16.675x^2 + 4266.878y - 34.757y^2 - 19.894xy$$

where, y represents the microwave irradiation power and x the reaction time of the model obtained by multiple regression.

The regression models obtained were used to calculate the response surface for each variable separately. The response surface plot for the peak areas (Fig. 3) shows a curvature that demonstrates a significant interaction between microwave irradiation power and reaction time, indicating that higher reaction time values and lower microwave power are optimal for the extraction process.

According to the overall results of the optimisation study, the following experimental conditions were chosen: microwave irradiation power 20% (140 w) and a reaction time of 90 s (Fig. S7 of supplementary material). Fig. 4 shows the chromatogram of spiked plasma solution (0.5 μg mL^{-1} ATN and PRO) analyzed under the most favourable conditions described above.

3.2. Method validation

The validation of the proposed method was carried out by establishing linearity, intra- and inter-day precision, accuracy, selectivity and sensitivity parameters according to International Conference on Harmonization (ICH) guidelines [37]. Regression equations, correlation of determination (r^2), linear dynamic ranges (LDRs), limits of detection and quantitation (LODs and LOQs) were calculated under optimal conditions and are summarized in Table 2.

3.2.1. Linearity

Calibration curves of the analytes were obtained for standard ATN and PRO solutions prepared in MeCN and for spiked plasma samples. Each calibration set included seven data points and each point was run at least three times. Table 2 shows the regression equations of the peak areas of ATN and PRO as a function of concentration. As can be seen, the calibration curves were linear over the concentration range studied, indicating no significant deviation from linearity ($r^2 > 0.9982$) for all cases. Matrix effects were determined by comparing the slopes of the calibration curves obtained with the standard solutions and spiked plasma. A paired Student t-test indicated that the slopes of the calibration (using standard solutions) and the addition standard graphs were not statistically different ($P < 0.05$). Hence, the standard calibration technique with standard solutions could be used for the determination of ATN and PRO in plasma samples.

3.2.2. Precision and recovery

Precision of the proposed procedure was characterised by the repeatability, which was calculated for 5 consecutive measurements at three concentration levels 0.05, 0.25 and 0.75 μg mL^{-1} of ATN and PRO in spiked plasma samples. The precision expressed as

		102.0[d]		106.4[d]
		104.4[e]		103.7[e]

[a] Standard solution.
[b] Spiked plasma; concentration level.
[c] 0.75 μg mL^{-1}.
[d] 0.5 μg mL^{-1}.
[e] 0.25 μg mL^{-1}.

coefficient variation (CV) was $<3.85\%$ for all tested concentrations. The inter-day-assay precision was also determined on five different days. The CV did not exceed 3.0% demonstrating the good stability and repeatability of the developed pretreatment system.

The recovery was calculated at three concentration levels 0.05, 0.25 and 0.75 μg mL^{-1} by comparison of responses of ATN and PRO from spiked plasma samples with those found by injection of standard solutions at the same concentrations.

The mean absolute recovery was between 90.25% and 106.32% for both analytes, and the extraction efficiency was constant over the range mentioned above. These values demonstrated that the RAM column could be used repeatedly in the MSFIA system without loss of extraction efficiency.

3.2.3. Selectivity

The selectivity criterion demonstrated that the proposed method is not affected by the presence of interferences. The method selectivity was determined by checking the chromatograms obtained from blank plasma samples and plasma spiked with ATN and PRO (0.5 $\mu g\ mL^{-1}$). Each sample was tested for interferences and no endogenous compounds were encountered. The retention time of ATN-di-TMS and PRO-TMS were 7.10 and 7.50 min, respectively.

3.2.4. Sensitivity

Sensitivity was determined by the limits of detection (LOD) and limits of quantitation (LOQ). The LOD and LOQ defined as the lowest concentration with a signal to noise ratio of at least 3:1 and 10:1, respectively. The lowest concentration that can be quantified with acceptable accuracy and precision was 0.006 $\mu g\ mL^{-1}$ for ATN and PRO, respectively. Furthermore, the limits of detection for both analytes were of 0.002 $\mu g\ mL^{-1}$. As can be seen, the method has sufficient sensitivity for real drug level monitoring of ATN and PRO in human plasma. The values of the analytical parameters reported in Table 2 are comparable with those obtained by other reported methods [8,10,12–14,18] making our approach competitive in terms of reproducibility and sensitivity. Table 3 presents a comparison of the developed MSFIA-SPE-MW/GC–MS results for on-line sample treatment and determination of ATN and PRO in human plasma with other methods (off line) found in the literature. The present method has comparable LODs, repeatability and extraction time. Also, it provides the possibility of overlapping the microwave-assisted derivatisation step, with the clean up, preconcentration, chromatographic separation and reconditioning of the RAM column, increasing the overall sample throughput (one sample every 7 min). This is a compelling reason to select the present method, with advantages of being faster, simpler, and more environmentally friendly since smaller volumes of organic solvents are used,

3.3. Application to plasma samples

The effectiveness of the proposed method was examined by analyzing plasma samples of 6 hypertensive volunteers, i.e. patients receiving ATN or PRO treatment. The plasma samples were supplied by the Department of Cardiology of the Hospital of the University of Los Andes (HULA). The criteria for inclusion in the study were: being over 18 and treated for hypertension with 50 mg ATN or 80 mg PRO. All blood samples were taken in the range between 2 and 4 h after dosing. For analysis, samples were prepared according to the proposed procedure and were measured at least three times. Table 4 shows the results of each sample analysed with the present method.

The mean concentrations found were $0.107 \pm 0.030\ \mu g\ mL^{-1}$ for ATN and $0.155 \pm 0.040\ \mu g\ mL^{-1}$ for PRO, respectively. These values were consistent with those reported in the literature in pharmacokinetic studies [10,13,18,38] indicating that the method is suitable for routine monitoring of the considered drugs. Additionally, plasma samples were also analysed by another validated method previously developed in our laboratory [39]. There was a good correlation between concentrations determined by both methods (r^2 correlation graph 0.9885 see Fig. S-8). The proposed method presents improved or similar analytical characteristics concerning the application range and limits of detection. Indeed, considering the organic solvent consumed and the effluent produced in the sample preparation step, the proposed MSFIA-SPE system is "greener", with lower values for both of them. In comparison with other automatic strategies proposed for the same analytes but not based on SPE hyphenated schemes, the present method is undoubtedly more suitable for screening purposes, attaining also a higher determination frequency (see Table 3.).

4. Conclusions

A semi-automated analytical method was developed and successfully applied to human plasma samples for the determination of ATN and PRO by GC–MS. The methodology includes an automatic SPE-MSFIA-MW procedure for extraction and derivatisation of analytes avoiding manual sample preparation. Microwave heating yielded excellent results regarding recovery and sensitivity of analytes, and also increasing the sample preparation throughput. The minimum manipulation of plasma samples

improved the precision, shortened the analysis time and lowered costs per analysis, compared to conventional "off-line" methods. This method has been successfully applied to several plasma samples from drug users with a sampling throughput of 7 samples h^{-1}, achieving the overlapping of the microwave-assisted derivatisation step, with the clean up, preconcentration chromatographic separation and reconditioning of the RAM column, increasing its usefulness for routine analysis. In addition, results were in good agreement with those obtained by a previously validated LC-FLD method conferring robustness to the proposed methodology. Thus, this method is proposed as an attractive alternative to perform pharmacokinetic studies in determination of ATN and PRO for clinical use. Further research will be focused in total automation of the entire analytical setup by hyphenation of the sample treatment with GC–MS injection, which would represent a significant improvement in sample manipulation and analysis throughput.

ABSTRACT

The cloud point extraction (CPE) of silver nanoparticles (AgNPs) by Triton X-114 allows chromium (III) ions to be transferred to the surfactant-rich phase, where they can be measured by electrothermal atomic absorption spectrometry. Using 20 mL sample and 50 μL Triton X-114 (30% w/v), the enrichment factor was 1150, and calibration graphs were obtained in the 5–100 ng L^{-1} chromium range in the presence of 5 μg L^{-1} AgNPs. Speciation of trivalent and hexavalent chromium was achieved by carrying out two CPE experiments, one of them in the presence of ethylenediaminetetraacetate. While in the first experiment, in absence of the complexing agent, the concentration of total chromium was obtained, the analytical signal measured in the presence of this chemical allowed the chromium (VI) concentration to be measured, being that of chromium (III) calculated by difference. The reliability of the procedure was verified by using three standard reference materials before applying to water, beer and wine samples.

1. Introduction

In the environment chromium is present in two oxidation states, Cr(III) and Cr (VI), which have different physiological effects [1,2]. Due to the high toxicity of the hexavalent form, several countries have established severe restrictions concerning the presence of this metal in waters and, since both the authorized concentrations and those usually found in these samples are very low, at the μg L^{-1} level [3,4], the need exists for sensitive, easy-to-carry out analytical procedures to facilitate routine control in the laboratory. The very low concentration involved means that inductively coupled plasma mass spectrometry (ICP-MS) should be a suitable analytical technique for the purpose. However, the difficulty of dealing with such low concentrations is increased by the need to speciate both forms of the metal due to the above mentioned toxicity, the result of which is that a liquid chromatographic (LC) step is often included in the analytical procedure [5]. The LC–ICP-MS combination allows the determination to be carried out but is not always easily available at the laboratory. Consequently, interest has increased in recent years to develop other approaches involving instrumentation that is commonly present in the laboratory and which may be underused.

The analytical procedures for the speciation of chromium at low concentrations have been reviewed by several authors [4,6–9] and the recent literature shows an increasing use of miniaturized preconcentration techniques to achieve an improvement in sensitivity with minimal handling of the sample. As a result, a diversity of non-chromatographic alternative choices to LC–ICP-MS has been proposed. Leaving aside a number of liquid–liquid microextraction systems [10–16], sometimes involving ionic liquids or hollow fibers [17–19], followed by the use of an atomic or even molecular technique for the final measurement, cloud point extraction (CPE) would seem to be a promising method. CPE is based on the observation that solutions of non-ionic surfactants may form micelles and become turbid when heated above the cloud point temperature, giving rise to two fractions that can be separated by centrifugation. The surfactant-rich phase (coacervate) concentrates the analyte, as occurs with classical liquid–liquid extraction, but with no need for an organic solvent [20]. CPE followed by measurement of the chromium in the coacervate by means of an atomic technique has already been used for chromium determination and speciation [21–26]. A complexing agent is usually incorporated in the sample solution to facilitate the transfer of the metal to the surfactant-rich phase. Most authors

have proposed electrothermal atomic absorption spectrometry (ETAAS) for the final measurement since, in addition to its high sensitivity, this analytical technique is selective and only requires a low volume of sample to be injected into the electrothermal atomizer.

During a study recently carried out in our laboratory on the CPE of silver nanoparticles (AgNPs) [27], it was observed that chromium species were also coextracted into the coacervate despite the absence of an auxiliary complexing agent. The AgNPs were used as obtained, with no modification by functionalization or physico-chemical treatment, so that they apparently acted directly as efficient carriers, transferring ultratraces of chromium to the coacervate. The direct interaction of chromium species with AgNPs has already been reported and represents the basis for sensitive molecular spectrophotometric and fluorimetric procedures [28–30] for determination in aqueous solutions but, to the best of our knowledge, there are no previous reports describing the analytical benefit that can be obtained by using the above mentioned co-extractant effect. Taking into account both the characteristics of CPE and ETAAS, a sensitive procedure for the speciation of extremely low chromium concentrations seemed feasible, and the results of the research into such a possibility are described in this manuscript.

2. Experimental

2.1. Instrumentation

All the measurements were carried out with a model 600 atomic absorption spectrometer (Perkin-Elmer, Shelton, USA) equipped with a transversely heated graphite atomizer and a Zeeman-effect background correction device. Pyrolytic graphite platforms inserted into pyrolytically coated tubes were obtained from the same manufacturer. Argon flowing at 250 mL min^{-1} was used as inert gas. Measurements were carried out using a chromium hollow cathode lamp (Perkin-Elmer) as the radiation source. Integrated absorbance was exclusively used as the analytical signal. The instrumental parameters are summarized in Table 1.

Once the procedure had been optimized, the autosampler provided with the instrument was not used. Instead, the aliquots were introduced into the atomizer by manual injection using a chromatographic-type syringe provided with a polytetrafluoroethylene tube in its tip to avoid physical contact between the plunger of the syringe and the solutions.

A 50 W ultrasound bath (ATU, Valencia, Spain) with temperature control was also used.

Table 1
Instrumental parameters for chromium determination.

Parameter

2.2. Reagents and samples

All the solutions were prepared with pure water (18 MΩ cm resistivity) obtained with a Milli-Q system (Millipore, Bedford, MA, USA). The glassware and plasticware (polypropylene) was washed with 1% (v/v) concentrated nitric acid solution, and then rinsed with water before use.

The chromium (III) and (VI) stock standard solutions (1000 μg mL^{-1}) were prepared from $Cr(NO_3)_3 \cdot 9H_2O$ and $K_2Cr_2O_7$ (Fluka, Buchs SG, Switzerland), respectively, in water, and diluted daily to obtain appropriate working solutions. Triton X-114, sodium tetrahydroborate ($NaBH_4$) and silver nitrate ($AgNO_3$) were obtained from Fluka. Concentrated nitric acid (65%), disodium ethylenediaminetetraacetate (EDTA) and the rest of the chemicals used were obtained from Merck (Darmstadt, Germany).

Tap water was collected from the mains supply of the University of Murcia and analyzed both directly and after passing through a domestic water purifier system. Wine, beer and bottled water samples were purchased in a supermarket. The seawater samples were obtained from near the shore, close to a harbor in south-eastern Spain. These later samples were filtered and maintained in plastic containers at 4 °C until they were analyzed (less than 48 h) by the general procedure.

In addition, three standard reference materials, namely NIST 1640a (trace elements in natural water), NASS-6 (seawater reference material for trace metals) and SPS-SW2 Batch 125 (reference material for measurement of elements in surface waters) with a certified content of total chromium were obtained from the National Institute of Standards and Technology, National Research Council Canada and Spectrapure Standards, respectively.

2.3. Preparation of silver nanoparticles (AgNPs)

The silver nanoparticles (AgNPs) were prepared according to the scientific literature [28]. For this purpose, 100 mL of 0.1 mM silver nitrate solution were placed in a flat-bottomed flask and, while the solution was vigorously stirred, 0.012 g of solid $NaBH_4$ were incorporated, maintaining the stirring for 10 min. The mixture was aged overnight in the dark. The AgNPs suspension thus prepared was stable for several days at room temperature.

2.4. General procedure

The sample solution (20 mL) containing chromium in the 5–100 ng L^{-1} range was placed in a centrifuge tube and 0.2 mL of a 1 mol L^{-1} nitric acid solution was incorporated to bring the pH close to 2, before heating to 60 °C. Next, 10 μL of a 0.1 mM AgNPs suspension and 50 μL of a 30% w/v Triton X-114 solution were added. The tube was gently shaken for a few seconds and then maintained at 60 °C for 10 min. The turbid mixture obtained was centrifuged at 4000 rpm for 5 min and a 10 μL aliquot of the recovered surfactant-rich solution was injected into the electrothermal atomizer. The heating program given in Table 1 was run, and the analytical signal due to total chromium was obtained.

For speciation, the experiment was repeated but incorporating 0.4 mL of a 0.3 mol L^{-1} EDTA solution immediately before adding the AgNPs suspension, while the rest of the procedure was the same. The analytical signal obtained corresponded to Cr(VI) which permitted Cr(III) concentration to be calculated by difference.

Calibration was carried out using Cr(III) and Cr(VI) standard solutions treated in the same way.

The wine samples were first diluted to ensure that the ethanol concentration was below 5% (v/v). In the case of beer samples, the same dilution step was carried out when necessary and the samples sonicated for 30 min for degasification.

3. Results and discussion

The literature reports [28–30] that AgNPs treated with citric or ascorbic acid interact with Cr(III), leading to a red-shift change in color from yellow to purple. The chromium (III) ions bind to the citrate or ascorbate covering the AgNPs, giving rise to a change in the aggregation of the solid particles and hence to a change in the color. The effect is also observed when hexavalent chromium is used, since this species is reduced by ascorbate or by the excess of reductant present in the dispersion of AgNPs, and is the basis for sensitive colorimetric and fluorimetric procedures for determining chromium. This spectral change is noticeable when AgNPs concentration is at the mg L^{-1} level. By our part it was observed that there is also an interaction between chromium ions and AgNPs in the absence of citrate and ascorbate, when using extremely low concentrations of the solid particles at the μg L^{-1} level. In such conditions, the dispersion is colorless and apparently not altered by the presence of chromium traces. However, when Triton X-114 is incorporated above the critical micellar concentration (0.2 mM) and the mixture is heated to provoke CPE, the AgNPs are extracted into the coacervate, a fact which is already known, but chromium ions are also transferred to the surfactant-rich phase, which has not been described before. The extraction of both AgNPs and chromium ions is practically complete. The transfer effect, that occurs for both Cr(III) and Cr(VI) does not occur in the absence of AgNPs and is the basis for the determination of the extremely low amounts of chromium studied here.

3.1. Optimization of the CPE

A number of experiments were carried out in which small amounts of AgNPs (in the 1–50 μg L^{-1}) range were first incorporated in solutions containing Cr (III) and Cr(VI) and then CPE was carried out with Triton X-114. The effect of the experimental conditions was studied for each of the chemicals involved.

In order to obtain a high enrichment factor, 20 mL of aqueous sample were used. The amount of Triton X-114 affects the final volume of the coacervate recovered. Thus, for 150 μL of 30% Triton X-114, the volume recovered was approximately 60 μL. To attain maximum sensitivity, most of the experiments were finally carried out using 50 μL of the surfactant solution, which permitted the recovery of approximately 18 μL of coacervate. The optimal temperature for the CPE was found to be 60 °C maintained for 10 min. The optimal pH was studied experimentally and found to be in the 1.5–2.5 range for both Cr(III) and Cr(VI). Consequently, the incorporation of a small volume of nitric acid to the water samples to achieve a pH close to 2 is recommended. A monochloroacetic/monochloroacetate buffer solution provides the same result but the direct adjustment of the pH proved suitable and was used in the rest of the experiments.

The results obtained when the effect of the AgNPs concentration was studied for both Cr(VI) and Cr(III) are shown in Fig. 1. As can be seen in the graphs, chromium species were not extracted in the absence of AgNPs but, when present, even in a small concentration, the analytical signals obtained in the coacervates were maximal and constant. It should be noted that the AgNPs solutions contain an excess of reductant (sodium tetrahydroborate) due to the way in which they are prepared. This means that Cr(VI) is reduced and then interacts with the solid particles, meaning that the response is not dependent on the oxidation degree of the chromium. A 5 μg L^{-1} AgNPs concentration was found to be sufficient to completely transfer the chromium species to the coacervate for the whole range of analyte concentrations studied.

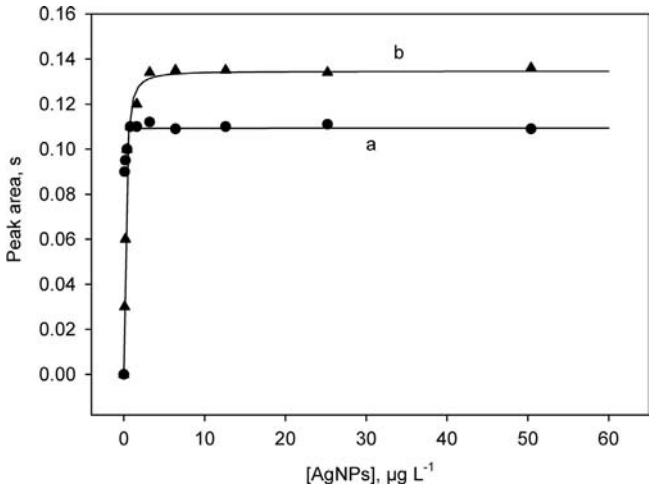

Fig. 1. Effect of the AgNPs concentration on the chromium signal obtained from the surfactant-rich phase. Lines a and b correspond to sample solutions containing 14 ng L^{-1} Cr(III) and 17 ng L^{-1} Cr(VI), respectively.

3.2. Optimization of ETAAS measurement

When the coacervates were injected into the electrothermal atomizer, the characteristic mass of chromium was higher than expected, probably as a consequence of the formation of chromium carbide due to the high amount of organic matter. To overcome this deleterious effect without diluting the coacervate (which would result in a decrease of the enrichment factor), a chemical modifier was tried. Some reports suggest the use of complexing agents [11,31,32], coating the atomizer with iridium [33] or the addition of a palladium salt [34]. The last was considered to be the most suitable way to increase sensitivity. A number of ashing–atomizing graphs were obtained in the usual way and it was verified that the incorporation of 20 μL of a 2000 μg mL^{-1} palladium solution together with the use of 1000 and 2300 °C as the calcination and atomization temperatures, respectively, resulted in well-defined chromium atomization profiles with a low characteristic mass (6 pg) and a low background, which was easily corrected by the Zeeman device. To avoid practical problems derived from the difference in the physicochemical properties of the coacervate and the modifier solution, the latter was first injected into the atomizer and the drying stage of the heating program was run. Next, the aliquot of coacervate was injected by means of a chromatographic syringe, and the entire program was run.

3.3. Chromium speciation

Since the chromium species transferred to the surfactant-rich phase with the aid of AgNPs is the trivalent form, speciation is possible. For this purpose, advantage can be taken of the relatively slow kinetics of Cr(III) complexation by the ethylenediaminetraacetate (EDTA) anion compared with the kinetics of the retention of this species on AgNPs. As can be seen in Fig. 2, the presence of a low EDTA concentration prevented Cr(III) from being transferred to the surfactant-rich phase. However, when the experiments were made using hexavalent instead of trivalent chromium, the

analyte was extracted in an extension that depended on the concentration of both AgNPs and the complexing agent. Since the experiments were carried out by first incorporating the EDTA solution in the sample solution and then the AgNPs suspension, a reasonable explanation for the observed behavior is that the retention of Cr(III) by the AgNPs is much faster than its complexation with EDTA. According to this hypothesis, the Cr(III) resulting from the reduction of Cr(VI) in the presence of EDTA is not complexed but rapidly and strongly retained on the solid particles. Only when the complexing agent concentration is high enough there is competition for Cr(III) with the nanoparticles and the signal decreases. If the AgNPs concentration increases, more EDTA is required for the competition effect to be observed. A 6 mmol L^{-1} EDTA and 5 μg L^{-1} AgNPs concentration were found to be suitable for the low concentrations of chromium involved in the experiments.

The reliability of the speciation scheme was checked by applying it to solutions prepared at three Cr(VI)/Cr(III) ratios. The results shown in Table 2 demonstrate that speciation at these low analyte concentrations is feasible.

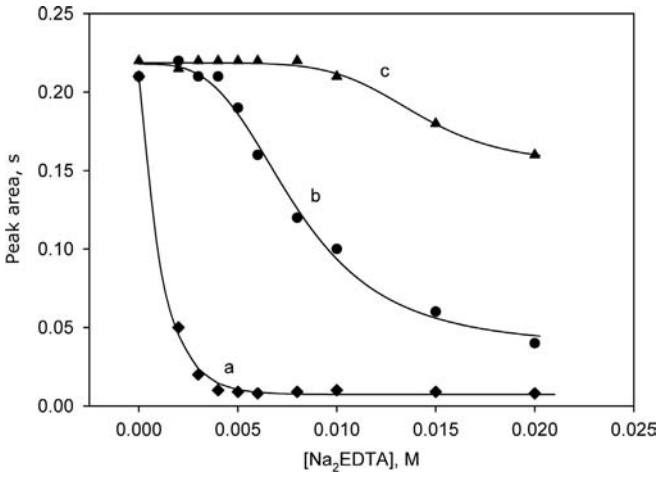

Fig. 2. Effect of the EDTA concentration on the chromium signal obtained from the surfactant-rich phase. Line a corresponds to a sample solution containing 50 ng L^{-1} Cr(III) in the presence of 5 μg L^{-1} AgNPs. Lines b and c, a 27 ng L^{-1} Cr(VI) solution in the presence of 0.5 and 5 μg L^{-1} AgNPs, respectively.

Table 2
Results (mean ± s, $n=5$) for the determination of Cr(VI) and Cr(III) in aqueous solutions.

Cr(VI)/Cr(III) ratio	Cr(VI), ng L^{-1}			Cr(III), ng L^{-1}		
	Added	Found	Recovery, %	Added	Found	Recovery, %
0.1	8	8 ± 1	101	80	81 ± 3	101
1	50	51 ± 2	102	50	51 ± 3	103
10	80	79 ± 3	99	8	8 ± 2	94

3.4. Analytical figures of merit: analysis of real samples

Using the optimized conditions, a linear relationship between the analytical signal and the chromium concentration in the sample was verified in the 5–100 ng L^{-1} range, with a detection limit (calculated on the basis of three times the standard deviation of y-residuals from the calibration graph) of 2 ng L^{-1}. The repeatability of the measurements was studied for three concentrations, namely 10, 20 and 50 ng L^{-1} and the relative standard deviations for 5 consecutive experiments in each case were 4.3, 3.8, and 3.8, respectively. The enrichment factor (EF) was calculated using the ratio between the slopes of a calibration line obtained from aqueous solutions submitted to the CPE procedure and the slope of a calibration line obtained with solutions that were not extracted. This experimental EF was found to be 1150.

Due to the characteristics inherent to ETAAS, selectivity was excellent. This foreseeable feature was verified by incorporating several foreign ions (Mg(II), Ca(II), Ba(II), Zn(II), Pb(II), Hg(II), Co(II), Ni(II), Cd(II), As(III), Al(III), Fe(III), Sb(III), As(V), sulfate and phosphate) up to a foreign ion:chromium ratio of 10,000 with no deleterious effect on the analytical signal. Only in the case of an AgNPs concentration of 0.5 μg L^{-1} was there a decrease in the analytical signal caused by Co (II), Ni(II) and Cd(II) when present in ion:chromium molar ratios exceeding 1000. This deleterious effect was attributed to the competition of these ions with chromium for the active sites of the solid particles, and disappeared when the recommended AgNPs concentration (5 μg L^{-1}) was used. Table 3 shows a summary of the main characteristics of the optimized procedure and of other comparable procedures based on CPE and ETAAS.

The procedure was checked by applying it to several real samples, namely water, beer and wine samples. The very low concentrations involved make it difficult to check the reliability of the results by direct comparison with those obtained using other approaches, and so three water samples with certified chromium contents were first used for this purpose. It should be noted that, due to the extreme sensitivity of the procedure here studied, these samples had to be diluted before being analyzed. The results obtained for these certified reference materials as well as for another six water samples of different origins are shown in Table 4, together with the results found by applying the standard additions method. When wine and beer samples were analyzed the presence of ethanol was seen to affect the CPE process. Additional experiments demonstrated that this

deleterious effect only appears for ethanol concentrations above 6% v/v, approximately. Taking advantage of the sensitivity of the procedure, this inconvenience can be easily overcome by dilution. Thus, wine and beer samples were diluted four and two times, respectively. In the case of beer, sonication for 20 min was used to degas the samples before analysis. The final results for wine and beer samples are given in Tables 5 and 6, respectively, together with its additional verification by means of the standard additions method.

4. Conclusion

Silver nanoparticles (AgNPs), even at the μg L^{-1} level, when submitted to CPE, interact with Cr(III) and completely transfer this species to the coacervate, where the metal can be measured by ETAAS. Due to the high sensitivity of ETAAS and the preconcentration factor inherent to CPE, a large enrichment factor for chromium is achieved, and extremely low amounts can be measured. Speciation is possible if ethylenediaminetetraacetate is used as an auxiliary reagent. The chemical reagents, as well as the instrumentation, are easily available so that the combination AgNPs–CPE–ETAAS appears to be a suitable alternative choice to LC–ICP-MS for the speciation of low amounts of chromium.

ABSTRACT

Canagliflozin is the first sodium–glucose co-transporter-2 inhibitor, approved by the US Food and Drug Administration for the treatment of type 2 diabetes mellitus. In this study, a sensitive UHPLC–MS/MS assay for rapid determination of canagliflozin in rat plasma was developed and validated for the first time. Chromatographic separation of canagliflozin and zafirlukast (IS) was carried out on Acquity BEH C18 column (100 × 2.1 mm, i.d. 1.7 μm) using acetonitrile–water (80:20, v/v) as mobile phase at a flow rate of 0.3 mL min^{-1}. Canagliflozin and IS were extracted from plasma by protein precipitation method using acetonitrile. The mass spectrometric detection was performed using electrospray ionization source in negative mode to avoid canagliflozin adduct ions formation. Multiple reaction monitoring were used for quantitation of precursor to product ion at *m/z* 443.16 > 364.96 for canagliflozin and *m/z* 574.11 > 462.07 for IS, respectively. The assay was fully validated in terms of selectivity, linearity, accuracy, precision, recovery, matrix effects and stability. The validated method was successfully applied to the characterization of oral pharmacokinetic profiles of canagliflozin in rats. The mean maximum plasma concentration of canagliflozin of 1616.79 ng mL^{-1} was achieved in 1.5 h after oral administration of 20 mg kg^{-1} in rats.

1. Introduction

Sodium–glucose co-transporter-2 (SGLT-2) inhibitors have emerged as a novel class of oral anti-diabetic agents [1]. Canagliflozin is the first orally active SGLT-2 inhibitor, approved by both US Food and Drug Administration (March, 2013) and European Medicines Agency (November, 2013) for the treatment of type 2 diabetes in adult patients [2–4]. It is a specific SGLT2 inhibitor and exhibits approximately 200-fold higher selectivity for SGLT2 over SGLT1[5]. Canagliflozin inhibits reabsorption of filtered glucose from the lumen of the proximal tubules of the kidney, thereby leading to lowered renal threshold for glucose (RTG) and increased urinary glucose excretion [2,5,6].

Absorption of canagliflozin is rapid with peak plasma concentrations (C_{max}) achieved within 1–2 h following oral administration. After multiple dose administration, steady state levels were attained in 4–5 days [2,6,7]. Absolute oral bioavailability of canagliflozin is 65%, and it is highly bound to plasma protein (99%), mainly albumin [8]. Following single dose oral administration, the terminal half-life was in the range of 10.6–13.1 h with a large volume of distribution of 119 L [6,9]. It is mainly metabolized by glucuronidation via uridine diphosphate glucuronosyltransferase 1A9 (UGT1A9) and uridine diphosphate glucuronosyltransferase B4 (UGT2B4) into two inactive metabolites (M1 and M7). About 33% of metabolites are eliminated in the urine and approximately 42% are excreted in the feces [2,10].

Being a novel oral antidiabetic agent, a sensitive and robust bioanalytical assay is required for the determination of canagliflozin in plasma samples to support pharmacokinetic, therapeutic drug monitoring and drug interaction studies. Previous literature published on pharmacokinetic characterization of canagliflozin only described the summary of the bioanalytical assay for the determination of canagliflozin [10]. In spite of its global approval, to our knowledge there is no published method exist for canagliflozin quantification in biological matrices.

Amongst the available analytical techniques, UHPLC–MS/MS has gained attention as both chromatographic separation and assay selectivity have been significantly improved using this technology. The use of Aquity BEH column in UPLC increases the separation efficiency by reducing the retention time and solvent consumption during chromatographic separation [11–14]. The present work is aimed at developing a sensitive, robust and specific UHPLC–MS/MS method, which can facilitates the rapid determination of canagliflozin in plasma samples.

2. Materials and methods

2.1. Chemicals and reagents

Canagliflozin (purity > 99%) was purchased from Beijing Mesochem Technology Co. Ltd. (Beijing, China). Zafirlukast was used as an internal standard (IS, purity > 98%) from AstraZeneca Pharmaceutical Wilmington, UK. HPLC grade methanol and acetonitrile were obtained from Fisher Scientific UK Limited, Leicestershire UK, whereas ammonium acetate of analytical grade was obtained from Qualikems Fine Chem. Pvt. Ltd. Vadodara, India. All aqueous solutions used in this study were obtained from Milli-QR Gradient A10R (Millipore, Moscheim Cedex, France) having pore size 0.22 μm. Blank plasma was prepared in laboratory from drug free healthy rats which were obtained from the Animal Care and Use Centre, College of Pharmacy, King Saud University, Riyadh, Saudi Arabia.

2.2. Stock solution preparation

Stock solutions (500 μg mL^{-1}) of canagliflozin and IS were prepared by dissolving accurately weighed amount of their respective standards in methanol. Two stock solutions for canagliflozin were prepared from two separate weightings. One solution was used for calibration curve samples while other for quality control samples (QCs). All solutions were stored in refrigerator at 4 °C.

2.3. Calibration standards, quality control and internal standard (IS) preparation

Stock solutions of canagliflozin and IS were further diluted with acetonitrile–water (50:50, v/v) to prepare the working solutions of calibration standards, quality control and IS. Nine concentration levels of the plasma calibration standards were prepared by spiking working standard solutions into rat blank plasma to obtain final concentration levels of 3.76, 10.7, 30.7, 76.8, 192, 640, 1600, 4000 and 6666 ng mL^{-1}. Similarly four QCs, at 4.31, 12.3, 320 and 5333 ng mL^{-1} was also prepared by spiking in the blank plasma and treated as LOQ QC, LQC, MQC and HQC, respectively. All calibration standards and QC concentrations were prepared by serial dilution of stock solutions using Microsoft excel version 2010. Both plasma standards and QC samples were kept at −80 °C until used during validation and/or samples analysis. The IS working solution (1000 ng mL^{-1}) for routine use was prepared by diluting the IS stock solution in acetonitrile–water (50:50, v/v) and stored in refrigerator at 4 °C.

2.4. Chromatographic separation and MS/MS conditions

The ACQUITY™ UPLC system coupled to triple–quadruple tandem mass spectrometer (Micromass® Quattro micro™ Waters Corp., Milford, MA, USA) was used in this study. The UHPLC system consisted of quaternary solvent manager, a binary pump, degasser, autosampler with an injection loop of 10 μL and a column heater–cooler. The chromatographic separation was achieved on Acquity BEH™ C_{18} column (100 × 2.1 mm, i.d., 1.7 μm, Waters, USA) maintained at 40 °C temperature. An isocratic flow, comprising of acetonitrile:10 mM ammonium acetate (80:20, v/v) as mobile phase was used at a flow rate of 0.3 mL min^{-1}. Canagliflozin and IS were eluted within one min with a total run time of 1.5 min only. The injection volume was 10 μL in partial loop mode and the temperature of the autosampler was kept at 15 °C.

Both canagliflozin and IS were detected by triple–quadruple tandem mass spectrometric detection with an electrospray ionization (ESI) interface running in negative ionization mode. The multiple reaction monitoring (MRM) transitions of m/z 443.16 > 364.96 for canagliflozin and m/z 574.11 > 462.07 for IS were used with dwell time 0.106 s. Nitrogen was employed as a desolvating gas at a flow rate of 600 L h^{-1}. The desolvation line temperature was 350 °C whereas source temperature was 150 °C. The collision gas (argon) flow was 0.1 mL min^{-1} and capillary voltage was set at 4.0 kV. The compound specific parameters like cone voltage and collision energy were set at 40 V and 16 eV for canagliflozin and 66 V and 32 eV for IS, respectively. The Mass Lynx software (Version 4.1, SCN 714) was used to control the UPLC–MS/MS system, and data was collected and processed using Target Lynx™ program.

2.5. Sample preparation

Plasma samples (calibration standards, QCs and unknown samples) stored at −80 °C were thawed at room temperature and vortexed for 30 s before sample preparation. In a fresh 1.5 mL centrifuge tube, 200 μL aliquot of plasma (blank, calibration standards, QCs and unknown samples) was added followed by 15 μL of IS (1000 ng mL^{-1}). The samples were vortexed for 30 s and were deproteinized by adding 385 μL of acetonitrile and again gently vortexed for one min. The samples were centrifuged for 10 min at 11,000g at 4 °C. After centrifugation, supernatant was transferred to a fresh tube and evaporated to dryness. The residues were reconstituted in 200 μL of mobile phase out of which 10 μL was injected into UHPLC–MS/MS for analysis.

2.6. Method validation

Method validation was performed following guidelines set by the US FDA and EMEA [15,16]. A full validation was performed in rat plasma in terms of selectivity, linearity of response, accuracy and precision, recovery, matrix effects, carry over effects and stability of analyte in various conditions.

2.6.1. Selectivity

Method selectivity was determined in rat plasma to rule out any interferences from endogenous matrix compounds with analyte and/or IS. Six different lots of blank plasma which was obtained from different rat along with plasma sample spiked with canagliflozin at LLOQ level (3.76 ng mL^{-1}) and IS at 100 ng mL^{-1} level were processed by the proposed extraction method and analyzed. The response of co-eluting interferences was evaluated by comparing the chromatograms of blank plasma with the spiked plasma with analyte and IS.

2.6.2. Calibration curve and assay linearity

Calibration curves in triplicate were prepared in spiked rat plasma samples at 9 different concentration levels in the range of 3.76–6666 ng mL^{-1}. The linearity of each calibration curve was evaluated by plotting the peak area ratios of analyte to IS versus the concentration of analyte and determined by weighted least squares linear regression method of $1/X^2$. The suitability of calibration curve was assessed by measuring the accuracy and precision value at each concentration level, which must be ≤ 15%. The lowest concentration of analyte in calibration curve was recognized as LLOQ, having a signal-to-noise ratio of ≥ 5

compared with blank sample and acceptable accuracy and precision of $\leq 20\%$.

2.6.3. Precision and accuracy

Precision and accuracy were determined in rat plasma at four different QC concentrations (LOQ QC, LQC, MQC and HQC). The intraday precision and accuracy were determined in replicate ($n=6$) on same day, while the inter-day precision and accuracy were determined in replicate ($n=18$) over three consecutive days. The deviation in mean value of precision was limited to $<20\%$ for the lowest QC samples and 15% for the other QC samples and accuracy was limited to be within $\pm 20\%$ for the lowest QC samples and $\pm 15\%$ for the other QC samples.

2.6.4. Recovery and matrix effects

The recovery and matrix effects in rat plasma were investigated at three QC levels (LQC, MQC and HQC). The recovery of canagliflozin from rat plasma was determined by comparing peak response ratio of plasma spiked with analyte prior to extraction (A) with those spiked with analyte after the extraction (B) i.e., the ratio A/B × 100 is defined as a percentage recovery. The absolute matrix effect (expressed as matrix factor) was determined by dividing the response of post-extraction spiked sample (B) to the analyte in to reconstitution solution (C) in the same concentration (B/C × 100). Same procedure was followed for IS (100 ng mL^{-1}) to assess recovery and matrix effects. Deviation in canagliflozin and IS response of a maximum of 15% was considered acceptable as recommended in EMEA bioanalytical guidelines [16].

2.6.5. Carry-over effects

For a robust method, it is important to eliminate any possible carry-over effect and to ensure long term performance of the method. The carry-over effects of canagliflozin in respect to autosampler contamination in rat plasma were investigated by injecting a double blank plasma extract samples after a ULOQ extract sample in triplicate. The carry-over effects were calculated by comparing the percentage peak area of double blank plasma to the area of the LLOQ sample. Same procedure was followed for IS also. The peak area response for blank plasma extract was limited to $\leq 20\%$ of the peak area of the LLOQ and $\leq 5\%$ of the IS to rule out any carry-over effect.

2.6.6. Stability

The stability experiments for canagliflozin were performed in rat plasma by analyzing six replicates of QC samples (LQC and HQC) under different conditions. All stability parameters were evaluated against freshly prepared calibration curve. Short-term stability of canagliflozin was assessed by processing and analyzing QC plasma samples after 12 h storage at room temperature. Freeze–thaw stability was determined after freezing the spiked QC samples at -80 °C and thawing at 25 °C three times. Auto-sampler stability was determined by keeping the reconstituted QC samples for about 48 h in the auto-sampler at 15 °C before analysis. Long-term stability of canagliflozin was determined by analyzing the spiked QC plasma samples which were stored at -80 °C for 30 days. The stock solutions and working solutions of canagliflozin and the IS were also evaluated for their stability at room temperature for 12 h and at refrigerator temperature (below 10 °C) for 15 days. The canagliflozin samples were considered stable if the deviation from the mean calculated concentration of quality control samples were found to be within the limits of accuracy ($\pm 15\%$) and precision ($\leq 15\%$).

2.7. Application to pharmacokinetic study in rats

This newly developed assay was applied to a canagliflozin pharmacokinetic study in male Wistar Albino rats weighing 220–230 g ($n=6$). Animal experiments were conducted in accordance with the guidelines of the Experimental Animal Care and Use Committee of College of Pharmacy, King Saud University Riyadh, KSA. After overnight fasting, all rats received canagliflozin (20 mg kg^{-1} oral, dissolved in HPMC) and blood samples (approximately 0.5 mL) were collected from the retro-orbital plexus into heparinized tubes at different time intervals (0, 0.5, 1, 1.5, 2, 2.5, 3, 4, 6, 8 and 20 h). Plasma samples were harvested by centrifuging the blood at 4500*g* for 8 min and frozen at -80 ± 2 °C until analysis. The pharmacokinetic parameters such as C_{max}, T_{max}, area under curve (AUC), half-life ($T½$), mean residence time (MRT) and elimination rate constant (K_{el}) were calculated using WinNonlin software (Pharsight Co., Mountain View, CA, USA).

3. Results and discussion

3.1. Optimization of mass spectroscopy condition

Initially 400 ng mL^{-1} solution of canagliflozin was directly infused using ESI sources in positive ion modes. Results of precursor ion spectra gave sodium $[M+Na]^+$ and ammonium $[M+NH4]^+$ adduct of canagliflozin at *m/z* 467 and 462 as strong signal instead of protonated molecule (which is commonly observed with neutral compound) during full scan mass analysis (Fig. 1). In previous reported studies, ammonium adducts ions in ESI positive mode (MRM transition of *m/z* 462.1 > 267.0) was adopted for canagliflozin determination and identification [10,17]. Due to possibility of contamination of alkali metal ions

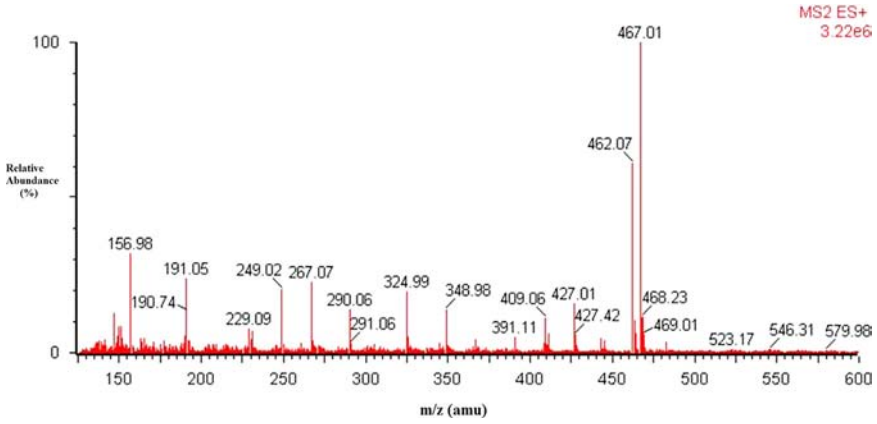

Fig. 1. Precursor ion spectra in positive ionisation mode which produced ammonium $[M+NH4]^+$ and sodium $[M+Na]^+$adduct of canagliflozin.

from other sources e.g. laboratory glassware and biological matrices and for selective and robust performance of assay, it is recommended to avoid adduct ions formation in LCMS/MS analysis [18]. Furthermore, presence of competitive metal adducts ions, may also reduce the sensitivity of the target analyte detection and assay performance. In order to avoid this competitive adduct ions formation, ESI in negative mode was chosen as an alternative source for ionization instead of positive mode. ESI^- produced a single abundant product ion peak at m/z 443 which consequently produced one major stable product ion at m/z 365. Using negative ionization conditions, we have successfully achieved sensitive detection and completely avoided the adduct ions formation of canagliflozin. Zafirlukast (IS) which also produced most abundant precursor ions in negative mode at m/z 574 and its fragment ions at m/z 462 was used as internal standard. Thus MRM detection was carried out by monitoring of precursor to product ion at m/z 443.16 > 364.96 for canagliflozin and m/z 574.11 > 462.07 for IS.

UPLC–MS/MS operation parameters, such as capillary and cone voltage, desolvation temperature, ESI source temperature and flow rate of desolvation gas and cone gas were further tuned to achieve optimum intensity of negative molecular ions $(M–H)^-$ of canagliflozin and IS. Canagliflozin produced predominant singly charged precursor $(M–H)^-$ ion when cone voltage was set at 40 V and dominant product ion (m/z 364.96) when collision energy was set at 16 eV. Similarly for IS, the optimized cone voltage was set at 66 V for precursor $(M–H)^-$ ion (m/z 574.11) and collision energy 32 eV for dominant product ion (m/z 462.07). Precursor ion and product ion spectra $(M–H)^-$ of canagliflozin and IS after infusion of 400 ng mL^{-1} solution in acetonitrile are shown in Fig. 2 and Fig. 3, respectively.

3.2. Optimization of chromatographic conditions

The chromatographic condition was optimized to achieve efficient separation of analyte and IS with good resolution, symmetric peak shape, minimum interferences with high signal response and shorter run time. Initially acetonitrile as organic modifier along with three aqueous phase (A) 0.1% formic acid (B) simple water (C) 10 mM ammonium acetate and (D) 10 mM ammonium acetate with 0.1% formic acid were tried in different ratios as isocratic mobile phase. Although the separation of analyte and IS were achieved with all combinations when the ratio of acetonitrile and aqueous phase was kept at 80:20. However, the highest ionisation response of both analyte and IS was achieved with acetonitrile and aqueous phase (B) i.e. simple water. The presence of formic acid or buffers in mobile phase may lead to adduct ions formation which results in suppression of responses. With respect to column, the Acquity BEH^{TM} C_{18} column of 100 × 2.1 mm and 50 × 2.1 mm diameter having the same particle size (i.d. of 1.7 μm) were tested. Best peak resolution was obtained with 100 × 2.1 mm diameter and was used for this assay with column oven temperature of 40 °C. Zafirlukast was selected as the IS, because it was separated sufficiently from analyte, had sensitivity in ESI negative mode and almost similar extraction recovery to the analyte. Both analyte and IS were eluted within 1 min with a total run time of 1.5 min which was sufficient for high throughput determination of canagliflozin. The representative total ion chromatography (TIC) of both canagliflozin and IS are presented in Fig. 4.

3.3. Sample extraction optimization

The purpose of sample extraction optimization is mainly to achieve high extraction recovery and low matrix effects in order to improve sensitivity and reliability of LC-MS/MS analysis. Strategy usually includes all possible common sample extraction options including solid phase extraction, liquid extraction and protein precipitation. With the emergence of UHPLC technology combined with high sensitive tandem mass spectroscopy, it is possible to quantify analytes at a low concentration without having a high extraction recovery, provided that the recovery remains constant over time and concentration [19]. With time-saving advantage and simplicity, the protein precipitation method was chosen as

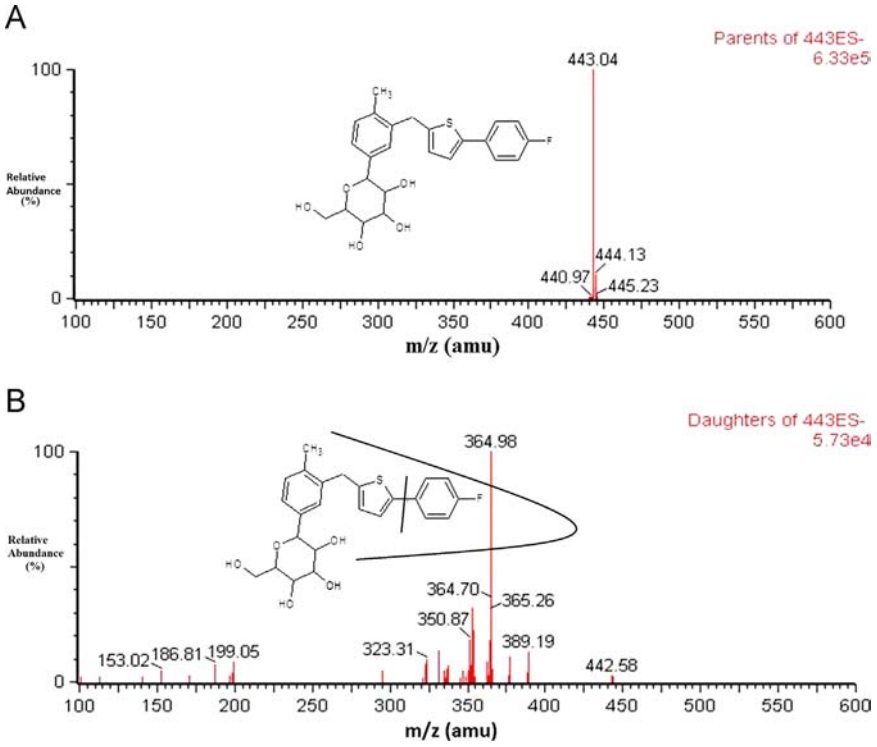

Fig. 2. Precursor ion (A) and product ion (B) spectra of canagliflozin.

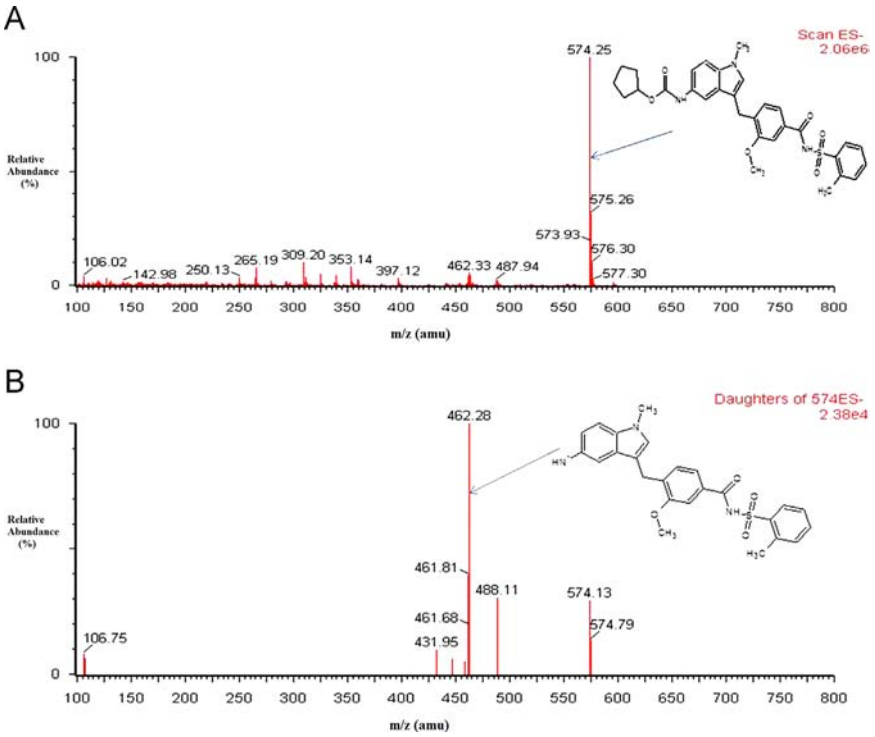

Fig. 3. Precursor ion (A) and product ion (B) spectra of IS.

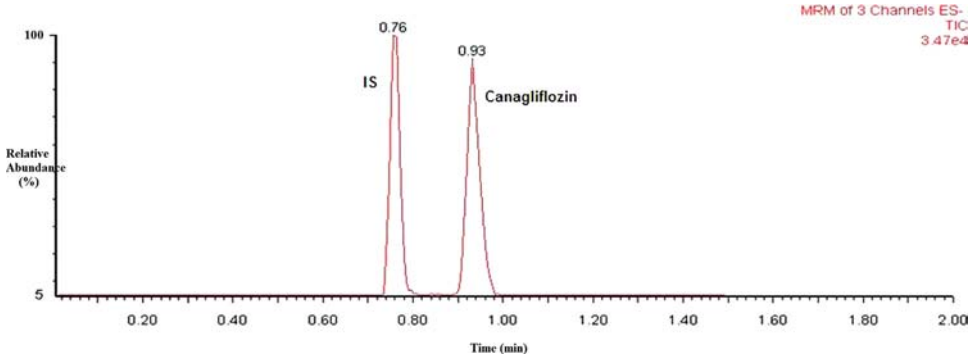

Fig. 4. TIC of canagliflozin and IS in mixed standard solution.

a generic extraction method. Initially we used both acetonitrile and methanol for protein precipitation. The result with methanol was not satisfactory as it resulted in high matrix effects, poor separation and low recovery of analytes compared to acetonitrile. Acetonitrile produced better results and was further optimized by evaporation of solvent under the stream of nitrogen and reconstituted in mobile phase to achieve high sensitivity and low ion suppression effects. The low ion suppression effects produced after sample drying and reconstitution in mobile phase might be due to more clean samples and compatibility of reconstitution solution (mobile phase) with eluting solvent.

3.4. Method validation

3.4.1. Selectivity

In this study, no significant interfering peaks ($\geq$ 20% in comparison to the spiked LLOQ and $\geq$ 5% in comparison to IS) in blank plasma (obtained from different rats) were observed at the corresponding elution time of canagliflozin and IS under the present optimal chromatographic conditions. This indicates that the present assay is selective for the test compound and suitable for quantification. Typical MRM chromatogram of canagliflozin and IS for blank plasma (showing no significant interference at the elution time of canagliflozin and IS) are shown in Fig. 5A.

3.4.2. Linearity and lower limit of quantification

The calibration curves were obtained by plotting the peak area ratios of canagliflozin to IS versus the nominal concentration of canagliflozin. The best linear fit with lowest total bias was achieved using $1/X^2$ weighing factor and adopted for method validation. Calibration curve showed good linearity in the range of 3.75–6666 ng mL^{-1} in plasma samples with the coefficient of correlation (R^2) of $\geq$ 0.997 during validation. The lowest point on the standard curve was 3.75 ng mL^{-1} and was accepted as LLOQ for this assay. Notably the present LLOQ is slightly lower than the previous reported HPLC–MS/MS method where $NH4^+$ adduct was used for canagliflozin quantification in ESI positive mode. Representative MRM chromatograms of canagliflozin and IS in spiked plasma at LLOQ level and 1 h after administration of canagliflozin in rat are shown in Fig. 5B and C, respectively.

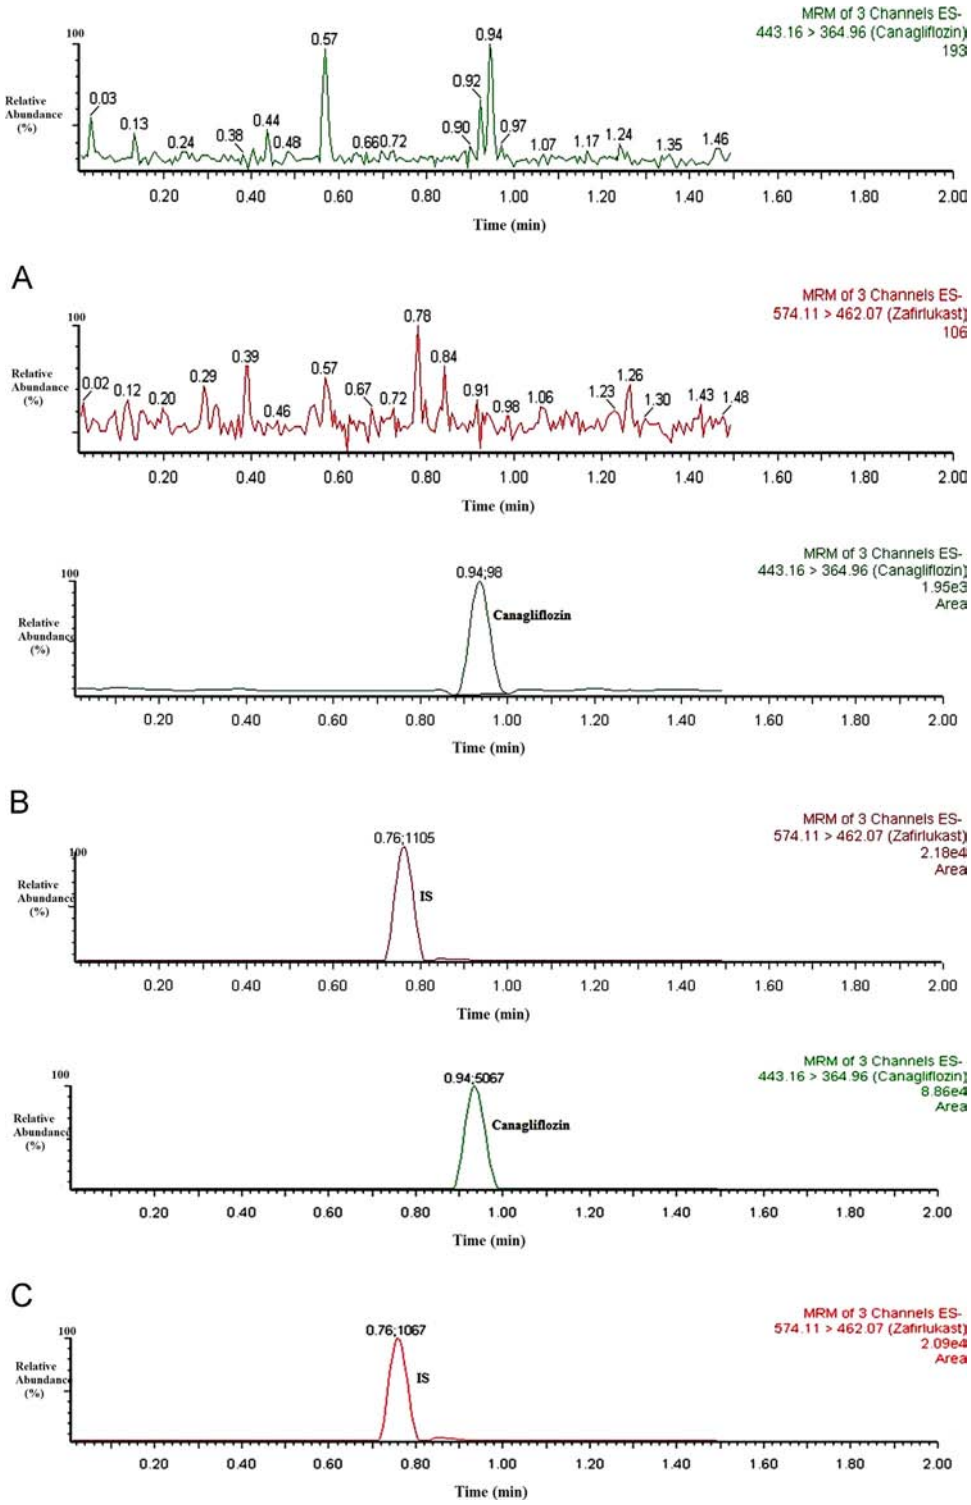

Fig. 5. Typical chromatograms of canagliflozin and IS in blank plasma (A); spiked plasma at LLOQ level (B) and 1 h after administration of canagliflozin (20 mg kg^{-1}, p.o.) in rat (C).

3.4.3. *Precision and accuracy*

The data for intra- and inter-day precision and accuracy of canagliflozin at four different QC levels in rat plasma are summarized in Table 1. The results demonstrated that the variation in intra-day and inter-day precision was ≤ 9.4 and ≤ 8.5, respectively. Similarly, the intra-day and inter-day accuracy ranged from 91.4 to 108.9 and 93.5 to 106.8, respectively. The results showed that the assay met the desired level of acceptance criteria and hence was considered accurate and precise for the analysis of canagliflozin in plasma sample and in other biological fluids.

3.4.4. *Recovery and matrix effects*

The extraction recovery and matrix effects for canagliflozin at three different QC levels (12.3, 320 and 5333 ng mL^{-1}) and IS (100 ng mL^{-1}) are presented in Table 2. The mean recovery of

Table 1
Intra-day and inter-day precision and accuracy values of canagliflozin in rat plasma.

Nominal conc. ($ng\ mL^{-1}$)	Run	Measured conc ($ng\ mL^{-1} \pm SD$)	Precision (CV, %)	Accuracy (recovery, %)
Intraday variation (6 replicate at each concentration)

12.3		12.1 ± 0.44	3.6	98.3
320		330.2 ± 18.5	5.6	103.2
5333		4983.7 ± 321.4	6.4	93.5

Table 2
Extraction recovery and matrix effect of canagliflozin (three QC samples) and IS in rat plasma ($n=6$).

Compound	Nominal concentration ($ng\ mL^{-1}$)	Extraction recovery		Matrix effects	
		%Mean ± %SD	CV%	%Mean ± %SD	CV%
Canagliflozin	12.3	82.7 ± 3.0	3.6	96.3 ± 1.9	2.0
	320	77.9 ± 5.6	7.2	93.7 ± 3.2	3.4
	5333	74.4 ± 4.1	5.6	91.5 ± 2.9	3.2
	Mean	78.3 ± 4.1	5.3	93.8 ± 2.4	2.6
IS	100	75.6 ± 4.3	5.6	92.5 ± 3.6	4.0

Table 3
Stability data of canagliflozin in rat plasma ($n=6$).

Stability	Nominal concentration ($ng\ mL^{-1}$) ($n=6$)	Mean ± SD	Precision (%CV)	Accuracy (%)
Bench top (6 h)	12.3	11.9 ± 0.53	4.5	96.8
	5333	5528 ± 121	3.5	103.8
Freeze thaw (3 cycle)	12.3	11.9 ± 0.76	6.4	96.5
	5333	5535 ± 193	8.3	89.3
In Injector (48 h)	12.3	13.3 ± 1.10	8.2	108.4
	5333	5730 ± 154	2.7	107.5
30 days at −80 °C	12.3	11.15 ± 0.56	5.0	90.6
	5333	4989 ± 231	4.6	93.6

canagliflozin was found to be 78.3% with a CV of 5.3% only. The recovery for IS was 75.6%. This result indicates that the recovery of canagliflozin by protein precipitation was in the acceptable range, consistent and concentration independent.

No significant matrix effects for canagliflozin were observed, suggesting that the ion suppression or ion enhancement due to plasma is negligible for this assay. The mean absolute matrix effect value was only 93.8% with CV of 2.6% for the three different concentrations.

3.4.5. Carry-over effects

No significant eluting peaks (peak area ≥20% for LLOQ and ≥5% for IS) were observed in the chromatograms of blank plasma samples injected after highest concentration level of calibration curve. Therefore, the carryover effects were negligible for this assay. A flush solvent of 80:20 v/v acetonitrile:water was used for the injection needle washing after every 10–15 unknown samples and is recommended for future application of this assay.

Table 4
Pharmacokinetic parameters of canagliflozin in male rats after administration of single dose (20 mg kg p. o.).

Pharmacokinetic parameters	Unit	Values (mean ± SEM)
C_{max}	$ng\ mL^{-1}$	1,616.79 ± 565.94
T_{max}	h	1.5

AUC_{0-inf}	$ng\ h\ mL^{-1}$	26,426.36 ± 7,287.83
$T^{1/2}$	h	21.34 ± 9.63
MRT	h	30.13 ± 14.06
K_{el}	h^{-1}	0.04 ± 0.02

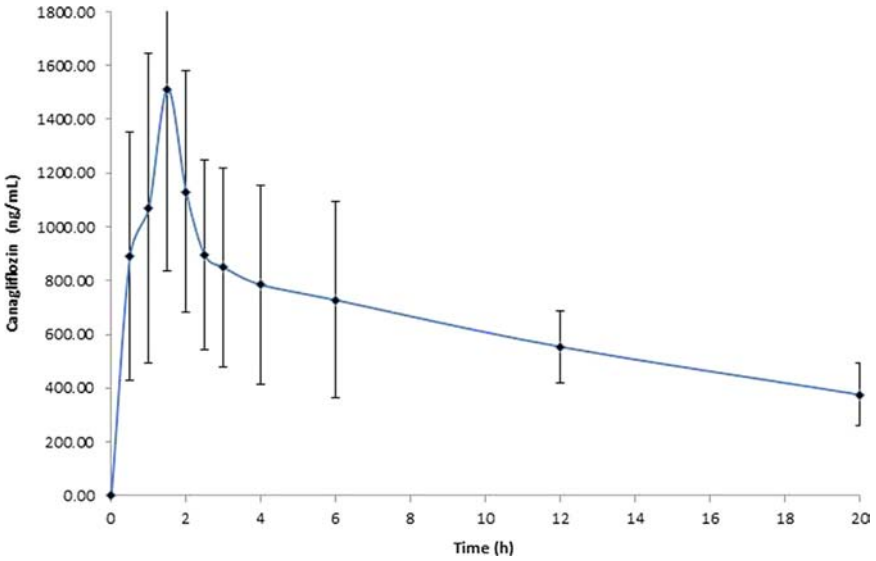

Fig. 6. Mean ± SE plasma concentration–time curves of canagliflozin after a single dose administration of 20 mg kg^{-1} p.o. in rats.

3.4.6. *Stability*

The canagliflozin stability (freeze–thaw, autosampler, short-term and long-term) results in rat plasma are summarized in Table 3. The results demonstrated that canagliflozin spiked in rat plasma was stable during three cycle of freeze–thaw, 48 h in autosampler after post preparation, at least 12 h at room temperature, and up to 30 days at around −80 °C. The stock solutions and working standard of canagliflozin and IS were also found to be stable for 15 days at refrigerator temperature (below 10 °C). Thus, there is no indication of canagliflozin instability in biological samples which can affect the method performance.

3.5. *Pharmacokinetic study in rats*

The validated UPLC–MS/MS assay was successfully applied to pharmacokinetic characterization of canagliflozin in healthy rats following oral administration of 20 mg kg^{-1}. The main pharmacokinetic parameters are summarized in Table 4. As shown, canagliflozin was found to be rapidly absorbed but slowly eliminated ($T_{,}^{1/2}$ 21.3 h) in rats. The corresponding mean peak plasma concentration of 1616.79 ng mL^{-1} was achieved after 1.5 h. The mean $AUC_{0-20\ h}$ was 14,721.36 ng mL h^{-1} with MRT of 30.13 h. The mean plasma concentration versus time profile of canagliflozin in rats is shown in Fig. 6.

4. Conclusion

In this study, we have developed and validated UPLC–MS/MS assay for the accurate quantification of canagliflozin in rat plasma. The assay is simple, rapid and sensitive over a wide calibration range (3.76–6666 ng mL^{-1}). The assay simplicity and short run time (only 1.5 min) enables high-throughput analysis of canagliflozin in a wide variety of clinical and experimental settings. The validated assay was successfully applied to a pharmacokinetic characterization of canagliflozin in rats.

h-FABP

ABSTRACT

The fabrication of a capacitive interdigitated immunosensor (CID) based on a mixed self-assembled monolayer (mSAM) film for the direct detection of heart fatty-acid binding protein (h-FABP) without any labeling is described. The capacitance changes of mSAMs vs. homogenous ordered self-assembled monolayers (hSAMs) on gold work electrodes/covalently bonded antibodies/buffered medium are utilized for monitoring the specific antibody–antigen interaction. Capacitance measurements in the absence and presence of Faradaic currents were performed. The electrochemical properties of mixed monolayers were compared with those of a pure monolayer of 11-mercaptoundecanoic acid (MUA) self-assembled on gold surfaces. Taking into account the stability of the studied monolayers during the electrochemical experiments with the Faradaic process, the best SAM functionalization method was used for developing a sensitive capacitive immunosensor with a non-Faradaic process for direct immune detection of human h-FABP. Under the optimized conditions, the proposed mixed self-assembled monolayer ($mSAM_1$) on gold electrode exhibited good insulating properties such as a capacitive behavior when detecting h-FABP from human serum in the range of 98 pg ml^{-1}–100 ng ml^{-1}, with a detection limit of 0.836 ng ml^{-1} comparative with a homogenous self-assembled monolayer (hSAM).

1. Introduction

Biochemical markers have an excellent sensitivity for the diagnosis of acute myocardial infarction (AMI), the world's main cause of morbidity and mortality (according to WHO's report for 2008).

Heart-type FABP (h-FABP) was first shown to be released from injured myocardium in 1988 [1]. Afterwards, several studies have investigated its application as a biochemical marker of myocardial damage, following the finding that h-FABP is the earliest available and probably most sensitive marker for injured myocardium [2,3]. The possibility of an early and quick diagnosis is extremely important in establishing the guiding therapy in order to save patients' lives. Likewise, the use of protein markers of low molecular weight leads to an earlier detection time [4,5]. In this context, h-FABP (15 kDa), a small protein that becomes elevated in concentration shortly after an AMI onset, appears to be an ideal target as a biomarker.

In the last 20 years, the development of various biosensors has been the objective of a large volume of research in both academic and industry enviroments, in order to develop alternative methods to the ELISA-based immunoassay [6–10]. Although used for many applications in medical diagnostics, ELISA methods are time consuming and involve relatively expensive equipment.

In the case of AMI, speed, specificity and sensitivity of the biochemical markers quantification are key factors in its diagnosis and treatment. Developing a simple, sensitive, regenerable capacitance-based immunosensor is of considerable interest because the capacitive measurement is a simple, rapid and inexpensive method based on the change in the capacitance electrode–electrolyte interface [11–15]. To the best of our knowledge, there are no reports of an interdigitated electrode immunosensors that use capacitive detection of the h-FABP cardiac biomarker.

When constructing a capacitive biosensor, the electrode surface is usually covered with an additional insulating layer to reduce Faradaic currents and the biorecognition element is immobilized on top of this layer [16]. Capacitance measurements in the absence of Faradaic currents also allow for the investigation of the influence of the electrical field on the biological recognition event by applying different direct current (dc) working potentials, and

have the advantage that no additional reagent is required for non-Faradaic impedance spectroscopy, rendering non-Faradaic schemes somewhat more amenable to point of care (POC) applications.

Two types of capacitive measurements can be performed: (1) using a single modified working electrode as a sensor, and (2) between and/or on the electrodes (in-plane arrangement of the interdigitated electrodes, or IDEs). The principle of the capacitance transducer is based on the theory of the electrical double-layer [17]. A metal electrode modified with a recognition biolayer can be described as a capacitor when placed in an electrolyte solution. The total capacitance is represented by the equivalent capacitance (C_e) and is built from several components. In this case, the first is the capacitance of the monolayer, C_{SAM}. The second is the capacitance of the protein layer and any part from the Stern layer, C_{pl}. The third is the capacitance of the diffuse layer, C_{dl}. The total value of the capacitance can be described by the following equation [18]:

$$1/C_e = 1/C_{SAM} + 1/C_{psl} + 1/C_{dl} \quad (1)$$

In the case of capacitive immunosensors, an electrode is coated with an antibody, which represents the biorecognition element and has a stable capacitance. When the analyte binds to the specific antibody on the electrode, it causes a change in the total capacitance. The use of the second type of capacitive immunosensors, IDEs, can provide a larger sensor surface for the immunoreaction. The capacitance between the IDEs can be described by the Helmholtz model by Eq. (2) [19]

$$C = \frac{A \times \varepsilon \times \varepsilon_0}{d} \quad (2)$$

where ε is the dielectric constant of the medium between the plates, ε_0 is the permittivity of free space, A is the area of the electrodes and d is the distance between the two electrodes.

For a biosensor based on a capacitive transducer, the immobilization of the recognition element is of vital importance for the ability to detect the binding event. The homogenous ordered self-assembled monolayers (hSAMs) ensure well-controlled surface structure and offer many advantages as far as the performance of the sensor, but they may lead to steric hindrance and disorder of the bulky terminal groups. In our prior study we have demonstrated distinguishable modification when the electron transfer resistance (R_{CT}) was recorded on mSAMs vs. hSAMs using a Faradaic process [20]. Also, the most widely used parameter for the characterization of SAM electrochemical properties is capacitance. The capacitance of a defect-free SAM is 20–100 times lower than that of bare gold, owing to the very low dielectric constant of the alkyl monolayer [21,22]. Prolonged incubation of the gold substrate in the thiol solution is necessary to prepare a stable SAM with a good capacitive behavior.

In the current work we have designed and fabricated a new capacitive immunosensor for h-FABP detection, without Faradaic process, by using self-assembled monolayers, which we have heterogeneously integrated onto the microelectrode microfluidic platform. Also, by using the Faradaic process we have carried out a comparative test of stability in terms of capacity changes between long-chain alkanethiols (11-mercaptoundecanoic acid, MUA) that formed a homogeneous adsorbed monolayer on the gold electrode, and a mixture of long chains and short chains adsorbed on the gold electrodes.

Under the optimized conditions, the proposed mSAMs on gold electrode exhibited good insulating properties such as a capacitive behavior to h-FABP from human serum in the ranges of 98 pg ml^{-1}–100 ng ml^{-1} with a detection limit of 0.830 ng ml^{-1} compared with hSAMs. Also, the results of these studies could be the starting point to developing multiplexed POC with panels of biomarker tests.

2. Experimental details

2.1. Materials

Monoclonal mouse anti-human h-FABP antibody and human antigen h-FABP were purchased from HyTest (Finland). A human serum assayed chemistry control, Lyphochek, was obtained from Bio-Rad Laboratories (USA). All other chemicals were purchased from Sigma-Aldrich (Germany).

2.2. Gold interdigitated electrodes (GID) preparation

The silicon sensor has gold interdigitated microelectrodes (GID), patterned by photolithography on silicon substrate. The fabrication summary steps are:

- p (100) type silicon wavers with 3 in. (76.2 mm) diameter and resistivity $\rho = 16$ W cm,
- oxidation layer (SiO_2) with 800 nm thickness;
- Ti/Au layer deposition with 15 nm/200 nm, deposition and patterning of a passivation layer phosphosilicate glass (PSG 4%) with the help of a mask for a lift-off process leaving open the electrodes' active area and the pads. The sensor chip has a 6 mm^2 × 12 mm^2 area and the IDE has a 1 μm width with a 10 μm gap. As a result, each gold interdigitated array contains 16 gold interdigitated fingers.

2.3. Gold surface preparation for electrochemical impedance spectroscopy (EIS) methods

The surfaces were a 3-inch silicon wafer p-type (100) with thickness of 350 μm and 16 Ω cm resistivity. On the oxide (thickness 800 nm) was deposited a metal layer sandwich consisting of 15 nm Ti produced by evaporation in high vacuum and a 200 nm Au layer deposited by the evaporation method. The working area is 0.9 cm^2.

2.4. Formation of the self-assembled monolayers

The gold interdigitated microelectrodes were cleaned sequentially in methanol, acetone and isopropanol for 10 min each. This was followed by a quick 2 min dip in piranha solution (H_2SO_4 70%, H_2O_2 30%, 3:1 v/v), then rinsed with deionized water. We repeated the procedure twice and finally dried them under a nitrogen flow.

Before placing the biosensor in the flow cell, the electrodes were treated and the hSAM and mSAMs were formed, following these procedures: for the hSAM, the GID electrode area was immediately immersed in an ethanol solution of 5 mM MUA; for the first mixed self-assembled monolayer ($mSAM_1$) other GID electrodes were immersed in 10 mM mixed solution consisting of MUA and MPOH in a 7:3 M ratio in absolute ethanol; for the second mixed monolayer ($mSAM_2$) the GID electrodes were immersed in 10 mM mixed solution of MUA: MPOH in a 1:9 M ratio. Different times were allowed for interaction between the alkanethiols and the GID electrodes: 1 min, 10 min, 30 min and 24 h.

The gold surfaces used for electrochemical characterization of the monolayers were similarly functionalized to form mSAMs and hSAM. Also, different times were allowed for the interaction between the alkanethiols and the gold surfaces: 1 min, 10 min, 30 min and 24 h. The capacitance EIS measurements were performed immediately after each incubation time.

Fig. S1 (Supplementary material) schematically illustrates (a) the gold interdigitated (GID) clean electrode, (b) $mSAM_1$/gold electrode fabrication, (c) $mSAM_2$/gold electrode fabrication and (d) hSAM/gold electrode fabrication. All fabricated electrodes were characterized using EIS.

2.5. SAMs characterization

The EIS was performed using the conventional three-electrode system with Ag/AgCl as a reference electrode, platinum as the counter electrode, and gold surface as the working electrode. The EIS measurement was carried out at equilibrium potential (open circuit potential generated between electrodes dipped in electrolyte), without external biasing in the frequency range of 100 mHz–100 kHz, with 10 mV amplitude using VoltaLab PGZ 100 Potentiostat/Galvanostat (Germany). The EIS and cyclic voltammetry (CV) measurements were performed using a cell with PBS solution (pH=7.4) containing a mixture of 5 mM $Fe(CN)_6^{4-}$ and 5 mM $Fe(CN)_6^{3-}$. For the intensity/V measurement, the potential was swiped from −50 mV to 900 mV with a rate of 100 mV/s.

2.6. Integrated microfluidic platform for detection of h-FABP

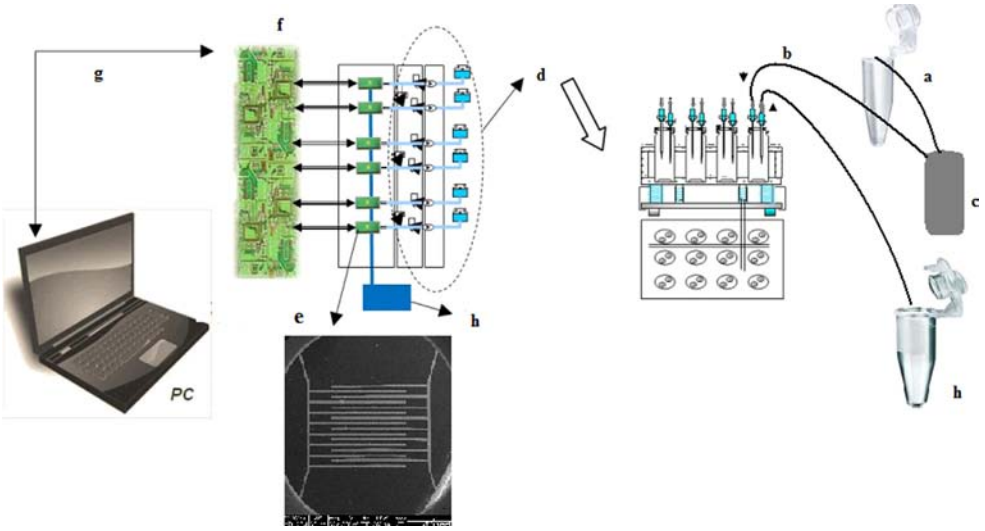
Scheme 1 depicts the block diagram of the microfluidic platform with GID integration. The legend explains all the components of the microfluidic platform. The immunosensor has a total area of $6\ mm^2 \times 12\ mm^2$ with the interdigitated gold electrode having a thickness of 10 μm; the active area is connected using pads (gold) to the capacitance read with AGILENT 4263B RCR.

2.6.1. Activation with EDC/NHS

The GID areas functionalized with SAM were immersed into a solution with NHS (20 mM) and EDC (100 mM) in PBS (pH=7.4) for 1 h to activate the terminal carboxylic groups to NHS esters. The modified electrodes were then rinsed with PBS and used immediately for antibody attachment.

2.6.2. Antibody immobilization

The hSAMs and mSAMs activated GID electrodes were incubated with 100 μl of 8 μg ml^{-1} anti-h-FABP antibody in PBS, which was pulled by a micropump system for 1 h at room temperature, then rinsed in PBS. After antibody covalent immobilization, the surfaces were blocked with a solution of 1% BSA in PBS for 1 h at room temperature, to avoid unspecific interaction, and then rinsed with PBS. The GID can be stored in the refrigerator until use for antigen h-FABP detection.



2.6.3. Antigen detection

For antigen detection, the GID electrodes immobilized with anti-hFABP antibodies were used to detect different antigen concentrations in the range 98 pg ml^{-1} to 100 ng ml^{-1} in PBS buffer. After the suction of the antigen solution and before recording of the capacitance, the signal was stabilized by washing with 5 ml PBS buffer, this being the base line. Two biofunctionalized immunosensors of $mSAM_1$ and hSAM were introduced in the microfluidic system as shown in Scheme 1e. After reading the blank signals (in PBS), the first step of the serial dilution was performed, namely 50 μl of antigen solution was suctioned on each electrode with the aid of micropumps, which are represented in Scheme 1c. A constant frequency of 1 kHz with an amplitude of 100 mV was applied. The capacitances for both electrodes were measured in real time for 30 min, at room temperature, until a constant value was attained. The same procedure was applied for each concentration of antigen in PBS. The specificity of the modified GID electrodes was determined by the antigen concentrations that have been spiked in BioRad human control serum. Then, the other new modified electrodes ($mSAM_1$ and hSAM) were introduced in the microfluidic system and the serial dilutions of the antigen were made in PBS: control serum (1:1). The same procedure as described above was performed.

2.7. Immunosensor non-Faradaic measurements

The potentiostatic-step method was chosen to be used as a transduction element for our immunosensor because the system at low frequency and low voltage could be described as a simple RC model [13,23]. An Agilent LCR Meter is connected through LabView interfaces for data acquisition, data analysis and presentation in real time.

All biochemical reactions between the h-FABP antigen added on the GID electrodes areas, and the antibodies the latter has been functionalized with, were transferred in capacitance changes that were measured in real time with AGILENT 4263B LCR meter, stored on the computer and interpreted. The measurement was

Scheme 1. The block diagram of the platform: (a) container with the biological sample or washing solution; (b) transport capillary samples/washing solutions; (c) peristaltic micropumps; (d) microvalve system, canals and reservoirs; (e) immunosensor with active area represented by gold interdigitated electrodes; (f) unit for electronic measurement signal amplification Agilent; (g) PC for data recording; and (h) exhaust system for biological sample/washing liquid.

carried out by applying a constant frequency of 1 kHz with an amplitude of 100 mV.

3. Results and discussion

3.1. SAMs characterization

Fig. S1 shows the different functionalization strategies tested to form three monolayers: $mSAM_1$, $mSAM_2$ and hSAM.

EIS with Faradaic process was used to characterize the insulating properties and to determine the capacitive behavior of the gold electrode at each stage of functionalization.

Although it has been demonstrated that long chain SAMs are much less easily damaged, thin layers are preferred for developing an immunosensor with direct detection of a small amount of protein because of the larger relative changes in capacitance caused by immune reactions [24]. mSAMs allow control of the density of the reactive species, to increase its accessibility and to bring chemical inertness to the underlying surface. Therefore, in order to control the accessibility of the carboxyl groups on the electrode surface, we used molar ratios with either MUA or MPOH excess in absolute ethanol ($mSAM_1$, 7:3 MUA: MPOH, and $mSAM_2$, 1:9 MUA: MPOH). For comparing the results we also used the homogeneous MUA layer on the electrode (hSAM). The functionalization of the gold surfaces was characterized using two electrochemical techniques: CV and EIS with Faradic and non-Faradic measurements.

3.1.1. Cyclic voltammetry measurements

Fig. 1(a–c) shows the cyclic voltammograms of the modified gold electrode for different immobilization periods of time (1 min, 10 min, 30 min and 24 h) in solutions of hSAM, $mSAM_1$ and $mSAM_2$, respectively. For all bare gold electrodes modified with monolayers, a decrease in the current is produced compared to that obtained at the non-modified electrodes. This is due to the blocking properties of the monolayers. The decrease of the anodic and cathodic currents in the first few minutes is more rapid for hSAM compared to $mSAM_1$ and $mSAM_2$. The $mSAM_2$ presents pinholes on the monolayer through which the redox probe can penetrate onto the surface, which explains why the ΔE_p value is smaller than that for hSAM and $mSAM_1$, even after a long time of incubation (>20 h). These pinholes are caused by the low percentage of MUA compared to MPOH that promotes the transfer of the negative redox ions $Fe(CN)_6^{3-/4-}$ to the electrode surface, thus decreasing the blocking properties of the $mSAM_2$ monolayer. Because the $mSAM_1$ monolayer shows the highest difference in the responses of bare gold vs. modified electrode, it was chosen for further development of the immunosensor.

According to the voltammetric behavior, the blocking reaction occurred more rapidly for hSAMs compared to mSAMs. The efficiency of the formation of SAMs for different immobilization times is more precisely described by the EIS results.

3.1.2. Electrochemical impedance spectroscopy measurements

In order to characterize the stability of the monolayers onto gold, the insulating properties and the capacitive behavior of the gold surfaces for each stage of functionalization with hSAM, mSAM1 and $mSAM_2$ have been investigated by EIS experiments with a Faradaic process.

The results can be interpreted using the equivalent circuit presented in the inset of Fig. 2 that includes the solution resistance (R_s), double layer capacitance (C_{dl}) and electron transfer resistance (R_{CT}) [17,22]. The Auto.R1R2C Fitting method is used to fit the

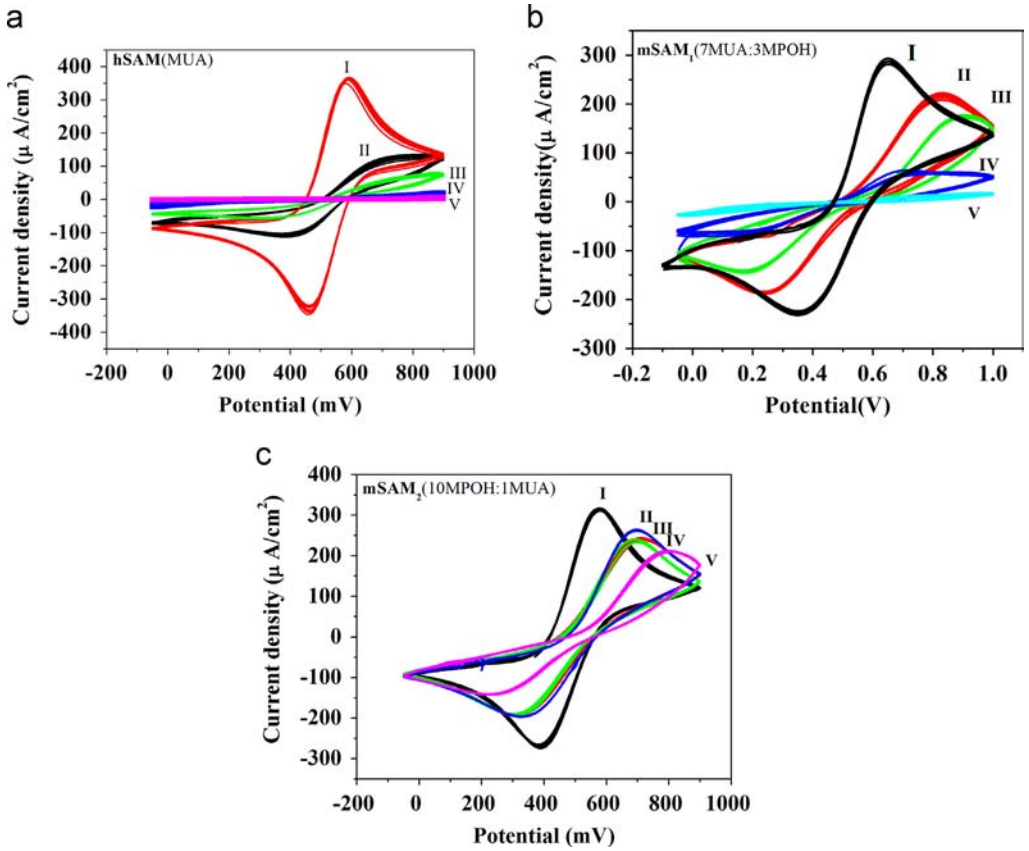


Fig. 1. Cyclic voltammograms of (a) hSAM, (b) $mSAM_1$ and (c) $mSAM_2$ on (I) bare gold and at different interaction times: (II) 1 min, (III) 10 min, (IV) 30 min and (V) 24 h. The electrolyte is PBS solution (pH=7.4) containing $Fe(CN)_6^{3-/4-}$ as a redox couple and the scan rate is 100 mV/s.

curve to a circle while running the sequence and the Bode Plot is used for monitoring the phase angle and capacitance after various incubation times of gold surfaces with thiol solutions for further formation of $mSAM_1$, $mSAM_2$ and hSAM. It is well known that the insulating properties in a high ionic strength solution are low and therefore the capacitance greatly increases and the stability of the monolayer decreases [13,25]. So, to keep a stable capacitance, a low ionic strength of 10 mM PBS was used. Also, it is known that SAM is viewed as a pure capacitor and is deemed defect-free when the phase angle (φ) is $\geq 88^\circ$ (for practical purposes), and to be a leaky capacitor when the φ value is $< 87^\circ$ over 1 kHz–50 Hz range [23,26].

As shown in Fig. 2, the phase angle (the Bode phase plots) for all SAMs formed after adsorption during 24 h increases with time and $mSAM_1$ and hSAM become capacitors. Regarding the adsorption kinetics of the hSAM layer, we monitored the capacitance values after incubation of the gold surfaces in MUA solution. The adsorption is fast after only 1 min of immersion and the capacity begins to decrease. After 10 min the capacitance decreases by 83% compared to the capacitance of bare gold (from 20.54 $\mu F\,cm^{-2}$ to 3.53 $\mu F\,cm^{-2}$). From 10 to 30 min, the capacitance slightly decreases (from 3.53 $\mu F\,cm^{-2}$ to 2.12 $\mu F\,cm^{-2}$). After 24 h of incubation, the capacitance for hSAM becomes 1.28 $\mu F\,cm^{-2}$, which indicates a 94% decrease compared to bare gold. A minimum 24 h incubation in thiol solutions is necessary to achieve $\varphi_{1\ Hz} \geq 88^\circ$ for hSAM. Similarly, a decrease in the capacitance and adsorption time has been observed for $mSAM_1$. After 24 h of incubation, it achieves the maximum phase angle of 88.66° for $mSAM_1$. Compared to hSAM, the capacitance for $mSAM_1$ decreases in the same way, but after 24 h of immersion it is slightly higher (1.616 $\mu F\,cm^{-2}$).

By comparison, capacitance in the first few minutes of immersion shows a slight instability for $mSAM_2$, mostly due to the lower percentage of MUA in the mixed solution. After 1 min, the capacity decreases significantly by 56%. However, after 10 min, there is a noticeable increase in capacity—by 33% compared to that at 1 min—probably due to the high percentage of MPOH compared to MUA that leads to the formation of pinholes in the structure of the monolayer. Only after 24 h does the capacity stabilize at a value lower than that of bare gold. It can be seen from Fig. 2 that the phase angle values of these SAMs follow the order hSAM > $mSAM_1$ > $mSAM_2$. Regarding the phase angle, there is a completely different behaviors for $mSAM_2$ because it does not achieve capacitive behavior even after 24 h of immersion. This probably happens because of the many defect sites that favor the leakage current, thus confirming that the blocking effect of $mSAM_2$ is low (also demonstrated by CV) and that the well-ordered structure is not obtained. Therefore, our results are in agreement with the observation made by Whitesides' group that the blocking effect of SAMs increases with the MUA percentage in the mixture [27].

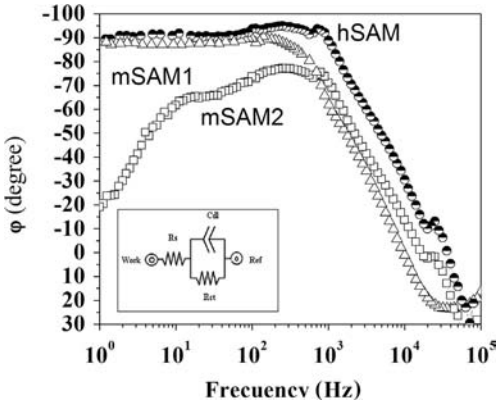

Fig. 2. Bode phase plots (φ vs. frequency) for $mSAM_1$, $mSAM_2$ and hSAM after 24 h immersion time in the PBS solution (pH=7.4). The inset figure is the equivalent electrical circuit with solution resistance (R_s), double layer capacitance (C_{dl}) and electron transfer resistance (R_{CT}).

3.2. Immunosensor non-Faradaic detection of h-FABP with microfluidic platform

The capacitance changes between the initial baseline in PBS and the measured capacitance values at specific concentrations of h-FABP (in PBS or human serum) immobilized onto functionalized GID electrode areas with antibody were used as the sensing signal. The experiments can be described as a simple RC model, as shown in the inset A of Fig. 3a and b, where R_s is the resistance at the electrode surface and C the total capacitance, according to Eq. (1).

To avoid the effect of the high conductivity of the working solution, the immunoassay binding event was performed in pH 7.4 at 10 mM PBS. The principle of our method is as follows: the binding of the h-FABP antigen to the $mSAM_1$/anti-h-FABP antibody/BSA surface and hSAM surface/anti-h-FABP antibody/BSA produces an increase in layers, and thus of the total capacitance for each surface according to the Eq. (1). The incubation time for

The capacitance responses of (a) mSA1/EDC/NHS/anti-h-FABP/BSA GID electrode and (b) hSAM/EDC/NHS/anti-h-FABP/BSA GID electrode after suction of 100 μL of buffer or of h-FABP solutions of different concentrations onto electrodes' surfaces: (I) 0 pg ml^{-1}, (II) 98 pg ml^{-1}, (III) 1.56 ng ml^{-1}, (IV) 3.125 ng ml^{-1}, (V) 50 ng ml^{-1}, (VI) 100 ng ml^{-1}. The inset figures B are the linearity curves for the capacitance measurements with different h-FABP concentrations in PBS for (a) $mSAM_1$/EDC/NHS/anti-h-FABP/BSA GID electrode and respectively for (b) hSAM/EDC/NHS/anti-h-FABP/BSA GID electrode; the inset figures C are the linearity curves for the capacitance measurements with different h-FABP concentrations in PBS:human serum for (a) $mSAM_1$/EDC/NHS/anti-h-FABP/BSA GID electrode and respectively (b) hSAM/EDC/NHS/anti-h-FABP/BSA GID electrode; the inset figure A is the RC model circuit with solution resistance (Rs) at the electrode surface and C is the total capacitance of the electrode layers; each capacitance measurement was run in triplicate and represented with error bars.

Table 1
The curve parameters of hSAM/EDC/NHS/anti-h-FABP/BSA GID electrode vs. $mSAM_1$/EDC/NHS/anti-h-FABP/BSA GID electrode after different hFABP concentrations in PBS.

Curve parameters	hSAM/EDC/NHS/anti-h-FABP/BSA GID electrode	$mSAM_1$/EDC/NHS/anti-h-FABP/BSA GID electrode
Linear equation	DC (nF) = −17.98 − 7.40 log $C_{h\text{-}FABP}$	DC (nF) = −39.27 − 6.71 log $C_{h\text{-}FABP}$
Correlation coefficient	R^2 = 0.975	R^2 = 0.981
Detection limit	968 pg ml^{-1}	836 pg ml^{-1}

immunoassay after each addition of h-FABP was 30 min. After immunoreaction, the capacitance decreases with incubation time and becomes constant after 30 min, indicating that saturation has begun. For each added concentration the capacitance change was monitored for 30 min. As is shown in Fig. 3a, the fabricated immunosensor is sufficiently sensitive to exhibit a change in signal for $mSAM_1$. The thickness of the layers is a very important characteristic of a capacitive sensor. It should be as thin as possible, so that the capacitive response due to the antigen − antibody interaction increases in size comparable with the recognition layer. In the case of hSAM, as shown in Fig. 3b, the decrease of the functionalized electrode capacity is obtained in a range of capacitance values lower than that for the $mSAM_1$ functionalized electrode. So, although long-chain SAMs are much less easily damaged, thin sensing layers are preferred for directly detecting small amounts of protein. For our mixed monolayer $mSAM_1$ with short and long chains, a larger change in relative capacitance comparative with hSAM was obtained. Under the optimization of experimental conditions, for the GID electrode $mSAM_1$/h-FABP antibody and hSAM/h-FABP antibody, both blocked with BSA, it was found that the capacitance changes (ΔC) were proportional with the logarithm of h-FABP concentration in the range of 98 pg ml^{-1}–100 ng ml^{-1} in PBS buffer, as can be seen in Fig. 3a (inset B) and respectively Fig. 3b (inset B). The regression equation, correlation coefficient and sensitivity for both gold electrode surfaces are presented in Table 1. The limit of detection for $mSAM_1$ and hSAM was found to be approximately 3× the standard deviation of the baseline samples (with PBS) and, combined with the good linear response, yielded the values 0.836 ng ml^{-1} for $mSAM_1$ and 0.968 ng ml^{-1} for hSAM.

3.2.1. Selectivity of the immunosensor

The selectivity of the immunosensor refers to the effect of possible interferences with the determination of the h-FABP in samples. For this, both biofunctionalized $mSAM_1$ and hSAM GID electrodes were introduced in the microfluidic system, and were exposed and incubated with BioRad control serum spiked with five concentrations of h-FABP: 98 pg ml^{-1}, 1.56 ng ml^{-1}, 3.125 ng ml^{-1}, 25 ng ml^{-1} and 100 ng ml^{-1}. The regression equation and the correlation coefficient for both gold electrode surfaces are presented in Fig. 3a (inset C) and b (inset C). As can be seen, the capacitance changes for $mSAM_1$ were evidently on a larger range than for hSAMs. It is probably that the high density and homogeneity of the hSAMs is a non-essential feature for the efficiency of our future capacitive sensor. The steric hindrance that can occur after the interaction between the h-FABP antigens with antibodies can lead to its removal from hSAM. It is evident that the interaction between anti-h-FABP and h-FABP was strong in the case of the mSAM/anti-h-FABP compared with hSAM/anti-h-FABP when the serum samples were used. The steric hindrance was higher for homogenous SAMs and therefore this decreased the capacity of the anti-h-FABP antibody to bind the h-FABP antigen in human serum.

The relative standard deviations (R.S.D) of the intra- and inter-assay for the immunosensor chip fabricated with $mSAM_1$ in order to detect h-FABP antigen in the linear detection range were 8% (n=5) for intra-assay and 12.1% (n=3) for inter-assay.

Table 2
The recovery of the prepared mSAM1/EDC/NHS/anti-hFABP/BSA GID capacitive immunosensor for h-FABP detection.

Sample no.	Added h-FABP (ng ml^{-1})	DC (nF)	Recovery (%)	R.S.D (%)
1	100	−55	102	1.03
2	50	−49.95	98.4	0.83
3	12.5	−45.91	95.82	2
4	1.56	−38.94	101	0.52

3.2.2. Recovery test of hFABP assay

Four samples with different hFABP concentrations were performed. All the experiments were carried out three times. As seen in Table 2, the average recovery was 99.3% with a relative standard derivation (R.S.D) of 0.52–2%.

3.2.3. Regeneration of immunosensor

Antigens were released from the GID electrode surfaces after suction of 50 μl of glycine: HCl (pH 2.5) for 3 min only, as the acid solutions may disturb the SAMs layers. After this, the electrode surfaces were incubated with h-FABP protein to verify the capacitance response and no noticeable change in capacitance response to the same amount of h-FABP in PBS was observed after quick acidic washing.

4. Conclusions

An integrated microfluidic platform with GID electrodes for direct detection of h-FABP is described. The $mSAM_1$ are suitable for fabrication of a label-free capacitive immunosensor. The capacitive immunosensor prepared with $mSAM_1$ can provide a low detection limit compared with a homogenous SAMs, due to a higher starting capacitive signal than that obtained when using a mixed SAM with short and long chains. The percentage of the long chain was optimized, and for the presented methods it has been demonstrated that the blocking effect of the SAM, and therefore the capacitive behavior, increased with the percentage of MUA in the mixture. The low percentage of MUA is not essential for this type of electrode, probably because the signal of the capacitance response will become unstable, as for the case of $mSAM_2$. Also, the 100% figure of MUA in the mixture decreased the efficiency of the future immunosensor due to the steric hindrance that can occur after interaction between antigens with antibodies. The low detection limit of the presented immunosensor, the good specificity of the assay for h-FABP detection, and the cheaper and faster capacitive measurements method were demonstrated for GID electrodes functionalized with $mSAM_1$. Also, this platform could provide a faster and cheaper system without susceptibility of antibodies for cross-reaction when using a multiplexed test with other important cardiac markers.

ABSTRACT

Detection of salt- and analyte-induced aggregation of gold nanoparticles (AuNPs) mostly relies on costly and bulky analytical instruments. To response this drawback, a portable, miniaturized, sensitive, and cost-effective detection technique is urgently required for rapid field detection and monitoring of target analyte *via* the use of AuNP-based sensor. This study combined a miniaturized spectrometer with a 532-nm laser to develop a laser-induced Rayleigh scattering technique, allowing the sensitive and selective detection of Rayleigh scattering from the aggregated AuNPs. Three AuNP-based sensing systems, including salt-, thiol- and metal ion-induced aggregation of the AuNPs, were performed to examine the sensitivity of laser-induced Rayleigh scattering technique. Salt-, thiol-, and metal ion-promoted NP aggregation were exemplified by the use of aptamer-adsorbed, fluorosurfactant-stabilized, and gallic acid-capped AuNPs for probing K^+, *S*-adenosylhomocysteine hydrolase-induced hydrolysis of *S*-adenosylhomocysteine, and Pb^{2+}, in sequence. Compared to the reported methods for monitoring the aggregated AuNPs, the proposed system provided distinct advantages of sensitivity. Laser-induced Rayleigh scattering technique was improved to be convenient, cheap, and portable by replacing a diode laser and a miniaturized spectrometer with a laser pointer and a smart-phone. Using this smart-phone-based detection platform, we can determine whether or not the Pb^{2+} concentration exceed the maximum allowable level of Pb^{2+} in drinking water.

1. Introduction

Numerous nanomaterials, including magnetic nanoparticles (NPs), metal NPs, quantum dots and carbon-based nanomaterials, have served as signal transducers in a number of reported biosensors because they exhibit high surface area-to-volume ratio, strong signal intensities, and tunable surface chemistry [1–3]. Gold nanoparticles (AuNPs) provide several physical and chemical advantages, making them one of the most popular materials for the fabrication of chemical and biological sensors. First, a number of chemical approaches have been available for a one-pot synthesis of highly stable AuNPs [4]. Second, they possess surface Plasmon resonance (SPR), Rayleigh scattering, electric conductance, redox behavior, and enzyme-mimetic activity [4–8]. Third, they offer extremely large ensemble surface areas with tunable modification options [9]. Fourth, these properties of AuNPs can be readily tuned by varying their size, shape, and the surrounding chemical environment [4]. With these advantages, the binding event between the recognition element and the analyte can cause the change in physicochemical properties of transducer AuNPs, such as the intensity and wavelength of SPR [10], the magnitude of conductivity [11], and the behavior of redox reaction [6]. These changes in turn can produce a detectable response signal for detecting a variety of analyte, such as heavy metal ions, anions, small molecules, proteins, and nucleic acids [4,8,10,12,13].

Because the optical properties of SPR of the AuNPs are strongly dependent on interparticle separation distances and particle size, the current gold standard for detecting the analyte-induced aggregation and growth of the AuNPs is to measure the wavelength and intensity of SPR, respectively. For example, the analyte-stimulated aggregation of the AuNPs drives interparticle surface plasmon coupling, causing a red-shift in the SPR peak [14]. Moreover, the H_2O_2- and dopamine-mediated enlargement of the AuNPs produced an increase in the intensity of SPR peak [15,16]. However, most of these sensors exhibit moderate sensitivity with detection limits for target analyte in the micromolar range. The plasmon scattering intensity of a single 60-nm diameter AuNPs resembles the fluorescence intensity of 10^5 fluorescein molecules. The strong scattering light of the AuNPs arises from the collective oscillation of conducting electrons. Thus, to improve the

sensitivity of AuNP-based colorimetric assays, numerous sensors are established based on the measurement of size-induced change in the maximum peak and intensity of a resonant Raleigh scattering [17]. For example, as compared to the dispersed AuNPs, the analyte-triggered aggregation of the AuNPs can scatter electromagnetic radiation strongly; this change can be monitored using dark-field light scattering [18], dynamic light scattering [19], hyper-Rayleigh scattering [20], and resonance Rayleigh scattering techniques [21]. Dark-field light scattering technique can observe the scattering light of the AuNPs at the single-particle level, but such technique are limited to the detection of relatively large particles (>40 nm) and the quantification of target analyte. Additionally, dynamic light scattering, hyper-Rayleigh scattering, and resonance Rayleigh scattering techniques are rather costly, time-consuming procedure, sophisticated, and non-portable.

Herein, we reported a highly sensitive light-scattering technique for sensing K^+, *S*-adenosylhomocysteine hydrolase (SAHH) activity, and Pb^{2+} based on the fact that salt- thiol-, and metal ion-induced aggregation of the AuNPs greatly enhances light scattering, respectively. The measurement of light scattering is easy to perform using a miniaturized spectrometer as a scattering detector and a 532-nm laser as an excitation light. The integrated scattering spectrum was obtained by placing the detector at right angle to the excitation beam. The proposed method can provide more than 10-fold improvement in limit of detection (LOD) compared to colorimetric assay.

2. Experimental

2.1. Chemicals

S-adenosylhomocysteine (SAH), SAHH (rabbit erythrocytes; 50,000 units/L; MW 240,000), homocysteine (HCys), bovine serum albumin (BSA, from bovine serum), human serum albumin (HSA, from human serum), trypsin (from porcine pancreas), lysozyme (from human milk), thrombin (from bovine plasma), myoglobin (from equine heart), cytochrome c (from bovine heart), hemoglobin (from bovine blood), fluorosurfactant (FSN), trisodium citrate, $HAuCl_4$, gallic acid, NaH_2PO_4, Na_2HPO_4, NaCl, $NaClO_4$, $MgCl_2$, $FeCl_3$, NH_4HCO_3, $Cd(ClO_4)_2$, NaOH, $Pb(NO_3)_2$, and $HgCl_2$ were obtained from Sigma-Aldrich (St. Louis, MO). $FeCl_2$, $CuCl_2$, $SrCl_2$, LiCl, KCl, $CoCl_2$, $NiCl_2$, $CaCl_2$, $MnCl_2$, $BaCl_2$, $ZnCl_2$ were obtained from Acros Organics (Geel, Belgium). The molecular formula of FSN is $F(CF_2CF_2)_{3-8}CH_2CH_2O(CH_2CH_2O)_xH$. Gold nanoparticles (15, 30, 50 nm) were purchased from Ted Pella Inc. (Redding, California). DNA sample (K^+ aptamer, 5′-GGG TTA GGG TTA GGG TTA GGG-3′) was synthesized from GenScript Corporation (Taipei, Taiwan). Isotonic phosphate-buffered saline ($1\times$ PBS; pH 7.4) was prepared by dissolving $Na_2HPO_4{\cdot}2H_2O$ (22.05 g), $NaH_2PO_4{\cdot}H_2O$ (2.07 g), and NaCl (4.5 g) in H_2O (1.0 L). Water used in all of the experiments was doubly distilled and purified by a Milli-Q system (Millipore, Milford, MA, USA).

2.2. Synthesis of 4 nm-sized AuNPs

The preparation of AuNPs was conducted by adding $NaBH_4$ (0.1 M, 1.5 mL) to a solution (50 mL) containing 250 μM $HAuCl_4$ and 250 μM trisodium citrate under vigorous stirring. The image of transmission electron microscopy (Tecnai 20 G2 S-Twin, Philips/FEI, Hillsboro, Oregon) demonstrated the size of the as-prepared AuNPs (Fig. S1, Supplementary information).

2.3. Apparatus

A diode-pumped solid state continuous laser (Labguide Co., Ltd) with a wavelength of 532 nm was used as an excitation light source when its output power was 5 mW. A miniaturized QE65000 Scientific-grade Spectrometer (Ocean Optics, Inc.) was used for collecting the scattering of the AuNPs. An Ocean Optics CUV-ALL-UV four-way cuvette holder (Ocean Optics, Inc.) equipped with fiber-optic couplings at each of four quartz *f*/2 collimating lenses was incorporated to a 1000 μm illumination fiber and a 1000 μm read fiber. An illumination fiber brings the excitation beam to a cuvette, while a read fiber transports the scattering signal back to Ocean Optics QE65000 spectrometer. The scattering spectrum was recorded using Ocean optics SpectraSuite spectroscopy software with 100 ms integration time. To reduce the cost of instrumentation and toward more portable system, a battery-operated green laser point (532 nm) and a smart-phone (Samsung, Galaxy SIII) were used in place of a diode-pumped solid state continuous laser and a Ocean Optics QE65000 spectrometer, respectively.

2.4. Sensing of potassium ion

Citrate-capped AuNPs (15 nm; 1.5 nM, 10 mL) were modified with K^+ aptamer (100 μM, 100 μL) for 2 h at ambient temperature. Metal ions (4–5000 μM) reacted with aptamer-modified AuNPs (0.75 nM) for 5 min at ambient temperature. The resulting solutions were incubated with $0.1\times$ PBS solution for 5 min at ambient temperature. The scattering spectra were collected using the proposed detection system.

2.5. Sensing of SAHH activity

Citrate-capped AuNPs (15 nm; 2.5 nM, 60 mL) were modified with FSN (10% w/v, 240 μL). FSN-stabilized AuNPs were stored at 4 °C until further use. Proteins (0–100 units/L, 100 μL) reacted with SAH (100 μM, 100 μL) in 50 mM phosphate buffer (pH 7.2) at 37 °C for 20 min. We incubated the resulting solutions (200 μL) with a solution (800 μL) containing FSN-AuNPs (0.1 nM) and phosphate buffer (100 mM, pH 5) for 10 min and recorded their scattering spectra.

2.6. Sensing of lead ion

The pH of $HAuCl_4$ was adjusted to 11.1 by adding 100 μL of 0.5 M NaOH. A solution of gallic acid was heated to 50 °C. Subsequently, gallic acid (0.1 mL, 38.8 mM) was added slowly to $HAuCl_4$ (10 mL, 1 mM) under vigorous stirring at ambient temperature for 6 h. The particle size of the formed AuNPs was 9 ± 1 nm. To estimate the concentration of gallic acid-capped AuNPs, we assumed that the reduction from gold(III) to gold atoms was 100% complete. According to this hypothesis, the concentration of gallic acid-capped AuNPs was calculated to be 40 nM. Metal ions (1–40 nM) were incubated with a solution containing gallic acid-capped AuNPs (0.63 nM), $NaClO_4$ (1 mM) and formic acid buffer (pH 4.5, 20 mM) for 20 min at ambient temperature. The scattering spectra were collected using the proposed detection system.

3. Result and discussion

3.1. Sensing of K^+ by salt-induced NP aggregation

Because the scattering cross section of a single AuNPs is proportional to the sixth power of its diameter [22], we initially investigated the effect of different-sized AuNPs (4, 15, 30, and 50 nm) on their light-scattering intensity in deionized water and $0.5\times$ PBS solution under irradiation with a 532-nm diode laser. The concentrations of different-sized AuNPs were all adjusted to 10^8 particles mL^{-1}. Note that the AuNPs are dispersed in deionized water, whereas they aggregated to large-sized particles in $0.5\times$ PBS. Salt-induced aggregation of the

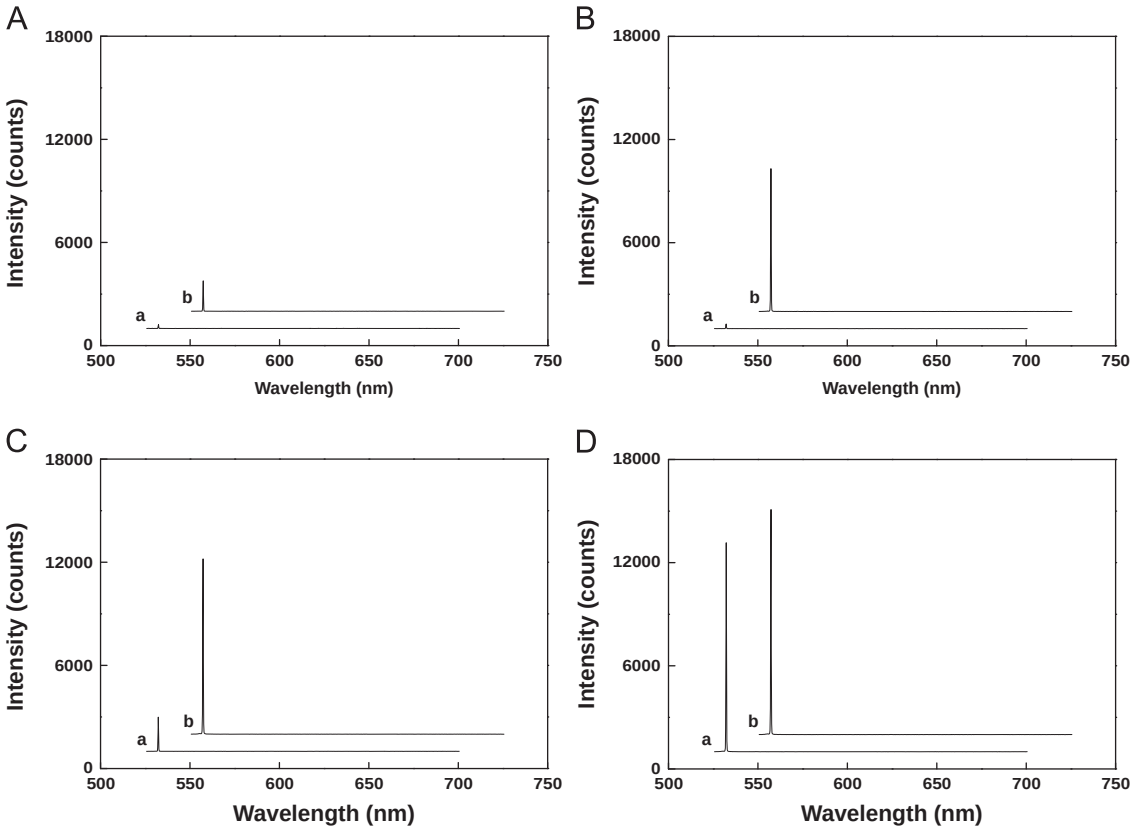

Fig. 1. Scattering spectra of (A) 4 nm, (B) 15 nm, (C) 30 nm, (D) 50 nm-sized AuNPs in the (a) absence and (b) presence of 0.5 × PBS. The concentration of the AuNPs was fixed at 10^8 particles mL^{-1}.

AuNPs is attributed to the fact that salt efficiently screens the surface charges of individual AuNP [23]. Fig. 1 shows a comparison of difference in light-scattering intensity between the dispersed and aggregated AuNPs. Expectably, the light-scattering intensity of the dispersed AuNPs tremendously increased with increasing their particle size, which is in agreement with Mie or Rayleigh scattering theory. Following the addition of 0.5 × PBS to 4, 15, 30, and 50 nm of the dispersed AuNPs, we observed a 8-, 30-, 5-, and 1-fold increase in the light-scattering intensity at 532 nm, respectively. For larger particles (30 and 50 nm), the light-scattering intensity at 532 nm was very strong even in the absence of salt, thus failing to measure the presence of the aggregated AuNPs. For smaller particles (4 nm), the aggregated AuNPs were too small to exhibit strong light-scattering intensity. We suggest that 15 nm AuNPs were more suitable for salt-induced aggregation of AuNP probes, owing to low background scattering from the dispersed AuNPs and an enormous increase in light-scattering intensity from the aggregated AuNPs.

Previous studies demonstrated that salt-induced aggregation of citrate-capped AuNPs was implemented for selective and sensitive detection of K^+, thrombin, and adenosine triphosphate [24–26]. This was exemplified with the use of aptamer-modified AuNPs for detecting K^+ (Fig. 2A). Citrate-capped AuNPs interacting with aptamer are dispersed well under high-ionic-strength conditions. The presence of K^+ induces the formation of K^+ – aptamer complexes, enabling aptamer to be removed from the NP surface [24,27–34]. Because of the removal of aptamer from the NP surface, salt-induced aggregation of the AuNPs occurs and causes an enhancement in light-scattering intensity. Because the enhancement of the light-scattering intensity mainly arose from the degree of the NP aggregation, the effect of salt concentration on the stability of aptamer-modified AuNPs was explored in the next study. Fig. S2 Supplementary information shows that aptamer-modified AuNPs remained dispersed when the concentration of PBS varied from 0–0.2 × PBS. Thus, in 0.1 × PBS, the scattering intensity of aptamer-modified AuNPs was measured before and after the addition of K^+. As the concentration of K^+ increased at fixed concentrations of citrate-capped AuNPs and aptamer, the scattering intensity of aptamer-capped AuNPs was progressively enhanced (Fig. 2B). The linear relationship (R^2 = 0.9965) of the light-scattering intensity at 532 nm *versus* the K^+ concentration was from 4–5000 μM (inset in Fig. 2B). Because 0.1 × PBS contains 17 mM Na^+ ions, we suggest that this system is capable of selectively detecting 4 μM K^+ in the presence of a 21,000-fold excess of Na^+ ions. This system enabled the detection of K^+ with limit of detection (LOD) corresponding to 1 μM, which is much lower than the LOD values obtained from aptamer-based colorimetric, electrochemical, and fluorescent sensors probes [24,27–34] (Table 1). Although dynamic light scattering, hyper-Rayleigh scattering, and resonance Rayleigh scattering techniques can be also utilized for observing salt-induced NP aggregation, the developed system consisting of miniaturized QE65000 spectrometer and diode laser can be portable and is interfaced to a personal computer via USB port. We next evaluated the specificity of the aptamer-based probe by monitoring the light-scattering intensity in the presence of other cation ions. Fig. 2C shows that only K^+ ions induced a remarkable change in light-scattering intensity because other cations were unable to remove aptamer from the NP surface. The combination of laser-induced Rayleigh scattering technique and aptamer-based sensor therefore provided high sensitivity and selectivity for K^+ ions.

3.2. *Sensing of SAHH activity by homocysteine-mediated NP aggregation*

Numerous previous studies reported that aminothiol triggered the aggregation of nonionic FSN-stabilized AuNPs through interparticle H-bonds and electrostatic attraction between adsorbed aminothiol molecules [35]. The successful monitoring of salt-induced NP aggregation suggests that laser-induced Rayleigh scattering technique may be

implemented to follow aminothiol-induced NP aggregation. In the presence of homocysteine, FSN-stabilized AuNPs with size of 15 nm provided relatively large difference in light-scattering intensity between the dispersed AuNPs and aggregated AuNPs as compared to 4, 30, and 50 nm-sized AuNPs (Fig. S2, Supplementary information). Thus, we proposed that this system was utilized to detect the activity of SAHH. Fig. 3A illustrates that SAHH catalyzes the hydrolysis of SAH to produce homocysteine and adenosine [30,36]. The produced homocysteine, at low pH condition, triggers the aggregation of FSN-stabilized AuNPs, leading to strong light-scattering under the excitation at 532 nm. As the concentration of SAHH increased at a fixed concentration of SAH, the light-scattering intensity at 532 nm of FSN-stabilized AuNPs was gradually enhanced (Fig. 3B). By plotting the light-scattering intensity at 532 nm against the SAHH concentration, a linear range (R^2=0.9962) for quantification of SAHH was observed from 15–50 units/L^{-1}. The LOD of SAHH was determined to be 3 units L^{-1} (approximately 0.2 nM). Our proposed system provided the greatest sensitivity toward SAHH activity among other reported methods, including AuNP-based colorimetric assay [36], UV–vis absorption [37], Ellman's reagent [36], and luciferase-based assay [38] (Table 2). Additionally, the combination of FSN-stabilized AuNPs and laser-induced Rayleigh scattering technique has great potential for sensing SAHH activity in red blood cells [39]. Other proteins were examined to determine the selectivity of our analytical system toward SAHH. Fig. 3C shows that SAHH caused a dramatic change in the light-scattering intensity, whereas the remaining proteins exhibited a negligible effect under an identical condition. According the abovementioned results, we suggest that our analytical system is

well suited to monitor thiol product-related enzyme reactions, such as glutathione reductase-catalyzed cleavage of glutathione disulfide [40], homocysteine thiolactonase-induced hydrolysis of homocysteine thiolactone [41], and acetylcholinesterase-triggered hydrolysis of acetylthiocholine [42].

3.3. Sensing of Pb^{2+} by interparticle crosslinking aggregation

Because the threat of heavy-metal pollution in environmental water is still an important issue for public health, laser-induced Rayleigh scattering technique was used to detect the conditions in which metal ions act as a bridge to link ligand-modified AuNPs together. Intensive researches revealed that AuNP-based colorimetric sensors were simple, selective, and sensitive to detect heavy metal ions in environmental waters [10,12]. This was exemplified by the use of gallic acid-capped AuNPs for probing Pb^{2+} in an aqueous solution [43–45]. Fig. 4A illustrates that Pb^{2+}-stimulated aggregation of gallic acid-capped AuNPs results from multivalent coordination between Pb^{2+} and phenolic hydroxyl groups of gallic acid [43–45]. As shown in Fig. 4B, the light-scattering intensity at 532 nm of gallic acid-capped AuNPs incrementally increased with increasing the concentration of Pb^{2+}. The calibration curve for quantifying Pb^{2+} was obtained by plotting the light-scattering intensity at 532 nm *versus* the concentrations of Pb^{2+} over the range from 1–40 nM (inset in Fig. 4B). The LOD of Pb^{2+} was estimated to be 0.3 nM, which is superior to the LOD values measured from AuNP-based colorimetric sensors [7,43–45], nanoparticle – DNAzyme-based colorimetric probes [46–49], AuNP-based hyper-Rayleigh scattering sensor [50], and AuNP-based dynamic light scattering sensor [51] (Table 3). Additionally, the LOD of the proposed method is much lower than the maximum level (15 μg L^{-1}–72 nM) of lead in drinking water permitted by the United State Environmental Protection Agency. Fig. 4C depicts that only addition of Pb^{2+} to a solution of gallic acid-capped AuNPs caused a dramatic change in the light-scattering intensity at 532 nm, signifying that our analytical system exhibited excellent selectivity toward Pb^{2+} over other metal ions. We suggest that the combination of laser-induced Rayleigh scattering technique and AuNP-based metal ion sensor could be used to probe other metal ions by modified specific ligand onto the surface of the AuNPs.

3.4. Smart-phone-based heavy metal ions reader

To further reduce the cost of instrumentation and toward more portable system, a laser pointer (< 20 mW) and a smart-phone were substituted for a diode laser and a miniaturized spectrometer, respectively (Fig. 5A). Fig. 5B shows a representative smart-phone-captured image of solutions of gallic acid-capped AuNPs in the absence and presence of 72 nM Pb^{2+}, *i.e.*, the safety level recommended by U. S. EPA, in drinking water. The illumination intensity of the laser pointer was sufficient to pass through the sample and control cuvettes, forming two readable signals in two image frames. To determine whether the contamination of Pb^{2+} in drinking water, the acquired scattering images (164 × 5 pixels) of these cuvettes were converted to pixel intensity (0–256 counts)

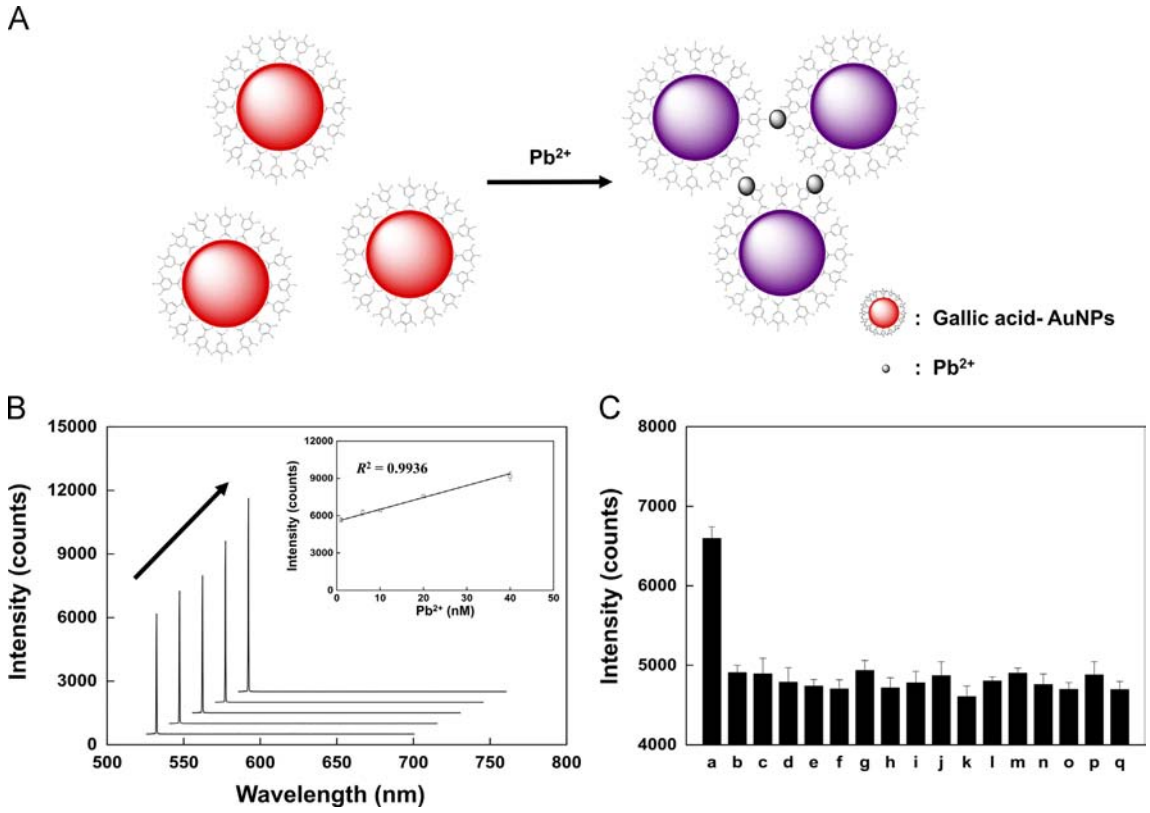

Fig. 4. (A) Illustration of the mechanism of gallic acid-capped AuNPs for sensing Pb^{2+} *via* the coordination between gallic acid and Pb^{2+}. (B) Scattering spectra of gallic acid-capped AuNPs in the presence of increasing Pb^{2+} concentration. The arrows indicate the signal changes with increase in Pb^{2+} concentration (1, 6, 10, 20, and 40 nM). (C) Scattering intensity at 532 nm obtained from the addition of metal ion to a solution of gallic acid-capped AuNPs. Metal ion: (a) Pb^{2+}, (b) Li^{+}, (c) Na+, (d) K+, (e) Mg^{2+}, (f) Ca^{2+}, (g) Sr^{2+}, (h) Ba^{2+}, (i) Fe^{2+}, (j) Fe^{3+}, (k) Co^{2+}, (l) Ni^{2+}, (m) Cu^{2+}, (n) Zn^{2+}, (o) Mn^{2+}, (p) Hg^{2+}, (q) Cd^{2+}. The concentration of Pb^{2+} is 10 nM, while the concentration of other metal ion is 1 μM. (B, C) Metal ions were incubated with a solution containing gallic acid-capped AuNPs (0.63 nM), $NaClO_4$ (1 mM) and formic acid buffer (pH 4.5, 20 mM) for 20 min at ambient temperature.

Table 3

via Image J (Fig. 5C). The intensity ratio of the sample to the control cuvette was calculated by the following equation:

$$\text{Ratio} = (I_1/A_1)/(I_0/A_0)$$

I_1 and I_0 are the integrated pixel intensities of the selected images in the sample and control cuvettes, respectively, while A_1 and A_0 are the area of the selected images in the sample and control cuvette. The intensity ratio of the sample to the control cuvette was computed to be 1.5, which corresponds to the maximum allowable level of Pb^{2+} in drinking water. In other words, if the intensity ratio of the sample to the control cuvette is higher than 1.5, samples of drinking water will contain above 72 nM Pb^{2+}. Thus, the combination of a laser point, a smart-phone, and a AuNP-based probe was suited to monitor the maximum allowable levels of Pb^{2+} in drinking water defined by the U. S. EPA.

4. Conclusion

We have reported a miniaturized, sensitive, and cost-effective platform for monitoring the change in light scattering from three AuNP-based sensing systems, including salt-, thiol-, and metal ions-induced

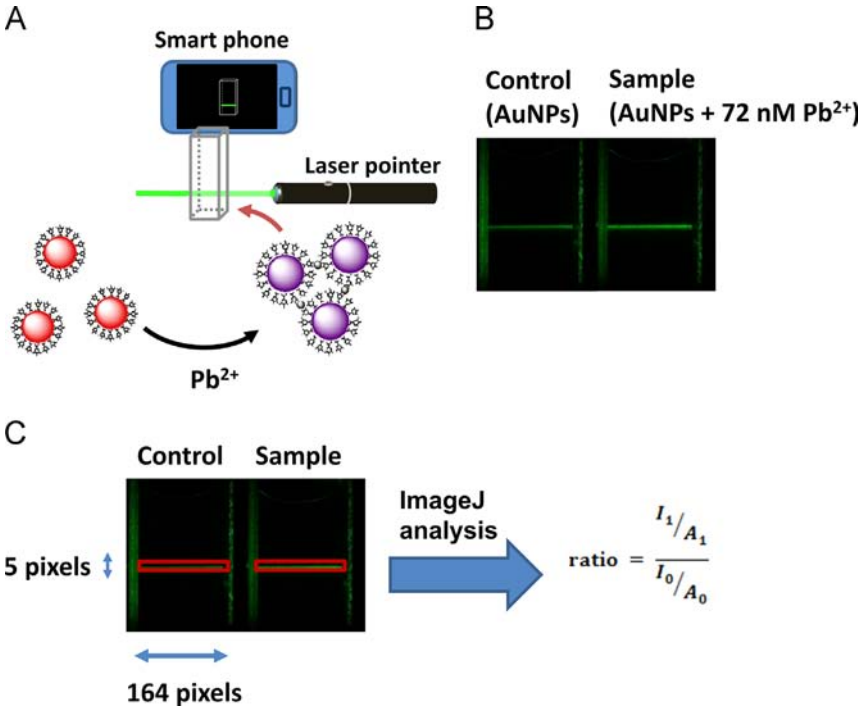

Fig. 5. (A) Schematic illustration of the portable device for the determination of Pb^{2+} in drinking water. (B) Photo images captured on the smart-phone under laser illumination. The left cuvette contained a mixture of gallic acid-capped AuNPs (0.63 nM), $NaClO_4$ (10 mM), formic acid buffer (pH 4.5, 20 mM), and drinking water, while the right cuvette contained the above mentioned mixtures in the presence of 72 nM Pb^{2+}. (C) Flow of image-processing steps to compute normalized pixel intensity. Conversion of selected image to integrated pixel intensity by ImageJ. The integrated pixel intensity was normalized by dividing it by the sum of pixel areas.

aggregation of the AuNPs. Salt-induced aggregation is exemplified by the use of aptamer-modified AuNPs for sensing K^+ in a high-ionic-strength solution. Laser-induced Rayleigh scattering technique coupled to aptamer-based sensor provided high sensitivity (LOD = 1 μM) and selectivity (21,000-fold) for K^+ ions. Thiol-triggered aggregation of the AuNPs is exemplified by the use of FSN-stabilized AuNPs for probing homocysteine, which is generated from SAHH-induced hydrolysis of SAH. The proposed detection system combined with FSN-stabilized AuNPs was highly responsive and selective for the SAHH/SAH system. Metal ion-promoted assembly of the AuNPs is exemplified by the detection of Pb^{2+} with gallic acid-capped AuNPs. By combining laser-induced Rayleigh scattering technique with gallic acid-capped AuNPs, the LOD of Pb^{2+} was down to 0.3 nM. Also, a sensitive, portable cost-effective smart-phone-based Pb^{2+} sensor platform was developed by replacing a diode laser and a miniaturized spectrometer with a laser pointer and a smart-phone. Previous studies reported that Cr^{3+} and Hg^{2+} triggered the aggregation of 5-thiol-(2-nitrobenzoic acid)- and 3-mercaptopropionate acid-capped AuNPs [8,52]. In the opinion of the authors, the smart-phone-based detection system combined with 5-thiol-(2-nitrobenzoic acid)- and 3-mercaptopropionate acid-capped AuNPs could be implemented for sensing Cr^{3+} and Hg^{2+} in an aqueous solution, respectively.

ABSTRACT

Propantheline bromide (PB) is a hydrolysable anti-cholinergic drug. A novel strategy for the online monitoring of PB degradation kinetics catalysed by hydroxyl ions is presented. This is achieved by the incorporation of an on-site PB-selective electrode constructed using as an ionophore. This sensor was used to track the hydrolysis of PB by continuous measurement of the decrease in the produced emf over time. The use of this new technique provides real-time observation and yields a continuous profile of the hydrolysis behaviour of PB under various pH conditions as well as the temperature dependency of each reaction. Moreover, a great advantage of this proposed on-line system is its higher accuracy for rate constant estimation relative to other off-line methods. This kinetic data analysis permitted the determination of the hydrolysis activation energy and prediction of the drug shelf life. The estimated activation energy from Arrhenius plot was 20.77 kcal mol^{-1}.

1. Introduction

In modern analytical laboratories, kinetic studies and accelerated stability experiments are the most important tools for solving problems encountered in quality control and for predicting both the optimum storage conditions and the expiry dates of pharmaceutical products. For the continuous monitoring of degradation kinetics, potentiometric sensors offer many attractions and considerable advantages. However, although the last 15 years have seen very rapid developments in the design of a wide range of electrode types selective towards a vast number of ions with varying degrees of selectivity [1,2], relatively little attention has been paid to the novel use of such electrodes. For tracking the concentration of easily hydrolysable drugs, it is sufficient to immerse the ion-selective electrode (ISE) in the degradation medium together with a suitable reference electrode and record the continuous decrease in emf due to the gradual decrease in the drug ion concentration. This permits real-time observation and yields a continuous profile for the hydrolysis behaviour of the drug under various pH conditions and the temperature dependency of each reaction. The presently used offline techniques, UV spectroscopy and HPLC–UV, yield discontinuous profiles and suffer from numerous problems, such as requiring multiple sample withdrawals, several sample preparation steps, expensive instrumentation and long monitoring time [3]. Meanwhile, an ISE must satisfy a set of general requirements common to all detection systems for monitoring a degradation process, i.e., sufficient sensitivity and stability, low background noise, low drift, rapid response time and sufficient selectivity for the drug over the product of the degradation reaction. Although the literature concerning the chemical stability of hydrolysable substances in drug preparations as analysed by offline chromatographic and spectrometric techniques is extensive [4–8], only a few cases have been reported for online monitoring techniques [9,10]. To the best of our knowledge, no wide systematic study of on-line drug degradation kinetics using on-line potentiometric sensors has been published in the literature. Only some papers have reported on similar topics, such as the in situ study of the dissolution of formulations of pharmaceutically active drugs [11] and electrochemical sensors for environment monitoring [12].

The present study was undertaken to further explore how potentiometry can be used for the reliable online monitoring of the degradation kinetics of easily hydrolysable ionisable/ionic drugs. Propantheline bromide (PB) was selected as a model based on its ester linkage and quaternary ammonium group, which endow it with the character of a strong cationic electrolyte. In this work, an ISE for PB was fabricated using a PVC membrane doped with 4-tert-butylcalix [8] arene as an ionophore. The ISE was used to detect PB, and the figures of merit were calculated and then used to detect PB in the presence of its alkaline degradation products, xanthene-9-carboxylic acid(XA) and diisopropyl(2-hydroxyethyl)methylammonium bromide (quaternary alcohol) (Scheme 1). Finally, the ISE was used to study the kinetics of the PB degradation in alkaline medium and calculate the hydrolysis rate constant and the hydrolysis

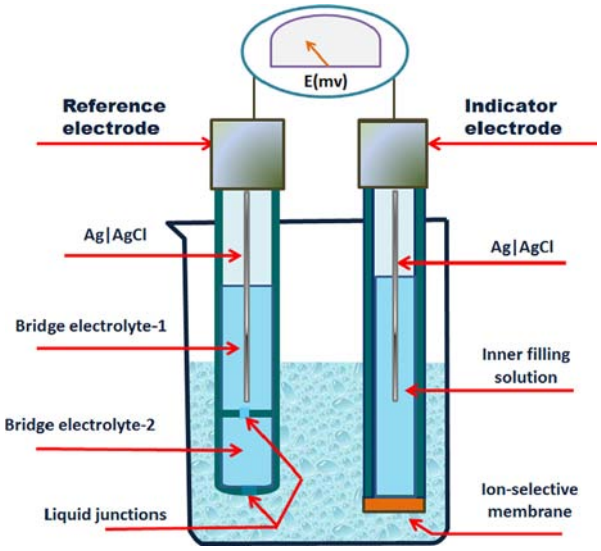
activation energy. One advantage of this technique is that more data points can be monitored than when using the off-line methods. Thus, all constants found for the kinetics of PB hydrolysis will be more accurate because they will be based on a larger number of data points.

2. Experimental

2.1. Chemicals and reagents

Propantheline bromide (PB), sodium tetraphenyl borate (NaTPB), and 4-*tert*-butylcalix [8] arene (*t*-Bu-CX8) were purchased from Sigma-Aldrich (Steinheim, Germany). Polyvinyl chloride (PVC) and 2-nitrophenyl octyl ether (NPOE) were obtained from Fluka Chemie GmbH (St. Louis, MO, USA), and tetrahydrofuran (THF) was obtained from BDH (Poole, England). Probanthin® tablets (15 mg/tablet) were purchased from Sigma Pharmaceuticals (New Zealand). Britton–Robinson buffer (BRB) (pH 2–12) was prepared by mixing different volumes of 0.04 mol L^{-1} acetic acid, 0.04 mol L^{-1} phosphoric acid, 0.04 mol L^{-1} boric acid and 0.2 mol L^{-1} sodium hydroxide.

2.2. Fabrication of membrane sensors



The PVC membranes were prepared in two separate 5-cm Petri dishes by mixing PVC (33.50%), NPOE (66.34%) and NaTPB (0.16%, 5.0 mmol kg^{-1}) to prepare sensor 1 and PVC (33.50%), NPOE (65.05%), NaTPB (0.16%, 5.0 mmol kg^{-1}) and *t*-Bu-CX8 (1.29%, 10.0 mmol kg^{-1}) to prepare sensor 2. The membrane components (600 mg in total) were dissolved in THF (6.0 mL), and the Petri dishes were covered with filter paper and left to stand overnight at room temperature to allow solvent evaporation, leaving a homogeneous, flexible and transparent membrane. Master membranes of 0.1 mm in thickness were obtained. From each master membrane, a disk (approximately 8 mm in diameter) was cut using a cork borer and pasted using THF to an interchangeable PVC tip that was clipped to the end of an electrode glass body. The electrodes were then filled with an internal solution of equal volumes of 10^{-4} mol L^{-1} PB and 10^{-4} mol L^{-1} KCl. Ag/AgCl wire (1-mm diameter) was used as an internal reference electrode. The sensors were conditioned by soaking in 10^{-4} mol L^{-1} aqueous PB solution for 24 h and stored in the same solution when not in use. The electrode produced in this way is shown in Scheme 2.

2.3. Potentiometric measurements

Potentiometric measurements were carried out using an Ag/AgCl double-junction-type external reference electrode (Thermo Scientific Orion 900200, MA, USA; 3.0 M KCl saturated with AgCl as an inner filling solution and 10% KNO_3 as a bridge electrolyte) and Jenway digital ion analyser (model 3330; Essex, UK). A Jenway pH glass electrode (Essex, UK) was used for pH adjustments.

2.3.1. Sensors calibration

The conditioned sensors were calibrated by separately transferring 50-mL aliquots of solutions (10^{-7} –10^{-2} mol L^{-1}) of PB into a series of 100-mL beakers. The membrane sensors, in conjunction

Scheme 2. Potentiometric cell assembly with a conventional, liquid inner contact ion selective membrane electrode as indicator electrode and a double junction reference electrode.

with the Ag/AgCl reference electrode, were immersed in the above test solutions and allowed to equilibrate under stirring. The potential difference (emf) between the membrane sensor (indicator electrode) and the reference electrode was recorded after stabilising to ±1 mV, and the emf was plotted as a function of the logarithm of PB concentration for a BRB solution of pH 7.0.

2.3.2. Potentiometric determination of PB in pharmaceutical preparation

Ten tablets were ground to a powder. A quantity of the powder equivalent to 112.09 mg of PB was transferred to a 25-mL volumetric flask, which was then filled to the mark with BRB of pH 7. The concentration of this solution was 10^{-3} mol L^{-1}. The potentiometric measurements were performed using the proposed sensor in conjunction with the Ag/AgCl reference electrode, and the potential readings were compared to the calibration plots.

2.3.3. Effect of pH on electrode response

The effect of pH on the response of the investigated electrodes was studied using 10^{-3} and 10^{-4} mol L^{-1} solutions of PB in BRB with pH ranging from 2.0 to 12.0.

2.3.4. Preparation of degradation product

A degraded sample of PB was prepared by adding 5 mL of NaOH (0.1 mol L^{-1}) to 10 mL of drug solution (10^{-2} mol L^{-1}) and refluxing for 10 min. The resulting solution was tested for complete degradation by HPLC using a mobile phase of 40:60 acetonitrile:0.05 mol L^{-1} phosphate buffer (pH 2.5), as reported previously [13]. The degraded solution was neutralised, transferred quantitatively into a 100-mL volumetric flask and brought to volume with deionised water.

2.3.5. Kinetic studies

2.3.5.1. Reaction order. A volume of 45.0 mL of BRB of pH 9.5 was placed into a 100-mL beaker on a hotplate thermostated at 25 °C. The PB-selective electrode and the reference electrode were immersed, and the data acquisition was started. Once the potential is stabilised, an appropriate volume (5 mL of 10 mmol L^{-1}) of the PB working solutions was added. The emf values for the solution [initial concentration C_o=448.4 μg mL^{-1} (10^{-3} mol L^{-1})] were measured continuously. The concentration of PB was calculated from the

corresponding regression equation using a calibration graph for PB in BRB solution of pH 9.5. The log % of remaining concentration against time was constructed for different pH buffers. The rate constants and the corresponding half-lives ($t_{1/2}$) were calculated.

2.3.5.2. Effect of buffer pH on reaction rate. A 5-mL volume of a 10 mM standard solution of PB was added into each of three 100-mL beakers, which contained 45.0 mL of BRB solution of pH 9.5, 10.0 and 10.5 thermostatically controlled at 25 °C. The emf values were monitored continuously as described above. The log % of the remaining concentration was plotted against time for different pH buffers. The rate constants and corresponding half-lives ($t_{1/2}$) were calculated.

2.3.5.3. Effect of temperature on reaction rate. A volume of 45.0 mL of pH 9.5 BRB was placed into a 100-mL beaker. This solution was heated thermostatically at 25 °C, 30 °C and 35 °C. The emf was monitored continuously as described above. The log % of the remaining concentration was plotted against time for different temperatures. Furthermore, an Arrhenius plot was constructed for the temperature effect on hydrolysis rate.

3. Results and discussion

Pharmaceutical product quality is of vital importance for patient safety. The presence of impurities may influence the efficacy and safety of pharmaceuticals. Impurities and potential degradation products can cause changes in the chemical, pharmacological and toxicological properties of drugs and thereby have a significant impact on product quality and safety [14].

This paper is positioned at the promising junction of two areas of recent and increasing interest: chemical kinetics and electroanalysis. To the best of our best knowledge, no ISE for the on-line monitoring of the degradation kinetics of drug hydrolysis has been reported so far. Thus, PB-selective sensors were fabricated in the hope that they may be used as a model system for on-line monitoring. Subsequently, the same procedure could be extended to other hydrolysable organic compounds without significant modification. This should provide a viable platform for the on-site monitoring of hydrolysis processes using ISEs.

3.1. ISE characteristics using t-Bu-CX8 as a sensing ionophore

The response of ionophore-based potentiometric sensors is usually governed by the molecular recognition between the analyte (guest) and the host molecule. Different macrocyclic ionophores have been proposed for use with organic drug guest molecules, such as crown ethers, calixarenes, cyclodextrins (CDs) and porphyrins.

The most important property of calixarenes (nano-baskets) is their ability to form supramolecular (inclusion) complexes with many appropriately sized organic ions and molecules, where the driving forces for this complexation are directed hydrogen bonding and cation–π-interactions (electrostatic attraction between the positive charge of the guest and the electron-rich faces of the aromatic rings of the phenol units) [15,16]. In the present work, the ionophore 4-*tert*-butylcalix [8] arene (*t*-Bu-CX8) was chosen because it possesses outstanding complexation properties toward quaternary ammonium ions [17].

The positive PB ion prefers the prevalent donation sites (OH groups) and large cavity size (11.7 Å) of calixarene structure. Fig. 1 shows the calibration curves for sensors 1 and 2. In the absence of the ionophore, i.e., in the case of sensor 1, the lowest slope and the highest selectivity coefficient values are found. A higher selectivity coefficient value corresponds to a more extensive attack of the electrode membrane by interfering cations. On the other hand, the *t*-Bu-CX8-based sensor 2 shows the best Nernstian slope (59.4 mV/decade) and selectivity coefficient values (discussed below). The host–guest complex is stabilised via the strong interaction between the cationic PB and the eight H-bonding sites of *t*-Bu-CX8. Moreover, calix [8] arene has a large internal cavity size (11.7 Å), which allows the drug to fit well in the calixarene cavity and bond strongly to the calixarene donation sites.

The electrochemical performance characteristics of the proposed sensors were systematically evaluated according to IUPAC standards [18]. Table 1 shows the results obtained over a period of one month for two different assemblies of each sensor. Typical calibration plots are shown in Fig. 1. The slopes of the calibration plots are 55.1 and 59.4 mV/concentration decade for sensors 1 and 2, respectively. Deviation from the ideal Nernstian slope (60 mV) is due to the response of the electrodes to the activity of the drug cation rather than its concentration.

The sensors displayed constant potential readings for day-to-day measurements, and the calibration slopes did not change by more than ±2 mV/decade over a period of 25 and 30 days for sensors 1 and 2, respectively. The detection limits of the two sensors were estimated according to the IUPAC definition. Table 1 shows that sensor 2 can detect PB in very dilute solutions down to 1×10^{-7} mol L^{-1}. This finding agrees with the idea that PB is

typically accommodated and bonded by the large cavity size and prevalent H-bonding sites of the *t*-Bu-CX8 ionophore.

3.2. Effect of pH and temperature

The optimal experimental conditions for quantitative measurements with the ion-selective electrodes were investigated. A pH value within the range of 3–7 is found to be best from the perspective of sensor function and the chemical form of the test solution of PB. Fig. 2 shows the potential-pH profile for 10^{-3} and 10^{-4} mol L^{-1} drug solutions. The slight change in potential readings at pH values below the previously mentioned range is attributed to the interference of hydronium ions, while the potential readings decrease gradually at pH values higher than the given ranges, which can be attributed to the degradation of the drug molecules.

The results suggest that the electrodes exhibit a slight increase in potential with increasing temperature in the range of 25–35 °C. However, the calibration plots obtained at different temperatures are parallel, and the limit of detection, slope and response time do not vary significantly with temperature, indicating a reasonable thermal stability of the PVC membranes up to 35 °C.

3.3. Dynamic response time

The dynamic response time is an important factor for analytical applications of ion-selective electrodes. In this study, the practical response time was recorded by increasing the PB concentration by up to 10-fold. The required time for the sensors to reach values within ± 1 mV of the final equilibrium potential was 10 and 6 s for sensors 1 and 2, respectively. The time traces of the calibration curve of the ISE for pH 7.0 BRB are presented in Fig. 3.

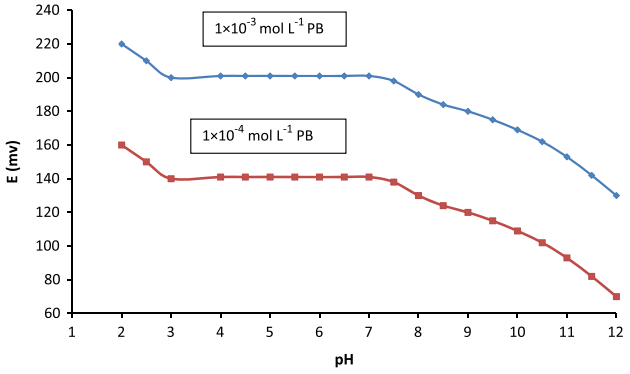

Fig. 2. Effect of pH on the performance of sensor 2.

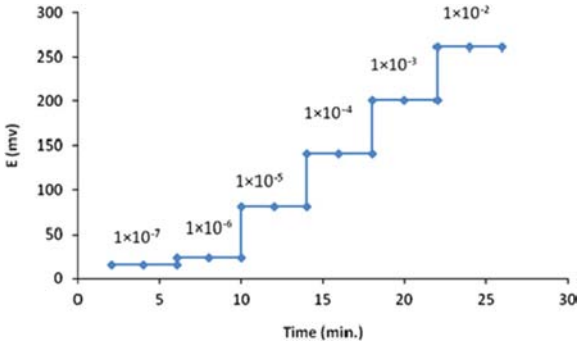

Fig. 3. Time traces of the response of sensor 2 towards PB.

3.4. Sensor selectivity

The selectivity of the fabricated ISE sensor was investigated in the presence of structurally related organic quaternary ammonium ions and in the presence of XA and the quaternary alcohol, the hydrolytic product of PB [19]. Fig. 4 shows the calibration curves for pyridostigmine bromide (PYD), neostigmine bromide (NEO) and rivastigmine hydrogen tartrate (RIV). It is obvious that near-Nernstian slopes and thus unbiased selectivity coefficients were obtained, as shown in Table 2. This can be attributed to the fact that these ions are easily ion-exchanged into the membrane. It is worth noting that an ammonium quaternary ion was expected to be bound by *t*-Bu-CX8. An explanation for the higher selectivity of the ISE towards PB could be its higher lipophilicity compared to other organic ions. The

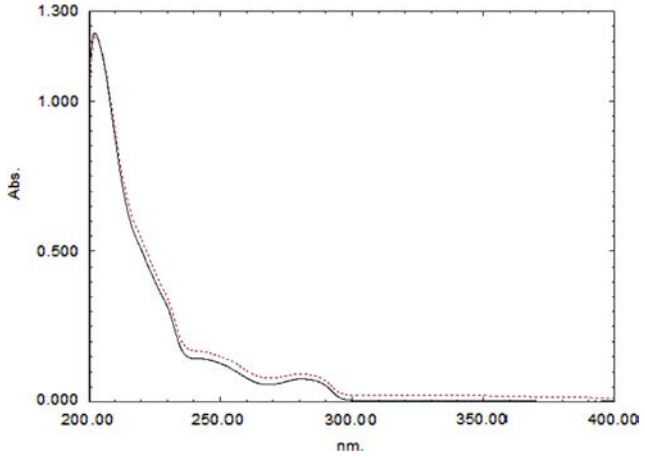

Fig. 5. Zero order spectra of 14 μg mL^{-1} of PB (—) and14 μg mL^{-1} XA (———).

inorganic ions exhibited an obvious non-Nernstian response, and to avoid biased values, no selectivity coefficients were determined. This can be attributed to the difficulty of the ion exchange of these inorganic ions into the lipophilic membrane. The XA shows a marked non-Nernstian response due to the absence of an electroactive group. This facilitates the development of a PB ISE for studying the kinetics degradation process. Reviewing other analytical methods, this may be considered a challenging analytical task. UV-spectrophotometry was unable to provide insight into the degradation process due to the complete overlap (superimposition) of the absorption spectra of XA and PB, as shown in Fig. 5. Moreover, PB was reported to be hydrolysed by adsorption into silica, catalysing the rate of ester decomposition [19] and thereby hindering the monitoring by TLC densitometry.

3.5. Potentiometric determination of PB in pharmaceutical formulation

The proposed sensor was successfully employed to assay PB in bulk powder and pharmaceutical formulation (Pro-Banthine® tablets). The results clearly indicated satisfactory agreement between the PB contents in different samples determined by the developed sensor and the official method (Table 3). The time

required for sample analysis was shorter (less than 1 min) than that of the British pharmacopeial (BP) official method (approximately 30 min) [20]. Moreover, the proposed sensor does not require preliminary drug extraction, as described in the BP method.

3.6. Degradation kinetics

Initial experiments were performed for the offline monitoring of the degradation of PB using ISE by placing a fixed concentration in BRB (pH 10.0) and then withdrawing aliquots at 30-s intervals. The aliquots were neutralised to pH 7 and completed to a definite volume, and then the emf was recorded. Such a kinetic study was tedious, produced a discontinuous nonlinear profile and hindered an accurate estimation of the rate constants.

The incorporation of ISE for on-site monitoring of the concentration of the target ion (drug) has the advantage of enabling real-time observation of the hydrolysis behaviour. The analytical throughput is controlled by the performance of the specific electrode, which mainly depends on the sensitivity and response time of the electrode used. Experimentally, the linear relationship between the log % of the remaining concentration against time indicated first-order degradation, as shown in Fig. 6. However, as the hydrolysis was performed in a large excess of BRB (pH 10), it follows a pseudo-first-order reaction rate, which is the term used when two reactants are involved in the reaction but one of them is in such a large excess (BRB) that any change in its concentration is negligible compared with the change in the concentration of the other reactant (drug).

Different parameters that affect the rate of the reaction were studied. The temperature dependence of PB degradation was studied by conducting the reaction at different temperatures using BRB of different pH, as shown in Fig. 7. At each temperature, the rate constant and $t_{1/2}$ were calculated. Next, the log of the rate constant was plotted against the reciprocal of the temperature in Kelvin (Arrhenius plot, Fig. 8) to demonstrate the effect of temperature on the rate constant. It was concluded that as the temperature increased, the rate of hydrolysis increased with a decrease in $t_{1/2}$ (Table 4). In addition, the energy of activation was determined by calculating the rate constant from the following equation [21]:

$$\log \frac{k_2}{k_1} = \frac{E_a}{2.303\,R}\left(\frac{T_2 - T_1}{T_1\,T_2}\right)$$

where "E_a" is the activation energy, "T_1" and "T_2" are the two temperatures in Kelvin, "R" is the gas constant, and "k_1" and "k_2" are the rate constants at the two temperatures used.

The calculated "E_a" was found to be 20.77 kcal mol^{-1}, which was consistent with the reported values of the hydrolysable esters, confirming the instability in alkaline medium[22].

Another factor that affects the rate of the reaction is the pH of the buffer solution. Therefore, BRB solutions of different pH were used to study the hydrolysis reaction. The rate of hydrolysis increased with increasing pH of BRB. It should be noted that the calibration curves at these higher pH values show no statistically significant difference in the corresponding Nernstian slope, as shown in Fig. 9. This is attributed to the instantaneous response time of the sensor, which facilitates the recording of the emf at higher pH before the start of the hydrolysis process.

Overall, we can conclude that extensive decomposition of PB was observed in aqueous alkaline solution. Consequently, appropriate protection is recommended during storage, and it is advisable to avoid alkaline conditions during analytical assays of PB.

4. Conclusion

The development of a new method was motivated by not only the search for better performance but also a problem in the actual application. To this end, a novel approach for further exploring the potential of ISE technique in online monitoring and real-time observation of the PB degradation was presented here. It should be emphasised that this study used as a model system for the degradation of PB only to evaluate the feasibility and benefits of the on-line coupling of a highly selective ISE system to a system of alkaline degradation, which can be extended to other degradation processes. The monitoring analyses are usually performed off-line and sometimes several days after the hydrolysis was performed and therefore do not reflect the actual values obtained. In the proposed system, quite reliable results are obtained using a selective, robust and easily constructed sensor, which provided

a low-cost, fast method for the real-time monitoring of the alkaline degradation of PB.

ABSTRACT

A novel magneto-DNA duplex probe for bacterial DNA detection based on exonuclease III (Exo-III) aided cycling amplification has been developed. This magneto-DNA duplex probe contains a partly hybrid fluorophore-modified capture probe and a fluorophore-modified signal probe with magnetic microparticle as carrier. In the presence of a perfectly matched target bacterial DNA, blunt 3′-terminus of the capture probe is formed, activating the Exo-III aided cycling amplification. Thus, Exo-III catalyzes the stepwise removal of mononucleotides from this terminus, releasing both fluorophore-modified signal probe, fluorescent dyes of the capture probe and target DNA. The released target DNA then starts a new cycle, while released fluorescent fragments are recovered with magnetic separation for fluorescence signal collection. This system exhibited sensitive detection of bacterial DNA, with a detection limit of 14 pM because of the unique cleavage function of Exo-III, high fluorescence intensity, and separating function of magneto-DNA duplex probes. Besides this sensitivity, this strategy exhibited excellent selectivity with mismatched bacterial DNA targets and other bacterial species targets and good applicability in real seawater samples, hence, this strategy could be potentially used for qualitative and quantitative analysis of bacteria.

1. Introduction

The analysis of bacterial DNA, which is a commonly used genetic marker, is important in the molecular diagnosis of infectious diseases, rapid classification, and phenotyping of bacterial species [1–3]. Most diagnostic approaches related to 16S ribosomal RNA (16S rRNA) segment are based on polymerase chain reaction (PCR) [4,5]. However, some drawbacks, such as critical experiment conditions and complex operation [6], made it become a significant bottleneck in molecular diagnosis. There is therefore a need of detecting method of bacterial DNA segment in a more rapid, convenient and easily operated manner, which could also be used for bacteria and cell analysis.

A nuclease-assisted biosensor capable of amplified detection of single-stranded DNA is of great demand in nucleic acids, molecule detection, and gene diagnosis [7,8]. Various signal amplification strategies based on nuclease, including FokI enzyme [9], polymerase, and nicking endonuclease [10,11] have been developed. Compared with other nucleases, exonuclease III (Exo-III) does not require a specific recognition site, and is effective on the blunt or recessed 3′-terminus substrates of double-stranded DNA [12,13]. Moreover, Exo-III can provide a diverse platform for amplified DNA detection [14].

Most Exo-III aided signal amplification methods reported were carrier-mobilized strategies, including the use of nanoparticles [15], quantum dots [16], single-walled carbon nanotube [17] and graphene oxide [18]. However, most of them, such as quantum dots, or gold nanoparticles, suffer severe background interference from absorption, scattering, especially in complex biological media, and their detection capability would be greatly diminished. So, some advanced carriers need to be developed. Magnetic microparticles (MMPs) [19,20], which can be easily separated and are biocompatible and stable, were rarely reported in this field. In comparison with the above material, some advantages can be shown. First, most biological samples exhibit virtually no magnetic background, so the above background problem would be circumvented. Second, MMPs show fast binding kinetics with single-stranded DNA with larger surface area and high flexibility in homogeneous solution with easy separation. He and his coworkers recently designed an approach using Exo-III coded MMP probes that can simultaneously detect two kinds of DNA [21]. However, the fluorescence signal decreased correspondingly as the two different DNA strands co-assembled at MMPs. Lu and her coworkers fabricated a large diameter microsphere with high density of DNA probes to

increase the sensitivity of the analytical technique [14]. However, the sensitivity of analytical technique with a fixed diameter microsphere remains a challenging issue [22], as the coverage of single DNA strands on MMPs possibly reach saturation.

Based above, we presents a novel perspective for bacterial DNA detection based on fixed-diameter MMPs. Coupled with Exo-III aided cycling amplification, the magneto-DNA duplex probe was introduced to enhance sensitivity. The reaction mechanism of this strategy is based on the following: first, the construction of magneto-DNA duplex probes composed of two fluorophore-modified DNA probes easily captures target DNA and enhances final fluorescence signal. Second, fluorescent dyes and fluorophore-modified signal probes are recovered because of easy separation of MMPs. Third, Exo-III provides a unique cleavage function for amplifying reaction. To the best of our knowledge, our strategy for the first time reported novel perspective of magneto-DNA duplex probe to improve detection sensitivity based on fixed-diameter MMPs. Further more, this strategy offers the merits of high sensitivity, excellent selectivity, and easy operation.

2. Material and methods

2.1. Chemicals and instruments

All of the oligonucleotides were custom synthesized and high-performance liquid chromatography (HPLC) purified by Sangon Biotechnology Co., Ltd. (Shanghai, China). The library of oligonucleotide sequences used in this study is shown in Table S1. The stock solution of DNA were dispersed in TE buffer (10 mM Tris–HCl, 1 mM Ethylene diamine tetraacetic Acid/EDTA, pH 8.0), and diluted to different concentrations with the same TE buffer when needed. Streptavidin-modified MMPs (1.0 μm, 10 mg/mL) were purchased from HuiEr Nanotechnology Co., Ltd. (Henan, China). Exo-III was ordered from Sangon Biotechnology Co., Ltd. (Shanghai, China), and Tris (hydroxymethyl) aminomethane hydrochloride (Tris) was purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Seawater was collected from Huiquan Bay of Qingdao (zone approximately 120° 15′ to 120° 25′ N, 36° 00′ to 36° 06′ E, 10 m to 20 m deep), and then filtered with cellulose acetate ultra-filtration membrane (4 μm). Cellulose acetate ultra filtration membrane was purchased from Bioscience Biotechnology Co., Ltd. (Shanghai, China). All chemicals and solutions used throughout this study were dissolved or diluted with ultrapure water.

An 8-well magnetic rack was ordered from Sangon Biotechnology Co., Ltd. (Shanghai, China), and a KYC-1102C air constant temperature table was purchased from Jiangnan instrument factory (Ningbo, China). The fluorescence spectra data were recorded from F-4500 Fluorescence spectrophotometer (Hitachi High-technologies Corporation, Tokyo, Japan). A laser scanning confocal microscope image analysis system (MRC-1024, Carl Zeiss AG, Germany) and a DYCZ-24DN mini double vertical electrophoresis apparatus (Liuyi instrument factory, Beijing, China) were also used. The ultrapure water was produced by Storage & Distribution system (Millipore Corporation, USA).

2.2. Determining capture probe coverage on MMPs

A 100 μL fluorescence and biotinylated capture probe (500 nM) was mixed with varying amount of MMPs (0, 1, 3, 5, 7, 10, 15, and 20 μL). The supernatant was obtained with magnetic separation after 30 min of incubation at room temperature. Fluorescence signal was recovered with Hitachi F-4500 fluorescence spectrophotometer (excitation wavelength = 494 nm).

2.3. Magneto-DNA duplex probe preparation

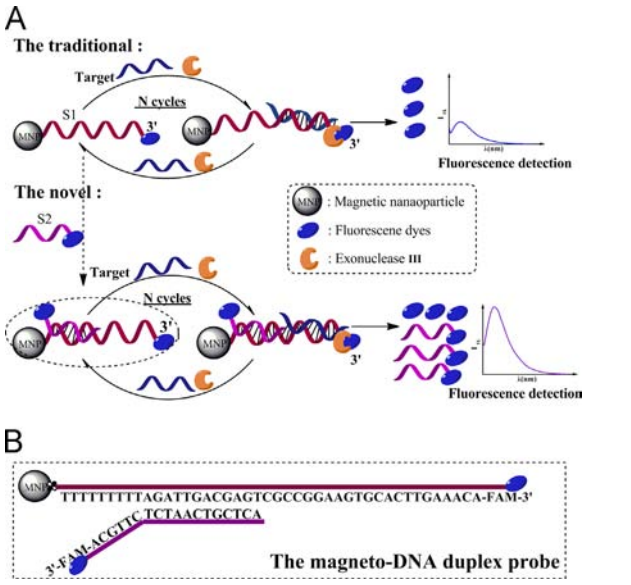
Streptavidin-modified MMPs (10 μL) was washed five times with 1 mL of washing buffer (10 mM Tris–HCl, 1 mM EDTA, 2 M NaCl, pH 7.5). The ultimate magnetic absorptions were resuspended in 1 mL binding buffer (10 mM Tris–HCl, 1 mM EDTA, 2 M NaCl, pH 7.5). The streptavidin-modified MMPs suspension were mixed with 100 μL–500 nM biotin-modified capture probes (S1) and 100 μL of 500 nM signal probes (S2). The mixture was incubated at 25 °C for 120 min with gentle shaking. The weekly bound capture probes were removed after repeated magnetic separation and cleaning. The rest of the absorption was resuspended in 1 mL reaction buffer (20 mM Tris–HCl, 5 mM $MgCl_2$, pH 8.0) and stored at 4 °C for further use.

2.4. Fluorescence microscopy imaging of the magneto-DNA duplex probe

Streptavidin-modified MMPs and fluorescence probe-conjugated MMPs (10 μL) were added onto a glass slide, and a cover slip was glued onto the glass slide using nail polish. The sample was then imaged using a confocal laser scanning fluorescence microscope.

2.5. Gel electrophoresis

Polyacrylamide gel electrophoresis (PAGE) was performed by using an unmodified capture probe, unmodified signal probe, and target DNA with the same sequence, as described in Table S1. The polyacrylamide gel was prepared with 30% (w/v) acrylamide solution, 10% (w/v) ammonium persulfate, 50 × Tris–acetate–EDTA (10 mM Tris, 5 M acetic acid and 0.625 M EDTA, pH 8.5, TAE), tetramethylethylenediamine with 1 × TAE buffer. Then, 10 μL of sample was mixed with 2 μL of loading buffer. The mixtures were run through PAGE at 170 V for 5 min and then 110 V for 60 min. The gel was stained with 0.5 μg/mL of anthodium bromide for 20 min, and a picture was taken using a digital camera under UV illumination.



2.6. Procedure for bacterial DNA detection

The detection of bacterial DNA based on Exo-III cycling amplification reaction was performed by mixing 10 μL magneto-DNA duplex probe, 10 μL of different concentrations of the target DNA, 4 μL of 10 × reaction buffer and 75 units of Exo-III to a final volume of 40 μL, followed by incubation at 37 °C for 90 min. The MMPs were then removed by magnetic separation, and the fluorescence signals of the supernatant were measured with synchronous scanning fluorescence spectrometry. Fluorescence was measured with 494 nm as the excitation wavelength, and the fluorescence emission spectra range was recorded from 500 nm to 650 nm. Excitation and emission slits were both set as 5 nm. Each experiment was repeated at least thrice to test reproducibility.

3. Results and discussion

3.1. Design and validation of the assay

We presented a novel magneto-DNA duplex probe for bacterial DNA detection. The magneto-DNA duplex probe was constructed as follows: fluorophore-modified capture probe (S1) was assembled on the streptavidin-modified MMPs, with optimized amount ratio of MMPs and S1 during the experiment. With the addition of fluorophore-modified signal probe (S2), S1 would hybridized with S2, leaving a 24-nt single-stranded DNA segment overhanging at its 3′-terminus (B part of Scheme 1). It should be noted that S2 only hybridizes partly with S1, leaving 5 nt single-stranded DNA segments overhanging at its 3′-terminus to resist the cleavage by Exo-III (Supplementary section S1.1.) because the resistance degree of Exo-III on single-stranded DNA at the 3′-protruding terminus is dependent on the length of the extension, with extensions 4 nt or longer being

Scheme 1. (A) Schematic of traditional Exo-III aided cycling amplification for DNA detection (top) and the novel Exo-III aided cycling amplification for DNA detection based on magneto-DNA duplex probe (bottom); (B) the base sequence diagram of the magneto-DNA duplex probe.

essentially resistant to cleavage [12]. The target DNA would partly hybridize with the overhanging single-stranded DNA segments of S1 to form a double-stranded structure with its 5 nt single-stranded DNA segments overhanging at the 3′-terminus to resist cleavage by Exo-III. Thus, only blunt 3′-terminus of S1 becomes an active site, which would stimulate the activity of Exo-III. Exo-III catalyzes the stepwise removal of mononucleotides from the 3′-hydroxyl termini of duplex DNA, liberating the fluorescent dyes of the capture probe and releasing signal probe S2. With the hydrolyzation of mononucleotides from the 3′-terminus, the target DNA is released and binds again to the single-stranded DNA segments of S1, which catalyzes a new cleavage cycle. After numerous cycling reactions, a certain amount of the S1′ s fluorescent dyes and the fluorophore-modified signal probe S2 were released into the supernatant. Released fluorescent fragments are recovered by applying a magnetic field to remove MMPs. The fluorescence signals of the supernatant are recorded with fluorescence spectrophotometer.

A small fragment of characteristic DNA sequences from the genome of each species was prepared to detect the bacterial DNA segment. *Desulfobacter curbatus* DNA was selected as the target DNA [23].

We studied the feasibility of this strategy. Fig. 1A shows that fluorescence intensity was weak in the absence of target DNA, this result can be attributed to the overhanging single-stranded DNA segments at the 3′-terminus to resist Exo-III cleavage and excellent separating ability of MMPs. On the other hand, in the presence of target DNA, the overhanging single-stranded DNA segments at the 3′-terminus of S1 would hydride with target DNA to form active site, activating the Exo-III aided cycling amplification. The fluorescence signals of the supernatant were observed with a $552 \pm 15\%$ signal increase, however, the corresponding signal gain of the traditional method was only $221\% \pm 7\%$ at the target concentration of 0.15 nM. The reaction buffer exhibited low fluorescence signals. Overall, this novel magneto-DNA duplex probe-aided method was feasible and more sensitive than the traditional one. The assay was further verified by PAGE test as shown in Fig. 1B. Compared with lane 1 (the blank), lane 2 (traditional method) and lane 3 (novel method) exhibited a bright band at 4 bp, indicating that the hydrolyzed segments produced by the Exo-III-aided cycling amplification shifted rapidly to the bottom. In contrast with the traditional one, the novel one showed an evident band of signal probe, indicating that the probe was released and can be captured for signal enhancement.

We further performed fluorescence imaging of the novel magneto-DNA duplex probe (Fig. 1C). The streptavidin-modified MMPs exhibited no fluorescence signal in the absence of capture probes and signal probes. Once the fluorescence-conjugated probes were introduced, a fluorescence image brighter (c) than the traditional one (b) was captured, indicating the successful building of the magneto-DNA duplex probe.

3.2. Determining capture probe coverage on MMPs

The capture probe coverage on MMPs was optimized. As shown in Fig. 2, a high fluorescence signal was observed at first. With more MMPs being added, more DNA was removed and a lower fluorescence signal was observed until 10 μL of MMPs was added, indicating that 10 μL of MMPs (10 mg/mL) can take 100 μL of FAM and biotinylated capture probe (500 nM) at most. The average number of capture probe on each MMP was estimated as 1.49×10^6 (Supplementary section S1.2). This result indicated that the capture probe coverage on fixed-diameter MMPs possibly reached saturation, hence, we designed the novel duplex probe to enhance fluorescence intensity.

3.3. Optimization of assay conditions

The activity of Exo-III is critical to the whole cycling amplification reaction under certain temperatures. This optimization experiment was performed by detecting 0.15 nM target DNA at 4, 25, 37, and 45 °C, and the blank was carried out without any target DNA. Fig. S2 (see Supplementary section S1.3) shows the experimental results that indicate the signals increased with temperature from 4 °C to 37 °C, which means the Exo-III activity enhanced and the relative fluorescence signal between target and the blank increased. When the temperature increased, the sample and the blank fluorescence signals decreased simultaneously, and the relative fluorescence signal narrowed. This phenomenon can be attributed to the high temperature that decreases the activity of Exo-III and the capture probe cannot be digested. Therefore, 37 °C was considered the optimum incubation temperature.

The fluorescence signal was measured by detecting 0.15 nM target DNA with 0, 25, 50, 75, and 100 units of Exo-III to investigate the influence of the amount of Exo-III used throughout this assay on target DNA detection. The blank sample was treated in the same concentration of Exo-III without target DNA. Fig. S3 (see Supplementary section S1.3) shows that the maximum interval of fluorescence between the target DNA and the blank sample was obtained at 75 units of Exo-III. Thus, 75 units of Exo-III were used in the following assay.

The incubation time was optimized for the performance of Exo-III-aided reaction upon analyzing the target DNA at a concentration of 0.15 nM. Fig. S4 (see Supplementary section S1.3) shows that the fluorescence signal gradually increased and reached the maximum value at 90 min. The signal intensity stabilized after 90 min. The incubation of 90 min was considered the optimized time of the whole reaction.

3.4. Analytical performance

Under optimal conditions, the relationship between the change of fluorescence intensity and the concentration of target DNA was investigated. Fig. 3 shows the fluorescence spectrum in the presence of different target DNA ranging from 40 pM to 800 pM and the related linear relationship. The relative signal intensity exhibited a

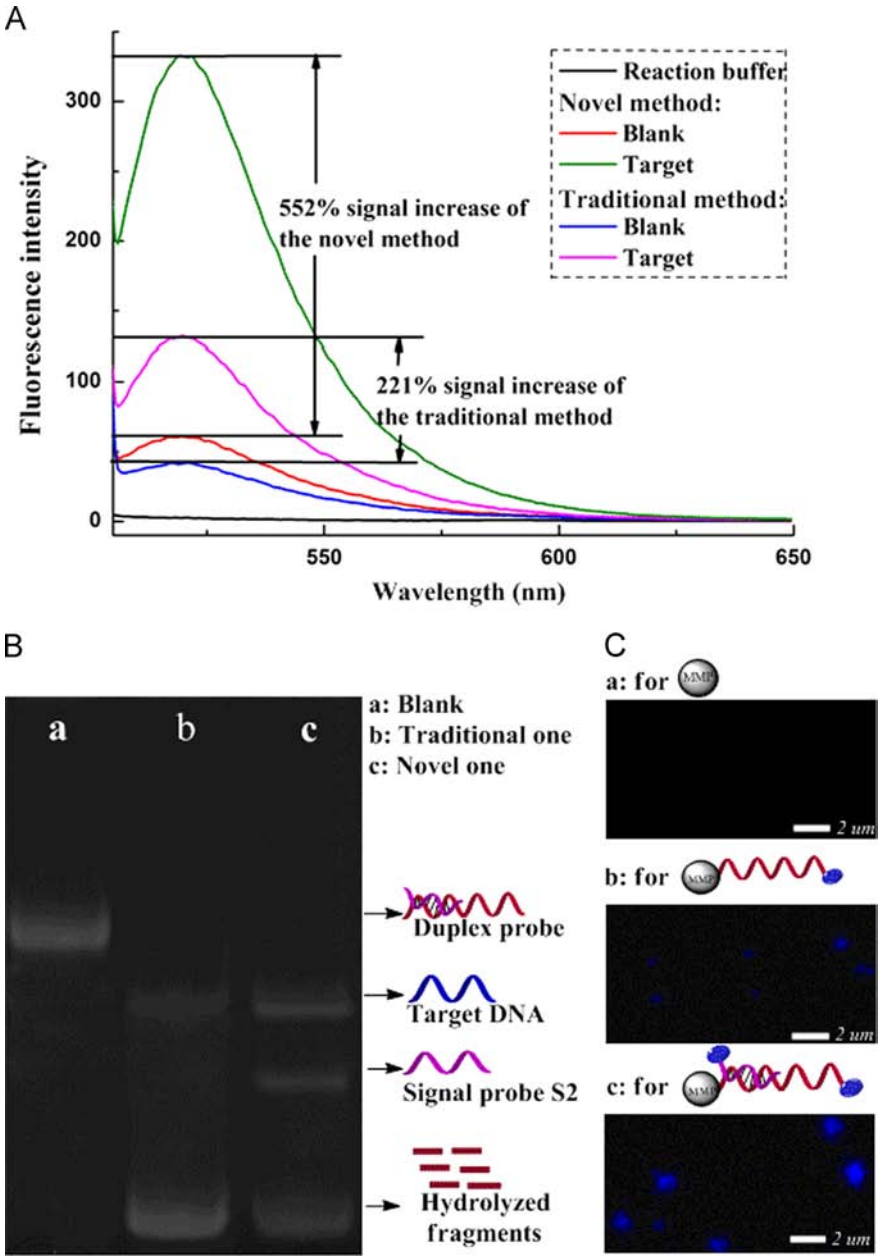


Fig. 1. (A) Fluorescence spectra and (B) polyacrylamide gel electrophoresis of (c) the novel cycling amplification reaction; (b) the traditional cycling amplification, and (a) blank with a target DNA of 0.15 nM. Experiment conditions: 75 U Exo-III, 37 °C with 90 min incubation; and (C) fluorescence imaging of (a) streptavidin-modified MMPs, (b) the single DNA probe (10 μM) modified MMPs, and (c) the magneto-DNA duplex probe-modified MMPs with 10 μM capture probe and 10 μM signal probe.

linear relationship with the concentration of target DNA in the range of 40–150 pM, and the regression equation can be represented as $Y=2.357X-73.00$ ($R^2=0.9985$, where Y is the relative fluorescence intensity and X is the concentration of the target DNA, The relative fluorescence intensity was calculated by $FL-FL_0$, where FL and FL_0 are the fluorescence intensities in the presence and in the absence of target DNA, respectively). The detection limit was determined to be 14 pM based on a linear fitting and the noise level of 3σ (where σ is the standard deviation of a lank solution, $n=12$), which was comparable to the reported Exo-III aided cycling amplification method (see Supplementary Table S3). Obviously, the introduction of magneto-DNA duplex probe presents a novel perspective of improving sensitivity based on fixed diameter MMPs. The sensitivity of this proposed method could be improved with more signal probes (S2) conjugated with capture probes (S1), as all signal probes would be released into the supernatant when Exo-III is activated. As a result, the sensitivity and flexibility of this strategy greatly improved.

3.5. Selectivity of the assay

The selectivity of an assay is another critical factor besides detection sensitivity. The selectivity of this magneto-DNA duplex probe-based strategy was evaluated in this assay with perfectly matched, single-base mismatched, three-base mismatched, and completely mismatched target DNA sequences at a concentration of 0.15 nM. Fig. 4A shows that the fluorescence signal decreased with the increase of mismatched base counts, and the completely mismatched sequence showed the same fluorescence signal with the control sample. Therefore, this proposed strategy is highly capable of differentiating perfectly matched and mismatched DNA targets. Control DNA targets of *Desulfobulbus propionicus*, *Desulfobacterium autotrophicum*, and *Desulfosarcina variabilis* were also employed to replace the same concentration of *D. curbatus* (0.15 nM) under the same experimental conditions for the *Magneto-DNA duplex probe* assay [23]. The results established the specificity of this method that could be

Error bars are the standard deviation of three repetitive measurements.

attributed to the specific hybridization of target DNA and the excellent digestion property of Exo-III. Thus, the proposed magneto-DNA duplex probe strategy exhibits high selectivity between target DNA, mismatched DNA targets, and good specificity in bacterial DNA target.

3.6. Strategy application in different fluids

Spike and recovery experiments were performed to further investigate the application of this technique in a complex environment. The bacteria used in this experiment are all marine corrosive microbes,

Comparison of fluorescence spectra yielded by Exo-III aided cycling amplification reaction based on magneto-DNA duplex probes with different concentrations of target DNA (0 nM, 0.10 nM, and 0.15 nM) in reaction buffer and seawater sample. Error bars are the standard deviation of three repetitive measurements.

and 10% of seawater sample (see Supplementary section 1.4) was selected as the reaction buffer, spiked with 0, 0.10, and 0.15 nM of target DNA. As shown from Fig. 5, the seawater sample and reaction buffer with same concentration of target DNA did not exhibit obvious fluorescence difference. The ultimate concentration of target DNA was determined by using calibration method, and the recovery rate was calculated at $97 \pm 5\%$, which reflects good application of the proposed strategy in different fluids.

4. Conclusion

We proposed a novel perspective of the magneto-DNA duplex probe-based strategy for bacterial DNA detection based on Exo-III-aided cycling amplification. This approach is simple, fast, and easy to operate, resulting in good separating ability of MMPs and excellent fluorescence intensity of DNA duplex probes. With the unique cleavage function of Exo-III, this approach exhibits excellent sensitivity with a detection limit as low as 14 pM, high specificity to well discriminate a one-base difference in DNA sequences, and favorable application in real seawater samples. The new perspective of magneto-DNA duplex probe can be potentially applied in bacterial detection and cell analysis.

ABSTRACT

A sandwich-type luminol electrochemiluminescence (ECL) aptasensor for highly sensitive and selective detection of platelet-derived growth factor BB (PDGF-BB) is fabricated. For this proposed ECL aptasensor, a multilayered AuNPs-electrochemically reduced graphene (AuNPs-EG) nanocomposite film was formed on the GCE surface as the base of the aptasensor through a co-electrodeposition method. The AuNPs-EG composites possess high conductivity to promote the electron transfer at the electrode interface and good biocompatibility and large surface area to capture large amounts of primary aptamer (Apt1), thus amplifying the detection response. Moreover, glucose oxidase (GOD) functionalized AuNPs labeled secondary aptamer (GOD–Apt2–AuNPs) was designed as the signal probe for the sandwiched aptasensor. Enhanced sensitivity was obtained by in situ generation of H_2O_2 from reaction between GOD and glucose and the excellent catalytic behavior of AuNPs to the ECL of the luminol–H_2O_2 system. Under the optimal conditions, the as-prepared ECL aptasensor exhibited excellent analytical property for the detection of PDGF-BB in the range from 1.0×10^{-13} to 5.0×10^{-10} mol L^{-1} with a detection limit of 1.7×10^{-14} mol L^{-1} ($S/N=3$). The application of the present protocol was demonstrated by analyzing PDGF-BB in human serum and human urine samples with the recoveries from 85.0% to 110%.

1. Introduction

Diabetic nephropathy (DN) is a major chronic microvascular complication of diabetes mellitus (DM), which is an important cause of increased morbidity and mortality in patients with DM [1]. Strong evidence suggests that several growth factors may contribute to the initiation and progressive fibrosis of DN.

Platelet derived growth factor (PDGF), one of the critical growth factors found in human platelets, has increased in importance due to its role in the regulation of cell growth and division [2]. It is composed of two disulfide-linked polypeptide chains, designated A and B, occurs in three isoforms: PDGF-BB, PDGF-AB and PDGF-AA [3]. Among these isoforms, PDGF-BB is known to be directly implicated in the cell transformation process and in tumor growth and progression [4]. Moreover, PDGF-BB is considered as a good predictor for early deterioration of renal function in DN [5]. Thus, precise and sensitive evaluation of PDGF-BB in biological samples will be substantial for disease diagnosis.

Detection of PDGF-BB has been attempted including the traditional antibody based radioisotropic method and ELISA [6,7]. However, the antibody used in these methods is temperature-sensitive, irreversibly denatured, and has a limited shelf life. These drawbacks limit the applications of the antibody-based assay. Aptamer is a specific DNA or RNA strand obtained from random-sequence nucleic acid libraries by SELEX (systematic evolution of ligands by exponential enrichment) technology [8]. They have been widely used as recognition elements for biochemical analysis due to their advantages of simpler synthesis, easier storage, lower cost and higher specificity [9]. Several aptasensors have been developed for detecting PDGF-BB based on electrochemistry (EC) [10], fluorescence [11,12], colorimetric colorimetry [13], chemiluminescence (CL) [14], and electrochemiluminescence (ECL) [15]. Among all the aptasensors, ECL-based methods have attracted intensive and extensive research interests, as they integrate the advantages of EC detection and chemiluminescent techniques, such as high sensitivity, low background, cost-effectiveness and high specificity [16]. Zhu et al. [17] reported an aptamer-based bio bar code immunomagnetic separation and ECL detection of PDGF-BB. [$Ru(bpy)_3^{2+}$] (TBR)-Au bio bar code-labeled aptamer was used as an ECL nanoprobe in the method. Recently, our group [15]

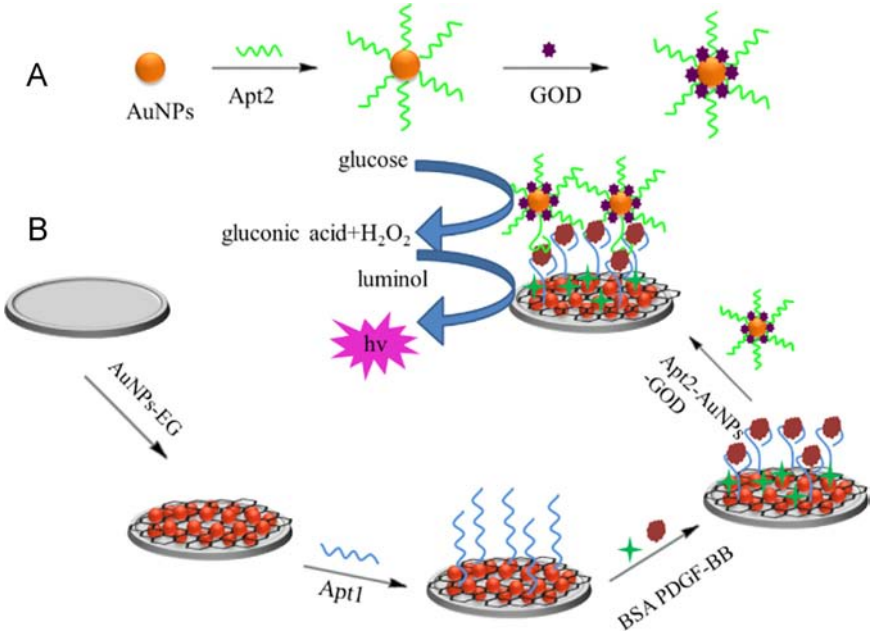
developed an ECL aptasensor featuring MoS_2–AuNPs composites as a matrix and aptamer modified CdSe–ZnS quantum dots as a signal probe for PDGF-BB detection.

Luminol, one of the most widely used efficient ECL luminophores, has some excellent inherent properties such as inexpensive, nontoxic and high light-emission yield [18,19], and luminol-based ECL studies have caught scientists' eyes in biochemical analysis. To achieve a sensitive detection for biochemical samples, many efforts have been devoted to amplifying the ECL signal of luminol. Generally, dissolved oxygen and hydrogen peroxide are used as a coreactant for the luminol ECL reaction to enhance the ECL intensity [20–22]. Nanoparticles with the merits of good biocompatibility, large surface area, excellent electrocatalytic activity and conductivity, could act as a versatile role for biochemical analysis, such as a good matrix for electrode modification or biological labels decorated with enzyme, aptamer or protein [23–26]. Moreover, some of the nanoparticles could catalyze H_2O_2 to generate a great amount of reactive oxygen species which could greatly accelerate the oxidization of luminol, leading to an amplified ECL signal. Cao et al. [27] developed an ECL immunosensor for ultrasensitive detection of carcinoembryonic antigen with a detection limit of 0.03 pg mL^{-1} using Pd and Pt nanoparticles decorated reduced graphene oxide (Pd&PtNPs@rGO) and glucose oxidase (GOD) labeled secondary antibody as the trace label. The sensitivity was enhanced by in situ generation of hydrogen peroxide with GOD and the catalysis of Pd&PtNPs to the ECL reaction of the luminol–H_2O_2 system. The synergetic effects of enzyme and nanopartciles for amplifying the luminol ECL signal in immunoassay provide an ingenious idea for the construction of aptasensors.



Herein, we developed a novel sandwich-type luminol ECL aptasensor for PDGF-BB detection using GOD decorated Au nanoparticles as labels. In this protocol, AuNPs-electrochemically reduced graphene (AuNPs-EG) composites were firstly electrodeposited on the glassy carbon electrode (GCE) as an aptasensor platform which could amplify the ECL signal of the luminol–H_2O_2 system for its fascinating conductivity and served as carrier to immobilize primary aptamers (Apt1) through chemical absorption between AuNPs and –NH_2 of aptamers [28,29]. Then, secondary aptamers (Apt2) and GOD decorated AuNPs were designed as the signal probe for the sandwiched aptasensor. The proposed ECL aptasensor exhibited a sensitive and stable response for the detection of PDGF-BB and achieved a wider linear range and lower detection limit. The proposed ECL aptasensor was applied to the detection of PDGF-BB in human serum samples and human urine samples.

2. Experimental

2.1. Reagents and apparatus

Human platelet-derived growth factor-BB (PDGF-BB) was purchased from Peprotech (USA). The aptamers for PDGF-BB (Apt1: 5′-NH_2-$(CH_2)_6$-TTT TTT TTT TCA GGC TAC GGC ACG TAG AGC ATC ACC ATG ATC CTG-3′, Apt2: 5′-SH-$(CH_2)_6$-TTT TTT TTT TCA GGC TAC GGC ACG TAG AGC ATC ACC ATG ATC CTG-3′), glucose oxidase (GOD) and 10 mmol L^{-1} phosphate buffer saline (PBS, pH 7.4) were purchased from Sangon Biological Co., Ltd. (Shanghai, China). The aptamer and protein solutions were prepared with 10 mmol L^{-1} pH 7.4 PBS, containing 137 mmol L^{-1} NaCl, 2.7 mmol L^{-1} KCl, and 1 mmol L^{-1} $MgCl_2$ and were stored at 4 °C until being used. Hydrogen tetra chloroaurate (III) trihydrate ($HAuCl_4 \cdot 3H_2O$) was obtained from Alfa Aesar (A Johnson Matthey Company, Ward Hill, MA), luminol from Sigma-Aldrich (St. Louis, MO, USA) and bovine serum albumin (BSA) from Siobio Biotechnology Inc. (Shanghai, China). All reagents were of analytical reagent grade and used without further purification. Ultrapure water was used throughout the experiments.

ECL emission was monitored with a model BPCL ultraweak luminescence analyzer (Institute of Biophysics, Chinese Academy of Science, Beijing, China). Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) measurements were carried out with a RST 5200 electrochemical workstation (Zhengzhou Shiruisi Technology Co., Ltd.). A conventional three-electrode system was used with a GCE (Φ=3 mm) as the working electrode, an Ag/AgCl (sat. KCl) as the reference electrode and a platinum electrode as the counter electrode. The morphologies of the samples were recorded on a Hitachi S-4800 scanning electron microscope (SEM) and a Tecnai G2 F20 transmission electron microscope (TEM).

Scheme 1. The procedure of the ECL aptasensor preparation.

2.2. Preparation of GOD–Apt2–AuNPs bioconjugates

AuNPs were prepared according to the previously described procedure [30]. The concentration of the AuNPs was calculated to be about 1.4×10^{-9} mol L^{-1}. The GOD–Apt2–AuNPs bioconjugates was prepared according to the literature reported previously [31,32]. 4 μL 10% (v/v) Tween 80 was firstly added into 1 mL AuNPs, and then the mixture was incubated for 30 min at 25 °C under gentle stirring. Subsequently, 50 μL of GOD (1 mg mL^{-1}) and 50 μL of Apt2 (5 μmol L^{-1}) were added into the as-mixture. After incubation at 25 °C under shaking for 4 h and keeping overnight at 4 °C, the resulted solution was isolated by centrifugation at 10,000 rpm for 15 min to remove the unconjugated aptamer and GOD. The GOD–Apt2–AuNPs hybrid nanoprobes were obtained by re-dispersing the conjugates in pH 7.4 0.1 mol L^{-1} PBS containing 0.05% (v/v) Tween 80 and 0.1% BSA and stored at 4 °C.

2.3. Assembly of sandwich-type ECL aptasensor

Scheme 1B shows the strategy for constructing the ECL aptasensor. First of all, the GCE was carefully polished by 1.0, 0.3, and 0.05 mm alumina powder respectively to a mirror finish and then sonicated in ethanol and ultrapure water in turn. A multilayered AuNPs-EG composite film was formed on the GCE surface through a co-electrodeposition method in a dispersion containing 1.0 mg mL^{-1} graphene oxide (GO) and 100 mmol L^{-1} $HAuCl_4$, while applying scan potential between −1.5 and 0.6 V and scan rate at 25 mV s^{-1} as previously demonstrated by Zhu et al. [31]. After deposition, the electrode was rinsed with H_2O. Then, 6 μL of 0.1 μmol L^{-1} capture Apt1 of PDGF-BB was applied to the AuNPs-EG modified electrode and incubated overnight at room temperature according to the literature [10]. After incubation, the Apt1/AuNPs-EG/GCE was rinsed with PBS (pH 7.4) carefully, immersed in 1% BSA solutions for 30 min at 37 °C to block the nonspecific binding sites. Followed by washing thoroughly with PBS, the modified GCE was incubated in PDGF-BB solution for 1 h at 37 °C (abbreviated as PDGF-BB/BSA/Apt1/AuNPs-EG/GCE). At last, as a sandwich format, the resultant electrode was immersed in the GOD–Apt2–AuNPs solution. Thus the proposed aptasensor was constructed successfully.

2.4. Measurement procedure

The aptasensors incubated with different PDGF-BB concentrations were placed in an ECL detector cell containing 3 mL PBS with 1.0×10^{-4} mol L^{-1} luminol and an appropriate concentration of glucose to record the change of ECL signals. ECL signals were obtained by CV scans with potential varying from −0.2 to 0.8 V and scan rate at 100 mV s^{-1}. The CV and ECL curves were recorded simultaneously.

2.5. Preparation of real-world samples

Human blood samples and human urine samples were from volunteers in Xinyang Central Hospital (Xinyang, China). The complete ethical approval has been obtained, and all the female volunteers gave written informed consent. The study was approved by the Institutional Review Board of Xinyang Central Hospital. The fresh blood samples were centrifuged immediately at 1000 rpm for 15 min to obtain serum. These serum samples were

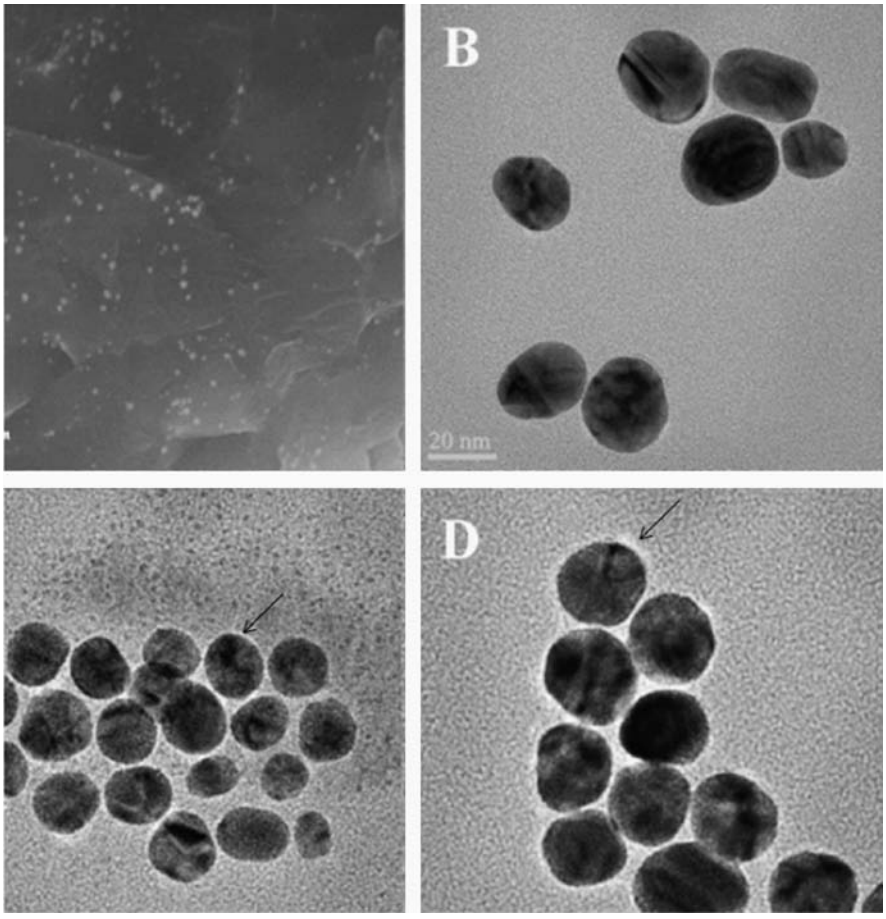


Fig. 1. SEM image of AuNPs-EG nanocomposite (A) and TEM images of bare AuNPs (B), AuNPs-aptamer (C), and GOD–Apt2–AuNPs (D).

stored at −20 °C before use. Urine samples were detected without pretreatment.

3. Results and discussion

3.1. Characterization of the AuNPs-EG nanocomposite, AuNPs, AuNPs–aptamer, and GOD–Apt2–AuNPs

Fig. 1 shows the SEM image of AuNPs-EG nanocomposite and TEM images of bare AuNPs (B); AuNPs–aptamer (C) and GOD–Apt2–AuNPs (D). Fig. 1A reveals that AuNPs (with an average diameter of ~18 nm) of AuNPs-EG nanocomposite were uniformly distributed between the graphene sheets. As for the bare AuNPs to prepare the GOD–Apt2–AuNPs nanoprobe, the average diameter was about 20 nm (Fig. 1B). As seen in Fig. 1C and D, AuNPs-aptamer and GOD–aptamer–AuNPs were surrounded by a transparent ring compared to the bare AuNPs images.

3.2. The characterization of ECL aptasensor

3.2.1. Electrochemical characterization

The stepwise ECL aptasensor assembly process was monitored by CV measurements. Fig. 2A presents the CV curves of the modified electrodes at different stages in the presence of a 5 mmol L^{-1} $K_3[Fe(CN)_6]/K_4[Fe(CN)_6]$ (1:1) mixture containing 0.1 mol L^{-1} KCl. It can be seen that the bare GCE produced relatively low CV intensity (curve a). Compared with the electrode only electrodeposited with AuNPs (curve b), the peak current of the electrode co-electrodeposited with AuNPs-EG nanocomposites further increased (curve c), which suggested the AuNPs-EG nanocomposites film significantly increased the surface area and electro-conductivity of the electrode interface and thus facilitated the interfacial electron transfer process. After Apt1 functionalization (curve d), the peak current significantly decreased due to the fact that aptamer severely blocked the electron transfer tunnel and reduced effective area of electron transfer. It demonstrated that Apt1 has been immobilized successfully. When the aptasensor was blocked with BSA (curve e) and incubated with PDGF-BB (0.1 nmol L^{-1}) (curve f), the CV responses were declined in succession for the hindrance of BSA and aptamer–PDGF-BB complex. Finally, the attachment of the hybrid nanoprobes onto the PDGF-BB surfaces further decreased the peak current (curve g) owing to the barrier effect of the conjugates against the electron communication between $[Fe(CN)_6]^{3-/4-}$ and the electrode surface.

As an effective method to investigate the interface properties of modified electrodes, EIS was also carried out to study the stepwise assembly of the aptasensor. The semicircle diameter which equals the electron-transfer resistance, reflects the restricted diffusion of the redox probe through the multilayer system related directly to film permeability. As can be seen from Fig. 2B, the results of EIS are consistent with the CV characterization.

3.2.2. ECL characterization

In the case of the luminol–H_2O_2 system, ROSs such as superoxide anion ($O_2^{\bullet -}$) and hydroxyl radical ($OH^{\bullet}$) reacts with luminol to produce excited 3-aminophthalate dianion and then emit lights [33]. According to the literatures [34], the probable mechanism is shown as follows: (LH^- is the deprotonated luminol and Ap^{2-*} is 3-aminophthalate)

$$LH^- - e^- \rightarrow LH^{\bullet} \rightarrow L^{-\bullet} + H^+ \quad (1)$$

$$\text{Glucose} + O_2 \xrightarrow{\text{GOD}} \text{Gluconic acid} + H_2O_2 \quad (2)$$

$$H_2O_2 + L^{-\bullet} \xrightarrow{\text{AuNPs}} Ap^{2-*} + \text{products} \quad (3)$$

$$Ap^{2-*} \rightarrow Ap^{2-} + h\nu \quad (4)$$

The fabrication process of the ECL aptasensor was characterized by ECL in 0.1 mol L^{-1} PBS contain 1.0×10^{-4} mol L^{-1} luminol and 10 mmol L^{-1} glucose solution. As shown in Fig. 3, the bare GCE produced low ECL intensity (curve a). After electrodepositing of AuNPs, a sharp increase of the ECL intensity was observed (curve b). Such improvement reflects that AuNPs can catalyze ECL of luminol. The ECL intensity further improved at AuNPs-EG/GCE

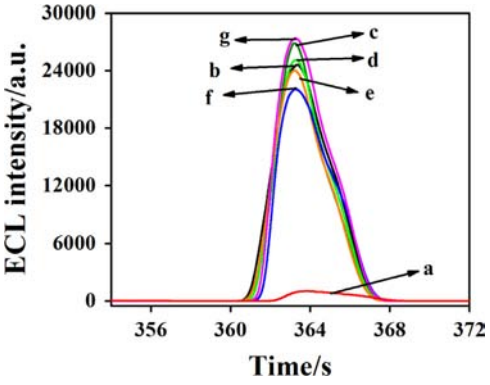

Fig. 3. ECL profiles of the stepwise modification. Bare GCE (a); AuNPs/GCE (b); AuNPs-EG/GCE (c); Apt1/AuNPs-EG/GCE (d); BSA/Apt1/AuNPs-EG/GCE (e); PDGF-BB/BSA/Apt1/AuNPs-EG/GCE (f); GOD–Apt2–AuNPs/PDGF-BB/BSA/Apt1/AuNPs-EG/GCE (g).

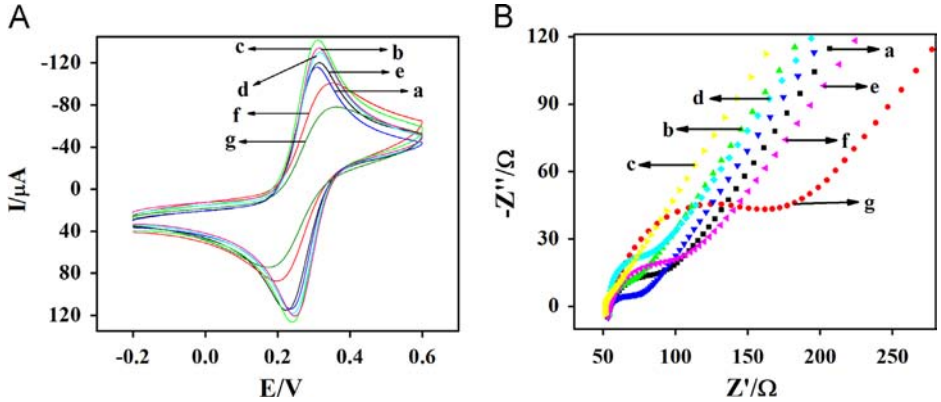

Fig. 2. CVs (A) and EISs (B) of electrodes at different stages in 5.0 mmol L^{-1} $K_3[Fe(CN)_6]/K_4[Fe(CN)_6]$ (1:1) containing 0.1 mol L^{-1} KCL. Bare GCE (a); AuNPs/GCE (b); AuNPs-EG/GCE (c); Apt1/AuNPs-EG/GCE (d); BSA/Apt1/AuNPs-EG/GCE (e); PDGF-BB/BSA/Apt1/AuNPs-EG/GCE (f); GOD–Apt2–AuNPs/PDGF-BB/BSA/Apt1/AuNPs-EG/GCE (g). $c_{PDGF-BB}$: 0.1 nmol L^{-1}.

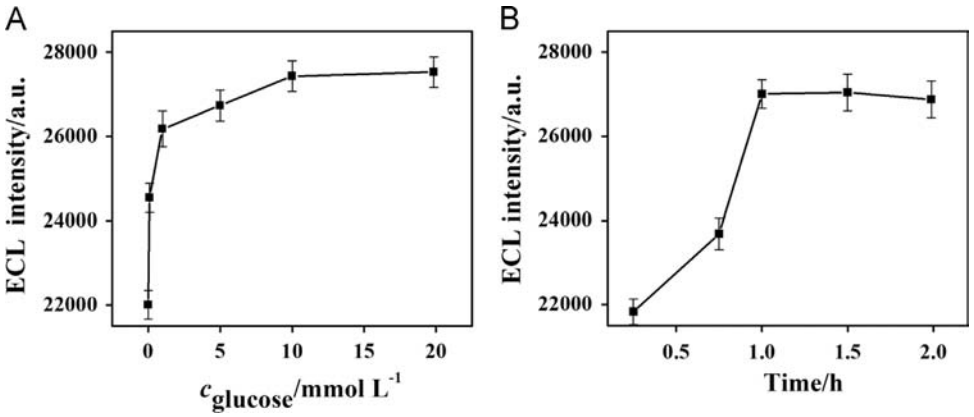

Fig. 4. Effect of the glucose concentration (A) and incubation time (B) on ECL response. Working solution: 0.1 mol L^{-1} pH 7.4 PBS containing 1.0×10^{-4} mol L^{-1} luminol and different concentrations of glucose, scan rate: 100 mV s^{-1}, scan range: −0.2–0.8 V.

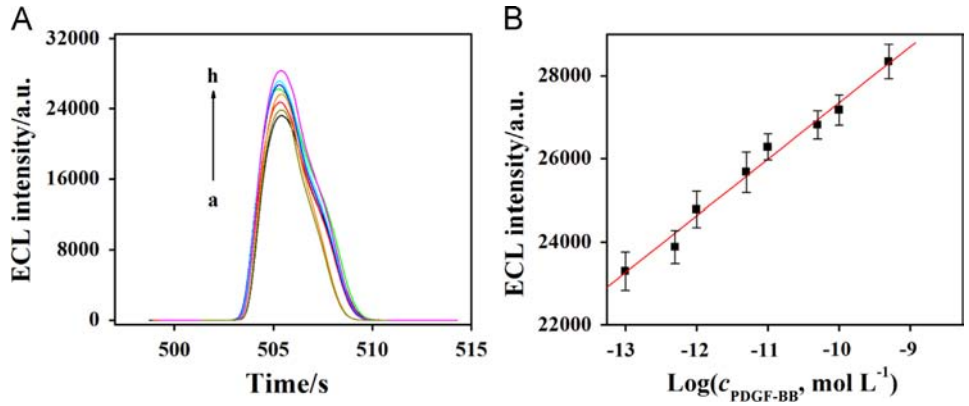

Fig. 5. ECL intensity–time curves of the aptasensor with different concentrations of PDGF-BB (A). The calibration plot against the corresponding log $c_{PDGF-BB}$ (B). Other conditions are as in Fig. 4.

(curve c), which is attributed to the AuNPs-EG nanocomposite films increased the surface area and electrical conductivity and facilitated the reduction of O_2 to generate $O_2^{\bullet -}$ in the solution dissolved with trace oxygen thus increase the ECL intensity. Then the ECL intensity dropped with the immobilization of Apt1 (curve d), blocking with BSA (curve e) and incubating with PDGF-BB (curve f) because of the formation of less conductive layers, which slowed down the electron transfer speed significantly and led to the decrease of ECL signal. However, when the GOD–Apt2–AuNPs bioconjugates were immobilized onto the modified electrode surface, an obvious enhancement of the ECL signal (curve g) appeared. The enhanced signal could be ascribed to the in situ generated H_2O_2 from reaction of GOD with glucose and the excellent catalytic behavior of AuNPs to the ECL emission of the luminol–H_2O_2 system.

3.3. Optimization of experimental conditions

The glucose concentration is an important factor for the ECL intensity. Fig. 4A displays the influence of the glucose concentration. With the increase of the glucose concentration, the ECL signal increased and then reached a plateau in 10 mmol L^{-1}. Hence, 10 mmol L^{-1} was selected. The effect of the incubation time of aptamer with PDGF-BB on the ECL signal was also investigated (Fig. 4B). The ECL emission was found to gradually increase with the increase of time and reach a constant value at 1 h. Therefore, 1 h was chosen.

3.4. Performance of the proposed ECL aptasensor

Fig. 5 depicts ECL signals of the aptasensor in response to PDGF-BB of varying concentrations under the optimal conditions. The calibration plot reveals that the ECL intensity of the aptasensor increases linearly with the logarithm of PDGF-BB concentration in the range of 1.0×10^{-13}–5.0×10^{-10} mol L^{-1}. The linear regression equation is I=40,959.0+1361.1 log$c$ with a correlation coefficient of R=0.9931. The detection limit was calculated to be 1.7×10^{-14} mol L^{-1} (S/N=3). Furthermore, the comparison of the proposed method with previous reports was listed in Table 1. Compared with other methods, the proposed ECL aptasensor exhibits high sensitivity and a wide linear range.

3.5. Specificity, reproducibility, and stability of the ECL aptasensor

Specificity is an important criterion for ECL aptasensor. To investigate the specificity of the aptasensor, some proteins such as human serum albumin (HSA), human immunoglobulin G (hIgG) and thrombin were used as the interferences to evaluate the specificity of the ECL aptasensor. The concentrations of the interfering substances were 0.6 mmol L^{-1}, 50 μmol L^{-1}, and 1.0 nmol L^{-1} respectively and the results are illustrated in Fig. 6A. In the absence of target protein, no apparent change of the ECL intensity was observed compared with that of the testing blank solution. Furthermore, the ECL signals of the mixture samples containing 0.01 nmol L^{-1} PDGF-BB, 0.6 mmol L^{-1} HSA, 50 μmol L^{-1} hIgG, and 1.0 nmol L^{-1} thrombin presented neglectable changes compared with that of the determination of 0.01 nmol L^{-1} PDGF-BB only. These results clearly indicated that the as-constructed sensor had an excellent sensing specificity

and was feasible for the determination of PDGF-BB in complex samples.

The reproducibility of the aptasensor was investigated. The inter-assay precision of the aptasensor was evaluated with the application of five electrodes. The relative standard deviation (RSD) is less than 5.0%. The stability of the ECL aptasensor was also recorded and the results are presented in Fig. 6B. Under consecutive cyclic potential scans for 36 cycles, the RSD for the change of the ECL signal is less than 1.0%, manifesting that the sensor had good stability.

3.6. Analytical application

It has been reported that PDGF might play a very important role in the initiation and progression of DN [1]. Determination of PDGF-BB in human body fluid could be used for early diagnosis of diabetic renal dysfunction. To demonstrate the applicability of the proposed method, the contents of PDGF-BB in human urine and human serum samples collected from DN patients and healthy people at Xinyang Central Hospital (Xinyang, China) were determined and the results are listed in Table 2. The results show that the value of DN in six patients (5.0–6.76 pmol L^{-1} for human serum, 11.5–52.8 pmol L^{-1} for human urine) is much higher than that in six healthy persons (0.14 pmol L^{-1} for human serum, ;0.12–0.43 pmol L^{-1} for human urine). The recovery of the aptasensor was also estimated by standard addition method (Table 3). Three different concentrations of PDGF-BB (1.0, 10, and 100 pmol L^{-1}) were added into human serum and urine samples with recoveries from 89.7–102% for human serum sample and 85.0–110% for human urine sample, respectively.

4. Conclusions

The work reported here develops a novel sandwich-type luminol ECL aptasensor for PDGF-BB detection based on in situ generated H_2O_2 as coreactant with GOD anchored AuNPs labeling. The high sensitivity and wide linear range obtained should be taken into account for the following reasons: (1) the hierarchical assembly of AuNPs-EG composite films and aptamer functionalization on the GCE surface provide not only a highly conductive and biocompatible electrode interface for ECL sensing but also an analog of extracellular matrix for the specific target recognition and adhesion; (2) AuNPs acted as an versatile platform not only to provide biocompatible surface area for the immobilization of abundant GOD and Apt2, but also to catalyze the ECL reaction of the luminol–H_2O_2 system; (3) amplified ECL of luminol response was obtained by in situ production of H_2O_2 with GOD as coreactant and the catalysis of AuNPs. The applicability of the aptasensor was successfully demonstrated in the determination of PDGF-BB in human serum and human urine samples. With high sensitivity, good selectivity and stability, the as-proposed ECL aptasensor provided great potential in biochemical analysis.

Molecular beacon

ABSTRACT

In this work, a fluorescence turn-on method for copper(II) detection is reported. A molecular beacon (MB) was designed as a template. Cu^{2+} was reduced to Cu^{+} in the presence of a reductant (ascorbic acid). Two short single-stranded oligonucleotides one was labeled with a 5′-alkyne and the other with 3′-azide group, proceeded a template-dependent chemical ligation through the Cu(I)-catalyzed azide-alkyne cycloaddition. The newly generated click-ligated long chain oligonucleotide, which was complementary to the MB, opened the MB hairpin structure and resulted in a turn on fluorescence. The increase in fluorescence intensity is directly proportional to the amount of Cu^{2+} added to the assay solution. The present assay is quite sensitive and allows the detection of 2 nM Cu^{2+}. The described assay also exhibits high selectivity over other metal ions.

