TALANTA REVIEW*

A CRITICAL REVIEW OF NEUTRON ACTIVATION AND TRACER METHODS FOR THE DETERMINATION OF THE NOBLE METALS

F. E. BEAMISH, K. S. CHUNG† and A. CHOW
Department of Chemistry, University of Toronto, Toronto 5, Canada

(*Received* 22 *March* 1966. *Accepted* 3 *June* 1966)

Summary—Neutron activation methods for the seven noble metals are critically reviewed up to December, 1965. The methods deal with the determination of trace impurities in each noble metal as well as traces of noble metals in media such as organic material, fission product and other solutions, ores, alloys, minerals, silica and base metals. The need for confirmatory evidence in the case of such complex materials as ores is emphasized.

THIS review deals with the analysis of the noble metals by methods which involve measurements of radioactivity and have been recorded in *Chemical Abstracts* and in miscellaneous sources of activation procedures up to and including December, 1965. An effort has been made to restrict detailed discussion to methods which provide general approaches to the determination of trace impurities in noble metals, or deal with traces of noble metals in various materials, or include typical methods of chemical separation.

Activation techniques are principally applied to determination of submicrogram amounts of constituents and so would not be expected to replace to an appreciable extent such established techniques of trace analysis as optical or X-ray spectrography, *etc.* However, for determination of submicrogram traces, no analytical tool of comparable value is available to the analytical chemist, and one may confidently expect rapid developments in neutron activation techniques.

These developments will include simpler and better methods of protection, more readily available sources of activation energy, cheaper measuring instruments, improved techniques of chemical separation, direct methods needing no prior chemical treatment, and a growing supply of trained technical operators. Smales[1] has stated that neutron activation methods "will grow steadily as analytical chemists become aware of its advantages and as training in elementary radiochemistry becomes more widespread. The techniques are quite easily learned, the cost of equipment is not outrageous by modern analytical standards, the cost of irradiation per sample is quite small, very few special laboratory modifications are required, and any health

* For reprints of this review see Publisher's Announcement near the end of this issue.
† On leave from the Atomic Energy Research Institute, Seoul, Korea.

hazard can be kept well under control at the levels required for most applications." The significant observation is also made that "like any other method of analysis, radioactivation has its limitations, and the user should be aware of them. There has undoubtedly been a tendency in published papers (neutron activation methods) so far to stress the advantages and neglect the limitations." Smales[1] dealt with problems associated with the decomposition of samples and containers under irradiation conditions. That unexpected decomposition difficulties can occur was made evident in an experiment by the present authors in which a violent decomposition of an activated solution of iridium occured after removal of the silica tubes from the aluminium radiation capsule. Although the cause of this explosion was not determined, it may have been the catalytic effect of iridium.

Accurate manipulations and analytical experience are just as necessary in activation techniques as in classical analysis, and chemical recovery determinations are not necessarily an adequate substitute. Published procedures do not always indicate the errors which can be associated with the chemical recovery method which may itself be partly invalidated by inapplicable variations in technique. Examples are discussed below for ores and concentrates, *etc.* Indeed, some proposed methods can only be used for liquid extracts from the ores. It may be emphasized that procedures applicable to the accurate determination of milligram amounts of noble metals of submicrogram quantities are not necessarily suitable for the chemical recovery by acid extractions.

There is also the problem of securing representative samples, especially in the case of ores, *etc.*, and particularly in the case of gold, which may occur in grains or nuggets. With these materials the use of the assay ton in the classical methods assists in achieving accuracy and precision of recovery. The problem of securing a representative sample of the size required for neutron activation increases the difficulty of obtaining results comparable to those obtained with the classical assay. No satisfactory comparison of results obtained by activation methods and by other established methods has so far appeared, and until one does, the activation methods must in general remain suspect when applied to such problems. Despite the different orders of magnitude of sensitivity, concentration methods can be applied to allow reasonable comparisons to be made when the concentrations of noble metal can be made appropriate to both classical and activation methods. Perhaps the greatest difficulty in making such comparisons lies not in the deficient sensitivities of the more established trace methods, but in ensuring the purity of the reagents used to concentrate the traces. For the determination of microgram and submicrogram traces of noble metals in rocks and ores no analytical procedure or technique yet recorded can be accepted as invariably accurate.

The few recorded results comparing the accuracy of the activation and established methods were not obtained under the conditions necessary to establish relative accuracy. For example, the spectrographic determinations of iridium in the metal phase of chondritic meteorites made by Nichiporuk and Brown[2] gave values that agreed closely with those obtained by Rushbrook, Ehmann *et al.*[3] by neutron activation procedures for other chondrites of known metal content, but both values can only be accepted with the reservation that such spectrographic results also require some confirmation.

It would seem that none of the neutron activation methods proposed for the

determination of the noble metals should be considered invariably applicable to samples of ores containing some of the most resistant types of noble metal minerals. A more extensive knowledge of naturally occurring, mechanically mixed, and dissolved noble metal constituents is needed. Without this knowledge, one cannot with complete assurance provide the standards which must be the basis for achieving accuracy within the theoretical limits of the techniques used.

Fukai and Meinke[4] gave an interesting discussion of the relative sensitivities of neutron activation and specific spectrophotometric methods. Sensitivity for neutron activation methods was defined as "the weight of an element that would produce a measurable amount of radioactivity after it had been irradiated by a given flux of neutrons for a given period of time." The general equation expressing the significant relationships was given as:

$$\frac{\text{activity} \times \text{atomic weight}}{6{\cdot}02 \times 10^{23} \times f \times \theta \times \sigma_{at}\left[1 - \exp\left(\frac{0{\cdot}693t}{t_{1/2}}\right)\right]}.$$

Neglecting the constants, the weight detectable is a function of activity, the cross section (σ_{at}), the flux (f), the half-life ($t_{\frac{1}{2}}$) and the time of irradiation (t). Sensitivity may be improved by a proper selection of these variables and use of suitably sensitive detecting instruments. Tables of sensitivity limits for various isotopes have been recorded, using arbitrarily chosen variables. Fukai and Meinke modified Schindewolf's[5] choice of variables by including a flux of 5×10^{11} neutrons.cm^{-2}.sec^{-1} and compared the sensitivities for noble metals with spectrophotometric data based on Sandell's sensitivity index[6] and a 5-ml volume used for the absorbance measurements. The sensitivities were expressed in weights and not in concentrations. The authors included comparisons on the basis of a sensitivity index defined as the negative logarithm of the sensitivity expressed in weight. The following results were recorded (the index for neutron activation is given in brackets): for osmium determined by thiourea 4·7 (7·4); for ruthenium by thiourea 6·0 (7·6); for rhodium by tin(II) chloride 5·7 (7·6); for iridium as chloroiridate 4·7 (9·7); for palladium by nitrosodiphenylamine, 6·3 (8·6); for platinum by tin(II) chloride 4·7 (7·7); for gold by rhodamine 6·7 (9·2). Although these figures are subject to variations depending on the choice of techniques or significant variables, the neutron activation methods seem to be more sensitive by 1 or 2 orders of magnitude. The activation sensitivities may be increased by irradiation for longer periods and by the use of higher neutron fluxes.

Jenkins and Smales[7] gave a table of estimated sensitivities for noble metals and other elements, based on an assumed irradiation with a flux of 10^{12} neutrons.cm^{-2}.sec^{-1} for 1 month followed by a 2-hr decay during which radiochemical purification is made with a quantitative yield. In the case of the noble metals, for which no procedures giving a quantitative yield have been recorded, the sensitivities provide only a guide for comparison with other trace methods. For 2·7 d gold-198 the estimated sensitivity 5×10^{-12} g; for 4·5 hr ruthenium-105, 1×10^{-9}; for 31 hr osmium-193, 1×10^{-9}; for 4·3 min rhodium-104m/rhodium-104, 5×10^{-3}; for 19 hr iridium-194, 1×10^{-11} for 18 hr platinum-197 with platinum-199, 1×10^{-9}. It must be emphasized that these sensitivities are theoretically derived and are seldom realized in the determination of noble metals because of interference from associated traces and radioactive phenomena. Jenkins and Smales state that the coefficient of variation normally

obtained at these sensitivities should be $<10\%$ for single determinations, and at higher concentrations might be only 1%. As with other methods the precision increases with an increase in the proportion of the trace element, and is affected by the background, which may be a composite effect of contaminants and the intrinsic background of the counting assembly.

Jenkins and Smales state that the method will provide high accuracy "if the activated species passes completely into true solution, without loss by volatility, adsorption, or persistent traces of insoluble residues, and if the dissolved species undergoes complete isotopic exchange with the added carrier." The present authors emphasize that the carrier element must be in the same form as the element to be determined. To achieve this, particularly in the case of ores, the sample and carrier should be thoroughly mixed, and fused or otherwise dissolved completely. Jenkins and Smales stated further that providing acceptable precision is secured, the absolute accuracy of the method depends on the availability of a standard whose composition is known to an accuracy greater than the maximum accuracy of the trace determination and the behaviour of the standard in activation must be exactly the same as that of the trace element to be determined. Though the activation method is less sensitive than spectrophotometric or even spectrographic methods to variations in solution composition or the identities of mechanically mixed constituents, those factors cannot be ignored, particularly in the case of trace determination of noble metals in rocks, ores, alloys etc. Unless adequate precautions have been taken, it should not always be assumed that the effective neutron flux is uniform for both sample and standard. Aside from variations in flux associated with the excitation source, variation in excitation resulting from self-shielding by the constituent being determined or absorption by other constituents must be considered. The essential difficulty here is common to all methods of determining trace constituents in materials such as rocks and is at least partially the result of a lack of knowledge of the identity of the noble metal mineral. However, if a homogeneous distribution of the noble metal constituent can be achieved, and particularly if the analytical chemist has adequate knowledge of the types of minerals probably present, selecting and preparing an activation standard is not difficult.

Each of the conditions for accuracy (mentioned by Jenkins and Smales), may be critical in the determination of traces of noble metals in naturally occurring materials. The problem of loss of platinum metals through volatility is of constant concern in their analysis but strangely has received little attention in the activation methods. Determining the chemical yield does not necessarily compensate for such losses. Obviously, in the preparation of samples for activation, losses resulting from oxide volatilization during heating and dissolution must be minimized particularly in the case of dissolution of osmium and ruthenium. If the noble metal constituent dissolved is not the same in the sample and the standards, an error that is not compensated by the standards can arise from volatilization after activation but before chemical separation.

Sufficient care is not always taken to achieve isotopic homogeneity in the solutions of the samples. Difficulty in achieving homogeneous isotopic distribution can be expected if the identity of the noble metal species extracted from the sample during the dissolution of sample and carrier is not fully known. Errors of this type could be minimized if carriers could be provided that were identical with the noble

metal constituent in the sample. That this inhomogeneity may be a critical factor has been shown for ruthenium*[8] and for fission product solutions[9].

Errors may also arise from incomplete dissolution of rock or alloy samples; residues often remain after acid treatments of ore samples and consist of a silicate or mixed silicates. Many activation methods for the determination of noble metal traces fail to direct attention to these residues, and usually there is the inference that the residue is to be discarded. Because of the ease with which noble metals react with silica to form corrosion-resisting compounds and/or solid solutions it is particularly important that all final residues be incorporated in the solution of the sample or at least be examined for noble metal traces. In the case of rocks, ores, *etc.*, in which such elements as iridium, rhodium, ruthenium and osmium, and silica are present together, particularly if the sample has been subjected to high temperatures, the residue should not be indiscriminately discarded.

A well-trained analytical chemist must find disconcerting the easy acceptance of such processes as hydrolytic precipitation, reduction, *etc.*, which invariably introduce some degree of difficulty into analytical methods and may not be devoid of error despite the device of chemical yield determination. It is not uncommon to find radiochemical methods involving a final precipitation of a noble metal by reduction with zinc or magnesium, or by hydrolytic methods. Such techniques tend to cause accumulation of contamination which is not always detected by the usual methods of determining radioactive purity, and may seriously affect the chemical yield. The analytical techniques normally used to ensure chemical purity are well known and their application is of particular importance in activation methods which give considerably less than quantitative yield.

The following review is arranged to deal collectively with procedures designed for specific materials such as fission product solutions, ores, rocks, silica, minerals, alloys and organic substances. In the case of those materials in which more than one noble metal is determined the discussions are collected under multi-component noble metal systems and again the discussions are arranged to deal with specific materials.

ACTIVATION METHODS APPLIED TO DETERMINE THE EFFICIENCY OF CHEMICAL SEPARATIONS

Neutron activation techniques are particularly useful for examination of the efficiency of analytical treatments of noble metals and for determining the losses and distribution of the noble metals in the various stages of industrial methods for their recovery and purification. Similarly, the techniques, properly arranged and applied, can provide useful information about the distribution of noble metals in the classical assay methods, *e.g.*, Kim *et al.*[10] have discussed the distribution of gold in the classical assay process. The gold content of each of the flux constituents, slags, pot wall, lead buttons and cupels was first determined qualitatively, significant amounts of gold being found only in the ore sample and the lead button. Negligible amounts of gold were found in the cupel area immediately adjacent to the gold bead. The quantitative results for the gold content of the ore sample and the assay button showed that recovery was acceptably complete and that there were negligible losses of gold at the various stages of a fire assay.