1. Introduction

Copper is one of the most abundant transition metals in the human body and is essential for human health [1]. Copper plays important biological roles as enzyme cofactors and as structural components of proteins [1–3]. The lack of copper in the human body may cause copper deficiency diseases, such as coeliac disease and anaemia [4]. However, high concentration of copper is also harmful to the human body, which may cause gastrointestinal disturbance [5], liver or kidney damage [6,7], and various neurological diseases, such as Alzheimer's disease and Parkinson's disease [8,9]. In recent years, continuous release of copper(II) into environmental water has been witnessed due to its extensive use in industry [5]. Therefore, selective and sensitive detection of copper(II) is of great importance.

Great efforts have been made for the development of techniques for selective copper(II) sensing. They include absorption spectrometry [10], atomic absorption spectrometry [11], inductively coupled plasma atomic emission spectroscopy [12], inductively coupled plasma mass spectrometry [13], and various electrochemical [14,15], colorimetric [16–19], and fluorescent methods [20–23]. Fluorescent methods have attracted more and more attentions because of their high sensitivity, simple operation, good reproducibility, and low-cost. Although a number of fluorescent sensors for copper(II) detection have been reported, simple, sensitive and selective methods without the use of harmful substances are still highly demanded.

The Cu(I)-catalyzed azide-alkyne cycloaddition (CuAAC) reaction reported by Sharpless [24] has emerged as one of the most prominent click chemistry reactions. And it has been used as a versatile, highly efficient and selective chemical tool in many fields [25,26]. It also possesses characters of high-speed and simplicity under mild conditions which earned its name "click reaction" [27]. A trace amount of Cu(I) could catalyze the Huisgen 1,3-dipolar cycloaddition reaction between an alkyne and an azide to form a 1,2,3-triazole [25], and the overall percentage of conversion is related to the amount of Cu(I) added to the reaction mixture. Based on the reduction reaction of Cu(II) to Cu(I) in the presence of a reductant, a number of methods for copper(II) sensing were proposed [28–34]. Recently, a few copper(II) sensors based on template-dependent oligonucleotide ligation were developed [35–39]. It has been shown that the CuAAC driven click reaction enables the ligation of oligonucleotides without any biological enzymes and it shows good biocompatibility [40–44]. However, these methods require the use of additional signaling unit, such as gold nanoparticles, graphene or organic dye, thus the reaction could not be monitored in a real-time fashion, and some used fluorescent turn-off sensing strategy which may increase the possibility of false positive signals [36–39].

Molecular beacon (MB) was originally designed for the sensing of oligonucleotides, nucleic acid point mutations, RNA targets in vivo, and for monitoring PCR reactions in real time [45].

The method shows high sensitivity and selectivity. Since its first report, MB has also been used for the development of a number of novel fluorescence turn-on assays for the sensing of nucleic acid binding protein, gene expression in living cells, enzyme activity, and many aptamer targeted proteins and small biomolecules, etc [46–51].

Herein, we describe a novel fluorescence turn-on strategy for copper(II) detection based on the template-dependent click ligation (Scheme 1). In the present method, a rationally designed MB (Oligo-MB) was adopted as a template. Two short oligonucleotides (Oligo-A and Oligo-B) labeled with a 5′-alkyne and a 3′-azide groups, respectively, were used. Oligo-A and Oligo-B could hybridize to the complementary sequences of the Oligo-MB, which brought the azide and the alkyne functional groups closer to each other. In the presence of Cu^{2+} and ascorbic acid, Cu^{2+} was reduced to Cu^{+}, and the two short oligonucleotides were ligated by the formation of a triazole linkage. The Cu(I) catalyzed click reaction between the azide and the alkyne functional groups resulted in the connection of Oligo-A and Oligo-B. The newly formed long chain oligonucleotide (Oligo-A-B) opened the Oligo-MB hairpin structure and turn on fluorescence was therefore observed. The increase in intensity could be directly related to the amount of Cu(II) added to the assay solution. Our Cu^{2+} detection method is sensitive, selective, simple, and inexpensive.

2. Experimental section

2.1. Materials

The oligonucleotides (Oligo-A, Oligo-B and Oligo-MB) and L-ascorbic acid were obtained from Sangon Biotechnology Co., Ltd. (Shanghai, China). Cupric sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$) were purchased from Sinopharm Chemical Reagent Co., Ltd. (Beijing, China). All other chemicals were of analytical reagent grade and used without further purification. The ultra pure water used in all experiments was obtained with a Milli-Q system (Millipore, MA, USA).

2.2. Instrumentation

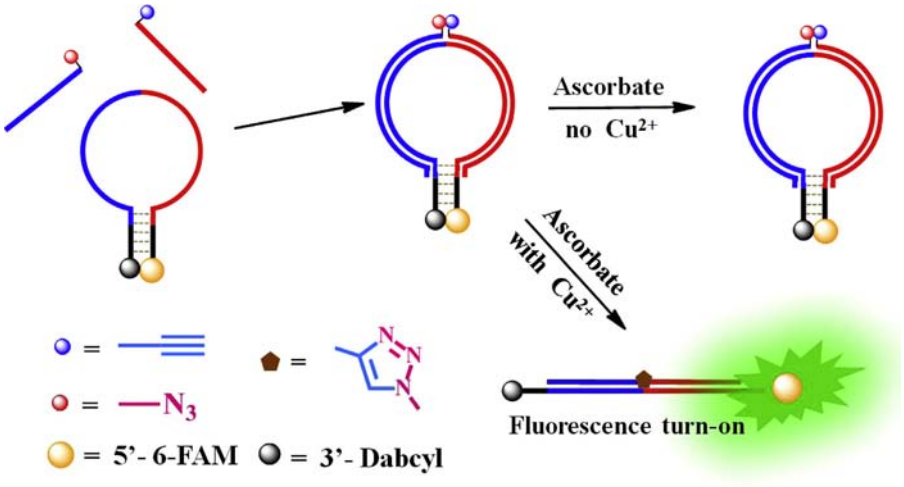
Fluorescence measurements were performed using a Fluoromax-4 spectrofluorometer (Horiba Jobin Yvon Inc., USA). Sample solutions were excited at 480 nm and the fluorescence emission spectra were recorded with slits for excitation and emission both of 5 nm. The quantification of nucleic acids was carried out via UV–vis absorption recorded on a Cary 50 Bio Spectrophotometer (Varian Inc., CA, USA). A PB-10 pH meter (Sartorius Scientific Instrument Co., Ltd. Beijing) was used to adjust the pH value of all buffer solutions.

2.3. Assay procedures

Oligonucleotide stock solutions were prepared with Tris–HCl buffer (20 mM, pH 7.4) and stored at 4 °C. Prior to the addition of different concentrations of Cu^{2+} at room temperature, the oligonucleotides and ascorbic acid were mixed and stored at 4 °C for 10 min. The assay solutions were incubated at 25 °C for an appropriate period of time before the fluorescence measurement. The final concentrations of Oligo-A, Oligo-B and Oligo-MB were 30 nM, 30 nM and 10 nM, respectively.

2.4. Lake water sample analysis

Lake water samples were acquired from the South Lake of Changchun, Jilin province, China. The samples were first centrifuged at 12,000 rpm for 10 min and filtered through a nitrocellulose filter (0.45 μm) to get rid of the insoluble materials. 100 μL lake water sample was added into the assay solution for the quantitative analysis (final sample volume: 400 μL). Known quantities of Cu^{2+} were added to the assay solutions and their recoveries were determined. The experiments were repeated three times and the average recovery values were obtained.



3. Results and discussion

3.1. The assay strategy

The sequences of the oligonucleotides for Cu^{2+} detection were carefully selected (Table 1). Oligo-MB with a fluorophore and a quencher at its termini was selected as a template. It was designed to be a stable hairpin structure at an ambient temperature. When Oligo-MB was in its hairpin state, the fluorophore and the quencher interacted with each other and the fluorescence of the

Scheme 1. Schematic representation of the copper(II) sensing strategy.

fluorophore was quenched [45]. Oligo-A and Oligo-B (each of 11 nt long) were complementary to Oligo-MB and could bind to Oligo-MB. Since they were relatively short oligonucleotides, their binding could not open the MB hairpin structure. However, their binding allowed to bring azide and alkyne groups labeled on Oligo-A and Oligo-B, respectively, more closer to each other, which effectively increased the local molarity of the reaction groups. The close proximity of Oligo-A and Oilgo-B and subsequently increase in local molarity enhanced the rate of click reaction. The newly formed longer Oligo-A-B through efficient click reaction could easily open the Oligo-MB hairpin structure and a turn on fluorescence was observed.

3.2. Feasibility of the assay

The melting temperature of Oligo-A and Oligo-B was approximately 23–24 °C. Oligo-MB has a melting temperature of 43 °C (Fig. 1). When the oligonucleotides were mixed and incubated for 120 min, the fluorescence intensity of the assay mixture did not increase. The results suggest that Oligo-A and Oligo-B could not open the Oligo-MB hairpin structure. However, when 50 nM Cu^{2+} was introduced, Cu^{2+} was reduced to Cu^{+}. Click reaction-assisted formation of Oligo-A-B stimulated the unfolding of Oligo-MB and subsequent gradual increase in the fluorescence intensity was observed with the prolonged reaction time, and the fluorescence intensity reached a plateau after about 120 min of reaction (Fig. 2). The results clearly demonstrate that our strategy for Cu^{2+} sensing is valid.

3.3. Optimization of assay conditions

To achieve the best sensing performance, important experimental conditions were optimized. In order to investigate the temperature effect on assay solution, we used various temperatures to probe the sensing performance as shown in Fig. 3. There was a rapid increase in the emission intensity as the solution temperature raised from 10 °C to 25 °C. It seems that the ligation efficiency increased at a higher temperature. However, if the assay temperature was higher than 30 °C, considerable amounts of Oligo-A and Oligo-B would dissociate from Oligo-MB which resulted in decreased ligation efficiency. Therefore, 25 °C was chosen as the reaction temperature in the following experiments. The concentration of ascorbic acid added to the assay solution was also optimized. We have experimented various concentrations of ascorbic acid as shown in Fig. 4. It was found that 500 μM ascorbic acid gave the best sensing performance. The assay buffer pH was selected at 7.4 since it was reported that at acidic pH values, the Cu^{+} catalytic activity may be reduced because of the disproportion reaction [36,39].

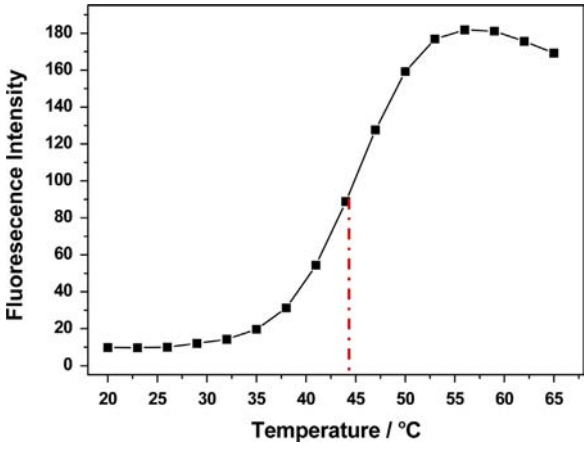

Fig. 1. Melting temperature determination of Oligo-MB in 20 mM Tris–HCl (pH 7.4). The solution was equilibrated for 5 min prior to the fluorescence measurement. Data points were taken at 3 °C intervals. Fluorescence intensity changes were recorded at 514 nm.

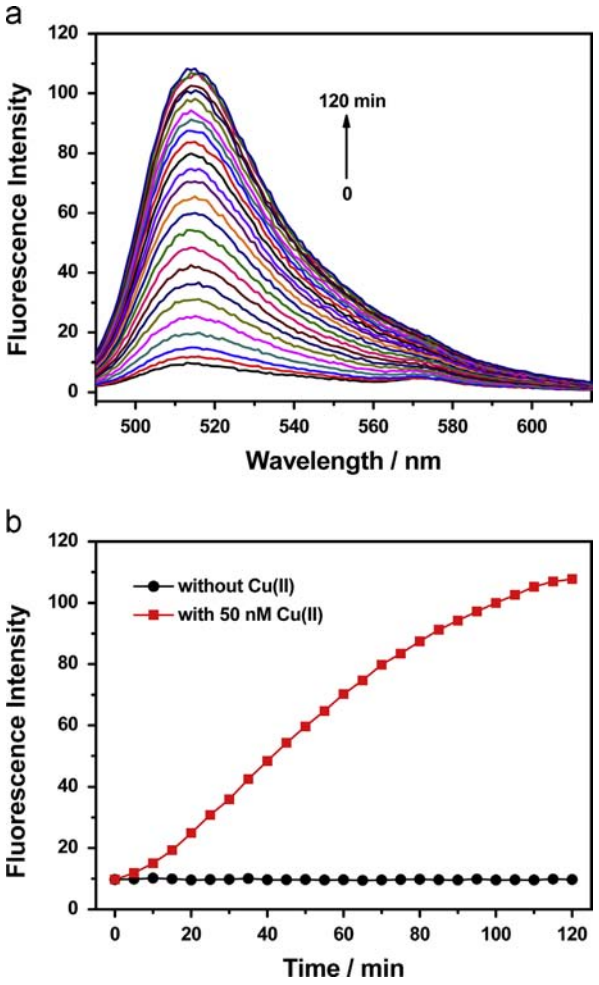

Fig. 2. (a) Oligo-MB emission spectral changes with reaction time; (b) changes in fluorescence intensity with reaction time with (red) and without (black) the addition of Cu^{2+}. The concentrations of ascorbic acid and Cu^{2+} were 500 μM and 50 nM, respectively. Buffer: 20 mM Tris–HCl (pH 7.4). The emission intensity was recorded at 514 nm at 25 °C. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

3.4. Sensitivity of the assay

Under the optimized conditions, we tested the sensitivity of the assay by adding different concentrations of Cu^{2+}. Fig. 5 shows gradual increase in the fluorescence intensity with the increasing concentration of Cu^{2+} from 0 nM to 50 nM, and the fluorescence intensity reached a plateau at about 50 nM Cu^{2+}. The linear detection range is 2–40 nM, and the linear calibration curve is: $I=2.73C+9.77$ (I and C refer to the fluorescence intensity and the concentration of Cu^{2+} in nM, respectively). The method is highly sensitive, 2 nM Cu^{2+} could be easily detected [16–23,35–39], which is much lower than the maximum allowed level of Cu^{2+} (20 μM, 1.3 ppm) in drinking water defined by the United States Environmental Protection Agency.

3.5. Selectivity of the assay

To evaluate the selectivity of the assay, other common metal ions including Ba^{2+}, Mg^{2+}, Ni^{2+}, Co^{2+}, Fe^{2+}, Cd^{2+}, Ca^{2+}, Zn^{2+},

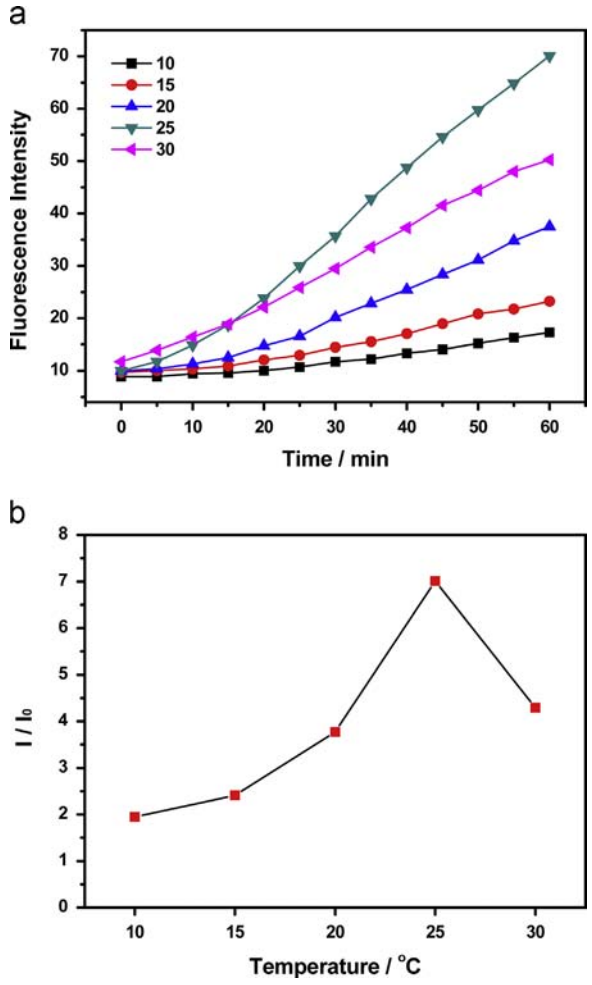

Fig. 3. (a) Fluorescence intensity changes with reaction time at different reaction temperatures. (b) Enhancement of fluorescence intensity after 60 min of reaction at different temperatures. The concentrations of ascorbic acid and Cu^{2+} were 500 μM and 50 nM, respectively. Buffer: 20 mM Tris–HCl (pH 7.4). Emission intensity was recorded at 514 nm.

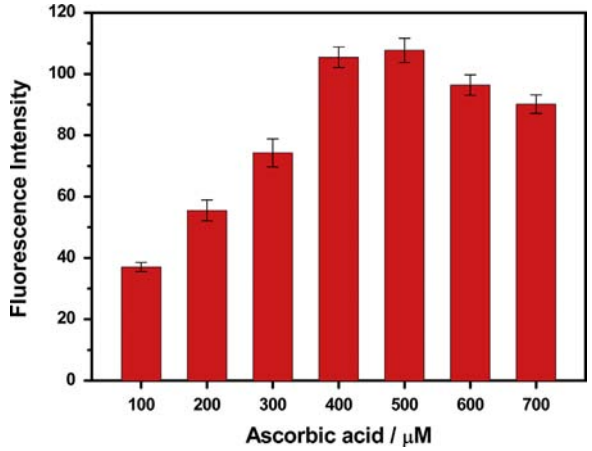

Fig. 4. Effect of the concentration of ascorbic acid on the performance of the assay. All the solutions were incubated with 50 nM Cu^{2+} at 25 °C for 120 min in 20 mM Tris–HCl (pH 7.4). The experiments were repeated three times and the average intensity values were given.

Mn^{2+}, Hg^{2+}, Pb^{2+}, Li^{+}, Na^{+}, K^{+}, and Ag^{+} were tested. As shown in Fig. 6, the results indicate that the proposed method is highly selective for Cu^{2+}. None of these metal ions interfered with the assay, even at much higher concentrations (50 μM).

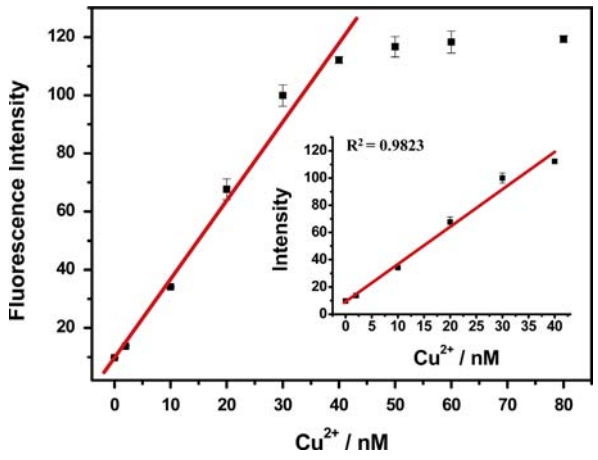

Fig. 5. Changes in emission intensity with Cu^{2+} concentration (0, 2 nM, 10 nM, 20 nM, 30 nM, 40 nM, 50 nM, 60 nM, 80 nM). The solutions were incubated at 25 °C for 120 min in 20 mM Tris–HCl (pH 7.4). The concentration of ascorbic acid was 500 μM. The experiments were repeated three times and the average intensity values were given.

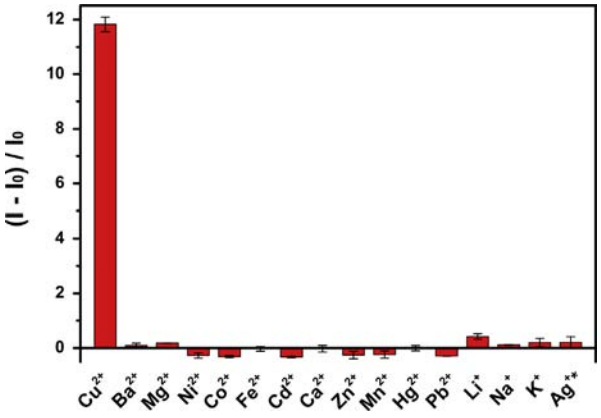

Fig. 6. Selectivity of the assay. The concentration of Cu^{2+} was 50 nM and the concentrations of the other metal ions (Ba^{2+}, Mg^{2+}, Ni^{2+}, Co^{2+}, Fe^{2+}, Cd^{2+}, Ca^{2+}, Zn^{2+}, Mn^{2+}, Hg^{2+}, Pb^{2+}, Li^{+}, Na^{+}, K^{+}, Ag^{+}) were 50 μM each. The experiments were repeated three times and the average intensity values were given. *Ag^{+} formed precipitate with Cl^{-} which was removed by centrifugation prior to analysis. If the precipitate was not removed, it caused slight interference with the assay.

Table 2
Copper(II) recovery in lake water samples.

Samples	Added (nM)	Found (nM)	Recovery (%)	RSD[a] (%, $n=3$)
1	20.0	20.6 ± 0.6	103.0	2.9
2	40.0	39.5 ± 0.9	98.8	2.3

[a] RSD: relative standard deviation.

3.6. Cu^{2+} assay in environmental water samples

To demonstrate the potential practical application of the assay for real sample analysis, lake water samples were tested. The water samples were acquired from the South Lake of Changchun (Jilin province). The samples were first centrifuged at 12,000 rpm for 10 min and filtered through a nitrocellulose filter (0.45 μm) to get rid of the insoluble materials. Recovery experiments were carried out. Different concentrations of Cu^{2+} (20 nM, 40 nM) were added to the assay solutions, and satisfactory recovery values were obtained. The results clearly show that our method could be used for the detection of Cu^{2+} in complex sample mixtures (Table 2).

4. Conclusions

In conclusion, a copper(II) ion sensing method with high selectivity and sensitivity has been developed. The concentration of Cu^{2+} in an aqueous buffer solution could be determined by the molecular beacon fluorescence recovery assay. 2 nM Cu^{2+} could be easily detected, and a linear response range of 2–40 nM Cu^{2+} was obtained. The fluorescent turn-on Cu^{2+} sensing strategy would reduce the possibility of false positive caused by the turn-off mode. And it could also be used for the analysis of environmental water samples. The method is simple, sensitive and selective, and it could potentially be used for the analysis of real biological samples because of the good biocompatibility and low toxicity.

ABSTRACT

A fully automated online solid-phase extraction (SPE) with directly coupled liquid chromatography–tandem mass spectrometry (LC–MS/MS) method for analysis of 34 trace organic compounds in diverse water matrices has been developed. The current method offers several advantages over traditional offline SPE methods including low sample volume (1.7 mL), decreased solvent use, higher throughput, and increased reproducibility. The method uses simultaneous positive and negative ESI for analysis of all compounds in one injection, which reduces cycle time (extraction+analysis) to <15 min. Method optimization included testing different online SPE cartridges, mobile phase compositions, and flow rates. The method detection limits (MDLs) ranged from 0.1 to 13.1 ng/L with 80% of the compounds having an MDL <5 ng/L. Matrix spike recoveries in three different water qualities were evaluated and ranged from 61.2% to145.1% with 95% of the recoveries ranging between 70–130%. As part of the method validation studies, linearity (0.9911–0.9998), intra-day variability (1.0–10.4%), inter-day variability (1.0–11.9%), and matrix effects were also assessed. The use of 26 isotopically-labeled standards increased the reliability of the method while retention time locking and use of two transitions for most compounds increased the specificity. The applicability of the method was tested on samples across treatment points from two wastewater plants, a septic tank, surface water and groundwater.

1. Introduction

The extensive utilization of organic compounds in modern society combined with increasing demands for water resources have resulted in widespread contamination of water resources. Many of these compounds have anthropogenic sources and are being produced in greater quantities than ever before around the globe [1,2]. These compounds including pharmaceuticals, personal-care products, pesticides, hormones and industrial contaminants, and are collectively termed as trace organic compounds (TOrCs). Several studies have shown that conventional water treatment processes generally are not effective in removal of TOrCs thus leading to their release into the environment with potential for contamination of drinking water sources [3,4]. While the adverse effects associated with exposure to individual compounds from drinking water is not expected to pose significant risk to public health [5], the long term exposure to mixtures of TOrCs and potential for synergistic effects is largely unknown [6–8]. Due to the vast number of TOrCs detected in water, regulatory actions to determine acceptable levels of all detected TOrCs is not feasible despite studies documenting adverse effects to the environment and wildlife [9–11]. Thus, it is prudent to monitor indicator TOrCs in water while sufficient toxicological data can be collected and studies on any potential mixture effects performed.

Currently, methods utilizing liquid chromatography–tandem mass spectrometry (LC–MS/MS) are considered the gold standard for sensitive analysis of multiple TOrCs in water [12–14]. However, to achieve requisite detection limits of low ng/L for many TOrCs, time consuming sample preparation steps are often required before LC–MS/MS analysis. The sample preparation step generally involves extraction and concentration of the target analytes with commensurate elimination of many interferences in the original matrix. Traditional off-line solid-phase extraction (SPE) and liquid–liquid extraction (LLE) are the most commonly used concentration and clean-up steps for analysis of TOrCs in environmental matrices [12,15,16]. These two techniques require a relatively large sample volume, are extremely time consuming, laborious, and require considerable amounts of organic solvents to perform. Further, these methods can potentially decrease the reproducibility and accuracy of analysis due to multiple sample manipulations that are required [17]. Considering the high degree of temporal [18] and geographical [19] variability, high-throughput time-sensitive analytical screening

methods would greatly advance the resolution of environmental monitoring. Also, considering the variability of methods currently used for TOrC analyses [20], the reproducibility and accuracy of the data must be enhanced by introducing automation into the entire analytical procedure.

The online SPE process offers several advantages over the offline techniques including reduction in sample preparation and thus increase in productivity [21]. Further, online SPE minimizes operator contact which reduces the possibility of contamination while also eliminating a solvent evaporation step that can result in loss of target analytes [22]. The introduction of the entire mass of analyte to the detector allows injection of much lower sample volumes while increasing the sensitivity of analysis [23]. Automation of the entire process (extraction+analysis) also improves the reproducibility of the method. In addition, online SPE cartridges can be reused as they are amenable to backwashing and have been shown to perform well even after treating several hundred water samples [24].

Over the last few years, several manufacturers have developed fully automated online SPE systems coupled to LC–MS/MS which has allowed for integration of sample clean-up, extraction and analysis. Consequently the use of online SPE methods in bioanalytical [25,26] and environmental [21,27] applications has increased. However, most of these methods have focused on analysis of specific classes of TOrC such as pharmaceuticals [28–30], hormones [24,31] or pesticides [32] only. Other methods still require multiple injections for analysis of all analytes [33], large sample volumes [34], require derivitization [35], or are not completely automated which may reduce the reproducibility and/or increase time of analysis.

The focus of this study was to develop a single method for rapid analysis of 34 indicator compounds comprising several classes of TOrCs in different water matrices with a fully automated online SPE coupled to LC–MS/MS. The objectives were to (i) use low sample volume (<2 mL), (ii) employ minimal sample preparation and automate the extraction step to reduce variability, (iii) perform simultaneous analysis of TOrCs both in electrospray (ESI) positive and negative mode with one injection, (iv) rapid cycle (extraction+analysis) time (<20 min) for high throughput analysis of samples, (v) achieve desired sensitivity of low ng/L detection limits for all analytes, and (vi) provide 'cleaner' and 'greener' methods for analysis of TOrCs in aqueous matrices compared to conventionally used offline pre-concentration techniques.

2. Experimental

2.1. Chemicals and reagents

All analytical standards used during the study were at least $>97\%$ purity and every effort was made to use standards of the highest purity commercially available. All native standards were purchased from Sigma-Aldrich (St. Louis, MO) except DEET and triclosan from Alfa Aesar (Ward Hill, MA) and meprobamate from Cerilliant (Round Rock, TX). Labeled surrogate standards were purchased from Cambridge Isotope Laboratories (Andover, MA) except $^{13}C_2$-PFHxA, $^{13}C_4$-PFOA and $^{13}C_4$-PFOS from Wellington Laboratories (Ontario, Canada); primidone-d_5, meprobamate-d_3, triclocarban-$^{13}C_6$ and $^{13}C_6$-diclofenac from Toronto Research Chemicals (Ontario, Canada); and gemfibrozil-d_6, benzophenone-d_{10}, benzotriazole-d_4, and diphenhydramine-d_5 from C/D/N Isotopes (Quebec, Canada). All solvents used were of purity suitable for LC–MS analysis. Methanol, isopropyl alcohol (IPA), and acetic acid were obtained from Fisher Scientific (Pittsburgh, PA), while acetonitrile (ACN) and HPLC grade water were purchased from Burdick and Jackson (Muskegon, MI). Detailed information about all target analytes and isotopes used in this study are shown in Table 1.

2.2. Selection of target list

The selection of TOrCs analyzed in this study was based on data presented in previous literature that rely on occurrence data, detection frequency, toxicological relevance, availability of robust analytical methods and ability to pose as 'indicators' of water quality [36–38]. Additionally, emerging classes of TOrCs like perfluorinated compounds and glucocorticoid steroids were also represented in our target list to show that the method can be used for their detection. The aim was to select a diverse list of compounds in terms of physical, chemical properties while representing traditionally monitored and frequently detected TOrCs along with newer classes of interest.

2.3. Sample collection and preparation

During this study, grab samples were collected from two wastewater treatment plants, a surface water, groundwater, and septic tank from various locations across the USA. All samples were collected in 20 mL amber glass vials dosed with 1 g/L of sodium azide as a preservative and stored in ice before transport to the laboratory. The samples were stored in a refrigerator at 4 °C on arrival at the lab. Five-ml of sample was then aliquoted into a 6-ml glass vial before being spiked with a mixture of all isotopically-labeled surrogates to achieve a final concentration of 100–200 ng/L in the sample depending on the type of analyte and sample matrix. All samples were doped with the surrogate standards within 72 h of collection to account for losses due to storage and degradation of analytes. The samples were then filtered using a 0.2 μm Captiva polyethylene styrene (PES) filter from Agilent Technologies (Santa Clara, CA) prior to analysis. All samples were analyzed within two weeks of collection.

2.4. Online SPE configuration

Automated pre-concentration of all samples was performed using an Agilent flexible cube (FlexCube) module coupled to a large volume autosampler (900 μL) with a programmable multi-draw capacity. In this method, 1.7 mL of sample was injected into the sample loop using two 850 μL autosampler injections. A schematic of the different valve positions on the online SPE system is shown in Supplementary materials (Fig. S1). The FlexCube online SPE unit consists of a built in single piston pump with four solvent lines and a 10-port switching valve that houses two online SPE cartridges for simultaneous loading of one cartridge while the other is being eluted or backwashed. Initially, the switching valve on the FlexCube was set to the LOAD position (position 1) during which the sample was loaded onto the SPE cartridge with 95/5 (v/v) water/ACN mixture containing 0.1% acetic acid (line A) from the FlexCube pump. During this time, the aqueous waste and matrix not retained on the SPE cartridge was allowed to go to waste. After loading was complete, the valve switched to the ELUTE position which resulted in the binary pump back-flushing SPE cartridge 1 to allow a gradient elution of the target analytes onto the analytical column. At the same time, SPE cartridge 2 was being cleaned with a strong solvent mix of 1:1:1 (v/v/v) isopropyl alcohol, methanol and ACN (line B) by the FlexCube pump to remove any retained target analytes or matrix from causing blank contamination and interferences in subsequent runs. A few minutes before the end of the run, the solvent channel on the FlexCube pump was switched back to its original line (line A) to allow SPE cartridge 2 to equilibrate and prepare it for the next sample.

Table 1
Class and use of TOrCs selected in this study with isotopes used for quantification.

Compound	Use	Category	Isotope[a]
Atenolol	β-Blocker	Pharmaceutical	Atenolol-d_7
Carbamazepine	Anti-seizure	Pharmaceutical	Carbamazepine-d_{10}
Clofibric acid	Lipid regulator metabolite	Pharmaceutical	Bisphenol A-$^{13}C_{12}$
Diclofenac	Anti-arthritic	Pharmaceutical	Diclofenac-$^{13}C_6$
Diphenhydramine	Antiarrhythmic	Pharmaceutical	Diphenylhydramine-d_5
Diltiazem	Anti-histamine	Pharmaceutical	Diltiazem-d_3
Fluoxetine	Anti-depressant	Pharmaceutical	Fluoxetine-d_5
Gemfibrozil	Anti-cholesterol	Pharmaceutical	Gemfibrozil-d_6
Hydrochlorothiazide	Antihypertensive	Pharmaceutical	Benzotriazole-d_4
Ibuprofen	Analgesic	Pharmaceutical	Ibuprofen-d_3
Meprobamate	Anti-anxiety	Pharmaceutical	Meprobamate-d_7
Naproxen	Analgesic	Pharmaceutical	Naproxen-$^{13}C_1d_3$
Primidone	Anticonvulsant	Pharmaceutical	Primidone-d_5
Propranolol	β-Blocker	Pharmaceutical	Atenolol-d_7
Sulfamethoxazole	Antibiotic	Pharmaceutical	Sulfamethoxazole-d_6
Trimethoprim	Antibiotic	Pharmaceutical	Trimethoprim-d_3
Benzophenone	UV blocker	Personal care product	Benzophenone-d_{10}
Caffeine	Stimulant	Personal care product	Caffeine-$^{13}C_3$
N,N-Diethyl-m-toluamide (DEET)	Insect repellant	Personal care product	DEET-d_6
Propylparaben	Preservative in cosmetics	Personal care product	Propylparaben-d_4
Tris (2-chloroethyl) phosphate (TCEP)	Flame retardant	Personal care product	TCEP-d_{12}
Tris (2-chloropropyl) phosphate (TCPP)	Flame retardant	Personal care product	TCEP-d_{12}
Triclocarban	Antibiotic	Personal care product	Triclocarban-$^{13}C_6$
Triclosan	Anti-microbial	Personal care product	Triclosan-$^{13}C_{12}$
Benzotriazole	Corrosion inhibitor	Industrial compound	Benzotriazole-d_4
Bisphenol A	Plasticizer	Industrial compound	Bisphenol A-$^{13}C_{12}$

Perfluoro octane sulfonate (PFOS)	Fluorosurfactant	Industrial compound	PFOS-$^{13}C_4$
Hydrocortisone	Anti-inflammatory glucocorticoid	Hormone	Carbamazepine-d_{10}
Norgestrel	Hormonal contraceptive	Hormone	Primidone-d_5
Testosterone	Androgen	Hormone	Carbamazepine-d_{10}
Atrazine	Herbicide	Pesticide	Atrazine-d_3
Simazine	Herbicide	Pesticide	Atrazine-d_3

[a] Used for quantification.

2.5. Liquid chromatography

An Agilent 1290 UHPLC binary pump was used to perform liquid chromatography for all analyses. Polypropylene solvent lines with metal frits were used to minimize potential system contamination of perfluorinated materials. An Agilent Poroshell 120 EC C-18 (2.1 mm × 50 mm, 2.7 μm) column was used for chromatographic separation of all analytes. The column was maintained at 30 °C throughout the run. A dual eluent mobile phase comprising of water with 0.1% acetic acid (A) and ACN with 0.1% acetic acid (B) at 350 μL/min was used for separation. For the first 4 min, the gradient was held at 5% B while the sample was loaded onto the online SPE cartridge and the binary pump was conditioning cartridge 2. At 4 min, the switching valve turned to the ELUTE position (position 2) and solvent B was linearly increased to 100% at 11 min. This gradient was held till 12 min before returning to the initial condition at 12.5 min. A post-time of 2 min was added to allow the column to re-equilibrate before the next analysis. This resulted in a total cycle time (extraction + analysis) of 14.5 min per sample.

2.6. Mass spectrometry

Mass spectrometry was performed on an Agilent 6460 triple quadrupole mass spectrometer. The optimization of the mass spectrometer was divided into two: (i) compound-specific optimization and (ii) source-dependent optimization. Details of the optimization process have been published previously [14]. The optimized compound parameters and retention times (RT) are shown in Supplementary material (Table S1) while source-dependent parameters for both ESI positive and negative modes (run simultaneously) are shown in Table S2.

The mass spectrometer was run in dynamic multiple reaction monitoring (DMRM) mode with a delta RT of 0.7 min for each compound. Fast polarity switching with the dielectric capillary allowed for simultaneous analysis in ESI positive and negative in the same run. Two transitions: a quantifier (most-abundant product) and qualifier were used for most of the compounds to increase specificity of the method. Data acquisition and analysis was performed using Agilent MassHunter software (version Rev B.06.00). Isotope dilution was used for quantification of all analytes [39]. In cases where the identical isotopic standard was not available, a closely-related isotope was used as a replacement (Table 1). RT locking and product ion ratio monitoring reduced the possibility of false positives in the method.

3. Results and discussion

3.1. Solid phase extraction cartridge selection

The selection of the online SPE cartridge is critical to the success of the entire analysis. Presently, the availability of different online SPE cartridges is significantly lower than conventional offline cartridges. Three online SPE cartridges from Agilent and an experimental cartridge packed in the lab were tested for their suitability to extract the target analytes from aqueous samples. PLRP-s (styrene-polydivinylbenzene, 2.1 mm × 12.5 mm, 15–20 μm), ZORBAX SB-AQ (reversed-phase alkyl group bonded to high-purity porous silica microsphere, 2.1 mm × 12.5 mm, 5 μm), ZORBAX Phenyl-hexyl (dimethylphenylhexylsilane, 2.1 mm × 12.5 mm, 5 μm) from Agilent and Carbon-X (experimental phase with activated charcoal, 2.1 mm × 12.5 mm 5 μm) were evaluated. To

assess which of these cartridges was most appropriate for extraction of target analytes, the absolute recoveries were calculated by comparing the peak areas obtained in online SPE mode and direct injection mode with the same amount of analyte in ultrapure water in five replicate injections. Fig. 1 shows the range of absolute recoveries obtained for the 32 target analytes tested with each cartridge (propranolol and hydrochlorothiazide were not tested). An absolute recovery between 70–130% was considered as acceptable and used as the criteria for cartridge selection. The PLRP-s cartridge had 26 analytes in this range and good reproducibility (RSD < 10%) for all but three analytes (bisphenol A, propylparaben and TCEP) so was the most suitable choice. The SB-AQ cartridge performed similarly but had slightly less reproducibility while extraction efficiency of some compounds with –NH group was lower than the PLRP-s. The Carbon-X cartridge had poor extraction recoveries (< 50%) for several of the analytes and it was later discovered that many of the target analytes were very strongly bound onto the cartridge and not entirely eluted. This was confirmed by passing 100% ACN through the Carbon-X cartridge at the end of the five replicates and monitoring the spectrum. Further, several analytes (like meprobamate, atrazine and carbamazepine) had very high extraction recoveries (> 150%) and large %RSDs probably due to carryover from one injection to the next for the Carbon-X. It should be noted that low absolute recoveries for some compounds are automatically corrected as both the calibration standards and samples are processed in exactly the same manner and go through the entire analytical process (extraction + analysis) in an automated online SPE setup. However, it is always desirable to get the maximum recoveries for best sensitivity but with a highly diverse analyte list trade-offs are inevitable. With this in mind, the PLRP-s cartridge was selected for all further analyses. The complete dataset of absolute recoveries for all four online SPE cartridges is provided in the supplementary material (Table S3).

3.2. Washing mobile phase composition and volume

The presence of organic substances in the matrix can cause severe matrix suppression especially in complex water matrices such as wastewater [40]. Hence a wash step is often needed after the sample has been loaded onto the online SPE cartridge. The wash mobile phase composition in the FlexCube pump was tested at three different ACN concentrations (0%, 5% and 10%) in water with 0.1% acetic acid. An aqueous mobile phase of 5% ACN with 0.1% acetic acid was finally used as it provided the best recoveries with high reproducibility. The 10% ACN mobile phase resulted in significant loss of the early-eluting polar compounds while the 0% ACN phase had lower recoveries for the apolar compounds. Similarly, the wash volume is another important parameter for optimization as too small a volume may not eliminate the interferences in the matrix while too large a volume can cause the target analytes to be washed off the cartridge. Six different wash volumes (2, 2.5, 3, 3.5, 4, and 5 mL) were tested with the loading flowrate maintained at 1 mL/min. Fig. 2 provides the range of absolute recoveries of all target analytes with the different wash volumes. It was found that a 4 mL wash volume provided best recoveries for most of the target analytes. The 2 mL load volume had poor recoveries for all compounds tested possibly due to the fact that there was not enough washing time to elute the target analytes off the cartridge. The 5 mL load volume had very low recoveries for the polar compounds that were likely washed out of the cartridge into waste before the switching valve sent the sample onto the analytical column. The supplementary material (Table S4) contains information of specific recoveries of each analyte with all six loading volumes.

3.3. Loading flowrate

In online SPE analysis, the autosampler injects the sample into the large-volume loop which is then carried onto the cartridge by the loading mobile phase solvent from the FlexCube pump. A high flowrate may result in less adsorption of target analytes onto the cartridge while a slow flowrate increases time of analysis and also provides competing matrix elements time to attach onto the cartridge. In this study, three different loading flowrates were tested by comparing the peak areas of each analyte with direct chromatographic injection. This analysis was run in multiple-reaction monitoring (MRM) mode where RTs were not locked due to the fact that different flowrates with same loading volume

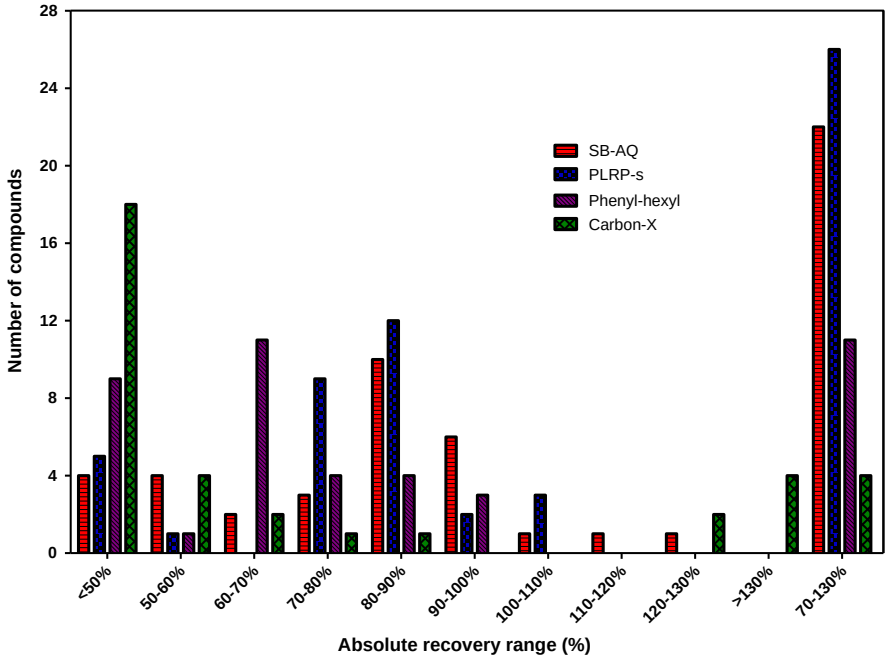

Fig. 1. Range of absolute recoveries for target analytes with four different online SPE cartridges.

caused the target analyte RT to shift. The absolute recoveries of all target analytes for the three different loading flowrates in order of increasing RT is illustrated in Fig. 3. It was found that the 1 mL/min flowrate provided best recoveries for the target analytes compared to the other flowrates. After all replicates for the condition were run, a set of blanks were injected to look for carryover. No carryover was found in the 1 mL/min samples indicating that the strong solvent mix was successful in washing any remaining analytes of the cartridge. The 1.5 mL/min flowrate had higher recoveries for the late-eluting analytes but some recoveries were extremely high with low reproducibility possibly due to carryover from previous injections. However, since 1 mL/min provided better results the potential carryover for the 1.5 mL/min flowrate was not investigated further.

3.4. Limit of detection (LOD) and method detection limit (MDL)

The instrument limit of detection (LOD) was based on an analyte signal to noise ratio (SNR) greater than three. A set of standards at 0.1, 0.2, 0.5, 1.0, 2.5, 5.0, 10 and 20 ng/L were analyzed to determine the LOD. The method detection limit (MDL) was calculated based on previous literature [41] by injecting eight

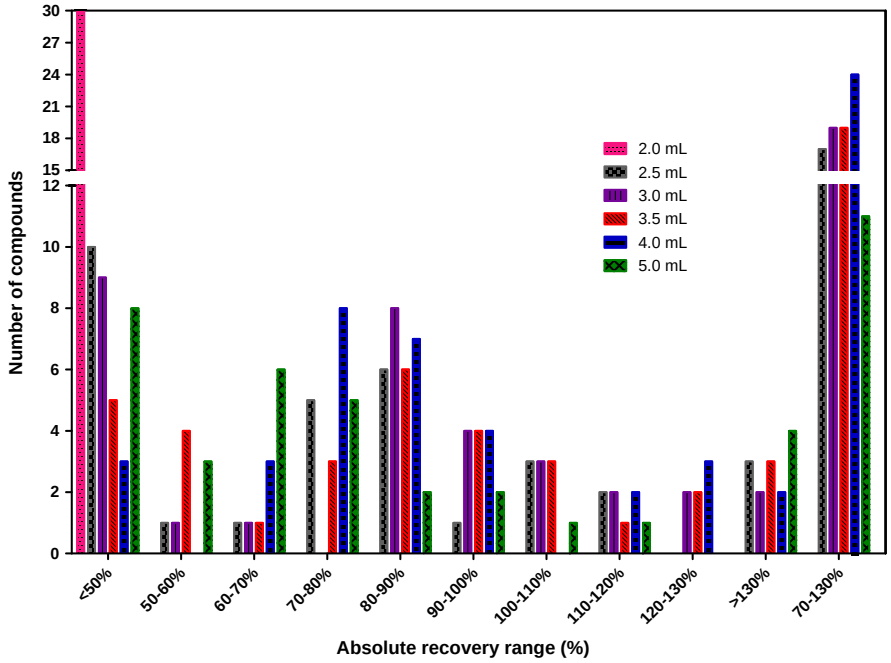

Fig. 2. Range of absolute recoveries for target analytes with different loading volumes.

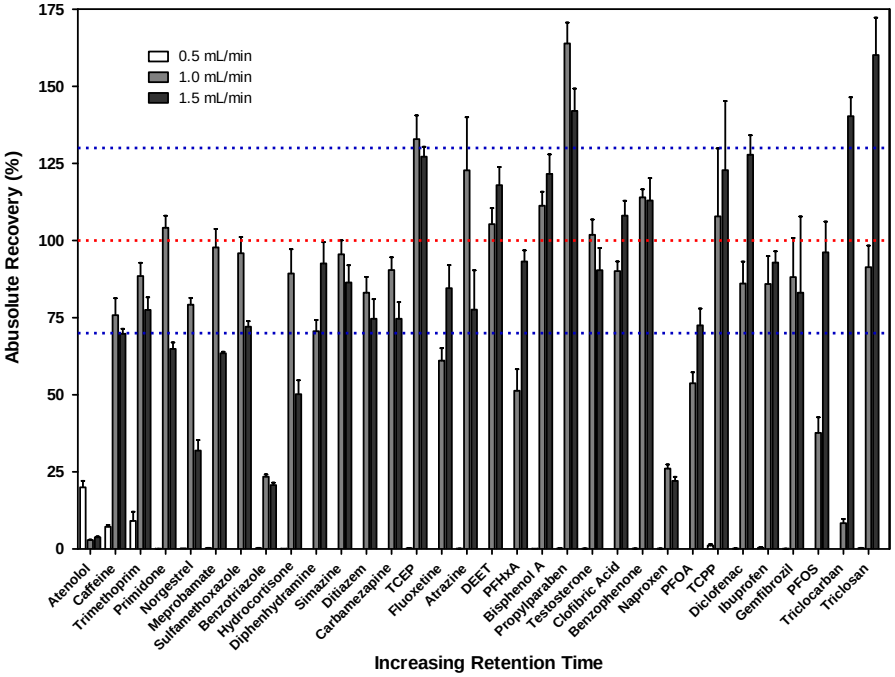

Fig. 3. Absolute recoveries of target analytes with three loading flowrates.

samples fortified with isotopically-labeled surrogate standards and target analytes at 2–5 times the LOD. The standard deviation of the eight replicates was multiplied by the student's *t*-test value for $n-1$ degrees of freedom at 99% confidence levels to determine the MDL of each target analyte. The calculated MDL for most analytes was <5 ng/L with only four compounds (benzophenone, benzotriazole, bisphenol A, and norgestrel) being >10 ng/L. The MDLs in this study (Table 2) were comparable and in most cases lower than previously published literature while using lower sample volumes of 1.7 mL [33,42]. A further advantage of using low sample volume was that the mass of isotopically-labeled standard added to each sample was much lower when compared to other published methods. The cost of isotopically-labeled IS standards can be prohibitively expensive often resulting in having to select a few IS to represent many compounds. With addition of lower masses of IS per sample, analysis costs are significantly lowered.

The method reporting limits (MRL) were determined individually for each sample as each water quality has different matrix effects on each analyte. When analyzing several different samples, it is not practically feasible to determine the MRL for each water quality. Hence, this method has been used to provide a realistic MRL for each sample while avoiding time-consuming MRL studies for each specific water quality. The details of this process have been described earlier [14]. Briefly, to calculate the MRL, the lowest calibration standard (usually at or close to MDL) was divided by isotope standard recovery (calculated by comparing peak area in ultrapure water) in that matrix to give the true MRL for each analyte in a sample. For analytes where matrix enhancement (IS recovery $>100\%$) was encountered, the isotope recovery was assumed to be 100% so not to get artificially low MRLs. For samples, where dilution was performed, the MRLs were suitably adjusted taking this into account. This method provides a realistic MRL for each sample without having to perform MRL studies on each water matrix.

Table 2
LODs, MDLs and practical MRLs in ultrapure water for all target analytes.

Analyte	LOD (ng/L)	MDL (ng/L)
Atenolol	1	2.5
Atrazine	0.2	0.3
Benzophenone	5	11.3
Benzotriazole	10	10.8
Bisphenol A	10	13.1
Caffeine	0.2	0.5
Carbamazepine	0.1[a]	0.1
Clofibric acid	0.2	0.7
DEET	0.1	0.3

Triclosan	1	2.6
Trimethoprim	0.1[a]	0.1

[a] Assumed as the lowest calibration standard (SNR $\gg 3$ at this concentration).

3.5. Matrix spike recoveries

Three different water matrices (ultrapure water, surface water and wasterwater effluent) were tested to evaluate the suitability of the method for analyte spike recoveries. Five replicate samples of ultrapure water and surface water (SW) were spiked with all target analytes at two levels (30 ng/L and 100 ng/L) while a wastewater effluent ($5\times$ diluted) was spiked at 100 ng/L. A summary of the recoveries for each analyte is shown in Table 3. In ultrapure water, recoveries were acceptable (70–130%) for all target analytes except norgestrel (61.2%) and fluoxetine (132.6%) in the low spike of 30 ng/L. The %RSD for both spiking levels in ultrapure water was $<10\%$ for more than 90% of the target analytes with most compounds having an RSD $<5\%$. In SW, recoveries varied from 69.2–137.1% for the 30 ng/L spike and 68.4–136.3% in the 100 ng/L spike with only two compounds outside the acceptable range in both spikes. The reproducibility for all compounds in SW was good as RSDs were $<12\%$ in both spike levels. All target analytes recoveries were within the acceptable range for the wastewater effluent (WWE) spike with the exception of PFOS (145.1%) while RSDs were less than 10% for all compounds but hydrocortisone (13.1%). The data shown is for the isotope corrected recoveries while absolute recoveries were lower as seen in earlier sections.

3.6. Matrix effect assessment

Matrix effects can pose severe challenges for low level quantification of analytes using ESI-LC–MS/MS [43]. Generally caused by interferences of co-eluting constituents in the matrix, they can result in loss of sensitivity and reproducibility. In this study, the matrix effect was calculated using 26 isotopically labeled standards in the analytical method. The isotopically labeled standards were spiked at 100 ng/L into three different matrices (surface water, wastewater effluent, 1:5 diluted wastewater effluent) and the matrix effect was calculated by comparing the peak area obtained in the matrix with peak area obtained in an ultrapure water sample according to Eq. (1).

$$\text{Matrix effect } (\%) = \frac{(PA_S - PA_M) \times 100}{PA_S} \quad (1)$$

where PA_s is the peak area in the standard (ultrapure water) and PA_M is the peak area obtained in the matrix. A positive value of matrix effect indicates signal suppression while a negative value indicates signal enhancement. Five replicate samples were analyzed in each matrix and of the standard in ultrapure water. The matrix effects for each analyte in the three different water qualities are represented in Fig. 4. The results indicate that while all the analytes were affected by suppression or enhancement in the three water qualities, the magnitude of effect was vastly different. For example, diltiazem-d_3 had $<10\%$ matrix effect in the three different water qualities whereas meprobamate-d_3 experienced much stronger suppression in all three water qualities (73.7%, 92.1% and 47.9% in SW, WWE and 1:5 WWE, respectively). Generally, the effects were greater in more complex matrices with the average matrix effect in the WWE (53%), being higher than SW (38%) and 1:5 diluted WWE (19%). The results from this study are in agreement with other studies and show the propensity of ESI methods to matrix effects. Hence, the authors strongly recommend the use of isotopically labeled surrogate standards for quantification in aqueous samples. For analytes where an isotopically labeled standard is not available, assigning an

appropriate one is critical as matrix effects are different for every analyte in each matrix and depend on chemical structure, retention time and nature of ionization [16,44].

3.7. Blanks, linearity and precision

The analysis of compounds at trace levels in any matrix is always susceptible to contamination. The use of automated extraction and analysis techniques reduces the possibility of contamination due to sample handling and human error. In this study, blanks with and without isotopically labeled standards were analyzed to check for the presence of target analytes. Except for DEET, none of the target analytes were detected in blanks. Only a small trace of DEET was detected similar to that reported previously [14]. Subsequently, the MDL and MRL for DEET were adjusted to minimize the possibility of false positives. Special precautions were taken to avoid contamination of prefluorinanted compounds including replacing all Teflon lines in the instrument with PEEK or stainless steel, use of metal solvent liner frits in the mobile phase bottles and use of a Poroshell EC 120 C-18 (2.1×30 mm^2, 2.7 μm) trapping column after the mixer of the pump to avoid potential contamination from solvents. Finally, a series of blanks ($n=5$) were analyzed for all the target analytes and all values were below the MDL. For analysis of real water samples, true blanks, method blanks and matrix spikes were run frequently to monitor contamination, instrument carry-over and robustness of the method.

The linearity of the calibration curves for each analyte was verified by preparing seven standards from the MDL to 100 ng/L (six points if the MDL > 10 ng/L) fortified with isotopically-labeled standards. The correlation coefficient (R^2) for all analytes was > 0.99 with 24 compounds (71%) having an $R^2 > 0.995$. The precision of the analytical method was verified using the intra-day and inter-day reproducibility (Table S7). Intra-day reproducibility calculated as % RSD was evaluated by analyzing four replicate injections of a 50 ng/L standard injected over the same day approximately three hours apart. The intra-day variability ranged from 1 to 10.4% with all the analytes except fluoxetine within 10%. The inter-day variability (% RSD) was determined by analyzing a 50 ng/L standard, prepared fresh everyday over four consecutive days and was < 10% for all compounds except atenolol with a range of 1–11.9%.

3.8. Analysis of water samples

The optimized method was used to determine the concentration of the 34 TOrCs in different environmental waters. Two conventional wastewater treatment plants (WWTP) were sampled at different treatment points to study treatment efficacy. WWTP 1 serves a largely urban population and has a capacity of 70 million gallons per day (MGD). It employs flocculation/sedimentation as primary treatment followed by an activated sludge process (sludge retention time ~4 days) as a secondary treatment and disinfection with free chlorine. WWTP 2 has a capacity of 2 MGD and serves a much smaller population (~17,000 people) with > 70% of the residents over 65 years in age. The first step in treatment of raw sewage is bar screens for grit removal followed by a biological oxidation ditch treatment (primary effluent), the mixed liquor is then sent to secondary clarifiers (secondary effluent) after which the water is disinfected with chlorine as hypochlorite before discharge (final effluent).

All pharmaceuticals analyzed were detected in the influent of both WWTPs with the anti-inflammatory drug Naproxen (avg. conc.:61,000 ng/L) and pain reliever Ibuprofen (35,000 ng/L) detected at highest concentrations. The metabolite clofibric acid however was not detected in both plants. Generally, most pharmaceuticals were present at > 1000 ng/L in the influent possibly indicating significant loading from humans as both plants served a domestic population. Similarly, all personal-care products analyzed were detected in the influent of the two WWTPs. Caffeine was the highest detected TOrC in the influent with an average concentration of 74,500 ng/L while none of the hormones tested were detected. No pesticides or perfluoroalkyl substances tested in this study was detected in the two plants. This could be due to the highly domestic nature of the wastewater indicating a lack of industrial and agricultural contribution to the waste.

The removal of TOrCs in wastewater depends on a number of factors including type of treatment process used, characteristics of the plant (like sludge retention time, pH and temperature) and physicochemical properties of the compound like biodegradability, sorption capacity, and water solubility [45,46]. The pharmaceuticals atenolol, trimethoprim, carbamazepine and sulfamethoxazole have low sorption coefficients and had poor removal after primary treatment in WWTP 1[47]. However these compounds with the exception of carbamazepine are well removed by biological processes as shown in the data (secondary effluent in WWTP 1 and primary effluent in WWTP 2) and corroborated by previous studies [48,49]. Similarly, caffeine has been shown to be easily biodegraded in activated sludge processes and this was evinced here as well with concentrations > 50,000 ng/L reduced to < 5 ng/L after biological treatment in both plants [50]. Moderate to high removals were seen for personal-care products like benzophenone and DEET in the primary and secondary treatments which is in agreement with previously published literature [51,52]. Finally, disinfection by chlorine can also oxidize some TOrCs leading to additional removal. Antimicrobial agents triclosan and triclocarban are extremely well removed by chlorine while flame retardants (TCEP and TCPP) have been shown to be resistant to most oxidants used in water treatment [4] and this was seen in the results as well. While several factors at each individual plant dictate the removals of these TOrCs, it can be seen that conventional treatment processes are not effective in complete attenuation of these compounds.

Analysis of a surface water revealed the presence of seven pharmaceuticals (carbamazepine, diltiazem, meprobamate, naproxen, primidone, sulfamethoxazole, and trimethoprim) ranging from 1.4 to 18 ng/L (Table 4). Five personal-care products (Benzophenone, caffeine, DEET, triclocarban and TCEP) were detected, with the UV-screen benzophenone (47 ng/L) being the highest detected TOrC in the SW. Both pesticides (atrazine and simazine) analyzed were present at < 5 ng/L. PFOA was detected at 27 ng/L in the SW while the other two PFCs analyzed were absent.

The groundwater (GW) sample collected from Tucson, AZ had the pharmaceutical-metabolite clofibric acid (22 ng/L) and insect-repellant DEET (5.4 ng/L) present at low concentrations while all other TOrCs analyzed were < MRLs. A grab sample collected from a septic tank showed the presence of all the personal-care products tested at concentrations > 100 ng/L. Caffeine (19,000 ng/L) was the TOrC detected at highest concentration with benzophenone (1600 ng/L) and triclocarban (1400 ng/L) also present at > 1000 ng/L in this sample. Only two pharmaceuticals (diphenhydramine and primidone) were present in this sample while all the hormones, pesticides and industrial compounds analyzed were not detected. The occurrence for all waters tested is presented in Table 4.

The presence of several trace-organic contaminants in surface and ground waters indicates that release of these compounds into the environment can enter water supplies and hence it would be prudent to monitor these chemicals while relevant toxicological studies are performed to evaluate health risk from water exposures.

4. Conclusions

A method utilizing fully automated online SPE coupled to LC–MS/MS with simultaneous positive and negative ESI for

NA: not analyzed.

analysis of 34 diverse trace organic contaminants including pharmaceuticals, personal-care products, hormones, pesticides, and industrial compounds in water has been developed. The method presented provides rapid screening and low-level quantification of analytes without sacrificing sensitivity, with MDLs ranging from 0.1 to 13.1 ng/L. Further, a method to determine the MRL of each sample using isotope recovery data without having to perform time-consuming MRLs in each matrix tested is described. A low sample volume (1.7 mL) coupled with a cycle time of < 15 min allows for high-throughput analysis. Critically, the use of fast polarity switching allowed for analysis of all 34 TOrCs in both ESI positive and negative mode with just one injection resulting in large time savings that is unique compared to other published OSPE methods. This fully automated online extraction coupled to LC–MS/MS method provides significant time, labor and solvent savings compared to previously published methods while also increasing the reproducibility of analysis. Results indicate that optimization of the type of online SPE cartridge, washing mobile phase composition, washing volume and flowrate are critical to obtain best sensitivity for analysis. The method has been validated with analysis of TOrCs across several different environmental water matrices.

IHSAB principle

ABSTRACT

We outline and review an approach to the construction of conductometric sensors that demonstrate considerably higher sensitivities than traditional metal oxide sensors. Simple sensor platforms do not require film-based technology, operate at room temperature, and can be obtained without the use of time consuming self-assembly processes. A combined nanopore coated micro-porous array is deposited with nanostructure directing acidic metal oxide island sites which vary in their Lewis acidity, decorate the micropores, and control an electron transduction process. The interaction of analytes with these island sites varies in a predictable manner and can be modified through in-situ functionalization of their Lewis acidity. The micropores allow rapid Fickian diffusion of analytes to the active nanostructured island sites whose reversible interaction with the analyte dominates the sensor response. We require only that the island sites be deposited at sufficiently low concentration so as not to interact electronically with each other. Highly accurate repeat placement of the depositions is not required. The nanoporous walls of the microarray act as a phase match for the deposition of a diversity of nanostructures that are selected for deposition from a variety of easily obtained solution-based sources as the forgiving deposition process requires a minimum of energy consumption and time. Comparisons to a variety of metal oxide systems are considered. Observed sensitivities and the sensor system reversibility can be predicted from the recently developing IHSAB model.

1. Introduction

Regulations for the detection, monitoring, and transformation of environmental constituents are increasing at a significant rate so sensor interfaces must be sensitive to low level exposures and have fast response times [1]. With concerns about the impact of gases on health and environmental concerns increasing, the reliable detection of several gases over a range of temperatures including, for example, NO_x associated with air pollution, combustion, and respiratory disease [2,3] is critical. NO is the primary monitor of an asthmatic attack and can also provide rapidly accessed noninvasive disease [4] detection. NH_3, which plays an especially important role in urban environments [5,6], is also produced albeit at much lower levels, during an asthma attack.

SO_x as well as NO_x play an important role in automotive and industrial exhaust, acid rain, photochemical smog, and corrosion [3]. Fuel combustion products contain toxic and odorless CO. PH_3 is an extremely toxic gas used for fumigation in agriculture and is a byproduct in the production of methamphetamines [7,8]. Historically, advances in gas sensor technology used to monitor these exemplary gases have been driven by sensitivity, selectivity, stability, response time, and durability.

There are a wide variety of gas detection devices which include infrared spectroscopic, mass sensitive, and solid-state sensors. Here, we consider solid-state devices which detect analytes by measuring an electrical property of the detection interface and from this measurement we can evaluate an interacting gas. These conductometric gas sensors can be made to consist of a sensitive interface layer decorated by nanostructure island sites. The nanostructure decorated interfaces that can be easily constructed, do not demand complex self-assembly, are much easier to implement and reproduce than film depositions, and require far fewer starting materials. These attributes suggest enhanced energy efficiency both in the transduction mechanism and in the simplicity of a design involving minimal manufacturing time.

The most common type of solid state sensor is the metal oxide sensor. These sensors [9,10] use the metal oxides of tungsten (WO_3), nickel (NiO), copper (Cu_xO), aluminum (Al_2O_3), titanium (TiO_2), tin (SnO_x), and zirconium (ZrO_2). Of the methods used to prepare these oxides, those that are most commonly cited in the literature require the use of thin films (< 1 μm). However, in some cases thick films are used, doped with noble metals or various nanoshapes designed to effect grain boundaries [10–17]. These metal oxide sensors must be heated to elevated temperatures that range from 100 to 600 °C [10,18–20] and, in many cases for the effective monitoring of a given analyte, must be precisely controlled.

The required temperature control of typical metal oxide sensors and the necessity to generate the sensing interface from film technology are two key problems that can be overcome with the technology that we outline in this monograph. We describe a conductometric gas sensor that can be made to consist of an easily designed sensitive hybrid nano/microporous interface transformed through the introduction of select nanostructures. Although the current interface is designed from porous silicon, the distinct approach that we employ can be extended to any extrinsic semiconductor onto which the hybrid nanopore coated microporous structure can be generated. This hybrid structure facilitates rapid Fickian [21,22] diffusion into a microporous framework whose nanoporous wall covering serves to provide a phase match for the selectively deposited nanostructures. In contrast to both

thin and thick films, which may respond in minutes [23] due to slow diffusion, the current structure, with which analyte interaction is diffusion dominated, allows a response in less than 2 s [22].

2. The interface

The basic semiconductor interface is illustrated in Fig. 1 [22]. This structure is produced by a hybrid etch procedure used to create the desired interfacial porous silicon support structure. The nanopore covered microporous structure of the interface has been created specifically to facilitate efficient gaseous diffusion [21,22] to the highly active nanostructure modified nanoporous coating. The active nanostructures can be chosen from a continuously expanding selection of metal oxides including, for example [21,22], MgO, TiO_2, SnO_x, NiO, Cu_xO, and Au_xO ($x \gg 1$), decreasing in the Lewis acidity of the metal sites. The surface-attached nanoparticles possess unique size dependent and electronic structure properties that form a basis for changing the sensitivity for exposure to specific analyte gases. This exposure alters the conductivity of the porous silicon attached to the gold contacts shown in Fig. 1. When operated in the electron transduction mode, the transfer of electrons to an *n*-type PS interface, as would occur with a basic analyte, increases the majority charge carriers which are electrons, decreases the conductometric resistance and increases conductance. The removal of electrons, as would occur with an acidic analyte, decreases the majority charge carrier concentration and the conductance and increases resistance. The opposite behavior will be observed for a *p*-type semiconductor interface.

The sensors we describe are fabricated from *n*-type and *p*-type silicon wafers as multiple sensors are created from a single wafer using an insulating and etch-resistant mask layer with an array of 2 mm × 5 mm windows. An insulating etch-resistant layer is created by depositing 200 nm of SiC by plasma-enhanced chemical vapor deposition (PECVD) and windows are removed from the SiC layer by reactive ion etching (RIE) where photoresist guides the RIE etching pattern. The revealed silicon is then electrochemically etched in a single cell configuration to produce a nanopore coated microporous interface. The PS morphology can be adjusted by adjusting etch parameters including time of etch and current density. The details of the micro-fabrication processes are straightforward and are described elsewhere [22,24,25].

3. Discussion

The nanostructure-decorated configuration depicted in Fig. 1 has several properties that are superior to traditional metal oxide thin film designs. First, the nanostructures are readily deposited to the microporous interface from a variety of solution-based sources (ex: electroless metal, sol–gel generated nanostructures, soluble metal chlorides) [22], which require no heating. Second, once deposited, the nanostructures can be readily functionalized, in-situ, predictably changing their interaction with a given analyte. This is exemplified as we convert the metal oxides to oxynitrides [24,26] or as we functionalize the nanostructured metal oxides with S–$H_z(CH_x)_y$ ($z=0,1$) groups [27,28]. The important consideration is that the nanostructured sites are easily modified.

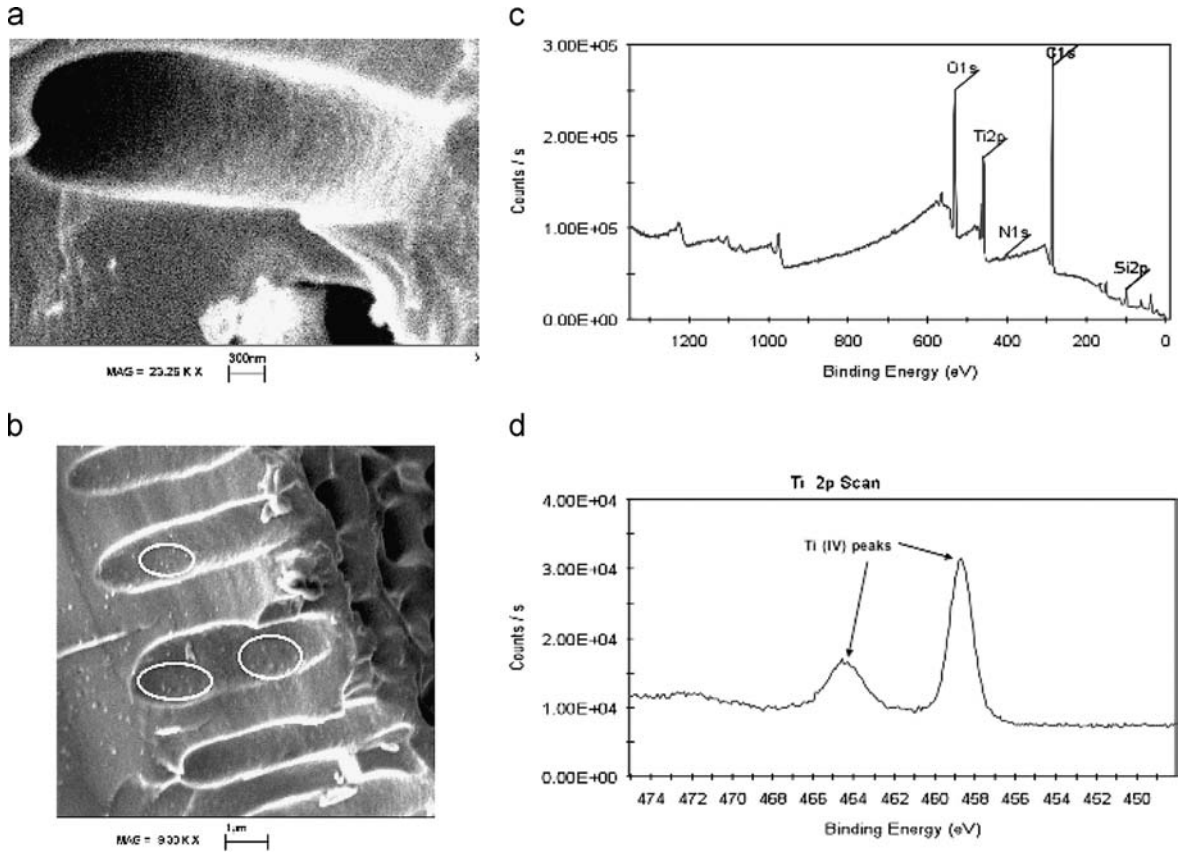

Fig. 3. (a) SEM image of undecorated *n*-type PS pore structure. The pore is approximately 1 μm in diameter and 4 μm in length. (b) SEM image of porous silicon structure deposited with TiO_2. Some of the TiO_2 nanostructures (10–20 nm) are encircled in white. (c) XPS spectrum for the decorated porous structure showing the overall XPS spectrum including background peaks and (d) close-up of Ti 2p XPS region. Those nanostructures can be subsequently nitridated to form $TiO_{2-x}N_x$ [30]. Reprinted from W. Laminack, J.L. Gole, Light enhanced electron transduction and amplified sensing at a nanostructure modified semiconductor interface, Advanced Functional Materials, 23 Copyright © 2013 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim [30].

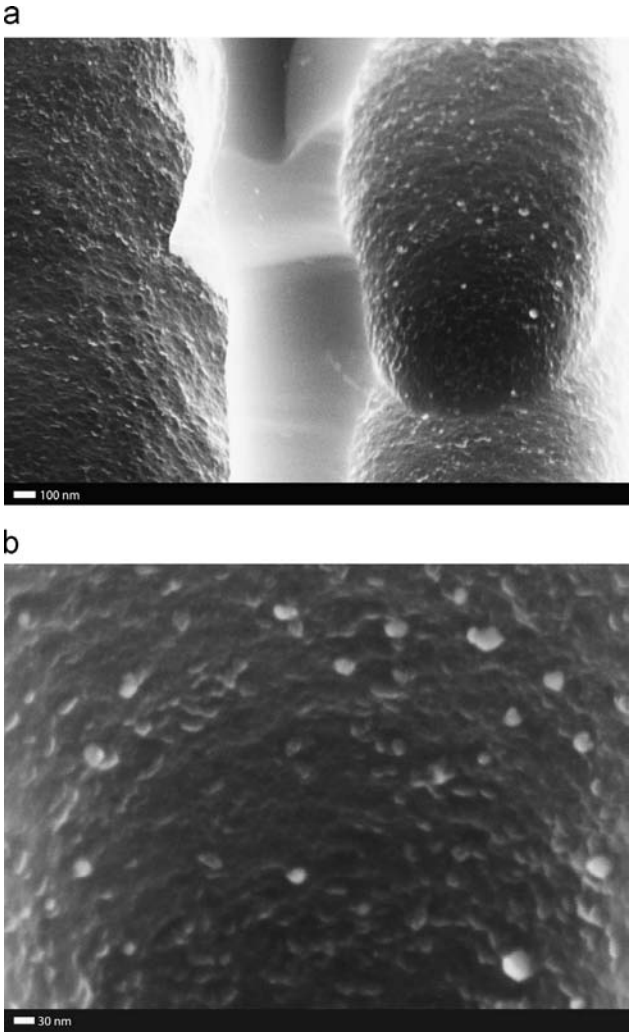

Fig. 4. (a) SEM image of thiol treated TiO_2 decorated porous silicon at 87.36 KX magnification. (b) SEM image of thiol treated TiO_2 decorated porous silicon at 274.17 KX magnification. The lighter images in the micrographs correspond to sulfur-based moiety functionalized titanium oxide [28]. Reprinted from W. Laminack, C. Baker, J.L. Gole, Sulfur–$H_z(CH_x)_y$ ($z=0,1$) functionalized metal oxide nanostructure decorated interfaces: evidence of lewis base and brönsted acid sites—influence on chemical sensing, Chemistry of Materials Submitted [28].

We provide examples of this ready deposition in Figs. 2–4. Note that the deposition does not require time consuming and costly self-assembly or the application of costly and time-intensive lithographic assembly. The nanostructured island sites once deposited to the interface are sustained on that interface in the size range 10–30 nm with no evidence for sintering. We require only that the concentration of the nanostructures be maintained at a level so as to avoid cross talk between these structures which will degrade the conductometric response of the interface.

In other words, there is an optimum deposition concentration for each nanostructure deposition. However, the deposition process requires no additional control and does not demand that the nanostructured islands be placed precisely at the same points in the micropores. This simplicity of design follows a process that is much more energy efficient than is thin or thick film design. With this form of interface preparation, we provide ready reproducibility, a factor that is not easily obtained in film preparation.

Counter to traditional metal oxide systems dispersed metal oxides on PS do not operate at high temperature. Therefore, they are more energy efficient and respond more rapidly due to their dispersed nature. Our room temperature operative design adds considerable flexibility not possible in a singly or multiply "coated" metal oxide interface. As metal oxide sensors need to operate at elevated temperatures, a power consuming heating element must be provided with the sensor housing. In several applications it is necessary to tightly control the temperature of the sensor element. This is intimately tied to the correct identification of the gas of interest. Distinguishing one gas from another requires that the heating element and sensor be well separated (channel) from the remaining electronics. This means that this configuration can be greatly affected by an impinging combustion or flue gas, rendering difficult the correct identification of gaseous species in the flow. In contrast, the PS sensor configuration depicted in Fig. 1 consumes less power as it does not require the complexity of a system separated sensor/heater configuration. However, again in contrast to traditional metal oxide systems, the PS sensor depicted in Fig. 1 can be extended in a heat sunk configuration to probe elevated temperature environments. This suggests that it might be used to monitor high temperature flue gas flows [22]. Figs. 5–8 provide an indication of the conductometric responses observed for several nanostructure directed systems.

The sensitivity obtained for the conductometric responses in Figs. 5–8 not only is greater than that for a typical metal oxide deposition but also compares very favorably with other modes of detection. X-ray Photoelectron (XPS) spectra taken for the nitridated and sulfur functionalized PS interfaces are sensitive to 0.1%. The typical time frame for the depositions used to obtain the conductometric data in Figs. 7 and 8 is 15–30 s. To obtain the XPS data we use deposition times which are at least 5 min. This corresponds approximately to an order of magnitude increase in concentration to generate signals in the 0.1% range. This indicates the significant sensitivity of the conductometric sensor responses. The magnitudes of the observed reversible interactions are described by the developing IHSAB model.

4. Power consumption

We have examined the *IV* response associated with the porous silicon sensor substrates, testing for linearity and bias. Fig. 9 shows the *IV* curves obtained for the operating sensor of Fig. 1. Here, we demonstrate forward and reverse scans for recently produced sensors which feature linearity over the entire testing range as well as no bias. Based on the linear *IV* curve, the continuous power consumption is between 25 and 60 μW/s over the range 1–1.5 V. We compare this result to the results of Ahlers et al. [32] (Fig. 10). The *IV* curves in Fig. 9 in concert with the analysis of Ahlers et al. [32] (Fig. 10) demonstrate that the nanostructure directed sensor systems require considerably less power for operation than do thick or thin film sensors. Mueller et al. [33] following Ahlers et al. [32] have recently discussed a MEMS toolkit for metal oxide based sensing systems. Using silicon micromachining technologies they have developed metal oxide gas sensor elements with very small heat consumption. The power of a single micromachined sensor element is found to be an order of magnitude less (Fig. 10) than that of thick film devices. In their Table 1, these authors quote heating powers, and necessary overhead heating requirements which sum to 1–1.5 W for a Thick-film sensor (column 1 Fig. 10) and 0.4–0.6 W (0.8 W including sensor) for a micromachined sensor array. The required power for the nanostructure directed PS systems we have considered is virtually in the noise level of Fig. 10. For this reason they are not shown in Fig. 10. We emphasize that the described system competes quite favorably with those micro-machined sensor systems whose construction may be more costly and time consuming.

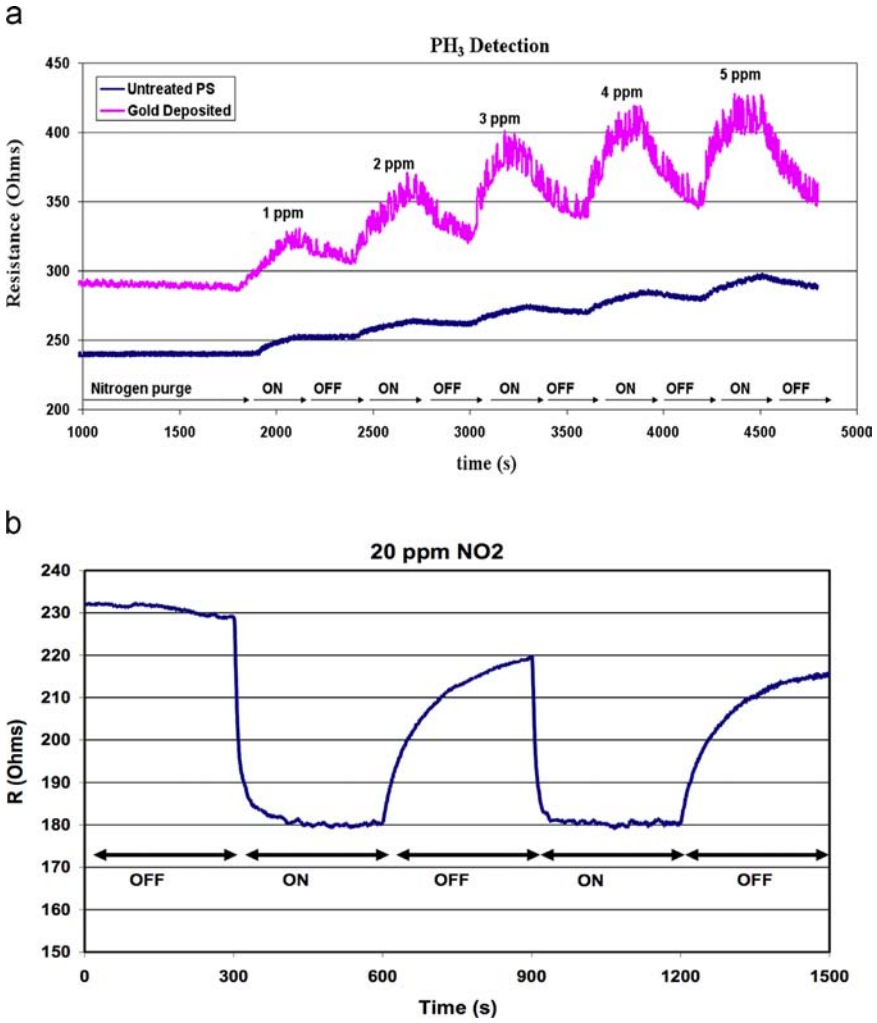

Fig. 5. (a) Improved response of a basic analyte, PH_3, to a *p*-type PS sensor with an electroless Au_xO coating. Here, 1, 2, 3, 4, and 5 ppm of PH_3 are pulsed onto the sensor surface every 300 s. A *p*-type sensor is used as the gold clustered oxide deposition enhances the response of the un-treated porous silicon interface by a factor of five. Reprinted from Chem. Phys. Chem., 11, Copyright (2010), with permission from Elsevier [29]. Reprinted from J.L. Gole, S. Ozdemir, Nanostructure directed physisorption vs. chemisorption at semiconductor interfaces: the inverse of the hard–soft acid–base (HSAB) concept, Chem. Phys. Chem. 11, Copyright © 2010 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim [29]. (b) Response of an acidic analyte, NO_2, to a *p*-type PS sensor. Conductivity increases upon exposure to the moderate acid. The return to baseline is not complete at this concentration as NO_2 sticks to the surface in this open experimental configuration [31]. Reprinted with permission from S. Ozdemir, T. Osburn, J.L. Gole, Nanostructure modified gas sensor detection matrix for NO transient conversion of NO to NO_2, Journal of the Electrochemical Society. 158 (2011) J201–J207 [31].

It is appropriate that we compare the outlined nanostructure directed interface with other metal oxide-based systems. While it is possible to create an exhaustive list of these sensor systems, this information can be obtained from several reviews in the literature [34]. Because SnO_2 and ZnO have been workhorses of the metal oxide sensor community we summarize a number of recent applications to the detection of several of the analytes that we have indicated in Section 1. Table 1 provides data on the detection of H_2S, SO_2, NO_2, CO, and NH_3. CO and NH_3 have also recently been detected using CuO thick films and nanowires. These results provide a comparative but by no means exhaustive list. For these analytes, concentrations at the sub-ppm level can be routinely measured at *room temperature* using the configuration of Fig. 1 (LEL (Lower Exposure Limit)=0.94 ppm for H_2S [35], 0.84 ppm for SO_2 [35], <0.5 ppm for NO_2 [36], 1 ppm for CO [37], <0.5 ppm for NH_3 [38] with low ppb range readily accessible [38], and <0.5 ppm for PH_3 [38–40] (amenable to extension to the ppb range)). The LEL's that we quote here correspond to the lowest measured concentration directly accessible to our measurements, in the linear regime of response, with no extrapolation. Thus the quoted LEL's are all upper bounds. Table 1 demonstrates that virtually all metal oxide systems operate at elevated temperatures. Further, processes that create thick film sensor elements, while sensitive, display significant response times, which can be on the order of minutes [23] (vs. seconds).

The data in Table 1 relate primarily to film based configurations where grain boundaries can pose complications. The data in the latter part of the table correspond to single crystalline nanowires or nanobelts, whose study can reveal important information concerning the reaction between target analytes and metal oxide surfaces free of grain boundaries. Nanowire and nanobelt diameters are on the order of several nanometers, comparable to the Debye length. This provides a much larger sensitivity than the corresponding thin film or bulk counterparts and several of these studies suggest the possibility of sensitivities in the ppb range. On a somewhat larger scale, Liao et al. [50] in detecting H_2S (100 ppm) found that thin nanorods have a much better sensing performance than thick nanorods. In extrapolation, researchers generally use the Langmuir absorption isotherm to fit the sensitivity–concentration curves of single nanowires whereas the power law, $S=a+bc^{\rho}$, is used to fit the concentration–sensitivity curves of film-based sensors [51]. It is to be noted that the sensitivities of single nanowire gas sensors are invariably less than nanowire film

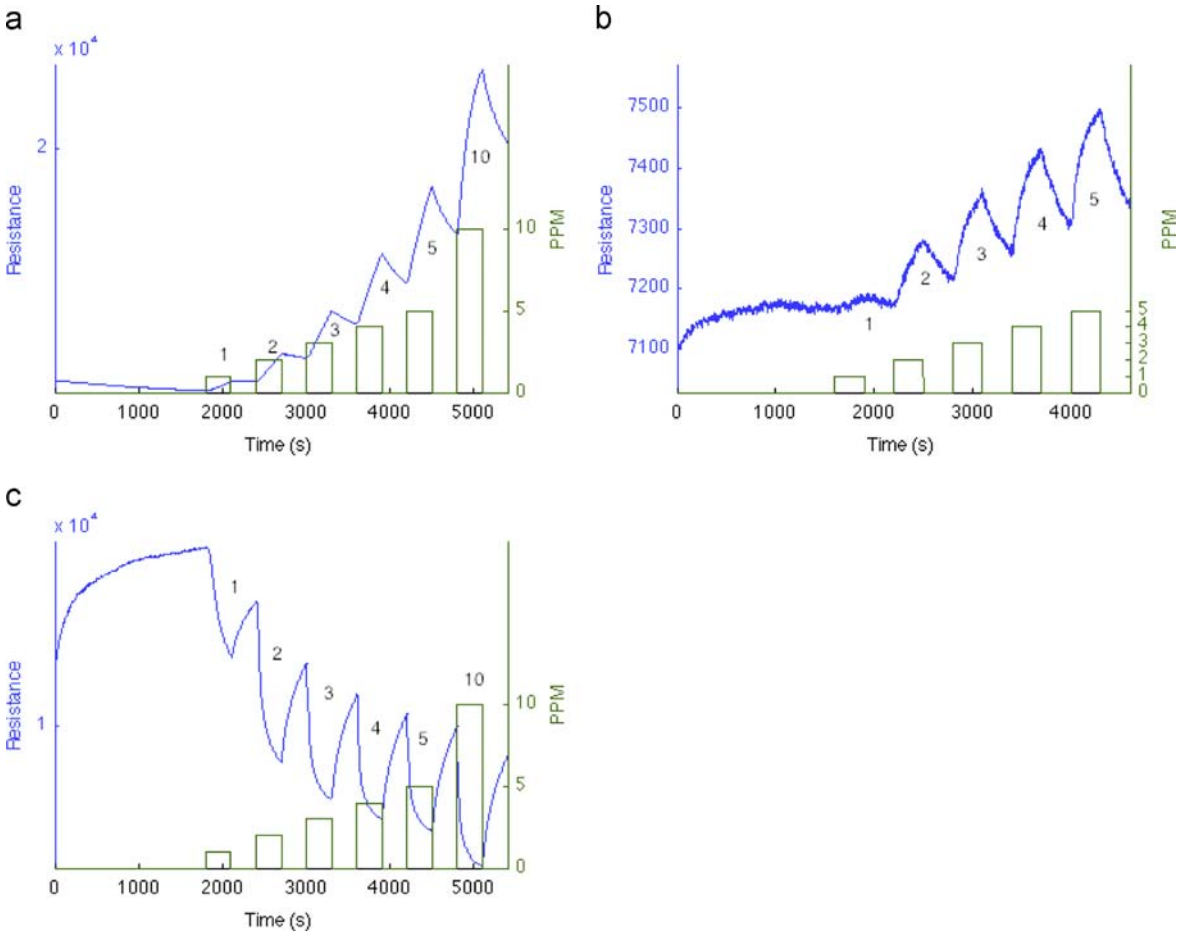

Fig. 6. Resistance response of *n*-type porous silicon sensors to 1–5 ppm and 10 ppm of (a) NO_2, (b) NO and (c) NH_3 [22,25]. NO_2 acts as a moderate acid, NO as a weak acid (resistance increase), and NH_3 as a strong base (conductance increase). Compare the results for NH_3 to those for PH_3 (Fig. 5(a)). Reprinted with permission from J.L. Gole, E. C. Goude, and W. Laminack, ChemPhysChem 13 (2012) 549–561 [25].

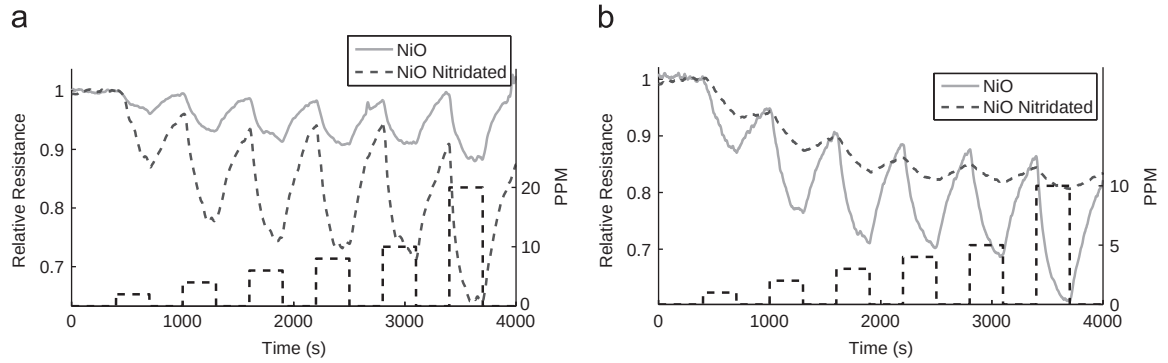

Fig. 7. Response to NH_3 (a) and NO (b) of a NiO treated PS interface before (solid gray) and after (dotted gray) a nitridation of the surface for 15 s with triethylamine. The boxes (black dashes) denote the analyte concentration from 1 to 10 ppm over the time of analyte gas exposure to the sensors. A rapid response is observed at each concentration. For NH_3, nitridation produces an increase in the interface response as monitored as an increase in conductance (decrease in resistance); however, for NO the nitridation decreases the interface response [26]. These responses are explained by the IHSAB concept. Reprinted by permission from W. Laminack, J.L. Gole, Direct in situ nitridation of nanostructured metal oxide deposited semiconductor interfaces: tuning the response of reversibly interacting sensor sites, ChemPhysChem, Copyright © 2014 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim [26]

gas sensors. For most of the elevated temperature studies in Table 1, there are difficulties in assessing whether an optimum temperature has been explored. Further, researchers studying 1D nanostructures, in general, may not follow a unified limit of detection when claiming the detection limit of their gas sensor reaches some ppb or ppm level [52].

Four of the last six entries in Table 1 suggest the possibility of extension to the ppb level of detection using nanowire or nanorod configurations. These studies show future promise but are somewhat difficult to gauge. For example, while it has been suggested [52] that Hernández-Ramírez et al. [57] can monitor CO concentrations of 100 ppb, these authors indicate only that they can measure concentrations less than 5 ppm. This is a very comprehensive study, which shows the promise for CO measurements both in dry air and at enhanced humidity levels. The results obtained by Zhao and Zhu [55] for NH_3 are impressive; however, it should be apparent that 5 nm nano-wire bundles are not easily

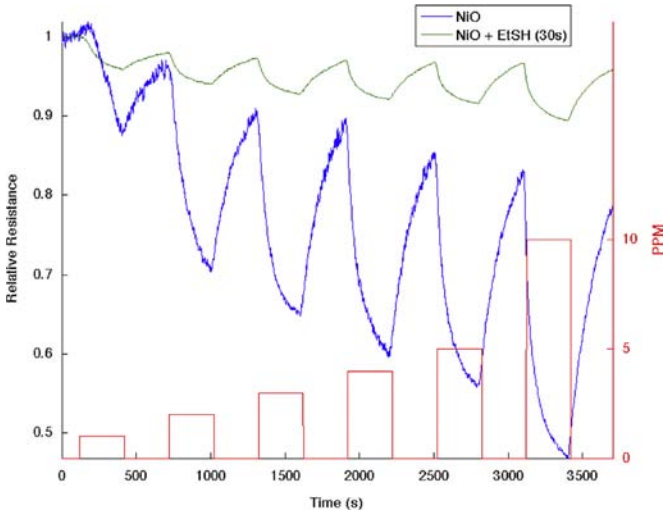

Fig. 8. (a) Response of ethanethiol treated nickel oxide nanostructure deposited porous silicon (PS) interface to NH_3 (a) exposure for 30 s and (b) exposure only to nickel oxide. The treated interface is more acidic than the Ni_xO treated PS acidic sites after a 30 s exposure. The boxes denote the analyte concentration from 1 to 10 ppm from the beginning of the gas introduction to the end. A rapid response is observed at each concentration [28]. These responses are explained by the IHSAB concept. Reprinted with permission from W. Laminack, C. Baker, J.L. Gole, Sulfur–$H_z(CH_x)_y$ ($z=0,1$) functionalized metal oxide nanostructure decorated interfaces: evidence of lewis base and brönsted acid sites—influence on chemical sensing, Chemistry of Materials. Submitted [28].

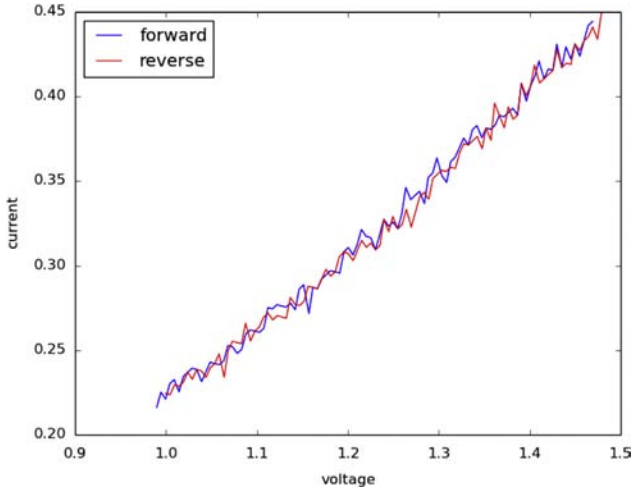

Fig. 9. *IV* curves for continuous sensor response.

prepared. The coupling of nanowires to a MEMS microhotplate again offers impressive results [56], but, however, this is again a difficult device to fabricate. Perhaps the most impressive result in Table 1 is the nanowire–nanogenerator self-powered gas sensor of Xue et al. It is clear that nanostructure bundles and nanorods can play a role of increasing importance in sensor applications.

5. Inverse Hard/Soft Acid/Base concept

By depositing metal oxide nanostructure islands to the PS interface, shown schematically in Fig. 1, the response of the sensor can be enhanced or diminished [25]. The Inverse Hard/Soft Acid/Base (IHSAB) model explains this phenomenon by linking chemical

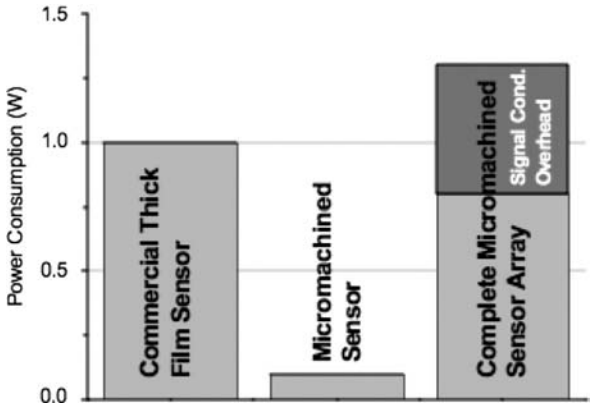

Fig. 10. A comparison of power consumptions. A full-fledged micro-machined sensor array with heater driver requires as much power as a single commercial thick film device. Additional power for signal conditioning electronics for a micro-machined sensor *array* is also indicated (from Ahlers et al. [32]). Reprinted by permission from S. Ahlers, P. Kreisl, G. Müller, A low-power metal-oxide based gas sensing system, 203rd ECS meeting, paper 2873, April 28, 2003, The Electrochemical Society [32].

selectivity and the balance of electron transduction and chemisorption [22,24–26] with the sensor response mechanisms. The IHSAB model predicts the interaction of acidic, basic, and amphoteric gas analytes with the nanostructure treated PS sensor interfaces. Table 2 provides an outline of the Hard/Soft identification of acids and bases. A hard acid will form a strong ionic bond with a hard base and a soft acid will form a strong covalent bond with a soft base. For the purposes of chemical sensing, we wish to minimize this bond formation [59–61]. The IHSAB model directs the fabrication of a nanostructure-treated PS gas sensor that behaves to stimulate an electron transduction physisorption-dominated mode as an inorganic gas analyte interacts with a decorated interface. Electron transduction dominates chemisorption, through the interaction of a hard acid and soft base or soft acid and hard base. There are different ways to control the size of the interaction of those molecules that are to be sensed with variably doped metal oxide nanostructure deposited sensing interfaces. However, the dominant factor is the HOMO–LUMO energy increment. If the donor orbital energy (highest occupied molecular orbital, HOMO) is not well matched with the acceptor (lowest unoccupied molecular orbital, LUMO), then the interaction will be weak. As the HOMO (donor)–LUMO (acceptor) energy gap decreases, there can be more charge transfer between the molecule (analyte) and the created interface, leading to a stronger Lewis acid–base interaction. Conversely, the greater the HOMO–LUMO energy gap, the greater the orbital mismatch, enhancing the electron transduction mode. The IHSAB principle is in large part based on controlling the size of the Lewis acid–base bond dissociation energy.

The estimated positions of deposited nanostructures and gas analytes on the IHSAB scale are shown in Fig. 11 relative to PS. As dictated by the scale and following the IHSAB model of interactions, PS deposited with Au_xO nanostructures will produce the largest response to NH_3 and PS deposited with TiO_2 will produce the largest response to CO. Within the IHSAB framework, metal/metal oxide nanostructure depositions can be selected for the PS sensor interface to create a predictable range of sensitivities for various gases [22,24–26]. The relative responses which we have observed to select *n*-type and for *p*-type systems thus allow the construction of the "Materials Positioning Table" for the acids and bases within the IHSAB concept. The analyte response data forms the basis for the development of this materials positioning diagram based largely on the interaction of the acidic metal oxides ranging from TiO_2 to Au_xO ($x \gg 1$) and the bases NH_3 to CO.

Table 1
Lower Exposure Limit of various gas sensor materials and methods.

Gas	Gas Concentration Lower Exposure Limit (LEL)	Response sensitivity	Operating temperature	Material	Method	Author
H_2S	1 ppm	5900[a]	200 °C	Ag (8 nm)-doped SnO_2	DC magnetron sputtering (SnO_2); Ag film coating	Jin et al. [41]
H_2S	3 ppm; 1 ppm LEL	40%[b]; unreported	74 °C	Ag-doped SnO_2	Polymeric sol–gel	Gong et al. [42]
H_2S	2.5 ppm	~85%[b]	400 °C	SnO_2	Spray pyrolysis	Griessler et al. [43]
H_2S	0.5 ppm	~1.4[a]	300 °C	SnO_2	Flame spray pyrolysis (FSP) (nanopowders); spin coating (sensor)	Liewhiran et al. [44]
H_2S	10 ppm	~1.45[a]	300 °C	CuO	Heating in open-air high purity copper foils (nanowires)	Shao et al. [45]
H_2S	1 ppm	~5[c]	25 °C	PS untreated	Nanopore covered μ-pores	Lewis et al. [35]
SO_2	50 ppm	~40%[b]	300 °C	SnO_2	Spray pyrolysis	Griessler et al. [43]
SO_2	20 ppm	~3.8[a]	300 °C	SnO_2	FSP (nanopowders) spin coating (sensor)	Liewhiran et al. [44]
SO_2	5 ppm	~45%[b]	350 °C	0.15 wt% V_2O_5/SnO_2	Simultaneous precipitation technique (nanopowder); painting (sensor)	Das et al. [46]
SO_2	1 ppm	~5[c]	25 °C	PS untreated	Nanopore covered μ-pores	Lewis et al. [35]
CO	50 ppm	8[a]	350 °C	0.2 wt% Pt/SnO_2	FSP (nanopowders); thermophoresis (sensor)	Mädler et al. [47]
CO	500 ppm	N/A[d]	200–400 °C	SnO_2	FSP (nanopowders); drop coating (sensor)	Sahm et al. [48]
CO	10 ppm	N/A	150 °C	CuO	Soft chemistry (nanospheres); thick film screen printing (sensor)	Hübner et al. [49]
CO	1 ppm	~3[c]	25 °C	PS, SnO_2 treated	Sn electroless solution	DeBoer et al. [37]
NO_2	5000 ppb	20[a]	220 °C	SnO_2	FSP (nanopowders); drop coating	Sahm et al. [48]
NO_2	< 500 ppb	~10[c]	25 °C	PS, TiO_2 treated	TiO_2 nanoparticle solution doped nanopore covered μ-pores	Laminack et al. [36]
NH_3	100 ppm	3.1[a]	200 °C	CuO	Heating in open-air high purity copper foils (nanowires)	Shao et al. [45]
NH_3	< 500 ppb	~50[c]	25 °C	PS, Au_xO treated	Au electroless solution	Ozdemir et al. [38]
PH_3	< 500 ppb	~10[c]	25 °C	PS, Au_xO treated	Au electroless solution	Ozdemir et al. [38,39] Laminack et al. [40]
H_2S	50 ppb	N/A	25–200 °C	ZnO	Nanorods	Wang et al. [53]
H_2S	1 ppm	N/A	RT[e]	In_2O_3	Nanowires 2–3 min response	Zeng et al. [54]
NH_3	10 ppb	(N/A)	RT	$W_{18}O_{49}$	Ultrathin (5 nm) nanowire bundles	Zhao et al. [55]
NH_3	100 ppb	N/A	300 °C	SnO_2	Coupling SnO_2 nanowire to MEMS microhotplate	Meier et al. [56]
CO	100 ppb (quote < 5 ppm)	N/A	300 °C	SnO_2	Single nanowire	Hernández-Ramírez et al. [57]
H_2S	100 ppm	N/A	RT	ZnO	ZnO nanowire nanogenerator-possible self-powered gas sensor	Xue et al. [58]

Table 2
Sampling of Hard/Soft Acid/Base designation of various materials [22,29].

	Hard	Borderline	Soft
Acids	H^+, Li^+, Na^+, K^+ Be^{2+}, Mg^{2+}, Ca^{2+} Cr^{2+}, Cr^{3+}, Al^{3+} SO_3, BF_3, Sn^{4+}, Ti^{4+}	Fe^{2+}, Co^{2+}, Ni^{2+} Cu^{2+}, Zn^{2+}, Pb^{2+} SO_2, BBr_3, Sn^{2+} NO_2	Cu^+, Au^+, Ag^+, Tl^+, Hg Pd^{2+}, Cd^{2+}, Pt^{2+}, Hg^{2+} BH_3
Bases	F^-, OH^-, H_2O, NH_3 CO_3^{2-}, NO_3^-, O_2	NO_2^-, SO_3^{2-}, Br^- N_3^-, N_2, H_2S C_6H_5N, SCN	H^-, R^-, CN^-, CO, I SCN^-, R_3P, C_6H_5 R_2S

6. Conclusion

The data that we have summarized indicate a novel mode to create metal oxide sensors with significant ease that facilitates the development of reversible conductometric sensor systems. These are energy efficient forgiving systems. We deposit metal oxide

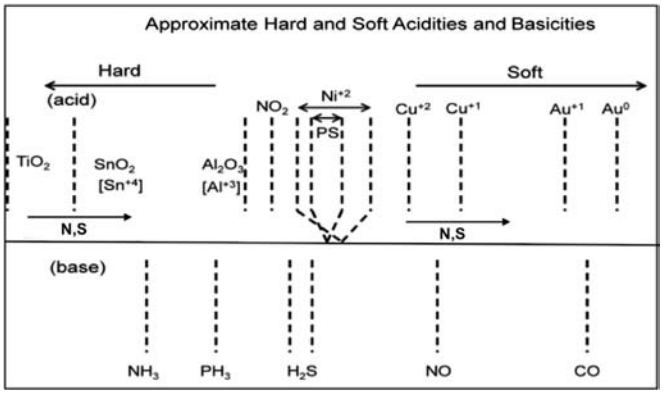

Fig. 11. IHSAB scale and estimated hard and soft acidities and basicities based on resistance changes relative to a *p*- and *n*-type PS interface [24]. Reprinted by permission from W. Laminack, J.L. Gole, Nanostructure-directed chemical sensing: the IHSAB principle and the effect of nitrogen and sulfur functionalization on metal oxide decorated interface response, Nanomaterials. 3 (2013) 469–485 [24].

sites with sufficient control so that thin (or thick) films are no longer required. The process enhances diffusion time and facilitates the ease and repeatability of construction. Rapidly responding, reversible, *room temperature* sensors have been created and evaluated for the detection of various inorganic gas analytes at low ppm concentrations. Counter to traditional metal oxide systems the dispersed metal oxides on PS operate at room temperature and can be heat sunk to operate at elevated temperatures. Therefore, they are more energy efficient as they respond more rapidly due to their dispersed nature. These sensors can be constructed using easily accessible solution based sources. This suggests that their scalability is eminently possible and multiple sensor configurations have already been constructed. Within the framework dictated by the IHSAB model, select metal oxide nanostructures have been deposited to the PS interface, to create an array of sensitivities to a variety of gas analytes. This array has been extended by the in-situ nitridation of metal oxide islands deposited to the PS interface, allowing greater flexibility for tuning the sensor response. The observed response behavior is explained largely by the developing IHSAB concept.

Photometry of phosphate

ABSTRACT

A compact photometric detector was constructed from an organic light emitting diode (OLED) based on a europium complex, europium(diben-zoylmethanato)$_3$(bathophenanthroline) (Eu(DBM)$_3$bath), as the light source and an organic photodiode (OPD) fabricated from a hetero-junction of two layers of copper phthalocyanine (CuPc)/fullerene (C_{60}) as the photo-detector on a microchip prepared from poly (dimethylsiloxan) (PDMS) and was applied to the determination of phosphate. The OLED and the OPD were fabricated by a vapor deposition method on an indium tin oxide (ITO) coated glass substrate with the following layered structure; Glass (0.7 mm)/ITO (110 nm)/4,4′-bis[N-(1-naphthyl)-N-phenyl amino]-biphenyl (α-NPD) (30 nm)/4,4′-di(N-carbazolyl)biphenyl (CBP): Eu^{3+} (8 wt%, 30 nm)/bathocuproine (BCP) (30 nm)/aluminum tris(8-hydroxyquinoline) (Alq_3) (25 nm)/magnesium and silver (MgAg) (100 nm)/Ag (10 nm) and Glass (0.7 mm)/ITO (110 nm)/CuPc (35 nm)/C_{60} (50 nm)/BCP (10 nm)/Ag (50 nm), respectively. The OLED based on the europium complex emitted a sharp light at the wavelength of 612 nm with a full width at half maximum (FWHM) of 8 nm. The performance of the photometric detector assembled was evaluated based on measurements of the absorbance of different concentrations of malachite green (MG) solutions for a batch system with 1 cm long path length. The molar absorptive coefficient of the MG solution, calculated from the photocurrent of the OPD, was in good agreement with the value reported in the literature. A microchip with two inlets and one outlet U-shaped channel was prepared by a conventional photolithograph method. The OLED and the OPD were configured so as to face each other through the PDMS microchip in parallel in order to align the light axis of the OLED and the OPD with the flow cell (optical path length of 5 mm), which was located at the end of outlet. For the determination of phosphate, an ion-association reaction between MG and a molybdenum-phosphate complex was utilized and a good linear relationship between the concentration and absorbance was observed in the concentration range 0–0.2 ppm, with a detection limit ($S/N=3$) of 0.02 ppm. The assembled photometric detector was also applied to the determination of phosphate by the flow injection of river water samples using the reagent solution containing MG and molybdenum ammonium in sulfuric acid. A good recovery (97–99%) for the river water samples, which had been spiked with the standard 0.08 ppm, with an RSD of ca 5% ($n=5$) was obtained using the constructed system.

1. Introduction

Phosphates, which are founds in bones, proteins, and which participate in energy production, are very important for the health of all living organisms. However, phosphate together with nitrogen compounds such as nitrate and nitrite also participate in eutrophication in aquatic environments, which can result in the production of algal blooms. Therefore, the determination of trace levels of phosphate has become a very important issue. A photometric flow injection analysis (FIA) system was proposed for the determination of phosphate, based on various methods, including a yellow vanadomolybdate method [1], a molybdenum blue method [2] and a malachite green method [3,4].

Attempts to downsize analytical systems by integrating separation, reaction, mixing and detection onto a single microchip, a so-called miniaturized total analysis system (μ-TAS) and a lab-on-a

chip (LOC) system have been of great interest in terms of making further progress in analytical chemistry and has attracted the interest of researchers from interdisciplinary fields [5,6]. The technique has many advantages such as rapid analysis, high portability, reduction in separation time, and negligible consumption of reagents due to its micrometer sized flow channels. The systems have been applied to numerous fields, including environmental monitoring, food safety and clinical diagnosis.

Numerous types of detectors for the μ-TAS and the LOC system, such as optical detectors, electrochemical detectors have been developed. The functional integration of a light source and a photo-detector within a microchip is the key issue for successfully assembling a micro-fluidic system [7,8]. There have been many reports dealing with the fabrication of optical detectors onto the μ-TAS and LOC systems, including inorganic light emitting diodes (LEDs) [9–14] as the light source and a silicon photodiode [15] as a photo-detector. For example, Yang et al. [12] reported on the development of a simple detection system based on light emitting diode induced fluorescence for microscale electrophoresis on a microfluidic platform. Under optimal conditions, a very high sensitivity to fluorescein and fluorescein thiocyanate (FITC) with a detection limit of 0.09 fmol and 0.18 fmol, respectively was achieved for a limited sample volume of 0.37 nL. This device has been successfully employed for the separation and detection of penicillamine enantiomers by derivatization with FITC. Recently a new light source and a new type of photo-detector based on organic materials, a so called organic light emitting diode (OLED) [16–20] and an organic photodiode (OPD) [21–23] have been utilized as an optical system for use in conjunction with the μ-TAS and LOC systems. Yao et al. [17] fabricated an optical system using a green OLED for the fluorescence detection of rhodamine 6 G and alexa 532. In this case they used a thin film interference filter to reduce the effect of the excitation light on the detection of fluorescence, as a result detection limits of 1.4 fmol and 35 fmol for alexa and rhodamine, respectively, were obtained for an injection volume of 0.7 nL. The results proved that OLEDs are promising light sources for use in microfluidic fluorescence detection systems which have a small size and are easy to integrate. Hofmann et al. [24] demonstrated the performance of an OPD based on CuPc/C_{60} for the monitoring of a peroxyoxalate based chemiluminescence reaction on a microfluidic device. A detection limit for peroxyoxalate of 1 mM was obtained with a good reproducibility of the photocurrent of the OPD below 1.5% ($n=3$) as the RSD.

However, only a very few attempts have been reported regarding assembling an optical system in which an OLED is combined with an OPD [25,26]. Banerjee et al. [25] reported on a method for the sensitive detection for rhodamine 6 G and fluorescein by the combined use of an OLED based on Alq_3 with an OPD based CuPc/C_{60}. The novel idea for this device involved the use of a pair of cross-polarization filters, which effectively eliminates the effect of the excitation light on the OPD detector. As a result they achieved a detection limit of 10 nM for the both fluorescent reagents. Pais et al. [26] reported a highly sensitive and disposable LOC for measuring fluorescence signals from rhodamine 6 G and fluorescein by combining an OLED based on a N,N-bis(1-naphthyl)-N,N-diphenyl-1, 1-biphenyl-4,4-diamine (NPB)/Alq_3 thin-film as the light source with an OPD based on a CuPc/C_{60} thin-film as the photo-detector. A limit of detection of 100 nM was reported for rhodamine 6 G, and 10 μM for fluorescein. These studies suggest that an integrated microfluidic device, with an OLED as the light source and an OPD as the detector, could be fabricated to produce a compact and economical LOC device for point-of-care diagnostics and on-site analysis. However, to date most of the above studies have been primarily limited to fluorescence detection, with no applications to analytically important needs.

In the present paper, we report on the fabrication of a highly sensitive photometric system for the determination of phosphate on a microchip via the use of a combination of an OLED and an OPD. One of the advantages of the proposed photometric detector for the microchip is the fact that the shape of the OLED and the OPD was flat, thus making it suitable for assembling on a flat shaped microchip. In this work, we used a new type of Eu^{3+} rare earth complex as an emission material for the OLED. Because the emission spectra of the OLED based on this complex is very sharp, with a FWHM of less than 10 nm, this OLED is suitable for the selective absorption of a reagent (MG) for phosphate. This is the first report of the use of a Eu^{3+} rare earth complex based OLED in a photometric detection system constructed by integrating with an OPD as a photo-detector. In this study, the performance of the photometric detector comprised of an OLED combined with the OPD was examined by the detection of MG solutions and the photometric detector was successfully applied to the determination of phosphate on a microfluidic platform.

2. Experimental

2.1. Materials and reagents

For the fabrication of the OLED, α-NPD, CBP, Eu(DBM)$_3$bath, BCP and Alq_3 were obtained from Tokyo Kasei Co., Ltd., (Tokyo, Japan) and were used without further purification. An ITO deposited glass plate (thickness of the ITO layer, 110 nm) was purchased from Sanyo Vacuum Industries Co., Ltd. (Osaka, Japan) and was cut at a size of 25 mm × 25 mm (including patterns of 7 stripes of 2 mm width and 23 mm length).

For the fabrication of the OPD, CuPc, obtained from Tokyo Kasei Co., Ltd., (Tokyo, Japan), was purified by three sublimations and was used as a p-type semiconductive material. C_{60}, 99.95% pure, was obtained from Material Technologies Research Ltd., (OH, USA) and was used as received as an n-type semiconductive material.

All solutions were prepared from analytical grade chemicals. Deionised water was purified by means of a Direct-Q™ water purification system and was used for preparing all solutions used in this study.

2.2. Preparation of solutions

To evaluate the performance of the OLED and OPD assembled on the PDMS microchip, MG (Wako Chemical Co., Ltd., Osaka, Japan) was utilized for absorbance detection. A 100 μM MG solution was used as a stock solution and stored in the dark at 4 °C. Working solutions were prepared by diluting the MG solution to various concentration before analysis.

To determine the absorbance of phosphate, a MG–molybdate reagent consisting of 2.2×10^{-4} M MG, 0.11 M $(NH_4)_6Mo_7O_{24}$, 1.3 M H_2SO_4 and 25% methanol was prepared as follows; a 7 mL aliquot of concentrated sulfuric acid (H_2SO_4, 98%, Wako Chemical Co., Ltd., Osaka, Japan) was slowly added to approximately 40 mL of deionised water in a beaker. The solution was allowed to cool to room temperature and 1.94 g of ammonium molybdate ($(NH_4)_6Mo_7O_{24}\cdot4H_2O$, 99%, Wako Chemical Co., Ltd., Osaka, Japan) and 0.0092 g of MG were then dissolved into the sulfuric acid solution. Finally this mixed solution was transferred to a 100 mL-volumetric flask and 25 mL methanol (Wako Chemical Co., Ltd., Osaka, Japan) was added to the flask and the solution made up to 100 mL with deionized water. The resulting solution was stored in the dark at 4 °C.

A 100 ppm phosphate stock solution was prepared at weekly intervals by dissolving potassium dihydrogenphosphate (KH_2PO_4, Wako Chemical Co., Ltd., Osaka, Japan) in deionized water. Standard solutions of phosphate were prepared daily by dilution of the stock solution.

2.3. Preparation of organic light emitting diode (OLED)

The OLED was fabricated by multilayer thermal deposition, as follows. A 25 mm × 25 mm glass substrate pre-coated with a 110 nm thick ITO layer (sheet resistance ≈30 Ω/square) of 7 stripes was degreased with solvents (acetone, isopropyl alcohol and deionized water) and cleaned in a UV–ozone chamber (Nippon Laser & Electronics Lab., NL-UV253) before being loaded into the deposition system. First, a 25 mm × 25 mm shadow mask with 12 mm × 16 mm opening was placed on the ITO deposited glass substrate. A 30 nm thickness of a α-NPD film layer was prepared by deposition onto the glass substrate, as a hole-transport layer (HTL) at deposition rates of 1 nm s^{-1}. Next, a 30 nm thick layer of CBP co-doped with $Eu(DBM)_3$bath was deposited onto the α-NPD film layer, as an emission layer (EML) at deposition rates of 0.08 nm s^{-1} for $Eu(DBM)_3$bath and 0.92 nm s^{-1} for CBP, respectively. As a result, the weight percentage of the Eu^{3+} complex in the EML was 8 wt%. A 30 nm thick layer of BCP was then deposited onto the EML as a hole-blocking layer (HBL), and a 25 nm thick layer of Alq_3 was deposited on the HBL as an electron-transport layer (ETL) at deposition rates of 0.8 nm s^{-1} and 1 nm s^{-1}, respectively. The resulting mask was replaced with another mask with an opening area of 2 mm × 19 mm for the preparation of a metal cathode. In order to prepare a metal cathode consisting of a MgAg (the ratio of Mg and Ag was 10:1) layer with a thickness of 100 nm, Mg and Ag were deposited onto the Alq_3 layer at deposition rates of 3 nm s^{-1} and 0.3 nm s^{-1}, respectively. A 10 nm thick Ag layer was deposited onto the MgAg layer. Finally, the resulting OLED was encapsulated by placing a cover glass with a UV cured epoxy seal at the perimeter, followed by irradiation with UV light in a nitrogen-filled glove box (KK-011 AS-Extra, ALS Technology, Kanagawa, Japan) to protect the OLED from humidity. The schematic of the OLED and a photograph are shown in Fig. 1(a) and (b), respectively.

2.4. Preparation of organic thin film photodiode (OPD)

Fabrication procedures for the present OPD were essentially the same as that for the OLED described in the previous section, as well as previously reported [27]. Briefly, a CuPc layer, a C_{60} layer and a BCP layer were prepared on the ITO deposited slide glass by a vapor deposition method. The thickness of the CuPc layer, the C_{60} layer and the BCP layer were 50 nm, 40 nm and 10 nm, respectively, and were controlled by adjusting the time and deposition rate (0.3 nm s^{-1}, under ca 5×10^{-4} Pa). Finally the organic layers of the resulting OPD were sealed by a cover glass with a UV-cured layer in a glove box, similar to the OLED encapsulation process. The structure of the OPD is the same as that of the OLED as shown in Fig. 1(a) and a photograph of the OPD is shown in Fig. 1(c).

2.5. Design and preparation of PDMS microchip

The microchip composed of polydimethylsiloxane (PDMS) with a U-turn shaped type microchannel (two inlets and one outlet) was prepared on the PDMS coated glass substrate using conventional soft lithography techniques [28]. The mask shown in Fig. 2 (a) was designed and printed onto a transparency sheet. The width, depth and the total length of the U-turn shaped channel to the outlet was 1.5 mm, 80 μm and 33.4 cm, respectively. The preparation procedures were as follows. To fabricate a mold for the PDMS microchip, 2 mL of SU-8 was spun onto the glass substrate (500 rpm for 10 s and then 2000 rpm for 30 s) using a spin coater (1H-DX, Mikasa Co., Ltd., Tokyo, Japan) and the resulting substrate was then heated on a hot plate (ND-1, As One, Osaka, Japan) at 65 °C for 3 min and then at 95 °C for 9 min. The mask was placed on the SU-8 coated substrate and the resulting mask was irradiated with a UV light for 60 s in an exposure box (BOX-W9B, Sunhayato, Tokyo, Japan). The resulting substrate was again heated at 65 °C for 2 min and then at 95 °C for 7 min on a hot plate. The substrate was immersed in a SU-8 Developer solution for about 10 min and washed with isopropyl alcohol and then baked at 150 °C for 5 min on a hot plate. To fabricate a flow cell for absorbance detection at the end of the outlet, an iron rod with a 2 mm∅ diameter and a length of 5 mm was placed at the position of the outlet of the mold. A 30 g aliquot of the pre-polymer of PDMS was mixed with 0.3 g of a cross-linking agent at a 10:1 ratio and the resulting mixture was then degassed in a vacuum for about 30 min. The resulting mixture was poured onto the mold with the perimeter surrounded by scotch tape and was heated at 75 °C for about 2.5 h. The PDMS mold and the iron rod were then detached from the PDMS with a microchannel and a glass substrate (0.7 mm × 70 mm × 50 mm), the surface of which was coated with a thin PDMS film formed by spin-coating at a rotation speed of 1000 rpm for 60 s. The PDMS with a microchannel and the glass substrate with the PDMS thin film were placed in a plasma generator (BD-20AC, Electro-Technic Products Inc., IL, USA) and irradiated with the plasma for 45 s. The resulting PDMS microchip and the glass substrate with the thin PDMS film were immediately attached and heated at 120 °C for 4 h in an oven to complete the adhesion process. Finally PEEK tubes (0.75 mm i.d.,

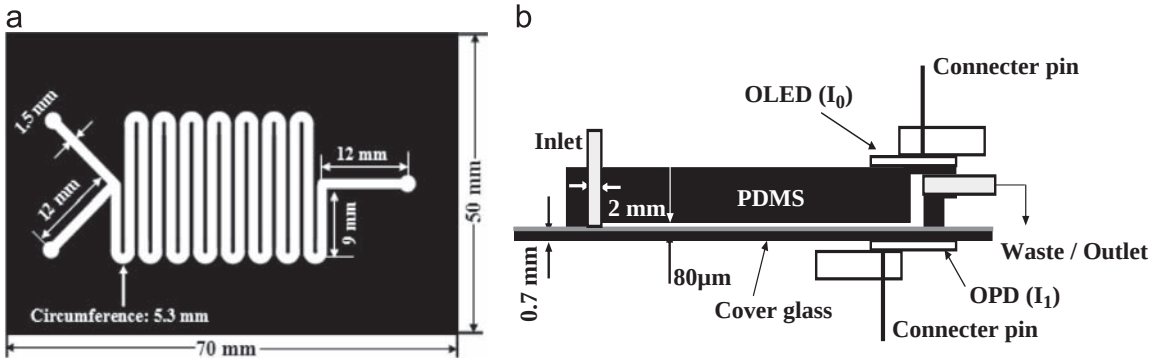

Fig. 2. (a) The top view of a microchip made by poly(dimethylsiloxane) (PDMS) with a U-turn shaped type microchannel and (b) the side view of the PDMS microchip equipped with a photometric detector assembled with an organic photodiode (OPD) and an organic light emitting diode (OLED). The length of the light pass of the flow cell is 5 mm.

1/16 in., o.d. 40 mm long) were mounted at the inlets and the outlet of the microchip with a silane-modified urethane resin adhesive (Epoclear, Konishi Co., Japan).

2.6. Characterizations of the present OLED and OPD and the experimental setup

The photoluminescence (PL) spectrum of the Eu^{3+} complex coated on a glass substrate was recorded using a spectrofluorometer (FP-6500, Jasco, Japan) at room temperature. The electroluminescence (EL) spectrum of the OLED was recorded using a multi-channel spectrometer (UBS2000, Ocean Optics). The current density (*J*)–voltage (*V*)–brightness (*B*) characteristics and external quantum efficiency (EQE) of the OLED were measured in ambient air with a semiconductor parameter analyzer (E5273A, Agilent) and an optical power meter (1930C, Newport).

The fabricated OPD was placed on a solar illumination stage and current-voltage curves (*JV* curves) in the dark and under simulated AM 1.5 solar illumination (Otento-Sun II, KP type, Bunkokeik, Japan) with a Xe-lamp (Model XCS-150A, Jasco, Japan) were obtained using a source meter (R6423, Advantest, Japan). The incident photo-to-current conversion efficiency (IPCE) was calculated from the photocurrent of the OPD, which was measured using the source meter under irradiation with monochromatic light, generated by a Xe lump source (SK-U1152X, Ushio Inc., Japan) and a monochrometer (SM-10P, Bunkokeiki, Japan) in the wavelength range from 400 nm to 800 nm at intervals of 10 nm. The incident light power of the monochromatic light was calibrated by using a Si photodiode (BS-520, Bunkokeiki, Japan) for calculating the conversion efficiency of the OPD.

In order to evaluate the performance of the photometric detector combined the OPD with the OLED, both of them were placed in the flow cell on the PDMS microchip, as described in the experimental section. The applied voltage to the OLED was changed from 5 V to 15 V and the photocurrents of the OPD were then measured for about 2 h while water was flowing through the microchannel of the PDMS microchip.

The schematic flow diagram for the photometric determination of phosphate using the optical detector assembled with the OPD and the OLED on the PDMS microchip is shown in Fig. 3. The OPD was directly placed on the PDMS microchip in order to adjust its detection area to the flow cell position in parallel to the PDMS microchip. The OLED was placed underneath the PDMS microchip in order to adjust its emission area to the flow cell to provide incident light for photometry. The photocurrent from the OPD for light transmitted through the flow cell was measured by a picoammeter (6485, Keithley Instruments, Inc., OH, USA). A DC voltage–current source meter (6146, DC Instruments, Inc., Japan) was used to supply current to the OLED. The intensity of the light

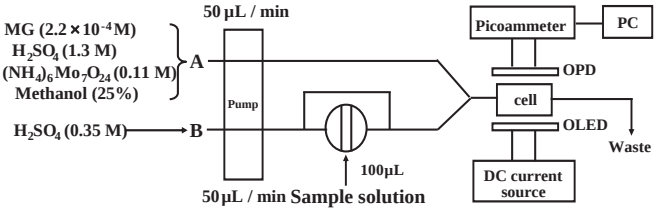

Fig. 3. Schematic flow diagram for the photometric flow injection determination of phosphate by the malachite green method (the flow cell is shown in Fig. 2, MG: malachite green).

emitted from the OLED was controlled by adjusting the applied voltage of the source meter.

2.7. Procedures for the determination of phosphate in a flow system

The flow system, shown in Fig. 3, consisted of two syringe pumps (NE-1002X, New Era Pump Systems Inc., NY, USA), one injector (9725, Rheodyne, CA, USA), the prepared PDMS microchip, the fabricated OLED and OPD, the DC voltage–current source and a picoammeter. Two black-color mask sheets with a pin hole of 2 mm in diameter were placed on the both side of a detection area of the flow cell on the PDMS microchip, and then the active pixel area of the OLED and the OPD were placed to adjust with the pin holes. The black mask sheets prevent the stray light from the OLED to the OPD. A MG–molybdate reagent solution containing 0.11 M ammonium molybdate, 2.2×10^{-4} M MG, and 1.3 M sulfuric acid was pumped using syringe pump 1 at a flow rate of 50 μL/min, and a 0.35 M sulfuric acid solution, used as a carrier solution, was pumped using syringe pump 2 at the same flow rate as the MG reagent solution. Sample solutions of phosphate at the different concentrations (0.04–0.2 ppm) were injected into the carrier stream from a sample injector with a 100 μL loop. The transmitted light from the OLED was detected by the OPD as a photocurrent in a peak-shaped signal.

3. Results and discussion

3.1. Fundamental performance of OLED and OPD

3.1.1. PL and EL characteristics of OLED

The current density (*J*)–voltage (*V*)–brightness (*B*) characteristics and the external quantum efficiency (EQE) of the OLED are described in the supplemental information together with Figs. S1 and S2. Fig. 4 shows the PL spectrum of a $Eu(DBM)_3$bath film coated on a glass substrate and the EL spectrum of an OLED, with a layered structure: ITO (110 nm)/α-NPD (30 nm)/CBP:Eu^{3+} (8 wt%

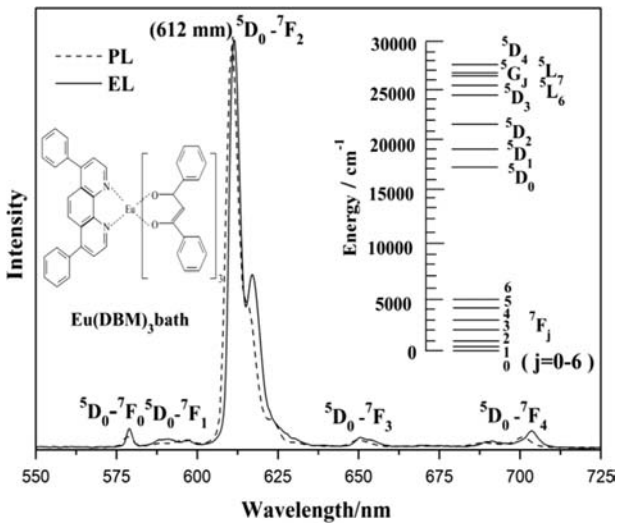

Fig. 4. PL spectrum of a Eu(DBM)$_3$bath film (thickness: ca 100 nm) coated on a glass substrate and the EL spectrum of an OLED based on a Eu(DBM)$_3$bath. Inset: molecular structure of Eu(DBM)$_3$bath and the partial energy level diagram of the free Eu^{3+} ion. The excitation wavelength of the PL is 254 nm. The structure of the OLED: ITO (110 nm)/α-NPD (30 nm)/CBP:Eu^{3+} (8 wt% Eu(DBM)$_3$bath doped in a CBP layer, 30 nm)/BCP (30 nm)/Alq_3 (25 nm)/MgAg (100 nm)/Ag (10 nm). The current density applied to the OLED is 1 mA/cm^2.

Eu(DBM)$_3$bath doped in a CBP layer, 30 nm)/BCP (30 nm)/Alq_3 (25 nm)/MgAg (100 nm)/Ag (10 nm). The EL spectrum of the OLED remained unchanged with the change in applied current density at 10 mA/cm^2 and 100 mA/cm^2. The inset shows the molecular structure of the Eu (DBM)$_3$bath complex and the energy level of free Eu^{3+} ions [29]. The Eu (DBM)$_3$bath was found to have excellent electron-transport properties in an earlier study [30–32]. From Fig. 4, the EL spectrum of the present OLED is almost the same as the PL spectrum of the europium complex, which is used as the emitting material of the OLED. This observation is common for many OLED emission spectra. The emission peaks are assigned based on the transition between energy levels shown in the figures. The main and strong emission was observed at 612 nm, which is a $^5D_0$–$^7F_1$ transition. The emission light of the OLED was red, as shown in Fig. 1(b). The Commission Internationale de L'Eclairage (CIE) coordinates of the EL of the Eu (DBM)$_3$bath-based device were calculated from the EL spectrum data to be $x=0.672$ and $y=0.335$, which are very close to the values of the National Television Standards Committee (NTSC) standard red of (0.67, 0.33) and the Phase Alternating Line (PAL) standard red of (0.64, 0.33). The only difference between the PL spectrum and the EL spectrum is that the PL spectrum at around at 612 nm is split into two peaks, at 612 nm and 616 nm in the EL spectrum. This phenomenon has been previously reported in the literature [33,34] and can be explained by the fact that the local symmetry of the crystal-field (CF) around the Eu^{3+} ion causes peak splitting. Namely, the observed split peaks are due to transitions to the $^7F_2$ multiplet, which is attributed to the CF acting on the Eu^{3+} ion in the complex. When a potential is applied to the OLED devices, the peak splitting becomes more prominent than the PL spectrum with the movement of electrons. The FWHM at 612 nm is 8 nm and the total peak width, including the split peak, is about 15 nm for the baseline of the spectrum.

3.1.2. *Incident photon to current conversion efficiency of OPD*

The current–voltage curves (*JV* curves) in the dark and under simulated AM 1.5 solar illumination of the OPD are described in the supplemental information together with Fig. S3. The incident photon-to-current conversion efficiency (IPCE) of the fabricated OPD is shown in Fig. S4, where a power of a standard light source was initially calibrated using the Si photodiode. As shown in Fig. S4, the maximum values of more than 25% of *IPCE* were achieved using the developed OPD at around 450 nm, which is due to the absorbance band of the C_{60} used for an accepter layer. Double peaks of the IPCE are observed at around 620 nm and 700 nm, which are due to the absorbance bands of the CuPc complex used as a donor layer. This IPCE spectrum indicates that the photosensitivity of the OPD to light in the wavelength range of around 600 nm to 700 nm is quite good. The latter conditions correspond to an absorbance spectrum of MG ($\lambda_{abs}=617$ nm) and the ion association complex of phosophomolybdate with MG ($\lambda_{abs}=640$ nm) (as shown in Fig. 6). The IPCE for the OPD is known to be governed by several factors. Since the diffusion length of the exiton is in the order of several nanometers, the charge carrier generated at the p-n junction interface is thought to affect the IPCE. Therefore the efficiency of absorbance of the organic layers of the OPD contributes to the IPCE. The data was shown in Fig. S4 suggests that the photocurrent mainly arises from C_{60} and CuPc. To study the effect of the thickness of the C_{60} and CuPc, we compared the fabricated OPD to a similar OPD reported in the literature [27]. A maximum IPCE of about 23% was obtained between 400 and 500 nm, which is lower than that obtained for the present OPD, which can be attributed to the thickness of the fabricated C_{60} layer, which was thicker (40 nm) than that reported in the literature (35 nm).

3.1.3. *Evaluation of light intensity of OLED as a light source and the photosensitivity of OPD as a photodetector*

The performance of the OPD as a phtodetector for the present work was evaluated by measuring the photocurrent when the light with the different powers from a conventional LED (maximum wavelength 630 nm) was irradiated to the OPD. The power of the light from the LED was determined preliminary by using a power meter (1918-C, Newport Co., CA, USA) by changing the applied current to the LED (0.01–0.1 mA) and the distance between the LED and the power meter or the LED (2–10 cm). As shown in Fig. 5(a), there was a linear relationship between the photocurrent of the OPD and the power of the light irradiated to the OPD.

The performance of the OLED as a light source for the present work was also evaluated by measuring the power of the emitted light from the OLED by the power meter at the constant distance between the power meter and the OLED. As a result, the relationship between the power of the OLED and the applied current to the OLED shown in Fig. 5(b) was obtained.

3.1.4. *Optimization of applied voltage to the OLED for detecting its light with the OPD*

When the OLED and the OPD were assembled into the flow cell, as shown in Fig. 6(a) as a photometric detector and water was then allowed to flow into the flow cell, the photocurrent of the OPD was monitored for about 10–50 min under the conditions where a constant voltage (5–15 V) was applied to the OLED. As shown in Fig. 6(b), when 5 V was applied to the OLED, no photocurrent in the OPD was observed. This observation is reasonable judging from the *J–V–B* characteristics of the OLED showed in Fig. S1, because of the turn on voltage of the OLED is 5.5 V. When the applied voltage was increased from 5 V to 15 V at ca 25 min intervals, the photocurrent of the OPD increased and a linear relationship between applied voltage and photocurrent was observed. However, when the applied voltage was as high as 15 V, the photocurrent gradually declined, reaching more than 85% of the initial photocurrent after about 25 min. This observation may be mainly due to the working current between the metal

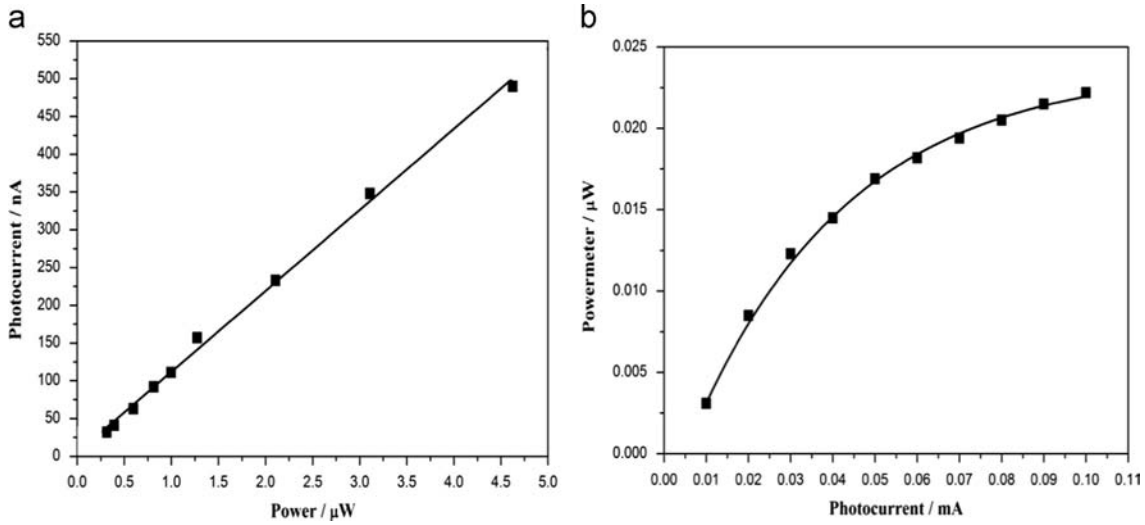

Fig. 5. (a) Relationship between the photocurrent of the present OPD and LED power measured by a power meter based on a silicon diode. The LED used for the light source has peak maxima of 630 nm (red). (b) Relationship between the given current of the present OLED and the power measured by a power meter based on a silicon diode.

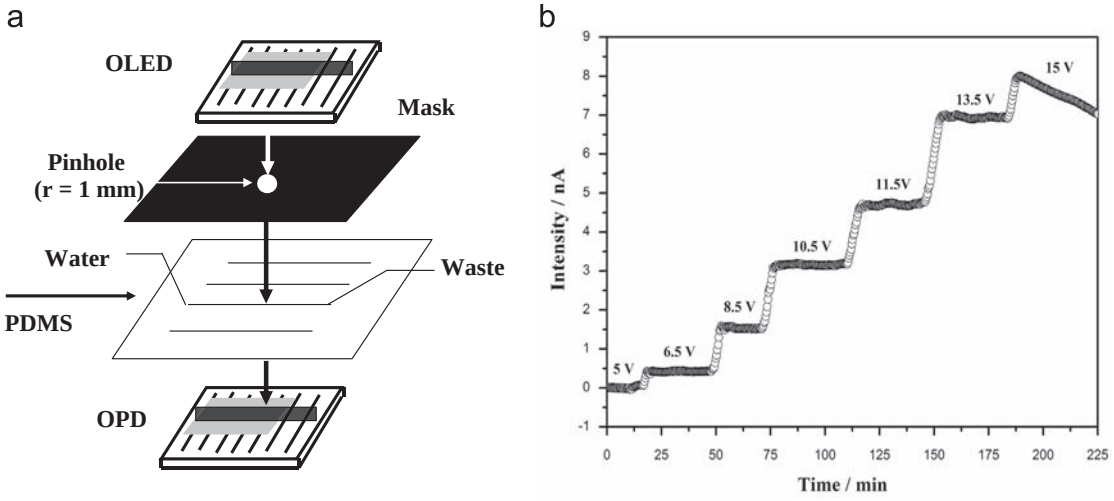

Fig. 6. (a) Experimental set up for evaluating the performance of a photometric detector assembled with the OPD and the OLED on a microchip and (b) the time-course of the photocurrent of the OPD for the emission light from the OLED at different applied voltages. The applied voltage to the OLED was increased from 5 V to 15 V every ca. 25 min. (Flow rate of water: 50 μL/min, the width, length and depth of the microchannel of the PDMS microchip are 3 mm, 5 cm, and 1 mm, respectively.)

cathode and the ITO anode of the OLED exceeding rated upper limit and excessive Joule heat generation would then lead to irreversible damage, as reported in the literature [24]. Indeed the OLED used in this experiment was no longer usable after this experiment. From Fig. 6(b), the applied voltages between 10 and 12 V appear to be the optimal operation voltage for the present OLED, because, if the applied voltage is too high, the OLED device can easily be broken, contrarily if the applied voltage is too low, the brightness of the light source is insufficient for photometric detection. An applied voltage of 10 V was used as the power supply for the OLED in the following experiments.

3.2. Performance of the OLED and the OPD for detecting MG absorbance

Fig. 7(a) and (b) shows the emission spectrum of the present OLED and the absorption spectrum of the MG solution, respectively. These spectra indicate that the maximum emission wavelength λ_{max} (612 nm) of the OLED is located almost the same wavelength of the maximum absorbance of the MG solution (615 nm). Prior to utilizing the OLED and the OPD as a photometric detector for the measurement of phosphate on a microchip, the photometric detector assembled with the OLED and the OPD was evaluated for detecting the absorbance of different concentrations of the MG solutions by a batch system using a quartz cell (1 cm path length). In this case, the OLED and the OPD were arranged in parallel through the quartz cell filled with the MG solutions. 10 V was applied to the OLED and the photocurrents of the OPD were measured using a picoammeter. As shown in Fig. 8(a). A 2.5 mL aliquot of the MG solution (0–8 μM) was placed in a quartz cell, the OLED and the OPD were facing each other, to permit the light axis through the quartz cell to be adjusted appropriately. In this case water was added to the quartz cell as a reference for the absorbance calculation. The time-course of the photocurrent of the OPD for different concentrations of MG solutions are shown in Fig. 8(b). The response of the OPD was rapid when a voltage of 10V was applied to the OLED. The fluctuation of the photocurrent was $\pm$0.02 nA for 2 min. The absorbance of the MG solution was

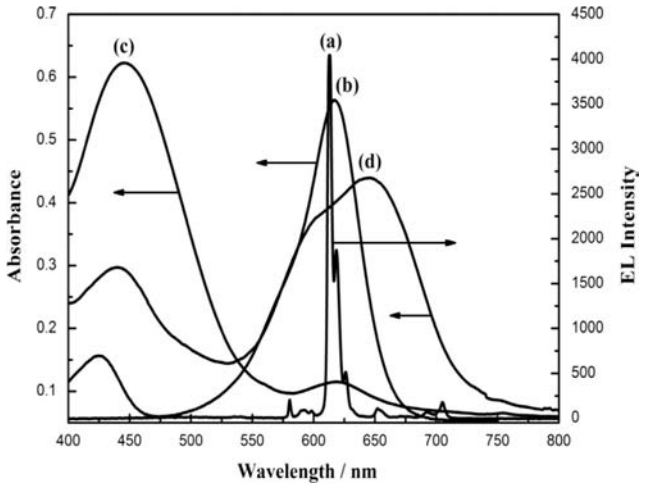

Fig. 7. (a) Emission spectrum (λ_{max}=612 nm) from the OLED, (b) absorption spectrum (λ_{max}=615 nm) of a 5 μM MG solution, (c) absorption spectrum of a 25% methanol water mixture containing 2.2×10^{-4} M MG solution and 0.11 M ammonium molybdate (λ_{max}=450 nm, abbreviated as MG reagent solution) and (d) absorption spectrum of a 25% methanol water mixture containing 2.2×10^{-4} M MG solution and 0.11 M ammonium molybdate and 0.14 ppm phosphate (λ_{max}= 640 nm).

calculated from the photocurrent of the OPD using the following equation based on the Lambert–Beer's law.

$$A\ (\text{absorbance}) = -\log\frac{I_1}{I_0} \quad (1)$$

where I_1=photocurrent for the MG solutions, I_0=photocurrent for water. A good linear relationship between absorbance and the concentration of the MG solutions was obtained with a correlation coefficient of 0.9977, as shown in Fig. 8(c). The molar absorptivitiy coefficient of the MG solution calculated from the calibration line in Fig. 8(b) is $9.78\times10^4\ M^{-1}\ cm^{-1}$, which is in good agreement with the reported value, $9.25\times10^4\ M^{-1}\ cm^{-1}$ [35]. This result indicates that the combination of the OPD and the OLED can function as a good photometric detector for the sensitive detection of MG solutions.

3.3. Phosphate determination on a microchip by using the photometric detector assembled with the OLED and the OPD

3.3.1. Suitability of OPD and OLED for the malachite green method for the determination of phosphate

The spectrophotometric determination of phosphate based on the molybdenum yellow method, in which phosphate reacts with ammonium molybdate to form a molybdenum phosphate complex, is well known. In order to enhance the sensitivity of this method, Motomizu et al. proposed a sensitive method (malachite green method) by taking advantage of an ion association reaction of MG with molybdenum phosphate [36] and their proposed method has been applied to flow injection analysis [37–39]. Namely the following reaction was used after the formation of molybdenum phosphate in an acidic medium at low pH.

$$H_3PMo_{12}O_{40}(\text{Yellowcolor}) + HMG^{2+}(\text{Yellowcolor},\ \lambda_{max} = 446\ \text{nm}) \rightarrow (MG^{+})(H_2PMo_{12}O_{40}^{-})(\text{Greencolor},\ \lambda_{max} = 640\ \text{nm}) + 2H^{+} \quad (2)$$

To stabilize the ion associate in the aqueous solution, methanol is added to the reaction solution. Another advantage of the method based on the formation of the ion associate with MG is that the color-forming reaction is fast and no heating is needed, as shown in Fig. 7(c) and (d) shows absorption spectra of the MG

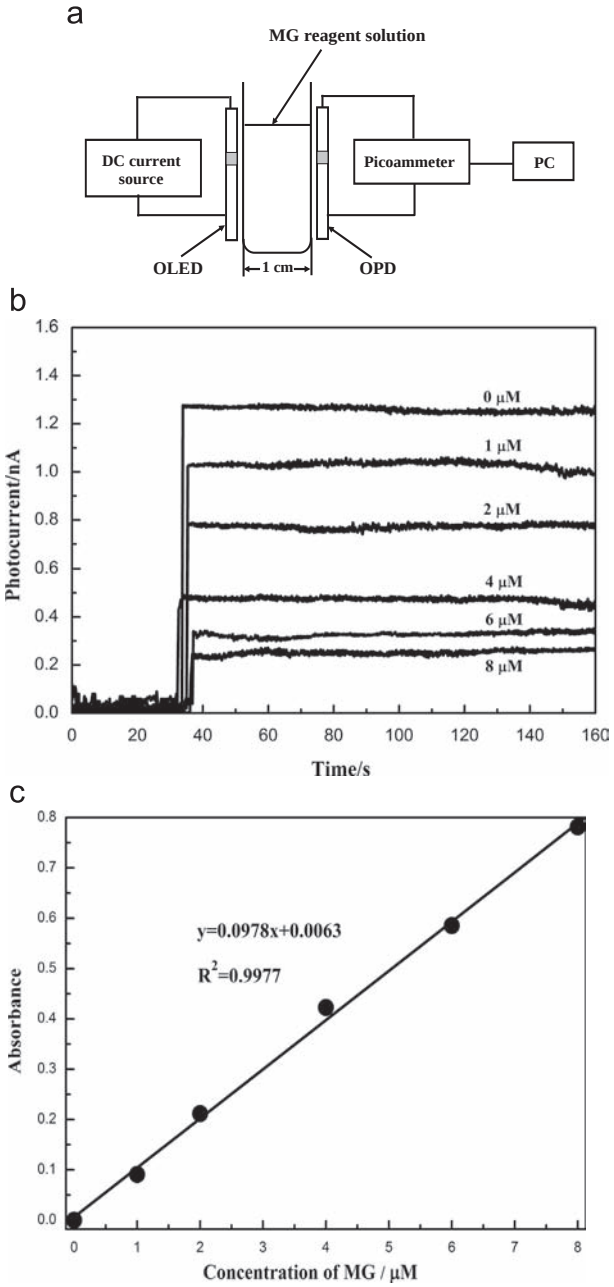

Fig. 8. (a) Experiment setup for measurements of the absorbance of a malachite green (MG) solution in a batch system, (b) the time-course of the photocurrent of the OPD for MG solutions at different concentrations during irradiation of the light from the OLED (applied voltage is 10 V) and (c) calibration plot for the MG solutions. The absorbance of the MG solutions was calculated from the photocurrent as a reference of the photocurrent observed for water.

reagent solution (a mixture of the MG solution and molybdenum ammonium) and a solution of the ion associate of MG with molybdenum phosphate, respectively. This indicates that after phosphate is added to the MG reagent solution, the maximum wavelength of the MG reagent observed at 450 nm is shifted to the maximum absorbance wavelength at 640 nm. The absorbance spectrum of the ion associate of the MG–molybdenum phosphate (in the range ca. 600–650 nm) is efficiently overlapped with the emission spectrum of the OLED. As shown in Fig. S3, the OPD shows sensitivity to the emission light of the OLED (λ_{max}= 612 nm) because the OPD has a broadband photo response from 600 to 700 nm. This means that the photometric detector

combined with the OLED and the OPD is suitable for the determination of phosphate based on the malachite green method.

3.3.2. Optimization of flow conditions and determination of phosphate

A flow system for the determination of phosphate shown in Fig. 3 was constructed according to the report by Motomizu et al. [36]. The concentration of the reagents of MG–molybdate and the carrier solution of hydrogen sulfate are adopted from the report. In order to optimize the flow condition, the flow rate was changed from 20 to 200 μL/min and the sample volume was changed from 20 to 150 μL. The results are shown in Fig. 9. As a result, the flow rates of the reagent solution and the carrier solution and the sample volume were selected as 50 μL/min and 100 μL, respectively, as shown in Fig. 3. Fig. 10(a) shows the photocurrent peak signals from the OPD for three injections of the same sample concentration. In this case, a voltage of 10 V was applied to the OLED. As shown in Fig. 10(a), the reproducibility of the peak height for the three injections is in the acceptable range. The noise level of the photocurrent of the OPD for the baseline signal was

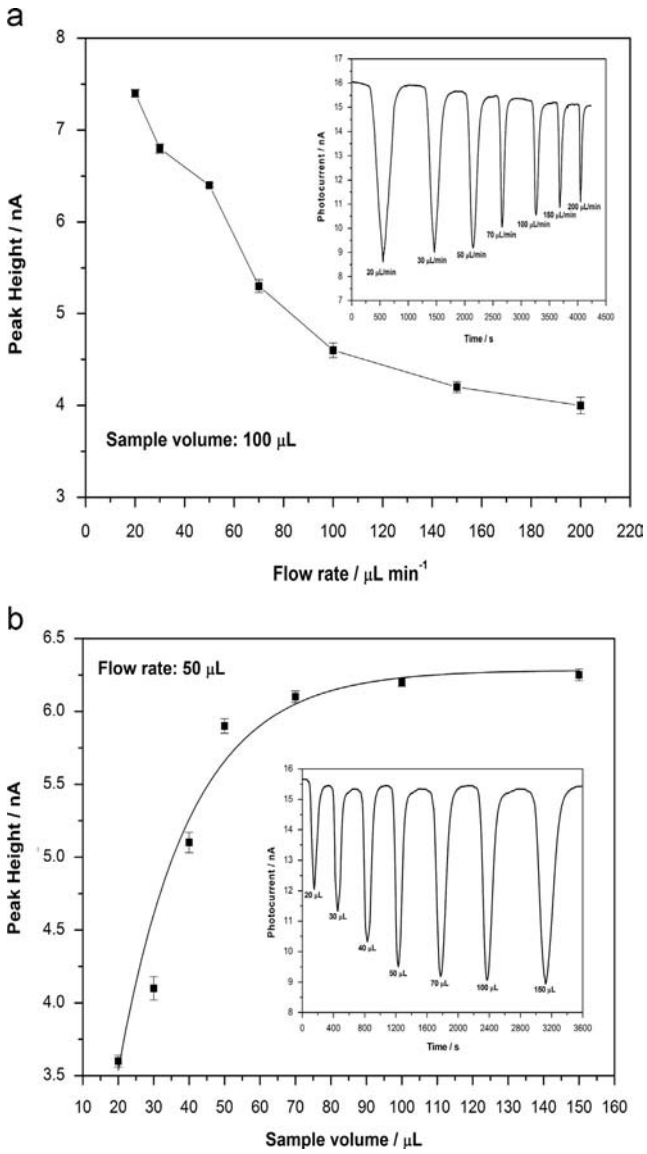

Fig. 9. (a) Effect of the flow rate on the peak height and (b) effect of sample volume on the peak height. The concentration of sample is 0.20 ppm. The corresponding peaks based on absorbance are shown in the inset.

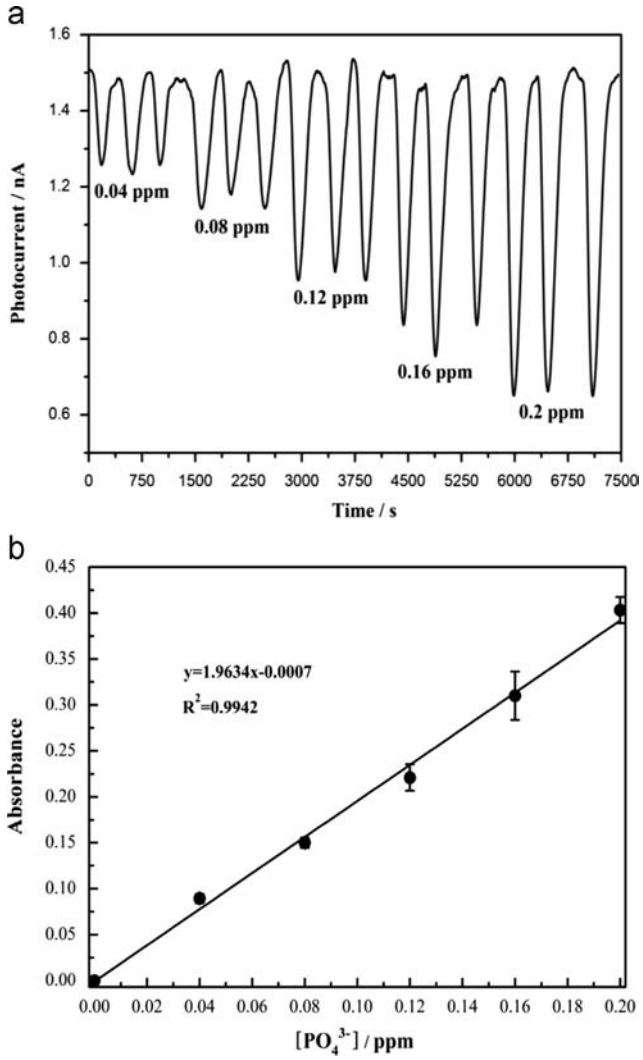

Fig. 10. (a) The output photocurrent signals of the OPD for different concentrations of phosphate solutions by the flow injection system, (b) the calibration line calculated from (a). The error bars represent the standard deviations for three times measurements. The applied voltage to the OLED was 10 V. The other flow conditions are the same as shown in Fig. 3.

± 0.015 nA. The sampling rate of this method was ca 10 h^{-1}. According to Eq. (1) and Fig. 10(b), the absorbance calculated from the photocurrent signal is plotted against the concentration of phosphate, as shown in Fig. 10(b). A good linear relationship between the absorbance and the phosphate concentration was observed, with a correlation factor of 0.9942. The lower detection limit defined as $S/N=3$ is ca. 0.02 ppm for phosphate using the present method. The comparison of the lower detection limit of our method with the other relevant method is shown in Table S1.

3.4. Application of the present method to river water samples

In order to apply the developed analytical system for determining phosphate levels in actual water samples, we collected samples of water from a river in Fukuoka city at distances of 300 m, 2100 m and 3000 m from the seashore. After obtaining the samples, they were filtrated through a membrane filter with the pore size of 0.45 μm and stored in a refrigerator at 4 °C. 22.5 mL aliquots of these samples were spiked by adding 2.5 mL of the 0.8 ppm standard phosphate solution, and the recoveries of phosphate added to the sample were measured by the procedure described in section of 2.7. In this case, the FIA system shown in

Table 1
Application of the photometric detector to the determination of phosphate in river water samples.

Sample	Added (ppm)	Found (ppm)	R.S.D, % (n=5)	Recovery, % (n=5)
River water 1	0.00	0.00	–	–
	0.080	0.076	4.0	99.3
River water 2	0.00	0.00	–	–
	0.080	0.076	4.7	98.4
River water 3	0.00	0.00	–	–
	0.080	0.075	3.9	97.5

Fig. 3 was applied to the determination of phosphate levels in river water samples. When we attempted to measure the concentration of phosphate in the river water samples in a preliminary experiment, we were unfortunately not able to detect phosphate, we spiked the river water sample with the standard phosphate solution at 0.08 ppm. Recovery tests were then carried out for the spiked samples using the FIA system and the results are listed in Table 1. Recoveries of 97–99% were obtained for the river water samples. The good recovery of the present method comes from the high selectivity of the reaction of molybdate with phosphate, which is used as the methods of the molybdenum blue and molybdenum yellow [40,41]. This indicates that the performance of the photometric detector assembled with the OPD and the OLED is similar to that for a conventional photometric detector.

4. Conclusions

In this work, we report on the development of a photometric detector assembled with an OLED and an OPD for the photometric flow injection determination of phosphate based on the malachite green method on a microchip. The performance of the photometric detector was evaluated by measuring the molar absorptivity of a MG solution and the result was in good accordance with the reported value. Under the optimized flow conditions for the determination of phosphate, a linear calibration line between the peak height based on an absorbance unit and the concentration of phosphate was observed in the range 0–0.2 ppm with the regression coefficient of 0.9942 and the detection limit of 0.02 ppm was obtained. In addition, we successful applied the present flow system with the photometric detector to the determination of phosphate in river water samples. The present photometric detector was assembled on a microchip because the shape of the OLED and the OPD was flat, thus making it suitable for insertion on a flat shaped microchip. In order to fabricate an OLED as a suitable light source for the malachite green method, a rare earth complex, $Eu(DBM)_3$bath, doped CBP was used as the emitting layer, since it provides a narrow emission spectrum (FWHM is ca. 10 nm). This type of light source is very suitable for the selective determination of analytes, because it is not necessary to use a grating, a monochromater or a band pass filter for the separation of a wavelength from the broadband light source. Especially for case of a fluorometric determination, such a type of sharp a light source has an advantage for the selective excitation of an analyte. We are currently attempting to fabricate an optical sensing system combining a sharp emission green OLED based on another type of rare earth complex with the OPD on a microchip for fluorescence detection. One of drawbacks of the OLED is a limited life time due to oxygen and humidity and fluctuation of the light intensity for long-life and stable light source for the photometric system. In the future it will be possible to fabricate optical devices such as the OPD and the OLED directly on a microchip by improving and enhancing the life time and stability.

ABSTRACT

In this study, a fast and simple approach to directly determinate lead in water samples by a low power dielectric barrier discharge (DBD) excitation source was developed using tungsten coil electro-thermal vaporization (WC ETV) for liquid microsample introduction. A 20 μL sample was dropped onto the WC, and then the sample went through the drying, pyrolysis, subsequently the analyte was vaporized and swept directly into the dielectric barrier discharge micro-plasma for emission, and the whole process took only 3 min. The effects of operating parameters such as plasma gas flow rate, plasma input voltage, pyrolysis current, vaporization current and interferences from concomitant elements were investigated. Under the optimal conditions, the limit of detection (LODs, 3σ) was calculated to be 7.7 μg L^{-1}. Repeatability, expressed as the relative standard deviation of the spectral peak height, was 4.6% ($n=11$) for 0.1 mg L^{-1} lead standard solution. The proposed method was successfully applied to the determinations of Pb in water samples.

1. Introduction

The contamination of lead in water has become a problem of global concern [1]. Of all the heavy metals, Pb(II) is important to consider in terms of food chain contamination because of its toxicity [2,3]. Pb(II) ions causes both acute and chronic poisoning, exhibits adverse effects on the kidney, liver, heart, vascular and immune system. Moreover, Pb(II) exposure causes chromosome aberration, skin allergy, cancer and birth defects [4,5]. Hence, there is a great demand to develop a simple and reliable method for the determination of the level of lead in water on-site.

In this perspective a number of methods have been developed for the determination of Pb(II) the well-known high-performance spectrometric instruments, such as atomic absorption spectrometry (AAS) [6], atomic fluorescence spectrometry (AFS) [7], inductively coupled plasma atomic emission spectrometry (ICP-AES) [8] and inductively coupled plasma mass spectrometry (ICP–MS) [9] can perform fast, sensitive, and accurate lead determinations. However, these methods are generally performed at laboratories, requiring complicated equipment (e.g., high power, large inert or special gases, high vacuum). These disadvantages limit their applications primarily to laboratory settings, and prohibit their use for rapid analyses under field conditions. Therefore, it is of much significance to develop compact and low-cost instruments [10], for in situ monitoring of Pb contamination in water.

In recent years micro-plasmas [11–15], embedded in portable analytical instrumentation, such as corona discharge, glow discharge, capacitively coupled plasma, and dielectric barrier discharge (DBD) [16] received increased attention for the development of portable instruments for elemental analysis because of their small size, low power consumption, cost effectiveness, and reduced inert gas requirement. The unique advantages of DBD include simple construction, low temperature and power consumption, and atmospheric operation [14]. However, direct introduction of liquid sample into the DBD micro-plasma for analytical atomic spectrometry can be a problem for its lowered excitation capability or can even extinguish it. Tombrink et al. [17] first introduced direct liquid analysis by using a capillary DBD, and Zhu et al. [18] developed a liquid-film DBD (LFDBD). In their studies, they solved the liquid sampling problem to some extent. Nevertheless, residual or concomitant moisture and matrix from liquid sample introduction still restrict the analytical performance of DBD micro-plasma for AES. The vapor generation (cold vapor and hydride generation) was mostly employed in DBD-AES for the sample introduction since it improves the sample introduction efficiency and reduces the introduction of water. However, only a limited number of elements is applicable to

CVG and the reported research mainly focused on mercury, arsenic and some nonmetals [11,15,19].

As well known, electro-thermal vaporization (ETV) has long been considered as an excellent sample introduction technique for analytical atomic spectrometry. It offers several advantages, including improved sample introduction efficiency, efficient separation matrix, requirement of small amounts of sample, and the capability to perform direct analysis of slurries and solids [20–27]. Most works on ETV employ graphite furnaces as electro-thermal vaporizers [22,24,26–28]. However, it requires heavy power supplies and water cooling systems, so they are seldom used in portable instrumentation [29]. A simpler and less expensive alternative is to use tungsten coil, which can be extracted from commercially available stage light bulbs. Because of their low mass and the specific heat of tungsten, tungsten coils (WC) present a faster heating–cooling regimen, which requires no complex bulky chillers. In addition, a simple low power source is enough to efficiently vaporize samples. Another advantage of WC vaporizers when compared to graphite furnaces is that carbon species are not formed from atomizer surface vaporization, which minimizes the formation of carbides [30,31]. In the past studies, tungsten coil has been widely used as atomizers in atomic absorption and atomic fluorescence spectrometry [32,33]. Meanwhile, it has also been employed as electro-thermal vaporizers in atomic emission [10,34,35], as for inductively coupled plasma [21,36] and microplasma [37–39]. For years, to the best of our knowledge, there are no reports on the hyphenation of ETV with DBD microplasma emission source. Until more recently, Hou et al. [40] firstly coupled W-coil ETV with DBD-AES and applied it to the determination of Hg, Zn, and Cd.

In the present study, the feasibility of coupling W-coil ETV with DBD-AES for directly Pb determination was demonstrated. A tungsten coil extracted from commercially available stage light bulb was used to vaporize samples without any previous sample treatment. The analyte vaporized from the tungsten coil ETV was transported to the DBD source for excitation, and then the lead could be measured by atomic emission spectrometry. Several experimental parameters were optimized, and analytical figures of merit were evaluated. Both the WC ETV device and DBD system are simple, easily fabricated, and low cost of operation, it provided a possibility to design a portable, miniature, and mobile AES instrument, especially for field analysis of Pb with low-power supply.

2. Experimental

2.1. Instrumentation

The W-coil ETV–DBD-AES system consisted of an ETV generation unit for sample introduction and a DBD atomic emission system for Pb excitation. For ETV unit, the tungsten filament extracted from a commercially available halogen display lamp

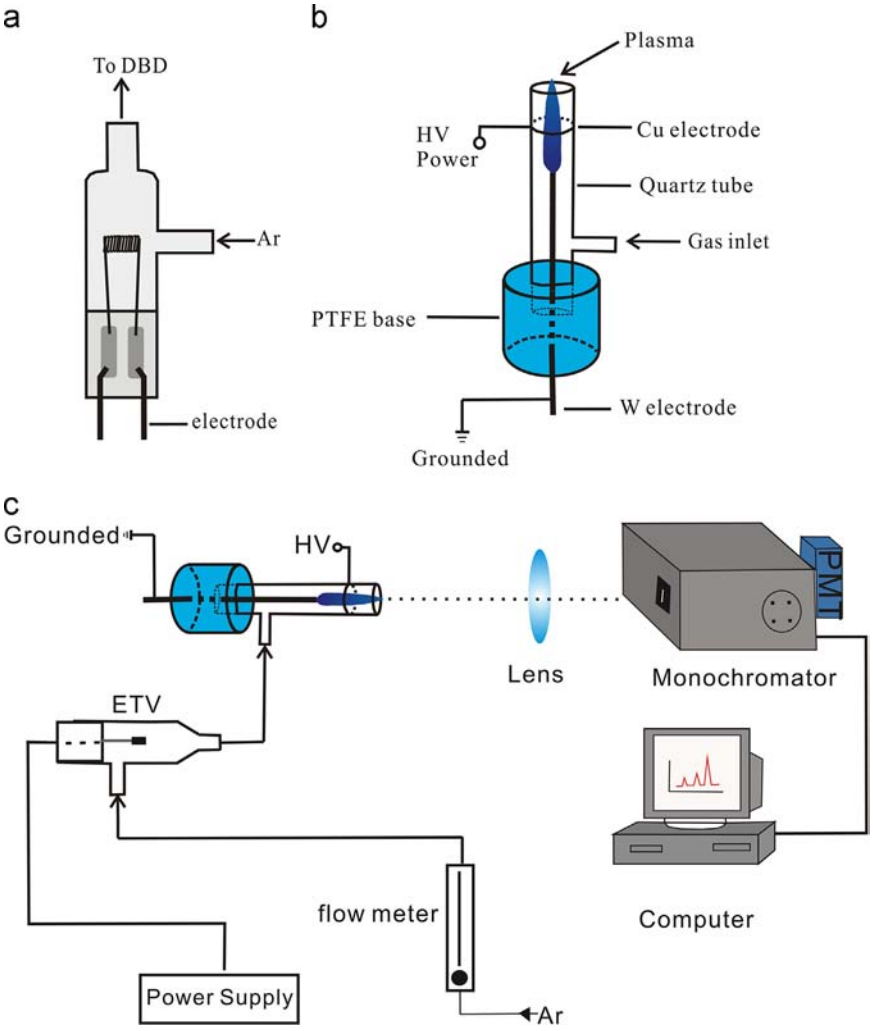

Fig. 1. The schematic diagram of the equipment. Vaporizer (a) and the DBD setup (b) and the whole instrument (c).

(G6.35, 24V, 300W, MINGAN, Jiangsu. China) was used as the vaporizer. The filament was coiled in ten turns when viewing from the side, the turns were 3 mm high and together they occupy a width of 6 mm. The glass envelope was carefully installed two branch pipes, argon gas flowed from lateral branch pipe (23 mm × 3 mm i.d., 5 mm o.d.) and swept the analyte into DBD plasma from the top of branch pipe (14 mm × 5 mm i.d., 7 mm o.d.) Fig. 1a provided the schematic diagram of the vaporizer. A commercial computer controlled DC power supply (ATTEN PPS3205T-3S., Shenzhen. China) was used as a programmable power supply for the W-coil ETV. A 15 cm polytetrafluoroethylene (PTFE) tube (1.2 mm i.d.) connected the ETV cell to the DBD instrument and served as the interface between the ETV cell and DBD instrument.

As the center unit of the entire system, the homemade cylindrical DBD emission source mainly consisted of a quartz tube, a tungsten rod electrode and a copper coil electrode. The 65 mm long quartz tube (3 mm inner diameter, 5 mm outer diameter) was mounted on a PTFE base. A tungsten rod (1 mm diameter) centered at the axis of quartz tube acted as the grounded electrode. Another copper coil electrode (HV) was wrapped tightly outside the quartz tube, 15 mm away from the top of the tube. The distance between the tip of the tungsten electrode and the copper coil electrode was about 5 mm. Fig. 1b provides the schematic diagram of the DBD setup. When an ac high voltage was applied to the electrodes, discharge plasma was self-ignited upon the tip of the tungsten rod, even appeared outside the quartz tube. The ac high voltage was provided by a CTP-2000 K discharge power supply (Suman Elec-tronics Co., Ltd., Nanjing, China). The input voltage for the discharge power supply was controlled by a TDGC2-1 voltage regulator (CHINT Electrics Co., Ltd., China). The discharge gas and sample flowed into the quartz tube through the sample introduction port at the bottom. Vaporized lead originating from electro-thermal evaporation was excited in the plasma. The emission signal was measured along the axial direction through the center of the quartz tube. The discharge was imaged 2.5:1 with a fused-silica lens (focal length = 100 mm) to the entrance slit of a monochromator (Zolix Instruments, Omni-λ5008, focal length = 500 mm) with a 1200 grooves mm^{-1} holographic grating. The monochromator is supplied with slits of 14 mm height, whose width could be adjusted from 10 μm to 3 mm. A PMTH-S1-CR131A photomultiplier tube was used as the detector.

The whole schematic diagram of the W-coil ETV–DBD plasma AES instrument was showed in Fig. 1c and the optimized operating parameters were given in Table 1. Inductively coupled plasma mass spectrometry (PerkinElmer Instrument., ELAN DRC-e., America.) was used to determine the groundwater samples to validate our results. The operating parameters of ICP–MS were also listed in Table 1.

2.2. Reagents and samples

The stock standard solution of lead (1000 mg L^{-1}) was purchased from National Analysis Center for Iron and Steel (Beijing, China). Working solutions were prepared by serial dilution of the stock solutions and stabilized in 0.5% HNO_3. Single-element standard solutions of Ba^{2+}, Ca^{2+}, Cd^{2+}, Co^{2+}, Cr^{3+}, Cu^{2+}, Fe^{3+}, K^{+}, Mg^{2+}, Mn^{2+}, Na^{+} and Zn^{2+} were used to assess the interferences from individual metals present at concentrations of 50 mg L^{-1} and 20 mg L^{-1} in solutions of 0.1 mg L^{-1} lead. All chemicals were analytical or even higher grade. Argon with a purity of 99.999% was used. Ultrapure water (18.2 MΩ cm^{-1}, resistivity) was obtained from a water purification system (9000502, Labconco water props, USA) and used for preparation of all solutions.

To obtain reliable analytical results, two reference solutions of water (GSB 07-1183-2000 and GBW (E) 080399) were used to check accuracy of the proposed method. Five groundwater samples (pH = 7.12–7.26) were acidified to a final HNO_3 concentration of 0.5%. In order to make the samples more homogeneous, 5 min ultrasonic vibration was used.

2.3. Experimental procedure

A 20-μL of a sample solution containing lead was deposited directly onto the W-coil with an Eppendorf Research Pipette. As the ETV program shown in Table 2, the tungsten coil was then heated to remove the solvent. As the liquid dried, the resistance of the W-coil increased, so progressively smaller currents were used to gradually dry the sample in order to avoid the loss of analytes. After the dry step, 5 s of pyrolysis step at 2.7 A was employed to eliminate the sample matrix, then 20-s cooling interval (0 current) for allowing the W-coil return to room temperature. This ensured that the high temperature heating step was most reproducible. During the cooling time, the catheter was connected with the DBD from the top of branch pipe of ETV, and then ignites the DBD plasma. The high temperature step was achieved 6.0 A applied for 3 s to vaporize the analyte. The vaporized lead was transported into the DBD plasma through the PTFE tubing by the Ar carrier gas stream. During this step, the transient emission signal was recorded, and the peak height was measured. A 20-s cooling step was employed at the end, to ensure that the W-coil was ready for the next injection of sample. The optimized experimental conditions are summarized in Table 2. Some of the optimum operating conditions given in Table 2 will be discussed below.

3. Results and discussion

3.1. Optimization of experimental conditions

In order to introduce vaporized lead into DBD efficiently, the interface between DBD and W-coil should be as short as possible. However, we found that the high voltage of the DBD would disturb the ETV if the W-coil was placed too close to the DBD. Thus, 15 cm length of connection tube was adopted after optimization. The effect of monochromator slit widths on the measurement of Pb emission was investigated. Because the 0.4 mm slit width gave the greatest signal-to-background intensity ratios (SBR), it was

Table 1
The optimized operating parameters of WC–ETV–DBD-AES and ICP–MS.

W Coil–ETV–DBD-AES		ICP–MS	
Negative high voltage of PMT (V)	850	Mass (Pb)	208
Integration time of PMT (ms)	50	RF power (W)	1100
Slit width of monochromator (mm)	0.4	Plasma gas flow rate (L min^{-1})	15
Wavelength (nm)	368.3	Auxiliary gas flow rate (L min^{-1})	1.2

selected in the whole experiments. Subsequently, several important parameters such as the flow rate of the Ar carrier gas, input voltage, pyrolysis current and vaporization current were evaluated by a univariate approach.

3.1.1. Effect of Ar carrier gas flow rate

In this system, the working gas plays three important roles: protecting tungsten filament from oxidation, transporting the vaporized analyte from the W-coil ETV to the DBD plasma and supporting the discharge. Low argon flow rate may lead to analyte loss during the transportation, while high argon flow rate results in short residence time of atoms in the DBD thus short time for excitation and measurements. In our study, Pb transient atomic emission signal (at 368.3 nm) generally presented asymmetric, irreproducible, and sometimes double-peaked, at an argon flow rate below 400 mL min^{-1}. The intensity of atomic emission for Pb increased sharply when argon flow rate increased from 400 mL min^{-1} to 600 mL min^{-1} and then began to decrease. Hence, an argon flow rate of 600 mL min^{-1} was selected for Pb.

3.1.2. Effect of input voltage of DBD

A voltage regulator was applied to control the input voltage for the discharge power supply. The impacts of the input voltage on the response signal intensity was studied. It was observed that when the voltage got 23 V the net Pb emission peak height signals was almost unchanged and signal to background ratio obtained the maximum. Finally 23 V was employed as the optimum input voltage in the subsequent studies.

3.1.3. Effect of pyrolysis current

In a typical heating program for the electro-thermal vaporization, a first drying step and a subsequent pyrolysis step were commonly used for removing the solvent and matrix from the sample, ideally without any analyte loss. As well known, higher current may cause serve analyte loss due to higher temperature, while lower current could not eliminate the solvent and matrix thoroughly. The effect of pyrolysis current was evaluated from 2.5 A to 2.9 A, and the result was shown in Fig. 2. The maximum intensity was obtained at 2.7 A, thus pyrolysis current of 2.7 A was selected in the subsequent study.

3.1.4. Effect of vaporization current

The vaporization current, responding to the temperature of the W-coil, was an essential factor for the vaporization. Analyte on the W-coil was released during the vaporization step, so the vaporization current significantly influenced the sample introduction efficiency. The effect of vaporization current from 4.5 A to 7.0 A on the DBD-AES responses of Pb were summarized in Fig. 3. No measurable signal from Pb was observed when current was less than 4.0 A, which because no analyte was released from the W-coil for the low temperature. The maximum responses were obtained

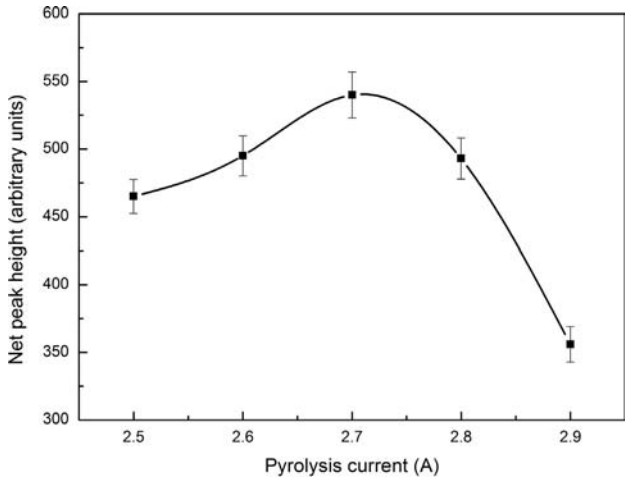

Fig. 2. Effect of the pyrolysis current (n=3). Experimental details: sampling volume, 20 μL; Pb concentration, 0.2 mg L^{-1}.

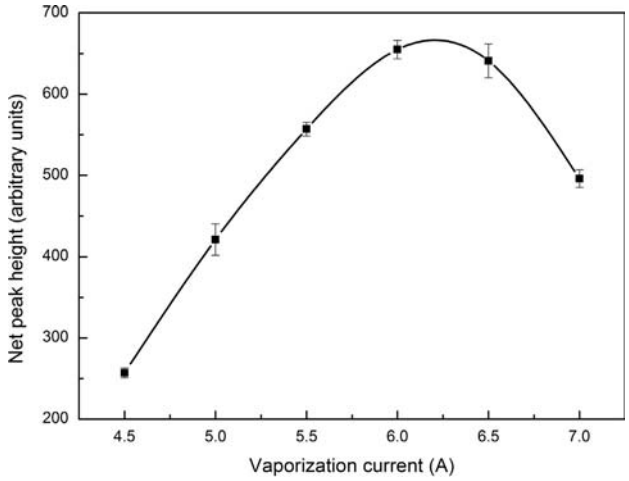

Fig. 3. Effect of the vaporization current (n=3). Experimental details: sampling volume, 20 μL; Pb concentration, 0.2 mg L^{-1}.

at 6 A. Therefore, 6 A was selected as the vaporization current for detection of Pb.

3.2. Interference study

In a ETV process, several metal ions may be simultaneously evaporated to their metallic states or colloidal forms, which covered the analyte to cause serious interferences [33]. To evaluate the analytical applicability of the proposed technique, the interferences caused by a series of metal elements including Ba^{2+}, Ca^{2+}, Cd^{2+}, Co^{2+}, Cr^{3+}, Cu^{2+}, Fe^{3+}, K^{+}, Mg^{2+}, Mn^{2+}, Na^{+} and Zn^{2+} in determining 0.1 mg L^{-1} lead were examined using WC–ETV–DBD-AES method and the results were summarized in Table 3. It is clear that there is no significant interference from these studied ions at concentrations of 20 mg L^{-1} or 50 mg L^{-1}. However, depression effects were observed for Na^{+}, Zn^{2+} or Cd^{2+} at concentrations of 200 mg L^{-1}. The interference mechanism is at present unclear. It indicated that the proposed method could be used for determination of trace lead in water sample almost free of interference from the complex matrix.

3.3. Analytical figures of merit

Under the optimized operating conditions, analytical working graphs were obtained for lead at 368.3 nm by ETV–DBD-AES. The

linearity of the calibration curve was examined by detecting of a series of standard solutions with concentrations ranging from 25 μg L^{-1} to 500 μg L^{-1}, which provided linear correlation coefficients (R) 0.9989 (Fig. 4). The limits of determination (LODs), calculated using the definition $3\sigma/S$ (σ is the standard deviation of 11 measurements of the blank and S is the slope of the calibration curve), was calculated to be 7.7 μg L^{-1}. Since only 20 μL sample volume was injected, the absolute LODs (equivalent to the absolute mass of the analyte) was 154 pg. The relative standard deviation of the spectral peak height was 4.6% ($n=11$) for 0.1 mg L^{-1} lead standard solution. All these results indicated that our proposed method has good sensitivity and repeatability and it could be used for the direct measurement of Pb in water samples.

Table 3
Recovery of Pb in the presence of metal ion interferences (Pb concentration: 0.1 mg L^{-1}, $n=3$).

Element	[M]/[Pb^{2+}]*	Recovery (%)	[M]/[Pb^{2+}]*	Recovery (%)
K^{+}	500	97.4 ± 3.3	2000	94.7 ± 2.0
Ca^{2+}	500	100.5 ± 6.2	2000	98.8 ± 5.4
Na^{+}	500	99.4 ± 5.3	2000	79.8 ± 7.4
Mg^{2+}	500	102.8 ± 3.5	2000	96.4 ± 2.3
Ba^{2+}	200	98.1 ± 4.4	2000	103.7 ± 4.9
Cd^{2+}	200	100.7 ± 7.6	2000	90.3 ± 3.7
Co^{2+}	200	98.4 ± 3.8	2000	96.3 ± 5.3
Cr^{3+}	200	97.3 ± 7.8	2000	97.8 ± 4.6
Cu^{2+}	200	105.5 ± 3.7	2000	99.2 ± 1.6
Fe^{3+}	200	103.6 ± 3.4	2000	96.2 ± 2.8
Mn^{2+}	200	102.8 ± 6.1	2000	99.4 ± 4.1
Zn^{2+}	200	94.8 ± 2.9	2000	88.2 ± 4.8

3.4. Real sample analysis

To validate the accuracy of the proposed method for water sample analysis, two reference solutions of water (GSB 07-1183-2000 and GBW (E) 080399) were analyzed with analytical results listed in Table 4. The t-test showed that there was no significant difference between the analytical results obtained by the proposed method and the certified value at the confidence level of 95%. Moreover, the proposed method was applied to the analysis of five groundwater samples. We also compared the results with those of the same samples determined from ICP–MS. According to the F-test, the F-statistics values of five sets of data are less than 10.00, and when the confidence level in 95%, $F=19.00$. Therefore, there was no significant difference between the analytical results obtained by the proposed method and ICP–MS at the confidence level of 95%. All the results indicated that our proposed method can be used for the determination of water sample.

4. Conclusion

A sensitive, simple and cost-effective method for determination of lead in water samples was developed. The proposed cylindrical DBD plasma could be readily coupled to tungsten coil electrothermal vaporization and the plasma source could excite lead

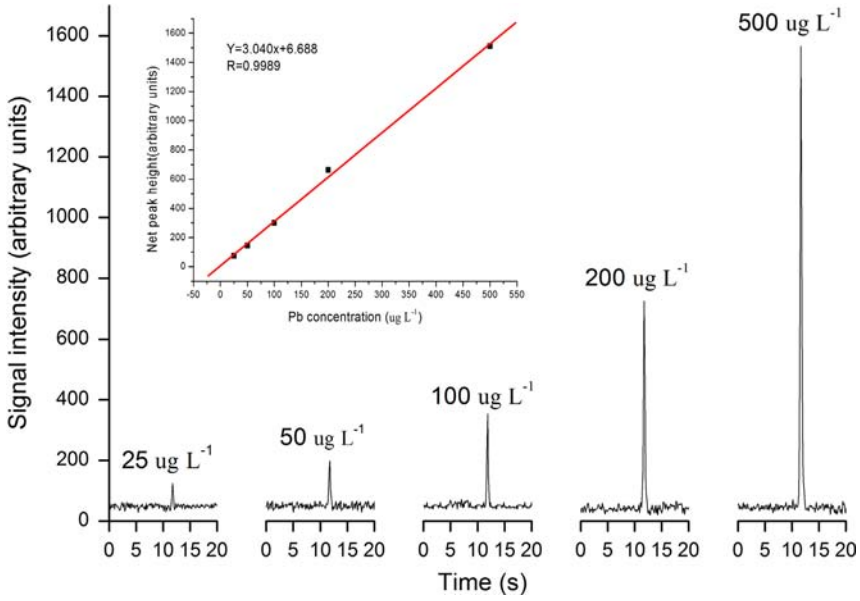

Fig. 4. Typical recoding of Pb emission signals obtained with standard solutions having Pb concentrations between 25 μg L^{-1} and 500 μg L^{-1}. The inset shows the calibration curve with peak height as the analytical parameter.

Table 4
Analytical results of for the determination of lead ($n=3$) in real samples.

Sample	Certified	This work	Found by ICP–MS
GSB 07-1183-2000	0.378 ± 0.017 mg L^{-1}	0.370 ± 0.018 mg L^{-1}	–

Sample 5	–	215.6 ± 6.8 ng mL^{-1}	228.1 ± 3.9 ng mL^{-1}

effectively. It offers several important advantages over other analytical method: low power consumption (< 30 W), small size, requirement of small amounts of sample (merely 20 μL), low cost of operation, and ease of fabrication. With all these merits, it provides a possibility to design a portable, miniature, and mobile AES instrument, especially for field analysis of elements with low-power supply. Moreover, ETV–DBD-AES system can be used to determine other elements simultaneously. In the future work, further improvement in the sensitivity and application for other type environmental samples would be of great interest to extend its use in field analytical chemistry.

ABSTRACT

A localized surface plasmon resonance (LSPR)-based sensor with an immobilized aptamer ligand was developed and used for the label-free and accurate detection of bacteria through observing the changes in the peak extinction intensity. The ability of this biosensor to recognize pathogenic bacteria was analyzed and conditions were optimized with different probe concentrations, incubation time for aptamer immobilization, and incubation time for cell binding. A single LSPR-based sensor was used to successfully detect and identify three different bacterial species as proof-of-concept experiments; in all cases, the sensor showed a detection limit of 30 cfu per assay. Furthermore, the sensor system could clearly identify various target bacterial species in a multiplexed mode with high specificities on a single chip. The label-free bacteria sensor developed by combining LSPR and aptamers will be useful for diagnosing various infectious diseases through a single convenient assay.

1. Introduction

Bacteria, which are part of a very large group of single-celled organisms, exist in all human habitats. Some of these bacteria are causative agents of various infectious diseases and can often cause death if not treated properly, in particular in immnuo-compromised patients. Pathogenic bacteria can infect humans, animals, and plants through the intake of food, water, and air, while can be transferred through the contact with infected surface or liquid. Thus, the rapid and accurate detection of pathogenic bacteria is of great importance in all areas related to health and safety, including clinics, food industries, environment, and defense. This has prompted the need for accurate assay systems for detecting bacteria, which could facilitate the use of early antibiotic interventions to treat infectious diseases associated.

Molecular diagnostic methods, which typically rely on the detection of nucleic acids (DNA or RNA) from clinical and environmental samples, can effectively detect bacteria with high sensitivity and specificity. In particular, polymerase chain reaction (PCR)-based assays have been demonstrated successful for the detection of small numbers of bacterial cells present in some samples [1,2]. However, these assays are time-consuming and require preparation of the target DNA, limiting their widespread use as diagnostic platforms. Thus, there has been an urgent need for new strategies for the rapid and simple detection of bacterial species with high sensitivity and specificity. Recently, various platforms for the direct detection of bacterial cells have been developed through the use of different sensing approaches, including the assessment of electrical signals [3,4], electrochemical sensing [5–8], surface-enhanced Raman scattering (SERS) [9–11], fluorescence signals [12,13], localized surface plasmon resonance (LSPR) [14], and optical sensing [15,16].

Among these sensing strategies, LSPR is considered a promising method for label-free and sensitive detection of biomolecules, as it displays an intensity change and/or a shift of the single sharp spectral extinction peak when an unmodified analyte binds to a local dielectric surface [17–20]. Another exciting technique that can be used for sensing cells is the employment of nucleic acid ligands known as aptamers. Compared with the antibodies that have traditionally been used for cell sensing, aptamers have the benefits of high affinity and specificity, long-term stability, easy synthesis and modification, low cost, and a wide spectrum of target analytes that can be designed [21]. These distinctive advantages of aptamers can potentially employ for the efficient detection of pathogenic bacteria.

Interestingly, however, despite such superb sensing capabilities of LSPR-based strategies and advantages of aptamer ligands, there has been no report, to our knowledge, on the use of LSPR-based bacterial cell sensor that employs aptamer ligands.

Here, we describe the label-free and accurate detection of bacteria using an aptamer-immobilized LSPR-based sensor. In this system, a multispot gold-capped nanoparticle array (MG-NPA) chip is composed of a dielectric layer comprising a thin gold (Au) layer on silica (Si) nanoparticles (NPs)-absorbed glass slide.

Using this sensor system, we successfully detected and identified three different bacterial species in a multiplexed mode. Combination of LSPR sensing platform with aptamer provides unique advantages. First, the well-defined MG-NPA structure used in this study results in sensitive and reproducible LSPR peaks [22–24]. Second, functionalization of specific aptamer ligands on the MG-NPA structure surface allows the simple and rapid detection of bacterial species without the need for any modification or the purification process of the test samples. Third, the use of multiple spots with different aptamers on a single chip allows us to simultaneously identify different bacterial species in a single assay. Therefore, the aptamer-immobilized LSPR-based sensor system developed in this study will be useful for convenient, rapid and accurate identification of bacterial species, including pathogenic bacteria, by simple assay.

2. Experimental

2.1. Materials

All chemicals were purchased from Sigma-Aldrich Co. Glass slides were purchased from Matsunami Glass Ind., Ltd, Japan. Si NPs were purchased from Polysciences Inc. NAP-5 column was purchase from GE healthcare Co. Reference bacteria were obtained from the Korean Collection for Type Cultures (KCTC; Korea) and the American Type Culture Collection (ATCC; USA), and cultured according to the provided instructions (Table S1 in Supporting information). Oligonucleotides were synthesized at Genotech (Korea). The sequences of the bacterial species-specific aptamers are as follows: *Lactobacillus acidophilus*-specific aptamer (Lac-apt), 5′-AGCAGCACAGAGGTCAGATGTAGCCCTTCAACATAGTAATATCTCT-GCATTCTGTGTGCCTATGCGTGCTACCGTGAA-$(CH_2)_3$-SH-3′ [25]; *Salmonella typhimurium*-specific aptamer (Sty-apt), 5′-TATGGCGG-CGTCACCCGACGGGGACTTGACATTATGACAG-$(CH_2)_3$-SH-3′ [26]; and *Pseudomonas aeruginosa*-specific aptamer (Pae-apt), 5′-CCCCCGTTG-CTTTCGCTTTTCCTTTCGCTTTTGTTCGTTTCGTCCCTGCTTCCTTTCTTG-$(CH_2)_3$-SH-3′ [27].

2.2. Preparation of the LSPR-based sensor

Glass slide (76 mm × 26 mm × 1 mm^3) was treated by ultrasonication for 10 min in acetone, ethanol, and ultrapure deionized (DI) water and then deposited subsequently with chromium (5 nm in height) and gold (40 nm in height) by using an E-beam evaporator (MHS 1800; MooHan Vacuum Co., Korea) at a base pressure of 4×10^{-6} Torr (1st Au layer deposition process on a glass slide, see Fig. 1a). For forming multiple spots on a single chip, a multi-spot (3 nm in diameter) silicon-rubber mask was attached to the surface of the Au-deposited glass slide. The slide with the mask was then treated with 1 mM 4,4′-dithiobutyric acid (DDA) for 1 h, and then incubated with Si NPs (100 nm in diameter) activated by 1% (v/v) 3-aminopropyltriethoxy silane (γ-APTES) and 400 mM 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) for 1 h (Silica nanoparticle deposition process, see Fig. 1a). The Si NP-modified slide was then rinsed thoroughly with DI water to remove the excess surface modified nanoparticles, and subsequently dried at room temperature (RT). Finally, a top Au layer (30 nm in height) was deposited onto the Si NP-modified substrate using the E-beam evaporator (2nd Au layer deposition process, see Fig. 1a).

2.3. Functionalization of the sensor surface using aptamers

The thiolated aptamers were treated with 1 M dithiothreitol (DTT) and purified using NAP-5 column. The sensor surface was exposed to 10 μM aptamer in phosphate buffered saline (PBS) at RT for 4 h under humidified condition, and then washed with 0.1% (w/v) sodium dodecyl sulfate (SDS) for 5 min, rinsed with DI water, and dried under a nitrogen stream.

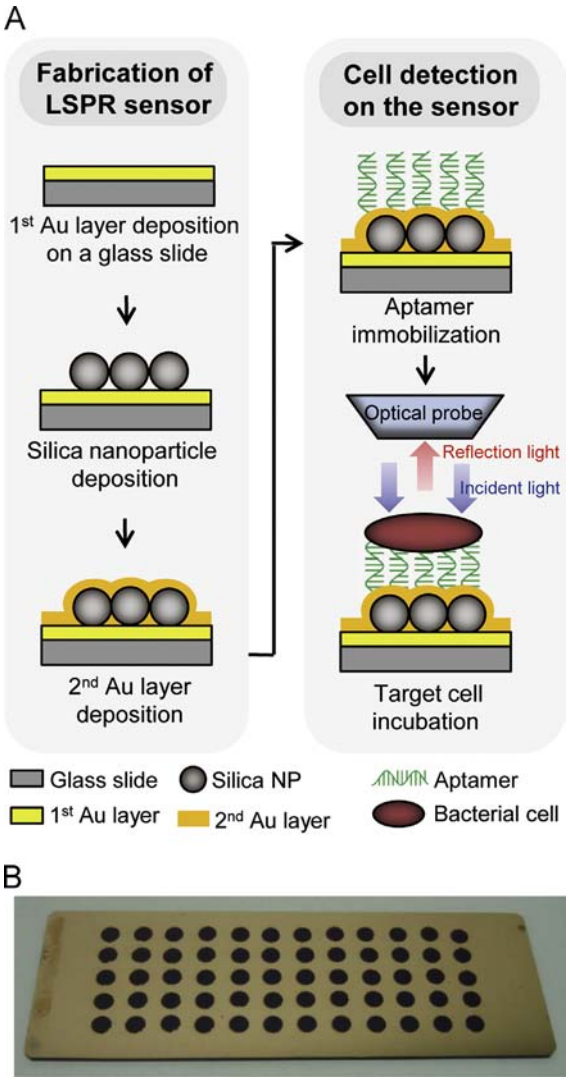

Fig. 1. Aptamer-immobilized LSPR sensor system. (a) Schematic representing the detection of bacterial cells using the aptamer-functionalized LSPR-based sensor; (b) multispot gold-capped nanoparticle array (MG-NPA) chip. Each spot (diameter of 3 mm) on chip consists of Si NPs with dielectric structure formed by the deposition of Au layer.

2.4. Detection of bacterial species

The samples with different bacterial species were dropped and incubated on different spots of the aptamer-functionalized sensor chip at RT for 1 h under humidified condition to prevent the evaporation of the samples. The slide was washed with PBS for 5 min and dried under the nitrogen stream. The LSPR spectra from the chip were measured at ambient conditions.

2.5. Instrumentation

The optical measurement system used to assess the LSPR spectra consisted of a light source (wavelength range, 360–2000 nm), spectrophotometer (wavelength range, 200–1100 nm) and an optical fiber probe bundle (fiber core diameter, 300 m; wavelength range, 250–900 nm) as a spectroscopy system, purchased

from Ocean Optics (USA). The optical properties of the LSPR sensor were assessed across a wavelength range of 400 to 750 nm, using the optical measurement system at RT. Scanning microscopic images of particles and cells were obtained using Hitachi SEM (S-4800; Hitachi, Japan).

3. Results and discussion

A schematic representation of bacterial species detection using the LSPR-based sensor is shown in Fig. 1a. First, the MG-NPA chip was fabricated by stepwise deposition of Au and Si NPs on a glass

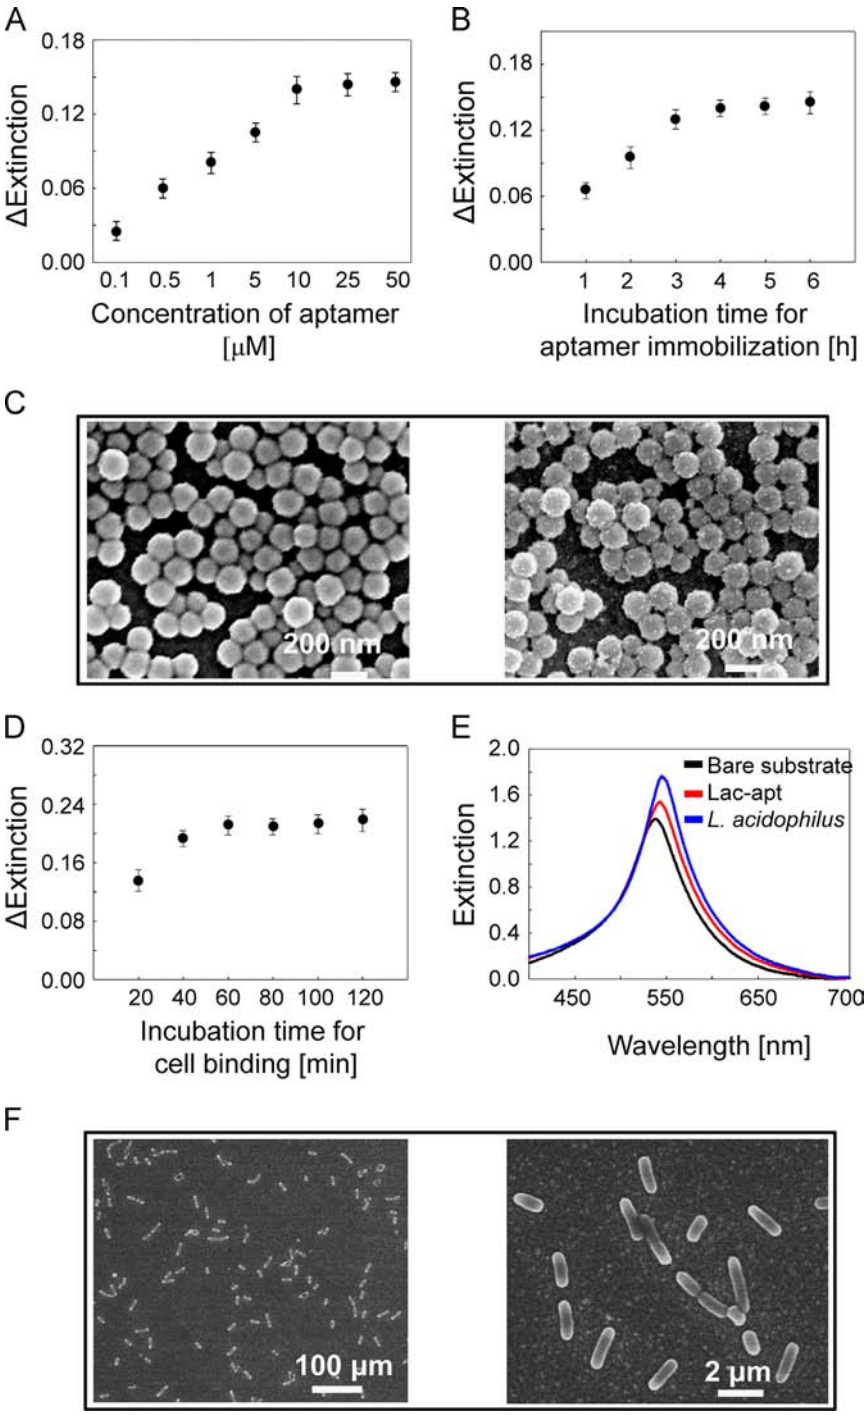

Fig. 2. Optimal conditions for cell sensing using the aptamer-immobilized LSPR-based sensor system. (a) Effect of aptamer concentration on LSPR optical properties. MG-NPA chips were incubated with different concentrations of the *Lactobacillus acidophilus*-specific aptamer (Lac-apt; 0.1, 0.5, 1, 5, 10, 25, and 50 μM); (b) effect of aptamer incubation time on LSPR optical properties. Aptamers (10 μM) were incubated with the chip for various times (1, 2, 3, 4, 5, and 6 h); (c) scanning electron microscope (SEM) images obtained (left panel) before and (right panel) after the immobilized aptamer on a chip was bound with its complementary DNA-attached Au NPs (see Supporting Information for a detailed method); (d) effect of cell incubation time on LSPR optical properties. *L. acidophilus* (10^9 cfu mL^{-1}) was incubated with the aptamer-immobilized chip for various times (20, 40, 60, 80, 100, and 120 min); (e) LSPR spectrum profiles obtained from the aptamer-immobilized chip after binding of the target cells; and (f) SEM images of bound cells (10^9 cfu mL^{-1} of *L. acidophilus*) on a chip.

substrate (see Section 2 and Fig. 1b). The dielectric structure of the chip yields a sharp and simple LSPR peak and shows sensitive responses upon binding of biomolecules [22–24]. The stepwise deposition of well-arranged Si NPs on the substrate produces a stable and reproducible LSPR peaks [22–24]. Next, the chip was functionalized with an aptamer, to enable subsequent binding reactions with the corresponding bacterial species. Aptamer-functionalized surface does not require any pre-treatment of test samples, allowing the simple and rapid detection of bacterial cells. Upon incubation of the chip with a sample, the presence of the target bacterial cells in the sample could be determined by observing a change in the LSPR peak. The LSPR-sensing process can be generally visualized by observing a red shift in the wavelength and/or a change in the extinction intensity of the peak. Unlike other noble metal structures, MG-NPA chip exhibits a clearer change in the peak extinction intensity compared to the wavelength shift upon binding of the target biomolecule [22–24].

To determine the optimal assay condition, the aptamer concentrations and incubation times were varied for aptamer immobilization and for cell-aptamer interaction on chips. First, the effect of varying conditions on aptamer immobilization on chips was investigated by using an aptamer specific to *L. acidophilus*. As shown in Fig. 2, the LSPR peak intensity was changed by varying the aptamer concentration (50, 25, 10, 5, 1, 0.5, and 0.1 μM) and incubation time (1, 2, 3, 4, 5, and 6 h). The change in LSPR peak intensity was maximized and saturated upon incubation of the chip with 10 μM aptamer for 4 h, indicating that the maximum binding of aptamer on the sensor surface was achieved under these conditions (Fig. 2a and b). In order to confirm the aptamer-binding capacity of the chip, the chip was sequentially treated with aptamer (Lac-apt) and its complementary DNA-attached Au NPs, and subjected to scanning electron microscope (SEM) analysis (see Fig. 2c and Supporting information). The Au NPs (~10 nm) were found to be densely and evenly bound on the Au chip surface. The number of aptamers on the spot of the chip was calculated following the method reported previously (see Supporting information) [28]. These data demonstrate that the chip was successfully functionalized with the utilized aptamer.

Next, the incubation time for cell-aptamer binding was optimized. The chip treated with 10 μM aptamer for 4 h was incubated with *L. acidophilus* (10^9 cfu mL^{-1}) for different times (20, 40, 60, 80, 100, and 120 min). As seen for the aptamer-bound chip, the cell–aptamer interaction on the chip also induced a change in the peak extinction intensity (Fig. 2d and e), which increased with the incubation time up to 1 h and became saturated thereafter (Fig. 2d). Cells captured by the aptamer-functionalized chip were also confirmed by SEM analysis (Fig. 2f). The bacterial cells went through the fixation process with 2.5% glutaraldehyde during the preparation of SEM specimen (see Supporting information). The fixation process can effectively maintain cell morphology [29]. Fig. 2 shows that an aptamer concentration of 10 μM per assay, an aptamer incubation time of 4 h, and cell binding time of 1 h are optimal. Thus, all subsequent experiments were performed under this condition.

As a proof-of-concept multiplex detection of bacterial species, the sensitivity and specificity of the assay were determined using three different bacteria, *L. acidophilus, S. typhimurium,* and *P. aeruginosa*, under the optimal condition determined above. *S. typhimurium* is a representative food-borne pathogen; together with *Escherichia coli* O157:H7, they cause an estimated 76 million illnesses and nearly 5000 deaths annually in the US [26]. *P. aeruginosa* is among the pathogens that cause nosocomial infections with increasing threat, and thus significantly increases the mortality risk of inpatients [27]. The detection limit of the assay was determined by changing the number of target bacterial cells per volume (cell concentration hereafter) over a range of 10^9–10^1 cfu mL^{-1} (upper panels of Fig. 3). The extinction intensity showed a logarithmic increase with respect to cell concentration over a range of 10^9–10^4 cfu mL^{-1} (lower panels of Fig. 3). The SEM images confirmed that the changes in LSPR peak intensities reflected the concentrations of bacterial cells bound to the chip surface (Fig. S1 in Supporting information). Interestingly, the slopes of these plots displayed subtle variations, indicating that the binding affinities between the different aptamers and their target cells were slightly different. The K_d values previously reported for these aptamers were 13 ± 3 nM for the *L. acidophilus*-specific

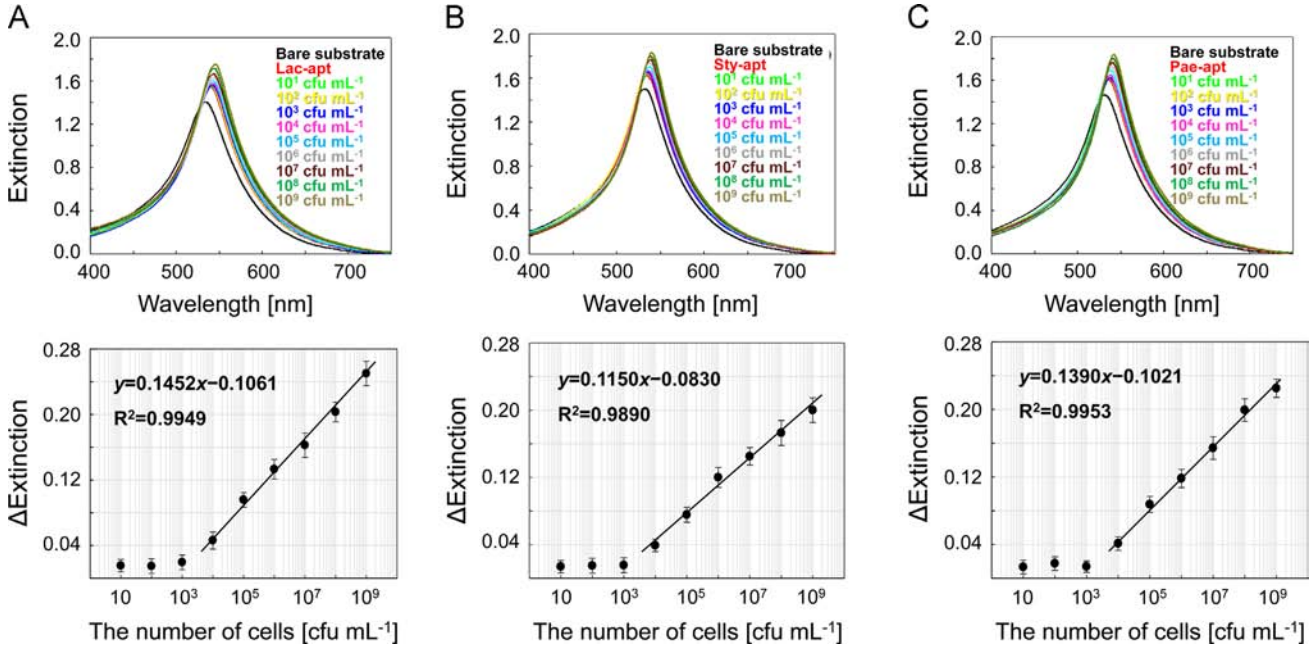

Fig. 3. The detection limits of the LSPR-based cell sensor. The detection limit was determined by observing the increases in LSPR peak intensities in response to different cell concentrations (10^1–10^9 cfu mL^{-1}) of (a) *L. acidophilus*, (b) *S. typhimurium*, and (c) *P. aeruginosa*. The upper panels show the LSPR spectrum profiles. The lower panels show the plots of the changes in LSPR signal intensity versus the target cell concentration. The data was obtained from three measurements, and the error bars represent standard deviations. Lac-apt, *L. acidophilus*-specific aptamer; Sty-apt, *S. typhimurium*-specific aptamer; Pae-apt, *P. aeruginosa*-specific aptamer.

aptamer [25] and 17.27 ± 5 nM for the *P. aeruginosa* specific aptamer [27]. Thus, our results suggest that the LSPR sensor enables the quantitative detection of bacterial cells. Considering the assay volume (3 μl), this sensing system can detect 30 colony forming unit (cfu) of bacteria in an assay. This detection limit is comparable to or slightly higher than other sensing methods including electrical signals [3,4], electrochemical sensing [5,7,8], SERS [11] and optical sensing [15,16] which showed the detection limit of 10^1–3×10^4 cfu mL^{-1}. It should be noted that very small amount of sample volume (3 μl) was used in our study, as compared to other sensors, which generally require samples ranging from tens to hundreds of microliters. Thus, the use of a larger assay volume with, for example, a microfluidic flow cell could allow more efficient detection of bacteria. The detection limit of our assay could also be improved by employing the aptamer with higher affinity and specificity. The detection limit of the aptamer-LSPR sensor system developed here is quite impressive when compared with those of other optical sensors [8–13,16].

In order to determine assay selectivity which is important for multiplexed detection, the multispot LSPR chip was functionalized with three different species-specific aptamers (Lac-apt, Sty-apt, and Pae-apt) and cross-checked whether each corresponding bacterial species were bound specifically to their corresponding aptamers. As shown in Fig. 4, the highest LSPR peak intensities were observed with proper binding between each aptamer and its specific target bacterium. As negative controls, cell-free PBS solution and *E. coli* were used; these did not trigger any significant change in LSPR peak intensity. Thus, these results indicate that the aptamer-functionalized LSPR-based sensor could clearly identify various target bacterial species in a multiplexed mode with high specificities on a single chip.

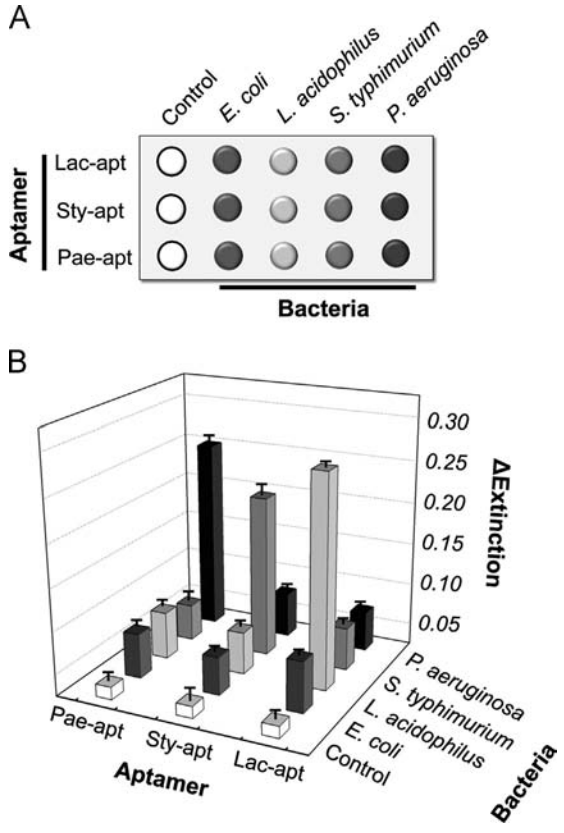

Fig. 4. Selective binding of bacterial cells to the aptamers immobilized on the LSPR sensor. (a) Design of the MG-NPA chip developed for the selectivity assay. Each species-specific aptamer was immobilized on each spot of chips and subsequently 10^9 cfu mL^{-1} of different bacterial cells were applied to spots; (b) a change in the extinction intensity of the peak at each spot could be used to assess the stringency of affinity. Cell-free PBS solution and *E. coli* were applied to chips as negative controls. The data were obtained from three independent measurements, and the error bars represent standard deviations.