It is difficult to find an explanation for the authors' results. The gold values obtained by neutron activation for the lead buttons produced by the fire assay and for the ore sample were in close agreement, which suggests an effective recovery by fire assay. Calculations from the results show for the ore a value of 0·90 troy oz per ton and for the average of the lead buttons 0·89 oz per ton. However, the single value recorded from the fire assay procedure is 0·84 oz per ton. The significance of the

* It should be noted that the ruthenium isotope used was probably ^{106}Ru; ^{110} Ruis not now recognized.

discrepancy is emphasized by the good precision obtained by the activation method for ore and lead samples weighing only 200–600 mg. Obviously there is an appreciable error in either the fire assay results or in the activation results. This problem of effectively comparing the efficiency of the two methods has not yet been solved and without doubt will involve an extensive research programme. In any case, the authors' purpose was not primarily a comparison of the methods but rather to assess the distribution losses, which would not be significantly affected by the discrepancies.

Presumably, the authors failed to recognize that the fire assay loss of gold to slags, cupels, *etc.* may well prove to be a function of such variables as temperature, rate of air flow, type of cupel, *etc.* and that one cannot generalize about losses from specific procedures and assay materials. It should be noted that the fire assay for gold almost invariably involves a cupellation to produce a silver-gold bead and distribution data obtained for formation of a final gold bead need not correspond to those for a silver-gold bead. Nevertheless, the results obtained by Kim *et al.*[10] do show a promising approach to the problem of determining noble metal losses during fire assay procedures.

Kim *et al.* activated 0·2–0·6 g of the various types of samples at $1{\cdot}3 \times 10^{12}$ neutrons.cm^{-2}.sec^{-1} through the pneumatic transfer system and $0{\cdot}7 \times 10^{13}$ neutrons.cm^{-2}.sec^{-1} in a rotary specimen rack. The flux was monitored with gold foils taped to the inner side of the cap of the nylon rabbit. The irradiated samples were fused with sodium peroxide in the presence of carrier gold. The chemical procedure involved extractions with ethyl acetate, back-extraction with ammonia solution and precipitation with hydroquinone; the purity of the gold from samples and standards was checked by half-life measurements.

Losses of gold during the various stages of fire assay were also discussed by Shima[11]. Gold-198 was used as a tracer and activity measurements were made on *aqua regia* extracts from the pot wall, slags, cupels and cupelled beads. To determine the location of the losses to the pot wall and the bone ash cupel Shima used autoradiography with X-ray films. After the assay the pot and cupel were cut into two parts and a thin vinyl membrane was placed between the film and the sample half. A 3-day exposure was used.

It was shown that for the cupel the gold loss was concentrated in the bone ash adjacent to the cupelled bead surface. As stated above, Kim *et al.*[10] found this loss to be negligible. The losses to the pot wall were associated with that part of it in contact with the flux and above the area adajcent to the fused lead button. These findings would, of course, be predicted from the nature of the assay, *e.g.*, one would not expect the complete removal of gold from the wall of a beaker by simply draining an aqueous gold solution. A second cleaning fusion is always required for fire assays if good accuracy is to be obtained. In the case of the cupel loss it is also to be expected that traces of gold will accompany the adsorbed litharge as indicated by Shima's results and it may be hoped that this phase of a fire assay for noble metals will be subjected to a careful examination. Although a variety of phenomena may be associated with the adsorption of gold by the pot wall in contact with fused media, the authors have found no report which deals adequately with this technique despite the commercial significance of the method and the many decades of its application. It is an involved problem and will require a consideration of each of many factors which determine the efficiency of a cupellation.

Shima used ores with high sulphide, high copper and iron, with copper, lead, zinc and silver, and with high silicate contents. For each type the usual fluxes were applied, each containing 30 g of litharge, 2 g of flour and a cover of 12 g of sodium chloride. The iron nail method was used for high-sulphide charges.

No details were given for such essential conditions as methods of sampling and of mixing the tracer and sample, or for temperatures and rates of heating during fusion and cupellation. Shima concluded that of the ores examined, the highest gold losses to the pot wall occurred with samples containing high iron and sulphur with some copper. For the slags, the highest losses occurred with copper ores containing a high sulphur content. With the cupel, presumably the high losses of gold were associated with samples of a high base metal and sulphur content. The author stated that with the iron nail method the results were not conclusive. In general, it was concluded that the losses of gold will vary with the composition of the sample and that cupel losses are higher than losses to the pot wall.

In the present authors' opinion, while the conclusions may well prove to be valid, the techniques and the data described by the author allow only superficial conclusions to be reached, and the failure to recover the added gold quantitatively may be the result of inadequate technique rather than losses by evaporation on fusion and cupellation as suggested by the author.

Extensive researches on fire-assay, solvent extraction and ion-exchange separations of the noble metals were recorded by Beyermann.[12] Radioactive isotopes were used to follow the distribution of the noble metals during the separation processes. This report includes a wide variety of approaches to methods of separation and will be reviewed in a report concerned with methods of separating the noble metals.

The efficiency of various methods for the analytical separation of platinum metals was examined by Lloyd and Morris,[13] by neutron activation techniques. The hydrolytic separation of platinum and the subsequent separation of rhodium from iridium by titanium(III) chloride as described by Gilchrist[14] was compared with the chromotographic method used by Payne.[15]

In reports such as these, it must be assumed that the separations accomplished by the authors are optimum in efficiency for the particular method. Perhaps a greater degree of confidence in such reported results would result from an inclusion of all the quantitative results obtained from the procedures under investigation. Lloyd and Morris[13] used ^{192}Ir as ammonium hexachloroiridate as the tracer and measured the gamma activity. The results given for efficiency of separation are inconclusive and although the measured activity of the iridium recovered suggests quantitative recovery this interpretation would be invalidated if appreciable contamination by rhodium was present. The authors' principal conclusion, for which no evidence is given, seems to be that Payne's method is more rapid than Gilchrist's.

In contrast to this report, in a second paper Lloyd and Morris[16] provided adequate results to establish that platinum could be effectively determined gravimetrically in the presence of iridium, and also gave results for the separation and gravimetric determination of rhodium and iridium.

To precipitate platinum in 10-mg amounts the authors used three methods, in which the precipitants were a solution of mercury(II) chloride and hypophosphorous acid, or solid mercury(I) chloride, or a slurry of mercury(I) chloride. Each method was checked gravimetrically and by the use of iridium-192 tracer, with a final radiometric examination with a gamma-scintillation counter for traces of iridium in the precipitated platinum.

To precipitate rhodium, mercury(I) chloride slurry was added to the solution of rhodium and iridium chlorides, containing potassium bromide. The rhodium precipitate was dissolved by hot hydrochloric acid saturated with bromine. The gravimetric recoveries of rhodium from samples containing 10 mg each of rhodium and iridium were reasonably accurate and the iridium contamination of the rhodium amounted to about 6 μg as determined by counting iridium-192. For the determination of iridium in the filtrate, potassium iodide was added and the mixture was then boiled to produce a precipitate which was then heated to 900°, reduced in hydrogen, and weighed.

Traces of palladium, gold and iridium in residues from the recovery of platinum metals have been determined by neutron activation. Herak and Morris[17] determined microgram and submicrogram quantities of the three elements in 0·5 ml of solution. The procedure involved irradiation of the sample and standards and separation of the activities in the sample. For gold the gamma radiation from gold-198 was used; for palladium the beta radiation from palladium-109 or alternatively the X-rays associated with the equilibrium mixture of silver-109m and palladium-109 could be used; for iridium the gamma rays from iridium-192 were applied. The metals were determined in order of increasing half-life, *e.g.*, palladium 13·6 hr, gold 2·70 d, and iridium 74·4 d. Standards and samples were irradiated for 6 days with a flux of $1{\cdot}2 \times 10^{13}$ neutrons.cm^{-2}.sec^{-1}. The samples were dissolved and milligram amounts of metal standards were added as carriers. Gold was isolated by solvent extraction with isopropyl ether which was first washed with hydrochloric acid and then treated repeatedly with iridium carrier. The final ether extract was evaporated and the gold was precipitated by sulphur dioxide and weighed to determine the chemical yield. The gold from the standards and sample was determined by measuring the intensity of the 0·411 MeV gamma rays Corrections were made for background, chemical yield and for any decay between the times of counting of the precipitates from samples and standards.

For palladium the aqueous phase of the gold-ether extraction was subjected to hydrolysis in the presence of nitrite, to remove the base metals selectively. The palladium and iridium complexes in solution were decomposed with hydrochloric acid, and palladium dimethylglyoximate was separated. This was dissolved and the metal precipitated by hypophosphorous acid. Dissolution of the metal by nitric acid was followed by a silver chloride scavenge and finally palladium dimethylglyoximate was again isolated, and weighed to determine the chemical yield. All counting rates for the glyoximate were corrected for paralysis time, yield, *etc.*, as in the case of gold.

For the isolation of iridium the filtrate resulting from the removal of palladium from the decomposed nitrite complexes was treated to form hydrated iridium dioxide. This was dissolved and iridium was removed by the addition of mercury(I) chloride in the presence of bromide and iodide.[18] The oxide was converted into metal and weighed to determine the chemical yield, then the activity was counted by gamma spectrometry as described previously.[18] In each case, the use of similar weights of samples and standard avoided the need for self-absorption corrections. Presumably there was no interference from any of the nuclides used for measurements. Although the authors did not state the chemical yield their results indicate reasonable precision. It may be noted that contamination of the filtrate from the nitrite separation of base metal could result in erroneous chemical yields of iridium.

METHODS FOR INDIVIDUAL ELEMENTS

Gold

Fission products

To separate gold from associated fission-products Cowan[19] removed oxidizing substances and used sulphosalicylic acid to complex extraneous fission product constituents, and then precipitated gold, including the carrier, by hydrogen iodide in hydrochloric acid solution. Tellurium(VI) was used as a hold-back carrier, its reduction to tellurium(IV) promoting exchange with the active species. The centrifuged gold was washed free from chloride and then treated with nitric acid. The precipitate was dissolved in *aqua regia* and the precipitation and purification steps were repeated. The gold solution was treated with a silver nitrate carrier, the silver chloride removed, and iron(III) chloride was added with enough sodium hydroxide to give a slightly basic medium; prolonged contact in a basic medium promoted loss of hydrated gold oxide. Gold was again precipitated, purified, extracted with ethyl acetate and finally precipitated by hydrogen iodide. The collected gold was washed, dried and weighed on filter paper. Counting of the 2·69 d gold-198 was done in a proportional counter.

Ores

Much research has been done on determination of gold in ores by neutron activation. Bailey and Schuler[20] applied the technique to ores of the Witwatersrand system. The gold values for the ores were compared with values obtained by fire assay; a statistical evaluation resulting from a reconnaissance survey was included.

Standards to simulate the ore samples were prepared by adding known amounts of gold to silica powder, grinding the mixture in a mill, drying, and rolling for 10 days. The gold was added in hydrochloric acid solution or as the cyanide complex. Portions (200 mg) of both sample and standards were irradiated in the neutron pile at Harwell. The chemical separation involved sintering with sodium peroxide and subsequent dissolution in *aqua regia*. About 40 mg of gold foil were added as a carrier and the mixture was treated with *aqua regia* and evaporated, and the residue was dissolved in hydrochloric acid. Silica was removed by centrifugation and hold-back carriers were added to the filtrate. Gold was precipitated by magnesium, then dissolved, and finally isolated with ethyl acetate. Aliquots of the organic layer were used for the determination. Measurements at the 0·41 MeV photopeak of gold-198 reduced the effects of traces of radioactive impurities which could contaminate the isolated gold. To determine the chemical yield an aliquot of the ethyl acetate was treated with hydroquinone to remove the gold, which was subsequently weighed as the ignited metal.

Comparisons of counts from ore samples were made with counts for similar weights of the irradiated standards prepared from a ground mixture of silica and known amounts of gold. The radiochemical purity of the isolated gold was checked by an examination of the half-life and the energy spectrum.

The results obtained from duplicate samples of ore indicated rather poor precision and the authors suggest such sources of error as shielding effects, instrumental deficiencies, adsorption of gold by silica during dissolution procedures, and sampling errors resulting from the need to use small samples for irradiation (instead of the large samples required for fire assay).

It must be noted that in any such comparison of fire assay and a proposed new method for the determination of gold in ores one may claim similarity of values but not accuracy of determination; a statistical or reconnaissance survey to provide fire assay results does not of itself indicate accuracy of gold values. As indicated by the authors[20] there is the difficulty that comparisons of this type with neutron activation methods involve the problem of obtaining a representative sample. Depending on the identity of the mechanically mixed gold constituent, obtaining a representative sample can be the most critical step in a fire assay even with samples of about an assay ton. With the present neutron activation methods for ores, only 0·1–0·2 g of sample are needed and the sampling problem becomes correspondingly more difficult.