In order to be useful in practice, a pathogen-diagnosing assay should be simple, sensitive, fast, and high-throughput. To date, aptamer-based assays for bacterial detection have employed electrical and optical sensors. These approaches have achieved high sensitivities, but are not amenable to high throughput detection in a single assay [3,4,7]. In contrast, the aptamer-immobilized LSRP sensing assay developed here is rapid, simple, and most importantly, capable of simultaneously identifying different bacterial species in a single assay by employing various specific aptamers. Although relatively few aptamers have been developed for clinically important pathogenic bacteria, the future availability of aptamers will allow multiplex detection of many different bacterial species in a single assay, thereby increasing the potential usefulness of this assay in a wide range of fields, including pathogen diagnostics. Furthermore, although the LSPR signals reported herein were measured using a large home-made instrument, portable instruments with LSPR-based sensors can be employed, enabling the facile and mobile detection of pathogenic bacteria in point-of-care diagnostics.

4. Conclusions

In summary, we developed an easy-to-build, aptamer-immobilized LSPR-based sensor for the simple, rapid, sensitive, specific, and multiplex sensing of bacterial species. Using this sensor system, three different bacteria could be detected with high sensitivity and specificity as a proof-of-concept demonstration. It is thus expected that the use of an LSPR-based sensor coupled with bacterial species-specific aptamers will enable efficient diagnostics of different bacterial species including pathogenic bacteria.

ABSTRACT

A novel mesoporous ZrO_2 immobilized magnetic Fe_3O_4 microsphere (m-ZrO_2@Fe_3O_4) was successfully synthesized and characterized by transmission electron microscope (TEM), X-ray diffractometer (XRD), nitrogen adsorption measurement (NAM), energy-dispersive X-ray analysis (EDX), vibrating sample magnetometer (VSM). Then the resultant m-ZrO_2@Fe_3O_4 and an n-octadecylphosphonic acid modified magnetic microsphere (Fe_3O_4-OPA) were employed as clean-up co-adsorbents of QuEChERS (Quick, Easy, Cheap, Effective, Rugged, Safe) method for the analysis of 42 pesticides and 7 polychlorinated biphenyls (PCBs) in fish samples. Lipid co-extractives such as fatty acids in QuEChERS extracts could be efficiently removed through the Lewis acid–Lewis base interaction between m-ZrO_2@Fe_3O_4 and carboxylic groups, while some other apolar interferents could be adsorbed through hydrophobic interaction by Fe_3O_4-OPA. Meanwhile, the magnetic property of adsorbents endows the clean-up procedure with manipulative convenience. Several parameters affecting the clean-up performance were investigated. Under the optimal conditions, the modified QuEChERS method combined with gas chromatography–tandem mass spectrometry (GC–MS/MS) for the multi-class, multi-residue analysis of pesticides and PCBs in fish samples was validated according to linearity, recovery and precision. Good linearities were obtained for all analytes with R^2 larger than 0.9903. Limits of detection (LODs) were found to be in the range of 0.02–4.40 ng/g. The method recoveries of all analytes spiked at three concentration levels in blank fish samples were from 69.8% to 117.1%, with the intra-day and inter-day relative standard deviations (RSDs) less than 13.4% and 16.5%, respectively.

1. Introduction

As an important source of proteins, minerals, vitamins and unsaturated essential fatty acids, fish have been considered to be an irreplaceable consumption component of a balanced human diet and their consumption has increased over worldwide [1,2]. However, fish can also significantly contribute to dietary exposure to various contaminants [1], such as pesticides and polychlorinated biphenyls (PCBs). Pesticides are widely used in agricultural and farming production all over the world to control a wide range of pests and diseases [3]. However, the unreasonable and excessive use of those substances present a concern in humanment health [4]. Polychlorinated biphenyls (PCBs) and some organochlorine pesticides, which are semivolatile, highly toxic, chemically stable, and persistent, have been identified as persistent organic pollutants (POPs) by the Stockholm Convention [5,6]. Those hazardous chemicals can be accumulated and amplified through the food chain, particularly in animal fat tissue [7]. Therefore, in order to decrease dietary exposure to pesticides and PCBs from fish, it is favorable to develop simple, efficient and sensitive method for the monitoring of their concentration level in fish.

Generally, the contaminants in fish are in low concentration and simultaneously accompanied by a large number of interferences, especially some lipid coextractives, which adversely affect the extraction efficiency and instrument performance [8,9]. Therefore, sample pretreatment techniques are highly required to remove those lipid coextractives prior to chromatography and/or mass spectrometry analysis. Conventional methods for analysis of pesticides and PCBs in fatty matrices such as fish always involve with Soxhlet extraction [10], pressurized liquid extraction (PLE)

[11,12], microwave assisted extraction (MAE) [13,14], followed by elimination of co-extracts using gel permeation chromatography (GPC) or solid-phase extraction (SPE) with different sorbents. Nevertheless, those methods usually need tedious extraction steps and use a great amount of organic solvent, which makes the whole analysis process time-consuming, labor-intensive and environmentally-unfriendly. Therefore, development of new sample pretreatment methods for determination of pesticides and PCBs in fish would be necessary.

The QuEChERS (quick, easy, cheap, effective, rugged and safe) method, which was originally developed by Anastassiades et al. for pesticide residue analysis in fruit and vegetables [15], has recently been applied to the analysis of various environmental contaminants in fish and shrimp [1,5,7,16–18], and other food [19,20]. In conventional QuEChERS methods, adsorbents are separated from the acetonitrile extract by centrifugation, which takes extra time and is not conducive to the high-throughput detection of a large number of samples [21]. Magnetic solid phase extraction (MSPE) is a novel sample preparation technique, in which the magnetic materials are first dispersed in a sample solution to adsorb target analytes or matrix components, and then the powdery magnetic materials can be easily and rapidly isolated from the solution with the help of an external magnetic field [22]. Recently, our group proposed a modified QuEChERS method by using magnetic graphitized carbon black and primary secondary amine as adsorbents for the analysis of pesticide residues in vegetables [21]. To the best of our knowledge, there were no available literatures using magnetic adsorbents in QuEChERS method for the simultaneous analysis of pesticides and PCBs in fish.

Zirconium dioxide (ZrO_2) has an amphoteric characteristic and its surface has amount of Lewis acid sites, which make it a good adsorbent of Lewis bases such as fatty acids. It has been reported that Lewis acid–Lewis base interaction and electrostatic interaction contributed to the adsorption of fatty acids on the surface of ZrO_2 [23]. Recently, a commercial sorbent composed of C_{18} and silica coated with ZrO_2 was used to remove matrix components for the analysis of hazardous substances in fish [5], bovine muscle [24], avocado and almonds [9,25], and edible oils [26]. Their results indicated that the matrix components such as fatty acids and glycerides could be efficiently removed from sample extracts by this ZrO_2 composite.

Although the appropriate sample preparation methods can remove most of the sample matrix components, the selection of chromatographic separation and detection methods for the qualitative and quantitative analysis of target analytes is of equal importance, especially for those complex food matrices accompanied with a low residue level of target analytes. Gas chromatography (GC) combined with various detectors was frequently used to inspect pesticides and PCBs in fish samples. In order to meet the growing number of test items and increasingly strict limits, the application of gas chromatography–tandem mass spectrometry (GC–MS/MS) for the simultaneous detection of multi-component has become popular due to its higher sensitivity and higher specificity [1,5,27,28]. In the present study, a novel mesoporous ZrO_2 immobilized magnetic Fe_3O_4 microspheres (m-ZrO_2@Fe_3O_4) and an n-octadecylphosphonic acid modified magnetic microspheres (Fe_3O_4-OPA) were prepared and employed as co-adsorbents of QuEChERS method for the analysis of 42 pesticides and 7 PCBs in fish. The mesoporous structure gave m-ZrO_2@Fe_3O_4 with a high surface area and high adsorption capacity, which was very significant to remove abundant coextractives in QuEChERS extract. At the same time, the magnetic property of adsorbents endows the clean-up procedure with manipulative convenience compared to traditional dispersed solid phase extraction (dSPE) in QuEChERS method. Based on this modified QuEChERS method using the magnetic m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA as co-adsorbents, a rapid, simple, efficient and sensitive GC–MS/MS method for the monitoring of 42 pesticides and 7 PCBs in fish samples was developed.

2. Experimental

2.1. Reagents and materials

Individual standard solution (1000 μg/mL) of 42 high purity pesticides and a mixture standard solution (10 μg/mL) of 7 PCBs

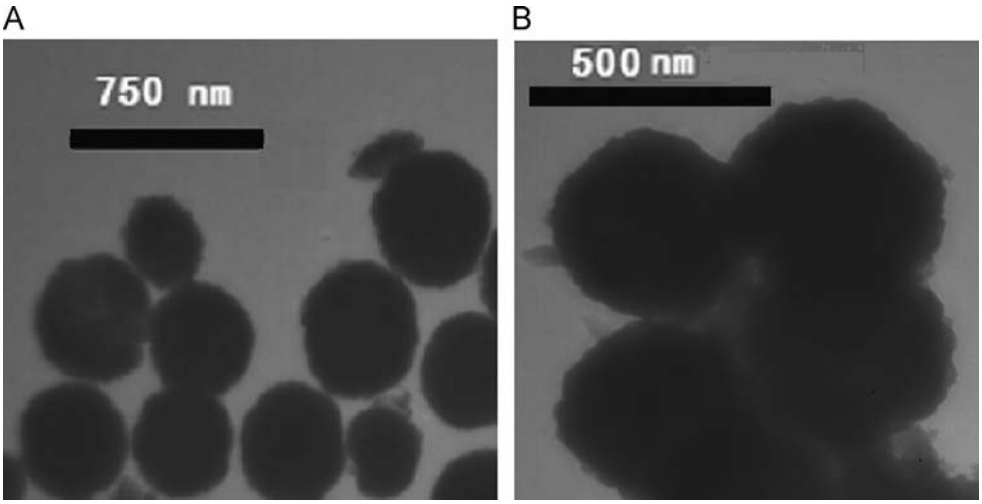

Fig. 1. TEM images of Fe_3O_4 (A) and m-ZrO_2@Fe_3O_4 (B).

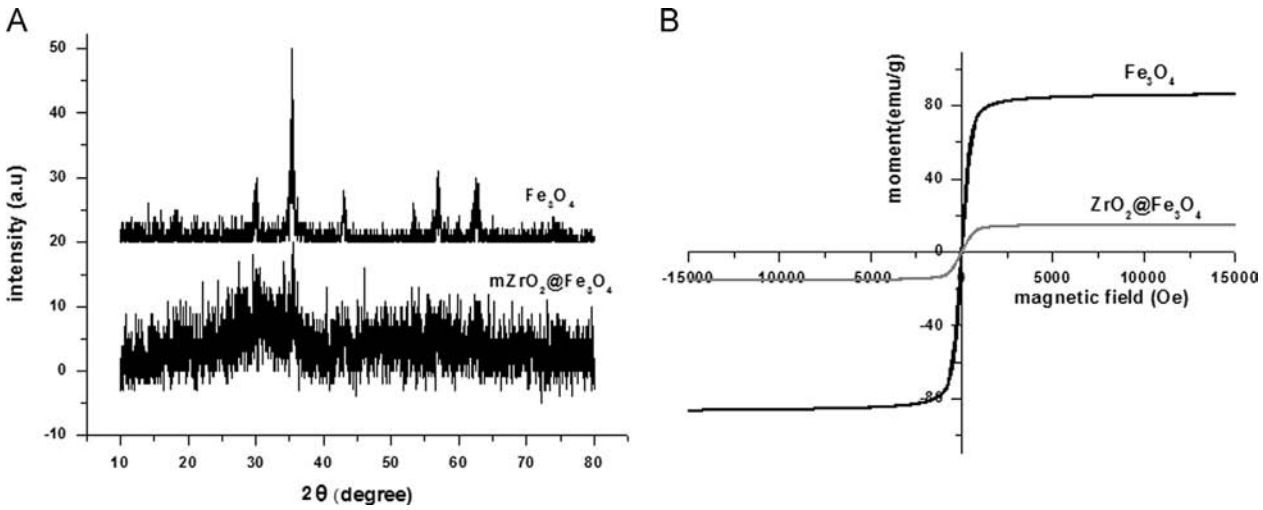

Fig. 2. (A) XRD patterns of Fe_3O_4 and m-ZrO_2@Fe_3O_4; (B) magnetization curves of Fe_3O_4 and m-ZrO_2@Fe_3O_4.

were purchased from Agro-Environmental Protection Institute, Ministry of Agriculture (Tianjin, China) and Anpel Scientific Instrument Co., Ltd. (Shanghai, China), respectively. The standard stock solution of a mixture 42 pesticides and 7 PCBs was made up to 2 μg/mL with acetone and stored at −18 °C. The working standard solutions were prepared daily.

Sodium chloride (NaCl), anhydrous magnesium sulfate ($MgSO_4$), iron (III) chloride hexahydrate ($FeCl_3 \cdot 6H_2O$), anhydrous sodium acetate (NaAc), polyethylene glycol 10000 (PEG 10000), ethylene glycol, ethanol (EtOH), ammonium hydroxide (NH_4OH), tetrahydrofuran (THF), and zirconyl chloride octahydrate ($ZrOCl_2 \cdot 8H_2O$) were all of analytical reagent grade and supplied by Shanghai General Chemical Reagent Factory (Shanghai, China). n-Octadecylphosphonic acid was purchased from TCI (Shanghai, China). Acetonitrile (ACN), methanol (MeOH) and acetone of HPLC-grade were obtained from Tedia (Ohio, USA).

2.2. Equipments and analytical conditions

GC–MS/MS analysis was performed using a Shimadzu GCMS-TQ8030 equipped with an AOC-20i autosampler (Kyoto, Japan). Data acquisition and analysis were performed using software from GCMS Solution (Shimadzu, Kyoto, Japan). The separation was . achieved on a fused silica capillary column (Rtx–5MS, 30 m × 0.25 mm i.d., film thickness 0.25 μm) (Restek, Pennsylvania, USA). The oven temperature was programmed at 40 °C for 4.0 min, increased to 125 °C at a rate of 25 °C min^{-1}, and then increased to 300 °C at a rate of 10 °C min^{-1} and held for 6.0 min. The solvent cut time was 7 min. The injection volume was 1.0 μL and splitless injection mode was used. The splitless time was 1.0 min. Helium (purity 99.999%) was used as the carrier gas at a flow rate of 1.0 mL min^{-1}. Argon (purity 99.999%) was used as a collision cell gas. The injection port, ion source and interface temperatures were set at 250, 230 and 250 °C, respectively. The QqQ mass spectrometer was operated in selected reaction monitoring mode detecting two transitions per analyte, which are listed together with the particular collision energies in Table 1.

2.3. Preparation of m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA magnetic microspheres

The magnetite microspheres were prepared through solvothermal reaction [29], which are described as follows: $FeCl_3 \cdot 6H_2O$ (5.4 g) was dissolved in ethylene glycol (160 mL) under magnetic

stirring for 0.5 h. Then NaAc (14.4 g) and polyethylene glycol (4.0 g) were added to the solution. After stirring for another 0.5 h, the resultant solution was transfered into a 200 mL Teflon lined stainless-steel autoclave. The autoclave was sealed and heated at 200 °C for 24 h, and then cooled to room temperature. The magnetic microspheres were collected with the help of magnet, followed by washing with ethanol and deionized water for 4 times. The product was dried in vacuum at 60 °Cfor 8 h.

Mesoporous ZrO_2 was directly coated onto the surface of magnetic Fe_3O_4 by the hydrolysis of $ZrOCl_2$ and using CTAB as the mesoporous template reagent according to a previous report with minor modification [30]. Fe_3O_4 microspheres (0.5 g) were dispersed in a solution containing 1.5 g CTAB, 400 mL deionized water, 7.5 mL concentrated NH_4OH solution (28%) and 300 mL ethanol. The mixture was stirred continuously for 30 min to form a homogenized dispersion. To the above dispersed solution, an aqueous solution of $ZrOCl_2$ (3.1 g dissolved in the minimum volume of water) was added drop-wise and then the reaction mixture was stirred for 6 h. Then the product was collected by a hand-held magnet and washed repeatedly with ethanol and deionized water. The obtained particles were redispersed in 250 mL of acetone and refluxed at 80 °C for 60 h. The resultant particles were then washed with deionized water, separated through magnetic decantation and dried in vacuum at 60 °C for 12 h. At last, the obtained m-ZrO_2@Fe_3O_4 was further calcined at 300 °C for 6 h to age.

The Fe_3O_4-OPA was prepared according to the previously described method [31]. OPA (1.0 g) was dissolved in 50 mL THF, then bare Fe_3O_4 (5.0 g) was added into the solution. The mixture was refluxed at 80 °C for 12 h. The final product was magnetically

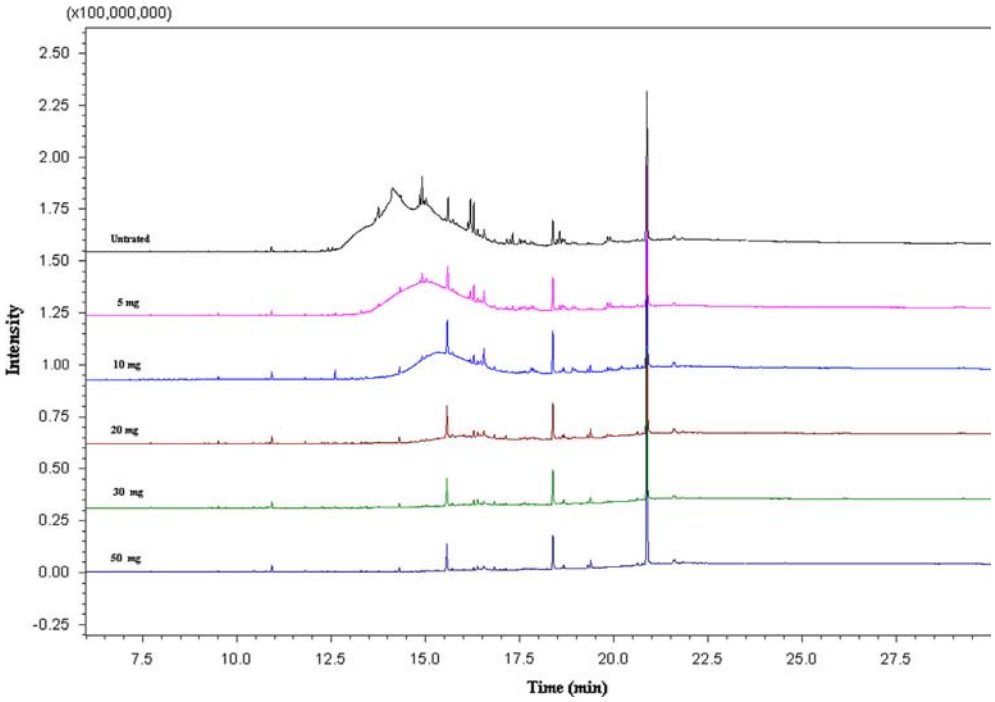

Fig. 3. Effect of the amount of m-ZrO_2@Fe_3O_4 on the clean-up performance.

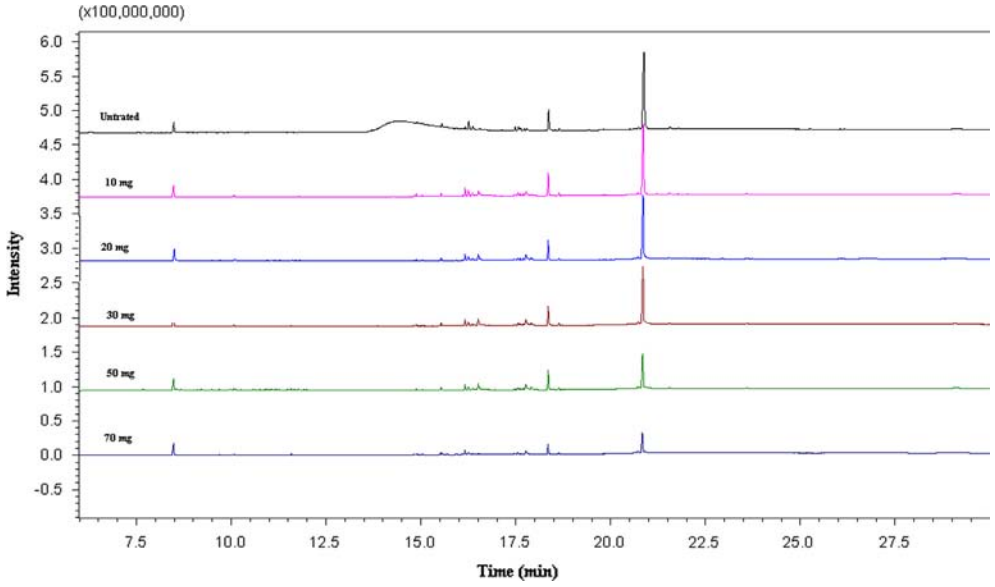

Fig. 4. Effect of the amount of Fe_3O_4-OPA on the clean-up performance.

collected and washed by water/ethanol/acetone/n-hexane successively and repeatedly, followed by drying at 60 °C for 6 h.

2.4. Characterization

The morphology of the particles was observed with a transmission electron microscope (TEM) (JEOL, Kyoto, Japan). The crystal structure of the materials was determined with a Bruker SMART APEX II X-ray diffractometer (XRD, Billerica, German) using Cu Kα radiation and rotating anode operated at 40 KV and 30 mA. The species of iron and zirconium was determined with a Shimadzu EDX-720 energy-dispersive X-ray analyzer (EDX, Kyoto, Japan) by using Mg-Ka radiation as the excitation source. Magnetization curves were determined with a PPMS-9 vibrating sample magnetometer (Quantum Design, San Diego, CA, USA). Nitrogen adsorption measurement was measured at 77 K on a JW-BK surface area and pore size analyzer (JWGB Sci. & Tech., Beijing, China). The composites were activated under vacuum and heated to 423 K for 6 h to remove any physically adsorbed substances before analysis. The specific surface area was calculated according to the BET (Brunauer–Emmett–Teller) equation at P/P_0 between 0.05 and 0.3. The pore volume and pore diameter were evaluated from the desorption branch of isotherm based on BJH (Barrett–Joyner–Halenda) model.

2.5. Sample preparation

The homogenized fish sample (10.0 g) was weighed into a 50 mL centrifugal tube. The samples was mixed with 10 mL ACN. Subsquently, the mixture was vortxed by hand for 1 min. Then 1.0 g NaCl and 4.0 g anhydrous $MgSO_4$ was added and shaken vigorously for 30 s. After centrifugation (7000 rpm, 8 min), the extract was transferred to an eppendorf vial (15 mL) containing 1.0 g of anhydrous $MgSO_4$. The vial was shaken by hand followed by standing for 1 min, and the supernatant was collected for the subsequent steps.

The clean-up procedure was performed by MSPE using m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA as co-adsorbents. 1 mL Supernatant was added into a 2 mL centrifugal tube containing a certain amount of magnetic adsorbents (m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA), then the mixture was shaken vigorously for 0.5 min. The supernatant was transfered into another tube with the aid of an external magnet, and was evaporated to dryness under a mild nitrogen stream at room temperature. The residue was dissolved in 1 mL acetone for GC–MS/MS analysis.

For recovery experiments, the known variable amounts of analytes were firstly spiked for 15 min in fish samples before sample preparation, and the following steps were the same as described above.

3. Results and discussion

3.1. Characterization of materials

The morphology and size of the prepared magnetic particles were characterized by TEM (Fig. 1). Obviously, bare Fe_3O_4 and m-ZrO_2@Fe_3O_4 were nearly monodispersed and sphere-like, with a diameter of 250–400 nm. The thickness of ZrO_2 coating layer was about 30 nm. Although there is slight aggregation or adhesion on the magnetic microspheres after the coating with ZrO_2, the overall morphology still maintains a distributed uniform state to some extent.

To further confirm that the m-ZrO_2@Fe_3O_4 microspheres are prepared successfully, EDX spectroscopy was applied to analyze the microspheres obtained, as shown in Supporting information Fig. S1. The results indicated the presence of Fe, Zr and O elements. Furthermore, a relative low level of Fe content obtained by EDX spectroscopy analysis further indicated that the surface of the Fe_3O_4 microspheres was successfully coated by ZrO_2.

Bare Fe_3O_4 and m-ZrO_2@ Fe_3O_4 were characterized by N_2 adsorption/desorption. It can be found that the surface area and pore volume of bare Fe_3O_4 are merely 17 m^2/g and 0.039 cm^3/g, respectively. The two parameters of m-ZrO_2@ Fe_3O_4 reach up to 221 m^2/g and 0.493 cm^3/g. Furthermore, the m-ZrO_2@ Fe_3O_4 yielded typical IV adsorption isotherm and H1 hysteresis loop, which are characteristic of a mesoporous material. Those results indicated that the mesoporous structure has formed on m-ZrO_2@Fe_3O_4. The highly porous ZrO_2 shell should be beneficial to enhance adsorption capacity of magnetic sorbent and speed up mass transfer to shorten equilibrium time.

Structural characterization of bare Fe_3O_4 and m-ZrO_2@ Fe_3O_4 has been carried out by wide angle XRD, as shown in Fig. 2A. For bare Fe_3O_4, the well defined crystal structure is evidenced by the corresponding peaks with 2θ at 30.1°, 35.3°, 43.1°, 53.5°, 57.0°, and 62.7° in the X-ray diffractogram, which are identified as the spinel phase of Fe_3O_4. After coating with ZrO_2, the diffraction peaks characteristic of magnetite nearly disappeared while a broad peak

around 30° was visible, which was likely due to the formation of amorphous ZrO_2 on the surface of Fe_3O_4.

The magnetic properties of bare Fe_3O_4 and m-ZrO_2@Fe_3O_4 were investigated by a vibrating sample magnetometer. As shown in Fig. 2B, both curves had no magnetic hysteresis loops, indicating that the as-prepared magnetic materials were super paramagnetic. Furthermore, the saturation magnetization (Ms) of m-ZrO_2@Fe_3O_4 (17.5 emu/g) is obviously lower than that of bare Fe_3O_4 (86.3 emu/g), implying the existence of a significant amount of ZrO_2 on the surface of Fe_3O_4. Because of the relatively high saturation magnetization values, the magnetic m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA could be rapidly and efficiently separated from the sample solution by an external magnet (as shown in Fig. S2 of Supporting information).

3.2. Optimization of sample pretreatment

To remove matrix components and obtain satisfactory recoveries of target analytes, several parameters including the adsorption time, the amounts of m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA were optimized in detail.

3.2.1. Optimization of the amount of m-ZrO_2@Fe_3O_4

The surface of m-ZrO_2@Fe_3O_4 has an amount of Lewis acid sites, which could adsorb Lewis bases such as fatty acids in QuEChERS extract of fish samples. The experiment was performed using 1.0 mL of the blank fish extract that was placed into a 2 mL Eppendorf vial containing a certain amount of m-ZrO_2@Fe_3O_4. After clean-up, the samples were analyzed by GC–MS in full scan mode, as shown in Fig. 3. The wide spectrum bands in chromatograms were indentified as fatty acids. With the increase

Table 4
Comparison of method performance and the time with the previous method for detection of pesticides and PCBs in fish samples.

Technique	Determination method	Analytes and LODs	Recoveries (%)	RSD (%)	Time required (min)[a]	Ref.
Traditional QuEChERS method	GC–MS/MS	14 PCBs: 0.1–0.5 μg/kg 18 pesticides: 0.5–5 μg/kg	72-119	< 20	> 5	[5]
	GC–MS	9 OCPs: 0.3–4.5 μg/kg	90-105	< 15	> 8	[16]
	GC-ECD	6 Pyrethroids: 8–14 μg/kg	81.1-108.0	< 4	> 8	[17]
	GC–MS/MS	16 OCPs: n.a[b] 18 PCBs: n.a	70-120	< 20	> 10	[1]
MSPD	GC–MS	7 Pesticides: n.a	57-107	< 26	> 15	[3]
ASE + GPC + SPE	GC-FPD	17 OPPs: 0.6–9.0 μg/kg	64.5-98.6	< 15	> 60	[11]
Proposed QuEChERS method	GC–MS/MS	7 PCBs: 0.02–0.06 μg/kg 45 Pesticides: 0.02–4.40 μg/kg	69.8-117.1	< 17	< 3	This work

[a] Time required referred to the time of clean-up process for pesticides and PCBs detection in fish samples, and was approximately estimated according to the literatures above.
[b] n.a, Not available.

in the amount of m-ZrO_2@Fe_3O_4, this wide peak gradually disappeared. 30 mg of m-ZrO_2@Fe_3O_4 was enough to remove those fatty acids.

3.2.2. Optimization of the amount of Fe_3O_4-OPA

Fe_3O_4-OPA with an octadecyl chain could remove some apolar matrix components. 30 mg m-ZrO_2@Fe_3O_4 and different amounts of Fe_3O_4-OPA (i.e. 10, 20, 30, 50, 70 mg) was used as co-adsorbents for clean-up in QuEChERS method. As shown in Fig. 4, the peak at 20.89 min in chromatograms was indentified as hydrophobic cholesterol. The peak intensity of cholesterol and other apolar matrix components gradually decreased with the increase in the amount of Fe_3O_4-OPA. Further increase of the amount of Fe_3O_4-OPA was problematic because some analytes may also be adsorbed by Fe_3O_4-OPA. Therefore, 70 mg of Fe_3O_4-OPA was selected to remove those matrix components.

3.2.3. Optimization of the adsorption time

The optimization of the adsorption time was performed under the optimal amounts of m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA. The adsorption time was conducted by increasing the vortex time from 0.5 to 3 min. The result indicated that the adsorption time had no significant influence on the clean-up efficiency. This phenomenon might be attributed to a thin porous layer of m-ZrO_2 on the surface of Fe_3O_4, which was favorable for the mass transfer of analytes. Therefore, 0.5 min of the vortex time was selected.

3.2.4. Reusability of m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA

The reusability of m-ZrO2@Fe_3O_4 and Fe_3O_4-OPA was also investigated to access the feasibility of the method for routine analysis. The magnetic materials were repeatedly subjected to perform MSPE of the fish QuEChERS solution. No obvious change in clean-up performance was found after five repetitive applications of the magnetic materials that were sequentially washsed with 1 mL MeOH/$NH_3 \cdot H_2O$ (v/v, 97/3) and 1 mL ACN. Therefore, the presented method is expected to be effective in practical applications.

Under the optimal conditions, typical chromatograms of blank fish extract without clean-up (a) and after clean-up (b), and blank fish extract after clean-up and spiked with 10 ng/mL analytes (c) were shown in Fig. 5. It can be seen that the as-prepared magnetic materials have good clean-up performance and only few interferences from the chromatogram of the clean-up sample are observed.

3.3. Validation of the method

3.3.1. Calibration curves, detection limits, limits of quantification

Matrix effects in the form of signal enhancement were always observed in GC–MS/MS, leading to unacceptable high recoveries [32]. Therefore, matrix-matched standards are necessary to correct for matrix effect for quantification analysis in the GC–MS/MS. In this study, matrix-matched calibration solutions spiking in blank fish extracts at seven concentration levels from 1 to 500 ng/mL were prepared to avoid the matrix effects. The calibration curves were established by plotting the peak areas of the analytes versus the concentrations of pesticides and PCBs. Limits of detection (LODs) and limits of quantifications (LOQs) were calculated as the concentrations corresponding to a signal of 3 and 10 times the standard deviation of the baseline noise, respectively. As listed in Table 2, all analytes showed good linearity with satisfactory squared regression coefficients (R^2) greater than 0.9903. The LODs and LOQs for these analytes were found to be in the range of 0.02–4.40 ng/g, and 0.08–14.66 ng/g, respectively.

3.3.2. Accuracy and precision

To assay the accuracy of the method, recoveries were investigated in spiked fish samples at three concentration levels of 10.0, 50.0 and 100.0 ng/mL. The recoveries were determined by comparing the calculated amounts of pesticides and PCBs in the samples (using calibration curves) with the spiking amounts. The precision of the method was assessed by determining the intra- and inter-day relative standard deviations (RSDs) at three concentration levels. As listed in Table 3, the method recoveries were in the range of 69.8% to 117.1% with RSDs less than 13.8%. Meanwhile, the intra-day and inter-day RSDs were below 13.4% and 16.5%, respectively.

3.3.3. Comparison with the previous methods

The comparison of method performance and clean-up time of our developed method with the previous methods are studied. As illustrated in Table 4, our proposed method took less clean-up time, had satisfactory precisions and recoveries, and showed better sensitivity than the previous method. The experimental and comparative results well indicated that our proposed method may be used to effectively monitor pesticides and PCBs in fish matrices.

3.3.4. Application of the proposed method for determination of pesticides and PCBs in fish

The proposed GC–MS/MS method was applied to the trace analysis of pesticides and PCBs in four kinds of fish samples (silver carp, bighead carp, mandarin fish, snakehead) from different

sources in Wuhan. No analytes were detectable in those samples. The recoveries for 42 pesticides and 7 PCBs spiked at 50 ng/g in those five fish samples were in the range of 80.8–116.7%, with RSDs less than 17.5%, indicating the good reliability and applicability of the proposed method for the analysis of pesticides and PCBs in different kinds of fish samples.

4. Conclusions

In this work, a mesoporous ZrO_2 immobilized magnetic Fe_3O_4 microspheres (m-ZrO_2@Fe_3O_4) and an n-octadecylphosphonic acid modified mesoporous magnetic particles (Fe_3O_4-OPA) were used as co-adsorbents of QuEChERS method for the analysis of 42 pesticides and 7 PCBs in fish samples, followed by separation and detection with GC–MS/MS. Compared to traditional QuEChERS method in which phase separation must be achieved by centrifugation, the modified QuEChERS method using magnetic adsorbents endows the clean-up procedure with manipulative convenience through applying an external magnetic field. Lipid coextractives such as fatty acids could be efficiently removed thorough the Lewis acid–Lewis base interaction between m-ZrO_2@Fe_3O_4 and carboxylic groups, while some other apolar coextractives such as cholesterol could be adsorbed through hydrophobic interaction by Fe_3O_4-OPA. The amounts of m-ZrO_2@Fe_3O_4 and Fe_3O_4-OPA, the adsorption time were optimized in detail to remove the matrix interferences as much as possible and obtain high recoveries of target analytes. Under the optimized conditions, the modified QuEChERS method combined with GC–MS/MS was applied to analyze pesticides and PCBs in real samples. Recoveries of 49 analytes spiked in three concentration levels were between 69.8% and 117.1% with RSDs less than 16.5%, indicating good reliability of the proposed methods.

Quantitative detection

ABSTRACT

Mycotoxin pollutants are commonly related to cereal products and cause fatal threats in food safety, and therefore require simple and sensitive detection. In this work, quantum-dot (QD) submicrobeads (QBs) were synthesized by encapsulating CdSe/ZnS QDs using the microemulsion technique. The resultant QBs, with approximately 2800 times brighter luminescence than the corresponding QDs, were explored as novel fluorescent probes in the immunochromatographic assay (ICA) for sensitive and quantitative detection of zearalenone (ZEN) in corns. Various parameters that influenced the sensitivity and stability of QB-based ICA (QB–ICA) were investigated and optimized. The optimal QB–ICA exhibits good dynamic linear detection for ZEN over the range of 0.125 ng/mL to 10 ng/mL with a median inhibitory concentration of 1.01 ± 0.09 ng/mL ($n=3$). The detection limits for ZEN in a standard solution and real corn sample (dilution ratio of 1:30) are 0.0625 ng/mL and 3.6 μg/kg, respectively, which is much better than that of a previously reported gold nanoparticle-based ICA method. Forty-six natural corn samples are assayed using both QB–ICA and enzyme-linked immunosorbent assay. The two methods show a highly significant correlation ($R^2=0.92$). Nine ZEN-contaminated samples were further confirmed with liquid chromatography–tandem mass spectrometry (LC–MS/MS), and the QB–ICA results also exhibited good agreement with LC–MS/MS method. In brief, this work demonstrates that QB–ICA is capable of rapid, sensitive screening of toxins in food analysis, and shows great promise for point-of-care testing of other analytes.

1. Introduction

Zearalenone (ZEN) is an estrogenic and carcinogenic mycotoxin produced by some *Fusarium* species, which can be found in corn, wheat, and cereal products. ZEN commonly remains in the food chain in the form of original molecules, and produces severe damage on the reproductive system of humans and animals [1]. Many countries have established regulations governing levels of ZEN in agricultural products. To minimize the risk to humans and animals, several analytical methods have been developed for the detection of ZEN in food samples, including gas chromatography (GC) [2], high-performance liquid chromatography (HPLC) [3,4], liquid chromatography-tandem mass spectrometry (LC-MS/MS) [5], as well as some immunochemical methods, such as enzyme-linked immunosorbent assay (ELISA) [6,7], fluorescence polarization immunoassay (FPIA) [8], and use of other immunobiosensors [9,10]. However, these methods are unsuitable for on-site routine screening because they require professional laboratory conditions, skilled operators, expensive instruments, and time-consuming sample pretreatments.

Recently, use of gold nanoparticle-based immunochromatographic assay (AuNP–ICA) has been recommended for ZEN qualitative and quantitative detection because of its rapidity, ease of use, and suitability for on-site analysis [11]. For example, Shim et al. and Li et al. reported AuNPs–ICA for qualitative determination of ZEN with visual detection limits (vLOD) at 2.5 ng/mL and 1.0 ng/mL, respectively [12,13]. Wang et al. also used AuNP-ICA for rapid simultaneous quantification of ZEN and Fumonisin B_1 (FB_1), in which the LODs for ZEN in a standard solution and real corn sample (dilution ratio of 1:60) were 0.35 ng/mL and 21 μg/kg, respectively [14]. Compared with fluorescent nanoparticle probes, traditional AuNP–ICA is always limited by its relatively low sensitivity. Quantum dots (QDs) are ideal fluorescent labels and have been widely used for improving the detection sensitivity of ICA due to their incomparable optical properties, such as broad UV excitation with narrow fluorescent emission spectra, large molar extinction coefficient, and high quantum yield

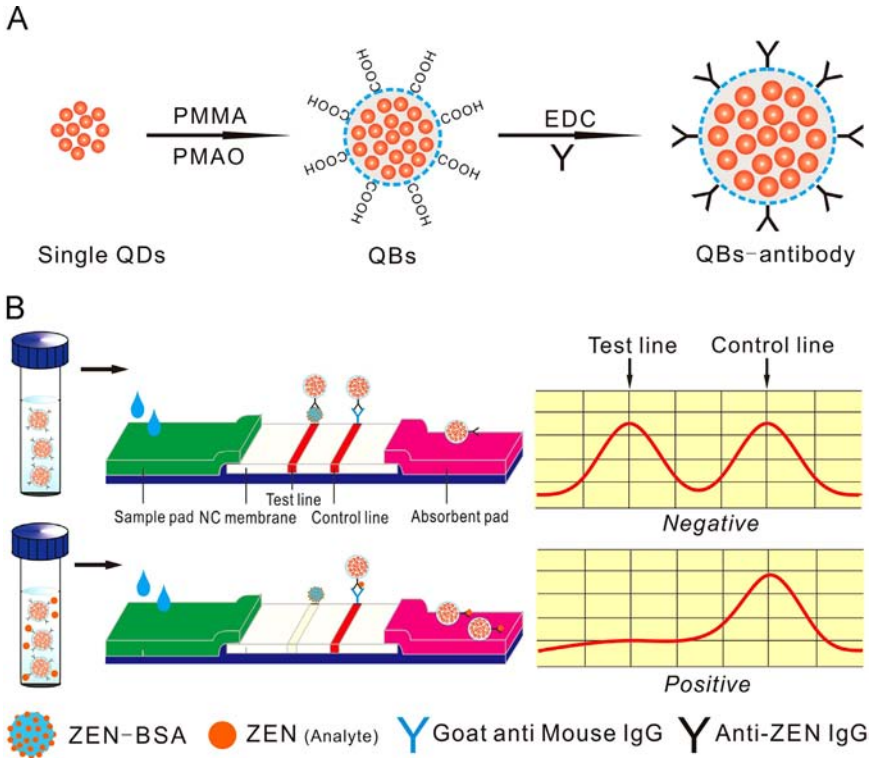
[15]. A few research groups have reported QD-based ICA methods (QD–ICA) for rapid detection of protein biomarkers and other small molecule compounds, and achieved high sensitivity [16,17]. Quantum-dot submicrobeads (QBs), in which numerous QDs are embedded in a polymer matrix, exhibit advantages in improving the sensitivity of immunoassay due to their stronger fluorescence intensity than the corresponding single QD. Zhang et al. used QBs as luminescent amplification probes and developed a dot-blot sandwich immunoassay for ultrasensitive detection of hepatitis B-virus surface antigen with a LOD at 0.078 ng/mL [18]. Li et al. also reported a QB-based sandwich ICA for quantitative and sensitive detection of prostate-specific antigen, in which the LOD achieved about 12-fold enhancement compared with QDs as probes [19]. However, the use of QBs as fluorescent probes for competitive ICA sensors has not been reported.

In the present study, highly luminescent QBs with carboxyl groups were introduced as ICA signal-amplification probes for sensitive and quantitative determination of ZEN in corns. A portable strip reader was used to record the fluorescent intensity of the test (FI_T) and control (FI_C) lines. The FI_T/FI_C ratio was adjusted to offset the interference from the inherent heterogeneity of the test strips according to our previous work [20]. Various parameters that influence the sensitivity and reproducibility of QB–ICA were systematically optimized. The performance of QB-ICA, including its LOD, median inhibitory concentration (IC_{50}), specificity, accuracy and precision, was evaluated. Moreover, the practicality and reliability of the proposed quantitative strip were compared with a commercial ELISA kit and were further confirmed by LC-MS/MS.

2. Materials and methods

2.1. Reagents and apparatus



ZEN, N-(3-dimethylaminopropyl)-N′-ethylcarbodiimide hydrochloride (EDC · HCl), bovine serum albumin (BSA), and N-hydroxysuccinimide (NHS) were purchased from Sigma-Aldrich Chemical (St. Louis, MO, USA). Donkey anti-mouse IgG antibodies were purchased from Beijing Zhongshan Biotechnology Inc. (Beijing, China). ZEN–BSA conjugates (mole ratio of 8:1) and anti-ZEN monoclonal antibodies (anti-ZEN mAbs) were prepared in our laboratory. The sample pad, nitrocellulose (NC) membrane, and absorbent pad were purchased from Schleicher and Schuell GmbH (Dassel, Germany). The ELISA kit was provided by Shanxi Defcred Biotech Co., Ltd (Shanxi, China). All other reagents were of analytical grade and purchased from Sinopharm Chemical Corp. (Shanghai, China).

Forty-six natural corn samples were collected from the grain procurement agencies in Shandong Province, China. All samples were ground and well mixed prior to use. The sample extraction was as follows: 5.0 g of the pulverized sample was extracted with 25 mL methanol–water mixture (6:4, v/v) for 20 min with vigorous shaking. After centrifuging at 5000 *g* for 10 min, the supernatant solutions were diluted six-fold with 0.01 M phosphate buffer saline (pH 5.0, PBS) for further use.

The BioDot XYZ platform, combined with a motion controller, BioJet Quanti3000 k dispenser, and AirJet Quanti3000 k dispenser for solution dispensing, was supplied by BioDot (Irvine, CA). The automatic programmable cutter was purchased from Shanghai Jinbiao Biotechnology Co., Ltd. (Shanghai, China). The portable fluorescent strip reader was obtained from Huguo Science Instrument Co., Ltd. (Shanghai, China). The water used for all the experiments was purified by Elix-3 and Milli-QA apparatus (Molsheim, France).

2.2. Preparation and characterization of QBs

As shown in Schematic 1A, the quantum-dot submicrobeads (QBs) were synthesized as previously reported with some modifications [21]. Briefly, CdSe/ZnS QDs with a maximum emission wavelength at 623 nm in $CHCl_3$ (1 mL; 20 mg/mL) were mixed with 1 mL $CHCl_3$ containing polymethyl methacrylate (60 mg/mL) and poly (maleic anhydride-alt-1-octadecene) (40 mg/mL). An

Schematic 1. (A) Schematic illustration of the quantum-dot submicrobead formation. (B) Schematic illustration of the QB-ICA method for quantitative detection of ZEN.

emulsion was obtained with sodium dodecyl sulfate (3 mg/mL; 5 mL) in water, using an ultrasonic homogenizer for 2 min. The nonpolar solvent ($CHCl_3$) was then evaporated using a rotary evaporator. The resulting water-soluble QBs were purified by centrifugation (6500 *g*, 10 min) and washed three times with pure water.

Fluorescence intensity of the resultant QBs was monitored using a Hitachi F-4500 fluorescence spectrophotometer (Tokyo, Japan). The average size and morphology of the spMNBs were determined using a high-resolution transmission electron microscope (JEOL JEM 2100, Tokyo, Japan).

2.3. Preparation and characterization of anti-ZEN mAb-labeled QBs

The unpurified ascitic fluid containing anti-ZEN mAbs was used to directly conjugate with QBs as previously reported with some modifications [22]. Briefly, 5 μg EDC, 0.6 mg QBs, and 300 μL of unpurified anti-ZEN ascitic fluid (0.3 mg/mL) were added to 1.8 mL of 0.01 M PB buffer (pH 6.0). After reacting at room temperature for 1 h under magnetic stirring, the mixtures were centrifuged at 13 500 *g* for 10 min. The QBs and anti-ZEN mAb conjugates (QB-mAbs) were resuspended with 2.0 mL of PBS (0.01 M, pH 7.4) containing 2% fructose, 1% polyethylene glycol (PEG 20000), 5% sucrose, 1% BSA, and 0.4% Tween-20. The resuspension solution was stored at 4 °C for further use. Dynamic light scattering (DLS) analysis of the free QBs and QB-mAbs probe was performed using a particle size analyzer (Malvern Instruments Ltd., Worcestershire, UK) to confirm the immobilization of anti-AFB_1 mAbs on the QB surface.

2.4. Preparation of QB-ICA sensor

The QB-ICA sensor was made of three parts: sample pad, nitrocellulose (NC) membrane, and absorbent pad. The ZEN–BSA conjugates (0.8 mg/mL) and goat anti-mouse IgG (1.0 mg/mL) were spotted onto NC membranes as the test (T) and control (C) lines, respectively, and then dried at 37 °C for 12 h. The sample pads were treated with 20 mmol/L sodium borate buffer (pH 8.0) containing 1.0% (w/v) BSA, 0.1% (w/v) NaN_3, and 0.25% Tween-20. The distance between the T and C lines was about 5 mm. After drying at 60 °C for 2 h, the sample pad, NC membrane, and absorption pad were attached to a plastic backing plate, and then cut into 4-mm-wide strips and packaged in a plastic casing for subsequent storage in a drying cylinder at room temperature.

2.5. Immunoassay procedure

As presented in Schematic 1B, the QB-mAbs probe and sample solution were pre-mixed at room temperature for 1.0 min, and then added onto the sample pad. With the aid of the capillarity of the absorbent pad, the QB-mAbs and ZEN immunocomplex formed migrate across the NC membrane and react with the goat anti-mouse IgG while excess QB-mAbs is captured by the ZEN–BSA, which results in a fluorescent band on the control and test lines, respectively. The more ZEN in the sample extracts, the lower the fluorescence intensity appears on the test line.

2.6. Assay validation

The accuracy and precision of QB–ICA were evaluated by analyzing the recovery and variation coefficients of the intra- and inter-assays [23]. The intra-assays were estimated by one batch of test strips for five replicates, while the inter-assays were analyzed once every day for three sequential days. The QB–ICA specificity was evaluated by analyzing the cross-reaction rate (Cr%) with five other common mycotoxins, including citrinin (CIT), ochratoxin A (OTA), deoxynivalenol (DON), FB_1, and aflatoxin B_1 (AFB_1). Cr% was calculated according to the following equation: $Cr\% = [(IC_{50\ ZEN})/(IC_{50\ analog})] \times 100\%$ [24]. The practicality of the QB–ICA sensor was compared with a commercial ELISA kit by analyzing 46 natural corn samples. To evaluate the method reliability, nine ZEN-contaminated samples were further confirmed with LC-MS/MS system (Agilent Corporation, MA, USA), which composed of a triple-quadrupole instrument (Agilent 6410) and an LC system (Agilent 1200 series). The sample cleaning up and LC–MS/MS operation were performed according to local standard GB/T 22286-2008 (Sichuan, China) with some modifications. Briefly, 5 g of ZEN-contaminated sample was extracted with acetonitrile: water (90:10, v/v) for 20 min on a horizontal shaker. After centrifugation at 8000 *g* for 10 min, 1 mL of supernatant and 9 mL of ultrapure water were mixed, and then passed through an immune affinity column which purchased from Beijing Rapid Bioscience Co., Ltd. (Beijing, China). The purified solution was filtered through a 0.22 μm cellulose membrane for the LC–MS/MS analysis. The LC system conditions for ZEN detection were as follows: the column was Agilent Zorbax Eclipse XDB-C18 (100 mm × 2.1 mm, 2.4 μm), which was maintained at 35 °C for chromatographic separation. The flow rate of the mobile phase was 0.30 mL/min and the injection volume of sample solution was 5 μL. The mobile phase consisted of solvent A (ammonium acetate, 10 mM) and solvent B (methanol). The chromatographic separation was performed as a gradient elution as follows: 0 to 6.0 min (80% A, 20% B), 6.0 to 6.1 min (15% A, 85% B), 6.1 to 8.1 min (5% A, 95% B), 8.1 to 12.0 min (80% A, 20% B). Ionization was achieved using electrospray ionization in anion mode with a spray voltage of −3500 V. The MS/MS acquisition was performed in multiple-reaction monitoring mode. The temperature and flow velocity for the desolvation gas (high-purity nitrogen, 99.99%) were 350 °C and 13 L/min, respectively. The monitoring ion pairs were chosen as ZEN m/z 317.1/175.2 (quantitation ion) and 317.1/131.2 (qualitative ions).

3. Results and discussion

3.1. Characterization of QBs and QBs-mAbs conjugates

The highly luminescent QBs were obtained by encapsulation of organic-soluble CdSe/ZnS QDs according a microemulsion method. To evaluate the fluorescent enhancement of the resultant QBs, fluorescence intensities of water-soluble CdSe/ZnS QDs with a maximum emission wavelength at 623 nm and the resultant QBs were monitored. As shown in Fig. 1A, the fluorescence intensity of QBs at concentration of 3.5×10^{-3} nM (dissolved in ultrapure water) was the same as that of water-soluble CdSe/ZnS QDs at 10 nM (dissolved in ultrapure water). Hence for the same numbers of QB and QD particles, the luminescence intensity of QBs was 2857 times higher than that of QDs according to the ratio of their concentrations under the same fluorescence intensity [$Con._{QD}/Con._{QB} = (10\ nmol/L)/(3.5 \times 10^{-3}\ nmol/L) = 2857$]. High-resolution transmission electron microscope (HRTEM) images (Fig. 1B) show that the QBs have relatively uniform size distribution with an average diameter of 247 nm, while Fig. 1B (inset) further indicates that numerous dark QDs are tightly embedded in the polymer matrix. Fig. 1C confirms a macroscopic metal lattice structure of CdSe/ZnS QDs. DLS analysis shows that the hydrodynamic diameter of the free QBs is about 255 nm, whereas that of the QBs-mAbs increases to about 295 nm. The results confirm that the anti-ZEN mAbs was successfully coupled on the surface of the QBs.

3.2. Optimization of the QB-based ICA and detection conditions

The QBs-mAbs probe was obtained by coupling the amino group of anti-ZEN mAbs with the carboxyl group of the QBs using

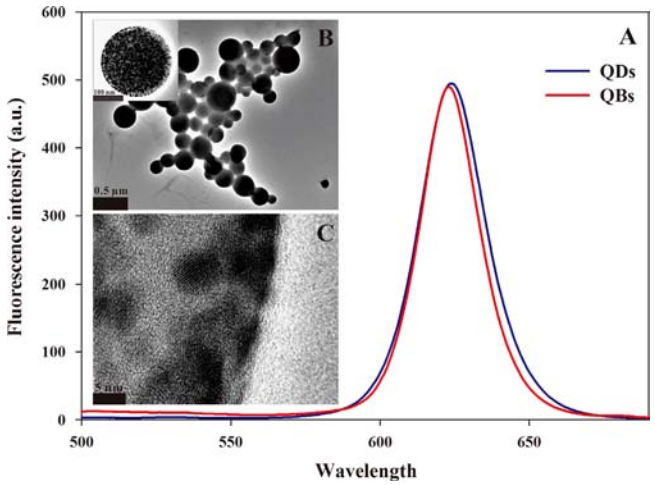


Fig. 1. Characterization of QBs. (A) The fluorescence intensities of water-soluble CdSe/ZnS QDs and the resultant QBs. The concentrations of QDs and QBs were 10 nM and 3.5×10^{-3} nM, respectively. an active ester method. The unpurified anti-ZEN ascites were used to label QBs directly to reduce the QB nonspecific bond with the NC membrane and the ZEN–BSA on the test line, because the mass of miscellaneous proteins in the ascites blocked the excess carboxyl groups of the QBs when the anti-ZEN mAbs bound on the surface of the QBs. To achieve the best sensitivity and high FI signals on both lines, a similar checkerboard titration was performed with a series of ZEN–BSA concentrations on the test line for various different contents of the QB-mAbs probe. The FI signals on both lines were recorded at 30 min. The means of FI on both lines were based on three duplicate measurements with the blank corn extract solution. The competitive inhibition rates are obtained by $(1-B_x/B_0) \times 100\%$, where B_0 and B_x represent FI_T/FI_C of the negative sample and a ZEN-spiked corn extract solution (1.0 ng/mL), respectively. As shown in Table 1, the optimal combinations were as follows: 0.8 mg/mL ZEN–BSA on the test line and 1 μL of QB-mAbs (60 μg/mL) pre-mixed with 69 μL sample solution. Under the optimal combination, the means of the FI_T and FI_C signals on both lines were 748 ± 18 and 539 ± 20, respectively. The competitive inhibition rate for the 1 ng/mL spiked sample was 59.9 ± 0.7% ($n=3$).

In a conventional strip, the labeled probes are irregularly sprayed on the conjugated pad which can hardly be standardized and easily lead to certain variability of FIs on both lines between the different strips [25,26]. In the present study, the conjugated pad was integrated with sample pad, and the QB-mAbs probe was introduced to pre-incubate with the ZEN standard (or sample) solution for 1 min to improve the quantitative reproducibility of QB-ICA sensor (Schematic 1B). The immunological dynamic analysis was used to optimize the detection conditions that influence the stability and sensitivity of ICA, including the interpretation time, the pH value, and methanol content in the sample solution. The immunological dynamic curve for QB-ICA was obtained as described in our previous work [20]. Briefly, 1 min after the solution was added onto the sample pad, the strip was inserted into a portable fluorescent reader. The FI_T, FI_C, and FI_T/FI_C ratio were recorded every 1 min for 30 min. The kinetic curves representing the interaction between the QB–mAbs probe and antigens (on NC membrane) are described by plotting the values of FI_T, FI_C, and FI_T/FI_C against running time. As shown in Fig. 2A, FI signals on both lines continue to increase sharply in the initial 25 min, and then kept gently increasing for the succeeding 30 min observation time. However, the FI_T/FI_C ratio quickly stabilized after 10 min. Thus, the interpretation time for ZEN quantitative analysis was set at 10 min for all succeeding studies.

The effect of pH value on the sensitivity of the strip was evaluated by running a series of solutions with pH values in the range of 5.0 to 9.0. The results in Fig. 2B indicate that the FI_T/FI_C value of the negative sample significantly decreased from 1.54 ± 0.10 to 0.60 ± 0.08 as the pH increased from 5.0 to 9.0. The competitive inhibition rate for the 1.0 ng/mL ZEN-spiked sample reached a maximum of 63% ± 6% in the pH 5.0 solution. These results indicate that weak acidic conditions (pH 5.0) improve the sensitivity of QB-ICA by promoting anti-ZEN mAbs and ZEN-BSA recognition.

The effect of methanol concentration on the sensitivity of QB-ICA was also investigated. The results, shown in Fig. 2C, indicate that the inhibition of QB-ICA continuously declined from 62.5% ± 4% to 32.8% ± 6% as the methanol concentration increased from 0 to 15%, and then remained relatively stable from 32.8 ± 6% to 34.4 ± 1% as the methanol content increased further to 25%. Due to the hydrophobicity of the ZEN molecule, the methanol content in the buffer was set at 10%.

Considering the above results, the optimized experimental conditions of QB-ICA for ZEN quantitative analysis are recommended as follows: the corn extract containing 60% methanol was diluted six-fold with 0.01 M PBS (pH 5.0); 69 μL of the diluted solution and 1 μL of QB-mAbs probe (60 μg/mL) were pre-mixed at room temperature for 1.0 min and then added onto the sample pad; after 10 min, the strip was scanned by a portable fluorescent reader for ZEN quantitative analysis.

3.3. Assay validation

Under optimal experimental conditions, a standard curve for the QB-ICA method was constructed by plotting the ratio of B_X/B_0 against the logarithm of ZEN concentrations. The standard solutions were prepared by spiking a ZEN stock solution (1.0 μg/mL) with a blank corn sample extract to final concentrations of 0, 0.0625, 0.125, 0.35, 0.75, 2.0, 5.0, 7.5, 10, 15, and 20 ng/mL, respectively. The results, shown in Fig. 2D, indicate that the method exhibits a wide dynamic linear range of 0.125 ng/mL to 10 ng/mL with a median inhibitory concentration (IC_{50}) of 1.0 ng/mL ($n=3$). The regression equation of the standard curve was $y=-0.160\ln(x)+0.504$ with a reliable correlation coefficient ($R^2=0.994$).

The LOD of the QB-ICA method was calculated at 10% inhibitory concentration to be 0.0625 ng/mL, which is 5.6 times higher than that of the previously reported AuNPs–ICA quantitative method. The LOD for a real corn sample was 3.6 μg/kg, according to the mean determined concentration of 20 randomly negative corn samples plus three-fold standard deviation [27,28], and then multiplied by the dilution factor of 30. The intra-assay recovery rates for ZEN-spiked concentrations of 0.5, 1.0, and 2.0 ng/mL were 108.0 ± 3.0%, 97.0 ± 1.5%, and 89.5 ± 1.7%, and those for the inter-assay were 106.0 ± 1.9%, 95.0 ± 3.5%, and 93.5 ± 4.4%, respectively (Table 2). The above results indicate that the precision and accuracy of the QB–ICA method are acceptable for ZEN quantitative detection. The QB-ICA specificity exhibits negligible cross-reactivity with other five common mycotoxins: CIT, OTA, DON, FB_1, and AFB_1.

To verify the practicability of the QB–ICA sensor, 46 real corn samples were analyzed using both QB–ICA and a commercial ELISA kit. The results indicate that the two methods have a good agreement ($R^2=0.92$, Fig. 3A). Nine random corn samples, found to be ZEN-contaminated using QB-ICA, were further analyzed by LC–MS/MS to confirm the reliability of QB-ICA. The results from

QB-ICA sensor also shows a highly significant correlation with LC-MS/MS method (R^2 = 0.96, Fig. 3B).

4. Conclusions

In summary, highly luminescent QBs have been employed to provide a competitive ICA system for rapid (10 min) and quantitative detection of ZEN in corn samples, in which the QBs have more than 2800 times brighter luminescence than the corresponding CdSe/ZnS QDs. The optimal QB-ICA exhibits a detection limit of 0.0625 ng/mL for ZEN, which is 5.6 times higher than that of a previously reported AuNPs-ICA quantitative method. Moreover, QB-ICA shows acceptable precision and accuracy, and has a highly significant correlation to the conventional ELISA and LC–MS/MS methods. On account of its significant advantages in luminescent signal amplification, the

ABSTRACT

An ultra-hydrophobic ionic liquid, 1-hexyl-3-methylimidazolium tris(pentafluoroethyl)trifluorophosphate ([HMIM][FAP]) was immobilized in the pores of a polypropylene hollow fiber for liquid–liquid–liquid microextraction (HF-LLLME) of chlorophenols (CPs) (4-chloro-3-methylphenol, 2,4-dichlorophenol and 2,4,6-trichlorophenol). The analytes were first extracted from 10 ml of water sample into the ionic liquid membrane, and then were extracted back into 5 μl of sodium hydroxide aqueous solution in the hollow fiber channel. After extraction, the acceptor solution was directly injected into a high-performance liquid chromatographic system for analysis. Extraction parameters such as extraction time, salt concentration in the sample, the pH of the sample and acceptor phase, and stirring rate during extraction were investigated. The relative standard deviations of the analytes varied from 4 to 6%. Limits of detection of <0.5 ng/ml were obtained for the three analytes. The squared regression coefficients relating to the calibration curve were ≥ 0.9941. The proposed method was applied to the analysis of CPs in canal water.

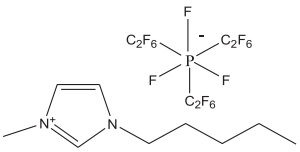
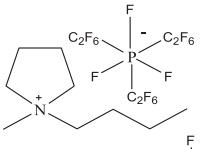
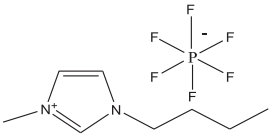
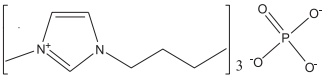
1. Introduction









Sample preparation is a critical step in analytical chemistry, particularly in environmental analysis. In general, liquid–liquid extraction (LLE) [1,2] is one of the most widely used pretreatment procedures. However, it is labor-intensive and time-consuming. In addition, it generally requires a large amount of potentially toxic and high-purity solvents. Over the past 2 decades, miniaturized, microscale sample preparation techniques have been developed as alternatives to LLE, such as liquid-phase microextraction (LPME) [3,6–10] and solid-phase microextraction (SPME) [4,5]. Jeannot and Cantwell developed a liquid-based extraction procedure based on a microdrop of solvent suspended at the tip of a Teflon rod [3]. They referred to the method as solvent microextraction. Later, the same authors [6] and He and Lee [7] developed an approach whereby the organic drop was supported at the tip of a micro-syringe needle. Different types of LPME, as this microscale liquid-based extraction mode is now generally known, have been investigated, such as continuous flow microextraction [8], static LPME [7] (later referred to as single-drop microextraction (SDME)), dynamic LPME [9] and headspace LPME [10]. The technique has been demonstrated to be a simple, fast, and cost-effective sample pretreatment method [11]. However, the instability of the solvent microdrop, problematic application to complex aqueous samples, relative low precision (when conducted manually), and sensitivity were often encountered [12]. In order to overcome these disadvantages, hollow fiber protected LPME was introduced. One mode of HF-LPME is HF-LLLME [12–14] which is a simple technique in which analytes are extracted into an organic phase from an aqueous donor phase, and subsequently extracted back into an aqueous acceptor phase. For this method, a hollow fiber is used to support the organic phase (held within the wall pores) and acceptor phase (confined within the channel of the membrane). Since the final phase is aqueous, it can be introduced into a reversed-phase high-performance liquid chromatographic (HPLC) system without further treatment. For HF-LLLME, the selection of the organic phase is a critical step to obtain efficient extraction. It should be immiscible with water, relatively less volatile, and be compatible with the hollow fiber. 1-Octanol [13], toluene [15], and undecane [16] are commonly used solvents in HF-LLLME. Since these are volatile organic chemicals, they pose potential risks to users.

Room temperature ionic liquids (ILs) are composed of organic cations and various anions. ILs have some significant advantages over organic solvents, such as low volatility, high thermal stability and the ability to interact with a variety of organic and inorganic

[BMIM][PF_6]		1.36	312	43.21
[BMIM][PO_4]		–	–	–

compounds [17]. Furthermore, they are considered as environmentally friendlier solvents, and thus serve as alternatives to conventional organic solvents. Since IL was used by Liu et al. in LPME [18], their application has become widespread in the extraction field [19,20]. ILs containing the hexafluorophosphate (PF_6^-) anion have been applied as supporting liquid for HF-LLLME. For example, 1-butyl-3-methylimidazolium hexafluorophosphate ([BMIM][PF_6]) was used in this manner for the extraction of aliphatic and aromatic hydrocarbons [21]. 1-Octyl-3-methylimidazolium hexafluorophosphate ([OMIM][PF_6]) was employed for the extraction of chlorophenols (CPs) [22] and sulfonamides [23]. However, Swatloski et al. reported that these ILs are hydrolytically unstable [24]. It has been found that after 5 min of SDME via direct immersion using [BMIM][PF_6], 50% of the microdrop volume was lost [25]. [OMIM][PF_6] is more hydrophobic; however, it was found that this IL also partially dissolved in aqueous solution after 30 min [18,26]. Recently, ILs containing tris(perfluoroalkyl)trifluorophosphateanion (FAP^-) have been shown to have excellent hydrolytic, thermal and electrochemical stability. The water uptake of these ILs are more than 10 times less than that of ILs with the PF_6^- [27]. Cong et al. have applied FAP-based ILs as SDME extraction solvents [25]. In our previous studies, 1-hexyl-3-methylimidazolium tris(pentafluoroethyl)trifluorophosphate ([HMIM][FAP]) was successfully used as extraction solvent in HF-LPME [28] and dispersive liquid–liquid microextraction [29,30] of analytes from aqueous samples.

CPs were used as the analytes in the present work. LPME methods, including ultrasound-headspace LPME [31], dispersive liquid–liquid microextraction (DLLME) [32], single drop LPME [33] and HF-LPME [34] have been applied to extract CPs from environmental water samples. [OMIM][PF_6] as the impregnated IL in the hollow fiber wall pores for HF-LLLME [22] and [BMIM][PF_6] based three-phase liquid–liquid–liquid solvent bar microextraction [35] of CPs from environmental water samples have been reported. In this work, we investigated the FAP-based IL, [HMIM][FAP], as the wall pore-impregnated solvent in HF-LLLME. The influence of HF-LLLME parameters such as extraction time, pH of the donor sample and acceptor phase, stirring rate during extraction, and salt concentration in the sample were optimized and the proposed method, with HPLC, were applied to determine CPs in canal water samples.

2. Experimental

2.1. Chemicals and materials

HPLC grade methanol was purchased from Tedia (Fairfield, OH, USA) and acetone was supplied by Merck (Darmstadt, Germany). 4-Chloro-3-methylphenol (p*K*a 9.6), 2,4-dichlorophenol (p*K*a 7.8), and 2,4,6-trichlorophenol (p*K*a 6.2) were supplied by Aldrich (Milwaukee, WI, USA), Ultrapure water was produced on a Milli-Q water purification system (Millipore, Milford, MA, USA). Sodium chloride was obtained from GCE (Chula Vista, CA, USA). [HMIM][FAP] and 1-butyl-1-methylpyrrolidinium tris(pentafluoroethyl) trifluorophosphate [BMPL][FAP] were purchased from Merck. 1-Butyl-3-methylimidazolium phosphate ([BMIM][PO_4]) and [BMIM][PF_6] were bought from Strem Chemicals (Newburyport, MA, USA). The structures and physical properties of the ILs investigated in this study are shown in Table 1. Sodium hydroxide and sodium dihydrogen phosphate were purchased from Merck and orthophosphoric acid (85% purity) was supplied by Carlo Erba (Milan, Italy).

Individual stock solutions of the pure CPs were prepared in methanol at 1 mg/ml concentrations and stored at 4 °C. Working aqueous solutions containing all three CPs at different concentrations were prepared daily. The concentrations of the analytes in the working solutions for the optimization experiments, were 1 μg/ml. Real water samples were collected from a canal in Singapore, and stored at 4 °C until ready for extraction.

Accurel Q3/2 polypropylene hollow fiber membrane with an inner diameter of 600 μm, wall thickness of 200 μm, and wall pore size of 0.2 μm, was obtained from Membrana (Wuppertal, Germany).

2.2. Instrumentation

HPLC analysis was carried out on a Waters (Milford, MA, USA) instrument with a Rheodyne (Cotati, CA, USA) 77251 injector equipped with a 20 μl sample loop, a Degasys DG-2410 degasser, a Waters 1525 μ binary pump and a Waters 2487 dual λ absorbance detector. The detection wavelength was set at 240 nm. Data was collected and processed by Empower version 5.0 (Waters) data analysis software.

Chromatographic separation was conducted on a Metaphase KR100-5-C18 (Bioscience, Kuala Lumpur, Malaysia) column (250 × 4.6 mm i.d.; packed with 5 μm particles) The mobile phase used consisted of 70% methanol and 0.01 M sodium dihydrogen phosphate solution, acidified to pH 2.5 with orthophosphoric acid, and delivered at a flow rate of 0.5 ml/min.

2.3. HF-LLLME procedure

Prior to extraction, a hollow fiber tubing was cut manually into a length of 2.5 cm and one end was heat sealed, before being cleaned with acetone under ultrasonication, and air dried. A 10 ml aliquot of sample solution was added to a 15 ml sample vial with a 15 mm × 6 mm magnetic stirring bar. The vial was placed on a MR3001K magnetic stirrer plate (Heidolph, Kelheim, Germany). Five microliters of the acceptor phase solution was introduced into the clean and dry hollow fiber using a 25-μl microsyringe with a flat needle tip. The fiber was then immersed in [HMIM][FAP] for 5 s for impregnation of its wall pores. The IL impregnated fiber, together with the needle, were placed in the sample solution. The magnetic stirrer was switched on to start the extraction. After extraction for a prescribed time, the hollow fiber assembly was removed from the sample solution. The extract was withdrawn into the microsyringe, and injected directly into the HPLC system for analysis. The used hollow fiber was discarded and a fresh one was used for the next extraction.

3. Results and discussion

3.1. Selection of IL

The type of solvent immobilized in the pores of the hollow fiber is an essential consideration for HF-LLLME. In general, the solvent selected should be compatible with the polypropylene fiber so as to be able to easily fill its wall pores. The immiscibility with the water sample and the acceptor phase should also be seriously considered as it acts as a suitable medium between the two phases. Furthermore, reasonably higher solubility of the analytes in the organic phase than in the water sample is necessary, as is the higher solubility of analytes in the acceptor phase than in the organic phase. The following ILs, i.e. [BMIM][PO_4], [BMIM][PF_6], [HMIM][FAP] and [BMPL][FAP] were investigated. All were easily immobilized in the pores of the hollow fiber by immersion into them for 5 s. Fig. 1 shows the extraction efficiencies for the three selected analytes using the 4 ILs during 20 min of extraction. The results clearly showed that higher extraction efficiency was achieved by [HMIM][FAP]. [HMIM][FAP], most probably by virtue of its high hydrophobicity and the presence of the imidazolium group (allowing π–π interactions between [HMIM][FAP] and the CPs), has greater affinity for the analytes compared with [BMPL]

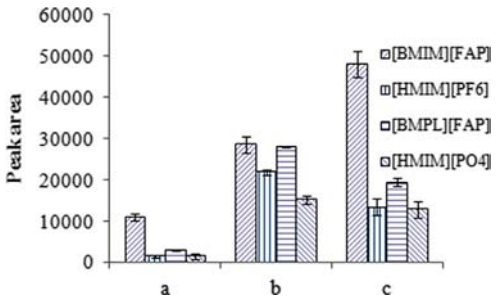

Fig. 1. Effect of different ILs on HF-LLLME efficiency. Spiked concentrations in water, 1 μl/ml for individual analytes; pH of sample solution, 2.5; pH of acceptor solution, 13; stirring rate, 500 rpm, extraction time, 20 min; (a) 4-chloro-3-methylphenol, (b) 2,4-dichlorophenol, and (c) 2,4,6-trichlorophenol.

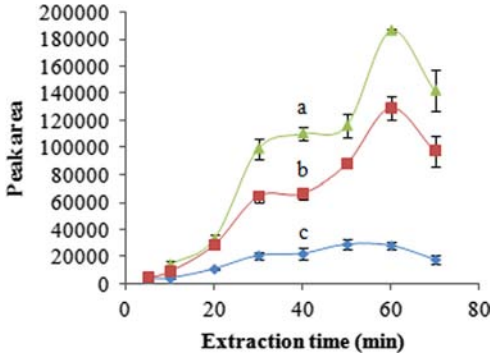

Fig. 2. Effect of extraction time on HF-LLLME efficiency. Spiked concentrations in water, 1 μl/ml for individual analytes; pH of sample solution, 2.5; pH of acceptor solution, 13; stirring rate, 500 rpm; (a) 2,4,6-trichlorophenol, (b) 2,4-dichlorophenol, and (c) 4-chloro-3-methylphenol.

[FAP]. The high viscosity of [BMIM][PF_6] may make it difficult for analytes to diffuse into the IL, thus leading to lower extraction efficiency. [BMIM][PO_4] provided the lowest extraction efficiency for the CPs. The reason may be due to the anions (PO_4^-) imparting less hydrophobic character causing small amounts of the IL to dissolve in the aqueous sample after 20 min extraction [18,26]. Thus, of the four ILs considered, [HMIM][FAP] was the only suitable solvent for the present work.

3.2. Effect of extraction time

HF-LLLME is an equilibrium-based process rather than an exhaustive extraction procedure. The extraction efficiency depends on the partition between the sample phase and the solvent phase, and further, between the solvent phase and the acceptor phase. A series of extraction times was investigated by considering a water sample containing 1 μg/ml of each analyte, at 500 rpm stirring speed. It can be seen from Fig. 2 that all analytes reached equilibrium after 60 min extraction. The reason for comparatively longer extraction times (in comparison to classical HF-LLLME using organic solvents and aqueous solutions) was that the relatively high viscosity of [HMIM][FAP] inhibited the mass transfer rate between the sample and the acceptor phase. Nevertheless, provided additional time (60 min) was allowed for, extraction efficiency was not compromised.

3.3. Effect of the acidity of donor phase and the alkalinity of the acceptor phase

The acidity of the sample phase and alkalinity of the acceptor phase are of great importance for HF-LLLME. As is known, CPs are weak acids. The pH of the sample solution should be lower than the p*K*a's of the CPs so as to suppress their ionization CPs so that they exist in their neutral states. In the present work, the pH of the sample solution was adjusted by adding different amounts of 30% orthophosphoric acid. The extraction efficiency showed no significant change across a pH range of between 1 and 4. Thus, a pH value of 2.5 was sufficient to maintain the neutrality of the CPs. Based on the extraction principles of HF-LLLME, the pH of the acceptor phase should trap the analytes to prevent them from being extracted back into the IL. Increasing the pH in the acceptor phase hastens the ionization of the analytes (via an acid–base reaction). As Fig. 3 shows, the peak areas of all the analytes increased with increase of the pH from 11 to 13. Relatively higher extraction efficiency was achieved at a pH of 13. However, at a pH of 14, the peak areas decreased. The reason for this observation is that the acceptor phase would be sufficiently alkaline to ionize the analytes when the pH of the acceptor phase at a value of 13.

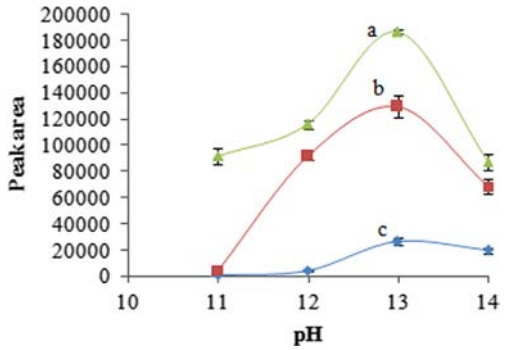

Fig. 3. Effect of pH of acceptor phase on HF-LLLME efficiency. Spiked concentrations in water, 1 μl/ml for individual analytes; pH of sample solution, 2.5; extraction time, 60 min; stirring rate, 500 rpm; (a) 2,4,6-trichlorophenol, (b) 2,4-dichlorophenol, and (c) is 4-chloro-3-methylphenol.

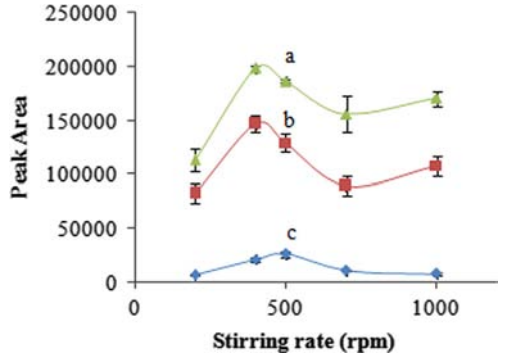

Fig. 4. Effect of stirring rate on HF-LLLME efficiency. Spiked concentrations in water, 1 μl/ml for individual analytes; pH of acceptor solution, 13; pH of sample solution, 2.5; extraction time, 60 min; (a) 2,4,6-trichlorophenol, (b) 2,4-dichlorophenol, and (c) 4-chloro-3-methylphenol.

However, at a pH of 14, the buffer capacity of the phosphate in the mobile phase was not high enough to neutralize the ionized CPs in the NaOH acceptor solution, and a proportion of the analytes was still ionized after injection into the HPLC system. Thus this led to the lower peak areas observed [22].

3.4. Effect of stirring rate

Agitation of the sample solution to mix it well, is one way to accelerate the mass transfer of the analytes from the sample, through the IL membrane and to the acceptor phase. In this study, different sample solution stirring rates were investigated. As seen from Fig. 4, peak areas increased with increasing stirring rates up to 400 rpm. However, at >400 rpm, peak areas decreased. It was observed that at >400 rpm the formation of air bubbles attached to the surface of the hollow fiber occurred, thus inhibiting the extraction across the wall pores by reducing the contact surface area between the hollow fiber and the sample. Thus higher stirring rates >400 rpm were detrimental to the extraction process. Therefore, 400 rpm was chosen for the subsequent experiments.

3.5. Effect of salt addition

In general, organic analyte solubility in aqueous solutions decreases with increasing salt concentration. Addition of salt to a sample solution can potentially increase analyte recovery in the most of the microextraction procedures through such a salting-out effect. The variation in salt (sodium chloride) concentration (5 to 40 mg/ml) on HF-LLLME was investigated. As Fig. 5 shows extraction efficiency improved with increasing salt concentration to a

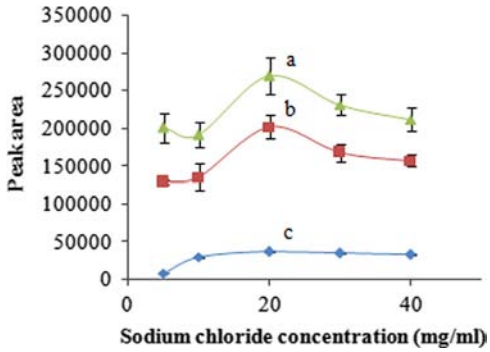

Fig. 5. Effect of salt concentration on HF-LLLME efficiency. Spiked concentrations in water 1 μl/ml for individual analytes; pH of acceptor solution, 13; pH of sample solution, 2.5; extraction time, 60 min; stirring rate, 400 rpm;(a) 2,4,6-trichlorophenol, (b) 2,4-dichlorophenol, and (c) 4-chloro-3-methylphenol.

Table 2
Quantitative results of HF-LLLME.

Analyte	RSD% ($n=6$)	Linear range (ng/ml)	r^2	LOD (ng/ml)
4-Chloro-3-methylphenol	4.3	10–500	0.9941	0.5
2,4-Dichlorophenol	4.6	5–1000	0.9994	0.3
2,4,6-Trichlorophenol	5.7	5–1000	0.9991	0.3

maximum value of 20 mg/ml of sodium chloride. Beyond 20 mg/ml, lower peak areas were observed. There was conceivably a threshold of optimum salt concentration for the most favorable extraction; beyond this value, the increase in viscosity due to higher salt concentration began to impede the mass transfer process.

3.6. Method validation

Under the optimum extraction conditions, linearity, repeatability and limits of detection (LODs) were investigated using spiked ultrapure water samples. The results are shown in Table 2. The linearity of calibration curves was studied for analytes at a concentration range between 5 and 1000 ng/ml (except for 4-chloro-3-methylphenol, between 10 and 500 ng/ml). All analytes showed good linearity with squared regression coefficients of between 0.9941 and 0.9994. The LODs were calculated based on a signal to noise ratio of 3, and ranged between 0.3 and 0.5 ng/ml. The repeatability of the chromatographic peak areas was studied for six replicate experiments using the optimum extraction conditions. The relative standard deviations (RSDs) were from 4 to 6%. The obtained results were comparable or better than those reported in previous microextraction studies, in which [OMIM][PF_6] was used as the impregnated IL in the hollow fiber wall pores for HF-LLLME [22], and [BMIM][PF_6] was employed in IL-based three-phase liquid–liquid–liquid solvent bar microextraction [35], of CPs from environmental water samples.

3.7. Canal water analysis

The proposed method was applied to the determination of CPs in canal water samples. There were no target analytes detected in the original samples, indicating that either the CPs were below the LODs of the present procedure, or the water was free of these contaminants. Nevertheless, in order to evaluate matrix effects, the samples were spiked at 50 and 500 ng/ml of the analytes. The spiked samples were extracted without pretreatment (i.e. unfiltered). For all sample solution at different concentrations, three

Table 3
Relative recoveries and precision of HF-LLLME of canal water spiked with CPs at different concentrations (50 ng/ml and 500 ng/ml).

Analyte	50 ng/ml		500 ng/ml	
	Relative recovery (%)	RSD (%)	Relative recovery (%)	RSD (%)
4-Chloro-3-chlorophenol	80	2.9	93	3.8
2,4-Dichlorophenol	102	4.5	97	6.1
2,4,6-Trichlorophenol	99	4.0	101	4.2

replicate extractions were conducted. The relative recoveries (Table 3), defined as the ratio of peak areas of the spiked real water extracts to spiked ultrapure water extracts, showed that these values varied between 80 and 102%, and RSDs were from 3 to 6%. These results showed that the matrix had little effect on HF-LLLME, due to the protection afforded by the hollow fiber. This indicates the present method is suitable for application to real world environmental waters.

4. Conclusion

In the present study, a new IL, FAP-based IL, [HMIM][FAP] was for the first time applied to HF-LLLME. In comparison with commonly used ILs containing PF_6^- and PO_4^-, [HMIM][FAP] is more hydrophobic, making it suitable for the HF-LLLME of CPs from aqueous samples. The proposed technique showed very effective sample clean-up and high sensitivity, with LODs of between 0.3 and 0.5 ng/ml levels, and satisfactory repeatability (RSDs lower than 6%). In addition, matrix effects did not pose significant problems, with relative recoveries of $>80\%$. It is likely that with its ultra-hydrophobility and compatibility with polypropylene hollow fiber membrane, [HMIM][FAP] has the potential to be applied to the HF-LLLME of trace levels of other acidic or basic analytes.

ABSTRACT

Iminodiacetic acid (IDA) is dicarboxylic acid amine, which may produce stronger interaction with polar or charged compounds than bidentate α,β-amino acid. In this article, a novel type of tridentate zwitterionic HILIC stationary phase was prepared by covalently bonding N-benzyl IDA on silica gel *via* copper(*I*) catalyzed Huisgen azide-alkyne 1,3-dipolar cycloaddition (CuAAC). The structure of this stationary phase and all related intermediates was confirmed by NMR, FT-IR, MS spectrum and elemental analysis. The new stationary phase showed good HILIC characteristics and high column efficiency (the theoretical plate number is up to 44000 plates m^{-1} in the case of guanosine) in the application of separation of polar compounds, including organic acids, organic bases, as well as highly polar and hydrophilic compounds, such as cephalosporins and carbapenems. Most of them displayed good peak shape and selectivity.

1. Introduction

Hydrophilic interaction liquid chromatography (HILIC) has been developed as a powerful separation technique for highly polar compounds that do not bind to reverse phase (RP) stationary phases. Owing to many specific advantages over conventional normal phase liquid chromatography (NP-LC) and reverse phase liquid chromatography (RP-LC), applications of HILIC on separation and analysis of highly polar and hydrophilic compounds have greatly increased [1–9]. For example, in proteomics, it has been applied in multidimensional peptide separation [10,11], analysis of posttranslational modifications (PTMs) such as glycosylation, N-acetylation and phosphorylation [12], as well as enrichment of low-abundance compounds in biological samples [13,14]. Highly polar zwitterionic HILIC stationary phases possess polar groups bearing both positive and negative charges, which may produce both hydrophilic and weak electrostatic interactions with polar and charged compounds easily. Mobile phase with lower content aqueous buffer can be used in LC for efficient separation and analysis, which results in a lower head pressure, thereby allowing for higher flow rates. Furthermore, the higher organic content makes it conveniently coupled to mass spectrometry (MS), and the high organic content in mobile phase can increase the MS sensitivity as well [15,16]. Up to now, a series of the zwitterionic HILIC stationary phases has been prepared by covalently bonded polar groups with both positive and negative charges on the surface of polymers, silica gel or other support materials, and most of them are zwitterionic phosphorylcholine and betaine type [17–20]. Only a few of α, β-amino acid type of zwitterionic stationary phases have been reported, which display good HILIC properties [21,22]. On the other hand, as a typical reaction of click chemistry, Cu(I) catalyzed Huisgen azide-alkyne 1,3-dipolar cycloaddition (CuAAC) reaction was widely applied in variant fields [23], such as bioconjugation [24–26], material sciences [27–29], organic synthesis [30–32] and drug discovery [33,34], and it has been regarded as a powerful strategy. So far, several covalently bonded stationary phases have been prepared by CuAAC [35–40], and all of them showed good chromatographic properties when they are applied in liquid chromatography. In previous work, we have developed click-lysine as a zwitterionic stationary phase for HILIC purpose, which could be applied not only in the separation and analysis of hydrophilic organic compounds under HILIC mode, but also separation and analysis of inorganic ions under ion chromatography(IC) mode [41,42]. Iminodiacetic acid (IDA) is a dicarboxylic acid amine, which

can act as a tridentate ligand. Chelex 100 resin, which is a styrene-divinylbenzene copolymer containing IDA groups, has been utilized in ion exchange columns, DNA extraction in preparation for polymerase chain reaction (PCR), trace metal removal, metal analysis, as well as in water testing in environmental and agricultural laboratories [43–45]. All of these applications are attributed to the strong interactions between IDA and polar or charged compounds, and these interactions should be stronger than the bidentate ligand such as α, β-amino acid. Herein, we designed and prepared the covalently bonded N-benzyl IDA to silica beads to form a new kind of stationary phase, which may display much different chromatographic properties. Applications in separation polar or charge compounds are expected.

2. Experimental

2.1. Apparatus and chromatographic conditions

FT-IR measurements were performed on a Nicolet 5SXC (USA). ^{1}H NMR was carried out on a Bruker 400 (Germany). Elemental analysis was measured on an elemental Vario EL III (Germany); high-resolution mass spectra (HRMS) were performed using Waters GCT Premier.

An Shimadazu LC-20AT HPLC system consisting of a binary pump, a degasser, an auto sampler, an automatic thermostatic column compartment, and a UV detector were used to perform the chromatographic experiments. Click N-benzyl IDA column (5 μm, 150 × 4.6 mm, i.d., homemade). HPLC acetonitrile and water were used as mobile phase, and ammonium formate buffer solutions (concentration from 10 mM to 40 mM) with pH ranging from 3.4 to 6.0 (adjusted by adding formic acid) were used as buffer.

2.2. Chemicals and reagents

Spherical silica (5 μm partical size; 10 nm pore size; 300 m^2 g^{-1} surface area) was purchased from Fuji Silysia Chemical Ltd. (Japan). HPLC grade acetonitrile and formic acid were from Sigma (USA) and Tedia (USA), respectively. Milli-Q ultrapure water was used throughout the HPLC experiment. Imino diacetic acid, 4-nitrobenzyl chloride, imidazole, sodium azide, acetylchloride, $CuSO_4$.5 H_2O, ammonium formate and sodium ascorbate were all domestic reagent (National Medicine Corporation Chemical Reagent Ltd., Shanghai, China) and used without further purification. 3-isocyanatopropyl-triethoxysilane and propargylamine (National Medicine Corporation Chemical Reagent Ltd., Shanghai, China) were purified by distillation before use. The solvent N-dimethyl formamide, methanol and ethanol (Ninfeng Chemical Reagent Ltd., Shanghai, China) were used as received. The test solutes used for HILIC evaluation were commercially available test compounds such as sulfadiazine, uracil, adenosine, uridine, inosine, adenine, guanosine, sorbic acid, orotic acid, 4-aminobenzoic acid, 4-hydroxybenzoic acid, 3,4-dihydroxybenzoic acid, caffeine, theobromine, theophylline, diprophyllin, quercetin from Aladdin Reagent Ltd., Shanghai, China, and cemandil sodium, ceftezole sodium, cefodizime, cephalosporins diltiazem, cefotiam hydrochloride, ceftazidime sodium, cefepime hydrochloride, cephradine, biapenem, doripenem, and meropenem from Zhejiang Hisoar Pharm. & Chem. Co., Ltd., Taizhou, China). Test solutes were filtered with a 0.45 mm membrane filter (organic membrane, BJ225-PT, Shanghai Jiapeng Science and Technology Ltd., Shanghai).

2.3. Sample preparation

The model compounds (sulfadiazine, uracil, adenosine, uridine, inosine, adenine and guanosine) were used for the performance and retention mechanism evaluation of click N-benzyl IDA column. The test compounds (uracil, uridine, guanosine, 3,4-dihydroxybenzoic acid, orotic acid and diprophylline) were used for the

investigation of retention behavior. The probe organic acids and alkaloids (sorbic acid, 4-aminobenzoic acid, 4-hydroxybenzoic acid, 3,4-dihydroxybenzoic acid, caffeine, theobromine, theophylline, diprophyllin and quercetin) were dissolved in ACN/H_2O (4:1, v/v) for chromatography test. The solutions of cephalosporins (cemandil sodium, ceftezole sodium, cefodizime, cephalosporins diltiazem, cefotiam hydrochloride, ceftazidime sodium, cefepime hydrochloride and cephradine) and carbapenems (biapenem, doripenem and meropenem) were all prepared by dissolving them in ACN/H_2O(1:2), followed by storage in a refrigerator for analysis and preparation of mixed samples.

2.4. Preparation of click N-benzyl IDA stationary phase and column packing

Hydrochloride catalyzed esterification of IDA in methanol afforded dimethyl imino diacetate, subsequent condensation with 4-nitrobenzyl chloride gave dimethyl N-4-nitrobenzyl imino

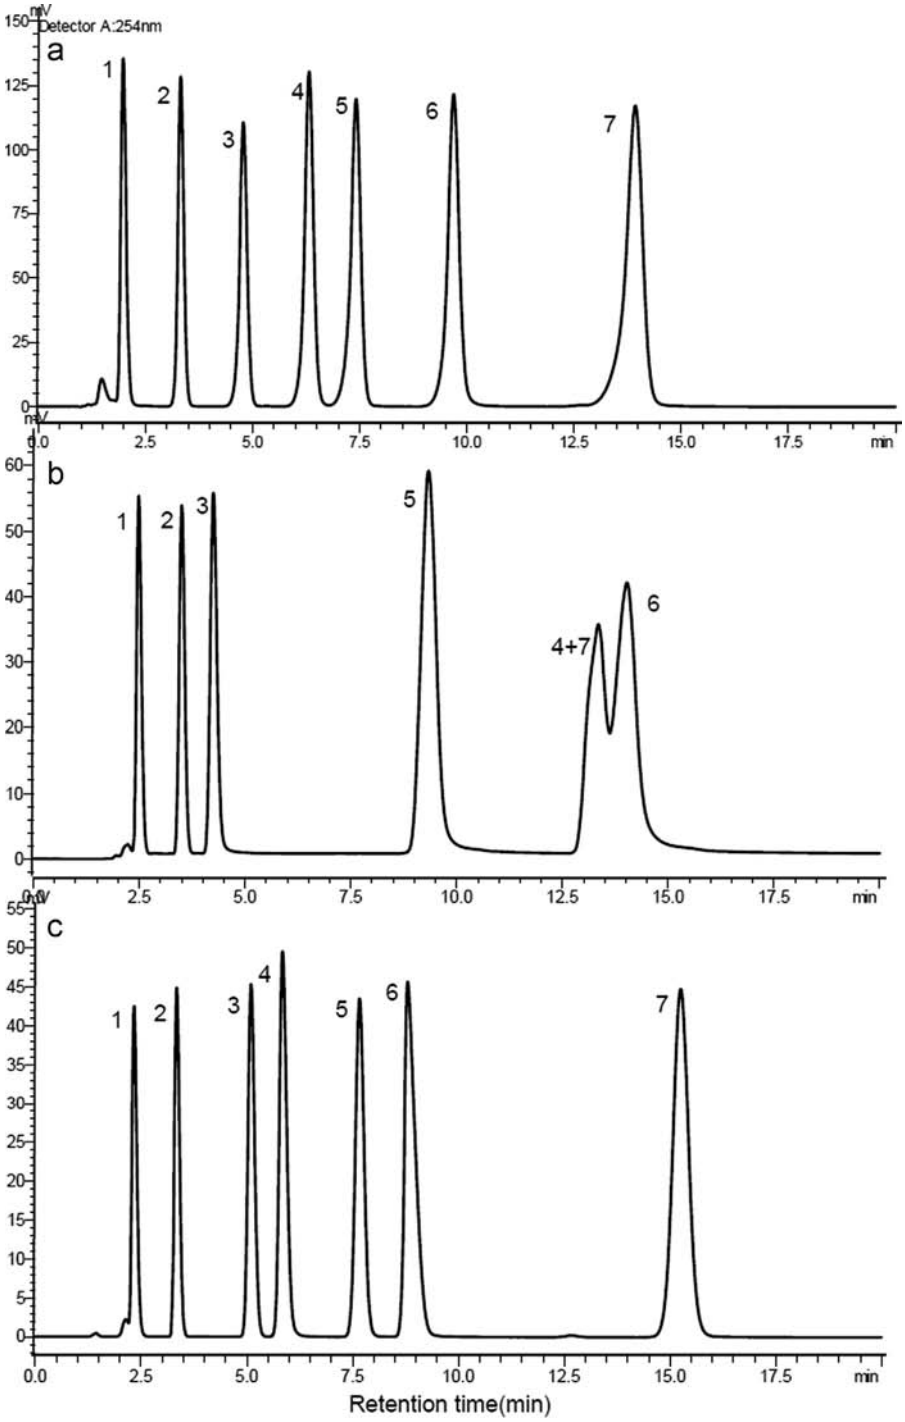

Fig. 2. Separation of nucleosides and bases on Click N-Benzyl IDA ((a) 5 μm, 150 mm × 4.6 mm i.d.), conditions: flow rate 1 mL min^{-1}; 35 °C; mobile phase: acetonitrile: water (80:20, v/v); UV: 254 nm. Peak identification: (1) sulfadiazine, (2) uracil, (3) uridine, (4) adenosine, (5) inosine, (6) adenine, (7) guanosine. Atlantis HILIC-silica ((b) 5 μm, 150 mm × 4.6 mm i.d.), conditions: flow rate 1 mL min^{-1}; 35 °C; mobile phase: ACN/50 mM ammonium formate (95/5, v/v), pH=4.6; UV: 254 nm. and ZIC-HILIC ((c) 5 μm, 150 mm × 4.6 mm i.d.), conditions: flow rate 1 mL min^{-1}; 35 °C; mobile phase: acetonitrile:water (90:10, v/v); UV: 254 nm.

Uridine	4.80	4.84	4.88
3,4-dihydroxybenzoic acid	3.28	3.35	3.41
Orotic acid	2.81	3.51	4.50
Diprophylline	2.98	3.00	2.99

[a] Mobile phase: ACN/ammonium formate, pH = 3.4, (80/20, v/v) for model compounds. Column temperature: 35 °C. Flow rate: 1.0 mLmin^{-1}. UV detection: 254 nm, t_0 = 1.6 min.

beads **5** were prepared by condensation of 3-isocyanatopropyl triethoxysilane with propargylamine in anhydrous DMF, and then directly polymerized with silica beads [35–37]. The click reaction between terminal alkyne-silica beads **5** and N-4-azidobenzyl IDA **4** via CuACC afforded the new stationary phase click N-benzyl IDA **6** (Fig. 1).

The click N-benzyl IDA stationary phase thus prepared was slurry-packed into stainless-steel columns (150 mm × 4.6 mm i.d.) with MeOH as slurry and propulsion solvents for the study of chromatographic behavior.

3. Results and discussion

3.1. Characterization of click N-benzyl IDA

The terminal alkyne-silica and click N-benzyl IDA stationary phase were characterized by FT-IR and elemental analysis. All

datum, including the increase of carbon content, the weakness of νCH on alkyne-silica at 2928 cm^{-1} and the enhancement of νC=O at 1650 cm^{-1} on click N-benzyl IDA stationary phase after "click" step, demonstrated that N-benzyl IDA was bonded to alkyne silica successfully. The results of elemental analysis and the surface concentration are shown in Table 1. The surface concentration (calculated from nitrogen content) of alkynyl group on alkyne-silica was 4.43 μmol m^{-2}, and the surface concentration of click N-benzyl IDA (calculated from the nitrogen content) was 2.23 μmol m^{-2}.

3.2. Chromatographic evaluation under HILIC model

After the click N-benzyl IDA column was prepared, the performance evaluation was carried out by using nucleosides and bases as probe compounds. As show in Fig. 2, seven nucleosides and bases were well separated with acetonitrile/water (80/20, v/v) as mobile phase. This new type of stationary phase showed great separation ability and selectivity, the mixed model compounds could be separated clearly in an appropriate time without using any buffer, and very good peak shapes are displayed. In addition,

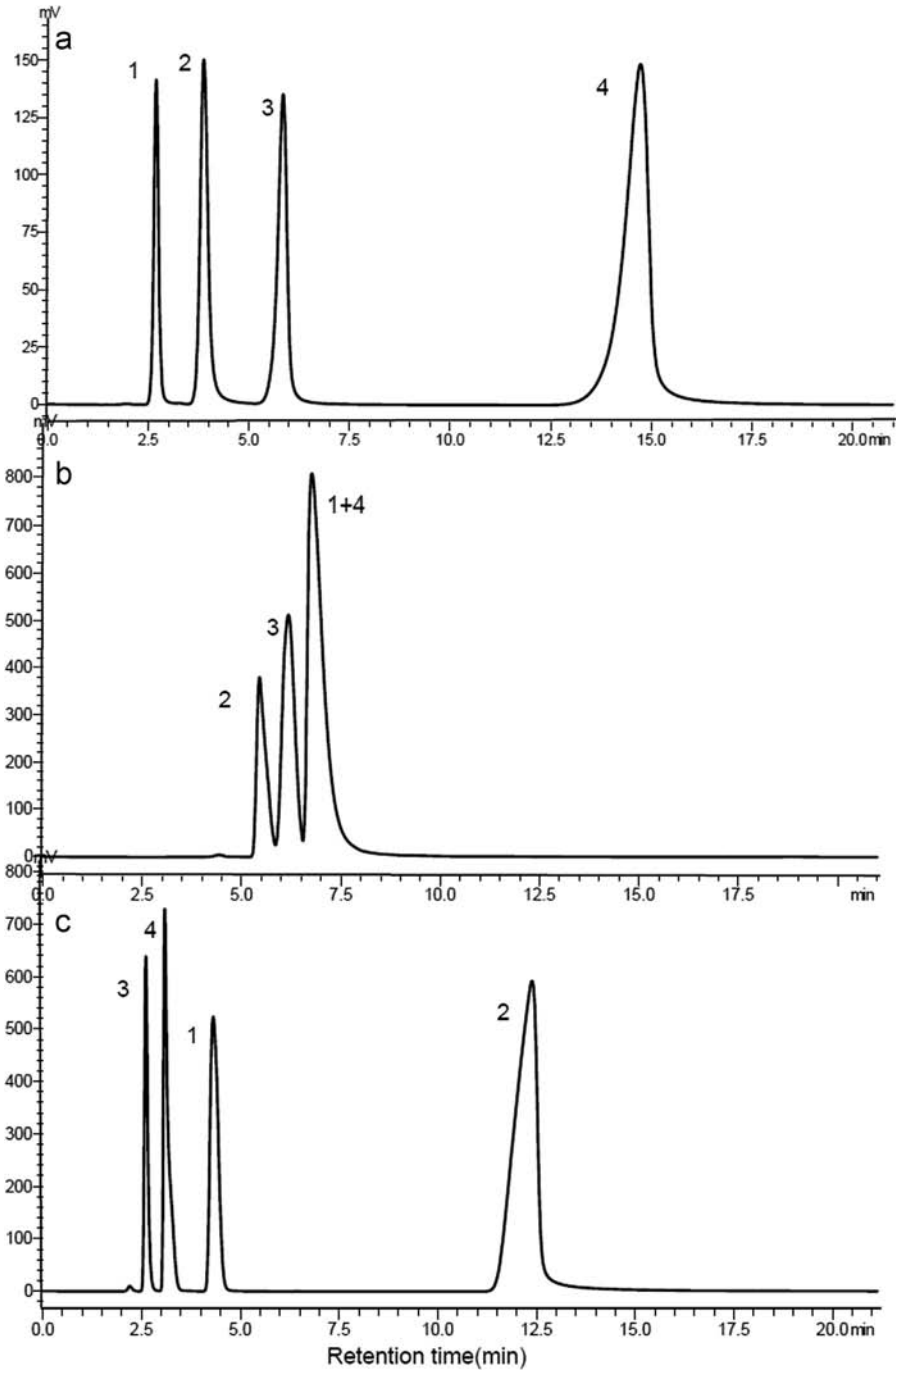

Fig. 5. The separation of four organic acids on Click N-Benzyl IDA ((a) 5 μm, 150 mm × 4.6 mm i.d.), Chromatography conditions: 95% ACN/5% H_2O (v/v), the column temperature: 35°C. Flow rate: 1 mL min^{-1}. Wavelength: 254 nm. Sample: the mixed acids. Injection volume: 5 μL. Peak identification: (1) sorbic acid, (2) 4-aminobenzoic acid, (3) 4-hydroxybenzoic acid, (4) 3,4-dihydroxybenzoic acid. Atlantis HILIC-silica ((b) 5 μm, 150 mm × 4.6 mm i.d.), chromatography conditions: flow rate 0.5 mL min^{-1}; 35 °C; mobile phase: ACN/50 mM ammonium formate (95/5, v/v), pH=3.2; UV: 254 nm. and ZIC-HILIC ((c) 5 μm, 150 mm × 4.6 mm i.d.), chromatography conditions: flow rate 1 mL min^{-1}; 35°C; mobile phase: ACN/10 mM ammonium formate (95/5, v/v), pH=3.2; UV: 254 nm.

the symmetry factors of these compounds are quite good with appropriate retention. In the case of guanosine, the peak symmetry factor is 1.07, retention factor is 7.71, and the theoretical plate number was about 44000 plates m^{-1} calculated according to the USP method. Compared with commercial HILIC (atlantis, Waters) and ZIC-HILIC (Merck), the hydrophilic characteristics were obviously enhanced. Under optimized chromatographic conditions, Click N-benzyl IDA displayed similar separation ability and chromatographic behavior to ZIC-HILIC, while Atantis column could not separate these analytes well, and it displayed different retention behavior from Click N-benzyl IDA. Furthermore, based on the polarity of mobile phase in this separation procedure, Click N-benzyl IDA should possess the strongest retention ability among the three stationary phases, which should be a good advantage for separation more broad range of polar compounds. The Van Deemter plot [47] for inosine on click N-benzyl IDA showed the optimal linear velocity was around 0.35 mm/s [Fig. 3].

Next, the chromatographic behavior of click N-benzyl IDA was studied by investigating the relationship between retention factors and the water content by using nucleosides and bases as probes, and the acetonitrile in combined with water was used as eluent (water content ranges from 10 to 30%, v). The natural logarithmic of retention factors (lnk) was plotted versus the water content (ψ) in the mobile phase. As shown in Fig. 4, Click N-benzyl IDA exhibited typical HILIC characteristics, and the retention time became shorter with the water content increase. The nonlinear relationship between lnk and ψ (Fig. 4) showed that there existed not only one pure partitioning mechanism but other interactions, such as hydrogen bonding, dipole–dipole interaction, ion exchange, chelation and electrostatic interactions. Good liner

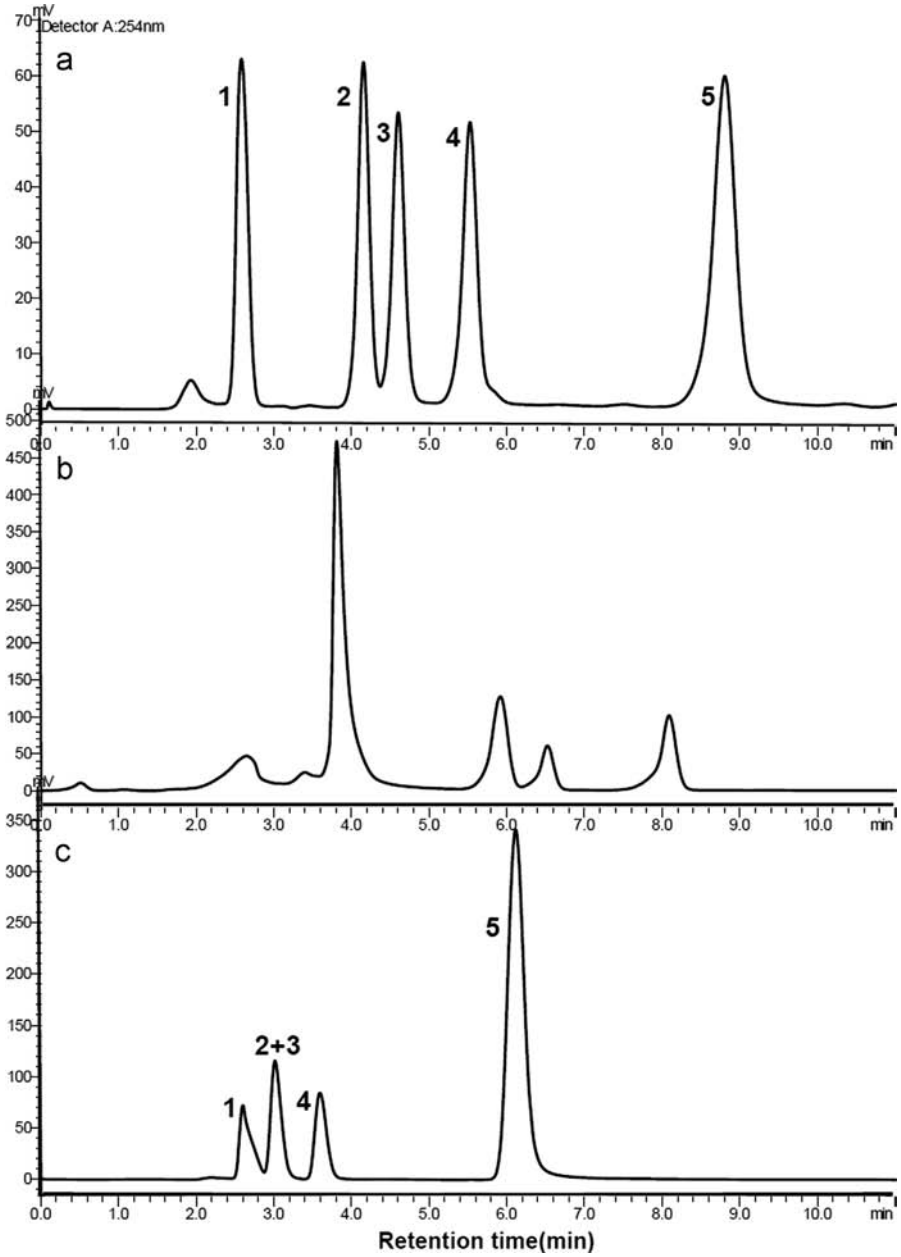

Fig. 6. The separation of five organic bases on Click N-Benzyl IDA ((a) 5 μm, 150 mm × 4.6 mm i.d.), Atlantis HILIC-silica ((b) 5 μm, 150 mm × 4.6 mm i.d.) and ZIC-HILIC ((c) 5 μm, 150 mm × 4.6 mm i.d.). Chromatography conditions: 95% ACN/5% H_2O (v/v), the column temperature: 35 °C. Flow rate: 1 mL min^{-1}. Wavelength: 254 nm. Sample: the mixed bases. Injection volume: 5 μL. Peak identification: (1) caffeine, (2) theobromine, (3) theophylline, (4) diprophyllin, (5) quercetin.

relationship between lnk and lnψ was also observed, and the correlation coefficient R of these nucleosides and bases (sulfadiazine, uracil, uridine, adenosine, inosine, adenine and guanosine) are −0.9967, −0.9976, −0.9989, −0.9988, −0.9956, −0.9975 and −0.9989, respectively. The results further demonstrated that the retention behaviors of these test compounds on click N-benzyl IDA were majorly consistent with the HILIC characteristics and controlled by several interactions. However, when the water content was further increased, some analytes (such as sulfadiazine, adenosine and adenine) displayed obvious mixed-mode chromatographic characteristics. The others also showed such characteristics, though it is not so obvious (Table 2).

The major functional groups of IDA are an amino diacetic acid, its pK_a value was 1.873 and its pK_b value is 12.124. Though the introduction of benzyl group and covalently bonding on silica gel may change its pK value little, its zwitterionic and HILIC property could be kept. Thus, the pH value and salt concentration may affect the retention of many analytes. We then investigated the retention of a wide range compounds (organic acids, nucleosides and bases as well as organic base) on click N-benzyl IDA under different pH values and salt concentrations. First, 10 mM ammonium formate buffer solutions with pH ranging from 3.4 to 6.0 (adjusted by adding formic acid) were used to investigate the retention behaviors of click N-benzyl IDA under different pH values. As shown in Table 3, with the pH value of the eluent increasing (pH from 3.4–6.0), the retention time of guanosine was increased, while the retention time of orotic acid was decreased. At this range of pH value, no obvious effect on their retention was observed for the separation of acids. These facts can be explained that the zwitterionic tridentate IDA containing both carboxylic acid and amine groups may produce several different interactions with different analyte structures, more detailed retention mechanism was not clear yet.

Under HILIC model, the salt concentration usually has obvious effect on retention, so the relationship between salt concentration and retention was investigated by varying ammonium formate concentration from 10 to 40 mM (pH 3.4) in the mobile phase of acetonitrile/water (80/20, v/v). As shown in Table 4, there is little change on the retention time of nucleosides and bases except orotic acid, this may be attributed the fact that most of these analytes were not charged in the mobile phase, thus the electrostatic effect was not applicable to nucleosides and bases. The

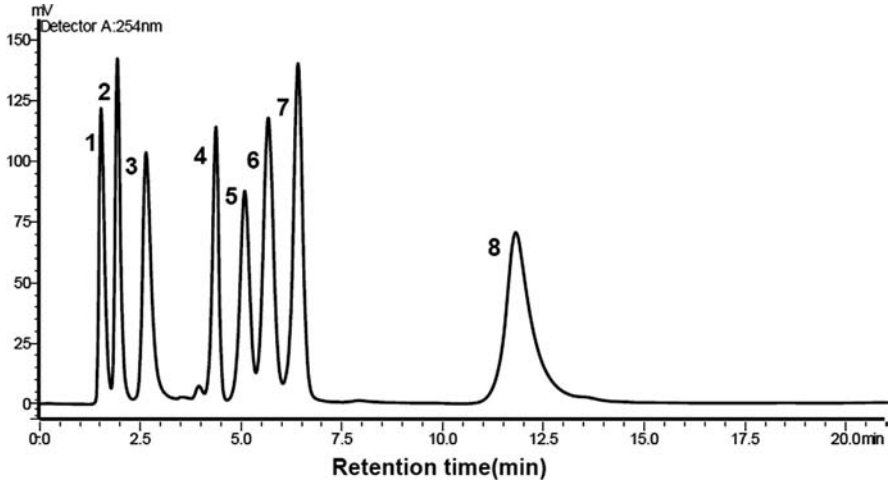

Fig. 7. Separation of eight cephalosporins on Click N-Benzyliminodiacetic acid (5 μm, 150 mm × 4.6 mm i.d.), conditions: mobile phase: ACN/10 mM ammonium formate (80/20, v/v). The column temperature: 35 °C. Flow rate: 1 mL min^{-1}. Inject volume, 3 μL. Wavelength: 254 nm. Peak identification: (1) cemandil sodium, (2) ceftezole sodium, (3) cefodizime, (4) cephalosporins diltiazem, (5) cefotiam hydrochloride, (6) ceftazidime sodium, (7) cefepime hydrochloride, (8) cephradine.

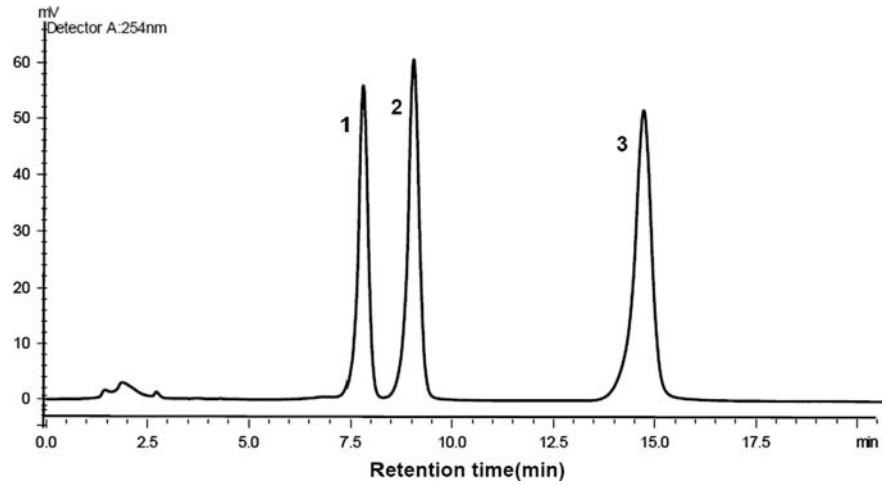

Fig. 8. Separation of three carbapenems on Click N-Benzyliminodiacetic acid (5 μm, 150 mm × 4.6 mm i.d.), conditions: mobile phase: ACN/10 mM ammonium formate (75/25, v/v), pH=4.5. The column temperature: 35 °C. Flow rate: 1 mL min^{-1}. Inject volume, 3 μL. Wavelength: 254 nm. Peak identification: (1) biapenem, (2) meropenem, (3) doripenem.

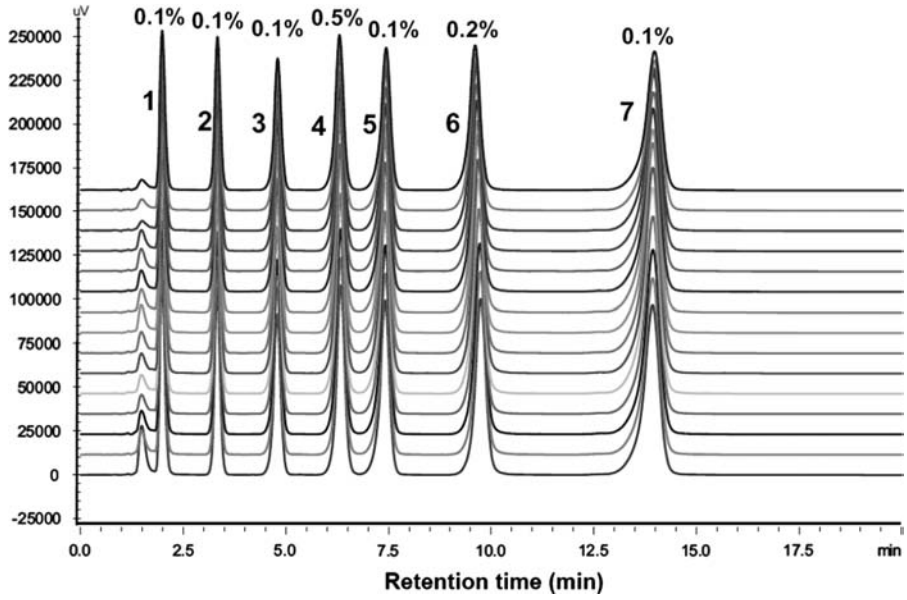

Fig. 9. Retention stability of seven nucleosides and bases on Click N-Benzyliminodiacetic acid by continuously injecting 15 times the mixed nucleosides and bases. Mobile phase: acetonitrile/H_2O (80/20, v/v). The column temperature: 35 °C. Flow rate: 1 mL min^{-1}. Inject volume, 1 μL. Wavelength: 254 nm. Peak identification: (1) sulfadiazine, (2) uracil, (3) uridine, (4) adenosine, (5) inosine, (6) adenine, (7) guanosine.

retention time of most of these analytes become longer with the increase of salt concentration, which is consistent with the HILIC chromatographic properties.

3.3. Application in separating of organic acids and organic bases

In order to broaden the applications of click N-benzyl IDA, it was then applied to the separation of organic acids and organic bases by using ACN:water (95:5, v-v) as mobile phase. The moderate-polar compounds, four organic acids (Fig. 5) and five organic bases (Fig. 6) were well separated with good peak shapes and good efficiency, and without using any other eluent additives. Usually, in order to obtain better peak shape and separation performance, especially for separation acids or bases, eluent additives such as acids, bases or buffers are used either in C18 or HILIC stationary phases. Under optimized conditions, ZIC-HILIC displayed similar separation ability to organic acids, while analytes elution order was different from Click N-benzyl IDA, which may be attributed to their different retention mechanisms. However, both atlantis and ZIC-HILIC could not separate these base analytes well, even many efforts on optimization of mobile phase were made.

3.4. Application in separating of cephalosporins and carbapenems

Cephalosporins and carbapenems are important antibiotics in pharmacology. Analysis requirements related to cephalosporins and carbapenems are very important for the pharmaceutical industry, thus HPLC and HPLC-MS techniques are powerful analysis tools for testing shelf stability, antibiotic resistance, detecting impurities and so on. When Click N-benzyl IDA was applied in the separation and analysis of cephalosporins and carbapenems, it displayed good retention and separation selectivity. As shown in Figs. 7 and 8 (see supporting information), the cephalosporins and carbapenems were efficiently separated with good peak shapes and appropriate retention time.

3.5. The stability of click N-benzyl IDA

Chemical stability is an important parameter for stationary phases. A mixture of nucleoside and base (sulfadiazine, uracil, uridine, adenosine, inosine, adenine and guanosine) was utilized to investigate the stability of click N-benzyl IDA through 15 continuous injections (Fig. 9, see supporting information). The relative standard deviations (RSDs) of the most nucleosides and bases were all at 0.1%, except adenosine and adenine were 0.2% and 0.5%, respectively. This result demonstrated a good stability of click N-benzyl IDA. In addition, the column was used for over one year without any deterioration, which further showed that the stationary phase can be widely and reliably used as separating material.

4. Conclusion

A zwitterionic tridentate click N-benzyl IDA column was prepared *via* click chemistry. This method showed high efficiency for bonding functionalized zwitterionic groups. Click N-benzyl IDA displayed good HILIC properties in the separation of hydrophilic nucleosides and bases. The chromatographic mechanism showed that this type stationary may possess several retention mechanisms, such as partition mechanism, hydrogen bonding interaction, chelate and electrostatic interaction mechanisms. The effect of pH and salt concentration on retention were investigated in order to understand its chromatographic properties. Under isocratic elution conditions, this new type of tridentated zwitterionic stationary phase could be used to efficient separate a wide range of compounds, from moderate to highly polar compounds. Furthermore, this type of stationary demonstrated good stability. Additional studies concerning the development of click N-benzyl IDA for the separation and detection of pharmaceuticals are underway.

ABSTRACT

This communication clearly highlights the importance and necessity for a comparison investigation between nitrogen-doped graphene (N–G) and graphene as a two-dimensional mat of metal nanoparticles (NPs). We presented Ag NPs as a model of metal NPs for fabricating Ag/N–G and Ag/graphene nanocomposites, respectively. Compared with Ag/graphene nanocomposites, the Ag/N–G nanocomposites could facilitate the electrochemical redox process of $S_2O_8^{2-}$, and showed improved electrochemiluminescence (ECL) performances including increasing ~2.25-fold ECL intensity and decreasing ~330 mV onset potential of $S_2O_8^{2-}$, respectively. Further, the as-prepared pentachlorophenol ECL sensor based on Ag/N–G nanocomposites showed a wider linear range and lower detection limit than those of the Ag/graphene nanocomposites. This study could be potentially useful for understanding the role of N–G in electrochemistry, and opening a new aspect for exploring and developing potential application of N–G based materials in electrocatalysis and sensing fields.

1. Introduction

Nitrogen-doped graphene (N–G), a novel kind of graphene derivatives, has received considerable interests due to its advantages superior to graphene including much larger functional surface area, higher ratio of surface active groups to volume, and higher electrical conductivity [1]. In particular, as a new desirable two-dimensional mat, N–G possesses more chemically active sites for further anchoring metals [2,3] metallic oxides [4–6] and other metallic compounds [7]. For example, Liang et al. [5] fabricated SnO_2/N–G nanocomposite as a high-performance electrode material for Li-ion batteries, which showed higher capacity than SnO_2. Yang and coworkers [6] found that the ultrathin MnO_2/N–G nanocomposite displayed enhanced electrochemical capacitive performances than MnO_2. Yang et al. [2] reported that the Au/N–G nanocomposite facilitated robust immobilization of antibodies, promoted electron transfer and exhibited excellent electrochemical activity, and the proposed immunosensor displayed excellent analytical performance for metalloproteinase-2 detection. Further, our recent study [3] proved that compared with pure Cu NPs, the Cu/N–G nanocomposite showed enhanced electrocatalytic activity to glucose oxidation, and the presented sensor showed excellent performances for glucose detection including wide linear range, low detection limit, high sensitivity and fast response time. All these results indicated that just like graphene, N–G could be used as a two-dimensional mat to fabricated N–G-based materials, which showed improved electrochemical performances. However, the comparison investigation between N–G and graphene as the two-dimensional mat in the electrochemical research has rarely been reported which is of great theoretic and applicable value.

Electrochemiluminescence (ECL) has gradually become an important and powerful analytical tool in many fields, such as environmental pollutant determination, pharmaceutical analysis and immunoassay owing to its distinct advantages of simplicity, rapidity, sensitivity, controllability and low background [8–10]. Among the different ECL types that have been classified, the kind of cathodic ECL reaction systems involving peroxydisulfate ($S_2O_8^{2-}$) plays an important role [11,12]. Although the ECL of $S_2O_8^{2-}$ solution is quite simple and cheap, its ECL application in sensing was still scarce due to the relatively weak ECL intensity. Therefore, it is very urgent to explore more effective methods to improve the ECL of $S_2O_8^{2-}$ and further develop the ECL applications of $S_2O_8^{2-}$ solution.

In this communication, Ag NPs as a model of metal NPs for fabricating Ag/N–G and Ag/graphene nanocomposites were presented, and the ECL performance between Ag/N–G and Ag/graphene in $K_2S_2O_8$ solution was compared. Using pentachlorophenol

(PCP) as an analyte model, Ag/N–G-based ECL sensor exhibited a wider linear range and lower detection limit than that of Ag/graphene, which could broaden the application of N–G-based material in the electrocatalytic and sensing fields.

2. Experimental

2.1. Chemicals and reagents

Graphite was purchased from Qingdao Tianhe Graphite Co., Ltd. PCP was purchased from Sigama Aldrich. $AgNO_3$, $K_2S_2O_8$ and glycine were purchased from Sinopharm Chemical Reagent Co., Ltd. Graphene oxide (GO) was prepared using modified Hummers method from graphite powders [13]. 0.1 M phosphate buffered solution (PBS, pH 7.0) was prepared by mixing stock standard solutions of NaH_2PO_4 and Na_2HPO_4. All the PBS solutions were air-saturated and doubly distilled water (18.2 MΩ; Millpore Co.) was used in all experiments and to prepare all buffers.

2.2. Apparatus

The morphologies were performed via transmission electron microscopy (TEM, Hitach H800, Japan). X-ray diffraction (XRD) was acquired on an X'Pert X-ray diffraction spectrometer (Philips, USA). X-ray photoelectron spectroscopy (XPS) was performed on a Thermo VG Scientific ESCALAB 250 spectrometer with a Mg *K*α radiator. The ECL emission was detected using a model MPI-A electro-chemiluminescence analyzer (Xi'an Remex Analysis Instrument Co. Ltd. Xi'an, China) with 800 V photomultiplier tube voltage. The conventional three-electrode system was employed with a modified glassy carbon electrode (GCE) as the working electrode, an Ag/AgCl (saturated KCl) as reference electrode and a Pt wire as the counter electrode.

2.3. Preparation of samples

Ag/N–G was prepared according to the literature with some modifications [14]. Briefly, 5 mL solution containing 10 mg GO, 30 mg glycine and 15 mg $AgNO_3$ was sonicated for 2 h, and then the resulting mixture was poured into an alumina crucible which was gradually increased from room temperature to 500 °C under argon atmosphere and maintained for 2 h. Ag/graphene was prepared using the same method without adding glycine. Similarly, N–G was prepared without adding silver nitrate, and graphene was prepared using the same treatment without adding silver nitrate and glycine.

2.4. Preparation of the modified electrodes

6 μL of 2 mg mL^{-1} Ag/N–G suspension was spread evenly onto the cleaned GCE surface and allowed to dry in ambient air for 24 h. For comparison, N–G/GCE, graphene/GCE and Ag/graphene/GCE were also prepared using a similar procedure.

3. Results and discussion

3.1. Characterization of the samples

The typical TEM images and the size-distribution histogram of Ag/N–G and Ag/graphene samples (Fig. 1A–C) show that Ag NPs ranging from 30 to 60 nm are evenly distributed on graphene and N–G sheet, respectively. Moreover, in both cases, particles appeared spherical, well dispersed and well-separated. And XRD

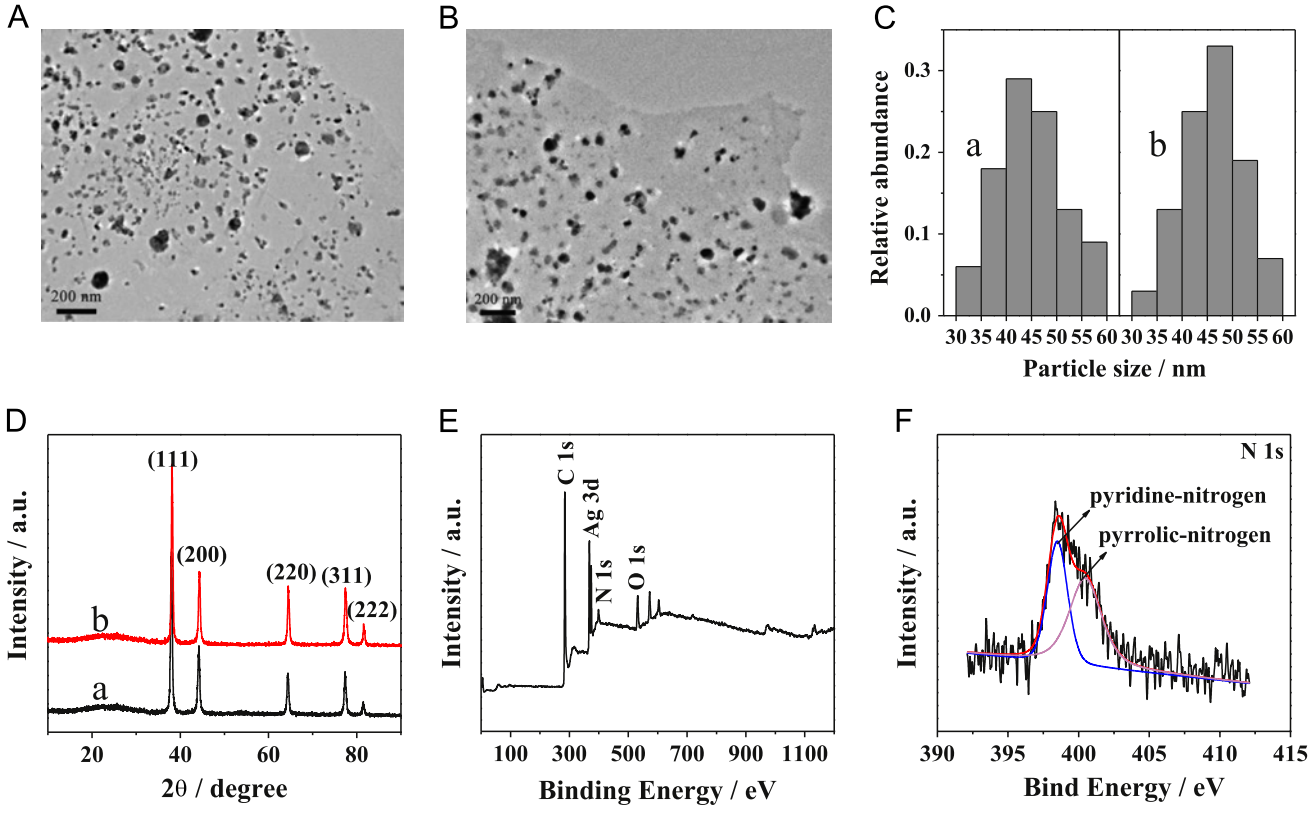

Fig. 1. TEM image of (A) Ag/N–G and (B) Ag/graphene. (C) The histogram of particle size distribution for Ag/N–G (a) and Ag-graphene (b). (D) XRD patterns of Ag/graphene (a) and Ag/N–G (b). (E) XPS spectra of Ag/N–G. (F) The high-resolution N 1s spectrum of Ag/N–G.

analysis (Fig. 1D) shows that Ag/N–G and Ag/graphene exhibited no obvious differences from the structure, which displayed obvious peaks corresponding to (1 1 1), (2 0 0), (2 2 0), (3 1 1) and (2 2 2) of metallic Ag [14,15]. Further, the full range XPS analysis (Fig. 1E) of Ag/N–G sample clearly illustrated the presence of nitrogen in the nanocomposite, which confirmed the successful doping of nitrogen atoms into the graphene networks. In addition, it can be seen that pyridinic and pyrrolic nitrogen species are formed in Ag/N–G (Fig. 1F). Pyridine N bonds with two C atoms at the edges or defects of graphene and contribute one *p* electron to the π system, while pyrrolic N refers to N atoms that contribute two *p* electrons to the π system.

3.2. Electrochemical and ECL behaviors of samples

Fig. 2A displays the ECL–time curves of the as-fabricated electrodes in the presence or absence of 0.1 M $K_2S_2O_8$. Compared with bare GCE (curve *a*), graphene/GCE (curve *b*) and N–G/GCE (curve *c*) in the presence of 0.1 M $K_2S_2O_8$, the ECL emissions of both Ag/graphene/GCE (curve *d*) and Ag/N–G/GCE (curve *e*) were enhanced obviously, and it should be highlighted that the ECL intensity from Ag/N–G/GCE is about 2.25-fold higher than that observed from Ag/graphene/GCE. On the other hand, no ECL emission was observed on either Ag/graphene/GCE (curve *f*) or Ag/N–G/GCE (curve *g*) in blank PBS solution. All these results above indicated that the ECL emission was produced from $K_2S_2O_8$ solution, which is similar to previous reports [16,17]. The possible ECL mechanisms are described as follows: the dissolved oxygen was reduced to $OOH^{\bullet}$ upon the potential scan with an initial negative direction, meanwhile $S_2O_8^{2-}$ was reduced to the strong oxidant $SO_4^{\bullet-}$, which could react with $OOH^{\bullet}$ to produce light-emitting species $^1(O_2)_2^*$.

To gain a better understanding of Ag/N–G enhancing the ECL signal of the peroxydisulfate solution, ECL–potential curves and cyclic voltammograms of Ag/N–G and Ag/graphene have been investigated in Fig. 2B. It can be seen that the ECL onset potential of the Ag/N–G/GCE (−0.41 V) was ~330 mV more positive than that of Ag/graphene/GCE (−0.74 V), which indicated that N–G could decrease the potential barriers of the ECL reaction obviously. Moreover, the reduction peak potential of $K_2S_2O_8$ at Ag/N–G/GCE was more positive for ~270 mV and exhibited higher reduction peak current of $K_2S_2O_8$ than Ag/graphene/GCE (inset of Fig. 2B). All these results suggested that N–G could be used as a excellent two-dimensional mat to anchor Ag NPs for accelerating the electron-transfer processes and improving the electrocatalytic activity, which could be attributed to the introduction of nitrogen in graphene. According to previous studies, the pyridinic nitrogen in N–G can provide a pair of electrons for conjugation with the π-conjugated rings which can introduce electron donor properties to graphene and improve the electrochemical performances of N–G; the pyrrolic nitrogen has higher charge mobility in N–G due to better electron-donor characteristics and enhanced carbon catalytic activity in electron-transfer reactions [3,6].

3.3. Analytical application of cathodic ECL emission of Ag/N–G/GCE and Ag/graphene/GCE

In order to compare the analytical application of cathodic ECL emission of Ag/N–G/GCE and Ag/graphene/GCE, the developed sensors were applied in the detection of PCP, which has been widely used in agriculture and industry and may cause the acute toxicities of organisms, endocrine disruptor and potentially carcinogenesis [18].

Fig. 3A and B presented the effect of various concentration of PCP on the cathodic ECL intensity of $K_2S_2O_8$ solution on Ag/N–G and Ag/graphene modified electrodes, and the ECL intensity decreased linearly with the increase of PCP concentration. Furthermore, the Ag/N–G/GCE displayed a wider linear range (0.1 pg mL^{-1}–110.1 μg mL^{-1}) and lower detection limit (0.03 pg mL^{-1}) than that of Ag/graphene/GCE (linear range: 10.0 pg mL^{-1}–11.1 μg mL^{-1}, detection limit: 3.3 pg mL^{-1}). These results might be ascribed to the introduction of nitrogen in graphene which enlarge the ECL signal for sensitive detection.

The detection of PCP has been reported based on its quenching effect on the ECL of carbon quantum dots resulting from an electron-transfer process [18,19]. Thus, the ECL quenching mechanism of PCP here might be attributed to electron transfer annihilation of $SO_4^{\bullet-}$. When PCP was added, it could would be adsorbed on the N–G surface and be oxidized resulting in a decrease in ECL.

The reproducibility of the sensor based on Ag/N–G was examined by measuring the ECL intensity responses upon 1 ng mL^{-1} PCP in 0.1 M PBS containing 0.1 M $K_2S_2O_8$. In a series of five electrodes prepared in the same way, a relative standard deviation (RSD) of 5.1% was obtained, indicating the reliability of this method. While 5 measurements for a single electrode were made upon the addition of 1 ng mL^{-1} PCP with RSD of 3.6%, demonstrating excellent reproducibility.

Furthermore, the selectivity of the ECL sensor was investigated using 2,6-dichlor-ophenol (2,6-DCP), 2,4,6-trichlorophenol (2,4,6-TCP) as the interferents. The $\Delta I/I_0$ (where I_0 is the initial intensity,

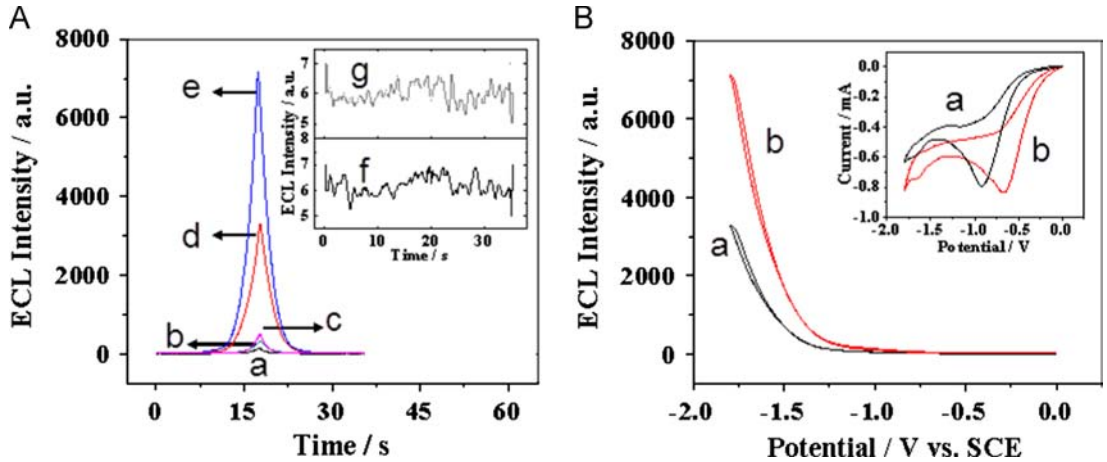

Fig. 2. (A) ECL–time curves of bare GCE (*a*), GS/GCE (*b*), N–G/GCE (*c*), Ag/graphene/GCE (*d*) and Ag/N–G/GCE (*e*) in the presence of 0.1 M $K_2S_2O_8$ in 0.1 M PBS. Inset: the ECL–time curves of Ag/graphene/GCE (*f*) and Ag/N–G/GCE (*g*) in 0.1 M PBS. (B) ECL–potential curves of Ag/graphene/GCE (*a*) and Ag/N–G/GCE (*b*) in 0.1 M PBS containing 0.1 M $K_2S_2O_8$. Inset: the corresponding cyclic voltammograms of them.

and ΔI is the interferent induced decrease in ECL intensity) to 1.0 ng mL^{-1} of these compounds were 4.49% (2,6-DCP), and 3.53% (2,4,6-TCP), whereas the $\Delta I/I_0$ to 1.0 ng mL^{-1} of PCP was 37.27%. Comparing the ECL inhibition ratio of these compounds with those of PCP, the ECL sensor showed a relatively high selectivity to PCP. In addition, some common ions (cations and anions), such as Na^+, K^+, Mg^{2+}, Cl^-, NO_3^-, also showed little effect on the ECL emission of Ag/N–G and thus did not interfere with the PCP detection.

4. Conclusions

In summary, a comparison of the electrochemical and ECL behavior based on graphene and N–G as substrates to anchor Ag NPs was achieved in peroxydisulfate solution. Compared with Ag/graphene, Ag/N–G showed improved electrocatalytic activity and enhanced ECL intensity in $K_2S_2O_8$ system. The enhancement could be attributed to the introduction of nitrogen in graphene, which in favor of the reduction of $S_2O_8^{2-}$, leading to generation of more quantity of excited states. The present work would be potentially useful for understanding the role of N–G in electrochemistry, and broaden the application of N–G-based materials in the electrocatalytic and sensing fields.

ABSTRACT

A simple and sensitive electrochemical impedimetric aptasensor based on gold nanoparticles (AuNPs) signal amplification was developed for the ultrasensitive detection of tumor markers (mucin 1 protein, MUC1 as a model). The designed cDNA, which is partly complementary with the aptamer of MUC1 was immobilized on the gold electrode. The detection of MUC1 could be carried out by virtue of switching structures of aptamers from DNA/DNA duplex to DNA/target complex. The change of the interfacial feature of the electrode was characterized by electrochemical impedance analysis (EIS) with the redox probe $[Fe(CN)_6]^{3-/4-}$. The quantitative detection of MUC1 protein was obtained from the changes of electron-transfer resistance (ΔR_{et}). Moreover, as the signal enhancer, the aptamer-modified AuNPs (Apt@AuNPs) conjugates was introduced on the electrode by the hybridization of cDNA with aptamer. As expected, the detection sensitivity for MUC1 was greatly improved, which may be due to the specific binding of MUC1 onto the surface of the Apt@AuNPs modified electrode. This proposed simple aptasensor has a low detection limit of 0.1 nM, and also exhibits several advantages of high sensitivity and good selectivity. This present work may provide a general model for the detection of tumor marker based on impedimetric aptasensor.

1. Introduction

Tumor marker is a substance abnormally expressed in malignancy and benign tumor compared with normal tissues. The content of tumor marker represents the current state of the tumor. The detection of tumor marker is significant for clinical diagnosis and judging those diseases related to tumor. For breast cancer, since human mucin-1 (MUC1) has been found highly over-expressed in breast cancer, it becomes one of the most common tumor markers to diagnose the breast tumor [1]. Therefore, enhancing the detection level of MUC1 plays an important role in the diagnosis of breast cancer.

Aptamers are nucleic acid ligands (DNA or RNA) which are artificially synthesized and selected in vitro through SELEX (systematic evolution of ligands by exponential enrichment) [2,3]. They have high specificity and affinity to various target molecules that includes peptides [4], dopamine [5], adenosine and ATP [6], metal ions [7], as well as proteins, such as growth factors [8] and thrombin [9]. In addition, the immunogenicity and toxicity of aptamers are proved much lower compared with antibodies when they used in biological environment or as a part of therapeutic and diagnostic agents [10], so aptamer has been widely used as a sensing element for developing biosensor. In recent years, aptamers have been screened for targeting and measuring some tumor markers, which have great value in evaluating the progress of cancer, monitoring the therapeutic response and predicting the recurrence [11].

MUC1 aptamers are of great importance in the assessment of breast cancer [12,13]. Up to now, limited researches have been conducted to directly detect the concentration of MUC1. Pang's group designed a fluorescent aptasensor utilizing graphene oxide (GO) to quench the fluorescence of single-stranded dye-labeled MUC1 aptamer, when MUC1 added, the quenched fluorescence was recovered significantly [14]. Yu's group constructed a hairpin DNA aptamers on gold and labeled with methylene blue (MB) for electrochemical measurements [15]. They also reported a method of quantitative detection of MUC1 by labeling a 3-component DNA hybridization system with quantum dot (QD)-based fluorescence readout [16]. Wei et al. performed a method based on electrochemiluminescence (ECL) resonance energy transfer (ERET) to detect MUC1 protein and MCF-7 cancer cells [17]. Among these studies, the electrochemical methods are more remarkable in the

development of aptasensors due to their fast response, high sensitivity, low cost and the result can be obtained at real-time.

As an effective electrochemical method, electrochemical impedance spectroscopy (EIS) can measure the response (current and its phase) of an electrochemical system to an applied oscillating potential as a function of the frequency [18–21]. The immobilization of biomaterials, including enzymes, antigens/antibodies or DNA on electrodes alters the capacitance and interfacial electron transfer resistance of the conductive electrodes. On account of its sensitivity with the changes of interfacial properties, this method has been extensively used to study the electrochemical changes induced by protein binding reactions resulting in interfacial electron transfer kinetics between the redox probe and the electrode changes notably when the binding procedure taking place [22,23]. Therefore, EIS can be used to monitor the different stages of each fabrication step for the biosensor, and the detection of identification process when an immobilized molecule interacts with analytes. Besides, in consequence of the advantages of EIS, for instance, high sensitivity, simplicity and requiring no external modification of the biomolecules, it is an ideal technology for label-free detection.

In the present work, a sensitive and label-free impedimetric aptamer-based electrochemical biosensor for the tumor marker of breast cancer (MUC1 as the model) was simply fabricated. A cDNA was used as the linker DNA, which was designed to be complementary with the MUC1 aptamer. Moreover, aptamer functionalized gold nanoparticles (Apt@AuNPs) were used as the signal amplifier and to capture the target molecule MUC1. The introduction of gold nanoparticles is favorable for amplifying electrochemical signals and the resulted electrochemical aptasensor shows high sensitivity, MUC1 can be specifically detected at a concentration down to 0.1 nM. This proposed aptasensor for tumor maker has some advantages of simplicity, high sensitivity, acceptable selectivity, good reproducibility and stability. Therefore, this work would lay a potential foundation for clinical application of the early breast cancer diagnosis, and it is also significant for the development of the electrochemical aptasensor for sensing other tumor markers.

2. Experimental

2.1. Materials and chemicals

$HAuCl_4 \cdot 3H_2O$ was from Sigma (St. Louis, MO). 6-Mercaptohexanol (MCH), Tris-(hydroxymethyl) aminomethane (Tris), Trisodium citrate was purchased from Bio Basic Inc. NaCl, $MgCl_2 \cdot 6H_2O$ were obtained from Amresco. All other reagents are of analytical purity and used as received. All samples and buffer solutions were prepared using ultrapure water obtained from a Milli-Q water purification system (Simplicity 185, Millipore Corp., Billerica, MA).

DNA1 (thiolated MUC1 aptamer, 5′–HS-$(CH_2)_6$-GCA GTT GAT C**CT TTG GAT A**CC CTG G-3′) and cDNA (5′-HS-$(CH_2)_6$-TTT TT**T ATC CAA AG**A-3′) were manufactured by Sangon Biological Engineering Technology & Services Co., Ltd. (Shanghai, China). DNA1 is a 25-base sequence that is MUC1 aptamer, as well as complementary sequence (bold part) to cDNA.

Thiolated MUC1 aptamer was diluted to 10 μM in 34 mM Tris–HCl buffer (pH 7.4, 233 mM NaCl, 8.5 mM KCl, 1.7 mM $MgCl_2$, 1.7 mM $CaCl_2$) for use. The obtained solution was stored at 4 °C before use. MUC1 (from the N terminus to the C terminus: APDTRPAPG) was purchased from Shanghai Apeptide Co., Ltd. The peptides were suspended in 10 mM phosphate buffer solution (PBS, pH 7.4) to obtain different concentrations for the subsequent experiment.

2.2. Preparation of AuNPs and DNA1-modified AuNPs (apt@AuNPs)

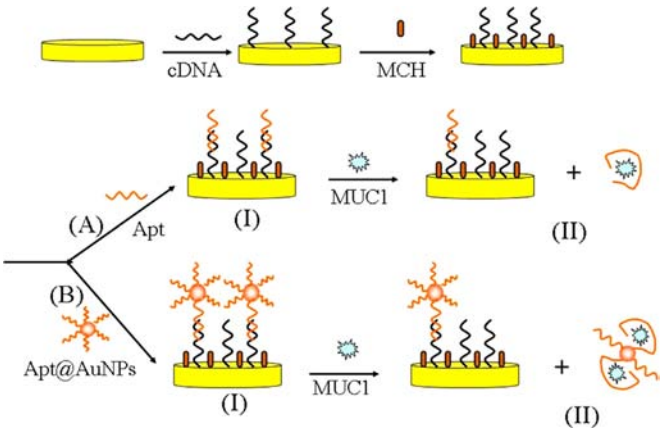
AuNPs with the diameter of about 13 nm were prepared by the reduction of $HAuCl_4$ in citrate solution according to reports in the literatures [24,25]. Briefly, 100 mL 0.01% (w/v) $HAuCl_4$ aqueous solution was heated and stirred vigorously with reflux, 2 mL 2% (w/v) trisodium citrate was added rapidly when $HAuCl_4$ aqueous solution became boiled. Color variation was obviously observed and then it was refluxed for an additional 15 min. The solution color turned to wine red, indicating the formation of AuNPs. The solution was cooled to room temperature with continuous stirring. The diameter of AuNPs was determined by UV–vis spectra with an characteristic absorption peak at 520 nm [24,26].

The DNA1-modified AuNPs (Apt@AuNPs) were prepared according to the procedures reported in literatures [27,28]. Briefly, a solution of AuNPs (1 mL) was mixed with the thiolated DNA1 (1 OD) overnight and then slowly brought to 0.05 M NaCl by adding concentrated NaCl solution (3 M), 10 mM phosphate buffer (pH 7.0). Then, after standing for 6–8 h, the concentration of NaCl was brought to 0.1 M and the solution was allowed to age for another 6–8 h. To remove the excess free aptamers, the conjugates were purified by centrifuging for 30 min at 14,000 rpm. The red precipitate was washed, centrifuged, and dispersed in 1.5 mL of 34 mM Tris–HCl buffer solution containing 233 mM NaCl, 8.5 mM KCl, 1.7 mM $MgCl_2$, 1.7 mM $CaCl_2$ (pH 7.4). A characteristic absorption of the Apt@AuNPs conjugates was at 523 nm, which indicates the MUC1 aptamers have been successfully attached onto Au nanoparticles, according to reports in the literature [24].

2.3. Preparation of the modified electrode

Before modification, the bare gold electrode (2 mm in diameter) was polished sequentially with 0.3 μm and 0.05 μm alumina slurry followed by ultrasonic cleaning in ethanol and ultrapure water. Subsequently, the gold electrode was cleaned in piranha solution (v/v 3:1 H_2SO_4/H_2O_2) (Caution: piranha solution reacts violently with many organic materials and should be handled with great care), followed by treatment with nitric acid. Afterward, the gold electrode was washed thoroughly with ultrapure water and dried under nitrogen gas. For modification of the electrode, 10 μL of cDNA (10 μM) was dropped onto the cleaned electrode and incubating for 16 h to form the self-assembled monolayer. After modification, the gold electrodes were incubated in 1 mM 6-mercaptohexanol (MCH) solution for 1 h to block the unmodified region of the gold surface. Then a 10 μL droplet of Apt@AuNPs conjugates solution was covered onto the Au/cDNA/MCH electrode and kept for 2 h to obtain the Au/cDNA/MCH/Apt@AuNPs electrode. For comparison, the Au/cDNA/MCH/Apt electrode was also fabricated by dipping 10 μL of thiolated MUC1 aptamer (Apt) solution onto the Au/cDNA/MCH electrode and incubating for 2 h. After each step, the electrode was rinsed thoroughly with ultrapure water and dried under highly pure nitrogen stream prior to electrochemical characterization. For each step of immobilization, the electrochemical impedance measurements were performed in the presence of equimolar $[Fe(CN)_6]^{3-/4-}$ as redox probe.

2.4. Apparatus and electrochemical measurements



Electrochemical impedance spectroscopy (EIS) measurements were performed on a CHI650D electrochemical workstation. A conventional three-electrode system was used with bare gold electrode as the working electrode, a platinum wire as counter electrode and a saturated calomel electrode (SCE) as reference electrode. All the potentials in this paper were in respect to SCE. All experiments were carried out at laboratory temperature.

For the detection of MUC1, the modified gold electrodes were immersed in the MUC1 solution (10 mM phosphate buffer solution, pH 7.4) with various concentrations and kept for 2 h, followed by a 5 min washing to remove Apt@AuNPs@MUC1 and nonspecific bound of MUC1. The impedance spectra were obtained in a frequency range from 100 mHz to 100 kHz and the amplitude of 5 mV in 5 mM $[Fe(CN)_6]^{3-/4-}$ solution containing 0.1 M KCl. The impedance spectra were plotted in the form of Nyquist plots.

3. Results and discussion

3.1. Design strategy of the aptasensor

An electrochemical sensing platform for highly sensitive detection of tumor marker (MUC1 as a model) was proposed. The assay protocol of the electrochemical aptasensor was depicted schematically in Scheme 1. The surface of the gold electrode was first modified with the thiolated cDNA and MCH via the self-assembly. The bold part of the MUC1 aptamer hybridized to the bold part of cDNA. The sensing interface was ready for the detection of MUC1. For Scheme 1A, when MUC1 introduced, the MUC1 aptamer-contained DNA1 preferred to form the aptamer-MUC1 complex, which resulted in the dehybridization and the MUC1-aptamer released into the solution (Scheme 1A-II). In this case, it was expected that the EIS of the DNA-modified electrode would decrease. On the other hand, in order to improve the sensitivity of the sensing interface, Apt@AuNPs was employed to hybridize with the MUC1 aptamer, as shown in Scheme 1B. Since Apt@AuNPs can bind more MUC1 molecules, and folding into a well-defined three-dimensional structure, which would lead to the Apt@AuNPs/MUC1 complex of huge weight falling off from the electrode (Scheme 1B-II). This may result in an obvious EIS signal change of the modified electrode, and offering a significant amplification for the detection of MUC1. The design is to fabricate an aptamer based biosensor by relying on the structure-switching properties of aptamers binding to their target molecules, which is applicable for the fabrication of other aptasensor.

Scheme 1. Schematic representation of the electrochemical aptasensor for the detection of MUC1.

3.2. EIS characterization of the modified electrode

On the basis of the charge transfer kinetics of the $[Fe(CN)_6]^{3-/4-}$ redox probe, faradaic impedance spectra with an $[Fe(CN)_6]^{3-/4-}$ redox probe were modeled using the equivalent circuit approach of Radi et al. [22], as shown in the inset of Fig. 1. The circuit includes the commonly existing electrolyte resistance (R_s) and Warburg impedance (Z_w) resulting from the diffusion of ions from the bulk of the electrolyte to the interface, double-layer capacitance (C_d), and the electron-transfer resistance (R_{et}). Among them, Ret can directly and sensitively respond to changes of the electrode interface [29,30]. Whereas a linear section characteristic at the lower frequency is attributable to a diffusion-limited process, a squeezed semicircle portion observed at higher frequencies corresponds to the electron-transfer limited process.

Electrochemical impedance spectroscopy (EIS) has been employed to characterize the modified electrode. Fig. 1 displays the EIS results of the (a) bare Au, (b) Au/cDNA, (c) Au/cDNA/MCH, (d) Au/DNA/MCH/Apt@AuNPs and (e) Au/cDNA/MCH/Apt electrodes in the presence of the equimolar $[Fe(CN)_6]^{3-/4-}$ redox probe, respectively. In the Nyquist plots of impedance spectra, a linear section at the lower frequencies is attributable to a diffusion-limited process, and a squeezed semicircle portion observed at higher frequencies would correspond to the electron-transfer limited process. The increase of the diameter of the semicircle reflects the increase of the interfacial charge-transfer resistance (R_{et}) [31]. It is noted that the bare gold electrode shows a very small semicircle domain

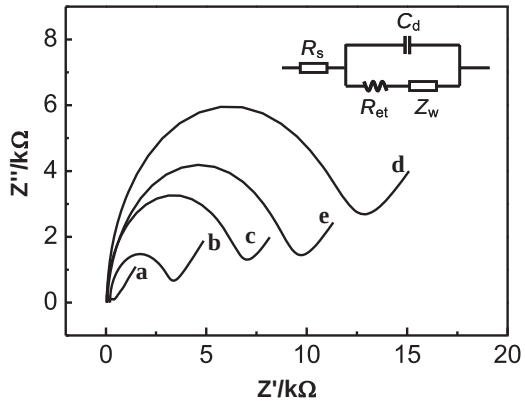


Fig. 1. Electrochemical impedance spectra of (a) the bare Au electrode, (b) the Au/cDNA electrode, (c) the Au/cDNA/MCH electrode, (d) the Au/cDNA/MCH/Apt@AuNPs electrode, (e) the Au/cDNA/MCH/Apt electrode in aqueous solution containing 0.1 M KCl and 5 mM $[Fe(CN)_6]^{3-/4-}$ (1:1) as the redox probe. The impedance spectra were obtained at the frequency range from 100 mHz to 100 kHz with a DC potential of +0.224 V. The amplitude was 5 mV.

(R_{et}=200 Ω, curve a in Fig. 1), indicating a very fast electron transfer process of $[Fe(CN)_6]^{3-/4-}$ [29]. The self-assembly of a negatively charged cDNA on the Au electrode surface effectively repels the $[Fe(CN)_6]^{3-/4-}$ anions and thus leads to an enhanced electron-transfer resistance (R_{et}=3540 Ω, curve b in Fig. 1), which demonstrates that thiolated cDNA has been self-assembled successfully on the electrode. It is also found that the assembly of MCH on the cDNA-modified electrode leads to a significant increase of R_{et} to 6890 Ω (curve c in Fig. 1). After hybridization with Apt@AuNPs, the value of R_{et} increases significantly to 12,690 Ω (curve d in Fig. 1). Compared to the Au/DNA/MCH/Apt@AuNPs electrode, the changes of electron-transfer resistance of the Au/DNA/MCH/DNA1 electrode modified without AuNPs is only varied from 6890 Ω to 8280 Ω (curve e in Fig. 1). This may be attributed to the bulky effect of Apt@AuNPs that hinders the electron-transfer on the surface of the electrode. Besides, the Apt@AuNPs bioconjugates will introduce more aptamers on the electrode, considering the property of the aptamer, it is not only nonconductive, but also the negatively charged phosphate backbone of aptamer repelling $[Fe(CN)_6]^{3-/4-}$ anions from the electrode surface [32], which would lead to an obvious change of R_{et}. Therefore, it is expected that the application of DNA-functionalized AuNPs can further enhance the sensitivity of the present sensing strategy.

3.3. Signal amplification of AuNPs for sensing MUC1

In order to prove the signal amplification of AuNPs in the electrochemical aptasensor for sensing tumor biomarker, we investigated the changes of the electron-transfer resistance (ΔR_{et}) of the two modified electrode, (a) Au/cDNA/MCH/DNA1 electrode and (b) Au/cDNA/MCH/Apt@AuNPs electrode in the equimolar $[Fe(CN)_6]^{3-/4-}$ solution after incubation with 10 nM MUC1 for 2 h. As shown in Fig. 2, the ΔR_{et} of the Au/cDNA/MCH/Apt@AuNPs electrode (ΔR_{et}=4960 Ω in Fig. 2b) is about 7 times higher than that of the Au/cDNA/MCH/Apt electrode (ΔR_{et}=690 Ω in Fig. 2a). This demonstrates that for sensing the MUC1, the Au/cDNA/MCH/Apt@AuNPs electrode exhibits much stronger impedance signal than the Au/cDNA/MCH/Apt. This can be ascribed to that more aptamers introduced by Apt@AuNPs can bind more MUC1, forming huge molecular weight of Apt@AuNPs/MUC1. Once the Apt@AuNPs/MUC1 falls down from the electrode can lead to much more obvious decrease of ΔR_{et}. Therefore, it is believed that the introduction of Apt@AuNPs is effective to improve the sensitivity of the aptasensor.

3.4. The EIS detection of MUC1

In this work, different concentrations of the target protein, MUC1, was detected by the EIS method using the Au/cDNA/MCH/Apt@AuNPs electrode. The electrochemical measurements were conducted after the Au/cDNA/MCH/Apt@AuNPs electrode was treated with (a) 0 nM, (b) 0.5 nM, (c) 1 nM and (d) 5 nM MUC1 for 2 h respectively, the corresponding results are shown in Fig. 3. It can be observed from Fig. 3 that the R_{et} values of the modified electrode decrease with the increase of the concentration of MUC1.

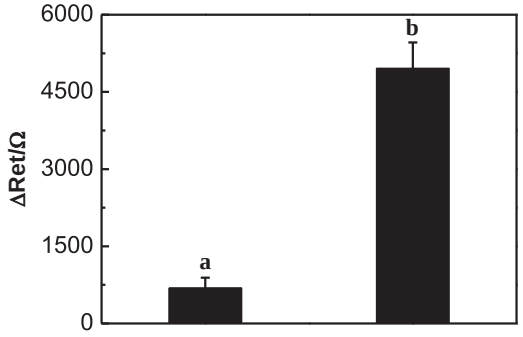

Fig. 2. The changes of the electron-transfer resistance (ΔR_{et}) of (a) the Au/cDNA/MCH/Apt electrode, (b) the Au/cDNA/MCH/Apt@AuNPs electrode after incubation with 10 nM MUC1 for 2 h.

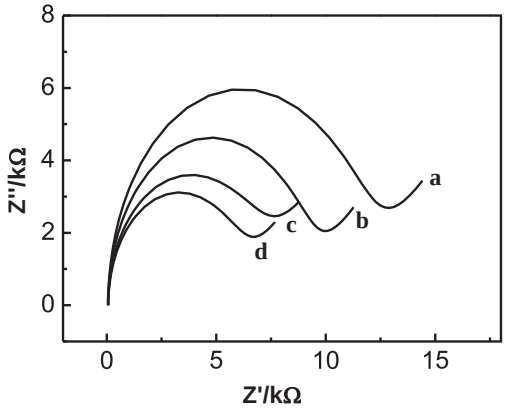

Fig. 3. Electrochemical impedance spectra of the Au/cDNA/MCH/Apt-AuNPs electrode after incubation with (a) 0 nM, (b) 0.5 nM, (c)1 nM, (d) 5 nM MUC1 for 2 h.

This is due to that more MUC1 protein was introduced on the modified electrode, and more Apt@AuNPs/MUC1 bioconjugates with high molecular weight would be formed. When the modified electrode was rinsed thoroughly with ultrapure water, the formed bioconjugates would fall down from the surface of the modified electrode because of the gravity, leading to a marked decrease of R_{et}. Therefore, it can be elucidated that the designed electrochemical aptasensor is feasible and effective for the sensitive detection of tumor biomarkers (MUC1 as a model).

Herein, the detection sensitivity of the present aptasensor was further investigated according to the above procedure. Fig. 4 represents the impedance response of the sensing platform to different concentrations of MUC1. As illustrated in Fig. 4, a series of MUC1 solutions from 0.1 nM to 50 nM were investigated, it can be seen that the ΔR_{et} values of the Au/cDNA/MCH/Apt@AuNPs electrode increase obviously with the increase of MUC1 concentration from 0.1 nM to 10 nM, and the ΔR_{et} values no longer increase significantly as the concentration increases from 10 nM to higher concentrations. Meanwhile, as the insert of Fig. 4 displayed, there is a linear relationship between ΔR_{et} and the concentration of MUC1 ranging from 0.5 nM to 10 nM, and the regression equation was ΔR_{et} (Ω)=0.8128+0.3884 c_{MUC1} (nM) (r=0.9658). This demonstrates that the designed aptasensor possesses the high detection sensitivity with a linear range, and MUC1 can be detectable at a concentration as low as 0.1 nM, which is much lower than that of some existing electrochemical aptasensor for MUC1. For example, Zhao et al. reported a "signal-on" electrochemical aptasensor for determination of two tumor markers with the detection of MUC1 is 20 nM [33]. Hu et al. developed a electrochemical aptamer biosensor based on HO-functionalized AuNPs amplification coupled with enzyme-linkage reactions with a detection limit of 2.2 nM [34]. Meanwhile, the detection limit of this label-free impedimetric aptasensor is also much simpler and more sensitive than the sensor based on other methods,for example, a detection limit of 250 nM was obtained by using quantum dot-labeling fluorescence method [16] or by using aptamer–antibody sandwich enzyme immunoassay [35].

3.5. Selectivity, reproducibility and accuracy

From the practical point, a biosensor should be not only sensitive but also specific. In order to evaluate the selectivity of the aptasensor, control experiments were performed using different proteins, including carcinoembryonic antigen (CEA) and tumor necrosis factor-α (TNF-α) to replace MUC1. The Au/cDNA/MCH/Apt@AuNPs modified electrode was incubated with 1 μM CEA, 1 μM TNF-α and 0.01 μM MUC1 for 2 h, respectively. As shown in

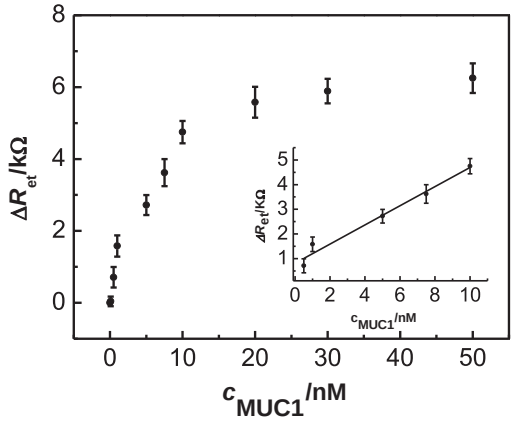

Fig. 4. The calibration curve corresponding to the detection of MUC1 based on the changes of electron-transfer resistance (ΔR_{et}) at the Au/cDNA/MCH/Apt@AuNPs electrode. The inset shows the linear curve of the aptasensor for MUC1.

Fig. 5, it is noted that incubation of the Au/cDNA/MCH/Apt@AuNPs electrode with TNF-α (Fig. 5b) or CEA (Fig. 5c) does not produce significant changes of ΔR_{et} response as compared to the case of MUC1 (Fig. 5a). These results demonstrate that the developed aptasensor has a sufficient specificity to its target molecule, MUC1.

The reproducibility of the aptasensor was also investigated at the MUC1 concentration of 10 nM. Every five freshly prepared modified electrodes have been used for the detection of 10 nM MUC1. All electrodes exhibited similar electrochemical response and the relative standard deviation is 4.1% for MUC1 detection. In addition, the reproducibility of measurements for the same electrode was investigated at the MUC1 concentration of 10 nM, and the relative standard deviation for six times is 4.6%. This demonstrates the aptasensor for MUC1 detection is highly reproducible.

The long-term stability of the sensing interface is further studied since it is an important issue for the practical implementation of MUC1 detection. The modified electrode, which was stored in Tris–HCl at 4 °C for 10 days, could still be used for the measurement of MUC1 without significant change of R_{et}. This implies that the proposed aptasensor has a sufficient stability for detection of MUC1.

Additionally, the accuracy of the impedimetric aptasensor has been evaluated by the standard addition method. A series of samples were prepared by adding MUC1 of different concentrations to human blood serum (obtained from Cancer Hospital of Hunan Province, China). The analytical results for MUC 1 are shown in Table 1. From Table 1, it can be seen that the recovery and relative standard deviation values are acceptable. This implies that the impedimetric aptasensor has a good accuracy, which also indicates a promising feature for the analytical application in complex biological samples.

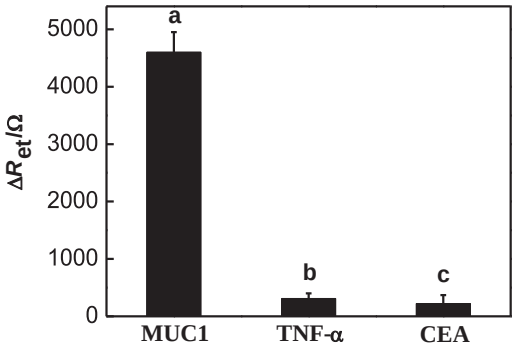

Fig. 5. The changes of the electron-transfer resistance (ΔR_{et}) of the Au/cDNA/MCH/Apt@AuNPs electrode after incubation with (a) 0.01 μM MUC1, (b) 1 μM TNF-α, and (c) 1 μM CEA for 2 h. The R_{et} of the Au/cDNA/MCH/Apt@AuNPs electrode was considered as the background.

Table 1
Determination of MUC1 added in human blood serum ($n=5$) with the proposed aptasensor[a].

Serum samples	Concentration of *MUC1* added (nM)	Concentration obtained with aptasensor (nM)	RSD (%)[b]	Recovery (%)
1	0.65	0.59	3.7	90.8
2	2.80	2.58	4.1	92.1
3	7.50	6.86	4.5	91.5
4	10.5	9.56	5.2	90.2

[a] Impedance measurements were carried out within the range of 100 kHz–100 mHz at the formal potential of the $[Fe(CN)_6]^{3-/4-}$ (1:1). The amplitude of the alternate voltage was 5 mV.

[b] RSD is relative standard deviation.

4. Conclusion

In this paper, a simple electrochemical impedimetric aptasensor for the detection of MUC1 protein has been developed based on AuNPs signal amplification. EIS method has been demonstrated to be a sensitive way to monitor the changes on the surface of the electrode during the process of building the aptasensor. With this aptasensor, MUC1 can be detected at a concentration down to 0.1 nM. The electrochemical aptasensor possesses good selectivity, reproducibility and stability. Besides, taking advantage of EIS technology, this label-free aptasensor is not only convenient for building and detection, it is also satisfying the fast speed and good detection limit. By changing aptamers of different target molecules, this method can be used to detect many kinds of tumor markers, so it may have potential prospect for other studies.

ABSTRACT

A sensitive and selective electrochemical sensor based on molecular imprinting polymers grafted graphene (MIPs-G) was developed for simultaneous measurement of 4, 4-methylene diphenylamine (MDA) and aniline by differential pulse voltammetry (DPV). MIPs-G was synthesized via free radical polymerization reaction using MDA and 4-vinyl pyridine as template molecule and functional monomer respectively. The obtained nanocomposites were characterized by transmission electron microscope, scanning electron microscope, Fourier transform infrared spectrometry, Raman spectroscopy and thermal gravimetric analysis. After removal template molecules, MIPs-G was used as electrode material for aromatic amines measurements. Due to the high binding affinity towards MDA and the π-π interaction with aniline, the MIPs-G based electrochemical sensor can be used for simultaneous detection of MDA and aniline by DPV. Under the optimized condition, the oxidation potentials for MDA and aniline were observed at 0.62 and 0.72 V, respectively. Moreover, MIPs-G modified glassy carbon electrode shows linear response towards MDA and aniline simultaneously over the range of 1.0 to 15 μM. The MIPs-G based electrochemical sensor has been applied for simultaneous measurement of MDA and aniline in plastic tableware.

1. Introduction

Since the concept of molecular imprinting was first realized by Dickey in 1949 [1], molecular imprinting technology has become a well-established approach to generate molecular recognition materials (molecularly imprinted polymers (MIPs)) with tailor-made selective recognition sites [2]. Due to high specificity, low cost, ease of preparation, thermal and chemical stability, MIPs have attracted considerable interest in a variety of fields, such as chromatographic separations [3], biomimetic sensors [4], solid-phase extraction [5], drug delivery [6], and catalysis [7] etc. MIPs have artificial antibody-like recognition ability because they bear cavities that are complementary in size, shape, and chemical functions to a target molecule. However, traditional MIPs suffer from some drawbacks such as high diffusion barrier, low-rate mass transfer, low binding capacity and poor site accessibility because of their high cross-linking nature [8]. In recent years, to overcome these drawbacks, a surface imprinting technique on nanomaterials has been developed to enable the recognition sites at the surface or in the proximity of the surface [9]. It has been proved that the nanostructured MIPs own the advantages of favorable selectivity and fast association/dissociation kinetics. For example, the nanostructured materials with a large surface area and high porosity, such as nanoparticles [10,11], nanowires [12], nanotubes [13,14], nanofibers [15,16], are excellent candidates for MIPs by surface imprinting.

Recently, graphene has attracted tremendous attention since it is mechanically exfoliated and observed by Novoselov and coworkers in 2004 [17]. Its unique thermal, electronic, mechanical properties and high specific surface area endow graphene with various applications in scientific and technological fields [18]. Moreover, as the thinnest nanomaterial ever discovered, graphene shows great promise as a versatile platform for MIPs with excellent performances, such as the high binding capacity, fast binding kinetics, good accessibility to the target species, low mass-transfer resistance, and easy removal of template molecules, etc. It is because that the atomic-thick structure of graphene could make most of template molecules situate at the surface [19]. Numerous methods have been made to synthesize graphene-based MIPs (MIPs-G), including atom transfer radical polymerization [20], reversible addition fragmentation chain transfer polymerization [19], free radical polymerization (FRP) [21] and electrochemical polymerization [22]. Due to its applicable to almost all of vinyl monomers with simple operation, FRP shows obvious

advantages in synthesis MIPs-G [23]. The applications of MIPs-G in adsorption [24], optosensing [25] and electrochemical recognition [26–30] were reported.

Aromatic amines are a class of toxic substances and represent one of the most important classes of environmental pollutants. In addition, aromatic amines have been widely used as raw materials in the manufacture of plastic tableware. Major types of aromatic amines in the plastic tableware are 4, 4-methylene diphenylamine (MDA) and aniline [31]. MDA and aniline have been identified as potential carcinogen by International Agency for Research on Cancer, and are limited to ppb levels in natural waters [32]. Therefore, it demands reliable, sensitive and repaid analytical methods for the measurement of MDA and aniline. Gas chromatography, liquid chromatography and capillary electrophoresis were reported to separate and detect aromatic amines [33–35]. These methods have the advantage of high-efficient separation, however, complicated procedure (for instance, chemical derivation) and expensive instruments are required. In view of time consuming and easy operation, there are growing needs to seek some other sensitive and rapid methods. Electrochemical method has emerged as fast and efficient tool for the analysis of aromatic amines [36,37]. However, as a disadvantage, this method has poor selectivity because of the similar structure of MDA and aniline. In this work, we describe a new strategy for simultaneous detection of MDA and aniline using MIPs-G as electrode material and the procedure is illustrated in scheme 1. MDA was used as the template and adsorbed on the surface of graphene through the π-π interaction [38], and 4-vinyl pyridine (4-VP) could pre-polymerize with template molecules via hydrogen bonds and van der Waals interaction [39]. After the thermal decomposition of 2, 2'-azobis (2-methylpropionitrile) (AIBN), free radicals would occur and the polymerizations begin to form MIPs-G nanocomposites. After removal of template molecules (MDA) through linear sweeping voltammetry, MIPs-G was used as electrode materials for simultaneous detection of MDA and aniline. MDA is binding preferentially at imprinting cavities and is oxidized electrochemically due to the high affinity and fast kinetics to uptake the template molecules. As for aniline, it is adsorbed on graphene via π-π stacking and then electrochemically oxidized. Due to the difference on surrounding environment, the electrochemical responses of MDA and aniline at MIPs-G modified electrode can be discriminated easily.

2. Materials and methods

2.1. Reagents

Graphene (physical reduction, Nanjing XFNano Chemicals, China), MDA (99.5%, Shanghai J&K Chemicals, China). Ethylene glycol dimethacrylate (EGDMA) and 4-VP were purchased from Aldrich and were distilled under reduced pressure to remove inhibitors. AIBN (99%) was purchased from Aladdin Chemicals (Shanghai, China). Other chemicals were purchased from Sinopharm Chemical Reagent Company. Phosphate buffer solution (PBS) was prepared with KH_2PO_4 and Na_2HPO_4. The solutions of MDA and aniline (1.0 mmol L^{-1}) were made by ethanol.

2.2. Apparatus

The surface morphological images were characterized by transmission electron microscope (TEM, TECNIG20, 200 KV) and scanning electron microscope (SEM, HITACHI S-4800). Fourier transform infrared (FTIR) spectra were performed on a NEXLIS FTIR (Nicolet, USA). Raman measurements were carried out using a confocal microprobe Raman system (LabRam II, Dilor, France). Thermal gravimetric analysis (TGA) was conducted on a SDTA851 TGA analyzer (Mettler Toledo, Switzerland) with temperature ranging from room temperature to 700 °C at a heating rate of 10 °C min^{-1} in the nitrogen flow.

Electrochemical measurements were conducted with a computer-controlled Autolab (TYPE III, Netherlands) electrochemical workstation at room temperature. A glassy carbon electrode (GCE, d = 3 mm) or modified-GCE was used as working electrode, with a platinum wire as auxiliary electrode and a saturated calomel reference electrode (SCE).

The official method based on liquid chromatography was performed on Aglint 1200 with a diode array detection (DAD) system. The DAD monitoring wavelength was set at 240 nm. An Eclipse Plus C18 column (4.6 × 250 mm, 5 μm) was used for separation and the injection volume was 10 μL. The stationary phase was a mixture of water and acetonitrile (9:1, v/v) at a flow rate of 1.0 mL min^{-1}.

2.3. Synthesis of MIPs-G

MDA molecules were used as the template and the synthesis route of MIPs-G was described as follows. Firstly, 20 mg graphene were dispersed in 20 mL mixed solution of trichloromethane and acetonitrile (v/v, 1:3). Then, 0.2 mmol MDA was added into the solution and mixed by ultrasonic for about 30 minutes until MDA was homogeneously dispersed. After that, 0.8 mmol 4-VP, 4.0 mmol EGDMA, and 30 mg AIBN were added and the resultant mixture was stirred at 60 °C for about 24 hours under the nitrogen protection. The resulting products were collected through centrifugation and washed thoroughly with methanol. Finally, the materials were dried under vacuum at 55 °C for 12 hours. As controlled samples, non-imprinted polymers (NIPs-G) were also synthesized by the same protocol of MIPs-G but in the absence of MDA.

Scheme 1. The synthesis route for MIPs-G via FRP and the electrochemical sensing of MDA and aniline.

2.4. Electrochemical measurements

1 mg MIPs-G (or NIPs-G, graphene) were added into 1 mL of 0.1 mol L^{-1} HAc with 0.5% chitosan under ultrasonication for one hour. Prior to use, the GCE was polished with 0.5 μm alumina powder and dried at room temperature. Then, 5 μL MIPs-G (1 mg mL^{-1}) were dropped on the surface of GCE and dried under IR lamp. The templates were removed by linear sweeping until no electrochemical signal of MDA was observed. After extracting the templates, the electrode was used to detect target molecules using differential pulse voltammetry (DPV) in 10 mL PBS containing different amount of MDA and aniline.

2.5. Sample treatment

As for plastic samples, white spoon, black spoon and black spatula were selected for market. Based on GB/T 5009.156-2003, the volume of soak solution was about 6 mL dm^{-2} based on the fixed contact area. 3% acetic acid was chosen as soak solution and the sample was soaked in it for two hours at 100 °C. After that, the extracting solution was adjusted to pH=9.0 with sodium hydroxide. Envi Chrom P solid-phase extraction column was used to enrich aromatic amine according to the literature [31].

3. Results and discussions

3.1. Characterization of MIPs-G

The morphology of graphene and MIPs-G was characterized by SEM and TEM, respectively. As shown in Fig. 1(a-d), the feature structure of graphene with some folds and wrinkles could be observed in all of the images, and these wrinkles are important for preventing aggregation of graphene and maintaining high surface area [40]. As for MIPs-G (Fig. 1(c) and (d)), some granular substances were grafted on the surface of graphene, indicating the formation of MIPs through FRP.

Fig. 2(A) shows the FTIR spectra of graphene, MIPs-G and MIPs. As shown in Fig. 2A(a), the absorbance at 1641 cm^{-1} was assigned to C=C stretch vibration of graphene, while the absorbance at 1103 cm^{-1} was attributed to C-O-C stretch, indicating the existing of oxygen-rich groups [41]. Fig. 2A(b) presents the characteristic vibration of MIPs. The bands at 1637, 1458 and 1390 cm^{-1} were assigned to C=N, C=C, and C-N stretching vibration, respectively, which indicated the existence of vinyl pyridine [42]. The peaks at 1731 and 1156 cm^{-1} were characteristics of the C=O and C-O stretching vibration of EGDMA. The characteristic peaks of MIPs were also appeared in the sample of MIPs-G (Fig. 2A(c)) with little blue shift to 1726, 1636, 1452 and 1252 cm^{-1}. It is probably due to the interaction between graphene and MIPs. Owing to the weak vibration, the absorption for graphene is hardly observed in Fig. 2A(c).

The Raman spectrum of graphene in Fig. 2B(a) exhibits a D-band at 1350 cm^{-1} due to the breathing mode of κ-point phonons of A1g symmetry, while the G-band at 1608 cm^{-1} is corresponding to the E2g phonon of the sp2 hybridization carbons in the 2-D lattice [43]. It can be seen that the similar peaks of D-band (1365 cm^{-1}) and G-band (1621 cm^{-1}) were also appeared in Fig. 2B(b), but the intensities were reduced obviously, probably due to the lower content of graphene in the composite [44]. The intensity of D and G expresses the sp2/sp3 carbon ratio, a measure of the extent of disorder present within the materials [45]. The i_D/i_G ratios of graphene and MIPs-G are 1.81 and 1.56, respectively, reflecting the decrease in disorder after polymerization. In addition, the G-band of MIPs-G shows a little blue shift, which provides an evidence for the strong interaction and charge transfer between graphene and MIPs [19].

The TGA curves of MIPs and MIPs-G are shown in Fig. 3. For MIPs (Fig. 3(a)), it appeared a gradual weight loss below 300 °C, which was likely due to the decomposition of labile oxygen functional groups [44]. The weight loss increased obviously from 300 °C to 430 °C and remained stable about 450 °C with about 89% total weight loss, which might be corresponding to the degradation of carbon skeleton for MIPs [44]. The TGA curve of MIPS-G shows a similar weight loss from 300 to 400 °C with about 84% weight loss. As graphene is relatively

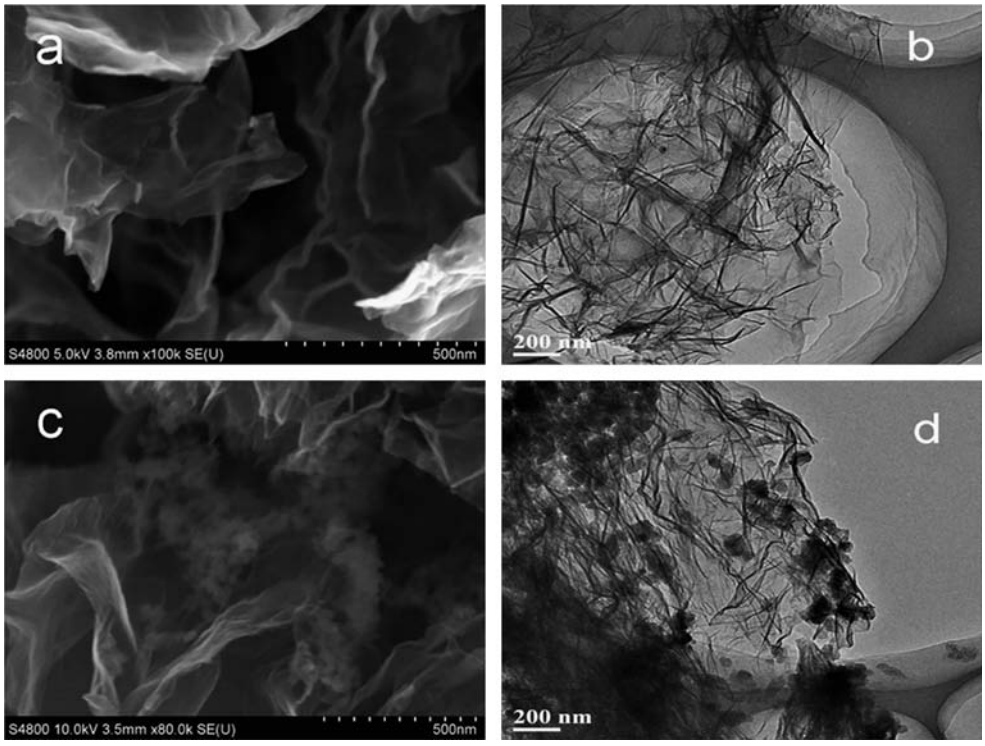

Fig. 1. SEM and TEM images of graphene (a, b) and MIPs-G (c, d) respectively.

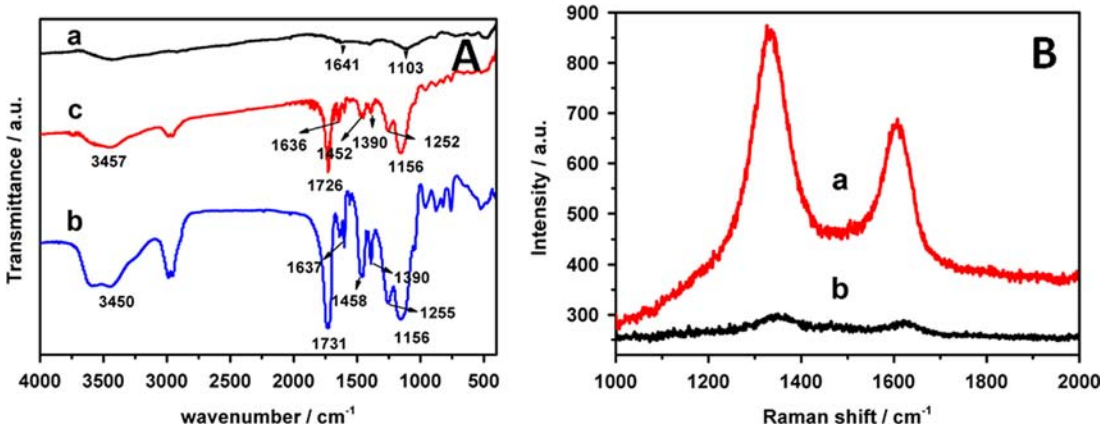

Fig. 2. (A). FTIR spectra of graphene (a), MIPs (b) and MIPs-G (c). **(B).** Raman spectra of graphene (a) and MIP-G (b).

thermal stable below 700 °C under nitrogen [46], the difference on weight loss between MIPs and MIPs-G was likely assigned to the existence of graphene. Based on the above results, the weight content of MIPs grafted on the surface of graphene was up to almost 95%.

3.2. Electrochemical characteristics of MIPs-G modified electrode

EIS is an effective method for exploring the features of the modified electrode [47]. The impedance measurement was performed in 5 mM $[Fe(CN)_6]^{3-/4-}$ with 0.1 mol L^{-1}KCl over the frequency ranged from 0.1 to 10^4 Hz at the formal potential of 0.18 V. The Rct for bare GCE (Fig. 4A(a)) is about 56 Ω, while the EIS for graphene modified electrode (Fig. 4A(b)) is almost straight due to the excellent electron-transfer ability. As for MIPs-G modified electrode (Fig. 4A(c)), the Rct is about 20 Ω, which is larger than that of graphene modified electrode because of the poor conductivity of MIPs.

The electrochemical behavior of MIPs-G modified electrode was also studied by cyclic voltammetry in 5 mM $K_3[Fe(CN)_6]$ solution. As shown in Fig. 4B, the oxidation and reduction peak currents increased with the scan rate over the ranging from 30 to 300 mV s^{-1}. A liner correlation of I_{pa} or I_{pc} versus $v^{1/2}$ is observed in the insert plot of Fig. 4B, indicating the electrochemical reaction is diffusion controlled.

3.2.1. Electrochemical behaviors of MDA and aniline

Graphene has been widely used as electrode materials because it has many advantageous properties like good conductivity, wide potential window, good electrocatalytic activity, easy modification, large specific surface areas and the capability of being mass-produced from bulk graphite [48]. The electrochemical behaviors of MDA and aniline at graphene modified GCE were investigated (Fig. 5). As shown in Fig. 5(a), MDA is electrochemically oxidized at 0.50 V and reduced at 0.11 V. As for aniline (Fig. 5b), an oxidation peak at 0.52 V and a reduction peak at 0.11 V are observed. It can be seen that the electrochemical responses of MDA and aniline at graphene modified electrode occur at almost the same redox potentials because of the similar chemical structure. Hence, MDA and aniline can't be detected at graphene modified electrode.

Fig. 6 demonstrates the DPV responses of MDA and aniline at MIPs-G modified electrode. As shown in Fig. 6(a) and (b), the oxidation potential for MDA and aniline is observed at 0.62 and 0.72 V, respectively. Fig. 6(c) shows the electrochemical responses of mixture of MDA and aniline (1:1) at MIPs-G modified electrode. It can be seen that two oxidation peaks at 0.62 and 0.72 V appear simultaneously, indicating the electrochemical oxidation of MDA and

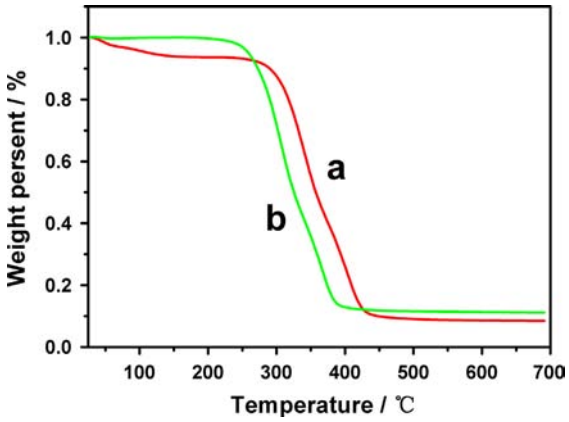

Fig. 3. TGA curves of MIPs (a) and MIPs-G (b) at a heating rate of 10 °C min^{-1} from room temperature to 700 °C under a nitrogen flow.

aniline, respectively. It shows that MDA and aniline can be differentiated at MIPs-G modified electrode. It can be explained that MDA and aniline can be simultaneously adsorbed on the surface of graphene because of the π-π interaction [49], therefore, the electrochemical behaviors of MDA and aniline at graphene modified electrode cannot be discriminated due to the similar chemical structure. As for MIPs-G, we assume that MIPs presenting on the surface of the graphene have special binding capability for template molecules, thus, MDA can be adsorbed preferentially by the imprinting sites due to the selective recognition. In addition, aniline is adsorbed on the surface of graphene which is not occupied by MIPs through π-π interaction. Due to the difference on surrounding environment, the electrochemical behaviors of MDA and aniline can be discriminated at the MIPs-G modified electrode. Furthermore, the cross-talk experiment between aniline and MDA was further investigated (shown in Fig. 6(d) and (e)). While the concentration of aniline is fixed (5 μM), the oxidation current varies linearly with the concentration of MDA over the range from 1.0 to 15 μM (R^2=0.9923) (Fig. 6(d)). On the other hand, the peak current is also linear with the concentration of aniline while the concentration of MDA is fixed (5 μM) (Fig. 6(e)). In addition, the oxidation peak current of MDA is almost the same with the change of the concentration of aniline, which might originate from the special binding capacity of MIPs-G for MDA. Moreover, the electrochemical behaviors of MDA and aniline at NIPs-G modified electrode were also studied (Fig. 6(f)). In a mixture with equal amount of MDA and aniline, only one obvious oxidation peak at 0.72 V can be observed, indicating the two aromatic amines can't be measured simultaneously due to the lack of recognition sites on the surface of NIPs-G. It is further confirmed

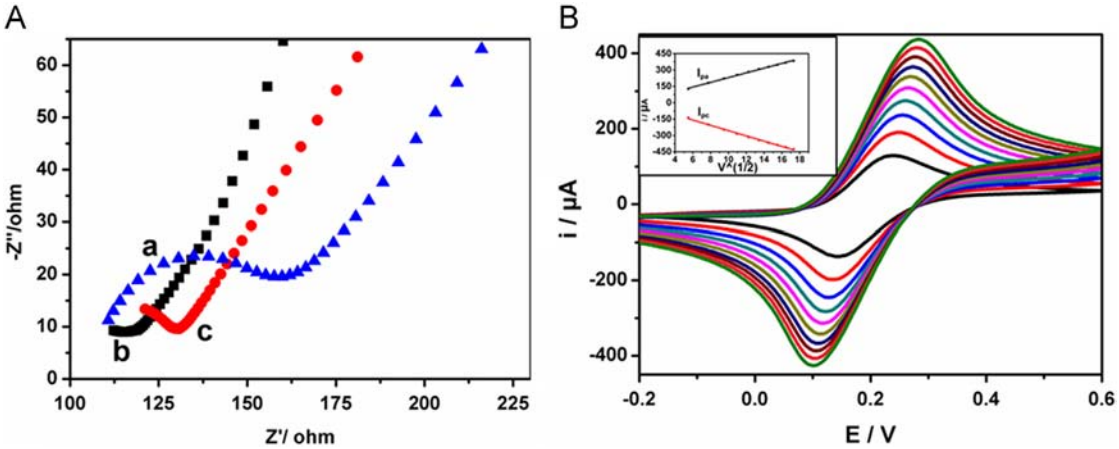

Fig. 4. (A). Electrochemical impedance spectra recorded in 5.0 mM $K_3[Fe(CN)_6]$ containing 0.1 M KCl at bare GCE (a), graphene modified GCE (b) and MIPs-G modified electrode (c). **(B).** Cyclic voltammograms of MIPs-G modified GCE in 5.0 mM K_3 $[Fe(CN)_6]$ with scan rate increasing from 30 to 300 mV s^{-1}, and the insert is the peak currents versus $v^{1/2}$.

that MIPs-G has a special binding capacity for the template molecules and can be used to detect MDA and aniline simultaneously.

3.3. Optimization of electrochemical conditions

The effect of experiment condition on the electrochemical response of MDA at MIPs-G modified electrode were further investigated (data not shown). The oxidation peak current gradually increased with an increasing pH from 4.0 to 7.0 and then decreased from 7.0 to 10.0. Thus, the experiment was performed at pH 7.0. Meanwhile, the oxidation potential shifts negatively and linearly with the increasing of the pH. The relationship between the potential and pH obeys the equation as follows, $E_{pa}(V)$= 0.78361–0.02625 pH. The potential negatively shifts 26.25 mV per pH unit, indicating one proton per two electrons involved in the electrochemical reaction [50]. The amount of the MIPs-G on the electrode surface also plays an important role for detecting MDA and aniline. In this work, the concentration of MIPs-G was fixed as 1.0 mg mL^{-1} and the amount of modifier on the electrode was controlled by change the dropped volume of modifier. As a consequence, the electrochemical response of MDA reaches maximum while the volume of modifier is 5 μL. Hence, 5 μL of MIPs-G (1.0 mg mL^{-1}) was chosen as the optimized amount of modifier. The accumulation time is also an important parameter that might affect the electrochemical response. In this work, MIPs-G modified electrode was dipped in the solution for a certain time to accumulate MDA and aniline before electrochemical detection, and the optimized accumulation time is 60 s. Under these conditions, the determination of MDA and aniline at different concentrations was performed. The DPV response was linear to the concentration of MDA and aniline over the range of 1.0 to 15 μM, and the linear equation was $I_{pa}(\mu A)=0.0352c(\mu M)-0.0113$ ($R^2=0.9962$) for MDA and $I_{pa}(\mu A)=0.0162c(\mu M)+0.0123$ ($R^2=0.9962$) for aniline, respectively.

3.4. Repeatability, stability and selectivity of MIPs-G electrode

Under the optimal conditions mentioned above, MDA and aniline solution were measured successively for five times with the same electrode. The relative standard deviation (RSD) of the peak current for MDA and aniline was 2.89% and 2.57%, respectively. The reproducibility of the imprinted sensor was investigated by measurement 2.0 μM MDA and aniline in PBS using three MIPs-G modified electrodes which were prepared under the same procedure. The RSD for MDA and aniline is about 4.18% and 6.80%, indicating a good sensor-to-sensor reproducibility. While the electrode was not used, it was stored in refrigerator in 4 °C. After one month, the electrochemical sensor was used to simultaneously measure MDA and aniline and about 92.0% of the initial peak current was obtained. It suggests that the imprinted electrochemical sensor exhibits satisfactory stability.

As for the selectivity of the sensor, some aromatic amines (such as phenylenediamine, hexamine, naphthylamine and 4-acetylene aniline) were selected to test the anti-interference ability of the MIPs-G modified electrode. The concentration of these substrates was the same as that of MDA. The results show that no electrochemical signal is observed for o-phenylendiamine and hexamine. It indicates o-phenylendiamine and hexamine could not affect the detection. As for naphthylamine and 4-acetylene aniline, the oxidation peak was located at 0.54 and 0.73 V, respectively. However, naphthylamine has no influence on the performance of the electrochemical sensor because the oxidation potential can be differentiated clearly. The oxidation peak of the 4-acetylene aniline is very close to that of aniline, indicating the potential interference. However, the major types of aromatic amines in plastic tableware were MDA and aniline [31], other aromatic amines was not found. It demonstrates that MIPs-G modified electrochemical sensor can be used for aromatic amines detecting in plastic tableware samples.

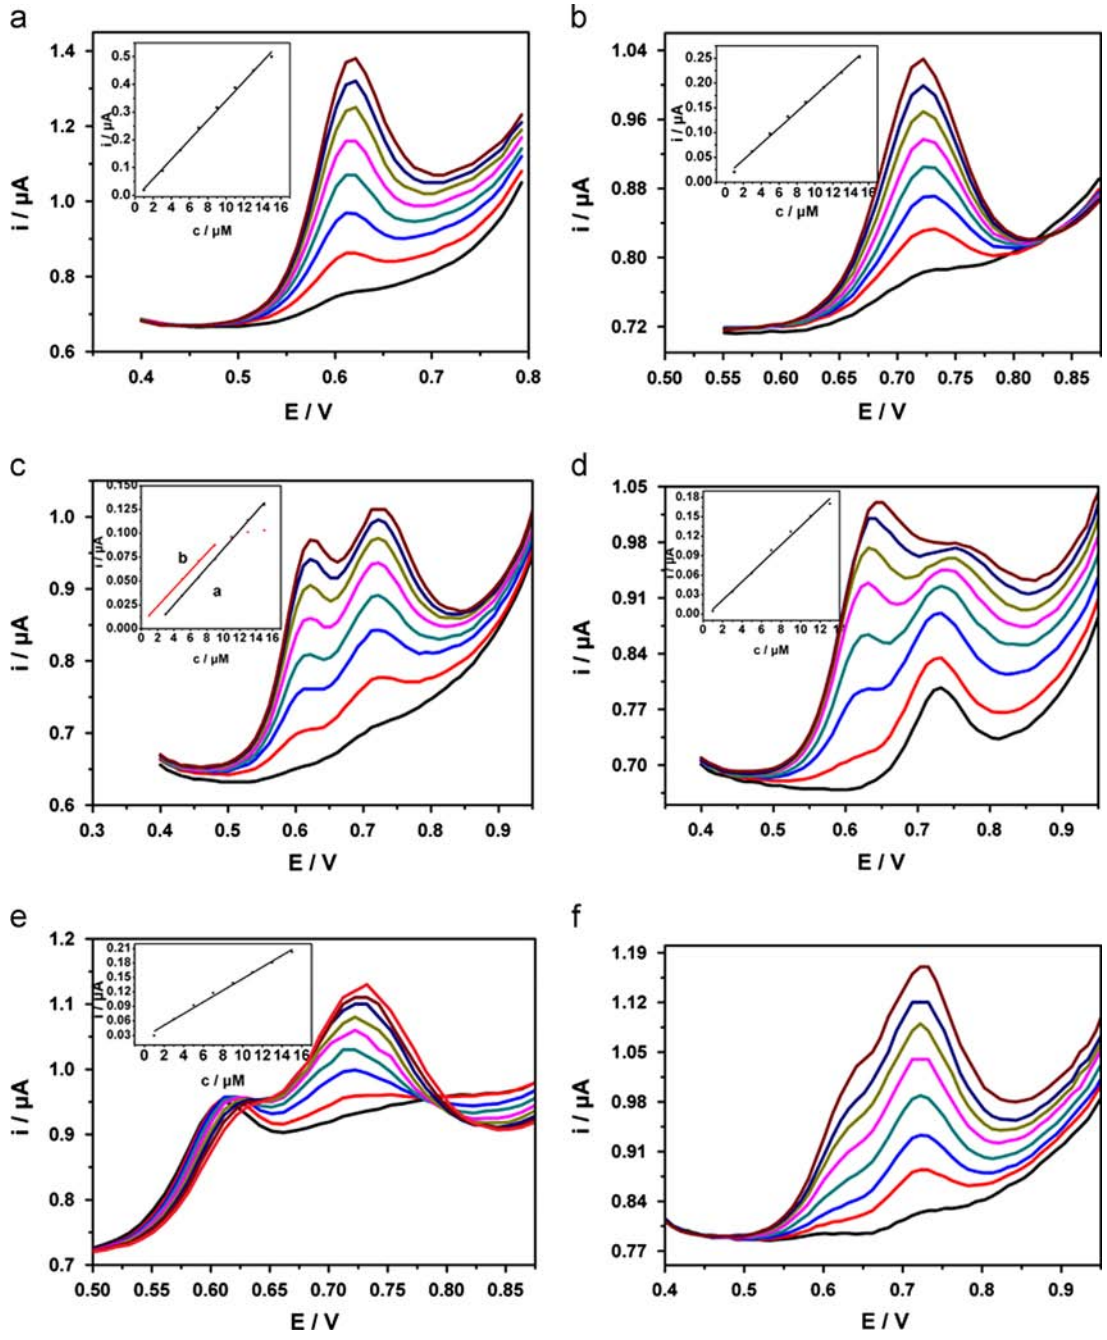

Fig. 6. DPV responses of MIPs-G modified electrode in PBS containing MDA (a), aniline (b), MDA and aniline (1:1) (c), fixed aniline (5 μM) with different concentration of MDA (d) and fixed MDA (5 μM) with different concentration of aniline (e). (f) DPV responses of NIPs-G modified electrode in PBS with MDA and aniline (1:1). The concentration of MDA and aniline varied from 1–15 μM. The inserts are the linear plots between the peak current and the concentration of analyte.

3.5. Sample analysis

In order to evaluate the practical application of MIPs-G modified electrode, MDA and aniline in white spoon (sample 1), black spatula (sample 2) and black spoon (sample 3) were measured. For the electrochemical measurements, 1 mL samples were diluted to 10 mL with PBS (pH7.0). However, no MDA and aniline were detected in all samples. Therefore, standard addition method was further used to evaluate the potential application MIPs-G modified electrode in sample analysis. A known amount of MDA and aniline were added into the solutions and the recovery was obtained (shown in Table 1). The recovery was ranging from 93.5% to 106%, indicating the electrochemical sensor can be applied for detecting MDA and aniline simultaneously in real samples. Meanwhile, the samples were measured by HPLC and the results were very close to these of MIPs-G modified electrochemical sensor (shown in Table 1). The consistency between electrochemical sensor and the official method confirms the imprinted electrode could be used in practice.

4. Conclusions

In this work, a sensitive and selective electrochemical sensor based on MIPs-G was developed for simultaneous measurement MDA and aniline. Owing to the unique conductivity and large surface area, graphene provides an excellent platform for the

development of MIPs-G based electrochemical sensing system. The MIPs-G modified electrode displays linear response towards MDA and aniline over the range of 1.0 to 15 μmol L^{-1}. Furthermore, the MIPs-G based sensor was used to determine MDA and aniline simultaneously in plastic food packing samples, and the acceptable recovery implied its feasibility for practical application.

Early diagnosis

ABSTRACT

Cancer and cardiovascular diseases are the major threats to global health. Hence, there is a growing demand for a range of portable, rapid and low cost biosensing devices for the detection of these diseases. Electrochemical immunosensors are simple, rapid, reliable and inexpensive devices and they have sensitive detection limits to monitor both levels of the biomarkers in normal and patient serum. Due to the specific binding of antibody to its corresponding antigen, immunosensors based on antibody–antigen interaction are one of the most widely used analytical techniques in the quantitative detection of these diseases. The changed levels of markers in patients are associated with diseases. In this article the biosensors and biomarkers, which were commonly used in terms of monitoring the diagnosis and treatment of cancer and cardiac diseases, are reviewed. In addition, the developed biosensors are compared in terms of precision, reproducibility, regeneration, stability and specificity.

1. Introduction

The pioneering study of Clark and Lyons, more than four decades ago, shed light on some analytical researchers in designing of biosensors, which perform as economical and fast tools for clinical, chemical, environmental and pharmaceutical studies. Because of its simple use and portability in relatively complex samples, biosensors offer a potential alternative to advanced bioanalytical systems [1].

A biosensor is composed of two components, a bioreceptor and a transducer. First part, the bioreceptor is a biomolecule that recognizes the target analyte, and second part the transducer converts the recognition event into a measurable signal [2]. Immunosensors are antibody–antigen based affinity biosensors, in which the detection of antigen as a target analyte is a result of the specific binding of the antigen to particular region of an antibody on the electrode surface [3]. Also, in electrochemical immunosensors antibody acts as a bioreceptor and antigen acts as a target analyte and transducer can be able to quantify the antigen concentration by using amperometric, potentiometric, impedimetric or conductometric signals. Fig. 1 shows a schematic presentation of an electrochemical immunosensor.

In recent years, optical and electrochemical detection methods have been used in early clinical diagnosis. Optical detection transduction method is less sensitive when coupled with radioimmunoassay, has short half-life of radioactive agents, concern of health hazards, and has disposal problems. On the other hand, electrochemical

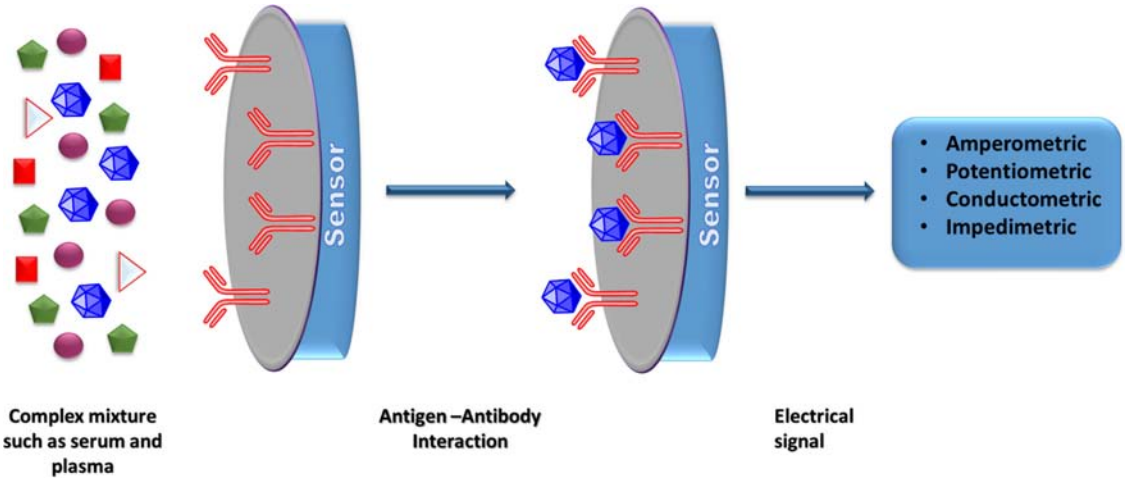

Fig. 1. Schematic representation of electrochemical immunosensor.

detection method shows no similar problems and electrochemical immunoassays and immunosensors enable fast, simple, and economical detection [4].

Electrochemical immunosensors are used as care devices since they are portable, simple, easy to use, cost effective and disposable in most cases [5,6]. Compared with traditional immunoassay methods, electrochemical immunosensors are specific, simple and convenient, and can offer multitarget analyses and miniaturization. They can perform in situ, real-time, automation detection [7].

Specificity for any given biomarker is often achieved by use of antibodies. The specific binding of an antibody to its target antigen in a complex mixture such as serum and plasma provides the detection and quantification of diseases at levels as low as picograms (pg) [8]. Also, this is another advantage of immunosensors.

In this study the biosensors and biomarkers, which were commonly used in terms of monitoring the diagnosis and treatment of cancer and cardiac diseases, are reviewed. And also, it focuses on recent development for tumor markers and cardiac markers testing and monitoring in clinical diagnosis. However, a wide range of researches have been published in this area. This review is limited to recent publication within the past nine years. Most reviews have been organized around only tumor or cardiac biomarkers and their diagnosis of biosensors. Herein we present different biomarkers used in several publications of electrochemical immunosensors for tumor and cardiac diseases and highlighted the major clinically relevant parameters, such as their detection limit/range and designing of bioassay. Moreover, in this review, we emphasize on the opportunities for further improvement in tumor and cardiac diseases diagnostic and treatment monitoring.

2. Electrochemical immunosensors

An antibody based biosensor was applied for the first time in the 1950s, leading the possibility of immune-diagnosis [4]. These types of biosensors have high specificity and low limit of detection due to their extreme antibody affinity to their antigen. Antibodies are proteins produced by the immune system. However, antigens can be a variety of different molecules, from protein to DNA, lipids, etc [6].

In developing immunosensors, the immobilization of antibody is an important step because antibody acts as the recognition element for antibody–antigen reaction. The performance of the detection and antigen binding capacity can be increased by a proper antibody surface. Thus the choice of the antibody immobilization method is very important in the design of an immunosensor. Several methods including physical [9–10] and chemical adsorption have been used for the preparation of oriented antibody molecular layers on the surface of the transducer. Self-assembly (SAM) technique has been used as chemical adsorption method for immobilization of antibody [11–13]. In this technique, a self-assembly monolayer is fixed on the surface through chemical bonds. Then the antibody is covalently attached to the monolayer by using cross-linkers.

Transducer types used in immunosensors are electrochemical (amperometric, potentiometric, conductometric, capacitative), optical (fluorescence, luminescence, refractive index), piezoelectric or calorimetric. The electrochemical immunosensors rely on the measurements of currents and/or voltage to detect binding between antibody and antigen.

In potentiometric measurements, the potential difference between a working and a reference electrode is determined by a voltammeter when there is no significant current flowing through them. The potential difference is measured due to the oxidation and reduction of the species in sample solution. The transducer may be an ion selective electrode (ISE) based on thin film or selective membranes as recognition elements. Analytical information is obtained when the ISE convert the biorecognition process into a potential signal.

In amperometric measurements, a current occurs as a result of electrochemical oxidation or reduction of an electroactive species. This type of measurement is taken by maintaining a constant amplitude voltage at working electrode (gold, platinum, and carbon) related to reference electrode, under a fixed potential, current pass through sample [8].

In impedimetric measurements, when biorecognition elements occur at the modified surfaces, the interfacial properties change. Thus impedimetric immunosensors can be used to determine quantitative parameters of electrochemical properties. Electrochemical reactions, known as electron transfers at the electrode surface, involve electrolyte resistance, adsorption of electroactive species, charge transfer at the electrode surface, and mass transfer from the bulk solution to the electrode surface. Each reaction process represented by an electric circuit consists of resistance, capacitors, or constant phase elements combined in parallel or in series. The most favorite model of electric circuit for a simple electrochemical reaction is the Randles–Ershler electric equivalent circuit model, consisting of electrolyte resistance (R_s), charge-transfer resistance (R_{ct}) at the electrode/electrolyte interface, double-layer capacitance (C_{dl}), and mass transfer resistance (R_{mt}), also Warburg impedance (W) [2,14].

In conductometric measurements, there is a relationship between a biorecognition event and conductance. While a reaction, a change in the ionic species concentration leads to change

the solution's electrical conductivity or current flow. A conductometric biosensor consists of two metal electrodes (usually platinum or silver) separated by a certain distance. An ohmmeter (or multimeter) is used to measure the change in conductance between the metal electrodes [15].

3. Tumor and cardiac markers

The National Cancer Institute (NCI) defines a biomarker as "a biological molecule found in blood, other body fluids, or tissues that is a sign of a normal or abnormal process or of a condition or disease. A biomarker may be used to see how well the body responds to a treatment for a disease or condition". Biomarkers can derive from various molecular origins, including DNA (i.e., specific mutation, translocation, amplification, and loss of heterozygosis), RNA, or protein (i.e., hormone, antibody, oncogene, or tumor suppressor) [16]. Different diseases are known to produce or alter the levels of different biomarkers. Therefore, sensitive and rapid diagnosis methods are very important for their detection. Tumor biomarkers are potentially one of the most valuable tools for early cancer detection, accurate pretreatment staging, determining the response of cancer to chemotherapy treatment, and monitoring disease progression. Also in tumor process, changed levels of tumor markers in patients are associated with certain tumor [17]. In addition, the early and quick diagnosis of cardiovascular disease is important not only for patient survival but also saving cost and a lot of time. Discussion of some of the major tumor and cardiac markers and developed for immunosensors for these diseases are presented below.

3.1. Tumor markers

Cancer is defined as abnormal and uncontrolled cell growth due to an accumulation of specific genetic and epigenetic defects and it is one of the main causes of mortality worldwide. Many factors including exposure to carcinogenic chemicals, radiation, genetic and environmental factors cause cancer [16]. There are more than 200 distinct diseases associated with cancer affecting different parts of the body and so clinical test of cancer is very complex [5]. In clinical analysis sensitive, precise, and accurate assays for the determination of tumor markers with low concentration level in complex biological samples are necessary for effective early diagnosis and treatment of cancer [18–20].

In the absence of a tumor, the tumor marker is of low level. Even a small tumor forms, levels of some markers rise. Thus the limits of detection (LODs) are important for early screening of a small tumor [7]. Methods and strategies based on biochemistry, immunology and molecular biology have been developed and used for the determination of tumor markers in human serum. Immunoassay techniques, which show highly specific molecular recognition, are frequently used methods in clinical quantitative detection of tumor markers. Radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), fluoroimmunoassay, chemiluminescent immunoassay, and electrochemiluminescent immunoassays are present among these techniques. Beside the sensitivity, precision and selectivity advantages, there are several disadvantages of these techniques. For instance they have radiation hazards, high cost, require qualified personnel and sophisticated instrumentation and they are also time consuming. Moreover, existing diagnostic tests (e.g., microtiter-plate ELISAs) are not sensitive enough for screening cancer at an early stage and can only detect proteins at levels corresponding to advanced stages of disease [7,21]. Compared with conventional immunoassay methods, electrochemical immunosensor offer several advantages, such as high sensitivity, fast analysis, simple pretreatment, small analyte volume, simple instrumentation, and minimal manipulation and therefore they are largely used [17,22].

Biomarkers can be presented intracellular or extracellular. Intracellular markers need to be collected and enriched if their concentration is very low [5]. In Table 1, the most common biomarkers is listed and in Table 2, the thresholds of some basic tumor markers in human serum are listed [7,23].