It may be noted also that the determination of chemical yield by precipitation from the ethyl acetate extract, used by Bailey and Schuler,[20] requires an effectively quantitative recovery of gold. Furthermore, the technique used to incorporate the gold carrier, particularly in the standards, is likely to lead to loss of precision and accuracy, and this is recognized by these authors. Their results for the gold content of the ores reflect the potential difficulties in the techniques used. There are wide variations in the duplicate values for a specific ore and the standards, as great as 50% for the former and 25% for the latter. One cannot accept the authors' conclusions that "comparable results were obtained" from the proposed method. However, in view of the inherent difficulties, the mean values for each ore are surprisingly similar to the average fire assay values.

Quartz and silicon

For the determination of gold in quartz Vobecký and Knotek[21] used 100–300 g samples and extracted with *aqua regia*. Aliquots of the solution were evaporated, and along with standards were

irradiated for 20 hr with a flux of $1{\cdot}5 \times 10^{13}$ neutrons.cm^{-2}.sec^{-1}. Gold carrier (2 mg) in the form of the chloride was added to the irradiated samples, followed by addition of 2*M* hydrochloric acid and extraction with ether, after which the standard was diluted to a concentration similar to that of the sample. Gamma measurements were made at 0·41 MeV over a period of 20 min. The purity of the counted sample was determined by measuring the half-life, which corresponded to that of gold-198. Extraction from 2*M* acid solution served to eliminate iron, arsenic and tellurium. The use of aliquots of the extracted gold solution meant that the quartz samples could be made large enough to be reasonably representative. The gold content was $7{\cdot}5 \times 10^{-6}$%.

An interesting and potentially useful activation method for the determination of gold, silver, cadmium, tantalum, rhenium and elements of group III of the periodic table, in high purity quartz and organic filter media, was recorded by Gleit *et al.*[22] The research was initiated to determine the minimum blank corrections to be used in a study of concentrations of trace elements in the atmosphere. The techniques applied to eliminate errors of contamination *etc.*, were such that the concentrations measured "may be the lowest ever determined by activation analysis; concentrations of less than 1 ppb* could be measured."

To avoid the dangers incident to exposure of the organic filtering media to irradiation, minimize volatility losses, and eliminate reagent contamination, the ashing process was accomplished by a stream of pure oxygen which had been excited by passage through an inductive field.

Gold standards were prepared by dissolving the metal in pure acids and diluting with conductivity water to give about 40 μg of gold/ml. Redistilled hydrochloric acid was used to convert the gold carrier into the complex salt. The standards, samples and blank quartz tubes were wrapped in quartz wool, transferred to aluminium cylinders, and irradiated for 4 days at an equivalent thermal neutron flux of 5×10^{13} neutrons.cm^{-2}.sec^{-1}. The capsules were then opened and the contents dissolved along with 20 mg of carrier. The chemical treatment involved a series of separations to isolate the gold, which was then purified by a method similar to that described by Cowan.[19] The activities of the 2·7 d gold-198 and the 3·18 d gold-199 were counted. The activities for the gold isotopes were separated by mathematical resolution of the two-component decay curve. Chemical yields were determined from gravimetric measurements of the recovered stable gold carrier. The relative error was considered to be less than 10%. The two principal sources of contamination were activities produced by activation of stable species in the quartz ampoules, and fission products arising from fissile species in the samples and ampoules. "Suprasil" ampoules were simultaneously irradiated and treated in the same way as the filtering media. Only a small fraction of the total gold activity was derived from the quartz ampoules. It is interesting that the authors suggest that a 30-fold variation in the gold values indicated the existence of particulate concentrations in the filtering media.

For the determination of gold and other impurities in silicon, James and Richards[23] used carriers to remove the commonly occurring impurities, scavenged with iron or aluminium hydroxide and arranged to produce a final precipitate of low formula weight in order to avoid excessive self-absorption and thus to increase the sensitivity. It is noteworthy that the authors preferred to use gravimetric methods even though 100% recovery was unnecessary. The results indicated gold values as low as 5×10^{-6} ppm.

There is interest in the work of Bemski and Struthers[24] who used activation methods to find that gold was introduced onto the surface of silicon during heat treatment at temperatures above 900° with a resulting change of the electrical characteristics of the silicon. Concentrations of 10^{14} atom/cm^3 in the bulk material were attained by heat treatment over the range 1100°–1300°. To confirm the conclusions based on the half-life and energy measurements, the authors used radiochemical separation with inactive carriers.

For the routine determination of some 40 elements including gold and platinum in ultra-pure silicon, Thompson *et al.*[25] used gamma-spectrometric and radiochemical methods. For gold the traces were of the order of 5×10^{-5} to 4×10^{-4} ppm and for platinum 9×10^{-4} to 2×10^{-3} ppm.

For the determination of gold in various siliceous raw materials by neutron activation Stefanov *et al.*[26] irradiated 0·05–0·5 g samples and standards for 3 hr at a flux of $2{\cdot}4 \times 10^{13}$ neutrons.cm^{-2}.sec^{-1}. The standards were prepared by adding gold solution to a filter paper and drying it under an infrared lamp. After irradiation the samples and standards were allowed to cool for 24 hr and those samples which resisted acid dissolution were dissolved with the aid of sodium peroxide. Carrier gold was added and nitric acid was removed by sulphuric acid. The dried sulphates were then treated with hold-back solutions of copper, sodium and potassium, or cobalt, zinc and manganese. The basic solution was centrifuged and the gold in the liquid extract was isolated with ethyl acetate. Finally, the organic layer was evaporated in the presence of hold-back carriers and gold was removed by hydroquinone. The filter paper with the gold was dried to constant weight under an infrared lamp.

With some modification the standards were similarly treated. Both the beta and gamma activities of the gold-198 were measured 30 hr after irradiation. The chemical yield for the sample was 45–75%

* This is the American billion, 10^9

and for the standards 94–95%. In view of the methods of separation used it would be interesting to have an explanation for the large discrepancies between the recoveries for the standards and samples.

The authors included a table in which the gold values obtained by an unstated chemical method were compared with the results from activation analysis. For the low values these were respectively $1{\cdot}1 \times 10^{-6}$ and $0{\cdot}87 \times 10^{-6}$ g and for the highest values $25{\cdot}4 \times 10^{-6}$ and $22{\cdot}75 \times 10^{-6}$ g. The associated impurities in the original samples were lead, zinc, copper, arsenic, manganese, silver, sodium, iron and magnesium. The purity of the separated gold was determined by decay measurements. To determine the sensitivity, samples were used in which no gold could be detected by either spectral or chemical methods. On a basis of a minimum count of 100 cpm and a background count of 50 cpm a sensitivity of $2{\cdot}8 \times 10^{-10}$ g of gold was expected. The error of measurements was about 24%.

For the determination of gold in dehydroceramics or lithium, potassium, aluminium silicates that had been neutron activated, Kudo[27] used a chemical separation which involved adjustment of the gold-198 solution to pH 3, reduction by hydrazine sulphate and the addition of *p*-dimethylaminobenzylidenerhodanine as a collector. The mixed precipitate was centrifuged and dissolved in *aqua regia*, and an aliquot of the solution was used for activity measurement with a gamma-ray spectrometer. More than 95% of 10 μg of gold could be removed along with silver and some copper. Zinc, EDTA or hydrogen fluoride did not interfere.

Gold in siliceous and cellulose acetate residues has been determined by measuring the gamma spectral peak at 0·41 MeV. Irradiation for 3 hr with a flux of 5×10^{11} neutrons.cm^{-2}.sec^{-1} was used with pure gold samples to obtain the calibration and gamma spectrum curves. The method was sensitive to 10^{-5}% of gold,[28] thus exceeding spectrographic and colorimetric methods in sensitivity by 2 orders of magnitude.

Rocks

In a study of the neutron activation methods for gold in rocks, Vincent and Crocket[29] disagreed with the assumption made by Vincent and Smales[30] and Goldberg and Brown[31] that errors due to self-shielding in the 5-mg fragments of gold foil (0·002 in. thick), irradiated as standards along with the rock samples, could be neglected.

Vincent and Crocket found that gross errors were introduced unless very small amounts of gold were irradiated as standards; their results showed that an evaporated acid solution containing a few micrograms of gold gave a specific activity some 37% higher than a gold foil 0·002 in. thick irradiated simultaneously at a flux of 10^{11} neutrons.cm^{-2}.sec^{-1}. The authors found no appreciable variation in activity with standards whose gold content did not exceed 10 μg. The standards were prepared by evaporating the strongly acid gold solutions in silica ampoules. It was assumed that in the rocks and mineral samples the traces of gold were so uniformly distributed that errors resulting from self-shielding were inappreciable; this conclusion found some support in the precision obtained with duplicate samples of widely differing weights. Errors resulting from the presence of platinum, which on irradiation could produce gold-199 with a half-life of 3·15 d, were considered unlikely.

Activation methods were used by De Grazia and Haskin[32] for the determination of gold in rocks in concentrations varying from 0·6 to 44 ppb*. About 0·3 μg of gold was detected. The procedure used was a modification of that proposed by Vincent and Smales.[30] Samples of 0·7–2·0 g obtained from ground portions weighing 15–20 g were irradiated at a flux of 5×10^{10} neutrons.cm^{-2}.sec^{-1} for 6–8 hr. Standards consisted of 1*M* hydrochloric acid containing 50 μg of gold and were irradiated along with the rock samples. The latter were then mixed with weighed gold powder, the mixtures fused in zirconium crucibles with sodium peroxide, and the melts dissolved in hydrochloric acid. Insolubles were discarded, presumably without examination. Ethyl acetate was used to extract the gold which was finally converted into metal. Standards were combined with gold carrier and treated in the same way. Chemical yields exceeded 85%. Counting was restricted to the 0·41 MeV peak of 2·69 d gold-198 by window adjustment, thus discriminating against the peaks at 0·208 and 0·158 MeV of gold-199 produced from the 30 min platinum-199. The authors acknowledged the difficulty in defining the error resulting from sampling difficulties for metals, such as gold, which sometimes occur in minute nuggets non-uniformly distributed throughout the sample.

For the determination of gold in ores without a radiochemical treatment Lobanov *et al.*[33] roasted the samples at 700–900° to eliminate the influence of the activated isotopes of associated volatile constituents. Gold in amounts of 0·1 g per ton could be determined and the average error was ±12%. Neutron activation methods for gold in igneous and sedimentary rocks were used by Perezhogin *et al.*[34] Samples (30 mg), packed in aluminium foil, were irradiated for 6 hr at a flux of $8{\cdot}7 \times 10^{14}$ neutrons.cm^{-2}.sec^{-1}. For increased selectivity the samples were irradiated in a cadmium block. The samples were dissolved in hydrofluoric, nitric and sulphuric acids and aliquots were used for the activity measurements.

* American billion (10^9)

Minerals

Mineral samples containing as little as 5×10^{-5}% of gold were used by Dvukhbabnaya *et al.*[35] whose method required no radiochemical separation. An error of 10% or less was achieved on the basis of the spectrum line at 0·41 MeV, provided the Compton background from sodium, arsenic and iron isotopes was less than the activity of the gold-198 peak. One hundred samples could be analysed simultaneously; a method for rhenium was also included.

In the determination of 5–10 ppm of gold in smaltite, Gauthier[36] activated 1-g samples of the mineral or of the mineral plus 10–15 μg of gold (as the chloride or as an ethyl acetate solution). The irradiated samples were combined with about 20 mg of carrier gold and treated with *aqua regia*. The filtered solution was treated with hydroquinone, the gold redissolved, and a second precipitation made; the gold was washed and weighed and its activity at 0·41 MeV was counted with a scintillation counter. Counting of the 0·97 MeV beta-rays was also possible but the former procedure was preferred. With a sample of smaltite the values found were 6·4 and 6·2 ppm, compared to 5·7 ppm by an unstated chemical method.

It may be suggested that the authors' method of mixing carrier and samples does not ensure homogeneity. Furthermore, it appears that the filtered residue was not examined for the presence of gold.

Meteorites

A radiometric determination of gold and rhenium in meteorites was used by Goldberg and Brown.[31] Measurements were made with the 2·7 d gold-198. Samples of the meteorites and gold standards were irradiated in the Argonne heavy-water pile, then dissolved in *aqua regia*; known amounts of gold carrier were added and, in the case of the meteorites only, gold was extracted with ethyl acetate and finally precipitated by hydroquinone. With the standard samples only the hydroquinone precipitation was applied. The ignited gold was weighed and the activity counted. The chemical yield averaged 75%. The effect of self-shadowing of samples and standards was examined. The gold content determined for two meteorite types varied widely from values previously recorded in the literature.