Carcinoembriyonic antigen (CEA) is a cell surface glycoprotein with a molecular weight of about 200 kDa [24,25] used as a biomarker for clinical diagnosis of colon tumors, breast tumors, ovarian carcinoma [25–27], gastric, pancreatic, lung carcinomas [18,25,26]. Therefore, CEA is a broad spectrum multi-tumor marker for clinical diagnosis [18]. The level of CEA for a non-smoker adult is < 2.5 ng/mL and for a smoker < 5.0 ng/mL [26,28]. A rising CEA level indicates progression or recurrence of the cancer [26,28,29,30].

Prostate-specific antigen (PSA) is one of the first tumor biomarkers for screening and diagnosing prostate cancer [16,31]. PSA is a 32–33 kDa single-chain glycoprotein [31]. A very low amount of this substance reaches the bloodstream forming free PSA (fPSA) and PSA complexed to a-1-antichymotrypsin (PSA-ACT). Total PSA (tPSA) is the sum of f-PSA and PSA-ACT complex in serum. tPSA level, in healthy males, is usually less than 4 ng/mL and increases in serum during prostate cancer [32].

Tumor marker, α-1-fetoprotein (AFP) is an oncofetal glycoprotein [33,34,35,36] with a single-chain alpha globulin containing

Table 2
The thresholds of basic tumor markers in human serum [5,7].

Tumor markers	Thresholds	Tumor markers	Thresholds
NSE	12.5 mg/L	CEA	3 μg/L
PSA	4 μg/L	CA125	35 kU/L
GST	3.2 U/L	CA153	25 kU/L
ALP	0	CA27-29	36.4 kU/L
CT	100 ng/L	CA549	11 kU/L
SCCA	1.5 μg/L	CA19-9	37 kU/L
Ferritin	250 μg/L	CA50	14–20 kU/L
hCG	5.0 IU/L	CA242	20 kU/L
AFP	10 μg/L	CA72-4	6 kU/L

Table 1
Common biomarkers utilized for cancer detection [16].

Type of cancer	Biomarker
Breast	BRCA1, BRCA2, CA 15-3, CA 125, CA27.29, CEA, NY-BR-1, ING-1, HER2/NEU, ER/PR
Colon	CEA, EGF, p53
Esophageal	SCC
Liver	AFP, CEA
Lung	CEA, CA 19-9, SCC, NSE, NY-ESO-1
Melanoma	Tyrosinase, NY-ESO-1
Ovarian	CA 125, HCG, p53, CEA, CA 549, CASA, CA 19-9, CA 15-3, MCA, MOV-1, TAG72
Prostate	PSA

590 aminoacids and 3.4% carbohydrate and has molecular weight of approximately 70 kDa [34]. In the blood of healthy adults, AFP presents less than 20 ng/mL [35]. The concentration increases in response to hepatocellular carcinoma [33,34,37,38], teroblastoma [34,37,38] and especially liver carcinoma.

Carbohydrate antigen 19-9 (CA 19-9) is a vital carbohydrate tumor marker [39,40]. It is commonly used for many malignancies, such as colorectal, gastrointestinal, hepatic carcinomas and pancreatic and biliary cancer [39].

Myeloctomatosis oncogene (c-Myc) oncoprotein, a product of c-Myc proto-oncogene, regulates the transcription of genes involved in normal cell growth, differentiation, and apoptosis [41]. The level of c-Myc oncoprotein increases when human cancers including breast cancer, lung cancer, melanoma and lymphoblastic leukemia develop [42].

Cancer antigen 125 (CA125) is a membrane mucin-like glycoprotein greater than 200 kDa, and has been used for monitoring the epithelial ovarian tumors [43,44].

Neuron specific enolase (NSE), a widely used biomarker for small-cell lung cancer, neuroblastoma, and neuroendocrine cancers, increases up to 1 μg/mL in serum of serious cancer patients [45,46].

Epidermal growth factor receptor (EGFR, ErbB-1; HER1 in humans) is a cell trans-membrane glycoprotein located at the cell surface. EGFR is useful in many tumors of epithelial origin, such as non-small cell lung cancer (NSCLC), breast, head and neck, gastric, colorectal, esophageal, prostate, bladder, renal, pancreatic, and ovarian cancers [47].

Cancer antigen 15-3, as a breast-associated mucin, and it is used as a biomarker for breast carcinoma patients with distant metastases [44,48,49].

Murine double minute 2 (MDM2) is a proto-oncogene, which can be amplified and over-expressed in a wide range of neoplasm tumors, such as sarcomas, lymphomas, breast cancers, lung cancers, and testicular germ cell tumors, 10% of glioblastomas and astrocytomas, and 40% of oral squamous cell carcinomas [50].

Squamous cell carcinoma antigen (SCCA), which is subfraction of the tumor antigen TA-4, is a tumor marker of cervical cancer. It is also associated with other types of cancer with epithelial or endodermal origins, including lung cancer, head and neck cancer, melanomas, and hepatocellular carcinoma. Squamous cell carcinoma antigen (SCC-Ag) is a glycoprotein with isoforms ranging from 45 to 55 kDa. The serum level of SCC-Ag is increased when the tumor size gets bigger or the disease reoccurs [51].

Human chorionic gonadotrophin (hCG) is an important diagnostic marker of pregnancy and one of the most important carbohydrate tumor markers. It is increased when abnormal placental invasion and placental immaturity occurs [52,53].

Human epididymis-specific protein 4 (HE4) is a new ovarian biomarker, originally predicted to be a protease inhibitor involved in sperm maturation. When HE4 over expresses in ovarian neoplastic tissue its level rises in the serum of patients with ovarian cancer. HE4 is not only expressed in the early stages of the disease, but is also an early indicator of disease recurrence [54].

HER-3 is a type of transmembrane growth factor receptor, which can activate intracellular signaling pathways in response to extracellular signals. Because of HER-3 being an incomplete receptor functionally, it is a dependent protein. Studies show that tumor progression in breast, ovarian, and pancreatic cancers, gastric carcinoma, malignant melanoma and metastases, and head and neck squamous cell carcinoma are linked to over expression of HER-3 [55].

VEGF is an important regulator of angiogenesis and vascular permeability, and is a powerful mitogen for endothelial cells. In breast cancer, VEGF is used as a marker of unfavorable prognosis. However, angiogenesis is essential for growth and tumor progression. It has been observed that patients with metastasis have higher levels of serum VEGF [12].

The developed immunosensors for cancer diagnosis in literature are summarized in Table 3.

Limbut et al. [56] developed an immunosensor for AFP detection. They used self-assembled thiourea monolayer (SATUM), self-assembled thioctic monolayer (SATAM) and 3-mercaptopropionic acid (SAMPAM) for covalent coupling of anti-AFP. They reported that all systems have given the same linear range with nearly the same sensitivity and detection limits. They obtained that all the systems had good stability, could be regenerated and reused up to 48 times with good reproducibility. On the other hand thiourea, which is cheaper than thioctic acid and 3-mercaptopropionic acid, is certainly a good alternative to be applied for the immobilization of antibodies on gold surfaces [56].

Precision, reproducibility, regeneration, stability, and specificity are the important parameters in terms of monitoring the quality of a newly developed biosensor.

The precision of the electrochemical immunosensor was evaluated by calculating the intra- and inter-assay variation coefficients (CVs). The CVs of intra- and inter-assay were similar; therefore precision and reproducibility of the immunosensors were acceptable. Zhong et al. [22] developed an electrochemical immunosensor for CEA detection. They calculated the CVs of intra- and inter-assays. The intra-assay precision of the analytical method was evaluated by analyzing four concentration levels five times per run. The CVs of intra-assay were 5.7, 4.9, 4.1 and 6.5% at 0.1, 10, 100 and 300 ng/mL CEA, respectively. Similarly, the CVs of the inter-assay were 5.3, 7.8, 6.7 and 6.1% at 0.1, 10, 100 and 300 ng/mL CEA, respectively. Another method for reproducibility of the immunosensor is calculating of relative standard deviation (RSD) in different electrodes for each concentration of antigen [22]. Yu et al. [82] and Han et al. [95] developed an electrochemical immunosensor for CEA detection. For all these immunosensors, the reproducibility of the response was examined by analysis of the same concentration of CEA (20 ng/mL) using independent determinations. The immunosensors have acceptable reproducibility with a relative standard deviation of 0.45 and 2.45% (less than 5.0%), respectively.

Yang et al. [111] and Li et al. [100] developed an electrochemical immunosensor for PSA detection. To evaluate the reproducibility of the immunosensors, they prepared a series of five electrodes for the detection of 1 ng/mL PSA and the relative standard deviation (RSD) of their measurements for five electrodes were 7.9 and 6.7%, respectively.

Regeneration is a key factor in their application and development of immunosensors; therefore many immunoanalysts are interested in reusing of immunosensors. Even though the antibody–antigen linkage can be broken under drastic conditions (e.g., in alkaline or acidic solutions or with chaotropic agents), the immobilized immunoreagents could also suffer from the functional damage or even be released from the immunosorbents [43,60]. Tang et al. [43] regenerated the immunosensor by dipping into versatile solution consisting of glycine–HCl (0.2 mol/L, pH 3.6) and NaCl (0.25 mol/L) for 5 min and then rinsing with a phosphate buffer solution of pH 7.0. Because of effectively dissociating the antigen–antibody complex and peeling the captured antigens off the immunosensors, they preferred glycine. Additionally, NaCl provides properly high ion-strength to partition of antibodies and antigens easily. After treatment with glycine solution and NaCl, anti-CA125 is still bound on the film surface and therefore again ready for antigen–antibody reaction. And they reported that no remarkable decrease was observed in current response after five measurements [43]. Zhuo et al. [93] rinsed immunosensor with 0.05 M NaOH and then used 0.05 M HCl, 4 M urea, 0.2 M glycine–hydrochloric acid (Gly–HCl) buffer solution to break bond between CEA and anti-CEA and the regenerated immunosensors were used to detect the same concentration. After first seven times regeneration by urea solution kept 95.97% of the original amperometric responses, first

Table 3
The developed immunosensors for cancer diagnosis in literature.

Biomarker	Immobilization strategies	Assay principle	Linear range	Limit of Detection	Reference
Alpha- fetoprotein (AFP)	Au/3-MPA/EDC/NHS/anti-AFP/1-dodecanethiol/AFP Au/thioctic acid/EDC/NHS/anti-AFP/1-dodecanethiol/AFP Au/thiourea/glutaraldehyde (glu)/anti-AFP/ethanolamine/1-dodecanethiol/AFP	Capacitive	0.001–100 μg/l	10 ng/L	[56]
AFP	SPCE/chitosan (Chi)/HRP-labeled anti-AFP/AFP	Amperometric	0–150 ng/mL	0.74 ng/mL	[57]
Carcinoembriyonic antigen (CEA)	GCE/MWCNTs-Chi/AuNPs/anti-CEA/BSA/CEA	Differential pulse voltammetry	0.3–20 ng/mL	0.01 ng/mL	[17]
CEA	SPCE/Chi/colloidal Au/CEA/HRP-labeled anti-CEA	Amperometric	0.5–25 ng/mL	0.22 ng/mL	[58]
CA 19-9 Carcinoma antigen (CA 125)	Graphite electrode/cellulose acetate (CA)/CA 19-9+CA 125+thionine/HRP-labeled antibodies	Differential pulse voltammetry	0–144 U/mL 0–150 U/mL	0.2 U/mL 0.4 U/mL	[59]
PSA	GCE/MWCNTs/ionic liquid/chitosan nanocomposite (MWCNTs/IL/Chi)/AuNPs-incorporated polyamidoamine dendrimer (AuNPs-PAMAM)/phtaloyl chloride (Ph)/anti-PSA+thionine/PSA/HRP-labeled anti-PSA	DPV impedimetric	0.05–80 ng/mL 5–25 ng/mL	0.001 ng/mL 0.5 ng/mL	[60]
CEA	ITO/polydopamine (PDA)/mesoporous silica nanoparticles (MSNs)-Ab1 (anti-CEA)/BSA/CEA/HRP-Ab2-AuNPs	Amperometric	10^{-2}–40 ng/mL	1.7 10^{-3} ng/mL	[61]

AFP	GCE/GS-Thi composite film/glu/anti-AFP (Ab1)/BSA/AFP/PB modified hydroxyapatite loaded with HRP and secondary anti-AFP antibody (PB@HAP-HRP-Ab2)	Amperometric	0.02–8 ng/mL	9 pg/mL	[113]
PSA	GCE/GO-Ab1/BSA/PSA/ferrocene (Fc) incorporated polystyrene spheres (Ps-Fc)-chitosan-Ab2	Amperometric	0.01–20 ng/mL	1 pg/mL	[114]
AFP	GCE/Au-Chi/anti-AFP/BSA/AFP/HRP conjugated anti AFP-silver nanowire-graphene hybrid nanomaterials (HRP-anti-AFP-AuNW-GPs)	Amperometric	0.05–400 ng/mL	5 pg/mL	[115]
Squamous cell carcinoma antigen (SCCA),	GCE/reduced graphene oxide-tetraethylene pentamine (rGO-TEPA)/Ab1/BSA/SCCA/Au@mesoporous carbon CMK-3-Ab2	Amperometric	0.03–20 ng/mL	0.01 ng/mL	[116]
CEA			0.05–20 ng/mL	0.013 ng/mL	
PSA	GCE/polyethyleneimine functionalized 3,4,9,10-perylenetetracarboxylic acid (PEI-PTCA)/AuNPs/Ab_1/BSA/PSA/biotinylated ALP/streptavidin (SA)/anti-PSA/Ab2/Au modified nickel hexacyano ferrates (Au@NiNPs)/onion like graphene sheets (O-GS)	Amperometric	0.01–50 ng/mL	3.4 pg/mL	[117]
fPSA	GCE/PEI-PTCA/AuNPs/Ab1/BSA/fPSA/bio-ALP/SA/anti-fPSA/Au modified prussian blue nanoparticles	Amperometric	0.02–10 ng/mL	6.7 pg/mL	
CEA	GCE/MWCNTs/EDC/NHS/Ab1/CEA/GOD-Aushell@GOD nanospheres	Amperometric	0.02–5 ng/mL	6.7 pg/mL	[118]
CEA	Au/Nafion-cysteine composite membrane/AuNPs/anti-CEA/BSA/CEA	Amperometric	0.01–100 ng/mL	3.3 pg/mL	[119]
Mucin-16 (MUC-16)	SPE/gold nanoelectrode ensemble (GNEE)/2-mercaptopropionic acid/2-mercaptoethanol/sulfo-NHS/EDC/anti-MUC-16/ethanolamine+BSA/MUC-16	Amperometric	0.001–300 U/mL	5.10^{4-} U/mL	[120]
CEA	GCE/three dimensional macro porous gold nanoparticles-graphene composites (3D-AuNPs/GN)/Ab1/BSA/CEA/HRP labeled anti-CEA (HRP-Ab2)/Thi/nanoporous silver (NPs)	Amperometric	0.001–10 ng/mL	0.35 pg/mL	[121]
SCCA	GCE/nitrogen doped graphene sheets (N-GS) in chitosan/glu/Ab1/BSA/SCCA/Pt-FeO4-Ab2	Amperometric	0.05–18 ng/mL	15.3 pg/mL	[51]
Human chorionic gonadotropin (hCG)	GCE/GS/acid treated MWCNTs/Au/Ab1/BSA/hCG/HRP-Ab2/Au/Thi/MCM-41	Amperometric	0.005–500 mIU/mL	0.0026 mIU/mL	[53]
Human epididymis-specific protein-4 (HE4)	ITO/chitosan-titanium carbide (TiC)/AuNPS/anti-HE4/BSA/HE4/biotin labeled HE4	Amperometric	3–300 pM	0.06 pM	[54]
CEA	GE/GS/EDC/NHS/Ab1/BSA/CEA/mesoporous platinum nanoparticles labeled antibody (M-PtNP-Ab2)	Amperometric	0.02–20	7 ng/mL	[122]
CA 125			0.05–20	0.002 U/mL	
CA 153			0.008–24	0.001 U/mL	
Apurinic/apyrimidinic endonıuclease-1/redox factor-1 (APE-1)	GCE/ethylenediamine/protein A(PA)/EDC/NHS/Ab1/BSA/APE-1/biotinylated ALP/nanochain modified streptavidin/Ab2/nickel hexacyanoferrates nanoparticle-decorated Au nanochains (Ni-AuNCs)	Amperometric	0.1–100 pg/mL	3.9 fg/mL	[123]
Vascular endothelial growth factor (VEGF)	Au/3-mercaptopropionic acid (3-MPA)/EDC/NHS/VEGF-R1/BSA/VEGF	Impedimetric	10–70 pg/mL	10 pg/mL	[12]
HER-3	Carbon nanotubes modified screen printed electrode/EDC/NHS/anti-HER-3/BSA/HER-3	Impedimetric	2–14 fg/mL	2 fg/mL	[124]
HER-3	ITO/APTES/glu/anti-HER-3/BSA/HER-3	Impedimetric	40–200 fg/mL	40 fg/mL	[55]
HER-3	Au/4-aminothiophenol/glu/anti-HER3/BSA /HER3	Impedimetric	0.4–2.4 pg/mL	0.28 pg/mL	[125]
HER-3	Au/hexandithiol(HDT)/AuNPs/Cys/glu/anti-HER-3/BSA/HER-3	Impedimetric	0.2–1.4 pg/mL	0.2 pg/mL	[126]

four times regeneration by Gly–HCl solution kept 96.21%, first three times regeneration by HCl solution kept 95.97%, first two times regeneration by NaOH solution kept 95.97%. Thus they chose urea solution as a suitable reagent for recycling the immunosensors [93].

Specificity is vital point of using biological molecules as recognition elements to develop immunosensors. To evaluate the specificity of the electrochemical immunosensor, control experiments are performed by adding other possible interferents. Yang et al. [30] studied specificity of immunosensor in the solution with 20 ng/mL CEA and with interference substance such as, α-1-fetoprotein (20 ng/mL), hepatitis B surface antigen (20 ng/mL), human chorionic gonadotropin (20 mIU/mL), carcinoma antigen 125 (20 ng/mL), prostate specific antigen (20 ng/mL), immunoglobulin G (20 ng/mL) and BSA (100 ng/mL). The ratios of current responses with CEA to the interfering substance were 5.69, 5.64, 5.74, 5.67, 5.75, 5.73 and 5.71, respectively [30]. Another specificity study was performed by Ravalli et al. [107] and they evaluated the experiment by using electrochemical impedance spectroscopy. And they observed that relative change in impedance originated from the specific monoclonal anti CA125 antibody and CA125 interactions, not from the inferences. So anti CA125 showed a good selectivity when compared with CA 125 [107].

Usually long time stability of the immunosensors was studied on a 30-day period. Feng et al. [81] measured the stability of the immunosensor by testing the response value. The response value of the immunosensor at 5 days, 10 days, 15 days, 20 days and 30 days maintained 98.8, 97.7, 95.9, 93.7, 90.9% of its initial response (C_{CEA} = 10 ng/mL), indicating the immunosensor had good stability. According to them, the Thi-CNTs sensing platform prevents the leak of hydrophilic thionine from the electrode, but also avoid the addition of mediator to the solution which may affect the activity of the antibody [81].

Liu et al. [38] developed an immunosensor for AFP detection. Its current response maintained about 96.2% of the original value after the storage periods of 40 days. They reported that the good stability of the immunosensor depended on two factors: the first one was the microenvironment of the layer-by-layer assembly film; the second was the polymer PEDOT, which offered a stable substrate for the immobilization of molecules [38].

3.2. Cardiac markers

Cardiovascular disease (CVD) is a kind of disease that affects heart and blood vessels. Many factors such as genetic, gender, age, high blood pressure and cholesterol, diabetes, obesity and overweight, smoking and stress cause CVD. It develops when a plaque builds up in the walls of the arteries. This plaque narrows the arteries and makes it difficult for blood to flow through and causes a heart attack or stroke [127,128].

Cardiovascular disease (CVD) leads to human death and World Health Organization (WHO) estimated that 17.3 million (30%) of all global deaths in 2008 were linked with CVD, 7.3 million of which were heart disease and 6.2 million were stroke [129]. Over 80% of the world's deaths from CVDs occur in low- and middle-income countries [127]. The number of people, who die from CVDs, mainly from heart disease and stroke, will increase to 23.3 million by 2030 [127,130].

The current diagnostic methods routinely used for CVD are electrocardiography (ECG), chest X-ray, echocardiography, cardiac catheterization, CT heart scan and blood tests [131]. For successful prognosis of the disease, early and quick diagnosis is vital for patients. The diagnosis of CVD has been based on the WHO criteria, whereby patients must meet at least two of three conditions: characteristic chest pain, diagnostic electrocardiogram (ECG) changes, and elevation of the biochemical markers in their blood samples. Although ECG is an important management tool for guiding therapy, it might not be always useful in every case because some patients might have normal electrocardiograms. Therefore, measurement of cardiac markers is critical in assisting the diagnosis of CVD [128].

There are several important characteristics of a biomarker including (a) high clinical sensitivity and specificity, (b) quick release of biomarker in the blood enabling early diagnosis, (c) capability to remain elevated for longer time in the blood, and (d) ability to be assayed quantitatively. For the accurate disease diagnosis, different types of biomarkers should be analyzed simultaneously because it is difficult to select a specific marker for the diagnosis of CVD [127].

Clinically used cardiac markers are summarized in Table 4 [127].

Myoglobin is a non-enzymatic cardiac protein and is the earliest marker of the acute myocardial infarction (AMI). As a cardiac biomarker, myoglobin is used together with troponin to help diagnosis of heart attack. Because of its small size of 17.8 kDa, it is released into plasma in major amount within 3 h of the onset of AMI and the plasma concentrations usually return to normal within 24 h. Normal serum myoglobin levels range from 30 to 90 ng/mL. After 1 h of the onset of myocardial infarction, serum myoglobin level can raise to 200 ng/mL or even higher. During a peak hour myoglobin level can raise to 900 ng/mL [132].

Human cardiac troponins (cTnT and cTnI) is known 'gold standard' because of their specificity and sensitivity to serological diagnosis and prognosis of acute myocardial infarction and acute coronary syndrome (ACS) [133,134]. cTnI has not been identified outside of the myocardium, but, cTnT is expressed in skeletal

Table 4
Clinically cardiac markers.

Cardiac Biomarker	Type of cardiovascular diseases	Cut-off levels
Troponin I (cTnI)	Detection of acute myocardial infarction (AMI)	0.01–0.1 ng/mL
Troponin T (cTnT)	Detection of AMI	0.05–0.1 ng/mL
Myoglobin	Early detection of AMI	70–200 ng/mL
C-reactive protein (CRP)	Early detection of inflammation/cardiac risk factor	$< 10^3$ ng/mL low risk 1–3 × 10^3 ng/mL intermediate risk > 3–15 × 10^3 ng/mL high risk
Creatine kinase MB subform (CK-MB)	Early detection of AMI	10 ng/mL
B-type natriuretic peptide (BNP)	Acute coronary syndromes/diagnosis of heart failure/ventricular overload	
N-terminal pro-B-type natriuretic peptide (NT-proBNP)	Acute coronary syndromes/diagnosis of heart failure/ventricular overload	0.25–2 ng/mL
Myeloperoxidase (MPO)	Detection of inflammation	> 350 ng/mL stratification risk
Heart fatty acid binding protein (11-FABP)	Myocardial necrosis	≥ 6 ng/mL stratification risk
TNF-α	Inflammation/cardiac risk factor	< 0.0036 ng/mL low risk ≤ 0.0036 ng/mL high risk
Interlukin-6 (IL-6)	Inflammation/cardiac risk factor	Low < 0.0013 ng/mL Mid 0.00138–0.002 ng/mL High > 0.002 ng/mL
Fibrinogen		Low < 3.58 × 10^6 ng/mL Mid 3.58–4.20 × 10^6 ng/mL

muscle to a smaller extent. Especially, the cTnT levels increase 2–4 h after the acute myocardial infarction symptoms and could be evaluated up to 14 days after the acute episode of myocardial damage [133]. cTnI starts to rise rapidly in the blood stream within 3–4 h after onset of acute myocardial infarction and remains to rise up to 4–10 days. The level of cTnI in normal patients levels of cTnI are around 10 ng/mL, but the cTnI concentration of AMI in patients goes up to 112 ng/mL (range 20–550 ng/mL) at 18 h.

C-reactive protein (CRP) is one of the plasma proteins known as acute-phase proteins, an indicator of a viral and bacterial infection, however low concentrations of CRP may also predict the risk of heart attack and stroke. CRP levels can rapidly increase up to 1000-fold over normal trace amounts with bacterial infection, trauma, surgery and other inflammatory events and decrease to normal within 12–14 days. The CRP level is typically less than 2 mg/L for healthy individuals. If CRP is higher than 3 mg/l, a person is at high risk of developing a cardiovascular disease [135].

Myeloperoxidase (MPO) is an abundant mammalian phagocyte hemoprotein which caused suddenly cardiac death. In acute coronary syndrome patients (ACS), MPO serum levels predict an increased risk for subsequent cardiovascular events [136].

P-selection, known as CD62P is a granule membrane protein 140 (GMP-140), and platelet activation dependent granule activation protein (PADGEM), was first discovered in endothelial cells in 1989 as platelet activation marker and categorized as one member of the cell adhesion molecules (CAM) family [137].

Soluble lectin-like oxidized low density lipoprotein receptor (sLOX-1) is an extracellular domain of lectin like oxidized

Table 5
The developed immunosensors for cardiovascular disease diagnosis in literature.

Biomarker	Immobilization strategies	Assay principle	Linear range	Limit of detection	Reference
Human cardiac troponin (cTnT)	NH_2-CNT-SPEs/polyethylene terephtalate (PET)/NHS-EDC-anti-cTnT/glycine/cTnT	Amperometric	0.0025–0.5 ng/mL	0.0035 ng/mL	[139]
cTnT	Au/polyethyleneimine (PEI)/carboxylated CNTs (COOH-CNT)/anti-cTnT/glycine/cTnT	Amperometric	0.1–10 ng/mL	0.033 ng/mL	[140]
CRP	Au/nanocrystalline diamond film (NCD)/mercaptopropionic acid (MPA)/EDC/NHS/anti-CRP/ethanolamine/CRP	Capacitance	25–800 ng/mL	-	[135]
cTnT	GCE/*o*-aminobenzoic acid (poly-*o*-ABA)/EDC/NHS/anti-cTnT/ethanolamine/cTnT	Amperometric	0.05–5 ng/mL	0.016 ng/mL	[141]
Myeloperoxidase (MPO)	GCE/*N*,*N*-dimethylformamide (DMF)-MWCNTs/1-ethyl-3-methylimidazolium tetrafluoroborate (EMIMBF4)/chitosan-cerium oxide (CeO2)/anti-MPO/BSA/MPO	Amperometric	5–300 ng/mL	0.2 ng/mL	[136]
P-selection	SPCE/CNT/gold nanobone /GNB)/3,4-ethylenedioxythiophene (EDOT)/EDC/NHS/anti-P-selection/BSA/P-selection/α-P-selection Ab-tagged liposome containing K4Fe(CN)6	Amperometric	10^{-13}–10^{-5} g/mL	0.85 pg/mL	[137]
Myoglobin	Au/4-aminothiophenol(4-ATP)/sulfosuccinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate(sulfo-SMCC)/half-antibody fragment/myoglobin	Impedimetric	10^{-14}–10^{-7} M	10–14 M	[142]
cTnT	SPE/polyethylene terephtalate (PTE)/anti-cTnT/biotin/glutaraldehyde (glu)/streptavidin microsphere/glycine/cTnT/HRP- conjugated anti-cTnT	Amperometric	0.1–10 ng/mL	0.2 ng/mL	[133]
Cardiac troponin I (cTnI)	İnterdigitated array (IDA) chip/poly(dimethylsiloxane) (PDMS)/NHS/BSA/anti-cTnI/protein G/cTnI/alkaline phosphatase (AP)-labeled anti-CTnI/enzyme substrate (PaPP)	Amperometric	0.2 ng/mL–10 μg/mL	148 pg/mL	[143]
cTnI	PDMS-GNP composite/anti-cTnI and anti-CRP (Ab1)/BSA/CdTe and ZnSe quantum dots-anti-cTnI and anti-CRP (Ab2)	Amperometric	0.01–50 μg/l	5 amol	[144]
Myoglobin (Mb)	Au/11-mercaptoundecanoic acid (MUA)+3-mercaptopropionic acid (MPA)/NHS-EDC/anti-Mb/BSA/Mb	Impedimetric	10–650 ng/mL	5.2 ng/mL	[132]
Mb	Graphite electrode/didodecyldimethylammonium bromide (DDAB)-Au/EDC/NHS/anti-human myoglobin (anti-HMB)/glycine/Mb	SWV	10–1780 ng/mL	10 ng/mL	[145]
hFABP	Au/MUA+3-mercaptopropanol (MPOH)/EDC/NHS/anti-hFABP/BSA/hFABP	Impedimetric	98 pg/mL–100 ng/mL	117 pg/mL	[146]
cTnI	SPE/AuNPs/anti-cTnI/BSA/cTnI	Capacitance	0.2–12.5 ng/mL	0.2 ng/mL	[147]
Mb	Crystal (E)-1-decyl-4-(4-decyloxyphenyl) diazenyl)pyridinium bromide (Br-Py) coated GCE)/polyethyleneimine-cp Coated gold nanoparticles film/anti-Mb/glycine/Mb	Amperometric	9.96–72.8 ng/mL	6.29 ng/mL	[148]
Soluble lectin-like oxidized low-density lipoprotein receptor I (SLOX-1) cTnI	Au/6-mercaptohexadecanoic acid/biotin-caproyl-DPPE/neutravidin/biyotinylated anti-SLOX or anti-cTnI/SLOX-1 or cTnI	Impedimetric	10^{-13}–10^{-7} M	10^{-13} M	[134]
Mb	Au-SPE/Myoglobin solution/(Mb imprinted) M1 film/proteinase K/poly(*o*-aminophenol) (PAP)/Myoglobin	Impedimetric Amperometric	0.5–53.5 μg/mL	1.5 μg/mL 0.8 μg/mL	[149]
Mb	ITO glass/APTES/AuNPs/MUA-MPA/antiMb/BSA/Mb	Impedimetric	0.01–1.65 μg/mL	1.4 ng/mL	[150]
CRP	Au-SPE/carboxylic-modified magnetic beads (HOOC-MBs)/EDC/sulfo-NHS/ethanolamine /biotinylated anti-CRP/streptavidin HRP (strp-HRP)/CRP	Amperometric	0.07–1000 ng/mL	0.021 ng/mL	[151]

low-density lipoprotein receptor-1 and releases as a soluble form. sLOX-1 is a useful marker for early diagnosis of acute coronary syndrome (ACS) [138] (Table 5).

Ko et al. [143] developed an immunosensor for cTnI detection. The detection limit from the calibration curve was calculated as 148 pg/mL. First, the proper orientation of antibodies by protein G that binds the Fc portion of the antibodies might lead to an effective recognition of the analyte. If the antibodies are randomly immobilized on the surface of the PDMS channel, the amount of immunoreaction between antibodies and antigens may be reduced because the Fab portion of antibodies may not sufficiently orient toward the target antigens. Therefore, the immobilization of the antibodies was performed through the interaction between Fc portion of the antibodies and protein G. Second, the best packing density of antibodies increased the sensitivity of their device by avoiding low numbers of antibodies immobilized onto the channel surface and steric hindrance. Third, avoiding the electrode fouling also contributed to the low limit of detection of this device [143].

Mattos et al. [141] developed an *o*-aminobenzoic acid film-based immunosensor for CTnT detection. It showed good performance in terms of operational stability, measuring it 100 times every 2 min. The relative standard deviation was approximately 3% [141].

Mattos et al. [141] and Lu et al. [136] kept the immunosensors they developed in the refrigerator at 4 °C and one found to be 91,6% of initial response after 18 days and the other 90% after 20 days.

Ávila et al. [151] used magnetic beads (MBs) for amperometric immunosensor development. MBs have demonstrated to be a useful tool to improve their sensitivity, reduce time of analysis of complex samples without pre-enrichment or purification steps. Au-SPEs and carboxylic-modified magnetic beads (HOOC-MBs) were used for the first time. Biotinylated anti-CRP reacted with streptavidin HRP (strp-HRP). The electrochemical detection of the enzymatic reaction product was measured disposable Au/SPE using 3,3′,5,5′-tetramethylbenzidine (TMB) as the electron transfer mediator and H_2O_2 as the enzyme substrate. They evaluated the selectivity of the magnetoimmunosensor toward various non-target compounds at their concentrations of 5 mg/mL BSA, 500 ng/mL D-dimer and 4000 g/mL heparin and two other non-target cardiac proteins of 7.5 ng/mL of amino-terminal pro-B-type natri-uretic peptide (NT-proBNP) and 500 ng/mL of cardiac troponin T (cTnT). The tests were performed either in the absence or in the presence of the potential interfering compounds by comparing with the magnetoimmunosensor for 500 ng/mL CRP. The presence of BSA, D-dimer and heparin did not interfere significantly in the CRP determination. Moreover, the target cardiac protein can be accurately determined in the presence of other two cardiac proteins (cTnT and NT-proBNP) at a concentration much higher than that normally found in these biological samples. A great selectivity achieved by using two specific antibodies in the design of the sandwich magnetoimmunosensor [151].

4. Future outlook

The antibodies for construction of immunochemical biosensors–immunosensors have been extensively used more than 35 years. Immunosensors are miniaturized analytical devices which selectively detect analytes and provide a concentration as a result of signal. In this review, attention is focused on the electrochemical immunosensors for tumor and cardiac biomarkers in clinical diagnosis.

In literature, the developed immunosensors were evaluated for the analysis of clinical serum samples and received a good corre lation with the enzyme linked immunosorbent assay (ELISA) [17,18,31,34,35,37,67,68,70]. Huang et al. [17] developed an immunosensor for CEA determination. They compared the results obtained from five human serum samples with the purposed method and ELISA. They reported that a good correlation between the results obtained by the proposed immunosensor and ELISA [17].

Kavosi et al. [60] evaluated the feasibility of their immunosensor for real sample analysis by using standard addition methods. They observed no significant difference results of two methods [60].

Zhang et al. [21] compared their biosensor response with the commercialized electrochemiluminescent method. They found no significant difference [21].

The electrochemical immunosensor can be miniaturized to a small pocket size device which makes them applicable for home use or the doctor's surgery as point of care (POC). For example, glucose biosensor is the most widely used an electrochemical biosensor which is based on a screen-printed amperometric disposable electrode. This type of biosensor has been widely used throughout the World for glucose testing in the home diagnosis. The recognition element of prostate cancer is anti-PSA antibody. The developed immunosensor for PSA offers an attractive possibility to screen prostate cancer in real time and on site. Also, electrochemical immunosensors offer a great selectivity and sensitivity for early clinical analysis. However, moving technology to commercial products may require more time and investments.

5. Conclusion

Biosensors, especially immunosensors, are of great value for use in clinical testing, because they are based on antigen–antibody reactions which are highly sensitive and specific. Moreover, they have vital role in measuring specific compounds in biol;ogical matrices, such as blood and plasma. Electrochemical immunosensors are simple, rapid, reliable and inexpensive devices. Thus they can be used in clinical diagnosis with confidence.

In this review, recent researches on biomarkers used for detecting cancer and cardiovascular diseases are summarized. Carcinoembriyonic antigen(CEA), prostate-specific antigen (PSA), α-1-fetoprotein (AFP), carbohydrate antigen 19-9 (CA 19-9), myeloctomatosis oncogene (c-Myc), cancer antigen 125 (CA125), neuron specific enolase (NSE), epidermal growth factor receptor (EGFR), cancer antigen 15-3, murine double minute 2 (MDM2), Squamous cell carcinoma antigen (SCCA), human chorionic gonadotrophin (hCG), human epididymis-specific protein 4 (HE4), HER-3, vascular endothelial growth factor (VEGF) are commonly used biomarkers in cancer diagnosis and Human cardiac troponins (cTnT and cTnI), myoglobin, C-reactive protein (CRP), myeloperoxidase (MPO), P-selection, soluble lectin-like oxidized low density lipoprotein receptor (sLOX-1) are commonly used cardiovascular disease biomarkers.

In developing immunosensors, the immobilization of antibody is an important step because antibody acts as the recognition element for antibody–antigen reaction. The performance of the detection of antigen binding capacity can be increased with a proper antibody surface. Thus the choice of the antibody immobilization method is very important in the design of an immunosensor. Several methods including physical and chemical adsorption have been used for the preparation of oriented antibody molecular layers on the surface of the transducer. The sensitivity of biomarkers is important for early diagnosis of diseases. Furthermore, the coupling of electrodes with nanostructured materials such as silicon nanowires, gold nanop;articles, carbon nanotubes, magnetic particles, quantum dots offer multiplexing capability for simultaneous measurements of biomarkers.

Acknowledgment

The support from TÜBİTAK (The Scientific and Technological Research Council of Turkey, Project number: 113 Z 678) is greatly acknowledged.

Maximum count least square support vector machine (maxc-LS-SVM)
Geographical origins

ABSTRACT

To deal with heterogeneous classification problem efficiently, each heterogeneous object was represented by a set of measurements obtained on different part of it, and the heterogeneous classification problem was reformulated in the framework of multi-instance learning (MIL). Based on a variant of count-based MIL assumption, a maximum count least squares support vector machine (maxc-LS-SVM) learning algorithm was developed. The algorithm was tested on a set of toy datasets. It was found that maxc-LS-SVM inherits all the sound characters of both LS-SVM and MIL framework. A comparison study between the proposed approach and the other two MIL approaches (i.e., mi-SVM and MI-SVM) was performed on a real wolfberry fruit spectral dataset. The results demonstrate that by formulating the heterogeneous classification problem as a MIL one, the heterogeneous classification problem can be solved by the proposed maxc-LS-SVM algorithm effectively.

1. Introduction

The application of near infrared spectroscopy (NIR) to perform classification has been spread across the analysis of food, agricultural, petroleum, and pharmaceutical products [1–3]. However, spectra obtained on heterogeneous objects, such as corn and pharmaceutical tablet, are often of high variance. Applying common classification methods on these spectra will result in weak conclusion. This is one typical category of heterogeneous classification problem. However, the heterogeneous classification problem has not yet been solved thoroughly [4].

The key on solving heterogeneous classification problem is to represent each heterogeneous object efficiently. In the literatures, pre-treatment is the most successfully and widely used techniques for solving the heterogeneous classification problem. One builds certain measurement protocol to improve the representativeness of measurements. Spectra measured by using integrating sphere [5–10], rotating the sample during spectra collection, or grinding the samples [11–14] are of this type. Significantly better results were observed while the measurement was taken by a patented measurement method [15]. However, when the spectra are needed to be collected in-situ, none of the above methods are applicable. Hwang et al. [16] developed a fast and non-destructive analytical method to identify geographical origins of rice samples via transmission spectral collected through packed grains. But the variation of packing thickness will prevent the measurement from yielding reproducible spectra.

Instead of receiving a set of measurements, each for a sample, an object can be represented by a set of measurements (instances). Therefore, the heterogeneous classification problem can be solved by formulating it as a multi-instance learning one. Instead of receiving labeled instances as in traditional supervised learning, the MIL learner receives a set of labeled bags. The majority of MIL studies are concerned with binary classification problems [17]. Most of these studies assume that a bag is labeled positive if there is at least one instance in it being positive. Otherwise, a bag is labeled negative if all the instances in it are negative.

Based on the classical MIL assumption, numerous MIL methods have been proposed in the literatures, and most of them have been reviewed in earlier studies [17–19]. These algorithms use mainly the information of one instance from each positive bag. However, there is commonly more than one instance in any positive bags and much of the information contained in these instances is lost.

The MIL assumption is first used to solve the problem of *musk* drug activity prediction problem [20]. From then on, many problems have been formulated as MIL problem, such as image categorization, object detection, and human active recognition

[18,21,22]. Although all early work in MIL assumes a specific concept class known to be appropriate for a drug activity prediction like domain, the classical MIL assumption is not guaranteed to hold in other domains. Recently, a significant amount of researches in MIL are concerned with cases where the classical view of MIL problem is relaxed, and alternative assumptions are considered instead [17]. Although not all these works clearly state what particular assumption is used and how it relates to other assumptions, the use of alternative assumptions has been clarified by reviewing the studies in this area.

In this work, a variant of count-based binary MIL assumption was adopted. It assumes that a bag is labeled positive if the product of the positive posteriors of instances, weighted by the bag prior, is larger than that of the negative ones. Otherwise, a bag is labeled negative. Base on this assumption, the maxc-LS-SVM algorithm was proposed to deal with the heterogeneous classification problem. For multi-class cases, the original classification problem was decomposed in the framework of Error-Correcting Output Codes (ECOC) by one-versus-one design [23]. The maxc-LS-SVM algorithm was modified correspondingly and its performance was compared with mi-SVM and MI-SVM [24] algorithm. The results of applying these approaches on toy datasets and a real herbal dataset clearly showed the advantage of maxc-LS-SVM algorithm.

2. Theory and algorithm

2.1. Least squares-support vector machine (LS-SVM)

This study will briefly focus on the basic concepts of LS-SVM because the theory of LS-SVM has been described extensively in the literatures [25,26]. LS-SVM encompasses similar advantages as SVM, but additionally, it requires solving only a set of linear equations, which is much easier and computationally very simple. The objective function defined in LS-SVM is [27]

$$\min_{\omega,b,e} J_P(\omega,e)=\tfrac{1}{2}\omega^T\omega+\gamma\tfrac{1}{2}\sum_{i=1}^{N}e_i^2$$
$$\text{subject to(s.t.)}: y_i[\omega^T\varphi(x_i)+b]=1-e_i,\quad i=1,\ldots,N \tag{1}$$

where w denotes the normal vector to the classification hyperplane, γ is the hyperparameter tuning the amount of regularization versus the sum squared error, e is the error variable, and $\varphi(x)$is the nonlinear map from original space to the high (and possibly infinite) dimensional space.

To solve the optimization problem efficiently, a Lagrange function is constructed and translated into its dual form

$$L(\omega,b,e;\alpha)=J_P(\omega,e)-\sum_{i=1}^{N}\alpha_i\{y_i[\omega^T\varphi(x_i)+b]-1+e_i\} \tag{2}$$

where α_i values are the Lagrange multipliers.

The conditions for optimality are

$$\begin{cases}\frac{\partial L}{\partial\omega}=0\rightarrow\omega=\sum_{i=1}^{N}\alpha_i y_i\varphi(x_i)\\ \frac{\partial L}{\partial b}=0\rightarrow\sum_{i=1}^{N}\alpha_i y_i\\ \frac{\partial L}{\partial e_i}=0\rightarrow\alpha_i=\gamma e_i,\qquad i=1,\ldots,N\\ \frac{\partial L}{\partial\alpha_i}=0\rightarrow y_i[\omega^T\varphi(x_i)+b]-1+e_i=0,\quad i=1,\ldots,N\end{cases} \tag{3}$$

From the conditions for optimality, it can be concluded that no α_i values will be exactly equal to zero, meaning that the advantages of automatic sparseness are lost. However, the model can be trained much more efficiently after constructing the Lagrangian by solving the linear Karush–Kuhn–Tucker (KKT) system, since it yields a linear system instead of a quadratic programming problem

$$\begin{bmatrix}0 & 1_N^T\\ 1_N & \boldsymbol{\Omega}+\gamma^{-1}I_N\end{bmatrix}\begin{bmatrix}b\\ a\end{bmatrix}=\begin{bmatrix}0\\ \boldsymbol{y}\end{bmatrix} \tag{4}$$

where $\boldsymbol{y}$ is a vector containing the reference values, $\boldsymbol{1}_N$ is a $[N\times 1]$ vector of ones and $\mathbf{I}$ is an $[N\times N]$ identify matrix. $\boldsymbol{\Omega}$ is the kernal matrix defined by $\boldsymbol{\Omega}_{ij}=\varphi(x_i)^T\varphi(x_j)=\mathbf{K}(x_i,x_j)$.

The classifier in the dual space takes the form

$$y(x)=sign\left[\sum_{i=1}^{N}\alpha_i y_i K(x,x_i)+b\right] \tag{5}$$

2.2. Maximum margin formulation of MIL

In traditional supervised learning framework, an object is represented by one single instance, i.e. measurement vector, and associated with a class label. The goal is to induce a classifier to label instances. While, MIL groups instances into bags and each bag is attached with a class label. More formally, an object is represented by a bag $\boldsymbol{B}=\{\boldsymbol{x}_1,\boldsymbol{x}_2,\ldots,\boldsymbol{x}_p\}$, which contains a set of D-dimensional instances. Each bag is associated with a label $\boldsymbol{Y}$.

Both mi-SVM and MI-SVM approaches [24] are modified and extended from Support Vector Machines (SVMs). The mi-SVM approach explicitly treats the instance labels as unobserved integer variables subjected to constrain defined by the (positive) bag labels. A generalized soft-margin SVM is defined as follows in primal form

$$\min_{\{y_i\}}\min_{w,b,\xi}\tfrac{1}{2}\|w\|^2+C\sum_i\xi_i$$
$$\text{s.t. }\forall i:\ y_i(\langle w,x_i\rangle+b)\geq 1-\xi_i,\xi_i\geq 0,y_i\in\{-1,1\} \tag{6}$$

where ξ is a non-negative slack variable, C is the hyperparameter tuning the amount of the degree of misclassification versus the sum squared error, y_i is the label of instance.

The mi-SVM formulation leads to a mixed integer programming problem. One has to maximize a soft-margin criterion jointly over possible label assignments and hyperplane. While, the MI-SVM approach extends the notion of margin to bag and maximizing the bag margin directly. The bag margin with respect to a hyperplane is defined by

$$\gamma_I\equiv Y_I\max_{i\in I}(\langle w,x_i\rangle+b) \tag{7}$$

Incorporating the above bag margin, an MIL version of the soft-margin classifier is defined by

$$\min_{w,b,\xi}\tfrac{1}{2}\|w\|^2+C\sum_I\xi_I$$
$$\text{s.t. }\forall I:\ Y_I\max_{i\in I}(\langle w,x_i\rangle+b)\geq 1-\xi_I,\xi_I\geq 0 \tag{8}$$

Unfolding the max operation by introducing inequality constraint per instance for the negative bags, or by introducing a selector variable $s(I)\in I$ which denotes the positive instance selected for the positive bags, one can obtain the following equivalent formulation

$$\min_s\min_{w,b,\xi}\tfrac{1}{2}\|w\|^2+C\sum_I\xi_I$$
$$\text{s.t.}\quad \begin{array}{l}\forall I:\ Y_I=-1\wedge-\langle w,x_i\rangle-b\geq 1-\xi_I,\forall i\in I,\\ \text{or}Y_I=1\wedge-\langle w,x_{s(I)}\rangle-b\geq 1-\xi_I,\xi_I\geq 0.\end{array} \tag{9}$$

MI-SVM can also be cast as mixed-integer program. One has to find both the optimal selectors and hyperplane.

A heuristic optimization scheme has been proposed to solve the mixed-integer programs by alternating the following two steps (i) for a given integer variables, solve the associated Quadratic Programming (QP) and find the optimal discriminant function,

(ii) for a given discriminant function, update the label of each instance in mi-SVM or the single selector variable in MI-SVM.

2.3. Multi-class classification

The above three algorithms are originally designed to perform binary classification. Although binary LS-SVM can be easily extended to deal with multi-class problems, it is usually more preferable to build a classifier distinguishing only two classes rather than to consider more than two classes in a model. In this study, the original multi-class problem was decomposed into easier to solve binary classifications by using a common strategy "one-versus-one" in the framework of ECOC, which is a simple but powerful framework to deal with the multi-class classification problem based on the embedding of binary classifiers [23].

The "one-versus-one" decomposition scheme divides an m class problem into $M=m(m-1)/2$ binary problems. Each problem is faced by a binary LS-SVM classifier, which is responsible for distinguishing between a pair of classes. The learning phase of the classifiers is done using a subset of samples, which contains any two classes of them, whereas samples with different class labels are simply ignored.

In prediction phase, a sample is presented to each of the binary classifiers. The output of a classifier, $r_{ij} \in \{0, 1\}$, denotes the output of the ith sample on the jth binary classifier. These outputs are represented by a vector $\mathbf{r}_i$

$$\mathbf{r}_i = [r_{i1}, r_{i2}, \cdots, r_{ij}, \cdots, r_{iM}], j = 1, \cdots, M \tag{10}$$

The predicted class can be obtained by Hamming decoding strategies as follows [23]:

$$Class = \min_{c=1,\ldots,m} \sum_{j=1}^{M} (1 - sign(r_{ij}, y_{cj}))/2 \tag{11}$$

where y_c is a codeword corresponding to class c.

The classification of individual instances was performed by using binary classification algorithm.

2.4. Maximum count LS-SVM

For a binary classifier, let $\mathbf{Y} \in \{-1,1\}$. It is assumed that a bag is labeled positive if more than half of the instances in the bag are drawn from positive sets. Specifically, the sum rule is used to decide the label of the bag

Classify $\mathbf{B}=\{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_p\}$ as positive, i.e. $\mathbf{Y}_i=1, j=1, 2, \ldots, p$ if

$$\sum_{j=1}^{p} \frac{y_{ij}+1}{2} \geq \sum_{j=1}^{p} \frac{1-y_{ij}}{2} \tag{12}$$

or negative, i.e. $\mathbf{Y}_i=-1, j=1, 2, \ldots, p$ if

$$\sum_{j=1}^{p} \frac{y_{ij}+1}{2} < \sum_{j=1}^{p} \frac{1-y_{ij}}{2} \tag{13}$$

where N is the number of bags, p denotes the number of instances in each bag.

For multi-class cases, let $Y \in \{1, 2, 3, \ldots, m\}$. Every instance of one object is presented to each of the basic *ovo*-LS-SVM classifiers. The classification result of one instance is represented by a vector $\boldsymbol{c}_j$ with element c_{kj} taken from {0, 1}. The value 1 means the instance is assigned to class k, while 0 not. These outputs are then combined into a score matrix $\mathbf{C}$:

$$\mathbf{C} = \begin{pmatrix} c_{11} & c_{12} & \cdots & c_{1m} \\ c_{21} & c_{22} & \cdots & c_{2m} \\ \vdots & & & \vdots \\ c_{p1} & c_{p2} & \cdots & c_{pm} \end{pmatrix} \tag{14}$$

From the score matrix, bags can be directly classified with the following determination function:

$$\mathbf{Y}_i = \arg \max_{k=1,\ldots,m} \sum_{j=1}^{p} c_{kj} \tag{15}$$

$i=1, 2, \ldots, N, j=1, 2, \ldots, p, k=1, 2, \ldots, m$. Tie break arbitrarily.

where m denotes the number of categories. The above equation is also fit to binary cases.

The main steps of maxc-LS-SVM can be summarized as follows:

Training data formalization: assign the bag label to its instances and use all instances for training.

Basic classifier training: estimate parameters of the basic classifiers.

Individual instance classification: classify each instance using the basic classifiers.

Bag classification: classify an object or bag B according to Eq. (15).

2.5. Performance indicator

For binary classification problem, there are a large number of well-known statistical metrics such as accuracy, precision, sensitivity, specificity, AUC, Cohen's kappa, etc. However, most of these performance indicators cannot be directly used for multi-class cases. In this work, only the metrics whose successful application on multi-class problems had been proved experimentally were adopted.

Accuracy rate, also known as classification rate, is the proportion of correctly classified instances in the population.

Cohen's kappa [28] is an alternative measure to accuracy rate, compensating for random hits. It evaluates the degree of agreement in classification over which would be expected by chance. Based on an m-class confusion matrix, the Cohen's kappa can be computed as follows:

$$kappa = \frac{N \sum_{i=1}^{m} h_{ii} - \sum_{i=1}^{m} T_{ri} T_{ci}}{N^2 - \sum_{i=1}^{m} T_{ri} T_{ci}} \tag{16}$$

where h_{ii} is the number of true positives for each class, N is the number of bags, m is the number of labels, T_{ri} is the rows' total counts and T_{ci} is the columns' total counts.

The theoretical range of Cohen's kappa statistic is from -1 (total disagreement) through 0 (random classification) to 1 (perfect agreement), which seems difficult to compare kappa with accuracy (0–1). Actually, most classifiers do at least the same as random guessing on most real-world datasets, so their kappa values score higher than zero by definition. It is generally assumed that a kappa score lying between 0.8 and 1 indicates that the corresponding classifier is almost in perfect agreement with the actual pattern.

The bootstrap cross-validation method (BCV) [29], which is a bootstrap smoothing version of cross-validation, was used to estimate the generalization error of each classification algorithm because it has less variation and bias. The bootstrap datasets are drawn with replacement for some large B between 50 and 200. For each dataset, an internal cross-validation error estimator was obtained with a predetermined classification rule. After B times

repeat, the averaged error estimation was calculated over all bootstrap bag sets.

3. Experimental

3.1. Toy data

The toy data has three classes (A, B and C). For each bag of one specific class, ρ percent of its instances were sampled from the Gaussian located at either (0, 0), (4, 1), or (1, 4), the rest were sampled from the Gaussian located at (2, 2). Every bag contains 30 instances. To be comparable with common NIR classifications, 50 bags were generated for each class. A sketch map of the two-way datasets with $\rho \in \{0.2, 0.4, 0.6, 0.8\}$ is shown in Fig. 1.

The toy data was used to simulate the heterogeneous classification problem. The feasibility of formulizing the heterogeneous classification problem as a multi-instance learning problem and the influence of bag size on the proposed maxc-LS-SVM algorithm were investigated on the toy data.

3.2. Herbal geographical origins data

Generally, the quality of *wolfberry fruit* varies with geographical origin, which makes its medical efficacy diverse. Therefore, it is necessary to distinguish accurately the geographical origins of *wolfberry fruit* to assure a traditional Chinese prescription effective. The *wolfberry fruit* dataset consists of samples collected from Inner Mongolia, Ningxia, and Qinghai provinces of China. For each sample, ten spectra (i.e. instances) were measured respectively on ten different parts of the *wolfberry fruit* surface. A sketch map of the ten instances is shown in Fig. 2(a).

Each instance was measured by using a portable Near-infrared Spectrophotometer (Ocean quest 256-2.5) equipped with an InGaAs detector and diffuse reflection optical fiber probe. The spectrum covering the range of 870–2530 nm at distinguishability of 9.5 nm was recorded. All the raw spectra were transferred into logarithm mode because they were initially recorded in reflectance mode. Totally, 29, 45, and 45 bags were formed for each geographical origin, respectively. An overlap plot of the transformed spectra is shown in Fig. 2(b).

The *wolfberry fruit* data was used to further illustrate the feasibility of formulizing the heterogeneous classification problem as a multi-instance learning one. A comparison study between the proposed maxc-LS-SVM and the mi-SVM, MI-SVM algorithm were also performed on the *wolfberry fruit* data.

3.3. Single instance pseudo dataset

In traditional learning framework, each object is represented by a single labeled instance. Thus, one instance from each bag was drawn randomly to form the pseudo dataset. Each instance was labeled with its bag's label.

3.4. Software and algorithms

All calculations were performed on a personal computer i7 880 processor with 6GB RAM under the Win7 Professional operating system using Matlab 7.9 (Mathworks, Inc., Natick, MA). The

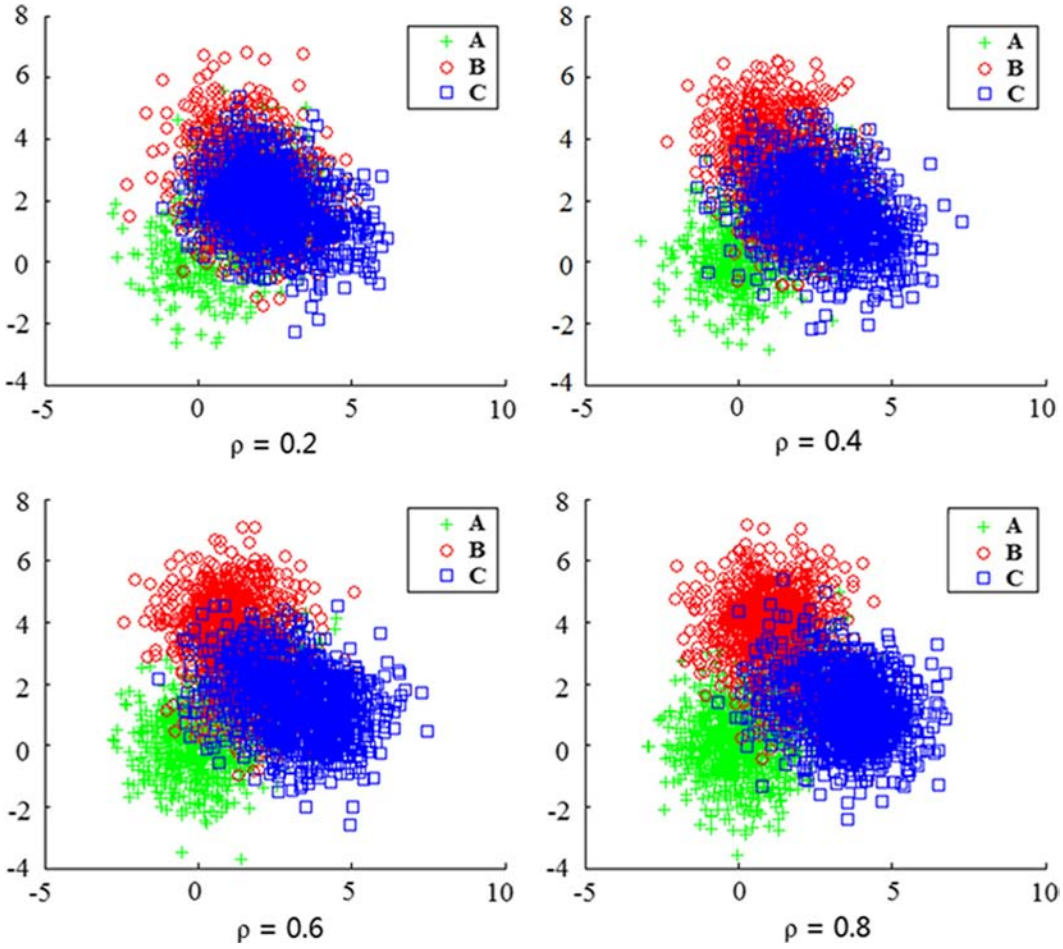

Fig. 1. The two way toy data with ρ=0.2, 0.4, 0.6, and 0.8, respectively.

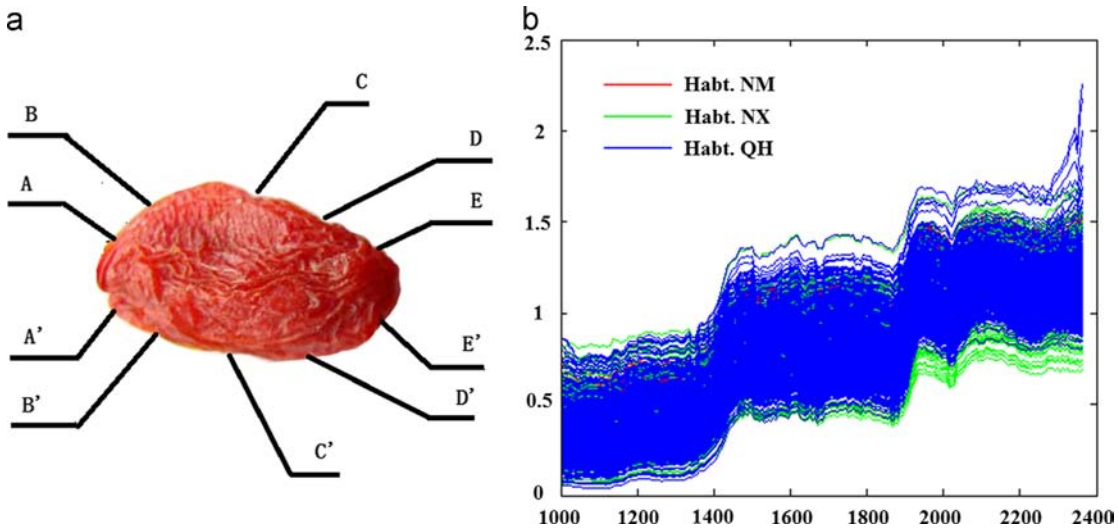

Fig. 2. (a) A sketch map of the locations of the ten instances for each wolfberry fruit sample; (b) an overlap plot of the transformed spectra. Habt. NM means the samples were original sampled from Inner Mongolia, similar, Habt. NX stands for Ningxia and Habt. QH denotes Qinghai.

maxc-LS-SVM algorithm was modification of function in the LS-SVMlab v1.8 [30]. The implementation of the MI-SVM and mi-SVM algorithm was based on a MIL toolbox publicly available at http://www.cs.cmu.edu/~juny/MILL/.

4. Results and discussion

A grid search method guided by 10-fold cross-validation was adopted to optimize the hyperparameters of MI-SVM and mi-SVM. Each pair (C, γ) in the cross-product of C ranging from 2^{-15} to 2^{3} and γ ranging from 2^{-5} to 2^{15} at the increment of 2 in the exponent was used to train every dichotomous classifier. Meanwhile, the optimal hyperparameters of LS-SVM were determined by coupled simulated annealing (CSA) algorithm and simplex algorithm.

4.1. The toy data

To be consistent with traditional classification method, one single-instance pseudo dataset was drawn for every bag datasets. The Cohen's kappa and accuracy were calculated by the BCV procedure on the single-instance pseudo dataset. However, the randomizations in producing the toy bag sets and in drawing the single-instance pseudo datasets present variability in the prediction metrics. Therefore, each of the four toy datasets was regenerated 100 times respectively to present a stable evaluation on the applicability of traditional classification method in heterogeneous classification problem.

With respect to $\rho=0.2$, the *Mann–Whitney U* test did not reject the equivalence between the linear and RBF (radial basis function) kernel using accuracy with the significance level of $\alpha=0.01$ (Table 1). However, opposite results were obtained on the comparison study between the linear and RBF kernel in term of Cohen's kappa. In addition, from the decision boundary illustrated in Fig. 3, it was observed that the decision boundary of RBF kernel was more efficient to separate one class from another, but was too complex and specific. Meanwhile, the decision boundary of linear kernel separate linearly the pseudo samples well. This means that the *ovo*-LS-SVM model built with RBF kernel overfit the classification problem. Thus, liner kernel is used in maxc-LS-SVM model to prevent possible over-fitting.

The results of applying maxc-LS-SVM on the simulated heterogeneous classification data were shown in Figs. 4 and 5. From the results on the toy data with $\rho=0.2$, it was found that the prediction ability of the model built using maxc-LS-SVM improved quite a lot, when it was compared with the model constructed using the base *ovo*-LS-SVM classifier (Fig. 4(a) and (b)). By varying the bag size from 5 to 30 at the increment of 5, the classification accuracy increased gradually. These results indicate that a powerful decision function can be constructed even the data is too weak to build a usable base classifier. The results presented in Fig. 5 support this opinion.

Table 1
A comparison between the learning effectiveness of linear kernel and RBF kernel LS-SVM on the toy datasets ($\alpha=0.01$).

ρ	Accuracy		*p*-Value	Kappa		*p*-Value
	Linear	*RBF*		*Linear*	*RBF*	
0.2	0.4355	0.4253	0.0405	0.1453	0.1813	**0.0000**
0.4	0.5753	0.5655	0.0439	0.3516	0.3357	0.0264
0.6	0.6703	0.6708	0.9318	0.4921	0.4906	0.7947
0.8	0.7981	0.7961	0.7851	0.6832	0.6816	0.8632

Regarding $\rho=0.4$, 0.6 and 0.8, the statistical analysis does not reject the null hypothesis that the base classifiers with linear and RBF kernel perform equally (Table 1) in terms of both kappa and accuracy. Further examination on the decision boundaries of RBF kernel reveal that each pair of classes can be separated linearly in the raw space (Figs. S1–S3 in the supplementary material). Considering the computational burden, linear kernel is preferred and used for further investigation.

The results presented in Fig. 4(a) clearly shows that the effect of random success on the accuracy matric decrease with the increase of ρ. In addition, a base LS-SVM classifier which performs better than random guessing can be obtained, even most of the instances from the toy data with ρ equal to 0.2 were shared by three classes (Fig. 5(a)). From the results summarized in Figs. 4 and 5, it can also be observed that all the classifiers built using maxc-LS-SVM perform significantly better than their corresponding base classifiers on the toy datasets ($\rho=0.4$, 0.6, 0.8, respectively). This means maxc-LS-SVM inherits the sound characters of LS-SVM. With the bag size varying from 5 to 30 at the increment of 5, the prediction accuracy gradually improved and even approached perfect agreement. Therefore, it can be concluded that by formulating the heterogeneous classification problem into a multiple instance

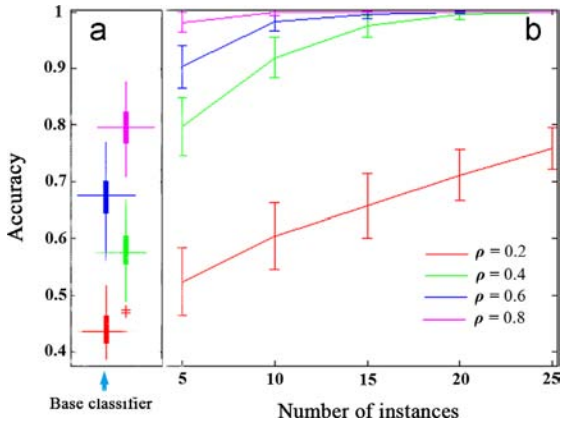

Fig. 4. The classification accuracy results of applying maxc-LS-SVM algorithm on the four toy datasets with the number of instances ranging from 5 to 25 at the increments of 5.

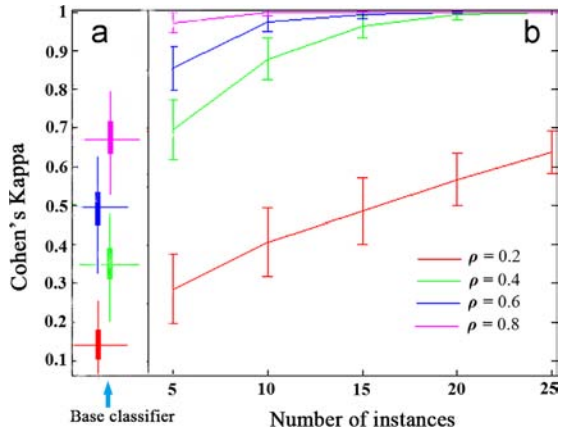

Fig. 5. A summary of the Cohen's kappa results of applying maxc-LS-SVM algorithm on the toy datasets with the number of instances ranging from 5 to 25 at the increments of 5.

learning one, the heterogeneous classification problem can be solved effectively.

4.2. The wolfberry fruit data

The results of applying *ovo*-LS-SVM method on the bootstrap pseudo data sets were listed in Table 2. It can be observed that the prediction accuracy of linear kernel *ovo*-LS-SVM was larger than that of the RBF kernel. That means linear kernel is more acceptable than RBF kernel in classifying the geographical origin of wolfberry fruits. From the results obtained on the toy data, it is concluded that the prediction ability of maxc-LS-SVM will be improved if more instances are included in a bag. So all instances measured on one wolfberry fruit were used to investigate the prediction performance of MIL algorithms. Besides, with bag size fixed, the comparisons among MIL algorithms become more objective.

Table 2
A summary of the prediction performance of the base classification method LS-SVM and the three multi-instance learning methods i.e. mi-SVM, MI-SVM, maxc-LS-SVM on the wolfberry fruit data.

	Accuracy		**Kappa**	
	Liner	*RBF*	*Linear*	*RBF*
LS-SVM	0.9276	0.7868	0.8870	0.6667
mi-SVM	0.5929	0.5371	0.4427	0.3741
MI-SVM	0.8205	0.7414	0.7106	0.5934
maxc-LS-SVM	0.9898	0.9754	0.9840	0.9616

The comparison results between maxc-LS-SVM and the other two MIL algorithms were tabulated in Table 2. For mi-SVM algorithm, neither linear nor RBF kernel could produce classifier comparable to LS-SVM algorithm in terms of both classification accuracy and kappa. There are two factors contributing to this phenomenon, one is the MIL assumption and the other is the relationship between bag and its instances. Since mi-SVM is a present based MIL algorithm, MI-SVM is first brought into comparison.

MI-SVM algorithm extends the notion of a margin from individual patterns to sets of patterns. And its prediction performance improved quite a lot when it was compared with mi-SVM algorithm. But the classification accuracy and kappa of MI-SVM algorithm were all still worse than that of LS-SVM algorithm. That means considering all instances in a bag as a whole is benefit for constructing a powerful classifier. However, adopting the whole learning strategy along is not enough to solve the heterogeneous classification problem thoroughly.

The maxc-LS-SVM algorithm, whose MIL assumption is different from that of mi-SVM and MI-SVM, performed much better than the base classifier in terms of classification accuracy for both linear and RBF kernel. And the kappa of liner kernel maxc-LS-SVM reached as high as 0.9840, which indicates that random success take a limited impact on the prediction results. Compared with the results obtained using mi-SVM and MI-SVM algorithm, it can be concluded that maxc-LS-SVM algorithm is more powerful in classifying the geographical origin of wolfberry fruit.

All the results demonstrate that by forming the heterogeneous classification problem into a multiple instance learning one, the heterogeneous classification problem can be solved effectively. The power of mi-SVM and MI-SVM has been demonstrated experimentally in image classification, which is a well-studied topic in the field of computer vision. But heterogeneous classification is a rather different application; the present-based MIL assumption is no longer applicable.

Additionally, it may be argued that it is unnecessary to complicate the heterogeneous classification problem, since the accuracy of base classifier using one instance for a object is already larger than 0.90. But it is still need to build a more powerful decision rule, because the wolfberry fruit is used as tonic Chinese herbal medicine, and distinguishing explicitly the geographical origin of wolfberry fruit is necessary to keep the prescription effect. Moreover, the kappa of linear kernel *ovo*-LS-SVM is only 0.8870, a more credible classifier should be constructed.

5. Conclusions

In this study, the heterogeneous classification problem was formulated as a multi-instance learning one. Based on a variant of count-based MIL assumption, the maxc-LS-SVM algorithm was developed to deal with multi-instance learning problem. The proposed algorithm inherits all the sound characters of both the base classifier and MIL framework. By incorporating the maximum count MIL assumption into the process of constructing a suitable learning algorithm, maxc-LS-SVM make full use of the information of each instance in the positive (or class specific) bags. A real wolfberry fruit spectral dataset, which contains 119 objects from geographical origins, was used in this experiment. In multi-class classification, the proposed method presented the optimal classification accuracy and kappa compared with the other two MIL methods (i.e., mi-SVM and MI-SVM). More importantly, it was concluded that the maximum count based MIL assumption was more applicable in the heterogeneous classification domain. While being potentially promising, the maxc-LS-SVM approach needs to be further evaluated with other heterogeneous classification applications. This is currently being pursued.

ABSTRACT

Clear coat searches of the infrared (IR) spectral library of the paint data query (PDQ) forensic database often generate an unusable number of hits that span multiple manufacturers, assembly plants, and years. To improve the accuracy of the hit list, pattern recognition methods have been used to develop search prefilters (i.e., principal component models) that differentiate between similar but non-identical IR spectra of clear coats on the basis of manufacturer (e.g., General Motors, Ford, Chrysler) or assembly plant. A two step procedure to develop these search prefilters was employed. First, the discrete wavelet transform was used to decompose each IR spectrum into wavelet coefficients to enhance subtle but significant features in the spectral data. Second, a genetic algorithm for IR spectral pattern recognition was employed to identify wavelet coefficients characteristic of the manufacturer or assembly plant of the vehicle. Even in challenging trials where the paint samples evaluated were all from the same manufacturer (General Motors) within a limited production year range (2000–2006), the respective assembly plant of the vehicle was correctly identified. Search prefilters to identify assembly plants were successfully validated using 10 blind samples provided by the Royal Canadian Mounted Police (RCMP) as part of a study to populate PDQ to current production years, whereas the search prefilter to discriminate among automobile manufacturers was successfully validated using IR spectra obtained directly from the PDQ database.

1. Introduction

Automotive paint systems consist of multiple layers of paint: a top coat consisting of a clear coat and a color coat layer which in turn is over one or more undercoats [1,2]. With the exception of the clear coat, each layer contains pigments and fillers. Paint data query (PDQ) is a forensic database of the physical attributes (color and layer sequence) and the chemical composition (filler, general binder and extended pigment composition) of each layer of the original manufacturer's paint system [3,4]. Digital libraries containing infrared (IR) spectra for each of these layers accompany the physical and chemical data. If the original manufacturer's paint system is present in a paint chip recovered from the scene of a crime, PDQ can assist in identifying the manufacturer and model of the vehicle provided that at least the color coat or one of the undercoat layers (primer, or e-coat) is present in the paint sample.

PDQ contains the physical and chemical data of each paint layer as well as search and retrieval software to generate a hit list. Searches of PDQ require the user to translate the composition of each layer of the unknown paint chip into specific text codes based on their IR spectra. A search query is then constructed based on the color, chemical composition and its layer sequence. In the case of an unknown sample consisting of only the clear coat, the text based portion of PDQ produces an unusable number of hits that span multiple manufacturers, models and years because modern clear coats in PDQ are designated as having only one of two possible formulations: acrylic melamine styrene or acrylic melamine styrene polyurethane. (For modern automotive paint systems, the clear coat is all too often the only layer of paint left at the crime scene.) Furthermore, there are no inorganic fillers or color with which to visually discriminate the paint sample except for the rare tinted clear coat. Pattern recognition methods applied directly to the IR spectra of clear coats through the development of search prefilters hold the potential for more specific searches.

In this study, library search prefilters were developed from IR spectra in the PDQ database using a two step procedure to determine the assembly plant and model of an automobile from a clear coat paint smear. The first step involves preprocessing the IR spectra using wavelets [5,6] to enhance subtle but significant features in the spectral data. In the second step, wavelet coefficients characteristic of the assembly plant of the automobile are identified using a genetic algorithm (GA) for pattern recognition

analysis and feature selection [7–10]. Previously published studies of IR search prefilters developed using this two step procedure [11–16] were limited to an individual class of compounds (e.g., carboxylic acids) or the modeling problems addressed were simpler because smaller training sets were used. This study is unique since both the manufacturer (General Motors, Ford, or Chrysler) and the assembly plant of the vehicle could be simultaneously ascertained from an IR spectrum of a clear coat paint sample using library search prefilters. All search prefilters (vehicle manufacturer and automotive assembly plant) developed in this study were successfully validated. Even in challenging trials where the samples evaluated were all the same manufacturer (General Motors) within a limited production year range 2000–2006, the respective assembly plant could be correctly identified. For the GM search prefilters, successful validation was demonstrated using 10 blind samples provided by the Royal Canadian Mounted Police (RCMP). Search prefilters developed for automotive manufacturer were successfully validated using IR spectra of clear coats obtained from the PDQ database.

The proposed search prefilters can simplify IR library searching of the PDQ database. Improving the discrimination capability between IR spectra in the PDQ database using this two step procedure also allows for comparison of all automotive clear coats in the database, reducing the dependence of the search on text based fields, resulting in improved ease of use and fewer errors by eliminating IR spectra in the PDQ library from the search that are not related to the unknown.

2. Materials and methods

IR spectra of 1314 clear coat paint samples applied to the metal surfaces of automobiles and trucks assembled at 21 General Motors (GM), 18 Chrysler, and 13 Ford assembly plants within the limited production year range of 2000–2006 were measured on four different spectrometers: two Thermo-Nicolet 6700s FTIR spectrometers, one BioRad 40A and one BioRad 60 FTIR spectrometer. All four spectrometers were equipped with DTGS detectors and all paint samples were collected in transmission mode using high pressure diamond anvil cells. For the two BioRad instruments, Harrick 4x beam condensers were used, whereas a Harrick 6x beam condenser was used in each Thermo-Nicolet 6700s instrument.

IR spectra of clear coats from plastic and fiberglass substrates were not used in the development of the search prefilters since automotive paint is often applied to these substrates at the plant that manufactures these components, not at the plant where the automotive vehicle containing these components is assembled. Table 1 lists the 21 g automotive assembly plants used in this study.

Data preprocessing was crucial to ensure a successful analysis of the data. In this study, data preprocessing consisted of aligning the IR spectra along the wavelength axis, application of the discrete wavelet transform to resolve overlapping spectral bands, and feature selection to identify informative wavelet coefficients using a genetic algorithm. Each step is described in detail below.

2.1. Spectral alignment

IR spectra of the clear coats were not properly aligned along their x or y-axes because the spectra were collected on four different spectrometers. There were differences in the alignment of the optical systems as these spectrometers were from different vendors and were manufactured in different years. Differentiating assembly plants within a plant group required finding small differences in similar IR spectra; hence, spectral alignment was crucial.

Sample preparation and placement can also affect wavelength alignment and the measured absorbance. If the aperture of the sample cell is small enough to become the limiting aperture of the spectrometer, any shift in the position of the sample from the center of the beam causes a shift in wavenumber and instrument line shape function. Under circumstances where the sample itself is not the limiting aperture, small wavenumber shifts may be observed if the sample is not positioned at a fixed angle from the IR beam. The beam may be refracted at an angle that displaces the image on the detector as the beam traverses the sample. As a result, the pathlength of the beam would be changed through the interferometer, altering the relationship of the interferogram to the He–Ne laser, resulting in small wavenumber shifts. For samples titled with respect to the laser beam, the pathlength within the sample changes, which may alter the measured absorbance.

The first step in this study was to align all spectra (along the wavelength axis) using OMNIC. For the measured absorbance to be very nearly equal to the true absorbance, the interferograms were multiplied by the Norton-Beer medium apodization function before application of the Fourier transform [17]. Although all spectra were measured at a nominal 4 cm^{-1} resolution, variations in the apparent frequency of the helium neon laser used and the alignment of the optical systems of the four instruments resulted in differences in the number of points in each spectrum for the same wavenumber range and their alignment along the wavenumber axis. The number of points collected per spectrum using the two Thermo-Nicolet instruments varied from 1878 points to 1958 points, whereas all spectra from the two BioRad instruments were represented by 1944 points. For a particular sample measured on all four instruments, spectral subtraction of the wavenumber axis for each measurement yielded a nonzero response at each wavelength when spectra from different spectrometers were compared. To remedy these two problems, each spectrum was normalized to the helium neon laser frequency of 15,798.0 cm^{-1}. An instrumental line shape function representative of the Thermo Nicolet instruments and developed in OMNIC was applied to the Bio-Rad spectra to ensure that all measurements made by the Bio-Rad instruments were comparable to spectra collected by the two Thermo-Nicolet instruments. The laser frequency value was set to that measured at the aperture setting to make peak positions independent of aperture setting. This ensured wavelength alignment along the x-axis for all clear coat paint spectra. After this preprocessing, each spectrum consisted of 1869 points for the entire mid-IR range of 400 cm^{-1} to 4000 cm^{-1}.

Variations in the spacing of the data points by the BioRad and Thermo-Nicolet instruments in the spectral range investigated is due to differences in the software used by the respective instrument manufacturers. It is well known among practitioners in IR spectroscopy that even if two spectrometers are off by only a quarter-point, pattern recognition methods that utilize the covariance matrix will perform poorly. Although the differences between the instruments were large enough to require alignment, these differences could not be detected visually. To authenticate wavelength alignment along the x-axis for all clear coat paint spectra of GM automobiles between the years 2000–2006, IR spectra of the same clear coat samples collected on both the BioRad and Thermo Nicolet instruments were subtracted before and after performing the alignment procedure. The subtraction yielded a nonzero response at each wavelength before the alignment procedure was implemented but zero at each point after alignment.

2.2. Wavelets

The fingerprint region of each spectrum (600 cm^{-1} to 1500 cm^{-1}), which is comprised of 468 points, was normalized to unit length and subject to wavelet analysis using the MATLAB

Wavelet toolbox 3.0.4 (MathWorks, Natick, MA). Outside of the fingerprint region, each IR spectrum consisted of only C–H stretching bands present in all clear coat paint spectra and noise (2100 cm^{-1} to 2500 cm^{-1}) due to the uncompensated absorption of IR radiation by the diamond anvil cell. Applying the discrete wavelet transform [18] to the fingerprint region, the 1314 IR spectra that served as the training set for the development of search prefilters for the PDQ database were decomposed into wavelet coefficients representing both the high and low frequency components of the signal. In this study, the Symlet6 mother wavelet at the 8th level of decomposition, i.e., 8Sym6, was used to denoise and to resolve overlapping spectral responses in the fingerprint region of each IR spectrum. Preprocessing of the IR spectra by wavelets produced 1080 wavelet coefficients for each IR spectrum.

2.3. Genetic algorithm for variable selection

Wavelet coefficients that contain information about the manufacturer or the assembly plant of the automotive vehicle were identified by a genetic algorithm (GA) for pattern recognition analysis. The pattern recognition GA identifies a set of wavelet coefficients that optimizes the separation of the classes in a plot of the two or three largest principal components of the aligned and wavelet transformed data. Because principal components maximize variance, the bulk of the information encoded by the selected coefficients is about the classification problem of interest. Spurious or chance classification, which often occurs when using other variable selection methods [19–21], is mitigated using principal components to assess the information content of the various wavelet coefficient subsets identified by the pattern recognition GA.

The principal component (PC) plot functions as an embedded information filter. A good PC plot can only be generated by coefficients whose variance or information content is primarily about class membership differences. Hence, the principal component analysis routine incorporated into the fitness function of the pattern recognition GA limits the search to these types of feature sets, thereby significantly reducing the size of the search space. In addition, the pattern recognition GA focuses on those classes and/or samples that are difficult to classify as the pattern recognition GA trains by boosting the relative importance (i.e., weights) of those classes and/or samples (i.e., vehicles). Samples that consistently classify correctly are not as heavily weighted as samples that are difficult to classify. Over time, the pattern GA is able to learn its optimal parameters in a manner similar to a neural network. The pattern recognition GA integrates aspects of artificial intelligence and evolutionary computations to yield a “smart” one-pass procedure for variable selection and classification. Further details about the operation of the pattern recognition GA can be found elsewhere [22,23].

3. Results and discussion

A hierarchical classification scheme was used to develop search prefilters for GM assembly plants, where the 21 g assembly plants were divided into five major plant groups based on a visual analysis of the extended fingerprint region (2000–600 cm^{-1}) of the clear coats. These five plants groups correspond to the two labels used by PDQ for modern automotive clear coats: acrylic melamine styrene and acrylic melamine styrene polyurethane. For Plant Groups 2 and 5, the carbonyl band corresponds to a doublet (see Fig. 1) indicative of acrylic melamine styrene polyurethane. The appearance of the doublet is due to the fact that there are two chemical sources for the carbonyl: acrylate and urethane. For Plant Groups 1, 3, and 4, the carbonyl band corresponds to a singlet (see Fig. 1) indicative of acrylic melamine styrene because only acrylate possesses a carbonyl. The fact that acrylic melamine styrene polyurethane can be divided into two distinct groups based on visual analysis of the fingerprint region of the IR spectra of GM automotive clear coats indicates that differences exist within this formulation in the relative amounts of styrene and urethane and it is reflected in the fingerprint region of the IR spectra of these clear coats. By the same token, differences in the fingerprint region of the clear coats for plant groups 1, 3, and 4 are based on changes in the relative amounts of the chemical components that define the acrylic melamine styrene formulation. The validity of the plant group concept to construct search prefilters has been demonstrated through extensive validation in previously published studies involving hundreds of samples [14,15]. The spectral analysis described in this paper utilizes this same approach in the identification of the blind paint samples provided by the RCMP. The delineation of the IR spectra, first by plant group, is based on

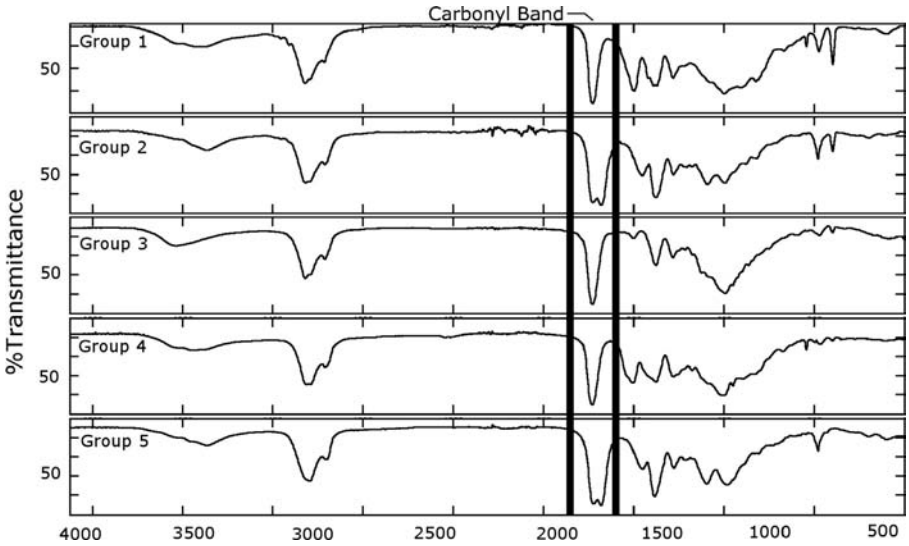

Fig. 1. IR spectra of clear coats from the PDQ library that are representative of the five GM plant groups. Carbonyl band in each IR spectra is denoted.

Table 2
Assembly plants comprising each plant group.

Plant group	Plant ID number	Assembly plant

2	3, 10, 21	Bowling Green, Hamtramck, Orion, Wilmington
3	6, 9, 16, 17, 20, 22, 25	Flint, Fremont, Linden, Lordstown, Oklahoma City, Oshawa, Shreveport
4	12	Janesville
5	24, 26, 27	Ramos Arizpe, Silao, Spring Hill, St. Therese

the paint chemistry of automotive clear coats and is necessary due to the large number of assembly plants (i.e., classes) in this study and the similarity of the IR spectra within each plant group.

An unknown is first assigned to a plant group using a single search prefilter and then a second search prefilter is used to identify the specific assembly plant or assembly plants within the plant group to which membership of the unknown is assigned. The assembly plants comprising each plant group are listed in Table 2. Several previously published studies on the use of the pattern recognition GA to develop IR search prefilters from wavelet transformed spectral data have demonstrated both the efficacy of this methodology and the low probability of overfitting the data using the pattern recognition GA for variable selection [11–16].

The first step in this study was to apply PCA [24] to the wavelet transformed IR spectra. Prior to PCA, each wavelet coefficient was autoscaled [25] to ensure that it had a mean of zero and a standard deviation of one. Autoscaling removes inadvertent weighting of the wavelet coefficients that otherwise would occur due to differences in magnitude among the coefficients. This ensures that each wavelet coefficient has an equal weight in the pattern recognition analysis of the data.

The 464 IR spectra that served as the training set for the development of the search prefilters for the PDQ database are summarized in Table 3. Fig. 2 shows a PC plot of the two largest principal components of the 464 wavelet transformed IR spectra and the 1080 wavelet coefficients representing each IR spectrum. Each paint sample is represented as a point in the PC map of the data (T-1=Plant Group 1, T-2=Plant Group 2, T-3=Plant Group 3, T-4=Plant Group 4, and T-5=Plant Group 5). The overlap of the clear coats from each plant group in the map of the data is evident.

The pattern recognition GA was used to identify wavelet coefficients characteristic of plant group. Informative coefficients were identified by sampling key feature subsets, scoring their PC plots, and tracking those plant groups and/or IR spectra that were most difficult to classify. The boosting routine used this information to steer the population to an optimal solution. After 200 generations, the pattern recognition GA identified 14 wavelet coefficients whose PC plot (see Fig. 3) showed clustering of the IR spectra on the basis of plant group.

To assess the predictive ability of the 14 wavelet coefficients identified by the pattern recognition GA, a validation set of 10 blind samples was used. The blind samples were not part of the PDQ database nor were they part of the training set used to develop the search prefilters. These samples were obtained by the RCMP as part of a project to populate PDQ to current production years.

IR spectra from the validation set were projected directly onto the PC map developed from the 464 IR spectra of the training set and 14 wavelet coefficients identified by the pattern recognition GA. Fig. 4 shows the projection of the blind samples onto the PC map of the training set data. Nine of the 10 blind samples are located in a region of the map occupied by samples from the same plant group.

Fig. 5 shows an IR spectrum of the misclassified blind sample (Sample #8) compared to an IR spectrum of a clear coat paint sample of the same make, model, year, and assembly plant from the PDQ database. The dissimilarity between these two IR spectra is evident. Both the blind sample and the library sample were measured on a Thermo-Nicolet 6700s FTIR spectrometer. To ensure that measured absorbances were nearly equal to the true absorbance values, the interferograms were multiplied by the Norton-Beer medium apodization function before application of the Fourier transform [17].

Fig. 6 shows the best hit from the PDQ database for blind sample #8 using the library search algorithm in OMNIC (Thermo Nicolet Corporation). Of all the modes available for the library search in OMNIC (correlation, absolute derivative, square derivative, absolute difference and square difference), correlation gave the most useful results in terms of the number of hits and the hit quality index. Consequently, the correlation mode was applied in library searching for all blind samples. Restricting the search to the fingerprint region gave the same results as using the entire mid-IR region after eliminating noise present in the clear coat paint spectra caused by the diamond transmission cell. The hit obtained from the PDQ database is a clear coat on a plastic bumper. In many

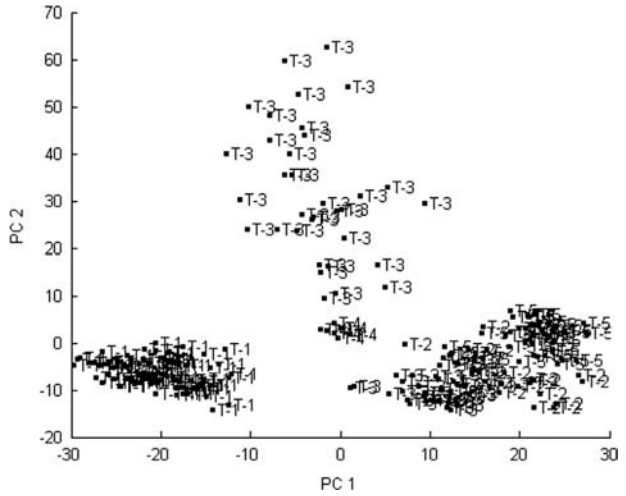

Fig. 2. PC plot of the two largest principal components of the 464 IR spectra and the 1080 wavelet coefficients comprising the training set. Each paint sample is represented as a point in the PC plot of the data (T-1=Plant Group 1, T-2=Plant Group 2, T-3=Plant Group 3, T-4=Plant Group 4, and T-5=Plant Group 5).

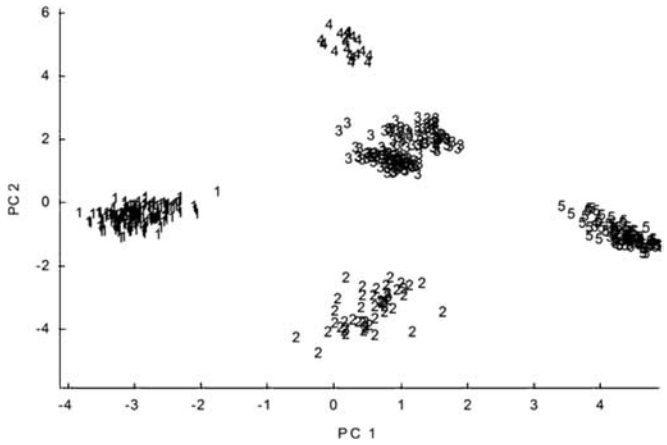

Fig. 3. PC plot of the two largest principal components of the 464 IR spectra of the training set and the 14 wavelet coefficients identified by the pattern recognition GA. Each paint sample is represented as a point in the PC plot of the data (1=Plant Group 1, 2=Plant Group 2, 3=Plant Group 3, 4=Plant Group 4, and 5=Plant Group 5).

cases, a clear coat is applied to plastic automotive components in the plant that manufactures the automotive component, not in the plant where the vehicle is assembled. (For metallic automotive components, the paint system for the component is applied to the substrate in the same plant where the vehicle is assembled.) Furthermore, bumpers and other plastic automotive components are replaceable and may not have the original automotive paint system of the vehicle. For these reasons, the training set used in this study is limited to automotive paint from metallic automotive components.

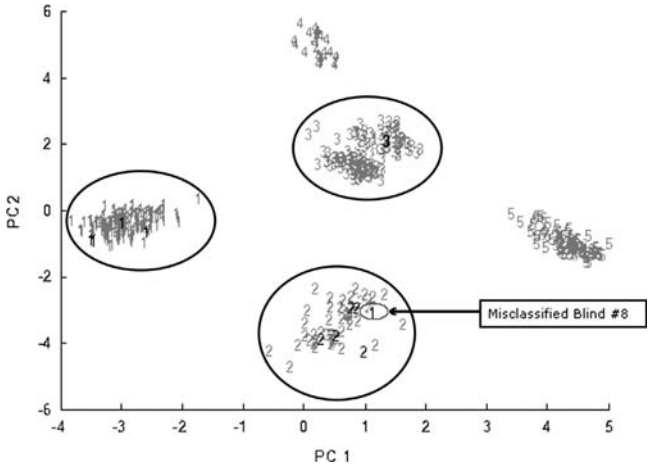

Fig. 4. Projection of the blind samples (in black) onto the PC map of the training set data (gray) for Plant Group. 9 of the 10 projected IR spectra are located in a region of the map occupied by spectra possessing the same class label. (1=Plant Group 1, 2=Plant Group 2, 3=Plant Group 3, 4=Plant Group 4, and 5=Plant Group 5.).

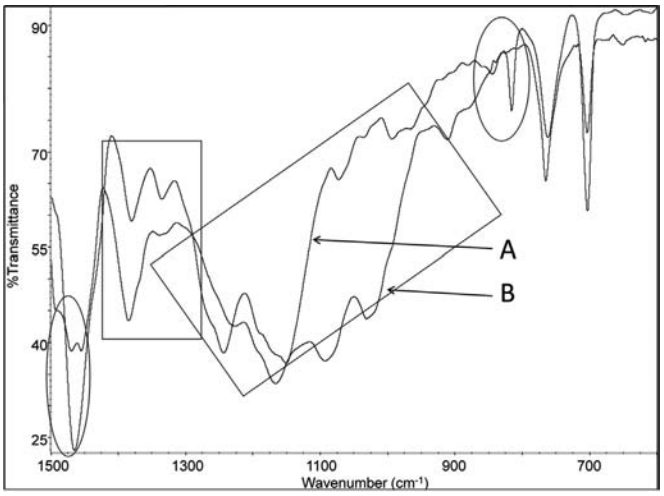

Fig. 5. An IR spectrum of (a) the misclassified blind sample (Sample #8) compared to (b) an IR spectrum of a clear coat paint sample of the same model, year and assembly plant from the PDQ database.

The next step in this study was to develop search prefilters to identify the IR spectra of the blind clear coat paint samples by assembly plant. For each plant group, a search prefilter was developed to discriminate the IR spectra by assembly plant within a plant group. Fig. 7 shows a plot of the two largest principal components of the 33 wavelet coefficients identified by the pattern recognition GA for the assembly plants comprising the first plant group (see Table 2). Each IR spectrum is represented as a point in the PC plot of the data. Plant 18 (Moraine OH) represented by the symbol T-18 in the PC plot is well separated from the other 6 assembly plants represented by the symbol T-1 in the plot. The IR spectra from the other 6 assembly plants (Arlington TX, Doraville GA, Fairfax KS, Fort Wayne IN, Lansing MI, and Pontiac MI) are superimposable, which prevented further discrimination by assembly plant of these clear coats. However, automobiles from these 6 assembly plants in the PC plot could be discriminated by production year. Furthermore, projecting the blind samples assigned to Plant Group 1 onto the PC map showed that each projected sample (P-18 for Moraine OH and P-1 for the other 6 assembly plants) lies in a region of the map with paint samples

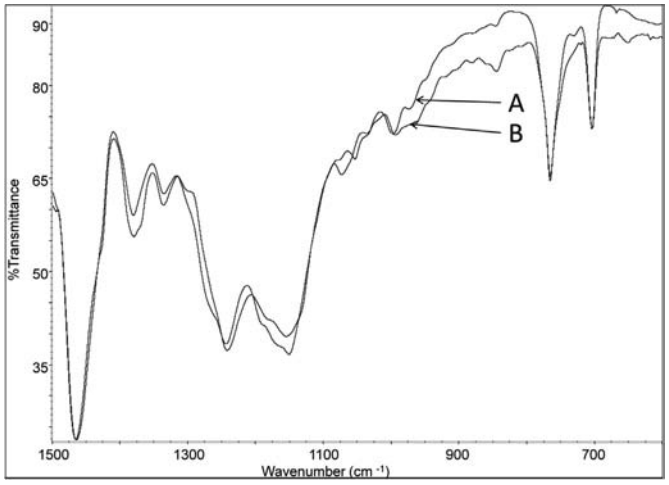

Fig. 6. An IR spectrum of (a) the misclassified blind sample and (b) the first hit from the PDQ database using OMNIC.

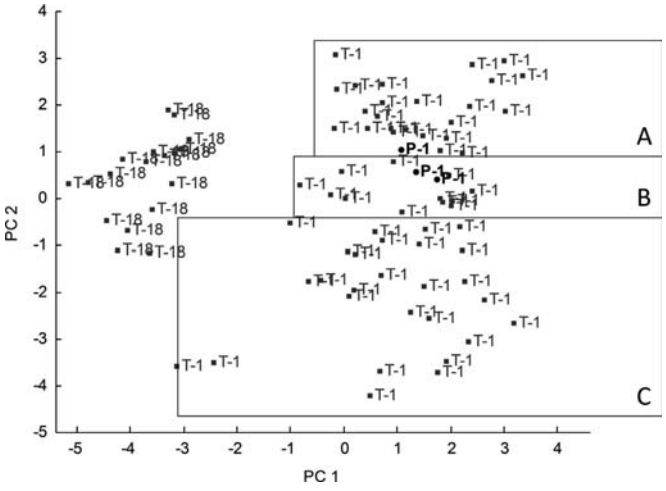

Fig. 7. PC plot of the two largest principal components of the 164 IR spectra of the training set and the 33 wavelet coefficients identified by the pattern recognition GA. Each clear coat paint sample is represented as a point in the PC plot of the data. (T-1 or P-1 = Arlington TX, Doraville GA, Fairfax KS, Fort Wayne IN, Lansing MI, and Pontiac MI and T-18 = Moraine OH.) Blind samples (P-1) are in bold. A = Arlington TX, Doraville GA, Fairfax KS, Fort Wayne IN, Lansing MI, and Pontiac MI (2000–2003); B = Arlington TX, Doraville GA, Fairfax KS, Fort Wayne IN, Lansing MI, and Pontiac MI (2000–2006); C = Doraville GA, Fairfax KS, Fort Wayne IN, Lansing MI (2004–2006).

that have the same production year range and class label. This result suggests that search prefilters developed from IR spectra of clear coats can be used to characterize automotive paint samples by assembly plant or a limited number of plants and can specify a limited production year range for these samples.

Fig. 8 shows a plot of the two largest principal components of the 54 IR spectra and the 23 wavelet coefficients identified by the pattern recognition GA for clear coats from Plant Group 2 (see Table 2). Again, each IR spectrum is represented as a point in the PC plot. All 3 assembly plants (Bowling Green KY, Hamtramck MI, and Orion MI) are well separated from each other in the PC plot of the data.

Fig. 9 shows the five blind samples assigned to Plant Group 2 projected onto the PC plot of the second plant group. Four of the 5 projected (blind) samples lie in a region of the map, which contain clear coat paint samples from the same assembly plant. Blind sample 4, which is from the Hamtramck Michigan Plant, was

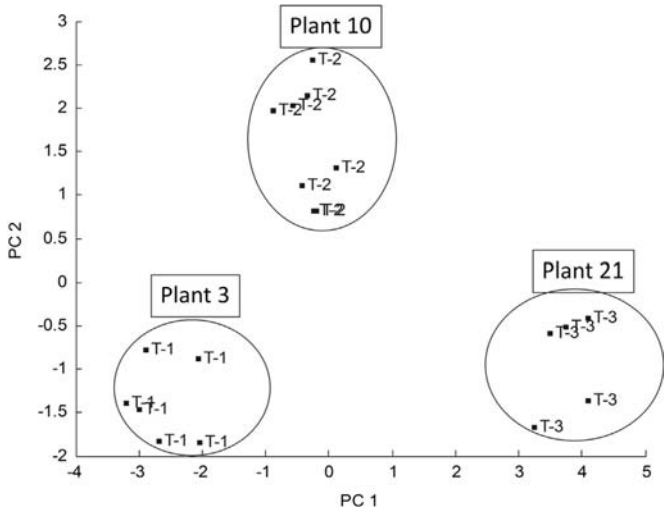

Fig. 8. PC plot of the 54 IR spectra and 23 wavelet coefficients identified by the pattern recognition GA for spectra from Plant Group 2 (T-1 = Bowling Green KY, T-2 = Hamtramck MI, and T-3 = Orion MI).

misclassified as an Orion Michigan Plant sample. There is only one IR spectrum (see Fig. 10) of this model (2006 Buick Lucerne) in the PDQ database; so this model was not well represented in the training set. A comparison of the misclassified Hamtramck Michigan Plant blind sample to the only IR spectrum of the same model, year, and assembly plant in the database (see Fig. 10) shows a peak present in the library spectrum (2006 Buick Lucerne), which is not present in the blind sample. This nullified the match.

Figs. 11 and 12 show the misclassified Hamtramck Michigan plant blind sample compared to the average IR spectrum from the Hamtramck MI plant and from the Orion Michigan plant. Although the match is better for Orion Michigan (the plant to which the blind sample has been assigned by the search prefilter), the similarity of these IR spectra underlies the challenges encountered in differentiating automotive clear coats by assembly plant for GM vehicles from Plant Group 2. Nevertheless, the search prefilters were able to correctly classify 4 of the 5 blind samples assigned to Plant Group 2.

Fig. 13 shows a plot of the two largest principal components of the 141 IR spectra and 13 wavelet coefficients identified by the pattern recognition GA for clear coats from Plant Group 3. Clustering of the spectra by assembly plant and model in the PC plot is evident for the paint samples comprising this training set. Fremont California (Plant 9) and Lordstown Ohio (Plant 17) form distinct clusters in the PC plot of the data as do the trucks from Oshawa (Plant 22). The Buicks from Oshawa Ontario lie in another cluster with SUVs from the Oklahoma City Plant. Chevrolets from the Oklahoma City Plant and from Oshawa, GMC trucks from Shreveport Louisiana and the Flint Michigan Plant, and GMC and Chevrolet trucks from Linden, NJ form another cluster. The lone blind sample assigned to Plant Group 3 is projected onto the PC plot in a region that contains clear coat paint samples from the same assembly plant.

Applying the search algorithm in OMNIC (Thermo Nicolet) to the 10 blind samples, only 4 blind samples were correctly identified compared to 8 using the search prefilters. To achieve the best results, the correlation mode was used to perform the matching, and the spectral region searched was restricted to the extended fingerprint region, which included the carbonyl band. The blind samples correctly classified by OMNIC were also correctly classified by the search prefilters. A summary of the results obtained for the 10 blind samples is shown in Table 4.

Eight of the 10 blind samples were correctly classified by the search prefilters. One misclassified sample is a clear coat paint

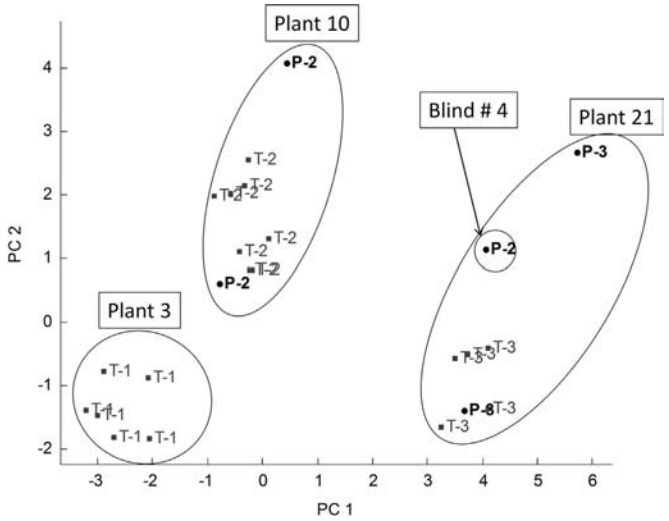

Fig. 9. Five blind samples (P-2=Hamtramck MI and P-3=Orion MI) assigned to Plant Group 2 are projected onto the PC plot of the 23 wavelet coefficients and 54 IR spectra from the second plant group (T-1=Bowling Green KY, T-2=Hamtramck MI, and T-3=Orion MI).

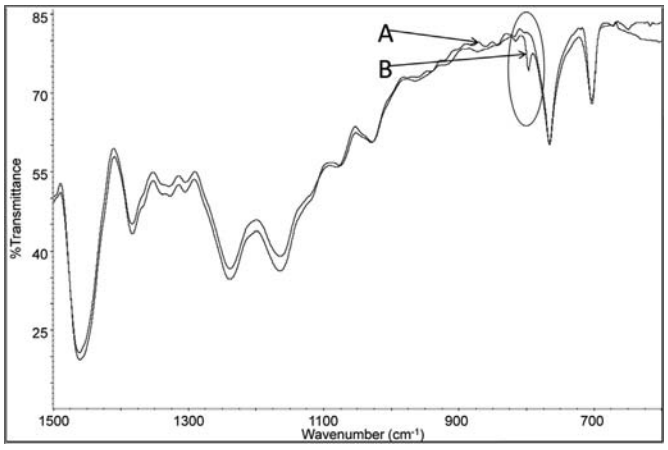

Fig. 10. IR spectrum of (a) the misclassified Hamtramck Michigan Plant blind sample compared to (b) the only IR spectrum of the same model, year and assembly plant in the PDQ database.

Training set samples are designated by T.

axes using OMNIC software. This allowed for all spectra to be compared even if they were collected on different spectrometers.

Selection of the appropriate mother wavelet was crucial in the development of the search prefilters as it ensured that information about the assembly plant of the vehicle could be extracted from the wavelet transformed spectra. In our previous studies [11–16], we have observed that a decrease in the ability of the pattern recognition GA to correctly classify mid IR spectra occurred when other mother wavelets were used for preprocessing. This result should not come as a surprise. For spectra that contain sharp peaks or discontinuities, it is well known among workers in the field that the Haar wavelet would be indicated for denoising [18]. When the spectra are comprised of broader peaks, the use of a smoother mother wavelet such as the Coiflet is strongly recommended. For mid IR spectra whose peaks are situated between these two extremes, either the Symlet or Daubechies mother wavelets would be expected to give good results for resolving overlapping bands and denoising data. However, the pattern recognition GA generally performed better when the mid IR spectra were preprocessed with Symlets than Daubechies [26], which can be attributed to the

shape of the mother wavelet relative to the shape of the IR peaks. Symlets are more symmetrical than Daubechies.

The purpose of this study is to demonstrate proof of concept, not to develop an on line fully operational pattern recognition based library search system. For this reason, the search problem was intentionally made more challenging through selection of samples from the same manufacturer within a limited production year range. This would test the capability of the search prefilers to differentiate between similar IR spectra. To use these GM search prefilters in an automated library search system, it will be necessary to develop a search prefilter to differentiate paint samples by automobile manufacturer. To demonstrate that GM automotive clear coats can be discriminated from those of other manufacturers, a search prefilter was developed to discriminate GM clear coats from Chrysler and Ford clear coats. For this study, 1314 IR spectra of clear coat paint smears (464 g, 433 Chrysler, and 417 Ford) within a limited production year range (2000–2006) were employed. To develop this search prefilter, the 1314 IR spectra were divided into a training set of 1183 clear coats and a validation set of 131 clear coats. Members of the validation set were chosen by random lot from the 1314 automotive clear coat paint samples. The IR spectra were standardized using spectral line functions previously developed for the GM automotive paint samples with the standardized spectra wavelet transformed prior to pattern recognition analysis. Fig. 14 shows a PC plot of the 53 wavelet

Table 4
Summary of the results obtained for the 10 blind samples.

Blind sample	Assigned plant group	Plant group	Assigned plant (s) search prefilters	Assigned plant OMNIC	Sample ID
1	2	2	10	10	10
2	1	1	4,5,8, or 14 (2004–2006)	18	14 (2004)
3	2	2	21	10	21

10	1	1	1, 4, 5, 8, 14, 23	8	14

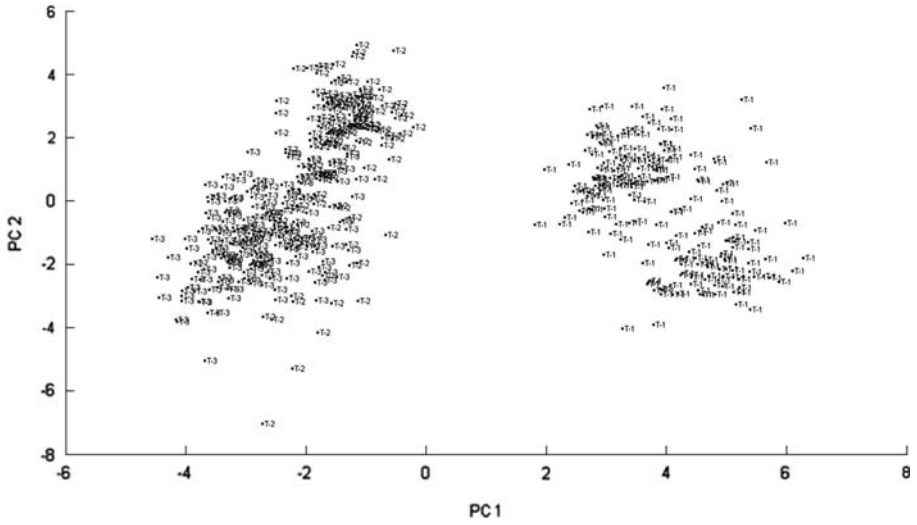

Fig. 14. Plot of the two largest principal components of the 1183 training set samples and 53 wavelet coefficients identified by the pattern recognition GA to differentiate clear coats by automobile manufacturer. T-1=GM, T-2=Chrysler, and T-3=Ford.

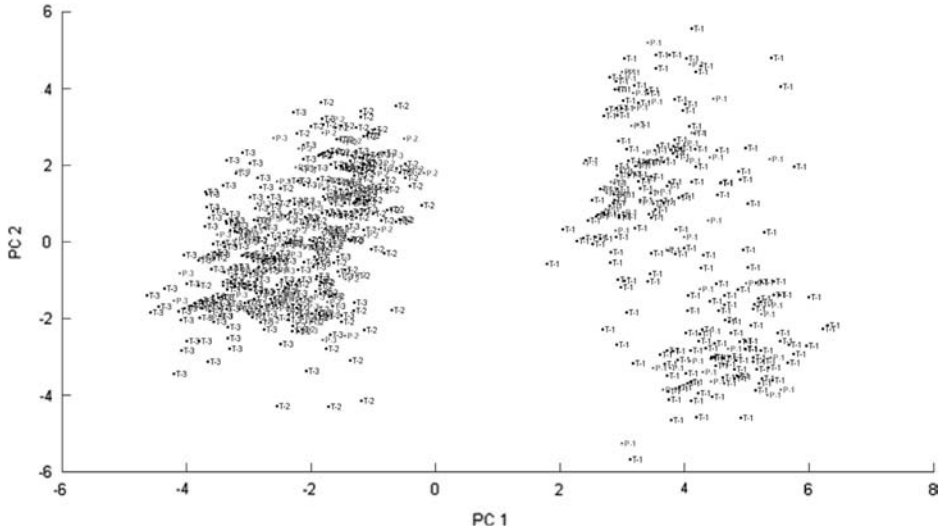

Fig. 15. Validation set samples (P-1=GM, P-2=Chrysler, and P-3=Ford) projected onto the PC plot developed from the 1183 training set samples and 53 wavelet coefficients identified by the pattern recognition GA. For the training set, T-1=GM, T-2=Chrysler, and T-3=Ford.

coefficients identified by the pattern recognition GA to differentiate clear coats by automobile manufacturer. GM clear coats can be readily differentiated from Chrysler and Ford clear coats using the wavelet transformed spectra.

To assess the predictive ability of the 53 wavelet coefficients identified by the pattern recognition GA, we chose to map the 131 clear coat IR spectra from the validation set directly onto the PC map developed from the 1183 training set samples and the 53 wavelet coefficients identified by the pattern recognition GA (see Fig. 15). Every GM clear coat plant sample in the validation set was correctly classified, i.e., each projected GM plant sample lies in a region of the map with clear coat paint samples that have the same class label. By comparison, several Chrysler and Ford validation set samples were misclassified. Evidently, spectral features correlated to the automobile manufacturer can be identified by the pattern recognition GA. This suggests that a search prefilter can be developed to discriminate GM automotive clear coats from those of other automobile manufacturers. When used in tandem with search prefilters developed for GM plant groups and for assembly plants, it should be possible to identify the assembly plant of a GM clear coat paint sample recovered from a hit and run accident where death or injury to a pedestrian has occurred.

4. Conclusions

Search prefilters have been developed to investigate the IR spectral libraries of the PDQ automotive database to differentiate between similar but nonidentical IR paint spectra. Crucial to the success of this study was the use of variable selection methods for the development of search prefilters to facilitate spectral library searching. The methodology used for the development of search prefilters in this study has not been widely reported in the literature. The search prefilters described here have the potential to facilitate spectral library searching of automotive clear coats because the size of the spectral library is truncated to those spectra corresponding to the assembly plants identified by the discriminants. Currently, the inability of PDQ to identify paint samples consisting of only the clear coat paint layer is a significant limitation to the use of PDQ to obtain trace evidence from automotive paint samples.

Information derived from the searches described in this paper can also serve to assess the general discrimination power of original automotive clear coat paint comparisons encountered in casework, and to succinctly communicate the significance of the evidence to the courts. Addressing these concerns is a direct response to a recommendation by the National Academies of Sciences report on strengthening forensic science in the United States [27].

ABSTRACT

Ascorbic acid (AsA), also known as vitamin C, is a vital small-molecule antioxidant with multiple functions in vivo. It's the major natural antioxidant found in plants and is also an essential component of human nutrition. AsA plays a key role in many diseases-related biological metabolism. Therefore, sensitive and selective detection of AsA is greatly important in pharmaceutical, clinical and food industry. Here a sensitive and selective sensor for ascorbic acid detection based on the recovered fluorescence of NAPS-NO (*N*-propyl-triethoxysilane-4-(4-ylamino-1-oxy-2,2,6,6-tetramethylpiperdine)-naphthalimide) probe is described. The fluorescence of the naphthalimide moiety of NAPS-NO is inhibited by the nitroxide group, which is covalently linked to the fluorophore. Then, ascorbic acid reacts rapidly with the nitroxide moiety of NAPS-NO to form hydroxylamine, and the fluorescence properties of the naphthalimide moiety are recovered and the ESR signal decayed. Over a wide range from 80 nM to 50 μM, a good linear relationship between the fluorescence intensity and the concentration of ascorbic acid was found and the detection limit was estimated to be as low as 20 nM. To confirm the practical usefulness of the fluorophore–nitroxide probe, we demonstrated the use of NAPS-NO for the measurement of AsA in human blood serum and also successfully determined the concentration of AsA in HEK 293 cell lysate. Results from confocal laser scanning microscopy experiments demonstrated that this chemosensor is cell permeable and can be used as a fluorescent probe for monitoring ascorbic acid in living cells.

1. Introduction

Ascorbic acid (AsA), which cannot be synthesized in the human body, is used in large scale as an antioxidant in food, animal feed, beverages, pharmaceutical formulations and cosmetic applications [1]. AsA is the major natural antioxidant found in plants and is also an essential component of human nutrition [2,3]. It plays a key role in biological metabolism and has been commonly used for the prevention and treatment of common cold, mental illness, infertility, cancer and AIDS, etc [4]. Thus, the development of a simple and rapid method for the determination of AsA with high selectivity and sensitivity is desirable for diagnostic and food safe applications [5].

A wide variety of analytical methods is available for the determination of ascorbic acid, such as titrimetric [6,7], spectrophotometric [8,9] and chromatographic [10–12] methods. These methods rely on different phenomena and registration techniques suffering from several limitations. The spectrophotometric methods measure either the resultant color of products of certain reactions involving ascorbate [13] or absorbance of ascorbic acid itself [14]. However, the low selectivity of the reactions involved decreases the accuracy of the ascorbate analysis. Thereby, the reliability of these methods is limited by relatively low specificity. A number of specific assays for reductants including ascorbic acid, uric acid, tocopherol etc. have been developed based on high performance liquid chromatography (HPLC) [15,16]. These techniques require several complicated preliminary steps. In addition, HPLC separations would consume relatively long time, therefore, could not be considered as an express-method. Early methods utilizing nitroxide radicals for ascorbate quantifications were based on measurements of only ESR signal from nitroxide, therefore, suffered from general drawbacks of ESR spectroscopy. Although this technique permits investigations in high optical density substance, the ESR measurements are limited by high cost and complexity of equipments and difficulties in acquiring and processing experimental data. At present, electrochemical approaches become

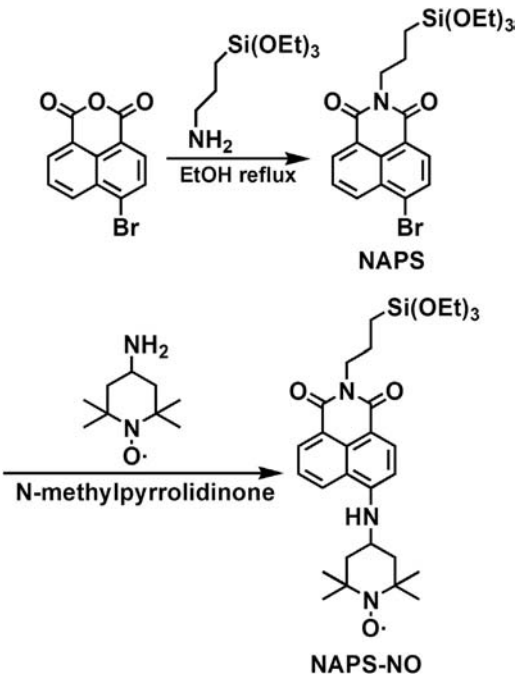
the major analytical methods for AsA determination because of their convenience and speediness. Nevertheless, the interference from other similar redox potential molecules can be serious, such as uric acid and dopamine [17]. What's more, the detection limit is always higher than that of fluorescence methods. Particularly, attempts have been made to detect ascorbic acid using nanoparticles. Wang et al. [17] developed a simple fluorescence sensor for sensitive turn-off detection of ascorbic acid by using protein-modified Au nanoclusters in aqueous media. Zhang et al. [18] fabricated an electrochemical sensor for selective detection of ascorbic acid in the presence of dopamine and uric acid by modifying the glassy carbon electrode with carbon-supported $NiCoO_2$($NiCoO_2$/C) nanoparticles. Wang et al. [19] prepared a palladium nanoparticle/graphene/chitosan/glassy carbon electrode which displayed excellent electrochemical catalytic activities towards ascorbic acid, dopamine and uric acid. But these methods have relatively high detection limit towards ascorbic acid. Fluorometric sensing is a preferable approach for detection of AsA due to its comparatively high selectivity, sensitivity, rapidity, operational simplicity, nondestructive methodology and direct visual perception [20].

In recent years, many fluorescent chemosensors were designed for ascorbic acid. Matsuoka et al. [21] synthesised several fluorescent nitroxide compounds based on naphthalene which were sensitive to ascorbic acid. They also demonstrated the use of Naph-DiPy nitroxide for the measurement of ascorbic acid in the plasma of osteogenic disorder Shionogi rats to confirm the practical usefulness of the fluorophore–nitroxide probe. Zheng et al. [22] demonstrated a fluorescent carbon dot probe, its fluorescence was quenched by Cr(VI) through inner filter effect, but Cr(VI) can be reduced to low valent chromium species easily by ascorbic acid, and then resulting in the elimination of the IFE and recovery of CD fluorescence. Therefore the CD – Cr(VI) mixture could behave as an off-on type fluorescent probe for ascorbic acid. Biqing et al. [23] developed a fluorescent turn-on detection for ascorbic acid based on hyperbranched conjugated polyelectrolyte. The fluorescence was superquenched by Cu^{2+} ions, upon addition of ascorbic acid, the paramagnetic Cu^{2+} ions can be transformed into diamagnetic Cu^{1+} ions, which inhibit the quenching and thus lead to fluorescence enhancement of the hyperbranched conjugate polymer. These fluorescent probes all have sensitive response to ascorbic acid, but none of them were used in intracellular environment.

Fluorophore-linked nitroxides represent examples of such fluorescent sensors. The standard redox potential of nitroxides is high enough (E° = 0.54 V vs SHE for piperidine) to oxidize ascorbic acid which have been the only significant reducing agent studied and used in earlier applications of nitroxide radicals to blood and food product [24]. The fluorescence is intramolecular quenched by the linked nitroxide through electron exchange interactions [25–27], but can be recovered when the nitroxide moiety reacts with certain types of radicals, such as methyl radicals and some reducing agents, such as ascorbic acid [28]. Because of this, fluorophore-linked nitroxides have been used for the determination of reducing agents as well as radicals [29–32]. Nitroxide can shuttle between the nitroxyl radical form, the reduced hydroxylamine, and the oxidized oxoammonium cation form with one- and two-electron transfer reactions [21,26]. When the hydroxyl radical or superoxide reacts with the nitroxyl radical, the oxoammonium cation is produced. Most nitroxides are reduced to the corresponding hydroxylamine by reacting with ascorbic acid [24,33–35]. At the same time, the quenching effect of nitroxides disappeared, thus creating a decay of the ESR signal and enhancement of the fluorescence. This indicates that fluorophore–nitroxide coupled systems can act as promising reagents for the rapid and convenient fluorometric detection of ascorbic acid.



Because of the strong yellow–green fluorescence and good photostability of 1,8-naphthalimide derivatives, they have found wide application in spectral area [36–38]. Here, we describe a new naphthalimide-linked nitroxide probe (NAPS-NO) with high sensitivity and selectivity for the detection of ascorbic acid. According to the previous reports [39,40], the introduction of 3-aminopropyltriethoxysilane can increase the hydrophilicity of the probe, thus resulting in favorable biocompatibility. At the same time, the silane structure can provide a suitable binding site for the further construction of inorganic–organic complex probes, which have the obvious advantage in the efficient separation and analysis of the targets.

A modified previously reported procedure [41,42] was employed for the synthesis of NAPS-NO. It was synthesized from the reaction of 4-Br-1,8-naphthalimide and APTES, followed by reaction with 4-amino-tempo (Scheme 1). The structure of NAPS-NO was characterized by ESR, ESI-MS, FT-IR, and fluorophotometry. The fluorescent intensity of NAPS could be inhibited by the linked nitroxide through electron exchange interactions. When AsA reacted with NAPS-NO, the fluorescent intensity could be recovered. The as-prepared chemosensor exhibited a linear response to AsA concentrations ranging from 80 nM to 50 μM with a detection limit of about 20 nM. The concentration of AsA in human blood serum and HEK 293 cell lysate was determined respectively by the internal standard addition method. Moreover, results of confocal laser scanning microscopy experiments demonstrated that NAPS-NO could be used for monitoring ascorbic acid in living cells.

2. Experimental section

2.1. Apparatus

ESR determination was performed with a Bruker A300 ESR Spectrometer. Fluorescence spectra were measured on a Hitachi F-4500 spectrophotometer equipped with a 1 cm quartz cell. Mass spectra were obtained with MAT-261 spectrometer. FT-IR was recorded on a Thermo Scientific Nicolet 6700 FT-IR spectrometer (Sugar Land, TX, USA). Confocal fluorescence imaging was taken using a Leica TCS SP5 laser scanning confocal microscope (excitation wavelengths 468 nm).

Scheme 1. Synthetic routes to NAPS and NAPS-NO.

2.2. Reagents

We purchased 4-Bromo-1,8-naphthalimide from Adamas Reagent Co., Ltd. 4-amino-1-oxy-2,2,6,6-tetramethylpiperidine was purchased from TCI. 3-aminopropyl-triethoxysilane was purchased from Alfa Aesar. The human serum samples were obtained from Wangjiang Hospital of Sichuan University. HEK 293 cell lysate (2×10^6 cells) was provided by the state key laboratory at Sichuan University. All solvents used for synthesis and measurements were redistilled before use. All the other chemicals were of analytical-reagent grade and used without further purification.

2.3. Cell culture and cell imaging

Hela cells were provided by the state key laboratory at Sichuan University (Sichuan, China). Confocal fluorescence imaging was performed with a Leica TCS SP5 laser scanning confocal microscope (excitation wavelengths 468 nm). Before the experiments, the Hela cells were exposed to 40 μmol L^{-1} ascorbic acid for 30 min at room temperature to allow the AsA to permeate into the cells. The cells were then centrifuged to remove excess AsA, and the treated cells were then incubated with 40 μmol L^{-1} NAPS-NO for another 30 min. Following incubation, the cells were imaged.

2.4. Synthesis of intermediates and probes (Scheme 1)

2.4.1. Synthesis of NAPS (N-propyl-triethoxysilane-4-Br-naphthalimide)

NAPS was synthesized according to Jozef et al. [39,40]. Under nitrogen, a solution of 4-Br-1,8-naphthalimide (0.6 g, 2 mmol) and 3-aminopropyl-triethoxysilane (APTES) (560 μL, 2.4 mmol) in EtOH (40 mL) was refluxed for 5 h, 4-Br-1,8-naphthalimide was almost no more left. In this type of reaction, EtOH was widely used as solvent [39,40]. The mixture was evaporated by rotary evaporation and the intermediate was directly investment in the next reaction. As shown in Fig. S1, ^{1}H-NMR (400 MHz, $CDCl_3$): δ=0.72–0.76 (m, 2*H*), 1.21 (t, *J*=7.0 Hz, 9*H*), 1.80–1.89 (m, 2*H*), 3.81 (q, *J*=7.0 Hz, 6*H*), 4.16 (t, *J*=7.6 Hz, 2*H*), 7.81–7.86 (m, 1*H*), 8.01–8.04 (m, 1*H*), 8.39–8.41 (m, 1*H*), 8.54–8.57 (m, 1*H*), 8.63–8.65 (m, 1*H*) ppm.

Synthesis of NAPS-NO

2.4.2. (N-Propyl-triethoxysilane-4-(4-ylamino-1-oxy-2,2,6,6-tetramethylpiperdine)-naphthalimide)

NAPS (0.48 g, 1 mmol) and 4-amino-1-oxy-2,2,6,6-tetramethylpiperidine (0.34 g, 2 mmol) was dissolved in 20 mL of 1-methyl-2-pyrrolidone. The mixture was heated for 24 h at 100 °C and excess of 4-amino-2,2,6,6-tetramethylpiperidine and 1-methyl-2-pyrrolidone were recovered by vacuum distillation. The crude product was purified by column chromatography on silica gel using a mixture of ethyl acetate and petroleum ether (1:1) yielding 0.2 g (37%) of orange crystals. As shown in Fig. S3, the HPLC spectra indicated that no obvious impurities were observed. HRMS (ESI^+) calcd for $C_{30}H_{44}N_3SiO_6$ $[M+H]^+$: 571.3078. Found: 571.3077. FTIR, cm^{-1}: υ(N–H) 3440, υ(C=O) 1700, υ(C–N) 1386, $\upsilon(SiO^{sym})$ 816, $\upsilon(SiO^{asym})$ 1119 (Fig. S4).

2.5. X-band ESR measurement

To determine the reaction between N–O groups and ascorbic acid, NAPS-NO (10 μM) was mixed with ascorbic acid solutions (0–50 μM). X-band ESR spectra were recorded at room temperature using a Bruker A300 ESR spectrometer (Germany; microwave power 9 mW, amplitude of 100-kHz field modulation 0.6 mT, time constant 2.56 ms) and were analyzed using an ESR data analyzer.

3. Results and discussion

3.1. Chemical properties of spin-labeled fluorescence probe

Reduction of the fluorophore–nitroxide probe by ascorbic acid has been monitored by two independent spectroscopic techniques: ESR and fluorescence. When NAPS-NO was mixed with ascorbic acid, its ESR signal decayed and the fluorescence intensity gradually recovered with different concentrations of ascorbic acid (Fig. 1a and b). As shown in the inset of Fig. 1b, the fluorescence enhanced a lot with the addition of ascorbic acid. This increase in fluorescence intensity clearly validated that NAPS-NO can serve as a highly sensitive sensor for AsA. As expected, the fluorescence intensity at approximately 540 nm increased with increasing AsA concentrations. Fig. 1b inset illustrated that this chemosensor exhibited a linear response toward negative logarithm of AsA concentration from 80 nM to 50 μM, the linear equation was $y=2915-381.4x$ and the linear relative coefficient was $R^2=0.993$. The detection limit of AsA was estimated to

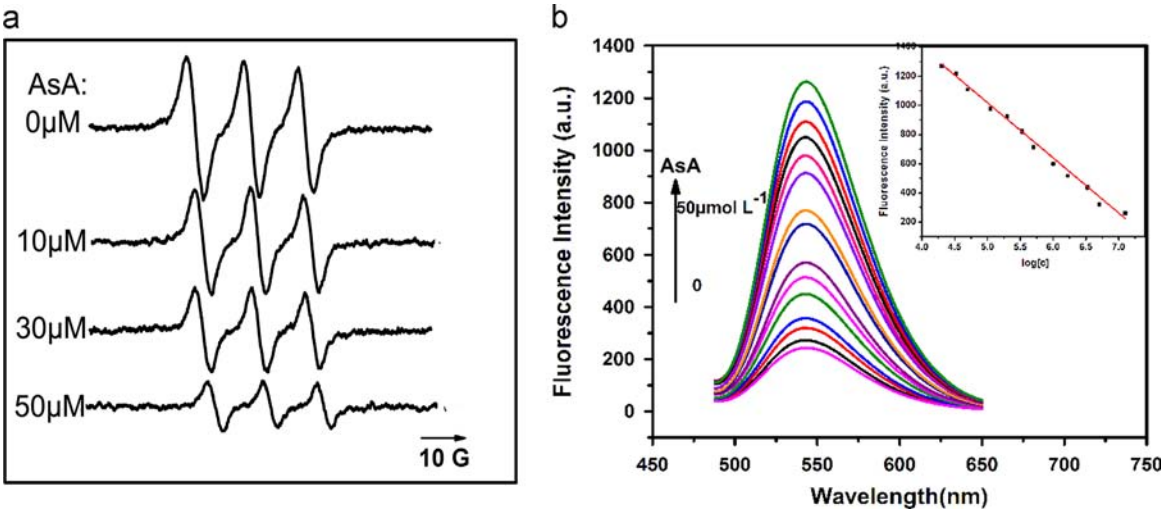


Fig. 1. (a) ESR signal decay and (b) fluorescence spectra of NAPS-NO (10 μM) in aqueous solution (50 mM PBS buffer, pH 7.0) upon addition of various concentrations of AsA (0–50 μM). Inset: plot of fluorescence intensity of NAPS-NO versus the negative log concentration of AsA (λ_{ex}=468 nm).

20 nM, which is lower than the AsA concentration detected by previous researches [15,28] in physiological sample. We also compared our technique with other methods (Table S1), and the results showed that our chemosensor provided lower detection limit and wider line range for the detection of AsA.

3.2. Evaluation of the response to other reductants and oxidants in vitro

NAPS-NO showed no fluorescence enhancement in response to glucose and BSA. In the case of other reductants, such as cysteine, dopamine etc., there were only slightly fluorescence enhancements could be detected (Fig. 2a). The oxoammonium cation is generated when a hydroxyl radical or superoxide reacts with the nitroxyl group at almost the diffusion-controlled rate [21]. Hence, we examined the reactivity of NAPS-NO towards ROS by fluorescence spectrometry (Fig. 2b). NAPS-NO did not show any obvious fluorescence enhancement in response to hydrogen peroxide, hydroxyl radical or high selectivity towards AsA over the other coexisting competitive species is a very important feature to evaluate the performance of NAPS-NO. Therefore, the competition experiments were also conducted. AsA was respectively added into the NAPS-NO solution containing different reductants or ROS. Relative fluorescence intensity was calculated by F/F_0, where F_0 and F were the fluorescence intensity of NAPS-NO containing AsA without and with the presence of reductants or ROS, respectively. As shown in Fig. 2c and d, glucose and BSA have almost no effect, whereas cysteine, dopamine, uric acid and GSH have relatively small effect on the fluorescence intensity of NAPS-NO-AsA system. H_2O_2 and ClO^- play no role, whereas · OH has a little impact on AsA detection. Fig. 2c and d showed that the extra addition of other reductants or ROS produced no obvious interference for AsA detection. These results indicated that NAPS-NO can act as a sensitive and selective AsA-specific fluorescent sensor, and it is expected to find potential applications in selectively and efficiently detecting AsA in biological to the previous reports [21,32], the fluorescence of fluorophore is quenched by the linked nitroxide through intramolecular electron exchange interactions, but can be recovered when the nitroxide moiety reacts with certain reactive oxygen species, such as hydroxyl radicals and some reducing agents, such as ascorbic acid. But they react in a different mechanism. Nitroxide can either accept one electron to be reduced to its diamagnetic counterpart hydroxylamine or donate one electron to be oxidized to its diamagnetic counterpart oxoammonium cation (Scheme S1) [43]. Based on the results of selectivity experiment, we proposed that the short life time of ROS species may result in its lower possibility of reaction with nitroxide than that of the reductants, which resulted in the selectivity of nitroxide towards reactive oxygen species. As for the selectivity towards other reductants, further research works are needed, and we are studying the reasonable mechanism constantly.

In this paper, phosphate buffer solution (PBS) was used throughout because it has been proved to be a good buffer for application of chemosensor in organism. The influence of pH value on the fluorescence intensity of NAPS-NO within the pH range of 5.5–9.0 was evaluated. As shown in Fig. S5, the fluorescence intensity increased with increasing pH until it reached the maximum at

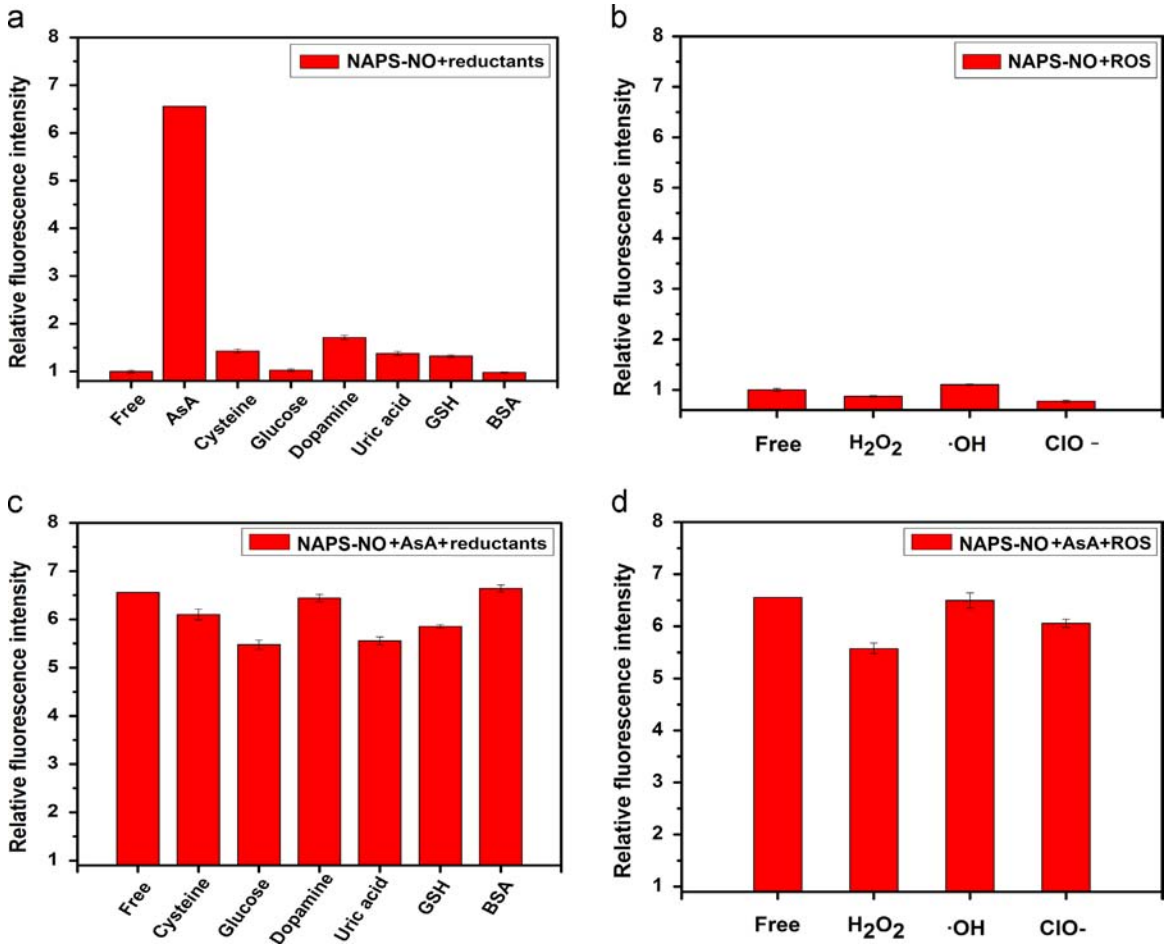

Fig. 2. Fluorescence responses of NAPS-NO (10 μM) to (a) various reductants (5 equiv.), AsA (5 equiv.) and (b) ROS (5 equiv.); fluorescence responses of NAPS-NO (10 μM) to AsA (5 equiv.) in the presence of (c) other reductants (5 equiv.) and (d) ROS (5 equiv.) (λ_{ex}=468 nm). Reductants including cysteine, glucose, dopamine, uric acid, GSH, BSA. ROS including hydrogen peroxide, hydroxyl radical, hypochloride.

pH 7.0 and thereafter decreased, thus we chose pH 7.0 as the optimal pH value to accord with that of neutral media and biological samples.

3.3. Determining the concentration of AsA in blood serum and recovery test

With the purpose of illustrating the reliability and accuracy of the proposed method, the developed sensor was applied to determine AsA in blood serum samples. Herein, 5 μL of blood serum was added to 500 μL of 10 μM NAPS-NO in PBS (50 mM, pH 7.0). Different concentrations of AsA standards were then added to the sample and the mixtures were measured. The fluorescence intensity of NAPS-NO with blood serum was enhanced following additions of different amounts of AsA. After linearly fitting the fluorescence intensity with the concentration of added AsA (Fig. S6), we successfully determined the concentration of AsA in blood serum to be 25 μM, which matched with that of the previous report [44]. Recovery experiments were also carried out by adding known amounts of AsA to the human serum sample. As shown in Table 1, the recovery of AsA was between 96 and 104% with RSD < 5%, which showed that the sensor was suited to detect AsA in blood serum samples.

Table 1
Recoveries of AsA from spiked blood serum samples.

Sample	Level added (μM)	Level found (μM)	Recovery (%)	RSD (%)
1	5	4.95	98.9	1.1
		4.84	96.8	3.2
		4.96	99.2	0.8
2	6	6.14	102.3	2.3
		6.17	102.9	2.9
		6.23	103.9	3.9
3	8	7.86	98.3	1.7
		7.89	98.6	1.4
		7.81	97.6	2.4
4	9	9.09	101.0	1.0
		9.05	100.5	0.5
		9.04	100.4	0.4

3.4. Determining the concentration of AsA in cell lysate

To further show the potential utility of NAPS-NO in biological samples, the probe was studied to detect AsA in cell lysate. A volume of 1 mL of HEK 293 cell lysate was transferred to a centrifuge tube and the large biomolecules were separated from the cell lysate by centrifugation at 12,000 rpm for 10 min. Then, 2 μL of cell lysate supernatant was added to 500 μL of 10 μM NAPS-NO in PBS (50 mM, pH 7.0). Different concentrations of AsA standards were added to the sample and the mixtures were measured. The fluorescence intensity of NAPS-NO with cell lysate was enhanced after additions of different amounts of AsA (Fig. S7). After linearly fitting, we successfully determined the concentration of AsA in cell lysate to be 1.51 μM, which accord with that of former report [45].

3.5. Cell labeling and imaging

We also proposed that NAPS-NO would permeate into cells because of its favorable amphiphilic properties. Laser scanning confocal microscopy was used to investigate this proposition.

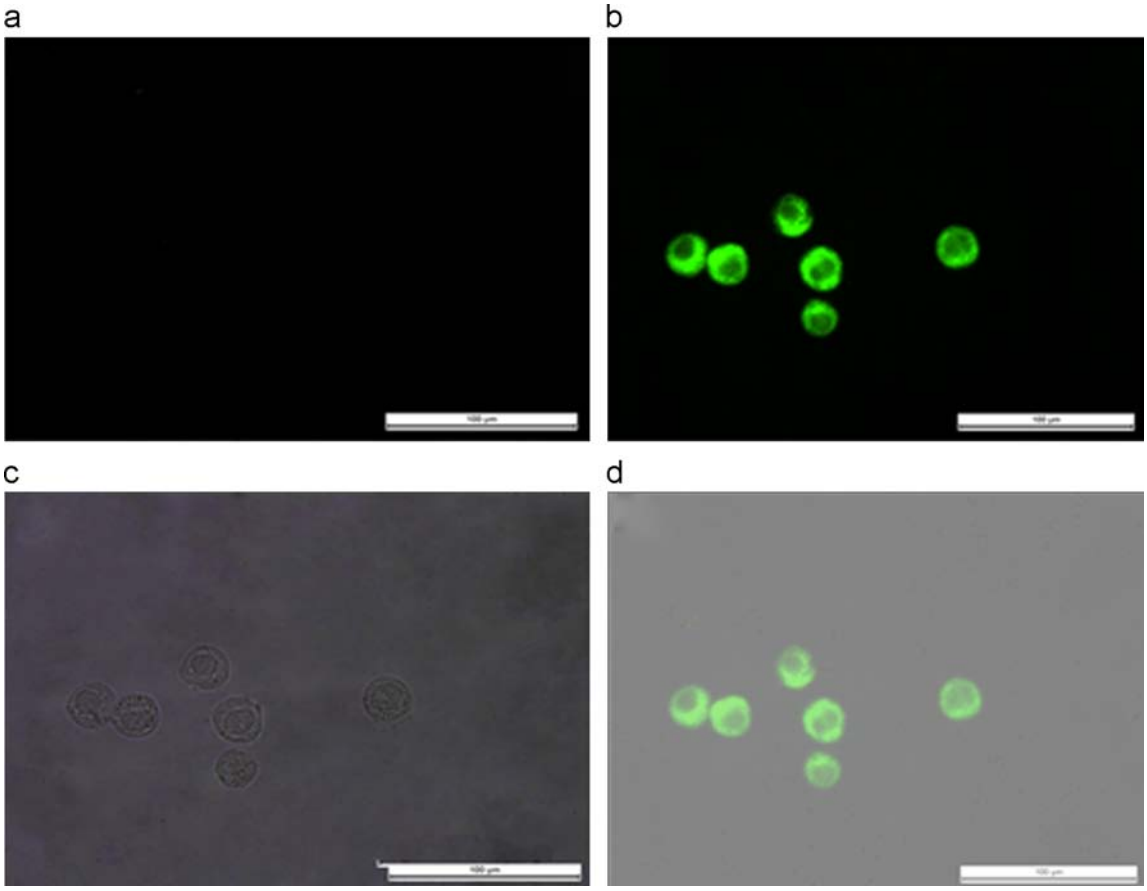

Fig. 3. Confocal fluorescence and brightfield images of Hela cells. (a) Fluorescence image of Hela cells stained with 40 μmol L^{-1} AsA for 30 min at 37 °C. (b) Confocal image of Hela cells that were further incubated with 40 μmol L^{-1} NAPS-NO for another 30 min. (c) Bright field image of cells shown in panel b. (d) The overlay image of b and c. The excitation wavelength was 468 nm.

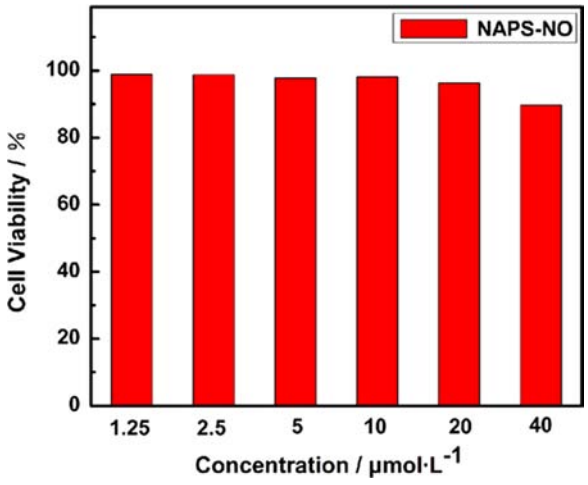

Fig. 4. Cellular toxicity of NAPS-NO determined by MTT assay. Effect of different concentration of NAPS-NO on viability of Hela cells.

Cultured Hela cells were incubated with 40 μmol L^{-1}AsA for 30 min at 37 °C, and an insignificant amount of AsA fluorescence was detected in the cells' interior (Fig. 3a). However, when the cells were supplemented with 40 μmol L^{-1} NAPS-NO for another 30 min, an enormous fluorescence increase from the intracellular area was observed (Fig. 3b). Bright field microscopic images (Fig. 3c) confirmed that the cells were viable throughout the imaging experiments. An overlay of fluorescence and bright field images revealed that the fluorescence signals were localized in the perinuclear region of the cytosol (Fig. 3d), indicating the subcellular distribution of AsA. These results demonstrated that NAPS-NO was cell permeable and might be used for monitoring AsA within biological samples. For future biological applications, the inherent cytotoxicity of NAPS-NO was tested using Hela cells by MTT assay. As shown in Fig. 4, the viability of Hela cells retained more than 90% after treated with NAPS-NO at 20 μmol L^{-1} for 48 h, even at 40 μmol L^{-1} cell viability remained 89%. The results suggested low cytotoxicity and good biocompatibility of NAPS-NO.

4. Conclusion

In conclusion, we proposed a new and simple fluorescent turn-on sensor to detect ascorbic acid in aqueous solution with very high sensitivity and wide detection range by using naphthalimide linked nitroxide as probe. The coordination of nitroxide with AsA was formed more easily, therefore, a recovered fluorescence intensity of naphthalimide moiety was observed. A good linear relationship was obtained from 80 nM to 50 μM for AsA and the detection limit was 20 nM. The chemosensor was successfully used to determine the concentration of AsA in human serum sample and HEK 293 cell lysate by using of standard addition methods. Furthermore, the excellent biological value of NAPS-NO was demonstrated by the fluorescence imaging with Hela cells. The developed method is expected to design new chemosensors based on organic fluorescent molecules and inorganic materials and applicate in clinical diagnostics and oxidative stress monitoring.

Acknowledgments

The work described in this paper was supported by the National Natural Science Foundation of China (21377089, 20927007 and 21177090). We would like to express our sincere thanks to Analytical & Testing Centre of Sichuan University for the MS measurements.

ABSTRACT

A method was developed for pesticide analysis in samples of high chlorophyll content belonging to the group of minor crops. A new type of sorbent, known as ChloroFiltr, was employed for dispersive-solid phase extraction cleanup (dispersive-SPE) to reduce the unwanted matrix background prior to concurrent analysis by gas chromatography and ultra-performance liquid chromatography coupled to tandem quadrupole mass spectrometry (GC–MS/MS and UPLC–MS/MS). Validation experiments were carried out on green, unripe plants of lupin, white mustard and sorghum. The overall recoveries at the three spiking levels of 0.01, 0.05 and 0.5 mg kg^{-1} fell in the range between 68 and 120% (98% on average) and 72–104% (93% on average) with relative standard deviation (RSD) values between 2 and 19% (7% on average) and 3–16% (6% on average) by GC–MS/MS and UPLC–MS/MS technique, respectively. Because of strong enhancement or suppression matrix effects (absolute values $>20\%$) which were exhibited by about 80% of the pesticide and matrix combinations, acceptably accurate quantification was achieved by using matrix-matched standards. Up to now, the proposed method has been successfully used to study the dissipation patterns of pesticides after application on lupin, white mustard, soya bean, sunflower and field bean in experimental plot trials conducted in Poland.

1. Introduction

A particular crop may be called “minor” if such small amounts are grown that it will provide a limited market for pesticides. If the crop is considered to be of low economic importance at a national level, the pesticide manufacturers have little interest to do expensive research and development work needed for the registration of pesticides for use on the crop, and as a consequence of such a situation, the crop will have limited options for protection against pests and pathogens. Therefore, there are little data, or effectively no data available, about efficacy and residue behaviour of candidate pesticides having potential to be applied for the protection of minor crops. For authorization of pesticides on minor crops, or for minor use, it is preferable to explore other possibilities for determining the efficacy and crop safety of pesticides than those based on the amount of data required for authorization on major crops [1,2].

Although minor crops are grown in relatively small amounts compared with major crops, they are of substantial economic importance in many countries. Which crops are minor largely depends on the specific country and region. In Poland, the list of the plants classified as minor crops is published by the Ministry of Agriculture and Rural Development, and it comprises various crop groups including vegetables, fruit and berry plants, industrial plants and cereals, herbaceous plants and forest nurseries plants [3]. In this work, we focus on the analysis of pesticide residues in green crops of various plants including lupin, white mustard, soya, sunflower, and field bean by using gas chromatography and ultra performance liquid chromatography coupled with tandem quadrupole mass spectrometry (GC–MS/MS and UPLC–MS/MS)-based methods.

It must be highlighted, that the majority of up to now published pesticide residue methods were mainly focused on analysis of less complicated matrices such as fruit and vegetables [4]. The main reason might be the fact that fresh fruits and vegetables are consumed in larger amounts than other crops, so there is a risk for high intake of pesticide residues, especially when they are present above their legislative maximum residue levels (MRLs) [5]. However, another reason is that multiresidue pesticide analysis in matrices of high chlorophyll content is more difficult owing to matrix interferences and complicated extraction procedures [6]. In pesticide analysis, green matrices, high in chlorophyll, represent a particular challenge due to a massive load of co-extractives in the extract. The co-extracted

chlorophyll is one of the most problematic matrix interferences in pesticide residue analysis because of its non-volatile characteristics. It may hinder identification of the pesticides of interest by contamination of the chromatographic systems, causing downtime, and reducing the overall analytical performance [7,8].

The use of graphitized carbon black (GCB) as a sorbent has been shown to be effective for removal of co-extracted chlorophyll and other pigments from extract of plant crops [9–15]. On the other hand, GCB is well-known to adsorb pesticides with planar functionality leading to unsatisfactory recoveries of a number of pesticides susceptible to this adsorption, e.g. chlorothalonil, cyprodinil, fenazaquin, mepanipyrim, pirymethanil, prochloraz, quinoxifen, quintozene and thiabendazole [16–18].

The main objective of this work was to investigate the possibility of application of a new type of sorbent, known as ChloroFiltr, in order to reduce the content of chlorophyll from extracts of green plants belonging to the category of minor crops, and thereby reduce the unwanted background while not affecting the recovery of the target pesticides. For the final determination, concurrent analyses were carried out by using a programmable temperature vaporization injector (PTV) gas chromatography–tandem quadrupole mass spectrometry (GC–MS/MS) and ultra-performance liquid chromatography–tandem quadrupole mass spectrometry (UPLC–MS/MS) to achieve improved selectivity and high accuracy. Comprehensive method validation was carried out to evaluate fitness for the intended application, and it involved determination of recovery, precision, linearity, assessment of matrix effects and estimation of measurement uncertainty.

The developed and validated method was applied to the study of dissipation patterns of pesticides in experimental plot trials after application to minor crops including lupin, white mustard, soya bean, field bean and sunflower.

2. Material and methods

2.1. Chemicals and reagents

Acetonitrile and acetone (for residue analysis) were obtained from Witko (Łódź, Poland). Anhydrous magnesium sulphate (reagent grade) and Supel Que Citrate (EN) tubes containing 4 g magnesium sulphate, 1 g sodium chloride, 0.5 g sodium citrate dibasic sesquihydrate, 1 g sodium citrate tribasic dehydrate, water with 0.1% formic acid (LC–MS Chromasolv) and methanol with 0.1% ammonium acetate were obtained from Sigma-Aldrich Sp.z o. o. (Poznań, Poland). Enviro Clean extraction tubes containing 900 mg magnesium sulphate, 300 mg PSA and 150 mg ChloroFiltr were obtained from UCT (Bristol, PA, USA). Deionized water of resistivity 18.2 MΩ cm was prepared with a Milli-Q Plus system from Millipore (Billerica, USA).

2.2. Pesticide analytical standards

Certified pesticide standards and internal standards triphenylphosphate (TPP) and simazine-d10 were obtained from Dr. Ehrenstorfer (Augsburg, Germany). Stock solutions (approximately 1000 μg mL^{-1}) were prepared in acetone. Purities of the standards were accounted for when calculating the concentration of each stock solution. A blend stock solution of all pesticides at a concentration of 10 μg mL^{-1} was prepared in acetone. The working standards at 0.005, 0.01, 0.02, 0.05, 0.2, 0.5 and 1.0 μg mL^{-1} were prepared by diluting this stock solution with acetonitrile and 0.1% ammonium acetate in methanol/0.1% formic acid in water (1:1, v/v) for the GC–MS/MS and UPLC–MS/MS analysis, respectively.

Matrix-matched standards were prepared differently for GC–MS/MS and UPLC–MS/MS analysis. For the GC–MS/MS analysis, a volume (1.5 mL) of the standard at appropriate concentration was evaporated under nitrogen and reconstituted in acetonitrile sample extract at a concentration of 0.5 g mL^{-1}. While for the UPLC–MS/MS analysis, a volume (1 mL) of the standard at appropriate concentration and 2 mL acetonitrile sample extract at a concentration of 0.5 g mL^{-1} were evaporated under nitrogen then reconstituted in 1 mL methanol with 0.1% ammonium acetate/water with 0.1% formic acid (1:1, v/v).

2.3. GC–MS/MS conditions

The GC–MS/MS analysis of was carried out using a Varian CP-3800 gas chromatograph coupled with a Varian 1200 triple quadrupole mass spectrometer (Varian Inc., Middelburg, The Netherlands). The analyte separation was obtained on a DB-5 30 m × 0.25 mm × 0.5 μm capillary column, protected by a deactivated guard column (2 m × 0.53 mm). Helium (purity 99.9999%) at a flow rate of 1.2 mL min^{-1} was used as the carrier gas. The column oven temperature programme was as follows: 80 °C (held for 3 min), programmed at 30 °C $min^{-1}$to 150 °C, then programmed at 10 °C min^{-1} to 300 °C (held for 10 min). Large volume injection (LVI) with programmed temperature vaporization (PTV) was used. The injection volume was 10 μL of sample extract in acetonitrile using a 100 μL syringe. The injector temperature programme was as follows: 70 °C (held for 0.5 min), programmed at 200 °C $min^{-1}$to 300 °C (held for 15 min). The injector split ratio was initially set at 100:1, the splitless mode was enabled at 0.5 min, at 4 min the split ratio was set at 50:1, and it was reduced to 20:1 at 10 min.

The mass spectrometer was operated in electron impact ionization mode (EI, 70 eV) with the filament current of 50 μA and electron multiplier voltage at 300 V above the voltage determined by automatic tuning with perfluorotribulylamine (PFTBA). The manifold ion source and transfer line temperatures were 40, 270 and 290 °C, respectively. The collision gas (argon, 99.9998% purity) was set at the collision cell pressure of 1.7 mTorr. Multiple reaction monitoring (MRM) transitions and other acquisition parameters can be found in supplementary data included with this article. Instrument control, data acquisition and evaluation was performed by using a Varian MS Workstation software, version 6.6.

2.4. UPLC–MS/MS conditions

The UPLC–MS/MS analysis was carried out using a Waters ACQUITY UPLC ultra-performance liquid chromatography system (Milford, USA) coupled with a triple quadrupole mass spectrometer (Waters Inc., Micromass, Quattro Premier XE). The nebulizer and desolvation gas was obtained from a nitrogen generator model NM30-LA (Peak Scientific, Renfrewshire, Scotland, UK). The analyte separation was achieved using a BEH C18 100 mm-× 2.1 mm × 1.7 μm UPLC column protected by a VanGuard Pre-Column 5 mm × 2.1 mm × 1.7 μm. The temperature of the column was thermostated at 40 °C. The column was eluted with the mobile phase: water with 0.1% formic acid (A) and methanol with 0.1% ammonium acetate (B) at the flow rate of 0.3 mL min^{-1} using gradient mode. Gradient was programmed to increase the amount of B from an initial content of 10–100% in 6 min, held for 1 min and returned to the initial conditions (10% B) in 1 min (from 7 to 8 min), held for 1 min. The total run time was 9 min. Sample extract volumes of 5 μL were injected into the system. The temperature of the autosampler was thermostated at 25 °C.

For the MS/MS data acquisition, the interface conditions were optimized for maximum intensity of the precursor ions: nebulizer and desolvation gas (nitrogen) flows were 100 L h^{-1} and 700 L h^{-1}, respectively, source block and desolvation temperatures were 120 °C

and 350 °C, respectively. Argon (99.9998% purity) was used as the collision gas at the pressure of 6.9×10^{-3} mbar. The optimization of multiple reaction monitoring (MRM) transitions was performed individually for each analyte on the instrument used in this work. All the compounds were analysed using positive electrospray ionization mode (ESI+) except for bentazone which was analysed in the negative electrospray ionization mode (ESI−). Multiple reaction monitoring (MRM) transitions and other acquisition parameters can be found in supplementary data included with this article. The instrument was controlled using Waters MassLynx 4.0 software and data evaluation was carried out using Waters TargetLynx software.

2.5. Sample preparation procedure

A 5 g homogenized sample was weighted into a polypropylene centrifuge tube (50 mL), internal standards (50 µL TPP at 150 µg mL^{-1} and 100 µL simazine-d10 at 87 µg mL^{-1}) were added and the sample was and extracted with 5 mL deionized water (Milli-Q) and 10 mL acetonitrile on a laboratory shaker (Heidolph Promax 2020, Schwabach, Germany) for 10 min. Then 0.5 g disodium hydrogencitrate sesquehydrate, 1 g trisodium citrate dihydrate, 4 g anhydrous magnesium sulphate, and 1 g sodium chloride were added and immediately shaken for 1 min, and then centrifuged for 2.5 min at 4500 rpm. A 6 mL aliquot of the acetonitrile supernatant was transferred to a polypropylene centrifuge tube (15 mL) containing 0.9 g anhydrous magnesium sulphate, 0.3 g PSA, and 0.3 g ChloroFiltr. The contents were vortexed for 1 min and centrifuged for 2.5 min at 4500 rpm. For the GC–MS/MS analysis, an aliquot (~0.4 mL) of the supernatant was transferred into an autosampler vial with a fixed insert. For the UPLC–MS/MS, 2 mL of the supernatant were evaporated to dryness under nitrogen, reconstituted with 1 mL 0.1% ammonium acetate in methanol/0.1% formic acid in water (1:1, v/v), and filtered using a 13 mm, 0.2 m GHP membrane into an autosampler vial. The final concentration of sample was 0.5 g mL^{-1} and 1 g mL^{-1} in the case of GC–MS/MS and UPLC–MS/MS analysis, respectively.

2.6. Validation study

The scope of the developed method comprises 25 pesticides (including 15 herbicides, nine fungicides and two herbicides). These are candidate pesticides having potential to be applied for control of the most important pests and pathogens affecting the production of the minor crops under study (i.e. field bean, lupin, sorghum, soya bean, sunflower and white mustard). Data on pesticides, matrices and conducted field experiments are detailed in Supplementary information included with this article.

The developed method was subjected to validation study using green, unripe plants of lupin, white mustard and sorghum samples (previously checked to be free of the target pesticides) in order to determine linearity, matrix induced effects, recovery, precision, limit of quantification (LOQ) and measurement uncertainty.

The calibration was carried out by internal standard method with reference to TPP and simazine-d10 which served as the internal standard for the GC–MS/MS and UPLC–MS/MS analytes, respectively. Linearity was studied by injecting standards at pesticide concentrations 0.005–1.0 µg mL^{-1} and 0.01–1.0 µg mL^{-1} in acetonitrile (GC–MS/MS) or 1 mL methanol with 0.1% ammonium acetate/water with 0.1% formic acid, 1:1, v/v (UPLC–MS/MS), and in matrix extracts of lupin, white mustard and sorghum. These concentration ranges corresponded to pesticide content in real samples between 0.01 and 2.0 mg kg^{-1} (GC–MS/MS) and 0.01 and 1.0 mg kg^{-1} (UPLC–MS/MS).

The percentage of matrix effect (%ME) was obtained for each analyte from the slopes of the calibration curves and was determined by comparing solvent and matrix-matched (lupin, white mustard and sorghum) slopes by using the formula: $\%ME = 100\% \times (1 - slope_{solvent}/slope_{matrix})$ [19].

The recoveries were studied at the three spiking levels of 0.01, 0.05 and 0.5 mg kg^{-1} ($n=6$) on lupin and additional recovery tests at 0.05 mg kg^{-1} ($n=6$) were carried out on white mustard and sorghum. Repeatability precision was expressed in terms of relative standard deviation (RSD) and calculated for each spiking level ($n=6$). The samples were spiked with the pesticides before proceeding with the extraction and the results from the recovery study were assessed for compliance with the European Union guidelines SANCO/12571/2013, according to which the average recovery should fall in the range of 70–120% with an associated RSD less or equal 20% [20].

The LOQ was defined as the lowest spiking level validated with satisfactory values of recovery (70–120%) and RSD ($\leq 20\%$).

The measurement uncertainty was estimated based on the data obtained in the validation study. The major uncertainty sources included in the uncertainty budget were the repeatability of recoveries from spiked samples and uncertainty of the average recovery calculated from rectangular distribution. The relative expanded uncertainty was calculated by using the coverage factor $k=2$ at the confidence level of 95% [21].

3. Results and discussion

3.1. GC–MS/MS and UPLC–MS/MS conditions

MRM-based data acquisition methods with two or three MS/MS transitions for each analyte were developed on both instruments in order to carry out reliable quantification and identification of the pesticides in samples. Optimization of the conditions was started by using pesticide standards with the mass spectrometer operating in full scan mode to obtain the single stage MS spectrum. Then the fragmentation pattern of the selected precursor ions was studied in product ion scan mode at different collision energies (5–50 eV). In the case of UPLC–MS/MS, the pseudo-molecular ion $[M+H]^+$ (and $[M-H]^+$ for bentazone) was present as the peak base of the MS spectrum for all the compounds except for desmedipham and phenmedipham. The $[M+H]^+$ ion was used as the precursor for the MS/MS fragmentation. In the case of desmedipham and phenmedipham, due to lack of sensitivity of $[M+H]^+$ ion, the ammonium adduct $[M+NH_4]^+$ was chosen as the precursor ion. For each target compound, the most selective and sensitive transitions were determined and used for the detection and quantification of the target analytes. To avoid chances of matrix interferences, two or three transitions were used except for internal standards (TPP and simazine-d10). The GC–MS/MS and UPLC–MS/MS acquisition conditions including precursor and product ions, collision energies and other parameters are detailed in Supplementary information included with this article.

3.2. Sample preparation and method validation

Plant pigments including chlorophyll may contribute to high background in chromatograms and occurrence of matrix effects and thereby affect identification and quantification of the compounds of interest. The pigments can thermally degrade in the injection liner or accumulate in the columns which can lead to increased maintenance of the instrument. Thus, routine analysis of pesticide residues in chlorophyll containing matrices might be difficult and the proper choice of sorbent(s) is critical to remove

co-extracted matrix interferences, while assuring good recoveries of the target analytes.

To prepare samples before chromatographic analysis, we employed the well-known and currently widely used quick, easy, cheap, effective, rugged and safe (QuEChERS) strategy to sample extraction and cleanup as this is a very flexible approach and offers many options for analysis depending on the range of pesticides and matrices being tested [22]. But we applied mechanical shaking for an extended time of 10 min (compared with 30 s of manual shaking in some other versions of the QuEChERS) [23]. Also, we lowered the sample amount (to 5 g) and added water (5 ml) before proceeding with the acetonitrile extraction to enable the extraction solvent penetrate better the plant tissues and ensure complete transfer of the analytes from naturally contaminated samples [24].

The QuEChERS technique inherently involves a dispersive-solid phase extraction (dispersive-SPE) step, for which the base sorbent is primary and secondary amine (PSA) which primarily removes fatty acids and other organic acids, sugars, and some pigments. The matrix constituents that might adversely affect the chromatographic analysis. In addition, a new type of sorbent, known as ChloroFiltr, was evaluated to help the dispersive-SPE performance and complement the PSA cleanup by reduction of the content of chlorophyll from green plant extracts [25,26].

Once the sample preparation method was selected, it was subjected to comprehensive validation study to prove its fitness for purpose through the assessment of analytical performance parameters including linearity, matrix effects, recovery, precision and estimation of measurement uncertainty.

3.3. Study of linearity and matrix effect

Generally, the linearity parameters were highly satisfactory. The calibration curves were studied by using internal standardization in solvent solutions and matrix-matched in extracts of lupin, white mustard and sorghum, and gave the coefficients of determination (R^2) of the least squared linear calibration curves >0.99. The exceptions occurred only for desmedipham, flufenacet, phenmedipham and prochloraz in the case of solvent-only calibration (GC–MS/MS), and bentazone in the case of solvent-only, lupin- and sorghum-matched calibration (UPLC–MS/MS). Detailed linearity data (equations and R^2 values) obtained by using solvent-only and matrix-matched standards can be found in Supplementary information included with this article.

The percentage of matrix effect (%ME) was calculated as the difference between the slope of the matrix-matched and solvent-only calibration curves divided by the slope of solvent-only calibration curve. %ME in the range between −20 and 20% can be considered as insignificant because such variability is close to the repeatability RSD values [27,28]. But for most of the compounds under study, much higher values of %ME were present and both enhancement as well as suppression effects could be observed (Table 1).

In the case of UPLC–MS/MS, the analyte responses produced by matrix-matched standards were nearly always substantially higher than the responses obtained for the equivalent standards in solvent, so the matrix enhancement effect occurred predominantly. Otherwise, in the case of GC–MS/MS analysis, the matrix effects occurred in a larger extent (−116 to 82%) but no consistent pattern with respect to different analytes could be observed, i.e. enhancement, suppression, or negligible matrix effects <20% (absolute value) occurred for different compounds.

The prevailing occurrence of enhancement effect in the case of UPLC–MS/MS technique was contrary to our expectation, because the ion suppression effect tend to be more common in positive electrospray mode (ESI+) [29]. A possible explanation for the phenomenon we observed might be a specific suppression of the internal standard (simazine-d10) occurring due to co-eluting matrix compounds which resulted in analytes overestimation. However, this was not a major concern due to consistency of this effect among the matrices which led to sufficiently accurate quantification, provided that matrix-matched calibration would be used.

Table 1
Matrix effects of the pesticides in the GC–MS/MS and UPLC–MS/MS analysis of lupin, white mustard and sorghum extracts, determined as $100\% \times (1 - \text{slope}_{\text{solvent}}/\text{slope}_{\text{matrix}})$.

Pesticides	Lupine		White mustard		Sorghum	
	GC	UPLC	GC	UPLC	GC	UPLC
Acetochlor	−76	43	−88	53	−72	43
Azoxystrobin	24	42	12	51	20	43
Bentazone	–	62	–	57	–	64
Boscalid	2	46	4	53	5	43
Clomazone	−88	38	−44	48	−59	32
Cyproconazole_1	−29	38	−19	43	−19	37
Cyproconazole_2	–	43	–	51	–	40
Deltamethrin 1	68	–	70	–	56	–
Deltamethrin 2	20	–	30	–	9	–
Desmedipham	75	39	77	47	73	38
Dimethenamid-P	−70	48	−62	55	−70	46
Dimoxystrobin	−19	39	−15	49	−15	39
Fluazifop-P-butyl	−22	1	−16	38	−16	20
Flufenacet	44	38	−48	49	37	41
Linuron	–	38	–	50	–	38
Metamitron	–	52	–	59	–	50
Metconazole	−31	39	−25	47	−28	35
Metolachlor-S	−45	42	−48	52	−48	61
Pendimethalin	−39	−91	−39	−5	−33	−50
Phenmedipham	79	37	82	46	77	34
Picoxystrobin	−26	30	−20	46	−20	35
Prochloraz	−11	27	−116	41	−2	28
Propiconazole 1	−40	41	−25	53	−30	41
Propiconazole 2	−45	–	−26	–	−36	–
Prosulfocarb	–	23	–	45	–	28
Quizalofop-P-ethyl	−4	−8	−4	31	−4	8
Tebuconazole	−23	40	−23	49	−14	38
Thiacloprid	–	46	–	51	–	40

By using either techniques (GC–MS/MS or UPLC–MS/MS), the matrix effects were relatively consistent among studied matrices for the majority of the pesticides, so application of matrix-matched standards in any matrix would give acceptably accurate results for quantification of pesticide residues in other matrices, as will be presented further in this section. The exceptions, in the case of GC–MS/MS technique, were flufenacet and prochloraz. Flufenacet exhibited positive effect in lupin and sorghum but negative in white mustard whereas prochloraz exhibited considerable stronger negative matrix effect in white mustard (−116%) than in lupin (−11%) and sorghum (−2%). In the case of UPLC–MS/MS technique, inconsistencies in the occurrence of matrix effects were observed for fluazifop-P-butyl, quizalofop-P-ethyl and pendimethalin. In the case of fluazifop-P-butyl and quizalofop-P-ethyl, stronger positive matrix effects was observed in white mustard than in lupin and sorghum. In contrast, in the case of pendimethalin, stronger negative matrix effects were observed in lupin (−91%) and sorghum (−50%) than in white mustard (−5%). Whereas negligible matrix effects, with absolute values <20% in all matrices, were only observed in the case of boscalid, dimoxystrobin and quizalofop-P-ethyl when using the GC–MS/MS technique.

Because of common occurrence of matrix effects in analysis of pesticide residues in chlorophyll containing matrices under this study, the use of matrix-matched calibration was necessary as a practical approach to compensate for matrix effects and achieve

Table 2
Average recoveries, RSDs and expanded uncertainties U, % ($k=2$, confidence level 95%) in the GC–MS/MS and UPLC-MS/MS analysis of pesticides in green lupin.

acceptably accurate quantificative results in both GC–MS/MS and UPLC–MS/MS analyses.

3.4. Recovery study and estimation of measurement uncertainty

For the purpose of evaluating the accuracy (trueness and precision) of the proposed method, a recovery study was carried out by spiking lupin, white mustard and sorghum samples with the target pesticides. The recovery and repeatability RSD values were determined by the analysis of six replicate spiked samples at each level (0.01, 0.05 and 0.5 mg kg^{-1}). The results for calculation of recoveries were obtained by using matrix-matched standards prepared in lupin extracts.

As can be seen in Table 2, most of the compounds presented satisfactory recoveries from lupin in the range between 70% and 120% with RSD values $\leq 20\%$, i.e. compliant with the EU criteria of SANCO/12571/2013 [20]. For a limited number of compounds, especially at the lowest spiking level of 0.01 mg kg^{-1}, the recovery and RSD results were slightly outside the acceptance criteria. The most problematic compound was bentazone which generally did not present satisfactory results. But the overall recoveries of the target pesticides at the three spiking levels of 0.01, 0.05 and 0.5 mg kg^{-1} fell in the range between 68 and 120% (98% on average) and 72–104% (93% on average) with RSD values between 2 and 19% (7% on average) and 3–16% (6% on average) by GC–MS/MS and UPLC–MS/MS techniques, respectively.

Additional recovery evaluation was carried out on white mustard and sorghum (spiking level 0.05 mg kg^{-1}, $n=6$). In this experiment, the results for calculation of recoveries were also obtained by using matrix-matched standards prepared in lupin extracts. Generally, the results were very satisfactory and fulfilled the recovery and precision requirements of SANCO/12571/2013 (Table 3). Flufenacet and

Thiacloprid	–	94 (2)	–	95 (1)

prochloraz were the exceptions, which presented lower recoveries in white mustard in the case of GC–MS/MS analysis and so was bentazone which presented lower recoveries in white mustard and sorghum in the case of UPLC–MS/MS analysis. These phemomena were likely caused by the occurrence of strong matrix effects, as it was discussed previously in this section. Matrix-matching in the same matrix will be needed to obtain more accurate quantification for these problematic compounds.

The limit of quantification (LOQ) was determined as the lowest spiking level at which the validation criteria were satisfied with average recovery 70–120% and RSD $\leq$20%, and it was 0.01 mg kg^{-1} (except for bentazone and metamitron).

The data derived from the validation study (recovery and RSD) were used to estimate the measurement uncertainty associated with the analytical results when using the developed method to analyse real samples. Precision was identified as the main contribution to the uncertainty, but the uncertainty associated with the recovery, as calculated from rectangular distribution, was also included in the uncertainty budget to avoid underestimation of the total uncertainty [21]. Taking into account the overall recovery and RSD data (Table 2), the calculated measurement uncertainty values ranged from 9% to 39% (17% on average) and from 6% to 36% (13% on average), by using GC–MS/MS and UPLC–MS/MS techniques, respectively (coverage factor k=2, confidence level 95%). These values were lower than a default value of $\pm$50% recommended by the SANCO/12571/2013 document, demonstrating fitness for purpose of the developed and validated method.

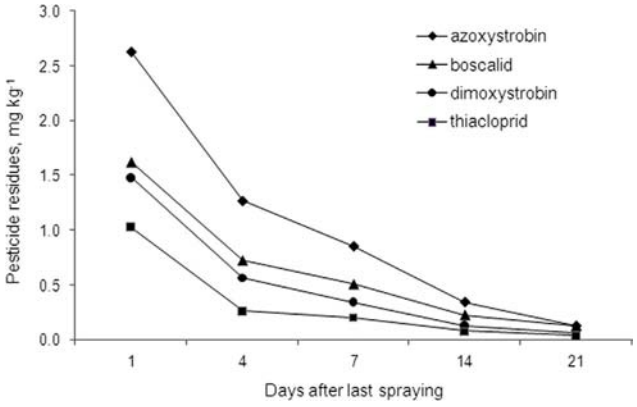

Fig. 1. Dissipation patterns of pesticides after application on lupin.

It must be highlighted that most of the pesticides under this study could be analysed by either techniques, GC–MS/MS or UPLC–MS/MS, therefore the one to offer better analytical performance parameters for the particular pesticide and matrix combination was used when analysing real samples.

3.5. Application to real samples

In this work, we focused on the study of dissipation rates of selected pesticides after application to lupin, white mustard, soya bean, sunflower and field bean. These plants were classified by the Polish Ministry of Agriculture and Rural Development as minor crops, for which there are limited options for protection against pests and pathogens. Our studies entailed the use of candidate pesticides having potential to be applied for the protection of these minor crops in field trials, followed by laboratory analysis for pesticide residues. Detailed data on tests that we have been conducted in experimental plots can be found in Supplementary information included with this article.

The aim of our work was to increase the knowledge in the residue behaviour and dissipation study of the pesticides, which have recently been proposed for the use in comprehensive protection of selected minor crops by means of extension of authorization of pesticides which are already registered for use in Poland on other crops (i.e. major crops).

The dissipation patterns of the pesticides were different probably due to the different chemical structures of the compounds, applied doses and preharvest times but the terminal pesticide residues, i.e. determined in the samples collected in the last sampling time, were always below the maximum residue levels (MRLs) [30]. Pesticide MRLs apply to edible plant parts but in this work unripe green plants were analysed in order to determine the dissipation patterns of the target pesticides and reassure preharvest intervals on the crops under study. Effectively, there was no need to analyse the final crops (seeds) because the target pesticides disappeared on the plants before harvest, and in most cases they fell below the method LOQ in the samples collected in the last sampling time.

We can conclude that the proposed pesticide application schedules were correct and the data concerning the pesticide residue dissipation suggest that the proposed pesticides can be safely used on the studied minor crops, without the risk of the presence of problematic residues, provided that good agricultural practices have been followed. Examples of pesticide dissipation

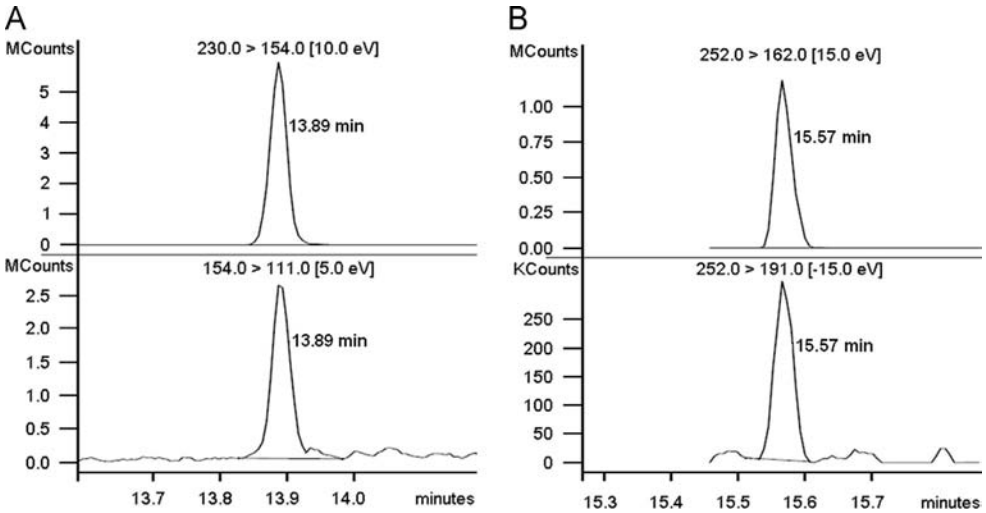

Fig. 2. GC–MS/MS chromatogrrasams of a sample of lupin containing residues of (A) dimethenamid-P (0.016 mg kg^{-1}), and (B) pendimethalin (0.028 mg kg^{-1}). The sample was collected 32 days after spraying with Wing P 462.5 EC.

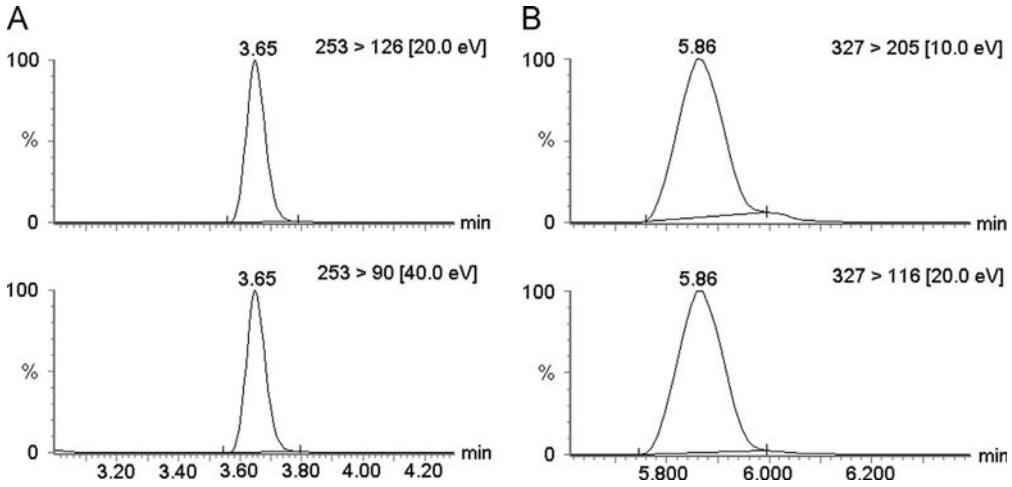

Fig. 3. UPLC–MS/MS chromatograms of (A) a sample of field bean containing thiacloprid (0.057 mg kg^{-1}, 21 days after spraying with Proteus 110 OD), and (B) a sample of sunflower containing dimoxystrobin (0.236 mg kg^{-1}, 14 days after spraying with Pictor 400 SC).

over time plots, showing concentration versus days after the last spraying, for different pesticides applied to lupin in a field experiment are shown in Fig. 1. Whereas, Fig. 2 shows GC–MS/MS chromatograms of a sample of lupin containing residues of dimethenamid-P (0.016 mg kg^{-1}) and pendimethalin (0.028 mg kg^{-1}) and Fig. 3 shows UPLC–MS/MS chromatograms of thiacloprid in field bean (0.057 mg kg^{-1}) and dimoxystrobin in sunflower (0.236 mg kg^{-1}).

The results obtained in this work will aid in the establishment of safe and proper use of pesticides for extension of authorization on minor crops in Poland.

4. Conclusions

Matrices high in chlorophyll present a special difficulty in pesticide residue analysis owing to interferences which can negatively affect the method performance characteristics and create an analytical challenge. As a solution to these problems, we investigated the use of a new QuEChERS-based method of sample preparation and report it for the first time. We used a new sorbent, known as ChloroFiltr, which served for selective reduction of chlorophyll from green plant extracts, and was used in combination with PSA to keep the sample cleanup as straightforward as possible in the dispersive-SPE mode.

The final analysis was carried out by using concurrent determinations by both GC–MS/MS and UPLC–MS/MS, and in the case of both techniques, the importance of using matrix-matched calibration was demonstrated as being of key importance for achieving accurate results. An important conclusion is also that relative consistency of matrix effects in both GC–MS/MS and UPLC–MS/MS analysis for a given pesticide between different matrices, makes it possible to quantify pesticide residues in different matrices using only one matrix-matched calibration curve.

After validation, the developed method was successfully applied to study the dissipation patterns of pesticide residues after application on crops belonging the group of minor crops (lupin, white mustard, soya bean, sunflower and field bean).

Stripping voltammetry

ABSTRACT

The behaviour of protonated ractopamine ($RacH^+$) at an array of micro-interfaces between two immiscible electrolyte solutions (micro-ITIES) was investigated via cyclic voltammetry (CV) and linear sweep stripping voltammetry (LSSV). The micro-ITIES array was formed at silicon membranes containing 30 pores of radius 11.09 ± 0.12 μm and pore centre-to-centre separation of 18.4 ± 2.1 times the pore radius. CV shows that $RacH^+$ transferred across the water | 1,6-dichlorohexane μITIES array at a very positive applied potential, close to the upper limit of the potential window. Nevertheless, CV was used in the estimation of some of the drug's thermodynamic parameters, such as the formal transfer potential and the Gibbs transfer energy. LSSV was implemented by pre-concentration of the drug, into the organic phase, followed by voltammetric detection, based on the back-transfer of $RacH^+$ from the organic to aqueous phase. Under optimised pre-concentration and detection conditions, a limit of detection of 0.1 μM was achieved. In addition, the impact of substances such as sugar, ascorbic acid, metal ions, amino acid and urea on $RacH^+$ detection was assessed. The detection of $RacH^+$ in artificial serum indicated that the presence of serum protein interferes in the detection signal, so that sample deproteinisation is required for feasible bioanalytical applications.

1. Introduction

Ion transfer across the interface between two immiscible electrolyte solutions (ITIES) [1–4] has received increasing interest in the field of electrochemistry, liquid | liquid extraction and membrane transport. Electrochemistry at liquid | liquid interfaces has moved from the transfer of model ions such as tetraalkylammonium ions to the detection of molecules of biological importance such as proteins, peptides, amino acids, drugs, neurotransmitters, food additives and DNA [5]. Thus it plays a potentially important role in new bioanalytical methods.

Ractopamine (Rac) (Fig. 1(a)) is a phenyl β-ethanolamine, with β-adrenergic agonist properties [6–9]. It is primarily used as a therapeutic drug for treatment of pulmonary diseases such as asthma in human and veterinary medicine [6,7]. Unfortunately, this substance is also illegally applied in the livestock industry as a nutrient repartitioning agent. Research shows that β-agonists divert fat deposition to the production of muscle tissues by increasing nitrogen retention, protein synthesis and lipolysis [6,7,9–11]. It also improves growth rate and feed conversion when fed to livestock (such as calves, poultry etc.) [8,9,12]. Recently, veterinary drug residues have become a public food safety concern where ractopamine-treated animals may pose adverse effects on human health, especially in the cardiovascular and central nervous systems [6,7,9,12,13]. Thus, it is banned in many countries, including within the European Union and China, although it is approved by the United States' Food and Drug Administration (U.S. FDA) [12,14–16]. As a result, rapid, simple and sensitive analytical methods for the detection of ractopamine residues are required.

To date, various analytical methods have been reported for the detection of ractopamine, such as immunoassays [9,10,17], electrochemical methods [6,7,13,16], gas chromatography–mass spectrometry [11], liquid chromatography tandem mass spectrometry [12,18] and high performance liquid chromatography [8,14,15]. Electrochemical methods offer the advantages of low instrumental cost and fast analysis, and thus may be the preferred methods in ractopamine detection [7]. Despite the fact that many electrochemical methods have been developed, those studies focused on solid | liquid interfaces, using primarily cyclic voltammetry (CV) [6,7,16]. The two phenolic groups in ractopamine are easily oxidised [6,7,13]. Differential pulse voltammetry (DPV) has also been employed for the detection of ractopamine [6,7,13].

To the best of our knowledge, no studies have been reported on the electrochemical detection of ionised ractopamine based on transfer across the ITIES. Thus, this study opens up the possibilities

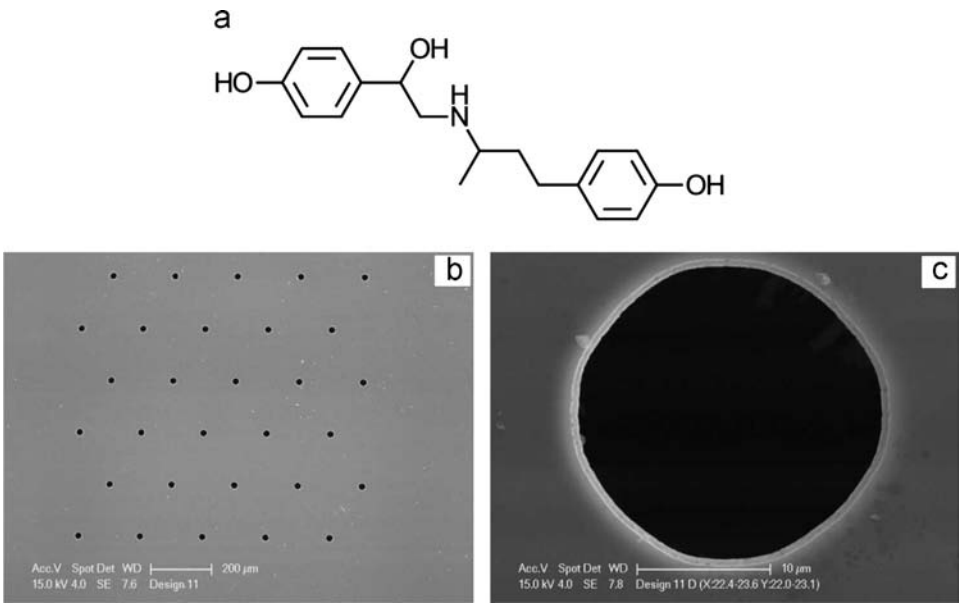

Fig. 1. (a) Molecular structure of ractopamine (b) SEM image of the full micropore array silicon membrane, and (c) SEM of a single micropore within the array.

for the detection of ractopamine based on charge transfer across micro-ITIES. However, the detection of other drugs at the ITIES via various electrochemical methods has been reported in the literature, namely the anticancer drug daunorubicin at a microporous polyethylene terephthalate (PET) membrane-supported ITIES [19], catamphiphilic drugs at a solvent polymeric membrane [20], and β-blocker drugs (propranolol, timolol and sotalol) at a microporous silicon membrane-supported ITIES [21]. Besides analytical studies, the ability of the ITIES to mimic the drug transfer across biological membranes has offered insight into mechanisms of drug action [19]. Voltammetry at the ITIES has been used to investigate the transfer characteristics of charged drug molecules, for example, the Galvani potential difference ($\Delta_o^w\varnothing$) for the ion transfer and the Gibbs energy of transfer, which is directly related [22]. Previous studies by Girault and co-workers [23,24] have shown that the ITIES is a suitable platform for the determination of the partition coefficient of the ionised species, which in turn defines the drug's lipophilicity in biological systems [19,20,22].

Direct drug detection in physiological matrices, such as blood and blood-derived samples, is important because it offers information regarding circulating levels. Yet, this can be hindered due to drug–protein binding [25]. The drug–protein interaction in blood plays an important role in determining drug transportation, absorption, distribution, metabolism and excretion [26–28]. Serum albumins are present at the highest abundance in blood (ca. 60% of the total albumin) [29,30], and these proteins exhibit high affinity towards drugs [26–28,31]. In addition, the pharmacological activity of drugs relates to their free concentration in blood [25]. The measurement of drug–protein interactions has seen the emergence of a number of novel label-free strategies [32]. In this study, albumin from bovine serum (BSA) is employed due to the fact that human and bovine serum albumins are homologous proteins [29,33,34]. BSA is a highly water-soluble globular protein, which has a molar mass of 69,000 amu and a hydrodynamic radius of ca. 3.25 nm [25,35]. BSA also has a low isoelectric point (pI of 5.4) and high negative net charge at neutral pH [36].

In this report, emphasis is placed on the electrochemical behaviour of protonated ractopamine ($RacH^+$) at the micro-ITIES array. Quantitative methods that involve the detection of $RacH^+$ by simple ion transfer at the water | 1,6-dichlorohexane (DCH) micro-interface array are presented, using CV and linear sweep stripping voltammetry (LSSV). Stripping analysis at micro-liquid | liquid interface arrays is appropriate for analyte detection in media such as biological fluids, soil extracts and water [37], thus this technique is examined in this study. The thermodynamic parameters for the transfer of ionisable ractopamine are discussed. In addition to the analytical parameters, the influence of the interfering substances, including serum protein, towards $RacH^+$ detection are also reported.

2. Materials and methods

2.1. Reagents

All reagents used were purchased from Sigma-Aldrich Pty. Ltd., Australia and used without further purification, unless stated otherwise. D-Glucose and sodium chloride (NaCl) were purchased from Ajax Finechem Pty. Ltd., Australia, L-ascorbic acid and potassium phosphate monobasic (KH_2PO_4) from BDH Laboratory Supplies, Australia, and sodium sulfate (Na_2SO_4) from Chem-Supply Pty. Ltd, Australia.

The aqueous phase solution of 10 mM lithium chloride (LiCl) was prepared in ultrapure water (resistivity of 18 MΩ cm) from a Milli-Q water purification system (Millipore Pty. Ltd., North Ryde, NSW, Australia). The organic electrolyte salt was prepared by metathesis of bis(triphenylphosphoranylidene)ammonium chloride (BTPPACl) and potassium tetrakis(4-chlorophenyl)borate (KTPBCl). The organic phase was mechanically stabilized as a polymer gel [38–41] and was composed of the supporting electrolyte (10 mM BTPPATPBCl) and low molecular weight poly(vinylchloride) (PVC) (10% w/v), dissolved in 1,6-dichlorohexane. Prior to the experiments, both the aqueous and organic phase solvents were mutually pre-saturated. The organic reference solution consisted of 10 mM BTPPACl dissolved in 10 mM LiCl (aqueous). Ractopamine hydrochloride and tetrapropylammonium chloride (TPrACl) served as the drug and model analyte species studied, respectively. A stock solution of TPrACl was prepared in 10 mM LiCl while the stock solution of ractopamine hydrochloride was prepared in methanol (MeOH) due to its low solubility in water [15].

In the interfering substances study, the interferents were prepared in 1 mM PBS solution as the supporting electrolyte, which contained 1 mM phosphate buffer, 0.27 mM potassium chloride (KCl) and 13.7 mM NaCl. D-Glucose, L-ascorbic acid, KCl, NaCl, Na_2SO_4, glycine and urea were the interfering substances studied, and the

concentration of each of these was fixed at 5.0 mM. The effect of artificial serum matrix [25,42,43] on the detection of $RacH^+$ was also investigated. The artificial serum used was composed of 1.5 mM KCl, 5.0 mM calcium chloride ($CaCl_2$), 1.6 mM magnesium chloride ($MgCl_2$), 4.7 mM D-glucose, 1.0 mM sodium phosphate monobasic (NaH_2PO_4), 1.0 mM KH_2PO_4, 2.5 mM urea and 0.6 mM bovine serum albumin, prepared in ultrapure water.

2.2. Preparation of micro-interface arrays

The micropore arrays used for micro-ITIES patterning were fabricated in 100 μm thick silicon membrane by lithographic patterning and wet and dry silicon etching methods at Tyndall National Institute, University College Cork, Cork, Ireland [41]. The micropores are depicted in Fig. 1(b) and (c), with 11.09 ± 0.12 μm radius, r_a, 30 pores in a hexagonal close-packed arrangement, and with pore centre-to-centre separation, r_c, of 18.4 ± 2.1 times the pore radius, r_a (i.e. $r_c = 18.4 r_a$). The silicon chip (5 mm × 5 mm) was sealed onto the lower orifice of a cylindrical glass tube ($d_{inner} = 2.5$ mm, $d_{outer} = 4.0$ mm) using silicone rubber sealant (Selleys, Australia and New Zealand) and allowed to cure for 72 h before use. The membrane was cleaned with acetone and dried in air before and after each electrochemical experiment. All the experiments were conducted at room temperature (20 °C).

2.3. Experimental procedure at the micro-ITIES array

The electrochemical techniques were performed using an Autolab PGSTAT 302N (Metrohm, The Netherlands) together with the Nova 1.7 or Nova 1.8 software supplied with the instrument. The electrochemical cell was housed in a Faraday cage for the duration of the experiment to minimize electrical noise. A two-electrode electrochemical cell was employed in this study since the *IR* drop effect at micro-ITIES system is not too high as compared to macro-ITIES system [44]. Both Ag|AgCl electrodes served as reference and counter electrodes in either phase. The applied potential, *E*, is defined as the potential difference between the two electrodes, with positive current due to the transfer of cations from the aqueous to the organic phase [20].

The borosilicate glass tube with membrane sealed to one end with silicone sealant contained 100 μL of the gellified-organic phase and 200 μL of the organic reference solution. This was then immersed in 6 mL of the aqueous phase solution in a 10 mL glass beaker. The electrochemical cells employed in this study can be schematically summarized as follows:

Ag|AgCl|*x* M ractopamine HCl + 10 mM $LiCl_W$||10 mM $BTPPATPBCl_{DCH}$|10 mM BTPPACl in 10 mM $LiCl_W$|AgCl|Ag	Cell 1
Ag|AgCl|0.1 mM ractopamineHCl + 5 mM interfering substance + 10 mM $LiCl_W$||10 mM $BTPPATPBCl_{DCH}$|10 mM BTPPACl in 10 mM $LiCl_W$|AgCl|Ag	Cell 2
Ag|AgCl|*x* M ractopamine HCl + artificial $serum_W$||10 mM $BTPPATPBCl_{DCH}$|10 mM BTPPACl in 10 mM $LiCl_W$|AgCl|Ag	Cell 3

where *x* is the concentration of ractopamine in the aqueous phase. In every electrochemical cell, $TPrA^+$ was spiked into the aqueous phase after the final $RacH^+$ or interferent injection, as a control of the potential axis.

Prior to the injection of analyte into the aqueous phase with a micropipette to achieve the required concentration, a background CV at 5 mV s^{-1} was recorded over a wide potential range so as to establish the limits of the available potential window. A quiet time of 5 s at the initial potential of each scan was implemented. In LSSV, the parameters pre-concentration potential, pre-concentration time and sweep rate were explored to determine the optimum values, and these were implemented in subsequent experiments.

3. Results and discussion

3.1. CV at the micro-ITIES array

CV profiles of 20 to 100 μM $RacH^+$ at the gelled micro-ITIES arrays (Cell 1) are presented in Fig. 2(a) and (b), in the form of experimental data and background-subtracted voltammograms, respectively. The p*K*a of the amine group in ractopamine is 9.4 [8], so that in the aqueous phase used in this work, 10 mM LiCl (pH ~ 6) [19,21], the drug is cationic. The CVs show that $RacH^+$ ions, which are initially present in the aqueous phase, are transferred into the gelled organic phase under potential control, on the forward CV sweep. These ions are transferred back from the organic into the aqueous phase, during the reverse scan.

The shape and magnitude of the voltammetric response are highly dependent on factors such as the diffusion regime shape, the position of the ITIES within the pores, the properties of the electrolyte solutions and of the transferring ion species, and the magnitude of the diffusion zone extension (δ) [45,46]. The interfaces employed here were inlaid so that each pore was filled with the organic electrolyte solution and the interface was at the aqueous side of the membrane [45]. Generally, for an inlaid micro-ITIES array, steady-state voltammograms are obtained in the forward CV sweep, indicating establishment of radial diffusion fields, while peak-shaped voltammograms are obtained on the reverse scans, attributed to linear diffusion control.

However, in this study, the CVs on the forward scan show that the foot of the ion transfer wave was at a very positive applied potential difference (0.8 V), close to the upper limit of potential window (Fig. 2(a)). The current increased steadily with applied potential up to the switching potential, so that a fully-develop stead-state wave shape was not obtained. On the reverse scan, a peak-shaped feature was observed, due to the transfer of $RacH^+$ ions which had been retained within the micropores. The incorporation of PVC in the organic phase increases the viscosity, and hence slows down rate of diffusion of ions in the organogel [45], so that the diffusion coefficient of a target analyte in the gelled organic phase may be ca. nine-times lower than in the aqueous phase [45].

The background-subtracted currents on the forward and reverse scans (Fig. 2(b)) increased linearly with $RacH^+$ concentration in the aqueous phase, with the maximum currents chosen to construct the calibration graphs of the forward scan (Fig. 2(c)). Theoretically, the current of the forward scan can be modelled by the Saito equation [47,48] if a steady-state current (radial diffusion control) had been achieved. At the ITIES, the potential window is restricted by the transfer of background electrolyte ions [5]. However, in this study it was found that $RacH^+$ transfer occurred at a potential just below the transfer of the background electrolytes and steady-state current for $RacH^+$ transfer was not achieved.

Following the final $RacH^+$ experiment, 100 μM $TPrA^+$ was spiked into the aqueous phase (Fig. 2(a) inset—top, and (b) inset) as a model ion and a potential axis reference ion [19,49]. The resulting CV showed a steady-state behaviour on the forward scan, while the reverse scan demonstrated a peak shape, in agreement with previous experiments and computer simulations [45]. This micro-ITIES array thus displayed the expected mass-transport behaviour. The foot of the ion transfer wave, and the half-wave potential were observed at approximately 0.45 and 0.52 V,

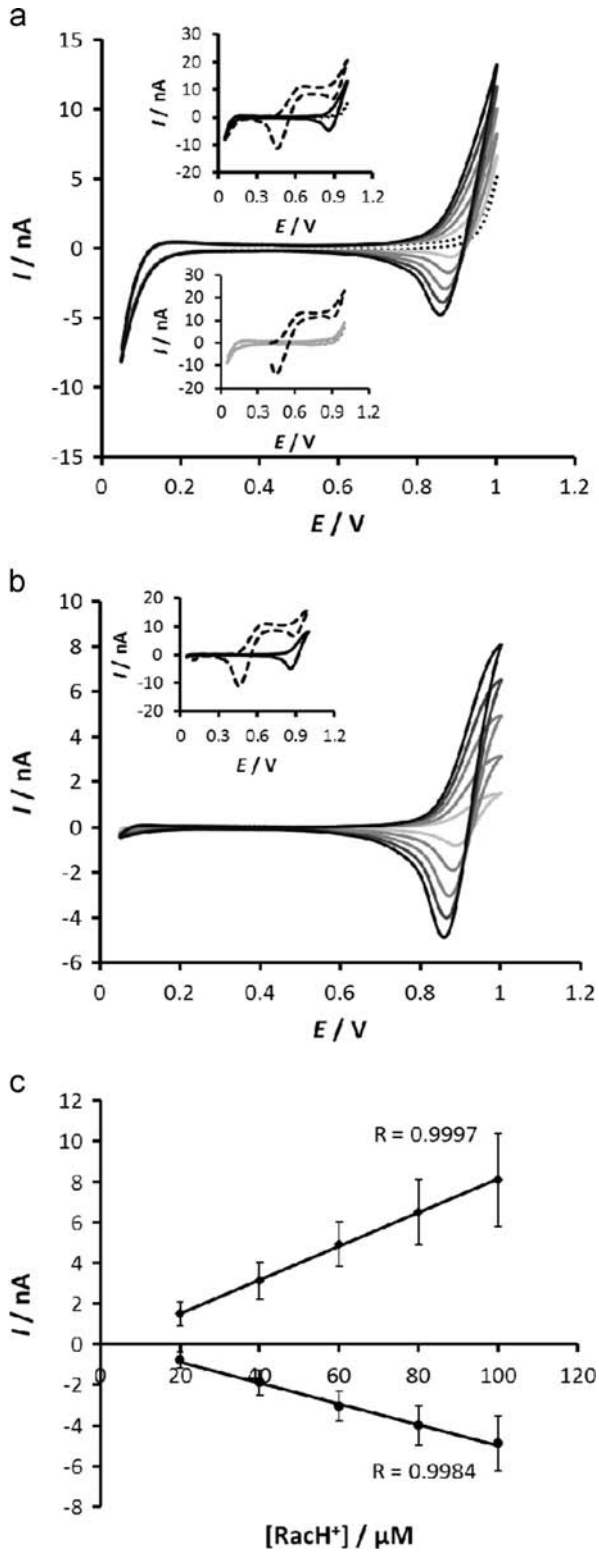

Fig. 2. Cyclic voltammograms of 20 (light gray) to 100 μM (black) $RacH^+$ transfer, in increment of 20 μM (a) and its corresponding background-subtracted CV (b) at 5 mV s^{-1} sweep rate. Inset (a—upper) and (b): voltammograms of blank (dotted line) and 100 μM $RacH^+$ with (dashed line) and without (solid black line) the addition of $TPrA^+$. Inset (a—lower) is a control experiment with 100 μM MeOH (solid gray line) added to the aqueous phase. (c) The corresponding calibration curve of the maximum currents (forward scan) and peak currents (reverse scan) against $RacH^+$ concentrations.

respectively, in agreement with previous studies [25,48]. The formula to calculate the steady-state current (limiting current) for ion transferring from the aqueous to the organic phase is given by the Saito equation modified for the number of micropores in the membrane [47]:

$$I_{ss} = 4zFDCr_aN_p \quad (1)$$

where I_{ss} is the steady-state current, z, D and C are the charge, diffusion coefficient and bulk concentration, of the transferring ions in the aqueous phase, correspondingly. F is the Faraday constant (96,487 C mol^{-1}) and N_p is the number of micropores. The steady-state experimental current was within ca. 10% of the current obtained from Eq. (1). This may indicate that the interfaces formed at the micropore mouths were not flat, in turn enhancing the radial diffusion to the interfaces so that the current is increased. The steady-state current for radial diffusion to an array of hemispherical micro-ITIES is given by [50,51]:

$$I_{ss} = 2\pi zFDCr_aN_p \quad (2)$$

However, in this case the experimental current was ca. 30% lower than that calculated from Eq. (2). This indicates that the μITIES were closest to inlaid microinterface behaviour.

There is a lack of information in the literature on the diffusion coefficient of ractopamine. Attempts to determine this from the oxidation response at glassy carbon electrode were not successful, due to the problems associated with fouling of the surface, probably by the adsorption of either the drug or its oxidation products. A similar fouling problem was reported previously for salbutamol oxidation at glassy carbon electrodes [52]. Therefore, an assumption of the diffusion coefficient value was made based on the published data for salbutamol sulfate ($D = 3.3 \times 10^{-6}$ cm^2 s^{-1}) [53], since ractopamine and salbutamol are a group of β-adrenergic agonist which possess similar chemical structures and functions [16]. Use of this value in Eq. (1) produced a steady-state current for the transfer of $RacH^+$ across microITIES array that was lower than the maximum current in the forward scan, suggesting the need for an accurate diffusion coefficient value.

A final control experiment was the impact of methanol on the CV, because the ractopamine stock solution was prepared in MeOH (see lower inset in Fig. 2(a)). The same injection volume used to prepare 20 to100 μM of analyte was applied. It was observed that the addition of MeOH had no observable effect on the analyte CV.

3.2. Thermodynamic parameters of $RacH^+$ transfer at the water | DCH interface

A number of thermodynamic parameters for the drug transfer were determined from the CV data. These are listed in Table 1.

The value of the formal transfer potential of an ionised drug is obtained by transposing the measured experimental value to the Galvani potential scale, as given by the following expression [54–58]:

$$E_{1/2}\,(\text{drug}) - \Delta_o^w\varnothing^{0'}(\text{drug}) = E_{1/2}\,(\text{TPrA}^+) - \Delta_o^w\varnothing^{0'}(\text{TPrA}^+) \quad (3)$$

where $\Delta_o^w\varnothing^{0'}(\text{TPrA}^+)$ is the formal transfer potential of the $TPrA^+$ ion. $E_{1/2}$ (drug) and $E_{1/2}$ ($TPrA^+$) are the experimental half-wave potentials of the drug and $TPrA^+$ transfer, respectively. In this study, a value of −0.086 V was used for $\Delta_o^w\varnothing^{0'}(\text{TPrA}^+)$ [59]. $TPrA^+$ ion was selected as a model ion since the transfer potential differs from that of $RacH^+$ and there is no mutual interference.

The Gibbs energy of transfer is directly related to the formal transfer potential of the ion transfer [60]. The ability to measure this value depends on the condition that the transferring ion has a lower magnitude of the Gibbs transfer energy than the ions of the supporting electrolytes [58,61]. However, for $RacH^+$, the ion of interest transfers at the upper limit of the potential window so that the experimental measurement of the half-wave potential ($E_{1/2}$ (drug)) was not possible. A similar observation was reported

Table 1
Thermodynamic data for the transfer of cationic β-agonist drug, protonated ractopamine ($RacH^+$) at the micro-water | DCH interface arrays.

Parameter	Value
p*K*a	9.4[a]
$\Delta_0^w\varnothing^{0'}$	~0.29 V (in DCH)
$\Delta G_{tr}^{0',w\to DCH}$	27.88 kJ mol^{-1}
log P_{DCH}^0 (ionised)	−4.89
log P_{n-oct}^0	2.4[b]

[a]Data obtained from Ref. [8].

by Osborne and Girault [58] for the transfer of ammonium ions across a water | 1,2-dichloroethane (DCE) interface and by Cacote et al. [62] for the direct transfer of Ag^+ ions across a water | DCE interface. A method to determine the $E_{1/2}$ of the species limiting the potential window was developed by Shao et al. [61], which was based on a set of simulated CVs in which the switching potential is set prior to the forward peak potential. The half-wave potential of the species limiting the potential window was then determined from the resultant working curve, which was a plot of I_{eos}/I_{rp} versus $E_{rp}-E_{1/2}$, where I_{eos} and I_{rp} are the current at the end of the forward scan and the return peak current, respectively, E_{rp} is the return peak potential and $E_{1/2}$ is the half-wave potential. However, the published working curve applied was developed for an ITIES subjected to linear diffusion on both forward and reverse transfer processes and hence is not applicable to the present situation. Our approach was to compare the shape of the experimental CV for $RacH^+$ transfer to that for $TPrA^+$ transfer recorded with different switching potentials [63,64]. Finding a shape for the model ion transfer process which match to that for $RacH^+$, by visual comparison, allowed the $E_{1/2}$ for the ionised drug transfer to be determined by assuming that similar current ratios and potential ratios apply to both ions (i.e. that they have similar transfer kinetics and are not distorted by experimental variables such as cell resistance and capacitance). The $E_{1/2}$ of the $RacH^+$ ion was estimated in this way to be 0.9 V. Taking into account the assumption that Walden's rule ($D^o/D^w=\eta^w/\eta^o$) applies to the transfers of $RacH^+$ and $TPrA^+$, the Galvani transfer potential of $RacH^+$ is obtained using Eq. (3) to be 0.29 V (Table 1) [58].

The formal Gibbs energy of transfer of any ionic species is expressed as [24,44,58]:

$$\Delta_o^w\varnothing^{0'}=\frac{\Delta G_{tr}^{0',w\to o}}{zF} \quad (4)$$

where $\Delta G_{tr}^{0',w\to o}$ is the formal Gibbs transfer energy of ion from the aqueous (w) to the organic (o) phase. The calculated value is presented in Table 1. The formal Gibbs energy of transfer of $RacH^+$ was 27.9 kJ mol^{-1} across a water | DCH interface. Values of 18.3 and 7.7 kJ mol^{-1} have been reported previously for protonated pyridine (PyH^+) transfer across a water | 2-nitrophenyl octyl ether (NPOE) interface, and protonated quinidine (QH^+) transfer across a water | DCE interface, respectively.

Another important thermodynamic parameter is the partition coefficient (log P) of a given solute between two immiscible solvents. This is a measurement of its relative affinity for the two phases, and is related to the free energy of transfer of the solute between the two solvents [24,65]. The measurement of the ionised drug partition coefficient is vital since most drugs (>70%) are ionisable under physiological conditions [44]. In this case, the partition coefficient of $RacH^+$ between water and DCH is obtained from Eq. (5) [19,44,60]:

$$\log P_{DCH}^0(\text{ionised})=-\frac{\Delta G_{tr}^{0',w\to o}}{2.3RT} \quad (5)$$

where R is the gas constant (R=8.31 J K^{-1} mol^{-1}) and T is the temperature in kelvin. The partition coefficient of the $RacH^+$ was −4.9 (Table 1), while the value for $DNRH^+$ was −8.0 [19], both for the water | DCH system. Comparison of the partition coefficients of the neutral form of both drugs in *n*-octanol–water systems shows that the log P_{n-oct}^0 value for daunorubicin was higher than that for ractopamine, meaning that ractopamine is more hydrophilic, since a lower partition coefficient value indicates a more hydrophilic property [19]. A review of the electrochemical investigations made on the transfer of ionisable drugs at ITIES to determine their partition coefficients employing voltammetric methods for water | nitrobenzene (NB), water | NPOE, and water | DCE systems does not include any data for the water | DCH system [22], as this has been introduced only relatively recently [59].

3.3. Optimisation of the LSSV parameters for the detection of $RacH^+$

In order to detect lower concentrations, LSSV was employed, as this entails a pre-concentration step that enhances sensitivity. In the pre-concentration step, $RacH^+$ was extracted from the aqueous to the organogel phase under potential control. Then, the pre-concentrated analyte was stripped out of the organogel using a voltammetric scan [21,37]. The pre-concentration step is important in LSSV as it enables the detection of lower concentrations relative to CV. This stripping analysis method is reported to offer greater sensitivity and lower detection limits, down to nanomolar and parts per billion levels [37]. As a result, the optimisation of LSSV parameters, namely the sweep rate, the pre-concentration potential and the pre-concentration time, was explored, employing Cell 1. Voltammetric scans were conducted in the negative direction, from 1.0 to 0.4 V.