The published procedures for meteorites used by Goldberg and Brown were discussed by Vincent and Smales.[80] Vincent and Crocket[39] applied the method to the determination of gold in basalts, dunites and chondritic meteorites. The results showed excellent precision for concentrations of gold as low as 10^{-3} ppm.

Sea water

Gold in sea water containing as little as 3 to 5 μg/m^3 has been determined by neutron activation techniques. Hummel[37] believed that this sensitivity for the method could be increased further by a reduction in the values for blanks. Samples of sea water, and standards along with blank silica tubes were irradiated for 2–6 days and then left for 2 or 3 days to allow the activity to fall to a suitable working level. The irradiated sea water samples were transferred to beakers, standard carrier gold solution was added and the gold was isolated by repeated alternation of the solvent extraction with ethyl acetate and precipitation by hydroquinone described by Goldberg and Brown.[31] Finally the gold was weighed and counted. The irradiated standard gold solutions were similarly treated. The activities of the sea water samples were corrected for the mean activities of the tubes (about 7% of the sea water activities) and for coincidence, background, and chemical yield, the latter varying between 60 and 80%. The purity of the precipitated gold was examined by measuring 6–7 half-lives and indicated that only the 2·69 d isotope was present. The author was very careful in avoiding contamination. Presumably his use of neutron activation for the determination of gold in sea water was prompted by "the wide variations and uncertainties in much previous work, owing almost certainly to the difficulties inherent in the classical methods when extended to their lower limits." From the descriptions of the earlier analytical methods used it would seem that the choices of "classical methods" were, in general, unfortunate. The separational techniques now available do permit the application of conventional and proved methods of determination. Recently,[37a] anion-exchange separations for gold in sea water have been applied which allow determination of about 9 μg per ton of water with a concentration factor of about 2×10^7. In the light of the present uncertainties about the character or identity of the dissolved gold constituents, geological influence on gold content, and variations in gold content, it would seem that there is here a fertile field of investigation requiring both conventional and neutron activation methods of determination.

Organic material

Neutron activation determinations of gold in marine organisms have been reported.[38] For contents of 0·003–0·093 ppm the probable error was about ± 30%. About 500 mg of biological ash

and standards containing 7×10^{-9} to $2{\cdot}4 \times 10^{-7}$ g of gold in solution were added to filter paper, dried, and irradiated by a neutron flux of $2{\cdot}5 \times 10^{12}$ neutrons.cm^{-2}.sec^{-1} for 14·1 hr. The samples were cooled for about 5 days and gold was isolated by extraction with ethyl acetate and finally precipitated by sulphur dioxide. The gamma activity of gold-198 was measured at the 0·41 MeV photopeak. For standardization the activities were normalized to 10 hr radiation at a neutron flux of 1×10^{12} neutrons.cm^{-2}.sec^{-1}.

Neutron activation methods were also used by Fukai and Meinke[39] for the determination of gold, *etc.*, in marine biological ashes. The authors suggested the possibility of some loss during the ignition processes but presumably no direct measurement of any ignition loss was made. The maximum overall errors were estimated as ±30%.

Gibbons[40] recorded two neutron activation methods for the determination of gold in biological material. The rapid method, recommended when an error of 5–10% was acceptable, involving precipitation by magnesium, dissolution of the precipitate, addition of sodium chloride and ammonium phosphate as hold-back carriers, and finally precipitation by hydroquinone. The gold activity was determined by plotting a gamma-energy spectrum and measuring the area under the peak at 0·41 MeV, taking the extrapolated Compton response as the base line.

The second, less rapid, method involved cooling the irradiated sample for 24 hr, addition of carrier gold solution, treatment with acids to remove organic matter, addition of the hold-back carriers, precipitation by magnesium, extraction with ethyl acetate, three precipitations with hydroquinone, and drying the gold to constant weight. The irradiated standard gold solution was finally precipitated by hydroquinone. The method applied to liver containing 0·010–1 ppm of gold gave an error of about 2%.

The application of neutron activation to determining the distribution of gold in various animal tissues was discussed by Tobias and Dunn.[41] Ten μg of gold in the form of thiosulphate were injected into the tail vein of a mouse. Subsequently samples of various organs and tissues were wet-ashed and irradiated, after which the sample was dissolved in *aqua regia*, aliquots were treated with carrier, and the gold was separated by precipitation as metal. The activity of gold-198 was determined after electroplating on platinum discs. In determining the distribution the authors used a monitoring sample prepared by simultaneously irradiating a sample of gold chloride. The authors predicted useful applications of the technique in biochemistry, plant nutrition, pharmacology and toxicology.

Activation methods were also used by Tobias and Dunn[41] to determine the distribution of gold in human blood from leukemia patients. The blood was fractionated into plasma, and white and red cells, the ashes of which were irradiated. Only 10 ml of blood were required for the determination of gold in the white cells, whose total volume in the body was calculated to contain 14 μg of gold. Approaches to associated medical problems were clearly indicated by the finding that the relative activity induced in the white cells per mg of dry ash was about 10 times as high as that for red cells and 50 times as high as that for plasma.

For the determination of gold in blood, Purser *et al.*[42] added the sample to filter paper which was then activated in a flux of 10^{12} neutrons.cm^{-2}.sec^{-1} for 4 days. Activity measurements were made after about 6 days (to allow the decay of sodium activity). The samples were counted on a wide channel (12–32 V) and the phosphorus-32 background activity, which was relatively constant from sample to sample, was estimated from 10–15 samples that contained no gold.

For the determination of gold in liver tissue, Raković[43] evaluated the method by adding 1 μg of gold to the organic tissues. These and standard gold samples, in which gold was deposited on filter paper, were irradiated for 48 hr at a flux of $1{\cdot}5 \times 10^{12}$ neutrons.cm^{-2}.sec^{-1}. After irradiation the samples were mixed with 60 mg of gold carrier, and 30% hydrogen peroxide, sulphuric, nitric and perchloric acids were added to destroy organic matter. *Aqua regia* was used to dissolve the gold, the salt was converted into chloride, and then dilute sulphuric acid and a hold-back carrier containing potassium and sodium chlorides and phosphates were added. Finally the gold was precipitated twice with oxalic acid, heated and weighed to determine the yield, and then beta-counted with an end-window Geiger-Mueller tube. The chemical yield for 6 samples each containing 1 μg of active gold varied from about 21 to 30%. This low yield could be expected with oxalic acid as the reductant. The weighed gold was found to be radiochemically pure. The impurities in the irradiated organic samples to which no gold was added produced 0·09–0·26% of the count rate measured for 1 mg of gold. The sensitivity of the method is limited primarily by the impurities. The author's results indicated that with 10^{-7} g of gold a precision of 5% could be achieved.

Vacik and Christian[44] recorded an activation method for determining 20–250 μg of gold per g of biological samples, which required no chemical separations and allowed direct qualitative and quantitative gamma-ray measurements. Samples and standards, the latter containing known amounts of gold chloride or gold thioglucose and liver tissue, were irradiated for 1 hr at a flux of 2×10^{9} neutrons.cm^{-2}.sec^{-1} and the activity was measured, after 12 hr decay, at the 0·41 MeV peak of gold-198 with a 3-V window. The potential interferences from the 15 hr sodium and from other

constituents normally found after tissue activation were avoided by the 12-hr cooling period and comparisons with standards indicated that only gold-198 provided the measured activity. The authors stated that by increasing the flux or the period of exposure the sensitivity could be increased to 1 μg of gold.

Alloys and metals

Copper. Nakai *et al.*[45] determined gold, manganese and sodium in copper metal. Irradiations of 200 mg of sample and standards were made with a flux of 3×10^{11} neutrons.cm^{-2}.sec^{-1} for 2 hr. The sample was dissolved and gold was extracted from the chloride solution with ethyl acetate. Copper and manganese were removed as sulphides and sodium was collected in the filtrate. For the determination the author used the gamma spectra of gold-198, manganese-56, and sodium-24.

To determine gold in electrolytic copper, Hirano *et al.*[46] separated copper before irradiation, to eliminate the radioactivity of copper-64. Gold was retained on an anion-exchange column of Amberlite IRA-400 and the resin was irradiated together with standards for 4–5 hr with a flux of 4×10^{11} neutrons.cm^{-2}.sec^{-1}. The residue was ashed and the gold-198 extracted with ethyl acetate and measured by gamma-ray spectroscopy. Correction for losses was considered unnecessary and good precision was obtained at the 0·01 ppm level.

Gold was determined non-destructively in copper-gold mixtures by Okada and Kamemoto.[47] In contrast to the flux of 2×10^{8} neutrons.cm^{-2}.sec^{-1} used by Anders[48] the authors used a flux of 3×10^{11} neutrons.cm^{-2}.sec^{-1}. Samples (12 mg) of mixtures containing about 90% copper and 10% gold were irradiated for 4·5 sec, cooled for 5 sec, counted for 5 sec, again cooled for 1 sec and counted for 5 sec. A sodium iodide scintillation detector and multichannel analyser were used to measure the 0·279 MeV gamma rays. Beta rays from the sample were absorbed by an aluminium disc. The active isotope was identified as gold-197m.

An extensive neutron activation analysis of the trace constituents in high purity copper was described by Cuypers.[49] Silver and nitric acid were removed successively, selenium was added, gold was reduced by hydrazine hydrochloride and carried down by the selenium. The gamma activity of gold-198 at 0·411 MeV was then measured.

Lead. Traces of gold and arsenic in high purity lead were determined by Hirano *et al.*[50] by irradiation in a flux of 7×10^{11} neutrons.cm^{-2}.sec^{-1} for 7 hr. The subsequent chemical separation involved addition of carriers, precipitation of lead sulphate, extraction of gold by ethyl acetate, distillation of arsenic and reduction of gold and arsenic. Chemical yields varied between 60 and 100%. The purity of precipitates was checked by measuring the decay rate and the maximum energy of the emitted beta particles. The error was stated as $\pm 10\%$.

Lead, bismuth, copper and zinc. Substoichiometric methods for the determination of traces of gold in lead, bismuth, copper and zinc were used by Alimarin and Perezhogin.[50a] The aurate ion in a wide range of mineral acid concentrations formed chloroform-soluble precipitates with tetraphenylarsonium chloride. The various coextracted elements, which included osmium in concentrations comparable to those of gold, did not interfere. There was no interference from up to 1 g of the primary base metals. The test samples, properly cleaned, together with standards of about 1 μg of gold deposited on filter paper, were irradiated for 20 hr at $8·7 \times 10^{12}$ neutrons.cm^{-2}.sec^{-1}, and cooled for 1 day for lead and bismuth, and 6–7 days for copper and zinc. Bismuth, copper and zinc in the presence of gold carrier were dissolved in nitric and hydrochloric acids. Lead with gold carrier was dissolved in nitric acid, hydrochloric acid was added and lead chloride was filtered off after an evaporation and addition of hydrochloric acid. The acid solutions of the base metals were evaporated almost to dryness, hydrochloric acid and 1 ml of 0·003*M* tetraphenylarsonium chloride were added and the whole shaken with 2 ml of purified chloroform. The extract was centrifuged and 1·5-ml aliquots were used for activity measurements of gold-198 at 0·41 MeV. The irradiated gold standards were dissolved in *aqua regia*, then an aliquot containing about 1×10^{-8} g of gold was mixed with carrier, and the tetraphenylarsonium chloroaurate was extracted with 2 ml of chloroform and the rest of the procedure used for the sample was applied. The authors were able to determine 5×10^{-11} g of gold with an error of $\pm 5\%$.

Beryllium. For the determination of gold and other trace impurities in beryllium, Negina and Zamyatnina[51] used extraction from hydrochloric acid solutions with diethyldithiocarbamate in chloroform. The extract was evaporated and the dry residue was dissolved in hydrochloric acid and treated to form sulphides which were then dissolved in hydrogen peroxide and concentrated hydrochloric acid. Gold was then isolated with diethyl ether. The test element and standard were prepared in the same gravimetric form and placed on the targets used for measurement. Standardizing the amounts on the target and the measuring conditions avoided the need for self-absorption and self-scattering corrections. Decay curves were used to indicate radioactive purity.

Platinum. Traces of gold in platinum have been determined by neutron activation techniques.[52] Samples and standards, the latter containing added gold, were irradiated for 2·5 hr with a neutron

flux of 8×10^{11} neutrons.cm^{-2}.sec^{-1}. The activity of gold-198 was measured by a discriminating gamma-counting method which avoided measuring the activity of gold-199 produced simultaneously by the reactions ^{198}Au(n, γ) ^{199}Au and ^{198}Pt(n, γ) ^{199}Pt $\xrightarrow{\beta^-}$ ^{199}Au. Interference from gold-198 produced from plantinum-196 could be neglected under the conditions used for the method. The transferred irradiated samples and standards were treated with carrier gold and *aqua regia*. The gold was extracted with ether, precipitated by hydroquinone, redissolved, extracted with ethyl acetate, finally precipitated by hydroquinone and weighed, and its activity was then counted.

The counting rates were corrected for background, for any significant decay between counting the samples and standards, and for chemical yield, which was about 75%. The gamma-ray spectrum of the precipitated gold indicated the absence of interference from gold-199. Decay measurements showed that only the activity of gold-198 was being measured. The gold content of various platinum samples ranged from 0·6 to 3·6 ppm. It was stated by the authors that the full sensitivity for gold is not realised in determinations in platinum, because of nuclear complications, but as little as 0·1 ppm of gold could be determined by their method, giving about 50 cpm above the background count.

Impurities in gold

For the determination of traces of cobalt, copper, tellurium, arsenic and antimony in gold, Yakovlev *et al.*[53] irradiated 200-mg samples and standards in a neutron flux of 5×10^{12} neutrons.cm^{-2}.sec^{-1} for 48 hr. Carriers were added, the samples were dissolved in *aqua regia*, and gold and tellurium were precipitated by sulphur dioxide and hydrazine. The precipitate was treated with concentrated nitric acid, gold was extracted by ether from 8*M* hydrochloric acid, and finally precipitated by hydroquinone. Details were given for the determination of impurities in the concentration range of about 10^{-5}–10^{-6}%. The error was ±10–15%.

Neutron activation methods were used by Yajima *et al.*[54] to determine trace impurities of copper, arsenic and antimony in gold and silver. Irradiation was made in a flux of 3×10^{11} neutrons.cm^{-2}.sec^{-1} for 1 or 3 days. The irradiated gold was dissolved in *aqua regia* and extracted with ethyl acetate. The nuclides measured were palladium-109, copper-64, arsenic-76, antimony-122 and gold-198.

General methods for gold

The relatively new and potentially useful technique of substoichiometric extraction for determination of gold traces was recorded by Beardsley *et al.*[55] Gold solutions in sulphuric or hydrochloric acid were treated with an known constant amount of copper diethyldithiocarbamate that was insufficient for a complete replacement of the copper in the complex by gold. The gold complex was then extracted with chloroform and the activity of a measured aliquot of the chloroform extract from the test sample was compared with that of the same amount of extract from a standard, both samples and standards containing carrier gold labelled with gold-198.

Methods such as these can be applied to avoid extensive radiochemical separation and can be highly selective provided appropriate extraction systems are available.

The method will be useful for determinations made on materials whose compositions are known with some certainty. On the other hand, at least as far as gold in ores, rocks, *etc.*, is concerned, there will be the problem of some uncertainty as to the presence of constituents which are potentially interfering. Although it is easy to find what the composition is by spectrochemical techniques, it is doubtful whether substoichiometric methods, as presently proposed, provide any significant advantages over the very simple radiochemical separation available for gold in complex ore materials.

The authors investigated interference by a variety of associated metals and of the acid media normally required for dissolution of samples, either indirectly by detection of any depression of the gold activity of the extract caused by the addition of various metal ions to the test solution, or directly by adding microgram or submicrogram amounts of radioisotopes of the ions concerned. There was interference from palladium and tin, that of the latter being avoided in the proposed procedure by the use of hydrogen peroxide.

It is unfortunate that the techniques used to identify interfering constituents did not include investigation of the dissolution processes. One cannot assume that foreign constituents added after dissolution would form the same species as they would if added before the dissolution procedure. While it may seem unlikely that there would be an adverse effect on the extraction procedure, experience with similar influences in spectrophotometric techniques sounds a warning note.

It is of interest to note that platinum was coextracted with gold, but presumably by a different mechanism. In any case, except for a very small contribution from the 0·28 MeV gamma ray of platinum-197, interference can be avoided. The authors investigated the effects of acidity, time required for extraction equilibria, and variations in proportions of gold carrier solutions. The permissible range of acidity was 0·01–10*N* sulphuric or hydrochloric acid and reaction equilibrium was reached within 20 sec. Dissolution procedures were provided for biological material, lead, silicon and rocks. Losses of gold during dissolution were investigated using a non-irradiated matrix

and a known amount of active gold. The losses for silicon, lead and kale were 6, 4 and 6% respectively.

Emery and Leddicotte[56] have discussed the analytical chemistry of gold, counting techniques, safety practices, *etc.*, and have given a collection of detailed radiochemical procedures. This report is a useful compilation of the carrier-free and carrier-separation techniques, types of nuclear bombardment, types of material analysed, separation time, and evaluations of the usefulness of the procedures for freeing radioactive gold isotopes from contamination with other radioactive species. The authors note that for the determination of gold in biological material the procedures of Tobias and Dunn[41] and of Gibbons[40] are usually applied, and for the analysis of meteoritic material the procedures proposed by Goldberg and Brown[51] and by Smales[57] are frequently used.

An interesting application of radioactive gold to analytical techniques was described by Pompowski and Szponar.[58] These authors used gold-198 to study migration phenomena in paper electrophoresis and chromatography. The results indicated that planimetry wax was not suitable for quantitative work.

Uranium. Abrao[59] used activation methods for the simultaneous determination of gold and uranium, over the range 18–23 ppm of gold.

The application of a neutron activation method for gold in diamond was recorded by Freedman.[60] After irradiation with a pile neutron source for 8 hr 1–2 μg of gold were found in a 100-mg sample of diamond. Its presence as a surface contaminant was discounted.

Ruthenium

It has been stated in reports dealing with the determination of osmium or ruthenium in submicrogram amounts that only neutron activation methods are sufficiently sensitivite. It may be that this attitude, which is without validity, has discouraged attempts to establish the accuracy of the activation methods. Although some comparisons have been made with spectrochemical methods, these comparisons are not valid unless the accuracy of the spectrochemical methods has also been proven. The spectrochemical methods are not the only established methods available for such comparisons.

Platinum

Killick and Morris[61] recorded a method of determining traces of ruthenium in platinum by a neutron-activation method together with the comments that with the samples used, no ruthenium could be detected by emission spectrographic analysis and that the limits of sensitivity exceeded those of most other analytical methods. These statements leave the inference that other analytical methods are inapplicable to the range of 1–2 ppm of ruthenium to which the authors applied their method. Both osmium and ruthenium can be so easily concentrated by distillation or solvent extraction that the sensitivities of most spectrophotometric reagents for them lie within the range of most published activation methods and there is thus available a most effective method of evaluating the relative accuracy of activation methods.

Killick and Morris[61] used thermal neutrons to activate samples of platinum together with standards made by adding powdered platinum to standard ruthenium solutions and evaporating to dryness. After activation the samples were dissolved in concentrated hydrochloric acid together with ruthenium carrier prepared from ruthenium(III) chloride. Nitric acid was added, and after dissolution was complete and nitric acid had been removed by evaporation, the hydrochloric acid solution was treated with osmium carrier, fumed with sulphuric acid, treated successively with potassium permanganate, iron(II) ammonium sulphate, nitric acid and then carbon tetrachloride to extract the osmium. The ruthenium in the aqueous phase was oxidized by silver(II) oxide and the octavalent oxide was extracted with carbon tetrachloride and back-extracted into sodium hydroxide and dithionite solution. A gold salt was added as a scavenger and ruthenium was finally precipitated as the hydrated oxide by methanol, and the activity of this form was counted. The chemical yield was determined by dissolving the ruthenium oxide, quantitatively oxidizing, and finally measuring the absorbance as for the carrier solution. The radiochemical purity of the ruthenium was checked by the usual methods. Counting rates were corrected for paralysis, background, chemical yield, and any significant decay differences between samples and standards. Interferences from the radionuclides content ranged from 0·83 to 1·96 ppm.

A method of distillation of carrier-free ruthenium by oxidation with lead(IV) oxide instead of peroxysulphate was described by Kanbara *et al.*[62] The tetroxide was collected in an aqueous solution of small amounts of nitric acid and hydrogen peroxide. The ruthenium in the distillate was coprecipitated with iron(III) hydroxide. The lead oxide was considered a more effective oxidant than peroxysulphate or permanganate.

Sea water

Radio-ruthenium in effluent and sea water was determined by Loveridge and Thomas[63] on aliquots of one litre. The procedure involved addition of ruthenium carrier, potassium peroxysulphate, potassium hydroxide, and potassium periodate. Radiochemical exchange was achieved

by heating at or near the boiling point for a few min. The resulting solution was cooled and slightly acidified, and the tetroxide was extracted by carbon tetrachloride. Methanol was used to precipitate ruthenium oxides from the organic phase. These were washed and transferred to an aluminium tray and beta-counted. The oxides were then dissolved in alkaline periodate and the chemical yield determined spectrophotometrically. The carrier solution was prepared from ruthenium trichloride by precipitation with methanol from a solution containing sodium hydroxide and potassium peroxysulphate, and re-dissolved in the latter media. The effectiveness of recovery from sea water and effluent was tested with ruthenium-106 tracer; overall recovery of 99% ± 2·5%, corrected for the chemical yield of the added carrier, was obtained. The efficiency of the chemical method of separation used by the authors may be measured by the recovery of the carrier. By weight the recoveries varied from 72 to 87%; by spectrophotometric measurements the range was 70–83%. The extent of interference from other possible fission products was acceptably small. Improved purity could be achieved by dissolution of the ruthenium oxide precipitate and treatment with a zirconium carrier.[64]

For the analysis of the effluent and of sea water the beta activity of the isotopic pair, ^{106}Ru-^{106}Rh was used as the reference standard and other Ru-Rh pairs were counted as if they were this pair. However, the weak beta particles of ruthenium-106 were screened by the use of a thin aluminium absorber, which restricted the beta counts to those of rhodium-106. The thin ruthenium oxide source caused little absorption of the rhodium activity and the results indicated that no correction for back-scatter was required.

Fission products

To determine ruthenium activity in a solution of the fission products of irradiated plutonium, Meadows and Matlock[9] took an aliquot of the solution in a separatory funnel, added ruthenium and zirconium carriers, concentrated sodium hydroxide solution, a solution of sodium hypochlorite, and hydrochloric acid to a pH of 4, and finally extracted the ruthenium tetroxide with re-distilled carbon tetrachloride. After an aqueous wash, the ruthenium was back-extracted from the carbon tetrachloride with sodium hydroxide solution containing sodium bisulphite. Ruthenium was precipitated from an aliquot of the alkaline solution by ethanol and filtered, and the activity was finally counted. The carrier ruthenium used in the method was standardized by precipitation with magnesium powder, and used for the spectrophotometric calibration curve needed for determination of the chemical yield. Because the fission-product ruthenium was not oxidized as rapidly as the carrier-ruthenium the isotopic exchange, after oxidation by the hypochlorite, was encouraged by allowing 1 hr for the oxidation. As might be expected there was some evidence of loss of ruthenium tetroxide immediately following the adjustment of acidity before the extraction.

The authors stated that "as in other radiochemical methods, 100% yield is not required so long as the yield of each sample is measured and the count rate is corrected for that yield." While this statement is acceptable with reservations, some of which were discussed in the introduction to this review, the authors' failure to recognize the significance of their technique is noted. The method used by the authors for determining the chemical yield does require an analytically complete recovery of the ruthenium by ethanol. This condition could have been avoided had the authors made a direct recovery determination, perhaps by reduction, of the oxide which was used for counting. It may be noted that the accuracy of the ethanol and the magnesium precipitation methods for ruthenium has not been proven analytically.

Rickard and Wyatt[64] recorded a radiochemical non-distillation method for the determination of ruthenium in aqueous solutions of fission products. The procedure required treatment of the fission solution with solutions of ruthenium carrier, sodium hydroxide, potassium periodate and sodium hypochlorite. Zirconium carrier was used to remove extraneous constituents and then the ruthenium was repeatedly precipitated by magnesium and by ethanol, and finally the ruthenium was reduced by magnesium, purified, transferred to a filter paper, washed, dried, and weighed, and its activity was counted. The accuracy compared favourably with that obtained by distillation of the ruthenium.

To separate radio-ruthenium from other fission products, Melnick modified the method used by Glendenin.[19] The tetroxide was distilled from a solution of perchloric acid, sodium bismuthate and fuming nitric acid. The solution of the sample containing the ruthenium carrier, the oxidants, and phosphoric acid to prevent volatilization of molybdenum, was heated to distil the tetroxide, which was collected in 6*M* sodium hydroxide solution from which hydrated oxides of ruthenium were then precipitated by ethanol. The oxides were dissolved in hydrochloric acid and the metal was then precipitated by magnesium and collected on filter paper, washed, dried, and weighed, and its activity was counted. The chemical yield was about 70%; duplicate analyses required about 3 hr. The 42 d ruthenium-103 was separated from the 106-isotope or determined in its presence by the use of a scintillation counter and an aluminium absorber to eliminate the 3·55 MeV beta ray from the 106-isotope. The latter may be counted on a beta proportional counter using an aluminium absorber to cut out the 0·68 MeV beta ray of ruthenium-103.

As part of a scheme for separating useful products from uranium fission Brezhneva *et al.*[65] separated ruthenium from the supernatant liquid of a calcium oxalate precipitation by the use of nickel sulphide which carried down 80% of the ruthenium. After dissolution of the sulphide, ruthenium was extracted from the nitric acid solution by tributyl phosphate; 99·0% could be extracted under optimum conditions.