To assess the impact of sweep rate on the results (figure not shown), the sweep rate value was varied between 5 and 100 mV s^{-1}, using 100 μM $RacH^+$. The pre-concentration potential was fixed at 1.0 V while the pre-concentration time was set at 60 s. A blank LSSV was recorded in the absence of analyte, so that background-subtracted LSSV could be obtained by subtracting the blank response from that of the analyte. The stripping peak current was found to be linearly-dependent on the square root of the sweep rate, indicating a linear diffusion-controlled organic phase to aqueous phase transfer process [41]. Despite this result, it was found that lower sweep rates produced a more clearly-defined peak shape, consistent with peak distortion by cell resistance and capacitance at the higher sweep rates. Consequently, all subsequent experiments employed a sweep rate of 5 mV s^{-1} since this sweep rate produced a well-defined peak shape with less sensitivity to these distortions.

The influence of the pre-concentration potential was studied by employing 20 μM $RacH^+$ with a 60 s pre-concentration time, while varying the pre-concentration potential from 0.60 to 1.00 V in increment of 0.05 V (Fig. 3). From the inset graph, it can be seen that the stripping peak current only appeared when the pre-concentration potential was higher than 0.85 V. As observed earlier by CV, $RacH^+$ transfers at an applied potential very close to upper limit of the potential window. The maximum stripping peak current was observed when the pre-concentration potential was 1.00 V, thus this potential was applied for all subsequent experiments.

The influence of pre-concentration time was studied at 1.00 V pre-concentration potential using 100 μM $RacH^+$, with variations in the pre-concentration time from 15 to 180 s. Over the time range of 0–1 min, the increment was 15 s, while in the range 1–3 min, the time increment was increased to 30 s (Fig. 4). The stripping peak

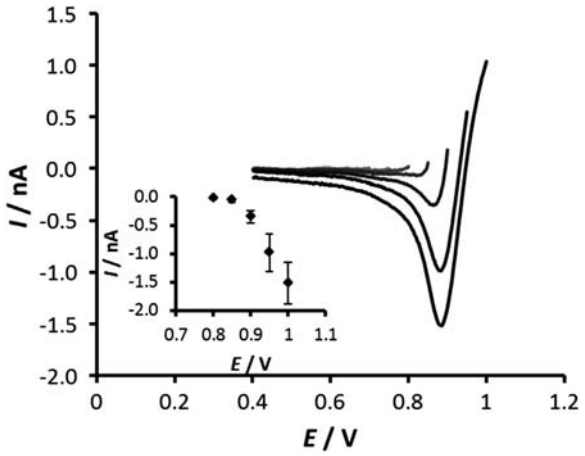

Fig. 3. Influence of pre-concentration potentials from 0.6 V (light gray) to 1.0 V (black) in increment of 0.05 V on the LSSV (background-subtracted) of 20 μM $RacH^+$. The pre-concentration time and sweep rate were fixed at 60 s and 5 mV s^{-1}, respectively. Inset: graph of current at selected pre-concentration potentials of 0.80, 0.85, 0.90, 0.95 and 1.00 V.

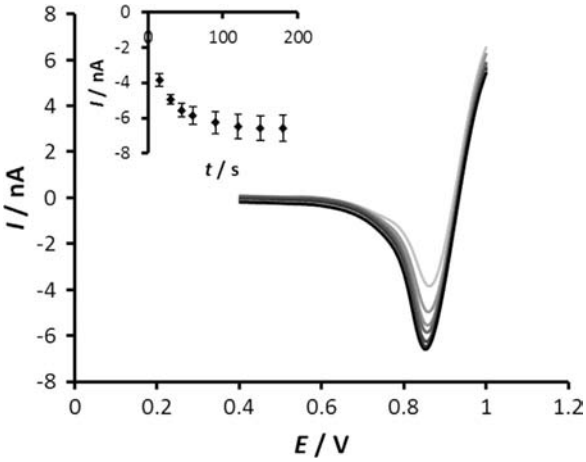

Fig. 4. Influence of pre-concentration times on the LSSV (background-subtracted) of 100 μM $RacH^+$. The pre-concentration potential and sweep rate were fixed at 1.0 V and 5 mV s^{-1}, respectively. LSSV response of 15 (light gray), 30, 45, 60, 90, 120, 150 and 180 s (black) pre-concentration times. Inset: calibration graph of peak current versus pre-concentration times.

current increased as the pre-concentration time increased, eventually reaching a constant value, as illustrated in the inset graph. This effect was reported previously for the detection of propranolol [21] and oligopeptides [39] at the micro-ITIES array, and was attributed the diffusion of analyte away from the interface to the bulk organic phase during the longer pre-concentration times. Therefore, during stripping step, these analytes are not stripped back to the aqueous phase and do not contribute to the stripping peak [37]. The optimum pre-concentration time of 120 s was selected and applied in all subsequent experiments.

3.4. LSSV analysis at the micro-ITIES array

Employing all of the optimised parameters (5 mV s^{-1} sweep rate, 1.00 V pre-concentration potential, 120 s pre-concentration time), low concentrations of $RacH^+$ in the range 0.1–1.0 μM were analysed and a calibration graph was plotted of stripping peak current versus concentration of $RacH^+$ (Fig. 5). The increase in $RacH^+$ concentration resulted in an increase of the stripping peak current, with a linear concentration dependence observed within the range studied, ($I_p = -0.2718$ (nA μM^{-1}) (concentration) -0.0974 (nA), $R = 0.9964$, $n = 6$). The calculated limit of detection

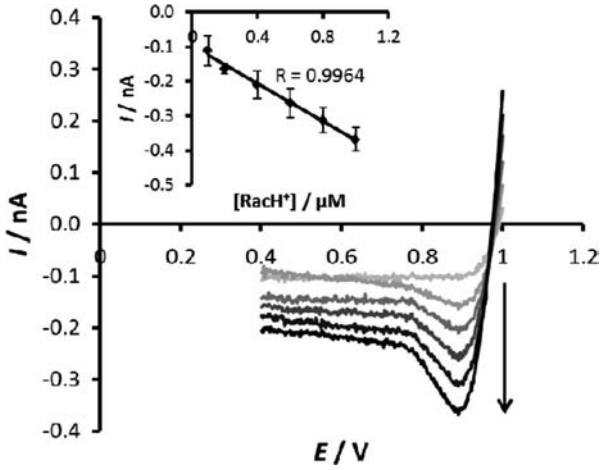

Fig. 5. Background-subtracted LSSV scans of increasing $RacH^+$ concentrations in the aqueous phase (indicated by arrow) at the micro-ITIES arrays at 5 mV s^{-1} sweep rate. LSSV response of 0.1 (light gray), 0.2, 0.4, 0.6, 0.8 and 1.0 μM (black) drug concentrations. Inset is the calibration curve of stripping peak current versus concentration.

(LOD) is 0.1 μM (34 ng mL^{-1}), based on 3 times the standard deviation of the blank ($3s_b$) [66]. This compares well with previously published values. LODs of 1.17 μM (CV and electrochemical impedance spectroscopy at a modified electrode) [67], 0.06 μM (DPV at a carbon nanotube-modified glassy carbon electrode (GCE)) [6], 0.05 μM (DPV at a graphene oxide-modified GCE) [13], and 0.06 μM (DPV at an ordered mesoporous carbon-modified GCE) [7] have been reported for ractopamine.

3.5. Influence of potentially interfering substances

Possible interferences in the detection of $RacH^+$ were investigated using substances such as a sugar, ascorbic acid, metal ions, an amino acid and urea [6,7,19,68]. These substances were selected since they are all models of substances likely to be present in a biological sample. This study was conducted using CV. The aqueous phase of the electrochemical cell (setup as in Cell 2) was spiked with the $RacH^+$ and individual interference substances at concentrations of 0.1 and 5.0 mM, respectively. The current signal for 0.1 mM $RacH^+$ was individually measured in the absence and presence of the interfering substances, and the current change was then determined. In addition, $TPrA^+$ was spiked to every aqueous test phase as a model ion and a potential axis reference ion. The results obtained are summarised in Fig. 6 and in Table 2.

Glucose was chosen as a model of possible sugar interference. Since it is an uncharged molecule and hence does not provide a current for transfer across the water | DCH interface, it is not expected to impact on the detection of $RacH^+$ since no ion transfer signal was detected (Fig. 6(a)). The potential interference of ascorbic acid was also investigated, and no transfer of ascorbate was observed (Fig. 6(b)). Ascorbic acid (p*K*a of 4.17 [19]) was de-protonated in the aqueous phase. The possible interference of metal ions such as K^+ and Na^+ were also evaluated. Metal ions, in particular K^+ and Na^+, are expected to transfer at the positive end of the potential window, which results in a decrease of the potential window [19,49,69]. Additions of KCl (Fig. 6(c)), NaCl (Fig. 6(d)) and Na_2SO_4 (Fig. 6(e)) to the aqueous phase did alter the $RacH^+$ ion transfer signal, in agreement with previous reports [19,69], with KCl having the greatest impact. Glycine was used as a model amino acid interferent and is widely reported in interference studies [6,7,19]. At physiological pH, glycine is a net neutral molecule hence it should not show any ion transfer behaviour at the interface (Fig. 6(f)) [19]. However, there was a slight increase in current at the positive end of the potential window when glycine was added. Note that although amino acids can be

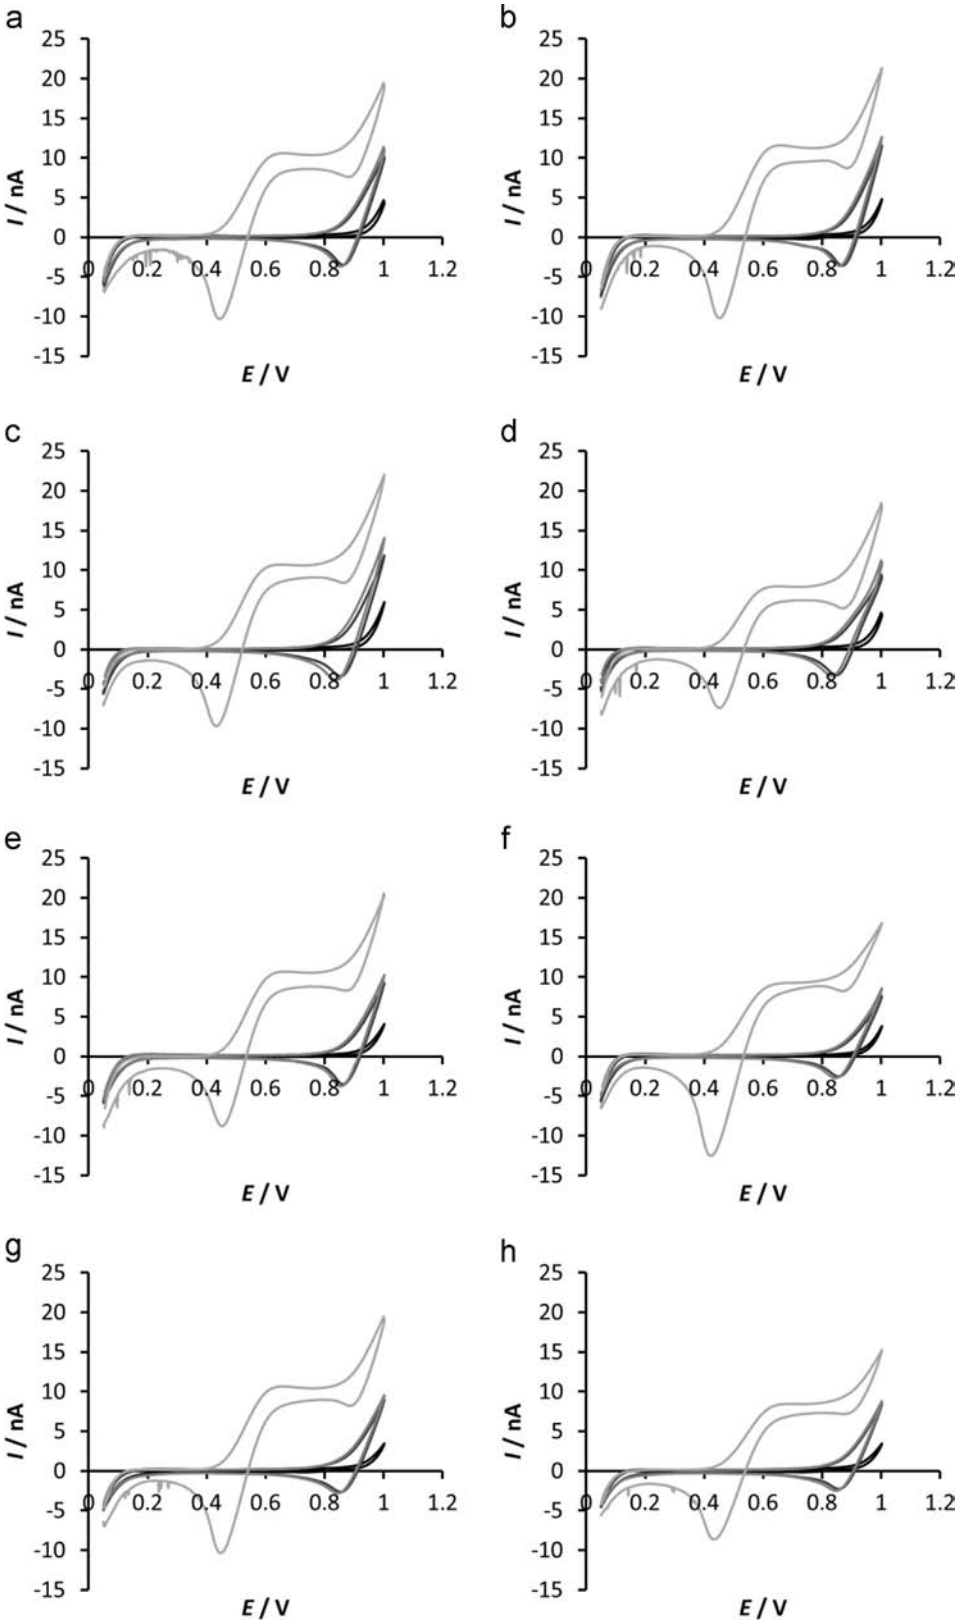

Fig. 6. Electrochemistry of the individual interfering substances at the micro-ITIES arrays. Cyclic voltammograms of the blank aqueous phase solution (10 mM LiCl) (black line), the aqueous phase spiked with 100 μM $RacH^+$ (dark gray line), the aqueous phase spiked with 100 μM $RacH^+$ and the interfering substances (medium gray line), and the aqueous phase spiked with 100 μM $RacH^+$, the interfering substances and 100 μM $TPrA^+$ (light gray line). The interfering substances studied: (a) D-glucose (b) L-ascorbic acid (c) KCl (d) NaCl (e) Na_2SO_4 (f) glycine (g) urea, and (h) PBS solution in the absence of the interfering substance (control). The interfering substance concentration in all cases was 5.0 mM, and run at 5 mV s^{-1} sweep rate.

Table 2
Influence of potentially interfering substances on the detection of protonated ractopamine ($RacH^+$) at the micro- water | DCH interface array. The concentration of $RacH^+$ and interfering substance in all cases were 0.1 mM and 5.0 mM, respectively. In the forward scan, the current was measured at the end of the scan, while in the reverse scan the minimum peak current was selected.

transferred across the ITIES [70], a low pH (pH $\leq$ 1.0) is required to ensure complete protonation of the amino acid, and an ionophore must be used to facilitate the transfer process. The possible interference of urea was also investigated (Fig. 6(g)). Urea did not show a transfer signal at the interface, since it is a neutral compound [71]. In addition, a control experiment to assess the impact of the PBS solution on the interfering substance CVs was conducted, since all the interfering substance stock solutions were prepared in PBS solution (Fig. 6(h)). The same injection volume as used to prepare 5.0 mM of interfering substance was applied. The addition of PBS was observed to have a minimal impact on the interfering substance's CV.

The current changes in the presence of interfering substances (% Relative difference, Table 2) were in the range of 6.2 to 19.2%, and 0.7 to 16.1%, based on the forward and reverse scan currents of $RacH^+$, respectively. The forward current is more sensitive to the presence of potentially-interfering substances than the reverse scan. Substances not expected to interfere produced a ~10% current increase in the forward scan. For both scans, KCl (Fig. 6(c)) demonstrated the highest current change. In all cases, the results exhibited 3% relative standard deviation (% RSD) from repeated measurements on a single electrochemical cell (n=3). Table 2 also summarises the total variation in the $RacH^+$ signal in the absence of potentially interfering substances (% RSD of 15.3 and 16.9% for the forward and reverse scans, respectively), which reflects the experimental day-to-day reproducibility of the experiments.

In addition, the background current signal demonstrated % RSD of 16.3, 19.3 and 10.3%, measured at the minimum, maximum and within the 'polarisation range' (at 0.6 V) potentials, respectively, based on the blank CVs shown in Fig. 6. On the other hand, the $TPrA^+$ current signal demonstrated % RSD of 15.8 and 12.7%, measured at the minimum reverse peak and maximum forward current for this ion (~0.6 V), respectively. Again, the variation in signals reflects the day-to-day reproducibility within the experiments.

Based on these observations, only potassium was seen to have a major impact on the detection of $RacH^+$, and none of the other substances produced ion transfer peaks. Furthermore, since the reverse peak is less impacted than the forward current, use of a stripping voltammetry approach is suggested.

3.6. Determination of $RacH^+$ in artificial serum

The determination of $RacH^+$ in artificial serum as the aqueous phase electrolyte solution was conducted using Cell 3. In this study, two types of artificial serum solutions were prepared; the first contained no BSA, while the second contained BSA at physiological concentration. These solutions were utilised to investigate the possibility that BSA can impede the detection of $RacH^+$, as reported previously for other ionised drugs at the ITIES [25,35].

Several ways have been identified for BSA to hinder the detection process: potential window shortening, drug–protein binding [25,72] or protein adsorption at the interface [25,35]. BSA is a water-soluble globular protein which has a net charge of ~ −17 at physiological pH (of 7.4) [36], while $RacH^+$ has a charge of +1. These opposite charges contribute to ractopamine-albumin binding, although the binding effect will reduce through shielding from the electrolyte ions. Zhang et al. [72] reported that ractopamine bound to BSA mainly by electrostatic and hydrophobic interactions. The formation of the ractopamine-albumin complex was spontaneous and the strong interactions indicated that the drug has a long residence time in blood plasma. Additionally, BSA may adsorb to the ITIES. Collins et al. reported that BSA diminished the signal of ionised propranolol in artificial serum, although detection was still possible [25]. Vanysek and Sun demonstrated that the transfer of Cs^+ ion across a water | NB interface was inhibited by the adsorption of BSA on the interface [35]. Plasma proteins such as albumin have been reported to be a major source of interference in plasma measurement at the ITIES [19,73].

CV of the two artificial serum matrices was carried out with the addition of 100 μM $RacH^+$. Prior to that, a background CV was run over a wide potential range to establish the limits of the available potential window (Fig. 7(a) and (b)). Incorporation of BSA in the artificial serum decreased the width of the potential window to 850 mV, from 950 mV in its absence. Since BSA shortened the potential window at the upper limit (Fig. 7(b)), the detection of ractopamine might be hindered as $RacH^+$ transfers at a very positive applied potential difference, close to the upper limit of the potential window, in the LiCl solution. It was observed that the $RacH^+$ transfer was possible in artificial serum without BSA. The protonated drug transferred close to the positive limit of the potential window on the forward scan, while on the reverse scan, a peak-shaped feature was obtained (Fig. 7(c)). A calibration curve in artificial serum solution without BSA was obtained by plotting the background-subtracted current (both forward and reverse scans) versus the $RacH^+$ concentration. The background-subtracted currents on both the forward and reverse scans increased proportionally with $RacH^+$ concentrations over the range studied (Fig. 7(c) inset).This is in agreement with the result obtained in aqueous LiCl electrolyte.

In contrast, no $RacH^+$ transfer was observed in artificial serum containing BSA (0.6 mM). A small current increment was observed on the forward scan, however no peak-shape feature was observed on the reverse scan (Fig. 7(d)). Since the current signal varied

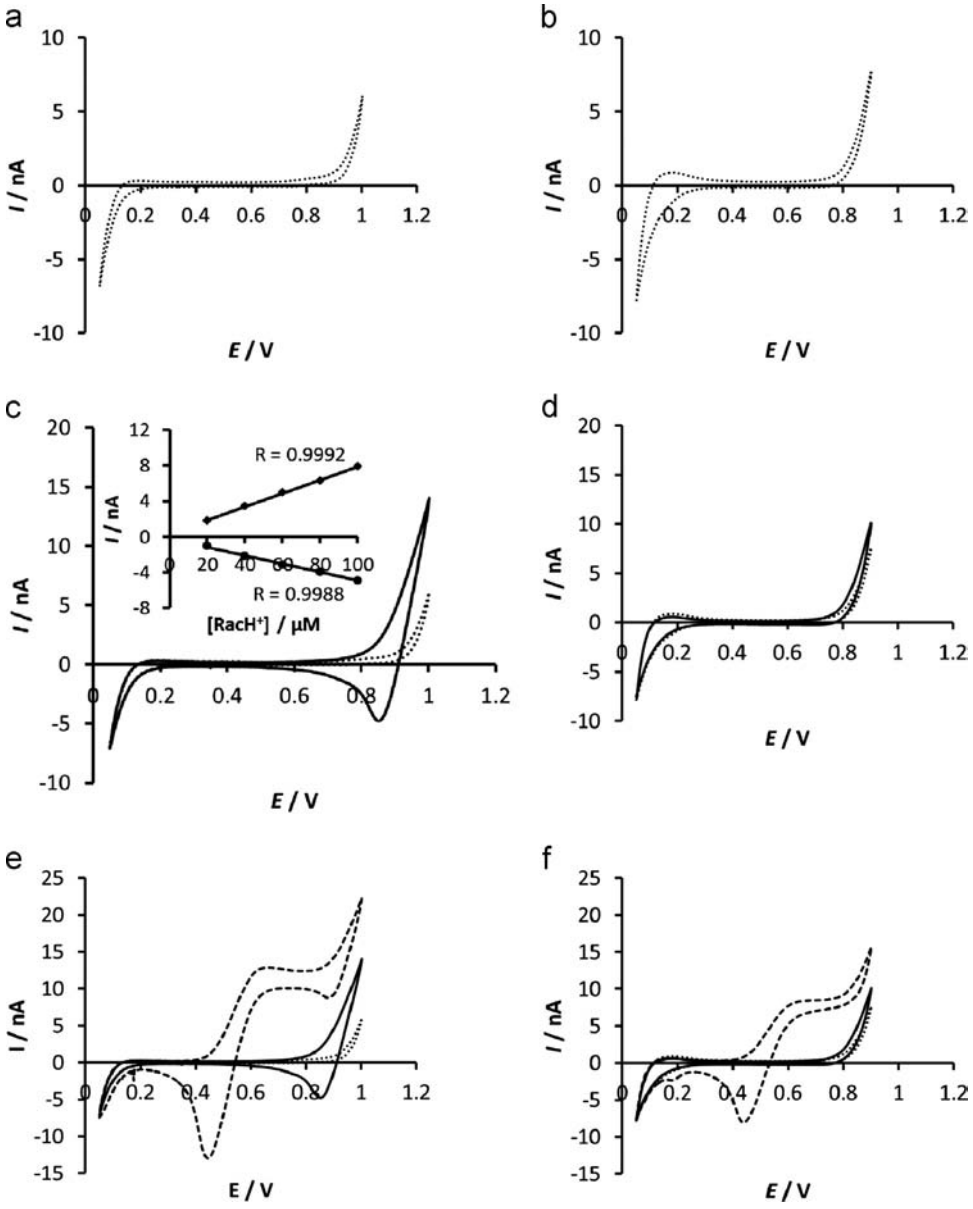

Fig. 7. Cyclic voltammetry at the micro-ITIES array of an artificial serum solution in the aqueous phase ((a) and (b)), 100 μM $RacH^+$ in an artificial serum solution ((c) and (d)), and an artificial serum solution of 100 μM $TPrA^+$ and 100 μM $RacH^+$ ((e) and (f)). Figures (a), (c) and (e) represent cyclic voltammetry of an artificial serum without BSA, while figures (b), (d) and (f) represent cyclic voltammetry in the presence of 0.6 mM BSA. Sweep rate applied was 5 mV s^{-1}. Inset in (c) is the corresponding calibration curve obtained for $RacH^+$ transfer on the forward and reverse scans.

linearly with the transferring analyte concentration, these results showed that the concentration of free $RacH^+$ in the aqueous phase was extremely low. This result is in agreement with previous studies which demonstrated that the presence of 1 mM BSA in artificial serum decreased the propranolol transfer current signal to ~6.4 nA, from ~9.7 nA in its absence [25].

In addition, $TPrA^+$ was also spiked into each artificial serum solution (Fig. 7(e) and (f)). No significant shift of the half-wave potential for the $TPrA^+$ ion was observed ($E_{1/2}$ of ~0.52 V) [25]. However, the steady-state current for $TPrA^+$ in the presence of BSA decreased from ~12.5 (no BSA present) to ~8.5 nA. A similar observation was also made on the reverse scan, where the peak current decreased from ~12.9 to ~7.9 nA in the absence and presence of BSA, respectively. This indicated that BSA adsorbed at the interface and inhibited ion transfer.

The results presented in this section demonstrate that reduction of the available potential window, complexation of the $RacH^+$ by BSA and adsorption of the BSA to the liquid | liquid interface, are the possible interference mechanisms for the detection of ractopamine in serum via ion-transfer voltammetry. Hence, deproteinisation of samples is necessary for this voltammetric analysis to be viable.

4. Conclusion

The voltammetric behaviour of the β-agonist drug, protonated ractopamine, at a water | DCH micro-interface array was investigated. The results show that protonated ractopamine can be detected via CV and LSSV. However, this drug transfers at a very positive potential, close to the positive limit of the available potential window; nevertheless, estimation of the half-wave potential enabled determination of some thermodynamic parameters for this drug, such as the Gibbs energy of transfer and the partition coefficient. In addition, a stripping voltammetry approach was employed successfully to detect

lower concentrations of the drug. The LOD was calculated to be 0.1 μM, which is suitable for applications to drug detection in real samples. Of a range of potentially interfering substances studied, only potassium ions were found to interfere in $RacH^+$ detection, due to its transfer at a potential close to the positive potential limit. Additionally, it was found that BSA diminished the ractopamine signal via potential window reduction, drug–protein complexation and protein adsorption at the ITIES. The results presented here indicate that voltammetry at the micro-ITIES array can be used for detection and characterisation of ionised drugs that transfer at high applied potentials but that analysis of biological samples will require deproteinisation. In the future, an improved performance, such as a lower detection limit, might be achieved with an electrochemical cell that provides a wider potential window, which will enable a more efficient pre-concentration reaction to be implemented.

Nanocomposite aptasensor

ABSTRACT

A unique nanocomposite was crafted by grafting hemin-binding-aptamer (HBA) onto carboxylated graphene (COO-GR). Infrared spectroscopy, Raman spectroscopy and diffuse reflectance spectra suggested that –NHCO– covalent bonds were formed between HBA and COO-GR. The resulting COO-GR/HBA functionalized electrode was used as a novel label-free biosensor. The square wave voltammetry was employed to realize the selective and specific detection of hemin. The obtained aptasensor possessed excellent performance with a detection limit of 0.64 nmol L^{-1} ($S/N=3$) and a linear range from 1 to 150 nmol L^{-1}. Moreover, COO-GR was shown to be a promising candidate in making aptasensors, carrying advantages over graphene in terms of the simplicity of sensor preparation and the reduction of background noise.

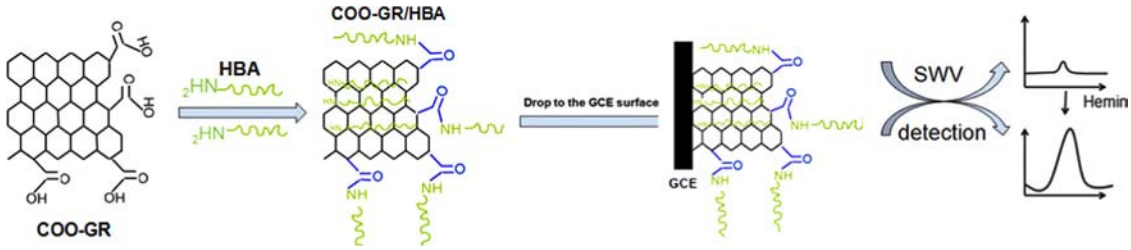
1. Introduction

Aptamers are capable of binding specific target molecules with high selectivity and affinity. Due to the ease of production in vitro, wide target range, modification ease, reversible thermal denaturation and unlimited shelf life, aptamers are believed to be excellent alternatives to antibodies for recognizing proteins [1–3]. During the past decades, aptamers have been widely studied and exploited for disease diagnoses, biological assay and aptamer-based sensors [4–7]. To monitor the aptamer–target molecule interactions, a label-free method for aptamer-based analysis would make the process simple and easy. However, the sensitivity and electrochemical stability of aptamer-modified electrodes are usually unsatisfactory. To this end, aptamers have to be immobilized onto a variety of solid substrates with large specific surface areas to improve their sensing performances [8–12].

Graphene is a two-dimensional (2D) sheet of covalently bonded carbon atoms, with the highest surface-to-volume ratio, excellent electrical and mechanical performance and thermal stability [13–15]. Graphene and its derivatives offer possibilities for highly sensitive detection with the advantageous large specific surface areas, and have been used as substrates in electroanalytical chemistry [16–18].

Hemin, a well-known natural porphyrinatoiron complex, is an important compound and has been applied in pharmacy, environmental science, food industry and bioscience and technology [19–21]. While there are many studies on the high electrocatalytic activity of hemin for peroxidation reactions in analytical applications as well as in the application of determination of H_2O_2 and related compounds [22–25], studies regarding the detection of hemin as a target are relatively scarce. In this context, it is of great importance to develop a new method for the determination of hemin with high sensitivity and selectivity.

Herein, we report a novel method to develop a highly sensitive label-free electrochemical aptasensor for hemin detection. The proposed method is based on a nanocomposite composed of hemin-binding-aptamer (HBA) and carboxylated graphene (COO-GR), as shown in Scheme 1. In particular, HBA and COO-GR composite was prepared by simply mixing the aqueous solutions of both components. The resulting nanocomposite was immobilized on the surface of glassy carbon electrode (GCE) to construct a sensing platform. The introduction of nanomaterials greatly improved the specific surface area and electrochemical stability of the aptamer-modified electrode. As a result, the modified electrode exhibited high performances on electrochemical sensing of hemin. We note that instead of graphene, COO-GR was employed due to its better dispersibility in water and ease of preparation of the COO-GR/HBA nanocomposite.



2. Experimental

2.1. Materials and reagents

HBA was purchased from Bioneer Trade Co., Ltd. (Shanghai, China). The sequence of HBA is 5′-NH_2-GTG GGT AGG GCG GGT

Scheme 1. Schematic diagram for the preparation of the aptasensor based on COO-GR/HBA nanocomposite for sensitive hemin detection.

TGG-3′ and complementary oligonucleotide sequence is 5′-NH_2-CAC ACA CAC ACA CAC ACA CAC-3′. Hemin was obtained from RED Chemical Co., Ltd. (Shanghai, China). Human serum was supplied by Nanjing Maternity and Child Health Care Hospital (Nanjing, China). COO-GR was purchased from Nanjing XFNANO Materials Tech Co., Ltd. (Nanjing, China). 1-Ethyl-3-(3-dimethy-aminopropyl) carbodiimide hydrochloride (EDC) and N-hydroxysuccinimide (NHS) were purchased from Sigma-Aldrich (Spain). All other chemicals were of analytical grade and purchased from Sigma-Aldrich (Netherlands). Double-distilled water (DDW) was used in making all aqueous solutions.

2.2. Characterizations

Zeta Potential was determined using Zetasizer Nano 90 (Malvern, Britain). The samples were dispersed in water with sonication at ambient temperature. Cyclic voltammetry (CV), differential pulse voltammetry (DPV), electrochemical impedance spectroscopy (EIS) and square wave voltammetry (SWV) were conducted using CHI660B electrochemical analyzer (CH Instruments, Chenhua Inc., Shanghai, China). A three-electrode system was employed consisting of a modified GCE working electrode, a platinum wire counter electrode and a Ag/AgCl (saturated with KCl) reference electrode. Fourier transform infrared (FTIR) spectroscopy was recorded with a Cary 5000 spectrophotometer (Varian Co., USA). 2 mg mL^{-1} COO-GR and 10 μmol L^{-1} HBA were mixed at a volume ratio of 4:1. An aliquot of the mixture (COO-GR/HBA), 2 mg mL^{-1} COO-GR and 10 μmol L^{-1} HBA were dropped on the cleaned KBr disks, respectively and dried under an Infrared lamp. Diffuse reflectance spectra were obtained with the same Cary 5000 spectrophotometer and samples were dropped on the cleaned quartz plates for characterization. Raman spectra were measured on a LabRAM HR800 confocal spectrometer (Jobin Yvon, France), with 514.5 nm Ar laser excitation.

2.3. Fabrication of COO-GR modified electrode

GCE was sequentially polished to a mirror finish with 0.3 μm and 0.5 μm alumina slurry and washed with absolute alcohol followed by rinsing thoroughly with DDW. Finally, the polished electrode was allowed to dry at room temperature after ultrasonication cleaning for 5 min in DDW. 10 μL of 1.6 mg mL^{-1} COO-GR was coated on a cleaned GCE surface and dried in air. The electrode was rinsed thoroughly with 0.1 mol L^{-1} phosphate buffer solution (PBS, pH 7.4) and DDW before application.

2.4. Fabrication of COO-GR/HBA modified electrode

2 mg mL^{-1} COO-GR and 10 μmol L^{-1} HBA were mixed at a volume ratio of 4:1. 10 μL of the mixture (COO-GR/HBA) was blended with 2 μL chitosan adhesive, coated on the cleaned GCE surface and dried in air. The electrode was rinsed thoroughly with 0.1 mol L^{-1} PBS (pH 7.4) and DDW before application.

2.5. Fabrication of graphene/HBA modified electrode

Graphene/HBA modified electrode was fabricated for comparison. Graphene coated GCE was prepared using the same method reported in our previous study [4]. The thus obtained graphene–GCE was activated with 0.5 mL of 0.1 mol L^{-1} PBS containing 10 mmol L^{-1} EDC and 10 mmol L^{-1} NHS for 16 h. Subsequently, the electrode was immersed in 1 mL of 1 μmol L^{-1} HBA containing 0.1 mol L^{-1} NaCl and 4 mol L^{-1} EDTA for at least 24 h at ambient temperature. Finally, the electrode was rinsed with copious DDW to remove any unfixed aptamer molecules.

2.6. Electrochemical measurements

The electrochemical performances of the modified electrodes were investigated by CV, DPV and EIS in a 0.1 mol L^{-1} PBS solution (pH 7.4) containing 10 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol L^{-1} KCl. CV was swept within potential scanning range from 0.6 to −0.1 V with different scan rates. DPV was conducted with pulse amplitude of 0.05 V, pulse width of 0.05 s and pulse period of 0.2 s. For EIS measurements, an AC sinusoid of 5.0 mV in amplitude was applied as input signal, with the DC potential set to 0.28 V over a wide frequency range from 10^0 to 10^5 Hz.

2.7. Detection of target hemin

Fresh hemin solutions were prepared prior to each experiment by dissolving hemin with a few microliters of 0.1 mol L^{-1} NaOH and subsequent addition of PBS to the requested concentrations. Highly pure N_2 was bubbled through the cell solution for about 20 min prior to each experiment. Detection of hemin was carried out by immersing the COO-GR/HBA modified electrode into a 0.1 mol L^{-1} PBS containing hemin with different concentrations. The resulting change of peak current upon the binding of HBA with hemin was monitored using SWV. SWV was performed with potential scanning from 0.8 to −0.1 V with quiet time of 120 s, scan increment of 4 mV, amplitude of 25 mV and frequency of 15 Hz.

3. Results and discussion

3.1. Chemical structure of COO-GR/HBA

FTIR, diffusion reflectance spectra and Raman spectroscopy were employed to examine the covalent bond formation between HBA and –COOH. Fig. 1A (a) exhibits the characteristic absorption peaks of COO-GR. A broad band ranging from 3600 to 3250 cm^{-1} indicates the presence of –OH groups. –COOH groups in COO-GR is evidenced by the C=O stretching vibration at 1725 cm^{-1}, the –COO asymmetric stretching shoulder peak at 1570 cm^{-1}, and –COO symmetric stretching vibration at 1415 cm^{-1}. A C=C aromatic ring stretching vibration is present at 1635 cm^{-1} [26]. Spectrum of HBA displays a broad band around 3166 cm^{-1}

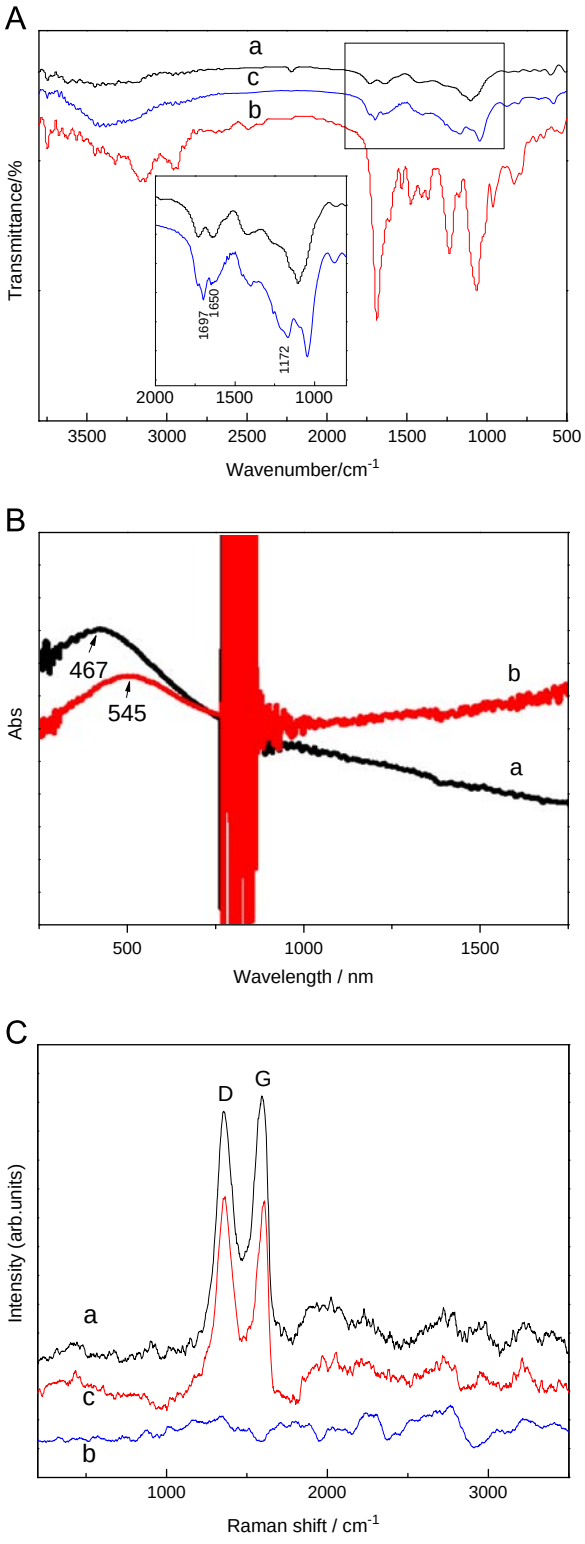

Fig. 1. (A) FTIR of COO-GR (a), HBA (b), and COO-GR/HBA (c). (B) Diffusion reflectance spectra of COO-GR (a) and COO-GR/HBA (b). (C) Raman spectra of COO-GR (a), HBA (b), and COO-GR/HBA (c).

of –N–H stretching vibration, an absorption peak of C=O at 1685 cm^{-1}, a stretching peak at 1228 cm^{-1} of –CN and a dissymmetric stretching vibration of phosphate radicals at 1066 cm^{-1} (b). In the spectrum of the COO-GR/HBA composite, the increase in the intensity of the band around 3400 cm^{-1} is assigned to the presence of –OH groups in COO-GR and –N–H in HBA. The new absorption peaks at 1697 cm^{-1}, 1650 cm^{-1} and 1172 cm^{-1} are attributed to the C=O vibration in –NHCO–, in-plane bending mode of –N–H, and –CN vibration, respectively (c). Diffuse reflectance also reveals the covalent binding of COO-GR and HBA. The noise around 800 nm was caused by the change of the detector from UV to visible light. The featured change of C=O absorbance band from 467 nm in COO-GR to 545 nm in COO-GR/HBA indicates a conversion from –COOH to –NHCO– (B). Raman spectroscopy is a powerful tool to characterize the bonding, ordering, and crystallite size of carbon materials. It is well known that the Raman band at ~1590 cm^{-1} (the G-band) is due to the in-plane phonon modes of graphene, showing the sp^2 bonding. The band around ~1360 cm^{-1} is due to disorder in the graphene layers caused by the presence of sp^3 bonding (the D-band). As can be seen in Fig. 1C, COO-GR also exhibits the two bands with the G band being higher (a), which is in agreement with the previous report [26]. It is reasonable that HBA does not show any featured bands in Raman spectroscopy (b). After binding with HBA, however, the D band of the COO-GR/HBA becomes prominent (c). The HBA molecules decorated on COO-GR cause the sp^2 delocalization due to their strong negativity. sp^2 structures close to the decorated points convert to sp^3 structures, leading to the increase of the D/G intensity ratio for COO-GR/HBA.

3.2. Comparison of COO-GR and graphene for the construction of aptasensors

To clearly show the advantage of COO-GR over graphene in this study, both COO-GR/HBA and graphene/HBA modified electrodes were prepared and characterized as follows. As shown in Fig. 2A, DPV reveals that the peak current of COO-GR/HBA increases compared with COO-GR–GCE; while the peak current of graphene/HBA decreases in comparison with graphene–GCE. In addition, both graphene and graphene/HBA modified electrodes present high background current while the COO-GR and COO-GR/HBA modified electrodes nearly have no background noise, indicating a higher signal to noise ratio (S/N) of the COO-GR based electrodes. EIS measurements (Fig. 2B) suggest that after binding with HBA the charge transfer resistance (R_{et}) of graphene increases by 196 Ω (from a to b) while the R_{et} of COO-GR decreases by 358 Ω (from c to d). The phenomenon is reasonable as graphene is known for its excellent electrical conductivity and immobilization of HBA on graphene will form an organic layer, thus unambiguously increases the surface resistance. As for COO-GR, the existence of carboxylic groups anchoring at the edges of graphene molecules destroys the sp^2 hybridization conjugation of the backbone, thereby inhibiting the electron transfer and resulting in a poor conductivity as well as a high impedance of the coated electrode. Interestingly, the R_{et} of COO-GR/HBA greatly decreases instead. We assume that the R_{et} at electrode/electrolyte interface is determined by two factors: (1) the electrical conductivity of the coating, and (2) the charges of the coating surface. A possible explanation to this phenomenon is that after binding with HBA, –NH_2 groups decorated on HBA are covalently bonded with –COOH to form strong amide bonds, leading to a change in charges of the resulting surface. This assumption is verified by Zeta potential measurements. In a solution with pH=7.4, the Zeta potentials of COO-GR and COO-GR/HBA are −7.65 mV and −0.905 mV, respectively. Another advantage of the current strategy is that the preparation of COO-GR/HBA is relatively simple in comparison with that of graphene/HBA due to the better water solubility of COO-GR (see Section 2).

3.3. Electrochemical characterization of the modified electrodes

Electrochemical properties of the modified electrodes investigated by CV, DPV and EIS are shown in Fig. 3. Compared with the

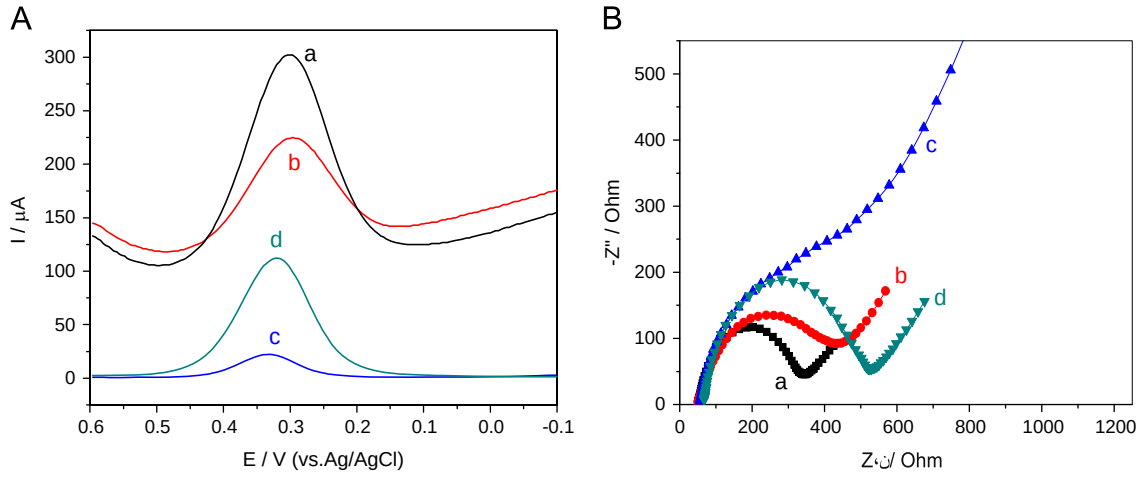

Fig. 2. DPV (A) and EIS (B) of GR (a), GR/HBA (b), COO-GR (c) and COO-GR/HBA electrode (d) in 0.1 mol L^{-1} PBS (pH 7.4) containing 10 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol L^{-1} KCl.

bare GCE, the COO-GR modified electrode exhibits relatively poor electrochemical performance. In particular, (1) the enclosed area in CV largely decreases, indicating its low charge capability; (2) the peak current in DPV decreases, implying its decreased conductivity; and (3) the R_{et} greatly increases. As discussed above, the existence of carboxylic groups anchoring at the edges of graphene molecules causes the destruction of sp^2 hybridization conjugation of the carbon backbone, leading to poor conductivity of the COO-GR coated electrode. However, after binding with HBA, the electrochemical performance improves as clearly evidenced by the enlarged enclosed area in CV, the increased peak current in DPV, and the decreased R_{et} in EIS. This is due to the fact that $-NH_2$ groups decorated on HBA are covalently bonded with –COOH to form strong amide bonds, and thus the amount of carboxyl groups on the electrode surface is greatly reduced, leading to less negative charges on the surface as confirmed by Zeta potential. The variation of the surface charges has a key influence on the R_{et} at the electrode/electrolyte interface.

3.4. Relationship between peak current and scan rate of CV

To understand the redox kinetics of the functionalized electrode, CV measurements of the COO-GR/HBA electrode at various scan rates were performed. The resulting plots are shown in Fig. 4A. Theoretically, when electron transfer at the interface is fast enough and redox reactions are totally reversible, the difference of peak current (ΔE_p) will remain constant and will not change with scan rate. However, in our study we note that with increasing scan rate from 10 to 200 mV s^{-1}, the anodic peak shifts to more positive positions, while the cathodic peak shifts to more negative positions. As a result, ΔE_p changes from 20 to 80 mV. Meanwhile, both anodic and cathodic peak currents increase with increasing scan rate. Fig. 4B displays the relationship between peak current (I_{pa} and I_{pc}) and square root of the scan rate $\nu^{1/2}$. The linear relationship is expressed by $I_{pa} = -3.807 \times 10^{-5}\nu^{1/2} + 1.341 \times 10^{-5}$ ($R^2_{pa}=0.9939$) and $I_{pc}=3.414 \times 10^{-5}\nu^{1/2} - 1.307 \times 10^{-5}$ ($R^2_{pc}=0.9920$), respectively. The results reveal a quazi-reversible electrochemical kinetics and diffusion-controlled process of the electrochemical reaction at the electrode surface.

3.5. Quantitative detection of hemin

As it is well known, COO-GR on its own can form molecular π–π conjugations with hemin molecules. In the meantime, COO-GR exhibits good electrocatalytic reducibility towards hemin. Thus, a COO-GR coated electrode was applied to directly detect hemin with SWV. Interestingly, the current peaks appear at 0.22 V and the peak current varies with hemin concentrations from 0.1 to 5 μmol L^{-1} (Fig. 5), indicating the responsibility of the COO-GR coated electrode to hemin. It is reasonable because more hemin molecules will be immobilized on to COO-GR when its concentration gets higher. However, no linear relationship was found between peak currents and hemin concentrations, which hinders the application of COO-GR modified electrodes in the quantitative detection of hemin.

To explore an ideal approach for quantitatively detect hemin, HBA was immobilized onto the COO-GR coated electrode to yield an aptasensor. Clearly, when the aptasensor was incubated in hemin solution, the peak current at 0.22 V in SWV increased with increasing hemin concentration, a same phenomenon observed for the COO-GR coated electrode. When the concentration of the hemin solution increases, more hemin molecules are immobilized on the electrode surface due to the specific recognition of HBA to hemin, leading to an increased peak current (Fig. 6A). The different phenomenon from that of the COO-GR coated electrode is as follows: there is a linear relationship between the peak currents and hemin concentrations from 1 to 150 nmol L^{-1}, after which the current reaches a plateau, implying the saturation of hemin on the electrode surface (Fig. 6B). The regression equation is $I=0.4685c+30.9130$, with a linear coefficient of $R^2=0.9940$ and a detection limit of 0.64 nmol L^{-1} ($S/N=3$). The resulting aptasensor exhibits better performance than the reported nano-ZnO-carbon paste electrode with a linear range from 3.07×10^{-9} to 3.07×10^{-7} mol L^{-1} and the fluorescence aptasensor with a linear range of 0.31–2.50 μmol L^{-1}. Furthermore, the detection limit of 0.64 nmol L^{-1} is lower than that of the reported electrochemical sensor (1.5×10^{-9} mol L^{-1}) as well as the fluorescence aptasensor (50 nmol L^{-1}) [27,28].

3.6. Specificity of the COO-GR/HBA aptasensor

Specificity is another important performance for aptasensors to accurately detect analytes in real applications. To evaluate the specificity of the fabricated COO-GR/HBA aptasensor to hemin, standard recoveries were determined based on the calibration curve in the presence of serum. We found that the peak currents at 0.22 V are almost the same for the blank solution and the serum solution (Fig. 7). Moreover, when the concentration of hemin in the mixture of serum and hemin was increased, the peak current increased accordingly, in spite of the presence of serum. This

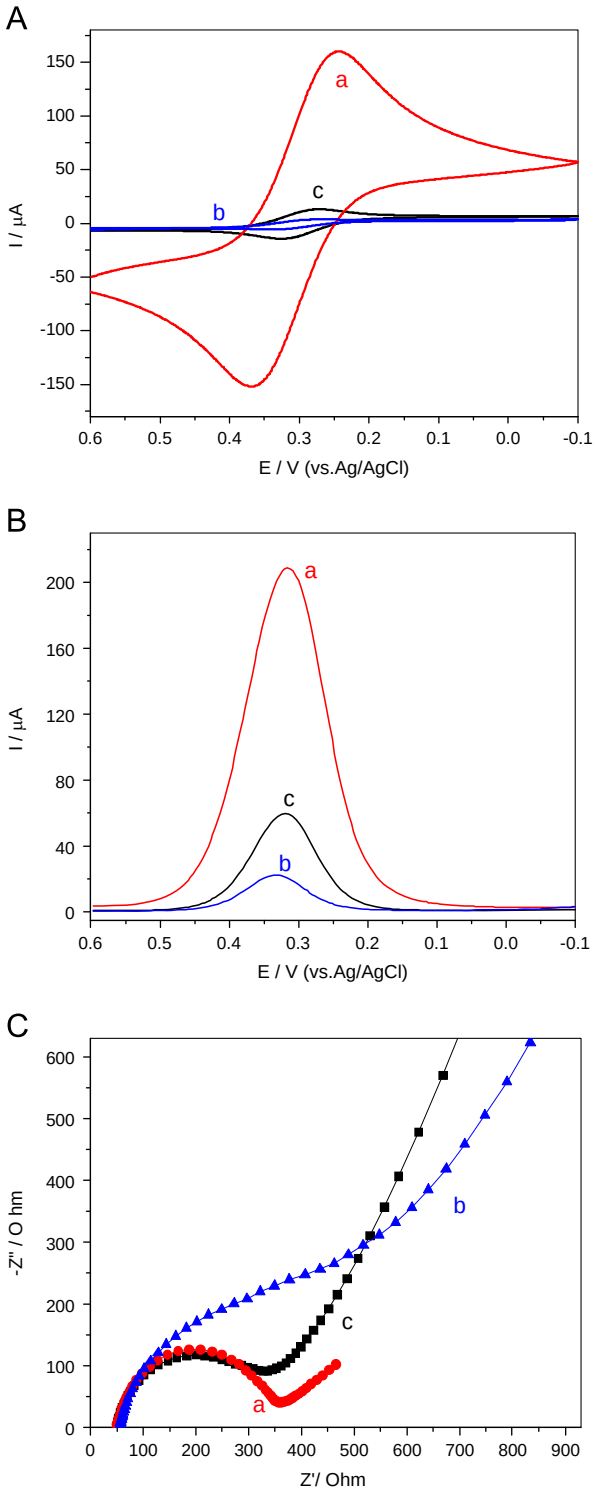

Fig. 3. Electrochemical characterization of bare GCE (a), COO-GR modified electrode (b) and COO-GR/HBA modified electrode (c) in 0.1 mol L^{-1} PBS (pH 7.4) containing 10 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol L^{-1} KCl. (A) CV, (B) DPV and (C) EIS.

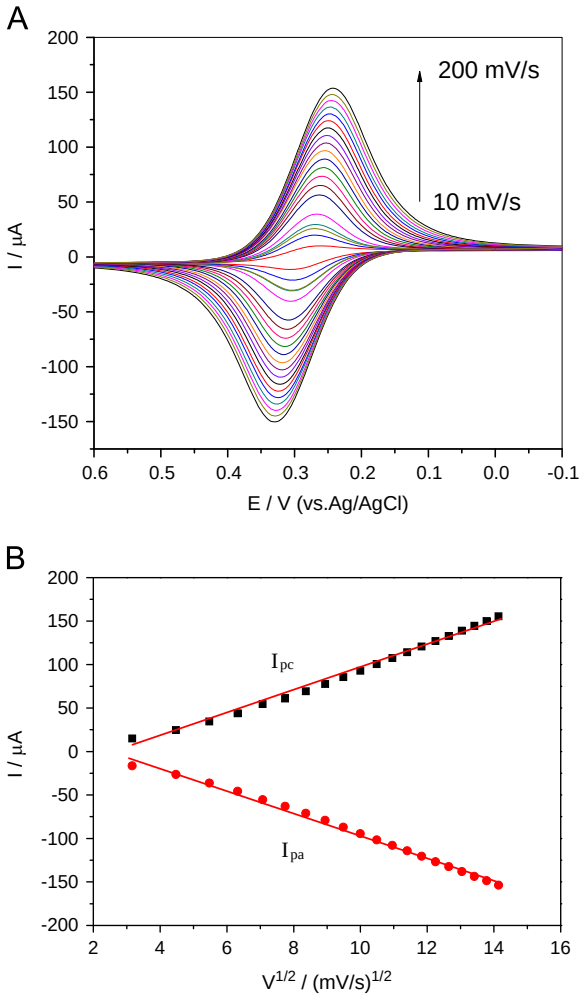

Fig. 4. (A) CVs of the COO-GR/HBA modified electrode with different scan rates in 0.1 mol L^{-1} PBS (pH 7.4) containing 10 mmol L^{-1} $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol L^{-1} KCl. (B) A Randles–Sevik plot of the electrode.

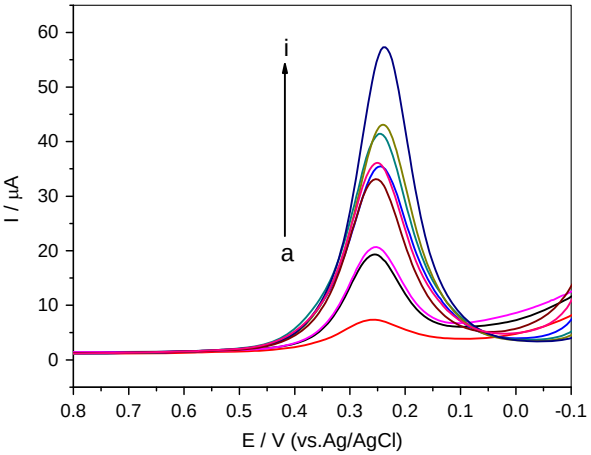

Fig. 5. SWV of the COO-GR coated electrode incubated in hemin with concentrations of 0 (a), 0.1 (b), 0.3 (c), 0.5 (d), 0.7 (e), 2 (f), 3 (g), 4 (h) and 5 μmol L^{-1} (i). Hemin was in 0.1 mol L^{-1} PBS containing 0.1 mol L^{-1} KCl.

demonstrates that the currents change only with hemin concentrations rather than other bio-substances in the mixture. The corresponding data shown in Table 1 indicate that all recoveries turn out to be 97.2–101.9% and fall in the confidence interval of 95–105%, indicating the reliability of the COO-GR/HBA aptasensors in the detection of hemin.

Furthermore, to evaluate the anti-interference property of the fabricated COO-GR/HBA aptasensor, possible interfering species such as K^+, Na^+, Ca^{2+}, NO_3^-, thrombin, adenosine, uridine, cytidine, lysozyme and glucose, which may be present in real samples, were examined in 0.1 mol L^{-1} PBS containing 50 nmol L^{-1} hemin. We found that 50.0-fold of the above species did not show remarkable interference to hemin determination.

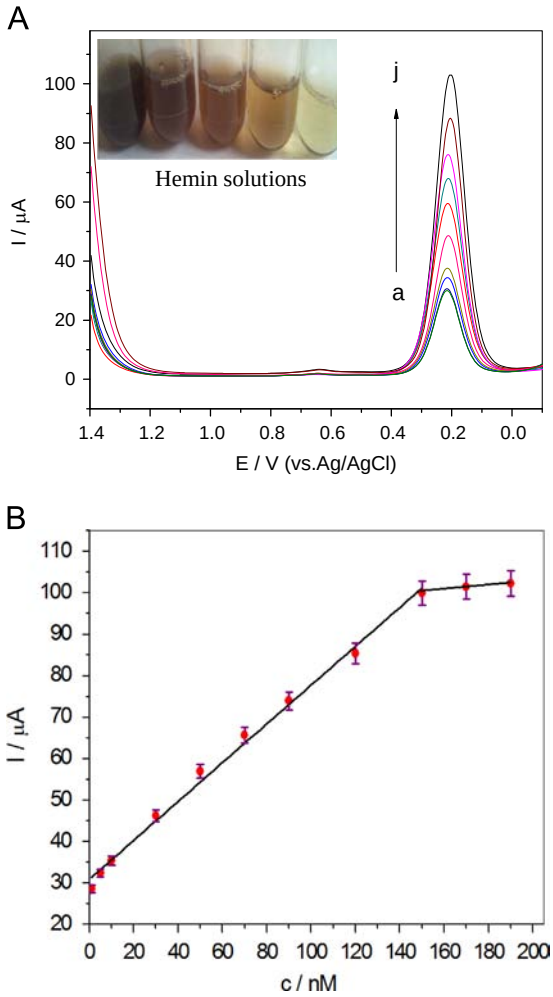

Fig. 6. (A) SWV of the COO-GR/HBA modified electrode incubated in hemin with concentrations of 0 (a), 1 (b), 5 (c), 10 (d), 30 (e), 50 (f), 70 (g), 90 (h), 120 (i) and 150 nmol L^{-1} (j) in 0.1 mol L^{-1} PBS (pH 7.4) containing 0.1 mol L^{-1} KCl. Inset in A is a digital image of hemin solutions with different concentrations. (B) Calibration curve showing the relationship between peak current and hemin concentration. The measurements were repeated 3 times to obtain the standard deviation.

The anti-interference of the COO-GR/HBA aptasensor is acceptable, ensuring its promising application in real sample analysis.

3.7. Analytical performance – repeatability, reproducibility and stability

The repeatability of the sensor response was tested by 10 times successive measurements with the COO-GR/HBA modified electrodes in 0.1 mol L^{-1} PBS containing 50 nmol L^{-1} hemin, giving a satisfying relative standard deviation (RSD) of 1.87%. The reproducibility was examined by six individual determination performed with different COO-GR/HBA modified electrodes in the above solution and the RSD was obtained as 3.69%. Moreover, the proposed aptasensor was stored in 0.1 mol L^{-1} PBS and kept at 4 °C in a fridge. After two weeks, we found that the sensor retained 90.94% of its initial activity. The above results indicated good analytical performance of the proposed aptasensor.

4. Conclusions

Graphene–HBA- and COO-GR–HBA-modified electrodes were crafted and their electrochemical properties were investigated. Although the COO-GR electrode has lower electrical conductivity than that of the graphene electrode, a large number of carboxylic groups in its structure provide active sites for binding with aminated aptamers, HBA. Redox kinetics of the resulting COO-GR–HBA aptasensor is demonstrated to be quazi-reversible and displays a diffusion-controlled process of the electrochemical reaction at the electrode surface. Using SWV as sensing technique, the proposed aptasensor is able to quantitatively detect the analyte of hemin and a detection limit as low as 0.64 nmol L^{-1} can be achieved. Moreover, COO-GR is shown to be a promising candidate in making aptasensors, possessing the advantageous attributes in terms of simplicity of sensor construction and reduction of background noise.

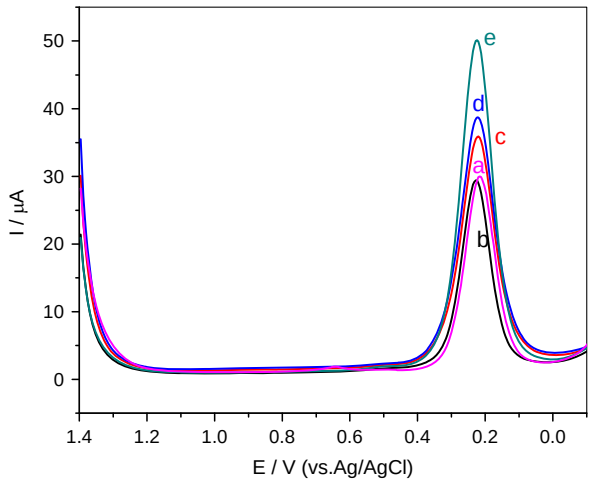

Fig. 7. Specificity analysis of aptasensor tested in blank (a), serum (b) and serum–hemin mixture (c–e). Hemin concentration in serum–hemin mixture is 5 (c), 10 (d) and 35 nmol L^{-1} (e).

Table 1
Standard recovery.

No.	Solution	Concentration of hemin (nmol L^{-1})	Peak current (μA)	Hemin concentration obtained from calibration curve (nmol L^{-1})	Recovery (%)
a	Blank	0	28.12	/	/
b	Serum	0	27.30	/	/
c	Mixture 1 (V_{serum}: V_{hemin}=1:1)	5	33.19	4.86	97.2
d	Mixture 2 (V_{serum}: V_{hemin}=1:2)	10	35.51	9.81	98.1

ABSTRACT

Lead is a hazardous compound that affects the central nervous system in people, particularly children, and may cause some reversible and irreversible diseases. Legal regulations try to prevent the exposure from products especially produced for children such as coating paints, jewelry, toys, bed linen, textile, etc. The aim of this study was to determine the lead levels of coating paints on children's outwear selling in district bazaar by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) and to specify the percent of non-complying samples. Here we described the solid matrix calibration method and confirmed the results with the microwave-assisted acid digestion method. Both comparative methods were validated by analysis of the certified reference materials (NIST SRM-612 glass matrix, NIST SRM-2582 powdered paint and ERM-EC681k) and bias% for accuracy and RSD% for precision were calculated lower than 6.8% and 7.3%, respectively. The recovery ranges of laser ablation and microwave-assisted acid digestion method for Pb were found to be between 88.2–98.1% and 95.3–101.3%, respectively. The limits of detection values were determined as 0.162 mg kg^{-1} for direct sampling in the ablation chamber and 0.002 ng mL^{-1} for aqueous solutions. Correlation result of 16 samples (r=0.99) examined in both methods was satisfactory. In coating paint samples, 14.65% of 198 (n=29) did not comply with the 90 mg kg^{-1} lead limit according to regulation. Validated quantitative laser ablation method may be preferred to quickly and reliably determine the Pb levels in other solid samples as well as coating paints.

1. Introduction

Lead (Pb) is known as a common environmental pollutant with long half life and its high levels accumulated in the body may cause intoxication in many organs and tissues. Chronic Pb exposure affects the central nervous system (CNS) and results in serious inhibition in learning and severe changes in behaviors, especially in children. Lead absorption may constitute a serious risk to public health, since it may cause slow cognitive development, impair intellectual performance in children and also increase blood pressure and cardiovascular diseases in adults [1–3]. Handling and mouthing of consumer products such as toys, clothing, and drawstring by children especially in 0–2 years old are the major ways of lead exposure via dermal contact and ingestion [4]. A study conducted showed a high proportion of recalls as well as a high number of deaths/injuries related to strangulation, lead paint or falls and these recalled products included hooded sweatshirts with drawstrings, baby cribs and children's jewelry [5].

Declared acute or chronic lead poisoning cases after oral or dermal exposure items like toys, batteries, fishing sinkers, jewelry, paints, etc. revealed the importance of prevention from lead exposure of children [6–9] and the regulatory limits of lead in consumer products are often lowered [10].

According to the Consumer Product Safety Improvement Act (CPSIA) by Consumer Safety Product Commission (CPSC) of the U.S. definition; "children's products that are designed or intended primarily for use by children 12 years of age or younger cannot contain greater than 100 mg kg^{-1} of total lead content in any accessible component part of the children's product as of the date of 2011 and the maximum limits of total lead that may be present in paint or any similar surface coatings produced for children as 90 mg kg^{-1}" since August 14, 2009. This limit applies to both paints and paint on toys and other articles intended for children and to certain household furniture items [11]. Also British standards about safety of toys (BS-EN71-3) determined similar limits for lead migration [12].

Regulations related to the use of hazardous chemicals in Turkey have recently been re-examined and adjusted to resolve some of the country's health and environmental issues to improve the quality of life and also for the adaptation to EU rules and regulations during the EU accession process. Over the last few years the public authorities

have been trying to meet the world standards and have taken concrete steps in this regard in Turkey.

A number of analytical methods about textile products including hazardous compounds conducted by atomic absorption spectrometry (AAS) or inductively coupled plasma mass spectrometry (ICP-MS) techniques in aqueous samples have been reported [13,14]. Over the last few decades, solid samples are being preferred to study by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), which is a developmental technique for in situ sampling. Although LA-ICP-MS is powerful for multi-element analysis and is easy to sample [15], in some cases, especially for specific matrices such as textile, coating surfaces, etc., studies are limited by the lack of standard reference materials (SRMs) in the case of a problem about elemental fractionation sources such as aerosol transport, vaporization, atomization, ionization, etc [16,17]. Several study results have been obtained by calibration curves generated from standard addition, direct liquid ablation or matrix-matched standard methods or in situ analysis without applying an internal standard by laser ablation in different sample types such as blood, rat brain tissue, anhydrous minerals and glasses [18–21]. Besides, numerous quantitatively validated reports and reviews have been published especially in geological and forensic fields explaining the technique in detail [22,23].

Researches on inorganic contents of textile products for both children and adults are limited while no published report is available about coating paints conducted either in Turkey or in other countries. A study determined the concentrations of some elements in textile samples such as Cu, Cd, Ni, Mn, etc. by flame and graphite furnace AAS after microwave digestion on textile products and they found concentrations of Cu and Cd in samples higher than the permitted values [24]. A study result of some elements with textile samples manufactured in Turkey was reported in another study conducted by AAS; the levels of Pb and Ni ions in textile material were found to be over the values for baby clothing according to Oeko-Tex [25]. Mataso and Cadore obtained validation results by an acid microwave closed vessel digestion method for textile products used as sports T-shirts and they found chromium in black fabrics as the major inorganic contaminant [14].

Children are exposed to Pb or other similar hazardous substances coming from environment or materials due to daily contact with clothes, bed linen, paints, toys, jewelry and similar products. In recent years, studies have investigated the presence of inorganic contamination in such kinds of consumables for children [26,27].

Guney and Zagury determined the total concentrations of As, Ba, Cd, Cr, Cu, Mn, Ni, Pb, Sb, and Se in toys and jewelry ($n=72$) for children bought on the North American market and compared these results to regulatory limits. According to their results, metallic toys and children's jewelry ($n=24$) 20 items had total concentrations exceeding migratory concentration limits of the European Union. High Pb levels (65%) were also found in some samples [28].

Revealing the hazardous compounds over the restricted limits in products is important, especially in terms of safety for the environment and health of citizens, and safety for workers exposed during the production process as well as for end users [10].

The aim of this study was determination of the Pb levels in coating paints on textile products produced for children and sold in district bazaars in Istanbul and to emphasize their compliance with regulations in our country with a new calibration strategy for LA-ICP-MS.

2. Experimental

2.1. Instrumentation

Measurements were conducted by a Thermo Electron X Series II ICP-MS (Germany), coupled to Nd:YAG laser ablation (LA) unit operating at 213 nm wavelength (New Wave Research Laser Ablation System, Merchantek, USA). For treatment of the samples a microwave acid digestion (CEM, Mars5, Matthews, NC, USA) was used. Water used was deionized (Millipore Direct-Q3 System, 18.2 MΩ cm).

2.2. Reagents and standards

Argon gas with $>99.999\%$ purity was used for the ICP-MS system (Okser, Turkey). Also used were 65% (w/w) HNO_3 and 35% (w/w) H_2O_2 solutions, purchased from Merck with supra pure quality. Certificated calibration solution (10 μg mL^{-1}) used was purchased from High-Purity Standards, Charleston; Indium (In) and Gallium (Ga) (1000 μg mL^{-1}) were used as internal standards (IS) (Absolute Standards, Inc., Hamden, CT, USA). Standard Reference Materials (SRMs) used for Pb were as follows: (i) National Institute of Standards and Technology (NIST) SRM 612 glass matrix (Gaithersburg, MD); (ii) NIST-SRM 2582 Powdered Paint (Gaithersburg, MD); (iii) European Reference Material, ERM-EC681k, low density polyethylene (Geel, Belgium). NIST-SRM 610 (Gaithersburg, MD) was also used as the external calibration standard.

2.3. Optimization

Preliminary optimization of instrumental parameters was conducted using aqueous standards (10 ng mL^{-1}) for an initial quality control of the instrumental performance to conduct both liquid nebulization and laser ablation ICP-MS methods. Afterwards, a second optimization with glass standard (NIST-SRM 612) was accomplished for laser ablation system. All the double charges and oxide levels were checked out. As an external standard, NIST-SRM 610 was analyzed at the beginning and the end of the sequence of the sample to correct for drift and variation during the experiment and to evaluate the capability of a laser ablation technique for the analysis of coatings.

2.4. Sample selection

Child outwear (0–12 years) containing coating paints and manufactured in Turkey were collected from four different district bazaars of Istanbul, ten samples from each bazaar were bought inexpensively and at least three different stallholders were chosen to buy samples. Totally 198 different colored coatings were obtained from forty products (Fig. 1). All these 198 samples were analyzed for ^{208}Pb by LA-ICP-MS and the selected 17 samples were verified by microwave-assisted acid digestion followed by liquid-based ICP-MS analysis.

2.5. Sample treatment and validation

2.5.1. Laser ablation

Each coating paint in different colors was cut into parts with approximately 0.5×0.5 cm dimensions from child outwear as shown in Fig. 2 (left side) and adhered on laminas with the cyanoacrylate adhesive which was also used as blank. NIST-SRM 2582 powdered one was converted to pellet form as follows: a 0.5 g portion of the pre-dried powder material was pressed with a manual hand press tool into a disk-shaped pellet 1.3 cm diameter with a thickness of approximately 3 mm.

NIST-SRM 610 and 612 are universal standards used for any kind of laser ablation applications, but the analysis parameters such as laser energy, scan speed, frequency, etc. applied to the glass matrix are different from coating paint surfaces. For this reason and for the lack of coating paint reference material, a calibration study was conducted in three different matrices, glass, polyethylene and powder, which have decreasing rigidity and increasing lead

Fig. 1. Child (0–12 years) outwear samples bought from district bazaars with several coating paint colors. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Fig. 2. Samples adhered on a lamina for ablation method to the chamber (left side), coated and stripped form of a sample prepared to microwave-assisted acid digestion method (right side).

concentration, respectively, after optimizing the analysis parameters with raster-type ablation. At the beginning of the calibration and linearity studies, all SRMs were analyzed with the same ablation conditions. Signals and ablation patterns were evaluated and proper energies were applied per SRMs until acceptable correlation coefficient was obtained for the calibration curve.

All three SRMs were also placed in the ablation chamber appropriately. We developed a new calibration strategy using three different SRMs including glass, polyethylene and powder matrices to quantitate Pb levels on coating paint textile samples produced for children. SRMs containing Pb certified values as 38.5, 98 and 208.8 mg kg^{-1} respectively were used to obtain the calibration curve in the Laser Ablation method. Three different laser energies were used to obtain a linear calibration curve as the structures and surfaces of SRMs were different from each other as detailed in Table 1. Ablation and analysis conditions of samples are also shown in Table 2. The limit of detection (LOD) and quantification (LOQ) of Pb were calculated as three times and ten times the blank (adhesive agent) deviation. Validation studies were conducted by sampling of SRMs and selected samples close to the regulatory limit (90 mg/kg^{-1}) with six replicates.

2.5.2. Microwave-assisted acid digestion

The calibration curve was prepared in 2% HNO_3 by incremental amount as 0, 0.1, 0.5, 1, 2, 5, 10, 25, 50, 100 and 150 ng mL^{-1}. Calculation of LOD and LOQ was the same with the LA method. To check out the contamination from vessel and fabric, a blank acid mix sample and uncoated fabric sample were separately digested. Additionally, two of SRMs (NIST-SRM 2582 and ERM-EC681k)

Table 1

were treated six times with the same procedure with samples for quality control and validation.

The developed quantitative ablation method was confirmed by an acid microwave closed vessel digestion method with 17 samples and SRMs. First of all, a few drops of acetone were applied onto the coated area of the sample to facilitate the removing of paint and stripped with the aid of a lancet as shown in Fig. 2 (right side). Stripped coatings were weighed (approx. 0.05–0.1 g) after drying at 100 ± 3 °C for a minimum of 3 h and placed in microwave vessels. Ten mL 65% (w/w) HNO_3 and 2 mL 35% (w/w) H_2O_2 were added. Sample preparation and treatment conditions are detailed in Table 3. The final solution was diluted to 25 mL volumetric flask after filtration. Samples were diluted tenfold using 2% HNO_3 and the added internal standards (20 ng mL^{-1} of Ga and In) before analysis. The analyzed conditions are also listed in Table 2.

In the statistical evaluation of the study, Spearmans's correlation test was used to determine the correlation of both methods.

3. Results and discussion

3.1. Laser ablation results

Tuning was performed using NIST-SRM 612 to achieve high and stable ion beam intensities and low oxidation rates. On the other hand, NIST-SRM 610 was used periodically as an external standard to control the variations as well as polyethylene SRM EC681k during the experiment. Also raster type ablation made it easier to achieve repetitive results for ^{208}Pb isotope. Samples were automatically calculated according to the calibration curve after treating the raw data for ablation time vs. gas blank time. The time-resolved spectra were treated to apply background correction and each sample was replicated three times in a run.

A linear calibration curve was plotted using SRMs by Laser Ablation with $R > 0.999$ correlation coefficient with calibration points of blank (adhesive agent), 38.5, 98 and 208.8 mg kg^{-1} of Pb and shown in Fig. 3 after optimization of laser parameters as described

above. Laser energy used for samples was the same with blank and SRM EC681k because of the surface similarity of coating paint matrix with polyethylene.

According to the results, 125 of 198 coating paint samples were found below 10 mg kg^{-1} (63.13%), 44 samples were found between 10 and 90 mg kg^{-1} (22.22%) and 29 of 198 coating paint samples were found over the 90 mg kg^{-1} limit level (14.65%). Numbers of samples found above 90 mg kg^{-1} Pb signified in regulations are listed in Table 4 regarding colors. Mean and median Pb concentrations of these unsuitable samples were 2357.6 and 579.0 mg kg^{-1}, respectively. Mostly yellow and its color tones such as orange, skin tone, brown, red and green were determined as positive in terms of lead. Percent of child outwear over the limitations was found to be 40.0% with 16 among 40 products collected from four different bazaars, whereas in the distribution by bazaars, almost equal distribution was observed as listed in Table 5.

3.2. Microwave-assisted acid digestion results

According to linear calibration ($R > 0.999$) in the range of 0–150 ng mL^{-1}, acceptable recovery and accuracy results of SRMs are shown in Table 6. LOD and LOQ of Pb were found to be 0.002 and 0.005 ng mL^{-1}, respectively.

Comparing the results in Table 6, validation performance of both methods were applicable with the obtained values. LOD and LOQ values and linearity range for both methods were also proper to determine Pb in terms of the accepted level. Seventeen samples were analyzed by both methods and 0.988 correlation (significant at the level 0.01; $n=16$) was found except for one sample with a result of 1539.9 and 274.2 mg kg^{-1} Pb for microwave-assisted acid digestion and laser ablation methods, respectively. Difference of this result might be caused by the heterogeneity of sampling area in the raster ablated [29]. Correlational plot comparing both methods is presented in Fig. 4.

Numbers of quantitative studies conducted by laser ablation in several types of sample are gradually increasing in recent years. Hsieh et al. reported four calibration curves built from aqueous standard solution and blood SRM applied onto membrane filter surface via pipette. Results were satisfactory for laser ablation [18]. In the other study conducted by Jurowski et al. by means of standard solution addition to the rat brain and a long established calibration method was developed [19]. Günther et al. also used standard solutions to direct liquid ablation and found the method suitable both for analyzing small volumes of complex aqueous solutions and for microanalysis of solids [20]. Additionally, matrix-matched quantitative studies to analyze forensic samples, glass, paint, etc. using laser ablation have become a powerful and flexible analytical technique for direct elemental and isotopic analysis of solids [22,23]. As a case in point, Latkoczy et al. produced inter-laboratory tests improved results for nearly all elements with a deviation of $<10\%$, and demonstrated that LA-ICP-MS can deliver absolute quantitative measurements on major, minor and trace elements [30].

To the best of our knowledge, developed and comparable quantitative laser ablation method for coating paints on textile products in this presented method is the first reported study to check the limited lead values specified in regulations. Calibration by SRMs in our study demonstrates a new approach among other calibration techniques in the area of direct analysis of solid certified standards. Besides, coated surface of samples which were

similar with polyethylene SRM ablated with the same laser energy to close the trueness. Correlation results between laser ablation and microwave-assisted acid digestion methods proved the accuracy of the selected ablation method parameters as well.

In comparison, both methods were applicable to determine the Pb level in coating paint samples in any textile product. But the LA-ICP-MS method developed in this study offers several analytical advantages. The method is less time consuming, has easy sample preparation, and has less contamination risk points. Additionally, laser ablation method made it possible to rapidly determine Pb levels of a large number of samples in the same ablation chamber. Moreover, it should not be forgotten that replication of samples is important to ensure the homogeneity of ablation surface.

4. Conclusions

The inter-comparisons presented in this paper demonstrate that both laser ablation and microwave-assisted acid digestion methods were proper to determine Pb level in a coating paint according to the validated result. And both methods could be applied not only to the textile industry but also to other consumer products such as toys, jewelry, hand tools, etc. to check the safety level of restricted inorganic compound besides Pb for children. In this study, developed full quantitative laser ablation method for coating paint on textile products is firstly published obtaining a calibration curve from solid certified materials.

Determination of trace metals such as Ni, Cd, Mn, Cu, Cr as well as Pb in textile productions is a substantial issue not only for the safety of consumers but also for the textile industry in terms of export and import control. This is also important to meet the world standards to protect the human health, to prevent environmental pollution and also to take a better place in the globalized world of trade business. In addition, primary prevention is a strategy that emphasizes the prevention of lead exposure, rather than a delayed response to exposure after it has taken place.

Matrix isolation

ABSTRACT

Electrodialytic ion transfer was studied as a matrix isolation tool for heavy metal determinations. An ion transfer device (ITD) was used for the transfer of heavy metal cations. Under optimized flow rates applied voltage and receptor composition, heavy metal ions were quantitatively transferred at concentrations spanning $\mu g\,L^{-1}$ to $mg\,L^{-1}$. As long as the sample pH was acidic, there was no significant sample pH effect on the transfer efficiencies. Significant salt concentrations (> 1 mM NaCl), however, decreased the transfer efficiency. This could be ameliorated (up to 5 mM NaCl) by transient instead of continuous sample introduction. The device was applied to the determination of Fe, Cu and Zn in equine and bovine serum; the reproducibility was better than conventional digestion method.

1. Introduction

Metals play important biologic functions in all living systems but nearly all are toxic in excess [1]. Thus, metals in various matrices, e.g., drinking and environmental waters, biofluids etc., are of wide interest. Typical analysis techniques include atomic spectrometry, induction coupled plasma mass spectrometry (ICP-MS), and ion chromatography (IC) coupled with post column reaction (IC-PCR). In particular, ICP-MS is widely used because it can provide rapid simultaneous multi element analysis with very good limits of detection [2]. If analyte concentrations are relatively high, biological samples can be directly introduced after dilution to keep matrix interferences manageable. However, this is not possible in many cases: injection of the neat or even diluted sample can cause clogging of the interface, loss of atomizing efficiency, polyatomic interferences etc. [3]. The problems are not unique to ICP-MS. In IC, IC-ICP-MS, or IC-PCR, which are particularly well suited for speciation analysis, suspended/colloidal material cause clogging while proteins exhibit strong adsorption on ion exchange columns [4].

Sample pretreatment strategies used to address these problems typically involve conventional or microwave-assisted [5] wet digestion [6–8], deproteinization [9,10], conventional or microchip based solid phase extraction (SPE) [11–13] etc. Occasionally, matrix effects can be corrected by a matrix-matched blank solution [14] or on-line standard addition [15,16]. Wet digestion is not without pitfalls; the use of large amounts of acids and chemicals invariably raise the blank [17]. Similarly in SPE, the absorption efficiency is strongly affected by the sample pH and on the specific metal of interest [18,19].

We recently reported on-line electrodialytic ion transfer devices (ITDs) for matrix isolation [20,21]. The targeted ionic solutes, small inorganic cations (alkali and alkaline earths) or anions [20], and organic acids [21] were quantitatively transferred from the sample to a deionized water acceptor leaving behind particles, proteins, and non-ionic compounds. The device design isolated the acceptor stream from the electrodes to avoid bubbles or redox conversion in the acceptor stream. While charge of ions, strongly affect their electrophoretic mobility, quantitative transfer under the optimized conditions was still possible regardless of the charge on the ion. However, detailed examination shows that multiply charged ions require slightly less applied voltage for quantitative transfer [20]. Obviously, a deionized water receptor cannot be used for transferring metal ions that form insoluble hydroxides but the use of an acidic receptor will also result in reverse transfer of the acid anion from the receptor, the net outcome being uncertain.

We optimized an ITD and its operating conditions for matrix isolation of metal ions such as Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{2+}, Fe^{3+},Ni^{2+}, Cr^{3+}, and Zn^{2+} and evaluated their transfer efficiencies in different matrices. We show here successful application of this technique for the determination of Fe, Cu, and Zn in human serum and compare them with results obtained by conventional wet digestion.

2. Experimental

2.1. Reagents

Chloride salts, $FeCl_3 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$, $ZnCl_2$, $CdCl_2$ (www.wako-chem.co.jp), $CuCl_2 \cdot 6H_2O$, $CoCl_2 \cdot 6H_2O$, $CrCl_3 \cdot 6H_2O$ and $FeCl_2 \cdot 4H_2O$ (www.nacalai.co.jp) were used. As a receptor and an isolator solution, 50 mM HNO_3 was prepared daily with trace metal analysis grade nitric acid. Ultrapure water ($>$ 18.2 MΩ cm) was used throughout.

2.2. Electrodialytic metal ion transfer device

Basic ITD structure, same as that was previously described [20], consisted of five flow streams layered atop each other and isolated by membranes. All channels had dimensions of 5×40 mm wide $\times$ long and were fabricated with gaskets constructed of Parafilm® pressure-imbedded in a nylon mesh with an overall thickness of 0.13 mm. Membranes separated the different channels. The central channel is intended for the sample to flow through, atop this is a regenerated cellulose dialysis membrane (DM, SpectraPor® Biotech regenerated cellulose dialysis membrane 129 020, molecular weight cutoff 8 kDa, www.spectrumlabs.com) through which the cation receptor solution flows. This channel is bounded atop by an anion exchange membrane (MAEM, Selemion® ASV, 0.13 mm thickness); the negative electrode is placed above the MAEM. The MAEM does not allow cation transfer; despite the electric field, cations that have been transported into the cation receptor channel cannot therefore further migrate to the cathode channel. The central channel is bounded on the bottom by the same type of dialysis membrane as the one on top, the anion receptor channel follows and this is separated from the anode channel by a cation exchange membrane (MCEM, Selemion® CSO, 0.10 mm thickness, both ion exchange membranes from www.agec.co.jp). The entire assembly was held together between two poly(vinyl)chloride (PVC) end plates and a number of screws. Each PVC plate also contained a 0.2 mm deep machined flow channel for placement of the platinized titanium mesh (0.1 mm thickness) electrodes. Five pairs of fluid inlet/outlet ports served the five flow channels.

2.3. Flow system

Fig. 1 shows the system schematically. Five independently adjustable miniature peristaltic pumps (PPs, WPX1-P1/16S4, www.welco.net) coupled with Pharmed® pumping tube (0.5 mm i.d. $\times$ 3.7 mm o.d.) served the flow channels. All pump voltages were adjusted to obtain a flow rate of 150 μL min^{-1} as measured by a liquid mass flow meter (LF-F30M-A, www.horiba.com). Except as stated, the sample (0.1 mL) was introduced into the ITD by a 6-port injector (I1) into the carrier stream. The acceptor solution receiving the metal ions was directly introduced respectively into the ICP-MS nebulizer or the IC system sample loop. The influent was ultrapure water in all the channels except for the cation receptor and cathode isolator channel. Except as stated the influents for the cation receptor and cathode isolator channel were 50 mM HNO_3 and a 10 mM pH 2.1 phosphate buffer solution, respectively.

2.4. Heavy metal determination by IC-PCR, ICP-MS and AAS

Metal ion concentrations were determined with IC-PCR, ICP-MS, or Atomic Absorption spectrometry (AAS).

Ion chromatographic determination was performed with post-column derivatization with 4-(2-Pyridylazo)resorcinol (PAR) and visible absorbance detection following manufacturer recommended procedure using Ionpac® CG5A (GC, 4×50 mm^2) and CS5A (SC, 4×250 mm^2, both from www.dionex.com). The eluent containing 1.17 g of dipicolinic acid, 0.976 g of K_2SO_4, 3.70 g of KOH and 2.8 mL of HCOOH in 1 L was pumped by a double plunger pump (P1, KP12-13, www.eyela.co.jp) at 1.0 mL min^{-1}. The sample (30 μL) was injected via a 6-port injector (I2, Cheminert C2-2346EH, www.vici.com). The postcolumn reagent (0.15 g PAR, 89 mL 2-dimethylaminoethanol, 25.2 g $NaHCO_3$, and 30.4 mL NH_4OH in 1 L) was teed in at 0.7 mL min^{-1} by a second double plunger pump (P2). The effluent was put through a serpentine-II pattern knitted reactor (RC, 0.5 mm i.d., 500 μL) [22] for good mixing ($\sim$0.3 min reaction time) and the absorbance was then monitored at 530 nm by an absorbance detector (D, Kratos Spectroflow 757). Both column and postcolumn reactor were kept in a column oven (HIC-6A, www.shimadzu.co.jp) at 50 °C. The IC-PCR system could separate and determine Fe^{3+}, Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Cd^{2+}, and Fe^{2+} with limits of detection (LODs) ranging between 3–30 μg L^{-1}.

ICP-MS (Elements, www.thermofisher.com) measurements were made with 1300 W RF power, 16.7 L min^{-1} of total argon flow, and a mass resolution of 300. The masses used for Cr, Mn, Co, Ni, Cu, Zn, and Cd were 53, 55, 59, 60, 65, 66, and 111, respectively.

Atomic absorption spectrometry (AAnalyst100, www.perkinelmer.com) was also used to determine higher levels of Cr, Mn, Cu, Zn, and Fe. Acetylene and air flows were 2 and 4 L min^{-1}, respectively. A multi-element hollow cathode lamp (Lumina®, N3050217, and N3050208 also form Perkin-Elmer) was used.

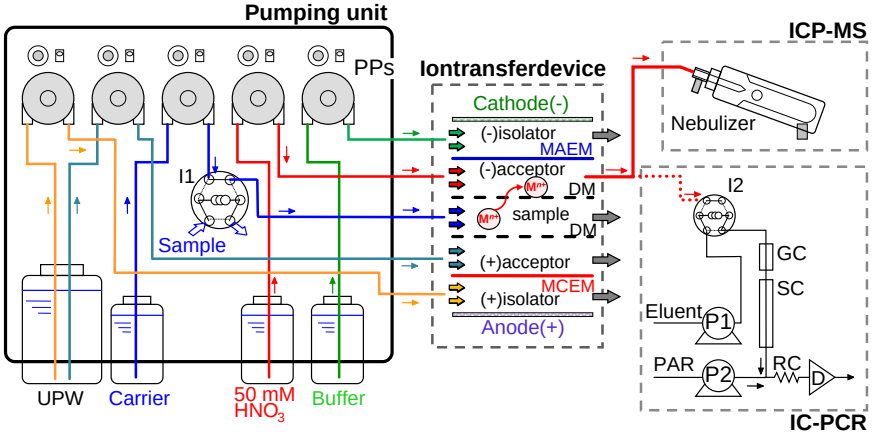

Fig. 1. Schematic flow diagram. UPW: ultrapure water, PPs: peristaltic pumps, MAEM: monovalent selective anion exchange membrane, MCEM: monovalent selective cation exchange membrane, P1, P2: plunger pumps, GC: guard column, SC: separation column, RC: reaction coil, D: absorbance detector, I1, I2: Injectors.

The wet digestion procedure used for comparative analysis was as follows: Sample (5.0 mL), H_2O_2 (2.5 mL) and concentrated HNO_3 (1.0 mL) were heated in a 15 mL polytetrafluoroethylene container until volume was reduced to 1.5–2.0 mL. After cooling, 1.0 mL conc. H_2SO_4 was added. The solution was heated again to fumes. The residue was then diluted with water, made up to volume and analyzed.

3. Results and discussion

3.1. Establishments of ITD for cationic metal ion transfer

Although alkali and alkaline earth metals have been successfully transferred from sample solution into the acceptor solution with an ITD using water in all channels, these ions form soluble hydroxides in the receptor channel. This is not possible for metals other than the alkali and alkaline earths, as the corresponding hydroxides are insoluble. Indeed, the continuous passage of a solution containing 100 μM ea. of Fe^{3+}, Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Cd^{2+}, and Fe^{2+} in 1 mM HNO_3 and water in all other channels with the application of voltage removed significant amounts of the metals from the sample stream, the metal concentrations in the receptor stream were below the LOD of the IC-PCR system (Table 1) but none of the transferred metals were detected in the receptor stream. Most likely insoluble hydroxides are adsorbed on the membrane(s).

Acids (50 mM HNO_3) and buffer (pH 2.1, 10 mM phosphate buffer) were, respectively, used as (−)acceptor and (−)isolator to avoid formation of insoluble hydroxides. The transfer efficiencies, which is defined as the response ratio with and without ITD treatment, improved dramatically and except for Fe^{3+}, near-quantitative transfer was achieved. The receptor acidity was high enough to avoid formation of hydroxides and keep it acidic despite the unavoidable transfer of some of the NO_3^- to the central compartment and hence to the anode receptor. In addition, the highly conductive (−)acceptor and (−)isolator solution decreased the electrical resistance of acceptor channel, and as a result at a constant applied voltage, the electric field strength on the sample channel increased, promoting the desired metal ion transport rate. Thus most of targeted metal ions were quantitatively transferred from a sample to an acceptor solution. However sufficient loss of nitrate towards the sample and the (+)isolator channels and its replacement by the phosphate buffer ion in the receptor channel occurred, causing the receptor pH to increase from ~1.3 to 3.03 during passage through the ITD. Even though at pH 2.1 $H_2PO_4^-$ is the dominant anionic form in solution in a phosphate system, phosphate is not necessarily transported through an AEM as the singly charged species. Ion exchange membranes can be made selective towards monovalent ions by incorporating a very thin layer of an oppositely charged layer atop a conventional ion exchange membrane [23]. For example, incorporating a very thin, highly cross-linked cation exchanger layer atop a standard anion exchange membrane greatly inhibits passage of multivalent anions and such a membrane is available as a monovalent selective anion exchange membrane (MAEM); a monovalent selective cation exchange membrane (MCEM) is correspondingly made of highly cross-linked anion exchange membrane atop a conventional CEM (www.selemion.com). We found it advantageous to use the MAEM and the MCEM, rather than the conventional ion exchange membranes; the pH of the (−)acceptor solution in this case increased barely over that of the initial 50 mM HNO_3.

While other ions were transferred near-quantitatively, ion transfer efficiency for Fe^{3+} was poor. Curiously, replacing HNO_3 with either trifluoroacetic acid (TFA) or $HClO_4$ as the (−)acceptor solution provided near-quantitative transfer for Fe^{3+}. Nitrate forms a complex with Fe^{3+} with the first formation constant being ~10 [24] while it is known that no complexation occurs with perchlorate [25]. There is no available data on the solution phase association of Fe^{3+} with CF_3COO^-; triflate is not known for its complexing properties – we presume that no complexation occurs here either. We ascribe the better performance of $HClO_4$ or CF_3COOH acceptors because the corresponding anions readily move through the dialysis membrane to the sample channel. If they form a lower mobility adduct than the form in which the cation was initially present, transfer will be inhibited.

3.2. Parameter optimizations

Acceptor acid concentration, applied voltage, and solution flow rates were optimized.

The effect of acceptor acid concentration was further examined for HNO_3 and TFA (Fig. 2a). The transfer efficiencies for all tested metal ions increased with increasing (−)acceptor acid concentration. All metal ions tested except Fe^{3+} were quantitatively transferred with 50 mM HNO_3. Higher HNO_3 concentrations resulted in excessive Joule heating ($i > \sim 0.15$ A) and were not pursued. All tested metal ions, including Fe^{3+}, were quantitatively transferred with 50 mM TFA. TFA was only used for IC-PCR detection as the metal background of our particular TFA reagent was too high for ICP-MS.

The applied voltage (V_{app}) provides the motive force for metal ion transport. The effect of varying V_{app} between 0 and 20 VDC is shown in Fig. 2b (100 μM ea. metal ion in a mixture, 50 mM TFA acceptor). Predictably, transfer efficiency increased with increasing

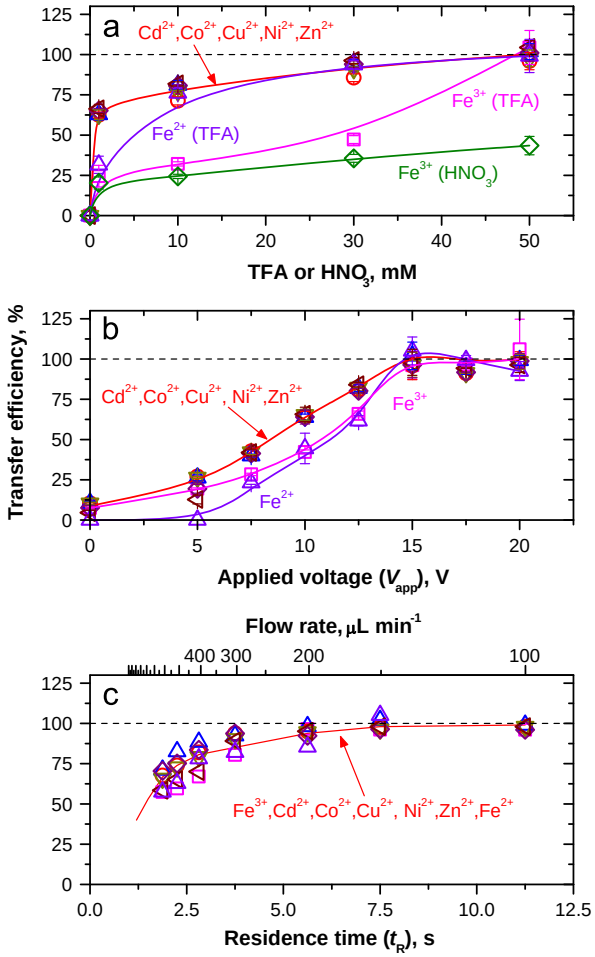

Fig. 2. Optimization of the effective factors. Optimization of the effective factors, acid concentrations (a), applied voltage (b), and residence time (c). The experimental conditions were (a) applied voltage: 15 V, solution flow rates:100 μL min^{-1}, (b) acceptor solution: 50 mM TFA, solution flow rates: 100 μL min^{-1}, and (c) acceptor solution: 50 mM TFA, applied voltage: 15 V.

V_{app}, reaching ≥95% for all tested metals by ~15 V. Transfer efficiency actually decreased slightly at V_{app} > 15 V because of back transport from acceptor to sample solution with larger Joule heating caused by larger currents [20]. V_{app}=15 V was used for all further studies.

The sample solution flow rate controls the ITD residence time. The transfer efficiencies as a function of residence times/flow rates are shown in Fig. 2c. For convenience, all flow rates were changed at the same time. Quantitative transfer was asymptotically approached with decreasing flow rate. We conducted all further experiments with a flow rate of 150 μL min^{-1} (t_R=7.5 s).

Metal ions mixture standards from μg L^{-1} to mg L^{-1} concentration levels were introduced into the ITD and analyzed by ICP-MS and AAS. Transfer efficiencies, obtained from the slopes of calibration curves are summarized in Table 2. At μg L^{-1} concentration levels, all metal cations studied were transferred with 97–104% efficiency. All but Fe^{2+}, Co^{2+}, and Ni^{2+} were tested at the 1–5 mg L^{-1} concentration as well and exhibited 97–99% transfer efficiency.

3.3. Effects of sample pH on ITD

Sample pH greatly affects chelating resin-based SPE of trace metals as the conditional formation constants are strongly pH-dependent. Sample pH must be preadjusted and often auxiliary weak complexing agents added to prevent precipitation [18,19]. In practice, sample pretreatment prior to chelating resin SPE must be optimized for each sample type. As the present ITD does not depend on chelation or ion exchange selectivities, it was of particular interest to examine the pH effects on the transfer efficiencies for different metals in the present device (Fig. 3). The sample standard (2.5 mg L^{-1}) pH was adjusted with acid or buffers: nitric acid for pH 1–3, 1 mM CH_3COOH/CH_3COONH_4 for pH 4–6, 1 mM K_2HPO_4/KH_2PO_4 for pH 6 and 7, 1 mM NH_3/NH_4Cl for pH 8–10. The sample was then introduced into the ITD. Both the pH-adjusted standard and the ITD-processed acceptor solutions were analyzed by AAS. The response ratio was considered as the recovery. Predictably, at pH < 2, recovery was subquantitative (~70–95% at pH 1), due to

Table 2
Transfer efficiencies under optimized conditions.

competition with the large amount of H^+ present. But in the important practical pH range of 2–7, ITD recovery was essentially quantitative except for Zn^{2+} at the higher pH end, likely due to the formation of neutral oxide/hydroxide. The immunity to pH dependence is all the more remarkable in comparison to iminodicarboxylate resins where the recoveries of alkaline earth metals, as well as those Cr, Co, and Ni are reportedly strongly affected by sample pH in this range [18,19]. At $pH > 7$, the recovery of all metals studied predictably began to be affected to varying degrees, the recovery generally decreasing with increasing pH due to the formation of oxides/hydroxides.

3.4. Effects of salts in sample solution

We have previously observed that the ITD could quantitatively transfer common inorganic ions up to ~20 meq/L [20]. The present device is not intended for concentrating trace metals from highly saline matrices, e.g., seawater but to perform matrix cleanup, e.g., in biological samples, rather than having to digest them. Additionally, in biological samples it may have the potential to distinguish free metal ions from those that are covalently bound, e.g., as the metal center in a metalloenzyme molecule. Nevertheless, even most such samples will contain significant amounts of alkali or alkaline earth cations aside from trace metal ions of interest. These cations, of higher mobility and generally present in greater concentrations, are expected to decrease trace metal recoveries. The objective was to determine to what extent of salt can be tolerated before the transfer efficiencies suffers markedly.

The recovery of 100 $\mu g\ L^{-1}$ Mn^{2+}, Co^{2+}, Ni^{2+} and Zn^{2+} were studied in varying concentrations of NaCl as the matrix. The dominant ions in biological fluids were selected as the analytes in this study. The recoveries began to decrease markedly at NaCl concentration > 1 mM (Fig. 4). Several factors may be responsible for this degraded performance: (i) competition from Na^+ (ii) decreased field strength from increasing sample conductivity, and formation of chloro complexes.

In the mode of operation described above, the membranes operate in a steady state transfer mode. It is well known for ion exchange membrane based electrodialytic suppressors used in IC that they will handle a much larger concentration and perform quantitative ion transfer when the same substance is injected as a transient plug rather than in a continuous basis. Injection of a discrete sample is also a more realistic test because sample availability may preclude steady state operation in many cases. We explored 100 µL injection of the trace metals in a saline matrix into a 1 mM HNO_3 carrier stream; the acceptor solution was directly introduced into the ICP-MS nebulizer, resulting in a response peak. Greater tolerance to salt was indeed observed; recoveries in this case were unchanged up to a 5 mM NaCl matrix. We have not explored if higher matrix concentrations can be tolerated with a smaller sample volume.

3.5. Application to serum samples

To evaluate and validate the present method, serum samples were (a) pretreated with the ITD or (b) digested; both were then analyzed by IC-PCR. A prescribed wet digestion method [26] was followed in modified form (see Section 2). The analytical results from the two methods (Table 3) statistically indistinguishable based on a *t*-test [27]. Relatively poor reproducibility of wet digestion methods has previously been reported [28]; the repeatability of the present method (3–5% RSD) was clearly much better.

4. Conclusions

An electrodialytic ion transfer device for heavy metal cations was introduced for matrix isolation and its successful use demonstrated. In the absence of large concentrations of other cations (equivalent to ≤ 5 mM NaCl), trace metal cations can be quantitatively transferred from the sample to an acidic acceptor solution that can be directly introduced to most analysis systems. The device will be particularly applicable to isolating metal ions from matrix components such as proteins, cells, particulate material, and non-ionic compounds.

ABSTRACT

Determining salt content is a vital procedure in the petroleum industry during the process of crude oil transportation, refining and production. Monitoring the salinity value using a fast and direct technique can substantially lower the cost of crude oil in its processing and its production stages. In the present work, a novel analytical method was developed to detect the amount of salt present in crude oil in a quick and reliable manner. The measurement is based on the rate of in-situ electropolymerization of a monomer such as aniline in association with the salt content in the crude oil. The salt dispersed in the hydrocarbon matrix is used as an electrolyte in the electrolytic system to induce an electropolymerization reaction upon the induction of voltages, in which the salt content is measured corresponding to the polymeric film formation on the working electrode surface. Acetonitrile and N-methylpyrrolidone (NMP) were used in the electrochemical cell as solvents, and cyclic voltammetry tests were performed for Arabian crude oil solutions in the presence of aniline. The method has shown an excellent detection response for very low concentrations of salt. Four Arabian crude oils with salt concentrations of 34.2, 28.5, 14.3 and 5.71 mg L^{-1} have produced current intensity of 180.1, 172.6, 148.1 and 134.2 μA at an applied current potential of 1.75 V (vs. Ag/AgCl), respectively. A Calibration curve was obtained in the range of 5–35 mg L^{-1}, giving limits of detection and quantitation at 1.98 and 5.95 mg L^{-1}, respectively. The in-situ electropolymerization based sensor has significant advantages over the existing techniques of salt monitoring in crude oil such as fast response, temperature independency, electrode stability, and minimum sample preparation.

1. Introduction

In the oil and gas industry, the concentration of salt in crude oil produced depends mainly on the production source such as a drilling well and a reservoir [1]. Interaction of hydrochloric acid and dolomitic limestone with the contents of the well during its treatment causes the formation of sodium, magnesium, and calcium chlorides in the crude oil [2]. Additionally, the injection of seawater into the wellhead for enhancing oil recovery leads to crude oil contamination mostly by sodium chloride [1,3]. Salinity in crude oil creates problem for the petroleum industry. Large quantities of salt in crude oil may cause severe corrosion in pipelines, storage tanks, preheat exchangers, and condensers [1–5]. Additionally, deactivation and fouling of catalysts may take place during the refining process due to the high salinity of the hydrocarbons [4]. The salt content also negatively impacts the market price of crude oil per barrel which ultimately lowers net return on investment [5]. The total amount of salt present in crude oil can vary dramatically, wherein it can be as high as 200,000 mg L^{-1} or as low as 10 mg L^{-1} [3]. Refining plants are equipped with a desalting process that is capable of reducing the amount of salts to a predefined level. Hence, the crude oil is analyzed before and after the desalting process to monitor the salt value and determine the efficiency of the desalting process.

Measurement of salt in crude oil is generally based on indirect techniques i.e., by measuring the electrical property of the hydrocarbon mixture [3]. This technique measures the difference in the electrical potential between conducting electrodes in a mixture of crude oil and solvents, wherein the salinity of the solution mixture is tied to the conductivity values reported [3]. Various analyzers utilizing such sensing techniques have been developed and are commercially available [1]. However, this sensing technique poses significant limitations such as reliability, long life-span, and accuracy during real-time analysis. Furthermore, electrode surface in these sensors is prone to corrosion, which changes its surface characteristics leading to erroneous readings. The physical deterioration of the electrode surface produces a larger error, especially during the measurement of low salt concentrations.

In addition, the laboratory method based on the ASTM method (D-3230) for measuring salt content in crude oil requires prior extraction of salt and extensive use of solvents [3].

We present in this paper, the development of an indirect and novel method based on electro-initiated polymerization via the controlled potential method to monitor the amount of salt present in crude oil [6]. The electropolymerization reaction is based on a free radical mechanism as the monomer polymerizes through applied potentials (i.e., voltages) in the presence of electrolytes. The mechanism and kinetics of many electropolymerizable monomers have received great attention in the past [7–10]. Various monomers can be used in electropolymerization methods including aromatic benzoid compounds such as aniline and phenylenediamine. The reaction of these monomers is usually an oxidative coupling polymerization with a small possibility of reductive polymerization [6]. The analytical solution described below utilizes this technique which involves the basic elements of an electrolytic chemical cell. In essence, the salt present in the crude oil can be utilized as a conductive solution for an electropolymerizable monomer, which on contact with electrical applied voltages, will start the polymerization process. The relationship between solution conductivity and the produced amount of polymeric material has been previously studied [11]. It is expected that an increase in electrolyte concentration will increase the rate of electropolymerization reaction [11]. Hence, the salt concentration in an electrolytic system can be measured by calculating the rate of electropolymerization (i.e., amount of the produced polymer on the working electrode). This hypothesis is intended to be used to measure the salt concentration in crude oil with a similar electrolysis method. This technique is expected to provide a direct readout of the salt value in a real-time analysis of crude oil without extensive sample preparation, leading to an enhanced capability of salt monitoring during crude oil transportation and processing.

2. Experimental

2.1. Materials and apparatus

Acetonitrile, thiophene, aniline, NMP, methanol, butanols, dibenzothiophene (DBT), sodium chloride (powder), dichloromethane, and hexane were purchased from Sigma-Aldrich, and methyl-tetra-butyl-ether (MTBE) was purchased from Burdick and Jackson (Honeywell). Arabian crude oil samples were obtained from the Abqaiq oil field in Saudi Arabia. Deionized water (DI) with 18 $M\Omega\,cm^{-1}$ was obtained by the Milli-Q system in our laboratory. The silver/silver chloride reference electrode (Ag/AgCl), platinum disk electrodes, and polishing kit were purchased from (BASi) Bioanalytical Services. Cyclic voltammetry experiments were performed on the EG&G potentiostat (Model 263A). The reference electrode (Ag/AgCl) was fitted with a flexible connector. All chemicals were used as received without any further purification.

2.2. Electropolymerization of aniline, DBT, and thiophene

The electropolymerization reaction was conducted using a similar procedure described in the literature [6–9]. Initially, 0.25 g of sodium chloride was dissolved in 1.0 mL of DI water to be used as the electrolyte solution. The mixture was then added to a 0.5 mL solution of aniline in the presence of 2.0 mL of acetonitrile. The prepared mixture was stirred using a magnetic stirrer for 15 min at an ambient temperature. Counter, reference and working electrodes were placed inside the mixture, and cyclic voltammetry was performed on the solution using an EG&G potentiostat. The potentiostat was scanned in the range of −3.0 to 4.0 V (vs. Ag/AgCl) electrode at a sweeping rate of 10 mV/s. The solution stirring rate during the cyclic voltammetry was kept low because a high stirring rate can hinder the rate of electropolymerization [10]. The experiment was repeated for other monomers as well (i.e., DBT and thiophene) under the same experimental conditions.

2.3. Electropolymerization of aniline in the presence of crude oil

The electropolymerization of aniline in the presence of crude oil was carried out using the same procedure as described before. However, NMP was added to the solution to enhance the electroconductivity of the mixture. 1.0 mL of aniline was initially dissolved in 5 mL of acetonitrile using a magnetic stirrer under an ambient temperature. In a separate container, 3.0 μl of crude oil was dissolved in 5 mL of NMP under the same conditions. Both solutions were then mixed together and stirred for 15 min with a magnetic stirrer. A standard amount of aqueous sodium chloride solution with a concentration of 3.4×10^{-6} mol L^{-1} was added to the mixture while stirring to ensure a standard concentration of salt present in the mixture. The final solution was placed inside a small glass vessel fitted with three electrodes. Once the electrodes were connected to the potentiostat, a sweeping potential was applied across the counter and working electrodes in the reaction cell using the same cyclic voltammetry parameters. These steps were repeated for four different Arabian crude oil samples, with four different quantities of salt ranging from 4 to 35 mg L^{-1}. The actual amount of salt present in the crude oil was determined by the ASTM Standard Method (D-3230).

3. Results and discussion

3.1. Electrolysis of monomers using cyclic voltammetry

A platinum disk electrode,with a small surface area (1 cm^2), was used as the working electrode so that very small quantities of analyte (i.e., crude oil) in micro liters are sufficient for the in-situ electropolymerization, while a platinum electrode with a larger surface area (1.5 cm^2) was employed as a counter electrode. Electrodes and solution were placed in a specially designed vessel, in which the electrode surface and the reference electrode junction area were completely immersed in the mixture to sustain electrical interference without noise or abnormalities. The sweeping of electrical voltages, at the monomer specific electropolymerization potential, induces the formation of a thin layer of polymeric film on the working electrode surface. The final output of the electrical scanning potentials represents the voltammogram of current vs.voltage; where the peak current (intensity) reflects the amount of the produced polymer on the working electrode. The intensity of the peak can be then correlated to the amount of salt present in the hydrocarbon matrix.

The first stage of the analytical method development consists of selecting an appropriate monomer for the in-situ electropolymerization reaction. DBT, thiophene, and aniline were therefore tested as potential monomers. The reaction was conducted without the crude oil mixture using only a 1.2×10^{-5} mol L^{-1} of aqueous sodium chloride solution. The resulting voltammograms of each monomer are shown in Figs. 1–3 for DBT, thiophene, and aniline, respectively. An electropolymerization reaction was not observed in the DBT solution as seen from the absence of a current peak in Fig. 1. This could be due to the steric hindrance effect present in the DBT structure that impedes the initiation of free radicals in a low salt content. Electrolysis of thiophene has produced a polymeric film as apparent from the current peak in Fig. 2. The thiophene monomer was electropolymerized at a current potential of 1.6 V (vs. Ag/AgCl), which produced a current intensity of 135 μA. However, a further repetition of the

experiment was performed which revealed the non reproducibility of the thiophene electropolymerization. The inconclusive result failed to provide a basis for thiophene to be used as a monomer for this analytical technique. In contrast, electrolysis of the aniline solution has produced a distinguished peak as seen in Fig. 3, which indicates the presence of an electropolymerization reaction at a current potential 2.1 V (vs. Ag/AgCl). The resulting current intensity was reproducible and the polyaniline film was found to be very stable. The reproducibility of the current intensity and stability of the polymeric film were the basis for incorporation of aniline in the analytical technique. The peak height of the aniline monomer is sufficient for crude oil analysis, considering the small amount of salts usually present in the hydrocarbon matrix after an effective desalting process.

3.2. *Effect of aqueous salt concentration on the electropolymerization rate of aniline*

The concept of measurement suggests that an increase in the polymerization rate is due to an increase in the amount of electrolyte present in the solution. To prove this hypothesis, the effect of sodium chloride concentration on the rate of aniline electropolymerization has to be initially studied without the presence of crude oil. The electrolysis of aniline was repeated using aqueous sodium chloride solutions with various concentrations ranging from 2.0×10^{-7} to 8.6×10^{-6} mol L^{-1}. Current intensities of the formation of polyaniline were measured at the same current potential 2.1 V (vs. Ag/AgCl). The peak heights for each solution were then plotted against the salt concentration in Fig. 4. The linearity of the graph illustrates that the rate of electropolymerization (amount of polyaniline produced) is directly proportional to the salt concentration in the solution. The results indicate that the electrolyte concentration in the aqueous solution controls the polymerization rate in an isothermal condition. This is in complete match with the conclusion of the previous results [11]. The previous study also concluded that an increase in concentration of sodium chloride will increase the electropolymerization rate of aniline in an aqueous solution [11]. This is mainly due to the presence of the anions in the system upon dissolution of the electrolytes that are involved in the polymerization reaction. This conclusion was assumed for aniline electropolymerization, since the produced polyaniline contains counter anions [11].

3.3. *Measurement of salt concentration in Arabian crude oil*

The relationship between salt concentration and the rate of aniline electropolymerization presented in Fig. 4 shows that at low concentrations of salt present in the solution, specifically below 1.1×10^{-6} mol L^{-1}, electropolymerization reaction was not induced in the hydrocarbon mixture. This may indicate that a very low amount of salt present in the crude oil cannot be detected using the in-situ electropolymerization method, which counts as a major obstacle for its reliability and effectiveness. However, a standard addition technique can be employed to resolve this limitation. A calculated amount of sodium chloride solution that has a concentration higher than 1.1×10^{-6} mol L^{-1}can be added

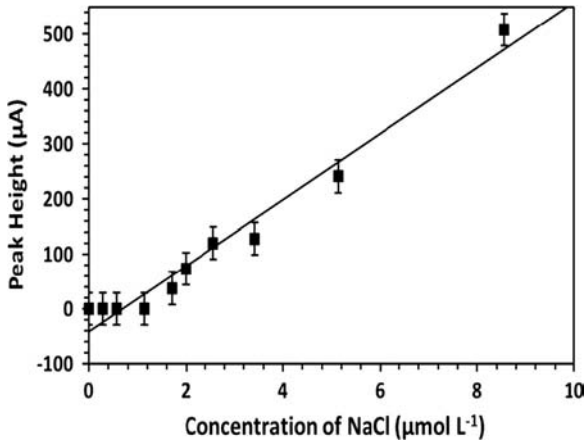

Fig. 4. The relationship between the salt amount in different concentration of sodium chloride solutions and the produced amount of polyaniline film on the working electrode represented by the peak height (current intensity).

during the solution and solvent mixing steps to set a measurable value beyond the limitations of the technique. In this manner, any concentration of salt in crude oil lower than 1.1×10^{-6} mol L^{-1}can be detected. The standard addition amount used here for the analysis of Arabian crude oil samples was 3.4×10^{-6} mol L^{-1} aqueous solution of sodium chloride. This amount was added to the acetonitrile solvent during the sample preparation steps.

In order to measure the salt amount present in crude oil, the same experimental scheme cannot be followed because of the complex nature of the inorganic materials present in the hydrocarbon matrix. The inorganic contents of crude oil are not fully dislodged upon its dissolving with a normal solvent leading to the absence of electrolytes in the system. Therefore, using a compatible solvent that dissolves the hydrocarbon mixture and the aqueous solution is mandatory for the proposed in-situ system. Furthermore, the selected solvent should be capable of enhancing the conductivity of the mixture, since the electrical properties of crude oil are known to be very poor [3]. After experimenting with numerous solvents, such as NMP, MTBE and methanol; NMP was found to be the most suitable solvent for the method. NMP had the ability to fully dissolve the crude oil in the mixture while dislodging the inorganic salts (mostly sodium chloride) present in the crude oil and enhanced the conductive properties of the hydrocarbon mixture. Therefore, the described method of electropolymerization reaction was modified by dissolving the crude oil in NMP prior to its addition into the reaction mixture. This modification ensures accurate measurement of the salt present in crude oil.

Four Arabian crude oils with salt concentrations of 34.2, 28.5, 14.3, and 5.71 mg L^{-1} (based on ASTM Method D-3230) were tested using the in-situ electropolymerization method. The overlaid voltammograms are shown in Fig. 5. The current intensities of each sample were calculated and the results are summarized in Table 1. The findings reveal the direct correlation between the salt content in crude oil and the produced current intensity. This well-matched correlation confirms the reliability of this technique, where an increase of salt content in crude oil increases the conductivity of the solution system paving the way for a thicker polymeric film on the working electrode. A calibration curve was obtained for the Arabian crude oil in the range of 5–35 mg L^{-1} of salt concentrations, as shown in Fig. 6, where the calculated R^2 for the fitted line is 0.998. The detection limit was calculated at 1.98 mg L^{-1} and the limit of quantitation was found to be 5.95 mg L^{-1}. The limit of detection (LOD) and limit of quantitation (LOQ) were calculated using the formulas (LOD= 3.3∗(standard deviation of measurements/slope of calibration curve)) and (LOQ= 3∗LOD), respectively. A solution of 5 mg L^{-1} was used to prepare a diluted solution of salt in crude oil and then was analyzed using the described technique to calculate the standard deviation for multiple measurements.

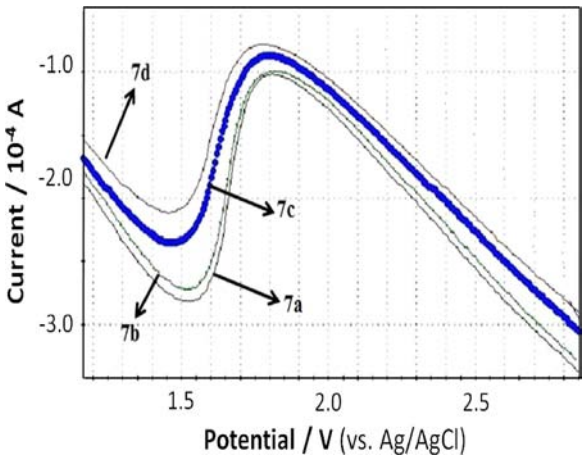

Fig. 5. Overlay of voltammograms of four Arabian crude oils with different salt concentrations at a scan rate of 10 mV/s. The different peak heights indicate the inducing of different polymerization rates when varying the salt amounts.

Table 1
Results of four Arabian crude oils analyzed by the in-situ electropolymerization sensor.

Crude oil	Salt concentration (mg L^{-1}) by ASTM D-3230	Current intensity (μA)	Electropolymerization voltage (V)
a	34.2	180.1	1.75
b	28.5	172.6	1.75
c	14.3	148.1	1.75
d	5.71	134.2	1.75

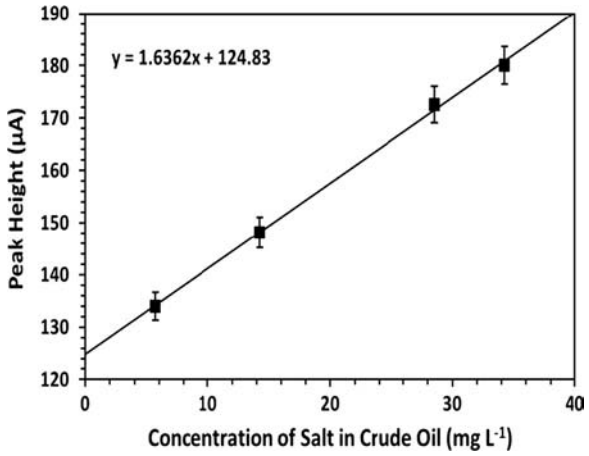

Fig. 6. Calibration curve of Arabian crude oil salt concentrations vs. the peak heights (current intensity) in the cyclic voltammograms.

It has to be mentioned here that the technique developed for monitoring the presence of salt in crude oil and hydrocarbon media is independent of many variables such as temperature, pressure, surface conditions, and flow rate of crude oil. There is no prerequisite to recalibrate the developed analytical method, as the physical surface area of the working electrode remains constant, in contrast to the existing methods. This technique does not require salt extraction prior to measurement and extensive sample preparation as the standard ASTM based test methods. Furthermore, the electrode surface is not exposed to corrosion and deterioration due to the small amount of crude oil needed for the analysis and the type of electrode material used. Table 2 summarizes the key differences between the developed in-situ electropolymerization sensor and the standard lab-scale test methods for measuring the salt content in crude oil [3]. These advantages make this new analytical method a promising tool in the petroleum industry to measure a critical property of crude oil.

4. Conclusions

An in-situ electropolymerization based sensor was developed to measure the salt concentration in crude oil. Aniline, DBT, and thiophene were initially tested as potential monomers for the analytical method. The electropolymerization of aniline was found to produce a measurable and reproducible amount of polymeric film on the working electrode. The amount of polyaniline produced on the electrode surface was directly proportional to the amount of sodium chloride, indicating that the rate of electropolymerization is

Table 2
Characteristics of the in-situ electropolymerization sensor in comparison to the standard test methods for measuring the salt concentration in crude oil.

In-situ electropolymerization sensor.	Standard lab-scale test methods [3].
Does not require salt extraction.	Requires salt extraction in Mohrs' and potentiometric tests.
Only two solvents are used in very small quantities.	Extensive use of solvents such as toluene, xylene, and mixed alcohols.
Robust stability of the electrode condition.	Corrosion of electrode surface is prone in the electrometric method due to the high amount of water in the sample.
No influence of sample viscosity on the measurement procedure.	Increase in the sample viscosity affects the mixing procedure.
The water content in the crude oil has no implication on the measurement due to the insignificant amount of analyte.	Large content of water in the crude oil influences the conductivity measurement leading to erroneous readings of salt.

influenced by the electrolyte content ranging from 2.0×10^{-7} to 8.6×10^{-6} mol L^{-1}. This approach was used with different salt concentrations of Arabian crude oil solutions, where a standard addition of 3.4×10^{-6} mol L^{-1}sodium chloride solution was employed during the sample preparation. Current intensities of 180.1, 172.6, 148.1 and 134.2 μA were calculated for four Arabian crude oils with salt concentrations of 34.2, 28.5, 14.3 and 5.71 mg L^{-1}, respectively. A calibration curve in the range of 5–35 mg L^{-1} was produced with a limit of detection and limit of quantitation at 1.98 and 5.95 mg L^{-1}, respectively. This analytical technique was able to measure the salt concentration in crude oil at very low levels without extensive sample preparation and prior extraction of salt.

ABSTRACT

This paper presents the results of mercury fractionation in muscle samples of dourada (*Brachyplatystoma rousseauxii*) from the JIRAU Hydroelectric Power Plant in the Madeira River Basin in the Amazon region of Brazil. The proteome of the dourada muscle was separated by two-dimensional polyacrylamide gel electrophoresis (2D PAGE). The mercury present in the protein spots was determined by graphite furnace atomic absorption spectrometry (GFAAS) after acid mineralisation in an ultrasound bath. The protein spots in which the presence of mercury was detected were characterised by electrospray ionisation tandem mass spectrometry (ESI–MS/MS) after tryptic digestion. The GFAAS determinations indicated that 65% of the mercury was linked to the protein fraction with a molar mass (Mm) of less than 90 kDa. The mercury concentrations in the seven spots in which this protein fraction was present were in the range of 11.40–35.10 μg kg^{-1}. Based on the mercury concentrations, it was possible to estimate that the protein spots contained approximately 1–3 mercury atoms per protein molecule. The ESI–MS/MS analysis allowed characterisation of the seven protein spots as the following proteins: protein NLRC5 (molar mass=18.10, pI=6.30); 39S ribosomal protein L36 mitochondrial (molar mass=15.40, pI=8.23); N-alpha-acetyltransferase 20 (Mm=15.95, pI=8.80); Mth938 domain-containing protein (Mm=15.01, pI=9.60); ubiquitin-40S ribosomal protein S27a (Mm=9.80, pI=7.60); parvalbumin alpha (Mm=12.40, pI=3.80) and parvalbumin beta (Mm=13.10, pI=3.45).

1. Introduction

The Amazon region has a great diversity of water bodies, including not only large rivers and lakes but also numerous streams, which further increase the water volume and the diversity of the ecosystems. These are key factors in maintaining a high diversity of fish in this region. The freshwater fish fauna of the Amazon is considered the richest in the world, with more than 1.300 described species. This diversity of fish from different regions within the Brazilian Amazon is still difficult to assess because the existing studies from several research institutes are sparse [1].

Commercial fishing is concentrated on approximately 40 exploited species, and among the most commonly caught are the following: dourada (Brachyplatystoma rousseauxii); pacu (Mylossoma sp, sp Myleus); jaraqui (Semaprochilodus spp.); tucunaré (Cichla spp.); filhote (*Brachyplathystoma filamentosum*); sardinha (*Triportheus* spp.); jatuarana (*Brycon* spp.); and curimatã (*Prochilodos vimboides*). These species represent 75% of the production of commercial fishing towns in the middle Madeira River of the Amazon in Brazil [2]

Mercury contamination by gold mining activity scarred the Amazon from the 1980s until the middle of the 1990s. The annual emission of mercury into the Amazon basin may have reached approximately 200 t, with Brazil, Bolivia, Venezuela, Guyana and Colombia as the largest emitters. The upper basin of the Madeira River was the second most productive region for gold mining in the Amazon, and this activity contributed to an average emission factor of Hg calculated by Pfeiffer et al. of approximately 1.3 kg of Hg per kg of gold produced in this basin [3,4].

Changes in land use due to agriculture, deforestation, fires, the annual dredging that occurs in some parts of the Madeira River waterway and the construction of hydroelectric plants can accelerate the process of remobilising the mercury in soil and river sediments and, furthermore, particular features of Amazonian environments can also create ideal conditions for mercury methylation, generating

methylmercury, which is a more toxic chemical form of this element [2]. Studies have shown that mercury concentrations have remained within natural levels in Amazonian rivers; however, it is known that transformations and processes occurring in the context of remobilising hitherto unavailable mercury species may change their chemical form, making them available for entry into aquatic ecological cycles [4,5].

In the Amazon, fish are the main source of food for coastal communities. Thus, the consumption of predatory fish may pose a risk to the health of these populations, particularly for women of reproductive age and children. The biological half-life of mercury in fish, depending on the species, may be several years. High concentrations of mercury in fish are commonly found in those species that occupy the top of the food chain. However, the extent of the food chain, the individual growth rate and the age of the fish are all factors influencing the variability of mercury levels in predators. Other variables to consider are changes in eating habits, which often vary depending on the stage of development and may also vary significantly between individuals of the same species [5–7]. Thus, mercury from natural and/or anthropogenic sources entering aquatic ecosystems participates in biogeochemical cycles mediated by microorganisms in which it is chemically transformed, undergoing biomagnification and bioaccumulation in the food chain. Thus, predatory fish, which accumulate high levels of mercury, can act as vehicles by which their consumers, such as reptiles, birds and humans, are exposed to this chemical form of mercury [8–10].

To evaluate the resource contamination in a region such as the Madeira River basin and its people, we must not only determine the amount of mercury in environmental components but also necessary biogeochemical knowledge about these ecosystems, which are already complex biogeochemical processes that control the bioavailability of this metal [2,11]. In this context, the synthesis and metabolic functions of some genes and proteins do not occur without the presence of metal ions and metalloenzymes, which are metalloproteins that act as catalysts in biological reactions to regulate biological and physiological functions in cells and organs. Thus, in the last decade interest in metallomics, a field of research in symbiosis with genomics and proteomics, has grown. Metallomics studies allow for determination of the distribution of a metal and/or metalloid species as well as elucidation of the physiological and functional characteristics of biomolecules that contain metal ions in their structures, such as metalloproteins and metal-bound proteins. In metallomics, the metallomes of metal ions or metalloid species present in a biological system (cells, tissues, or body fluids) in the free or complexed form are defined [2,12–14].

Based on the above information, this paper presents results obtained in a quantitative metallomics study of samples of dourada muscle (*Brachyplatystoma rousseauxii*) using 2D PAGE to obtain proteome samples, graphite furnace atomic absorption spectrometry (GFAAS) for quantitative determination of the mercury in the protein spots obtained from the proteins' fractionation and electrospray ionisation tandem mass spectrometry for characterisation of the protein spots in which the presence of mercury was detected.

2. Materials and methods

2.1. Sample collection

The two fish species used in this metallomics study of mercury were chosen based on their trophic levels and because they are among the species most widely consumed by the local riverine population. These fish species were dourada (*Brachyplatystoma rousseauxii*) because, by being a predator species, it has a greater tendency to accumulate mercury due to its feeding on fish that are omnivores and herbivores. A total of three individuals of this species were collected in the Jirau region of the Madeira River (Lat W – 64°43′36″ and Long S – 09°16′21″). The fish were anaesthetised with a benzocaine solution (100 mg L^{-1}) and euthanized to remove muscle samples. A pooled sample of muscle was ground in a Turrax homogeniser, transferred to 15 mL polypropylene flasks and stored in a freezer at −80 °C.

2.2. Sample preparation

Approximately 2.00 g of the pooled muscle samples of each species (weighed in triplicate) was macerated in deionised water using a mortar and pestle. The extracts containing the proteins were separated from the solid portion, centrifuged at 13,000*g* and stored at 4 °C in a refrigerated centrifuge. The protein extracts obtained from these samples were transferred to Eppendorf® tubes and then submitted to the fractional protein precipitation process.

2.3. Fractional precipitation and resolubilisation of protein pellets

To obtain proteins of low molecular weight, precipitation of the proteins contained in the protein extracts was done in two steps (fractional precipitation) [12,13]. In the first step, aliquots of 1 mL of ethanol–chloroform (ratio of 12.5:1 v/v) and the protein extract solution were transferred to 2 mL microtubes in a 1:1 (v/v) ratio. The homogeneous mixture was kept in the refrigerator for 15 min, which was long enough for the formation of a protein precipitate. After this time, the heterogeneous mixture was centrifuged for 10 min at 10,000*g* at 4 °C. The supernatant was then separated for further precipitation, and the obtained precipitates (pellets with proteins of high molecular weight >90 kDa) were kept in microtubes and stored at −20 °C for later determination of their total mercury contents.

In the second precipitation step, 1 mL of the supernatant obtained in the first precipitation stage and 400 μL of hydrochloric acid–ethanol solution (2.5:1 ratio) were added to 2 mL microtubes. This precipitation step was conducted at −20 °C for 3 h, thereby ensuring that the precipitation occurred quantitatively. Then, the heterogeneous mixture was centrifuged at 10,000*g* at 4 °C in a refrigerated centrifuge for 10 min and the supernatant was discarded. The protein precipitate (pelleted proteins of interest with low molecular weights <90 kDa) was washed four times with 1 mL of ice-cold ethanol (−20 °C) to remove traces of hydrochloric acid. This procedure was conducted with replicates ($n=3$) to ensure pellets were obtained that could be used both for quantification of the total protein and the total mercury in the 2D PAGE runs. For quantification of the total protein, the protein pellet was resolubilised in 0.50 mol L^{-1} NaOH and the Biuret method was used [14–17].

2.4. Determination of Hg in the total and in protein spots

Samples of muscle tissue from each fish species studied and/or protein spots were mineralised as follows: 250 mg samples of fish muscle tissue and/or three protein spots cut from polyacrylamide gels for electrophoresis runs of 2D PAGE were transferred to digestion flasks. To each flask was then added 3 mL of concentrated sulphuric acid and 1 mL of hydrogen peroxide 30% (w/w). The set of vials was placed in a UNIQUE ultrasound bath at a temperature of 40 °C and 135 W to complete mineralisation of the sample (clear extract). Then, the acid extracts were transferred to 5 mL volumetric flasks and supplemented up to volume with ultrapure water. To validate the method of mineralisation, standard certified fish protein NRC DORM 4 containing 410 ± 55 mg kg^{-1} of total mercury was also used. The total mercury determination was carried out by GFAAS after acidic mineralisation of the protein pellet and/or the protein spot. This determination was carried out with a SHIMADZU AA-6800 atomic absorption spectrometer equipped with background absorption correction with a self-reverse (SR) system, a pyrolytic graphite

tube with an integrated platform and an ASC-6100 autosampler. Argon was used as the inert gas and the flow rate was kept constant at 1 L min^{-1} throughout the heating program except in the atomisation stage, when the gas flow was interrupted. The absorbance signals were measured for the peaks [3].

2.5. Electrophoretic runs – 2D PAGE

The electrophoretic runs were carried out using 13-cm strips of premade gel containing immobilised ampholytes with a pH range from 3 to 10 in the first dimension of the electrophoretic process (isoelectric focusing electrophoresis, IEF PAGE). In the second dimension of the electrophoretic process, a (SDS PAGE) polyacrylamide gel with a concentration of 15% (w/v) was used. The 2D PAGE runs were carried out using only the low molar mass protein pellets (pellets obtained in the second stage of precipitation). The two steps of the electrophoretic runs were carried out according to the procedure described by Lima et al., Santos et al., Neves et al., Silva et al. [15–18].

After the run, which lasted approximately 250 min, the proteins were revealed using a colloidal Coomassie stain reagent consisting of a solution of ammonium sulphate 8% (m/v), phosphoric acid 1.6% (v/v), Coomassie blue G-250 0.08% (m/v) and methanol 25% (v/v). Before staining, the proteins were fixed for 60 min using a solution containing acetic acid 10% (v/v) and ethanol 40% (v/v). The dye was allowed to remain in contact with the gel for 72 h, after which it was removed through successive washes with deionised water [15–18].

The resulting muscle gels were digitised in a scanner (GE Healthcare, Uppsala, Sweden) and analysed using ImageMaster 2D Platinum 7.0 scanner software (GE Healthcare, Uppsala, Sweden). The image processing was always performed for four gels obtained from the same electrophoretic separation process per aliquot of protein extract. The gels were correlated by matching the spots of the four gels and then comparing them in terms of their distribution, volume, relative intensity, isoelectric point (pIs), molar mass (Mm) and the estimation of the mass of protein per spot [2,15–19].

2.6. Tryptic digestion of protein spots for characterisation by ESI–MS/MS

The protein spots selected for the characterisation step were extracted from the gel using a scalpel and cut into segments of approximately 1 mm^3. The segments were transferred to 2 mL microcentrifuge tubes containing 1% (v/v) acetic acid, and then were subjected to the following steps: removal of the dye, reduction and alkylation, tryptic digestion (using a trypsin solution containing 10 ng μL^{-1} of this enzyme) and elution of peptides [20]. Extracts were dried in a vacuum centrifuge (Eppendorf, Hamburg, Germany) and peptides were dissolved in 10 μL 3% CAN with 0.1% formic acid [20].

2.7. Characterisation of proteins by ESI–MS/MS

Aliquots of the solutions containing the peptides identification was performed on a nanoAcquity UPLC-Xevo QTof MS system (Waters, Manchester, UK). The peptides were separated with a linear gradient of 7–85% mobile phase B (0.1% formic acid in ACN) for 31 min at a flow rate of 0.4 μL/min. The Xevo® G2 Q-TOF mass spectrometer was operated in positive mode, and data were collected in the MS^E method in elevated energy (19–45 V). Source conditions: capillary voltage, 2.5 kV; sample cone, 30 V; extraction cone, 5.0 V and source temperature, 80 °C. ProteinLynx Global Server (PLGS) version 3.0 was used to process and search the continuum LC–MS^E data, setting carbamidomethylation of cysteines as fixed modification and oxidation of methionines as variable modification, allowing one missing cleavage and maximal error tolerance of 10 ppm. Protein identification was performed by homology using the UniprotKB database (http://www.uniprot.org/). At this stage, it is important to know the taxonomic classification of the fish species studied. Thus, the species used in the search was the "Otophysi" series, which is within the superorder Ostariophysi and includes the Siluriformes order to which the dourada belongs [21].

3. Results and discussion

3.1. Determination of total protein

Determination of the total protein concentration in the extracts obtained from the resolubilisation of protein pellets from dourada muscle tissue was obtained with the aim of applying a known amount of protein mass on the IEF strips for the electrophoretic runs. The total protein concentration in the extracts from the low molecular mass pellets (< 90 kDa) was 11.20 ± 0.30 g L^{-1}.

Based on the results of the total protein concentration present in the muscle tissue samples, it was possible to calculate the sample volume of protein extract to be used in the IEF strips in the hydration step prior to isoelectric focusing (separation of proteins in 1D) in order to obtain a protein mass of 375 mg, which, based on the IEF manual system, might favour a better separation of proteins using the 3–10 pH gradient [15,16].

3.2. Protein fractionation by 2D PAGE

The 2D PAGE electrophoresis experiments were performed using extracts from the resolubilisation of the lower molecular weight mass protein pellets from dourada muscle tissue samples. In the protein spots on the gels obtained in the electrophoretic runs, mercury mapping by GFAAS was carried out, and in spots in which the presence of mercury was determined, the proteins were characterised by ESI–MS/MS.

The 2D PAGE electrophoresis experiments on dourada muscle tissue were performed with four replicates. Fig. 1 shows a representative gel obtained in the 2D PAGE electrophoresis run replicates. The protein spots highlighted with circles are those in which mercury was detected, and the concentration of this element was determined by GFAAS. As seen in Fig. 1, the dourada gel shows good resolution, demonstrating the efficiency of the protein fractionation process. Correlation analysis between gels showed that, on average, over 70% of the protein spots were present in all four replicate 2D PAGE runs. It should be noted that the average number of spots found in the gels and the matching gels (correlation gels) showed a relative standard deviation of less than 5%, and these results are much more robust compared with results from the literature [22–26], demonstrating that the optimised conditions of the 2D PAGE were efficient.

3.3. Quantitative evaluation of total mercury

In addition to being determined in samples of muscle tissue of the fish species and in the protein spots, total mercury was also determined in the low and high molecular eight mass protein pellets obtained in the fractional protein precipitation process. The objective of this procedure was to make a mercury mass balance in relation to the concentration of this element in the tissue samples and extracts of the protein pellets. The NRC DORM 4 certificate standard was used to validate the optimised method for the determination of mercury [3]. The concentrations of mercury in the samples and certified standard determined by GFAAS were as follows (μg kg^{-1}): muscle tissue = 331 ± 7, molar mass < 90 kDa = 215 ± 3, molar mass > 90 kDa = n.d. (not detected), and NRC

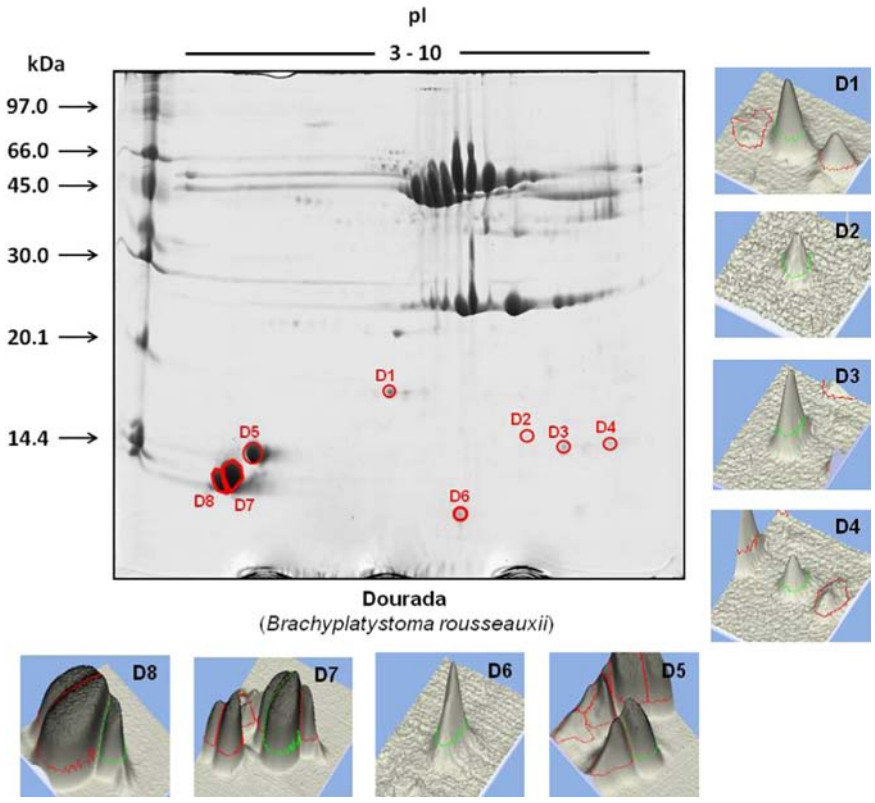

Fig. 1. 15% gel (w/v) obtained by 2D PAGE (pH range 3–10) for muscle tissue samples of dourada. The numbers and circles in red indicate the spots that have been identified for the presence of mercury, were characterised by ESI–MS/MS, and are also presented in 3D. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

DORM 4=408 ± 3. Analysing these results, it was observed that approximately 65% of the mercury in muscle tissue samples was linked to the lower molecular weight protein pellets (< 90 kDa), while in the protein extracts of the higher molecular weight pellets (> 90 kDa), the presence of mercury was not detected. From these results, it can be inferred not only that the extraction process was effective but also that most of the mercury present in the dourada muscle samples is really linked to the protein fraction, and the remainder (approximately 35%) may be linked to other macromolecules present in the muscle tissue (e.g., lipids). The data presented are considered fairly robust because they were validated based on results obtained in the mercury determination of the NRC DORM 4 certified standard (protein of fish muscle). It can be seen that the experimental value of the standard deviation obtained for the samples is less than 1%, and the experimental absolute value of the certificate standard (408 μg kg^{-1}) is approximately 0.5% less than the absolute value of the certificate (410 mg kg^{-1}), which proves the accuracy and precision of the optimised method for the determination of mercury.

The mercury concentrations in protein spots obtained in the 2D PAGE runs of the lower molecular weight pellets were also determined using the optimised GFAAS method [3]. These determinations indicated the presence of mercury in the protein spots highlighted with circles in the polyacrylamide gels shown in Fig. 1. Table 1 shows the values of the mercury concentrations determined for each protein spot with their respective molar masses (Mm) and isoelectric points (pI) in addition to the protein mass estimated using ImageMaster 2D Platinum 7.0.

Analysing the results shown in Table 1, it can be observed that the mercury concentrations in the protein spots have values in the range from 11.40 to 35.10 mg g^{-1}. However, the results presented in Table 1 do not provide much information without the characterisation of the proteins in these protein spots. Thus, the estimates of the protein masses in the protein spots (the mass of protein per spot was based on calculating the volume of each protein spot in the polyacrylamide gel – as determined by the

Table 1
Values obtained in the determination of the mercury concentrations in the protein spots of muscle tissue of dourada by GFAAS.

Protein spots	Molar mass (kDa)	pI	Protein mass (μg)	Concentration of Hg (mg g^{-1})

D1–D8: protein spots of muscle tissue of dourada.

image processing software) and the mass amounts of mercury were converted into the number of protein molecules and moles of mercury. These calculations allowed for an estimate of how many mercury atoms were present per protein molecule [15–18]. The results obtained in these calculations are shown in Table 2 in terms of the number of mercury atoms per protein molecule in the protein spot under consideration.

Based on the results presented in Table 2, it is possible to estimate the proportion of mercury atoms per protein molecule in a protein spot by dividing one value by the other. Thus, the following can be inferred: spots D3–D5 and D7–D8 have approximately one mercury atom per protein molecule in the protein spot; spots D2 and D6 have approximately two mercury atoms per protein molecule; and spot D1 has three mercury atoms per protein molecule. These results, although estimates, suggest that there may be a stoichiometric relationship between the number of mercury atoms and the number of protein molecules in the spots, which would be a possible indication that these spots include metalloproteins and/or metal-binding proteins.

3.4. Characterisation of the protein spots by ESI–MS/MS

Characterisation of the protein spots in which the mercury was identified and quantified (spots highlighted with circles in the polyacrylamide gels shown in Fig. 1) was performed using ESI–MS/MS as a tool in the structural component of the metallomics study. In characterising the protein spots, it is normal to find more than one protein in the database search [27]. However, a condition of engagement in the closure of the protein class was made using that with the highest score and/or coverage and especially considering the pI and molecular weight data obtained by 2D PAGE (experimental data) in relation to the theoretical molar mass obtained from the *Uniprot* database. Table 3 shows the characterisation data obtained from the ESI–MS/MS analysis of the likely protein identified considering the engagement conditions described above. With regard to no proteins being identified in the D5 protein spot, the difficulty of the characterisation process can be related to some failure in the tryptic digestion step or a low protein concentration generating peptides that it is impossible to sequence, or it can be due to limited information available in the databases on the proteins of fish; in this case the applicable database is the database on Amazon fish species.

The results presented in Table 3 show that it was possible to characterise six different types of protein by ESI–MS/MS and that one of these proteins may be a mixture of isoforms (D7 and D8 spots, D7 – *parvalbumin-2*, *parvalbumin alpha and parvabulmin beta*). *Protein NLRC5*, which is a protein that acts in the homeostatic control of innate immunity and mechanisms of antiviral defence, was identified. This protein consists of peptide sequences containing leucine, which has an amino group and a carboxylic acid group, as the primary amino acid [28]. The incorporation of metal ions by this protein has not been reported in the literature. However, spot D1, which features, based on the data of the GFAAS determination, three mercury atoms per molecule of protein, was characterised as protein NLRC5. Thus, based on the data obtained by ESI–MS/MS and GFAAS, it can be inferred, in this case, that the mercury is bound to coordination sites in the protein by nonspecific binding and is not acting as a metal cofactor forming a *metal-binding* protein [14]. The *39S ribosomal protein L36 mitochondrial*, which addresses a protein component of the mitochondrial ribosome subunit and actively participates in the synthesis of other proteins inside the mitochondria, was also identified. This protein is not associated with metal ions considering the information obtained in the literature so far [29]. However, any other protein present in chains with terminal nitrogen atoms may have non-specific binding with divalent metal ions, such as mercury. Moreover, the data of the GFAAS determination showed that this protein has three mercury atoms per protein molecule, which allows the inference that this protein may be a *metal-binding* protein [14]. *N-alpha-acetyltransferase 20*, an enzyme that is part of the catalytic subunit of the NatB complex (alpha-N-acetyltransferase B) and helps catalyse the acetylation of methionine residues of N-terminal peptides beginning with Met–Asp–Glu–Met, Met–Met–Gln and Asn, was another protein identified. It is necessary in order to maintain the structure and function of complex fibres of actomyosin and proper cell migration [30]. Through the methionine residues present in its structure, it can act on a molar basis and form stable complexes with Hg^{2+} ions [31]. Spot D3 of dourada muscle tissue was characterised as the enzyme with mercury attached to its structure, presenting a strong connection with this element, which qualifies this spot as a possible biomarker candidate. It should also be noted that the data obtained by GFAAS indicated a stoichiometric ratio of one mercury atom per N-alpha-acetyltransferase 20 molecules, which reinforces the hypothesis that this enzyme can act as a mercury biomarker. *Mth938 domain/containing protein* was also identified, a cytoplasmic protein component that acts in fat cell differentiation and in the positive and negative regulation of apoptotic processes [30]. An association of this protein with metal ions has not been reported in the literature. However, by presenting peptide sequences with proline and leucine residues with terminal amino and carboxylic groups, it can have non-specific binding with divalent metal ions such as mercury. The data obtained by GFAAS indicated a stoichiometric ratio of one mercury atom per *Mth938 domain/containing protein* molecule, which allows the inference that this protein may be a *metal-binding* protein [14]. In addition, *ubiquitin −40S ribosomal protein S27a*, which is a protein that when covalently linked

may be involved in DNA repair, cell cycle regulation, endocytosis and lysosomal degradation, was identified. It may also be involved in signalling processes, leading to activation of the NF-kappa-B factor and, in its free form, can activate protein kinases and play a role in cellular signalling. This protein has domains with specific groups for binding of zinc (zinc-finger metal binding domains) [32]. Due to possessing specific domains linked to zinc atoms, which has similar characteristics to mercury (both soft acids), it can also bind other divalent ions such as copper, cadmium and mercury [8,31]. Spot D6 was characterised as being this protein with mercury atoms linked to its structure. The data obtained by GFAAS showed that the D6 spot had a stoichiometric ratio of two mercury atoms per *ubiquitin −40S ribosomal protein S27a* molecule, so it can be inferred that this protein may act as a biomarker of this element. *Parvalbumin*, which is a protein of low molecular weight (11–12 kDa) and has the isoforms *parvalbumin-2*, *parvalbumin alpha and parvalbumin beta*, was the final protein identified. Usually all three isoforms bind calcium ions. This protein is directly involved in the process of muscle relaxation after contraction. It is basically formed by peptide sequences containing serine and alanine, which have amino acid structures with carboxylic, amino and hydroxyl groups susceptible to complexation with divalent metal ions, especially calcium and magnesium [32,33]. *Parvalbumin* linked to mercury was the protein most identified in the protein spots analysed, and different isoforms of this protein were characterised in spots D7 and D8 of dourada muscle tissue. The literature, so far, does not include any paper that discusses the possibility of mercury and/or other potentially toxic metals being bound to parvalbumin or its isoforms. However, the beta isoform of this protein has a cysteine residue in the peptide sequence that can form specific linkages with metal ions with soft acid features such as Hg^{2+} [14,31]. Thus, protein spots D7 and D8 could be potential candidates for mercury biomarkers.

4. Conclusions

With optimisation of the experimental conditions in the developed components of selectivity (2D PAGE) and sensitivity (GFAAS) in the metalloproteomic study proposed, it was possible to characterise eight protein spots by ESI–MS/MS in which the presence of mercury was confirmed by GFAAS. Based on the results obtained so far, it is possible to draw the following conclusions. The protein pellet fraction with a molar mass <90 kDa has approximately 65% of the mercury concentration determined in the dourada muscle tissue samples (the fish species studied). Mercury was not detected in the protein pellet fraction with a molar mass >90. With the data on mercury concentrations determined in the protein spots, it was possible to predict a stoichiometric relationship between the number of mercury atoms per molecule of protein in the protein spot. This ratio presented itself in the range of 1–3 mercury atoms per molecule of protein in the protein spot. The characterisation data on the protein spots allowed the identification of proteins and/or enzymes in eight protein spots, among which two proteins, parvalbumin (with alpha and beta isoforms) and *ubiquitin −40S ribosomal protein S27a*, as well as the *N-alpha-acetyltransferase 20* enzyme, may be candidate mercury biomarkers due to their inclusion of groups with characteristics of soft bases and specific domains linked to zinc atoms, which have similar characteristics to mercury (soft acid). In general terms, the preliminary results obtained can be considered unpublished for the Amazon fish studied, constituting a starting point for metalloproteomic studies related to mercury toxicity in fish from this region of Brazil.

ABSTRACT

A new isotope-dilution liquid chromatography–tandem mass spectrometry (LC–MS/MS) method for determination of sulfur mustard (SM) has been developed using a direct chemical derivatization method by nucleophile potassium thioacetate (PTA) in aqueous solution. The reaction conditions for derivatization, such as reaction temperature, time, solvent and concentration of PTA, were optimized for high performance. Reversed phase liquid chromatography was suitable for analysis of such a PTA derivatized SM in complex environmental samples. Compared with other conventional gas chromatography or gas chromatography–mass spectrometry methods for direct detection on SM, better sensitivity and selectivity were achieved by this direct derivatization and LC–MS/MS method, where SM can be detected as low as 0.05 ng/mL in acetonitrile. The linear range was from 0.1 to 1000 ng/mL. The relative standard deviation (RSD) of the intra-day precision was less than 11.8%, and RSD of the inter-day precision was less than 12.3%. The whole procedure for both derivatization and analysis was quick and simple, and the total time was less than 1 h. This established method has been successfully employed for determination of spiking samples both in water and soil. A detection limit of 0.1 ng/mL was achieved for river water, while the SM in soil sample could be detected at 0.1 ng/g.

1. Introduction

Sulfur mustard (SM) is an alkylating chemical agent and known as a major class of chemical warfare agents (CWAs). SM was massively used in World War I and the Iraq–Iran war in 1980s. It is reported that over 100,000 Iranians (military or civilian) were exposed to SM during the Iraq–Iran war, and a large proportion are still suffering with long-term consequences of exposure [1]. It should be noted that great concern related to SM has arisen up to now, i.e., a large amount of CWAs, including SM, was dumped into the ocean areas [2] or buried underground [3] from World War II, and these abandoned chemical weapons or CWAs have caused serious environmental contamination and many casualties or fatalities [4,5]. Thus, it is of great importance to develop a sensitive and robust analytical method for determination of SM in aqueous or soil samples, in light of verification purposes and environmental concerns.

Determination of SM and related chemicals in aqueous or soil samples can present reliable evidence of the original existence of SM as well as the abuse and abandonment of CWAs. When dissolved in water, the hydrolysis of SM is completely prevented or slowed down because of low aqueous solubility as well as formation of oligomeric and polymeric layers by the degradation products [6]. Thus, if existed in abandoned munitions on the seabed, SM would remain intact for a long time. Another most employed sample for the examination of SM is soil, in which organic compounds including SM can be preserved for a long time as a result of high adsorption capacity [7]. Hence, SM can be kept as its original formation in soil for several years [8]. In 1994, Black et al. [9] reported that traces of SM can still be detected in several soil samples collected from a village in northern Iraq attacked by chemical weapons years ago.

However, there is inevitably a variety of degradation products of SM in environmental samples because of its relative high activity. Thus, determination of common degradation products may act as a proof of the original existence of SM. But, there are also some disadvantages with the detection of degradation products, for example, it cannot tell whether the sample still contains intact SM, not to mention the amount of intact SM it contains; and some non-specific degradation products such as thiodiglycol (TDG) cannot confirm the presence of SM individually [10]. As we know, the detection of intact CWAs is the most solid and direct evidence for verification of CWAs, however, the concentration of CWAs like SM was usually very low in environmental samples. So if there is

no method with a sufficiently high sensitivity, then analyzing the degradation products of SM for retrospective detection would be the second choice.

So far, gas chromatography (GC) or gas chromatography–mass spectrometry (GC–MS) are still the preferred analytical technologies for detection of SM and its degradation products [9], but these recommended methods are time-consuming due to complicated preparation procedures for aqueous samples and relatively low sensitivity. Recently, several types of enrichment technology combined with GC–MS have been applied to SM detection, such as solid phase micro-extraction [11], single drop micro-extraction [12], and static headspace-trap [13] technique, and a limit of detection (LOD) of 1 ng/mL in water was achieved. However, these new techniques all require specialized systems or modified absorbent matrices for the determination of SM, which are both expensive and highly professional. Furthermore, some decontamination and enrichment procedures, involving in heating processes [6,13], would easily lead to the degeneration of SM in aqueous environment.

Nowadays, it has been shown that liquid chromatography–mass spectrometry (LC–MS) technique with atmospheric pressure ionization (API) has been increasingly used for detection of water-soluble or non-volatile CWAs and degradation products, in light of its feasibility for aqueous samples, and high sensitivity and selectivity, especially with tandem mass spectrometry [14,15]. And the Organization for the Prohibition of Chemical Weapons (OPCW) has already realized the prospects of LC–MS techniques, so its designated laboratories were encouraged to employ LC–MS analysis as a complementary technique with GC or GC–MS in Proficiency Test with environmental samples, as well as the Confidence Building Exercise on Biomedical Sample Analysis organized by OPCW. However, LC–MS(/MS) method has never been considered for analysis of SM, because of its high alkylation reaction activity with LC column packing material and protic solvent used in common, as well as instability with high temperature and voltage in ESI ion source. Replacement of the halogen groups of SM and related halogen preserved compounds by nucleophiles groups would be a good concept, as by that way it can efficiently prevent SM from alkylation reaction with the matrix and significantly improve the sensitivity in LC–MS. Reversed phase liquid chromatography (RPLC) can then be adopted for quantitative determination of such a SM derivative with MS/MS.

In this article, we developed a direct chemical derivatization method through a covalent reaction between nucleophile potassium thioacetate (PTA) and SM in water, as a direct derivatization approach, so as to detect such a SM derivative by LC–MS/MS analysis. The key point in this derivatization is the higher electronegativity of PTA, its thioacetate anion prior to hydroxide can attack episulfonium cation formatted by SM in water solution and replace chloride readily. The final product bis-(thioacetate) ethyl thioether (BTAETE) was verified with good chromatographic behaviors and excellent mass spectrometric intensity. It makes the determination of SM in water-soluble samples by LC–MS/MS become possible, which greatly reduces pretreatment procedures and improves the detection sensitivity. The reaction conditions for derivatization were optimized for better sensitivity and repeatability. Quantitative analysis with isotope-dilution LC–MS/MS method and the applications on environmental samples were then followed.

2. Experimental

2.1. Caution

SM is a highly reactive alkylation vesicant and cytotoxic agent. Handling of this agent should be carried out in the well-ventilated fume hoods. The use of gloves and stringent protective measures must be adopted.

2.2. Materials and reagents

All reagents were of analytical reagent grade. SM (the purity is over 96%) was supplied by the Institute of Chemical Defense of Chinese People's Liberation Army, and deuterated internal standard d_4-SM as the internal standard (IS) was home-synthesized with a purity of 98% and a deuterated ratio of ca. 100% [16]. Mustard sulfone and mustard sulfoxide were synthesized in house according to previously published procedures [17] and their purities were determined to be more than 95%. Acetonitrile and methanol (HPLC grade) was purchased from J&K Scientific Ltd (Beijing, China). Formic acid (for mass spectrometry, purity is 98%) and potassium thioacetate were obtained from Sigma-Aldrich Inc. (MO, USA). Dichloromethane and n-hexane were purchased from Sinopharm Chemical Reagent Co., Ltd (Beijing, China). Ultrapure water was generated by Milli-Q A10 purification system (Millipore, Billerica, MA, USA).

2.3. Preparation of BTAETE

The stock aqueous solution of PTA was prepared at 100 mg/mL, while SM solution in acetonitrile was at 5% (v/v). For SM derivatization, 1.0 mL PTA stock solution and 1.0 mL 5% SM stock solution (ca. 61 mg) were transferred into a 20 mL headspace vial, then sealed with a polytetrafluoroethylene (PTFE) cap and heated at 100 °C for 1 h.

The reaction solution was extracted with 2 mL of dichloromethane, and then the extracted solution was loaded onto a silica gel column and eluted by an n-hexane/dichloromethane solution at a ratio of 1:3 (v/v). Solvents were removed from collected fractions using rotary evaporation under reduced pressure to give refined product with a pale yellow oil appearance. It was identified as bis-(thioacetate) ethyl thioether (BTAETE) by high resolution MS (HRMS) and NMR, and its purity was greater than 98% by HPLC-Ultraviolent Vis detection. The reaction yield was ca. 44%. ^{1}H NMR ($CDCl_3$): δ3.09 (4H, t), 2.75 (4H, t), 1.58 (6H, s). MS (ESI-HRMS m/z): 239.0229 $[M+H]^+$.

2.4. Preparation of solutions

Standard stock solutions of SM, BTAETE, mustard sulfone and mustard sulfoxide were prepared in acetonitrile, and all stored at −20 °C. A series of standard working solutions of SM at concentrations of 1, 5, 20, 100, 500 ng/mL, and 2, 10 μg/mL were prepared by serial dilution of the stock solution with acetonitrile. Quality control (QC) working solutions were prepared at concentrations of 2.5, 100, 7500 ng/mL. The IS working solution of d_4-SM at a concentration of 370 ng/mL was prepared by dilution of the stock solution. An aliquot of 5 μL of standard or QC working solution and 5 μL of IS working solution were spiked into 40 μL acetonitrile, making the final concentrations at 0.1, 0.5, 2, 10, 50, 200, 1000 ng/mL to establish standard curve of BTAETE and evaluate precision and trueness. The LOD was defined as the lowest concentration at which the signal of the analyte peak from background noise (signal to noise ratio, S/N, is greater than 3) can be reliably differentiated, while the lower limit of quantification (LLOQ) is greater than 10 [18]. The working solutions of BTAETE at concentrations of 1.0, 5.0, 20, 100, 500 ng/mL were prepared by dilution of the stock solution for evaluation of the recovery as well as derivatization efficiency.

2.5. Sample preparation

The stock solution of PTA in water was prepared at 50 mg/mL and stored at 4 °C, then diluted at concentrations of 0.1, 1 and 5 mg/mL with water. For the determination of SM in samples, 50 μL of the spiking sample solution containing IS and 50 μL PTA solution were transferred into a 2 mL headspace vial, then capped the vial and shaken, following heated at 50 °C for 0.5 h. When investigating the most suitable reaction conditions for derivatization, the temperature, time, solvent, pH and concentration of PTA were varied.

Natural water samples were collected from the Yongding River in Beijing with a relative equivalent of mud, and kept at 4 °C. Prior to analysis, the river water samples were centrifuged at 14,000*g* for 10 min, and then transferred the supernatant into a clean vial. An aliquot of 1 mL sample was spiked with a solution of SM in acetonitrile to the concentration of 100 ng/mL. Immediately and individually, 45 μL triplicates of the spiking solution were transferred to headspace vials, 5 μL IS and 50 μL PTA in 50% acetonitrile solutions at a concentration of 1 mg/mL were added for derivatization reaction. After that the supernatant at a volume of 50 μL was transferred into the injection vial insert for LC–MS/MS analysis. LC–MS/MS analysis was performed within the same day, and the recoveries of the spiked SM in the natural water samples were calculated from calibration curve established with a series of standard working solutions prepared in Section 2.4.

Natural soil samples were collected from one suburban area of Beijing, China. Prior to detection, the soil samples were homogenized and freeze-dried at −40 °C for 24 h in order to reduce degradation by endogenous microbials. Triplicates of 0.2 g soil sample were weighted directly into headspace vials, then spiked by 5 μL SM solution at the concentration of 100 ng/mL and shaken for 1 min. Subsequently, 5 μL IS and 90 μL PTA in 50% acetonitrile solutions at a concentration of 1 mg/mL were added for derivatization reaction. After that, the aliquot of samples were transferred into clean vials, and centrifuged at 14,000 *g* for 10 min, and then the supernatant at a volume of 50 μL was transferred into the injection vial insert for LC–MS/MS analysis. The recoveries of the spiked SM in the natural soil samples were calculated.

2.6. Isotope-dilution LC–MS/MS analysis

Separation was performed using an ACQUITY UPLC system (Waters Co., Manchester, UK) consisting of a binary pump and an autosampler. The analytical column is a 2.7 μm particle size CAPCELL CORE C18 column (SHISEIDO, Kyoto, Japan) with a length of 100 mm and i.d. of 2.1 mm. Mobile phase A was water containing 0.1% formic acid, while phase B was acetonitrile. The mobile phases were run at 20% B in the first 1 min, followed by a 4 min linear gradient run to 95%B, then returned to its initial setting and the column was conditioned for 2 min. The flow rate was 0.3 mL/min, and an injection volume was 5 μL. The LC elutes were directly delivered to a 5500 QTrap tandem mass spectrometer (AB Sciex, Framingham, MA, USA) except elutes in the first 1 min to avoid possible contamination of the Turbo V™ source.

In MS/MS analysis, the transitions of the analytes were selected based on their full scan mass spectra obtained by direct electrospray ionization-MS of standard solutions without LC separation. MS equipment was operated in a positive MS/MS mode at a unit resolution for both *Q*1 and *Q*3 using multiple reaction monitoring (MRM) with a dwell time of 100 ms for BTAETE and d_4-BTAETE. The transition of precursor to product ion was monitored at *m*/*z* 238.7→103.0 for BTAETE, *m*/*z* 242.7→107.0 for d_4-BTAETE. Meanwhile, the derivatization products of hemisulfur mustard (*m*/*z* 181.0→103.0), mustard sulfone (*m*/*z* 271.0→103.0) and mustard sulfoxide (*m*/*z* 255.0→213.0), as well as unchanged mustard sulfoxide (*m*/*z* 175.0→63.0), were also monitored. All analytes' parent ions and primary fragment ions with attribution are listed in Table 1. The collision energy was all set at 20 eV, the declustering potential was 80 eV, and the collision cell exit potential was 16 eV. The source conditions were: source temperature, 550 °C; pressures for gas 1 and gas 2, 50 kPa; for curtain gas, 20 kPa. The data were analyzed using Analyst® (version 1.5.1, AB Sciex, Framingham, MA, USA). SPSS software package v15.0 (SPSS Inc., Chicago, USA) was used for orthogonal experimental design and results analysis.

3. Results and discussion

3.1. Mechanism of PTA derivatization of SM

In general, the derivatization reaction should be fast and complete preferable for analytical purpose. Since SM is a highly reactive electrophile, it tends to form an episulfonium ion by an internal S_N2 type mechanism when interacting with other molecules. As shown in Fig. 1, substitution reaction is then completed by an external S_N2 type mechanism, via thioacetate anions attacking episufonium ions. In this reaction, formation of the episulfonium ion is the rate-limiting process and can occur rapidly in the polar solvents [19].

Through the replacement of chloride atoms with two thioacetate groups by S_N2 mechanism, the derivatization can overcome the shortcoming that LC–MS technique is unfavorable for analysis

Table 1
The parent ions and primary fragment ions with attribution of derivatization products of SM, d4-SM, hemisufur mustard, sulfone mustard, sulfoxide mustard, as well as unchanged sulfoxide mustard in ESI.

Compounds	Formula	Parent ion	Fragment ion	Attribution
Derivatization of SM (BTAETE)	$C_8H_{14}O_2S_3$	238.7	103.0	$[M+H\text{-}HSC_2H_4SCOCH_3]^+$
			163.1	$[M+H\text{-}HSCOCH_3]^+$
			196.9	$[M+H\text{-}COCH_2]^+$
Deribatization of d4-SM (d4-BTAETE)	$C_8D_4H_{10}O_2S_3$	242.7	107.0	$[M+H\text{-}HSC_2H_4SCOCH_3]^+$
			167.0	$[M+H\text{-}HSCOCH_3]^+$
Derivatization of hemisulfur mustard	$C_6H_{12}O_2S_2$	181.0	102.9	$[M+H\text{-}HSC_2H_4OH]^+$
			162.9	$[M+H\text{-}H_2O]^+$
Derivatization of sulfone mustard	$C_8H_{14}O_4S_3$	271.1	102.9	$[M+H\text{-}HSO_2C_2H_4SCOCH_3]^+$
			229.1	$[M+H\text{-}COCH_2]^+$
Derivatization of sulfoxide mustard	$C_8H_{14}O_3S_3$	255.0	213.0	$[M+H\text{-}COCH_2]^+$
			103.0	$[M+H\text{-}HSOC_2H_4SCOCH_3]^+$
Unchanged sulfoxide mustard	$C_4H_8OSCl_2$	175.0	63.0	$[M+H\text{-}SOC_2H_4Cl]^+$

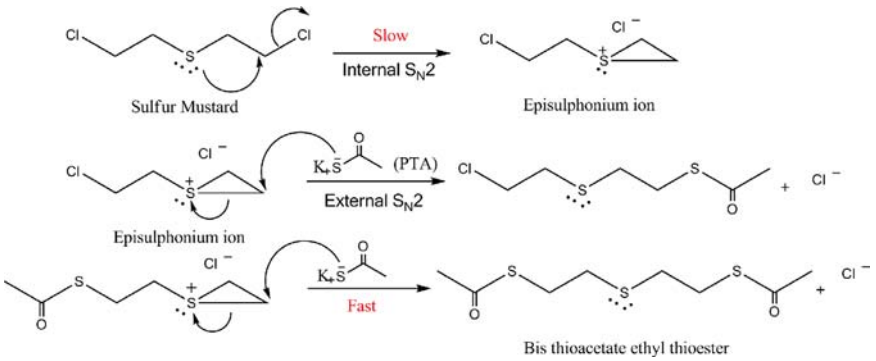

Fig. 1. The derivatization reaction mechanism of SM with PTA.

of SM and related chemicals, because of their high alkylation activity with LC column packing material or protic solvents used in LC. BTAETE of non-alkylation activity is very suitable for LC–MS/MS analysis. The expected mass of the derivative of alkylating agent is $M_w - nX + n$TA, for example in SM, where M_w is the molecular weight of SM, X is Cl (atomic weight 35), TA is thioacetic acid (molecular weight 75), and n is equal to 2, a result is 238.

With regard to two major mustard oxidation products, mustard sulfoxide and sulfone, the sulfur in SM is believed to be lower oxidative reactive because of the presence of two large electron-withdrawing chlorine atoms [20]. Likewise, SM is apt to be relatively oxidized to the sulfoxide, which converts more slowly to the sulfone [21]. The rate of alkylation runs faster for SM than mustard sulfoxide or sulfone, in accordance with the effect of acute exposure to SM or related chemicals [22], as mustard sulfoxide and sulfone also own vesicant toxicity by their alkylation activity [8], and this oxidation of SM is a useful decontamination procedure as a result of formation of crystalline solids without percutaneous adsorption by the skin [23]. The derivatization experiments in tube also showed that it needs more severe conditions for mustard sulfoxide and sulfone than for SM (see Fig. 2). Because of inconsistent reaction conditions, we only developed the derivatization method for SM in this paper.

3.2. Parameters for derivatization

A series of parameters such as reaction temperature, time, pH, solvent and concentration of PTA, and matrix composition were optimized for highest sensitivity and intensity in analysis. As known, the derivatization reagent PTA is water-soluble and can slightly dissolve in organic solvents, while SM is preferred to be dissolved in an aprotic polar solvent to match its lipophilicity and slow down its hydrolyzation. A series of miscible solvents were investigated to check their feasibility for derivatization. Water and DMSO were suitable for preparation of PTA solution in higher concentration than acetonitrile and isopropanol, and SM in acetonitrile showed 20–30% higher response than DMSO and isopropanol after derivatization. Finally, water was chosen for dissolution of PTA and acetonitrile for SM. Because, first, although SM would slowly hydrolyze in water by S_N2 mechanism, it was noted that PTA more easily attacks episulfonium cation formed by SM than hydroxide ion; second, acetonitrile could disperse SM into water as well as its compatibility with LC analysis and "cleaner" background in MS.

In this study, an experimental design by orthogonal array (a Latin square $L_9(3^4)$) was constructed to evaluate the effects of derivatization by the following factors: reaction time (A), temperature (B), concentration of PTA (C), and Blank (D), (D) was setup for calculation of error. The data were analyzed using SPSS statistical software (SPSS for Windows version 16.0; SPSS Inc, Chicago, USA). Then the range analysis was applied to the data

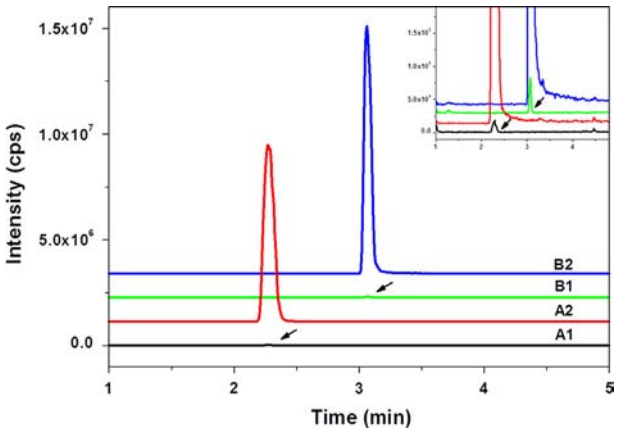

Fig. 2. The extracted ion chromatograms of mustard sulfoxide (A) and mustard sulfone (B) by derivatization with two different reaction conditions at the same concentration of 10 μg/mL. Condition 1, heated at 50 °C for 30 min, and condition 2, heated at 100 °C for 60 min. Inset shows a partially enlarged view.

Table 2
Parameters for derivatization of SM with PTA.

Parameter	Level		
	1	2	3
PTA (mg/mL)	0.1	1	5
Temperature (°C)	R.T.[a]	50	80
Reaction time (min)	10	30	60

[a] R.T. represents room temperature at ca. 25 °C.

analysis, and the setup parameters and obtained results were shown in Table 2 (for data details see Supplementary material). It was shown that 30 min of reaction time, 50 °C of reaction temperature, and 5.0 mg/mL of PTA concentration were the optimal derivatization conditions, and the rank order of the three parameters was $R_C > R_B > R_A$, as well as no unignorable interaction effect was found in such a design. However, it was discovered that the poor resolvability of PTA at higher concentration in organic solvent would affect the derivatization reaction and its stability. Eventually, derivatization of SM in acetonitrile using 1 mg/mL of PTA in water at equal volume, and heated at 50 °C for 30 min were adopted as the most favorable conditions.

The ratio of acetonitrile to water (v/v) and the effect of pH were also tested for optimization of this derivatization. When using the same concentration of SM at 100 ng/mL in acetonitrile and PTA solution at the concentration of 1 mg/mL in water, the response intensity of derivatization product BTAETE could achieve a relatively

1.2 or 4.7 times higher value when the ratio of acetonitrile to water was 1:1 rather than 1:2 or 1:4 by mixing different amounts of SM and PTA solution. It demonstrates that decreasing the volume of PTA solution can improve sensitivity in the case of a far excess of PTA than SM in the acetonitrile–water mixture. To illustrate potential pH effects, the robustness of the derivatization was measured at different apparent pH values by adding formic acid or 1 M NaOH to a mixture of acetonitrile–water at 50:50 (v/v). A lower response was observed at low pH (pH 3) compared with neutral or weak basic pH and almost undetectable at extreme high pH (pH 12), as a result of inhibition of formation of cationic episulfonium compound at low pH and appearance of elimination reaction at extreme high pH value [21]. PTA solution at the concentration of 1 mg/mL was tested in neutral pH value, so the pH value of derivertization reaction was under control at pH 7 more or less.

3.3. Method validation

Under the optimized parameter conditions for UPLC–MS/MS analysis, the examples of chromatograms including SM in natural water and soil at different concentrations are shown in Fig. 3. The developed method was validated with samples spiked with SM in acetonitrile, and was also successfully employed for determination of spiking samples both in water and soil by isotope-dilution LC–MS/MS. The selectivity was assessed by evaluating the unequivocal chromatographic separation and comparison among blank reaction solution, IS spiked blank, and standard spiked samples. Data from the method validation are given in Table 3.

The results show the established method can overcome the shortcoming of low repeatability caused by instability of sulfur mustard in a variety of matrices samples, because through derivatization it can greatly improve stability of analyte in the operation process by transferring the molecules of sulfur mustard with high alkylation activity into the form of BTAETE with non-alkylation activity. And the optimized direct derivatization is more convenient and universal since no decontamination or enrichment apparatus was necessary, no equilibrium time between sample and analyte was needed, only addition of common chemicals into samples at mild condition without solvent exchanging.

3.4. Limit of quantification, linearity and reproducibility

In this work, the LOD of SM was determined as 0.05 ng/mL by giving a S/N ratio greater than 3, whereas LLOQ was 0.1 ng/mL by S/N ratio greater than 10. In typical GC or GC–MS method for direct detection of SM with the recommended pretreatment procedure such as liquid–liquid extraction or solid-phase extraction, the reported LOD was ca. 50 ng/mL [24,25].

Table 3
Method validation for the determination of SM.[a]

Parameter		Value	
LOD (ng/mL)		0.05	
LLOQ (ng/mL)		0.10	
Linearity (R^2)		0.1–1000 ng/mL (0.995)	
Precision and trueness ($n=6$)		(RSD%)	(RE%)
LLOQ (0.1 ng/mL)	Intra-day	11.8	6.9
	Inter-day	12.3	3.4
Low (0.25 ng/mL)	Intra-day	3.9	−4.3
	Inter-day	5.3	−1.2
Medium (10 ng/mL)	Intra-day	7.1	−1.3
	-river	5.4	1.1
	-soil	7.4	−2.4
	Inter-day	9.3	−0.3
High (750 ng/mL)	Intra-day	7.3	4.1
	Inter-day	9.7	1.5
% Matrix effects ± SD ($n=3$)			
BTAETE (10 ng/mL)	River	87 ± 3.9	
	Soil	92 ± 3.3	
% Recovery ± SD ($n=3$)			
SM (10 ng/mL)	Acetonitrile	95 ± 2.5	
	River	80 ± 3.7	
	Soil	83 ± 10	

[a] Except for special annotation, data are obtained in acetonitrile solvent.

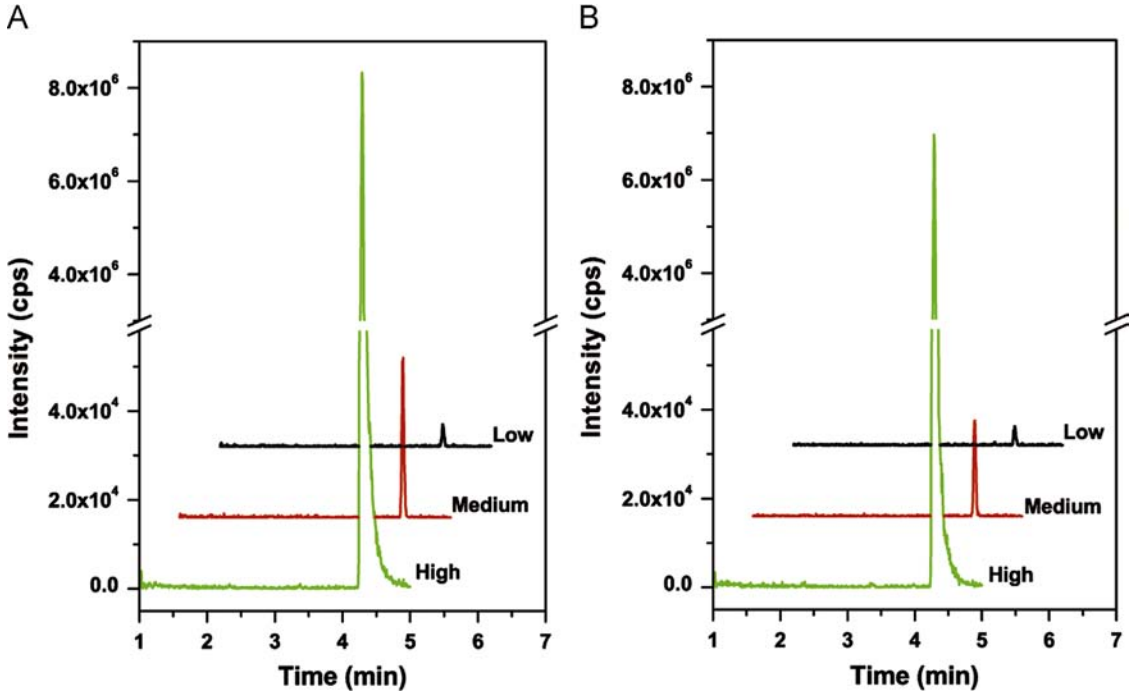

Fig. 3. The extracted ion chromatograms of SM in river water (A) and soil (B) at low (0.25 ng/mL), medium (10 ng/mL) and high (750 ng/mL) concentration.

The linearity and precision of method were investigated within the concentration range from 0.1 ng/mL to 1 μg/mL. Good linearity and method repeatability were obtained in the investigated range. Precision and trueness were measured at LLOD and three QC concentration levels, 0.25, 10, 750 ng/mL. As shown in Table 3, all inter-day and intra-day precisions were less than 12.3%, while the trueness represented by relative error (RE) was from −4.3% to 6.9%, showing our LC–MS/MS coupled with a derivatization procedure has a good feasibility for determination of SM.

3.5. Matrix effects and recovery

The matrix effects was observed at 87% and 92% respectively with river and soil samples by applied post-extraction spiking BTAETE procedure [26], which was evaluated by comparing the BTAETE in matrix and in acetonitrile at concentration of 10 ng/mL.

As it involves the derivatization reaction in our method, we also took the reaction efficiency into consideration by evaluation of the recovery of SM in different matrices. The recovery was investigated by spiking SM into different matrices, then derivatized and quantified BTAETE through the established standard curve of BTAETE in blank reaction system, and the result was calculated by

$$\%\ \text{Recovery} = \frac{C_{\text{BTAETE}}}{C_{\text{SM SPIKING}}} \times \frac{Mw_{\text{SM}}}{Mw_{\text{BTAETE}}} \times 100 \quad (1)$$

where C_{BTAETE} and $C_{SM\ spiking}$ represent the calculated concentration of BTAETE and spiking concentration of SM, while Mw_{BTAETE} and Mw_{SM} mean the molecular weight of BTAETE and SM.

Here this recovery, combining reaction efficiency, matrix effects, extraction efficiency and other factors, and the results were shown as 95%, 80% and 83% separately in acetonitrile, river and soil samples as shown in Table 3. In light of the data of matrix effects presented above, it concludes that the majority of SM molecules in the reaction system were transformed into BTAETE. As shown in Fig. 4, when derivatization of SM at relatively high concentration, for example 1.0 μg/mL, some reaction by-products within very small amounts have been monitored, such as hemisulfur mustard and mustard sulfoxide, as well as the BTAETE's mono-oxidation product bis-(thioacetate) ethylsulfinyl ethane (BTAESE). Although BTAESE can be formed by either derivertization of mustard sulfoxide or oxidation of BTAETE, actually the main contribution of the peak intensity was from partial oxidation of overdosed BTAETE. Since it was not convenient for the reaction of mustard sulfoxide under current conditions, especially unchanged mustard sulfoxide existed at a very low concentration.

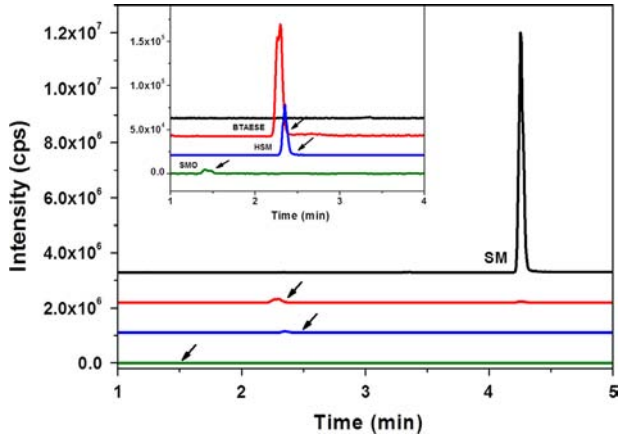

Fig. 4. The extracted ion chromatograms of derivatives of SM and hemisulfur mustard (HSM), mono-oxidation product of BTAETE (BTAESE) and unchanged mustard sulfoxide (SMO) in acetonitrile at the concentration of 1.0 μg/mL. Inset shows a partially enlarged view.

3.6. Determination of SM

Considering the hydrolysis problem of SM, the analysis for water or soil samples were operated immediately after spiking SM, then IS and PTA were added at once. And the selectivity was assessed by comparison among blank matrices reaction solution, IS spiked blank matrices, and standard spiked samples.

This established method with good validation was applied for quantitative determination of spiked natural water and soil samples. A detection limit of 0.1 ng/mL was achieved for the river sample, whereas the SM in soil sample could be detected at 0.1 ng/g. In light of application of stable isotope dilution, the trueness was 1.1% and −2.4% (RE), while the precision was 5.4% and 7.4% (RSD) for spiked river and soil samples respectively, shown in Table 3. Thus, the derivatization method was proved to be well applicable for different environmental samples, including natural water and soil samples.

4. Conclusion

In this work, we developed an isotope-dilution LC–MS/MS method with direct derivatization for determination of SM in aqueous samples, which would be a complementary technique with traditional GC or GC–MS. This method has obtained a good sensitivity lower to 0.05 ng/mL and a wide linear range from 0.1 ng/mL to 1 μg/mL. The total analysis time including sample preparation and instrument analysis was less than 1 h, and the method was easy to handle and has been successfully employed for trace SM determination in environmental samples, such as river water or soil samples. It is of great importance that via such a direct derivatization approach, LC–MS/MS technique can be applied for detection of SM, and it also has good prospects in bioanalysis of SM *in vivo* to meet the challenge of toxicological research.

Wines

ABSTRACT

Herein we describe an easy one step synthesis of carbon nanodots (C-dots) by thermal carbonization of 6-bromohexylboronic acid using two different amine compounds, polyethyleneglycol bis(3-aminopropyl (PEGA) and 1,2-aminopropane (DPA), at 180 °C in atmospheric oxygen. The as-synthesized C-dots were characterized by FTIR, HRTEM, NMR and fluorescence. The C-dots prepared using PEGA showed a strong emission at 440 nm with excitation at 362 nm. These C-dots exhibited analytical potential as sensing probes for tannic acid (TA) determination. pH effect, interferences, and analytical performance of the method were investigated. The method was found effective in the linear concentration range from 0.1 to 10 mg L^{-1} TA achieving a limit of detection equal 0.018 mg L^{-1} TA. The applicability of the method was demonstrated by direct measurements of TA in red and white wine samples. Validation of the method was achieved by spiking the wine samples with different standard TA concentrations obtaining recoveries in the range (90–112.5%). A probable mechanism by which TA quenched the C-dots fluorescence was proposed.

1. Introduction

Tannic acid (TA) is a natural hydrolysable polyphenol compound present in fruits and different kinds of vegetables and, along with other condensed polyphenols, can be found in several beverages including wine, beer, coffee, black tea and white tea. TA is composed of a polyol residue derived from D-glucose, which hydroxyl groups may be partially or fully substituted with galloyl units (gallotannins) [1]. It is used as a food additive (code number E-181) as clarifying agent, flavor adjunct and flavoring agent [2] as well as additive in medicinal products due to its astringent, diuretics and anti-inflammatory activities [3,4]. Moreover, TA has also applications in the tannery industry to transform animal skins to leather and for re-tanning with Cr(III) to prevent leather putrefaction [5]. As an organic pollutant associated with the tanning industry, TA has been found to be toxic to aquatic microorganisms and may form metal complexes that alter the aquatic ecosystem [6,7]. Due to its wide range of applications, analysis of tannic acid is of importance not only in food but also in the medical and environmental fields. Many analytical methods are based on the overall oxidation properties of polyphenols and, consequently, devoted to the determination of total phenolic content rather than specific determination of each component [8–12]. However, many efforts were attempted to measure TA in several kinds of food and beverage samples, as well as in industrial waters. So, a number of methods are available to quantitatively determine tannic acid content in waters, pharmaceuticals and foods, including spectrophotometry [13], electrochemical methods [14–16], luminescence [17–19] and chromatography [20,21]. Each method has its advantages and drawbacks. For example, the determination of tannic acid in wines by the traditional spectrophotometric Folin–Ciocalteu method, based on the formation of a blue phosphotungstic phosphomolybdenum complex, is simple but lacks selectivity as many other compounds in wine interfere. Chromatographic methods allow the determination of tannic acid along other polyphenols but are time consuming and expensive. Electroanalytical methods with different types of electrodes were used for TA determination, but the presence of ascorbic acid limits the use of some of these methods, or laborious sample pretreatments are needed to remove ascorbic acid before analysis [15,16]. These examples demonstrate that sensitive, selective and rapid TA detection is still a challenge.

Recent developments in analytical nanotechnology open the opportunity to develop new sensitive and selective methods for tannic acid determination. Carbon nano dots (C-dots) were found recently to be promising materials in analytical and bioanalytical

Scheme 1. Schematic representation of PEGA-C-dots synthesis .

applications, due to their unique optical properties, such as broad excitation spectra, tunable emission wavelength and stable photoluminescence [22]. Exploiting C-dots in analytical chemistry is relatively recent and most methods depend on the C-dots surface functional groups and/or their surface passivation effects. The number of analytical assays using C-dots has been increasing, but in the best of our knowledge, no work has been described for TA determination in real samples using carbon nanodots.

Herein we report a straightforward synthesis of passivated C-dots in one step via thermal carbonization method (Scheme 1), using two different amino precursors, polyethyleneglycol bis(3-aminopropyl) (PEGA) and 1,2-aminopropane (DPA). Those C-dots prepared with PEGA were found sensitive and selective fluorescent nanosensors for TA and were successfully applied to direct TA detection in real red and white wine without sample pretreatment. The synthesis reaction process as well as the mechanism for the selective sensing are also proposed.

2. Experimental

2.1. Materials

All the reagents used were highly pure analytical grade chemicals and used without further purification. The following reagents were used in this study: polyethylene glycol bis(3-aminopropyl) (PEGA), 6-bromohexylboronic acid (BrHBA), glucose, fructose, sucrose, gallic acid, citric acid, calcium chloride, and disodium hydrogen phosphate, all purchased from Sigma-Aldrich. Ascorbic acid, sodium fluoride, potassium chloride, and sodium sulfite were purchased from Merck. 1,2-diaminopropane, tartaric acid and caffeine were purchased from Fluka. NaOH, and HCl were purchased from Prolabo. TA was purchased from Hopkin & Williams chemicals (England).

2.2. Synthesis of C-dots

PEGA-C-dots and DAP-C-dots were synthesized by a thermal carbonization method, using PEGA and DAP, respectively. Typically, 1 mmol of PEGA was dissolved in about 25 mL of milli-Q water. To this solution, 0.25 mmol of BrHBA was added. The solution was then stirred and heated at 150 °C. The heating was continued until near dryness, after which 1 mL of milli-Q water was added. The process was repeated 5 times. Finally the temperature was raised to 180 °C. A yellow solution was formed and heating continued until obtaining a reddish-brown color solution to ensure the formation of the C-dots. The obtained PEGA-C-dots solution was then completed to 25 mL of milli-Q water filtered by nylon filters (0.45 μm) and purified through dialyzer tube (MWCO, 3.5 kDa) for 3 days. The purified solution was divided into two aliquots, the first one was dried completely for characterization analysis while the second was used for the analysis experiments of tannic acid. The pH of the aqueous PEGA-C-dots solution resulted to be 6.43. The same procedure was carried out to prepare DAP-C-dots using DAP instead of PEGA.

2.3. Spectrofluorimetric measurements

In a typical pH effect determination procedure, 100 μL of TA (so that the final concentration is 5 mg L^{-1}) were diluted by about 4 mL of universal buffer (in the range 3–11.5) and then 100 μL of C-dots solution was added. Finally, the solution was completed by the same buffer until a final volume of 5 mL. The fluorescence was measured immediately after the preparation in a 1-cm quartz cuvette 3 times at 440 nm with excitation at 362 nm and slit widths of excitation and emission as 20 and 10 nm, respectively. The average fluorescence data were calculated and presented as a graph. Similarly, for interference measurements, 100 μL of TA (final concentration is 5 mg L^{-1}) was mixed with the interference material (final concentration is 10 mg L^{-1}) and diluted by about 4 mL of universal buffer solution pH=9. Then, 100 μL of C-dots solution was added and finally the solution was completed to 5 mL using the same buffer solution. The subsequent fluorescence was measured as mentioned above with the same instrumental conditions.

2.4. Fluorescence quantum yield measurement

The fluorescence quantum yield was calculated through the well-established comparative method using quinine sulfate as a reference. The following equations were used in the quantum yield measurement:

$$\Phi_C = \Phi_{st}\frac{F_C}{F_{st}}\frac{A_{st}}{A_C}\frac{{n_C}^2}{{n_{st}}^2} \quad (1)$$

$$\Phi_C = \Phi_{st}\frac{G_C}{G_{st}}\frac{{n_C}^2}{{n_{st}}^2} \quad (2)$$

where ϕ is the quantum yield, F is the calculated integrated fluorescence intensity, n is the refractive index, A is the optical density (measured with a UV–Vis spectrophotometer, Perkin Elmer, Lambda 900), and G is the gradient of F vs A linear plot. The subscripts C and st refer to C-dots and the reference fluorophore, respectively. Quinine sulfate dissolved in 0.1 M H_2SO_4 (n=1.33) of quantum yield equal 0.54 at λ_{ex}=350 nm was used as a reference. C-dots were dissolved in milli-Q water (n=1.33).

2.5. Analysis of wine samples

The white wine sample (Soldepeñas, www.felixsolis.com) and red wine samples (Don Mendo, www.sanvelro.com) were used in the application experiment. The pHs of the wines were found 3.31 and 3.43, respectively. TA standards were prepared in 10% ethanol solution to avoid the effect of alcohol and sample pretreatment. Wine samples were diluted so that the alcoholic content was reduced to 10%. In a typical procedure, 100 μL of sample were spiked by 100 μL standard TA (0, 1, and 3 mg L^{-1}) followed by 4 mL buffer solution pH=9 (Na_2HPO_4 and NaOH and/or HCl) and 100 μL of the PEGA-C-dots solution. Finally, the solution was diluted to 5 mL by the same buffer. Fluorescence was measured at 440 nm with excitation at 362 nm. TA was quantified by running a calibration curve using standard solutions. All determinations were carried out in triplicate.

2.6. Instrumentation

HRTEM (JEOL JEM-2100F, 200 kV) was used to determine the size and morphology of the synthesized C-dots. A Varian 620-IR instrument was used to analyze FTIR spectra in the range 600 to 4000 cm^{-1}. ^{1}HNMR and ^{13}CNMR (NAV400 with 9.0 T magnet shielded, 600 MHz) were used for structural analysis of the synthesized C-dots in D_2O

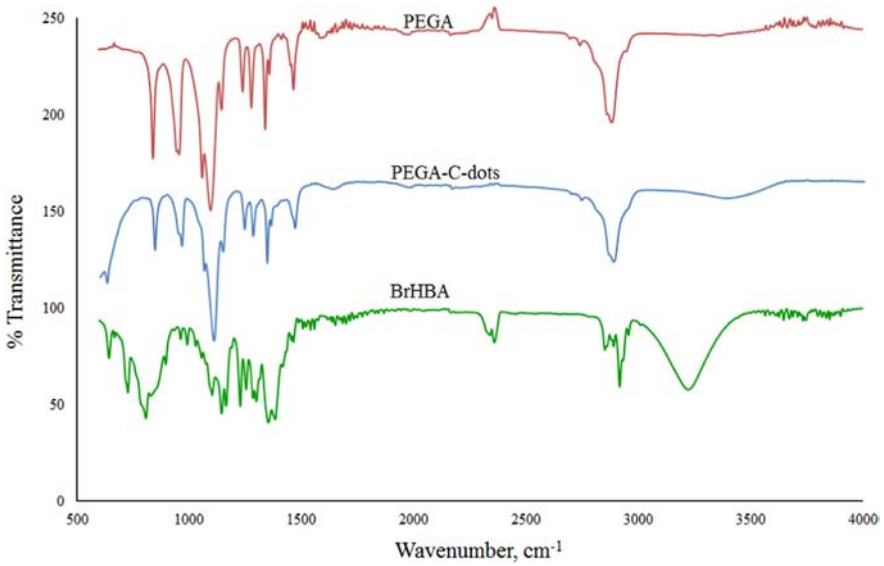

Fig. 1. FTIR spectra of PEGA-C-dots and their precursors.

solvent. Fluorescence spectra were measured using a Cary Eclipse Varian spectrofluorimeter.

3. Results and discussion

3.1. Synthesis and characterization of C-dots

The up-down strategy was used to synthesize C-dots via thermal carbonization method. It is well known that the reaction between the amine group and the alkyl halides proceeds easily and does not need extreme conditions. Higher temperatures than 180 °C were avoided in order to prevent product decomposition. According to the Scheme 1, it was expected that upon heating the long chain product formed between PEGA and BrHBA adhered to the C-dots surface. To confirm this reaction route, the same strategy of synthesis was performed using DAP, a small molecular weight amine, as precursor (Fig. S1).

3.2. FTIR analysis

Fig. 1 shows the spectra of the synthesized PEGA-C-dots and that of reaction precursors for comparison. Two characteristic peaks were identified in the synthesized PEGA-C-dots, the first at 1290 cm^{-1} ascribed to C–H wag (observed only in terminal alkyl halides) and a second at 650 cm^{-1} ascribed to C–Br stretching vibration. Similarly, the same two characteristic peaks were observed in DPA-C-dots (Fig. S2). The absence of characteristic peaks of B–O deformation at 500–550 cm^{-1}, B–O rocking at 725 cm^{-1}, B–OH deformation (at 1210 and 1305 cm^{-1}) and B–N stretching at 780 cm^{-1} in both types of C-dots suggested a pyrolytic deboronation mechanism according reaction route depicted in Scheme 1.

3.3. HRTEM and NMR analysis

The size and the morphology of the as-synthesized PEGA-C-dots and DPA-C-dots are spherical with size range 5 ± 3 nm as demonstrated by the HRTEM images (Fig. S3). Typical ^{13}C NMR spectra of PEGA-C-dots (Fig. S4) showed no signals in the range of 165 to 180 ppm corresponding to sp^2 carbons; however, signals in the range of 40 to 80 ppm revealed the presence of aliphatic sp^3 carbons [23]. On the other hand, ^{13}C NMR spectra of DAP-C-dots (Fig. S5) showed signals in the range of 165 to 170 ppm due to sp^2 carbons that could be ascribed to graphite carbons/planes and signals in the range of 40 to 80 ppm corresponding to aliphatic sp^3 carbons. The ^{1}HNMR spectra of PEGA-C-dots and DPA-C-dots are displayed in Figs. S6 and S7, respectively. Peaks in the range 3.4–3.5 ppm for RCH_2-Br and 0.5–5.0 ppm for R_2NH [23] for both types of C-dots confirmed the information obtained by FTIR.

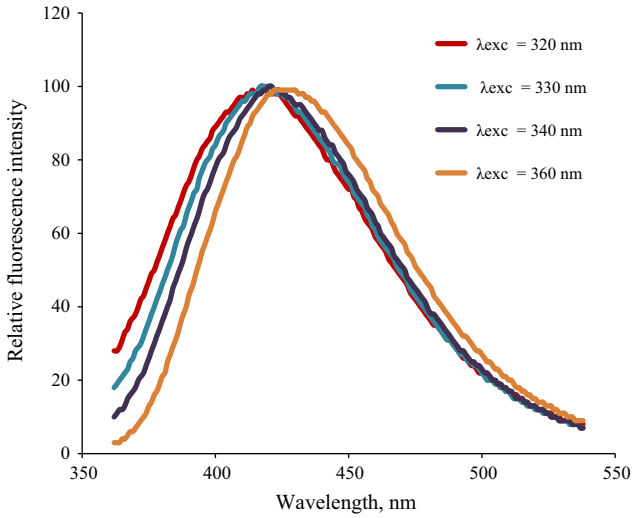

Fig. 2. PEGA-C-dots emission fluorescence as a function of excitation wavelength. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

3.4. Fluorescence features of the as-synthesized carbon nanodots

The fluorescence emission peak of PEGA-C-dots at pH 3 (0.2 M Na_2HPO_4/0.1 M citric acid) was blue shifted with the change of excitation wavelength (Fig. 2), a phenomenon frequently observed in C-dots which origin still remains unclear. Notwithstanding, it is frequently ascribed to different functional groups that create surface defects with the result of different energy levels [24]. In further experiments, excitation and emission wavelengths of 362 and 440 nm, respectively, were used. The full width at a half maximum at the different excitation wavelengths demonstrated a narrow size distribution of as-prepared PEGA-C-dots (90 ± 5 nm), thus confirming the absence of fluorescence color-dot size relationship.

On the other hand, the fluorescence quantum yield of the C-dots excited at 362 nm in milli-Q water was calculated to be 0.3%, a value similar to that found for other C-dots obtained from combustion soot of candles [25] or by using a plasma-induced method [26].

3.5. pH effect

The effect of pH is very important in this investigation, as the fluorescence of PEGA-C-dots in the absence and presence of TA is pH dependent. The influence of pH in the range 3–11.5 was investigated for TA interaction with PEGA-C-dots and results shown in Fig. 3. In the acidic pH range 3–6 a white precipitate was formed in presence of TA, particularly at concentrations of TA higher than 5 mg L^{-1}. Maximum quenching effect took place in basic media and a pH=9 was taken as the optimum value for further experimental measurements.

3.6. Analytical figures

Under the optimum experimental conditions, the sensitivity, the linear response range and the limit of detection of TA by PEGA-C-dots fluorescence quenching were determined. Calibration curve, obtained from a Stern–Volmer semilog plot, was linear within the range 0.1 to 10 mg L^{-1} TA being the calibration equation $\log(F^{\circ}/F)=0.0597$ C {mg L^{-1}}, ($R^2=0.994$), where F° and F account for the fluorescence intensities of PEGA-C-dots in the absence and presence of TA, respectively and C represents the concentration of TA in mg L^{-1}. A detection limit of 0.018 mg L^{-1} TA was calculated (%RSD=0.2). As far as we know, no fluorescence methods for TA based on the use of C-dots have been described to date. From Table 1, it is apparent that the present method, exhibits high sensitivity and low detection limit when compared with some electrochemical and optical methods. Among them, that based on the TA oxidation by chitosan capped silver nanoparticles has been recently published for TA determination [27].

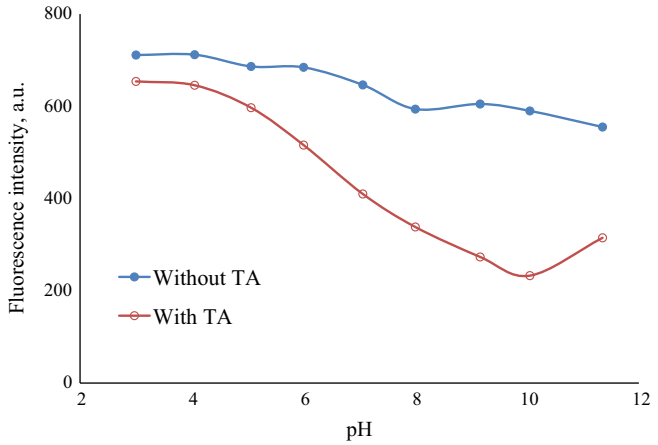

Fig. 3. pH influence on PEGA-C-dots fluorescence in absence and presence of TA (5 mg L^{-1}) at $\lambda_{ex}=362$ nm.

The effect of coexisting compounds on the PEGA-C-dots fluorescence quenching detection of 5 mg L^{-1} TA at pH 9 was investigated. The concentration of all compounds used was 10 mg L^{-1}. The tolerance limit was estimated with a ±5% relative error in fluoresence intensity. The major interference compounds chosen were ascorbic acid, sulfite, caffeine, Mg^{+2} and Ca^{+2} in addition to some abundant components in wine such as gallic acid, sucrose, glucose, fructose, tartaric acid and Na^{+}. It was found that these compounds have no significant effect on the fluorescence emission of PEGA-C-dots by TA. These analytical figures offer a high potential of sensitivity and selectivity for TA in wine samples with no need of sample treatment and it could be comparable to other analytical techniques used for TA determination in such samples.

3.7. Interaction of PEGA-C-dots with TA

The above experimental results showed that the fluorescence quenching observed on adding TA to a C-dots solution at pH=9 remained stable over a long time, indicating that a stable method could be optimized for TA. On the other hand, it was observed that gallic acid did not quench the PEGA-C-dots fluorescence. Carbon dots are known to be excellent electron acceptors and donors [28]; so, a possible mechanism for TA quenching may be attributed to an electron transfer process from the photo excited C-dots to the aromatic groups in TA. The PEGA-C-dots may be wrapped by the TA mimicking dendrimers, so allowing an effective non-radiative energy transfer process (Fig. 4).

On the contrary, in presence of gallic acid such interaction with PEGA-C-dots was not possible and fluorescence quenching did not take place.

3.8. Real sample analysis

Under the optimum experimental conditions described, TA determination in red and white wine samples was performed to validate the method. No sample pre-treatments were made but dilution with buffer. The fluorescence spectra of PEGA-C-dots without and with wine samples spiked by different concentrations (0, 1, and 3 mg L^{-1}) are illustrated in Fig. S8. Table 2 shows the results of TA obtained in wine samples after their dilution. Each result was the average of three samples. It is obvious that satisfactory recoveries were achieved for the spiked samples and results demonstrated that the method offers potential for quantitative determination of TA in wine samples.

4. Conclusions

In summary, we have been successfully synthesized passivated C-dots in an easy one step in which a deboronation process took

place. The as-synthesized PEGA-C-dots were found sensitive and selective towards TA, so that a promising fluorescence sensing system for TA detection in wines has been developed. The probe system of TA based on PEGA-C-dots fluorescence quenching showed analytical advantages such as rapid detection, high sensitivity and selectivity, wide linear response range, and low cost. A possible mechanism for TA sensing was attributed to a wrapping of the PEGA-C-dots by the TA mimicking dendrimers, so allowing an effective non-radiative energy transfer process.

Quinolones
Macrolides
Bacterial resistance

ABSTRACT

The analysis of antibiotics in animal faeces is important to obtain more insight in the possible formation of bacterial resistance in the animals' gut, to learn about the dissemination of antibiotics to the environment, to monitor trends in antibiotic usage and to detect the illegal and off-label use of antibiotics. To facilitate these studies a comprehensive method for the analysis of trace levels of 44 antibiotic compounds including tetracyclines, quinolones, macrolides and sulfonamides in animal faeces by liquid chromatography in combination with tandem mass spectrometric (LC–MS/MS) detection is reported. The method is fully validated according to European regulation and showed satisfactory quantitative performance according to the stringent criteria adopted, with the exception of some of the macrolide compounds, which can be analysed with somewhat high measurement uncertainty. A large survey was carried out monitoring swine and cattle faeces and the outcomes were striking. In 55% of the swines, originating from 80% of the swine farms and in 75% of the calves, originating from 95% of the cattle farms, antibiotics were detected. Oxytetracycline, doxycycline and sulfadiazine were the most detected antibiotics, followed by tetracycline, flumequine, lincomycin and tylosin. Over 34% of the faeces samples contained two or more different antibiotics with a maximum of eight. Possible explanations for these findings are given and the effects are discussed.

1. Introduction

Antibiotics are medical agents that either kill bacteria or inhibits their growth. Antibiotics can be produced by microorganisms but also be synthetically produced and can be used for both human and veterinary purposes. Antibiotics are excessively used in both human and animal health and as a negative side-effect, bacteria become resistant. Nowadays, bacterial resistance is a major threat for human healthcare: in the USA, 23,000 people per year are dying due to bacterial infections which cannot be cured by antibiotic treatment [1]. Therefore, policies on the use of antibiotics have become more stringent within most countries aiming to decrease bacterial resistance and its dissemination. The focus is mainly on the decrease of antibiotic usage in human health as well as in veterinary practices, because resistant bacteria are easily transferred from animal to human [2]. In The Netherlands, a specific measure was the implementation of mandatory registration of antibiotics delivered to and used by farmers to prevent off-label usage.

After administration of antibiotics, 30–90% of the dose given is excreted in non-metabolized form or as active metabolites [3–5] and as a result high levels of antibiotics and active metabolites are expected to be present in faeces [6]. As a matter of fact, the presence of veterinary antibiotics in liquid waste from swines was previously confirmed [7]. Because slurry is used to optimise the growth and harvest in agriculture, antibiotics are unwillingly disseminated throughout the environment and are found in surface water, soil and crops [8–15] which is expected to contribute to adverse ecotoxicological effects [4,5,16,17] and the emergence of microbial resistance [18–23].

Analysing antibiotics in animal faeces is expected to be effective in several ways. First to obtain more insight in the possible formation of bacterial resistance in the animals' gut, leading to valuable information on the relation between residues and resistance. Second to learn about the dissemination of antibiotics to the environment and possible ecotoxicological effects. Third to monitor trends in antibiotic usage at the farms using non-invasive sampling and last to enforce policies on the use of antibiotics and thus to prevent the illegal and off-label use of antibiotics. We conclude that the analysis of antibiotics in faeces could be very informative and therefore a multi-method to detect a wide range of veterinary antibiotics in faeces is needed.

Multiple analytical methods for the analysis of antibiotics are available focussing on regulatory limits established for food products. Only a few multi-analyte methods on the analysis of antibiotics in faeces are published [12,24–31]. Most of these

studies solely focussed on samples taken in Asia and they cover only a minor part of the relevant veterinary antibiotics, up to 17 in total. No fully validated multi-methods applying liquid chromatography (LC) coupled to tandem-mass spectrometry (MS/MS) for the analysis of a wide range of antibiotics in animal faeces is available and no data is available on the antibiotic content of faeces of swines and calves in Dutch animal breeding.

We present a multi-method for the analysis of veterinary antibiotics in faeces aiming for the detection, quantification and confirmation of 4 tetracyclines, 18 sulfonamides, 14 macrolides and 10 quinolones using LC–MS/MS. The method was fully validated for swine faeces according to Commission Decision 2002/657/EC [32]. Using this method 340 different swine faeces samples and 340 calf faeces samples obtained from 20 swine respectively 20 cattle farms were monitored for the presence of antibiotics. Results are presented here.

2. Material and methods

2.1. Reagents and equipment

HPLC grade methanol (MeOH) and acetonitrile (ACN) was obtained from Biosolve (Valkenswaard, The Netherlands). Milli-Q water was prepared using a Milli-Q system at a resistivity of at least 18.2 MΩ cm^{-1} (Millipore, Billerica, MA, USA). Formic acid, ammonium formate, citric acid monohydrate, disodiumhydrogenphosphate (Na_2HPO_4) dihydrate and disodium ethylenediaminetetraacetate (Na_2EDTA) were obtained from VWR International (Darmstadt, Germany) and lead acetate from Sigma Aldrich (St. Louis, MO, USA).

The reference standard of oxytetracycline hydrate, tetracycline HCl, chlortetracycline HCl, doxycycline hyclate, ciprrofloxacin, danofloxacin, enrofloxacin, flumequine, marbofloxacin, nalidixinic acid, norfloxacin, oxolinic acid, sarafloxacin HCl trihydrate, dapsone, sulfacetamide, sulfachloorpyridazine, sulfadiazine, sulfadimidin, sulfadimethoxin, sulfadoxin, sulfamerazine, sulfamethoxazole, sulfamethizole, sulfamethoxypyridazine, sulfamonomethoxin, sulfaphenazole, sulfapyridin, sulfaquinoxalin Na, sulfathiazole, sulfisoxazole, erythromycin, gamithromycin, josamycin, lincomycin HCl, natamycin, pirlimycin HCl, spiramycin, tildipirosin, tulathromycin, tylosin tartrate, valnemulin, amoxicillin, ampicillin, penicillin G Na, penicillin V K, cloxacillin Na hydrate, dicloxacillin Na H_2O, nafcillin Na hydrate, oxacillin Na hydrate were obtained from Sigma-Aldrich, gamithromycin from Hovione (Loures, Portugal), tylvalosin tartrate from ECO Animal Health (London, United Kingdom), tilmicosin and tiamulin fumarate from LGC standards (Teddington, Middlesex United Kingdom) and tildipirosin from MSD Animal Health (Boxmeer, The Netherlands).

Ciprofloxacin d_8 HCL hydrate, difloxacin d_3 HCl hydrate, enrofloxacin d_5 HCl, nalidixic acid d_5, norfloxacin d_5, oxolinic acid d_5, sarafloxacin d_8 HCl, lincomycin d_3, spiramycin d_3, sulfachloropyridazine $^{13}C_6$, sulfadimidine $^{13}C_6$, sulfadimethoxine d_6, sulfadoxine d_3, sulfamerazine $^{13}C_6$, sulfamethoypyridazine d_3, sulfapyridine $^{13}C_6$, sulfaquinoxaline $^{13}C_6$, sulfathiazole $^{13}C_6$, sulfisoxazole $^{13}C_6$, penicillin G d_7 and penicillin V d_5 were obtained from Witega (Beril, Germany), danofloxacin d_3 mesylate, flumequin $^{13}C_3$, gamithromycin d_4, sulfadiazine d_4, sulfamethoxazole d_4, dapson d_8, from Toronto Research Chemicals (Toronto, ON, Canada), erythromycin ^{13}C d_3 from Cachesyn (Mississauga, ON, Canada), tetracycline d_6 from Santa Cruz Biotechnology (Santa Cruz, CA, USA), and demeclocycline and lomefloxacin from Sigma Aldrich.

Stock solutions of the tetracyclines, sulfonamides, penicillins were prepared in MeOH, of the quinolones in ammoniated MeOH and of the macrolides in ACN at 1000 mg L^{-1}. Mix solutions of the individual antibiotic groups were prepared at 10 mg L^{-1} in MeOH and a spiking solution was prepared containing 0.25 μg L^{-1} of the individual sulfonamides 1.0 μg L^{-1} of the individual quinolones, macrolides and sulfonamides, and 2.5 μg L^{-1} of the individual penicillins in MeOH. A mixture of the internal standards was prepared at 5 μg L^{-1} in MeOH.

Citric acid solution (0.1 M) was prepared by dissolving 21 g citric acid monohydrate in 1 L of water. Phosphate solution (0.2 M) was prepared by Na_2HPO_4 in 1 L of water. EDTA solution (0.2 M) was prepared by dissolving 74.4 g Na_2EDTA in 1 L of water. McIlvain–EDTA buffer (0.1 M, pH 4.0) was prepared by mixing 500 ml citric acid solution with 280 ml phosphate solution. 74.4 g Na_2EDTA was added. Stir using a magnetic bar for 30 min. Check the pH and if needed set to pH 4.0 by adding either citric acid solution or phosphate solution. Add water to a total volume is 2 L. Lead acetate solution was prepared by dissolving 100 g lead acetate in 500 mL of water. Ammonium formate solution (1 M) was prepared by dissolving 6.3 g ammonium formate in 100 mL water. Mobile phase A was prepared by diluting 2 ml ammonium formate solution, 160 μL formic acid to 1 L with water. Mobile phase B was prepared by diluting 2 ml ammonium formate solution, 160 μL formic acid to 1 L with MeOH.

2.2. Sample preparation

The faeces samples were homogenised by stirring with a disposable wooden rod, 2.0 g was weighted into a 50 mL poly propylene (PP) centrifuge tube and 80 μL internal standard solution was added. 4 mL of McIlvain–EDTA buffer and 1 mL ACN were added to the sample. The sample was vigorously shaken by hand and placed in a rotary tumbler for 15 min. After shaking 2 mL of lead acetate solution was added and again the sample was vigorously shaken by hand. After centrifugation (3500 g, 10 min) the extract was transferred into a clean test tube and diluted by adding 13 ml 0.2 M EDTA solution. A Phenomenex (Torrance, CA, USA) Strata-X RP 200 mg/6 mL reversed phase solid phase extraction (SPE) cartridge was conditioned with 5 mL MeOH and 5 mL water. The complete extract was applied onto the SPE cartridge which was subsequently washed with 5 mL of water and dried by applying vacuum for 5 min. The antibiotics were eluted from the cartridge using 5 mL MeOH followed by evaporation of the solvent (40 °C, N_2). The residue was redissolved in 200 μL MeOH and subsequently 300 μL water was added before transferring the final extract into an LC–MS/MS sample vial.

2.3. LC–MS/MS

The LC system consisted of a Waters (Milford, MA, USA) model Acquity with a Phenomenex Kinetex C_{18} analytical column of 2.1 × 100 mm^2, 1.7 μm, placed in a column oven at 40 °C. The gradient was: 0–0.5 min, 1% mobile phase B, 0.5–5.0 min, linear increase to 100% B with a final hold of 1.0 min and an equillibration time of 3.5 min, operating at a flow rate of 0.3 mL min^{-1}. The injection volume was 10 μl. Detection was carried out by LC–MS/MS using an AB Sciex (Ramingham, MA, USA) Q-Trap 6500 mass spectrometer in the positive electrospray ionisation (ESI) mode. The operating parameters were: capillary voltage, 2.0 kV; cone voltage, 25 V; source offset, 20 V; source temperature, 150 °C; desolvation temperature, 550 °C; cone gas flow, 150 L h^{-1}; and desolvation gas, 600 L h^{-1}. The antibiotics were fragmented using collision induced dissociation (N_2) and the scheduled Selected Reaction Monitoring (SRM) transitions (20 s window) are presented in Table 1. Data was processed using Multiquant software V2.1.1 (AB Sciex).

Table 1
SRM transitions of the antibiotics and their internal standards.

2.4. Method validation

A full validation for swine faeces was carried out according to Commission Decision 2002/657/EC [32]. The following parameters were determined: linearity, trueness, repeatability, within-laboratory reproducibility, decision limit (CCα), detection capability (CCβ), selectivity and stability. For each compound a target level was set based on the expected detection limits obtained from method optimisation data: for sulfonamides 5 μg kg^{-1}, for the tetracyclines, quinolone and macrolides 20 μg kg^{-1} and for the penicillins 50 μg kg^{-1}. The validation was carried out at three different levels (0.5, 1.0 and 1.5 ∗ target level), on three different occasions, by two different technicians and including swine faeces samples from different origin ($n=21$).

Quantitative results were obtained using isotopically labelled internal standards. If available corrections were carried out using the corresponding labelled internal standard. Josamycin, tilmicosin and tylvalosin were corrected using spiramycin-d_3, pirlimycin using lincomycin-d_3, tulathromycin and valnemulin using gamithromycin-d_4, natamycin using sulfisoxazole, tiamulin and tylosin using nalidixic acid-d_5, tildipirosin and marbofloxacin using lomefloxacin, oxytetracycline using tetracycline-d_6, chlorotetracycline and doxycycline using demeclocycline, sulfacetamide using sulfadiazine-d_4 and sulfamonomethoxine using sulfamethoxypoiridazine-d_3, sulfaphenazole using sulfadoxin-d_3,

2.4.1. Linearity

On three different days a matrix matched calibration line was prepared including 0, 0.5, 1, 2 and 3 * target level by adding solutions of the antibiotics to aliquots of a blank swine faeces sample. Calibration lines were constructed by plotting the peak areas, corrected by the corresponding internal standard, versus the added concentration and carrying out least squares linear regression. The linearity was considered acceptable if the coefficient of correlation was at least 0.990.

2.4.2. Trueness, repeatability and within-lab reproducibility

On each of the days seven different blank swine faeces samples were selected and analysed as such and spiked at 0.5, 1.0 and 1.5 * target level. Of one batch, similar to the batch used for the calibration samples, an additional six spikes were performed at target level. For each sample the antibiotic's concentration was calculated using the calibration line constructed on the same day. The trueness was calculated by dividing the average calculated level by the nominal concentration. According to 2002/657/EC [32] the trueness should be between 70% and 110% for validation levels between 1.0 μg $kg^{-1}$and 10.0 μg kg^{-1} and between 80% and 110% for validation levels from 10.0 μg kg^{-1}.

Note that because different faeces samples were used within one day, the repeatability is not the pure repeatability as stated in 2002/657/EC [32]. However, using different faeces samples a better understanding of the between sample variation is obtained and the validation better reflects a routine analysis situation. To obtain information on the true repeatability (within a single batch of faeces) the variation of seven aliquots originating from a single batch, at target level on each of the validation days ($n=3$) is evaluated using the same criteria. For clarity this parameter is indicated as RSD_r and the repeatability including matrix variation is indicated by RSD_{r*}.

According to 2002/657/EC [32] the relative within-lab reproducibility (RSD_{RL}) and RSD_r are considered acceptable if they are below the value calculated from the Horwitz equation [33] respectively two third of this value, i.e. below 31.7% respectively 21.1% at a validation level of 10 μg kg^{-1}. Thompson [34], demonstrated that the Horwitz equation is not applicable to the lower concentration range (<120 μg kg^{-1}) and suggested a complementary model. However, these findings are based upon data from products of animal origin and because we consider faeces a more difficult matrix, we did not adopt these more stringent criteria and applied the criteria established in 2002/657/EC [32]. Based on this the RSD_{RL} and RSD_r are acceptable if they do not exceed the values mentioned in Table 2. For RSD_{r*} the same criteria as for RSD_r are adopted.

2.4.3. Decision limit and detection capability

Because there are no legal limits for antibiotics in faeces, here the decision limit, CCα, is the limit at and above which it can be concluded with an error probability of 0.05 that a sample contains the antibiotic compound indicated. The detection capability, CCβ, is the lowest concentration of a compound that, with an error probability of 0.05, will result in a positive finding (above CCα) [32]. For the antibiotics CCα and CCβ were calculated according to the procedure described in 2002/657/EC [32] for banned substances using the linearity approach as stated in ISO 11843 [35], to reflect the lowest levels that can still be determined. This procedure results in a value for CCα and CCβ on each validation day. The reported values are the highest values found on the different days, reflecting a worse case situation. Because CCα and CCβ are calculated from the within-laboratory reproducibility, no specific criteria are set for these parameters.

Table 2
Adopted performance criteria according to 2002/657/EC [24].

Concentration level (μg kg^{-1})	Trueness (%)	RSD_r (%)	RSD_{r*} (%)	RSD_{RL} (%)
2.5	70–110	26.0	26.0	39.0
5	70–110	23.4	23.4	35.2
7.5	70–110	22.1	22.1	33.1
10	80–110	21.1	21.1	31.7
20	80–110	19.0	19.0	28.6
30	80–110	17.9	17.9	26.9

2.4.4. Selectivity

The selectivity of the method was studied based on a practical and a theoretical study. Firstly, the 21 analysed blank samples were checked for interferences at the retention times corresponding to the β-lactam reaction products. Secondly, the procedure previously described for validation of selectivity was applied to estimate the probability of interfering substances [36].

2.4.5. Stability

Stability data for the antibiotics in solution were reported previously [37]. The stability of final extracts was determined by storing these extracts at −18 °C after analysis. After 8 days, the matrix matched calibration standards, the blank samples and the samples spiked at target level ($n=7$) were defrosted and injected in the LC–MS/MS system again. The linearity, the trueness and the repeatability of this series was evaluated based on the established validation criteria to determine whether quantitative analysis is still possible after storing the sample extracts at −18 °C for eight days.

2.5. Faeces sampling

Twenty swine farms and 20 cattle farms were randomly selected. At the slaughterhouse, of each of these farms, 17 animals were selected and faeces was taken directly from the gut. These samples ($n=680$) were immediately transported to the laboratory and stored at <-18 °C. The samples were analysed in batches of 40–80–80 samples using the presented method. Quantification was carried out by preparing a matrix calibration line by adding the antibiotics to blank animal faeces at levels ranging from 0–200 to 200 μg kg^{-1} for tetracyclines, quinolones and macrolides and 0–50–50 μg kg^{-1} for sulfonamides. Of samples that showed peak intensities exceeding the calibration line, the antibiotic concentration was estimated by extrapolation.

3. Results & discussion

3.1. Extraction

The extraction of faeces samples was performed by shaking in McIlvain buffer, pH 4.0/acetonitrile (4:1 v/v). To assess if this extraction procedure is appropriate, it was compared to extraction

Validation parameters that do not comply with the criteria for products of animal origin as established by 2002/657/EC [24] are underlined.

using ultrasonification. Three incurred faeces samples were selected: one containing oxytetracycline, one with sulfadiazine and one with tylosin. These samples were homogenised by stirring and eight aliquots were transferred to seperate tubes. Four tubes were extracted according to the described procedure, the other four were extracted by ultrasonification (15 min). The results are presented in Fig. 1. The data was evaluated by an *F*-test and Student's *t*-test. Ultrasonification does not yield higher extraction efficiency and because of ease and sample throughput, it was chosen to extract samples by shaking.

3.2. LC–MS/MS

To find the most optimal LC-system, five analytical columns were compared (all 2.1 × 100 mm^2), being a Phenomenex Kinetex C_{18} and C_{18} XB, a Waters Acquity UPLC BEH and HSS-T3, all 1.7 μm particles, and a Waters Cortecs C_{18}+ 1.6 μm. Using the presented LC system the retention times of all antibiotics showed a similar pattern, with the HSS-T3 column yielding slightly larger retention. More striking differences were observed for the peak width: the Kinetex C_{18} XB and the Cortecs C18+ showed severely broader peaks for especially the tetracyclines. Tildipirosin, the first eluting compound showed broad peaks for the Kinetex C_{18} XB, Acquity UPLC BEH and the Acquity UPLC HSS-T3 column. For tulathromycin especially the Acquity UPLC HSS-T3 column showed significant broader peaks and for oxolinic acid and nalidixic acid, significantly broader peaks were observed using the Kinetex C_{18} XB. Clearly the column materials that are especially developed to enhance peak shapes for basic drugs (Kinetex C_{18} XB and Cortecs C_{18}+) showed relatively poor results for zwitterionic compounds like tetracyclines and some acidic acids. Therefore these column materials can be considered less suitable for multi-antibiotic applications. Overall, the best results were obtained using the Kinetex C_{18} column, however clear limitation in the injection volume in relation to the percentage of organic modifier in the injected solvent were observed. Finally the Kinetex C_{18} column was selected with an injection volume of 10 μL and a maximum of 40% MeOH in the injected solvent.

As the number of SRM transitions is relatively large an insufficient number of scans over a peak is obtained when monitoring all SRMs during the whole run time. Therefore scheduled SRM was used applying ± 20 s intervals around the programmed retention times, which resulted in > 10 scans per peak. A representative chromatogram of a faeces sample spiked at target level is presented in Fig. 2. For clarity extracted ion chromatograms of the individual ion transitions are presented in Supplementary data (S1).

3.3. Internal standard selection

Because for some antibiotics included no isotopically labelled internal standards are available, a study was carried out to determine the most suitable internal standards for each antibiotic compound. Peak areas obtained from the first validation run were subjected to a statistical correlation analysis. For each antibiotic the internal standard that showed the highest correlation with it was selected as the most suitable. In most cases the combination of an antibiotic compound with a structurally related internal standard proved to be optimal. In some cases however, an internal standard belonging to a different compound group was selected, usually based on it having a similar retention time. Internal standards selected for each compound are presented in the experimental section.

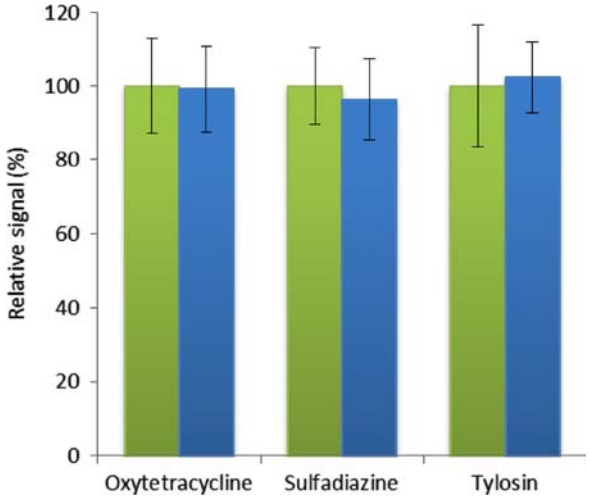

Fig. 1. Comparison of extraction by (green, left bar) shaking and (blue, right bar) ultrasonification for three incurred samples containing either oxytetracycline, sulfadiazine or tylosin ($n=4$). Vertical bars indicate the least significant difference. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

3.4. Matrix effects

The aim of the method was to include tetracyclines, quinolones, macrolides, sulfonamides and penicillins. However, during the method optimisation and validation it was observed that some penicillins were not recovered in specific faeces samples. As a result the between matrix variation was extremely large. It is suggested that these effects are not the result of low recovery of the extraction or clean-up procedure applied, but that these penicillins degrade in the faeces matrix, having a high bacterial activity, directly after spiking. This is supported by the fact that these effects were primarily observed for amoxicillin, ampicillin, penicillin G and penicillin V, the penicillins that are most sensitive towards β-lactam ring structure hydrolysis. To test this hypothesis,

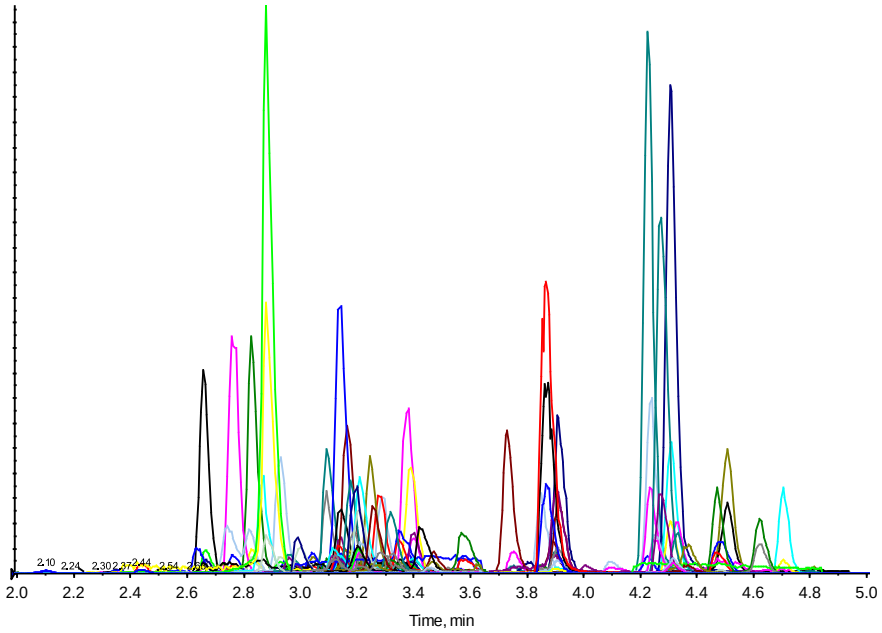

Fig. 2. Representative extracted ion chromatograms of a blank swine faeces sample spiked at target level with the antibiotics.

we applied a previously published method [38] for the analysis of, among others, penicillins in muscle to swine faeces. This method encompasses a forced hydrolysis, to include degradation products of the β-lactams. This method showed satisfactory results for all penicillins, supporting the hypothesis that penicillins are unstable in the faeces matrix. Similar effects were observed for chlortetracycline, which is a naturally occurring antimicrobial compound and also has a short half-life in faeces [39]. The quick degradation of chlortetracycline in faeces has been reported previously [21,40] and might be explained by the presence of resistant bacteria in some faeces samples. These effects were in our laboratory previously observed in soil samples. As a result, the penicillins and chlortetracycline were not included in the validation study.

3.5. Validation

3.5.1. An overview of the validation results is presented in Table 3

For all compounds the trueness is between 87% and 110% and thus complies with the adopted performance criteria. The RSD_r complied with the criteria for all compounds except for tylosin. The results for RSD_{r*} and RSD_{RL} complied with the criteria for most substances. The following compounds did not comply with the adopted criteria for RSD_{r*} and/or RSD_{RL} at or above target level: danofloxacin, josamycin, natamycin, pirlimycin, tulathromycin, tylosin, tylvalosin and valnemulin. Because the precision within a single batch of faeces is acceptable (low RSD_r), clearly the matrix is the main factor influencing the final quantitative result. Thus, if a sample is found to be a suspected positive for these compounds, exact quantification can be carried out using multiple level standard addition. For these antibiotics the target level of 20 $\mu g\ kg^{-1}$ proved to be quite challenging, as can be also be seen from the calculated values for CCα, which directly results in a relatively high variation.

Also for oxytetracycline the target concentration proved to be challenging. This results in high standard deviations at the lower validation levels, but the quantitative performance of the method proved to comply with set criteria for quantitative analysis at concentrations at or above the target level.

For all other compounds the RSD_r is below 11.3%. Taking into account matrix variation, the RSD_{r*} is below 14.3% and the RSD_{RL} is below 21%. Based on these results it is concluded that the presented method is suitable for quantification of the antibiotics present in swine faeces at relevant levels. For danofloxacin, josamycin, natamycin, pirlimycin, tulathromycin, tylosin, tylvalosin and valnemulin and slightly higher measurement uncertainty should be taken into account when performing a quantitative analysis.

The calculated decision limits (CCα), indicating the limit of detection, vary from 0.5–65 to 65 $\mu g\ kg^{-1}$. Based on the samples spiked at the lowest level included in the validation, the calculated values of CCα are realistic and sufficiently low to detect relevant concentrations of antibiotics in swine faeces.

3.5.2. Selectivity

For each antibiotic compound, two product ions were selected and based on those the probability of an interfering signal (P(I)) was calculated [36]. In all cases the selected ion transitions, in combination with their chromatographic separation were considered sufficiently selective which was also apparent from the absence of interfering signals in the blank swine faeces samples.

3.5.3. Stability

Stability data on the antibiotic solutions were previously reported [37]. It was found that the sulfonamide and macrolide solutions are stable for at least 12 months and quinolone solutions at least 6 months at $< 4\ ^{\circ}C$. Storage of the tetracycline solutions is more critical: these should be kept $< -18\ ^{\circ}C$ for a maximum of 2 months.

The stability of swine faeces extracts showed that even if extracts are stored at $-18\ ^{\circ}C$ for 8 days, results similar to those of fresh extracts are obtained. It is concluded that faeces e extracts obtained with the described method are stable for at least 8 days when stored at $-18\ ^{\circ}C$.

3.6. Swine and calf faeces analysis

Twenty pig farms and 20 cattle farms in The Netherlands were randomly selected. Of each of these farms 17 animals were selected in the slaughter phase directly from the gut which indicates that withdrawal periods are taken into account. Because the presented method proved to be sufficient for the analysis of cattle faeces as well, all 680 samples were analysed using the presented method. The

results of the individual farms are presented in Tables 4 and 5 for swine and cattle respectively. Concentrations above the calibration line were calculated based on extrapolation and are therefore rough estimates. Also results for tylosin should be considered indications because the measurement uncertainty for tylosin is relatively high as discussed above.

A large number of antibiotics was detected in the faeces samples. In 55% of the swines, originating from 80% of the swine farms, antibiotics were detected. For the calves in 75% of the faeces samples, originating from 95% of the cattle farms, antibiotics were detected. Oxytetracycline, doxycycline and sulfadiazine were most frequently detected, followed by tetracycline, flumequine, lincomycin and tylosin. All antibiotics detected are registered for swine and/or calve production, but ciprofloxacin (also enrofloxacin detected in this sample but its identity was not confirmed) and flumequine are considered last resort antibiotics and should be used sparingly.

For some compounds detected, the concentrations indicate recent use. Possibly, withdrawal periods were not taken into account which could suggest illegal and/or off-label use of antibiotics. Another plausible option is a delayed excretion due to re-adsorption (from e.g. bones) but there is no scientific data available showing this could explain these high concentrations. Low concentrations could either point at recent use in combination with a high excretion rate, or administration of the antibiotic at an earlier time. Other possibilities are that these levels are the result of contamination at the farm or from re-adsorption or recirculation.

Furthermore, it is noteworthy that in many cases several antibiotics were detected in a single sample (34% of the faeces samples

Table 4
Overview of antibiotics found in swine faeces.

Stable #	Antibiotic detected	Number of positive animals	Concentration ($\mu g\ kg^{-1}$)		
			Lowest	Highest	Median

[a] Identity not confirmed according to 2002/657/EC [24] due to low signal of second ion transition.

contained two or more different antibiotics), up to three for swine and eight for cattle. It is unlikely that such a diversity of antibiotics was administrated to a single animal. A theoretical explanation could be that the mixtures present at high concentration (mainly observed for the tetracyclines) are the result of the administration of illegal, non-purified preparations. Low concentrations might be the result of contamination within the farm.

Finally it is important to notice that the concentrations of some antibiotics found can select for resistant bacteria [41], especially if the sum of the concentration of different antibiotics within a single sample is considered. Furthermore the effect the combination of antibiotic residues found in relation to the selection of resistant bacteria remains unknown and is a risk factor. Note that only the native antibiotic was searched for and that antimicrobially active metabolites might be present in the samples as well [6] (e.g. N4-acetylsulfonamides [42]), increasing the level of antimicrobial activity in the faeces samples even further. By using faeces as fertilizer in agricultural practices, antibiotic residues as well as resistant bacteria are unintendedly disseminated throughout the environment [43], which is a serious risk for human health.

4. Conclusions

A comprehensive analysis method for the analysis of 44 antibiotics belonging to the tetracyclines, quinolones, macrolides and sulfonamides was successfully developed and fully validated for swine faeces according to 2002/657/EC [32]. The validation showed good trueness, repeatability and within-lab reproducibility for all compounds except for some macrolides and is considered adequate for the detection of antibiotics in animal faeces at relevant levels. The method was applied to the analysis of antibiotics in an extensive monitoring study of swine and cattle faeces and the outcomes were striking. The incidence of antibiotics in the faeces samples was high: in 55% of the swine faeces and 75% of the calve faeces samples at least one antibiotic compound was detected. Also mixtures of antibiotics were found (up to eight in a single animal) and in some cases the concentrations were severe (some exceeding 1 mg kg^{-1}). These results suggest that antibiotics are used off-label and that carry-over of antibiotics on the farm could be of importance. The analysis of faeces is a simple and non-invasive strategy to successfully monitor for antibiotic use in animal breeding and to obtain knowledge on the dissemination of antibiotic residues and resistant bacteria throughout the environment.

ABSTRACT

Proficiency testing (PT) for the determination of pesticide residues in soybean samples was organized by the National Metrology Institute of Japan (NMIJ). The candidate certified reference material, NMIJ CRM 7509-a, that was prepared from the raw soybeans containing target pesticides (diazinon, fenitrothion, chlorpyrifos, and permethrin) was used as the test sample. Forty participants submitted two sets of analytical results along with the details of the analytical method and conditions they applied. Two types of assigned values were established for each target pesticide: one was derived from the analytical results of the participants, and the other was provided from the analytical results by isotope-dilution mass spectrometry (IDMS). The latter values were 7.4–16% higher than the former values, plausibly because the analytical values from the IDMS measurements were not affected by the recovery ratio of the target pesticides during the analytical process. Thus, two kinds of *z*-scores were calculated for individual participants using the corresponding assigned values: one (z_1-score) showed the relative performance score for the present PT and the other (z_2-score) could be used for evaluation of the trueness of their analytical methods.

1. Introduction

Various pesticides are used worldwide to protect foods against pests and diseases [1]. However, high levels of residual pesticides in foods may result in adverse effects on human health. In Japan, the Positive List System for Agricultural Chemicals Remaining in Foods was introduced in 2006 to prohibit the distribution of foods that contain agricultural chemicals above a certain level, even if the maximum residue limits (MRLs) have not been established [2]. Under this system, analysis of a wide variety of residual pesticides in foods that are under quarantine or in the market is routinely performed.

Analytical protocols for determining the presence of pesticide residues in food samples usually involve complex extraction of the target pesticides, multi-step clean-up of the obtained extracts, and sensitive and selective quantification via a chromatographic technique [3–5]. Ensuring the reliability of the results is crucial to control the risk associated with pesticide residues. Proficiency testing (PT) is one of the key elements in the implementation of an appropriate quality assurance program and performance monitoring procedure for chemical analysis laboratories [6,7]. Consequently, a number of PT programs for the determination of pesticide residues in food samples have already been organized [8–15].

The National Metrology Institute of Japan (NMIJ) has recently undertaken the development of crop certified reference materials (CRMs) for the validation/verification and quality assurance of pesticide residue analysis. The candidate materials used for development of the CRMs were prepared from raw crops containing the target pesticides. Characterization of the target pesticides was carried out by isotope-dilution mass spectrometry (IDMS), which has the potential to be a primary method of measurement [16–19]. To date, we have issued five kinds of CRMs in this field [20–23].

Another recent undertaking of the NMIJ is the organization of PTs for inorganic-constituent analysis of food samples to support skill upgrading of food analysis laboratories [24,25]. In 2012, the NMIJ initiated another PT program for pesticide-residue analysis of food samples. The first round PT was carried out using the candidate soybean powder material, NMIJ CRM 7509-a [23], as a test sample. In this PT, two kinds of assigned values were

established: one was derived from the analytical results of the participants, and the other was provided from the analytical result used in the certification of CRM 7509-a. In this article, the process and the results of the PT are reported and the difference between the two assigned values is discussed.

2. Experimental

2.1. Test samples

An outline of the preparation of the test samples is presented as follows: the raw soybeans (*Glycine max*, cv. Enrei) were cultivated so as to contain *O*,*O*-diethyl-*O*-2-isopropyl-6-methyl-pyrimidin-4-yl phosphorothioate (diazinon), *O*,*O*-dimethyl-*O*-4-nitro-*m*-tolyl phosphorothioate (fenitrothion), *O*,*O*-diethyl-*O*-3,5,6-trichloro-2-pyridyl phosphorothioate (chlorpyrifos), and 3-phenoxybenzyl (1*RS*, 3*RS*, 1*RS*, 3*RS*)-3-(2, 2-dichlorovinyl)-2, 2-dimethylcyclopropanecarboxylate (permethrin). The soybeans were air-dried, freeze pulverized, mixed, bottled into amber glass bottles (10 g each), sterilized by γ-irradiation (15 kGy), and then the prepared samples were stored at ca. −80 °C until use. The homogeneity of the prepared samples was evaluated by the Japan Food Research Laboratories (Tokyo, Japan) by quantifying the target pesticides. The relative standard uncertainties related to the inhomogeneity were evaluated according to ISO Guide 35 [26] with values of 1.89% for diazinon, 4.00% for fenitrothion, 3.10% for chlorpyrifos, and 3.16% for permethrin. The details of the preparation and the homogeneity evaluation of the test samples have been described elsewhere [23].

2.2. Determination of pesticides in the test samples by NMIJ

The analytical results used in the certification of NMIJ CRM 7509-a were utilized in the present PT. These results were obtained by three analytical methods (Method 1, Method 2, and Method 3) conducted at NMIJ, the flow diagrams and the corresponding target pesticides of which are shown in Fig. 1. These methods consisted of extraction and clean-up processes that were based on the Analytical Methods for Residual Compositional Substances of Agricultural Chemicals, Feed Additives, and Veterinary Drugs in Food [3] and IDMS quantification by GC/MS measurements. Specifically, the initial analytical results (0 month) of the long-term stability assessment that were obtained by Method 1, and the analytical results of the characterization that were obtained by Method 2 or Method 3 were used to obtain the assigned values 2 (described in Section 2.4.). These analyses were performed in Nov. 2011, which was about four months prior to distribution of the samples to the participants. Additionally, the analytical results of the short-term stability monitoring that were obtained by Method 1 were used to evaluate the stability of the PT samples. These analyses were performed two weeks before distribution of the sample (April 2012) and three weeks after the deadline for submission of the participant results (August 2012).

2.3. Analysis by the participants

This PT round was announced to food manufacturers, agricultural producers, testing laboratories, public research institutes, etc., in Japan and was subscribed by 43 participants. On May 8, 2012, the test samples (2 bottles) and working instructions were sent to each participant by a delivery company using a refrigerated transport. The participants were asked to store the samples at −30 to −20 °C in the dark, and then to perform duplicate analysis of the target pesticides (the target pesticides to be determined were selectable by each participant). The participants were also asked to report the details of the analytical method and quantification conditions (such as the purity or concentration of primary calibrants, linear range of the calibration curves, the extraction and clean-up procedure, and the quantification method and its conditions) as well as the analytical results with observed chromatograms using a prescribed sheet in Excel format. The deadline was set to July 31, 2012.

2.4. Establishment of assigned values

For each target pesticide, two kinds of assigned values were established. The assigned value 1 (X_m) was obtained from the analytical results of the participants as follows: the outliers of the results were excluded by Cochran's test and Grubbs' test, and the median of the included results was then calculated. The normalized interquartile range (*NIQR*) was also calculated by multiplying the interquartile range (the difference of quartile 3 and quartile 1) of the included analytical results by 0.743. The assigned value 2 (X_{NMIJ}) was the weighted mean of the NMIJ analytical results obtained by the corresponding analytical methods (Method 1 and either Method 2 or Method 3). Simultaneously, the predicted reproducibility standard deviation ($PRSD_R$), which is the expected inter-laboratory precision for each target pesticide, was calculated using the modified Horwitz equation [27].

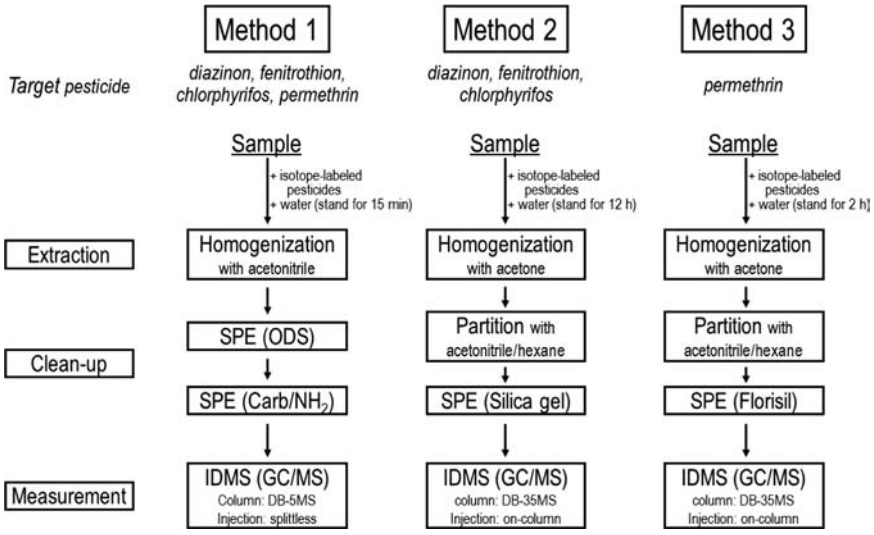

Fig. 1. Flow diagrams of the analytical methods for respective target pesticides used by NMIJ.

2.5. Calculation of z-scores

The performance of each participant was evaluated via the z-score approach in accordance with the ISO/IEC 17043 [28], ISO 13528 [29], and the International Harmonized Protocol for the Proficiency Testing of Analytical Chemistry Laboratories [7] methods. Because two kinds of assigned values were established in this PT, the corresponding z-scores (z_1 and z_2) were calculated using the following equations:

$$z_1 = \frac{x_i - X_m}{NIQR} \quad (1)$$

$$z_2 = \frac{x_i - X_{NMIJ}}{PRSD_R} \quad (2)$$

where x_i represents the analytical result for the target pesticide of the individual participants.

3. Results and discussion

3.1. Stability assessment of the test samples

The target pesticides of the test samples were assayed on three occasions (in November 2011, April 2012, and August 2012) by the NMIJ using Method 1. A one-way analysis of variance (ANOVA) test ($p < 0.05$) indicated that for each target pesticide, the difference in these three data points were not significant. These results suggested that the concentrations of the target pesticides in the PT samples stored at NMIJ remained unchanged during the period from the measurements to obtain assigned value 2 to the deadline for submission of the analytical results by the participants. Furthermore, the pesticide concentrations should remain constant if the participants stored the samples under the instructed conditions (at −30 to −20 °C in the dark). The relative standard deviation of the concentration for permethrin during the stated period was 6.87%, whereas the standard deviation for the other target pesticides was calculated to be below 0.

3.2. Analytical methods and results of the participants

Analytical results were submitted by 40 participants. Answers to the questionnaire on the analytical method and quantification conditions (matrix-matching of the calibration solutions, collection of the observed analytical values with the recovery ratio) that the participants applied are summarized in Fig. 2. More than half of the participants utilized the Multiresidue Method for Agricultural Chemicals by GC/MS (Agricultural Products) (hereafter referred to as “Multiresidue Method”) as the extraction and clean-up method; this is an analytical method established by the Analytical Methods for Residual Compositional Substances of

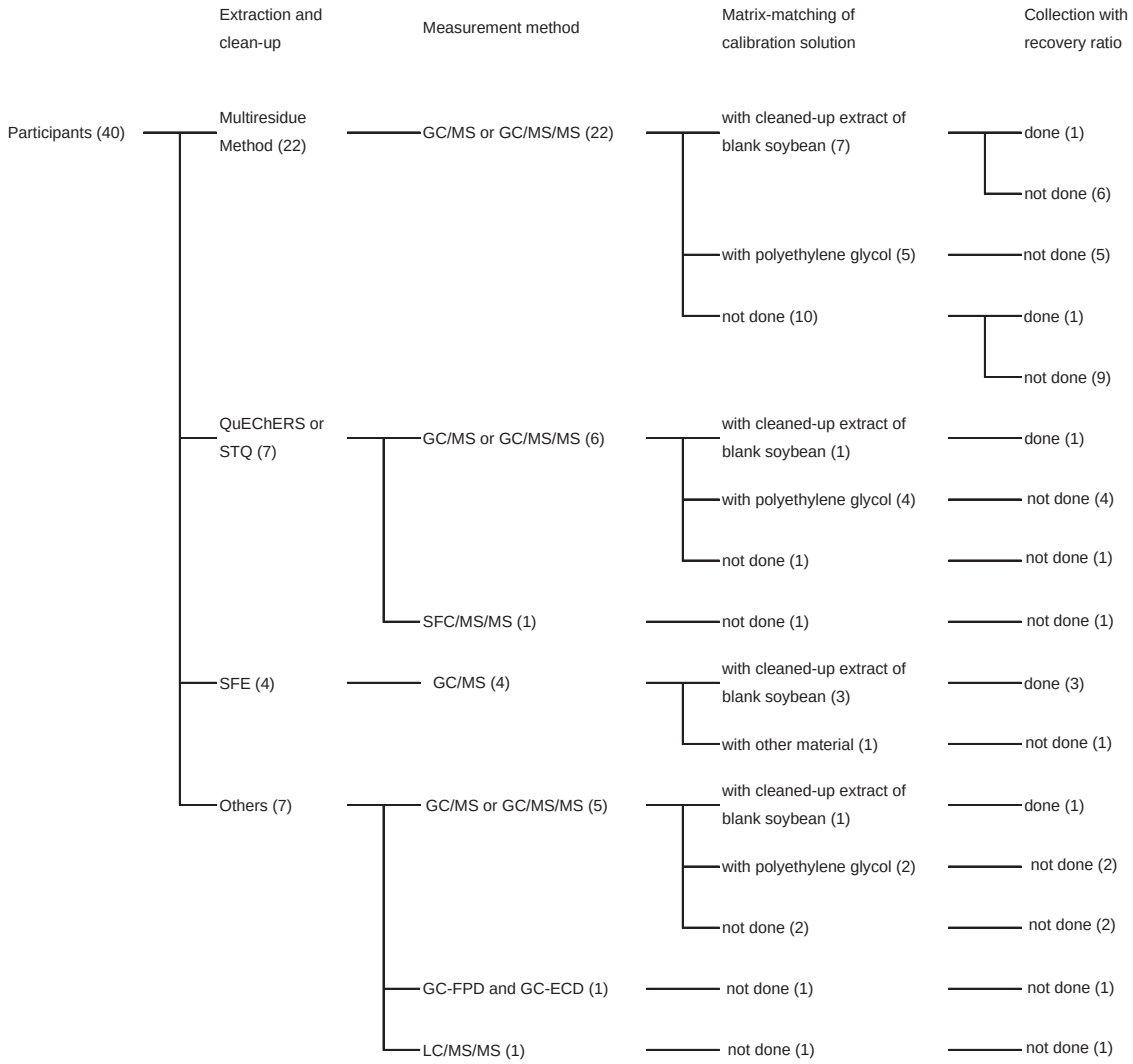

Fig. 2. Summary of the analytical methods and quantification conditions used by the participants. Numbers in parentheses indicate the frequencies of the participants.

Agricultural Chemicals, Feed Additives, and Veterinary Drugs in Food [3]. This method was verified by the Ministry of Health, Labour, and Welfare, Japan, and is intended for use in the Positive List System for Agricultural Chemical Residues in Foods [2]. The procedure is almost the same as that of Method 1, in which the target pesticides are extracted with acetonitrile followed by clean-up using SPE (see Fig. 1). In a spike and recovery test, as a criterion, the recovery ratio of each target pesticide should be in the range 70–120% [30]. If this criterion is met, the observed analytical results from the "Multiresidue Method" can be used without collection of the data based on the corresponding recovery ratio. Therefore, most participants who used this method in the present PT did not collect their analytical values. On the other hand, seven participants applied either the QuEChERS method [5,31] or the STQ [32] method; in both methods, acetonitrile was used as the extraction medium. The latter method consisted of extraction of the target pesticides by the QuEChERS method and clean-up of the extracts using small-size SPE cartridges. Supercritical fluid extraction (SFE), which can shorten the analytical time in comparison with the classical solvent extraction [5,33], was used by four participants. In all cases, carbon dioxide was used as the extraction medium without any modifier. Three participants cleaned up the extracts using SPE cartridges. Moreover, three participants collected the observed analytical values with the recovery ratios of the target pesticides, given that the trapping efficiency of some target pesticides by the collection solvent, which was placed at the end of the system, was not close to 100%.

The results of analysis of the concentration of fenitrothion were submitted by all the participants, whereas those for diazinon and

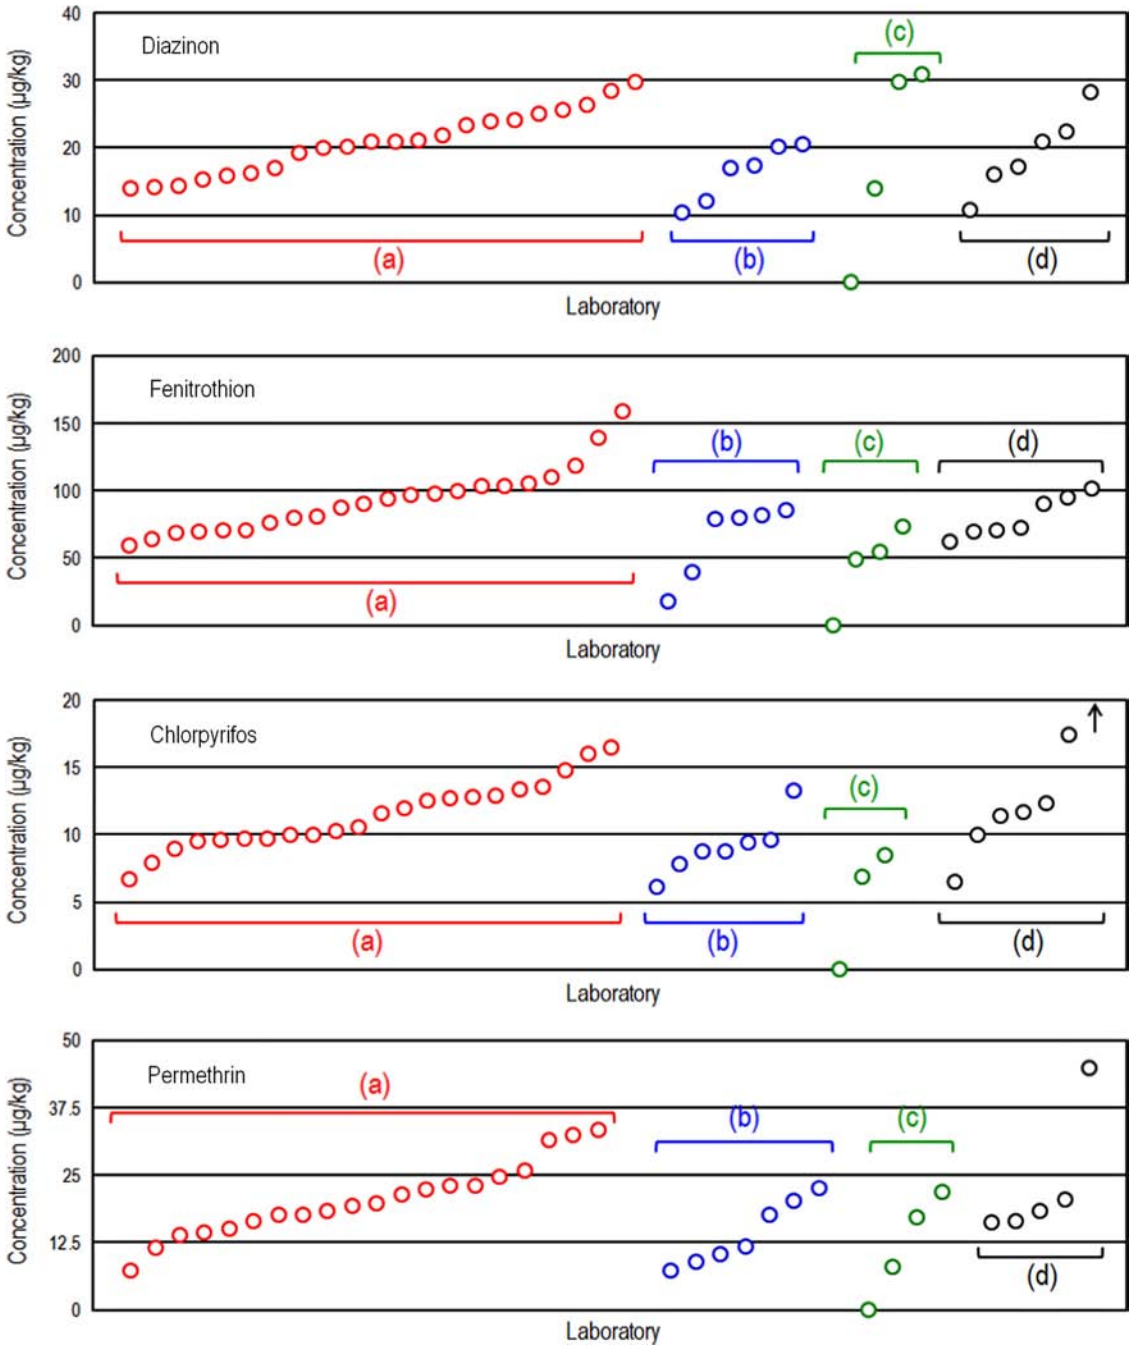

Fig. 3. Effect of the extraction and clean-up method on the analytical results of the participants. (a) Multiresidue Method for Agricultural Chemicals by GC/MS (Agricultural Products), (b) QuEChERS method or STQ method, (c) SFE method, and (d) other methods.

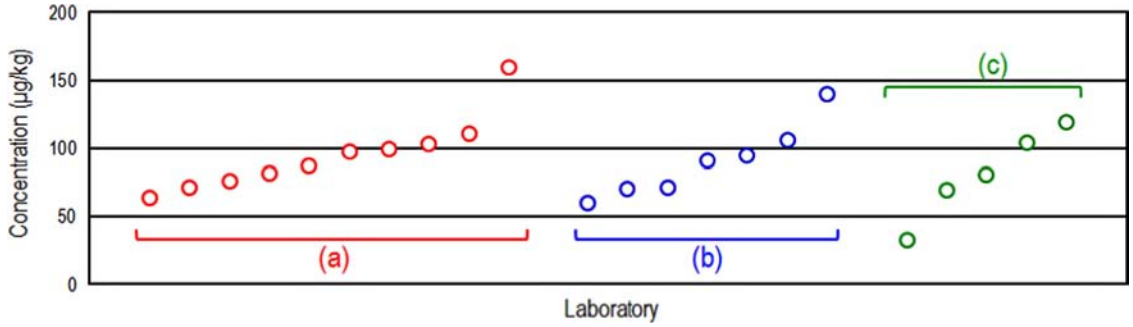

Fig. 4. Effect of matrix-matching of the calibration solution on the analytical results of the participants for assay of fenitrothion. The results obtained by the Multiresidue Method for Agricultural Chemicals by GC/MS (Agricultural Products) are indicated. (a) Without matrix-matching, (b) with matrix-mating using cleaned-up extract of blank soybean, and (c) with matrix-matching using polyethylene glycol.

Table 1
Assigned value 1 and other fundamental statistics.

Pesticide	Quartile 1	Assigned value 1 (median)	Quartile 3	*NIQR*
Diazinon	16.0	20.3	24.1	6.0
Fenitrothion	69.5	80.7	98.3	21.3
Chlorpyrifos	8.9	10.0	12.9	2.9
Permethrin	14.5	18.1	22.5	6.0

The unit of the values is μg/kg.

chlorpyrifos were submitted by 39 participants, and that for permethrin was submitted by 37 participants. Fig. S1 shows histograms of the analytical results. For each target pesticide, an unimodal distribution was obtained for the relationship between the analytical concentration and the number of participants (frequency). A Kolmogorov–Smirnov test ($p > 0.05$) was performed to evaluate the distribution of the analytical results, in which the normality of the distribution was supported for all target pesticides.

The analytical results were plotted based on the method employed, as shown in Fig. 3. One participant that applied SFE obtained results below 0.05 μg/kg for all of the target pesticides, probably due to an error in the conversion of the units. Fig. 3 indicates that even with the use of the same analytical method, there was considerable variation of the observed analytical values among the laboratories. Thus, the effect of the analytical method on the results was not significant. Similar consideration was given to the effect of the matrix-matching of the calibration solution on the analytical values. It is well known that the response of analyte of the sample solution (which was prepared from a real food sample herein) in GC/MS measurement is sometimes higher than that of the calibration solution [34–36]. To avoid this effect, 12 participants used calibration solutions that were matrix-matched using the cleaned-up extract of the blank soybean, and the other 11 participants employed calibration solutions containing polyethylene glycol. As an example, the analytical results of fenitrothion obtained by the Multiresidue Method were plotted based on the type of calibration solution, as shown in Fig. 4. The effect of matrix-matching of the calibration solution on the observed values was much less significant than the variation of the values among laboratories. Note that both the target pesticides and matrix used in the present PT were quite limited, further investigation is required for a more general evaluation of these effects.

3.3. Evaluation of the participants' performance using assigned value 1

3.3.1. Assigned value 1

The median of the analytical results of the participants was used as the X_m value given that this approach is considered robust and has been widely adopted by Japanese PT providers [37]. Initially, the analytical result from the participant that had made an error in the conversion of the units was rejected as an outlier. Subsequently, Cochran's test and Grubbs' test were carried out, in which one result was rejected for diazinon and chlorpyrifos, and three results were rejected for permethrin in the latter test. Using the remaining results, the fundamental statistics (including the X_m and *NIQR* values) were obtained, as shown in Table 1. When compared with the MRLs [38], the X_m values were 20% for diazinon, 40% for fenitrothion, 3.3% for chlorpyrifos, and 36% for permethrin, expressed as relative concentrations. These concentrations were deemed suitable for evaluation of the performance of the individual participants.

3.3.2. Assessment using z_1-scores

For each participant, the z_1-scores for the respective target pesticides were calculated using Eq. (1). The distribution of the participants' z_1-scores is shown in Fig. 5. Based on the ISO/IEC 17043 protocol, the participants' performance was ranked into the following classes:

(1) $|z_1| \leq 2.0$, "satisfactory" performance,
(2) $2.0 < |z_1| < 3.0$, "questionable" performance, and
(3) $3.0 \leq |z_1|$, "unsatisfactory" performance.

The number of participants in the individual classes is summarized in Table 2. If the participants' $|z_1|$ values follow the normal distribution, the ratio of the participants having $|z_1|$ values ranking in the second or third classes should comprise almost 5% of the entire participants. The observed ratios in the present PT were 5% for diazinon, 13% for fenitrothion, 13% for chlorpyrifos, and 16% for permethrin, where the ratio was slightly higher for target pesticides other than diazinon.

3.4. Evaluation of the participants' performance using assigned value 2

3.4.1. Assigned value 2

For each target pesticide, the weighted mean of the analytical results obtained by Method 1 and either Method 2 or Method 3 was calculated, and the result was used as the X_{NMIJ} value. The analytical methods used here were based on IDMS, and independent extraction and clean-up procedures were applied to avoid any possible analytical bias. The uncertainty corresponding to the Assigned value 2 was then estimated according to the ISO Guide 35 by combining the standard uncertainty of the analytical results and those corresponding to the inhomogeneity and instability of the PT samples. The details of these processes are described in the Supplementary material, and the results are summarized in

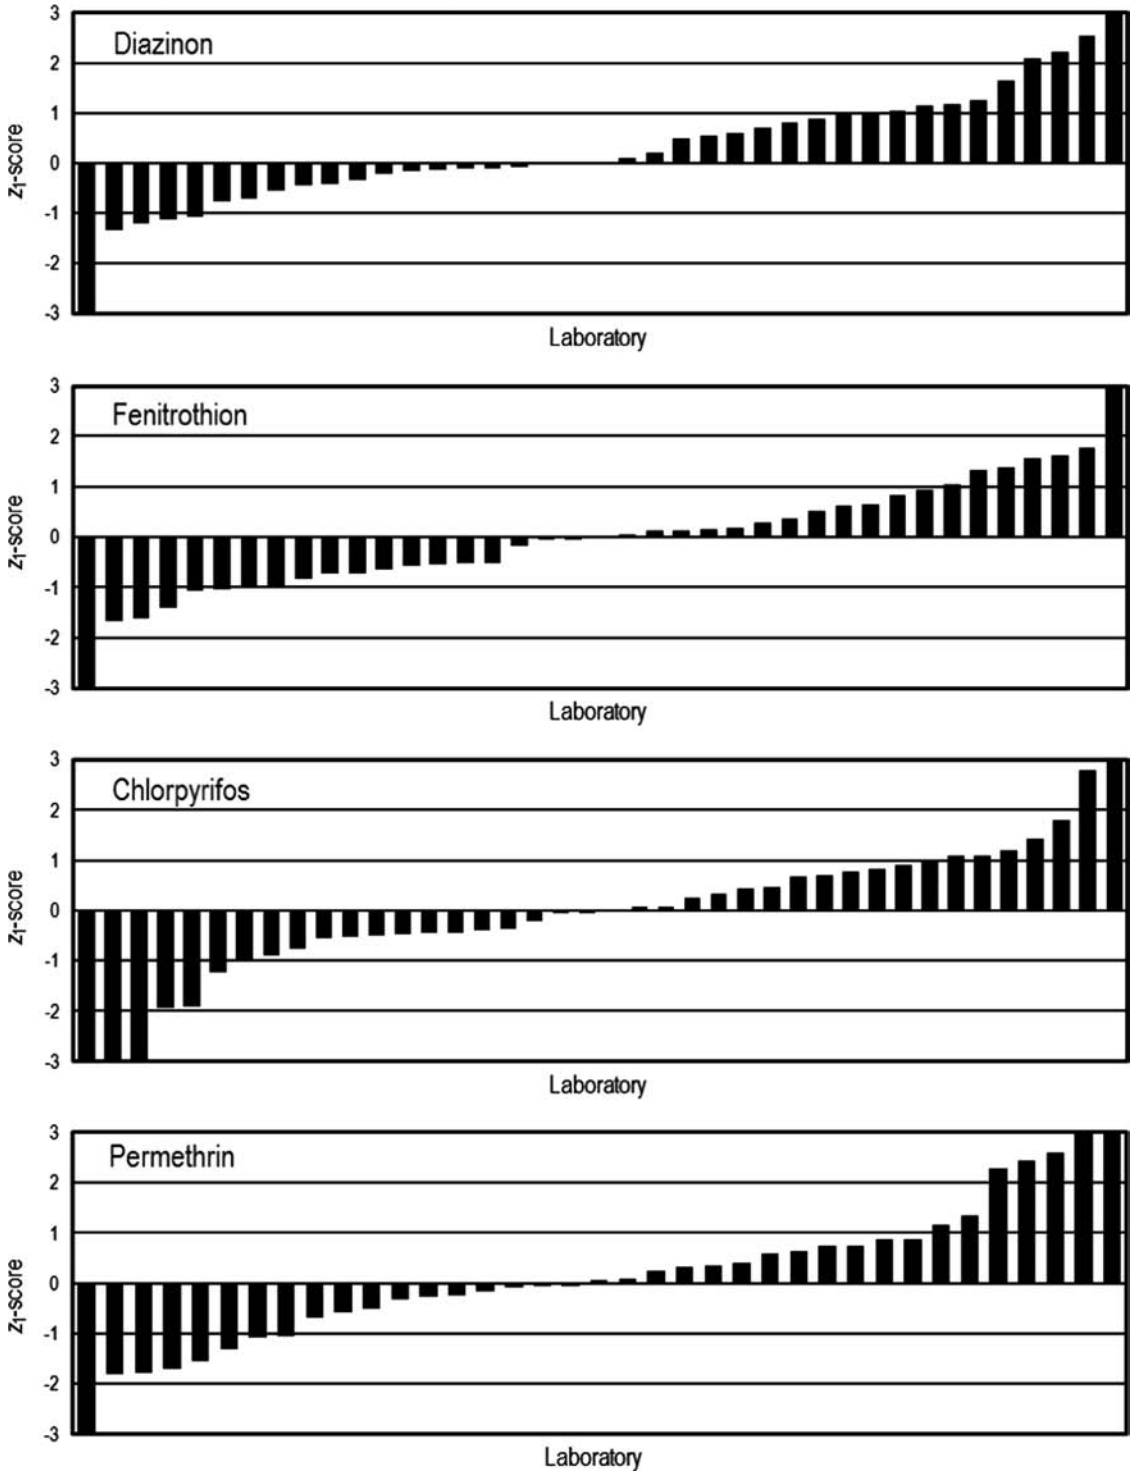

Fig. 5. Distribution of the participants' z_1-scores.

Table 2
Classification of the participants' z_1- and z_2-scores.

Pesticide	Number of participants	$\|z_1\| \leq 2.0$	$2.0 < \|z_1\| < 3.0$	$3.0 \leq \|z_1\|$	$\|z_2\| \leq 2.0$	$2.0 < \|z_2\| < 3.0$	$3.0 \leq \|z_2\|$
Diazinon	39	37	0	2	34	3	2
Fenitrothion	40	35	3	2	33	3	4
Chlorpyrifos	39	34	3	2	35	2	2
Permethrin	37	31	3	3	26	7	4

Table 3
Assigned value 2 with corresponding combined standard uncertainty and $PRSD_R$.

Pesticide	Assigned value 2	Combined standard uncertainty of assigned value 2	$PRSD_R$
Diazinon	21.8	0.6	4.8
Fenitrothion	87.9	5.6	19.3
Chlorpyrifos	11.6	0.6	2.5
Permethrin	19.9	1.9	4.4

The unit of the values is μg/kg.

Table 3. The strategy to obtain the Assigned value 2 and the corresponding uncertainty is the same as that used to certify the NMIJ CRMs [39], and the obtained X_{NMIJ} values seemed highly reliable and traceable to SI units.

3.4.2. Assessment using z_2-scores

If the participants submitted the analytical results with the corresponding uncertainties, their performance could be assessed using Assigned value 2 via the E_n-number approach [28]. However, at present, it is not easy for most food-analysis laboratories in Japan to estimate the uncertainties of their analytical results. In the present PT, therefore, participants were asked only to submit two sets of the analytical results without uncertainties. Thus, the performance of the participants using Assigned value 2 was also assessed by the z-score approach. For this purpose, the $PRSD_R$ value was calculated for each target pesticide using the modified Horwitz equation. Table 3 shows the results, where the relative

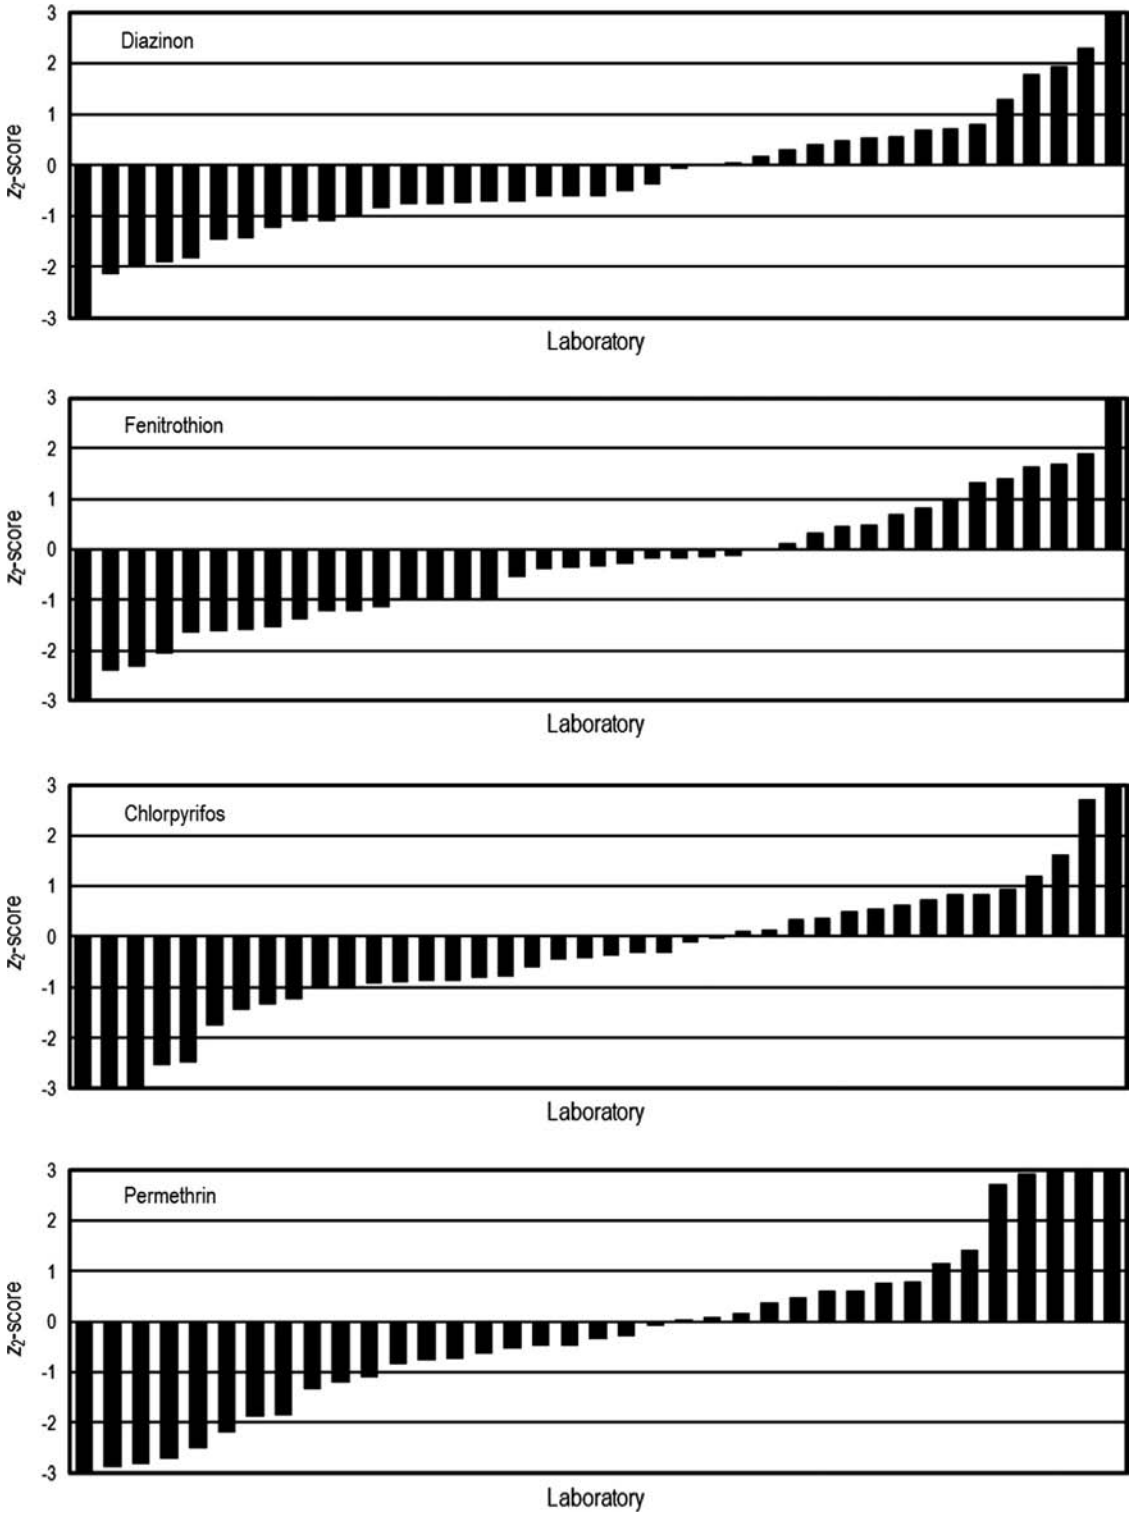

Fig. 6. Distribution of the participants' z_2-scores.

percentage of the respective $PRSD_R$ values was 22% in relation to the corresponding X_{NMIJ} values, and the $PRSD_R$ was much larger than the combined standard uncertainty of the Assigned value 2.

The z_2-scores for the individual target pesticides were then calculated for each participant using Eq. (2). Fig. 6 shows the distribution of the participants' z_2-scores. The performance of the participants was ranked into the following classes:

(1) $|z_2| \leq 2.0$, "satisfactory" performance,
(2) $2.0 < |z_2| < 3.0$, "questionable" performance, and
(3) $3.0 \leq |z_3|$, "unsatisfactory" performance.

The number of participants in the individual classes is also summarized in Table 2. The ratio of the participants having $|z_2|$ values ranking in the second or third classes was 13% for diazinon, 18% for fenitrothion, 10% for chlorpyrifos, and 30% for permethrin. Most participants quantified permethrin according to the following process: *cis*- and *trans*- isomers were individually quantified using corresponding calibrants and the observed concentrations were then summed. This might result in a higher ratio of permethrin in comparison with the other pesticides.

3.5. Comparison of two assigned values

Because assigned value 1 was obtained using the analytical results of the participants, this value possibly depended on the analytical method and quantification conditions used by the participants, the participants' skill, etc. Therefore, the analytical methods and quantification conditions of all participants were listed in the final report of the present PT. On the other hand, assigned value 2 was obtained by the analytical methods based on IDMS at NMIJ. The observed X_{NMIJ} values were 7.4–16% higher than the corresponding X_m values. As described above, most participants did not correct their observed analytical values with the recovery ratios of the target pesticides during the analytical process. At NMIJ, the recovery ratios of isotope-labeled pesticides spiked onto the samples were monitored. The recovery ratios were 79–91% in Method 1. In the IDMS measurement, the recovery ratios of the target pesticides did not affect the analytical values if equilibrium between the target and isotope-labeled pesticides was achieved. The differences between the two assigned values may be due to the difference in the impact of the recovery ratio during the two processes. In previous PTs for the determination of pesticide residues in food samples, the assigned values (concentration) obtained using the participants' analytical results were lower than the spiked concentrations employed for preparation of the test samples [15,40]: these results support our previous conclusion that the differences between the two assigned values may be due to the difference in the impact of the recovery ratio during the two processes.

Because assigned value 2 was higher than the corresponding assigned value 1, the z_2-score tended to be higher than the corresponding z_1-score (if the *NIQ*R and $PRSD_R$ values were not significantly different). This difference between the two scores might be confusing to the participants; therefore, the participants were advised that the z_1-scores showed the relative performance score for the present PT. They were also advised to use the z_2-scores in their evaluation of the trueness of their analytical methods.

4. Conclusion

A new PT program for pesticide-residue analysis of food samples was initiated, and the first round of the program was carried out using the candidate soybean material, NMIJ CRM 7509-a, as the test sample. Two kinds of assigned values were established using either the participants' analytical results or the NMIJ's IDMS analytical results, and the corresponding *z*-scores were calculated for individual participants. The participants could select the appropriate score according to the purpose of their assessment. The effects of the analytical method and quantification conditions on the participants' analytical results were also cursorily considered; further investigation is required to evaluate these effects more generally.

Acknowledgments

The authors thank KANSO Technos for preparing the test samples and Japan Food Research Laboratories for evaluating their homogeneity. Gratitude is extended to the Korea Research Institute and the National Institute of Metrology, China, for analysis of test samples to ensure the analytical results of the NMIJ. This work was partly supported by the Research and Development Projects for Application in Promoting New Policy of the Agriculture Forestry and Fisheries (No. 21044) of the Ministry of Agriculture, Forestry and Fisheries, Japan, and the Health and Labour Science Research Grant of the Ministry of Health, Labour, and Welfare, Japan.

ABSTRACT

The rapid, selective and sensitive measurement and monitoring of hazardous materials as analytes are the central themes in the development of any successful analytical technique. With this aim, we have synthesized the thiobarbituric-capped gold nanoparticles (TBA-capped Au NPs) involving chemical reduction of $HAuCl_4$ using 2-thiobarbituric acid (TBA) as a reducing and capping agent. The morphology of the TBA-capped Au NPs was confirmed using transmission electron microscope images. For the first time this article reports that the developed TAB-capped Au NPs displays selective, ultrafast and sensitive colorimetric detection of fluoride ion in aqueous samples. The detection of fluoride ion was confirmed by the disappearance of the localized surface plasmon resonance (LSPR) band at 554 nm using UV-vis spectroscopy. The interaction of F^- with TBA-capped Au NPs in aqueous solution has also been confirmed by Raman and FTIR spectroscopy. One of the most exciting accomplishments is the visual detection limit for fluoride ion has been found to be 10 mM at commonly acceptable water pH range 7–8. The whole detection procedure takes not more than 40 s with excellent selectivity providing sample throughput of more than 60 per hour.

1. Introduction

Metal nanoparticles such as gold nanoparticles (Au NPs) have attracted much attention with wide applications in highly sensitive chemical sensors due to their optical and electrical properties [1,2]. These properties of Au NPs are precisely determined by their dimension [2], shape [3], composition of materials [4,5], surrounding media [6] and relative distance between the particles [7–9]. Therefore, NPs show the intense plasmon resonance band in the visible region [10,11] which is exquisitely sensitive to their aggregation states [12,13].

Fluoride is commonly added to drinking water and toothpaste because of their beneficial effects on dental health. The deficiency of fluoride causes poor dental health and osteoporosis [14,15], while over exposure to fluoride ion causes fluorosis and urolithiasis [16–19]. Even small excess amount of fluoride consumed from tap water can damage bones, teeth, brain, disrupt thyroid function, lower intelligence quotient and/or cause cancer [14–19]. Thus, the Environmental Protection Agency (EPA) has set a maximum level of fluoride ion in water as 1 ppm and that over 2 ppm is considered a health risk [20]. Therefore, the accuracy in detection and determination of fluoride ion in aqueous samples is an extremely important aspect in the public interest. Recently, the colorimetric sensors or nanoprobes have been widely used for selective and sensitive detection for several analytes including alkali metal ions [21,22], heavy metal ions [23,24], oxo anions [25–27], fluoride ion [24,28–37], iodide ion [38], DNA and biomolecules [39–42], hydrogen peroxide [43], organophosphates [44], etc. However, there is still need to develop methods for sensing of fluoride ion due to its various applications.

Fluoride has unique properties compared to other elements as a result of its relative by small size and highest electronegativity. Thus, a number of compounds that are able to bind fluoride ion with high affinity and selectivity have been reported, but only a few reports are available in the literature for fluoride ion probes that utilize the unique optical properties of Au NPs [30,35]. However, the sensitivity and selectivity of this probe were poor compared to the properties of the other probes based on fluorescence and colorimetric probes [35]. The disadvantage on nanoprobes development is that the limited Au NPs are acquirable. In most cases Au NPs have been synthesized by citrate, which dispersed in an aqueous solution through the ionic repulsion of the surface-adsorbed ions. In the presence of electrolytes, due to the charge shielding, the ionic stabilized NPs undergo uncontrolled aggregation. The stabilized Au NPs are protected with non-ionic hydrophilic molecules, but the

0039-9140/© 2014 Elsevier B.V. All rights reserved.

thick protecting layers preventing the core metals to be close together, which are responsible for the change in color in the solution [45]. Therefore, it is essential to develop Au NPs protected with a monolayer of hydrophilic molecules.

Mostly sensors are fluorescent sensors containing quinoline [46], coumarin [47], anthracene [48], fluorescein fluorophores [49–55], pyrroles [56], quinoxalies [57–59] and azophenols [60,61]. Although, fluorescent sensors are widely used in biological studies, they usually require complicated synthesis involving various reaction condition and expensive chemicals. On the other hand, detection method used often required expensive equipment. Thus, it is of great interest to develop new chemical sensors which use easily synthesized chemicals and possesses good selectively and high sensitivity. Fluoride ion sensors are in great demand due to the involvement of fluoride in a variety of environmental issues and healthcare [36,62]. Therefore, a variety of fluoride sensors have been developed [24,28–37]. A selective and sensitive chemosensor that makes use of transition between Au NPs agglomeration states to develop a signal in the presence of fluoride ion is an attractive approach to fabricate fast usability fluoride ion probes [30,35]. With the aim to obtain more sensitive and selective chemosensors, an increasing number of papers have recently appeared, in which the chemosensor have been anchored to different supports [49]. In addition, the application of Au NPs as colorimetric sensors have usually been based on detecting the peak shifts in surface plasmon resonance (SPR) either due to the change in the dielectric constant around the NPs as a result of analyte molecule adsorption or to the analyte induced agglomeration of the NPs [13]. Both effects have provided the selectivity in detection by the functionalized capping agents, highlighting the importance of the synthesis by chemical reduction methods and their stabilization of NPs for use a solution based sensors [63].

In continuation of our interest on developing analytical methods for fluoride removal [15,16] and development of nanosensor for the detection of cations using Au nano-rods [17], and with continuous report on hazardous fluoride contamination in drinking water in rural habitations of Central Rajasthan, India [16], we continued our work towards the development of novel rapid, selective and sensitive method for visual detection and monitoring of hazardous fluoride ion. Thus, herein we introduce an easy, simple and quantitative preparation of the modified Au NPs with 2-thiobarbituric acid (TBA) where UV–vis absorption study has demonstrated that the fluoride selective aggregation is associated with dramatic color change in aqueous solution which leads to rapid, selective and sensitive method for visual detection and monitoring of hazardous fluoride ion. The different agglomeration states of Au NPs produce a different color in the solution. This study has also demonstrated that TBA is a potential candidate to devise the reliable ultrafast colorimetric sensor for the naked-eye visualization of fluoride ion detection at trace level.

2. Materials and methods

2.1. Chemicals

Tetrachloroauric acid and 2-thiobarbituric acid purchased from Sigma-Aldrich (USA) were used as received without any further purification. The regents for all anions (sodium fluoride, potassium

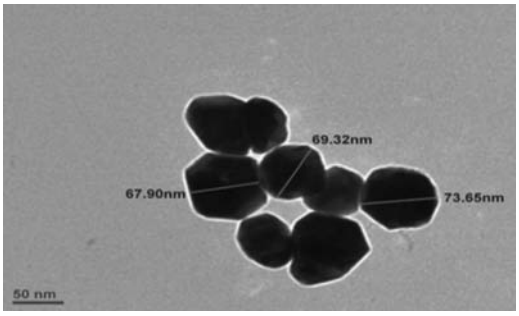

Fig. 2. TEM image of 2-thiobarbituric-capped gold nanoparticles.

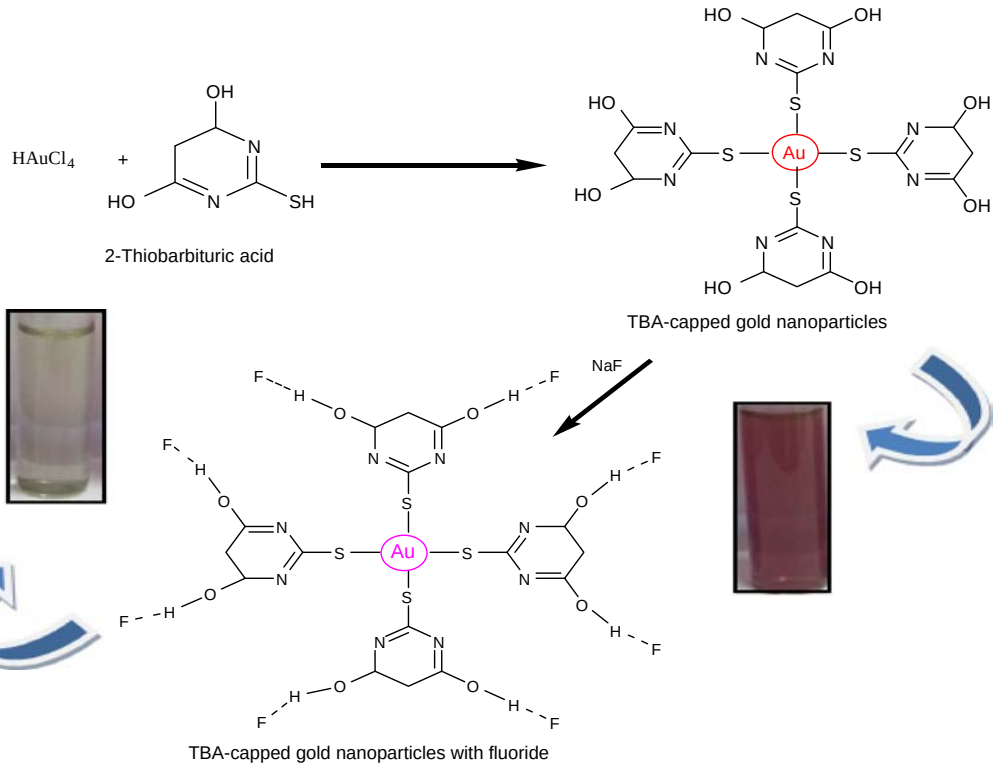

Fig. 1. A schematic representation for fabrication of 2-thiobarbituric capped gold nanoparticles and sensing of fluoride ions.

bromide, sodium chloride, potassium iodide, potassium carbonate, acetic acid, sodium nitrate, potassium dihydrogen phosphate) were purchased from E. Merck Ltd, Mumbai, India. All the solutions were freshly prepared for the synthesis of nanoparticles. Distilled water passed through a Millipore system (resistivity 18 MΩ. cm) was used in the preparation of all the solutions and throughout the experiments. All glassware used were first rinsed with aqua regia and then thoroughly washed with distilled water followed by Millipore water.

2.2. Synthesis of TBA-capped Au NPs

Thiobarbituric-capped Au NPs was synthesized by a wet chemical reduction method where TBA acts as reducing agent as well as capping agent [64]. In synthesis of TBA-capped Au NPs, the aqueous TBA solution (20 mL, 2–20 mM) was added to the boiling solution of $HAuCl_4$ (50 mL, 0.2 mM) under vigorous stirring in a round bottom flask equipped with a condenser. On addition of TBA to tetrachloroauric acid solution a transition in color of the reaction mixture was observed from red to colorless within 10 s. The reaction mixture was further boiled for 30 min under reflux and then cooled with stirring to room temperature i.e. 25 °C. The pH of the TBA-capped Au NPs solutions was adjusted to desired pH 5–8 with 0.1 M NaOH solution.

2.3. Characterization technique

Optical absorption measurements were performed using (Perkin-Elmer Lambda 750) UV–vis-NIR spectrophotometer. The particle size and morphology of the NPs were examined using transmission electron microscope (FEI Tecnai G20) operated at an accelerating voltage of 220 keV. All the samples for transmission electron

microscope (TEM) were deposited on carbon coated copper grid by placing the drops of diluted samples of TBA-capped Au NPs. Fourier transformation infrared (FTIR) spectrometer (Agilent Cary 660, USA) and Raman spectrometer (Deltanu Advantage 532) were used to obtain information of an element to element bonding or interaction.

3. Results and discussion

The absorption spectrum of Au NPs showed the maximum peak at 554 nm attributed to the localized surface plasmon resonance (LSPR) band. The thiol group is essential to synthesize well dispersed TBA-capped Au NPs. In the synthesis of TBA-capped AuNPs, the position of thiol group plays an important role in the reaction mixture. The analytical method developed herein is novel, rapid, very simple and highly selective which involves the use of sodium fluoride in the presence of TBA-capped Au NPs for the visual detection of hazardous fluoride ion.

3.1. TBA-capped Au NPs fluoride interaction

A schematic representation of synthesis of TBA-capped Au NPs and its interaction with fluoride ion is shown in Fig. 1. The typical LSPR absorbance band of TBA-capped Au NPs at 554 nm provided red color in the absence of fluoride ion and the solution was stable under the experimental conditions. When the fluoride was added to TBA-capped Au NPs solutions, the color dramatically changed from red to colorless and the absorption bands were red shifted i.e. at longer wave length within mixtures which indicated the aggregation of TBA-capped Au NPs [65]. The color transformation was completed within 40 s. On the other hand, other anions did not induce any color change at 10 mM concentration. The UV–vis spectra of the reaction mixture remained unchanged in the presence of fluoride ion over several hours. This observation concluded the formation of H–F hydrogen bonding in the reaction mixture of TBA-capped Au NPs and fluoride ion. It may be attributed to the high charge density and small size of fluoride ion which enabled the formation of hydrogen bonding by interaction with the hydroxyl groups of TBA moieties (Fig. 1). The color change occurred in the reaction was easily monitored by the naked eye.

3.2. Morphological study of TBA-capped Au NPs

The morphology of the TBA-capped Au NPs was studied using TEM images. Fig. 2 shows a typical TEM image of TBA-capped Au NPs. The shape of the gold nanoparticle was slightly irregular. The average particle size (68–74 nm) can be tuned over a size range of 1–20 nm by varying the concentration of TBA in the reaction mixture.

3.3. Visual color change studies

The sensing of halide anions such as F^-, Cl^-, Br^-, I^- and oxo anions such as CH_3COO^-, NO_3^-, CO_3^{2-}, $H_2PO_4^-$ was studied using UV–vis spectroscopy in aqueous solution. The effect of the addition of these anions to TBA-capped Au NPs solutions is shown in Fig. 3 as photographic images which clearly shows that the color changes only after the addition of F^- (10 mM) to the solution and causes a red shift in the LSPR band. It is remarkable to note that the color changes occurred only when F^- was added while of addition other anions such as CH_3COO^-, NO_3^-, CO_3^{2-}, $H_2PO_4^-$, Cl^-, Br^- and I^- failed to cause any significant change in color. This study confirmed that the addition of 10 mM of fluoride ion solution induces the appearance of color change in the reaction mixture.

3.4. FTIR study of TBA-capped Au NPs

Fourier transformation infrared spectroscopy (FTIR) was performed to find the fluoride binding with TBA-capped Au NPs in the samples and related infrared spectra are shown in Fig. 4(a, b and c). The FTIR spectrum for the Au NPs was compared with corresponding surfactant i.e. TBA and it was found that the S-H stretching frequency (2360 cm^{-1}) of bound surfactants disappeared (Fig. 4a and b). This suggests that the bonding of the thiobarbituric to the gold surface takes place through the S-H end. Further the S-H bond cleaved upon S-Au chemisorption is in good agreement with the study done by Hasan et al. on the fate of sulfur bound hydrogen during the formation of a thiol monolayer on gold [66]. The S-H absorption is typically weak and occurs at a lower wave number (frequency) than the corresponding O-H vibration because of the higher atomic mass of sulfur [67]. Due to a high atomic number of gold its vibrational feature is also expected to appear at lower wave number and appeared at 530 cm^{-1} (Fig. 4b) [68]. The appearance of a new weak band at 2365 cm^{-1} (Fig. 4c) was assigned to the H—F hydrogen bond formation in fluoride ion treated TBA-capped Au NPs solution [67]. It may be due to the weak interaction of fluoride ion with hydroxyl group of TBA as shown in Fig. 1. It was found that the band at 1640 cm^{-1} remained unchanged in all the cases which is consistent with the greater affinity of Au for S-H bond compared with C=N. This observation was consistent with earlier reports that the rigid chain conformation on the nanoparticle surface generates

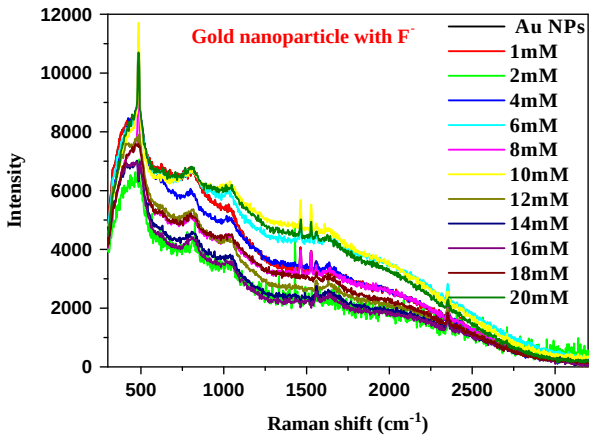

Fig. 5. Raman spectra of 2-thiobarbituric-capped gold nanoparticle with the addition of 1–20 mM of NaF.

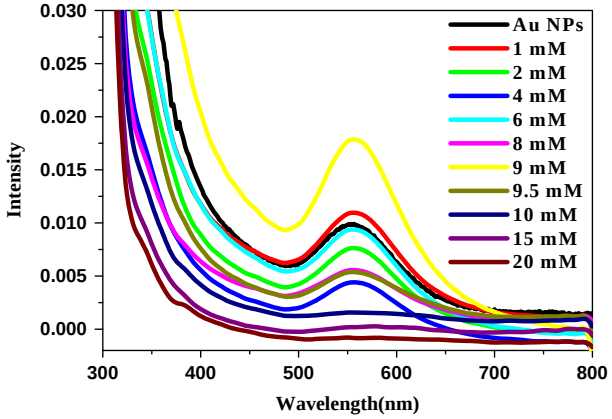

Fig. 6. UV–vis spectra of 2-thiobarbituric-capped gold nanoparticles solution having 10 mM concentration with the addition of different fluoride ion concentrations in the range 1–20 mM in the solution.

a crystalline-like state of chains and restricted their mobility [69]. The band at 3460 cm^{-1} appeared due to O-H stretching present in TBA moieties, which remained same in all the spectra [70].

3.5. Raman spectroscopy study of TBA-capped Au NPs

The Raman spectroscopy has frequently been used to detect vibrations in molecules based on the processes of infrared absorption and Raman scattering which provides information on chemical structure. Raman spectra of TBA-capped Au NPs in presence of different concentration of F^- (1–20 mm) are shown in Fig. 5 which are dominated by the bands around 1030 cm^{-1} and 1530 cm^{-1} attributed to C-S and C-C stretching vibrations respectively. The behavior of other peaks in Raman spectra is consistent with colloidal states [71]. The S-H stretching at 2580 cm^{-1} and S-H bending at 917 cm^{-1} in the Raman spectrum disappeared, indicating dissociative chemisorption of TBA onto Au by rupturing S-H bond [72]. The appearance of a sharp peak at 1470 cm^{-1} evidenced the formation of Au-S bond. These features generally appeared in Raman spectra of thiol [73].

3.6. Sensing assay of fluoride ion

To verify practicality, the proposed method was applied to detect the fluoride ion on the aggregation of Au NPs. 1 mL portion of different concentrations (1–20 mM) of fluoride ion were added individually to 2 mL of TBA-capped Au NPs solutions. The resulting mixtures were allowed to react for 1–5 min. The absorption changes between 550–700 nm were monitored. The extinction at a wavelength above 600 nm was similar to the collective plasmon resonance of closely spaced Au NPs which indicated the anion i.e. F^- induced aggregation of NPs. At certain threshold concentration

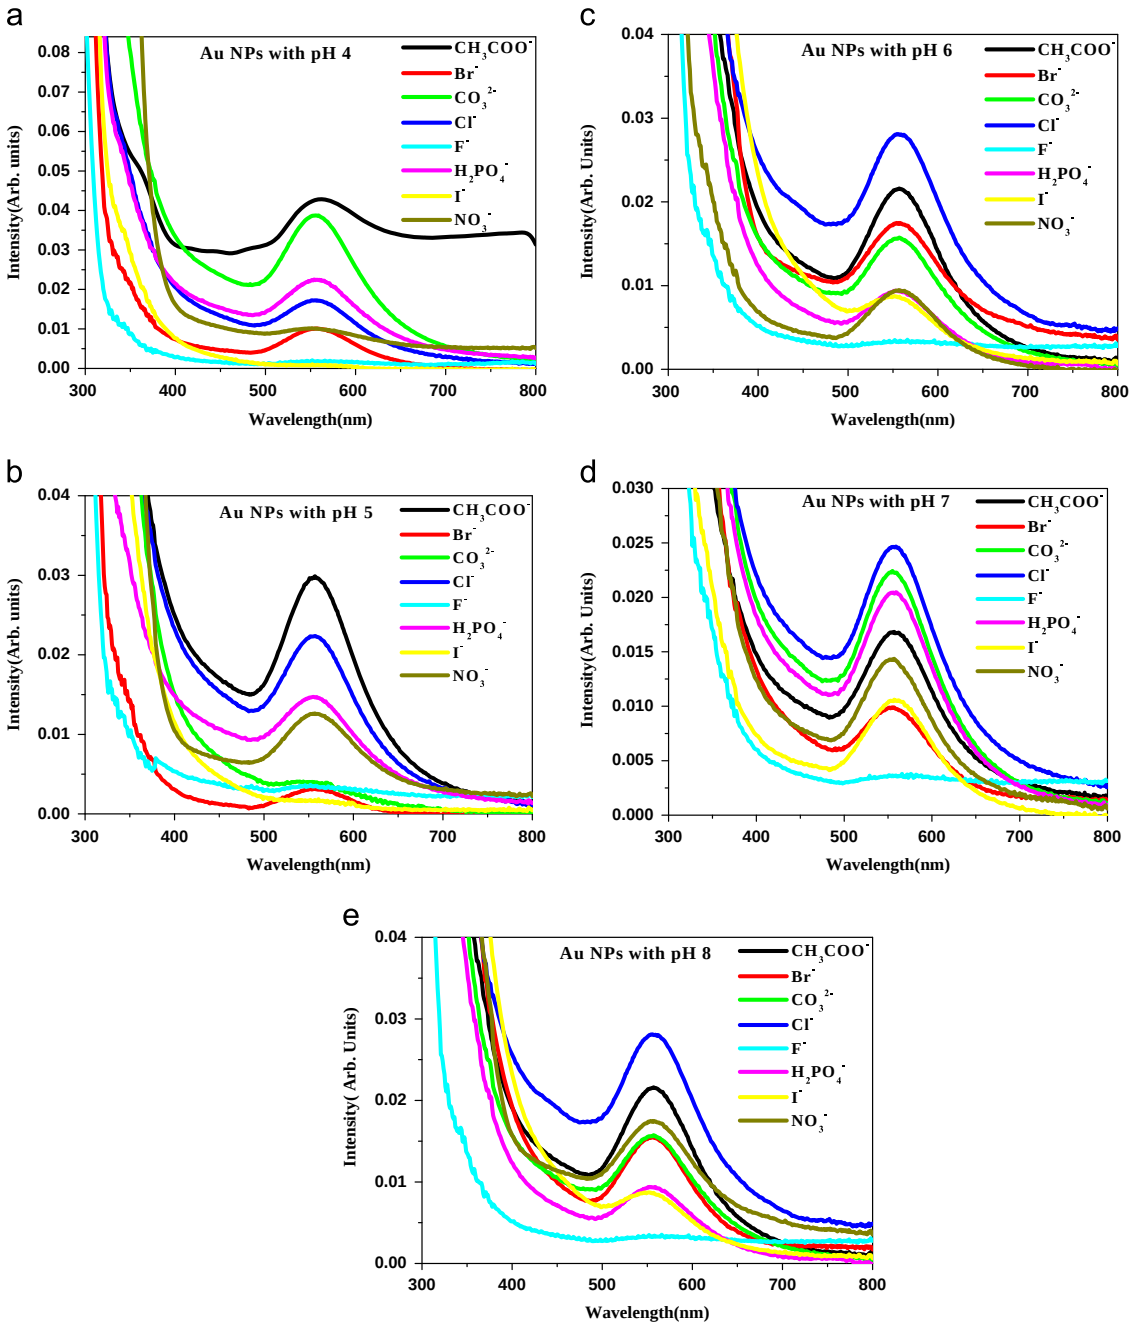

Fig. 7. UV–vis spectra of TBA–capped Au NPs solution having 10 mM concentration at different pH: (a) pH 4, (b) pH 5, (c) pH 6, (d) pH 7 and (e) pH 8.

of F^-, difference in the concentration can be detected by the naked-eye as the color change from red to colorless [35].

The UV–vis spectra of TBA-capped Au NPs solution upon addition of increasing fluoride ion concentrations in the range of 1–20 mM is shown in Fig. 6. Fig. 6 clearly shows that with increasing the amount of fluoride ion in the solution, the intensity of peaks decreased and at the certain concentration peak just disappeared. The peak width was also increased with the addition of higher concentration of fluoride ion in the solution. The changes observed in both parameters revealed the aggregation of NPs [13,65]. The addition of fluoride ion to the TBA-capped Au NPs solution caused dramatic changes in the plasmon band while the interaction was very strong at 10 mM F^- concentration. This concentration displays the colorimetric detection of F^- where the characteristic peak at 554 nm i.e. LSPR disappeared. UV–vis spectra at different concentrations of fluoride showed that with increased concentration of F^- in the reaction mixture, the peak position remained same while decreased in its intensity as well as broadening in the spectra occurred.

3.7. Effect of pH and TEM study

To investigate the effect of pH on the aggregation, the pH of TBA-capped Au NPs solution was varied by using 0.1 M NaOH from 4 to 8 [74]. The UV–vis spectra in the presence of different anions, obtained at different pH, are shown in Fig. 7 (a-e). With increasing pH i.e. increasing density of OH^- in the solution, the nucleophilicity of F^- increased to bind with protective surface of NPs. This result also indicates that the sensing process of F^- is govern by hydrogen bonding and by adsorption phenomenon, otherwise at pH 8, I^- ions could have also bonded with the hydrogen of capping agent i.e. TBA. With an increasing pH of the solution, the efficiency of interaction of larger anions decreases due to their decreased interaction [75]. At pH 8 almost all anions were stable due to their larger size while smaller F^- has strong tendency to disperse its excess charge through the formation of hydrogen bond with the capping agent. This study concluded that the selectivity of F^- ion detection increased with increasing pH of the solution.

The variation of pH from 4 to 8 of Au NPs did not show any change in the red color of the solution which confirmed the stability of the disperse state of TBA-capped Au NPs in the studied pH range. Initially, the pH of TBA-capped Au NPs solution was monitored to be around 2.7–3.0. On decreasing the pH of the solution, the position of the absorption peak remained same while changes observed in their shape and intensity. Very low pH decreases the electrostatic stability of Au NPs by decreasing hydroxyl (–OH) group concentration. The low intensity as well as very broad peaks indicated that the number of Au NPs at the surface significantly decreased by the aggregation of Au NPs or due to decrease in particle to particle distance.

The aggregation of Au NPs at pH 5 to 8 was further confirmed by TEM analysis. The TEM micrographs of Au NPs solution at pH 5, 6, 7 and 8 are shown in Fig. 8(a-d) which clearly show high aggregation at pH 5 and least at pH 8. The TEM images of Au NPs at various pH show that the aggregation occurs maximum at pH 5 while the particles are still dispersed without signs of aggregation at pH 6–8. The maximum aggregation at pH 5 is attributed to the fact that aggregation takes place due to the closer confinement of the particles [65]. TEM images of TBA-capped Au NPs after addition of fluoride ion indicate the formation of aggregated Au

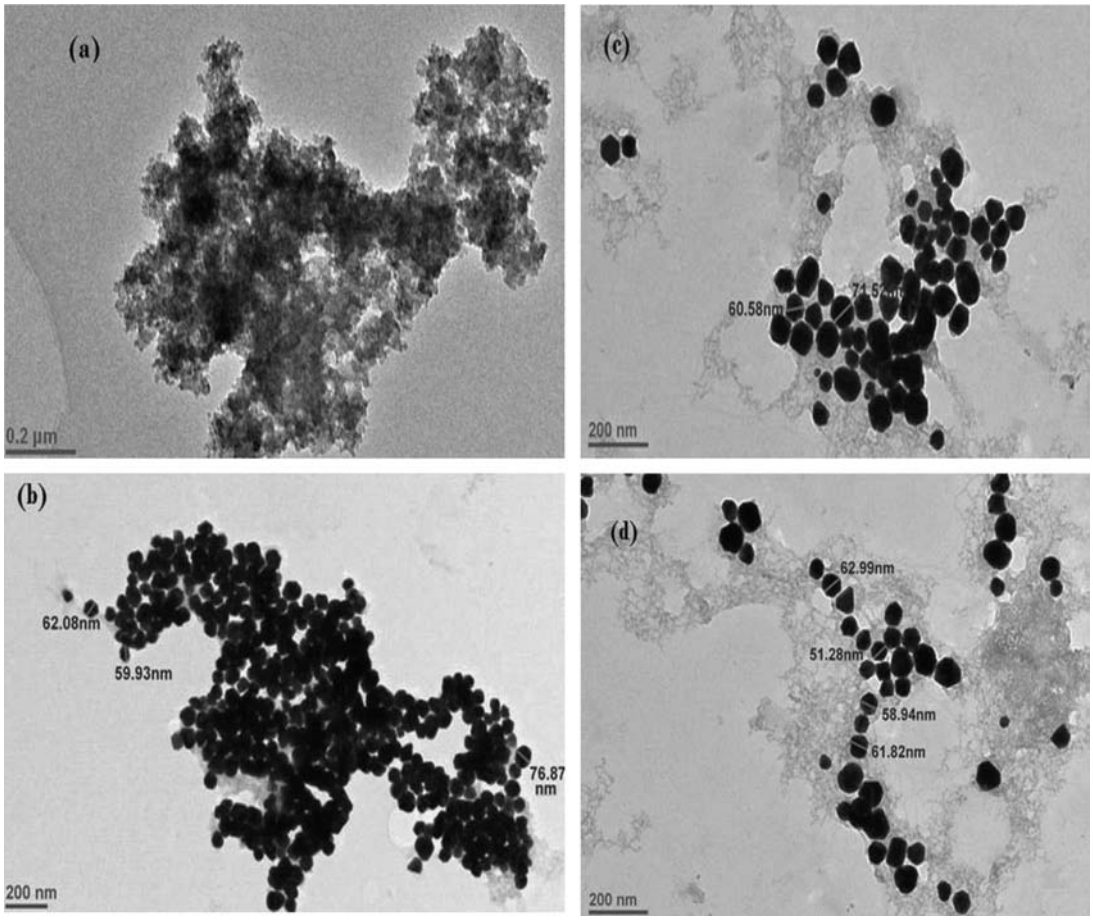

Fig. 8. Transmission electron microscope images of gold nanoparticles at different pH: (a) pH 5, (b) pH 6, (c) pH 7 and (d) pH 8.

NPs as shown in Fig. 8(a). This is attributed to the reduction of interparticle distance. When the distance among the aggregated particles decreases to less than the average particle diameter, the electric dipole-dipole interaction and coupling between the Plasmon's of neighboring particles into the aggregates leads to the formation of a new absorption band at longer wavelengths i.e. red shift the same was observed in Section 3.1 [65,76,77] while the broadening is attributed the slow rate of interaction [65,77].

4. Conclusions

In summary, we have demonstrated a simple way for the development of TBA-capped Au NPs by the chemical reduction method and used as platform for the detection of fluoride ion. In aqueous solution, halide anions (except fluoride) and oxoanions did not induce the aggregation with TBA-capped Au NPs. The color change associated with F^- aggregation has successfully been used for the naked eye detection of F^- at 10 mM concentration in aqueous solution. The reaction of F^- with TBA-capped Au NPs in aqueous solution has also been confirmed by Raman and FTIR spectroscopy.

ABSTRACT

Classical measurements of performances are typically based on linear scales. However, in analytical chemistry a simple scale may be not sufficient to analyze the analytical performance appropriately. Here partial order methodology can be helpful. Within the context described here, partial order analysis can be seen as an ordinal analysis of data matrices, especially to simplify the relative comparisons of objects due to their data profile (the ordered set of values an object have). Hence, partial order methodology offers a unique possibility to evaluate analytical performance. In the present data as, e.g., provided by the laboratories through interlaboratory comparisons or proficiency testings is used as an illustrative example. However, the presented scheme is likewise applicable for comparison of analytical methods or simply as a tool for optimization of an analytical method. The methodology can be applied without presumptions or pretreatment of the analytical data provided in order to evaluate the analytical performance taking into account all indicators simultaneously and thus elucidating a "distance" from the true value. In the present illustrative example it is assumed that the laboratories analyze a given sample several times and subsequently report the mean value, the standard deviation and the skewness, which simultaneously are used for the evaluation of the analytical performance. The analyses lead to information concerning (1) a partial ordering of the laboratories, subsequently, (2) a "distance" to the Reference laboratory and (3) a classification due to the concept of "peculiar points".

1. Introduction – the need for several indicators

Evaluating analytical performance may be assessed, e.g., through interlaboratory comparisons and/or proficiency testings or comparisons of analytical methods or through the optimization process of an analytical method. In the following we will apply the analytical performance of a series of laboratories as an illustrative example how analytical performance advantageously can be evaluated beyond the restrictions imposed by a single-quantity-approach such as the evaluation by checking only the accuracy (see below). Participation in interlaboratory comparisons or proficiency testings and a satisfying result from these are typically a prerequisite for obtaining accreditation to perform a given analysis.

Result of the single laboratory maybe expressed of the *z*-score (see below) only, which measure of how "far away" the single analytical result is from the accepted value, i.e., the *z*-score [1,2]. The *z*-score of the reference laboratory by definition being 0 (Eq. (1)). Obviously, the *z*-score does not as such tell the full story and other measures should be considered simultaneously. These (in the present case three) measures will a priori form a grid in the three-dimensional space and laboratories can be represented as a point in the space spanned by the three coordinates. The projection to each of these three coordinates bears information of its own right and it seems to be careless to aggregate the three quantities in order to obtain an easy to handle scale for ranking purposes. Various approaches for aggregating the indicators have been reported [3,4]. However, such aggregation of the indicators may unequivocally lead to compensation effects where high values in one indicator may compensate low values in another [5].

Taking all three indicators into account simultaneously is a bit more complicated than the use of a single scalar as we are facing a multi-indicator system (MIS). Partial order theory applied in multi-indicator systems is also known as Hasse diagram technique (HDT) [6,7] and appears in this connection as a highly advantageous tool. The visual representation of a partial order can be performed by a so-called Hasse diagram. In the Hasse diagram comparable objects are connected by a sequence of lines [6] and the diagram is characterized by its structure that comprises levels, chains and antichains (see

below). An often heard criticism of partial order ranking approaches is that the method is lacking of a unique or absolute ranking, i.e., the presence of incomparabilities. In a Hasse diagram incomparabilities are causing that the Hasse diagram (cf. Fig. 2) has not only a vertical (ranking) but also a horizontal geometrical configuration. Hence, applying partial ordering implies comparison among different objects. The consequent application of this concept leads to figures, which are known in algebra as (directed) graphs.

2. Theory and methods

2.1. Indicators

The z-score denotes the standard score [2] or accuracy [1,8] of the measurements, which enables a comparison between two scores from different normal distributions.

$$z = (m - \mu_a)/s_a \quad (1)$$

where m is the reported value from the laboratory and μ_a and s_a are the accepted value (mean) and standard deviation, respectively, as generated by the Reference laboratory, i.e., the laboratory assigned to perform the interlaboratory comparisons and proficiency testings [9]. In other words: a Reference laboratory is by definition considered as the "best". Also the standard deviation of the laboratory measurements is important to judge the laboratory performance, i.e., the precision of the measurements [1]. Finally a further possible factor to bring into play to elucidate the laboratory performance is the skewness of the distribution of the laboratory measurements [10]. This factor (indicator) tells about the shape of the distribution and thus to what extent the measurements are in analytical or statistical control [11]. The three parameters are all standard output from statistical treatment of the results from a series of replicate measurements (vide infra)

Obviously these factors – or indicators – for evaluating laboratory performance on an individual basis can be easily compared and thus each of them then may constitute the basis for ranking of the laboratories, i.e. the performance of the laboratory relative to each other as well as to the Reference laboratory. As such this may constitute an evaluation tool for selecting laboratories for specifics task. However, only part of the story is told and the information basis is obviously limited.

In the present study the absolute values of the z-score, |z|, and the skewness, |skew|, together with the standard deviation, s, are applied as indicators. The [0, 1] normalized indicators are called r_i (i=1, 2, 3) and any possible triple of values of a certain laboratory is consequently called r. Thus, each laboratory is characterized by a data profile, i.e., an ordered set of indicator values (|z|,s,|skew|).

Generally indicators r_i can be normalized to a [0, 1]-scale (called rn_i) by

$$rn_i(x) = (r_i(x) - r_i\ \mathrm{min})/(r_i\ \mathrm{max} - r_i\ \mathrm{min}) \quad (2)$$

where $r_i$max and $r_i$min being the maximum, minimum value with respect to the objects. Here the indicators r_i are assumed to be already normalized and we consider r as the triple (r_1, r_2, r_3)=(normalized z-score, normalized standard deviation, normalized skewness).

2.2. Partial order

2.2.1. Overview

In this paper the numerical aggregation for example by calculating a composite indicator CI is avoided.

$$\mathrm{CI} = \sum g_1 \cdot rn_i \quad g_i : weights, \quad i = 1, \ldots, 3 \quad (3)$$

The alternative is based on partial order methodology. The subject "Partial Order" is of increasing interest in the mathematical field as well as in many other applied fields. Here a pretty simple variant of partial order is applied to study MIS, according to a recent paper by Bruggemann and Carlsen [12]. This methodology can be applied, whenever a MIS and a data matrix are available and a ranking is of interest. For example partial order was applied in environmental sciences, in biology, in economy and social sciences. Good overviews can be found in Refs. [7,13]. Partial ordering can be considered as a non-parametric method as, in contrast to standard multidimensional analyses no assumptions about linearity or distribution of the indicators are made and are necessary.

2.2.2. The basical equation of Hasse diagram technique

In Partial Ordering the only mathematical relation among the objects is "$\leq$" [6,7,14]. The "$\leq$"-relation is the basis for a comparison of laboratories and constitutes a graph. A laboratory x is connected with laboratory y if and only if the relation $x \leq y$ holds. The crucial question is, under which conditions it can be claimed that $x \leq y$. Here, a system is described by a series of indicators r_j, the MIS. A laboratory, x, characterized by the a set of indicators $r_j(x)$, j=1, …, m can be compared to another laboratory y, characterized by the indicators $r_j(y)$, when

$$\mathrm{r}_i(x) \leq r_i(y) \quad for \quad all \quad i = 1, \ldots, m \quad (4)$$

Eq. (4) is a very hard and strict requirement for establishing a comparison. It demands that all indicators of laboratory x should be better (or at least equal) than those of laboratory y through comparison of the single indicators, respectively. To be still a little bit more technically: Let X be the group of laboratories studied, i.e., X={REF, lab1, lab2, …., lab20}, the laboratory lab$x$ will be ranked higher than laboratory lab$y$, i.e., lab$x$ > lab$y$ or still more condensed $x > y$, if at least one of the indicator values for lab$x$ is higher than the corresponding indicator value for lab$y$ and no indicator for lab$x$ is lower than the corresponding indicator value for lab$y$. However, if r_j(lab$x$) > r_j(lab$y$) for some indicator j and r_i(lab$x$) < r_i(lab$y$) for some other indicator i, lab$x$ and lab$y$ will be called incomparable (notation: lab$x$||lab$y$) expressing the mathematical contradiction due to conflicting indicator values. A set of mutual incomparable objects is called an antichain. When all indicator values for lab$x$ are equal to the corresponding indicator values for lab$y$, i.e., r_j(lab$x$)=r_j(lab$y$) for all j, the two objects will have identical rank and will be considered as equivalent, i.e., lab$x$∼lab$y$.

Eq. (4) is the basic for the Hasse diagram technique (HDT) [6,7,14], which is a special (statistically oriented part of partial order theory). Hasse diagrams are visual representation of the partial order. In the Hasse diagram comparable objects are connected by a sequence of lines [14–17]. For construction of the Hasse diagram, a uniform orientation of the indicators should be secured, i.e., high indicator values correspond to "bad" objects and low values to "good" objects. In Fig. 2 (Section 3) the Hasse diagram based on the data given in Table 1 is shown. Thus, in the present case the higher a laboratory is placed in the Hasse diagram the farther away from the performance of the Reference laboratory it is.

2.2.3. Structure of a Hasse diagram

A Hasse diagram is characterized with it structure that comprises levels, chains and antichains (cf. Fig. 2).

Level: The horizontal arrangement of objects within a Hasse diagram. The level structure gives a first approximation to a weak order (i.e. tied ranks are not excluded: thus, for example in the ordering of four objects $a < b = d < e$ there is a tie, i.e., the equivalence of b and d with respect to the rank.) of the objects from "good" (bottom) to "bad" (top). Unfortunately, this will often give rise to many tied ranks as all objects in a level automatically will be assigned identical ranks. Typically, it is desirable that the degree of tied ranks should be as low as possible, i.e., there is a need for a linear

Table 1
Summary statistics of the laboratories.

Laboratory	*z-Score*	*s*	*Skewness*	$r_1=\|z\|$	$r_2=s$	$r_3=\|skew\|$

REF	0	0.1	0	0.000	0.000	0.000

ranking of the single objects. This is obtained looking at chains only. However, it is not immediately obtainable when incomparable objects are included.

Chain: Chains are a subset of X, i.e., $X' \subseteq X$, where all objects in X' fulfill Eq. (4). Chains are characterized by their height that equals the number of objects in X'. Chains are of interest as they can be regarded as a complete order, or ranking of the objects of X', which means that for objects within a given chain all indicators are monotonously varying, i.e. simultaneously decreasing from top (start vertex) to bottom (end vertex).

A maximal chain is a chain for which no other objects can be found as a member of the chain.

A maximum chain is a chain, where the height equals the number of levels.

Between a start vertex and an end vertex there may be several chains of different heights. We call such chains "parallel" chains.

2.2.4. Average ranks

Beyond weak orders, derived from the level structure, partial order methodology provides a weak order by calculating the average rank of the single objects [18]. In cases where only a relatively low number of objects are studied (typically < 25) an exact method for calculating average ranks is available, based on lattice theory [19–21]. Lattice theory avoids the computational difficult combinatorial problem of finding every linear order compatible with the partial order. For example the partial order of three objects a, b, c as $a < b$, $a < c$ would have two compatible linear orders, namely $a < b < c$ and $a < c < b$. However, when the number of objects is n then at maximum n! linear orders must be found, which makes special algorithms, such as those based on lattice theory necessary. A detailed explanation is outside the scope of the present study and appropriate references should be consulted [19–21]. For larger systems, approximations have been presented [18,22–24].

2.2.5. Peculiarity of a data profile

The Hasse diagram in Fig. 2 shows that the following equation is sufficiently often fulfilled:

$$r_i(x) > r_i(y) \Rightarrow r_j(x) > r_j(y). \quad (5)$$

Eq. (5) expresses qualitatively that most often an increase in one of the indicators is implying an increase in another indicator. In the picture of mainstream this means that the elements typically are located within a slim ellipsoid ranging from (0, 0, 0) to (1, 1, 1). Ideally the column wise [0, 1]-normalized tuples r would be expected as points in an ellipsoid-like manifold. Thus, in the present 3-dimensional case it can a priori be expected that the majority of points representing the single laboratories are located around a straight line starting in (0, 0, 0), corresponding to the Reference laboratory, REF, and ending in (1, 1, 1). However, since the Hasse diagram in Fig. 2 is neither completely flat (complete antichain) nor completely thin (complete chain, i.e., a total order) deviations from the line through (0, 0, 0) and (1, 1, 1) obviously are envisaged [25]. Hence, some of the laboratories may be better represented by a pattern, generally described by the set $h(m)$.

$$h(m) = \{0,1\}^m - \{(0,0,\ldots,0),\ (1,1,\ldots,1)\} \quad (6)$$

Here $m=3$. In other words, we want to disclose which labs are located closer to one of the other 6 corners of $h(3)$, for example to (1, 0, 0) or (0, 1, 0). We define such element as peculiar as a verbal expression for deviating from the "main stream" [25].

In more mathematical terms a "near-enough-factor", f, was introduced [25]. In the m-dimensional case the maximum squared Euclidian distance between (0, 0,…, 0) and (1, 1,…, 1) in $h(m)$ is $D_{max}=m$ meaning that the distance between two given points is found on a scale from 0 to m. Hence, we regard laboratories as peculiar, where the distance, d, to one of the corners in $h(m)$, $d < f \bullet D_{max}$. These peculiar labs are represented by an indicator pattern that appears unbalanced relative to laboratories exhibiting more balanced patterns, i.e., being located around the (0, 0, 0) to (1, 1, 1) line. Thus, if f is selected as 0.05 only laboratories with highly unbalanced indicator profiles will be found, i.e., very close to one of the 6 corners of interest.

The term "very close" refers to a relative distance to the maximal distance of 3 within the cube. Thus, $f=0.05$ can be interpreted as 5% of the maximal distance, i.e., $d \leq 0.15$ to one of the peculiar corners and will consequently be denoted as extreme or peculiar due to the significant unbalance in the indicator profile. In other words it can be said this corresponds to a 95% level, meaning that laboratories not being found as extreme on a 95% level are found located around the (0, 0, 0)–(1, 1, 1) straight line. The limit would analogously be 0.3 for an f value equal to 0.1, corresponding to a 90% level.

2.2.6. Sensitivity

The sensitivity determines the relative importance of the single parameters on the structure of partially ordered sets [26]. The leading idea is to find distances between partial ordered sets (posets), where one poset is the original one including all indicators and the others are such posets where one indicator is left out. The indicator, whose elimination from the data matrix leads to the maximal distance to the original one, i.e., leading the highest degree of changes in the Hasse diagram is most important for the structure of the partial order. This kind of sensitivity analysis may be called "indicator-related sensitivity", because the effect of one indicator is studied.

2.2.7. Scanning analysis

Due to the very nature of the partial order methodology, even small differences in the [0, 1]-normalized indicator values may lead to incomparabilities and thus the lack of fulfillment of Eq. (4), i.e., lab$x$ appears incomparable to lab$y$ (vide supra). However, in that analysis all incomparabilities were displayed without regard to the possible importance of the single incomparabilities. In total there are 145 pairs of laboratories lab$x$, lab$y$ with lab$x \parallel$ lab$y$. In contrast a $\leq$ relation could only be found for 65 pairs (lab$x$, lab$y$). Hence a somewhat more nuanced view is necessary. Only if

the differences in indicator values are larger than Δ, the incomparability between two laboratories is considered as relevant. This idea can be expressed in mathematical terms be expressed as Eq. (7).

$$|r_i(labx) - r_i(laby)| > \Delta \text{ and } |r_j(labx) - r_j(laby)| > \Delta, \quad (7)$$

and

$$sgn(r_i(labx) - r_i(laby)) \neq sgn(r_j(labx) - r_j(laby)) \text{ with } sgn(\ldots) \neq 0 \quad (8)$$

with sgn(x) = −1, 0, +1 according to $x < 0$, $= 0$, > 0, respectively.

Note, by the notation r_i(lab$x$) the value of laboratory x with respect to the ith indicator is meant.

In practice this is calculated applying the module scan_incomp4.py in the PyHasse software package, applying the values of the scanning parameter Δ (min, max, steps from min to max) as input [25]. The lower the Δ values the smaller differences between the indicators values will be regarded as real. Thus, only if the differences in indicator values are larger than Δ, the two indicators will be regarded as incomparable, with remarkable data differences and therefore are to be contextually be interpreted as exerting a real conflict.

2.2.8. Tripartite graphs

A systematic introduction to the concept of tripartite graph has previously been reported by Bruggemann and Voigt [27]. Here an intuitive approach is presented. Imagine that lab$x$ has worse values (i.e. higher values) in comparison to laby in the first and second indicator, but better value (i.e. lower value) in the third indicators. This fact can graphically represented as follows (Fig. 1).

Graphs, such as that shown in Fig. 1 are helpful to explain the role of the indicators. In the case, shown in Fig. 1 we see that the pairs of indicators ($r1$, $r3$) or ($r2$, $r3$) are causing the incomparability of lab$x$ with laby. This logical "or" relation with respect to the role of indicators can be applied in several ways. Either one can search for the minimum number of indicators leading to the observed incomparabilities, or – as is done here – to check for numerical discrepancies in indicator values as in Eq. (7) and focus on those pairs of indicators, which not only cause an incomparability, but also, where the numerical differences are greater than Δ (Eq. (7)).

2.2.9. Software

All partial order analyses were carried out using the PyHasse software [28]. PyHasse is programmed using the interpreter language Python (version 2.6) [29–33] Today, the software package contains more than 100 modules and is available upon request from the developer, Dr. R. Bruggemann (brg_home@web.de). A simplified version of PyHasse operating on a web-based browser is under development and will soon be available.

Statistical analyses in connection with the data generation were carried out applying the freely available software R [34].

2.3. Data

The present study is of methodological nature. To this purpose a hypothetical group of 20 laboratories are supposed, each of them "analyzing" an identical sample 5 times. The "results" of the analyses were randomly generated. Based on these 5

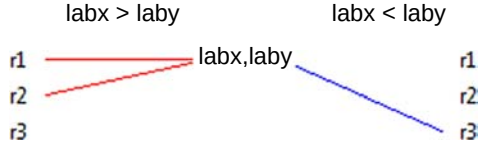

Fig. 1. Example of a tripartite graph.

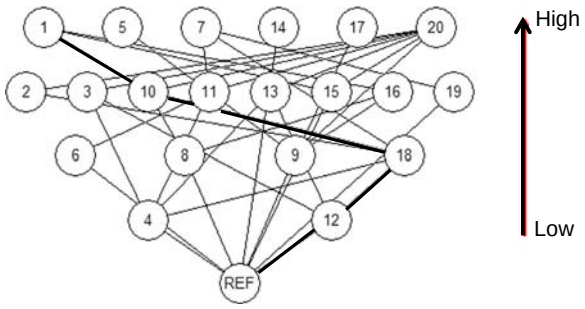

Fig. 2. Hasse diagram constructed based on the data shown in Table 1, the indicators being the absolute z-value,|z|, the standard deviation, s, and the absolute skewness,|skew|. The low to high designation refers the distance of the Reference laboratory (REF) to the single laboratories (here given by their respective numbers). Bold line: Visualization of one of the two possible chains connecting REF and lab1.

"measurements" 3 indicators, i.e., z-score, standard deviation and skewness were estimated by conventional statistics [34] and Eq. (1) and subsequently used for input in the partial order analyses (vide infra) to obtain additional insight in the performance of the laboratories. The z-score and the skewness for the Reference laboratory, REF, were per definition both set to 0 and the standard deviation to 0.1. In Table 1 the z-score, the standard deviation and the skewness derived from the individual laboratories are given.

A look at the data (Table 1) discloses that a given laboratory may report too low or too high z-scores as well as positively or negatively skewed data. However, In order to keep the presentation as simple as possible the absolute values of the z-score and the skewness are applied as indicators for an absolute "distance" from the Reference laboratory, without judging if positive or negative is good or bad, respectively.

3. Results and discussion

A simple linear ordering of the laboratory performance in proficiency testings may be obtained using the absolute value of the z-score as single indicator and thus obtaining a measure for the "distance" of the single laboratory from the Reference laboratory. Likewise also orderings based on the standard deviation and the skewness may be applied. However, it is immediately clear from the data (Table 1) that these orderings, which all offer important information, do not coincide and consequently, in order to obtain the complete picture it is necessary to consider all three indicators simultaneously. As an alternative to the classical aggregation methods applied for MIS we proposed to use partial ordering. The resulting ordering based on the three indicators applied in the present study, i.e., the absolute z-score, |z|, the standard deviation, s, and the absolute skewness, |skew|, can be visualized in a Hasse diagram (Fig. 2).

It is immediately seen that the Hasse diagram (Fig. 2) are characterized by

- Levels (in the present case 5), cf. Section 3.2, Table 3
- Chains (vertically comparable laboratories), cf. Section 3.1, Table 2 (one chain marked, cf. Fig. 2)

The presence of the relatively high number of incomparabilities (145) is often the cause for dismissing partial ordering approaches. However, in the following it will be demonstrated that important information may be retrieved from these incomparabilities.

3.1. Chains

Chains are structures within the Hasse diagram where all indicators weakly monotonously increase upward in the diagram.

Table 2
Number, height and composition of chains between REF and the laboratories in the. top level – level 5 – of the Hasse diagram, providing chains of maximal length.

Chain	Number of chains	Height	Chain composition	Characterization
REF→lab1	2	5	REF, lab4, lab18, lab10, lab1 REF, lab12, lab18, lab10, lab1	Maximum chains
REF→lab5	1	3	REF, lab9, lab5	Maximal chain
REF→lab7	4	4	REF, lab4, lab11, lab7, REF, lab4, lab18, lab7, REF, lab6, lab11, lab7, REF, lab12, lab18, lab7	Maximal chains
REF→lab14	1	2	REF, lab14	Maximal chain
REF→lab17	1	3	REF, lab9, lab17	Maximal chain
REF→lab20	4	5	REF, lab4, lab18, lab2, lab20, REF, lab4, lab18, lab10, lab20, REF, lab12, lab18, lab2, lab20, REF, lab12, lab18, lab10, lab20	Maximum chain

The presence of chains is interesting as the single chains are realizations of a unique ordering for a subset of objects. Thus, the laboratories within a chain can be seen as an absolute linear ordering of these laboratories with respect to all three indicators simultaneously. However, due to the very nature of the partial ordering several chains may lead from one laboratory, e.g., the Reference laboratory (REF) to a laboratory placed higher in the diagram. In Fig. 2 one of the possible chains of maximal height, 5, (a maximum chain) connecting the Reference laboratory to Laboratory 1 (lab1) is shown.

It is worthwhile to note that in the present case with only one minimal element, REF, we find that REF is comparable to all 20 laboratories included in the study. Thus, it is possible to find absolute ordering for all laboratories relative to REF, but obviously not between all laboratories. To illustrate this Table 2 gives the number of maximal/maximum chains for all the connections between REF and the 6 laboratories in the top level of the Hasse diagram as well as the chain composition that states the absolute ordering between the included laboratories. It should be noted that several other maximal chains of varying heights between selected elements exist. It is further noted that due to the level structure (cf. Fig. 2) the maximum heights of a chain will be 5.

It can immediately be seen that not all laboratories are represented in the chain structures given in Table 2. Thus, the laboratories 3, 8, 13, 15, 16 and 19 are not found. These are still comparable to REF and as such an absolute ordering to REF can be established. However, they are members of parallel chains between REF and a top-level element, where another chain of a greater height exists. As an example REF and lab1 are also connected through the chain REF, lab8, lab10, lab1 of only height 4. However, as Table 2 shows, there are parallel chains of larger height.

Taken Table 2 and the chain REF < lab4 < lab18 < lab10 < lab1 as an example, there is a simultaneous increase of all three indicator values. In that sense a graph–theoretical distance can be introduced. The laboratory lab1 has the maximum possible distance from REF. In contrast the laboratories lab4, lab12, lab9, lab6 and lab14 have a minimum distance to the reference laboratory REF. The laboratories lab1 and lab20 have the same graph-theoretical distance to REF (cf. Table 2 and Fig. 2; chain: REF, lab4, lab18, lab10, lab20), nevertheless the pattern of their data values is different. Beside the fact that the graph-theoretical distance as an ordinal concept gives no information about the proximity of two laboratories another deficiency is to be noted: Any additional laboratory, measured by the triple of indicators may be located in one of these chains. Nevertheless it is not known, how to classify it. This task will be discussed in Section 3.3.

3.2. Average ranks

In cases like the here studied a typical request is a linear ordering of the studied objects (here laboratories). Partial order methodology offers attractive alternatives. The level structure as derived from the Hasse diagram (Fig. 2) a priori offers a ranking, although rather rough and with many ties, of the single laboratories. (cf. Table 3).

Table 3
Level structure (cf. Fig. 2).

Level	Level composition
5	lab1 lab5 lab7 lab14 lab17 lab20
4	lab2 lab3 lab10 lab11 lab13 lab15 lab16 lab19
3	lab6 lab8 lab9 lab18
2	lab4 lab12
1	REF

In addition to the rough ranking based on the level structure we have different models to get linear orders of the laboratories, such as single-indicator based ranking, a ranking based on an aggregated indicator value applying weighted sums (Eq. (3)) or an average ranking based on the exact lattice theoretical method (cf. Section 2.2.4), which for a subsequent comparison is assumed as the ideal ranking.

The more detailed approach is to derive average ranks of the single laboratories [22–24]. The average rank of a lab*x* is called Rkav(x). The resulting ranking is in general a weak linear order as several laboratories may have identical Rkav-values. In Table 4 the average ranks are calculated based on the exact method [19–21]. The necessary calculations can be performed by the PyHasse software. The ranking due to Rkav-values can be compared to the ranking obtained based on the |z| score. The significant differences are obvious. In some cases, e.g., lab11 major disagreements are seen. Hence, this strongly supports the hypothesis that a ordering solely based on the |z| score does not reveal the complete picture.

In order to quantify the comparison of the different ranking methods the Sum of Ranking Differences (SRD) may be applied [35–37]. Supposing the average rank (Table 4) as the ideal ranking, it turns out that neither the single-indicators ranks (as e.g. based on |z|, cf. Table 4) nor those of based on *s* or |skew| are getting close (SRD of Rkav, |z|, of Rkav, *s* and Rkav,|skew is estimated to 100, 111 and 82, respectively). The comparison of Rkav-values to a ranking, based on an aggregated indicator value, applying equal weights (Eq. (3)) leads to a SRD of 32. It should be noted [35–37] that the lower the SRD value the better the ranking. To judge the SRD values they should be compared to the maximum SRD value, SRDmax. In the present case with 21 elements (laboratories) SRDmax is calculated to 220 [36]. With this in mind the ranking based on the aggregated values (equal weight) appears reasonable satisfying, whereas the single-indicator based rankings appear rather unsatisfactory.

Table 4
Average rank of the 21 laboratories for comparison the ranking based on the absolute *z*-score, |z|, is given.

Laboratory	Rkav	|z|rank
lab20	19.8	16
lab1	19.0	18
lab7	18.1	11
lab2	14.3	10
lab10	14.0	12
lab5	13.6	19
lab17	13.6	21
lab16	13.4	17
lab3	12.6	14
lab13	12.6	7
lab11	12.5	4
lab15	9.7	13
lab19	9.5	3
lab18	8.8	9
lab6	6.7	2
lab8	6.4	8
lab9	5.3	15
lab12	4.4	6
lab4	4.2	5
lab14	11.5	20
REF	1.0	1

3.3. Classification

The basic idea is to measure labs by a multidimensional system of rules.

So far the Hasse diagram, shown in Fig. 2 reveals only the set of all comparisons among the 21 laboratories. As the data are randomly generated an additional real laboratory will be just an extra vertex in the Hasse diagram. However, in order to classify this additional laboratory rules are needed, i.e. a membership to classes must be established. The most simple rule is to accept the system of randomly generated data where the single indicators have values in the closed interval [0, 1] and to consider a strong proximity (as expressed by *f*, see below) of a real lab to points of $h(3)$ as classifier. Hence, the extreme points, such as (0, 0, 0) (as the best one (Reference lab)) or (1, 0, 0) as a point where the *z*-score is the worst possible, but skewness and standard-deviations are as good as the values of the Reference lab, are of interest. As outlined in the former section there are 2^m extreme points. In our case with three indicators ($m=3$) a classification will be performed by 2^3, i.e. by 8 extreme points (corresponding to the corners of a cube, Fig. 3).

The mainstream of data may be considered as a cloud of points (i.e. cloud of points representing the objects, the labs) in a 3D-space which is oriented in the way that there are labs near the line from (0, 0, 0) to (1, 1, 1) (cf. Fig. 3). As an increase of one indicator value does not necessarily imply an increase of the value of another indicator, the cloud of points will encompass points which are considered as mutually incomparable. A realization of tuples having simulated data such as (1, 0, 0) or (0, 1, 0) does not necessarily appear. Therefore the reasoning is the other way round: Are there realized tuples which can be considered as near to extreme patterns which are not representative for the main stream start and end, i.e., (0, 0, 0) or (1, 1, 1). Here for demonstration purposes we arbitrarily selected $f=0.05$ (Section 2.2.5). The results are shown in the Table 5. It is seen that applying $f=0.05$ six laboratories, i.e., 28.57% of the 21 laboratories included in the study appear to extreme, or peculiar.

It can be deduced that the pattern [0, 1, 0] is approximately (due to $f=0.05$) realized 3 times, the pattern [0, 0, 1] only once, and the pattern [1, 0, 0] appears two times. No simultaneous appearance of two 1's in the extremal pattern is observed. The simultaneous appearance of 0 and 1 indicates that some labs are unbalanced: Good values in two, but a bad value in another aspect. These data fits nicely with the 3D plot depicted in Fig. 4.

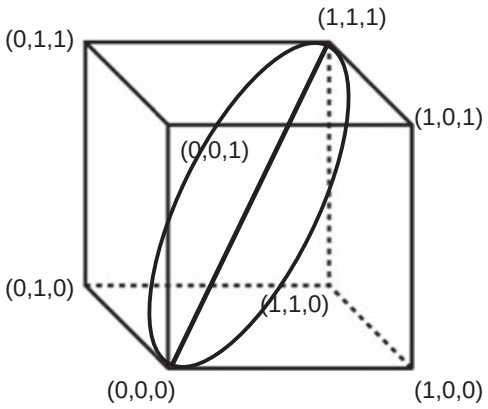

Fig. 3. The extreme points of $h(3)$ (Eq. (6)) themselves provide the structure of a partial order, applying Eq. (4).

Table 5
Extreme, or peculiar laboratories on a 95% level.

Laboratory	Pattern	Interpretation
lab6	[0, 1, 0]	This lab is close in |z| and skew but far away in *s*
lab8	[0, 0, 1]	This lab is close in |z| and *s* but far away in |skew|
lab11	[0, 1, 0]	This lab is close in |z| and skew but far away in *s*
lab14	[1, 0, 0]	This lab is close in *s* and skew but far away in |z|
lab17	[1, 0, 0]	This lab is close in *s* and skew but far away in |z|
lab19	[0, 1, 0]	This lab is close in |z| and |skew| but far away in *s*

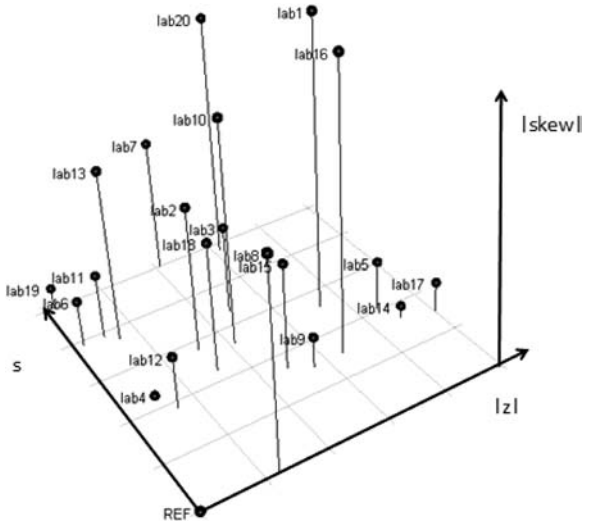

Fig. 4. 3D plot of the 21 laboratories based on the 3 indicators |z|, *s* and |skew|.

An additional laboratory can now be measured by a multirule-system, corresponding to the MIS, introduced: After selection of an f-value it will be associated to one of the 8 points and gets its classification according to Table 5.

3.4. Sensitivity

Three different indicators have been included and a priori they all provide information on the performance of the single laboratory. However, they may not be equally important in their impact

on the structure of the Hasse diagram. In order to elucidate the relative importance of the three indicators a sensitivity study of the partial ordering was conducted [26].

In Fig. 5 the relative importance of the |z|, *s* and |skew| indicators are visualized as calculated applying the PyHasse software.

The relative importance of the three indicators was calculated to be |z|=0.397, *s*=0.444 and |skew|=0.159, respectively, clearly substantiating the primary importance of |z| and *s* when discussing laboratory performance whereas the skewness apparently plays a somewhat secondary, but not negligible role.

3.5. "Real" incomparable elements

Obviously partial ordering may be considered hampered by the fact that even minute differences in indicator values may lead to incomparabilities. However, it may be appropriate to look only at numerically relevant discrepancies (cf. Section 2.2.7).

To illustrate the effect of varying Δ-values, Table 6 summarizes the results for two values of Δ (out of a systematic variation of Δ from 0.1 to 1), i.e., a low value (Δ=0.35) and a larger value (Δ=0.6), respectively. In Table 6 it is displayed which indicator pair exceeds this limit (cf. Eqs. (7) and (8)) and how often this exceeding is realized in terms of incomparable laboratories.

Table 6 can be read as follows using the second row (0.35, |z|, |skew|, 16) as an example: Here for 16 cases within the poset, the Hasse diagram is showing, the indicators |z| and |skew| lead to incomparabilities, whose numerical values are $>=$0.35. Here the focus is on the role of the indicators. In order to obtain further insights into the incomparabilities, it is of obvious interest to disclose which laboratories are representing for example incomparabilities due to large discrepancies of their indicator values. Such information has been compiled in Table 7 using the case with Δ=0.6 as an illustrative example. Table 7 should be read as follows using the second row (lab8,lab17, |z|,|skew| −0.759, 0.607) as an example: Immediately it can be realized that the differences in the indicator values, according to Eq. (7) are larger than Δ=0.6.

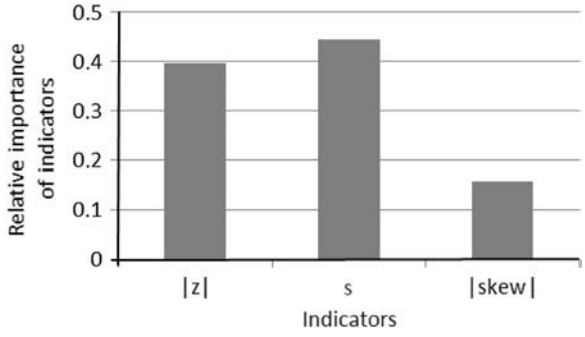

Fig. 5. Relative importance (sensitivity) of the |z|, *s* and |skew| indicators.

Table 6
Incomparabilities as function of the Δ-value.

Δ	Indicator pair	Realizations by the labs
0.35	|z|, *s*	29
0.35	|z|, |skew|	16
0.35	*s*, |skew|	18
Sum of realizations		63
0.6	|z|, *s*	3
0.6	|z|, |skew|	2
0.6	*s*, |skew|	2
Sum of realizations		7

Table 7
Incomparabilities between pairs of laboratories for Δ=0.6 and the involved indicator values.

Pairs of laboratories	Indicators causing the incomparability	Difference in indicator values
lab8, lab14	|z|, |skew|	−0.656, 0.667
lab8, lab17	|z|, |skew|	−0.759, 0.600
lab8, lab19	*s*, |skew|	−1.000, 0.633
lab14, lab19	|z|, *s*	0.863, −0.667
lab16, lab19	|z|, *s*	0.621, −0.704
lab16, lab19	*s*, |skew|	−0.704, 0.911
lab17, lab19	|z|, *s*	0.966, −0.704

Table 8
Incomparabilities between pairs of laboratories for Δ=0.7 and the involved indicator values.

Pairs of laboratories	Indicators causing the incomparability	Difference in indicator values
Lab16, lab19	*s*, |skew|	−0.704, 0.911
Lab17, lab19	|z|, *s*	0.966, −0.704

Especially this is true for |z| and |skew| for the labs lab8, lab17 (second row) and lab8, lab14 (first row).

A systematic variation of Δ from 0.1 to 1 showed that Δ=0.7 is the largest value for the discrepancies appearing in the 21 laboratories. The correspondingly striking lab- and indicator-pairs are given in Table 8

3.6. Tripartite graphs

In order to elucidate the incomparabilities between single laboratories two groups are selected from the top level (Fig. 2), where the most striking laboratories are located in the ranking due to the partial order theory. For each of these two groups three laboratories are for illustrative purposes arbitrarily selected, i.e., group 1: lab1, lab5 and lab7, and group 2: lab14, lab17, lab20. It should be emphasized that any other two groups, in which the laboratories apparently are not connected, could be selected for such a study. From the Hasse diagram (Fig. 2) it is clear that the objects of the first group are not connected with those of the second group. Technically the two groups are "separated subsets" [7] and their separation can be explained by the concept of a tripartite graph, Fig. 6A.

In Fig. 6A three labs on the one side (1, 5, 7) and three labs on the other side (7, 14, 20) are displayed. Hence, 3×3 pairs are possible and these 9 pairs are shown in the middle of the figure. The incomparability can be caused by different indicator pairs. For example (lab1, lab17) is incomparable due to conflicts in data with respect to |z|, *s* or |z|, |skew|. To understand the role of indicators it is of interest to trace back the role of |s| and |skew|. A closer look at Fig. 6A reveals that |skew| (on the left side) is connected with seven pairs of lab, meaning that lab1, lab7, lab5 in seven cases have larger values in |skew|, whereas |z| or |sd| are causing larger values for lab17, lab20 or lab14. Furthermore, one can see that almost everywhere where |skew| is responsible for a larger value of the objects of the first subset also *s* is responsible. An exception is (lab7, lab20) where only *s* is responsible. Hence, it is a fair approximation to visualize the peculiarity of the two subsets by a scatterplot (Fig. 7).

However, Figs. 6A and 7 do not take into account that a relation lab$x$ > lab$y$ with respect to some indicators and lab$x$ < lab$y$ with respect to some others may numerically be irrelevant. Hence, the

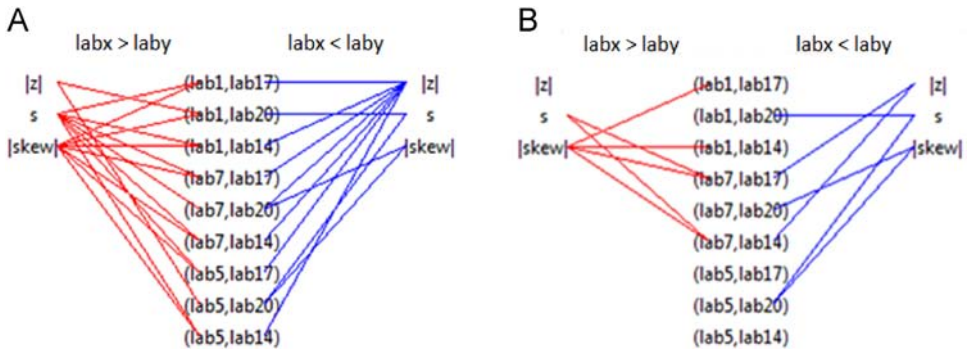

Fig. 6. (A) Tripartite graph of two groups of objects, taken from the top level of the Hasse diagram, Fig. 2. (B) Tripartite graph, where all indicator – (lab*x*, lab*y*) – connections with absolute numerical differences below 0.3 are filtered out (cf. text).

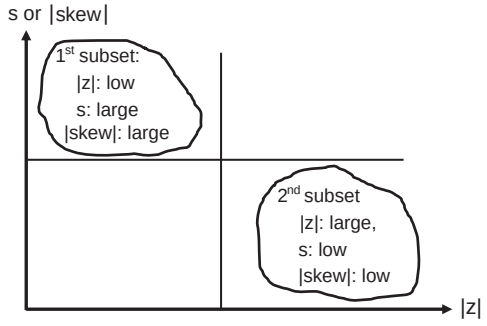

Fig. 7. Approximate graphical model, explaining why the two subsets are not connected. Here the two subsets are {lab1, lab5, lab7} and {lab14, lab17, lab20}.

analysis with tripartite graphs can be performed by filtering out too low values, when the single indicators have a metric.

In Fig. 6B only those indicator pairs are taken into regard whose absolute numerical differences are larger than 0.3. The value 0.3 is here arbitrarily selected to illustrate the concept. When a statistical analysis is performed, usually an idea about numerical noise would be disclosed. Subsequently, the limiting values should be selected accordingly.

This filtering out procedure results in a far clearer diagram, which is easier to be interpreted. It is immediately disclosed that now some incomparabilities can be resolved into comparabilities. See for example the pair (lab7, lab20). This pair is only connected with |skew| (on the right side of the tripartite graph). It can be deduced that the incomparability lab7||lab20 is caused by values less 0.3 in *s* and/or in |z|.

Similarly the pair lab5, lab17 is not connected at all with any of the indicators. Thus, the originally seen incomparability between those two laboratories was apparently caused by only slight and eventually irrelevant data differences. To sum up, it appears clear that only two pairs of laboratories (one taken from the first, the other from the second subset) remains with a "relevant" incomparability (lab7,lab17) and (lab7,lab14). Subsequently these three laboratories, lab7, lab14 and lab17, maybe placed in the scatter plot depicted in Fig. 7. Thus, lab7 would be located in the upper left part, whereas lab17 and lab20 would be located in the lower right part.

Note, that the replacement of $x\|y$ by $x > y$ or $x < y$ obviously may lead to a cascade of changes in a Hasse diagram, due to the axioms of partial order theory. Therefore, the obvious step to construct an enriched Hasse diagram is here not performed.

4. Conclusions and outlook

The present paper demonstrates that partial order methodology offers some tools to evaluate laboratory performance in interlaboratory comparisons or proficiency testings without making any presumptions or pretreatment (apart from a normalization which automatically is done by the appropriate PyHasse modules) of the analytical data provided by the laboratories. The methodology makes it possible to take into account a series of indicators reflecting the performance of the single laboratory. Hence, the method constitutes an alternative to the typical evaluation that is based on single-indicator orderings ore aggregation methods such as described by the simple Eq. (3). The average ranking method has been compared to single-indicator rankings as well as to a ranking based on an aggregated indicator value applying the SRD method.

In the present study the *z*-score, the standard deviation and the skewness have been chosen as indicators. However, the methods described are in no way limited to these indicators. Other additional indicators could be kurtosis or, when talking method development chromatographic conditions like temperature and flow rate. Note, however that the number of indicators should be carefully studied, as too many indicators tend to enhance the number of incomparabilities without inferring essential information.

Several rules to measure objects within the context of relevance applied, allow the identification of laboratories and their relative position. In order to perform a classification, the concept of peculiar points of a set $\{0, 1\}^m$ is of interest. A mainstream of points in the m-dimensional space may form a cloud from (0,…,0) to (1,…,1) points. Thus, the laboratories are of interest, which significantly deviate from this mainstream. Within the simulation study 6 laboratories out of totality of 21 ones turned out to be peculiar, i.e., not belonging to the mainstream. In no case an extreme deviation occurs, where two indicators are large and only one strikingly low.

The relative importance of the single indicators for the overall ordering is derived clearly demonstrating the *z*-score and the standard deviation are of major importance whereas the skewness apparently is only of secondary importance in relation to the overall evaluation of the laboratory performance.

A priori incomparability expresses a conflict in data. However, this does not take into account that such data conflicts may be caused by even very low numerical difference in indicator values and may thus lead to a confusing and even misleading picture. To deal with this the concept, a so-called scanning analysis was introduced in order to filter out such possibly insignificant differences in indicator values. In the illustrative example presented in this paper it was shown that accepting only numerical differences indicator values larger than 0.35 ($\Delta \geq 0.35$) reduced the number of incomparabilities from the original 145 to only 63 (cf. Table 6). Subsequently the focus was directed towards which laboratories are in mutual conflict with respect to which indicator pairs. This was analyzed applying the concept of the tripartite

graphs. Again, a clearer and less confusing picture developed, when only incomparabilities whose numerical discrepancies were considered as significant were included.

Although incomparabilities are often the reason, why modern decision support tools do not consider partial order, we have shown that the discussion of partial order with its inherent incomparabilities allow a refined view on data. Hence, a four step-procedure for data evaluation is suggested:

(1) Construct the partial order and visualize it by a Hasse diagram. The Hasse diagram informs the evaluator about relative ordering of the single objects, here laboratories.
(2) Perform a classification, by allocating laboratories to the points of the partially ordered space of $\{0,1\}^m$. This leads not only to a relative ordering, but also a measurement of distances to the reference object, here the Reference laboratory.
(3) Check, how far a weak order, provided by techniques of partial order theory is in coincidence with the ordering due to single indicators. Here a sensitivity analysis can be helpful, to select the most important (with respect to the ordering) indicator as a ranking index.
(4) Consider those laboratories that are mutually incomparable and whose conflicts in data are thought of as relevant. Apply techniques, such as scanning analyses and tripartite graphs to disclose the reasons for the incomparability. This information may then constitute the basis for advising the laboratories how to improve the performance.

Hence, the present paper has demonstrated that the presence of incomparabilities (being an inherent feature in partial order ranking) may disclose important characteristics.

Ongoing work focuses on a further elucidation of incomparabilities as an information source possibly through an active interplay between partial order methodology and multivariate statistics. Thus, discussion of data discrepancy has shown that it should be possible to combine multivariate statistical techniques with partial order theory [26]. The research in that field is pretty active and it should be noted that the combination of Kohonen networks [38,39] and cluster analysis [40,41], will provide important advices in this field.

Finally it should be emphasized that the methodologies applied in this paper, are generally applicable in cases dealing with the analyses of multi-indicator systems, which in the present context comprise comparisons of analytical methods as well as optimization of an analytical procedure.

ABSTRACT

Silver nanoparticles (AgNPs) were biosynthesised by a *Klebsiella oxytoca* strain BAS-10, which, during its growth, is known to produce a branched exopolysaccharide (EPS). *Klebsiella oxytoca* cultures, treated with $AgNO_3$ and grown under either aerobic or anaerobic conditions, produced silver nanoparticles embedded in EPS (AgNPs-EPS) containing different amounts of Ag(0) and Ag(I) forms. The average size of the AgNPs-EPS was determined by transmission electron microscopy, while the relative abundance of Ag (0)- or Ag(I)-containing AgNPs-EPS was established by scanning electrochemical microscopy (SECM). Moreover, the release of silver(I) species from the various types of AgNPs-EPS was investigated by combining SECM with anodic stripping voltammetry. These measurements allowed obtaining information on the kinetic of silver ions release from AgNPs-EPS and their concentration profiles at the substrate/water interface.

1. Introduction

Recently, a number of novel materials containing silver nanoparticles (AgNPs) have been introduced [1–3]. Their usage in commercial goods, such as cosmetics, apparels, medical and electrical devices [4,5], prompted researchers to investigate on AgNPs toxicity towards human cells, aquatic organisms [6] and, more in general, bacterial strains [7–10]. On the other hand, because of the latter property, AgNPs have received increasing attention as antimicrobial agents towards many Gram-positive and Gram-negative bacteria, fungi and viruses [11].

Nowadays, various methodologies are available for the synthesis of AgNPs [7,12–15], and are based on either chemical or biological approaches. The latter have received increasing attention due to the growing need of developing environmental-friendly technologies in material synthesis [12–14]. To this purpose, several microorganisms have been explored as potential cell-factories for both intra- and extracellular synthesis of nanoparticles of various metals [14]. For the biological synthesis of AgNPs, a variety of microorganisms, coming from bacteria and fungi, have been reported [16–19]. The mechanism is related to multiple phenotypic characteristics of the microorganisms, which can produce polymers, such as polysaccharides [20], which can, consequently, embed and stabilise the metal nanoparticles. These AgNPs-containing materials, in view of their biocompatibility, have potential applications as antimicrobials, especially in biomedical fields and food packaging [6,10,20].

The toxicity of AgNPs depends on several properties of the nanoparticles such as size and shape, surface area and charge, capping agents, bioavailability of the individual particles or silver forms [21–23]. With regard to the latter aspect, it is not yet clear whether the AgNPs toxic effects are due to the release of free Ag^+, the nanoparticles themselves or a combination of both species [24–27]. Therefore, investigations on the AgNPs redox properties and their reactivity at interfaces with aqueous environments is highly desirable.

Scanning electrochemical microscopy (SECM) is gaining increasing applications for the in situ investigation of localised phenomena and reactivity of substrates with high spatial resolution [28]. SECM is a scanning probe microscopy technique, which is based on the amperometric signal generated at a microelectrode by redox-active species in solution, which can perform quantitative local electrochemical experiments for studying heterogeneous and homogeneous reactions [29], for high-resolution imaging of the chemical reactivity and topography of various interfaces and surfaces [30,31]. In the field in which the present work falls, SECM has been used to characterise antimicrobial silver films [32], to

evaluate the interaction between Ag(I) ions and fibroblast cells [33] and to establish the effect of AgNPs on HeLa cells activity [34]. Aspects concerning the characterisation of pristine biosynthesised AgNPs in terms of oxidation state of silver and release of silver ions at interfaces have been less investigated. In fact, AgNPs could contain Ag(0), Ag(I) or both forms, this implying a different reactivity upon their contact with water [35].

Recently, it has been reported that *Klebsiella oxytoca (KO)* cultures, treated with $AgNO_3$ solutions, are able to synthesise AgNPs [36], which are embedded in branched exopolysaccharides (EPS) (AgNPs-EPS) [37]. These materials, produced under aerobic ($AgNPs^{aer}$-EPS) or anaerobic ($AgNPs^{anaer}$-EPS) conditions, could contain various forms of silver species and therefore could manifest different reactivity.

In this article, we report an SECM-voltammetric investigation devoted at establishing the oxidation state and reactivity of AgNPs-EPS biosynthesised by a strain of *KO*, and evaluating the amount of diffusable Ag(I) released at the substrate/solution interface.

2. Materials and methods

2.1. Materials and microbial strain

All chemicals were of reagent-grade and used as received, unless otherwise stated. Potassium hexachloroiridate(III) (Sigma Aldrich) was used as redox mediator in SECM investigations. The Nutrient Broth was purchased from Difco. Glycerol, sodium hydrogen carbonate, ammonium nitrate, magnesium sulphate heptahydrate, sodium dihydrogen phosphate, potassium acetate, sodium citrate, sodium hydroxide and silver nitrate were purchased from Sigma Aldrich. The chloride-free NAC medium, used for cell cultures, contained: 2.5 g l^{-1} sodium hydrogen carbonate, 1.2 g l^{-1} ammonium nitrate, 1.5 g l^{-1} magnesium sulphate heptahydrate, 0.6 g l^{-1} sodium dihydrogen phosphate, 0.132 g l^{-1} potassium acetate and 14.7 g l^{-1}sodium citrate. *Klebsiella oxytoca* was isolated from acid mine drainage of pyrite mines as reported in detail elsewhere [38].

2.2. Cultivation of K. oxytoca BAS-10 and production of AgNPs-EPS

Aerobic and anaerobic AgNPs-EPS were prepared as follows. 200 μL of a suspension containing *KO* BAS-10 cells, kept in cryovials at −80 °C in 25% glycerol and Nutrient Broth, were finally inoculated in chloride-free NAC medium. The pH of the NAC medium was previously adjusted to pH 7.6, by adding NaOH [39]. The *KO* BAS-10 cultures were grown both in aerobic and anaerobic conditions, at a controlled temperature of 30 °C. Aerobic conditions were ensured by stirring the cultures with an orbital stirrer under air-exposed media. For the anaerobic growth, the cultures were placed in a pirex bottle that had been previously saturated with nitrogen, then sealed and maintained under nitrogen blanket. At stationary phase of growth, $AgNO_3$ (to provide 50 mg L^{-1} of total Ag) was added to both types of *KO* BAS-10 cultures. These were left for 24–48 hours, till the metal-enriched polysaccharide flocculated in the bottom of the flask. AgNPs-EPS obtained in both aerobic and anaerobic conditions were subsequently separated by centrifugation and then treated with cooled ethanol in order to obtain a final hydroalcoholic solution 70% v/v. The colloidal materials were kept at 5 °C overnight, dried out under vacuum and grinded in a mortar.

2.3. TEM measurements on AgNPs-EPS

For the analysis of TEM, 1 mg each of $AgNPs^{aer}$-EPS and $AgNPs^{anaer}$-EPS was suspended in 1 ml of milli-Q water and sonicated for 10 min. Then, a 5 μl aliquot of each suspension was placed on a platinum grid coated with Formovar resin and then allowed to dry prior to TEM observations. The TEM images of the AgNPs were obtained using a JEOL JEM 100b (Tokyo, Japan) operating under standard conditions. The size distribution of the AgNPs was determined by image analyses of micrographs using the free source software Image J64 (NIH, USA).

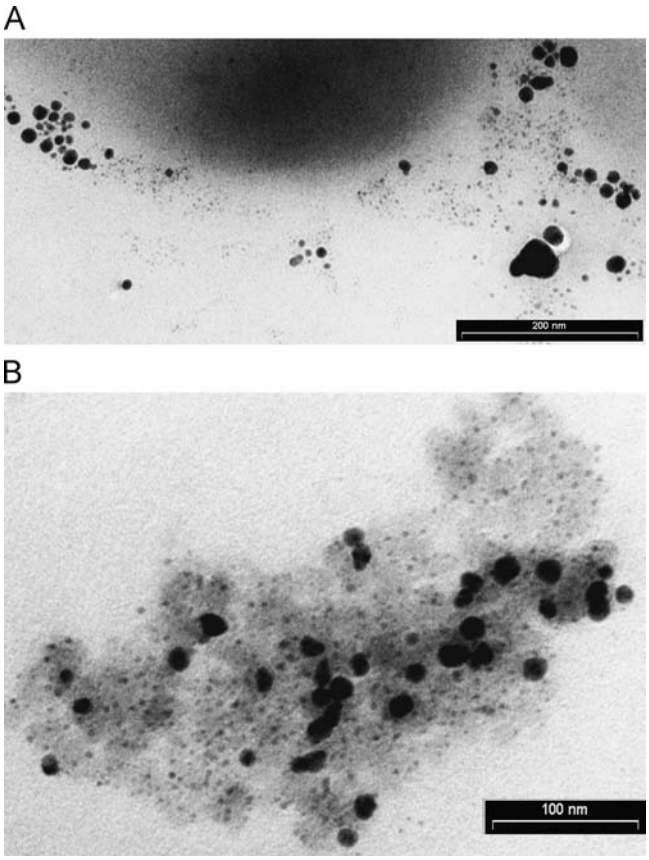

Fig. 1. TEM micrographs obtained on AgNPs-EPS obtained in anaerobic **(A)** and aerobic conditions **(B)**.

2.4. SECM and voltammetric experiments on AgNPs-EPS

SECM and voltammetric experiments were performed in a two-electrode cell, which comprised a working (or SECM tip) electrode and a reference/counter electrode. Platinum disk microelectrodes with nominal radius of 12.5 μm were employed as tip/working electrodes in either SECM or voltammetric measurements. They were prepared by sealing platinum wires within glass capillaries [40]. Afterward, they were tapered to a conical shape, polished with graded alumina powder (5, 1 down to 0.3 μm) and then characterised by cyclic voltammetry at low scan rates and by SECM to evaluate the actual electrode radius of the microelectrode and the overall tip radius to the electrode radius ratio (*RG*) [28,40]. The tips employed here had *RG* values over the range of 8–10. In all electrochemical measurements, a reference/counter electrode Ag/AgCl in saturated KCl was used. A CHI920B workstation (CH Instruments) was employed for both SECM and voltammetric experiments. Measurements, for establishing the oxidation state of the various types of AgNPs (immobilised onto a glass substrate as described below) by SECM, were performed in solutions containing 1 mM K_3IrCl_6 as redox mediator, and 0.1 M KNO_3 as supporting electrolyte. Diffusion controlled oxidation of $IrCl_6^{3-}$ at the SECM tip (vide infra) was achieved by applying a constant potential (E_{tip}) of +0.9 V (see inset in Fig. 2). Current against tip to substrate distance plots (i.e., approach curves) were constructed using normalised currents, $I_N = I/I_{bulk}$, (I is the actual tip current; I_{bulk} is the current

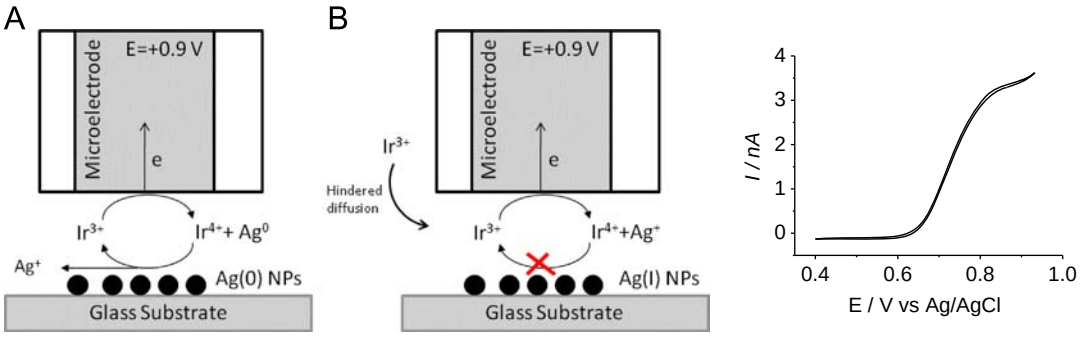

Fig. 2. Schematics of the operating principle for SECM measurements involving: **(A)** negative feedback on Ag(I)NPs and **(B)** positive feedback on Ag(0)NPs. Inset: cyclic voltammetry recorded with a Pt microdisc 12.5 μm radius in a 1 mM K_3IrCl_6+0.1 M KNO_3 solution. Scan rate 10 mV s^{-1}.

measured in the bulk of the solution), against normalised distances $L=d/a$ (d is the tip-substrate distance and a is the microdisc radius). Normalised currents were also used for drawing SECM line scans. For voltammetric and SECM measurements of Ag(I) species, the electrolyte solution consisted of 0.1 M KNO_3. In this measurements, the tip-substrate distance was determined by using the negative feedback approach curves recorded employing oxygen, dissolved in the aerated solution, as redox mediator [41]. The release of silver ions was monitored by using anodic stripping voltammetry (ASV) [42]. Unless otherwise stated, all electrochemical measurements were performed in aerated solutions.

2.5. Immobilisation of the AgNPs-EPS for SECM and voltammetric experiments

For both SECM and voltammetric measurements, $AgNPs^{aer}$-EPS and $AgNPs^{anaer}$-EPS were immobilised onto glass slides. The latter were first washed with ethanol, rinsed with distilled water and dried with nitrogen. The clean slides were afterward soaked in 10% poly-L-lysine (Sigma Aldrich) solutions for 5 min and then dried under chemical hood at 60 °C for 1 h. 20 μL of aqueous suspensions containing 10 mg ml^{-1} AgNPs-EPS were placed on the poly-L-lysine layer [33] and dried at 30 °C overnight. This procedure allowed obtaining several series of three spots (each about 3 mm diameter) of each type of AgNPs-EPS samples.

3. Results and discussion

3.1. TEM analysis

Fig. 1 shows typical TEM micrographs of the $AgNPs^{aer}$-EPS (Fig. 1 A) and $AgNPs^{anaer}$-EPS (Fig. 1B) samples investigated. The high electron-dense spots, due to AgNPs, are embedded on the polysaccharide matrix, and display, predominantly, a spherical shape. Digital analysis provided an average size of 11 ± 5 nm. This value is within those obtained for AgNPs produced by using other bacterial exopolysaccharides [20].

3.2. SECM investigation

The oxidation state of the silver species present in the AgNPs-EPS was investigated by using SECM, operating in the feedback mode in a solution containing K_3IrCl_6 as redox mediator. With this procedure, two phenomena could be observed depending on whether the sample examined was unreactive (or insulating) or reactive (or conducting) [28]. In the first case, the current decreased as the microelectrode, from the bulk solution, was brought towards the substrate (negative feedback); in the second case, the current increased due to the recycling of the redox mediator at the SECM tip (positive feedback). Under our conditions, negative or positive feedback occurred depending on whether the AgNPs-EPS substrates contained Ag(I)NPs or Ag(0) NPs, respectively. This can be understood by considering the scheme shown in Fig. 2. When the substrate contains Ag(0)NPs (Fig. 2 A), the following electrochemical reactions can occur:

$$IrCl_6^{3-} \rightarrow IrCl_6^{2-} + e- \quad (1)$$

reaction at the tip

$$IrCl_6^{2-} + Ag(0) \rightarrow IrCl_6^{3-} + Ag^+ \quad (2)$$

reaction at the substrate

Reaction (2) represents a heterogeneous bimolecular electron transfer process, which is shifted towards the right hand side because the standard redox potential of the $IrCl_6^{2-}/IrCl_6^{3-}$ couple is higher than that of the Ag(I)/Ag(0) species. Thus, when the tip is close to the substrate, the redox mediator is regenerated and the current increases. On the other hand, in the presence of Ag (I) species, reaction (2) does not occur and the substrate hinders the diffusion of the redox mediator (Fig. 2B) [28]. Fig. 3A shows typical normalised current against normalised distance plots recorded while approaching the microelectrode to the $AgNPs^{aer}$-EPS or $AgNPs^{anaer}$-EPS spots. For comparison, approach curves recorded above a clean glass surface, at an EPS sample produced by *KO* cells untreated with $AgNO_3$, and theoretical diffusion controlled approach curves for either positive (red straight line) or negative feedback (blue dashed line) are shown. It is evident that above both the $AgNPs\text{-}EPS^{aer}$ and $AgNPs\text{-}EPS^{anaer}$ spots, positive feedback is recorded. On the other hand, above either the clean glass surfaces or the Ag-free EPS, negative feedback responses are obtained. These results indicate that in both types of materials reaction mechanism (1)–(2) is operative, thus denoting the presence of Ag(0) species. However, the extent of positive feedback, at a given tip to substrate distance, depends on the specific sample investigated, it being larger above the $AgNPs^{anaer}$-EPS. This is conceivably due to a higher amount and readily available Ag(0)NPs in the latter sample with respect to the $AgNPs^{aer}$-EPS. Instead, as expected, negative feedback responses were recorded above either the clean glass surface or the AgNPs-free EPS samples, where reaction (1)–(2) cannot occur. It must be considered that negative approach curves (as those for the glass slide) were also recorded in some zones of the AgNPs-EPS spots investigated, indicating that, locally, either AgNPs-EPS rich of Ag(I) NPs or no AgNPs-EPS material was present.

The distribution and density of Ag(0) in the AgNPs-EPS materials was evaluated by SECM operating in line-scanning mode. These experiments were performed by positioning the SECM tip at ~10 μm above the sample and then recording the current along

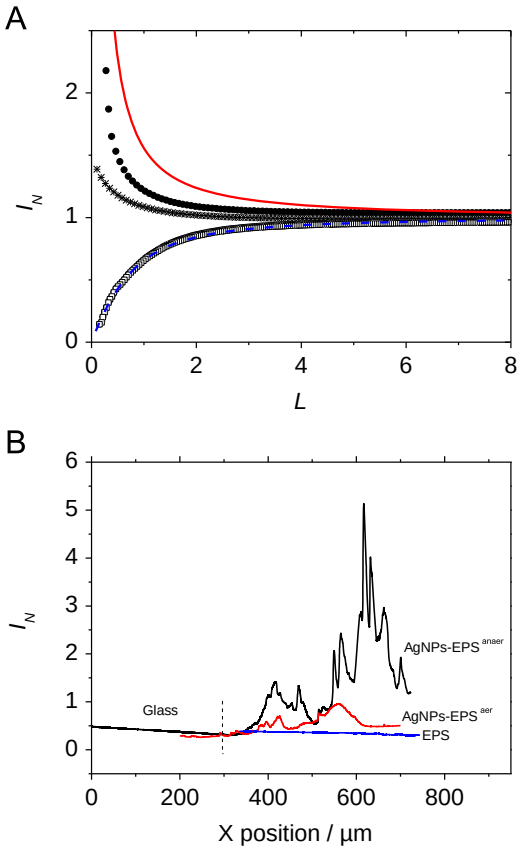

Fig. 3. **(A)** Approach curves recorded above: (∗) AgNPs^{aer}-EPS; (•) AgNPs^{aenaer}-EPS; (⋄) a clean glass surface; (○) EPS untreated with $AgNO_3$; theoretical for (red line) positive and (black line) negative feedback approach curves. **(B)** SECM line-scans recorded above a border region between the clean glass slide and (black line) Ag-NPs^{anaer}-EPS, (red line) Ag-NPs^{aer}-EPS; (blue line) Ag-free EPS.

the x (or y) direction. Fig. 3B shows typical SECM line scans recorded above a border region between the clean glass slide and the AgNPs^{anaer}-EPS (black line) or AgNPs^{aer}-EPS (red line) spots. As is evident, current increments, conceivably due to the positive feedback effect, were recorded when the microelectrode travelled above both types of spots (from 350 to 700 μm in Fig. 3B). Instead, low and almost constant currents were recorded as long as the microelectrode was moved above the glass slides (from 0 to 350 μm in Fig. 3B). Line scans with similar features and low current changes were also obtained above the AgNPs-free EPS samples (see blue line in Fig. 3B). In this case, the current change was essentially due to the roughness of the samples investigated, which could also affect the tip current responses [44]. The latter finding also indicates that the topography of the investigated samples is flat enough and does not affect significantly the overall current responses due to the AgNPs-EPS film.

Comparing the line scans recorded above the AgNPs-EPS samples, it is evident that normalised currents were, in general, higher above the AgNPs^{anaer}-EPS spot, confirming that the latter sample contained larger amounts of Ag(0)NPs as previously observed comparing the positive feedback approach curves. Form TEM images and considering that the EPS matrix provided images of quite flat surfaces, at this level of resolution, it is reasonable to assume that the roughness of the AgNPs-EPS samples does not affect the feedback current responses.

Considering again Fig. 3A, it is evident that the approach curves, recorded above both types of AgNPs-EPS spots, in no case fit that for diffusion controlled positive feedback. This could be attributed to several factors, including the facts that the Ag(0)NPs, embedded in the polysaccharide matrix, do not form large interconnected silver clusters, or that the kinetic of the heterogeneous bimolecular electron transfer process, involved in reaction (2), is not fast. At this stage, we are unable to differentiate among the various factors.

3.3. Study of the release of Ag(I) species

Information on reactivity of AgNPs and the release of Ag(I) species at the AgNPs-EPS/water interface was obtained by combining SECM and voltammetric experiments. The measurements were performed on AgNPs-EPS modified glass-slide spots immersed in a 0.1 M KNO_3 aerated-aqueous solution. Under these conditions, Ag(I) species, eventually present in the samples, or formed by corrosion of Ag(0)NPs, could diffuse to the aqueous solution and thereby collected at the microelectrode tip (scheme in Fig. 4). In these experiments, the tip-substrate distances were established using oxygen (from the air saturated solution) as redox mediator. Oxygen was used in order to avoid any possible interference due to the oxidising action of the $IrCl_6^{2-}/IrCl_6^{3-}$ couple towards Ag(0)NPs.

Evidences for the formation of Ag(I) species or the presence of soluble Ag(0)NPs were, initially, gained by using cyclic voltammetry (CV) with the microelectrode positioned at 10 μm above the substrates. Cyclic voltammograms were recorded in the potential window from 0.05 to 0.80 V, where both reduction of Ag(I) species and oxidation of Ag(0), accumulated at the microelectrode surface, could occur [43]. Fig. 5 shows a typical CV recorded at 50 mV s^{-1} with the Pt microdisc positioned above a AgNPs^{aer}-EPS spot, after 2 hours the introduction of the 0.1 M KNO_3 solution. The potential was initially scanned from the rest potential (0.25 V) towards

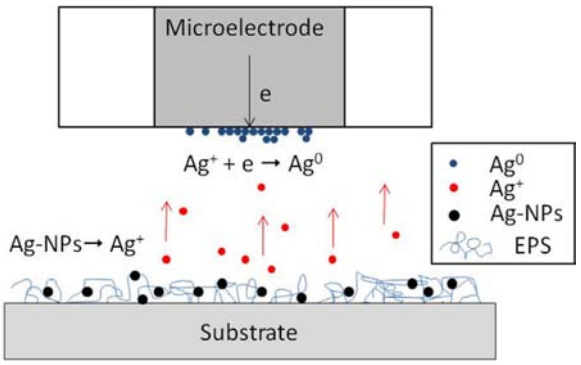

Fig. 4. Schematic of the Ag(I) species release from the AgNPs-EPS substrate and collection at the SECM tip.

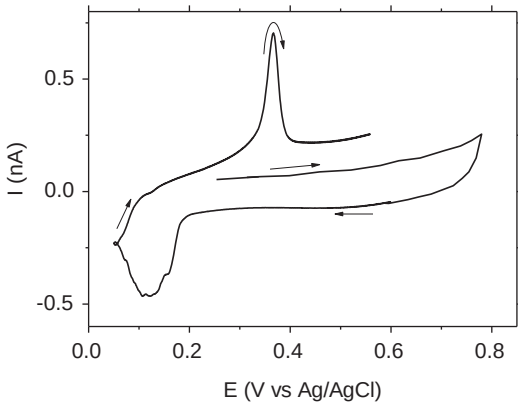

Fig. 5. Cyclic voltammograms recorded by using a 12.5 μm Pt microelectrode placed 10 μm above a Ag-EPS^{aer} spot after two hours immersion in a 0.1 M KNO_3 aqueous solution. Scan rate: 50 mV s^{-1}

positive potentials, to oxidise, eventually, soluble or colloidal Ag(0) NPs-containing compounds; then from the anodic limit the potential was scanned towards negative potentials where Ag (I) species could be reduced; afterwards, the potential was scanned again towards positive values to oxidise Ag(0) accumulated at the electrode surface. As is evident from Fig. 5, no wave is observed during in first anodic scan, indicating that no or negligible amount of Ag (0) was present within the microelectrode/substrate gap. Instead, a cathodic peak at 0.2 V and an anodic one at 0.4 V, due to the reduction of the Ag(I) species and the oxidation of Ag(0) accumulated onto the electrode surface, respectively, were obtained during the subsequent negative and positive scans. The peak shaped response, obtained in the cathodic scan, instead of a steady-state (or pseudo-steady state, typical for microelectrodes) [45], suggested a thin layer behaviour [46] and that almost all Ag(I) species, present within the tip/substrate gap, were depleted.

CVs similar to that shown in Fig. 5 were also obtained above a AgNPs^{anaer}-EPS sample (not shown). However, in the latter case, valuable voltammograms could be obtained only after longer (i.e. 4–5 h) immersion times of the sample in the water solution. This finding suggested that the Ag(I) species released from AgNPs^{anaer}-EPS, which is richer of Ag(0)NPs, involved a more complex pathway, including the metal corrosion process.

To achieve a better sensitivity in the measurements, and for quantitative determination of silver(I) species released from the AgNPs-EPS samples, anodic stripping voltammetry was employed [47,48]. A first series of ASVs was carried out for obtaining information on the dissolution rate of the Ag(I) species. To this purpose, the Pt microelectrode was positioned at 10 μm above the samples and ASVs were recorded with time. The ASVs were performed using a deposition time of 60 seconds, a deposition potential equal to −0.1 V vs. Ag/AgCl and linear sweep voltammetry at 50 mV s^{-1} during the stripping step. Fig. 6A B show typical ASVs thus recorded for different elapsed times after the samples had been immersed in the water solution. For both samples, the stripping peak height increases with time, confirming that increasing amounts of Ag(I) species dissolved to the water phase. The concentration (C^b_{Ag+}) was estimated by comparing the anodic charge involved in the ASV peaks, recorded above the AgNPs-EPS samples, to those obtained in $AgNO_3$ solutions of known concentrations. Fig. 6C shows plot of C^b_{Ag+} against immersion time (t_i). It is evident that the Ag(I) concentration increases with time for both AgNPs-EPS samples; however, after about 20 and 25 min for the AgNPs-EPS^{aer} and AgNPs-EPS^{anaer} sample, respectively, the concentration levels off. This is probably due to the achievement of an equilibrium between soluble Ag(I) and Ag(I)

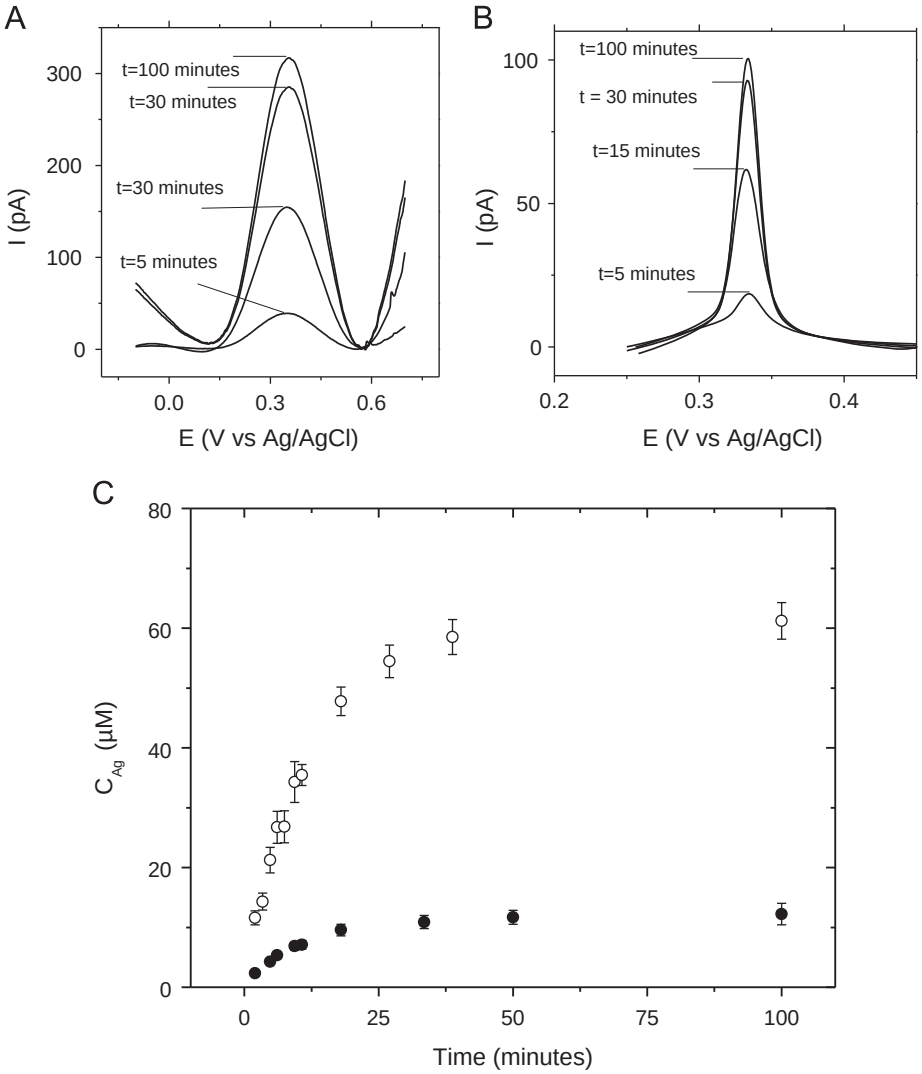

Fig. 6. ASVs recorded at different times with a Pt microdisc positioned at 10 μm above **(A)** Ag^{aer}NPs-EPS and **(B)** Ag^{anaer}NPs-EPS. **(C)** Concentration against elapsed time after immersion in the 0.1 M KNO_3 solution of (○) Ag-NPs^{aer}-EPS and (●)Ag-NPs^{anaer}-EPS samples. ASVs parameters: deposition time 60 s, deposition potential −0.1 V and, 50 mV s^{-1}during the stripping step. Error bars are established on the basis of three consecutive ASVs.

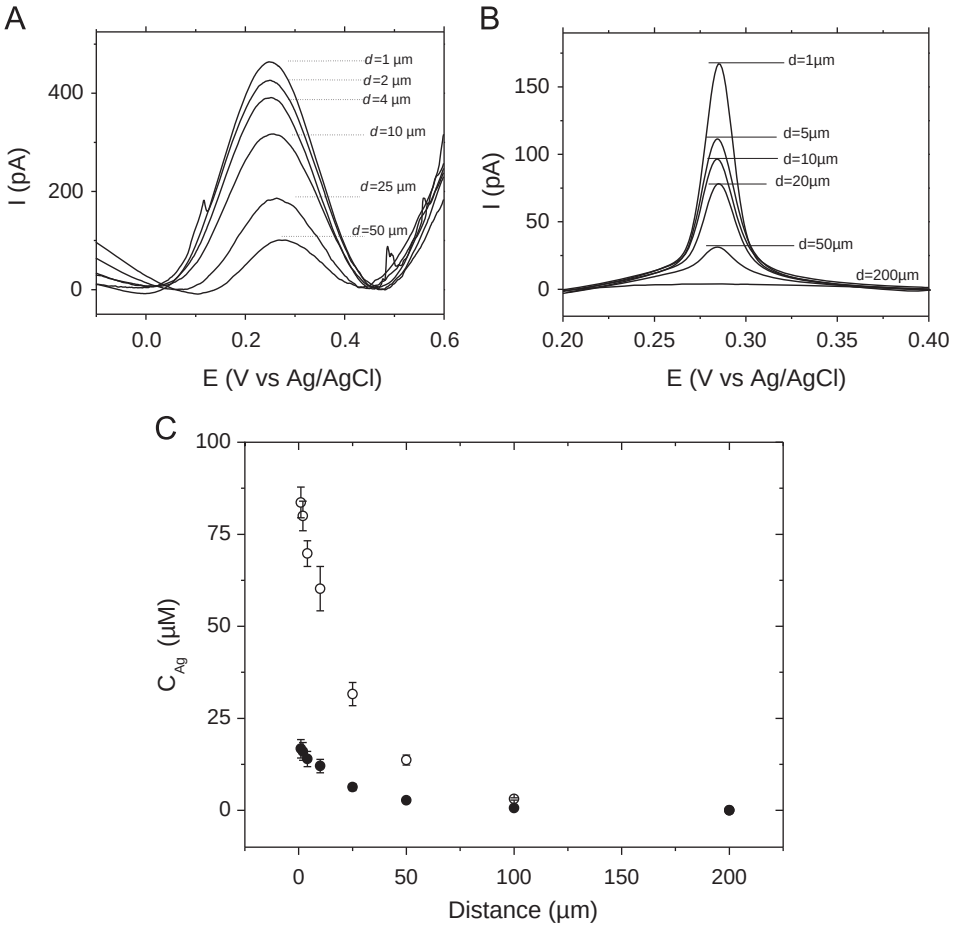

Fig. 7. ASVs recorded at different tip-substrate distances with a Pt microdisc after the samples had been immersed in 0.1 M KNO_3 for 30 minutes. **(A)** for $AgNPs^{aer}$-EPS and **(B)** $AgNPs^{anaer}$-EPS. **(C)** Concentration profiles for (○) $AgNPs^{aer}$-EPS and (●) $Ag\text{-}NPs^{anaer}$-EPS. NPs-EPS bound species. It is interesting to note that the amount of Ag(I) released from $AgNPs^{aer}$-EPS is sensibly higher (4–6 times) than that of $AgNPs^{anaer}$-EPS. These results therefore, once again, confirm that the composition of the AgNPs-EPS materials are differently rich of Ag(I)NPs or Ag(0)NPs.

The concentration profiles of Ag(I) species at the samples samples/solution interface at equilibrium (i.e., at the time where C^b achieved the plateau region, in the present case 30 min) were also evaluated by performing a further series of measurements in which ASVs were recorded at different tip to substrate distances (Fig. 7A,B). Fig. 7C shows concentration against distance plots, and, as is evident, for both samples the amount of Ag(I) species in the solution decreases as the tip-substrate distance increases. For distances greater than 100 μm, the amount of Ag(I) was not detectable under the above ASV conditions. These results, again, support the circumstance that multiple equilibria involving Ag(I)-bound to AgNPs-EPS or sparingly soluble species affect the overall dissolution process. Also in these measurements, the amount of Ag(I) released from $AgNPs^{aer}$-EPS is higher than that of $AgNPs^{anaer}$-EPS.

4. Conclusion

In this work, AgNPs, embedded in an exopolysaccharide matrix, biosynthesised using a *K. oxytoca* BAS-10 strain, have been characterised to establish their chemical properties and reactivity at the sample/solution interface. This information has been gathered by using scanning electrochemical microscopy and voltammetry. This study has proven that Ag(0) or Ag(I) forms are present in the AgNPs-EPS materials and their abundance depends on whether the materials were prepared under aerobic or anaerobic conditions. As expected, Ag(I) forms predominate in the $AgNPs^{aer}$-EPS material, conceivable due to the presence of oxygen, which could promote the oxidation of Ag(0)NPs to provide easier diffusable Ag(I) species. This could imply a potentially higher antimicrobial activity of the $AgNPs^{aer}$-EPS composite. The antibacterial activity of both $AgNPs^{aer}$-EPS and $AgNPs^{aner}$-EPS towards both Gram-positive and Gram-negative bacteria is currently under investigation in our laboratory.

Reversed phase chromatography

ABSTRACT

The enantioselectivity of immobilized β-cyclodextrin phenyl carbamate-based silica monolithic capillary columns was compared to our previously described polymer counterpart. 2,3,6-Tris(phenylcarbamoyl)-β-cyclodextrin-6-methacrylate was used as a functional monomer for the preparation of β-cyclodextrin (β-CD)-based silica and polymer monoliths. The silica monoliths were prepared via the sol–gel technique in fused silica capillary followed by modification of the bare silica monoliths with an anchor group prior to polymerization with β-CD methacrylate using either 2,2′-azobis(isobutyronitrile) or benzoylperoxide as radical initiators. On the other hand, the polymer monoliths were prepared via the copolymerization of β-CD methacrylate and ethylene glycol dimethacrylate in different ratios *in situ* in fused silica capillary. The prepared silica/polymer monoliths were investigated for the chiral separation of different classes of pharmaceuticals namely; α- and β-blockers, anti-inflammatory drugs, antifungal drugs, dopamine antagonists, norepinephrine-dopamine reuptake inhibitors, catecholamines, sedative hypnotics, diuretics, antihistaminics, anticancer drugs and antiarrhythmic drugs. Baseline separation was achieved for alprenolol, bufuralol, carbuterol, cizolertine, desmethylcizolertine, eticlopride, ifosfamide, 1-indanol, propranolol, tebuconazole, tertatolol and *o*-methoxymandelic acid under reversed phase conditions using mobile phase composed of methanol and water. The silica-based monoliths showed a comparative enantioselectivity to the polymer monoliths.

1. Introduction

The interest in chirality and its consequences has risen significantly in the last two decades due to scientific and economic reasons. Chiral drugs constitute approximately one-third of all drug sales worldwide and it is expected that nearly 95% of the pharmaceutical drugs will be chiral by 2020 [1]. This imposed strict regulations in approving new chiral entities that include full documentation of the separate pharmacological, toxicological and pharmacokinetic profiles for the individual enantiomers as well as their racemates (mixture of enantiomers) [2]. Accordingly, pharmaceutical companies are yet shifting toward the development of single pure enantiomer drugs via preparative chiral separation techniques rather than the time-consuming chiral syntheses [3]. This raises the need for a high throughput, robust, reliable, environmentally benign and relatively cheaper separation technique of chiral pharmaceuticals to allow their commercialization [4,5].

Miniaturization of the analytical techniques reduces the total analysis time, reagents consumption and is able to handle small samples. Nano-LC is one of the microfluidic techniques where reduction in both column inner diameter (10–300 μm) and flow rate (200–1000 nL/min) are combined [6]. The advantages of miniaturization also include the reduced cost of the packing stationary phase; this is of particular interest when costly chiral stationary phases (CSPs) are used [7]. However, packing the capillaries with small particles (usually 3–5 μm diameter) require high level of experience because of the need of retaining frits [8]. This problem can be overcome using monolithic materials [9–15].

Silica-based monoliths are prepared by sol–gel process which involves the hydrolysis of a mixture of silane oxides followed by condensation and polycondensation reactions [16]. They have a characteristic bi-continuous structure providing mesopores with high surface area (several hundred square meters per gram) which makes it highly efficient for the separation of small molecules [17]. The polar surface of silica-based monolith renders it useful for normal phase liquid chromatography (NPLC) and hydrophilic interaction liquid chromatography (HILIC). Alternatively, silica skeleton needs to be derivatized to be suitable for reversed phase liquid chromatography (RPLC) [16]. On the other hand, polymer-based monoliths are prepared via the *in situ* copolymerization of

one or more monovinyl monomer with a divinyl cross linker in suitable porogenic solvents (binary or trinary) in a single step process [9]. Free radical polymerization is the common mechanism and the polymer is formed within the capillary to form a continuous porous bed. Polymer monoliths are not only considered for the separation of macromolecules (proteins and peptides) but also for small organic molecules. Remarkable amount of research has been done to increase the surface area of the polymer monolith to ensure adequate separation of small organic molecules [18,19].

The ease and speed of preparation of polymer-based monoliths compared to the technically challenging procedures for silica-monoliths preparation render polymer monoliths an attractive tool in the field of separation science. Nonetheless, polymer monoliths tend to swell or shrink upon exposure to organic solvents compared to silica monoliths, while silica monoliths show lower stability at temperature higher than 60 °C and pH higher than 8.5 compared to the higher temperature and chemical stability of the polymer monoliths. Therefore, both polymer and silica monoliths have their own merits and drawbacks and each of the stationary phases could be tailored to obtain the optimum separation according to the sample nature. To introduce chirality in silica-based monolith, the CS is immobilized on the activated silica skeleton [20] or encapsulated during the sol–gel procedure [21]. On the other hand, to introduce chirality in polymer-based monoliths, the chiral selector (CS) is copolymerized as a functional monomer [22] or immobilized after the monolith preparation [23], [24] in a one pot polymerization procedure or post-polymerization surface modification of reactive groups, respectively [25]. Various classes of CSs are available for enantioselective separation of racemic mixtures, such as, molecularly imprinted polymers, ligand exchange, brush-type, macrocyclic antiobiotics-based, protein/glycoprotein- based, cellulose/amylose derivatives and cyclodextrin (s) derivatives [26–35]. Bonding of β-CD into monoliths has been previously achieved via the copolymerization or post modification approaches. The former is considered a simple and less time consuming compared to the latter. However, due to diversity of monomers precursors, it is time and laborious consuming to prepare different kinds of monolithic columns to establish a robust monolithic backbone. Thus, post modification of raw monoliths with high robustness, tailorability and column efficiency becomes a good alternative [36,37].

The purpose of this study is to compare the enantioselectivity of β-CD-based silica monoliths prepared via the post modification approach to that of β-CD-based polymer monoliths previously prepared via the one pot copolymerization approach [38]. Whether the two approaches would display similar, broader or complimentary chiral discrimination ability is another raised question.

2. Experimental

2.1. Reagents and materials

Benzoyl peroxide (BOP, >97%), ethylene glycol dimethacrylate (EDMA, 98%), 3-(trimethoxysilyl)propyl methacrylate (98%), 1-propanol (99%), 1,4-butanediol (99%), methacryloyl chloride (97%), phenyl isocyanate (>98%), trifluoroacetic acid (TFA, ≥99.5%), sodium hydroxide, toluene, tetramethoxysilane (TMOS), methyltrimethoxysilane (MTMS), poly(ethylene glycol) with molecular weight of 10,000, urea, hydrochloric acid and acetic acid were purchased from Aldrich (Milwaukee, WI, USA). β-Cyclodextrin was purchased from TCA (Tokyo, Japan). Acetone (AR grade), ethanol (HPLC grade) were purchased from BDH (Kilsyth, Vic., Australia). Acetonitrile (HPLC grade) was purchased from Merck (Darmstadt, Germany). Methanol (HPLC grade) was purchased from Scharlau (Sentmenat, Spain). All other reagents were of the highest available grade and used as received. The fused-silica capillaries (100 μm and 150 μm inner diameter) were purchased from Polymicro Technologies (Phoenix, AZ, USA). 2,2′-azobis(isobutyronitrile) (AIBN) was obtained from Wako (Osaka, Japan). (3-Aminopropyl)triethoxysilane, tetrahydrofuran, pyridine and uracil were purchased from Sigma Aldrich (St. Louis, MO, USA). Pyridine and toluene were dried before use over molecular sieves (4 Å) also from Sigma Aldrich (St. Louis, MO, USA), toluene was distilled from calcium hydride (Sigma Aldrich, USA). Tetrahydrofuran was distilled prior to use. Water used for dilutions and experiments was purified by Nanopure Infinity water system (NJ, USA). Racemic analytes were mostly purchased from sigma Aldrich.

2.2. Preparation of the monolithic columns

β-CD functional monomer (Fig. 1) was prepared according to the previously described method [38]. The hybrid-type monolithic silica columns were prepared from a mixture (9 mL) of TMOS and MTMS in a 3:1 ratio, poly(ethylene glycol) (0.9 g), and urea (2.025 g) in 0.01 M acetic acid (20 mL) as described previously [39] resulting in a monolithic silica having through-pore size of 2.0 μm and skeleton size of 1.5 μm. Briefly, TMOS (9 mL) was added to a solution of poly(ethylene glycol) (PEG, 0.9 g, *Mwt*=10,000) and urea (2.025 g) in 0.01 M acetic acid (20 mL) and stirred at 0 °C for 45 min. The resultant homogeneous solution was charged into a fused–silica capillary tube (100 μm ID, Polymicro, AZ), which had

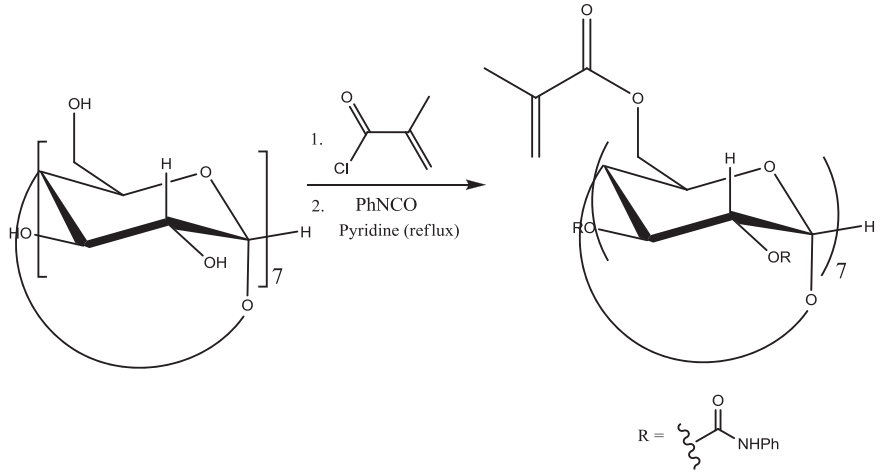

Fig. 1. Schematic diagram showing the preparation of 2,3,6-tris(phenylcarbamoyl)-β-CD-6-methacrylate [38].

been treated in advance with 1 M NaOH solution at 40 °C for 2 h, and allowed to react at 40 °C. Gelation occurred within 2 h, and the gel was subsequently aged in the capillary overnight at the same temperature. Then, temperature was raised, and the monolithic silica column was treated for 4 h at 120 °C to complete the formation of the mesopores with ammonia generated by the hydrolysis of urea, followed by methanol wash. After drying, heat treatment was carried out at 330 °C for 24 h, resulting in the decomposition of organic moieties in the capillary [40]. Usually, 4-m capillary columns were prepared from the same reaction mixture. After preparation, both ends (10–15 cm) of the capillary were trimmed, and several 50-cm long columns were obtained.

Before modification of the surface silanol groups, the monolithic silica capillary columns were evaluated using methanol/water: 80/20 (v/v) as a mobile phase and uracil as the test analyte. The columns exhibited the plate heights in the range of 18–27 μm and a theoretical plate numbers in the range of 16,000–76,000. After the evaluation, the monolithic silica columns were used for modification with 3-methacrylamidopropyltriethoxysilane (MAS) (Fig. 2) followed by polymerization with 2,3,6-tris(phenylcarbamoyl) β-cyclodextrin-6-methacrylate. The anchor group MAS was prepared via previously reported method [41]. *In situ* polymerization of the CS onto the MAS-modified silica surface

Columns were prepared *in situ* as illustrated in Fig. 3; 0.40 μL (0.38 mmol) methacryloyl chloride was added to 0.42 g (0.37 mmol) β-CD dissolved in 9 mL pyridine. The solution was stirred for 6 h at room temperature then 1.9 mL phenyl isocyanate was added and the solution was refluxed for 18 h. 20 mg/mL AIBN or BOP in dioxan was then prepared separately and added to the reaction mixture at a concentration of 0.1 g/mL. The mixture was then filtered through Sartorius Minisart RC 15 0.2 μm pore size filters (Goettingen, Germany), the MAS modified silica columns were then filled with the mixture using a syringe pump or via N_2 gas, the capillaries were placed into 80 °C oven for 24 h to complete the polymerization reaction. Finally the modified columns were washed with dioxan for 24 h and conditioned with the mobile phase prior to use.

The surface modification in fused silica capillaries (150 μm ID) was done by using the same procedure of Schaller et al. [42]. As previously described, only the two permeable polymer-based monolithic capillary columns were prepared via *in situ* copolymerization of binary monomer mixtures consisted of β-CD derived functional monomer and EDMA as a crosslinker along with three porogens namely; 1-propanol, 1,4-butanediol and water in the presence of 1 wt% AIBN (with respect to monomers) [38]. The filled capillaries were then sealed with a septum, placed in 70 °C water bath for 18 h for the polymerization reaction to take place. The unreacted monomers were removed from the monolithic columns by pumping with methanol at a flow rate of 100 μL/h for 4 h before being conditioned with water and mobile phase, both for 1 h at 30 μL/h. Polymer composition in the prepared columns is shown in Table 1.

2.3. Instrumentation

The nano liquid chromatographic system was from Dionex Corporation (UltiMate® 3000 capillary LC system) which featured an integrated flowsplitter connected to a continuously monitored flow meter and control valve to maintain a constant flow rate in the range from 0.1 to 1.0 μL/min. It also comprised a binary pump, a vacuum degasser, an autosampler and a UV detector. The Chromeleon® Chromatography Management System version 7.00 was used for the data processing and control of the HPLC system.

2.4. Standard solutions and sample preparation

Stock solutions of the racemic analytes at concentrations of 1 mg/mL in filtered HPLC grade methanol were prepared. Prior to injection, the stock solutions were further diluted 10× and filtered through Sartorius Minisart RC 15 0.2 μm pore size filters (Goettingen, Germany).

Tested compounds—β-blockers: alprenolol, celiprolol, metoprolol, pindlol, propranolol, acebutolol, carbuterol, bufuralol, tertatolol, atenolol. *α-blockers:* naftopidil. *Antiinflammatory drugs:* ketoprofen, ibuprofen, naproxen, flurbiprofen, indoprofen, cizolirtine, cizolirtine carbinol, carprofen, etodolac, desmethylcizolirtine, glafenine. *Antifungal drugs:* hexaconazole, cyproconazole, tebuconazole, miconazole, diniconazole, sulconazole. *Dopamine antagonists:* eticlopride. *Norepinephrine–dopamine reuptake inhibitor:* nomifensine. *Catecholamines:* arterenol, normetanephrine. *Sedative hypnotics:* aminoglutethimide, phenylglutethimide, *N*-acetylaminoglutethimide, 4-bromogluthethimide, pentobarbital, *p*-hydroxyphenobarbital. *Diuretics:* etozoline. *Antihistaminics:* chlorpheneramine. *Anticancer drugs:* ifosfamide. *Antiarrhythmic drugs:* tocainide. *Miscellaneous:* 1-acenaphthenol, *o*-methoxy mandelic acid, 4-hydroxy-3-methoxymandelic acid, 1-indanol, 1-(2-chlorophenyl)ethanol, 1-phenyl-2-propanol. Chemical structures of the investigated racemates and their suppliers are listed in Table 2.

2.5. HPLC conditions

The mobile phase A and B consisted of 0.1% TFA in water (v/v) and methanol (v/v) or 0.1% TFA in water (v/v) and acetonitrile. For all samples, the injected volume was 0.2 μL. Preliminary UV analyses were performed at several different wavelengths (219–270 nm) for each compound, in order to select the optimum wavelength for all the analytes and best utilise a single wavelength UV detector.

3. Results and discussion

3.1. Silica monoliths: Preparation and characterization

In order to attach the β-CD derivative on silica monolith via the copolymerization approach, surface activation of the bare silica is required. Hence, at the first step of modification, an anchor, *N*-(3-trimethoxysilylpropyl)methacrylamide, was chemically bonded to the silica skeleton at 80 °C. At that temperature, no thermal polymerization of the anchor was detectable by a ^{1}H-NMR measurement of the residue [41]. Surface coverage of the anchor group was evaluated by injecting toluene/benzanilide mixture into MAS-modified capillaries to compare the dead volume (toluene retention) to benzanilide retention time. Columns showed retention

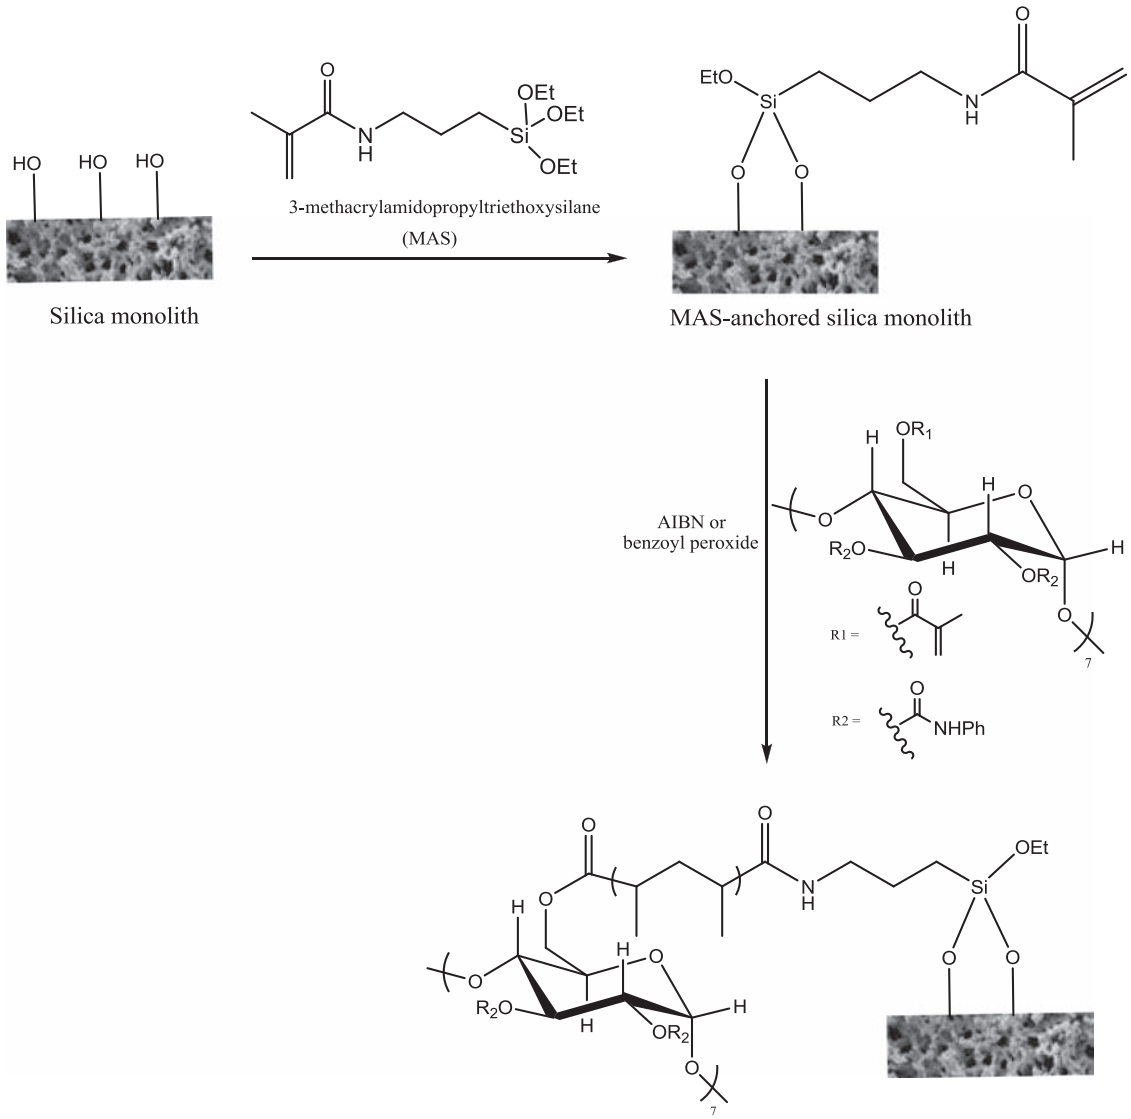

Fig. 3. Schematic diagram for the preparation of β-cyclodextrin-modified silica monolith.

Table 1
Polymer composition in the prepared monoliths [38].

Entry	β-CD monomer (wt%)	EDMA (wt%)	1-Propanol (wt%)	1,4-Butanediol (wt%)	Water (wt%)
A1	10	30	48	6	6
A2	20	20	48	6	6

factors in the range of 1.5–2 were used for the β-CD copolymerization to ensure optimum coverage of the chiral selector. SEM was used to examine anchor-modified silica monoliths for agglomeration of the silane solution during modification. Fig. 4 shows SEM of the silica monolith before (left) and after (right) MAS modification. The capillaries showed homogenous porous structure (Fig. 4).

3.2. Polymer monoliths: Preparation and characterization

For comparison purposes, the previously described polymer monoliths [38] were prepared via *in situ* copolymerization of 2,3,6-tris(phenylcarbamoyl)-β-CD-6-methacrylate as a functional monomer and EDMA as a cross linker in the presence of ternary porogenic system composed of 1-propanol (48%), 1,4-butanediol (6%) and water (6%) (Fig. 5). While the porogen composition was kept constant, the ratio of the functional monomer to the cross linker was varied in attempt to study the effect of CS concentration and column porosity on the enantioselective separation of rcaemates (Table 1).

SEM for A1 and A2 showed homogenous porous structures with interconnecting channels allowing the flow of mobile phase under low column backpressure (Fig. 6).

3.3. Enantioseparation of different classes of pharmaceutical racemates using silica- and polymer-based monoliths

Four columns; AIBN, BOP, A1 and A2, were investigated for the enantioselective nano liquid chromatographic separation of a set of different classes of racemic pharmaceuticals namely: β-blockers, α-blockers, antiinflammatory drugs, antifungal drugs, dopamine antagonists, norepinephrine-dopamine reuptake inhibitors, catecholamines, sedative hypnotics, diuretics, antihistaminics, anticancer drugs and antiarrhythmic drugs. The choice of compounds was arbitrary and guided by our previous investigations [25,38]. A mobile phase composed of acetonitrile and water mixture ranged from 10 to 90% (v/v) was initially tested for the enantioselective separation. No enantioselective separation was observed under

this condition. However, when aqueous methanol-based mobile phase was used, baseline separation ($Rs \geq 1.5$) was achieved for propranolol **7**, ifosfamide **39**, alprenolol **1**, tertatolol **4**, 1-indanol **47**, tebuconazole **25**, *o*-methoxymandelic acid **46**, celiprolol **2**, cizolirtine **21** and eticlopride **29** while acceptable resolution (*Rs* 1–1.5) was achieved for diniconazole **27**, ketoprofen **12**, metoprolol **6**, desmethylcizolertine **20**, carbuterol **3**, normetanephrine **42** and 6-hydroxyflavanone **44**. Separation (α) and resolution (*Rs*) factors for the baseline/acceptable resolved compounds are listed in Table 3 (cf. Table 3). Comparative chromatograms showing the enantioselective separation on polymer monoliths (A1 and A2 columns) *vs* silica monoliths (AIBN and BOP columns) are also shown in Figs. 7–10. It is worth pointing out that some analytes were resolved on either of the polymer (A1/A2) or silica (AIBN/BOP) monoliths. It was also observed that the silica-based monoliths showed broader enantioselctivities toward diverse chemical

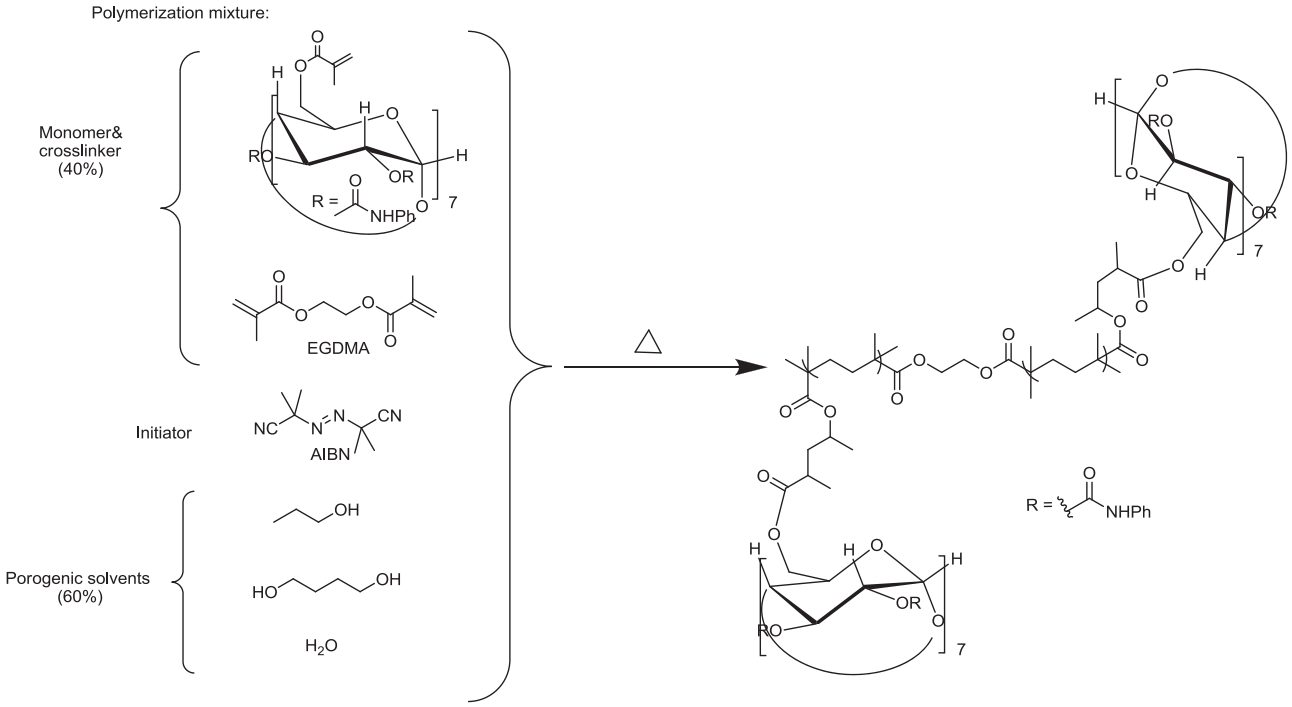

Fig. 5. Schematic diagram showing the preparation of β-CD functionalized polymer monolith [38].

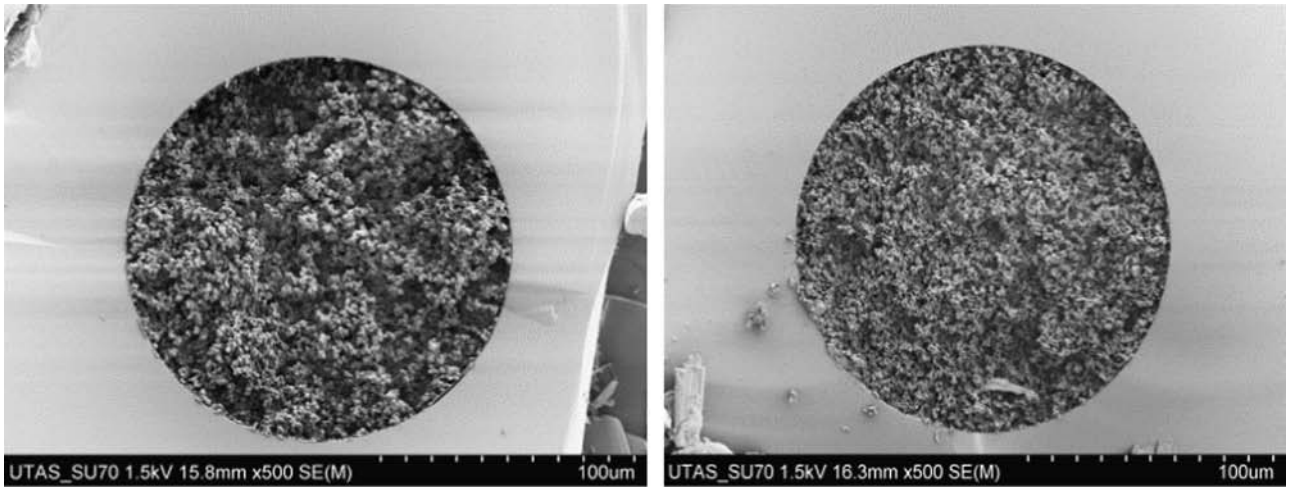

Fig. 6. Scanning electron micrograph of A1 (left) and A2 (right) at 500 × showing homogenous porous monolithic structure [38].

classes of pharmaceutical racemates for example polyhalogenated aromatics such as miconazole **26** and aromatic amides such as eticlopride **29** (Figs. 11 and 12, respectively). Interestingly, the sympathomimetic arternol **41** and its metabolite normetanephrine **42** were acceptably resolved using the silica-based β-CD columns (Figs. 13 and 14) which was not achievable using the polymer monoliths.

It is worth mentioning that the enantioselective separation was achieved under reversed phase conditions which allow the use of less costly solvents and provide easier sample preparation from serum or plasma [43]. Moreover, it eliminates the use of health hazardous solvents such as *n*-hexane. The capillary columns prepared in this study are 10,000 less in internal diameter and operate with one million time less solvent volume than the conventional columns. Consequently, they consume less solvent and produce faster and reproducible separations.