Osmium

Meteorites

For the activation determination of osmium and rhenium in meteorites, silica, *etc.*, Morgan[66] combined a variety of procedural innovations for chemical recoveries. Here, as with all similar activation applications, these innovations will not necessarily be applicable to quantitative analysis. It is perhaps unfortunate that little, if any, of such work includes results which would indicate that a proper attempt was made to evaluate critically techniques that are fundamentally suspect; a chemical yield determination is not always an adequate substitute for such an evaluation. A case in point is Morgan's[66] assumption that exposure of irradiated meteorites to air before chemical treatment is unlikely to result in any significant loss of osmium. While this may be so in specific instances, such an assumption can and ought to be supported experimentally, particularly when nanogram amounts of osmium are to be determined. The method of preparing standards chosen by Morgan[66] involved the addition of a standard osmium solution to 20–30 mg of Specpure silica in a dry silica ampoule which was reweighed, centrifuged, dried at 80° overnight, sealed and irradiated. In the present authors' opinion, based partly on an accumulation of experimental data, this approach to the preparation of irradiation standards is not acceptable without some experimental support. In the case of osmium and most other noble metals such evidence may readily be obtained by applying the method to similar complex material of which the osmium content has been determined by proven procedures. The ease of selective isolation of fractions of micrograms of osmium from gram samples of materials such as the chrondrites used by Morgan, allows a ready evaluation of the activation method.

The chemical separation of osmium and rhenium used by Morgan[66] involved the use of an anion-exchanger and elution with nitric acid solutions. This method, now being studied by the present authors, has not been developed analytically and it would be of considerable interest to know the results which supported the statements that the "anion-exchange behaviour of osmium depended on the number of chloride ions in the anionic complex" and that "virtually quantitative elution of osmium could be achieved with 0·8*N* nitric acid provided that the flow-rate was reduced to 0·25–0·5 ml/min and not more than 5 mg of osmium carrier was used."

Rock samples (0·1–0·2 g) along with standards were irradiated at a thermal flux of 9×10^{12} neutrons.cm^{-2}.sec^{-1} for 1 week and then allowed to stand for about 24 hr. The sample was transferred to a zirconium crucible and carrier solution prepared from ammonium hexachloro-osmate was added, followed by ethanol to prevent loss of osmium tetroxide. Sodium hydroxide was added to provide a medium for complete isotopic exchange. The mixture was dried, sodium hydroxide was added, and heat carefully applied; the fused mixture was cooled, sodium peroxide was added, and the fusion was completed. The cooled fused residue was dissolved and transferred to a beaker and centrifuged to isolate base metal oxides. The supernatant liquid was treated with ethanol and hydrochloric acid and filtered to remove silica. The filtrate was passed through a small amount of De-acidite FF anion-exchanger to isolate osmium and rhenium, and osmium was selectively eluted with 0·8*M* nitric acid at the required flow-rate of 20–30 ml/hr. The eluate was drained into a sodium hydroxide solution to which ethanol was added. Finally the osmium was precipitated as the hydrated oxide, which was treated first with phosphoric and sulphuric acids and then with permanganate, the excess of which was removed with iron(II) ammonium sulphate; then cold nitric acid was added and the osmium tetroxide was extracted with chloroform. After back-extraction into thiourea-hydrochloric acid solution, osmium was precipitated by potassium chromithiocyanate and the precipitate was dried and weighed. The chemical yield varied between 30 and 60%.

The standards were prepared as described above and given a similar chemical treatment.

The beta count-rate of osmium-191 was corrected for dead time losses, background, and self-absorption loss, the last determined empirically. The validity of the self-absorption correction was checked by determination of the gamma ray activity of the 0·646 MeV photopeak of osmium-185. Interference from self-shielding and from the osmium radionuclides resulting from iridium and platinum was considered to be negligible. Results on various chondrites vary between 0·3 and 0·9 ppm; values which are within the applicable range of standard osmium methods.

For the determination of osmium and rhenium in iron meteorites Herr *et al.*[67] used cleaned compact pieces weighing 1–2 g and irradiated for 3 days at a flux of 10^{13} neutrons.cm^{-2}.sec^{-1}. After exposure the chips were cleaned in nitric acid and weighed. For the activity measurements osmium-193 was used and in some cases osmium-191 was used as a control. The standard of pure potassium chloro-osmate was activated with the sample and carried through the determination described

below. For osmium determinations the samples and standards were dissolved in sulphuric acid containing potassium hexachloro-osmate. After a 2 hr dissolution period the osmium tetroxide was distilled from chromium(VI) oxide solution and collected in hydrochloric acid containing thiourea. This solution was concentrated and the tetroxide distilled from a sulphuric acid–chromic oxide solution and collected in a sulphur dioxide–hydrochloric acid solution. The osmium was again removed by passing a current of air through the boiling solution, and collected in a thiourea-hydrochloric acid solution. This final treatment removed interference from ruthenium and other elements. The chemical yield was determined spectrophotometrically and was 60–70%. The osmium values for 10 iron meteorites varied from about 0·6 to 3·2 ppm, which would permit the application of direct spectrophotometric osmium determinations.

Ruthenium

Neutron activation methods have been used to determine traces of osmium in ruthenium sponge. Gijbels and Hoste[68] isolated the osmium by distillation from a sulphuric acid–hydrogen peroxide solution. Use was made of 16 d osmium-191, the samples being processed about 14 days after irradiation for 3–5 days at a neutron flux of $4{\cdot}8 \times 10^{11}$ neutrons.cm^{-2}.sec^{-1}. In ruthenium samples irradiated and processed under the same conditions, the main activity is caused by the 41 d 103-isotope. The efficiency of separation was determined with tracers either alone or in the presence of 1–10 mg of osmium or ruthenium carrier. In the latter case the solution of tracers was added to the carrier sponge, then the mixture was evaporated, and the residue was fused with sodium peroxide and transferred to the distillation flask with water and acids. The distillate from the sulphuric acid and hydrogen peroxide mixture was collected in sodium hydroxide solution and diluted to standard volume, and the activities of both distillate and pot liquid were measured by a gamma scintillation counter with a pulse-height analyser to eliminate the activity of rhodium-105. The material balance fitted within 2%.

The ruthenium contamination of the osmium distillate both with and without carriers was less than 0·01% of the total ruthenium activity. The authors noted the beneficial effects on the separation if the solution was aged for several hours before distillation. However, with increasing size of the ruthenium sample there was an increase in the degree of contamination. Examination of the distillate showed that the osmium was contaminated by a small and fairly reproducible amount of ruthenium interference. If the osmium content is low the interference can thus become significant. This should be remembered when applying established methods of separating and determining osmium and ruthenium.

Ruthenium interference was appreciably reduced by use of a 3 in. × 1 mm wafer instead of a 3 in. × 3 in. detector. With the latter a correction for the ruthenium content of the osmium distillate is required when the osmium content of the sample is less than 30 ppm; with the wafer, only when the osmium content is below 10 ppm. The addition method of analysis was used, and the standard deviation was determined from the slope and the intercept with the ordinate. For a commercial ruthenium sponge the osmium value was approximately 17 ppm, for spectrographically pure ruthenium 33 ppm, and for a sample prepared by the authors about 1·7 ppm. There was good agreement between values obtained by the use of the wafer and the crystal.

Gijbels and Hoste extended this investigation[68] to include the determination of ruthenium and iridium in osmium sponge.[69] Carriers were not required. The initial chemical separations used by the authors were analytically acceptable methods but the results obtained were surprisingly unpredictable. The method for isolation of osmium by acid-peroxide distillation used previously by the authors[68] removed 99·8% of the osmium. The residual osmium in the pot liquid resisted continued distillation and although the classical treatment of the pot liquid with perchloric acid removed most of the residual osmium and all of the ruthenium an examination of the ruthenium distillate indicated distillation of traces of iridium. Thus the osmium and iridium contamination in the distillate was so high that ruthenium could not be detected in the osmium sponge. These findings are of exceptional importance in view of the fact that distillation from perchloric acid solution has been an accepted method of separating ruthenium from iridium. Fortunately, the authors will record the result of further researches dealing with the problem of co-distillation of iridium. Because of these difficulties the separational procedures were varied to include the usual osmium distillation with sulphuric acid and hydrogen peroxide, followed by an interim destruction of peroxide by the addition of potassium permanganate, then a continuation of the acid-peroxide distillation. Ruthenium was then removed by distillation from a sulphuric acid–sodium bromate medium. It may be noted that in some instances there remained a slight but not unexpected contamination from osmium. The proposed procedure was applied to the samples of osmium sponge and the addition method of analysis was again used. The addition method provided better results than the usual technique when amounts of ruthenium and iridium up to 3–7 times the original content were added to the sample.

For the analysis 10 samples of sponges were used to which were added known amounts of ruthenium and iridium on filter papers. The samples were irradiated for 3–7 days at a neutron flux of

4×10^{11} neutrons.cm^{-2}.sec^{-1}. The contents of the container were fused in a nickel crucible with sodium peroxide.* The fused melt was treated to remove osmium. The sodium hydroxide receiving solution contained 99·999–99·9999% of the osmium content of the ruthenium. Treatment of the pot liquid with sulphuric acid-sodium bromate removed more than 99% of the ruthenium activity and the residual pot liquid contained 99·995% of the iridium content of the sample.

A correction was required for the small amount of osmium contamination in the ruthenium distillate especially when the ruthenium activity was very low.

The radionuclides used for the determinations a few days after irradiation were osmium-191 and -185 (16 d and 93·6 d respectively), ruthenium-193 (39·8 d) and iridium-192 (74·4 d). The gamma-spectra of these isotopes were measured with a 3 in. × 3 in. NaI (Tl) detector. Activities of other constituents such as gold-198 could be neglected if measurements were made 2 or 3 weeks after the end of irradiation.

The results gave an iridium content of about 21 ppm in commercial osmium, about 1·5 ppm for spectrographically pure osmium, and about 0·5 ppm for a purified osmium sample.

The authors concluded that the neutron activation method applied to 10-mg samples allowed determinations of ruthenium down to about 10 ppm and iridium down to 0·5 ppm. In the opinion of the present authors the determination of traces of platinum metals in samples of osmium or ruthenium sponge by these neutron-activation methods provides no improvement in sensitivity or accuracy over applicable spectrophotometric methods.

Rhodium

A method of determining rhodium by thermal neutron activation was described by Steele and Meinke.[70] From the various neutron reactions, the authors selected the reaction ^{103}Rh (n, γ) ^{104}Rh + ^{104m}Rh for the determination. The rhodium-104, with a half life of 44 sec was used for a non-destructive method and the equilibrated species of rhodium-104 and -104m with an effective half life of 4·4 min, for a destructive method. The average time required for a determination by the former method was 7 min and by the latter about 20 min.

Irradiation fluxes varied from $9{\cdot}9 \times 10^{11}$ to $1{\cdot}3 \times 10^{12}$ neutrons.cm^{-2}.sec^{-1} but the results were normalized to a flux of 10^{12} neutrons.cm^{-2}sec^{-1}. For the non-destructive method the time elapsed from the end of irradiation to the start of the counting period varied from 19 to 54 sec. Counts were corrected for decay and analyser dead time, and background radiation from other activities was eliminated by extrapolation of the base line under the photopeak of 0·56-MeV.

Calibration data for the non-destructive determination of rhodium were obtained by 42-sec irradiations of known amounts of rhodium and subsequent determination through the gamma-ray scintillation spectra. The method was accurate to within about ±6% over the weight range 0·1–1 μg of rhodium. For the range 0·01–0·1 μg the error was about ±20%. In the presence of the halogens, tungsten, arsenic, antimony, copper, zinc and other elements with gamma peaks near 0·56 MeV, there may be interference, and a chemical separation is then required. The authors predicted that activation analysis of rhodium using the high energy beta-ray of rhodium-104 would improve the sensitivity.

The destructive method for rhodium-104m required heating the irradiated samples with sodium peroxide, dissolving the products in hydrochloric acid, treating with sodium hydroxide, adding rhodium chloride carrier, tartaric acid, and pyridine, and filtering into a separatory funnel and rinsing with hydrochloric acid. The solution was made basic with sodium hydroxide and the pyridine-rhodium layer was separated. Gamma-ray measurements were made on an aliquot. The chemical yield was determined by measuring the absorbance at 440 mμ of the pyridine-rhodium complex. The counts at the 0·56 MeV photopeak were corrected for decay, analyser dead-time, neutron flux variations, and the chemical yield. A calibration curve was prepared by this separation technique. The error of the method was about ±20% over the range 0·10–1 μg of rhodium. The average time for the determination was about 20 min including the 5 min irradiation time.

For the determination of radio-rhodium, Gilmore[19] used a procedure involving reactions which merit investigation with a view to analytical application. In successive stages of separation rhodium was precipitated as the iodide (RhI_3), then as the complex $Cu_3[Rh(CN)_6]_2$), and finally by electro-plating, the last method also being used for standardization.