3.4. Insights into the chiral recognition mechanism

The prediction of the chiral recognition mechanisms of CSPs has mainly been based on empirical rules or speculations due to the complexity of the enantioselective separation [44]. Racemates of homologous series of closely related chemical structures tend to interact differently with the chiral selectors resulting in large differences in both enantioselectivities and elution order [45]. It is well established that CDs form transient diastereomeric inclusion complexes with enantiomers by means of the cavity under reversed phase chromatographic conditions. Additionally, derivatization of the external rim hydroxyl groups affords CD derivatives with higher solubility and variable cavity depth with multiple interaction sites [8]. Phenyl carbamate derivatives have been widely explored for the enantioselective separation, their enantioselectivity can be further modulated by introduction of groups

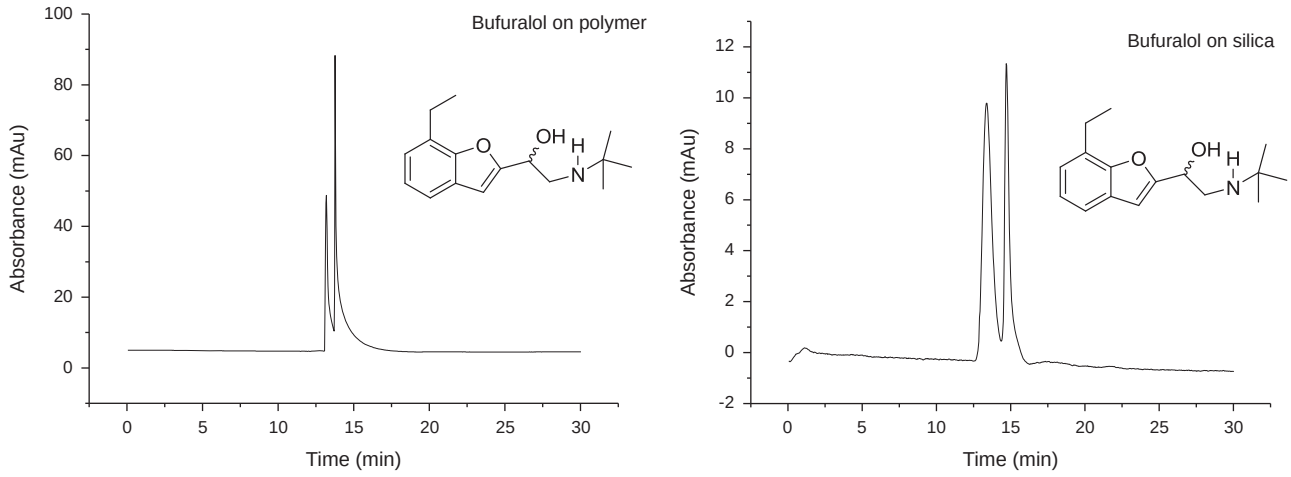

Fig. 7. Enantioselective nano-LC separation of bufuralol: Left: on A1 capillary column (150 μm ID, 25 cm length). Mobile phase: methanol/water (0.1% TFA) 10:90 v/v, UV: 270 nm, flow rate: 0.3 μL/min, Right: BOP capillary column (100 μm, 15 cm), mobile phase: methanol/water (0.1% TFA) 80:20 v/v.

with different electronic effects on the phenyl ring. This suggests that the most important adsorbing sites for the chiral discrimination of on phenyl carbamate derivatives is the polar carbamate group [46]. As demonstrated from testing 50 racemates from different chemical and pharmaceutical classes on four 2,3,6-tris (phenylcarbamoyl)-β-CD-based CSPs, 7 out of the 11 baseline resolved racemates were for chiral centers with secondary alcohols with adjacent electronegative nitrogen bearing alkyl side chain; this underlines the importance of these groups in providing three points of interactions which is required for the chiral recognition as the side chain on the chiral carbon is also thought to be concerned in the chiral recognition mechanism [47]. We postulate that the chiral separation was achieved via the formation of hydrogen bond-stabilized inclusion complexes within the β-CD cavity and the carbamate moiety. It was also observed that the enantioselective separation was mostly achieved at high water content mobile phase; this indicates that water improved the magnitude of interaction between the racemates and the CSP. Aqueous mobile phases allow the inclusion of the whole molecule or just its lipophilic part into the hydrophobic cavity of CD, it has been previously reported that the resolution of this kind of CSP is improved by increase in water content [47]. Interestingly, mobile

phase composed of mixture of acetonitrile and water in the range of 10–90% v/v did not furnish any enantioselective separation. On the other hand, when methanol-based mobile phase was used, enantioselective separation was observed; this underlines the importance of solvent polarity in determining retention and chiral separation mechanism in terms of the inclusion complex stability.

It was also demonstrated that the monolith backbone did not play a major role in the chiral separation as mostly the same racemates were resolved on silica or polymer backbone. It is worth

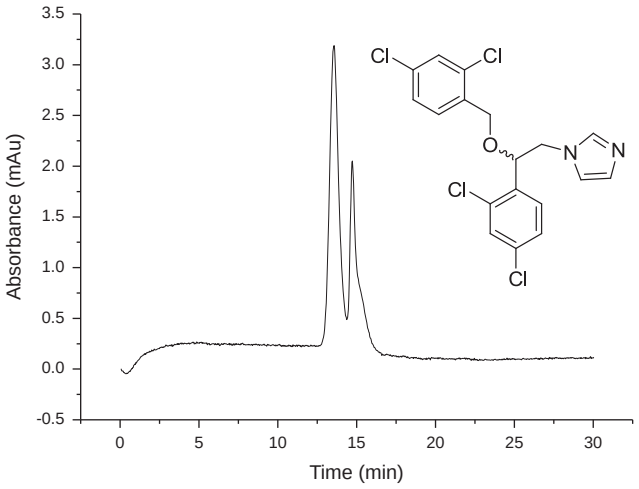

Fig. 11. Enantioselective nano-LC separation of miconazole on BOP capillary column (100 μm, 15 cm), mobile phase: methanol/water (0.1% TFA) 80:20 v/v, UV: 240 nm, flow rate: 0.3 μL/min.

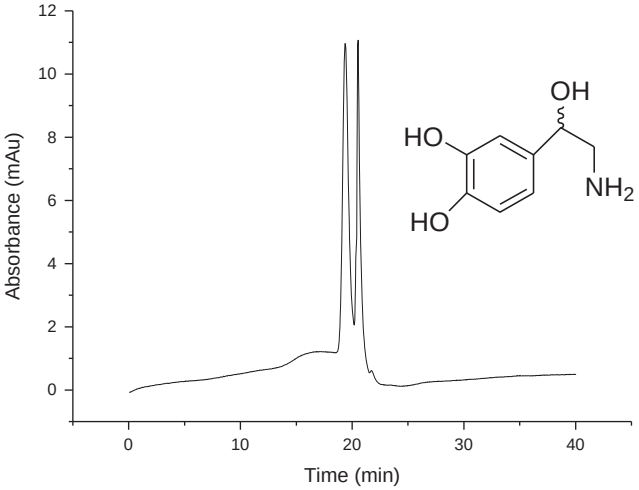

Fig. 13. Enantioselective nano-LC separation of arterenol on AIBN capillary column (100 μm, 25 cm), mobile phase: methanol/water (0.1% TFA) 15:85 v/v, UV: 219 nm, flow rate: 0.5 μL/min.

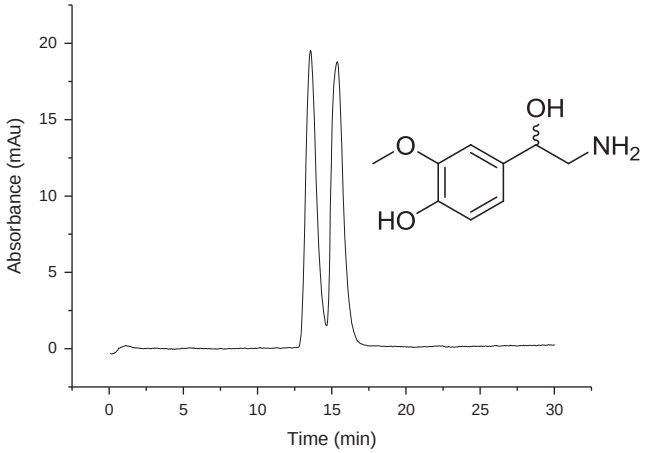

Fig. 14. Enantioselective nano-LC separation of noremetanephrine on BOP capillary column (100 μm, 15 cm), mobile phase: methanol/water (0.1% TFA) 85:15 v/v, UV: 219 nm, flow rate: 0.3 μL/min.

mentioning that polymer monoliths are of smaller surface area and bigger pore size compared to the silica monolith and this had affected the retention times of the racemates but not the enantioselectivity.

4. Conclusions

New β-CD-based CSPs were prepared via the copolymerization of β-CD methacrylate either in one pot or post modification approaches. The prepared columns were investigated for the enantioselective separation of racemates from twelve pharmaceutical classes. β-CD-based silica monolithic capillary columns displayed broader enantioselectivities, nonetheless, the polymer monolith is less time consuming and can be easily reproduced compared with the technically challenging silica monolith preparation. With further option of variation of the porogens/functional monomers ratio composition, tailoring of polymer skeleton will be possible for each separation problem which is still a time consuming process. The enantioselective separation was conducted under reversed phase conditions which augments the environmentally benign nano-liquid chromatographic separations.

Flow-through immunoassay

ABSTRACT

Here we present a new and rapid immunofiltration assay for simultaneous detection of HIV p24 and hepatitis B virus antigens. The assay platform is composed of a 13 mm nitrocellulose filter spotted with capturing bioprobes and inserted in a Swinnex® syringe filter holder. Samples and reagents are flown through the nitrocellulose filter by manual pressure on the syringe. A colorimetric detection allows for naked eye results interpretation. The assay provides sensitivity in the picomolar range in just 5 min, even using low volumes of sample in complex matrix. Probe deposition by spotting allows for flexible combinations of different capturing agents and multiple diagnoses; furthermore, the very simple and inexpensive set-up makes the syringe-based immunoassay on paper microarray a suitable diagnostic system for resource-limited settings.

1. Introduction

Conventional and standard methods for pathogen detection include cell culture, PCR and enzyme immunoassays, which are often laborious, require well-equipped dedicated laboratories and take from several hours to several days to perform. Conversely, increased access to diagnostic products requires the development of tests that can be used in remote areas (with no or minimal laboratory infrastructures) by people with little or no laboratory training and that meet the ASSURED criteria [1]. Ideally, for these applications, the detection platform should be simple to use and interpret, stable under a wide range of operating conditions (such as temperature and humidity), portable, disposable and able to perform multiplex tests. Many attempts have been focused on the development of tests based on microfluidic immunoassays targeted at low resource settings (LRSs) [2–4]. However, only a few are complete sample-to-result systems capable of testing blood samples [5–8]. Lateral flow tests (LFTs) may be seen as the gold-standard microfluidic platform in terms of cost, handling simplicity, robustness, market presence and number of lab-on-a-chip applications [9]. The amount of sample and the reagent consumption are moderate, and the concept is mainly used for qualitative and semi-quantitative assays, intended for untrained users. However, the simplicity of LFT is also its main drawback. Assay protocols within capillary driven, flow-through cellulose strips follow a fixed process scheme with limited number of unit operations. Moreover, the highly precise liquid handling and metering is extremely challenging. Other severe drawbacks of LFTs lie in the fact that multiple screening applications, though possible, are difficult to implement.

In LFTs, samples flow in a horizontal direction through a nitrocellulose (NC) membrane towards the adsorbent pad. The horizontal flow causes three major limitations [9,10]: assay time (determined by NC flow rate), "hook effect" (interference due to excess of antigen) and line interference, which makes it difficult to use multiple lines due to the front-line reaction interfering with the behind-line reaction. In immunofiltration assays, the sample and reagents are filtered sequentially through a porous membrane containing spots or lines of capturing antibodies. Succesful examples of immunofiltration assays for detection of small molecules were demonstrated for methamphetamine [11] and the herbicide simazine [12] using water-soluble polyelectrolytes as carriers for the assay reactants. Though highly sensitive, the proposed assays detect only single analytes.

Multiplexed flow-through immunoassays were developed for IgM and antigens specific to *Salmonella typhi* using a 96 well plate connected to a vacuum manifold [13] and a microfluidic cartridge driven by a pneumatic system [14]. Recently, a vertical flow immunoassay was introduced [9] simply by vertically stacking all the components of an LFT, resulting in the detection of C-reactive protein (CRP) concentrations from 0.01 to 10 μg/mL in 2 min. An immunoflow protein platform that actively pumps the sample through an NC membrane was developed, demonstrating detection by fluorescence of 1 pM CRP. Comparing the flow assay to protein microarrays with

conventional incubation by shaking method the rate of binding is increased by a factor of 10, allowing reduction of assay time without compromising sensitivity. However, all of the above cited works use external actuators like vacuum manifolds or pumps to flow liquids through the membranes.

Here we present a new and rapid immunofiltration assay, suitable for LRSs, for simultaneous detection of HIV p24 and hepatitis B virus (HBV) antigens with sensitivity in the picomolar range. The assay platform is composed of a 13 mm nitrocellulose filter spotted with capturing bioprobes and inserted into a Swinnex® syringe filter holder. Samples and reagents are flown through the nitrocellulose filter by manual pressure on the syringe; alternatevely, liquids can be actuated by a programmable syringe pump. A colorimetric detection enables naked eye results interpretation. Probe deposition by spotting allows for flexible combinations of different capturing agents and multiple diagnosis; furthermore, the very simple and cheap set-up make the syringe-based immunoassay on paper microarray a suitable diagnostic system for resource limited settings.

2. Materials and methods

2.1. Materials

Several filter papers were evaluated: Nitrocellulose Protran BA85 (0.45 μm porosity), Protran BA83 (0.20 μm porosity), PVDF Westran S (0.20 μm porosity) and Westran CS (0.45 μm porosity) from Whatman (GE HealthCare Europe GmbH, Milano, Italy) nitrocellulose BioTrace NT-Blotting, Biotrace NT-transfer (0.20 μm porosity) and PVDF-transfer (0.45 μm porosity) were from Pall Corporation (Pall Italia SRL, Milano, Italy). Biotrace NT-transfer (0.20 μm porosity) was selected for bioassay development. Swinnex® filter holders were from Millipore (Merck KGaA, Darmstadt, Germania). Luer-lok syringes were purchased from Becton Dickinson and Company (Becton Dickinson Italia, Milano, Italy). PBS (phosphate buffered saline), trizma base, bovine serum, tween 20, BSA (bovine serum albumin), and streptavidin–alkaline phosphatase from *Streptomyces avidinii* were purchased from Sigma (St. Louis MO). NBT/BCIP stock solution was purchased from Arrayit Corporation (Sunnyvale CA). HIV p24 antigen, hepatitis B virus (HBV) superficial antigen, corresponding capture and detection biotinilated-antibodies were kind gifts from Dia.Pro., Milano, Italy. The antibody pairs for sandwich immunoassays of HIV p24 and HBV antigens are mouse monoclonal antibodies providing limits of detection in the low pg/mL range when used in proprietary ELISA tests commercialised by Dia.Pro.

2.2. Spotting protocols

Capture antibodies for HIV p24 antigen and hepatitis B superficial antigen (1 mg/mL in PBS) were spotted on Biotrace-NT membranes using a SciFlexArrayer S5 spotter from Scienion (Berlin, Germany). For each replicated spot, 20 droplets (400 pL each) were deposited using a dot-pitch of 800 μm. Streptavidin–alkaline phosphatase (1 U/mL) was spotted as the positive control, and anti-α lactalbumin antibody was used as the negative control. After overnight binding, membranes were washed with PBS and passivated by BSA 2% w/v in PBS for 1 h.

2.3. Incubation protocols

The membranes were inserted on a 13 mm diameter Swinnex® syringe filter holder. Samples containing a mixture of HIV p24 antigen and HBV superficial antigen (HBV-SAg) at different concentrations from 0 to 50 ng/mL either in incubation buffer (Tris/HCl 0.05 M, pH 7.6, NaCl 0.15 M, Tween 20 0.02% w/v, BSA1% w/v) or in pure bovine serum were manually injected through the spotted membranes for 45 s. The sample was then allowed to stay in contact with the membrane for a total incubation time of 5 min. The membranes were then washed with 2 mL washing buffer (0.05 M Tris/HCl, pH 9, 0.25 M NaCl, 0.05% *v*/*v* Tween 20) and 2 mL PBS and then incubated for 10 min with a mixture of biotinylated detection antibodies for HIV p24 antigen and HBV-SAg (1 μg/mL each in incubation buffer) followed by colorimetric detection.

2.4. Colorimetric reaction and detection/quantification protocol

For colorimetric development, the arrays were incubated with streptavidin–AP, 0.1 U/mL in PBS for 10 min at room temperature and washed with PBS. They were then incubated in dark with an NBT/BCIP stock solution in 10 mL Tris–HCl, 0.1 M, pH 9.5 and 0.1 M NaCl for 10 min at 37 °C to speed up the colorimetric reaction and then washed with water. Room temperature incubation for 20 min provides similar results.

The results were visible with naked eye. Pictures of the arrays were taken using a stereo-microscope equipped with a Nikon SMZ 1500 camera and the Infinity Capture software from Lumenera Corporation. ImageJ software was used to analyse the images as follows: luminosities of spots and background were evaluated through the “Measure” function designing circular areas whose colour intensity was calculated by subtracting the backgroud around the spots. The relative intensity (*RI*) of the signals corresponding to the analytes and reported in the graphs was then calculated with the equation

$$RI = (A - N)/P$$

where *A* is the average intensity of analyte corresponding to spots; *N* is the average intensity of negative control spots and *P* is the average intensity of positive control spots. The relative intensities of 6–8 replicate spots were averaged.

2.5. Determination of the limits of detection

For detection limit experiments, the membranes were incubated with a mixture of HIV p24 and HBV-SAg at 100, 50, 20, 5, 2, 1, and 0 ng/mL in PBS or pure bovine serum. The membranes were then incubated with a mixture of biotinylated detection antibodies for HIV p24 and HBV-SAg followed by colorimetric detection and quantification as described above. Calibration curves (dose–response curves) were generated using a three-parameter equation in the OriginLab software. The detection limit was defined as the analyte concentration corresponding to a signal 3 times the standard deviation (SD) above the background signal as calculated from the linear range of the calibration curves.

3. Results and discussion

3.1. Selection of the porous membrane

Seven types of porous membranes, commonly used for western blotting, were tested to perform a colorimetric microarray assay for the detection of HBV superficial antigen (HBV-SAg) as described in Section 2. Relative intensity (*RI*) of spots was detected for a blank sample and for 10 ng/mL HBV-SAg. Fig. 1 reports the quantification of the average intensity of spots and the pictures of the microarray test for 10 ng/mL HBV-SAg performed on different membranes. The Pall nitrocellulose BioTrace membrane with a porosity of 0.2 μm was selected as the object of this study based on the higher intensity of signals, better morphology of spots and lower background intensity.

3.2. Operational set-up

The assay set-up is depicted in Fig. 2. It is composed of a 13 mm diameter nitrocellulose filter spotted with bioprobes inserted in a Swinnex® syringe filter holder. Probe deposition by spotting allows for flexible combinations of different capturing agents and multiple diagnose on the same filter. The sample and the reagents of a sandwich immunoassay are flown through the nitrocellulose filter by manual pressure; alternatively, liquids can be actuated by a programmable syringe pump. After removing the filter from the syringe, a colorimetric detection enables naked eye results interpretation and/or analysis by a camera. This assay set-up differs from available point-of-care platforms in that it is a combination of microarrays and immunofiltration allowing multiplex colorimetric detection of viral antigens in a short assay time. Due to the filtration process, the mass transfer of analytes and reagents to the immobilised antibodies is very efficient, resulting in an assay time of only 5 min (the sample is pushed through the filter for 45 s, and allowed to stay in contact with the membrane for 4 min more). Microarraying probes allow for flexible combinations of different capturing agents and multiple diagnosis. Furthermore, the sequential manual application of assay reagents, the naked eye visible results and the very simple and inexpensive set-up make the syringe-based immunoassay on paper microarray a suitable diagnostic system for resource limited settings.

3.3. Optimisation of sample volume

In order to verify the effect of sample volume on the sensitivity, the assay for the detection of HIV p24 antigen was performed by pushing through the membrane 0.5, 1.0 and 1.5 mL of sample and

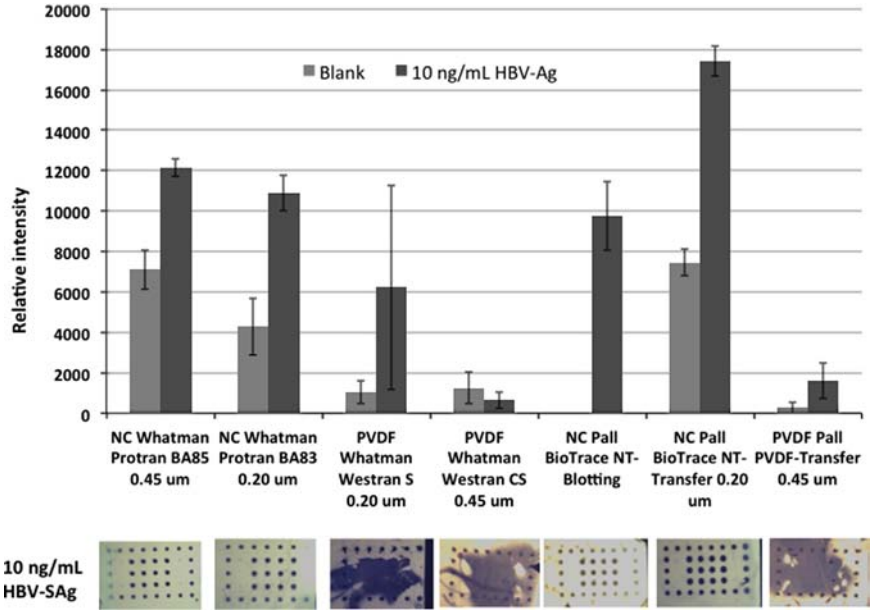

Fig. 1. Microarray test for the detection of HBV superficial antigen performed on seven types of porous membranes, commonly used for western blotting. Relative intensity of spots was detected for a blank sample and for 10 ng/mL HBV-SAg on the central 4×4 array surrounded by an 8×5 frame array as the positive control (streptavidin conjugated to alkaline phosphatase). Lower panel: pictures of the microarray test for 10 ng/mL HBV-SAg performed on the different membranes. The Pall nitrocellulose BioTrace membrane with a porosity of 0.2 μm was selected as the object of this study based on the higher intensity of signals, better morphology of spots and lower background intensity.

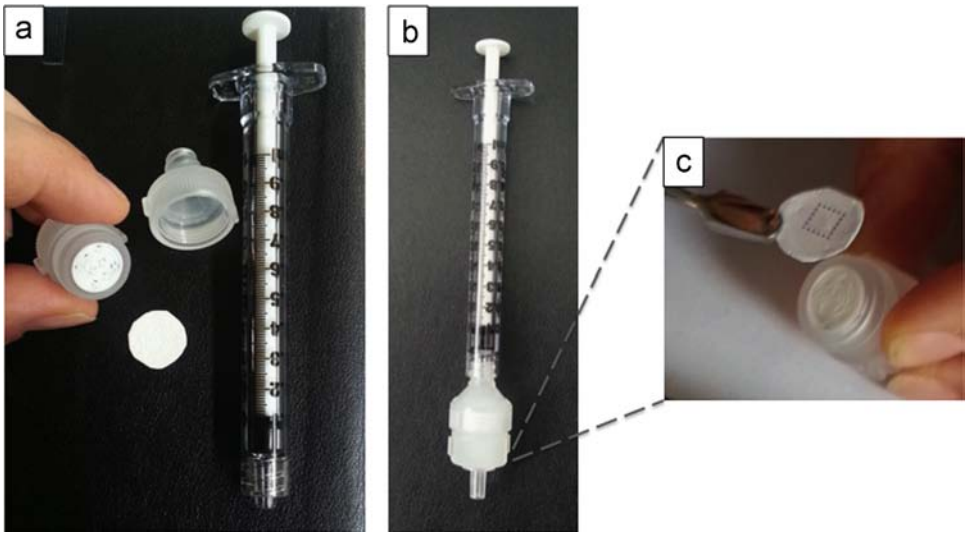

Fig. 2. (a) The assay set-up is composed of a 13 mm nitrocellulose filter spotted with bioprobes and inserted into a Swinnex® syringe filter holder; (b) sample and reagents of a sandwich immunoassay are flown through the nitrocellulose filter by manual pressure; and (c) colorimetric detection allows for naked eye results interpretation.

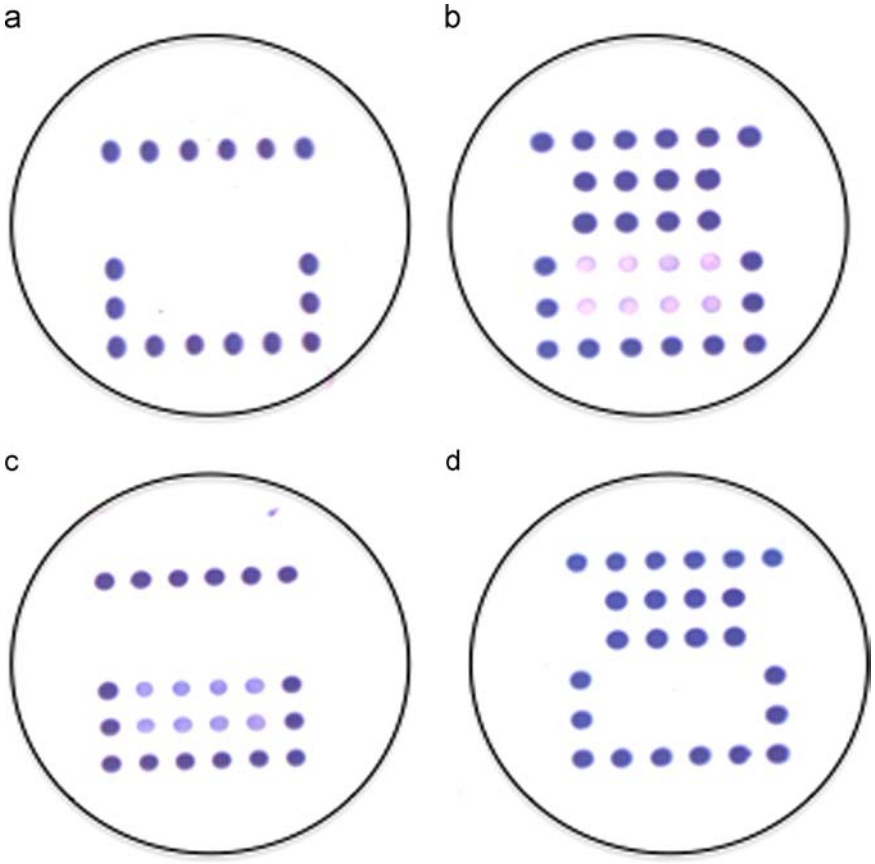

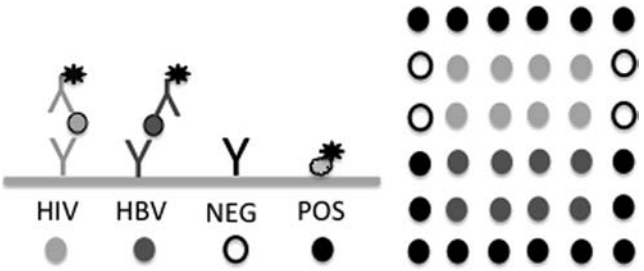

Fig. 3. Detection of HIV p24 antigen (concentrations ranging from 0 to 50 ng/mL) when using different sample volumes: 20 μL, 0.5, 1 and 1.5 mL. The average relative intensity of spots is reported.

Table 1
Limits of detection (LOD) of HIV p24 antigen when using different sample volumes. The assay was performed as described in Section 2.

Sample volume (mL)	0.02	0.5	1	1.5
LOD p24 (ng/mL)	2.79	2.64	0.67	0.42

allowed to stay in contact for an additional 4 min. Furthermore, an experiment was performed using only 20 μL of sample deposited by a pipette and incubated on the membrane for 5 min. Several concentrations of antigen spiked in the buffer were tested (0, 1, 2.5, 5, 10 and 50 ng/mL) in order to determine the limits of detection (LODs) in each of the tested conditions. After incubation with a mixture of the AP-labelled detection antibodies, naked eye visible microarrays were developed by colorimetry for easy detection of the spots. Fig. 3 reports the average relative intensity obtained for each antigen concentration when the four volume amounts were used. A common trend is clearly observable: the larger the sample volume used, the higher the intensity detected in almost every condition. The LODs for HIV p24 antigen using the different sample volumes were calculated as described in Section 2 and are reported in Table 1. The minimum amount of sample used, 20 μL, resulted in a LOD of 2.79 ng/mL whereas the maximum amount of volume tested, 1.5 mL, provided a LOD of 0.42 ng/mL. Provided the assay is not limited by the amount of capturing probe, we observed that keeping the incubation time constant, the higher the volume tested, the better the sensitivity performance. However, the higher LOD of the smaller volume test remains a remarkably low LOD; therefore, the sample volume in the flow through assay can be adjusted, depending on the type of test, to use the minimum sample amount to reach the required sensitivity.

Scheme 1. Spotting scheme. A sandwich immunoassay for the diagnosis of HIV and HBV co-infection is carried out by spotting monoclonal capturing antibodies for HIV p24 antigen and HBV superficial antigen (HBV-SAg); negative control is a non-correlated antibody and positive control streptavidin labelled by alkaline phosphatase (AP). The presence of HIV p24 and HBV-SAg in the sample is detected by biotin-labelled monoclonal detection antibodies and revealed by AP–streptavidin in a colorimetric, naked eye visible microarray.

3.4. Co-infection assay format

Monoclonal capturing antibodies for HIV p24 and HBV-SAg were spotted on the membrane as reported in Scheme 1; a non-correlated capturing antibody is used as negative control whereas streptavidin conjugated to alkaline phosphatase (AP) is the positive control. A scheme of the sandwich immunoassay is reported in Scheme 1. Section 2 reports the optimised assay conditions that were chosen in order to minimise assay time and reagent consumption while keeping the sensitivity performance high. In the first assay step, the sample (500 μL) is manually pushed through the filter in 45 s and allowed to stay in contact with the membrane for 4 min with a total incubation time of less than 5 min. Injection velocity (11 μL/s) and total incubation time were

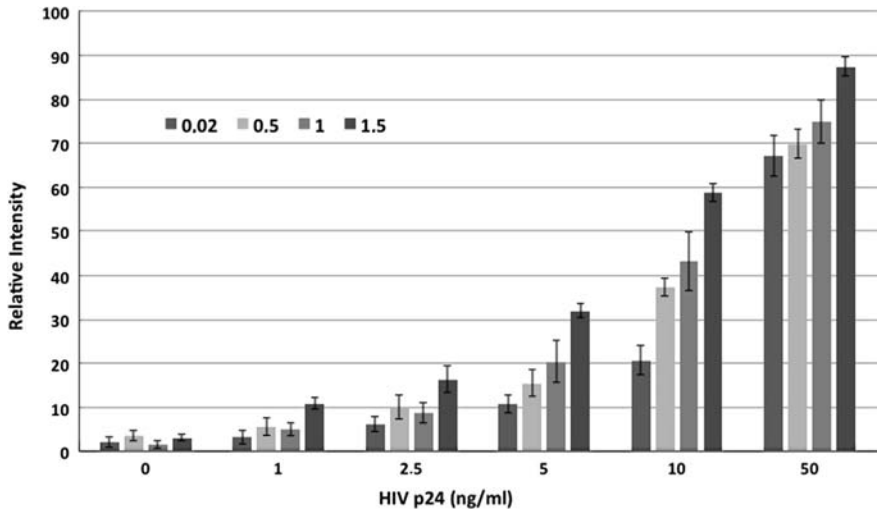

Fig. 4. Pictures of the paper array after colorimetric assay. (a) Detection of blank sample; (b) detection of 10 ng/mL HIV p24 and 10 ng/mL HBV-SAg; (c) detection of 10 ng/mL HBV-SAg and (d) detection of 10 ng/mL HIV p24.

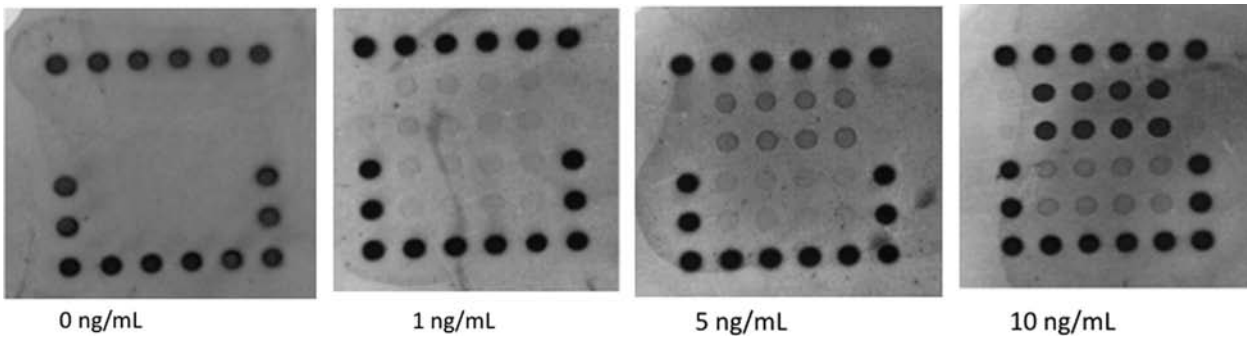

Fig. 5. Pictures of the flow through assay for detection of HIV p24 and HBV-SAg at 0, 1, 5 and 10 ng/mL performed in pure bovine serum. Spots corresponding to the detection of 1 ng/mL are distinguishable from the blank. The assay provided a limit of detection of 0.95 ng/mL for HIV p24 and 1.12 ng/mL for HBV-SAg in 5 min incubation when 1 mL of sample was used.

optimised to strike a balance among ease of manual operation, sample volume consumption, total assay time and performance. After incubation with a mixture of the AP-labelled detection antibodies, naked eye visible microarrays are developed by colorimetry for easy detection of viral antigens resulting in co-infection diagnosis. Typical results are shown in Fig. 4, where detections of a blank sample (Panel a) and a mixture of 10 ng/mL of HIV p24 and HBV-SAg (Panel b) are shown. Panels (c) and (d) show the detection of 10 ng/mL HBV-SAg and HIV p24 antigen respectively. The assay described above was performed using a mixture of 0, 1, 2.5, 5, 10 and 50 ng/mL HIV p24 antigen and HBV-Sag; the co-infection assay resulted in a limit of detection of 1.27 ng/mL for HIV p24 and 2.21 ng/mL for HBV-SAg. Considering a molecular weight of 24 kDa for the HIV p24 antigen and 98 kDa for the HBV-SAg, the limits of detection obtained with 500 μL sample and 5 min incubation are 90 pM for HIV p24 and 13 pM for HBV-SAg.

The effects of a real sample matrix on the membrane background and sensitivity were investigated performing the assay on a bovine serum in which different concentrations of antigens were spiked. Specifically, the assays were performed using a mixture of 0, 1, 2.5, 5, 10 and 50 ng/mL HIV p24 antigen and HBV-SAg spiked in pure bovine serum; 1 mL of serum was incubated for 5 min and the assay was performed as described in Section 2. Fig. 5 reports the pictures of the assay performed at 0, 1, 5 and 10 ng/mL. Spots corresponding to 1 ng/mL antigens spiked in the bovine serum are clearly distinguishable from the blank sample in accordance with the limits of detection provided by the test: 0.95 ng/mL for HIV p24 and 1.12 ng/mL for HBV-SAg. Despite the higher background found when using serum the limits of detection are in the picomolar range even using a complex matrix, thus demonstrating the applicability of the flow through assay in real samples.

4. Conclusions

In the context of pathogen detection, a recurring challenge is to diagnose the diverse co-infections that account for a significant fraction of HIV-associated morbidity and mortality [14]. Standard care at the time of HIV diagnosis includes testing for related opportunistic infections such as those caused by hepatitis C virus (HCV) and hepatitis B virus (HBV) [15]. These multiple diagnoses typically require extensive use of serological diagnostic tools, often in diverse formats, costly and functionally too complex for most LRSs where disease burden is high. The ability to rapidly and inexpensively discriminate HIV mono-infections from more complex co-infections using a simple platform would be a significant advance in the field [16]. A sensitive and multiplex rapid test for HIV co-infection diagnostics would be useful in mobile clinics, correctional facilities, displaced population camps, counselling centres and for immigrant screening, to name a few highly burdened LRSs. Furthermore, military personnel and medical professionals in pre-hospital trauma management require multiplexed tests for use in emergency screening for transfusion transmitted diseases (where no FDA-approved donor screening tests are available) to mitigate risk when emergency blood collections are necessary in austere environments. A microarray for multiplexed detection of HIV p24

and HBV superficial antigen has been recently developed leading to LODs of 54 pg/mL and 45 pg/mL respectively [17]. However, the assay uses silicon chips and a fluorescence scanner for detection with a sample incubation time of 2 h. On the contrary, the flow-through assay presented here, due to manual sequential application of reagents, naked eye visible results and the very simple and cheap set-up makes the syringe based immunoassay on paper microarray a suitable diagnostic system for RLSs. Furthermore, microarraying probes allow for flexible combinations of different capturing agents to develop multiple diagnosis dedicated to specific disease burden.

ABSTRACT

A microfabricated three-electrode on-chip device with a vibration motor for stripping voltammetric detection of Cd^{2+} and Pb^{2+} ions is introduced. Gold electrodes on a glass substrate are utilized as the counter electrode directly, as well as the working electrode with bismuth coating. The reference electrode is achieved by painting silver/silver chloride layer on the gold layer. Polydimethylsiloxane (PDMS) cover is bonded onto the glass substrate, organizing a compact module. A vibration motor in the device provides vibration as the alternate for stirring to improve detection limits and decrease deposition time. Cyclic voltammetry (CV) is performed with the on-chip reference electrode and a commercial liquid electrolyte Ag/AgCl electrode, showing that the potential shift is less than 20 mV. Differential pulse stripping voltammetry (DPSV) is used to detect Cd^{2+} and Pb^{2+} ions. Linearity is well defined from 10 μg/L to 80 μg/L for both ions. Detection limits for Cd^{2+} and Pb^{2+} ions are 0.7 μg/L and 1.2 μg/L, respectively, at 325 s deposition without vibration; the limits are 0.11 μg/L and 0.25 μg/L at 120 s deposition with vibration. The reliability is verified by detecting Cd^{2+} and Pb^{2+} concentrations of natural water samples and comparing with the results obtained from inductively coupled plasma mass spectrometry (ICP-MS).

1. Introduction

Heavy metal ions, such as Cd^{2+}, Pb^{2+} and Cu^{2+}, cannot be metabolized in vivo, and they stay in the ecological system [1]. Due to their toxicity and cumulative behaviors, they are of considerable ecological hazard and detrimental effect on human health [2]. Atomic absorption spectrometry (AAS) and inductively coupled plasma mass spectrometry (ICP-MS), which have good precision, high sensitivity and low detection limits, are two typical methods to monitor concentrations of heavy metal ions in the laboratory. However, they are expensive and not suitable for field application because of their complex operations and complicated reagent preparations [3,4].

Electrochemical methods, such as stripping voltammetry, are extensively applied for field measurements of heavy metal ions due to their sensitivity, selectivity, portability and low cost [5,6]. In electrochemical detection, the working electrode often performs an important role because all the reactions occur on its surface. Electrodes with mercury film are often utilized as working electrodes in stripping voltammetry. However, due to the application of highly toxic mercury, new potential pollution will take place [7].

Nowadays there are a number of studies on mercury-free microfabricated electrodes, whose range include new electrode material, novel structure, module package and disposable application [8,9]. In contrast to traditional electrodes, the microfabricated electrodes have special advantages such as increase of mass transport, high signal-to-noise ratio, low cost and good uniformity [10]. Therefore, microfabricated electrodes with different types, such as micro-wire electrode, metal-film electrode and screen-printed electrode, have been applied to detection of heavy metal ions [11,12]. Among the microfabricated electrodes mentioned above, the electrodes with bismuth modification play an important role and are recognized as one of the most powerful tools in heavy metal ion analysis [13]. In brief, two main strategies are often adopted in preparing bismuth-modified electrodes: simultaneous depositing of bismuth and heavy metal onto the working electrode surface (*in situ* bismuth coating) and pre-coating bismuth film (*ex situ* bismuth coating) [14]. By *in situ* bismuth coating, impurities formed on the surface of working electrode can be removed with each cycle, as well as bismuth film can be renewed for each detection; however, this method may bring coating issues in detecting natural samples, and the performances of the *in situ* bismuth coating may be affected by the properties of

the samples, worsening the accuracy, precision and sensitivity [14,15]. By *ex situ* bismuth coating, electrodes often show better precision in measurements for natural samples with periodic bismuth-coating renewal or disposable application [16].

There are increasing demands for the microfabricated electrodes with bismuth modification or other modification methods in detection of heavy metal ions. However, the microfabricated electrodes in those applications still suffer from some disadvantages. In some measurements, traditional electrodes are often used as the reference and counter electrodes, so the maintenance for the traditional electrodes, especially for the liquid electrolyte Ag/AgCl electrode, is still needed [17]. Besides, typical detection limits of the microfabricated electrodes are about 1–2 μg/L, which are insufficient for the detection of trace heavy metal ions with less than 1 μg/L concentration [18,19]. Moreover, long deposition time, which may be 300–500 s, is often required to get better signal-to-noise ratio and lower detection limits [20].

In this study, we introduce a novel microfabricated three-electrode on-chip device with a vibration motor; the integration of all three electrodes contributes to simplification of the instrumentation; vibration produces stable convection conditions and thin diffusion layer for the working electrode [21,22], which help to achieve quick measurement and improve the detection limits of Cd^{2+} and Pb^{2+} ions. Thermal evaporation is utilized to deposit gold layer with specialized shapes and connections on a glass substrate. Two 2 × 2 mm square gold electrodes, which are parallel connected externally, are adopted as the working electrode with *ex situ* bismuth coating. In this configuration, each of two gold working electrodes is also possible to be separated and modified with different coatings for detection of more ions in the future. Silver/silver chloride layer is painted onto a rectangular gold surface thus resulting in a solid on-chip reference electrode. A U-shape gold electrode is used as the counter electrode, which surrounds the reference electrode and provides shielding from possible electromagnetic interference. A compact module and an integrated measurement cell are organized by bonding a master-mold-based polydimethylsiloxane (PDMS) cover layer onto the glass substrate. Furthermore, a coin-size vibration motor installed in the module provides vibration function as the alternate for stirring (Fig. 1).

2. Experiments

2.1. Reagents and materials

Silver/silver chloride paste was purchased from Gwent group, United Kingdom. Dow Corning PDMS (Sylgard 184) and silicone adhesive were purchased from Krayden, Inc. (Westminster, Colorado, USA). Coin-size vibration motor was purchased from Digikey, USA. Standard solutions (1000 mg/L Zn^{2+}, Cd^{2+}, Pb^{2+} or Cu^{2+} in 2% HNO_3), acetate buffer (0.1 M, pH 4.6) and phosphate buffered saline (PBS, 0.01 M, pH 7.4) were purchased from Fisher Scientific, USA. Standard solutions (1000 mg/L Sn^{2+} in 2% HNO_3, 1000 mg/L Sb^{3+} in 10% HNO_3) were purchased from Ultra Scientific, USA. Potassium ferri(III)cyanide ($K_3[Fe(CN)_6]$), potassium ferro(II)cyanide ($K_4[Fe(CN)_6]$), bismuth nitrate ($Bi(NO_3)_3 \cdot 5H_2O$), KCl and HNO_3 were purchased from Sigma-Aldrich, USA and of guaranteed reagent (GR) grade. All solutions were prepared with 18 M Ohm cm deionized water from Milli-Q ultrapure water purification system.

2.2. On-chip device fabrication

Fabrication procedures for the microfabricated three-electrode on-chip device are presented in Fig. 2. Firstly, a polytetrafluoroethylene (PTFE) master mold for TE is designed with AutoCAD software and manufactured with a computerized numerical control (CNC) machine. A PDMS mask is acquired by replicating from the PTFE master mold, exposing areas for TE process. Secondly, a 25 × 50 × 1 mm glass substrate, which is covered by the PDMS mask, is prepared. Chromium layer with 15 nm thickness is deposited onto the glass substrate as the adhesive layer with TE instrument (Auto E306, Edwards, United Kingdom), and then 200 nm gold layer is deposited onto the adhesive layer accordingly. In the next step, the PDMS mask is removed, and the glass substrate is rinsed with isopropyl alcohol and deionized water.

A PDMS cover master mold is fabricated with similar process, and a PDMS cover layer with 10 mm thickness is prepared. A 10 × 12 mm hollow area in the PDMS cover layer is reserved for

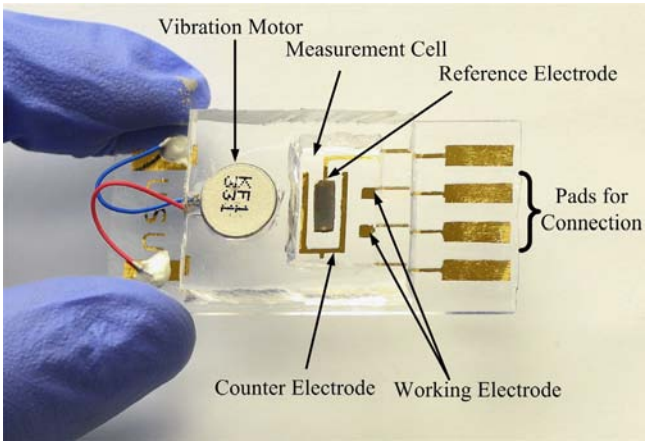

Fig. 1. Photo of the microfabricated three-electrode on-chip device.

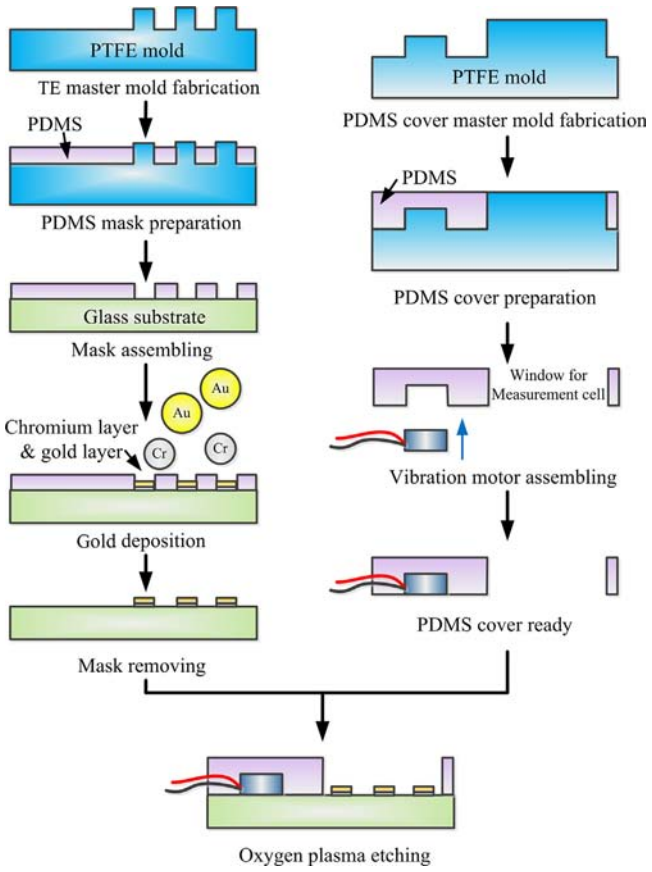

Fig. 2. Basic process flow for the fabrication of the on-chip device.

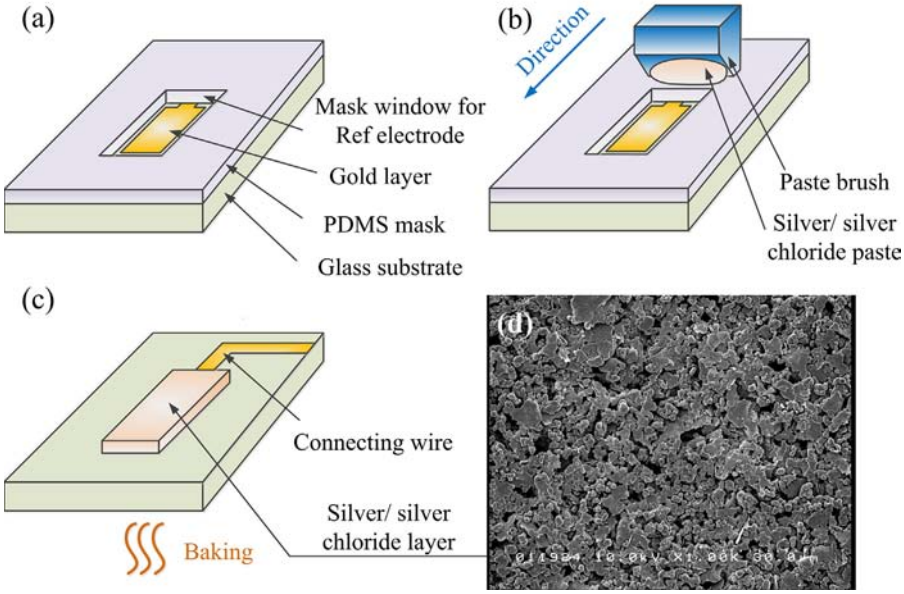

Fig. 3. Schematic representation of the on-chip reference electrode preparation: (a) a PDMS mask exposes the reference electrode area, (b) silver/silver chloride film is painted, (c) the PDMS mask is removed and the device is baked, (d) to form a solid silver/silver chloride layer, whose microstructure is shown by an SEM image.

the measurement cell, as well as the space with 10 mm diameter and 5 mm thickness is reserved for the vibration motor. After that, the motor is assembled into the PDMS cover layer. Finally, the glass substrate and the PDMS cover layer are bonded with oxygen plasma etching (45 s).

2.3. Fabrication of Ag/AgCl reference electrode

To fabricate a solid on-chip reference electrode, film painting process is introduced. It is important to do this step after the PDMS bonding to avoid undesirable influence from oxygen plasma etching. The fabrication procedures are illustrated in Fig. 3. Firstly, ethanol is used to clean the electrodes in the measurement cell, and then the electrodes are dried in nitrogen steam. Secondly, the area in the measurement cell is covered by a 0.2 mm thickness PDMS mask, exposing a window for the reference electrode (Fig. 3a). Then silver/silver chloride paste is painted into the window (Fig. 3b). This step can be fulfilled by either a machine for surface-mount technology (SMT) or manual operation. After the painting step the PDMS mask is removed, and the device is baked at 75 °C (Isotemp oven, Fisher, USA) for 150 s to organize a solid silver/silver chloride layer. A scanning electron microscope (SEM; S-4000, Hitachi, Japan) image of the solid silver/silver chloride layer is given in Fig. 3d, showing uniform microstructures. Moreover, the bare wire of the reference electrode in the cell is covered and protected by silicone adhesive. Finally, cyclic voltammetry (CV) experiments are conducted to assess the performance of the on-chip reference electrode.

2.4. Working electrode preparation

Bismuth coating on the working electrode is performed after reference electrode validation. Firstly, the electrodes, as well as the measurement cell, are rinsed with deionized water. After that, bismuth-coating solution, which contains 0.02 M Bi^{3+} and 0.1 M KCl, is put into the measurement cell. A constant deposition potential of −0.95 V is applied to the working electrode for 300 s. The vibration motor is disabled in the bismuth-coating process. Finally, the electrodes in the measurement cell are rinsed with deionized water and ready for further experiments.

2.5. Electrochemical experiments

A commercial potentiostat analyzer (CHI-1220, CH instruments, USA) is utilized in all electrochemical experiments. To assess the performance of the on-chip reference electrode, CV experiments are performed in solution which contains 0.05 M $K_3[Fe(CN)_6]$, 0.05 M $K_4[Fe(CN)_6]$ and 0.01 M PBS, as well as 0.1 M KCl as supporting electrolyte. Besides, a commercial liquid electrolyte Ag/AgCl electrode (CHI-111, CH instruments, USA) is used for comparison experiments to evaluate the performance of as-fabricated Ag/AgCl reference electrode. Moreover, the effect of vibration on electrochemical responses is evaluated by detecting heavy metal ions, such as Cd^{2+} and Pb^{2+} in water sample, with differential pulse stripping voltammetry (DPSV).

2.6. ICP-MS detection of natural water samples

The ion profiles of natural water samples are detected by Agilent 7700 ICP-MS in Utah Water Research Laboratory. Fifty milliliter of each sample is digested using an Environmental Express hotblock and refluxed at 115 °C with 5 mL trace metal grade nitric acid. Once samples evaporate to 10 mL, they are cooled and ultrapure water is used to fill back to 50 mL volume. Samples are filtered with a 0.45 μm plunger filter and then ready for ICP-MS analysis.

3. Results and discussions

3.1. Evaluation of the fabricated on-chip reference electrode

CV is a popular technique which is widely used for studying electrochemical performance of electrodes. In the CV experiments, the counter electrode, working electrode (without bismuth coating) and reference electrode in the on-chip device are used firstly. Ferri(III)cyanide/ferro(II)cyanide redox couple is chosen to evaluate the performance of the on-chip reference electrode. The potential scan window is of −0.2 V − 0.4 V. Ferro(II)cyanide is oxidized to ferri(III)cyanide in the forward scan, as well as ferri(III) cyanide is reduced to ferro(II)cyanide in the backward scan. The

redox peaks can be achieved in both forward and reverse scans. The performance of the on-chip reference electrode can be evaluated by the shapes and positions of the redox peaks [23]. A group of CV curves are obtained by measuring the current of the working electrode at different scan rates (25 mV/s, 50 mV/s, 75 mV/s and 100 mV/s). The shapes of all the CV curves are nearly identical and show clear redox peaks (supplementary Fig. S1a). The peaks show regular gradient slopes with increasing scan rates, and there is no obvious potential shift between the peaks. The reduction peak and oxidation peak can be found at around 0.105 V and 0.2 V, respectively. The potential difference of redox peaks is about 95 mV due to the microfabricated structure of the working electrode, which is larger than approximate 60 mV for traditional gold working electrode [24].

Comparison of CV experiments is performed accordingly by using a commercial liquid electrolyte Ag/AgCl electrode as well as the counter electrode and working electrode in the on-chip device. The comparison of CV experiments are with the same setting for electrochemical parameters. CV curves for the contrast experiments (supplementary Fig. S1b) are similar to the curves for the on-chip reference electrode. The reduction peak and oxidation peak at around 0.09 V and 0.185 V can be viewed. It can be deduced that the potential shift between the on-chip reference electrode and commercial reference electrode is less than 20 mV.

3.2. Evaluation of the vibration function

DPSV experiments are performed for detection of Cd^{2+} and Pb^{2+} ions. Deposition potential is −1.0 V and scan window is −1.0 V - −0.4 V; amplitude of pulse is 25 mV; step potential change is 5 mV; period of pulse wave is 50 ms. Solution containing 0.1 M acetate buffer (pH=4.6), 50 μg/L Cd^{2+} and 50 μg/L Pb^{2+} ions is adopted in this stage. The above initial setting for DPSV is similar to recent studies [25]. The counter electrode, reference electrode and working electrode in the on-chip device are used. Before the measurements, bismuth coating is carried out on the surface of the gold working electrode. With and without vibration, the DPSV responses are recorded and compared to each other.

Firstly, the vibration condition is optimized. Suggested working voltage of the motor is ranged from 1 V to 3 V DC. The vibrating frequencies are monitored by using an oscilloscope (MSO 2024 A, Tektronix, USA) with a current probe in this working range, as well as the DPSV current peaks for 50 μg/L Cd^{2+} and 50 μg/L Pb^{2+} ions are recorded with 50 s deposition time (Fig. 4). The peaks for Cd^{2+} ion reach saturation when the motor voltage is over 2.4 V, and the peaks for Pb^{2+} ion drop down when the motor voltage exceeds 2.2 V. As a result, the optimized working voltage for the motor is confirmed as 2.2 V.

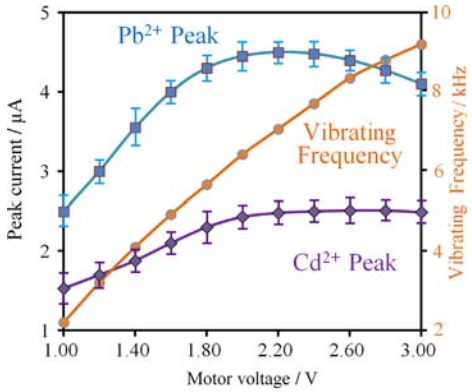

Fig. 4. DPSV current peaks for solution containing 50 μg/L Cd^{2+} and 50 μg/L Pb^{2+} ions (50 s deposition) vs. motor voltage (n=3).

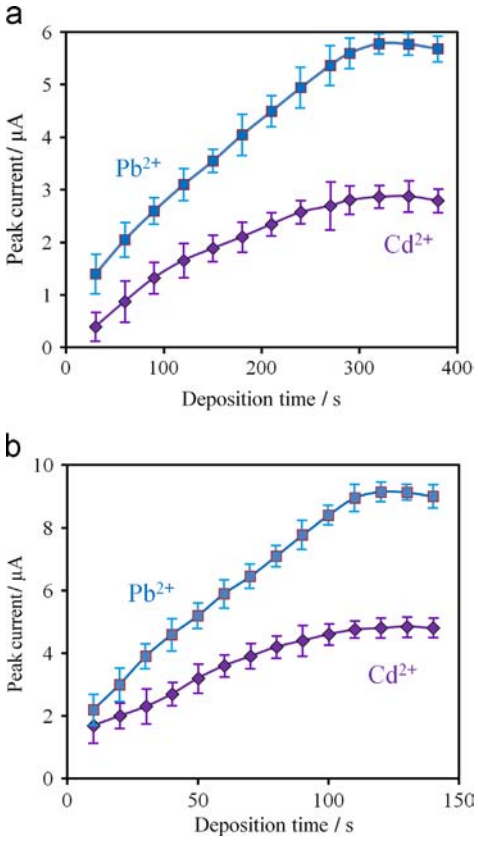

Fig. 5. Effect of the deposition time on the DPSV current peaks of Cd^{2+} and Pb^{2+} (a) without vibration and (b) with vibration for solution containing 50 μg/L Cd^{2+} and 50 μg/L Pb^{2+} ions (n=3). (a) w/o vibration and (b) w/ vibration.

After that, comparison DPSV experiments is carried out accordingly. During the experiments, all parameter settings remain unchanged except the deposition time and vibration condition. The current peaks for Cd^{2+} and Pb^{2+} ions are about 0.6 μA and 1.4 μA with 50 s deposition time when the vibration motor is disabled. The peaks increase to about 1.2 μA and 2.5 μA with 120 s deposition time. In contrast to results without vibration, the peaks more than 2 μA and 4 μA for Cd^{2+} and Pb^{2+} ions, respectively, can be obtained with vibration and 50 s deposition time (supplementary Fig. S2).

Furthermore, the effects of deposition time on current peaks are investigated by two groups of experiments as shown in Fig. 5. In the first group, the vibration is disabled, and the range of deposition time is 25 s–375 s. The current peaks for Cd^{2+} and Pb^{2+} ions increase obviously in the range of 25 s–325 s, and they drop down with more than 325 s deposition time (Fig. 5a). Maximum current peaks for Cd^{2+} and Pb^{2+} ions are approximately 2.8 μA and 5.7 μA with 325 s deposition time, respectively. Vibration is enabled during deposition step in the second group, and the range of deposition time is 10 s–140 s. The maximum current peaks, as much as 4.3 μA and 8.9 μA for Cd^{2+} and Pb^{2+} ions, respectively, are acquired with 120 s deposition time (Fig. 5b).

Moreover, solution containing 0.1 M acetate buffer, 5 μg/L Cd^{2+} and 5 μg/L Pb^{2+} ions is prepared. The detection limits of the on-chip device are calculated as three times of the standard deviation (3σ) of the analytical results for this low concentration solution [18]. The detection limits for Cd^{2+} and Pb^{2+} ions are 0.7 μg/L and 1.2 μg/L without vibration (325 s deposition time), respectively; the detection limits for Cd^{2+} and Pb^{2+} ions can reach as low as 0.11 μg/L and 0.25 μg/L with vibration and 120 s deposition time, which are noticeable better than recent reports [18,19]. It can be

concluded that vibration function brings quicker deposition, higher sensitivity and lower detection limits for Cd^{2+} and Pb^{2+} ions detection.

3.3. Measurements for multi-concentration samples

Eight solutions containing 0.1 M acetate buffer, 10 μg/L–80 μg/L of Cd^{2+} and Pb^{2+} ions (10 μg/L step) are prepared. DPSV experiments are with vibration and 120 s deposition time. Typical DPSV curves for these solutions are shown in Fig. 6a. Current peaks for Cd^{2+} and Pb^{2+} ions are well defined, showing regular increment over the concentration range. The calibration plots of current peak versus ion concentration are presented in Fig. 6b, which show that the linearity is well defined from 10 μg/L to 80 μg/L. The calibration curves and correlation coefficients are $y=0.121x - 0.82$, $r=0.996$ for Cd^{2+} and $y=0.192x - 0.37$, $r=0.991$ for Pb^{2+}, respectively.

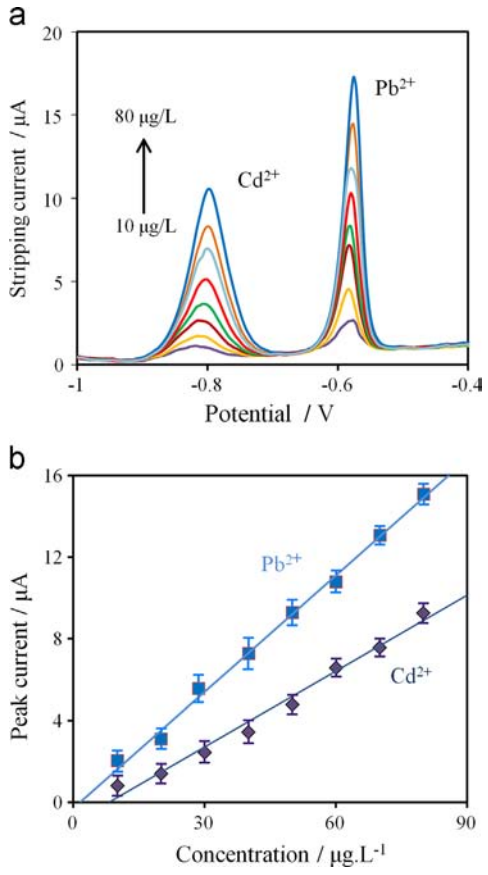

Fig. 6. (a) Typical voltammograms and (b) calibration plots for the microfabricated three-electrode on-chip device in simultaneous detection of Cd^{2+} and Pb^{2+} ions ($n=3$).

Table 1
Tolerated ratios to 5 μg/L Cd^{2+} and 5 μg/L Pb^{2+} in 0.1 M acetate buffer (±5 % deviation).

Foreign Substance	Tolerated Ratio to Cd^{2+}	Tolerated Ratio to Pb^{2+}
Zn^{2+}	45	36
Cu^{2+}	3.5	6
Sn^{2+}	25	8
Sb^{3+}	30	28

3.4. Interference study

The interference of foreign substances, such as Zn^{2+}, Cu^{2+}, Sn^{2+} and Sb^{3+}, is studied in the DPSV measurements with solution containing 0.1 M acetate buffer, 5 μg/L Cd^{2+} and 5 μg/L Pb^{2+} ions. Each substance is considered as interfering agent when the current peak for Cd^{2+} or Pb^{2+} exhibits a deviation more than ±5% [26]. The tolerated ratios to concentrations for Cd^{2+} or Pb^{2+} ions are presented in Table 1. Cu^{2+} ion is found to have an obvious influence on the stripping response for Cd^{2+} and Pb^{2+} ions. The result is in compliance with previous report, and the influence may be caused by the inter-metallic compounds formed in deposition process [27]. Moreover, Sn^{2+} ion also performs a noticeable effect on Pb^{2+} ion, since the stripping potentials for Sn^{2+} and Pb^{2+} ions are close [28].

3.5. Analysis of natural samples

Measurements for natural water samples are also performed. Two natural samples were acquired from Logan River, Logan City, USA, on March 10, 2014. The first sample was from the upstream part ahead of the city. The second sample was from the downstream part in the city. To avoid the interference of sample background, method of standard additions (MSA) is introduced and executed twice. In each MSA stage, diluted standard solution containing 500 μg/L Cd^{2+} and Pb^{2+} ions with adequate volume is added into the samples, keeping 1 μg/L concentration increment for Cd^{2+} and Pb^{2+} ions. Current peaks for the original samples, 1st MSA and 2nd MSA are recorded, respectively, and the concentrations can be calculated according to the original peaks and the MSA peaks [29]. The data are presented in Table 2. The DPSV results meet with standard ICP-MS measurements with less than 15% relative error except Cd^{2+} concentration of the first sample, because it is below the detection limits of the on-chip device.

3.6. Stability and renewal procedure for the device

The stability for the on-chip device is studied with solution containing 0.1 M acetate buffer, 50 μg/L Cd^{2+} and 50 μg/L Pb^{2+} ions. After each bismuth coating, the device shows good stability in approximate 50–60 DPSV measurements, and the relative standard deviations are less than 2.4% and 2.8% for Cd^{2+} and Pb^{2+}, respectively. After that, a renewal procedure is required due to the loss of bismuth

Table 2
Cd^{2+} and Pb^{2+} measurements for natural water samples based on DPSV and ICP-MS.

(a) Sample 1	Original Peak	1st MSA Peak	2nd MSA Peak	Calculated Concentration	ICP-MS Concentration	Relative Error
Cd^{2+}	Not detected	N/A	N/A	N/A	0.04 μg/L	N/A
Pb^{2+}	9.8×10^{-8} A	2.4×10^{-7} A	3.7×10^{-7} A	0.71 μg/L	0.83 μg/L	14%
(b) Sample 2	Original Peak	1st MSA Peak	2nd MSA Peak	Calculated Concentration	ICP-MS Concentration	Relative Error

Sample 1 was from the upstream of Logan River. Sample 2 was from the downstream of Logan River.
Detailed calculation process based on original peaks and MSA peaks is introduced in previous study [29].

coating. During the renewal procedure, the bismuth film on the working electrode is removed with filter paper firstly; and then the device is rinsed with isopropyl alcohol and deionized water; finally the bismuth coating is performed on the working electrode.

The life- cycle for the on-chip device is more than 500 measurements, which is acceptable considering the relative low cost (less than 7 US dollars) for the device. After that, the gold layer for the working electrode and counter electrode may drop off from the substrate. The reference electrode keeps stable and needs no special maintenance in the life cycle.

4. Conclusion

In this study, we introduce a microfabricated three-electrode on-chip device with a vibration motor for stripping voltammetric detection of Cd^{2+} and Pb^{2+} ions in standard and natural water samples. The counter electrode, reference electrode and working electrode are fabricated in the on-chip device. A coin-size vibration motor is also integrated in the device, providing vibration function as the alternate for stirring to improve detection limits and reduce deposition time.

The performance of the on-chip reference electrode is evaluated by CV experiments. Redox peaks for the on-chip reference electrode keep relatively stable at different scan rates. The potential shift of redox peaks between the on-chip reference electrode and commercial reference electrode is less than 20 mV. DPSV experiments validate that higher current peaks, less deposition time and lower detection limits for Cd^{2+} and Pb^{2+} ions can be achieved synchronously from vibration.

The microfabricated three-electrode on-chip device is also used to detect Cd^{2+} and Pb^{2+} ions for both laboratorial standard water samples and natural water samples. The DPSV current peaks exhibit good linearity from 10 μg/L to 80 μg/L for Cd^{2+} and Pb^{2+} ions, respectively, in laboratorial standard water samples. The concentrations for natural samples are calculated based on MSA in DPSV measurements and compared with ICP-MS results, which validate the measurement reliability for the on-chip device.

ABSTRACT

This work describes the quantitative analysis of $(NH_4)_2CO_3$ and NH_4HCO_3 using a simple solution phase titration method. Back titration results at various $(NH_4)_2CO_3$–NH_4HCO_3 ratios demonstrated that 6:4 ratio caused a 3% error in their differentiation, but very high errors were found at other ratios. A similar trend was observed for the double indicator method, especially when strong acid HCl was used as a titrant, where still less errors (2.5%) at a middle ratio of $(NH_4)_2CO_3$–NH_4HCO_3 was found. Remaining ratios with low $(NH_4)_2CO_3$ (2:8, 4:6) show high +ve error (found concentration is less) and high $(NH_4)_2CO_3$ (7:3, 8:2, and 9:1) show high –ve error (found concentration is higher) and vice versa for NH_4HCO_3. In replacement titration using Na_2SO_4, at both higher end ratios of $(NH_4)_2CO_3$–NH_4HCO_3 (2:8 and 9:1), both –ve and +ve errors were minimized to 75% by partial equilibrium arrest between $(NH_4)_2CO_3$ and NH_2COONH_4, instead of more than 100% observed in back titration and only double indicator methods. In the presence of $(NH_4)_2SO_4$ both –ve and +ve error% are completely reduced to 3 ± 1 at ratios 2:8, 4:6, and 6:4 of $(NH_4)_2CO_3$–NH_4HCO_3, which demonstrates that the equilibrium transformation between NH_2COONH_4 and $(NH_4)_2CO_3$ is completely controlled. The titration conducted at lower temperature (5 °C) in the presence of $(NH_4)_2SO_4$ at higher ratios of $(NH_4)_2CO_3$–NH_4HCO_3 (7:3, 8:2, and 9:1) shows complete minimization of both –ve and +ve errors to 2 ± 1%, which explains the complete arresting of equilibrium transformation. Finally, the developed method shows 2 ± 1% error in differentiation of CO_3^{2-} and HCO_3^- in the regeneration process of $NaHCO_3$ from crude desulfurized sample. The developed method is more promising to differentiate CO_3^{2-} and HCO_3^- in industrial applications.

1. Introduction

Growing awareness of the risks of climate change has generated public concerns, and over the last two decades the sequestering of air pollutants has been of major research interest. As the world's population and energy demand increase, continued industrialization will undoubtedly increase levels of atmospheric pollutants like NO_x, SO_x, and CO_2. In particular power plant and steel plant furnaces emit SO_x and NO_x (called flue gases), which are removed using wet or dry sorbent methods [1]. Flue Gas Desulfurization (FGD) is performed using the wet sorbent method. However, due to the large amount of space required for installation, the large volume of water required and high capital and operating costs [2], research has shifted toward dry methods of SO_2 removal. Various types of solid sorbent/catalysts are being used for dry FGD, such as, calcium based [3], sodium based [4], activated carbon [5], metal oxide [6], and zeolite sorbents [7], waste-derived siliceous materials [8], and mediated electrocatalytic oxidation (MEO) [9,10]. Many of these methods have limitations in terms of their commercialization. Among these methods, sodium-based sorbents are considered more effective for FGD, especially for SO_x. These processes are conducted mainly using sodium carbonate (Na_2CO_3), sodium bicarbonate ($NaHCO_3$), and trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$). In this process, either sodium bicarbonate ($NaHCO_3$) (or) sodium carbonate (Na_2CO_3) reacts with SO_2 to form Na_2SO_3 which is further converted to sodium sulfate (Na_2SO_4) in the presence of excess oxygen, as explained by the following equation sequences [1–4]:

$$2NaHCO_3 + SO_2 \rightarrow Na_2SO_3 + 2CO_2 + H_2O \quad (1)$$

$$2NaHCO_3 \rightarrow Na_2CO_3 + CO_2 + H_2O \quad (2)$$

$$Na_2CO_3 + SO_2 \rightarrow Na_2SO_3 + CO_2 \quad (3)$$

$$Na_2SO_3 + 1/2O_2 \rightarrow Na_2SO_4 \quad (4)$$

However, it had a few drawbacks: (i) sodium bicarbonate is expensive; (ii) the resulting by-product from the sodium

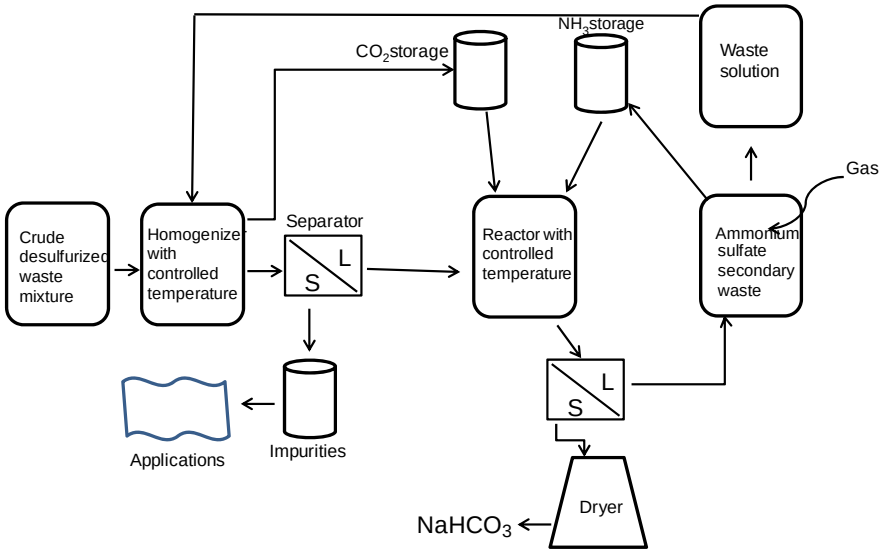

Fig. 1. Schematic representation for the regeneration pathway of $NaHCO_3$ from desulfurized waste sample.

bicarbonate–SO_x reaction (sodium sulfate) is of limited economic value; and (iii) sodium sulfate disposal is expensive and poses significant environmental challenges. To regenerate sodium bicarbonate from secondary waste Na_2SO_4 (SS) provides an efficient way of avoiding the above mentioned drawbacks [11]. The regeneration of sodium bicarbonate from sodium sulfate is schematically presented in Fig. 1.

The regeneration of sodium bicarbonate involves three steps: (i) separation of the sodium sources from their impurities, (ii) regeneration of $NaHCO_3$ (SBC) using NH_4HCO_3 (ABC) or gases of NH_3 and CO_2, and (iii) utilization of secondary waste solution $(NH_4)_2SO_4$ (AS). In these regeneration processes, analysis of each ion plays a crucial role in finalizing the experimental conditions such as the molar ratio of reactants and water content. Particularly the secondary waste AS containg solution, which includes additionally $(NH_4)_2CO_3$ (AC) and ABC, should be exactly analyzed to perfect the minimization of error. Identifications of CO_3^{2-} and HCO_3^- ions are very difficult through analysis by titration due to their complex equilibrium process as follows [5–9,12,13]:

$$NH_{4(aq)}^+ + H_2O_{(l)} \rightleftharpoons NH_{3(aq)} + H_3O_{(aq)}^+ \quad (5)$$

$$CO_{3(aq)}^{2-} + H_2O_{(aq)} \rightleftharpoons HCO_{3(aq)}^- + OH_{(aq)}^- \quad (6)$$

$$CO_{3(aq)}^{2-} + NH_{4(aq)}^+ \rightleftharpoons HCO_{3(aq)}^- + NH_{3(aq)} \quad (7)$$

$$HCO_{3(aq)}^- + NH_{3(aq)} \rightleftharpoons H_2NCOO_{(aq)}^- + H_2O_{(l)} \quad (8)$$

$$H_2NCOO_{(aq)}^- + H_2O_{(l)} \rightleftharpoons CO_{3(aq)}^{2-} + NH_{4(aq)}^+ \quad (9)$$

First, the differentiation of CO_3^{2-} and HCO_3^- by a back titration method using $BaCl_2$ as a precipitant for $CaCO_3$ has been identified to be infeasible [14]. They found more restriction in minimizing the error in quantification of each compound and no detailed studies about various concentration ratios of CO_3^{2-} and HCO_3^- [15]. Later, double indicator Warder's titration method was used to differentiate the CO_3^{2-} and HCO_3^- as a next level [16,17]. However, quantifying the CO_3^{2-} and HCO_3^- is difficult due to lack of endpoint identification; color change is very feeble in case of AC and ABC [18,19], and no detailed study has been performed by the titration method. In the late 1990s, it was reported that FT-IR, NIR, Raman spectroscopies and powder-XRD can differentiate AC and ABC quantitatively and qualitatively [20–22]. The XRD 2θ peaks of ABC and AC are at 16.5 and 34.4, respectively, and can be used to analyze the solid state compositions of mixtures [21]. In the case of FT-IR analysis, there is a possibility of quantitative differentiation of ABC ($1200-1450\ cm^{-1}$ for asymmetric CO stretch and $\sim 1600\ cm^{-1}$ for symmetric CO stretch) and AC ($\sim 1300-1600\ cm^{-1}$ for asymmetric CO stretch). The FT-IR spectra of both solid and solution phases of AC and ABC are quite similar and difficult to distinguish because of broad peaks due to both carbonate and bicarbonate between 1200 and $1700\ cm^{-1}$ and the same peak at $3098\ cm^{-1}$, which is due to the ammonium ion [22]. As reported by Meng et al., by variation of oxygen – hydrogen (OH) bond of ABC at 1450 nm, which is not present in the carbonate, one can differentiate quantitatively in solid state samples [21]. However, it is difficult to distinguish the bicarbonate from carbonate ion in aqueous solution due to interference of hydroxyl (OH) groups in the water, which restricts the NIR analysis in solution samples. ^{13}C NMR studies have demonstrated the qualitative differentiation of ABC and AC at room temperature [23]. Even the fast equilibrium of HCO_3^-/CO_3^{2-} anions results in their two NMR peaks, which permits identifying the HCO_3^-/CO_3^{2-} ions quantitatively. Through the Raman spectra, the ABC and AC in solution phase have been differentiated quantitatively using scattered light of the peaks at $\sim 1015\ cm^{-1}$ (for bicarbonate) and $\sim 1065\ cm^{-1}$ (for carbonate) [24]. However, Raman analysis needs an internal standard for exact differentiation of both ABC and AC. The mixture of our secondary waste contains internal standard compound Na_2SO_4, which should be analyzed additionally using another method. Accordingly several issues must be resolved for the quantitative analyses of ABC and AC in the solution phase, especially in samples obtained during the regeneration of SBC from desulfurized crude waste.

There are some models to control the reaction and its coordinates to get a high yield and purity in regeneration of SBC from desulfurized waste [25,26]. Currently there are no reports on controlling the reaction based on analysis of ions present in the crude waste (before reaction) and secondary product waste (after reaction). In the present work a method is developed based on analysis of ions present in crude waste and secondary waste, to control the reaction in the SBC regeneration process. Herein, validations of back titration at different ratios of AC ad ABC were performed for its confirmation. Then, the double indicator method was repeated with different ratios of AC and ABC to check its applicability for their differentiation. Additionally replacement titration, by SBC, was studied. In order to check the equilibrium of CO_3^{2-} and HCO_3^-, AS and temperature effect were studied.

Finally, the developed method was tested on a real sample from desulfurized crude waste regeneration process of the SBC.

2. Experimental section

2.1. Chemicals

Ammonium bicarbonate and ammonium carbonates were purchased from Aldrich. Phenolphthalein, methyl orange, bromocreasol green, phenol red, sodium carbonate, barium chloride dehydrate, sodium hydroxide, and phosphoric acid were purchased from Daejung Chemicals, Korea. Hydrochloric acid and acetic acid were purchased from OCI, and Duksan Korea respectively.

2.2. Reagents

0.1 M stock solutions of hydrochloric acid, acetic acid and phosphoric acid were prepared by dissolving approximately 8.4 ml of 11.6 M hydrochloric acid in 1 L of deionized water, 5.8 ml of 17.4 M acetic acid in 1 L of deionized water, and 6.8 mL of 14.6 M phosphoric acid in 1 L of deionized water respectively. These solutions were standardized by titration against standard sodium carbonate.

2.3. Back titration

This method is the oldest method to differentiate two components by precipitating one component [14]. In order to differentiate AC and ABC, various ratios such as (2:8), (4:6), (5:5), (6:4), (7:3), (8:2), (9:1) were chosen. The back titration was performed using two steps. In the first step, total alkalinity was determined by placing a 5 ml sample in a 100 ml conical flask, adding methyl orange indicator and titrating against standardized 0.1 M HCl, as shown in Eq. (10). The end point change from yellow to red was considered as a measure of total alkalinity. This procedure was repeated till concordant values were obtained and the average value was taken. In the second step, 5 ml of sample was taken in a 100 ml conical flask, then 16 ml of NaOH and 0.88 ml of 10% $BaCl_2$ solution were added along with a few drops of phenolphthalein indicator. Instantly, the white precipitate ($BaCO_3$) generated in the sample mixture solution was then immediately titrated against standardized 0.1 M HCl solution after using a high speed centrifuge for a short time (30 s), as shown in Eq. 11. The disappearance of pink color is an indication of end point. The volume of consumed HCl was recorded and the test was repeated for concordant values.

Step 1: Total alkalinity:

$$NH_2COONH_4 \text{ and } (NH_4)_2CO_3 + NH_4HCO_3 + 3HCl \rightarrow 3NH_4Cl + 2H_2O + 2CO_2 \quad (10)$$

Step 2: Differentiate HCO_3^- and CO_3^{2-}

$$(NH4)_2CO_3 + NH_4HCO_3 + NaOH + BaCl_2 \xrightarrow{2HCl} 3NH_4Cl + BaCO_3 + H_2O + NaCl + H_2CO_3 \quad (11)$$

2.4. Double indicator method

There are some reports for differentiation of sodium carbonate and bicarbonate in the reaction mixture [16,17], and a few reports for ABC and AC without detailed experimental conditions [15]. The same method has been adopted to identify ammonium carbonate and ammonium bicarbonate [27]. Briefly, ammonium carbonate and ammonium bicarbonate mixture was dissolved in 100 ml of water. 5 ml of this solution was transferred into a conical flask. 2 drops of phenolphthalein were added and pink color appeared. When titrated against 0.1 M acids the pink color disappeared, which is the endpoint of ammonium carbonate solution. To the same solution 2 drops of phenol red were added and the solution became yellow. After titration again with acetic acid the yellow turned into red, which is the ammonium bicarbonate endpoint. For phosphoric acid and hydrochloric acid, methyl orange is used for ammonium bicarbonate and the end point is orange to red. In all titration experiments, the titration time was 0.5–3 min for all titrations at all ratios of AC and ABC. In the AC determination step, the time spent is between 0.5 and 1.5 min. The error% of ABC was calculated by substracting the AC value obtained from the phenolpthalein indicator by total alkalinity (ACl) value obtained from the second indicator (methyl orange). As shown in Eqs. (12)–(14). to cross check, the AC value added with ABC, which is equal to carbamic acid (CAm) or carbonic acid (CA) that developed during titration. Then, the CAm or CA was subtracted by ACl to get right ABC.

$$C_{ACl} - C_{AC} \text{ or } C_{ACm} = C_{ABC} \quad (12)$$

$$C_{AC} + C_{ABC} = C_{CAm \text{ or } CA} \quad (13)$$

$$C_{ACl} - C_{CAm \text{ or } CA} = C_{ABC} \quad (14)$$

In the replacement titration, two times the concentration of Na_2SO_4 was added and repeated as a double indicator method of titration. In stabilization experiments, $(NH_4)_2SO_4$ and temperature were included as two times higher molar concentration and 25 to 5 °C variation respectively. The room temperature experiments were carried out at 20 ± 2 °C. All the experiments were repeated until the results were reproducible.

2.5. Analysis of real regeneration process samples

First, an industrial desulfurized sample 10 g was dissolved in 250 ml of deionized water and filtered to remove impurities, and separated the salt solution for analysis. The Na^+ and NH_4^+ ions were estimated using ion selective electrodes (ISE) that purchased from VAN LONDON Phoenix.CO (No.: NA715XX for Na+ and No.: NH415XX) with the help of iSTEK multimeter (Model No.: pH-240 L) from USA. Prior to the analysis, the electrodes and instruments were calibrated as per the instruction that given by a manufacturing company. In another way, the NH_4^+ was cross checked with standard procedure by UV-Visible spectroscopy (Shimadzu, UV160A) from Japan, by the indophenol blue method at 630 nm [28].

The sulphate ion in the sample was estimated in the form of Barium sulphate by the addition of Barium chloride precipitating agent along with Conditional reagent followed by UV–vis spectrophotometric absorption at 420 nm [29]. All metal ions that present in the real sample was analyzed by ICP-MS (model ELANDRCe, Perkin Elmer) from USA.

3. Result and discussion

3.1. Conventional back titration on differentiation of $(NH_4)_2CO_3$/$(NH_4)HCO_3$

As evidenced in previous reports, SBC and SC can be differentiated effectively by back titration with an error of less than 5%. However, they never considered ACm equilibrium in back titration to differentiate ABC and AC in CO_2 absorption process using ammonia [14]. In the present case, desulfurized waste contains many salts that including SBC and SC in different ratios, which

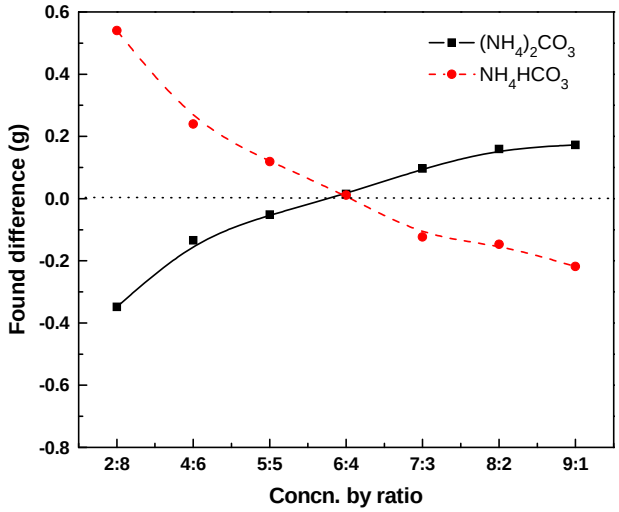

Fig. 2. Effect of different concentration ratios on found concentration differences of $(NH_4)_2CO_3$ and $(NH_4)HCO_3$ in their identification through back titration.

must be accurately identified for further reaction with ABC to regenerate SBC. After reaction or to control the reaction, differentiation of ABC and AC is important. By keeping all in mind, we have started optimizing conditions in back titration such as the effect of NaOH and $BaCl_2$ addition time in particular of AC to ABC ratio 6:4. The obtained results are presented in supporting information Table S1. There appears minimized error% during the both NaOH and $BaCl_2$ addition time in 30 s. Using these selected conditions, the back titrations to identify the ABC and AC in different ratios at room temperature was performed and the obtained results are depicted in Fig.2. At high concentration of AC, the found concentration of AC increased to 0.35 g than (+ve error) the actual input value. At the same time, the found ABC is very decreased to 0.54 g (-ve error) than the originally added in 8:2 ratio. The found difference of both ABC and AC increased and decreased in a similar manner with increasing ratio up to 6:4, where the found difference is almost 0.01 g which equal to less than 3% +ve error. Further increasing the ratios beyond 6:4 of AC and ABC, the found difference shows a reverse trend which means, the found AC is decreased than the originally added and ABC is increased than the input concentrations. The overall found difference explains that the highest concentration of AC or ABC are tended to convert to another form chemically. The chemical equilibrium may dominate more at high end concentration ratios. It is reported that the ABC is converted to AC at high temperature and excess of CO_2 [27]. In a similar way, AC converted to ABC in excess CO_2 and H_2O [30]. But only containing of both ABC and AC, how the conversion has occurred? Instead of conversion, we suggest the possibility of equilibrium stabilization, as shown in the following eqs. (15 and 16). Another possible way for high error % is the formation of ACm from AC in water as shown in eqs. 8 and 9. It is evidenced that the ACm will not precipitate in precipitation step upon addition of $BaCl_2$ [31] to remove the AC from the titer solution in related to avoid its interference during the back titration of the consumed NaOH with HCl. In case ACm remains in titer solution, the consumed HCl volume will vary which in turn leads high error% in determination of AC, as shown in eq. (17)

At High $(NH_4)_2CO_3$: $(NH_4)_2CO_3 \rightleftharpoons NH_4HCO_3$ (15)

At high NH_4HCO_3: $(NH_4)_2CO_3 \rightleftharpoons NH_4HCO_3$ (16)

$$NH_2COONH_4 + NH_4HCO_3 + NaOH + BaCl_2 \xrightarrow{HCL} 2NH_4Cl + BaCO_3 + H_2O + NaCl + NH_2COOH \quad (17)$$

3.2. Double indicator method

Because of defined differences in the pH value of ABC (8.3), and AC (9), the two indicator method could possibly provide accurate ABC and AC concentrations. In consideration of ACm, the pH of ACm 8.9 [32], which is very close to the pH of AC, it clearly helps to differentiate ABC even if it exists because of phenolpthalein used as indicator. Since ABC, ACm, and AC are weak bases, acid selection could minimize errors. We selected three different acids, that is, acetic acid (weak base vs weak acid) and phosphoric and hydrochloric acids (weak base vs strong acid). As evident in literature, In order to know the time dependent equilibrium of AC, ACm, and ABC, the sample titration time at minimum (1 min) and maximum (720 min) were done and the results are tabulated and presented in supporting information Table S2. After 1 min, the error% has increased to only 7 to 10 at AC to ABC of 75:25 ratio. In consideration of practical difficulties, 1 min sampling time was selected for all the titrations. During analysis, we found difficulties in end point measurements, especially for AC and ACm determinations, when only a pale pink was obtained after adding phenolphthalein. This color change behavior just contrary to the SBC and SC differentiation, there was able to judge a clear difference in end point and correct value. The titration results obtained for ABC and AC are depicted in Fig. 3. In plot (b) of Fig.3 illustrates the titration of acetic acid with $(NH_4)_2CO_3/(NH_4)HCO_3$ mixture. During titration, AC or ACm becomes ABC or CAm and carbonic acid (CA) at second endpoint while the use of methyl orange indicator as shown in eqs. 18–20' in case of ACm. The % errors were calculated using eqs. (12–14).

$$(NH_4)_2CO_3 + NH_4HCO_3 + HCl \rightarrow 2NH_4HCO_3 + NH_4Cl \quad (18)$$

$$NH_2COONH_4 + NH_4HCO_3 + HCl \rightarrow NH_4HCO_3 + NH_2COOH + NH_4Cl \quad (18')$$

$$2NH_4HCO_3 + 2HCl \rightarrow 2NH_4Cl + 2H_2CO_3 \quad (19)$$

$$NH_4HCO_3 + NH_2COOH + HCl \underset{\leftrightarrow}{\longrightarrow} NH_2COOH + H_2CO_3 + NH_4Cl \quad (19')$$

$$NH_2COOH + HCl \rightarrow NH_4Cl + CO_2 \quad (20')$$

Depending upon the acid, which we used, the error% is varying for both the ABC and AC or ACm that can be defined as the -ve error% (found value is higher than originally taken) and +ve error%

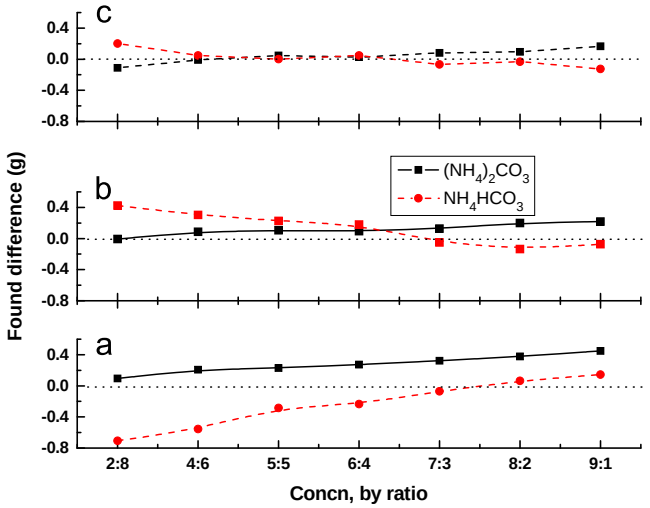

Fig. 3. Effect of acids on titration of different concentration ratios of $(NH_4)_2CO_3/(NH_4)HCO_3$ mixture in their identification by double indicator method: (a) Phosphoric acid; (b) Acetic acid; (c) Hydrochloric acid.

(found value is less than originally taken). The $(NH_4)_2CO_3$ error was a minimum of 5.2 +ve% when carbonate to bicarbonate ratio is 2:8 and with increasing AC ratio –ve error% increases to > 10.0%. Except titration using phosphoric acid, the other two acids CH_3COOH (plot (b) in Fig.3) and HCl (plot (c) in Fig.3) shows a similar trend and vice versa for ABC. The titration of $(NH_4)_2CO_3$/$(NH_4)HCO_3$ mixture with phosphoric acid (plot (a) in Fig.3) shows ABC of 8.7 +ve error% when carbonate to bicarbonate ratio is 2:8, which increases with decreasing of ABC ratio. In a similar way, AC shows –ve error% at lower ratio that increases with decreasing AC, as shown in Fig.3(plot (a)). Among three acids, titration using HCl shows (Fig.3(plot (c)) –ve error% in both AC and ABC differentiation with the existence of a similar equilibrium error problem as found in back titration method. The error% of the both AC and ABC might have also from ACm formation in the first step using phenolpthalein titration where ACm converted to CAm directly, instead of ABC formation, as seen in equation 18'. This ABC and ACm equilibrium (eqn. 19') at high end ratios of AC and ABC might have influenced to receive this high error% in the both –ve and +ve. In higher ABC, more of ACm might have formed and vice versa at lower ABC that makes an equilibrium variation depending upon the concentration of ABC, which leads high error% in their determination. Further works can be carried out using HCl acid.

3.3. Identification through replacement titration by Na_2SO_4

It is known that alkali salts reacts with ABC and AC form alkali carbonate and bicarbonate [11]. Using this approach, sodium sulfate was added accordingly to the concentrations of ABC and AC to convert them to SBC and SC, as shown in the eqs. 21, and 22, this facilitates the accurate differentiation of ABC and AC.

$$Na_2SO_4+(NH_4)_2CO_3 \rightarrow Na_2CO_3+(NH_4)_2SO_4 \quad (21)$$

$$Na_2SO_4+2(NH_4)HCO_3 \rightarrow 2NaHCO_3+(NH_4)_2SO_4 \quad (22)$$

Even the all salts are dissolved in the reaction mixture, due to the high association constant of SBC (0.72) and SC (8.3) [33] makes remain intact and makes easy to differentiate the carbonate and bicarbonate via SBC and SC and the obtained results are depicted in Fig.4. The AC both +ve and –ve error% is controlled within 75% in high end ratios. It is believed that the Na^+ ion effectively replaces the NH_4^+ of AC. In the case of ABC determinations, the excess Na_2SO_4 shows controlled error percentages at most ratios

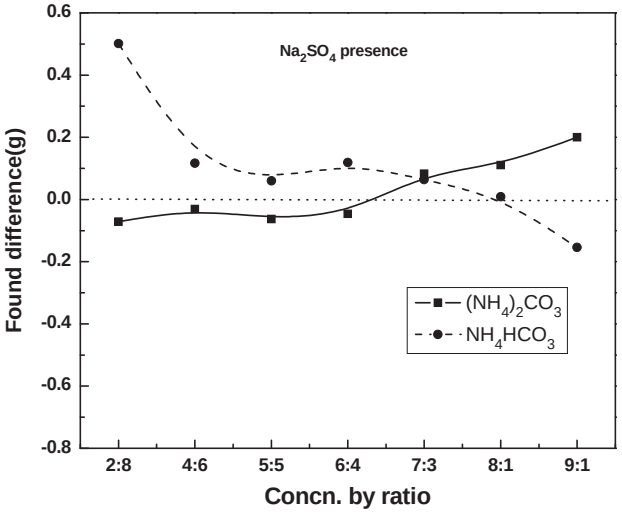

Fig. 4. Replacement titration with Na_2SO_4 on different ratios of $(NH_4)_2CO_3$/$(NH_4)HCO_3$ mixture on their differentiation by double indicator method. Added Na_2SO_4 concentration = 0.14 M.

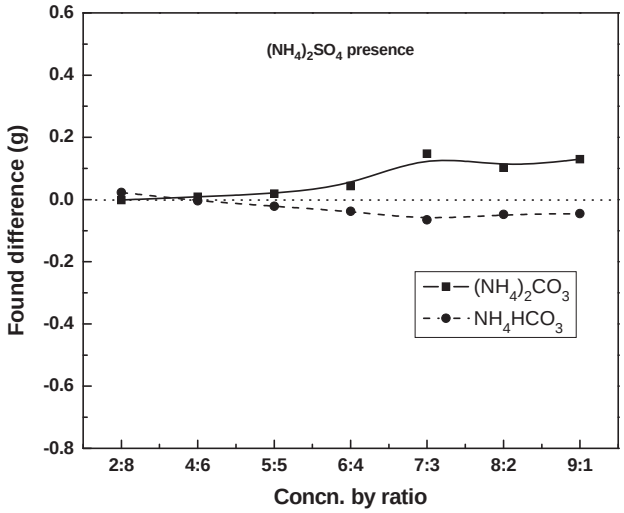

Fig. 5. Effect of $(NH_4)_2SO_4$ with different ratios of $(NH_4)_2CO_3$/$(NH_4)HCO_3$ mixture on their identification by double indicator method. Added $(NH_4)_2SO_4$ concentration = 0.15 M.

except high end ratio of 9:1, indicating effective replacement of the Na^+ ion in ABC. The reason why the minimized error occurred is, only a small amount of AC becomes ACm that might not converted to SC while addition of SS due to sodium ammonium carbamate and double salt formation as shown in eq. 23. But one positive effect of the presence of sodium sulfate is that it enables the differentiation of ABC and AC without its interference. Nonetheless, more accurate differentiation is required regardless of ABC/AC ratio.

$$Na_2SO_4+NH_2COONH_4 \rightarrow NH_2COONa+NH_4.Na.SO_4 \quad (23)$$

3.4. Approach through the effect of equilibrium control by addition of salt and temperature

As explained by eqs. 1 and 2, a common ion in the equilibrium change is sodium ion. One possibility of minimizing equilibrium change involves the addition of excess ammonium ion to the titration solution, here ammonium sulfate is probably a good choice, as shown by eq. 25. Ammonium sulfate added titration results to identify the ABC and AC are depicted in Fig. 5. There appears the error% for both +ve and –ve errors has controlled within in 3 ± 1% upto the ratios of 2:8 to 6:4 of AC and ABC. Also, there might be an equilibrium arrest between AC and ACm if add the AS (eqn. 24) for this both +ve and –ve error% minimization. Beyond these ratios, the both -ve and +ve error% were not controlled within the error limit. These results explain higher the AC concentration in the reaction mixture makes higher the both –ve and +ve error%, which means the equilibrium only between AC and ABC at high concentration. In other words, at high ratios of AC, AS is not able to control the conversion to ABC, as shown in eq. 25. But, the both –ve and +ve error% are almost controlled in all the ratios of AC and ABC when compared with no salt addition and in presence of Na_2SO_4, as shown in Fig.7.

$$NH_2COONH_4 \xrightarrow{(NH_4)_2SO_4} (NH_4)_2CO_3 \quad (24)$$

At higher AC ratio:

$$(NH_4)_2CO_{3(n)}+H_2O+NH_4HCO_{3(n)} \rightarrow (NH_4)_2CO_{3(n-1)}+(NH_4)HCO_{3(n+1)}+NH_4OH_{(n)} \quad (25)$$

It is seen from eq. 13 that there is a possibility of AC decomposition to ABC via H_2O at high concentration ratios and forms NH_4OH in

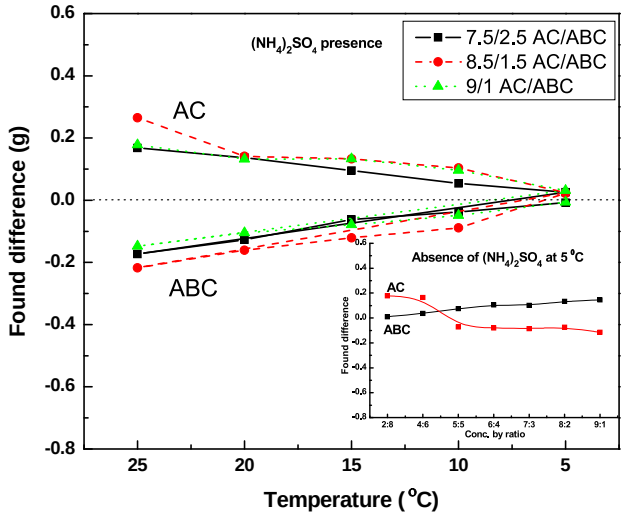

Fig. 6. Effect of temperature with high ratios of $(NH_4)_2CO_3/(NH_4)HCO_3$ mixture on their differentiation in presence of $(NH_4)_2SO_4$ by double indicator method. Added $(NH_4)_2SO_4$ concentration = 0.15 M. Insert figure: Concentration difference effect in absence of $(NH_4)_2SO_4$ at 5 °C on different ratios of $(NH_4)_2CO_3/(NH_4)HCO_3$.

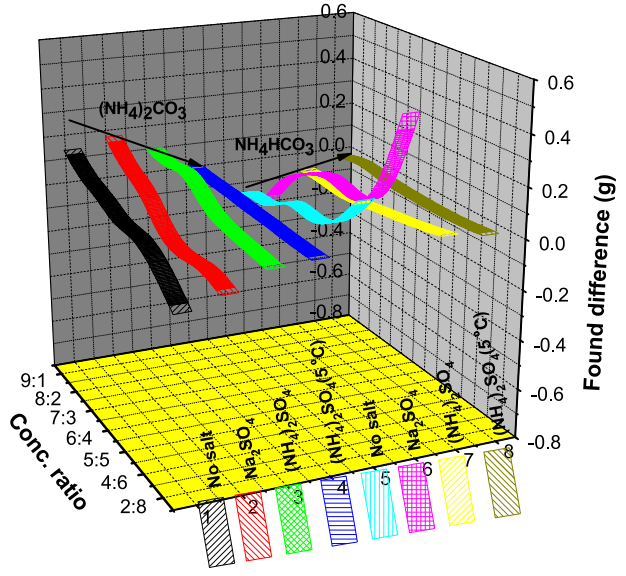

Fig. 7. Overall comparitive plot on differentiation of $((NH_4)_2CO_3/(NH_4)HCO_3$ ratios with different experimental conditions using double indicator method: (a) without addition of salts; (b) With Na_2SO_4; (c) With $(NH_4)_2SO_4$; (d) At 5 °C with $(NH_4)_2SO_4$.

solution or NH_3 might have liberated from solution. Moreover, the concentration we took is very less (0.1 M) for titration, which makes no loss of NH_3 by liberation. We tried to check the pH value after phenolpthalein titration, but found no change or high pH value. It is well known that the reaction can be arrested at low temperature [34], and thus, there is a possibility that the conversion of AC could be controlled by decreasing temperature. As a first trial, the higher AC ratios were considered to check temperature effect and the obtained results are presented in Fig. 6. The five different temperatures examined from 25 to 5 °C shows a clear decrease in the both –ve and +ve error%. Irrespective of the higher three ratios, the both –ve and +ve error% decreased with decreasing temperature to within an error% of (3 ± 1). Nonetheless, only low temperature (5 °C) with absence of AS shows ca. 20% error in both +ve and –ve in all the ratios, as shown in the insert figure of Fig.6. At lower ratios.

2:8 and 4:6, the ABC differentiation is very effective (within 3% error) at 5 °C in the absence of AS and it starts increase with

Scheme 1. Equilibrium arrest between AC, ACm, and ABC at different conditions.

increasing AC to ABC ratios, the differentiation error% is increased up to 20%, which indicates AS is the only component responsible to arrest or control the equilibrium transfer between AC to ACm, and AC to ABC, as shown in Scheme 1. The both AS presence (AC and ACm equilibrium arrested) and low temperature (AC and ABC equilibrium arrested) give highly synergistic effect for clear differentiation of AC and ABC at all ratios. For clear differentiation, comparative results are plotted and presented in Fig. 7, here shown how the error trend of AC and ABC is minimized at different experimental conditions. It clearly explains the accurate identification ABC and AC is only possible by titration in the presence of AS at 5 °C, especially along with impurities. We believe that this present condition may support to get more accurate identification when analyze through an instrument.

At 5 °C in presence of AS in all ratios:

3.5. Validation through real sample

The desulfurized crude sample was first purified by adding water and then reacted with NH_3 and CO_2 to produce $NaHCO_3$. In order to finalize the reaction conditions, ABC and AC determination are important in a secondary waste solution of AS, as shown in reaction 26. The total reaction process was carried out as shown in Fig.1. In brief, 11.1 Kg of crude desulfurised waste were dissolved in 24.12 L of water. The slurry solution heated to 45°C along with stirring about 30 min. Then the slurry was then transferred to filter press machine, which was operated at 45°C and 4 atm pressure. Typically ~11 wt% of insoluble impurities were collected from the filter press. The filtered solution has analyzed by titration for carbonate and bicarbonate, ISE for sodium ion, IC for both cations and anions. In these given conditions, approximately 90 wt% (obtained salt weight/(total raw waste weight-impurities weight) x 100) sodium sources through filter press method have been recovered. The exact weight and volume that obtained were depicted in row 7 in Table 1. The analyzed filtered desulfurized solution was then sent to carbonation tank to produce $NaHCO_3$ using ammonia solution and CO_2 gas. Based on the analysis value of sodium source, the ammonia solution 0.9 mol ratio against sodium source was taken for the production of sodium bicarbonate. Under optimized conditions of temperature, water volume, and pressure, sodium bicarbonate production process were done using the carbonation tank. Then the reaction slurry sent to peeler type decanter modified with the overhead temperature controller. The peeler type decanter was operated at 45 °C temperatures both on overhead and reactants slurry, 800 mesh filter and 3500 rpm. The product error was predicted based on the analyses of both solid and secondary waste liquid by titration, UV-Visible spectroscopy, and ISE methods. The total ions of both solid and liquid that found are displayed in row 11–12 in Table 1. The found difference of BC and C in the presence of all is $2 \pm 0.5\%$. This indicates validation of the present method and very crucial to finalize the further modification in perfection process.

$$\text{Crude waste} + NH_3 + CO_2 + H_2O \rightarrow NaHCO_3 + (NH_4)_2SO_4 \quad (26)$$

4. Conclusions

The AC and ABC were identified within an error% successfully by simple titration. Back titration results confirm it will differentiate

only one ratio of AC and ABC (6:4) and leave a high error to all other ratios makes unsuitable in their complete identification. Also, the double indicator titration method confirms, similar as the back titration method, not suitable to identify the AC and ABC except one ratio (5:5). In a replacement titration through the addition of Na_2SO_4 minimizes the identification of AC and ABC error% a less than the only double indicator method confirms partial equilibrium arrest between ACm and SC and conversion of AC and ABC to SC and SBC. Instead of SS, AS addition give 3 ± 1 error% up to the ratios of 6:4 confirms the effective minimization in complete equilibrium arrest between ACm and AC, and conversion of AC to ABC. Beyond this 6:4 ratio, the error% has increased with increase in ABC concentration, which concludes only equilibrium between AC and ABC conversion. Finally, at low temperature 5 °C, the error% is completely arrested all equilibriums and minimized the error%, even at high ratios 7:3 of AC and ABC. The validation of the present method in real sample analysis is perfectly working to identify the BC and C in the presence of excess AS within an allowed error%. These results conclude that low temperature in the presence of excess AS is more suitable to differentiate the AC and ABC by titration analysis.

ABSTRACT

During the past decade, the number of terrorism acts has increased and the need for efficient explosive detectors has become an urgent worldwide necessity. A prototype, Nebulex™, was recently developed in our laboratory. Basically, it couples the solubilization of an analyte from the atmosphere by a nebulization process and *in-situ* detection. This article presents the development and integration of an electrochemical sensor for the detection of nitromethane, a common chemical product that can be used to make an improvised explosive device. A gold screen-printed electrode was used in a flow-cell and a detection limit of 4.5 μM was achieved by square wave voltammetry. The detection method was also determined to be selective toward nitromethane over a large panel of interfering compounds. Detection tests with the Nebulex™ were thus carried out using a custom-made calibrated nitromethane vapor generator. Detection times of less than one minute were obtained for nitromethane contents of 8 and 90 ppm_v. Further measurements were performed in a room-measurement configuration leading to detection times in the range of 1–2 min, clearly demonstrating the system's efficiency under quasi-real conditions.

1. Introduction

In a context of terrorism menace, the use of canine corps still represents the most sensitive and reliable solution to detect explosive traces [1–3]. However, dog-handler teams involve high costs for training and maintenance. Moreover, the effective time a dog can be used is limited to less than 1 h [3,4]. Hence, extensive interest has in recent years been devoted to developing artificial systems able to surpass these limitations [4–6]. Beside the purpose of global security, these developments also have implications on environmental protection depending on the impact of explosive compounds on human health and ecosystems [7,8].

Nitromethane (NM) is a common chemical compound used for example as a solvent in chemical laboratories or as a fuel in motor sports. But it can also be utilized in the fabrication of an improvised explosive device [9]. According to the high availability of this compound, NM can be classed as a very significant target for explosive detectors. This compound is highly volatile with a vapor pressure of 37 000 ppm_v at 20 °C and explosion limits of 7.3–63% (v/v) in air [10]. NM is also classified as a hazardous substance for human health with occupational exposure limits fixed to 20 ppm_v in the United States of America and 100 ppm_v in France [11].

NM is detectable with most commercially available combustible gas sensors (semiconductor or metal oxide sensor technology) or volatile organic compound detectors (photoionization technology). Although sensitive, these devices aim at detecting a large panel of chemical species and do not allow the recognition of one specific target substance. Thus, several investigations have been performed in order to produce a more selective response to the presence of NM both in liquid or gaseous phases. Recent developments include dog sniffers [12], photometric titration [13], fluorescence spectroscopy [14,15], laser-induced fluorescence [16], thermal analysis [17], gas chromatography [18,19], conductometric gas sensors [20] and electronic noses [21,22]. The best performances for gas sensors are in the range of 2–30 ppm_v with times of detection close to few seconds. Better detection limits have been obtained with gas chromatography (0.02 and 0.4 ppm_v) but using several experimental steps and long-time exposures (4 h and 10 min, respectively).

Finally, electrochemistry is a particularly suitable method for the detection of NM as it potentially combines several advantages including high sensitivity, a short measuring time, low costs,

compactness and possibilities of miniaturization for integration. Some interesting approaches have been proposed [23–26] but have important limitations that preclude any further developments, *i.e.* mainly the use of a complex working electrode made of multi-materials and an atmosphere free of oxygen.

We have re-evaluated the potential of this technique for the detection of NM but our investigations were restricted to the development of an easily integrable system, *i.e.*, with constraints of a low-cost material, possible miniaturization and air containing oxygen. In a first investigation [27], we performed a screening of several experimental parameters that govern the electrochemical response in aqueous solution. Finally, square wave voltammetry (SWV) was selected with a gold working electrode in a phosphate buffer solution of pH 7.5. We also evaluated the use of a screen-printed electrode immersed in a custom-made bubbling vapor solubilization unit to detect NM vapors. Even if detection times of 30 s were obtained for NM vapor contents of 100 ppm_v, the efficiency of this assembly was mainly limited because of the heterogeneous stirring of the solution produced by the bubbling process, which resulted in noisy voltammograms.

The major problem has here been solved by using a portable detection device, Nebulex™, which was developed in our laboratory a few years ago [28]. This device is based on an original concept coupling the solubilization of analytes present in the atmosphere (vapors or particles) *via* a nebulization process instead of bubbling and the continuous detection of analytes within the solution. Initially, applications of Nebulex™ were focused on the detection of peroxide and nitroaromatic compounds by an optical measurement (absorbance or fluorescence) [29].

In the present study, we have investigated the possibilities of extending this concept to the detection of NM vapors.

The integration of miniaturized screen-printed electrodes with a flow-cell linked to the nebulization tank of Nebulex™ was evaluated. The efficiency of this assembly was determined by performing vapor detection tests, first under calibrated laboratory conditions and, subsequently, in a room-measurement environment that represents quasi-real conditions of use.

2. Experimental section

All the chemicals were of analytical grade and were used without further purification. All the solutions were prepared with deionized water with a resistivity above 18.2 MΩ at 25 °C (Milli-Q direct UV3, Millipore).

Nitromethane (NM) stock solutions were prepared on a monthly basis by dissolving liquid NM (Aldrich) in water. These solutions were stored in the dark at room temperature. Buffer solutions were prepared by dissolving KCl salt (Sigma-Aldrich) and K_2HPO_4 salt (Fluka) to obtain final concentrations of 1 M and 0.1 M, respectively. The pH was measured with a pH-meter (PHM201, Meterlab) and a combined electrode (XC161, Radiometer). It was adjusted to 7.5 by addition of aliquots of 1 M HCl (Fluka).

The NM concentration in air during the detection tests was determined by high performance liquid chromatography (HPLC) titration of the content of bubblers exposed to NM vapors. The experimental assembly comprised a vessel containing a determined amount of NM (pure or in solution), three bubblers containing water, a flow regulator and a pump. The vacuum created by the pump enabled to suck ambient air into the vessel thus carrying NM vapors into the bubblers. Then, the content of the bubblers was titrated by HPLC (Alliance 2695, Waters). A C-18 column of 150 mm length with an internal diameter of 4.6 mm and a pore size of 5 μm was used. The mobile phase was a mixture of water and methanol with a 50/50 ratio (v/v), the liquid flow rate was 1 mL min^{-1} and the detection was made by UV–vis absorbance at 215 nm. Vapor detection tests performed in the laboratory with Nebulex™ were realized under experimental conditions previously evaluated with this titration assembly and thus, the precise NM concentration in air was known. In the case of untested conditions for NM vapor generation, the concentration was estimated by extrapolation of known conditions.

The electrochemical measurements were performed using a portable potentiostat (PalmSens, Palm Instrument BV) with disposable screen-printed electrodes (SPE) consisting of a gold working electrode, a platinum counter electrode and a silver pseudo-reference electrode (DS250BT, Dropsens). The gold working electrode was pretreated and the silver of the pseudo reference electrode was converted to silver chloride according to the literature [27]. The voltammetric detection of NM was performed using square wave voltammetry with a 4 mV potential step, a 20 Hz frequency and a pulse amplitude of 30 mV. This set of parameters was selected following several optimizations to obtain the best compromise between sensitivity and speed of measurement. All voltammetric experiments were performed without removal of atmospheric oxygen.

The influence of interfering compounds towards the NM detection was studied by inserting an SPE in a flask containing 25 mL of the buffer solution. Five interfering compounds (25 μL of each one) were successively introduced, followed by 3 aliquots of 25 μL of a diluted NM solution (corresponding to 25 μM of NM for each added aliquots). Thus, the ratio of each interfering compounds toward one aliquot of NM was about 1000/1 in weight depending on the density of each compound. Repetitive SWV scans were performed during all the experiment and the current at the NM reduction peak potential was plotted *vs.* the time. The same experiments, in which NM was added before the aliquots of interfering compounds, were also performed to easily check the impact of these compounds on the NM reduction peak intensity (not shown). Three sets of interfering compounds were tested: a set of solvents (acetone, ethanol, toluene, dichloromethane and acetonitrile); a set of cleaning products (multi-use cleaning product, floor cleaning product, liquid soap for hand washing and 2 sorts of shower gels) and a set of various products (*eau de Cologne*, 2 sorts of fragrances, dogs and cats repulsive spray and an aniseed aperitif).

A schematic representation of how the Nebulex™ functions is given in Fig. 1(A). A vacuum is created in the nebulization tank which enables to suck ambient air into the device. The transit of air in the system of nozzles allows the formation of an aerosol by the Venturi effect. The droplets in this aerosol are very small conducing to a very efficient solubilization of analytes from the atmosphere due to the large exchange area between the air and the liquid. A vapor condenser was disposed between the nebulization tank and the pump to reduce the loss of nebulized solution. The flow rate of air used in the following experiments was about 3.5 L min^{-1} and the volume of nebulized solution was 30 mL.

The electrochemical detection system was integrated in the Nebulex™ device by inserting the SPE in a flow cell (Dropsens, *cf.* Fig. 1(B)). A flow of the nebulized solution was generated between the tank and the cell in a closed circuit by using a peristaltic pump (KNF). A short tube with a larger cross-section was added in the circuit before the flow-cell to absorb pressure pulses produced by the pump, resulting in a steady flow of solution and smooth voltammograms. However, this module has also induced a large pressure loss which reduces the flow to a maximum value of 3 mL min^{-1}. This flow-rate was used during the detection tests in order to obtain the lowest time of transit for the nebulized solution between the tank and the measurement cell.

The detection time during the vapor detection assays was defined as the duration separating the beginning of the exposure and the moment at which the current was shifted outside of the noise area. This noise area is calculated as the average current value

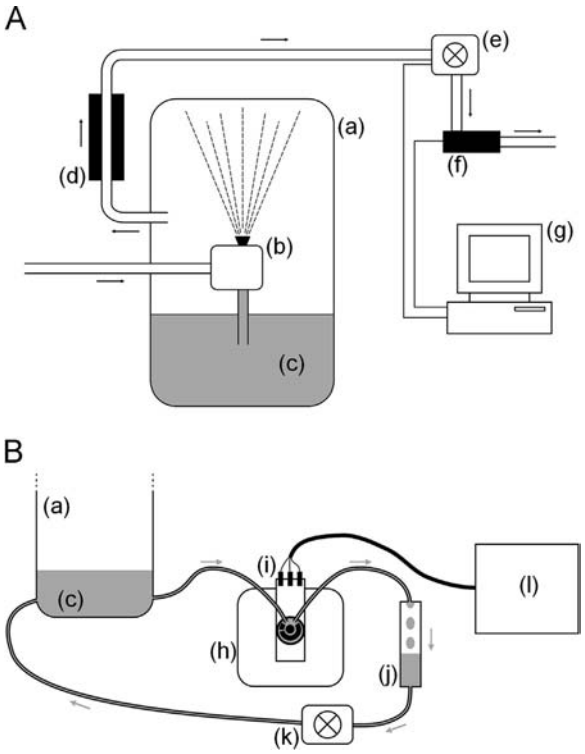

Fig. 1. Principle of the Nebulex™ device (A) and scheme of the electrochemical measurement assembly (B). over a set of blank measurements, more or less 3 times the standard deviation (3σ).

For the vapor detection tests in room-measurement conditions, a small amount of NM (5 mL) was deposited at the center of a clean room (32 m^3 in volume), corresponding to a theoretical vapor concentration of about 50 ppm_v. However, only 2 mL were vaporized as about 3 mL of residual liquid NM were left after detection. This shows that a maximum NM concentration of about 20 ppm_v in the gas phase was reached during the experiments. The Nebulex™ device was positioned in the next room and the suction pipe was inserted in the measurement room through the wall. The distance between the end of the suction pipe of the Nebulex™ and the NM source was about 1.2 m and the duration between placing the NM in the room and the beginning of the vapor detection measurement was 30 minutes.

3. Results and discussion

In our first study [27], performances and repeatability of SPEs towards electrochemical detection of NM were evaluated. It was first found that the potential of the NM reduction peak was highly reproducible ($\pm$ 4 mV with 12 different SPEs) due to the transformation of the Ag pseudo-reference to the AgCl pseudo-reference. The gold activation procedure also gave rise to a very stable NM peak intensity with a relative standard deviation of 4.5% on the slope of the current *vs.* NM concentration with 12 different SPEs. The repeatability and performances of the SPEs were also evaluated in the experimental flow-cell assembly used in the present study and similar results were obtained. NM was determined with a sensitivity of 210 nA/μM and a limit of detection (LOD) of 4.5 μM was calculated on the basis of three times the signal-to-noise ratio (3 S/N).

In the present study, the impact of several common interfering compounds on the detection performances was investigated to evaluate the selectivity of our detection method toward NM. These measurements were carried out directly in the electrolytic solution instead of working in the vapor phase *via* the solubilization device in order to maximize the influence of the interfering compounds, and mainly to avoid the false negative results due to poor volatility or poor water solubility.

As can be seen in Fig. 2, only the multi-use cleaning product and the liquid soap for hand washing had a slight impact on the detection curve. Additional measurements were performed on these two isolated compounds to have a better insight into their specific response. The first one produced a negative shift of the base-line all over the examined potential range. Such an effect can be easily identified by checking the root voltamograms (no reduction peak, no NM). The impact of the liquid soap for hand washing is more troublesome because of the appearance of a reduction peak at exactly the same potential than the NM reduction peak. However, this peak remained tiny (*ca.* 0.5 μA) and did not shift the current curve outside of the noise area, even if more soap was added. Moreover, all the interfering compounds were added in a very large proportion compared to each NM aliquot (about 1000/1 in weight). Thus, the interfering impact with respect to the detection performances of these two compounds, as well as the others, can be reasonably neglected. These results allow appreciating the robustness of the method in a realistic environment of use.

The content of NM vapors used in the detection assays was calibrated beforehand. In all the experiments, the NM concentration fraction in the bubblers was about 90% for the first bubbler, 10% for the second and under the HPLC LOD (3.2 μM) for the last. It could thus be deduced that the sum of the amount of NM titrated in the first two bubblers corresponded to the total amount of NM carried by air. Consequently, the NM concentration in air could be calculated taking into account the sum of the titrated amount of NM in the bubblers divided by the total volume of air passing through the bubblers during the experiment. This was expressed as a partial pressure using the ideal gas law.

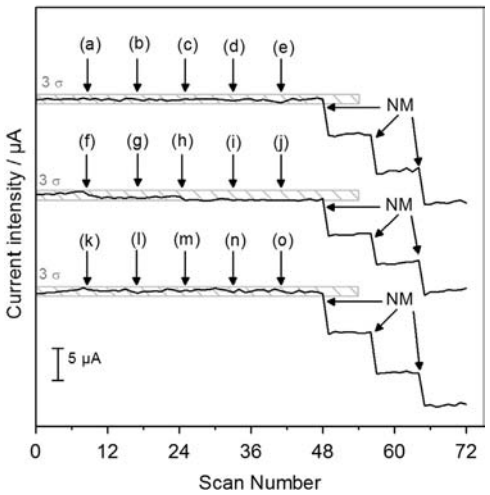

Fig. 2. Plot of the current at the NM reduction potential *vs.* the time during the additions of 25 μL aliquots of (a) acetone; (b) ethanol; (c) acetonitrile; (d) toluene; (e) dichloromethane; (f) multi-use cleaning product; (g) floor cleaning product; (h) liquid soap for hand washing; (i) and (j) 2 sorts of shower gels; (k) eau de Cologne; (l) and (m) 2 sorts of flagrances; (n) dogs and cats repulsive spray and (o) aniseed aperitif. "NM" corresponds to a 25 μM increase of the NM content of the solution. The gray area corresponds to the noise area and constitutes three times the standard deviation obtained from a set of blank measurements.

The experimental parameters governing the NM concentration in air are the amount of NM in the vessel and the vessel geometry. Varying these two parameters enabled to establish an NM vapor concentration range from 0.7 to 8.2 ppm_v. This range was deliberately much lower than the vapor pressure of NM as the purpose of this study was the detection of trace amounts.

The NM solubilization efficiency of the Nebulex™ was also evaluated. Experiments were carried out under previously calibrated conditions for NM vapor generation, but by using the Nebulex™ instead of the bubblers. The content of the nebulization tank after exposure to the NM vapors was titrated by HPLC and compared to the NM concentration in air. A solubilization yield of about 50% was obtained without any prior optimization of the system. An improvement of this efficiency will be possible in the future by performing numerical simulations of both aerosol formation and condensation of droplets from the aerosol to the tank.

The detection of NM vapors with the Nebulex™ device was first attempted under laboratory conditions using an NM concentration in air of 8.2 ppm_v. The resulting voltammograms as a function of time are shown in Fig. 3(A). The measurement of ambient air produced a repeatable base-line with a low level of noise. The reduction peak appeared after a few scans following the exposure to NM vapors. The device was also evaluated to detect NM at a concentration of 90 ppm_v (Fig. 3(B)), which corresponds to the French occupational exposure limit for this compound [11]. In this case, the reduction peak of NM appeared with a higher intensity but was still not observed directly after the beginning of the exposure.

The detection time was determined for each experiment by plotting the current at the NM reduction potential *vs.* the time (*cf.* Fig. 4). Detection times were 36 s and 48 s for the exposures to 90 ppm_v and 8 ppm_v of NM, respectively. Thus, even if the NM concentration in air was decreased by a factor ten or more, giving a less intense NM reduction peak, the detection time was only increased by the duration of one scan. As can be seen in Fig. 4, a short time after the exposure to NM vapors, the reduction current increased linearly with the duration of the experiment. For low NM gas concentrations, the slope of the linear domain was weak. In this case, the detection time can be improved by increasing the NM concentration in the solution. This can be achieved by an

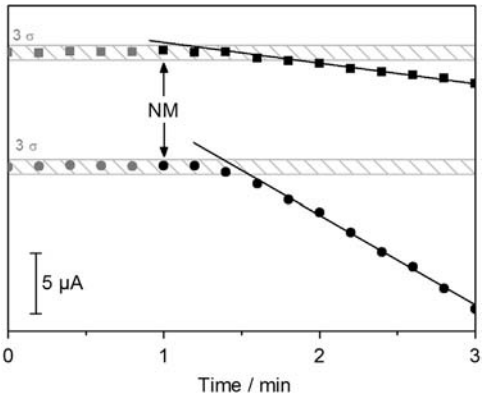

Fig. 4. Plot of the NM reduction current *vs.* the time during the detection tests of NM vapors at concentrations of 8 ppm_v (squares) and 90 ppm_v (dots). Gray squares/dots correspond to the exposure to NM free air (blank measurement) and black squares/dots correspond to the exposure to NM containing air. The gray area corresponds to the noise area and constitutes three times the standard deviation obtained from a set of blank measurements. Only the points outside of the noise area are considered to constitute the linear regressions.

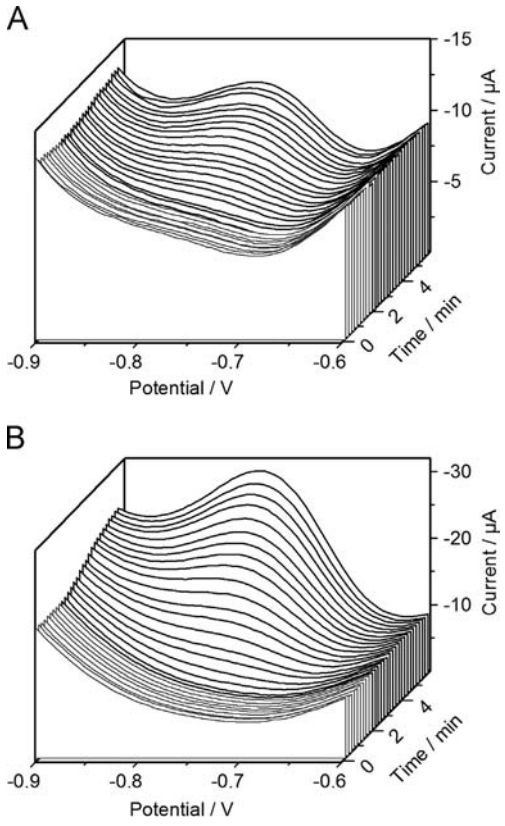

Fig. 3. Voltammograms as a function of the time during detection tests of NM vapors at concentrations of 8 ppm_v (A) and 90 ppm_v (B). The gray curves correspond to measurements of ambient air and the black curves correspond to measurements of NM vapors.

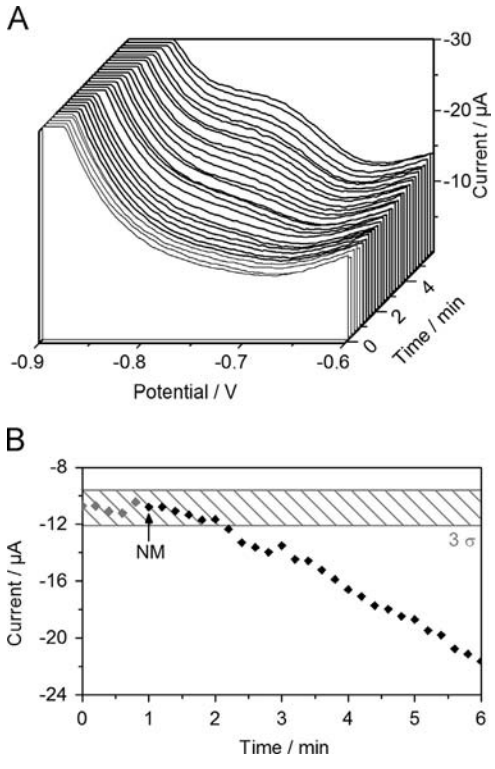

Fig. 5. (A) Voltammograms as a function of the time during a detection test of NM vapors in a room-measurement configuration. The gray curves correspond to the measurement of ambient air and the black curves correspond to the measurement of NM vapors. (B) Plot of the NM reduction current *vs.* time during the same experiment. Gray diamonds correspond to the exposure to NM free air (blank measurement) and black diamonds correspond to the exposure to NM containing air. The gray area corresponds to the noise area and constitutes three times the standard deviation obtained from a set of blank measurements.

optimization of the nebulization process. The initial transient period corresponds to the time the NM takes to reach the SPE from the aerosol. This short period gives a limit of the detection time that cannot be overpassed even at high gas concentrations. A reduction of this delay is possible by an optimization of the measurement circuit from the nebulization tank to the SPE with regard to fluid flow concepts.

Finally, the Nebulex™ device was evaluated in conditions of room-measurements. Liquid NM was left in an empty room and the vapors were sucked into the Nebulex™ device in the adjacent room. The results of one of these experiments are shown in Fig. 5. Measurement conditions were in this case not as ideal as in the laboratory: the base-line corresponding to the measurement of air without NM was not as repeatable and the noise area was broader. The NM reduction peak was nevertheless observable from about 1 min after the beginning of the exposure to the NM vapors. The detection slope (reduction intensity *versus* the time) is closed to two times higher than the one obtained for the experiment at 8 ppm_v of NM vapor concentration. This data is coherent with the maximum theoretical average NM vapor concentration of 20 ppm_v that can be reached in the room (see experimental section).

A detection time of 1 min 20 s after the beginning of the exposure to NM vapors was determined according to the method described above. In addition to the broader noise area, the detection time was also extended because of the use of a longer suction pipe passing through the wall. Even though performances were degraded in unclean (but real) conditions of use, the possibility of detecting NM in a room-measurement configuration within a reasonably short time (*i.e.*, in a one-minute range) was here demonstrated. The next step will be the evaluation of environmental conditions on the system performances. Several parameters can be varied, including the amount of NM, the distance between the NM source and the suction pipe, the presence of obstructing objects, *etc.*

4. Conclusion

This article has described a novel system for the detection of NM vapors with the Nebulex™ device. Electrochemistry was selected as the analytical technique because of its low cost, high sensitivity and fast measurement capability. A flow-cell and an SPE were used to integrate the detection system in the device leading to an LOD of 4.5 μM for NM. Moreover, no significant perturbation of the detection signal was noted after exposure to 15 potential interfering compounds showing the robustness of the method in a realistic environment. The vapor generation used for the detection was calibrated and the solubilization efficiency of the nebulization process was determined.

Finally, the feasibility of electrochemical detection of NM vapors with the Nebulex™ device was successfully demonstrated. Detection times of less than one minute were obtained even for an NM vapor content below 10 ppm_v. The detection of NM vapors in a room-measurement configuration, which is more representative of real conditions of use, was also achieved. In this case, the detection time was slightly longer, due to the experimental conditions not being as clean as in laboratory tests, but was still in the 1 min range.

The LOD obtained with the present system is in the same order than those of other gas sensors. However, this limit can be improved by accumulating analyte vapors over several minutes. Moreover, the presence of NM can be confirmed *a posteriori* by chemical analysis of the nebulized solution.

Routes of improvement were identified to enhance the efficiency of the Nebulex™ device which will eventually be tested in more realistic conditions.

ABSTRACT

The complexity of the matrices of the analytes from a biological sample or environmental origin can disturb the separation and data analysis steps. Thus, the major incentive of recent research trends in environmental and bioanalysis research is to achieve faster, simpler, inexpensive, and more environmental-friendly sample preparation techniques. Application of auxiliary energies is one of the efficient strategies to reach the aforementioned purposes. Among these, application of electrical driving force in different extraction techniques has found remarkable consideration in recent years attributed to its ability in control of different properties of an extraction system such as selectivity, clean-up, rate, and efficiency by imposition of a variable potential difference. This review attempts to explain the principles of electrically assisted solid based extraction techniques as well as different roles of electrical field in these methods in more details. Also, advantages, disadvantages, and limitations of these techniques are discussed providing coherent information and useful insights for future researches.

1. Introduction

Sample preparation is of vital importance in analysis of trace amounts of target analytes or their analysis in complicated matrices. Some sample cleanup, analyte isolation from the interferences, and their preconcentration to a suitable level may be required before instrumental analysis. Sample preparation could be explained as the experimental steps required making a sample ready for analysis. A good sample preparation method should be as fast as possible, reproducible, involve minimum number of steps, has relatively low cost, be environmental friendly, and offer high recoveries, and also have the potential to become automated [1].

Solid phase based extraction techniques are well-known sample preparation methods, which have been associated with many advances in the past few years. Liquid–solid extraction or solid phase extraction (SPE) was first introduced as a replacement for liquid–liquid extraction (LLE). The technique utilizes a solid support to isolate and preconcentrate the analyte of interest [2–4]. A typical SPE has four processing steps; including conditioning, sample application, washing impurities, and elution of target analytes. Pawliszyn et al. have presented for the first time the miniaturized format of SPE; named solid-phase microextraction (SPME), in which sampling, isolation, and enrichment of analytes and its introduction into the analysis instrument can be done in one step [5]. SPME requires a small amount of extraction phase coated on a solid support. Selectivity of this technique is determined by composition of the extraction phase.

Electrical field induced extraction technique is a topic that is less investigated. A significant growing trend can be observed in the annual number of publications related to the electrically assisted extraction techniques as well as the number of citations to these works in the literature. Thus, it can be concluded that these methods are gradually becoming a quite common place in the analysis of various environmental and biological samples.

In this review, the focus is centered on the electrically assisted solid based extraction techniques to present a general vision of the effect of electric fields on carrying out sample treatment and also to evaluate the real potential of these methods. Advantages, disadvantages, and limitations of these techniques are discussed. These points can be helpful in future scientific researches to overcome current problems and improve electrical induced solid based extraction methods.

For this purpose, a comprehensive survey of past and present novelties and applications of the electrically assisted solid based extraction techniques will be provided. Also, a conceptual clustering method was applied for investigation of different aspects of various electrically assisted techniques and a powerful and innovative way was employed to keep information in the mind for a long period of time.

2. Solid based extraction techniques

Electrochemical techniques have found remarkable applications in SPE and SPME techniques including synthesis of sorbents and enhancement of extraction [6–9]. In the case of synthesis of sorbents, the electrochemical method provides tailoring of key characteristics including thickness, conductivity, degree of oxidation, color, and morphology [10]. This fact has propelled various research groups toward synthesis of new coatings [11–14]. Among the newest, there has been growing interest in conducting polymers due to their multifunctional properties [11].

The idea of application of electrical field in solid-phase extraction originates from a technique termed electrochemically modulated liquid chromatography (EMLC) [15]. EMLC was first reported by Fujinaga et al. in 1963 [16]; then by Blaedel and Strohl [17] and independently by Roe in 1964 [18]. Generally, an electrical field has two effects in the solid based extraction techniques; it directly affects the surface of solid sorbents and provides manipulation possibility of extraction [7–9,19–21], or has an indirect effect so that only provides an electrokinetic migration of charged analytes toward solid sorbent [22] or facilitates elution of the analytes [6]. Electrically assisted solid-phase extraction/microextraction and electrokinetic trapping are the instances for direct and indirect effects of electrical field in solid based extraction techniques, respectively.

According to the literature, the substantial increasing trend in application of the electrical field in solid based extraction techniques can be attributed to several reasons;

1. Properties of the conducting polymer can be modified by varying the conditions during the electropolymerization step to enable extraction of analytes with different sizes and charges.
2. Compared to conventional solid based extraction techniques, in which a material with a fixed number of exchange sites is employed, electrically assisted one offers higher flexibility. This is because the properties of the material and thus the number of exchange sites can be externally controlled by electrochemically controlling the charge of the material [23,24].
3. The use of polymer based fiber films in solid based extraction techniques can be extended to the analysis of neutral, electroinactive analytes by taking the advantage of electrochemically controlled hydrophobic/hydrophilic ‘switching’ [25].
4. Electrically assisted solid based extraction techniques can be used to extract ions and analytes that normally need to be derivatized prior to traditional solid based extractions [26,27].
5. In electrically assisted solid based extraction techniques, the extraction and desorption steps are performed merely by altering the potential of the conducting polymer coated electrode. In this approach, there is thus no need for changes of the solvent in order to enable desorption of the compounds [28].
6. By altering the electrochemical potential of the polymer, desorption of electrostatically held analytes may also be faster compared to the desorption techniques normally used in traditional solid based extractions [29]. This makes the technique particularly interesting for use in conjunction with miniaturized analytical systems.

2.1. Electrokinetic trapping

Electrokinetic trapping is a technique, in which charged species migrate in opposite direction of their net charge under electrical field and are trapped by different strategies such as solid sorbent [30], ion selective membrane [31], hydrogel plug [32], and microporous polymer network material (monolith) [33]. The retained charged species are released from the trap by a pressure driven flow in the absence of the electric field. This technique has drawn much attention due to its potential application in biological sciences; especially for preconcentration of proteins and DNA [30–33].

Singh et al. used silica sorbents as trapping materials for preconcentration and determination of chicken egg albumin so that preconcentration values greater than 1000-fold were achievable by this way [30]. Schematic presentations of the setup used are shown in Fig. 1A and B. About 10 cm of a 30-cm fused silica capillary column was packed with porous silica particles as the stationary phase. The capillary column was conditioned at a pH of about 8.3 using 50 mM tris(hydroxymethyl)aminomethane (TRIS) buffer. A sample containing 100 mg L^{-1} of chicken egg albumin as well as caffeine in 50 mM TRIS was electrokinetically injected onto the stationary phase by applying a voltage of about 50 kV through the stationary phase by means of power supply and electrodes.

It should be noted that albumin species were labeled with fluorescein to permit detection possibility by laser induced dispersed fluorescence. Albumin has a negative charge at pH 8.3, whereas caffeine is a neutral compound in this pH and therefore, can be used as an evidence for electrokinetic trapping of albumin. The electrodes are disposed on either side of the stationary phase and preferably in inlet and outlet reservoirs. The voltage was applied for about 10 min, during which the uncharged caffeine was eluted from the column.

Under the influence of the applied electric field, only neutral caffeine was eluted in about 8 min from the packed column (Fig. 1C) and no evidence was observed for elution of negatively charged albumin species during different investigated times

(60 min and 12 h) of maintaining the voltage. After confirmation of no elution of albumin, application of the voltage was stopped and pressure was applied to the inlet end of the column by a pump (Fig. 1B) to force fluid through the column; thereby eluting the charged molecules retained on the stationary phase (Fig. 1D).

Other applications including selective modification of protein, the use of retained proteins as immobilized catalyzers, and preconcentration of DNA can be considered for this technique. As can be seen, the electrical field has no direct effect on solid based extraction procedure (trapping) here and only helps the migration of charged species toward trapping materials.

2.2. Solid-phase extraction

As it was mentioned in Section 2, the idea of application of electrical field in solid-phase extraction originates from EMLC [15,34–36]. Briefly, EMLC is a unique combinatory technique that simultaneously has the advantages of both electrochemistry and liquid chromatography. A three-electrode electrochemical cell configured as a HPLC column is used in EMLC (Fig. 2) [37]. The working electrode is a conductive material such as porous graphitic carbon (PGC) or glassy carbon coated with conductive materials such as polypyrrole (PPy) that acts as the stationary phase [37]. This characteristic makes it possible to manipulate analyte retention and enhance separation efficiencies through changing the potential applied to a conductive stationary phase. Electrochemical alteration of the stationary phase is similar to the gradient elution in conventional liquid chromatography.

It should be noted that EMLC not only can be used as a separation technique but also can be applied as an extraction method. For example, EMLC coupled with inductively coupled plasma-mass spectrometry (ICP-MS) detection has been employed by Hasan et al. [38] in the extraction mode for removal of some metal ions from deionized water or diluted acids to clean up blank solutions. Implementation of EMLC in chip based device and application of molecular imprinted polymer (MIP) coated conductive stationary phases to create selective phases may be innovative and interesting directions in this field.

SPE can be classified into two general groups; including conventional and electrochemically ones (Fig. 3). Each of the above-mentioned groups is subdivided into two planar and non-planar types and each type can be carried out in various formats. The focus in this review is on electrochemical solid-phase extraction (EC-SPE) and the conventional one has been reviewed by several other authors [2,39–42].

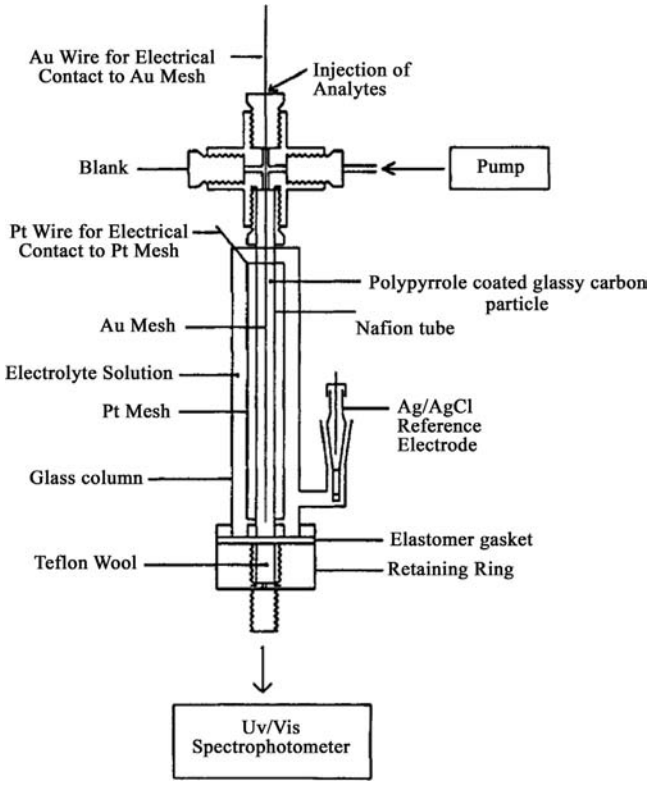

Fig. 2. A schematic presentation of an electrochemically modulated liquid chromatography (reproduced with permission of ACS-Ref. [37]).

(C) and (D) Elution curves for caffeine as uncharged and protein as charged species, respectively; (1) electrodes, (2) stationary phase, (3) frits, (4) fused silica capillary column, (5) laser induced dispersed fluorescence, and (6) pump [30].

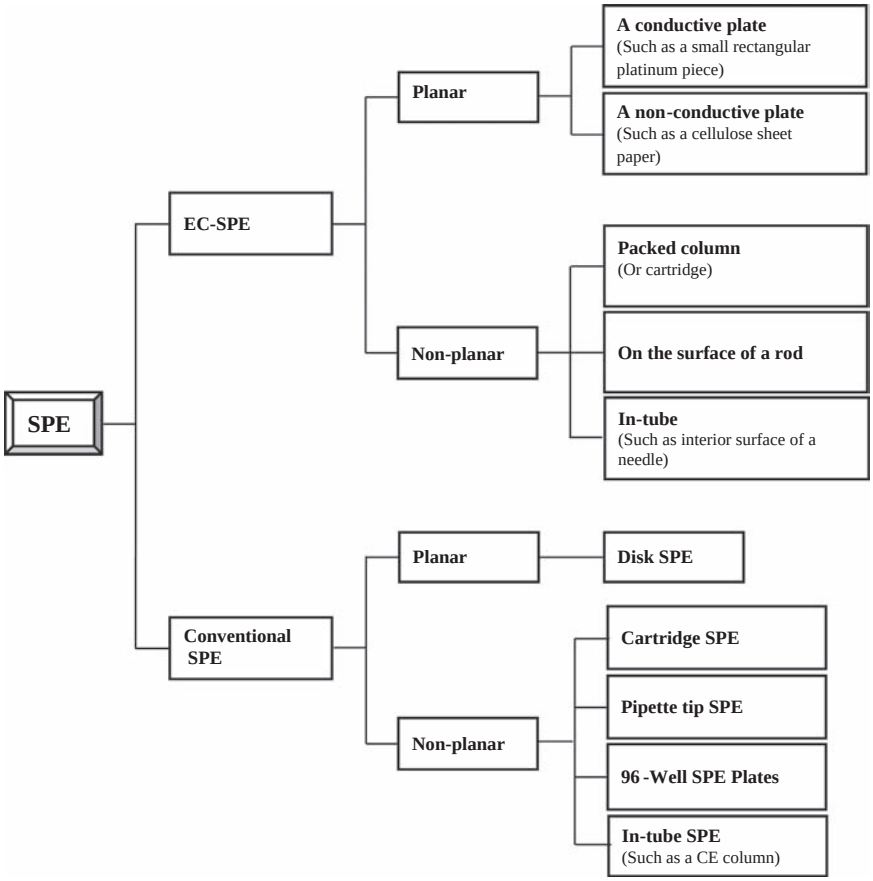

Fig. 3. General classification of solid-phase extraction techniques.

Electrical field has been used in EC-SPE for both assisted extraction and synthesis of solid sorbent aims, solely or simultaneously [6,43–50]. Electrosynthesis of solid sorbent in SPE depends on conductivity of the sorbent substrate. Some examples are interior needle electropolymerization of pyrrole at a constant potential of +1.5 V within 20 min for headspace solid-phase dynamic extraction of some polycyclic aromatic hydrocarbons (PAHs) by Bagheri et al. [50], EC-SPE and amperometric determination of nitrite with PPy nanowire modified electrode deposited on the surface of a graphite rod with diameter of 8 mm under the condition of applied potential of 0.8 V for 300 s by Wang et al. [43], and in-situ EC-SPE of anions and cations using PPy and over-oxidized sulfonated polypyrrole deposited on the surface of a $1.0 \times 0.5\ cm^2$ platinum foil at a constant potential of +0.80 V during 8 min by Şahin et al. [45]. In the first example, electrical field has only been used for electrosynthesis of SPE coating, while in the two subsequent cases both electrosynthesis and assisted extraction can be seen during SPE procedure. In EC-SPE, the extraction is obtained by oxidizing/reducing the conductive polymer, which caused movement of counterions (dopants) in and out of the conductive polymer to maintain its electroneutrality. An introduction to conductive polymers and their different applications, the most commonly used materials to synthesize conductive polymers, and the extraction mechanism by these polymers will be presented in the next section.

An important aspect of EC-SPE, which is almost ignored in comparison with conventional SPE, is on-line combination of this technique with analytical instruments such as chromatography and spectrometry apparatus. In 2005, an on-line EC-SPE using PPy coated electrodes and a thin-layer electrochemical flow cell interfaced to electrospray ionization (ESI-MS) and ICP-MS was developed for determining trace levels of bromide ions in tap water by Liljegren et al. [49]. Determination of bromide at the concentration level of 3 μM was possible using a modified thin-layer electrochemical flow cell coupled with ICP-MS in the tap water sample. The interference effects of various anions were investigated and the results indicated that their impacts can be reduced by electropolymerization of PPy in the presence of bromide ions. Also, different desorption techniques namely stopped-flow desorption and desorption in flowing solutions were examined and the first system exhibited substantial supremacy in comparison with the second one. Regarding the results obtained and possibility of electrochemical control of both extraction and desorption steps in EC-SPE, this technique could be a well-suited candidate for inclusion in miniaturized Lab-on-a-Chip (LOC) systems.

One of the recent advances in EC-SPE is utilization of PPy-modified surface cellulose paper sheets derived from *Cladophora* sp. algae for electrically assisted planar solid based extraction, introduced by Mihranyan et al. [46]. They showed that composites of PPy with cellulose in the form of paper sheets can function as ion exchange membranes by applying an electrical potential to the composite and switching the PPy between its oxidized and reduced states. This novel composite exhibited excellent mechanical stability and could be bent, twisted, or folded without disrupting its mechanical integrity. Also, a high surface area is obtained by this strategy, which improves the ion exchange capacity of conductive paper. More extraction efficiency is expected for a large surface area material with a relatively thin coating of conducting polymer in comparison with a rather thick conductive coating covered a substrate with small surface area. In this work, the PPy-cellulose composite was prepared by oxidative chemical polymerization of pyrrole monomers on cellulose paper sheet in the presence of iron (III) chloride at the room temperature. It was

observed that electrical field only accelerates extraction step and has no effect on the synthesis procedure due to non-conductivity of cellulose paper sheet substrate. Therefore, electrical field in SPE can be used in synthesis, extraction, or both steps.

It should be noted that conductive polymers can be synthesized either chemically or electrochemically [47]. The supremacy of chemical methods to electrochemical ones is that they do not need a conductive substrate for synthesis.

A few attempts have been so far made in this filed [44,46–48]. Gelin et al. investigated the anion absorption properties of this new composite as a function of anion size (nitrate, chloride, and *p*-toluene sulfonate) and anion concentration. Also, they studied how the material behaves in solutions containing more than one anionic species (*p*-toluene sulfonate as a large anion and chloride as a small anion) [44]. It was found that nitrate ions have a slight difference with chloride ions to incorporate in the composite. This is while the composite capacity to host large *p*-toluene sulfonate ions is about 50% compared to the values for the smaller ions at the same oxidation conditions in this study. The results also indicate that anions at electrolyte solution with high concentrations can physically cover most of the composite surface before diffusing into the bulk of the polymer so that the distance between surface sites closely matched the sizes of the anions. Moreover, anomalous behaviors were observed in mixtures containing both chloride and *p*-toluene sulfonate ions. In mixtures with high concentrations of the larger anion, the transport of small ions into the composite was hindered while facilitated transport was observed for small ions at low concentrations of *p*-toluene sulfonate ions.

Also, the authors claimed that no loss of capacity during repeated oxidation and reduction of the polymer indicating that trapping of anions in the reduced polymer did not limit the electroactivity of the present material [44]. However, in the first article in this field, it was reported that after 60 cycles incorporation ability of the film was retained about 85%, which was corresponding to almost 10 h of continuous use [46].

Razaq et al. studied the effects of two different oxidizing agents, iron(III) chloride and phosphomolybdic acid (PMo), in four different electrolyte solutions containing anions with various sizes (chloride, aspartate, glutamate, and *p*-toluene sulfonate) on anion exchange properties of fibrous PPy/Cladophora composites [47]. The results showed larger number of absorbed ions per sample mass for iron (III) chloride in comparison with PMo in all four electrolyte solutions. The highest extraction efficiency was obtained for larger anions in the presence of PMo whereas this result was achieved using iron (III) chloride for small anions. Also, high ion exchange capacities and extraction and desorption rates were observed for large anions using high surface area composites coated with relatively thin layers of PPy.

In another work, Razaq et al. evaluated high-capacity conductive nanocellulose paper sheets for electrochemically controlled solid phase extraction of three DNA oligomers [48]. The ion exchange capacity of the synthesized nanocomposite was at least two orders of magnitude higher than previous reported composite. It was shown that all three oligomers could be straightforwardly extracted from a solution containing an excess of buffer ions with a release efficiency of 40% for the smallest oligomer; indicating that the present material is very promising for development of inexpensive and efficient electrochemically controlled ion-exchange membranes for batch-wise extraction of biomolecules.

Morales-Cid et al. presented a new role of electrical field for SPE technique in a flow system coupled on-line to capillary electrophoresis–mass spectrometry (CE-MS) equipment via a horizontal split-flow interface, which is electrical assisted elution; an indirect effect [6]. Strata X and C_{18} minicolumns were used to preconcentrate the tetracyclines and amines, respectively. Minicolumns of both sorbents were constructed by packing 14 mg of the material in 3 mm id Teflon tubing.

In such system, two major effects are theoretically expected by applying a voltage during the elution step; electrical attraction of the analytes and their subsequent stacking in the flow system immediately before the eluent–buffer interface, and more facilitated analyte elution [6]. Decreasing the eluent volume, need to employ unusual eluents, increasing the determination sensitivity, and decreasing the peak width are the expected impacts of the aforementioned effects. All these advantages were experimentally observed [6]. For example, Fig. 4A shows electropherogram obtained for determination of a 5 mg L^{-1} concentration of tetracycline (1), 2-chlortetracycline (2), and oxycycline (3) without a voltage (A) and a 3 ng L^{-1} concentration using a 10 kV voltage to assist elution-SPE (B). As can be seen, a substantial improvement was obtained for determination sensitivity. However, in spite of the advantages reported, this technique has not been extensively investigated probably due to complicated manifold for this system.

The indirect effect of electrical driving force on SPE with different sorbent materials has been known as a powerful method for improvement of sensitivity of separation techniques such as CE [51]. Fig. 4B shows a schematic representation of this kind of preconcentrator setup. The proposed method allows preconcentration

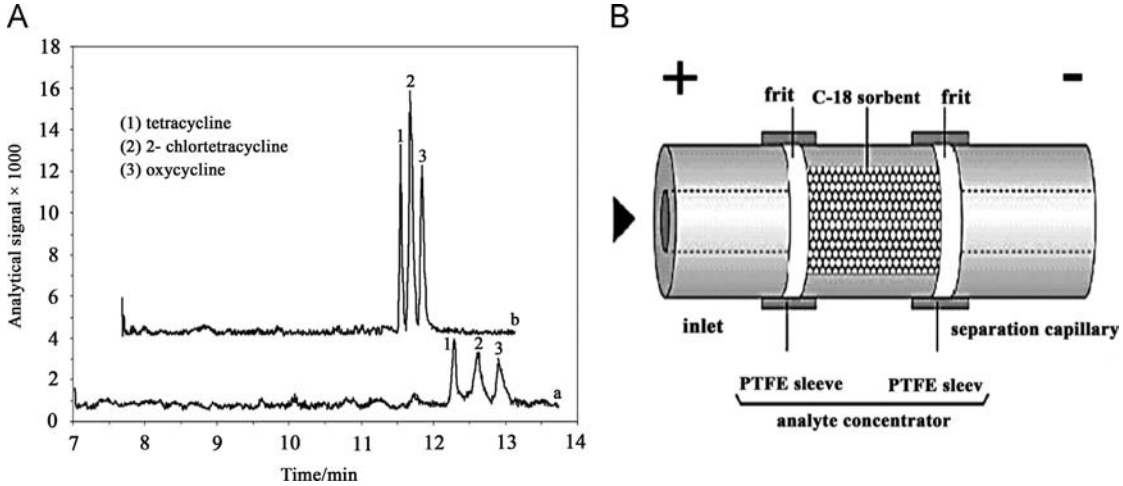

Fig. 4. (A) Electropherogram obtained in determination of a 5 mg L^{-1} concentration of each tetracycline without a voltage (a), a 3 ng L^{-1} concentration using a 210 kV voltage to assist elution-SPE (b), (B) schematic representation of an in-line pre-concentration SPE cartridge (reproduced with permission of Wiley and Elsevier-modified-Refs. [6,51]).

and separation with greater selectivity and higher sensitivity (100- to 200-fold) with respect to CE without in-line preconcentration [51–57].

Generally, elution of an analyte without need to organic solvents, as well as possibility to control analyte retention/elution, more facilitated preconcentration and kinetics due to orientation of charged analytes trajectories toward the pores of the stationary phase, and more rapidity of electrophoretic mobility in comparison with diffusion are the effects that can be counted for electrical field in SPE [58].

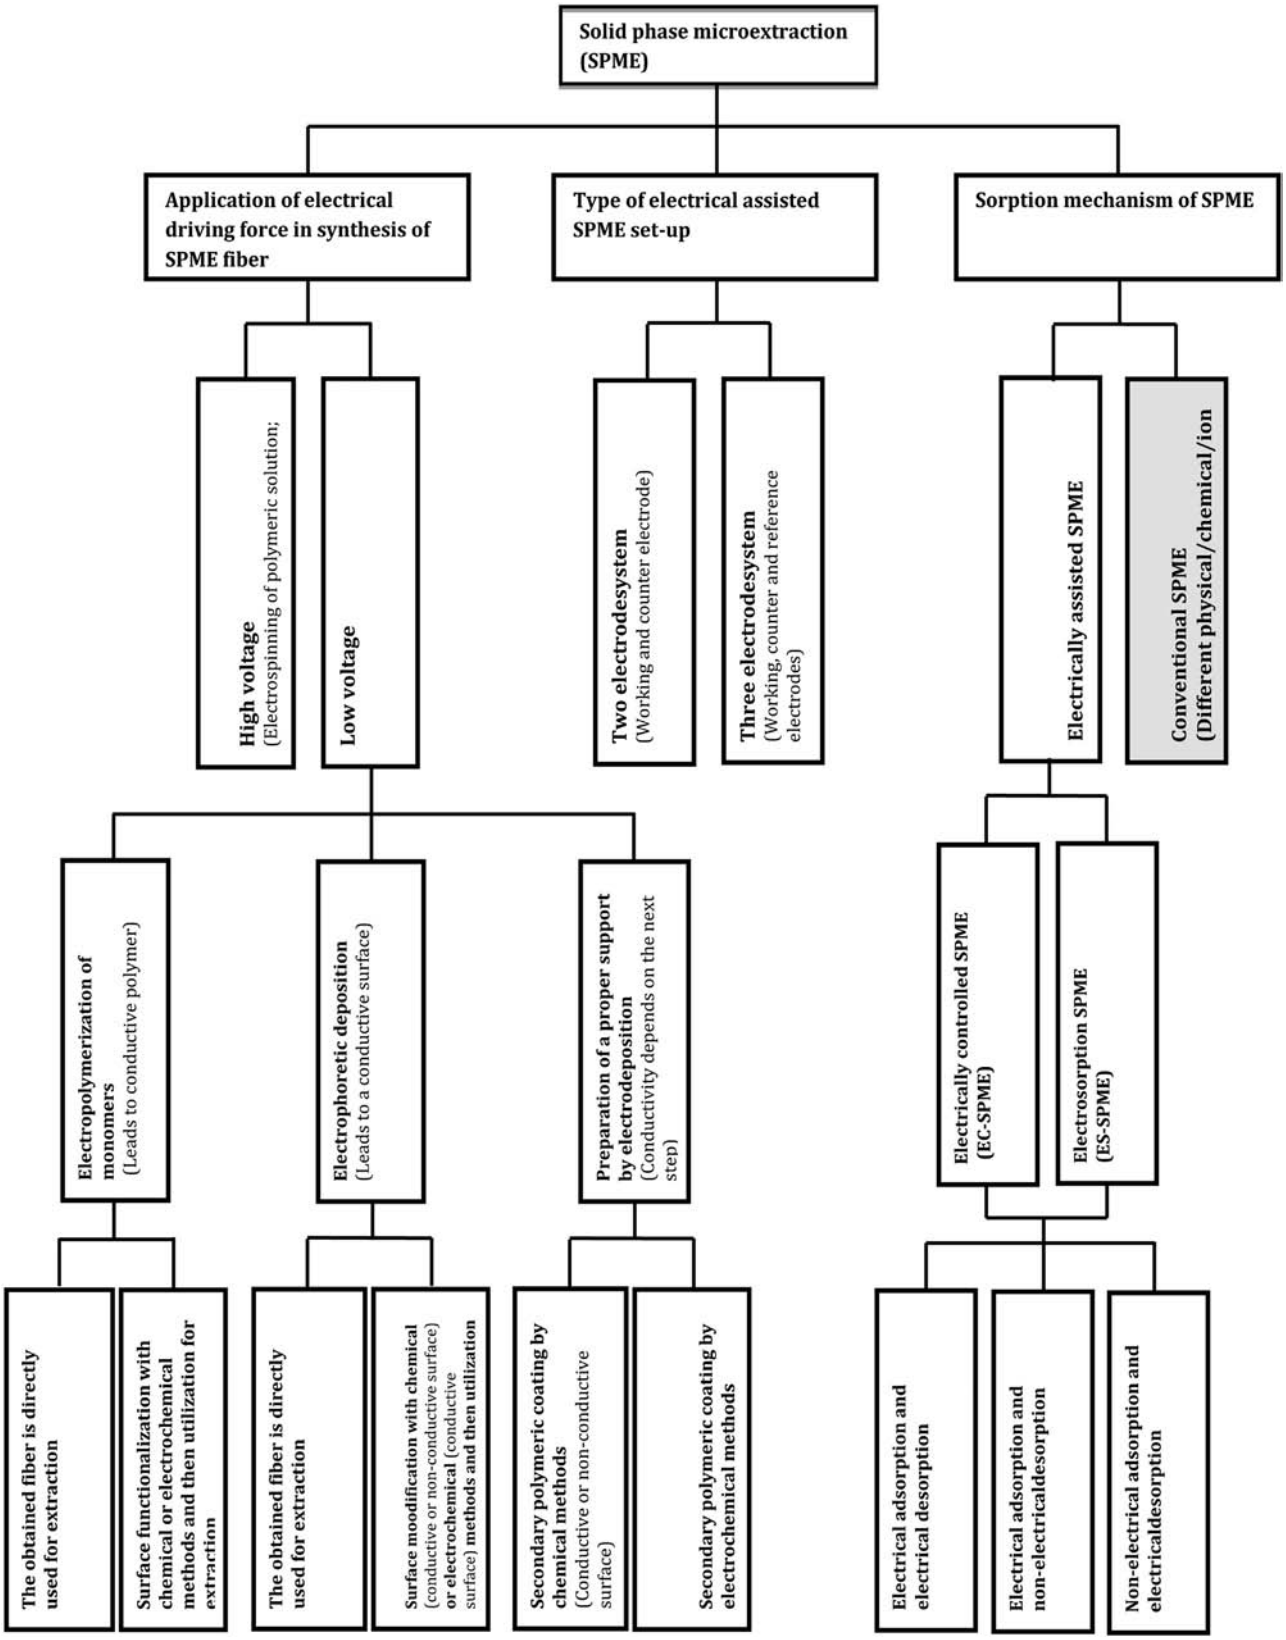

Fig. 5. A general classification for different aspects of electrically assisted solid-phase microextraction including synthesis, type of setups used, and sorption mechanisms (the gray box is related to non-electrically based techniques to give a more comprehensive insight).

Also, detection of extracted analytes in EC-SPE can be carried out either by electrochemical techniques [43,44,46,47] or by different analytical approaches such as chromatographic [45,50] or spectrometry techniques [49].

2.3. Solid-phase microextraction

Nowadays, SPME, a solvent-free miniaturized extraction technique, which was invented by Pawliszyn in 1989, is known as a simple and efficient sample preparation method and has been widely used in different fields including environment, food, natural products, pharmaceuticals, biology, toxicology, and forensic medicine [5,59,60]. As the scope of SPME grew, new improvements were achieved in different aspects of SPME such as appearance of new coatings and application of auxiliary energies that allowed an increase in the specificity of this extraction technique. The main objective of this section is to describe the principles of electrically assisted solid-phase microextraction (EA-SPME) and the recent developments associated with this concept. The discussion covers fundamental understanding about types of EA-SPME setup, application of electrical driving force in synthesis of SPME fibers, and sorption mechanism in EA-SPME (Fig. 5).

2.3.1. Types of electrochemical setup used for SPME

This subject can be viewed from two different perspectives; the setup used for carrying out EA-SPME and the ones for synthesis of SPME coating [61–86].

The most commonly used setup for EA-SPME is the one-compartment three-electrode system consisting of a working electrode, a counter electrode, which is chiefly a platinum wire and a reference electrode, which is chiefly a saturated calomel electrode (SCE) or Ag/AgCl [62,87–89]. In 2008, Öpik et al. introduced an interesting three-electrode system coupled with electrochemical quartz crystal microbalance (EQCM) for EA-SPME as well as electrosynthesis, overoxidation, and characterization of L-aspartic acid-imprinted PPy films [68]. Enantioselectivity of the fabricated film was determined either under stationary conditions with externally applied potential control or in a flow injection analysis (FIA) system.

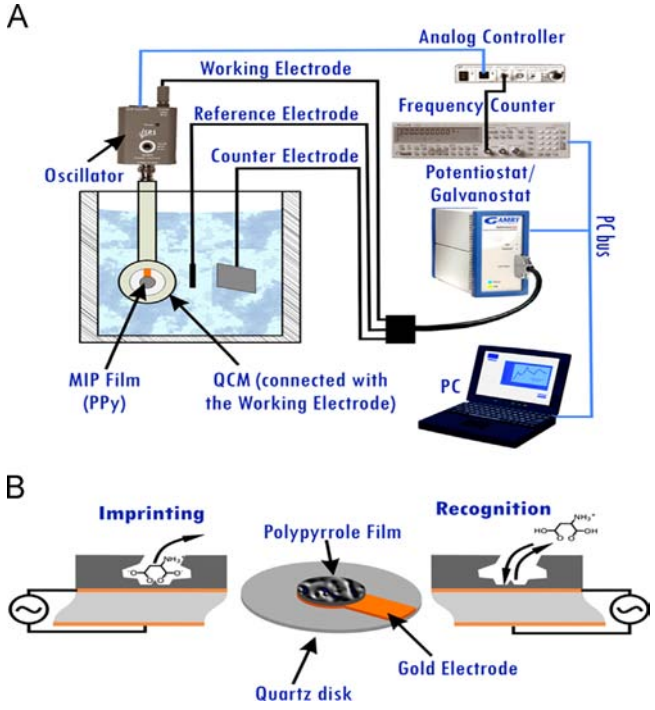

Fig. 6. (A) Simplified diagram of the electrochemical setup used for EQCM experiments. (B) Schematic representation of the chiral recognition of L-aspartic acid by L-aspartic imprinted OPPy films (reproduced with permission of Elsevier-modified-Ref. [68]).

A custom-made Teflon electrochemical cell was used for synthesis and electrochemical measurements (Fig. 6). The face of a 1-in. diameter, polished, gold-coated, 5-MHz crystal served as the working electrode while a rectangular-shaped platinum plate (4×1.5 cm^2) was used as the auxiliary electrode and Ag/AgCl (3 M KCl) as the reference electrode. The results suggest feasibility of preparing molecularly imprinted films by electropolymerization for enantioselective recognition of amino acids and suitability of EQCM for both monitoring the selective recognition as well as electrochemical modulation of the binding process. This method provided a controllable thickness for the fabricated film according to the density of the growing film and the Sauerbrey equation [68].

However, two-electrode system can also be found for EA-SPME in the literature [74,77,81]. Wu et al. developed EA-SPME technique using the lab-made carbonic fiber to determine phenol, *p*-chlorophenol, nitrobenzene, and chloroform in water [81]. The EA-SPME cell was composed by two electrodes; carbonic fiber as the working electrode, and a piece of platinum as the counter-electrode. Different electric voltages were applied to explore the feasibility and applicability of the method. Also, Lee et al. used a pencil lead electrode in a two-electrode system to extract parathion onto the electrode surface with a reductive potential applied of -600 mV for 60 s [77]. However, it should be noted that a three-electrode EA-SPME method with a pencil lead as working electrode was developed for determination of methamphetamine by Djozan et al. [74].

It is worth mentioning that electrode distance is an effective parameter that affects both synthesis and EA-SPME procedures and should be optimized. For instance, it has been understood that the narrowed electrode distances create more efficient adsorption [81]. This phenomenon may be attributed to more heat generation on the surface of electrodes by applying voltage in longer distances, which causes depletion of adsorbed analytes due to exothermic nature of the adsorption process [81].

In another work, Yamin et al. introduced electromembrane surrounded solid-phase microextraction (EM-SPME), in which a carbonaceous pencil lead was simultaneously acted as the cathode and the sorbent inside the lumen of a piece of hollow fiber [90]. The hollow fiber was used as the support for liquid organic membrane around the sorbent. Using organic liquid membrane not only increases the selectivity, but also highly improves sample cleanup and makes it possible to apply high voltages that increase the extraction recovery. It was shown that EM-SMPE has a great potential for analysis of nonvolatile or ionizable compound in complicated matrices [90].

Different coatings were electrically synthesized for SPME by electropolymerization of various types of monomers, mostly PPy [61,64,69,91,92], or electrodeposition of non-polymeric materials such as single-wall or multiwall carbon nanotubes [62,70,72]. According to the literature, a three-electrode system has been used for electropolymerization [61,64,79,91,92], whereas electrodeposition of non-polymeric materials was carried out using a two-electrode system [62,70,72]. In recent years, new two-electrode systems have been developed [83,85,86], which will be discussed in the next section.

2.3.2. Application of electrical driving force in synthesis of SPME fiber

As it is known, the fiber coating is the key part of the SPME; so that this fact has propelled various research groups toward synthesis of new coatings [62,64,65,72]. Among the newest, growing interest has been in conducting polymers due to their

multifunctional properties [64]. Both chemically and electrochemically methods can be applied for synthesis of conductive polymers [47,93]. Although the electrochemical method should be carried out on the surface of a conductive substrate, it has substantial supremacies in comparison with regular SPME in the case of aromatic, polar, and charged analyte species [64]. For these types of analytes, extra steps such as use of complexing agents may be needed. These reagents in the most cases are toxic and expensive [64]. Also, the electrochemical method provides tailoring of key characteristics of conducting polymers including thickness, conductivity, degree of oxidation, color, and morphology [94]. Unlike the chemical method, which has a limited choice domain for dopant ions, an extensive range can be selected for electrochemical polymerization. The limitation of the chemical method originates from the fact that in contrast to the electrochemical method, a neutral polymer is firstly synthesized in the chemical method and subsequently a strong oxidant/reductant, which must be generated from the chemical oxidants/reductants, is used to produce the conductive form of the polymer [95].

The parameters with key roles in electrosynthesis are the solvent, type of dopants [94], type of monomer, applied potential range, electropolymerization time, deposition method [96], and the number of cycles, as well as the scan rate when a cyclovoltammetric (CV) technique is used [64]. For instance, the results of the study by Batina et al. showed that a supporting electrolyte containing KI yields relatively thick and highly conductive films whereas KF produces little conductive, very thin films [94].

In EA-SPME, the ion-exchange capacity of conductive film was generally controlled by the film thickness. Beyond a certain thickness value, diffusion limitation starts to limit the extraction amount. It is shown that as the film thickness increases, the sensitivity will also increase. Thicker coatings have therefore higher ion exchange capacity and result in larger dynamic range before the coatings become saturated [45,97]. Therefore, this issue has an important effect on the success of extraction and should be controlled during the fabrication process. Growth of the films can be controlled based on the charge amount passed during electrosynthesis and determined by scanning electron microscopy (SEM) technique [45,75,97]. Also, a controllable thickness can be achieved using the combination of EQCM and electropolymerization according to the density of the growing film and the Sauerbrey equation [68]. An alternative to improve the ion-exchange capacity of the electrode is increasing the surface area of the electrode, while keeping the film thickness constant. This strategy has recently been applied by Mihranyan et al. [46].

Stability of the synthesized polymeric film is an important issue affected by several factors. The substrate properties may have a great impact on the stability of the deposited thin film [96]. Different electrode materials including gold, glassy carbon, and ink-made carbon composite electrodes were investigated for PPy deposition by Li et al. [96]. Some composite carbon substrate materials demonstrate the best performance. This observation has been attributed to roughness and large surface area of carbon substrate, which can enhance adhesion and enforce the stability of the PPy film structure [96].

As shown in Fig. 5, both low voltage and high voltage electrical fields can be utilized for electropolymerization purposes. However, a completely different story exists between high voltage and low voltage synthesis methods. In the low voltage method, an electrochemical cell consisting of two or three electrodes is used and polymerization is carried out in electrolyte solution containing dopant ions and monomers. Different deposition techniques such as CV, galvanostatic (constant current) and potentiostatic (constant voltage) methods can be used during low voltage electropolymerization that influence the electrochemical activity of the films. Li et al. demonstrated creation of PPy films by galvanostatic deposition with more electrochemical activity compared with the films produced by CV and potentiostatic methods [96]. Also, an insulated film will be created instead of a conductive film by applying potentials in the region required for overoxidation [94].

Application of the high voltage method termed electrospinning in SPME dates back to its appearance as an attractive patterning technique [85,98–100]. By definition, electrospinning is an authoritative method that can draw fibers from polymer solutions and simultaneously integrating them onto microfabricated structures [85]. This technique is based upon the same principle as ESI-MS. However; the fiber jet production is the dominant phenomenon comparing with the formation of charged droplets mist in ESI-MS [101].

Polymeric solution that is used in electrospinning consists of polymers with high molecular weights and accordingly high viscosity and surface tension. This solution is filled into a syringe connecting to a pump to create regular injection during the electrospinning process. Applying voltage between syringe and collector, which is rotated by a rotor, leads to overcoming the surface tension by electrostatic repulsion, deformation of spherical droplets to Taylor conical form, and finally ejection of the polymer jet from the Taylor cone toward collector [83,102]. During coating progress, formation of polymeric droplets is prevented by entanglement of polymer chains as well as the surface tension [83,102]. Diameter of polymer jets becomes smaller within their flying toward collector electrode. This leads to formation of nonwoven nanofibers mat with diameters in the range of micro to nano [83,102]. Various materials with different shapes can be used as the collector electrode [103]. Fig. 7A is a schematic view illustrating an electrospinning device [83].

Electrospinning has been utilized in different fields of science [83,104]. However, it is not a long time this field has been presented in the analytical chemistry. This methodology has been used in solid phase extraction [105,106], affinity membranes [107], semi-micro solid phase extraction [108], and more recently as a SPME fiber [83,102].

As can be seen in the high voltage method, electropolymerization is carried out in the space between two electrodes by applying excessively high voltages in the ranges of 4000–25000 V and no electrolyte solution is utilized here [85]. The other difference between high and low voltage methods is that in the first one, polymer solution is used instead of monomer solution to produce polymeric films.

The conductivity of synthesized films by electrospinning depends on the composition and conductivity of the prepared polymeric solution as well as the diameter of electrospun nanofibers. Fabrication of nanofibers with sub-30-nm diameter has been reported using electrospinning of polyaniline/polyethylene-oxide mixture [99,100]. The results demonstrated polyethylene-oxide, as an insulating impurity, leads to substantially lower conductivity in comparison with pure bulk materials and intensity of this behavior increases by decreasing the diameter of nanofibers; so that nanofibers with 15 nm were found to be insulating [100].

As shown in Fig. 5, the low voltage method can be utilized for synthesis of SPME fibers by electropolymerization of monomers [88,89], electrophoretic deposition of some special materials such as carbon nanotubes [62,70,72], and preparation of a proper substrate for next coating step using electrodeposition [82].

Synthesis of SPME fibers with low voltage electropolymerization of monomers has been reported by different research groups [62,64,87–92,97]. As shown in Fig. 5, a conductive fiber is obtained by this method, which can directly be used for extraction. Also, the nature of its surface can be modified using an extra functionalization step either chemically or electrochemically and subsequently be used for extraction [109]. The functionalization of PPy film electrodes [109] can be achieved by electrostatic

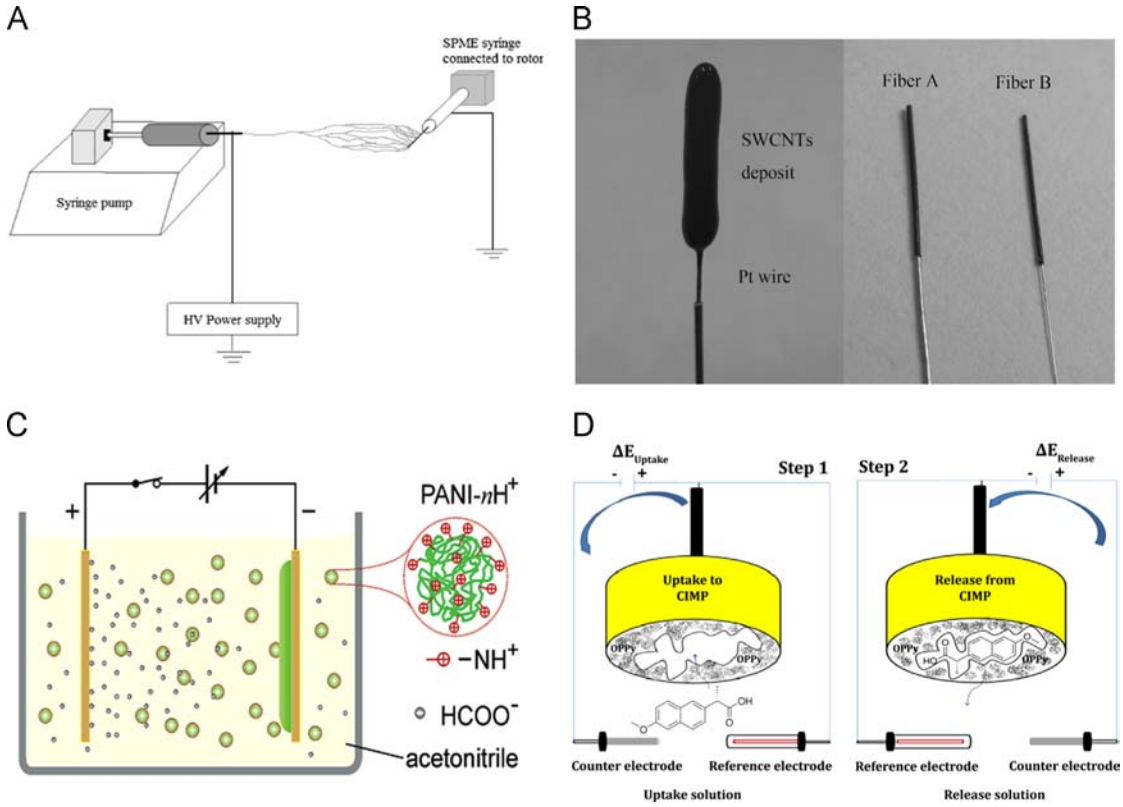

Fig. 7. (A) Scheme of the electrospinning setup, (B) deposition of SWCNTs on Pt wire (left) and the prepared fibers coated with SWCNTs (right), (C) a schematic illustration of the setup used for electrophoretic deposition of polyaniline from its colloidal suspension, (D) selective uptake/release of naproxen to MIP by electrochemically controlled solid-phase sorbent (reproduced with permission of Elsevier and ACS-modified-Refs. [72,83,85,91]).

incorporation of multi-charged anionic complexing ligands during the electropolymerization step, or using active groups that are covalently attached to the polymeric skeleton. These complexing film materials have been synthesized in two steps by chemical derivatization moieties of conducting polymer films previously coated by electropolymerization onto electrodes, and then applied as a cation-exchange film that might be useful for electrosorption SPME (ES-SPME).

An extensive range of monomers including pyrrole [89], sulfonated pyrrole [97], aniline [80,85], *p*-phenylenediamine-co-aniline [78], 3-methylthiophene [76], 3-octylthiophenone [66], 3-dodecylthiophene [63], 3-hexadecylthiophene [66] have so far been used to fabricate conductive SPME fibers. However, among them, pyrrole is the most frequently investigated monomer due to its relative ease of synthesis on various substrates from organic or aqueous media by electrochemical or chemical methods, environmental stability of its polymeric film, and ability to interact with different compounds due to its multifunctional properties including hydrophobicity, acid–base character, π–π interaction, polar functional groups, ion exchange property, hydrogen bonding, and electroactivity [91,92,110]. Pyrrole has been used not only to synthesize SPME sorbents, but also in other fields of analytical chemistry such as preparation of modified electrodes [111,112].

In 2004, Su et al. demonstrated polymerization of pyrrole between an electrode gap (5 μm) when a 10 V dc voltage is applied to the saturated vapor of pyrrole at 24 °C and the relative humidity of 35% [86]. Occurrence of chemical reaction is signaled by the decreasing gap resistance, with 95% reduction in the first hour. In control experiments without any voltage applied, there is no deposition and the resistance does not change when other conditions are kept identical; this indicates that the electric field in the gap directs and facilitates the growth of PPy.

The strength threshold of electric field for the polymerization reaction is about 10^4 V m^{-1} at the relative humidity of 35%. The existence of thin water layers on ionic surfaces in the ambient environment is well known [113,114]. When high electric field ($> 10^5$ V m^{-1}) is generated across the gaps, the polymerization would likely occur within the tiny hydrous environment similar to electrochemical polymerizations in solution. This electrical polymerization method is a simple and robust method that can provide deposition of the conducting polymers. However, this technique has not yet utilized for preparation of SPME coatings; however, it seems that this potential application would open a new window to the world of extraction science.

Electrophoretic deposition of some special materials to fabricate new fiber coatings is of the recent progresses in SPME [62,70,72]. Electrophoretic deposition is usually employed in processing of ceramics, coatings, and composite materials. In this technique, charged particles, which are dispersed in a proper solvent, migrate toward a conductive substrate under electrical field [72,115], accumulate there, and form a homogeneous and rigid deposit. It should be noticed that unlike electrochemical deposition, in this technique, deposition occurs by particle coagulation instead of electrochemical reaction [62,70,72,115].

For the first time in 2009, electrophoretic deposition was utilized for fabrication of new conductive SPME fibers by Li et al. [72]. A platinum wire was electrophoretically coated with single-walled carbon nanotubes (SWCNTs@Pt) and applied to determine phenols in aqueous samples. Fig. 7B shows the electrophoretically deposited SWCNTs on the surface of a platinum wire which has been removed from the SWCNTs/ dimethylformamide (DMF) suspension [72]. Vaporization of DMF in the deposit by subsequent heating leads to closer assembling of SWCNTs and enormously increasing their interaction and finally fabrication of a stable film.

The fabricated coatings showed high durability; so that neither swell in organic solvents nor strip off from the substrate surface. This can be attributed to the strong Van der Waals attractions between the surfaces of the SWCNTs [72].

The prepared fiber showed similar or superior efficiency in comparison with polyaniline fiber due to the high surface area of SWCNTs as well as the presence of oxygenated groups in the structure of nanomaterials. In another work by the same group, SWCNTs@Pt was used for microextraction of trace anions including F^-, Cl^-, Br^-, NO_3^-, and SO_4^{2-} in deionized water [70]. In the second work, a platinum plate was used as the substrate for the working electrode instead of a platinum wire and also, an electrically assisted extraction procedure was carried out compared with conventional SPME procedure in the first work. Regarding the above-mentioned points, different durability was reported during analysis of phenols and anions (more than 80 and 50 times, respectively) for a unique fiber.

Tan et al. used the method presented by Li et al. [72] for deposition of multi-walled carbon nanotubes on the surface of a platinum wire (MWCNTs@Pt) [62]. Subsequently, a surface modification was carried out using PPy, producing a molecularly imprinted polymer to create selective extraction of fluoroquinolone antibiotics. The fabricated coating showed an excellent mechanical stability so that no falling was observed from platinum wire with gentle scrape by a piece of paper. The peak area of the fiber after more than 50 successive electrically assisted extractions was more than 90% of the value obtained for the first extraction, indicating high durability of the fiber.

In 2004, Li et al. presented an interesting method for controlled deposition of polyaniline from colloidal suspensions [85]. First, polyaniline was electrochemically synthesized from aniline using CV, then converted into its emeraldine base form by soaking in a concentrated ammonium hydroxide solution, filtered, washed, and then dried in a vacuum oven. The polyaniline colloidal suspension was prepared by first dissolving the emeraldine base form of polyaniline in formic acid, and subsequently dispersing the polyaniline/formic acid solution into acetonitrile. The key aspect of generating a polyaniline colloidal suspension lies in the unique combination of formic acid and acetonitrile. As illustrated in Fig. 7C, by applying an electric field, the positively charged polyaniline colloids are collected onto the electrode that has a negative bias, and, as a result, a thin film of polyaniline can be formed on the electrode surface. This method has not yet been used in any of the chemically or electrochemically SPME techniques. However, it may open a new horizon toward generation of modern SPME coatings.

If conductive materials such as carbon nanotubes are used during electrophoretic deposition, a conductive SPME fiber will be obtained that can directly be utilized for extraction [70,72], or its surface could be modified either electrochemically [62] or chemically for subsequent analysis. A conductive film is created by an electrochemical modification again whereas the conductivity of SPME fiber using a secondary chemical step depends on application of a strong oxidant/reductant during the fabrication process. As mentioned before, in chemical methods, a neutral polymer is firstly synthesized and to produce the conductive form of the polymer, a strong oxidant/reductant should be used. Electrochemical modification of an electrophoretically prepared surface was reported by Tan et al. [62], but no chemical modification was reported so far.

The results show that electrophoretic deposition offers advantages of low cost, process simplicity, uniformity of deposits, no need to use adhesive, control of deposit thickness, and production of films with high mechanical stability and durability [72,115].

The other application of low voltage electrical fields in synthesis of SPME fibers is preparation of an appropriate substrate for next fabrication step by electrodeposition of a special material (Fig. 5). In this case, conductivity of the coating prepared depends on the final synthesis step and a behavior the same as the one mentioned for electrophoretic deposition method related to chemically or electrochemically modifications is expected here (Fig. 5).

Kanatharana et al. developed a new SPME fiber by electrodeposition of porous Zn film on the surface of an Ag wire followed by coating with polyethylene glycol sol–gel (Ag/Zn/PEG sol–gel) [82]. It provides a powerful analytical tool in terms of simple preparation, low cost, flexibility, robustness, high thermal stability, and long lifetime; up to 359 extractions compared with commercial fibers. Furthermore, the proposed fabricated fiber provides good repeatability as well as fiber-to-fiber reproducibility and therefore, recalibration is omitted during replacement of a new fabricated fiber with the old one.

In this work, Ag/Zn/PEG sol–gel fiber was applied to determine styrene residues in cooked rice sample using a conventional SPME procedure and no electrical field was utilized during the extraction. As can be seen here and also in other reports [62–86], electrosynthesized fibers can be used for both EA-SPME and conventional SPME techniques. However, it should be noted that in the first case the fiber should certainly be conductive while it is not important for the second technique.

Although most conductive SPME fibers used in electrically assisted solid based extraction technique have been prepared electrically [63,64,87–92,97], some works have reported chemical fabrication of conductive polymers and subsequently application in an electrically assisted extraction procedure [65,89]. As mentioned before, conductive polymers can be synthesized either chemically or electrochemically. For instance, Chen et al. chemically prepared a conductive MWCNTs/Nafion coated fiber and applied it as the working electrode in a three-electrode system to determine cationic (protonated amines) and anionic (deprotonated carboxylic acids) compounds in aqueous samples [65] by applying suitable negative and positive potentials, respectively. In another work, this electrode was utilized for determination of some basic drugs using a mild negative potential in urine samples [89].

Therefore, one can have an electrochemically synthesized SPME fiber and electrical extraction, an electrochemical synthesis and non-electrical extraction or a non-electrochemical synthesis and electrical extraction. However, it should be noted that it is possible to use a combination of chemical and electrochemical processes during each of the synthesis and extraction steps of SPME. For instance, in a SPME extraction procedure consisting of two sorption and desorption steps, sorption can be carried out electrically and desorption chemically or vice versa [63,65]. This will be explained in more details in the next section.

Selectivity has always been an important issue to evaluate the efficiency of an extraction technique. In SPME, in order to increase selectivity, a lot of effort has been placed on development of either the preparation method or the material used as the fiber coating phase. For instance, it is possible to control selectivity in the microextraction process using a cation exchange conductive SPME fiber due to dependency of polymer morphology on the size of the dopant ions and the interactions between irreversibly incorporated dopants and ions. However, these strategies showed poor selectivity. To overcome this difficulty, in recent years, new materials such as MIPs were synthesized and used as the coating [61,62,64,68,91,92]. MIPs are synthetic materials that are prepared in the presence of a template molecule, and are identical with the target molecule the polymer should later selectively bind [68].

Both chemical and electrochemical methods can be utilized for removal of templates from the synthesized polymeric film [61,62,64,69,91,92]. For instance, Şahin et al. used 0.05 M phosphate buffer to remove ascorbic acid templates from a molecularly imprinted PPy-modified pencil graphite electrode [61]. Tan et al.

immersed the MIPPy/MWCNTs/Pt fiber into methanol–acetic acid (80:20, v/v) washing solution (at least 5 times) to remove the fluoroquinolone template molecules [62]. Nagaoka et al. developed electrodes coated with overoxidized polypyrrole films for chiral discrimination of glutamic acid in its cationic form with the goal of improving selectivity and sensitivity of currently used MIPs [64]. The overoxidation was performed by scanning the potential repeatedly in a range of −0.3 to +1.0 V (or +1.4 V) at a rate of 40 mV s^{-1} until the background current attained a value below 50 nA cm^{-2}. This method was also applied for determination of two types of anionic species including naproxen and salicylate by Alizadeh et al. in two subsequent papers [91,92]. A schematic presentation of an electrically controlled SPME (EC-SPME) system for selective uptake/release of naproxen using a conductive MIP fiber based on PPy is shown in Fig. 7D.

Generally, the use of MIPs, as a selective solid-phase for sample preparation, may be potentially attractive because they mainly afford selectivity, robustness, and long shelf-life [62,64].

2.3.3. *Sorption mechanism of EA-SPME*

As shown in Fig. 5, SPME technique can be classified into conventional and electrically assisted ones. In conventional SPME, there are different sorption mechanisms depending on the nature of coating and analytes that lead to physical, chemical, or ion exchange interactions. However, the chemical one is not proper because it is seldom reversible and so it should be avoided by selection of an appropriate fiber.

The sorption mechanism in EA-SPME can be subdivided into EC-SPME and ES-SPME. In ES-SPME, the extraction is primarily driven by electrophoresis and complementary charge attraction, in which negative or positive potential can be easily altered to enhance the extraction of cationic or anionic analytes [65]. When an electric field is applied, the charged ions move towards the fibers with an opposite charge and an electrical double layer is formed on the fiber surface. Charged species are therefore concentrated and kept on the double layer. When the electric field is removed or reversed, the ions in the fiber are released back to the bulk solution. No reduction or oxidation of coating occurs during ES-SPME [70]. Furthermore, EC-SPME is carried out using a conductive polymer film, which provides movement of counter ions in and out of the conductive polymer to maintain its electroneutrality by applying a suitable voltage [65].

Generally, incorporation of a dopant with high mobility into the structure of a conductive polymeric film leads to formation of an anion exchanger whereas a cation exchanger coating will be produced when a dopant with low mobility is used during synthesis [116]. A schematic illustration of EC-SPME mechanism for a cation exchanger conductive PPy film is presented in Fig. 8A. Here, poly(styrenesulfonate), (PSS), has been used as the low mobility dopant [116]. When a negative potential is applied, the PPy chain is reduced and results to appearance of negative charges into the film structure due to the presence of the anionic sulfonyl groups of PSS. To compensate the negative charges, cations existing into the surrounding solution adsorb on the surface of the polymeric film. Applying a positive potential leads to oxidation of PPy chain and formation of positive charges, compensated by anionic sulfonyl groups. In this case, the cations adsorbed are desorbed back into the solution.

The EC-SPME mechanism for extraction of anions is shown in Fig. 8B. Similarly, anions are adsorbed by applying a suitable positive potential and consequently oxidation of the conductive film, whereas a negative potential reduces the polymer and results in the expulsion of the previously incorporated anions to return polymer neutrality.

In ES-SPME, instead of using a conductive polymer as the stationary phase, carbonaceous materials, such as pencil lead [74,79], activated carbon fiber [73], and carbon nanotubes [62,70,72] are used as coatings to prepare the SPME fiber. Carbonic fibers may be good choices as working electrodes in EA-SPME due to high conductibility and resistance against temperature elevation as well as chemical corrosion in water [81].

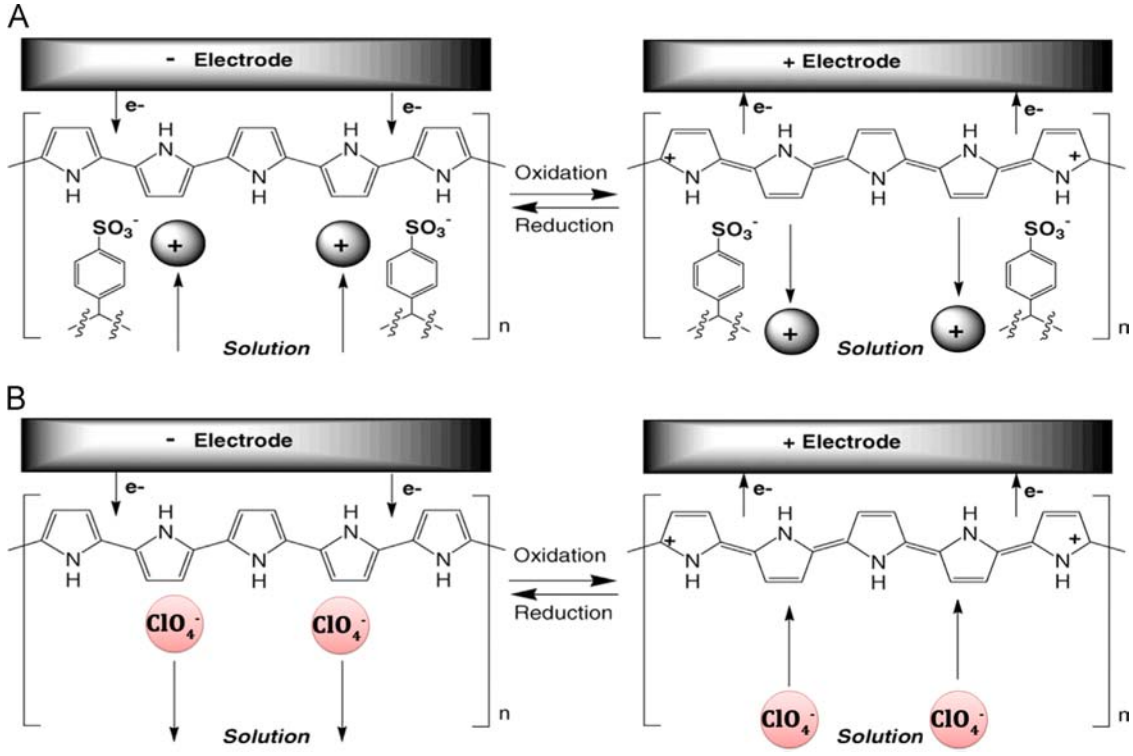

Fig. 8. (A) Scheme of the electrochemically switchable cation exchanger process and (B) anion exchanger procedure (reproduced with permission of Elsevier-modified-Ref. [116]).

As can be seen in Fig. 5, during an EA-SPME procedure, electrical field can be used for both adsorption/desorption steps [64,88], only used for adsorption and a non-electrical desorption is utilized for analysis [62,65], or only used for desorption and adsorption is carried out non-electrically [63,66]. The latter case is one of the most interesting applications of electrical field in EA-SPME, which was for the first time introduced by Mark et al. in two subsequent papers [63,66]. In the first step, neutral arsenobetaine were adsorbed on the surface of poly(3-dodecylthiophene) film due to hydrophobic interactions and under the diffusion controlled extraction process. Then, a positive potential was applied to oxidize the fabricated conductive polymer to its hydrophilic state, which provides a sufficient driving force for desorption of the analyte from the extraction phase into an aqueous solution for subsequent analysis.

Interestingly, it has been claimed that electrical field can affect adsorption of non-ionized compounds [81]. Wu et al. utilized an ES-SPME system to examine the effect of different voltages in the range of −1.5 to +1.5 V on the adsorption efficiency of phenol and *p*-chlorophenol as ionizable compounds and nitrobenzene and chloroform as neutral species [81]. The results showed that different effects of voltage on adsorption processes are attributed to the molecular structure of the investigated compounds. For instance, −1.0 V voltage increased nitrobenzene adsorption about 33%, and +1.5 V raised the amount to 122%, while −1.5 V decreased the adsorption of phenol to 91.1%. To the best of our knowledge, it is the first report of electrically assisted adsorption of neutral compounds and may be an interesting topic for the future researches in the field of electrical induced extraction techniques.

Conductive polymeric films can be used not only for extraction purposes in analytical chemistry, but also as electrochemically switchable ion exchangers for industrial aims such as softening the drinking water. For instance, Weidlich et al. designed a special cell arrangement containing two cation exchanger electrodes based on modified PPy nanoparticles separated by an anion exchanger membrane for continuous operation of the water softening process [116].

Şahin and coworkers have recently reported simultaneous extraction of cationic and anionic species in trace levels including chloride, nitrate, sulfate, calcium, and magnesium using a PPy electrode and an overoxidized sulfonated polypyrrole (OSPPy) electrode [45]. Both PPy and OSPPy electrodes were immersed in the same target solution to act as anode and cathode, respectively. They also used these electrodes as a potentiometric detector in ion chromatography, to determine some anions and cations in water samples [87]. This idea can be extended as a novel interesting technique for industrial applications and will provide many advantages like low cost, ease of modification, renewal, and miniaturization. For instance, its application for water softening instead of the method utilized by Weidlich et al. [116] removes the need for dividing membrane and reduces the process cost.

A summary of recent papers in EA-SPME for determination of various anions, cations, and neutral compounds is presented in Table 1. As shown here, electrical field has found an important position in solid based extraction techniques so that a substantial increasing trend is observed in the literature after the first suggestion by Pawliszyn et al. [110,118]. This can be attributed to several reasons;

1. The properties of the conducting polymer can be modified by varying the conditions during the electropolymerization step to enable extraction of analytes of different sizes and charges.
2. Compared to conventional SPME, in which a material with a fixed number of exchange sites is employed, EA-SPME offers higher flexibility owing to the material properties and thus the number of exchange sites can be externally controlled by electrochemical controlling of the material charge [48,119].
3. The use of polymer based fiber films in SPME can be extended to analysis of neutral, electro-inactive analytes by taking the advantage of electrochemically controlled hydrophobic/hydrophilic 'switching' [63].
4. EA-SPME can be used to extract ions and analytes that normally need to be derivatized prior to traditional SPME extractions [120,121].
5. In EA-SPME, the extraction and desorption steps are merely performed by altering the potential of the conducting polymer coated electrode. In this approach, there is thus no need for changes of the solvent to enable desorption of the compounds [28].
6. Desorption of electrostatically held analytes, by altering the electrochemical potential of the polymer may also be faster compared to the desorption techniques normally used in SPME [29]. This makes the technique particularly interesting for use in conjunction with miniaturized analytical systems.

On the other hand, difficulties in obtaining reproducible extractions as well as high preconcentration factors are the main problems encountered by EA-SPME. The first problem results from morphological changes in conducting polymer coating due to successive oxidation and reduction of the stationary phase during every measurement [76], and the second one is caused by requiring the solution at milliliter volumes to desorb the analytes as well as low adsorption capacity of SPME fiber [28,29]. However, some efforts have recently been carried out to overcome the problems such as synthesis of new fiber coatings, fabrication of polymeric coatings with high surface area, and development of integrated electrode device proving desorption into low microliter volumes [28,29,46]. Also, as can be deduced from the information in Table 1, EA-SPME has rarely been investigated in real samples with complicated matrices such as biological fluids. Surrounding SPME fiber utilizing a porous membrane may be a suitable solution to this issue. Abilities of porous membranes in sample pretreatment techniques, which were addressed in Section 2.3.1, could be a suitable reason for the claim.

3. Solid based extraction techniques as lab-on-a-chip

Recently, downsized installations or LOC systems have been developed to perform laboratory analyses of chemistry, biology, and medicine over a miniaturized chip. Separation techniques were highly benefited from the LOCs. Electrophoretic techniques are perfectly suited for downscaling due to their smaller separation lengths, which is following by increase in electrical fields.

Nyholm et al. have employed an integrated three-electrode device as a new method for controlling the potential conditions to extract, transfer, and desorb anions and cations [29]. This SPME system containing a glassy carbon rod ($40 \times 1.0\ mm^2$), a silver tube (o.d. 2.0 mm, i.d. 1.6 mm), and a stainless steel tube (o.d. 5.0 mm, i.d. 4.0 mm), which operates as the working, pseudo-reference and counter electrode, respectively. A glassy carbon rod and a silver tube were insulated by heat-shrinkable PTFE tube (o.d. 3.1 mm, wall thickness 0.05 mm) and then both electrodes were inserted into a stainless steel tube. PPy coating was electrodeposited on the surface of the glassy carbon working electrode to obtain the required ion exchange capacity. Both the working and reference electrodes are able to vertically move with respect to the stainless steel counter electrode.

As the device is lifted out of a solution after an extraction, a small amount of the solvent, which is held by the capillary force, remains between the electrodes. The potential control over the whole extraction process increases using the device designed by Nyholm; since this design offers potential controlling at all times. Also, potential controlled desorption into vials containing as little

as 200 μL of the solution is possible. All potentials are given with respect to the silver quasi-reference electrode (QRE). The working and reference electrodes are extended during the extraction, desorption, and washing steps while both electrodes are in the transfer mode during the device movement from one solution to another. The capillary held sample solvent was replaced with an analyte-free solution during the washing step by fully extending the working and reference electrodes and repeatedly moving the electrodes with respect to the stainless steel counter electrode for 15 s in a stirred 500-mL volume of the washing solution. The results demonstrated that using an integrated three-electrode device effectively facilitated the electrochemical solid-phase extraction and 1.5–2 orders of magnitude higher extraction efficiencies were obtained compared to conventional SPME. Also, the risk of sample loss during different analysis steps was decreased using this downscaled installation. Therefore, electrochemical SPE was introduced as an interesting miniaturized analytical device.

Also, Nyholm et al. have used PPy coated microarray electrodes for EC-SPME as a preconcentration step in downsized flow systems on individually addressable gold microband electrodes [28]. In this study, a capillary was positioned in a vertical position over the electrode array during both the extraction process and the detection of the desorbed compounds to maintain a flow of analyte solution over the band electrodes. On the other hand, the silicon chip was positioned in a vertical position at the electrolyte surface to enable a flow of analyte solution over the microband electrodes and to perform suitable conductivity between these electrodes and the reference and counter electrodes. Therefore, any contact between the microband electrodes and contamination of the electrolyte are avoided and potentiostatic control of the working electrodes is enabled due to the flow of analyte solution emerging from the capillary.

In comparison with the traditional SPME, significant preconcentration by a factor of approximately 210 and low limit of detection (LOD) of about 625 nmol L^{-1} were obtained by performing the extraction process for only a few minutes and good linearity between the extraction time and detection response at both mmol L^{-1} and μmol L^{-1} concentrations of chloride as the model analyte was achieved.

In another work, a three dimensional microporous polymer network material, or monolith, cast-to-shape in a microchannel was introduced by Shepodd et al. [33]. A system for separation of charged compounds from uncharged species was designed. A fused silica capillary column with an internal diameter of about 110 μm and a porous polymer monolith, prepared by photopolymerization, disposed along a protein of its length. To condition the capillary column, it was perfused with 20 mmol L^{-1} Tris buffer at a pH of about 8.3 (also other suitable buffer materials can be used). Then, about 1–5 kV electrical potential was applied to the porous polymer monolith using a power supply and electrodes. The electrodes were disposed on either side of the stationary phase while the presence of the eluted molecules was detected by laser induced dispersed fluorescence as they passed the detection window. An ultra-microporous material can be interposed between the electrodes and the capillary column, which carries the current. Therefore, it can be used to introduce the fluid into the capillary column and the electrodes. It should be noted that the pores are fine enough that the pressure-driven or electroosmotic flow is negligible.

Using polymer monolith, charged proteins are trapped and retained from a mixture of charged and uncharged species in an electric field. Then, the electrical field eliminates and the retained charged proteins are released from the porous polymer monolith by a pressure-driven flow. Since the pressure-driven flow is independent of direction (i.e., neither reverse fluid flow nor a multi-directional flow field is required), unlike prior art systems, a single flow through the porous polymer monolith can be employed. This invented monolithic polymer material can act as a chromatographic medium. Also, the porous polymer monolithic can be used for preconcentration of charged proteins in a dilute solution by retaining these charged species.

4. Concluding remarks and future trends

Different applications of electrical field were overviewed consisting of its roles as the extraction and elution driving force and electrochemical synthesis. Following that, advantages and disadvantages of proposed methods were discussed and new installations were introduced in this review. The most prominent application of electrical driving force is seen in SPME methods including fiber synthesis and extraction processes. However, some techniques such as EA-SPE that have not found remarkable attention in analytical chemistry are the staircases to development and emerging of subsequent sample preparation methods. In the field of extraction, electrical driving force has some positive effects in selectivity and sample cleanup as well as extraction recovery and speed and offers the possibility of having precise control over the beginning and termination of the extraction. Also, noticeable potential of electrical driving force is not only restricted to extraction and sample preparation techniques and they have shown high efficiency to synthesize various types of coating films. Another interesting field in electrical field stimulated extraction techniques is their application in designing microchip-based devices or LOCs. However, there are limited reported works in solid-phase based LOC systems. Therefore, further studies are required for development of this new aspect to make it a known and useful device in the real world. Limitation of solid-phase based installations for on-line coupling to analysis instruments is also one of the drawbacks of this type of extraction methods, which needs more work and serious efforts.

ABSTRACT

For the first time, interaction of vitamin B7 (VB7) with bovine serum albumin (BSA) was investigated with the aim of developing a method for the analysis of BSA. The interaction of VB7 with BSA was investigated by cyclic voltammetry (CV), linear sweep voltammetry (LSV), and differential pulse voltammetry (DPV) at a multi-walled carbon nanotubes-modified glassy carbon electrode (MWCNTs/GCE). The recorded electrochemical data was combined with UVvis and fluorescence (F) spectroscopic data into a row- and column-wise augmented matrix and resolved by multivariate curve resolution-alternating least squares (MCR-ALS) as an efficient chemometric tool, and this assisted in the further elucidation of the above interaction. Also, with aid of MCR-BANDS method, the absence of rotational ambiguity was verified in the obtained results and we confirmed that the obtained results were unambiguous and reliable. The binding of VB7 to BSA was also modeled by molecular docking methods. Excellent agreement was found between the experimental and computational results. The differences of DPV responses of VB7 in the absence and presence of BSA (ΔI) were found to be linearly related to BSA concentration between 0.5×10^{-9} mol L^{-1} and 35.0×10^{-9} mol L^{-1}, and a limit of detection (LOD, $3S_b/b$) of 0.22×10^{-9} mol L^{-1} was calculated. Finally, the DPV method was further applied to the determination of serum albumin (SA) in serum samples obtained from Holstein cows and the results were in good agreement with those obtained by a medical diagnostic laboratory whose method was based on traditional cellulose acetate electrophoresis. The MWCNTs/GCE showed enhanced electron transfer kinetics, large electroactive surface area, and was highly sensitive, selective, and stable towards SA determination. The satisfactory analytical performance of the proposed method would make it potentially advantageous for a broad range of biosensing and clinical applications.

1. Introduction

In living organisms, there are a variety of small molecules with various biological and pharmaceutical functions. Vitamin B7 (VB7, also called vitamin B8 or H, Fig. 1) is a water-soluble vitamin and an essential co-factor for five biotin-dependent carboxylase enzymes. It is synthesized in a wide variety of bacteria and plants. However, several microorganisms as well as higher animals are notable to synthesize it and their needs in this vitamin are met by dietary intake [1]. Besides the typical clinical features, recent evidence indicates that the pregnant women develop biotin deficiency during normal pregnancy [2,3].

Abbreviations: VB7, vitamin B7; BSA, bovine serum albumin; Trp, tryptophan; SA, serum albumin; CV, cyclic voltammetry; LSV, linear sweep voltammetry; DPV, differential pulse voltammetry; MWCNTs, multi-walled carbon nanotubes; GCE, glassy carbon electrode; F, fluorescence; MCR-ALS, multivariate curve resolution-alternating least squares; MD, molecular dynamic; LOD, limit of detection; TBS, Tris–HCl buffer solution; MVD, molegro virtual docker; EFA, evolving factor analysis; PCA, principal component analysis; SIMPLISMA, simple to use self-modeling mixture analysis; ITTFA, iterative target transformation factor analysis

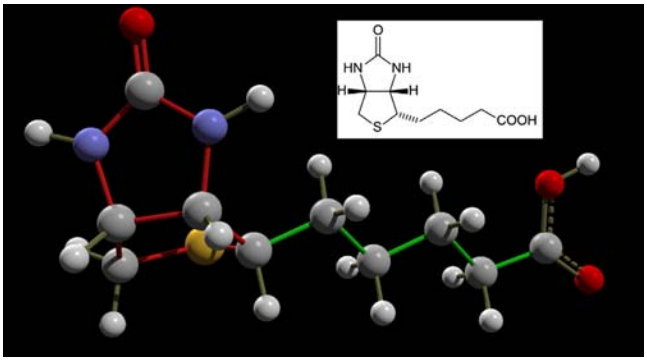

Fig. 1. Molecular structure of VB7.

Among biomacromolecules, serum albumin (SA) is a soluble protein, which is a major constituent of the circulatory system, and it commonly serves as a depository and a transport molecule for many exogenous compounds [4,5]. Consequently, simple, rapid and low cost analysis for SA proteins would be useful [6,7]. Studies on the binding of small molecules with plasma proteins will facilitate the interpretation of the metabolism and transport processes of such substances, and the binding of small molecules with bovine serum albumin (BSA) is a typical example of such interactions. Thus, it is an appropriate protein to use for such investigations, partly because of its structural homology with human serum albumin (HSA) [8].

There are a variety of techniques currently available for obtaining information about protein–ligand interactions such as the measurement of kinetics and binding affinities. Two traditional methods, X-ray diffraction and NMR spectroscopy, employed to obtain structural information of proteins and protein–ligand complexes. Both of these methods have disadvantages: X-ray diffraction requires the preparation of a crystal, which can be time consuming or even impossible; and NMR spectroscopy is not easily applied to larger proteins of more than a few hundred amino acids. Other analytical techniques that can be applied to proteins in solution are spectrophotometry, chemiluminescence, resonance light scattering [9–12]. Compared with spectroscopic methods, electrochemical assay is simple, easily implemented, and has low-cost and fast response. On the other hand, the interpretation of electrochemical data can contribute to elucidation of the interaction of ligand with biomacromolecules.

Chemometrics methods of data analysis, such as multivariate curve resolution-alternating least squares (MCR-ALS), are well known for their ability to resolve different kinds of data and extract profiles of individual chemical components from composite responses. Such results generate valuable information, which other-wise cannot be obtained by conventional methods, and which consequently, enable further analysis of the problem under investigation as is the case with the biosystems in this work.

To the best of our knowledge there is no report on the interactions between VB7 and BSA in the literature, and this work reports a detailed study on the mentioned system for the first time. The main aims of this study were: 1. Investigation of interaction of VB7 with BSA at a MWCNTs/GCE at physiological conditions by CV, LSV, and DPV and also in combination with UV–vis and fluorescence (F) techniques by the use of MCR-ALS. 2. Research and development of an electrochemical method for BSA analysis in conjunction with VB7 which could be suggested for biosensing and clinical applications.

2. Experimental and theoretical details

2.1. Chemicals and solutions

BSA, and VB7 were purchased from Sigma Chemical Company (St. Louise, MO). Multi-walled carbon nanotubes were purchased from io-li-tec, Ionic Liquid Technologies. All other reagents were of analytical grade, and doubly distilled water was used throughout. All solutions used in this work were prepared in Tris–HCl buffer solution (TBS, 0.05 mol L^{-1}, pH 7.4, containing 0.1 mol L^{-1} sodium chloride to maintain the ionic strength of solution). Stock solutions of VB7, and BSA was prepared by dissolving proper amount of their solid powder in the TBS (0.05 mol L^{-1}, pH 7.4) and were kept at dark in a refrigerator for about a week only.

2.2. Instruments and softwares

Electrochemical experiments were performed using a μ-AutolabIII/FRA2 driven by the Nova 1.8 software. A conventional three-electrode cell was used with a saturated calomel electrode (SCE) as reference electrode, a Pt wire as counter electrode and a bare or modified GCE as working electrode. The SEM experiment was made on a KYKY-EM 3200 scanning electron microscope. All fluorescence spectra were measured on a Cary Eclipse fluorescence spectrophotometer equipped with a water bath and a 1.0 cm quartz cell. The UVvis spectra were measured on an Agilent 8453 UVvis Diode-Array spectrophotometer controlled by the Agilent UVvis ChemStation software. A JENWAY-3345 pH-meter equipped with a combined glass electrode was used to pH measurements. The chemical structure of the VB7 was constructed by Hyperchem package (Ver. 8.0), and energy minimization for VB7 was performed by AM1 semi empirical method with Polak-Ribiere algorithm until the root mean square gradient of 0.01 kcal mol^{-1}. The known crystal structure of BSA (PDB Id: 3V03) was obtained from the Brookhaven Protein Data Bank. Water molecules were removed, and hydrogen atoms were added. The molegro virtual docker (MVD) software was employed to generate a docked conformation of VB7 with BSA. LIGPLOT [13], a program for automatically plotting protein–ligand interactions, was used to analyze the interactions between BSA and VB7. MCR-ALS and MCR-BANDS were implemented using the graphical interfaces provided by Prof. Tauler in his web page [14]. The recorded experimental data was smoothed, when necessary, and converted to matrices by means of several homemade MATLAB (Version 7.14) programs. A simple homemade MATLAB program was used for computing the concentrations of VB7 and BSA and their ratio in all voltammetric and spectroscopic experiments. All calculations were run on a DELL XPS laptop (L502X) with Intel Core i7-2630QM 2.0 GHz, 8.0 GB of RAM and Windows 7-64 as its operating system. The MD simulations were performed on a computer with a Linux Fedora 15 as its operating system.

2.3. Fabrication of MWCNTs/GCE and BSA/MWCNTs/GCE

Prior to the electrode modification, the GCE surface was polished with PK-4 polishing kit, BASi MF-2060 successively followed by rinsing thoroughly with redistilled deionized water until a mirror like finish was obtained. It was then dipped in a beaker containing 0.2 mol $L^{-1}H_3PO_4$ solutions to remove the adhered powder, rinsed with distilled water and dried at room temperature for 10.0–15.0 min. The MWCNTs (4.0 mg) was added to 1.0 mL dimethylformamide. A homogeneous and stable suspension of 4.0 mg mL^{-1} MWCNTs was obtained with the aid of ultrasonic agitation for about 30.0 min. A known volume (40.0 μL) of this solution was adsorbed onto the surface of the clean and dried GCE using a micropipette and dried under room temperature. The BSA/MWCNTs/GCE was prepared with the following procedure: an 8.0 mL of the BSA solution (0.40 mg mL^{-1} dissolved in TBS (0.05 mol L^{-1}, pH 7.4)) was dripped on the MWCNTs/GCE surface and dried by passing very slow rate of air for 10.0 min to

form a stable gel-like film. Then BSA/MWCNTs/GCE was kept at 4.0 °C in a refrigerator until use.

2.4. Procedures

Solutions used in the F and UVvis experiments were prepared in TBS (0.05 mol L^{-1}, pH 7.4) containing appropriate amounts of BSA or VB7. The total added volume (BSA or VB7) was less than 0.2 mL. Titrations were performed manually using suitable micropipettes. A mixed solution was shaken thoroughly and equilibrated for 5.0 min. F or UVvis spectra were then recorded.

Solutions used in the voltammetric experiments were prepared in TBS (0.05 mol L^{-1}, pH 7.4) containing appropriate amounts of BSA or VB7. The total added volume (BSA or VB7) was less than 0.4 mL. A given VB7–BSA system was stirred for 10.0 s, and then the sample was analyzed as required.

2.5. Development of the augmented matrix for MCR-ALS

Experiment 1 ($\boldsymbol{D}_{DPV}^{VB7}$): The concentration of VB7 was kept constant (5.5×10^{-4} mol L^{-1}), and BSA was added to the solution in the range of 0.0–5.5×10^{-4} mol L^{-1}.
Experiment 2 ($\boldsymbol{D}_{DPV}^{BSA}$): The concentration of BSA was kept constant (2.5×10^{-4} mol L^{-1}), and VB7 was added to the solution in the range of 0.0–12.5×10^{-3} mol L^{-1}.
Experiment 3 ($\boldsymbol{D}_{LSV}^{VB7}$): The concentration of VB7 was kept constant (4.0×10^{-4} mol L^{-1}), and BSA was added to the solution in the range of 0.0–4.0×10^{-4} mol L^{-1}.
Experiment 4 ($\boldsymbol{D}_{LSV}^{BSA}$): The concentration of BSA was kept constant (2.0×10^{-4} mol L^{-1}), and VB7 was added to the solution in the range of 0.0–1.0×10^{-3} mol L^{-1}.
Experiment 5 ($\boldsymbol{D}_{CV}^{VB7}$): The concentration of VB7 was kept constant (6.0×10^{-4} mol L^{-1}), and BSA was added to the solution in the range of 0.0–6.0×10^{-4} mol L^{-1}.
Experiment 6 ($\boldsymbol{D}_{CV}^{BSA}$): The concentration of BSA was kept constant (1.0×10^{-4} mol L^{-1}), and VB7 was added to the solution in the range of 0.0–5.0×10^{-4} mol L^{-1}.
Experiment 7 ($\boldsymbol{D}_{F}^{VB7}$): The concentration of VB7 was kept constant (6.0×10^{-7} mol L^{-1}), and BSA was added to the solution in the range of 0.0–6.0×10^{-7} mol L^{-1}.
Experiment 8 ($\boldsymbol{D}_{F}^{BSA}$): The concentration of BSA was kept constant (1.0×10^{-7} mol L^{-1}), and VB7 was added to the solution in the range of 0.0–5.0×10^{-7} mol L^{-1}.
Experiment 9 ($\boldsymbol{D}_{UVvis}^{VB7}$): The concentration of VB7 was kept constant (1.0×10^{-6} mol L^{-1}), and BSA was added to the solution in the range of 0.0–1.0×10^{-6} mol L^{-1}.
Experiment 10 ($\boldsymbol{D}_{UVvis}^{BSA}$): The concentration of BSA was kept constant (1.0×10^{-6} mol L^{-1}), and VB7 was added to the solution in the range of 0.0–5.0×10^{-6} mol L^{-1}.

2.6. Foundations in applying MCR-ALS

The MCR-ALS method for the analysis of electroanalytical data is summarized elsewhere [15,16], and here only a working summary is provided. The goal of MCR is to decompose composite measured profiles such as voltammograms or spectra into the different pure profiles for each species in a mixture. The resulting extracted information for the pure components may be in the form of single bands or more complex profiles. Such data can be arranged into $\boldsymbol{D}$ (M × N) matrix with M objects and N variables e.g. wavelength or potential. The MCR decomposition of a matrix is carried out according to the following equation:

$$\boldsymbol{D}=\boldsymbol{C}\boldsymbol{S}^{T}+\boldsymbol{E} \tag{1}$$

where $\boldsymbol{D}$ is the matrix of the experimental data, with dimensions of $M\times N$. The matrix, $\boldsymbol{C}$ (M × P), describes the concentration profiles of the P species involved in the given measured profiles. The matrix, $\boldsymbol{S}^{T}$ (P × N), is then the contribution of the measured profiles of these P species in the N columns of the data matrix (pure signals' profiles). $\boldsymbol{E}$ ($M\times N$) is the matrix of residuals, which contains the data variance unexplained by the product, $\boldsymbol{C}\boldsymbol{S}^{T}$. One important and frequently used iterative approach to solve Eq. (1) is MCR by alternating least squares (ALS). The optimization process starts from initial guesses of $\boldsymbol{C}$ and $\boldsymbol{S}^{T}$, and these are then refined to yield profiles with chemical meaning.

When the same chemical system is monitored using more than one technique, e.g. DPV, LSV, CV, F and UVvis, a matrix is constructed, which consists of row- and column-wise augmented data, i.e. five types of information are presented. The individual data matrices corresponding to the five types of technique are placed side-by-side. The related model for MCR-ALS analysis is shown below:

$$\begin{bmatrix}\boldsymbol{D}_{DPV}^{VB7}\boldsymbol{D}_{LSV}^{VB7}\boldsymbol{D}_{CV}^{VB7}\boldsymbol{D}_{F}^{VB7}\boldsymbol{D}_{UVvis}^{VB7}\\ \boldsymbol{D}_{DPV}^{BSA}\boldsymbol{D}_{LSV}^{BSA}\boldsymbol{D}_{CV}^{BSA}\boldsymbol{D}_{F}^{BSA}\boldsymbol{D}_{UVvis}^{BSA}\end{bmatrix}=\begin{bmatrix}\boldsymbol{C}^{VB7}\\ \boldsymbol{C}^{BSA}\end{bmatrix}$$

$$\left[\boldsymbol{S}_{DPV}^{T}\boldsymbol{S}_{LSV}^{T}\boldsymbol{S}_{CV}^{T}\boldsymbol{S}_{F}^{T}\boldsymbol{S}_{UVvis}^{T}\right]+[\boldsymbol{E}_{DPV}\boldsymbol{E}_{LSV}\boldsymbol{E}_{CV}\boldsymbol{E}_{F}\boldsymbol{E}_{UVvis}] \tag{2}$$

If $\boldsymbol{D}_{\mathrm{DPV}}$, $\boldsymbol{D}_{\mathrm{LSV}}$, $\boldsymbol{D}_{\mathrm{CV}}$, $\boldsymbol{D}_{\mathrm{F}}$, and $\boldsymbol{D}_{\mathrm{UVvis}}$ are the data obtained with the five techniques, there are two matrices of concentration profiles, $\boldsymbol{C}^{\mathrm{VB7}}$ and $\boldsymbol{C}^{\mathrm{BSA}}$, and five row-wise augmented matrices of measured profiles, $\boldsymbol{S}_{\mathrm{DPV}}^{\mathrm{T}}$, $\boldsymbol{S}_{\mathrm{LSV}}^{\mathrm{T}}$, $\boldsymbol{S}_{\mathrm{CV}}^{\mathrm{T}}$, $\boldsymbol{S}_{\mathrm{F}}^{\mathrm{T}}$, and $\boldsymbol{S}_{\mathrm{UVvis}}^{\mathrm{T}}$, which contain the pure signals for the techniques used to obtain $\boldsymbol{D}_{\mathrm{DPV}}$, $\boldsymbol{D}_{\mathrm{LSV}}$, $\boldsymbol{D}_{\mathrm{CV}}$, $\boldsymbol{D}_{\mathrm{F}}$, and $\boldsymbol{D}_{\mathrm{UVvis}}$, respectively.

When the augmented matrix of the five data matrices is being built, the number of analyte species, P, can be obtained with the aid of Evolving Factor Analysis (EFA) [17] or Principal Component Analysis (PCA) or other methods based on factor analysis. The EFA method provides an estimation of the regions or windows where the concentration of different components is changing or evolving, and it also provides an initial estimation of how these concentration profiles change during the experiment. This method is based on the evaluation of the magnitude of the eigenvalues associated with all the submatrices of a matrix built up by adding successively all the rows of the original data matrix. The calculation is performed in two directions: forward (in the direction of the experiment) and backward (in the opposite direction of the experiment), e.g. Abdollahi and Mahdavi illustrate how concentration profiles obtained from EFA may be used as initial estimates for the concentration matrix input in the constrained ALS optimization [18]. PCA, an alternative approach to EFA, is a common chemometrics tool; it yields the number and direction of the relevant sources of variation in a bilinear data set [19]. Once the PCs, P, are determined and an initial estimate of their concentration profiles is obtained, it becomes easier to obtain improved estimates of either the concentration values or pure signals' profiles. Constraints in ALS optimization are implemented to facilitate the finding of pure or most representative contributions to the data matrix using real variables. The resolution methods start with initial estimates of $\boldsymbol{C}$ and work by optimizing iteratively the concentration, while introducing the available information about the system [19]. During the optimization, the suitable constraints are applied to ensure that the final solution is chemically meaningful [20]. The lack of fit (lof) [21], which is defined as the difference between the input data, $\boldsymbol{D}$, and the data reproduced from the $\boldsymbol{C}\boldsymbol{S}^{T}$ product obtained by MCR-ALS, was used as a parameter to evaluate the goodness of fit of the model according to the following expression:

$$lof\ (\%)=100\sqrt{\frac{\sum_{i,j}e_{i,j}^{2}}{\sum_{i,j}d_{i,j}^{2}}} \tag{3}$$

where d_{ij} is an element in the raw data and e_{ij} is the corresponding residual after the model variation is removed.

However, the solutions to Eq. (1) obtained by MCR-ALS are not unique. They can have rotational and intensity ambiguities. To solve this limitation, column- and row-wise augmentation schemes (Eq. (2)) can be used for simultaneous resolution. This kind of simultaneous data analysis is more powerful compared to that described by Eq. (1) and allows for improved resolution of very complex data structures. In general, this method should be useful to overcome some uncertainties in the analysis of the data related to coincidental processes or small signal shifts. Thus, in this work, an augmented data matrix, was constructed and resolved by the MCR-ALS approach.

However, because of the combination of completely different types of data, e.g. voltammetric and spectroscopic data some considerations must be performed in the analysis of the augmented matrix:

1. Due to the fact that voltammetric and spectroscopic signals are of very different magnitude, submatrices must be scaled in order to have a similar weight on the iterative ALS optimization of the augmented data matrix; in a first approach, this is done by dividing submatrices by their maximum values prior to their combination into an augmented data matrix.
2. The concept of component is a critical point. For spectroscopic data component is associated to pure chemical species in solution [22,23], but for electrochemical data component must be associated to a single electrochemical process giving a signal, including not only redox processes but also some other possible phenomena like, for instance, electrode adsorption of a species [15,16] or capacitive currents due to the charging of the electrical double layer at the electrode surface. Anyway, in many situations, a single electrochemical process is produced by a single species.
3. Taking into account the impossibility of applying a closure constrain (i.e., the mass balance) to the matrices obtained at different concentration levels, a normalization of the signals has been made along the MCR-ALS iterations. Considering that such normalization should be common to DPV, LSV, CV, F, and UVvis parts of each pure signal, it has been made by dividing the pure signal by its maximum absolute value (alternative normalization procedures have been tested but the results were similar).
4. To combine voltammetric and spectroscopic sub-matrices into an augmented matrix, all sub-matrices must contain the same number of rows and columns and must share the same distribution of the chemical species along the experiments. Ideally, this condition can be fulfilled using exactly the same total concentrations of VB7 and BSA in all titrations, but this is not possible because the concentrations required for voltammetric experiments are higher than those for spectroscopic ones. Thus, in the present work, voltammetric and spectroscopic experiments have been performed at different total concentrations but at the same values of ratio.

3. Results and discussion

3.1. Morphological studies of the composite electrodes

Fig. 2A and B shows the SEM images of MWCNTs/GCE and BSA/MWCNTs/GCE, respectively. The SEM image of MWCNTs/GCE (Fig. 2A) shows the MWCNTs twining around each other and attached to the GCE. It is clear that MWCNTs almost homogeneously distributed on the electrode surface by forming a thin layer. When BSA was immobilized on the electrode surface the clear MWCNTs image became dim and the protein adsorbed and aggregated onto the surface of the tubes (Fig. 2B); therefore, it demonstrated that MWCNTs were wrapped by BSA.

3.2. Voltammetric studies of VB7–BSA interactions

3.2.1. Cyclic voltammetric studies

Useful information about the interaction of ligands and biomacromolecules usually can be acquired from the cyclic voltammetry (CV) that is one of the most important electroanalytical techniques due to the similarity among various redox chemical and biological processes [24]. Therefore, CV was used to study the interactions of VB7 with BSA. Fig. 3A compares the CVs of VB7 in TBS (0.05 mol L^{-1}, pH 7.4) at GCE (curve a) and MWCNTs/GCE (curve b). As can be seen, MWCNTs exhibited excellent electrocatalytic behavior towards irreversible oxidation of VB7 as evidenced by enhancement of the VB7 oxidation peak current and shift in its oxidation potential to lower values in comparison with the bare GCE. From the CV of the VB7 at MWCNTs/GCE (Fig. 3A, curve b), the E_p and $E_{p/2}$ values were 653 and 572 mV, respectively. When irreversible oxidation occurs at an electrode, at $E_{p/2}$, the corresponding current, i, is given by $(I_d/2)$, and at 25 °C, $|E_p - E_{p/2}| = 47.7/\alpha n$ [25], where n is the electron transfer number, and α of an irreversible electrode process is generally assumed to be 0.5 [26]. Thus, n was calculated to be 1.17 i.e. ~1.

BSA did not exhibit any observable peak at the MWCNTs/GCE at pH 7.4, when BSA was added to the VB7 solution, the oxidation peak shifted towards higher potentials and a decreasing oxidation current was observed (Fig. 3B, curves b–s). This shift may be attributed to the changes of the molecular environment around the VB7 molecule as a result of its interaction with BSA [27]. This observation is consistent with the view that the VB7–BSA interaction occurred between the most hydrophobic segments of the VB7 molecule and the hydrophobic region of the BSA cavity.

Since binding of VB7 to BSA may influence the major electrochemical kinetic parameters of VB7 (such as α (transfer coefficient) and k_s (electrochemical rate constant)) the CVs of VB7 at various scan rates (υ) were recorded at the surface of both BSA/MWCNTs/GCE (VB7–BSA) and MWCNT/GCE (free VB7). Fig. 4A shows the typical cyclic voltammograms of VB7 at various scan rates on the surface of BSA/MWCNTs/GCE. A linear relationship between peak current (I_p) and υ revealed that VB7 oxidation was an adsorption-controlled process (Fig. 4B). Furthermore, from the slopes of the linear plots of I_p vs. υ the surface concentrations of electroactive species (Γ) were estimated as 5.71×10^{-3} and 4.76×10^{-3} mol cm^{-2} for the free VB7 and the bound VB7–BSA, respectively, according to the following equation [28]:

$$I = n^2F^2A\Gamma\upsilon/4RT \quad (4)$$

where n represents the number of electrons involved in reaction (one electron), A is the surface area (0.05 cm^2) of the GCE, T is temperature (25 °C), Γ (mol cm^{-2}) is the surface coveraged and other symbols have their usual meaning. As it is shown by increasing the scan rate, the shifted to a more positive potential. For a totally irreversible and an adsorption-controlled process, the relationship between E_P and υ can be expressed by the Laviron's equation [29]

$$E_p = E^0 - 2.3RT/\alpha nF[\log(RTK_s/nF) - \log \upsilon] \quad (5)$$

where E^0 (V) was the formal potential, and other symbols have their usual meaning. k_s and αn values can be obtained from the intercept and the slope of the linear plot of E_p vs. log υ (Fig. 4C), if the E^0 is known. The E^0 value can be deduced from the intercept of E_p vs. υ (Fig. 4D) plot by extrapolating the line to $\upsilon = 0$ V s^{-1}. By knowing E^0 and graphical representations of E_p vs. log υ for VB7 in the absence and presence of BSA, the α and k_s were obtained from the slope and intercept, respectively. On the assumption that the number of electrons involved in the VB7 oxidation is 1 the values of α for an

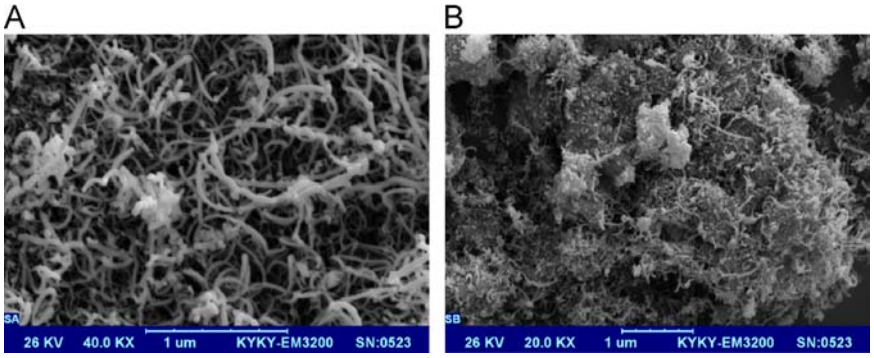

Fig. 2. The SEM images of (A) MWCNTs/GCE, and (B) BSA/MWCNTs/GCE.

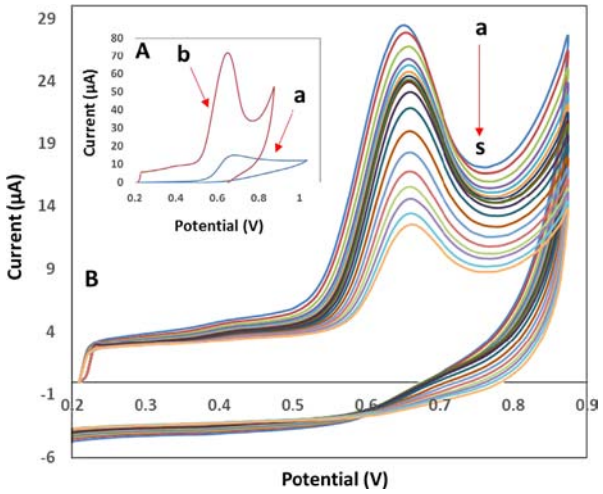

Fig. 3. (A) Cyclic voltammograms of 0.10 mM VB7 in TBS (0.05 mol L^{-1}, pH 7.4) at (a) bare GCE, and (b) MWCNTs/GCE, and (B) cyclic voltammograms of 6.0×10^{-4} M VB7 in TBS (0.05 mol L^{-1}, pH 7.4) at MWCNTs/GCE with different concentrations of BSA (a-s): 0.0–6.0×10^{-4} mol L^{-1} (in steps of 3.33×10^{-5} mol L^{-1}), In all cases scan rate was 50.0 mV s^{-1}.

irreversible surface reaction can be obtained as 0.374 and 0.371 for the free VB7 (at MWCNTs/GCE) and the bound VB7–BSA (at BSA/MWCNTs/GCE), respectively. Also, k_s can be obtained as 3.00 and 2.74 for the free VB7 (at MWCNTs/GCE) and the bound VB7–BSA (at BSA/MWCNTs/GCE), respectively. As can be seen, the values of α and k_s are decreased in the presence of BSA. Decreasing of α may be due to higher absorption of VB7–BSA complex at the electrode surface and decreasing of k_s may be attributed to the lower rate of electron transfer of VB7 in the form of VB7–BSA complex.

3.2.2. Linear sweep and differential pulse voltammetric studies

The LSVs (Fig. 5A) and DPVs (Fig. 5B) of VB7/BSA mixtures in a TBS (0.05 mol L^{-1}, pH 7.4) collected at a MWCNTs/GCE, indicated that the anodic peak current decreased continually and the peak potential shifted a little to more positive values with the addition of BSA. The peak current from this VB7 reaction did not disappear completely with the increase of the BSA concentration; this is unexpected if a competitive adsorption occurred at the electrode. It has been observed, that when an interaction of some biopolymers such as hemoglobin, albumin and DNA with small molecules takes place at quite a low protein concentrations and a short accumulation time, only about 10% of the electrode surface may be covered; this implies that very little competitive adsorption of small molecules can occur [30]. The decrease in peak current without any changes in the electrochemical parameters suggested the formation of an electroinactive VB7–BSA complex because VB7 becomes embedded within the BSA structure, which results in the decrease of the equilibrium concentration of VB7 in solution. However, there is another possible explanation for these observations, and it involves the possible unfolding of the BSA protein as the concentration of the ligand increases. As a result, the protein structure unravels, and this provides pathways for ligands to access the tryptophan or tyrosine residues, which then can be oxidized at MWCNTs/GCE [31].

3.2.3. Determination of binding constant of VB7 to BSA

In this section, the binding behavior of VB7 to BSA/MWCNT/GCE was measured by recording the cyclic voltammograms of VB7 at various concentrations (not shown). It was observed that the peak current increased by increasing the VB7 concentration (C_{VB7}) and then trended to saturation values, as expected with the shape of Langmuir adsorption. Thus the adsorption thermodynamics follows equation [32]:

$$C_{VB7}/I = (1/K_b I_{max}) + (C_{VB7}/I_{max}) \quad (6)$$

where I, I_{max}, and K_b are the peak current, maximum peak current, and the binding constant at BSA/MWCNT/GCE surface, respectively. Regression of C_{VB7}/I on C_{VB7} at BSA/MWCNT/GCE obeyed the following equation: $C_{VB7}/I = 7.416 + 5555.56\ C_{VB7}$ and K_b value can be obtained from the intercept of this equation as 4.12×10^4 mol^{-1} L.

3.3. Analysis of fluorescence quenching mechanism of BSA by VB7

BSA has two tryptophan (Trp) residues that possess intrinsic fluorescence: Trp-212, located within a hydrophobic binding pocket of the protein, and Trp-134, located on the surface of the molecule. Tryptophan emission dominates the BSA fluorescence spectrum in the UV region. When other molecules interact with BSA, Trp fluorescence may change depending on the impact of such interaction on the fluorophore–quencher complex [33]; this is often manifested in the decrease of the quantum yield of fluorescence from the fluorophore i.e. the BSA, and can be induced by a variety of molecular interactions with the quencher molecule. Fluorescence quenching refers to any process, which decreases the fluorescence intensity of a sample, and quenching mechanisms are usually classified as dynamic or static. They are distinguished by their different temperatures and viscosities dependence; thus, dynamic quenching depends on diffusion, and therefore, the biomolecular quenching constants are expected to increase with increasing temperature. In contrast, increased temperature is likely to result in lower values of the static quenching constants.

For fluorescence quenching, the decrease in intensity is usually described by the well-known Stern–Volmer equation [34]

$$F_0/F = 1 + K_{SV}[Q] \quad (7)$$

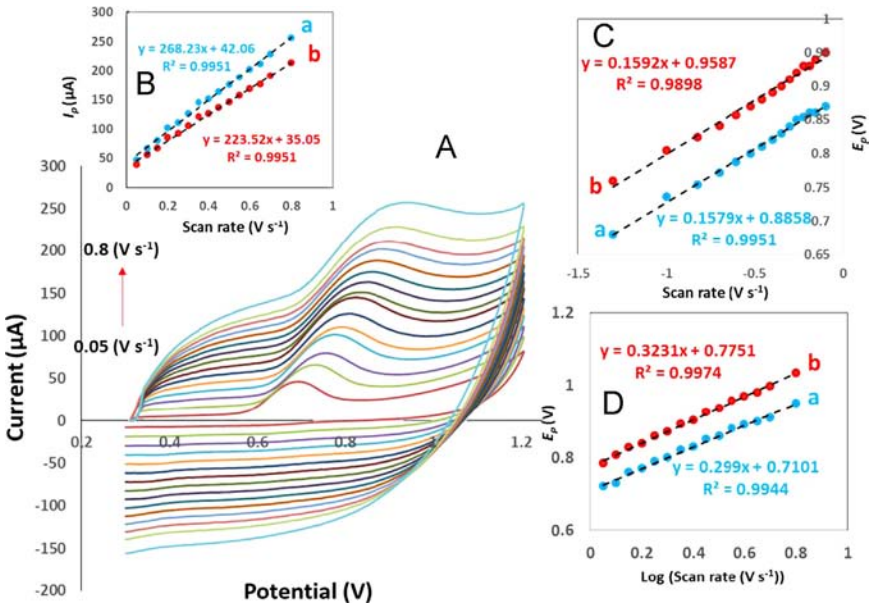

Fig. 4. (A) Cyclic voltammograms of 0.10×10^{-3} mol L^{-1} VB7 at BSA/MWCNTs/GCE in TBS (0.05 mol L^{-1}, pH 7.4) at different scan rates, and (B) The plots of peak currents vs. scan rate for (a) free VB7 (at MWCNT/GCE) and (b) bound VB7–BSA (at BSA/MWCNTs/GCE). (C) and (D) The variations of peak potential vs. υ and log υ for (a) free VB7 and (b) bound VB7–BSA, respectively.

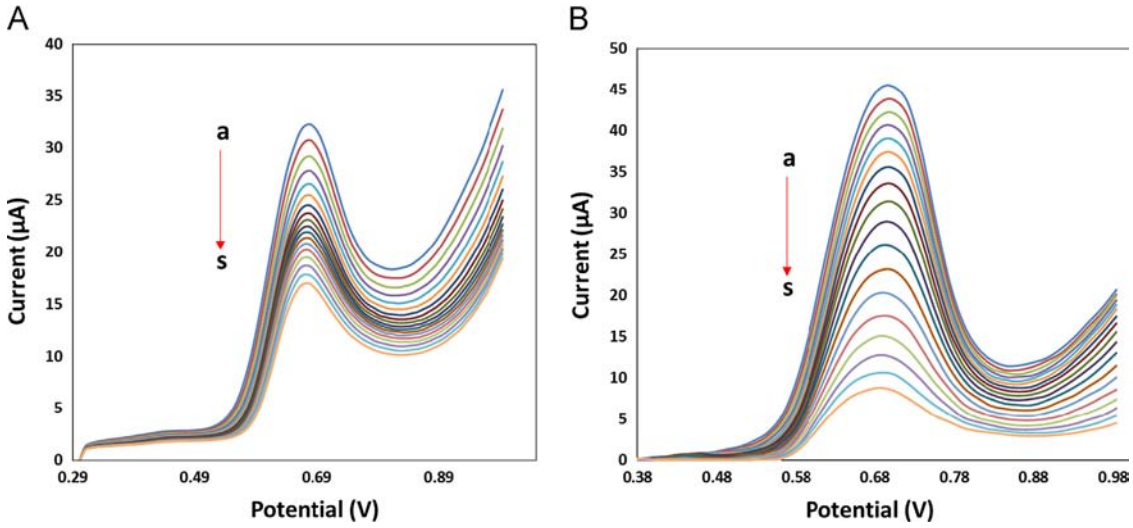

Fig. 5. (A) The LSVs of VB7 (4.0×10^{-4} mol L^{-1}) in TBS (0.05 mol L^{-1}, pH 7.4) in the presence of increasing concentrations of BSA in the range of 0.0–4.0×10^{-4} mol L^{-1}, and (B) Typical DPVs of VB7 (5.5×10^{-4} mol L^{-1}) in TBS (0.05 mol L^{-1}, pH 7.4) in the presence of increasing concentrations of BSA in the range of 0.0–5.5×10^{-4} mol L^{-1}.

where F_0 and F denote the steady-state fluorescence intensities in the absence and in the presence of the quencher. K_{SV} is the Stern–Volmer quenching constant, and [Q] is the concentration of the quencher. The degree of fluorescence quenching as a function of temperature when VB7 was added to BSA, was clearly discernable (Fig. 6A). The values of K_{SV} (Table 1) decreased with increase in temperature, which indicated that the probable quenching mechanism of this interaction was initiated by the formation of a complex rather than by dynamic collision.

3.4. UV–vis studies of VB7–BSA interactions

The interaction of VB7 with BSA was also investigated by UV–vis absorption titration in TBS (0.05 mol L^{-1}, pH 7.4) by maintaining the VB7 concentration constant but changing the BSA concentration. As shown in Fig. 6B, an absorbance peak at 280 nm is shown by VB7 in TBS (0.05 mol L^{-1}, pH 7.4) with the addition of BSA into VB7 solution, the absorption at 280 nm is increased gradually (hyperchromism), and two new absorption peaks at 254, 324 nm is remarkably forming. Based on the above results, we suggested that the alterations in UVvis spectra maybe related to interactions of VB7 with BSA.

Further discussion of the VB7/BSA interaction on the basis of direct observations of the measured profiles was difficult, and multivariate analysis previously discussed was applied to extract further information, especially as function of concentration of the VB7 and BSA reactants.

3.5. Interpretation of the MCR-ALS results

As previously discussed in detail (Section 2.6), the ten individual data matrices obtained from DPV, LSV, CV, F, and UVvis in Figs. 3 and 5–7 were combined into an augmented data matrix (first term of Eq. (2)), and then this augmented matrix was submitted for simultaneous resolution by the MCR-ALS (Eq. (2)) as a powerful chemometric tool. The intention was to extract

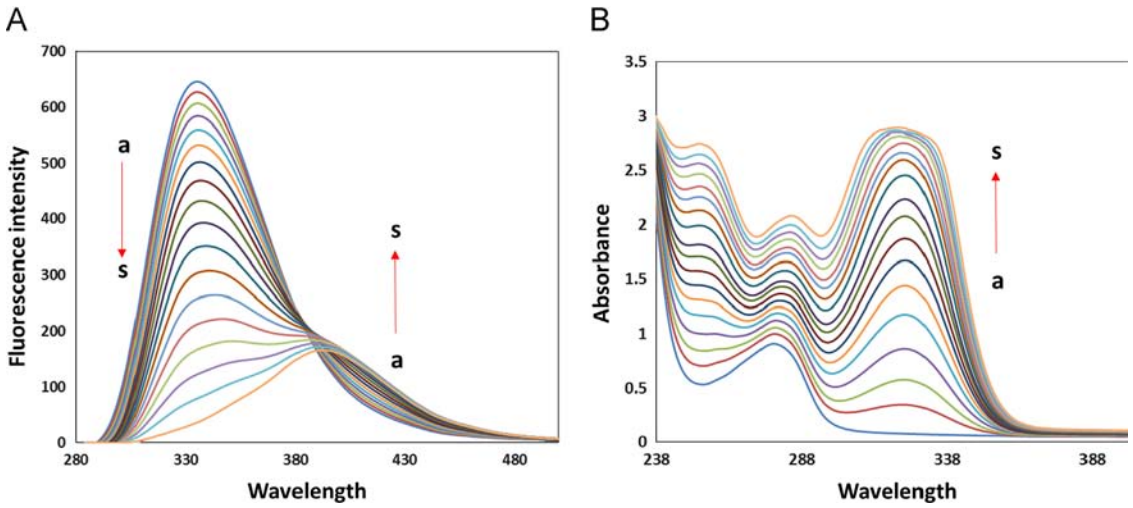

Fig. 6. (A) Fluorescence emission spectra of BSA (1.0×10^{-7} mol L^{-1}) in TBS (0.05 mol L^{-1}, pH 7.4) in the presence of increasing concentrations of VB7 in the range of 0.0–5.0×10^{-7} mol L^{-1}, λ_{ex}= 270.0 nm, and (B) UVvis absorption spectra of 1.0×10^{-6} mol L^{-1} VB7 in TBS (0.05 mol L^{-1}, pH 7.4) in the presence of increasing concentrations of BSA in the range of 0.0–1.0×10^{-6} mol L^{-1}.

Table 1

[a] Linear correlation coefficient.

information regarding: (i) any BSA–$VB7_m$ complex, and (ii) the relative concentrations of the various reactant and product species. First, the number of contributions to the augmented matrix was determined by SVD and here, the SVD detected four components. These four components may be related to free VB7, free BSA and two BSA–$VB7_m$ complex spices. The second step in the MCR-ALS method, is finding an initial estimate for either pure spectra or voltammograms, which can be obtained by the use of EFA or simple-to-use interactive self-modeling mixture analysis (SIMPLISMA) [35,36]. EFA is usually used to estimate the concentration profiles of the species involved in an evolutionary chemical process whereas SIMPLISMA is mainly used to obtain an estimate of the pure instrumental responses such as pure spectra or pure voltammograms. Since the data matrices in this study do not possess variables in both directions and concentration profiles apply here, initial estimates for MCR-ALS were obtained here by EFA. EFA was basically designed to work with full rank two-way data sets and straightforward analysis of rank-deficient matrix does not provide useful information. To overcome this limitation, de Juan et al. [37] have proposed an evolution of the original algorithm. This new approach is based on a two-step strategy. First, rotational ambiguity is reduced by matrix augmentation. The augmented data matrix, is formed row- and column-wise augmented matrix. Then, EFA is applied to the unfolded full rank augmented data set eventually providing information about contributions that are otherwise hidden. PCA was also employed to select the appropriate number of components to describe the four systems, and it was found that the first four PCs explained 99.9% of the total data variance in the combined matrix. Thus, both the EFA and PCA methods estimate the same number of factors or chemical species involved.

One of the advantages of MCR-ALS rather than the other iterative methods such as iterative target transformation factor analysis (ITTFA) is that in iteration process some constraints should be applied on the data matrix, which results in obtaining more reliable results. It should be noted that due to the presence of CV data which contain negative values, the non-negativity constraint was only employed on concentration profiles. Unimodality constraint was applied to signal profiles. Applying a closure constraint to the matrices obtained at different concentration levels is impossible.

By applying the mentioned constraints, the ALS optimization was started. As previously mentioned, the lof which is defined as the difference between the input data ($\boldsymbol{D}$) and the data reproduced from the product ($\boldsymbol{CS}^T$) obtained by the MCR-ALS, was used as a parameter to evaluate the goodness of fit of the model. In this work, the best lof value was found to be 6.61% which implies that almost all of the variability in the experimental data presented as a product of the extracted signals and the concentration profiles, is explained.

The results of MCR-ALS are shown in Fig. 8. Fig. 8A shows that concentration of VB7 is decreasing and two new complex species are forming upon the addition of BSA. As can be seen, the concentration of one of these complex spices (red dashed line) increased sharply and reached to a maximum at the ratio, $r_{BSA/VB7}\sim1$. Therefore, it may be concluded that this species is a 1:1 BSA–VB7 complex species. On the other hand, Fig. 8A shows that with the mole-ratio method, the concentration of the second BSA-VB7 complex spices (dark blue dashed line) increased slowly to $r_{BSA/VB7}\sim0.5$ and reached equilibrium position as the concentration of BSA increased. Thus, these results indicated that the second spices is a 1:2 BSA–VB7 complex species. The same conclusions about stoichiometries of the complex spices could be obtained from Fig. 8B.

The pure voltammetric and spectral profiles extracted by the application of the MCR-ALS (Fig. 8C–G) provided new qualitative information about the nature of the complex spices. From these figures the valuable information about the nature of the involved complex species in each technique could be obtained. According to these results, it is clear that both complex species are electroactive at the MWCNTs/GCE. The measured and extracted pure spectral and voltammetric profiles agreed reasonably well. The extraction of the voltammetric profiles and their reasonable agreement with the measured data indicated that the MCR-ALS method was applied successfully. The BSA measured curve suggested that the protein in its original structural format was electroinactive, and the extracted profile approximated this profile no obvious extracted bands were evident. However, the complexes' curves, unlike that for the BSA, indicated the presence of electroactive species. To achieve this result

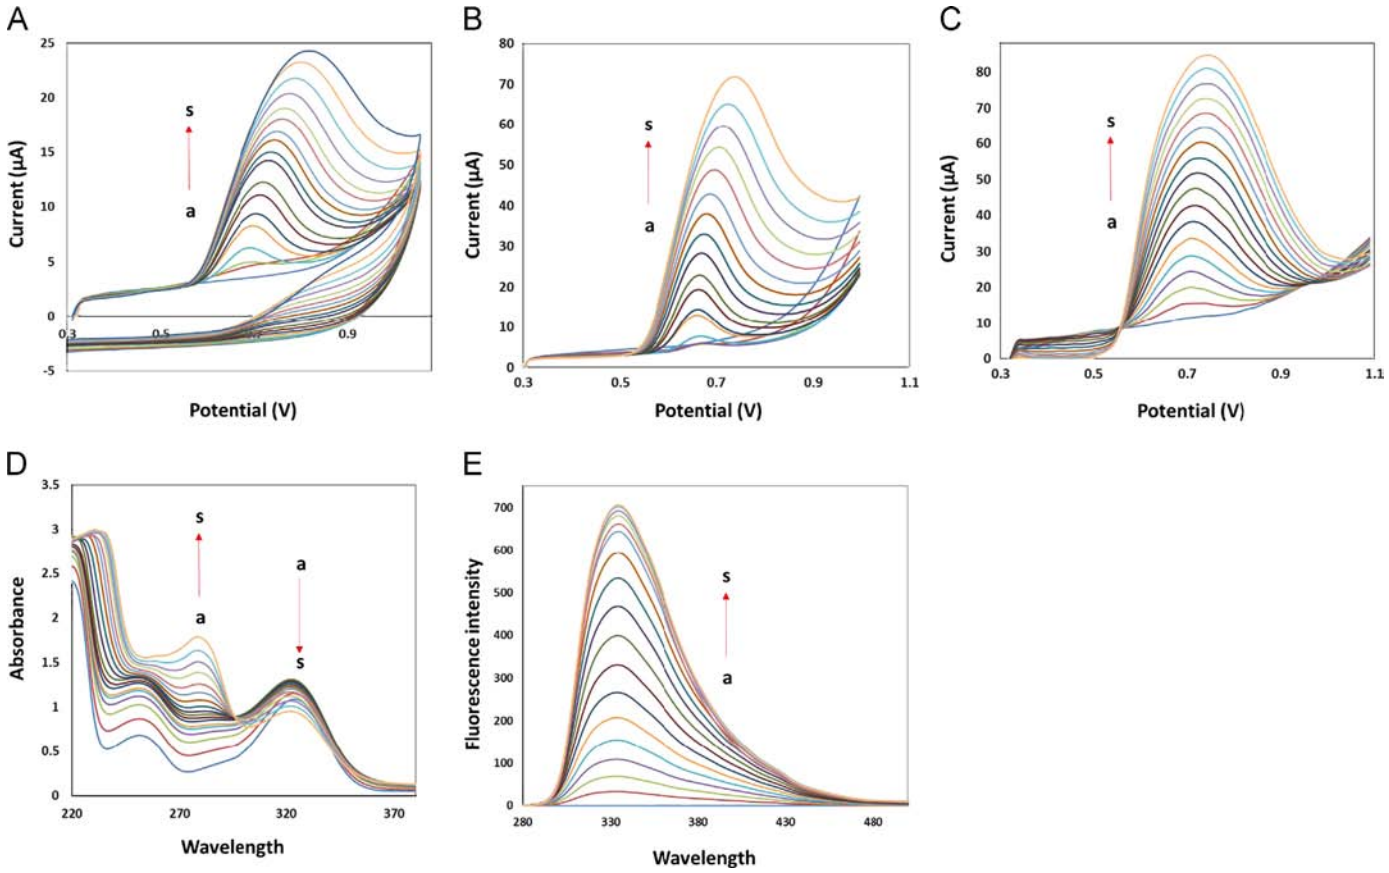

Fig. 7. Response profiles obtained from different experiments described in Section 2.5. (A) Experiment 6, (B) Experiment 4, (C) Experiment 2, (D) Experiment 10, and (E) Experiment 7.

for the reaction occurring at electrode's surface, it is necessary for the potentially oxidizable tryptophan and tyrosine side chain residues to be accessible. This would be facilitated somewhat by an unfolded rather than the originally folded structure of the BSA protein. Therefore, it seemed reasonable to suggest that the binding of the three VB7 molecules facilitated the unfolding of the BSA structure. The plot with coincided experimental and theoretical absorbance data that has been represented in Fig. 8H which is a strong evidence for high quality of fitting process.

3.6. MCR-BANDS analysis to study the extent of rotational ambiguities

One of the advantages of MCR rather than the other bilinear methods like principle component analysis (PCA) and SVD, is its physical meaningful solution due to the use of "natural" constraints [38]. However, in some data analysis, unfortunately MCR method suffers from the existence of ambiguities in the solution. Because of this fact, instead of a unique solution, a band of feasible solutions fitting equally well the experimental data can be obtained [39]. Thus, an important point when using MCR methods is finding a unique solution with interpretable and reliable means to explain the measured experimental data. In 2001, Tauler proposed the method of MCR-BANDS, which was closed to Gemperline's concept to estimate the feasible solutions [40]. This method is based on the calculation of maximum and minimum of relative contribution of every component in the mixture [38,40]. Although Tauler-Gemperline method could not measure correctly the rotational ambiguity [41] MCR-BANDS can provide a good indication of the extent of the rotational ambiguity [42].

In the present study, the MCR-ALS method assisted to obtain reliable results which were in agreement with experimental observations. However, to evaluate the existence of rotational ambiguities in the obtained results, the MCR-BANDS method was used. MCR-BANDS was applied to the data matrix described by the profiles of MCRALS results. Also, the same constraints as those used in MCR-ALS were applied for MCR-BANDS. The maximum and minimum values of the relative contribution function (f^{max} and f^{min}, respectively) were obtained for BSA (f^{max}= 0.271 and f^{min}= 0.271), VB7 (f^{max}=0.6907 and f^{min}=0.6907), BSA-VB7 (f^{max}=0.4289 and f^{min}=), and BSA-$VB7_2$ (f^{max}=0.2521 and f^{min}=0.2521). Interestingly, there is no difference between the f^{max} and f^{min} values for all the resolved components. It means that practically there is no remaining rotation ambiguity [38]. Elimination of rotational ambiguity could be attributed to the application of appropriate constraints and augmentation. When matrix augmentation was ignored, significant differences between the corresponding f^{max} and f^{min} values were observed (the data were not shown). Based on previous reports, one of the approaches can be used to avoid rotational ambiguity in MCR methods is the use of local rank and selective constraints apart from "natural" constraints [35,43]. It seems that, for these electrochemical data, the use of this kind of constraints, i.e. selectivity in the iterative procedure leads to a unique solution.

3.7. Hard-modeling approach

In the case of hard-modeling approaches, a model is applied to guide the decomposition of matrix $\boldsymbol{D}$ following Eq. (1). As an example, in the case of protein-drug interaction, the model

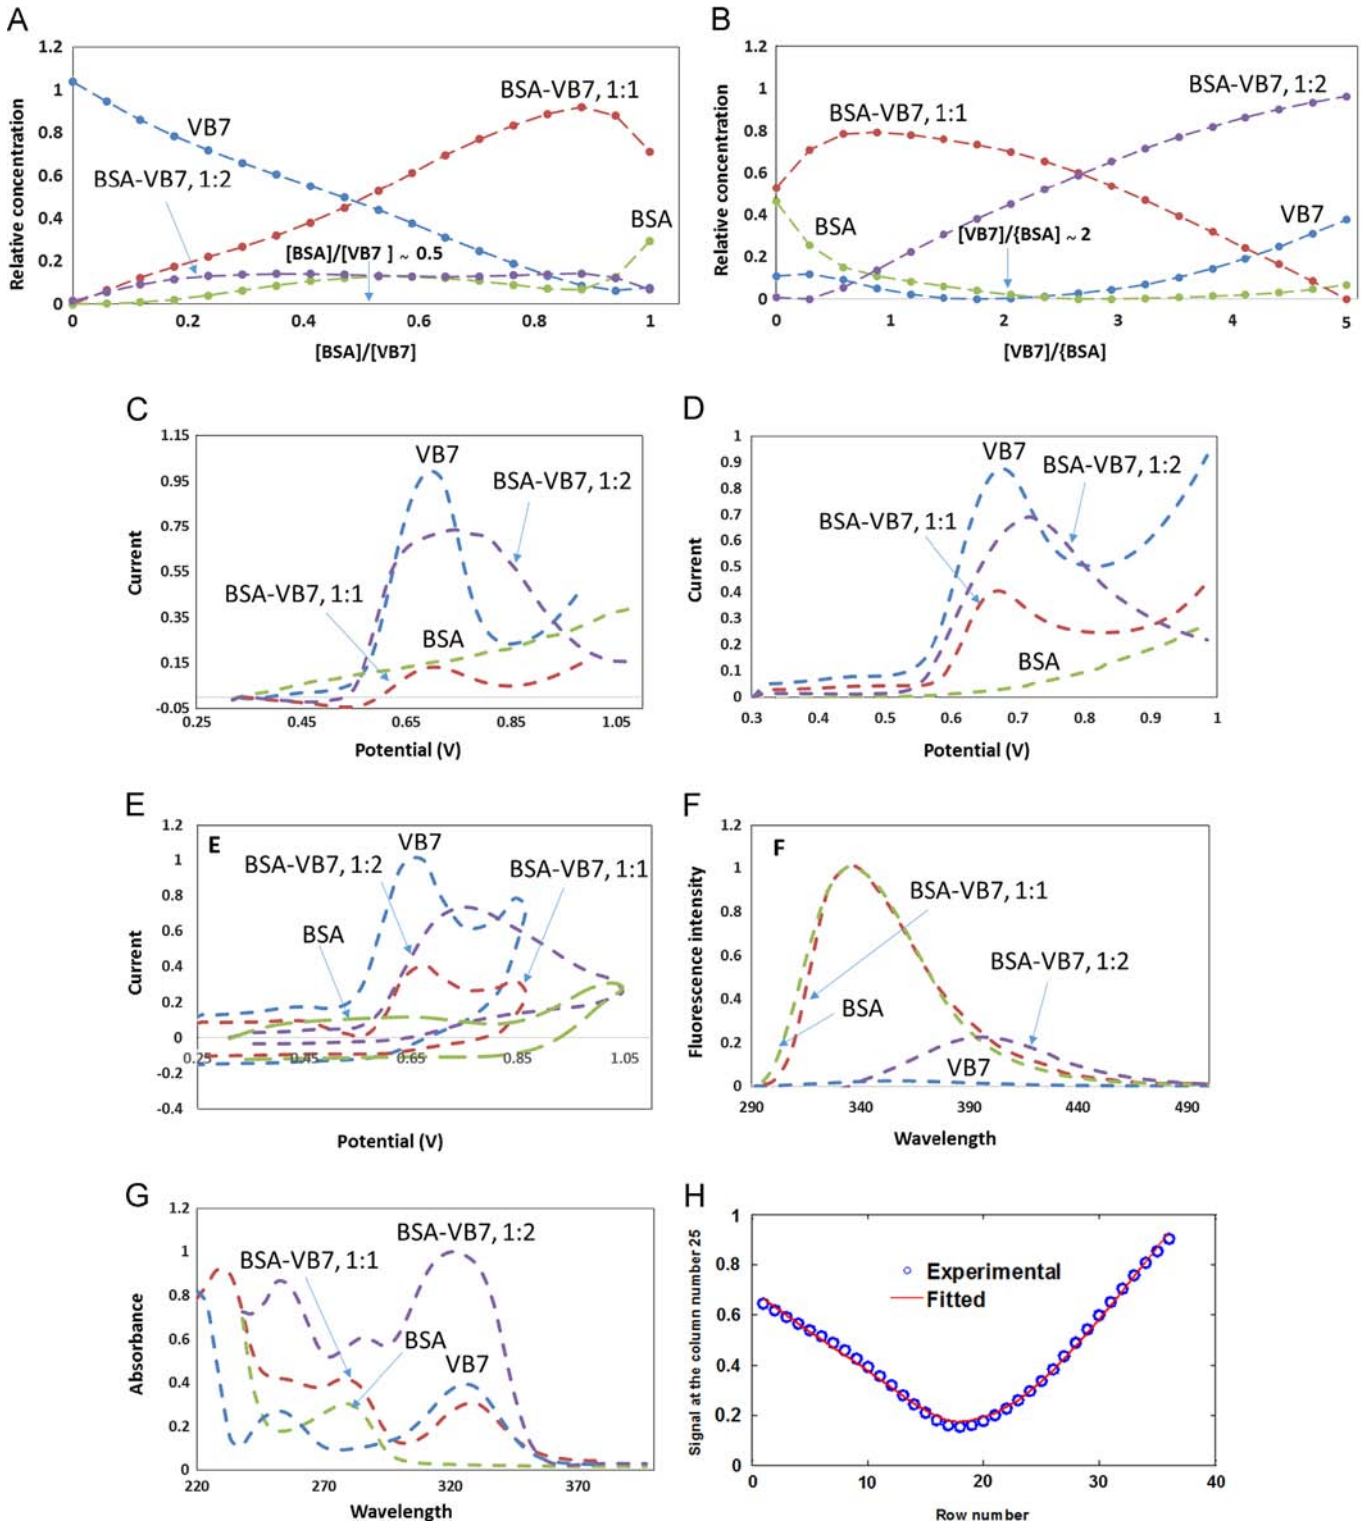

Fig. 8. The results of applying MCR-ALS to augmented matrix: (A and B) Extracted concentration profiles. (C-G) Extracted signal profiles of different species involved in DPV, LSV, CV, F and UVvis experiments, respectively. (H) The plot of experimental (points) and fitted (calculated) data (line).

includes the stoichiometry of the species formed, as well as initial trial value for the binding constant. This value is used to build an initial estimation of the concentration profiles included in ***C***. Once this estimation is obtained, a least squares fit is performed to obtain the pure spectra in $\boldsymbol{S}^{T}$ that best match the concentration profiles in ***C*** and the data in ***D***. A residual matrix ***E*** is then calculated from the difference between the data in ***D*** and the reproduced data matrix. The optimization procedure continues by tuning the stoichiometry of the proposed species until a desired level of residuals ***E*** is reached. A more detailed explanation of the mathematical basis of the algorithms used in these calculations can be found in Dyson et al. [44].

EQUISPEC, a hard-modeling algorithm, was applied to an augmented matrix (combined spectroscopic and voltammetric

data) to compute the binding constants and also verify the results of Section 3.2.3. The results of this study are shown in Table 2. As can be seen, there is a good agreement between the binding constant values computed by EQUISPEC and also with the results reported at Section 3.2.3.

3.8. Molecular docking studies

In this study, the MVD software was used to realize the binding mode of VB7 at the active site of BSA (see Fig. 9A–C). The main aspect for the ligand docking postures was considering the effective interaction of the drug with the various amino acid residues in the active site. The binding site were obtained as Val 546, Phe 550, Leu 574, Phe 508, Thr 578, Ala 527, Leu 582, Leu 531, Val 575, Phe 506, Gln 579, Lys 535, His 534, and Phe 501. LIGPLOT was used to explore the hydrogen bonds interactions between BSA and VB7 as shown in Fig. 9D. Two hydrogen bonding interactions are observed between VB7 and Thr 578 and Gln 579 of BSA, with a distance of 2.99 and 3.00 Å, respectively.

3.9. Analytical applications

3.9.1. Analytical characterizations

The BSA measured curve suggested that the protein in its original structural format was electroinactive, and the extracted profile approximated this profile no obvious extracted bands were evident. Therefore, developing an electroanalytical method for its determination is sensible. Since DPV has a much higher sensitivity than CV, it was used to estimate a lower limit of detection (LOD). Under the optimized conditions for DPV (step potential 0.005 V, modulation amplitude 0.025 V, modulation time 0.05 s, interval time 0.5 s, and scan rate 0.01 $V\,s^{-1}$), the MWCNTs/GCE in the presence of 0.5×10^{-6} mol L^{-1} VB7 in TBS (0.05 mol L^{-1}, pH 7.4) (Fig. 10, curve a) detects BSA in a concentration range of 0.5–35.0×10^{-9} mol L^{-1} (Fig. 10, curves b-l) with a limit of detection (LOD, $3S_b/b$, S_b is the standard deviation ($n=6$) of the blanks, and b is the slope value of the respective calibration graph) of 0.22×10^{-9} mol L^{-1}. Moreover, the sensitivity for BSA detection calculated from the slope of the respective calibration graph was to be 0.0404 μA nM^{-1}, indicating the high sensitivity of the proposed biosensing system.

3.9.2. Stability, repeatability, and reproducibility

Stability of the MWCNTs/GCE was tested by keeping the electrode in TBS (0.05 mol L^{-1}, pH 7.4) for 10 days and then the CVs were recorded and compared with the CVs obtained before immersion. The results indicated that the peak current changed only slightly which indicates that it has good stability. The stability of MWCNTs/GCE over time was checked during a period of 2 months. In between measurements the sensor was kept at room temperature in the dry state. A graph of I_p vs. days reveals that a small change in the DPV signal (approx. 5%) was observed after 2 months of storage. These results indicate that MWCNTs/GCE is significantly stable and has good capacity to perform repeated measurement for 2 months. In order to study the repeatability of the electrode preparation procedure, six modified electrodes based on the same fabrication procedure were prepared and used for the determination of 20.0×10^{-9} mol L^{-1} BSA. The *RSD* for the peak currents for all the six electrodes was calculated to be 3.1%. The reproducibility of the proposed method was checked by determining the *RSD* for 10 replicate measurements on a single electrode in 20.0×10^{-9} mol L^{-1} BSA. It was found out to be 2.3%. These results indicate that the modified electrode has high repeatability and reproducibility in both the preparation procedure and the DPV determinations.

Table 2
Results of applying EQUISPEC.

Analyzed matrix	$K_b(\times10^4$ L $mol^{-1})$
$\left[\boldsymbol{D}^{VB7}_{DPV}\boldsymbol{D}^{VB7}_{LSV}\boldsymbol{D}^{VB7}_{CV}\boldsymbol{D}^{VB7}_{F}\boldsymbol{D}^{VB7}_{UVvis}\right]$	5.98×10^4
$\left[\boldsymbol{D}^{BSA}_{DPV}\boldsymbol{D}^{BSA}_{LSV}\boldsymbol{D}^{BSA}_{CV}\boldsymbol{D}^{BSA}_{F}\boldsymbol{D}^{BSA}_{UVvis}\right]$	4.01×10^4
$\begin{bmatrix}\boldsymbol{D}^{VB7}_{DPV}\boldsymbol{D}^{VB7}_{LSV}\boldsymbol{D}^{VB7}_{CV}\boldsymbol{D}^{VB7}_{F}\boldsymbol{D}^{VB7}_{UVvis}\\ \boldsymbol{D}^{BSA}_{DPV}\boldsymbol{D}^{BSA}_{LSV}\boldsymbol{D}^{BSA}_{CV}\boldsymbol{D}^{BSA}_{F}\boldsymbol{D}^{BSA}_{UVvis}\end{bmatrix}$	4.66×10^4

3.9.3. Interference study

Possible interference for the detection of BSA at the MWCNTs/CCE was investigated by the addition of various ions to TBS (0.05 mol L^{-1}, pH 7.4) in the presence of 0.5×10^{-6} mol L^{-1} VB7 and 10.0 nM BSA. Common interference such as L-arginine (10-fold), D-tryptophan (15-fold), L-glutamine (8-fold), L-leucine (10-fold), Citronensaure-1-hydrate (12-fold), glucose (20-fold), vitamin B_6 (10-fold), tyrosine (12-fold), and cysteine (15-fold) had no effective interference with the current response of 10.0 nM BSA (signal change $<7\%$), suggesting that this proposed method has good selectivity toward determination of BSA in biological samples.

3.9.4. Validation of the proposed method

The validity of the method was demonstrated by the analysis of both synthetic and real samples. Synthetic samples were prepared based on the interferences of foreign substances and BSA. The analytical results of the determination of BSA in synthetic samples are summarized in Table 3. The present method also demonstrates the capability to detect and quantify BSA in biological samples such as serum samples obtained from Holstein cows. The results in Table 3 showed close agreement to those obtained by our method and the cellulose acetate electrophoresis method. Compared with the cellulose acetate electrophoresis method, the proposed sensor is simple, easily implemented, and has low-cost and fast response. Thus, accurate and successful determination of BSA in biological fluids as demonstrated here may allow one to propose the present sensor as a promissory, cheap and accessible alternative for the clinical analysis of protein.

4. Conclusion

In this study, the interaction of VB7 with BSA was investigated at a GCE modified with MWCNTs for the first time. The voltammetric studies revealed a remarkable decrease in anodic current of VB7 upon the addition of BSA with positive shift in peak potentials which indicates the interaction of VB7 with BSA. The MWCNTs/GCE showed an effective electrocatalytic activity towards VB7 oxidation as well as enhancement of the microscopic area and currents in voltammetric investigations. The binding of VB7 to BSA results in a series of changes in electrochemical behavior and spectral characteristics, confirming that the interaction between VB7 and BSA. The application of the MCR-ALS for the resolution of the expanded data matrix produced the estimates of the pure signals of VB7 and BSA which were in good agreement with the measured responses. The results showed that the MCR-ALS is a powerful chemometric tool to resolve complex combined data and showed significant potential for investigating the mechanism of the interaction of BSA with targeting small compounds at the molecular level. Combination of voltammetric and spectroscopic methods is of potential importance in understanding the mechanism of binding of small molecules to biological macromolecules. Finally, DPV technique was applied for determination of BSA in biological

samples such as serum samples. The proposed methodology provided a new, sensitive, selective electrochemical sensor utilizing unique properties of MWCNTs such as high specific surface area, electrocalytic and adsorptive properties. MWCNTs modified GCE resulted in catalytic effects toward the electro-oxidation of VB7 since it enhances the oxidation peak currents and lowers the oxidation potential. Therefore, simple and applicable electrochemical sensor allowed the successful determination of BSA in biological samples.

Food colorants

ABSTRACT

In this work, a new method for the determination of food colorants in beverage samples is developed, using diamino moiety functionalized silica nanoparticles (dASNPs) as both adsorbents in dispersive solid-phase microextraction (dSPME) and pseudostationary phases (PSPs) in capillary electrophoresis (CE) separation. dASNPs were firstly used as adsorbents for the preconcentration of four colorants by the dSPME process. After that, colorants were efficiently separated by CE using 30 mM phosphate buffer (pH 6.0) containing 2 mM β-CD and 0.9 mg/mL dASNPs as additives. All factors influencing dSPME and CE separations were optimized in detail. The investigated analytes showed good linearities with correlation coefficients (R^2) higher than 0.9932. The limits of detection for the four food colorants were between 0.030 and 0.36 mg/L, which are lower than those reported previously. The established method was also used to analyze four colorants in beverage samples with recoveries ranging from 82.7% to 114.6%. To the best of our knowledge, this is the first time to use NPs both as extractants in dSPME and pseudostationary phases in CE for the analytical purpose.

1. Introduction

Food colorants, natural or synthetic, are commonly added to foods to compensate for the loss of natural colors that are destroyed during processing and storage, and to provide the desired colored appearance. However, some synthetic colorants may be pathogenic, especially when they are consumed in excess. At present, about ten kinds of synthetic colorants are permitted to be used as food additives in some countries including China, and their maximum permissible amounts in food are rigidly specified [1] to safeguard consumers' interests. As a result, the analysis of trace colorants in food is of great importance.

Several methods have been widely used to analyze the colorants in food, such as thin-layer chromatography (TLC) [2], gas chromatography (GC) [3], high-performance liquid chromatography (HPLC) [4,5] and HPLC–mass spectrometry (LC–MS) [6]. Among them, HPLC is the most widely used method because it can offer good repeatability and acceptable sensitivity with the traditional UV–vis detection. However, most HPLC methods established for colorant analysis suffer from limited separation ability, and are time consuming especially when the simultaneous determination of a broad range of food colorants is needed. As an alternative method, capillary electrophoresis (CE) has also been used for the analysis of food colorants due to its many advantages, such as high column efficiency, short analysis time and minimal amounts of samples [7–12]. However, lower detection sensitivity, limited selectivity and severe matrix interferences are still drawbacks of the traditional CE technique, which greatly restrain its further use in real sample analysis.

In the past decade, nanoparticles (NPs) have been used in conjunction with CE [13,14], in which they usually worked as pseudostationary phases (PSPs). When NPs are used as PSPs, they are suspended in the electrolytes and are continuously pumped through the capillary by the electro-osmotic flow (EOF) during separation, which guarantees that an entirely fresh dynamic stationary phase is used for every analysis. NPs can also serve as efficient platforms with large surface area for multiple interactions, leading to enhanced separation selectivity and column efficiency. NPs used in CE usually include polymer NPs [15], gold NPs [16], molecularly imprinted polymer NPs [17], latex NPs [18], carbon nanotubes [19] and silica NPs [20–22] etc.

Dispersive solid-phase microextraction (dSPME) [23] is based on the solid-phase extraction (SPE) methodology. In dSPME, the extraction of the analytes is fulfilled by the addition of small

amount of dispersive solid adsorbents in bulk solution. After extraction, the adsorbents containing the retained analytes are settled by centrifugation or filtration, which are later washed with a small volume of solvent for the desorption of analytes. In the dSPME process, it is much easier for the target analytes to interact fully with the adsorbents, so higher adsorption capacities could be obtained in comparison with those in the traditional SPE. Furthermore, the dSPME method is simple, rapid and cost-effective. Since its emergence, dSPME has received considerable attention and has been recognized as a promising sample pretreatment technique [24–26].

NPs have attracted much attention of the analytical scientists recently due to their higher specific surface area when used as the sorbent materials [27,28]. The introduction of NPs in dSPME will present additional advantages such as quicker mass transfer and shorter equilibrium time [29]. Recently, several kinds of NPs including gold nanoparticles [30,31], carbon nanoparticles [24,32,33], molecular imprinting nanoparticles [34,35] and magnetic nanoparticles [25,29,36] have been used as sorbent materials in dSPME.

In this work, we used dASNPs as sorbent materials in dSPME for the extraction of representative four food colorants: carminic acid, tartrazine, sunset yellow, brilliant blue. The four food colorants are water-soluble dyes with two or three sulfonic groups in their structures (Fig. S1). The pretreated samples were then separated by CE still using dASNPs as PSPs. Under optimized experimental conditions, four food colorants were baseline separated within 8 min. The obtained enrichment factors were 18.6, 18.7, 13.6 and 20.8 for carminic acid, tartrazine, sunset yellow and brilliant blue respectively. The present method was also applied for the determination of colorant additives in some fruit juice beverages with satisfactory results. Some articles concerning the electrophoretic analysis of sulfonated dyes were reported [37,38]. To the best of our knowledge, this is the first report on the use of NPs as both extractants and PSPs for the preconcentration and separation of analytes in real samples.

2. Experimental

2.1. Reagents and materials

All chemicals were analytical grade unless noted otherwise. Double-distilled water (DDW) purified by a Nanopure II system (Barnstead, NH, USA) was used throughout the experiment. Thiourea was purchased from Tianda Kewei (Tianjin, China). Phosphoric acid, sodium hydroxide, sodium dihydrogen phosphate, hydrochloric acid were purchased from Tianjin Guangfu Chemicals (Tianjin, China). Tetraethoxysilane (TEOS) (98%), N-(β-aminoethyl)-γ-aminopropyl triethoxysilane (dATES) were purchased from Guotai-Huarong New Chemical Materials (Zhangjiagang,China). Citric acid, ascorbic acid and benzoic acid were from Heowns Biochemical Technologies (Tianjin, China). β-CD was purchased from Shandong Xinda chemicals (Shandong, China). Malic acid, succinic acid, tartaric acid, tartrazine, sunset yellow, carminic acid and brilliant blue standard solutions were from National information center (Beijing, China).

dASNPs were synthesized according to the method reported previously by our lab [39]. Briefly, a total amount of 1.2 mL of ammonia was added to a conical flask in the presence of 25 mL of EtOH and 2.0 mL TEOS (~9 mmol) by slow stirring. After 24 h of reaction under stirring at 30 °C in thermostatic water bath, the functionalized reagents were added with extra TEOS with the volume ratio of dATES: TEOS=1:1 for particle co-condensation. The amount of functionalized reagents (dATES) added corresponds to approximately 5% (0.45 mmol) of the initial amount of TEOS. The reaction continued for another 24 h, and the particles thus formed were centrifuged and washed with ethanol and DDW repeatedly, then vacuum-dried at 80 °C for 6 h.

dASNPs thus formed are sphere-like, monodisperse and uniform in shape, with an average size of approximately 110 nm. as shown in Fig. 1A.

2.2. Apparatus and operating conditions for CE

TEM tests were carried out on a Philips Tecnai G20 at 200 kV (PHG, Amsterdam, Netherlands). A KH-50B ultrasonic cleaner (Kunshan Hechuang Instrumental, Kunshan, Jiangsu, China) and a QL-901 vortex (Haimen Kylin-Bell Lab Instruments Co., Jiangsu, China) were used to disperse dASNPs in background electrolyte or sample solutions. A TG16-WS centrifuge (Hunan Xiangyi Lab Instruments Co., Changsha, China) was used to centrifuge the samples. The zeta potential of dASNPs was determined with Zetasizer Nano ZS equipments (Malvern Instruments, Worces-tershire, UK). All CE experiments were carried out on a TH-3000 HPCE–HPLC amphibious system equipped with a UV detector and CXTH-3000 data handling software (Tianhui Instruments, Baoding, China). The detection wavelength was set at 220 nm unless noted otherwise. Fused-silica capillaries of 375 μm o.d. and 75 μm i.d. (Yongnian Optic Fiber Co, Hebei, China) were used throughout the experiment.

A capillary with the total length of 36 cm and the effective length of 27 cm was made by scraping off 3–5 mm of the polymer outside the capillary at an appropriate place. Prior to the first use, the capillary was successively rinsed by methanol, DDW, 1 mol/L NaOH, DDW, 1 mol/L HCl, DDW and phosphate buffer solution (PBS) for 20 min each. The EOF was determined by using thiourea as the neutral marker.

Separation voltage was set at 8 kV or −8 kV and current is 40 μA. Electrokinetic injection (−7 kV × 3 s) was selected as the injection mode throughout the experiment. 30 mM PBS (pH 6) with 0.9 mg/mL dASNPs and 2 mM β-CD was employed as background electrolyte solution.

2.3. Preparation of standard solution and food samples

Standard solutions of tartrazine (0.5 mg/mL), sunset yellow (0.5 mg/mL), brilliant blue (0.5 mg/mL) and carminic acid (1.0 mg/mL) were prepared in DDW and stored away from light at 4 °C in refrigerator. The working standard solutions with different concentration were prepared by stepwise diluting the standard solutions with PBS just before use. PBS was prepared by dissolving a certain amount of sodium dihydrogen phosphate in DDW and then adjusted to the appropriate pH value with 1 mol/L NaOH or concentrated

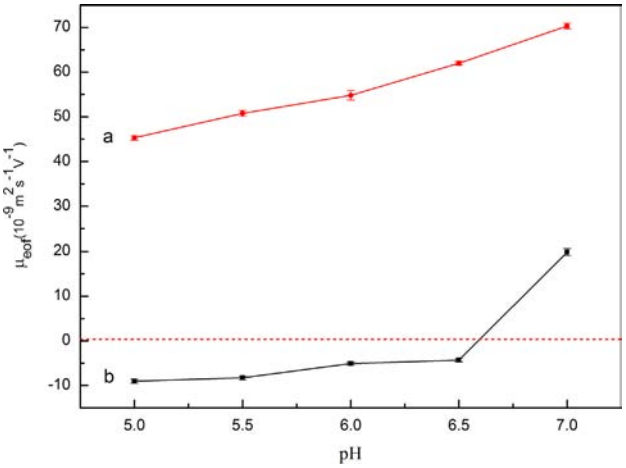

Fig. 1. The effect of buffer solution pH on EOF without dASNPs (a) and with dASNPS (b), (n=3).

H_3PO_4. Background electrolyte solutions were prepared by dissolving β-CD and dASNPs in PBS. Before use, all solutions were filtered through a 0.45 μm Nylon filter and degassed by ultrasonication.

The proposed method was applied to determine the food colorants in four beverage samples (Fruit juice 1–4) produced in Tianjin, China. All the samples were purchased from local supermarkets. The beverages were previously filtered through a 0.45 μm Nylon filter to remove the potential suspended particulate matter, and then diluted with DDW to 1:10, then adjusted to pH 2.5 with concentrated H_3PO_4 or 1 mol/L NaOH after degassed by ultrasonication.

2.4. dSPME procedure

The proposed extraction process is as follows: an aliquot of 9 mL of the aqueous standard solution (or the beverage sample) which was adjusted to pH 2.5 with concentrated H_3PO_4 was placed in a 10 mL plastic centrifuge tube. Then 18 mg amount of dASNPs was added and the mixture was ultrasonicated for 2 min, and vortexed for 8 min. dASNPs enriched with the analytes were centrifuged (10,200 r/min) for 10 min. Next, the analytes were desorbed by 1 mL PBS (10 mM, pH 7) with 15 min ultrasonic agitation. After the mixture was centrifuged (10,200 r/min) for 10 min, the elution solution was collected in a sample tube for subsequent CE analysis.

3. Results and discussion

3.1. Capillary separation

3.1.1. EOF characteristic

EOF is a very important factor in CE separation because analytes move through the capillary by EOF drive, as well as self-electrophoretic mobility if they are charged. Both of the magnitude and direction of the EOF have direct effect on separation efficiency. Knowing the characteristics of the EOF will be helpful to select optimal separation conditions for different analytes. From Fig. 1a, we can see the direction of EOF is cathodic (i.e., from anode to cathode) in the investigated pH range. It was experimentally found that the addition of dASNPs in the background electrolyte can significantly alter the curve of EOF vs pH (as shown in Fig. 1b). From Fig. 1b, we can see that the direction of EOF is anodic (i.e., from cathode to anode) in the pH range of 5–6.7, and the magnitude of EOF decreases as the pH increases. At pH above 6.7, cathodic EOF is regained and the magnitude increases as the pH increases.

As is well known, the EOF in CE system is determined by the net charges on the inner wall of capillary column. For bare silica capillary column, cathodic EOF will be obtained in ordinary pH range because the ionization of silanol groups on capillary wall. When dASNPs are dispersed in the acidic electrolyte, they are positively charged because of the primary and secondary amino groups on their surface. These positively charged NPs tend to be adsorbed on the inner surface of capillary column, mainly through electrostatic interactions with the negatively charged silanol groups. Thus an anodic EOF will be obtained. With the pH of buffer solution increases, the protonation degree of amino groups decreases accordingly. At the same time, however, the ionization degree of silanol groups increases. As a result, cathodic EOF will regenerate and increase with the increasing of pH of buffer solution.

3.1.2. Effect of the concentrations of dASNPs and β-CD on separation

Among the papers previously published on the determination of colorants by CE [11,12,40–43], β-CD was commonly used as background electrolyte additive to improve the resolution. Furthermore, higher pH buffer solutions (usually alkaline) were usually used to produce higher cathodic EOF to surpass the anodic electrophoretic mobility of analytes [11,12,41]. Even so, longer analysis times were usually needed.

As shown in Fig. 1b, the addition of dASNPs in lower pH background electrolyte would result in a reversed EOF, which has been verified to be favorable for the separation of acidic compounds in our previously published paper [39]. The influences of the concentration of dASNPs and β-CD on the separation of four colorants are shown in Fig. 2A. In the absence of dASNPs in background electrolyte, the time needed for the separation was long and wide peaks were obtained for the last eluted compounds (Fig. 2A.c). The addition of β-CD has proved to be beneficial to the separation. When no β-CD was added in the background electrolyte, carminic acid and tartrazine could not be baseline resolved (Fig. 2A.b). When β-CD was added into the carrier electrolyte, a change in the elution order of the colorants was observed probably due to a stronger interaction between β-CD and tartrazine. Fig. 2A. a shows the satisfactory separation of all the colorants within 8 min in the background electrolyte containing both β-CD and dASNPs, which is faster than those previously reported by CE [11,29,41].

The amount of dASNPs in the buffer solution was gradually increased and their impact on separation was investigated. As shown in Fig. 2B inserted, the reversed EOF increased with the increasing concentration of the dASNPs. As a result of this, the migration times of the analytes were shortened at higher concentration dASNPs. However, when the concentration of dASNPs was increased to 1.2 mg/mL, the electrophoretic peaks of most analytes overlapped. At the same time, baseline noise was gradually elevated and capillary blockage happened much frequently, which would result in inconvenient operation. To achieve higher resolution and shorter analysis time, the concentration of dASNPs was chosen to be 0.9 mg/mL.

The effect of β-CD with the concentration ranging from 1 to 4 mM on separation was investigated. As shown in Fig. 2C, better resolution and longer migration windows of analytes could be obtained with the increasing of concentration of β-CD in buffer solution. However, higher concentration β-CD would result in higher viscosity of the background electrolyte solution, which would result in inconvenient operation. So 2 mM β-CD was finally selected for further experiment.

3.1.3. Effect of buffer solution pH on separation

The buffer solution pH plays a significant role in the separation process, because it has multiple effects on several factors influencing separation, such as EOF, the ionization of analytes, the net charges on NPs and the stability of the suspension. To investigate the influence of pH on separation, pH values ranging from 5 to 7 were examined in this work and the results are as shown in Fig. 2D. From Fig. 2D, we can see that carminic acid and tartrazine could not be baseline resolved when pH was 5. All the colorants could be well resolved when pH was above 5, but the migration time increased with the increasing of pH. One probable reason for the extended migration time is the decrease in both the electrophoretic flow of analytes and the EOF of the separation system (as shown in Fig. 1b). pH 6.0 was chosen as the optimum pH to achieve good resolution and short analysis time for subsequent experiments.

3.1.4. Effect of concentration of background electrolyte on separation

The ionic strength of the buffer solution also has effect on the resolution. Different buffer concentrations in the range of 10–40 mM were investigated and the results are shown in Fig. S2. It was experimentally showed that the resolution between

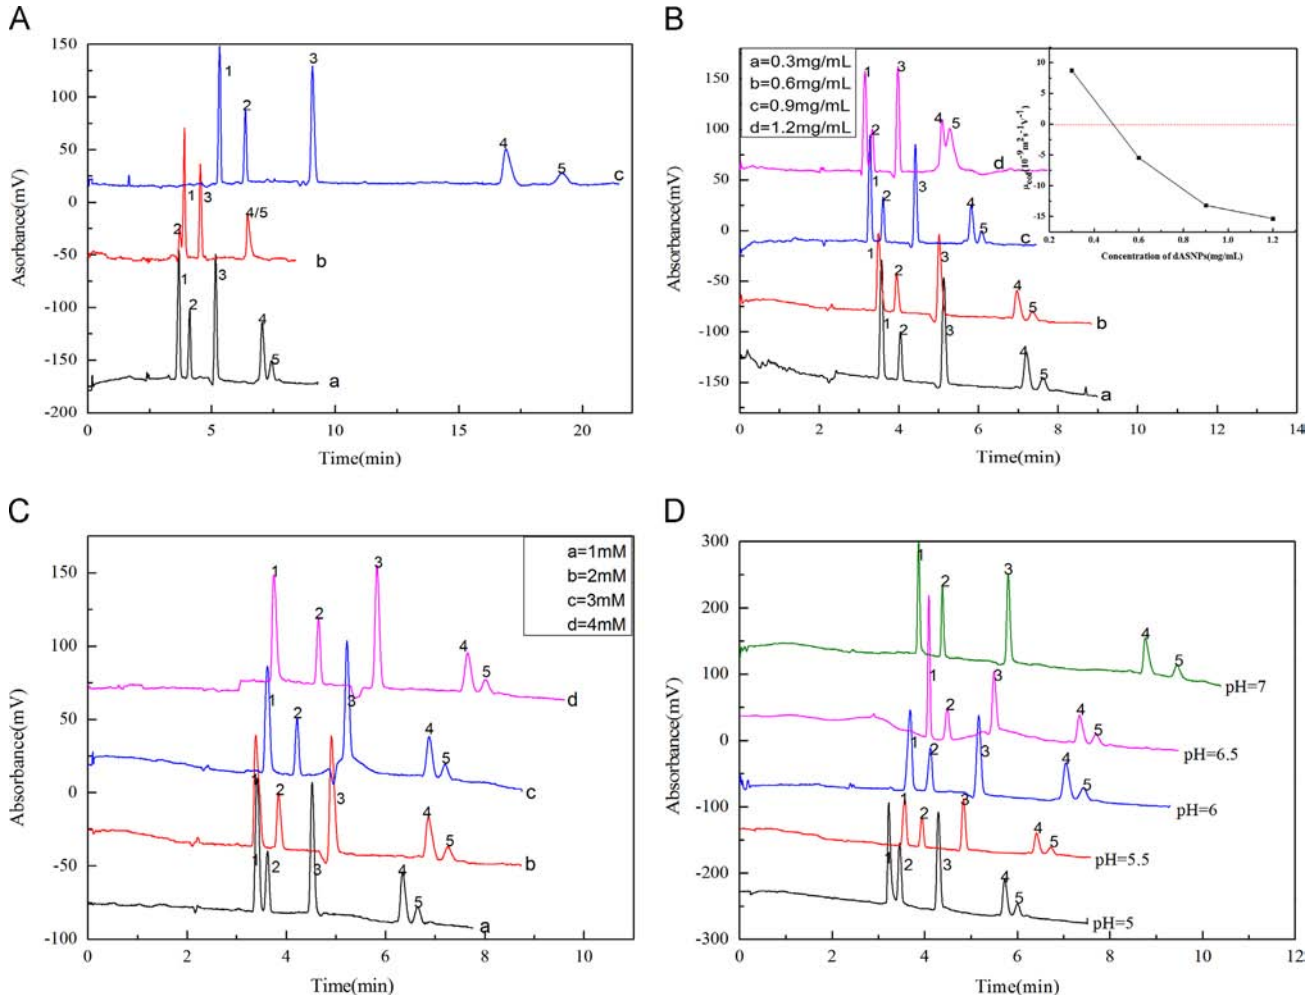

Fig. 2. The electropherograms of four colorants under different experimental conditions. Experimental conditions: (A.a) 30 mM PBS (pH 6.0) with 0.9 mg/mL dASNPs and 2 mM β-CD; (A.b) 30 mM PBS (pH 6.0) with 0.9 mg/mL dASNPs; (A.c) 30 mM PBS (pH 6.0) with 2 mM β-CD; (B) 30 mM PBS (pH 6.0) with 2 mM β-CD and different concentrations of dASNPs; (C) 30 mM PBS (pH 6.0) with 0.6 mg/mL dASNPs and different concentrations of β-CD; (D) 30 mM PBS with 0.6 mg/mL dASNPs and 2 mM β-CD under different pH conditions. The other conditions are mentioned in Section 2.2. Peak identities: (1) carminic acid; (2) tartrazine; (3) sunset yellow; (4) brilliant blue isomer I; (5) brilliant blue isomer II. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

carminic acid and tartrazine was moderately improved with the increasing of PBS concentration. The best resolution occurred when the PBS concentration was 40 mM. However, higher buffer concentration would result in less stable baseline due to the production of more Joule heat. As a compromise, the concentration of buffer was finally chosen to be 30 mM.

3.2. Optimization of dSPME

Many parameters would affect the extraction efficiency during the extraction process. Therefore, various conditions such as sample solution pH, the amount of dASNPs, extraction time, and the composition of desorption solvent were optimized to achieve optimal extraction efficiency.

3.2.1. Effect of sample solution pH

The acidity of sample solution is a critical parameter affecting extraction efficiency, since it determines the analytes ionic state as well as the surface charge of the adsorbent. Since the surface of dASNPs is modified by amino groups (–NH-, $–NH_2$), it will be different charged at different pH. Generally, the amino groups are more easily protonated under acidic conditions than basic conditions. Under the investigated pH range from 2 to 5, the signals for food colorants increased first and then decreased, best results were obtained at pH of 2.5 (as shown in Fig. 3A). Under lower pH, the electrostatic interaction between dASNPs and colorants would decrease because colorants were not fully ionized. With pH increasing above 2.5, the electrostatic interaction between dASNPs and colorants also decreased because deprotonation of amine groups of dASNPs. Optimum pH of 2.5 was so selected for the further work.

3.2.2. Effect of the amount of dASNPs

The amount of adsorbent also affects extraction efficiency. The amount of sorbent was also studied. The concentration of dASNPs in the extractant phase was examined in the range of 1–6 mg/mL. As shown in Fig. 3B, the best results were obtained when a concentration of 2 mg/mL (total of 18 mg) was used. Further increasing the amount of sorbent would result in an obvious decrease in analyte signals because higher volume of desorption solvent would be needed. Therefore, the concentration of 2 mg/mL was chosen as the optimal amount.

3.2.3. Effect of ionic strength of sample solution

Increasing the ionic strength in aqueous sample is beneficial to salting out effect generally and may alter the diffusion rate of analytes from aqueous solution to solid phase. So the salt

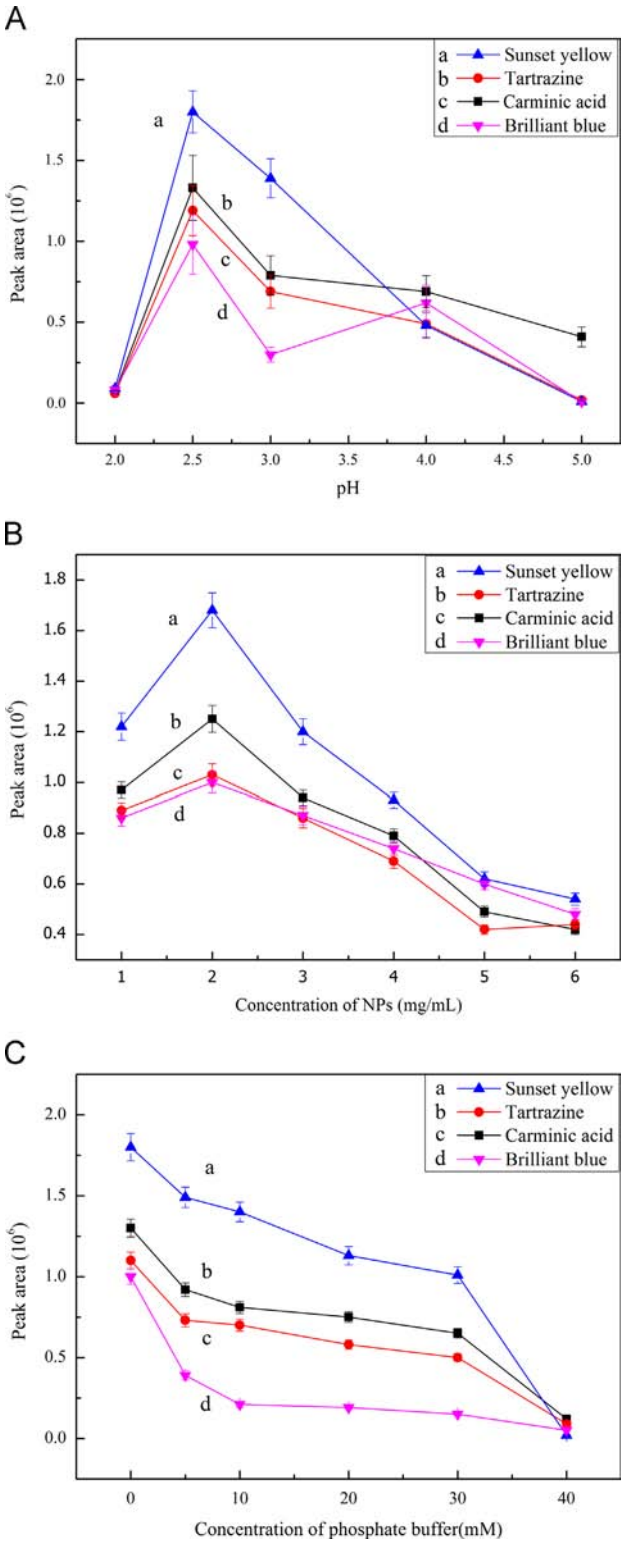

Fig. 3. The effects of the sample pH (A), concentration of dASNPs (B) and ionic strength of sample solution (C) on the extraction of the four food colorants from standard solution samples (carminic acid 2 ppm, tartrazine 1.5 ppm, sunset yellow 1 ppm, brilliant blue 2.5 ppm) ($n=3$ for all extraction and separation). Experimental conditions: (A) adsorption conditions: 2 mg/mL of dASNPs, 9 mL DDW with different pH; desorption conditions: 1 mL of 10 mM PBS (pH 7) as elution solvent; (B) adsorption conditions: 9 mL DDW (pH 2.5) with different concentration of dASNPs; desorption conditions: 1 mL of 10 mM PBS (pH 7) as elution solvent; (C) adsorption conditions: 2 mg/mL of dASNPs, 9 mL PBS with different concentrations; desorption conditions: 1 mL of 10 mM PBS (pH 7) as the elution solvent. The other conditions are mentioned in Section 2.2. Peak identities are the same as Fig. 2. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

concentration on extraction efficiency was investigated by adjusting the concentrations of PBS solution from 0 to 40 mM. The results showed that the extraction efficiency of four food colorants decreased with the increased concentrations of PBS (as shown in Fig. 3C). The main reason might be that high ionic strength was disadvantageous to the dispersion of dASNPs in sample solution. Therefore, no additional salt was added during the dSPME process.

3.2.4. The effect of extraction time and mode

The effect of extraction time on the extraction efficiency for food colorants was studied from 5 to 30 min. Results indicated that extraction efficiency increased when the extraction time increased from 5 to 10 min. However, when time was longer than 10 min, the extraction efficiency decreased slightly. It seems the analytes bind strongly with the sorbent and the distribution equilibrium was easy to achieve in 10 min. However, the analytes could not be pulled down easily from the sorbent by desorption solvent with the further increase in extraction time. Therefore, the extraction time was selected as 10 min.

Three different processes for sample agitation during the extraction step were evaluated. Experiment results showed that extraction efficiency obtained only by ultrasonication or vortex was lower than that by a mix of them. Ultrasonication is beneficial to the homogeneous dispersion of NPs in solution, which enables the analytes to interact fully with the sorbent. However, too long ultrasonication will result in the increase in temperature of sample solution, and so the desorption of analytes from sorbents. Ultimately, a procedure of ultrasonication for 2 min and then vortex for 8 min was selected.

3.2.5. Optimization of desorption conditions

Two different buffer solutions including 10 mM PBS and Tris–HCl were evaluated as desorption solvents. The experimental results showed that PBS offered the best recoveries, and so it was selected as desorption solvent in the following work.

The effect of the pH of desorption solvent was studied in the pH range of 6–10 and the results are shown in Fig. 4. It was experimentally found that the best results were obtained at about pH 7. There would be two main types of interactions between colorants and the surface of dASNPs: (1) electrostatic interaction and (2) hydrogen bonding. Zeta potential (ζ) measurement showed that the isoelectric point of dASNPs was about 7.0 (as shown in Fig. S3). When the pH of desorption solvent was lower than 7.0, dASNPs would be positively charged. Colorants would be retained on dASNPs through electrostatic interaction, and so they were not easily be desorbed. When the pH of desorption solvent was higher than 7.0, electrostatic interaction between colorants and dASNPs would decrease gradually. However, hydrogen bonding interaction between them would increase and gradually become the dominant interaction. Furthermore, higher pH would change the surface property of silica-based dASNPs, which would also be disadvantageous for desorption of analytes.

The amount of desorption solvent is another important factor to obtain reliable and reproducible analytical results. In comparison with lower recovery by small amount of desorption solvent, too much desorption solvent would definitely decrease preconcentration factor and so the sensitivity of analytical method. For this purpose, different volumes of desorption solvents from 0.2 to 2 mL were investigated. The experimental results showed that 1.0 mL of PBS (10 mM, pH 7) was sufficient for desorption of colorants from dASNPs.

The effect of desorption time was investigated at 5, 10, 15, 20 and 30 min by ultrasonication. It was found that the desorption efficiency reached maximum at 15 min. Therefore, 15 min was selected as optimum time.

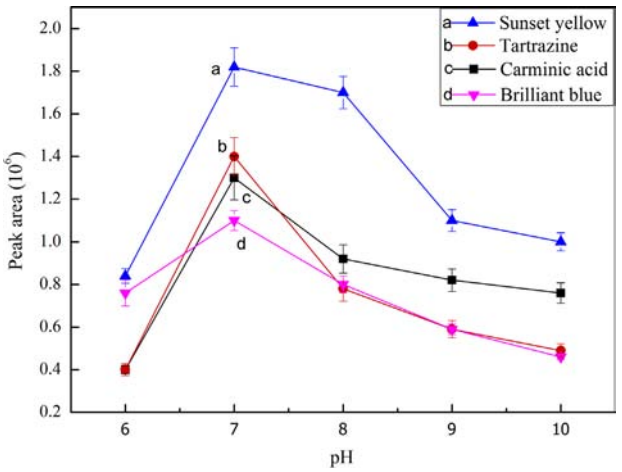

Fig. 4. Effect of the pH of desorption solvent ($n=3$). Experimental conditions: adsorption conditions: 2 mg/mL of dASNPs, 9 mL sample solution (pH 2.5), desorption conditions: 1 mL of 10 mM PBS with different pH as desorption solvent; the concentration of four colorants are the same as in Fig. 3. Peak identities are the same as in Fig. 2.

3.3. Effect of coexisting species in beverage

Citric acid, ascorbic acid and benzoic acid are commonly used as additives in beverages. Malic acid, succinic and tartaric acid are the most likely existing organic acid in apples and grapes. The influences of these organic acids on the analysis were then investigated in detail. The experimental results showed that citric acid, malic acid, succinic and tartaric acid could not be detected after the preconcentration process. The main reason is that these acids have very weak UV absorption at 220 nm. Another reason is associated with the dSPME procedure, during which the pH of sample solution is adjusted to 2.5. Under pH 2.5, it is not easy for the electrostatic interactions to happen between these acids and positively charged dASNPs because the carboxyl groups in these organic acids rarely dissociate. Ascorbic acid and benzoic acid can be separated completely from the studied four food colorants under optimal experimental conditions for beverage samples, so both of them do not interfere with the determination (see Figs. S4–5 in the supplementary files).

3.4. Analytical features of merit of the proposed dSPME method

The features of merit of the dispersive solid-phase microextraction method proposed in this paper are summarized in Table 1. The analytes were quantified with peak areas, and the peak area of brilliant blue was the total area of the two isomers. The corresponding calibration graphs for the four colorants were then constructed using aqueous standards under the optimized extraction procedure. The coefficient of determination were found to be in the range of 0.9932–0.9988. The limits of detection were calculated as the concentration providing an analytical signal three times the background noise (Table 1), which varied between 0.030 and 0.36 mg/L. The intra-day RSDs for five replicate separations of a standard mixture solution were 1.40–2.67% for the migration time and 3.18–7.65% for peak area. Fig. 6S shows the electropherograms of the analytes before and after preconcentration. The concentration factor was defined as the concentration ratio of the analyte after and before preconcentration [44,45].

In Fig. S6a and b, the sample matrix (30 mM PBS for Fig. S6a and b) is the same. We can get the preconcentration factors of 8.4, 6.9, 6.7 and 8.9 for the four colorants separately, which are mainly due to the dSPME process. In Fig. S6a and c, the sample matrix (10 mM PBS for Fig. S6a and 30 mM PBS for Fig. S6c) is different. The preconcentration factors of 18.6, 18.7, 13.6 and 20.8 were obtained for the four colorants separately. Besides the dSPME process, electrostacking effect also took effect in the injection process due to the conductance difference between sample matrix and background electrolyte, which would definitely further improve the preconcentration factor.

Table 1
Analytical figures of merit of the proposed method.

Analytes	Linear range (mg/L)	R^2	Detection Limit (mg/L) ($S/N=3$)	Peak area (RSD %) ($n=5$)	Migration time (RSD %) ($n=5$)
Carminic acid	0.31–10	0.9958	0.060	5.46	1.40
Tartrazine	0.31–10	0.9943	0.072	4.23	2.12
Sunset yellow	0.16–5	0.9932	0.030	3.18	1.32
Brilliant blue	0.63–10	0.9988	0.36	7.65	2.67

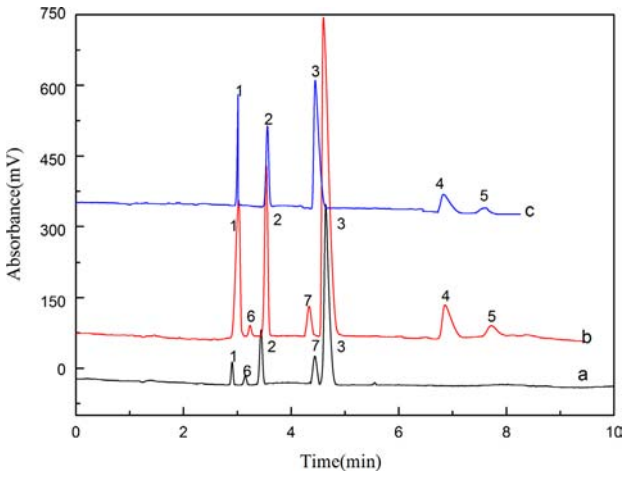

Fig. 5. The electropherograms of fruit juice 4 before (a) and after (b) being spiked with four colorants, and four colorants standard solution (c). Experimental conditions are mentioned in Section 2.2. Peak (1–5) identities are the same as in Fig. 2. Peak (6) and (7): unknown.

3.5. Application to beverage samples

The proposed method was applied to determine the content of the four colorants in four kinds of beverages (Fruit juice 1–4) (Fig. 5). The beverage samples were previously filtered through a 0.45 μm Nylon filter to remove the potential suspended particulate matter, and then diluted with DDW (pH 2.5) to 1:10 after degassed by ultrasonication. Fig. 5 shows the electropherograms of beverage samples before (a) and after (b) being spiked with four colorants, and aqueous standard solutions (c) under the optimum experimental procedure. As can be seen from Fig. 5, no interferences from the sample matrix overlapped with the target analytes. The recoveries of beverage samples spiked with the four colorants were determined in the range of 82.7–114.6%. Analytical results of four colorants in food samples are listed in Table 2. Therefore, the dSPME procedure described in this work has double functions of cleanup and preconcentration that can be applied to real sample analysis.

4. Conclusions

In this work, dASNPs were successfully used as both adsorbent in dSPME and PSPs in CE for the preconcentration and chromatographic separation of four food colorants in beverages. The results indicate that dSPME is an efficient sample preparation technique for the extraction of food colorants in complex matrix. Under optimum conditions, four

Table 2
Analytical results of food colorants in beverage samples.

Food colorants	Beverage samples (concentration/mg/L)			
	Fruit juice 1 ($n=3$)	Fruit juice 2 ($n=3$)	Fruit juice 3 ($n=3$)	Fruit juice 4 ($n=3$)
Carminic acid	ND*	ND	ND	0.87 ± 0.025
Tartrazine	0.99 ± 0.041	0.91 ± 0.039	0.66 ± 0.03	1.40 ± 0.11
Sunset yellow	ND	ND	1.36 ± 0.041	9.28 ± 0.45
Brilliant blue	ND	ND	ND	ND

* ND, not detected.

colorants can be well separated by CE in 8 min, which is faster than those previously reported. The LODs for four colorants are in the range of 0.030–0.36 mg/L after dSPME process, which are over 60-fold lower than those achieved with direct CZE analysis [41]. The proposed method promises simplicity, less organic solvent consumption and high sensitivity. Also, it allows determination of food colorants in beverage with good accuracy and repeatability.

ABSTRACT

Aquatic organisms from freshwater ecosystems impacted by waste water treatment plant (WWTP) effluents are constantly exposed to constant concentrations of pharmaceuticals, endocrine disruptors and related compounds, among other anthropogenic contaminants. Macroinvertebrates inhabiting freshwater ecosystems might be useful bioindicators of exposure to contaminants, since their lives are long enough to bioaccumulate, but at the same time may integrate short-term changes in the environment. However, studies about potential bioaccumulation of emerging contaminants in these organisms are very scarce. The objectives of this study were to develop an analytical methodology for the analysis of 41 pharmaceuticals and 21 endocrine disruptors in freshwater invertebrates. In addition, bioaccumulation of these contaminants in three macroinvertebrate taxa inhabiting a waste water treatment plant -impacted river was evaluated. The method for the simultaneous extraction of both families of compounds is based on sonication, purification via removal of phospholipids, and analysis by ultra performance liquid chromatography coupled to a mass spectrometer (UPLC–MS/MS) in tandem. Recoveries for pharmaceuticals were 34–125%, and for endocrine disruptors were 48–117%. Method detection limits (MDLs) for EDCs were in the range of 0.080–2.4 ng g^{-1}, and for pharmaceuticals, 0.060–4.3 ng g^{-1}. These pollutants were detected in water samples taken downstream the waste water treatment plant effluent at concentrations up to 572 ng L^{-1}. Two non-esteroidal anti-inflammatory drugs, diclofenac and ibuprofen, and four endocrine disruptors – estrone, bisphenol A, TBEP, and nonylphenol – were detected in at least one macroinvertebrate taxa in concentrations up to 183 ng g^{-1} (dry weight). An isobaric interference was identified during the analysis of diclofenac in *Hydropsyche* samples, which was successfully discriminated via accurate mass determination by TFC-LTQ Orbitrap.

1. Introduction

Numerous anthropogenic chemicals have been detected in wastewater treatment plants (WWTP) effluents and surface water in recent years, including pharmaceuticals (PhACs) and endocrine disrupting compounds (EDCs) [1–4]. This situation is of special concern in the Mediterranean region, where WWTP effluents often represent a high proportion of stream flow (particularly under water scarcity scenarios [5,6]), and pollutants such as PhACs and EDCs may be present at relatively high concentrations and cause adverse effects to aquatic organisms [7]. For instance, PhACs have been designed to modify specific biochemical pathways in target organisms [8]. On the other hand, EDCs are compounds that belong to different chemical families, characterized by their capability to alter the endocrine system of exposed organisms by mimicking or counteracting natural hormones, which could have severe consequences even at very low concentrations [9,10]. Several examples support the potential effects of these compounds on the river fauna: the feminisation of male fish in effluent-dominated rivers closely related to the presence of the synthetic hormone 17α-ethinylestradiol (EE2) [11,12], altered fish reproduction by some anti-inflammatory compounds, and altered behaviour and endocrine functions due to exposure to antidepressants [13,14]. Within this context, the recent Directive on the review of priority substances in surface water bodies has selected three of these

compounds (diclofenac, ethinylestradiol, β-estradiol) as candidates for the "watch list" in the European priority compounds list [15].

A better understanding of how these compounds are transferred from water to biota could help determining the potential of ecosystem damage associated with the discharge of WWTP effluent containing these contaminants [16]. Among freshwater organisms exposed to these bioactive compounds, invertebrates have been less frequently studied than vertebrate species (i.e. fish) [17,18]. However, these organisms are susceptible of being affected by these compounds, and because of their sedentary life, they are representative of the local conditions in freshwater ecosystems [10,19]. Benthic macroinvertebrates are prey of other consumers, constituting a secondary contaminant entry for upper trophic levels. Their relatively long lives facilitate the incorporation of contaminants in their bodies, whereas they also integrate short-term changes in the environment. Therefore, aquatic macroinvertebrates appear to have the potential to be useful biomonitors of pollution [20]. Trichoptera (caddisflies) are already considered a bioindicator group, and these insects are frequently used to assess the ecological status of basins in Mediterranean rivers (e.g. [21]).

Many pollutants have been recurrently detected in macroinvertebrates (invertebrates large enough to be seen without the use of a microscope), and these organisms have been used as bioindicators of a wide variety of compounds, such as pesticides, PCBs, hormones, and metals [18,22–26]. The capability of macroinvertebrates to bioaccumulate PhACs and EDCs has also been established under controlled exposure conditions (see Table S1). However, information about bioaccumulation of PhACs and other EDCs under natural conditions is still non-existent for the great majority of these compounds. A first critical step to understand the bioaccumulation dynamics of these compounds is to develop and validate analytical methods for their extraction and determination in biota matrices [6,27]. Therefore, the objectives of this study were two-fold: (i) to develop an efficient analytical methodology for the simultaneous analysis of PhACs and EDCs in aquatic invertebrates, and (ii) to assess persistence, distribution, and bioaccumulation of these trace contaminants in macroinvertebrate communities affected by WWTP effluents.

2. Materials and methods

2.1. Standards and solutions

A list of the target analytes, their physico-chemical properties and purity of standards and reagents can be found in the supplementary material (Table S2). Individual stock standards and isotopically labeled internal standards were prepared in methanol at a concentration of approximately 1000 mg L^{-1}. Stock solutions and 20 mg L^{-1} mixtures in methanol were stored at −20 °C. Working standard solutions (1 mg L^{-1}) of all compounds, and mixtures of isotopically labelled internal standards were prepared in methanol/water (1:9, v/v for PhACs; 1:1, v/v for EDCs) before each analytical run.

2.2. Sample collection and pre-treatment

The study was conducted in a section of the River Segre, a tributary to the River Ebro in the Pyrenees (NE Iberian Peninsula). Although industrial and agricultural activities are scarce in this area, the river receives the discharge of a WWTP effluent (29 742 population equivalents). Water and invertebrate samples were collected in two sites, respectively: upstream (500 m) and downstream (1500 m) of the local WWTP in October of 2012. Invertebrate samples from three different taxa were collected, namely the gastropod *Ancylus fluviatilis* (*Planorbidae* family), which are air-breathing limpets that graze on biofilms, the filterer trichopteran *Hydropsyche* spp., (*Hydropsychidae* family), in larval and pupal (aquatic) stages, and the predator flatworm *Phagocata* spp. (*Planariidae* family).

River water (100 mL) was collected to determine the presence of PhACs and EDCs in the aqueous phase. River samples were filtered through 1 μm glass fiber filters followed by 0.45 μm nylon membrane filters and kept at −20 °C until analysis. Macroinvertebrates were collected and placed in a 50 mL Falcon tube filled with river water. Individuals were kept for 24 h in filtered stream water to allow for gut clearance. Approximately 70–120 individuals of each taxon were collected per sampling point and composited Composites were freeze-dried, homogenized with a mortar, and kept at −20 °C until analysis. A prior test was performed to determine the water content in the three taxa, which ranged between 77% (*Hydropsyche*) and 90% (*Ancylus*).

2.3. Extraction and purification optimization

Water samples were analyzed for PhACs and EDCs according to Gros et al. [28] for the analysis of PhAC, and also applied for the analysis of EDCs. Ultra-pure water (100 mL) was spiked with a mixture of the target analytes and subsequently subjected to the extraction method described next. Briefly, 3 mL of EDTA 1 M (4%, v/v) were added to water samples. A Baker vacuum system (J.T. Baker, The Netherlands) was used to pre-concentrate the samples in Oasis HLB cartridges (60 mg, 3 mL). They were loaded with 100 mL of water samples and eluted with 6 mL of methanol. The extracts were evaporated under a gentle nitrogen stream and reconstituted with 1 mL of methanol–water mixture (50:50, v/v for EDCs; 10:90, v/v for PhACs), and 10 μL of IS mixture (1 mg L^{-1}) was added to the final extract.

Macroinvertebrates samples were spiked with a mixture of both families of analytes and subsequently subjected to the chosen extraction methodologies described next to obtain the best recovery results for the target compounds. Sonication (Branson Digital Sonifier, model 102C) was the chosen method for extraction following preliminary studies. Samples were placed in a 50-mL Falcon tube in an ice bath, where 3 mL of solvent were added to the samples and vortexed. Ultrasonic probe was plunged in the solution and sonication was applied in 3 cycles of 120 s, with amplitude (intensity) of 30%. Sample size and extraction solvent were tested: 50, 100 and 200 mg of freeze-dried biomass, whereas extraction solvents tested were methanol (100%) and water/acetonitrile (1:3, 1% formic acid, v/v). Samples were centrifuged at 11000 rpm, for 5 min. Supernatant was collected and 1.5 mL of the extract was taken for further purification.

Four procedures were tested during cleanup optimization on the basis of the analytes recovery and the purity of the extract: solid-phase extraction (SPE) performed in a J.T. Baker® vacuum system with (i) Florisil cartridges (1 g, 6 mL), (ii) Oasis HLB (60 mg, 3 mL), and (iii) an Oasis HLB 96-well plate (30 μm, 30 mg). Another technique for the removal of phospholipids and proteins in plasma and serum, common matrix interferences in biological analysis, was also tested: (iv) an Ostro™ 96-well plate, which exhibits selective affinity towards phospholipids while remaining non-selective towards a range of basic, acidic and neutral compounds. Extracts were subjected to different treatments using each of the four clean-up strategies above mentioned:

(i) Extracts were redissolved in 10 mL of acetonitrile and loaded to the cartridge at 1 mL min^{-1} after conditioning with 10 mL of *n*-hexane and 10 mL of acetonitrile.
(ii) Extracts were redissolved in 200 mL of water with EDTA at 1%. After conditioning the cartridges with 6 mL of methanol and 6 mL of water, they were loaded into the cartridges and the eluted in 6 mL of methanol.

(iii) Extracts were redissolved in 1.5 mL of water 1% EDTA. Oasis HLB 96-well plate was placed in a manifold and wells were conditioned with 1.5 mL of methanol and 1.5 mL of water consecutively applying a vacuum extraction. Extracts were loaded and then eluted in 1.5 mL of methanol.
(iv) Extracts were redissolved in 750 μL of water/acetonitrile (1:3, 1% Formic acid, v/v). Ostro™ 96-well plate was placed in a manifold and wells were added 750 μL of fresh solvent and then carefully mixed with the extract in the well. After extraction by vacuum, purified extracts were collected.

All purified extracts were then evaporated and redissolved in 1 mL of methanol-water mixture (50:50, v/v for EDCs; 10:90, v/v for PhACs), and 10 μL of IS mixture (1 mg L^{-1})was added to the final extracts.

2.4. Instrumental analysis

2.4.1. UPLC–QqQ–LIT

For the analysis of PhACs, water and biota extracts were analysed according to Gros et al. [28] using a ultra performance liquid chromatography (UPLC) system (from Waters Milford, MA, USA) coupled to a hybrid quadrupole linear ion trap mass spectrometer Qtrap 5500 (Applied Biosystems, Foster City, CA, USA), equipped with an electrospray ionization source (ESI). Chromatographic conditions for the positive ionization mode were an Acquity HSS T3 column with methanol and 10 mM formic acid/ammonium formate (pH 3.2) as the mobile phase at a flow rate of 0.5 mL min^{-1}. For the negative ionization mode, an Acquity BEH C18 column was applied using acetonitrile and 5 mM ammonium acetate/ammonia (pH=8) at a flow rate of 0.6 mL min^{-1}. For the analysis of EDCs, extracts were analysed using the method developed by Jakimska et al. [29] in the same instrumental set up, using the Acquity BEH C18 column for both positive and negative modes. The chromatographic separation was achieved with methanol and water (pH 9) as mobile phase at a flow rate of 0.4 mL min^{-1}. The acquisition of the compounds into the analyser Qtrap was done in selected reaction monitoring (SRM) mode with the monitoring of two transitions. The most intense transition was used for quantification purposes when it was possible, whereas the second one was used to confirm the identity of the target compounds. Besides the monitoring of the SRM transitions and their retention time, the relative abundance of the two SRM transitions in the sample were compared with those in the standards, and the relative abundances in the samples must be within ± 20% of the two SRM ratios in the analytical standards. Pharmaceutical diclofenac was quantified with the second SRM transition for the insect *Hydropsyche*, as the first SRM transition was overlapped by an isobaric interference.

2.4.2. HPLC–HRMS

For the confirmation of the presence of diclofenac in *Hydropsyche*, a turbulent flow chromatograph coupled to a hybrid linear ion trap—Orbitrap mass spectrometer (TFC-LC-LTQ Orbitrap Velos) equipped with an ESI was used. The chromatographic system operating in off-line was equipped with a Hypersil Gold PFP column (10 mm × 2.1 mm id, 1.9 μm, ThermoFisher Scientific Company; Villebon-France). The LC eluents were solvent A: acetonitrile and solvent B: HPLC-grade water. The mobile phase gradient was programmed as follows: 0 min 5% A, 0.02–1.50 min 60% A, 1.5–2.0 min 100% A, 2.0–3.0 min 100–5% A, 3.0–3.7 min 5% A. The total chromatographic run time was 3.70 min. The analyser was working in negative ionization mode, and all the data was acquired and processed with Xcalibur 2.1 software (Themo Fisher Scientific, River Oaks Parkway, San Jose, USA). The mass spectrometer was operated with the following parameter settings: spray voltage, 2.5 kV; sheath gas, 60 arbitrary units; auxiliary gas, 20 arbitrary units; sweep gas, 0 arbitrary units, capillary temperature, 350 °C; S-lens RF level, 60; heater temperature, 400 °C. Optimal normalized collision energy (NCE) was set at 30 during all the analysis. Two experiments were performed in two corresponding chromatographic runs. First experiment consisted in two scan events. Scan event 1 performed by full scan from 100 to 350 Da with nominal mass resolving power of 60,000 FWHM in order to detect the accurate mass measurements of the [*M*–*H*] ions of diclofenac. Scan event 2 was a "Dependent Scan" at 30,000 of resolution and allowed the fragmentation of peak of diclofenac found in Scan Event 1 into the ion trap and then analysed into the Orbitrap in order to obtain the fragment ions (MS^2). Second experiment consisted in the fragmentation of the product ions from the first experiment obtaining the MS^3 at a resolution of 7500 FWHM. Identification of diclofenac was based on different criteria: the retention time, the isotopic pattern, the fragmentation pattern, the double bound equivalent (DBE) and the accurate mass (with errors below ± 2 ppm at the time of matching the theoretical mass with the measured mass). All the experiments were performed with a diclofenac standard (25 ng mL^{-1}), a sample extract (spiked also at 25 ng mL^{-1}) and the environmental samples taken upstream and downstream the WWTP.

3. Results and discussion

3.1. Extraction and purification optimization

Sonication was selected as extraction method according to preliminary studies. Energy was transmitted from the probe directly into the sample with high intensity and the sample was quickly processed. Two solvent mixtures were considered during the optimization: methanol (100%) and 0.1% formic acid in water/acetonitrile (1:3, v/v). Higher recoveries were obtained using 100% methanol for the majority of the compounds (see Fig. 1). Sample size (50, 100 and 200 mg, always referred as dry weight) was evaluated as an important parameter, due to the small size of the considered organisms, which is usually a limiting factor during sampling. A compromise was reached in between limit of detection and matrix effect, and 100 mg was selected as the final biomass.

For the purification of the extracts, florisil cartridges were discarded as a viable option, despite being commonly used for the elimination of matrix interferences such as lipids [30,31], due to the low recoveries for most of the target compounds. Oasis HLB cartridges have been widely applied for the analysis of pharmaceuticals [32–34]. A comparison between normal 6 mL cartridges and a 96-well microplate with Oasis HLB stationary phase was performed. Recoveries were similar for the majority of the compound, and significant differences were not be detected between both techniques. Finally, OSTRO™ plate was applied, as it was developed to remove phospholipids and precipitate proteins from small volumes of sample [35]. OSTRO™ resulted as the most appropriate technique, with the highest recoveries for the majority of the target compounds and good reproducibility (see Fig. 2).

Presented results led to the selection of an extraction protocol method based on extraction with ultrasonic probe (120 s, 3 cycles, 30% amplitude) of 100 mg (dry weight) of sample homogenized in 3 mL of methanol. Extract (1.5 mL) was the evaporated to dryness and redissolved in 0.75 μL of a mixture of water/acetonitrile containing 0.1% formic acid. Extract was passed through the OSTRO™ plate, followed by 0.75 μL of the same fresh solvent. Purified extract was divided in two aliquots for the analysis of both families of compounds by UPLC–MS/MS. Aliquots were evaporated to dryness and redissolved in: (a) methanol/water (1:1, v/v) for EDCs; (b) methanol/water (1:9, v/v) for PhACs.

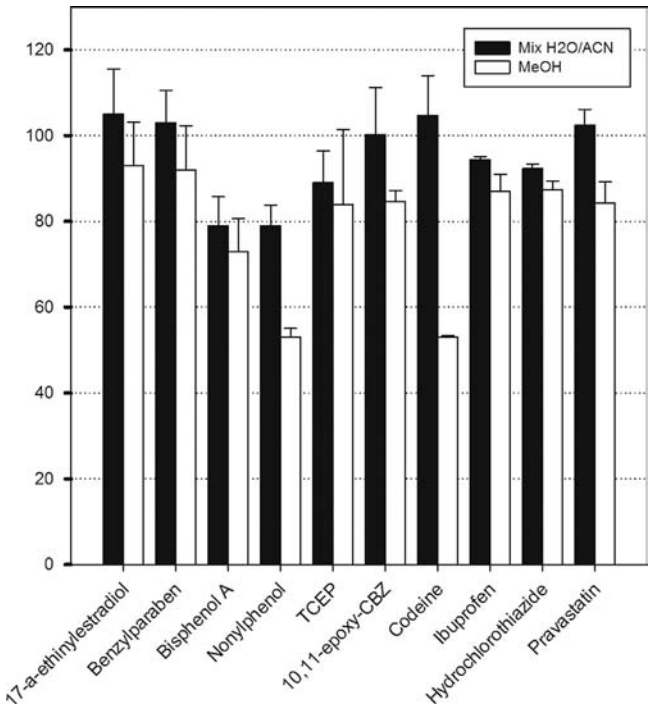

Fig. 1. Comparison of extraction efficiencies (%) of some EDCs and PhACs by sonication using two solvents: a mixture of water/acetonitrile (1:3) and 100% methanol ($n=3$).

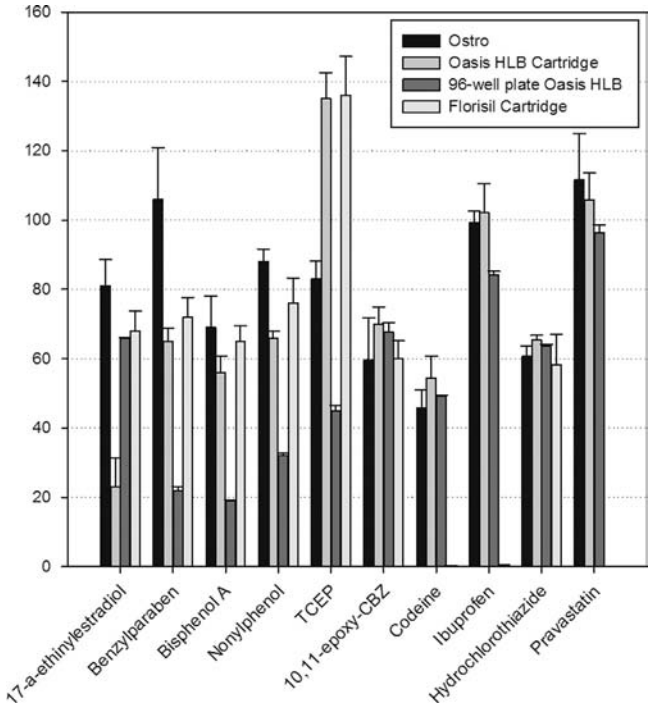

Fig. 2. Comparison of cleanup efficiencies (%) of some EDCs and PhACs by solid phase extraction (SPE) with Oasis HLB and Florisil cartridges, a 96-well-plate Oasis HLB stationary phase, and with Waters OSTRO™ plate ($n=3$).

3.2. Method validation

Method detection limits (MDLs) and method quantification limits (MQLs) in macroinvertebrates for both contaminant families are presented in Tables 1 and 2. Both, MDLs and MQLs, were considered as the minimum amount of analyte with a signal-to-noise ratio of 3 and 10, respectively and were determined in samples spiked at 10 ng g^{-1} ($n=3$). MDLs for EDCs were in the range of 0.08–2.4 ng g^{-1}, and for PhACs, 0.06–4.3 ng g^{-1}.

Calibration curves were generated using linear regression analysis ($r^2 > 0.98$) in the concentration range from 0.1–100 ng g^{-1}. Ion suppression was measured in 20% of the target compounds (data not shown), so isotopically-labelled compounds were used to compensate possible matrix effects with ESI. Accuracy of the instrumental method was calculated from three repeated injections of a spiked sample at 10 ng g^{-1} in the same day as the deviation of the measured mean concentration from the spiked concentration, expressed in percentage, as described by Bogialli et al. [36]. The instrumental precision (intra-day and inter-day) was calculated from five repeated injections in the same day and in five consecutive days. Both values were lower than 20% for EDCs and PhACs.

3.3. Application to environmental samples

3.3.1. Determination of PhACs and EDCs in water

A total of 81 multiple-class human and veterinary PhACs and 19 EDCs and related compounds, as well as some transformation products, were analysed. PhAC and EDCs water concentrations are presented in Table S3. Recovery percentages and method detection limits for EDCs in water samples are presented in Table S4. Twenty-two PhACs and 6 EDCs were detected downstream the WWTP, in concentrations ranging from non-detected to 573 ng L^{-1} and 261 ng L^{-1}, respectively. In contrast, only a PhAC (2-hydroxy-ibuprofen) and 3 EDCs (caffeine, nonylphenol and 1-*H*-benzotriazole) could be quantified upstream the WWTP. Overall, a clear increase in PhACs & EDCs concentrations was observed in the downstream over upstream sites, indicating that the WWTP effluent is a source of contaminant inputs to the River Segre.

Regarding PhACs, non-steroidal anti-inflammatory drugs (NSAIDs) were the most abundant compounds. The highest value was found for 2-hydroxy-ibuprofen (573 ng L^{-1}) followed by acetaminophen (222 ng L^{-1}) and ibuprofen (193 ng L^{-1}). Lower but still considerable levels were found for the diuretic hydrochlorothiazide (311 ng L^{-1}), and the lipid regulator gemfibrozil (285 ng L^{-1}). Other significant groups were the β-blocking agent atenolol (28 ng L^{-1}) and psychiatric drugs such as carbamazepine and venlafaxine. These concentrations are in agreement with a previous study carried out in the same area, where concentrations of some of these PhACs were between 10 and 500 ng L^{-1} [37]. In similar studies performed in surface waters affected by the effluent of a WWTP, concentrations for the majority of these PhACs were in the range from non-detected to 600 ng L^{-1} [28,38], including ibuprofen metabolites, which have been detected at significant concentrations (up to 1 μg L^{-1}) and higher than the values found for the parent compound [39,40].

In the case of EDCs, the triazoles tolyltriazole (261 ng L^{-1}) and 1-*H*-benzotriazole (194 ng L^{-1}) were the most abundant compounds. Other significant groups were: the stimulant caffeine (207 ng L^{-1}), the flame retardants TBEP and TCPP (65 and 71 ng L^{-1}, respectively), and nonylphenol (116 ng L^{-1}). Similar levels of concentrations for TBEP, caffeine and nonylphenol have been detected by several research groups in river and groundwater from Europe, USA, and Australia [41–44].

3.3.2. Determination of PhACs and EDCs in macroinvertebrates

Several compounds were detected in three species of macroinvertebrates (Table 3). PhACs were not detected in the upstream samples in any species, whereas three EDCs – TBEP, estrone and nonylphenol – were measured in upstream samples in at least one of the three taxa., Two NSAIDs drugs (diclofenac and ibuprofen) were detected downstream of the WWTP in *Hydropsyche*. Four

Table 3
PhACs & EDCs concentration (ng g^{-1}, dry weight) in macroinvertebrates from the Segre River (NE Spain).

	Hydropsyche		Ancylus		Hirudo	
	Upstream	Downstream	Upstream	Downstream	Upstream	Downstream
PhACs						
Ibuprofeno	n.d.	183	n.d.	n.d.	n.d.	n.d.
Diclofenac	n.d.	12.4	n.d.	n.d.	n.d.	n.d.
EDCs						
Estrone	n.d.	n.d.	n.d.	n.d.	17.6	12.4
Bisphenol A	n.d.	8.70	n.d.	n.d.	n.d.	n.d.
TBEP	17.9	31.1	7.70	31.8	22.3	20.6
Nonylphenol	n.d.	n.d.	75.5	96.3	76.7	130

EDCs (estrone, bisphenol A, TBEP, and nonylphenol) were detected overall across the three taxa.

It is generally accepted that substances with a logarithm of octanol–water partition coefficient (log K_{ow}) values equal or higher than 3 have the potential to bioaccumulate in organisms, and particularly in lipid tissues [45]. EDCs detected in macroinvertebrates in this study have a log K_{ow} ranging from 3.9 (TBEP) to 5.7 (nonylphenol) (see Table S2), which could make them susceptible for bioaccumulation in aquatic organisms according to this concept [46]. This seems a plausible hypothesis, as the other three EDCs detected in water (1*H*-benzotriazole, tolyltriazole and caffeine), detected at concentrations around 200 ng L^{-1} but with log $K_{ow} < 2$, were not detected in macroinvertebrates. In fact, TBEP was the most ubiquitous compound, as it was detected in samples upstream and downstream for the three macroinvertebrate taxa in concentrations up to 32 ng g^{-1}. TBEP has previously been detected in other organisms, such as herring gull eggs, flathead gray mullet, common carp and Mediterranean barb in similar concentrations [29,47,48]. Nonylphenol was also detected both upstream and downstream the WWTP effluent in *Ancylus* and *Phagocata*, with maximum concentrations for *Phagocata* of 77 ng g^{-1} in the upstream sample and 130 ng g^{-1} downstream the WWTP. This compound has also been detected in concentrations between 206 and 435 ng g^{-1} in mysid shrimps, a crustacean found in marine and freshwaters in the Netherlands [49]. In Italy, concentrations of nonylphenol up to 240 ng g^{-1} were measured in Mediterranean mussel (*Mytilus galloprovincialis*) in a coastal water ecosystem receiving industrial and municipal WWTP effluents [50]. The natural hormone estrone was only detected in *Phagocata* both upstream and downstream the WWTP at 12–18 ng g^{-1}. Estrone has also been detected in fish muscle elsewhere [29,47,51]. However, the likelihood that this hormone was endogenous of *Phagocata* individuals cannot be dismissed. For example, in the polychaete *Nereis virens*, estradiol has been detected in male and female coelomic fluid [52]. There also evidence that indicates that some mollusks are able to synthesize sex steroids, including estrone [46,53,54]. Estrone, estradiol, testosterone, and progesterone have been found in gastropods [55], cephalopods [56], and various bivalves such as Pacific oysters (*Crassostrea gigas*), Yesso scallops (*Patinopecten yessoensis*) [57], and Blue mussels (*Mytilus edulis*) [54,58,59]. However, some authors affirm that there is no convincing evidence for biosynthesis of vertebrate steroids by invertebrates, for example mollusks [60], which might suggest that the presence of estrone in *Phagocata* could be due to uptake from water. Finally, Bisphenol A was only detected in the downstream sample in *Hydropsyche* at 8.7 ng g^{-1}. Although it was detected in biota samples, this compound was below detectable concentrations in the corresponding water sample, which may suggest that this compound could be more persistent in the macroinvertebrate tissue compared to water. Bisphenol A has been detected in fish tissues of several countries in concentrations up to more than 200 ng g^{-1} [29,47,50,51,61].

In the case of PhACs, four of the analyzed compounds had a log $K_{ow} > 3$. However, only two of them, ibuprofen and diclofenac, were detected in macroinvertebrates, whereas gemfibrozil and bezafibrate, present at relatively high concentrations and with log K_{ow} between 3.9 and 4.3, were not detected in the samples. This suggests that accumulation of PhACs is not only regulated by their log K_{ow}. Pharmaceuticals are, in general, hydrophilic compounds and quite often ionized at the pH of surface waters, with acidic and/or basic chemical functional groups, which affects the lipophilicity of these compounds, and thus, the bioaccumulation in aquatic organisms [62]. For instance, accumulation of fluoxetine in fish and algae is significantly affected by variation in pH [63,64]. Ibuprofen and diclofenac have p*K*a < 5, thus would be primarily ionized at the pH ~7.8 of the river water, and the anions would be more soluble than the neutral molecule, leading to a reduction of the sorption by hydrophobic partition onto organic matter [65]. Actually, their log *D* is 0.85 at pH ~7.8 (calculated by ChemAxon), much lower than for the detected EDCs, which suggests that other mechanisms other that lipophilicity are influencing bioaccumulation in *Hydropsyche*. In this study, concentrations of PhACs ibuprofen and diclofenac in *Hydropsyche* were in the range from non-detected to 183 ng g^{-1}, similar to those detected in fish bile [66], and tissues [67]. Sorption of these compounds to colloids in water may occur, act as a long-term storage and being a sink for PhACs [62]. A recent study estimated calculated that the colloidal phase contributed between 22–33% of diclofenac and 9–28% of ibuprofen in the aquatic system, highlighting the important role of colloids as carrier of contaminants [68]. An increased exposure to these compounds could take place due to the filter-feeding habits of *Hydropsyche* [69], which could enhance its uptake.

3.4. Presence of diclofenac in trichopterans

Extremely high concentrations of the anti-inflammatory diclofenac were measured in the *Hydropsyche* extracts when quantifying with the first transition (SRM_1) (see Section 2), both in the upstream and downstream sample. However, SRM_2 was not detected in the upstream sample, and ratio could not be calculated. According to EU Commission Decision 2002/657/EC [70], a requisite to confirm a compound by low resolution mass spectrometry is that the relative intensities of the detected fragment ions have to correspond to those of the calibration standard at comparable concentrations within a minimum of tolerance: 20%. Since diclofenac is known to have low intensity of the second transition produced during the fragmentation (294→214) [66], as the relative intensity (% of base peak) in a standard is ≤10%, thus this tolerance can reach 50%. In both the upstream and downstream *Hydropsyche* samples, SRM_1 was detected at similar intensity. SRM_2 was detected in the downstream sample but the ratio was 30 times higher than the ratios obtained with the diclofenac standard. Extracts of

Phagocata and *Ancylus* from the upstream site were spiked with 25 ng mL^{-1} of diclofenac to calculate the SRM_1/SRM_2 ratio of diclofenac in a complex matrix. Ratios of diclofenac in *Phagocata* and *Ancylus* spiked extracts did comply with the aforementioned rule. However, when the upstream *Hydropsyche* sample was spiked with 25 ng mL^{-1} of diclofenac, the ratio was still much higher than in the standard. Based on these results, the presence of an isobaric interference in *Hydrophsyche* was postulated. In order to confirm this hypothesis and to ensure the correct quantification of diclofenac in the environmental samples, further measures and analytical strategies were taken. A Hypersil Gold PFP column, which provides an alternative selectivity to C_{18} columns to resolve mixtures of halogenated compounds and non-halogenated compounds, was tested to achieve the separation of diclofenac and the suspected interference. The upstream *Hydropsyche* extract spiked with diclofenac at 25 ng mL^{-1} and the non-spiked downstream sample were injected and two peaks were indeed resolved in both cases with the Hypersil Gold PFP column – RT: 1.3 min and 1.6 min (see Fig. 3a) – while in the C_{18} column only one peak appeared. SRM_1 was detected in both peaks separated by Hypersil Gold column, whereas SRM_2 was only detected in the second peak, and the SRM_1/SRM_2 ratio in the second peak confirmed that it was diclofenac. An isobaric interference was assumed to co-elute with the target compound using C18 column, and that interference was only separated with the Hypersil Gold PFP column.

The probability of having an interfering isobaric ion largely decreases with increases in mass resolution and mass accuracy. Therefore, on a second step for confirmation purposes, the accurate mass of the parent compounds in the two resolved chromatographic peaks were determined by injection of the downstream sample in the TFC-LTQ Orbitrap using the same Hypersil Gold PFP column. Measured accurate mass was *m/z*: 294.1714 at RT: 1.3 min and *m/z*: 294.0090 at RT: 1.6 min. Comparing these values with the theoretical mass of diclofenac (*m/z*: 294.0089 and formula $C_{14}H_{11}NCl_2O_2$), an error of 552 ppm and 0.34 ppm was calculated for the isobaric interference (RT: 1.3 min) and suspected diclofenac (RT: 1.6 min), respectively. The low error (< 5 ppm) at RT: 1.6 min added one more confirmation criteria for the identification of diclofenac. In contrast, the most plausible molecular formula suggested by the software for the interfering isobaric mass (ion *m/z*: 294.17069) was $C_{16}H_{25}NO_4$, with a low error (2.8 ppm) and did not include Cl, which is very distinctive for diclofenac.

Accurate mass of the daughter ions was also calculated. The mass spectrometer was operated in a data-dependent-acquisition (DDA) mode in this study, which means that the full-scan analysis with the Orbitrap analyser was followed by a MS–MS scan when the accurate *m/z* of diclofenac was detected. Accurate mass of the product ion (SMR_1) of diclofenac was thus determined in the upstream spiked sample as *m/z*: 250.0190. This mass was detected in the downstream non-spiked sample at the RT: 1.6 min with an error of 1.129 ppm for the calculated molecular formula $C_{13}H_{11}NCl_2$. Conversely, the isobaric interference (*m/z*: 294.1714 and RT: 1.3 min) formed ions with different *m/z* values to those of diclofenac. Product ion of that interfering mass was identified as *m/z*: 250.1453 and the

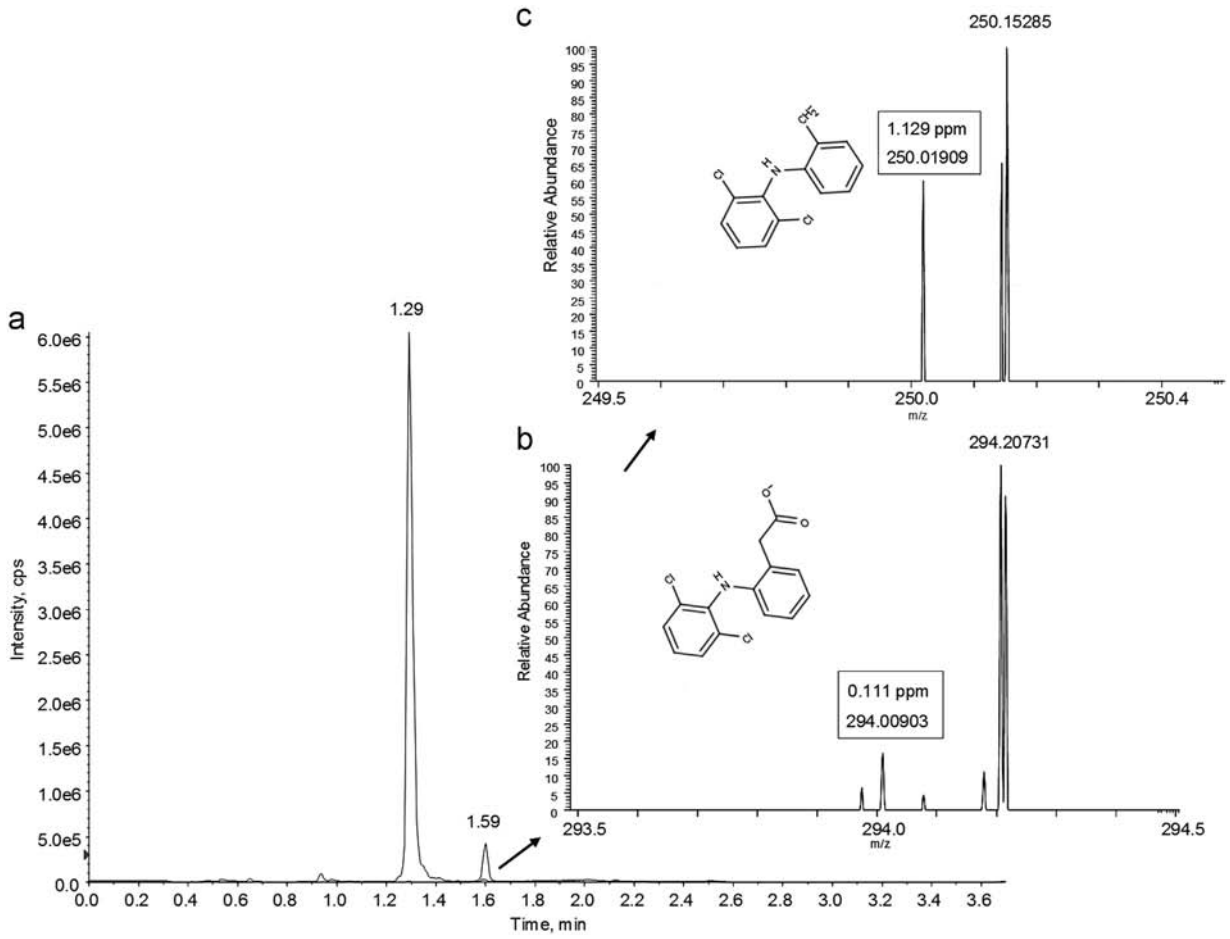

Fig. 3. (a) Chromatographic separation of diclofenac and matrix interference in a *Hydropsyche* sample performed in the Acquity UPLC tandem Qtrap MS; (b) accurate mass of diclofenac, *m/z* 294.009, determined in the Orbitrap MS: (c) Accurate mass of main product ion, *m/z* 250.019, was present in the data dependant scan of this *Hydropsyche* sample which confirmed that diclofenac was present.

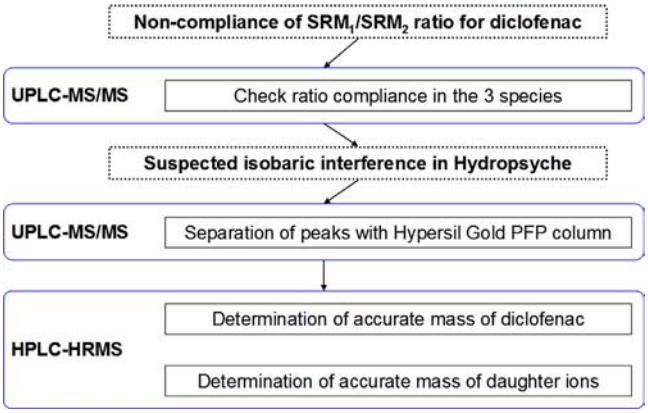

Fig. 4. Workflow applied for the interference discrimination in *Hydropsyche* samples.

molecular formula was $C_{14}H_{20}NO_3$ with an error of 1.092 ppm, being different to the daugher ion of diclofenac.

Other than RTs and accurate mass determination, fragmentation of the ionized molecule can also provide additional information for identification and improve specificity. Product ion of SMR1 of diclofenac (*m/z*: 250.0190 and RT: 1.6 min) was further fragmented in a MS^3 scan event, and gave the ion *m/z*: 214.0430, whose molecular formula was $C_{13}H_{11}NCl$.

According to EU Commission Decision 2002/657/EC, a precursor ion and a product ion at high resolution can achieve the minimum requirement for identification for high resolution mass spectrometry. Both, the accurate mass of *m/z* 250.0190 acquired at 60,000 FWHM, as described in Fig. 3c, and the accurate mass of the precursor ion *m/z*: 294.0090 were determined in the *Hydropsyche* downstream sample. Throughout the experiments, Orbitrap analyser provided excellent accuracy, which means that the matrix components were discriminated drastically. Thus, we were able to determine the presence of diclofenac in *Hydropsyche* samples at the downstream sampling site using SMR2 for quantification and the accurate mass of precursor ion and a product ion at high resolution for confirmation purposes. The workflow applied for the discrimination of the interference is shown in Fig. 4.

4. Conclusions

A simple, rapid, sensitive and efficient analytical method was developed for the determination of 41 PhACs and 21 EDCs in aquatic macroinvertebrates. The final multi-residue procedure consisted of an extraction by sonication, followed by purification of extract lipids, and the analysis was performed by UHPLC–MS/MS, which provided the necessary sensitivity and selectivity for these trace contaminants. The procedure was validated and it is characterized by good accuracy and precision, providing low quantification limits for macroinvertebrates. The method was applied to assess the bioaccumulation of these contaminants in three macroinvertebrate taxa (*Ancylus, Phagocata* and *Hydropsyche*) from a WWTP-impacted river. Two NSAIDs drugs, diclofenac and ibuprofen, and four EDCs – estrone, bisphenol A, TBEP, and nonylphenol – were detected in at least one macroinvertebrate taxa in concentrations up to 183 ng g^{-1}, which seems to indicate that invertebrates have the potential to be useful bioindicators of exposure to PhACs and EDCs.

Acknowledgments

This study has been financed by Spanish Ministry of Economy and Competitiveness through the project SCARCE (Consolider- Ingenio 2010 CSD2009-00065). This work was partly supported by the Generalitat de Catalunya (Consolidated Research Group: Catalan Institute for water Research 2014 SGR 291). We want to thank Jeremías Bodo for his contribution with the graphical abstract. Anna Jakimska has been financially supported for the preparation of a doctoral dissertation within the funding of a doctoral scholarship awarded by Polish National Science Centre on the basis of the decision number 2013/08/T/ST4/00637. We also thank Nuria Cáceres for her help during sampling.

Three-phase solvent bar micro-extraction

ABSTRACT

Silver ion inputs into the environment due to human activities have been increased in the last years because it has been used as a bactericide with application in medical, homecare and self-care products. In addition, it is toxic at low concentration for aquatic organisms. In estuarine waters, salinity and dissolved organic matter (DOM) regulate Ag^+ concentration by the formation of complexes as $AgCl_n^{(n-1)-}$ and Ag-DOM.

Difficulties of Ag^+ analysis in estuaries are associated to its low concentration level and interferences of sample matrix. Liquid and solid phase extraction methods have been used for speciation of silver in waters; however, miniaturized methods that offer a better environmental profile are desirable. Hollow fiber liquid phase micro-extraction (HFLPME) allows obtaining higher pre-concentration factors with a reduction of waste generation. Notwithstanding, some operational improvements are needed to permit their use as a routine method that can be afforded using a configuration of three-phase solvent bar micro-extraction (3PSBME).

In this work, tri-isobutylphosphine sulphide (TIBPS) has been used as an extractant for Ag^+ pre-concentration in estuarine waters by 3PSBME. Under optimized conditions, Ag^+ has been pre-concentrated 60 times and the method presents a limit of detection of 1.53 ng L^{-1}. To evaluate which Ag species is transported by TIBPS, Cl^- and DOM have been added to synthetic samples. As a result, a decrease in Ag pre-concentration efficiency after additions has been observed and quantified. Results showed that Ag^+ is selectively transported by TIBPS from estuarine water samples after comparison of the results with those obtained by the reference method of liquid extraction with APDC/DDDC.

1. Introduction

During the last years, silver inputs into natural water resources have been increased and diversified due to the use of silver and silver compounds in several applications and everyday-used products, such as home and self-care products, fabrics recovery, additives for paints, etc [1–4]. All of them are based on silver capability as a bactericide and fungicide [5]. In particular Ag^+ has been identified as the main reason for its toxicity for aquatic organisms [6]. Ag^+ analysis normally requires pre-concentration and/or separation of the metal from the sample due to its low concentrations and matrix effects on analytical methods [7,8]. In the case of natural waters and in particular for estuarine waters, Ag speciation is ruled by salinity and dissolved organic matter (DOM) being mainly in the form of $AgCl_2^-$ and $AgCl_3^{2-}$ [9,10].

Complexation of silver by Cl^- and DOM affects Ag^+ concentration in estuaries, modifying availability of the metal for aquatic organisms [11,12]. For this reason, different alternatives have been proposed for selective analysis of Ag^+ in natural waters that are based on sample pre-treatment using liquid-liquid extraction and solid phase extraction [9,13]. Also bulk liquid membranes (BLM) have been applied for selective transport of Ag^+ in natural water with the objective of simplifying sample preparation [14]. In general, these techniques present drawbacks associated to solvents and reagents consumption and the need of highly sensitive instrumental techniques for quantification of the metal [9,15].

In order to overcome these drawbacks, sample preparation processes can be miniaturized using micro-extraction methods. Among others, hollow fiber liquid phase micro-extraction (HLFPME) has gained increasing attention in the last years for trace metals analysis, due to its pre-concentration capability and stability [16]. It can be used in a three-phase (3HFLPME) configuration in which simultaneous extraction and re-extraction can be carried out [17]. 3HFLPME consists in the transport of the metal ion from the sample to a small volume of aqueous acceptor solution located inside the fiber. Transport takes place through an organic solution of an extractant agent that is placed in the fiber pores [8,16]. This methodology has been applied for selective pre-concentration of

the free ion of Pb, Cd, and Ni in seawater analysis using kriptofix-22DD as extractant [18].

In spite of the advantages it presents, HFLPME has not been established as a routine technique because it normally needs a support for the fiber, special devices are required to set up fiber's modules, and leaks may appear in the connection with the support [17]. These limitations can be overcome using a three-phase solvent micro-extraction bar (3PSBME), in which the ends of the fiber are thermally sealed [19]. This way, the fiber can be left free into the sample without needing any support, making the 3HFLPME portable and easy to handle, without diminishing features related with high pre-concentration factors and chemical selectivity [16,20].

The aim of this work was the application of 3PSBME to selectively pre-concentrate Ag^+ for Ag speciation in estuarine water samples. In this work, tri-isobutylphosphine sulphide (TIBPS) has been selected as an extractant due to its capability, for selective transport of Ag^+ through liquid membranes from estuarine water samples, offering an approach to silver speciation [14].

2. Materials and methods

2.1. Reagents and solutions

All reagents were analytical-reagent grade unless otherwise stated. Potassium nitrate (99%) and sodium chloride (99,5%) were obtained from Scharlau (Barcelona, Spain). Kerosene and ammonia (30%) were obtained from Panreac (Barcelona, Spain). Sodium thiosulphite (100%), 1-pyrrolidine-dithiocarbamate (APDC) and diethylammonium-diethyldithiocarbamate (DDDC) were purchased from Merck (Darmstadt, Germany). Tri-isobutylphosphine sulphide (TIBPS) was provided by Cytec Industries Inc. (NJ, USA) and humic acids were obtained from Aldrich (Steinheim, Germany). Aqueous solutions of silver were prepared from a 1000 mg L^{-1} standard solution obtained from Merck (Darmstadt, Germany) and samples for optimization studies contained 0.1 mg L^{-1} of silver. Deionized water of resistivity lower than 18.2 MΩ cm was obtained by a Millipore Quantum Ultrapure water supplier (Millipore, USA). Acetylene, air, and argon for atomic spectrometry were obtained from Air Liquid (Madrid, Spain).

2.2. Apparatus

Polypropylene Accurel PP S6/2 hollow fibers of 0.2 μm pore size and 1800 μm internal diameter were used in this study (Membrana, Germany). Samples were stirred using an IKA-Big Squid magnetic stirrer (Ika-Werke, Germany). Silver concentration in the aqueous solutions was quantified using a continuum source atomic absorption spectrometer model ContrAA (Analytikjena, Germany), using a flame atomizer (FAAS) for optimization studies and graphite furnace atomizer for application to real samples (GFAAS). Graphite furnaces used were made in pyrolitic graphite (Analytikjena, Germany). Humic acids were measured as dissolved organic carbon (DOC) in a total carbon analyzer Analytik Jena multi N/C 3100 (Analytikjena, Germany).

2.3. Set-up of hollow fiber membranes: three-phases solvent bar micro-extraction (3PSBME)

In order to set up the three phase solvent bars, 5 cm of fiber was cut and one of its ends was thermally sealed using a hot tip and flat ended tweezers. The internal part of the fiber was filled with the acceptor solution containing $S_2O_3^{2-}$ and the other end of the fiber was thermally sealed. This solvent bar was immersed into the organic solution of kerosene containing TIBPS as extractant to impregnate the fiber pores. Finally the excess of organic solution on the fiber was rinsed with deionized water and the fiber was placed into the sample. After extraction time, the acceptor solution inside the fiber was recovered and measured by atomic absorption spectroscopy. In all cases, three aliquots of each sample were extracted. Additionally, internal replicates were carried out adding three solvent bars to every aliquot of sample [21].

2.4. Optimization

Silver pre-concentration by 3PSBME using TIBPS as extractant agent takes place by coupled cotransport [15]. For this type of mechanism, a cationic complex is formed by Ag and TIBPS. For this reason, the use of a counter-ion (NO_3^-) is needed to form a neutral ion pair $\{(AgTIBPS)^+NO_3^-\}$, which can be solubilized in the organic solution, to be transported until the organic-acceptor solution interface. Thus, the ion pair reacts with the acceptor agent ($S_2O_3^{2-}$) and the metal is retained in the acceptor solution. Therefore, NO_3^- concentration in the sample, TIBPS concentration in the organic solution impregnating the fiber pores, $S_2O_3^{2-}$ in the acceptor, and stirring rate were optimized. Univariate optimization was conducted, varying one of the parameters each time while the rest were kept constant.

The extent of silver transport from samples into the acceptor solution was measured as enrichment factor (*EF*) of Ag in the acceptor. This factor is calculated by the ratio between the concentration of silver in the acceptor phase at a certain experiment time (t) ($[Ag^+]_t$) and the initial concentration of silver ion in the sample ($[Ag^+]_0$) (Eq. (1)).

$$EF = \frac{[Ag^+]_t}{[Ag^+]_0} \quad (1)$$

2.5. Instrumental determination of silver

Instrumental analysis of silver concentration in the acceptor solution was carried out by atomic absorption spectroscopy at a wavelength of 328.1 nm and setting up the spectrometer detector between pixels 98 and 102.

For optimization studies, 100 μg L^{-1} Ag was used as initial concentration in the sample. For this reason, analysis of initial Ag^+ concentration in the sample as well as in the acceptor solution was carried out by FAAS using acetylene as fuel and air as oxidizer. To ensure that enough amount of sample was available for measurement in FAAS, the recovered acceptor solution was diluted into 1.5 mL of deionized water. Besides, calibration standards were prepared with the same matrix as the acceptor solution samples by addition of the corresponding amount of $Na_2S_2O_3$.

In the case of silver at natural concentration levels graphite furnace atomic absorption spectroscopy was used for quantification, applying Ar as inert gas. In this case, the acceptor solution was

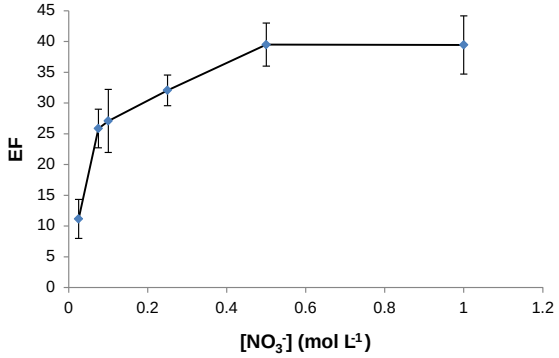

Fig. 1. Optimization of NO_3^- concentration in the sample at 0.1 M TIBPS in the organic phase, 1 M $Na_2S_2O_3$ in the acceptor and 800 rpm stirring speed.

directly recovered from the fiber into a vial and analyzed by GFAAS. Measurements were carried out using ash temperature 1200 °C and atomization temperature 1800 °C in the presence of 5 μg of Pd

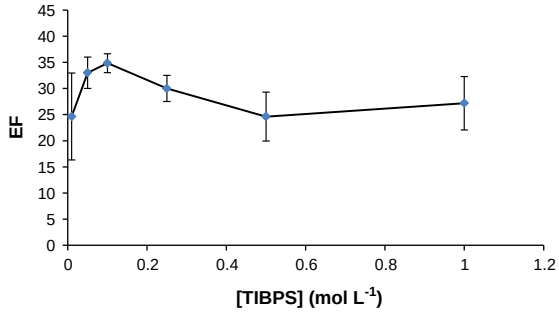

Fig. 2. Optimization of TIBPS concentration in the organic phase at 0.1 M NO_3^-, 1 M $Na_2S_2O_3$ in the acceptor and 800 rpm stirring speed.

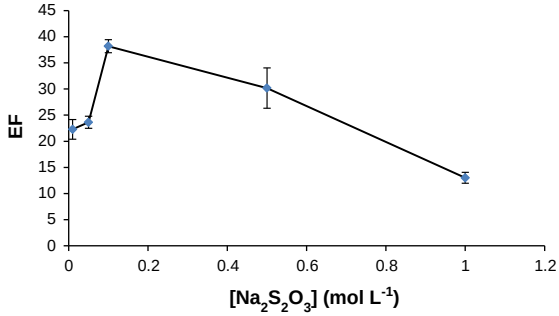

Fig. 3. Optimization of $Na_2S_2O_3$ concentration at 0.1 M NO_3^- in the acceptor, 0.5 M TIBPS in the organic phase, and 800 rpm stirring speed.

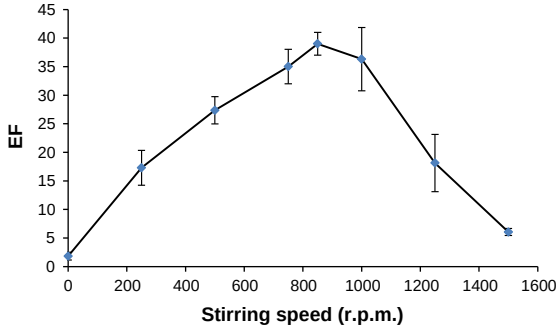

Fig. 4. Effect of stirring speed on enrichment factor under optimized chemical conditions.

$(NO_3)_2$ as matrix modifier [8]. Volume of sample injected was 20 μL and three replicates of each sample of acceptor solution were analyzed. Under these conditions, a limit of detection (LOD) of 0.09 μg L^{-1}, measured as the concentration that offers a signal equal to three times the standard deviation, for the blank signal divided by the slope of the calibration curve was obtained. Linear range of the GFAAS method was 0.1–5 μg L^{-1} [22].

3. Results and discussion

3.1. Optimization of silver pre-concentration by 3PSBME

The first step was the selection of a solvent to impregnate the fiber pores. In this work, different solutions of TIBPS in kerosene and dihexylether were compared for impregnation of the fiber pores. Dihexylether was reported to present higher impregnation capability of Accurel PP 50/280 fibers [8]. In the case of the Accurel PP S6/2 fibers used in this work, kerosene offered similar results as dihexylether. Therefore, kerosene was selected for further experiments because it presents lower cost and better environmental profile.

Initial conditions for optimization were those previously optimized for silver pre-concentration in fibers Accurel PP 50/280: 0.1 M NO_3^- in the sample, 0.1 M TIBPS in the organic phase, 1 M $S_2O_3^{2-}$ in the acceptor, and time of experiment of 4 hours [8]. During optimization, initial concentration of 100 μg L^{-1} of Ag was used in all cases. The effect of nitrate anion concentration was evaluated in the range 0.01–1 M. As it can be observed, enrichment factor was increased by the increasing concentration of nitrate in the sample until it was stabilized at 0.5 M NO_3^- (Fig. 1). Following, the effect of TIBPS concentration on *EF* was studied from 0.1 M to 1 M. Fig. 2 shows that *EF* was improved by the increasing concentration of TIBPS up to 0.1 M, but a decrease in the enrichment factor and poorer reproducibility can be observed at higher concentration. This could be consequence of a loss of diffusion through the organic phase due to an increase in the viscosity of the organic solution. For this reason, 0.1 M TIBPS was used for further experiments. Finally, concentration of the acceptor agent was evaluated in the range 0.01–1 M and a maximum enrichment factor was obtained at 0.1 M $S_2O_3^{2-}$ (Fig. 3).

Evolution of the enrichment factor with stirring speed was also evaluated. As a result, *EF* was improved with the increasing stirring rate up to 900 rpm. At higher stirring speed, transport efficiency decreased because the organic phase was removed from the fiber pores (Fig. 4). Besides, experiment time was studied and a linear increase of the enrichment factor was observed with time until it was stabilized at 120 min. Finally optimized conditions

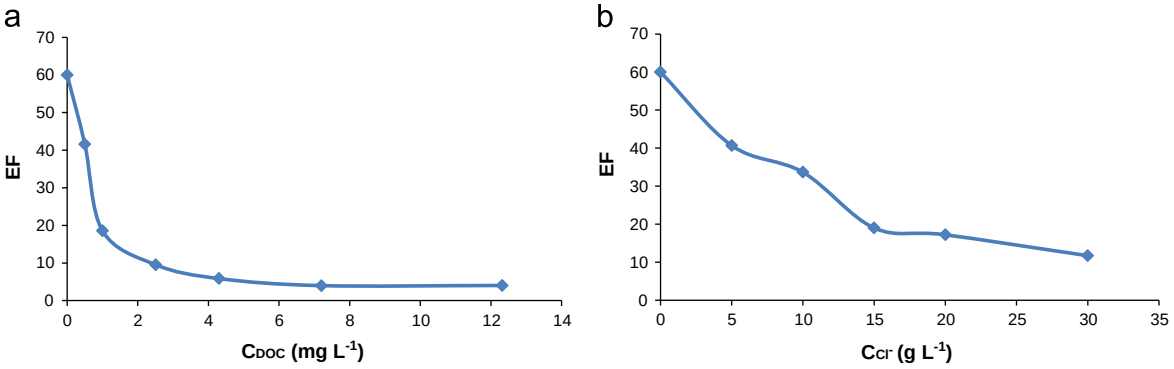

Fig. 5. Effect of a) dissolved organic carbon and b) chloride concentration on Ag^+ enrichment factor.

were 0.5 M NO_3^- in the sample, 0.1 M TIBPS in the organic phase, 0.1 M $S_2O_3^{-2}$ in the acceptor, and 120 min of experiment.

After optimization, samples containing concentrations in the range 0.1–100 μg L^{-1} Ag were analyzed and an average enrichment factor in the whole range of concentration of 60.0 ± 3.2 times was obtained. This fact supports the idea that *EF* is not affected by initial Ag^+ concentration.

3.2. Selective transport of free silver through 3PSBME

In the case of silver, it has been described that Ag^+ is responsible of its toxicity [6,14,19]. Concentration of Ag^+ in estuarine waters is controlled by salinity and dissolved organic matter concentration [9,10]. As a consequence, total silver concentration can be expressed as the sum of Ag^+ and complexes formed with Cl^- and dissolved organic matter in the form of $AgCl_n^{(n-1)-}$ and Ag-DOM, respectively. In order to evaluate which silver species is pre-concentrated by the proposed system, known concentrations of Cl^- and organic matter were added to samples containing 100 μg L^{-1} of Ag. On the one hand, humic acids (HA) were used as a source of DOM, and they were measured as dissolved organic carbon (DOC). On the other hand, NaCl was used as a source of chloride ion.

As it can be seen in Fig. 5a, addition of HA in the range 0.5–12 mg L^{-1} DOC resulted in decreased *EF*, being the slope of the curve higher in the range 0.5 to 2.5 mg L^{-1} DOC. In the case of addition of Cl^- from 1 to 30 g L^{-1}, a decrease in the transport efficiency was also observed, being more regular than in the case of HA (Fig. 5b). These results support the hypothesis that silver species formed after addition of Cl^- and AH were not transported from the sample using TIBPS as extractant. Besides, the combined effect of the HA and Cl^- on *EF* was evaluated and the result was represented by a response surface (Fig. 6). Linear relationship between the logarithm of the enrichment factor and Cl^- concentration and the logarithm of DOC in the samples was observed, offering a fit of 94.82% to the experimental data (Eq. (2)). Therefore, the enrichment factor for silver in samples of known concentration of Cl^- and DOC could be predicted.

$$Log(EF) = 1.4806 - 0.0116C_{Cl^-} - 0.09331Log(C_{DOC}) \quad (2)$$

Taking into account that Ag^+ was assumed to be selectively pre-concentrated, its concentration was directly estimated by 3PSBME, using the *EF* obtained for samples without addition of Cl^- and HA. Additionally, knowing the predicted enrichment factor (EF_p) for known concentration of *HA* and Cl^-, the total concentration of silver Ag_t was estimated by Eq. (3).

$$Ag_t = \frac{Ag^+_{Acceptor}}{EF_p} \quad (3)$$

Finally, total silver (Ag_t) could be considered as the sum of an inert fraction (Ag_i) constituted by $AgCl_n^{(n-1)-}$ and Ag-HA, which were not transportable through the organic phase (Eq. (4)), and Ag^+ that could be transported into the fiber.

$$Ag_t = Ag^+ + Ag_i \quad (4)$$

3.3. Application to real samples

Before application to real samples, a study of methodological blanks was carried out. Blank samples were pre-concentrated using the 3PSBME system and the concentration of Ag in the acceptor solution was measured by GFAAS. Limit of detection of the proposed method was calculated as the average concentration of ten independent blanks samples plus three times their standard deviation, offering a LOD of 1.53 ng L^{-1} [22].

In order to check the capability of the proposed method for predicting total concentration of silver in estuarine conditions of salinity and organic matter, synthetic samples of known total Ag concentration were spiked with different concentrations of DOC and Cl^- and then analyzed. Results of predicted Ag_t by the proposed method were compared with direct measurement of Ag by FAAS in samples prior to the addition of Cl^- and HA. As it can be observed in table 1, no significant differences could be observed between both results after comparison by a *t* test ($n=2$, $\alpha=0.05$) [22].

Finally, real samples from the Guadalquivir River estuary (Spain) with salinities in the range 0–15 and seawater samples from the Bay of Cádiz (Spain) were analyzed by the proposed method. Samples were filtered on-line during sampling and stored frozen in low density polyethylene flasks until they were utilized.

Reference method of liquid-liquid extraction with APDC/DDDC was used to evaluate the accuracy of the proposed method [23]. This method is used for analysis of total silver concentration and results were compared with those of the estimation of total silver in the samples by the proposed method using a *t* test ($n=2$, $\alpha=0.05$). As it can be seen in Table 1, no significant differences were observed for the analysed samples between the reference and the proposed method [22].

4. Conclusion

Three-phases solvent bar micro-extraction appears as a reliable and simple alternative for routine application of hollow fiber micro-extraction in the speciation ultra-traces of Ag^+ in estuarine waters. The extractant agent tri-isobutylphoshine sulphide has proved to be selective for transporting Ag^+ in the presence of Cl^- and humic acids. The effect of addition of Cl^- and HA to samples, to simulate estuarine conditions has allowed estimating silver fractions as Ag^+ and Ag associated to Cl^- and organic matter.

ABSTRACT

The design of a label-free aptamer for separation of recognition sequence from signal reporter is significant to ensure the high-efficiency affinity between aptamer and target. This work develops a label-free triple-helix aptamer (THA) as sensing platform for "signal-on" fluorescent detection of thrombin. THA was composed of aptamer sequence and help DNA 1 (H1), which contained the complementary sequence of hexachloro-fluorescein (HEX) labeled help DNA 2 (H2). The specific recognition event between aptamer and thrombin triggered the dismission of THA to release H1. The released H1 then reacted with the signal probe of H2/graphene oxide (GO) nanocomposite to form H1-H2 duplex, leading to the fluorescence recovery of H2 due to the detachment of H1-H2 duplex from the surface of GO. With employment of THA as a signal transducer and GO as a "superquencher", this method shows a sensitive response to thrombin with a wide concentration range from 5 to 1200 nM. The limit of detection is 1.8 nM (S/N=3) with excellent selectivity. Considering the universality of THA, the proposed aptasensor would provide a platform for homogeneous fluorescent detection of a wide range of analytes.

1. Introduction

Triple-helix DNA (THD) is one of nontraditional nucleic acid structures, which involves a third strand in the major groove of a Watson-Crick duplex via Hoogsteen hydrogen bonding [1–4]. Based on groove recognition of THD towards biomolecules, the THD has been extensively employed as therapeutic agents in biomedical and biotechnological applications [5–6]. Recently, THD has been used as template for preparation of site-specific silver nanoclusters with high-stability [7]. By modifications of its nuclear acid structure, THD as signaling probe has been applied in detection of double-stranded DNA (dsDNA) [8,9], microRNA [10], DNA [11], Hg^{2+} [12], and adenosine triphosphate [13], in combination with the techniques of fluorescence and chemiluminescence. The above methods are on the basis of spatial change of THD structure after target recognition for fluorescent signal readout with THD labeling. However, such structural alteration may not induce the enhanced signal for sensitive detection. Therefore, the further functionalization of THD is a promising way in the design of new molecular biology tools, especially for integrating with aptamer as a recognition element.

Aptamers are single-stranded DNA or RNA nucleic acids isolated from random-sequence nucleic acids libraries by SELEX [14,15]. By reason of their high affinity, aptamers are considered to be promising recognition elements for biosensor applications in a wide range of targets including small molecules, ions, and proteins [16–30]. For example, a silver nanocluster functionalized aptamer as sensing platform was designed for multiplexed analysis of pathogenic DNAs via fluorescence resonance energy transfer (FRET) between silver nanocluster and graphene oxide [31]. A sensitive aptasensor was constructed by using two-photon dye labeling aptamer as molecular probe for quantitative detection of adenosine triphosphate [32]. However, due to the requirement of labeling fluorophores or quenchers on the aptamers, these methods are expensive, time-consuming and inconvenient. Meanwhile, another significant problem arises that modifications of dyes on aptamer will influence aptamer's affinity and specificity to target [33]. In order to solve these problems, a triple-helix molecular switch was developed by using a hairpin-shaped aptamer sequence and a dual-labeled oligonucleotide serving as a signal transduction probe [34]. In this work, we design a label-free triple-helix aptamer (THA) as sensing platform for "signal-on" fluorescent detection of thrombin.

Thrombin plays a key role in regulation of tumor growth, metastasis, and angiogenesis [35] and thus it is worth to develop a sensitive and specific method for detection of thrombin in biological samples. Here, by integrating with the advantages of graphene oxide (GO) as efficient supporter and quencher [36], a

label-free THA was developed as sensing platform for convenient and homogeneous fluorescent detection of thrombin (Fig. 1). First, the label-free THA and signal probe were conveniently synthesized by the mixing of Apt29 and help DNA 1 (H1), and the hexachloro-fluorescein labeled help DNA 2 (H2) and GO, respectively. After aptamer-thrombin recognition event, the released H1 could react with signal probe of GO/H2 to form H1-H2 duplex, leading to the detachment of H2 from the surface of GO, and thus an enhanced fluorescence was realized for readout. Based on the distinguishment of GO towards single-stranded DNA against double-stranded DNA [37,38] and high affinity between aptamer and target, a fluorescent strategy is achieved for specific detection of thrombin. The label-free THA provides a convenient way for constructing the powerful sensing platform towards the versatility of target in bioanalysis and clinical diagnosis.

2. Experimental

2.1. Materials and reagents

The oligonucleotides along with hexachloro-fluorescein (HEX) labeled DNA were synthesized and HPLC-purified by Sangon Biological Engineering Technology & Co. Ltd. (Shanghai, China). The oligonucleotide sequences were shown in Table 1. Thrombin (Tmb) and horseradish peroxidase (HRP) were purchased from Sigma-Aldrich (Shanghai) Trading Co. Ltd. Bovine serum albumin (BSA) was obtained from Nanjing Sunshine Biotechnology Co. LTD. Human immunoglobulin G antibody (IgG) was obtained from Sangon Biological Engineering Technology & Co. Ltd. (Shanghai, China). Graphene oxide (GO) was obtained from XFNano Materials Tech Co. Ltd. (Nanjing, China). Inorganic metal salts were obtained from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). All other reagents were of analytical reagent grade and used as purchased without further purification. Phosphate buffer solution (PBS) (10 mM, containing 20 mM KCl and 2.5 mM $MgCl_2$, pH 6.2) was used for homogeneous fluorescence detection of thrombin. Tris–HCl buffer (20 mM, containing 100 mM NaCl, 5 mM KCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, and 8.5% glycerol (v/v), pH 7.4) was used to dissolve thrombin. Human blood serum samples were obtained from Jiangsu Province Tumor Hospital (Nanjing, China). Ultrapure water obtained from a Millipore water purification system ($\geq$ 18 MΩcm, Milli-Q, Millipore) was used in all experiments.

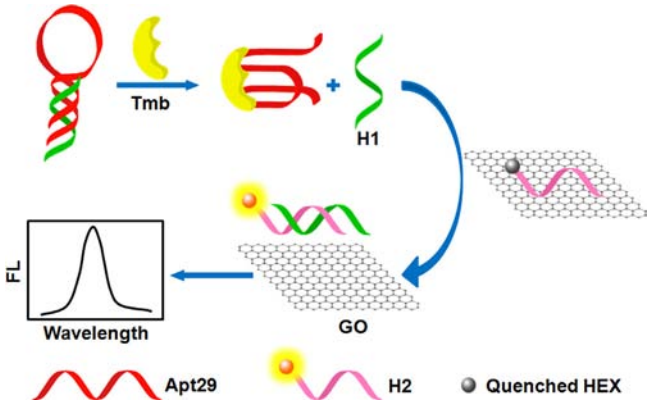

Fig. 1. Schematic illustration of label-free triple-helix aptamer as sensing platform for fluorescent detection of thrombin.

2.2. Apparatus

The synchronous scanning fluorescence spectra were recorded from 500 to 620 nm with a step of 1 nm at the excitation wavelength of 482 nm on a RF-5301PC spectrofluorometer (Shimadzu Co., Japan) equipped with a xenon lamp. The slit width was 5 nm, and the stokes shift ($\Delta\lambda$) was 18 nm for HEX.

2.3. Preparation of triple-helix aptamer and signal probe

The DNA stock solutions of Apt29 (1 μM) and help DNA 1 (H1, 1 μM) were first heated at 90 °C for 10 min, and gradually cooled down to room temperature. Subsequently, THA (0.5 μM) was prepared by mixing the same volume of Apt29 (1 μM) and H1 (1 μM) in 10 mM PBS, and then incubated at room temperature for 30 min.

To obtain the optimal performance, a series of GO dispersions were involved in the preparation of signal probe (GO/H2). The optimal ratio of GO (150 μg mL^{-1}), H2 (1 μM) and PBS was 5:2:43 in volume. The final concentration of the signal probe of GO/H2 was 15.2 μg mL^{-1}.

2.4. Homogenous fluorescence detection of thrombin

4 μL THA (0.5 μM) were mixed with different concentrations of thrombin in a certain volume of PBS to form 50 μL of reaction mixture. After the mixture was incubated at 37 °C for 40 min, 50 μL GO/H2 and 100 μL PBS were added to the reaction mixture at room temperature for 50 min. Subsequently, the final solution was used for fluorescent detection.

3. Results and discussion

3.1. Principle of sensing platform

The mechanism of label-free THA as fluorescent sensing platform for detection of thrombin based on GO is shown as Fig. 1. The work employed THA as a signal trigger which was composed of Apt29 and H1 by Watson-Crick and Hoogsteen base pairings [5]. In the absence of Tmb, H2 was absorbed on GO surface by π-π stacking, and its fluorescence was quenched though FRET [39], that is, the fluorescence of GO/H2 was turned off. Upon the introduction of Tmb, THA structure was dismissed and thus released H1 due to the specific recognition between Apt29 and Tmb. Afterwards, the released H1 reacted with signal probe of GO/H2 to form H1-H2 duplex that was desorbed from surface of GO, leading to the recovery of the fluorescence of signal probe. Therefore, the "signal-on" fluorescence strategy was simply achieved for the sensitive detection of Thrombin with high specificity.

Table 1
Oligonucleotide sequences used in this work.

Oligonucleotide	Sequence
Apt29	5'–CTCTCTTT***AGTCCGTGGTAGGGCAGGTTGGGGTGACT***TTTCTCTC-3'
help DNA 1 (H1)	5'–AAAGAGAGCGTA-3'
help DNA 2 (H2)	5'–TACGCTCTCTTT-HEX-3'

HEX is hexachloro-fluorescein. The aptamer sequence is bold in italic type.

3.2. Feasibility of strategy

The feasibility of the proposed method was demonstrated by fluorescence emission spectra of signal probe under different conditions (Fig. 2). The fluorescence spectrum of GO/H2 exhibited extremely weak fluorescence intensity owing to the strong adsorption of H2 on the surface of GO and the high fluorescence quenching efficiency of GO by FRET (curve a). The introduction of THA brought about no change of fluorescence intensity, because THA was bond up by Watson-Crick and Hoogsteen base pairings (curve b). Once THA was mixed with Tmb followed by GO/H2, the fluorescence intensity increased 37.4 times than that of GO/H2 (curve c). When mixing GO/H2 with free H1, an obvious fluorescence restoring of HEX labeled to H2 was obtained (curve d). These results indentified that THA could release H1 to trigger the fluorescence recovery of HEX in the presence of Tmb, leading to a "signal-on" fluorescence of sensing platform for detection of the target.

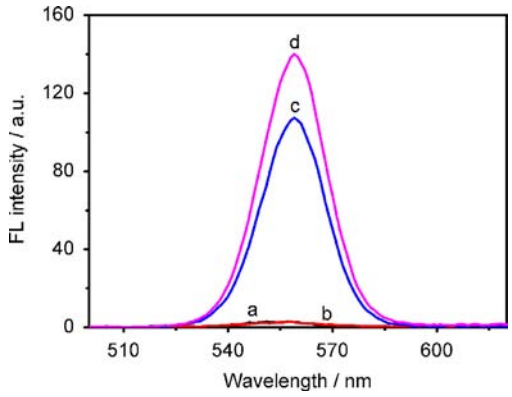

Fig. 2. Fluorescence emission spectra of GO/H2 (a), THA+GO/H2 (b), THA+Tmb+GO/H2 (c), and GO/H2+H1 (d). The concentrations of THA, Tmb, H1 and GO/H2 were 10, 1000, 100 nM and 3.8 μg mL^{-1}, respectively.

3.3. Optimization of conditions

In order to achieve the optimal performance, the concentration of GO as a critical factor for detection efficiency was optimized. As shown in Fig. 3A, the fluorescence intensity ratio of sensing platform, F/F_0, first increased and subsequently decreased as the concentration of GO increased. The results demonstrated that small amount of GO was insufficient to quench the HEX labeled on H2, and by contrast excess GO provided spare area to absorb THA or released H1 resulting in that low fluorescence intensity was recovered. Therefore, the corresponding concentration of GO (3.75 μg mL^{-1}) was chosen as the optimal value for the next experiments.

The effects of reaction time between Apt29 and H1, THA and Tmb, as well as THA/Tmb and signal probe on fluorescence intensity ratio of F/F_0 were investigated step by step. After mixing Apt29 with H1 at the same molar, 30 min was identified as the optimal time to ensure that THA was completely formed (Fig. 3B). For incubation time of THA and Tmb, the value of F/F_0 increased and reached a plateau at 40 min (Fig. 3C), which indicated the THA fully reacted with Tmb and liberated H1. When addition of GO/H2 into the mixture, the F/F_0 ratio first increased and subsequently reduced (Fig. 3D). The phenomena could be explained that the liberated H1 from THA couldn't completely react with signal probe within a short time. But a long reaction time could result in fluorescence enhancement of background due to

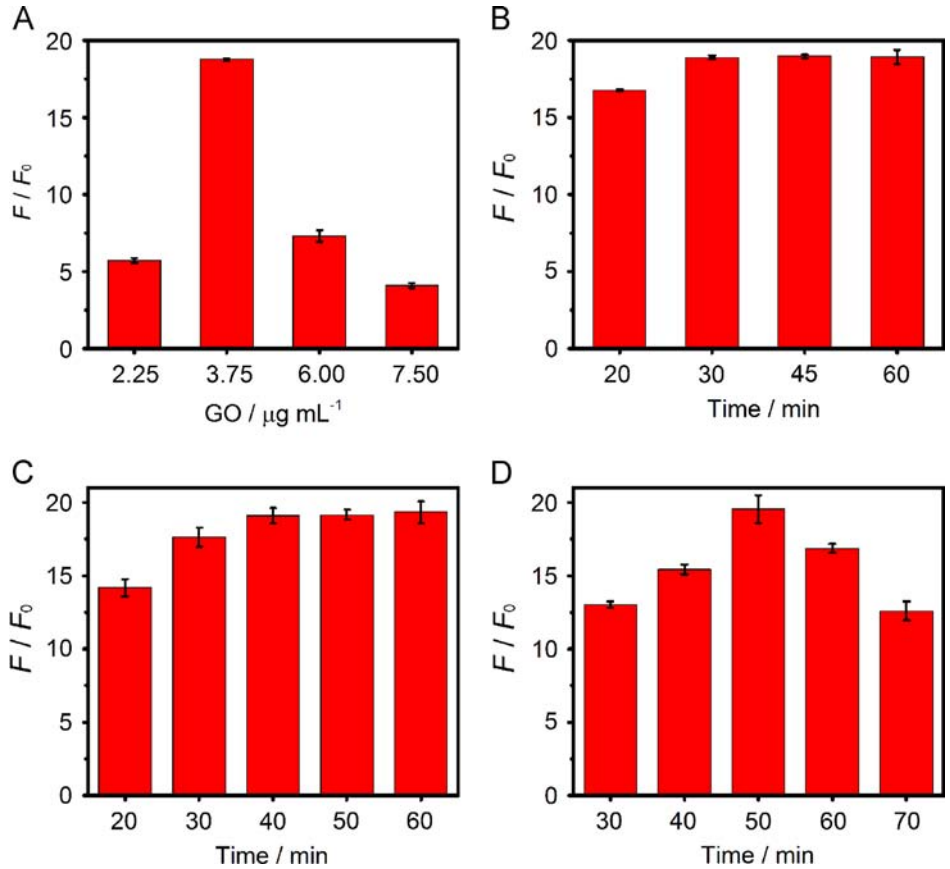

Fig. 3. Effects of (A) GO concentration, incubation time for (B) Apt29+H1, (C) THA+Tmb, and (D) THA+Tmb+GO/H2 on the fluorescence ratio of F/F_0. F and F_0 are the fluorescence intensities of sensing system in the presence and absence of Tmb, respectively. All assays were carried out in 10 mM PBS with 500 nM Tmb, 10 nM THA, while the other parameters were under their optimal conditions.

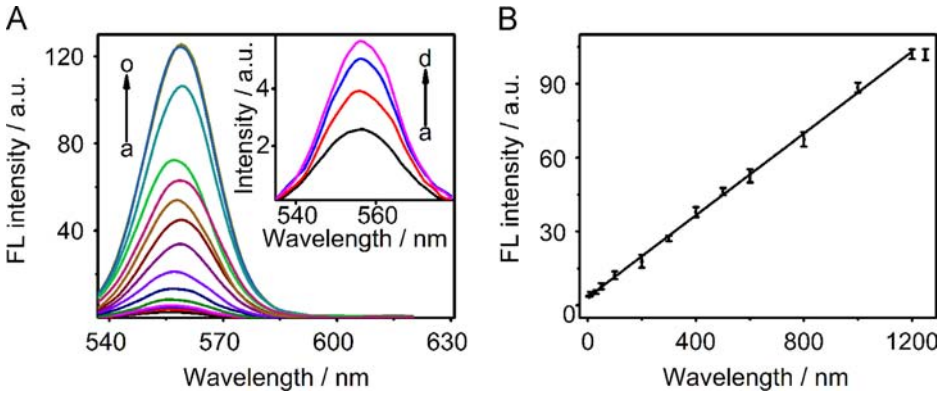

Fig. 4. (A) Fluorescence emission spectra of sensing platform in response of Tmb at 0, 5, 10, 30, 50, 100, 200, 300, 400, 500, 600, 800, 1000, 1200 and 1250 nM (from a to o). Inset: Amplified fluorescence emission spectra in response of Tmb at 0, 5, 10, 30 nM (from a to d). (B) Calibration curve for Tmb detection.

Table 2
Comparison of the fluorescent label-free aptamer-based biosensors for thrombin.

Detection method	LOD (nM)	Linear range (nM)	Ref
Fluorescent detection using triple-helix aptamer	1.8	5–1200	This work
Fluorescent aptasensor based on multi-branched pyrazine derivative	50	5–2500	41
Fluorescent detection based on H_2O_2-catalyzed oxidation via hemin/G-quadruplex DNAzyme	10	0–100	42
Fluorescent detection based on QDs/Ru complex photoinduced charge transfer	50	200–1600	43
Fluorescent detection based on inhibition of polymerase reaction	62.5	0–500	44

the competition of THA with the absorbed H2 onto GO, and thus the F/F_0 ratio reduced [40]. Hence 50 min was chosen as the optimal reaction time for fluorescence detection.

3.4. Tmb detection

Under the optimal concentration of GO and reaction time, the fluorescence intensity of sensing platform enhanced dramatically with the increasing concentration of Tmb in the wide range from 5 to 1200 nM (Fig. 4). The linear regression equation was $I=3.30+0.08\times c$ ($R^2=0.9989$), where I is the fluorescence intensity and c is the Tmb concentration. The detection limit was estimated to be 1.8 nM at 3σ. As shown in Table 2, the detection limit of the proposed aptasensor for thrombin was lower than those of the previous fluorescent label-free aptamer-based methods [41–44]. The high sensitivity and the wide detection range of our method are attributed to the high-efficiency affinity between label-free THA and Tmb, and the strong fluorescence quenching effect of GO on fluorophore labeled on single-stranded DNA. In addition, a relative standard deviation was calculated to be 4.2% for 300 nM thrombin with 6 different aptasensors, indicating acceptable reproducibility.

3.5. Selectivity of sensing platform

To evaluate the selectivity of our strategy for Tmb, the fluorescence responses of sensing platform to Tmb and other proteins containing HRP, BSA and IgG were individually investigated at the same concentration (500 nM). As shown in Fig. 5, the fluorescence intensity of Tmb was approximately 5.9 times higher than that of IgG. For BSA and HRP, the fluorescence intensity of target was 3.4 times and 3.8 times higher than negative controls, respectively. The results could be attributed to that nonspecific adsorption of interference proteins onto GO caused a fraction of H2 to be discharged from surface of GO. The selectivity of the sensing platform resulted from the specific recognition of aptamer to Tmb and the specific hybridization of H1 with H2. It could be summarized that THA as fluorescent sensing platform is promising

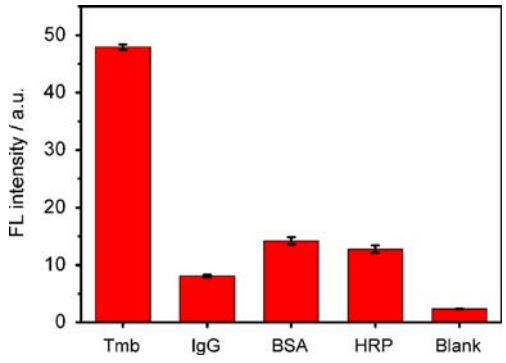

Fig. 5. Fluorescence intensity changes of the aptasensor toward Tmb and other proteins under the same condition. The concentrations of Tmb, IgG, BSA and HRP were 500 nM.

to be applied in homogeneous fluorescent detection of Tmb and related analytes.

3.6. Tmb detection in serum samples

Considering sensitive detection of thrombin in real sample is of great importance for disease diagnosis and drug discovery, thrombin in serum samples was detected by the proposed aptasensor. A series of samples were prepared by spiking the standard solution of 500 nM to different human blood serum samples. All of recoveries were from 97.7% to 92.9%, indicating the proposed strategy could be promising for thrombin detection in real biological samples.

4. Conclusions

The novel label-free triple-helix aptamer was successfully constructed as sensing platform for homogeneous fluorescent detection of target. THA is composed of aptamer sequence and help DNA 1, which functions as the recognition element for specific recognition of Tmb, and the trigger for fluorescence recovery of signal probe,

respectively. Taking advantages of the specific recognition of aptamer to Tmb and the specific hybridization of H1 with H2, the THA-based sensing platform could selectively detect thrombin with a wide linear range and a low detection limit. Moreover, the separation of aptamer from signal reporter ensures the high affinity between aptamer sequence and target. Besides, this method possesses some merits such as convenient operation and low cost. The label-free triple-helix aptamer as a universal signal transducer can provide a simple, sensitive, selective homogeneous protocol in bioanalysis.

ABSTRACT

A novel approach to the quantification of relatively small amounts of water present in low polarity, aprotic solvents is proposed. This method takes advantage of protolitic reaction of 4-methylumbelliferone dissolved in the solvent with water, acting as a base. The low emission intensity neutral 4-methylumbelliferone is transformed in reaction with water to a highly fluorescent anionic form. Thus the increase in emission intensity is observed for increasing water contents in aprotic solvents. For low water contents and highly lipophilic solvents, this method yields (in practical conditions) higher sensitivity compared to biamperometric Karl Fischer titration method in volumetric mode.

It is also shown that organic compounds of protolitic character (amines, acids) not only interfere with water contents determination but increase the sensitivity of emission vs. water contents dependence. Introduction of aqueous solution of strong acid or base (HCl or NaOH) has similar effect on the system as introduction of pure water.

1. Introduction

Determination of water contents, particularly in the case of organic solvents is essential for many practical applications, especially in industrial processes. Clearly, there is an interest in methods allowing quick and easy access to information on water contents in different organic media. The golden standard for water determination is coulometric Karl Fischer titration, for example [1]. In general, this is the most reliable method, however, in the case of minute water concentrations and especially highly lipophilic, aprotic solvents problems related to sampling and especially tendency of water to spontaneously accumulate close to more hydrophilic surfaces – e.g. glassware, may result in inaccurate determination results [1,2]. In aprotic and non-alcoholic solvents Karl Fischer method is less sensitive because the Bunsen reaction is favored and water/iodine molar ratio changes toward 2:1 in contrast to the 1:l molar ratio found in the protic Karl Fischer environment [3]. For oil samples the results obtained by volumetric and coulometric Karl Fischer methods usually considerably differ even after correcting for the instrumental bias. Thus it was suggested that the volumetric method should be preferred over coulometric method to measure all of the water content in oil samples [4,5]. Moreover, Karl Fischer titration can hardly be performed as an integral part of technological process, or be used to continuously monitor any occurrence of water in the sample media. Thus, different alternative methods of water quantification have been proposed, including advanced techniques like NMR [6], infrared spectrometry [7,8], UV/Vis spectrometry [9,10]. Many of them tried to apply fluorometry for determination of water contents in organic solvents as well for example [11–14]. The latter approach, however, requires application of fluorophore of emission spectra dependent on the presence of water in the studied system. Different compounds have been proposed/tested in this respect, most of them were tailor made (synthesized) for water determination purpose. Moreover, in most cases the increase of water contents in the sample was accompanied with decrease (quenching) of emission signal (e.g. [11,13]). For practical analytical applications, however, commercially available fluorophores probes, and optimally leading to increase of the emission signal with increasing analyte (water) concentrations are preferred. Among widely available, cost-effective ligands 4-methylumbelliferone (4-MU), pH-sensitive, widely used, bright fluorophore is known to be soluble in variety of organic solvents. It was also shown that the emission spectrum of 4-MU probe is dependent on the solvent used and on the presence of acid/bases in the sample, for example [15,16]. The dependence of emission intensity on water contents in ethanol in the presence of constant concentration of hydrochloric acid was also reported [15]. Nevertheless, to our best knowledge, the above-mentioned reports have not led to analytical application of 4-MU as water-sensitive probe for organic media.

The herein proposed approach is based on assumption that in the lipophilic solvents (*even in the absence of acid or bases in the system*) dissolved neutral 4-MU can spontaneously undergo

protolitic reaction with water leading to formation of highly fluorescent species, especially deprotonated 4-MU, a bright fluorophore [15]. It is rational to expect that fluorescence intensity in this case should be dependent on the amount of water present, thus allowing quantification of water in the sample, especially in emulsion. The herein proposed approach was used to quantify amount of water present in the sample of a model organic medium: hexadecane. The effect of other (model) protolitic agents present in the sample on the resulting emission signal was also studied. The proposed method was also applied for toluene and cyclohexane model solvents. Application of 4-MU to quantify minute contents of water in aprotic, lipophilic solvents to our best knowledge has not been proposed in literature.

Results of 4-MU-based water quantification using herein proposed method have been compared with water determination results performed using the classical approach – biamperometric Karl Fischer titration in volumetric mode, showing that especially for low amounts of water present in the sample, herein proposed method offers higher sensitivity.

2. Experimental

2.1. Reagents

Hexadecane (HD), 4-methylumbelliferone (4-MU), HYDRANAL® - Composite 5 K (Titration), HYDRANAL® - Medium K, HYDRANAL® - Water Standard 10.0, toluene, cyclohexane, hexanoic acid, palmitic acid, octanoic acid, isopentyl amine, octadecyl amine and molecular sieves were from Aldrich (Germany). Octylamine, hydrochloric acid and NaOH were of analytical grade and were obtained from POCh (Gliwice, Poland).

Doubly distilled and freshly deionized water (resistance 18.2 MΩcm, Milli-Qplus, Millipore, Austria) was used throughout this work. All solvents were dried over freshly activated molecular sieves (MS 4A).

2.2. Apparatus

Fluorimetric experiments were performed using a spectrofluorimeter Cary Eclipse (Varian). After exposure at an excitation wavelength, unless otherwise stated, equal to 320 nm, emission intensity was observed within the range from 350 nm (or 370 nm) to 600 nm. The slits used were 5 nm both for excitation and emission, while the detector voltage was maintained at 800 V.

Biamperometric Karl Fischer titration in volumetric mode was performed using Titration Equipment: 716 DMS Titrino (Metrohm) and 728 Stirrer (Metrohm), platinum electrodes (400 mV) were used. Chloroform was added to the working solution as a solubility promoter so that the KF titration was conducted in the homogeneous solution. This procedure was found to give more reproducible results. The requirements of complete dissolution in KF method was also discussed earlier [5]. Emulsions were prepared using homogenizer Hielscher, model UP 200 S.

2.3. Preparation of 4-MU stock solutions

4-MU stock solutions in tested solvents were prepared by dissolving 2 mg of 4-MU in 80 ml of a solvent (either hexadecane, toluene or cyclohexane) under sonication (cycle 0.5, power 70%) yielding a concentration 0.025 mg/ml. Sonication was continued for another 5 min. Then the mixture was left for 24 hours to complete dissolution of the fluorophore. Thus prepared solutions were used for fluorimetric measurements.

2.4. Preparation of the samples

Water was introduced to one of the tested solvents (hexadecane, cyclohexane, toluene) containing 4-MU. To assure that introduced water is mixed with dry solvent, the sample was sonicated for 60 seconds. Samples for Karl Fischer titration control experiment were prepared in the same manner.

3. Results and discussion

4-MU is a well-known fluorescent pH indicator, showing strong emission at about 450 nm in aqueous alkaline solutions, this emission is characteristic for deprotonated form of 4-MU – when it is present as anion, Fig. S1 [15,16]. Analytical usefulness of this reagent has been proven in numerous applications, including those where the enzymatic reaction leads to formation of highly fluorescent 4-MU anion, from optically silent enzymatic substrates (for example using alkaline phosphatase, glucuronidase, β-glucosidase and other enzymes).

Fig. 1. presents excitation and emission spectra obtained for 4-MU dissolved in concentration 0.025 mg/ml in hexadecane. As it

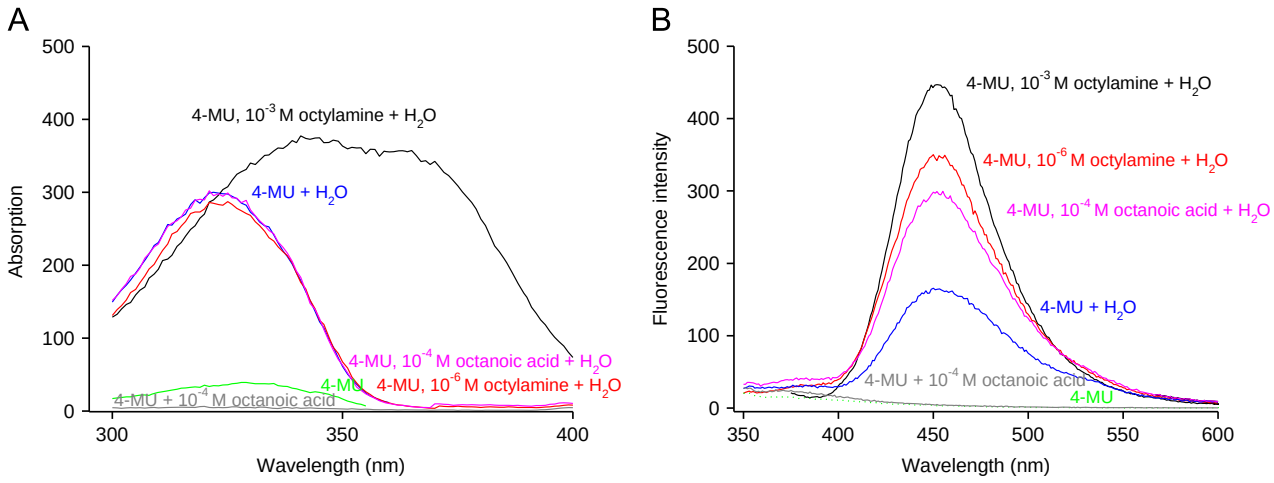

Fig. 1. (A) Excitation and (B) emission spectra (excitation wavelength 320 nm) recorded for 4-MU (0.025 mg/ml) in HD, in the absence and in the presence of model additives tested: (green line) 4-MU in HD, (navy line) 4-MU in HD in the presence of 0.16% v/v water in HD, (red line) 4-MU in HD in the presence of 10^{-6} M octylamine and 0.16% v/v water in HD, (black line) 4-MU in HD in the presence of 10^{-3} M octylamine and 0.16% v/v water in HD, (grey) 4-MU in HD in the presence of 10^{-4} M octanoic acid, (magenta) 4-MU in HD in the presence of 10^{-4} M octanoic acid and 0.16% v/v water in HD.

can be seen in Fig. 1, for 4-MU dissolved in HD weak absorption (at about 320–330 nm) and practically no emission is observed. It should be stressed that 0.025 mg/ml concentration of 4-MU is the highest practically achievable for HD solutions. The emission intensities observed at about 380 nm for the same concentration of 4-MU in toluene were yet lower compared to HD, Fig. S2, and were very weak for cyclohexane (the latter are not included in Fig. S2). It should be stressed that the presence of emission peak at 380 nm confirms, that as expected, neutral 4-MU is present in dry tested solvents [15] (structure A in Fig. S1).

As 4-MU is known to be sensitive to the presence of protolitic agents in sample, the effect of presence of model compounds of this nature was tested. The introduction of protolitic reagents to the model solvent tested, HD, results in only small changes in the emission spectra, Fig. S3. The presence of tested acids: hexanoic, octanoic or palmitic in 10^{-3} M concentration results in 4-MU emission observed at about 380 nm, suggesting that still neutral 4-MU is present in the system, regardless acid added. For higher concentrations of acid added to HD, 10^{-1} M, apart from significant increase of peak at 380 nm, additional peak is formed at about 490 nm, Fig. S3, inset. The latter is typical for neutral tautomer form of 4-MU, structure C, Fig. S1 [15]. This behavior is similar to that reported earlier for strong acid (HCl) introduced to protolitic solvents as water or ethanol [15]. Thus, it is probable that, in the absence of other protolitic agents, even relatively weak (in aqueous environment) acids are able to induce the change of the structure of neutral 4-MU molecule, leading to formation of above mentioned neutral tautomer characterized with emission at about 490 nm.

On the other hand, introduction of a base: isopentylamine, octylamine or octadecylamine in low concentrations, $< 10^{-6}$ M, did not affect the emission spectra obtained. Regardless of the amine used, similar behavior was observed, the exemplary results obtained for octylamine are shown, Fig. 2. For low concentration of amine present in the sample, both excitation and emission spectra recorded resemble those of 4-MU in HD recorded in the absence of amine. However, for higher concentration of amine ($> 10^{-5}$ M) the intensity of emission of 4-MU dissolved in HD was significantly dependent on concentration of amine, as shown on example of octylamine, Fig. 2. For the amine concentration equal to 10^{-5} M a small shoulder is formed on 4-MU emission spectra with a maximum at 450 nm, at wavelength typical for deprotonated form of 4-MU, Fig. S1 B. Further increase of amine contents to 10^{-4} M and 10^{-3} M results in formation of a well-developed emission peak with maximum at 450 nm (excitation 330 nm), clearly pointing out to deprotonation of 4-MU as expected for presence of a base in the sample [15].

Introduction of water to (net) HD containing 4-MU (5 μl to 3 ml, corresponding to 0.17% v/v or 0.093 M concentration) leads to similar change of 4-MU emission spectra as introduction of any amines in 10^{-4} M concentration, Fig. 1. On the excitation spectra a pronounced absorption peak is formed with maximum at about 320 nm. On the emission spectra a strong peak is formed with a maximum at about 450 nm, suggesting the presence of deprotonated form of 4-MU in HD. Thus, it can be assumed that in the absence of other deprotonating agents, water as a base reacts with 4-MU and this reaction leads to deprotonation of 4-MU and formation of structure depicted in Fig. S1 B. This process can be accompanied by partition of 4-MU anion to the water phase, due to its higher (compared to neutral 4-MU) solubility in water. Thus the protolitic reaction of 4-MU with water in aliphatic environment is promising for the analytical, fluorimetric water determination.

Fig. 3. presents emission spectra of 4-MU dissolved in HD, recorded for changing water concentration in the sample from $1.7.10^{-2}$% v/v ($9.3.10^{-3}$ M) to 0.6% v/v (0.37 M). As it can be seen from Fig. 3 introduction of even relatively small amount of water, reaching $1.7.10^{-2}$% v/v, to 4-MU containing HD results in formation of emission peak at wavelength typical for deprotonated form of 4-MU, at 450 nm (excitation wavelength 320 nm). Increase of the amount of water introduced to the sample results in clear increase of the intensity of emission observed at 450 nm. The linear dependence of emission intensity on water contents was observed within the range from $1.7.10^{-2}$% to 0.33% v/v, that is up to 0.185 M water in HD, Fig. 4. Within this range the correlation coefficient, R^2, of the dependence of emission intensity on water contents was equal to 0.987, Table 1. Further increase of water contents in the sample to 0.67% v/v (0.37 M) resulted in some increase in the recorded emission, yet not linear. In this range also the magnitude of error increases, Fig. S4. The plateau of the signal obtained can be attributed to different effects; however, it should be stressed that for these water contents the amount (mole) of water was more than 2000 times higher compared to amount (mole) of 4-MU present in the sample. It can also result from the protolitic reaction, and from acid–base equilibrium prevailing in the sample.

The advantage of herein proposed approach is clearly seen when comparing the results of fluorimetric evaluation of water

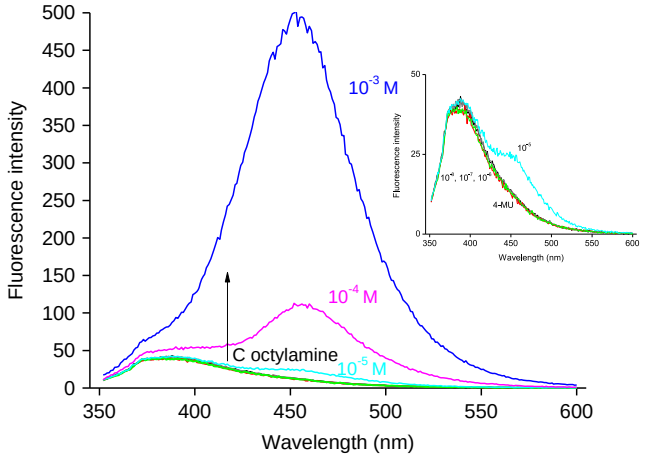

Fig. 2. Emission spectra recorded in different concentrations of octylamine in HD: (black line) 4-MU in HD, and gradually increasing octylamine concentration (grey line) 10^{-8} M, (red line) 10^{-7} M, (green line) 10^{-6} M, (cyan line) 10^{-5} M, (magenta line) 10^{-4} M and (blue line) 10^{-3} M. Inset – magnification of spectra obtained for low concentration of octylamine in HD, excitation wavelength 330 nm.

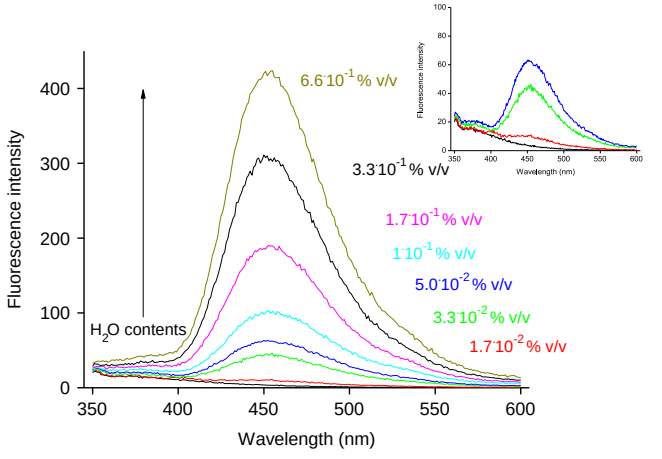

Fig. 3. Emission spectra recorded in different concentrations of water in HD: (black line) 4-MU in HD and gradually increasing water contents from $1.7.10^{-2}$% v/v ($9.3.10^{-3}$ M) to 0.6% v/v (0.37 M). Inset: magnification of spectra obtained for low concentration of water in HD: (black line) 4-MU in HD, (red line) $1.7.10^{-2}$% v/v ($9.3.10^{-3}$ M) water, (green line) $3.3.10^{-2}$% v/v ($1.8.10^{-5}$ M), (blue line) 5.10^{-2}% v/v ($2.8.10^{-2}$ M).

Dependence of intensity of emission read at 450 nm on the change of water contents in HD sample obtained (A) from fluorimetric experiment, in HD sample (■) in the absence of octylamine, (●) in the presence of 10^{-6} M octylamine, (▲) in the presence of 10^{-4} M octanoic acid, (▲) in the presence of 10^{-2} M octanoic acid and (■) in the presence of 10^{-3} M octylamine (using excitation equal to 360 nm); (B) amount of water determined plotted against amount of water added for Karl Fischer titration of HD samples, inset: magnification of the low water contents range of Karl Fischer titration.

Table 1
Summary of analytical performance of 4-MU as water sensitive fluorescent indicator

System	Hexadecane	Hexadecane $+10^{-2}$ M octanoic acid	Hexadecane $+10^{-6}$ M octylamine	Hexadecane $+10^{-3}$ M octylamine	Toluene	Cyclohexane
$\lambda_{excitation\ (nm)}$	320	320	320	360	320	320
$\lambda_{emission\ (nm)}$	450	450	450	450	450	450
Water contents (%, v/v)	$1.7.10^{-2}$–0.33	< 0.2	$1.7.10^{-2}$–0.33	< 0.3	$1.7.10^{-2}$–20	< 0.2

contents changes using 4-MU as indicator, with results of Karl Fischer titration, Fig. 4. For Karl Fischer titration, as it can be seen from Fig. 4, introduction of relatively small amounts of water to the sample, below 0.1% v/v, yields negligible changes of estimated water amount pointing out to significant negative error of water contents estimation. It should be stressed that Karl Fischer titration is dependent on the sampling procedure, and in the case of relatively low water contents, e.g. accumulation of water introduced to lipophilic HD at the interface of the sample and used vessel, significantly affects obtained results. Herein described approach takes the advantage of emission changes, resulting from 4-MU spontaneous protolitic reaction with water. As 4-MU is dissolved in whole volume of HD, any contact of the sample with water results in change of the emission spectra. Thus, as seen in Fig. 4, fluorimetric approach is significantly more sensitive for relatively low water contents. On the other hand, for higher water contents, > 0,5% v/v, Karl-Fischer method offers higher sensitivity, without limitation on high water contents.

Taking into account that fluorimetric response of 4-MU dye for different water contents in HD originates from protolitic reaction with water acting as a base, it seems justified to check how the presence of base or acid in the sample influences the analytical performance of this system.

As discussed above (Fig. 2), the presence of base (amine) at the concentration 10^{-6} M, in the absence of water, does not affect the emission spectra of 4-MU in HD. Similarly the presence of 10^{-6} M octylamine in HD did not affect the dependence of emission on changes of water contents in the sample. Both the excitation and emission spectra were comparable within the range of experimental error with that recorded in the absence of amine in solution (Fig. S5). Similarly, the dependence of emission intensity at 450 nm on water contents in the sample was linear within the range from $1.7.10^{-2}$% to 0.33% v/v with R^2 equal to 0.988, Table 1.

Increase of octylamine concentration in HD to 10^{-3} M results, in the presence of water, in a significantly broader peak observed on the excitation spectra of 4-MU, Fig. 1. Thus in this case the excitation wavelength used was equal to 360 nm. The emission intensities recorded in the presence of water (0.17% v/v) were significantly higher compared to that recorded for water containing samples in the absence of amine or in the presence of 10^{-6} M octylamine. The emission intensity vs. water contents dependence recorded in the presence of 10^{-3} M octylamine, Fig. S6, for low water contents (< 0.3% v/v) was linear with R^2=0.991, Table 1. The sensitivity of determination was not only higher than for Karl Fischer titration, but also it was the highest among tested model systems. The sensitivity obtained for 10^{-3} M amine present was more than two times higher compared to the system tested in the absence or in the presence of low octylamine concentration in HD, Fig. S5 and Fig S6. Moreover, in the presence of amine in HD the error measured as SD of three replicates is significantly smaller, except for the highest water content tested, which is already at plateau of the dependence, Fig. S4. Thus introduction of amine in 10^{-3} M gives possibility of fine tuning of sensitivity of fluorimetric water contents determination in aprotic solvents, offering significantly higher sensitivity within this region compared to Karl Fischer titration, Fig. 4. However, the linear range of the dependence of emission on contents of water was shorten compared to above-described cases, for higher water contents the decrease of fluorescence intensity was observed, Fig. 4.

The significant increase of sensitivity of water contents determination, especially at low water contents, observed for the 10^{-3} M amine presence in the sample results from the properties

of amine – which is stronger base than water. Thus amine influence on 4-MU deprotonation and concomitant formation of emission signal is potentially stronger than that of water. With increasing water contents in the sample hydrophilicity of the medium increases, protolitic reaction between 4-MU and amine, resulting in protonation of amine on expense of creating of 4-MU anion, is facilitated, resulting in higher sensitivity of water contents determination. The strong emission signal observed can be also to some extent related to formation of structures resembling reversed micelles, containing water in their cores and being stabilized by protonated amine oriented with protonated amine group toward hydrophilic environment of water and with the alkyl chain oriented toward HD. It is probable that the anionic, deprotonated and water-soluble form of 4-MU formed will be present inside the reverse micelles resembling structures, being stabilized with positive charges of the protonated amine, this will ultimately yield higher emission intensity. This effect is probably of low importance for low (10^{-6} M) amine contents in the sample as the population of positive charges that may be created is relatively low, whereas at higher amine contents the enhancement of sensitivity of water determination is clearly seen.

Introduction of acid, as a model compound octanoic acid was used, in 10^{-4} or 10^{-2} M concentration, did not affect the emission or absorption peak positions. The excitation and emission spectra and their maxima, recorded in the presence of octanoic acid, at two concentrations used, were not affected compared to spectra recorded for similar system, yet in the absence of acid, Fig. 1. Introduction of water to HD-containing octanoic acid resulted in increase of emission at 450 nm, similarly as for net HD-containing 4-MU (the maximum of excitation peak was observed at about 320 nm), Fig. 1. The effect of presence of octanoic acid in the system predominantly was observed on the emission intensity vs. water contents dependence. Although for increase of water contents $<0.1\%$ v/v the increase of intensity was slightly higher compared to HD system containing 4-MU in the presence of 10^{-3} M octylamine, the further increase of water contents resulted in much smaller increase of intensity of emission and the dependence was reaching plateau, regardless the concentration of acid present in the HD. Formation of plateau can be related to the fact that octanoic acid is stronger acid than 4-MU, thus deprotonation of 4-MU in this case is not enhanced by water addition. On the other hand, dissociation of octanoic acid, if occurs, leads to formation of water containing reversed micelles resembling structures with anionic charge at the water/HD interface. Thus due to electrostatic repulsion, incorporation of negatively charged 4-MU anion is less likely compared to positively charged water/HD interface in the case of amine reversed micelle resembling structures formed.

Thus although the presence of carboxylic acid in the model solvent HD limits possibility of analytical quantification of the water contents to the low amounts only, the proposed method is robust enough to clearly distinguish samples containing water from those free from water additions.

For analytical application of herein proposed system the information on response time of the system for water addition as well as stability of emission signal in time was collected, Fig. S7, using HD as model solvent. As shown above the intensity of emission recorded in the presence of 10^{-3} M octanoic acid was much lower compared to signals recorded in the presence of water, moreover the intensity of emission was fluctuating in time especially in the presence of octanoic acid in HD.

Introduction of water to the sample leads to pronounced increase of emission, Fig. S7, regardless of the system tested. In the absence of protolitic compounds in HD stable signal was obtained after about 3 min. For sample containing amine or acid emission signal was increasing faster, the stable signal was achieved after about 2 min time. The fastest response was observed for system containing octylamine, regardless of concentration of water tested ($3.4.10^{-2}$% v/v or $1.7.10^{-1}$% v/v), the maximum intensity of emission signal was observed after 1 min. This result is supporting the thesis that presence of amine and possible formation of reverse micelle-like structures favors reaction of 4-MU with water added to the system. It should be stressed that regardless of the system studied (either without additives or containing acid or base) emission signal in the presence of water was stable in experiment time.

Last, but not the least, the above-described experiments confirm, that the proposed system is not only highly sensitive for low water contents but also the results are not interfered by the presence of organic impurities of protolitic character in the sample. This effect is due to spontaneous and beneficial effect of reverse micelles resembling structures formation (provided that the concentration of impurities is high enough) and was not observed for introduction of aqueous solution of acid (HCl) or base (NaOH) solution to the sample. In the latter case, the effect observed was equivalent within the range of experimental error, to that of addition of (neutral) water to the sample, Fig. S8.

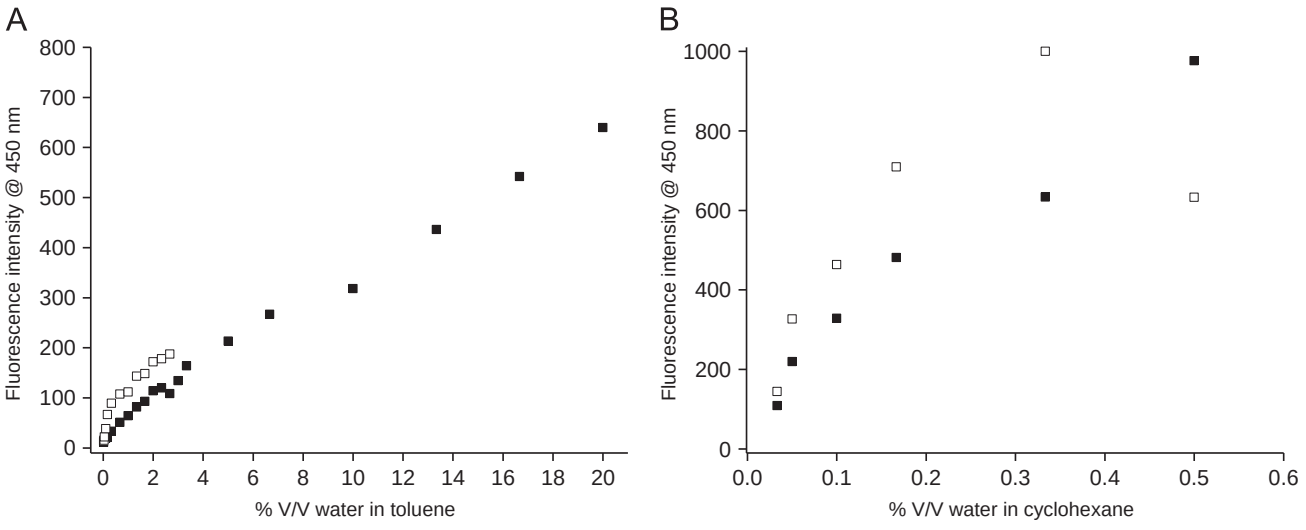

Fig. 5. Dependence of intensity of emission read at 450 nm on the change of water contents in (A) toluene and (B) cyclohexane: (■) 4-MU in tested solvent, (□) in the presence of 10^{-6} M octylamine in tested solvent.

The herein proposed simple method of water quantification using protolitic reaction of 4-MU was also tested on example of other solvents – toluene and cyclohexane.

For 4-MU dissolved in toluene introduction of water resulted in formation of emission peak at 450 nm, of intensity dependent on water contents, Fig. 5. As it can be seen in Fig. 5, similarly as for HD, a linear dependence of intensity of emission on contents of water in the sample was recorded; however, for toluene the linear range of responses was much broader compared to HD. For tested range 0.017% v/v to 20% v/v of water in toluene, it was characterized with R^2 equal to 0.991, Table 1. As it can be seen in Fig. 5, especially for low water contents, $< 0.7\%$ v/v, a further increase of sensitivity is observed if the octylamine is present in the toluene in concentration 10^{-6} M, that is at the concentration of no beneficial effect in the case of hexadecane. Probably the advantageous effect of already low concentration of amine present in toluene is related to higher polarity of this solvent compared to HD. Toluene partially participates in stabilization of water droplets within, thus even low contents of amine actively increases deprotonation of 4-MU molecules and their partition into aqueous phase.

For cyclohexane containing 4-MU, similarly as for above discussed examples, introduction of water resulted in formation of emission peak at 450 nm, of intensity dependent on water contents in the sample, Fig. 5. The linear dependence of emission intensity on water contents was however, limited to about 0.2% v/v of water ($R^2 = 0.967$), Table 1. Similarly as for toluene, introduction of amine in 10^{-6} M concentration to the cyclohexane has resulted in increased emission, however recorded dependence was not linear. Increase of water contents above 0.33% v/v resulted in decrease of recorded emission.

4. Conclusions

The herein presented results clearly show that minute water contents, especially in highly lipophilic, nonpolar solvents like hexadecane, can be determined with high sensitivity due to protolitic reaction of 4-methylumbelliferone with water, acting as a base. The emission intensity of deprotonated 4-MU anion well correlates with water contents in the nonpolar solvent. For low concentrations, this system offers higher sensitivity compared to Karl Fischer titration. Moreover, presence of organic acid and especially organic base leads to further increase of sensitivity, with increasing concentration of this additive in the solvent. This effect can be attributed to formation of structures resembling reversed micelle within the low-polarity solvent – with water core and stabilized with protonated (in the case of amine) or deprotonated (in the case of acid) organic ion located at the water – solvent interface. This spontaneous process in the case of added base (amine) supports partition of ionized 4-MU into the minute water phase.