The chemical separation involved addition of rhodium carrier, fuming the solution of nitric, perchloric and sulphuric acids to remove ruthenium, addition of perchloric and hydrochloric acids, addition of molybdenum and cobalt carriers and potassium iodide, and a separation of rhodium(III) iodide. The precipitate was dissolved in potassium cyanide, tellurium carrier was added and dissolved iodine was removed by sodium nitrite. The solution was scavenged with an iron salt in ammoniacal medium and treated successively with barium, tellurium, and antimony carriers, in a sulphide solution.

* Attention is drawn to the authors' use of a filter paper and its fusion with sodium peroxide. This technique may result in a violent explosion.

Copper nitrate was added to isolate the copper-rhodium complex, which was then dissolved, and the rhodium cyanide complex anion $[Rh(CN)_6]^{-3}$ was isolated and dissolved in sulphuric acid. After some repetition of separational steps, the rhodium was plated out on a weighed platinum disc. The cathode deposit was cleaned, weighed, mounted, and beta-counted. The chemical yield was about 60% and 6 determinations per day could be made.

Ruthenium

Rhodium in C. P. ruthenium metal was determined by activation analysis without the use of a chemical separation.[71] Samples (500 mg) were irradiated for 5 sec at a flux of $1{\cdot}4 \times 10^{11}$ neutrons. $cm^{-2}.sec^{-1}$ and transferred immediately to a pulse height analyser. Despite the presence of the activity of ruthenium-105, the fast decaying gamma ray of the 42 sec rhodium-104 at 550 keV was easily distinguished in the series of gamma ray spectra obtained at 24 sec intervals. A rhodium content of 31 ppm could be isolated by distillation of the ruthenium tetroxide.

Platinum

Two methods for the determination of rhodium in platinum were proposed by Gauthier.[86] In one procedure rhodium was determined directly without a chemical separation. Samples and standards were subjected simultaneously to a short irradiation and the gamma activity was measured for 10 sec at intervals of 5 sec, thus permitting a determination of purity. In general, long-period activities could be neglected. The precision was about 5%.

The second method involved the production of 36·5 hr rhodium-105 from the reaction $^{104}Ru(n, \gamma)$ $^{105}Ru \xrightarrow{\beta^-} {}^{105}Rh$. The ruthenium tetroxide was removed by distillation and the rhodium-105 was collected by iron hydroxide precipitation. The rhodium was reduced in hydrogen and oxidized to yield rhodium(III) oxide.

A known volume of the dissolved rhodium-105 was added to a hydrochloric acid solution of the platinum and the rhodium was removed by hydrolysis with barium carbonate. The hydrated oxide was washed, dissolved in hydrochloric acid, and rhodium sulphide precipitated by hydrogen sulphide. The rhodium sulphide was ignited to the oxide which was fused selectively with potassium hydrogen sulphate. The melt was dissolved in water, and the solution was filtered to remove platinum which is relatively inert in the fusion, and rhodium was again precipitated as the sulphide. This was washed, ignited, reduced in hydrogen, and weighed, and its activity was counted. A known weight of pure rhodium was similarly treated chemically and a volume of the rhodium-105 tracer, identical to that for the sample, was added. The precision of 4% was about equal to that found for the direct method. Both methods were used for alloys of platinum containing 5, 7 and 11% rhodium.

Meteorites

A variety of analytical methods has been proposed for the determination of noble metals in meteorites. Continued interest in the development of improved methods for meteorites has been encouraged by "the apparent unreliability of previous analytical results for a number of trace elements".[72] Because neutron activation methods lend themselves particularly to the determination of small traces a considerable effort has been made to obtain results by this method. In view of the fact that more accurate results provide some of the incentive for these investigations, it is surprising that little or no effort has been made to confirm the neutron activation results by the application of established methods. As far as the noble metals are concerned, there are spectrophotometric methods available whose sensitivities are sufficient for determinations in many types of meteorites, and some of these applications have been recorded.[73]

With a view to providing more reliable results for the content of rhodium, silver and iridium in chondritic meteorites, Schindewolf and Wahlgren[72] developed a rapid neutron activation method which involved a sodium peroxide fusion, addition of rhodium carrier, treatment with nitrite in a slightly basic medium to hydrolyse the base metals, and a fast filtration by suction. Rhodium in the filtrate was precipitated as the potassium-rhodium-nitrite complex, which was then dissolved in acid, and the metal precipitated by zinc. The chemical yield was determined by weighing after counting. Only 9 min were required for the fusion and chemical separation. The authors state that isotopic exchange between the rhodium of the meteorite and the carrier was confirmed with the 220 d rhodium-102. In the absence of details concerning the zinc precipitation one may expect that the chemical yield obtained by weighing could have a considerable error which is not made evident by a proven purity of isotope.

The standards used by the authors were prepared by adsorption of the rhodium solution on filter paper. Because of the short half-life (4·4 min rhodium-104) the standards and samples were irradiated separately and the activities were monitored by weighed gold foil. It would be expected that the standardization techniques used by the authors would involve the usual errors associated with the matrix differences between sample and standard. Furthermore, it is not made clear how the

use of the 220 d rhodium-102 ensured the isotopic exchange claimed between the carrier rhodium and the activated rhodium in the solution of the carrier.

Counting with the beta proportional counter required about 20–30 min. The degree of reproducibility of the method was determined by the addition of known amounts of the standard to the sample, followed by irradiation, complete separation, and determination. The results indicated an error of 10–15%. However, this technique does not prove the accuracy of the results for the rhodium content of the meteorite.

A general problem associated with the determination of noble metals, particularly the "insoluble noble metals" in iron meteorites is concerned with the potential resistance to dissolution by certain of the noble metal minerals and alloys. Metals such as iridium, osmium, ruthenium and rhodium not infrequently occur in natural formations in a physical condition which is exceptionally resistant to corrosion by normal fusions, acids or even mixed acid treatments. The resistance to mineral acid attack of each of these four metals, in sponge form, with the exception of rhodium in sulphuric acid, is generally recognized. The senior author has in a series of papers dealt with the successful dissolution by mineral acids of iron-nickel-copper alloys containing traces of noble metals. By analogy it would be expected that methods of decomposition by mineral acids or by fusion with sodium peroxide would provide complete dissolution. However, because of the not unlikely possibility that natural occurrences involving prolonged exposure to high temperature may result in alloys with high corrosion resistance, and because an insoluble platinum metals alloy may well contain traces of any one noble metal, all procedures designed to provide a method of determining a noble metal should be concerned with achieving complete dissolution or failing that, at least a qualitative examination of even trace residues.

Iridium

Radiochemical procedures for the determination of iridium were reviewed by Leddicotte[74] in a monograph which included descriptions of the general chemistry of iridium, methods of dissolution, safety practices, general radiochemical information, *etc.* Condensed details were given for 6 procedures.

Noble metals

Kamemoto *et al.*[75] used a non-destructive method for the determination of iridium in amounts of 4·5–90 μg. Fifty-mg samples of platinum, rhodium, palladium and gold and standard iridium were irradiated for 2 hr with a flux of 3×10^{11} neutrons.cm^{-2}.sec^{-1}. Activity measurements were made by comparing the gamma-ray photopeaks of iridium-192 in standards and samples.

Osmium

A non-destructive method of determining iridium in osmium samples containing 9–40% iridium was described by Maxia *et al.*[75a] Mixtures containing powdered metallic osmium and iridium were irradiated for 110 hr with a flux of 10^6 neutrons.cm^{-2}.sec^{-1}. With less than 9% iridium the low activities resulted in doubtful values. Activation at this low flux would permit a wider use of activation methods but it is doubtful whether this particular method is more useful than the classical analytical methods.

Platinum

Methods for determining $1{\cdot}18 \pm 0{\cdot}34 \times 10^{-5}$ mg of iridium in 99·999% pure platinum were described by Airoldi and Germagnoli.[76] From the gamma activity of gold-199 resulting from the beta emission of the 29 min platinum-199, the number of platinum atoms was calculated. From the sum of the closely similar gamma energies of about 300 keV of the 74·4 d iridium-192 the number of iridium atoms was calculated. A second method for iridium involved the prior decay of the platinum activity over a period of 49·4 days.

Javanovitz *et al.*[77] described a neutron activation technique for the determination of traces of iridium in platinum. The work was undertaken to find the practical sensitivity, to evaluate certain chemical separations and the determination of iridium in platinum, and to find the iridium content of certain platinum samples.

The neutron irradiations were made in the Argonne and Oak Ridge reactors. Iridium-192 with a half-life of 74 d was produced from iridium-191 which has a capture cross-section of 1000 barns. A gamma ray scintillation spectrometer was used to avoid minor interferences from other nuclides and to allow an accurate evaluation of the contribution of ^{193}Ir to the platinum counting rates. Counting rates for the sample and standards were measured under the iridium peak at 300 keV. Samples of platinum were purified by fractional crystallization of the hexabromoplatinate. The time required for the transfer the irradiated samples and for the chemical separations allowed the decay of the 19 hr

^{197}Ir and ^{194}Ir. The principal constituents of the radioactivity were then ^{192}Ir, ^{195m}Pt, ^{191}Pt and ^{194}Pt the last three having an overall decay period of 3·8 d. Gold-199 with a half-life of 3·15 d is one of the daughter products and was removed by solvent extraction during the chemical separations. The procedure involved the simultaneous irradiation of pure platinum metal and freshly precipitated hydrated iridium oxide for 12–24 hr. The platinum was dissolved to yield the chloride, and measured amounts of iridium chloride were added. The gold was extracted with ethyl acetate and the iridium was precipitated as the hydrated oxide and separated on filter paper by suction, and then taped to an aluminium disk; the iridium activity induced in the platinum was measured. The platinum filtrate was treated again with the iridium oxide, which was then reprecipitated and counted to ensure complete recovery of active iridium. The final solution of platinum was treated to produce the metal and the residual active iridium was determined. The iridium standards were dissolved and the iridium content determined spectrophotometrically. After activation the weighed iridium sample was dissolved in hot hydrobromic acid and an aliquot was spotted onto a filter paper, dried and counted. Variations in counting rate were determined by the use of equal amounts of the active iridium with different amounts of carrier. Only reasonable statistical fluctuations were observed. Geometric factors were carefully controlled. The results showed that the relative standard deviation for a 0·04 ppm sample was about 10%. The significant errors were ascribed to weighing and variations in chemical treatment and not to the counting rate statistics. The possibility of self-absorption resulting from the high neutron capture cross-section was examined by varying the weights of the standard samples. Self-absorption was not serious provided the iridium content was less than 6 mg. The formation of ^{192}Ir from ^{192}Pt was not significant because the latter is usually present in platinum in low proportions, and high energy neutrons are required for the conversion. The sample was irradiated in a position in the reactor where which the fast neutron flux is negligible in comparison with the thermal neutron flux, but this could limit the sensitivity of the determination.

The method was applied to test the efficiency of the hydrolytic separation of platinum from iridium. The authors commendably note that the "effectiveness of this separation is critically dependent upon the exact conditions and timing with which operations are performed" and that "some practice and experience by the analyst are required before even moderate reproducibility can be achieved." With separations of this nature it is a reasonable conclusion that it is really the analyst's ability that is being tested. The authors found that the 40 mg of iridium carrier initially separated from 100 mg of platinum carried with it 99·10% of the iridium activity. A second and third treatment of the platinum filtrate yielded 0·7% of the activity with the final unrecovered proportion of about 0·2% ascribed to either an inert complex or radiochemical impurities.

It may be suggested that the authors' final reduction of the platinum solution to the metal, which was then examined for iridium activity could be ineffective for the recovery of a trace of iridium. Even magnesium will not necessarily remove iridium quantitatively from a chloroiridate solution. The authors did not specify either the reducing reagent or the procedure used. Furthermore, the results gave only the percentages obtained from the total counts. Any appreciable failure to precipitate iridium in the final platinum filtrate would result in a misinterpretation of the efficiency of the method.

Dopel and Dopel[78] discussed the advantages and disadvantages of neutron activation, spectrographic, and chemical methods of determining traces of iridium in rhodium and platinum. Whereas the established methods have a sensitivity of 10^{-3} to 10^{-2}%, neutron activation techniques could be used for 10^{-5}% iridium or even less. The uncertainties of spectral determinations of concentrations of iridium lower than those accessible to chemical methods did not arise in the neutron activation methods, which required only one iridium standard. Furthermore, the activation methods provide more comprehensive information about the composition of the sample, although they are subject to restrictions associated with favourable conditions for neutron capture, decay periods, and emission energies.

The spectrographic and activation results for the iridium content of rhodium and platinum were in reasonable agreement.

Rhodium

Morris *et al.*[18] gave a neutron activation method for iridium in rhodium without a chemical separation. This was done by a special arrangement which made it possible to plot count rates against pulse height. Because of the large absorption cross-sections for thermal neutrons of both iridium and rhodium and the possible self-shielding differences between samples and standards, the standards were prepared by adding known quantities of ammonium hexachloroidate solution. Samples (0·1 g) and standards were irradiated with a neutron flux of 10^{12} neutrons . cm^{-2} . sec^{-1}. After 8 days the intensities of the photo-peaks 0·316 and 0·47 MeV gamma of iridium-192 were measured in arbitrary units for samples and standards in turn. A check showed that only the gamma rays from ^{192}Ir were being counted. The range of iridium content measured was 3–170 ppm.

The application of gamma–gamma coincidence measurements to the detection and determination of iridium was discussed by Herr and Wolfe.[79] The method was applied to iron oxide, meteorites and purified platinum. The iridium values obtained were closely similar to those obtained by independent methods (which were not specified). For pure platinum the iridium content found was 221 ppm, compared to 217 by the independent method. For platinum of higher purity the values were <44·4 and 42 ppm. The coincidence measurements were made after 14 days decay.

A limited chemical treatment was described. This involved addition of iridium carrier, dissolution in *aqua regia*, conversion into chlorides, addition of gold carrier, and precipitation of the iridium as the hydrated dioxide. In the case of meteorite samples, iridium could be isolated finally as caesium hexachloroiridate. Two single-channel analysers were adjusted to 0·3 MeV for the iridium measurements. The coincidence zero level was 0·03 cpm. Under the conditions used, the sensitivity for iridium was 8×10^{-11} g. The authors state that with irradiation for 2 weeks at 10^{14} neutrons . cm^{-2} . sec^{-1}, the sensitivity could have been increased to 5×10^{-15} g of iridium.

It was noted that valuable samples of meteorites could be analysed non-destructively after a 4-week decay period. Errors arising from self-shielding and depression of the neutron flow were discussed, and specific effects of arsenic and antimony minerals, with the conclusion that antimony introduces significant error.

The authors discussed the general advantages of the gamma–gamma coincidence method, especially its very high selectivity and the elimination of time-consuming chemical treatments. With simple systems there is the advantage of avoiding the destruction of samples.

Undoubtedly, coincidence methods will find extended and useful applications in determinations involving the noble metals, and development of improved counting equipment may confidently be expected.

Palladium

Techniques for the radiometric determination of palladium have been recorded by Spacu and Voicu.[80] The radioactive isotopes palladium-109 and iodine-131 were used to form the insoluble complexes $[PdPy_2I_2]$, $[PdPy_2(SCN)_2]$ or $[PdPy_4][Cr_2O_7]$. Solutions containing 0·5–20 mg of palladium and some pyridine were titrated with a solution of $Na^{131}I$. The activity of the supernatant liquid was monitored to determine the first appearance of activity in the solution. For more than 1 mg of palladium the error varied between 0·34 and 5·5%. A variation of the method involved the simultaneous use of palladium-109 and iodine-131, in which case the end point was located at the minimum of activity in the solution. Precipitation of palladium with thiocyanate or dichromate gave results similar to but less accurate than the iodide results.

A second technique involved extraction of the complexes with chloroform, evaporation of the solvent, and measurement of the activity of the residue. The sensitivity was 0·2 mg of palladium for the iodide precipitate and 0·6 mg for the thiocyanate precipitate.

Iodine-131 indicator was also used by Tölgyessy and Schiller[81] to determine cations which produce an insoluble iodide. The titration beaker was fitted with a Geiger-Mueller counting tube. The titrant for palladium was 0·1*M* potassium iodide containing 1 ml of iodine-131 solution with a specific activity of 0·842 mc/ml.

Procedural details of 17 previously published radiochemical methods for palladium have been recorded, 16 of them involving selective isolation by dimethylglyoxime.[82]

Meteorites

For the determination of palladium in meteorites, Brown and Goldberg[83] irradiated 300–500 mg samples along with standards of palladium dimethylglyoximate. The samples were allowed to cool to remove the 26 min activity of palladium-110. The irradiated samples were dissolved in hydrochloric acid, palladium carrier was added, then ammonia until its concentration reached 0·4*M*, and the glyoximate was precipitated. The precipitate was dissolved in nitric acid, iron carrier was added to scavenge in ammoniacal medium, and was followed by a scavenge with silver iodide. The precipitation steps were repeated and finally the glyoximate was precipitated, weighed and prepared for counting. The irradiated palladium standard was dissolved in nitric acid, treated with carrier and diluted to give a count rate similar to that of the samples.

With such analyses it is unfortunate that few reports suggest any attempt to compare the results with those of established analytical methods. *p*-Nitrosodimethylaniline and other reagents are sensitive enough to be used to determinate less than 1 ppm of palladium in meteorites. Presumably, with the activation methods, it is too often accepted without question that homogeneous distribution of isotopes and carrier is achieved in the sample solution, that energy measurements which confirm the identity of the precipitated metal also indicate the chemical purity of the weighed precipitate. The present authors believe that when neutron activation methods are applied to complex materials such as meteorites, confirmation of these assumptions is required.

Fission product solutions

For the separation of palladium from fission products, Melnick[19] modified Glendenin's procedure,[19] and precipitated the metal first by magnesium and then repeatedly with dimethylglyoxime. Selenium was the only contaminant, appearing as the metal. The precipitate was purified by dissolving it and scavenging with silver chloride and iron(III) hydroxide. The chemical yield was about 75% and duplicate determinations took 5 hr. Techniques were described for counting the activities of palladium-109 and -112 together or separately. Beta counting was started 15 hr after the chemical separation to allow equilibration between 3·2 hr silver-112 and 21 hr palladium-112.

For the separation of palladium from fission products, Alexander *et al.*[84] dissolved the activated uranium foil in *aqua regia* containing palladium carrier. Silver chloride was precipitated with added silver carrier and palladium was extracted as the dimethylglyoximate into chloroform and then back-extracted into concentrated ammonia solution. The solution was scavenged with iron(III) hydroxide, and zinc was added to precipitate metallic palladium. This chemical separation could be done in 3 min. The separation, with some variations, was used to study the short-lived isotopes of palladium-113, -114, and -115 which have half-lives of 1·4 ± 0·1 min, 2·4 ± 0·1 min, and 45 ± 3 sec, respectively.

Platinum

Killick and Morris[85] recorded a procedure for the determination of traces of palladium in platinum. The method was "evolved to provide greater sensitivity than is available with most conventional analytical procedures." The concentration ranges covered were about 0·3–3 ppm. The results given do not indicate an improvement in sensitivity; indeed available spectrophotometric methods will provide greater sensitivity, precision and accuracy. The chemical separation used by the authors involved precipitation by dimethylglyoxime and repeated precipitation as hydrated palladium(II) oxide, removal of silver with a silver carrier, and solvent extraction of gold. The chemical yield was not stated. The authors activated samples and standard with a thermal neutron flux of 10^{12} neutrons. cm^{-2}. sec^{-1} and the activity of 13·5 hr palladium-109 was measured. Corrections were made for chemical yield, paralysis and background. Similar weights of palladium dimethylglyoximate were counted, and self-shielding differences between samples and standards were avoided by adding known small quantities of standard palladium solutions. Decay characteristics of the precipitate were measured to ensure that only the activities of palladium-109 were measured. The time needed for chemical separation ensured the removal of the relatively short lived palladium-111.

Platinum

Aluminium

A comparison of chemical and neutron activation methods of determining platinum and chlorine in alumina-base platinum-chlorine type re-forming catalysts was made by Guinn and Wagner.[86] Unfortunately the chemical method was not specified, which eliminates much of the usefulness of the comparison. The gamma spectrum of 0·72–0·79 MeV of the 30 min platinum-199 was used for the determinations which involved no chemical operations. For determinations of amounts of platinum of the order used for spectrophotometric methods the authors preferred the activation method because of the relatively short period required for a determination. The values reported for platinum indicated good precision for both methods but the discrepancies between the two methods were significant. Additional comparisons of this type made with clearly delineated and acceptable techniques may be hoped for.

MULTI-COMPONENT NOBLE METAL SYSTEMS

Rocks

Gold and palladium. Neutron activation techniques were used by Vincent and Smales[30] to determine palladium and gold in igneous rocks. These authors deal briefly with the deficiencies of some of the recorded earlier methods of assay. It may be noted here that the methods chosen by the authors for comparison are by no means representative of the best classical methods, and that the comment that "the possibility of serious losses of trace amounts of precious metals during the fire assay seems largely to have been overlooked, or at best seriously under-estimated" is incorrect and so is the inference that results have been available to indicate the failure of classical methods in the determination of trace amounts of the noble metals in ores. To the best of the present authors' knowledge no results have been recorded to indicate either the success or failure of recovery of microgram amounts of noble metals from ores. Here distinction must be made between loss of a metal present as a trace and trace losses associated with the recovery of larger amounts of metal.

It is further stated[30] that "since most of the available data on the palladium and gold contents of rocks have been obtained by some kind of fire assay some doubt must always remain as to their

accuracy, and the adoption of a radioactivation method, eliminating all possibility both of losses of palladium and gold from the samples and of reagent contamination, seemed desirable." Presumably, the authors feel that by avoiding losses one may remove doubt concerning accuracy and that neutron activation techniques will accomplish this very desirable situation. This has not been accomplished during the decade following the report, and a neutron activation method for ore samples which, in general, eliminates doubt concerning the accuracy of palladium and gold determinations is not likely to be developed within the predictable future, if at all.

Vincent and Smales irradiated 100–200 mg of rock powder and standards of palladium and gold foil for about 12 hr. The irradiated rock powder was sintered with sodium peroxide, the moistened sintered cake was transferred to a small beaker and carrier gold and palladium were added as foil. The mixture was treated with *aqua regia*, the solution evaporated, and the hydrochloric acid extract was centrifuged to remove the silica. Hold-back carriers of sodium nitrate, potassium chloride, copper(II) chloride, and nitrates of cobalt, zinc and manganese were added to the centrifuged liquid; palladium and gold were precipitated by magnesium, the precipitate was redissolved in *aqua regia*, and gold was finally extracted from the chloride solution with ehtyl acetate. The organic layer was evaporated, and after a purification process, including the use of hold-back carriers, the hydroquinone-gold precipitate was purified and weighed to establish the chemical yield, and then the activity of the 2·7 d gold-198 was counted.

The irradiated gold standard was allowed to stand for about 1 week, then dissolved, and suitable aliquots were treated with carrier gold foil and the gold was isolated and treated as described above for the irradiated ore.

To isolate palladium the aqueous extract from the gold separation was treated to precipitate palladium dimethylglyoximate; this was then dissolved, and the resulting solution was treated with solutions of iron(III) chloride, manganese(II) chloride, bromine water and ammonia. The filtrate from the hydrated oxides was treated with hold-back carriers, and then subjected to a silver iodide precipitation and then a reprecipitation of palladium dimethylglyoximate. After repeated reprecipitations, the precipitate was dried and weighed, and its activity was counted. The irradiated palladium standard was treated with carrier, the dimethylglyoximate precipitated and weighed, and the activity of the 13·3 hr palladium-108 counted. The chemical yield for gold was about 80% and for palladium 50–60%.

On the basis of a counting rate of 10 cpm above the background, the use of a 100 mg sample and a 50% chemical yield, the authors accepted a sensitivity limit of 0·01 ppm of palladium. For gold with a 70% chemical yield the limit was 0·002 ppm. In both instances with more favourable irradiating conditions, *etc.*, the limits may be reduced to 0·005 ppm of palladium and 0·0005 ppm of gold. Such techniques as scavenging with highly adsorbent hydrated oxides, *etc.*, should be examined experimentally to determine the effect, if any, on isotopic homogeneity. The statement that "the active atoms of the analysis element contributed by the rock interchange freely with the inactive atoms from the carrier, having identical chemical but different nuclear properties" presupposes that the chemical properties of the dissolved metal constituents are indeed identical, and this also should be checked.

Ores

Neutron activation methods for the determination of noble metals in ores have been reported. As stated in the introduction, if the irradiated ore is not completely dissolved, the proposed procedures can be accepted only as methods of determining noble metals in liquid extracts; they cannot be properly described as methods of determination in ores.

Palladium and platinum. Morris, Hill and Smith[87] used neutron activation methods to determine palladium and platinum in pentlandite, pyrrhotite and chalcopyrite concentrates obtained from Sudbury ores by flotation and magnetic separation. Finely ground samples (0·5 g), some with addition of aliquots of standard palladium and platinum solution, were irradiated for 1 week in a nuclear reactor flux of $1{\cdot}2 \times 10^{12}$ neutrons . cm^{-2} . sec^{-1}. The irradiated materials were cooled for about 5 hr, treated with palladium and platinum carriers, and then dissolved in nitric and hydrobromic acids. It may be assumed that at least a small insoluble residue remained. The acid extract was evaporated and the residue treated with hydrobromic acid, and the metals were precipitated by magnesium. The supernatant liquid was discarded and the precipitate was dissolved in nitric and hydrochloric acids, gold carrier was added, and the gold was extracted with ethyl acetate. The aqueous phase was treated to precipitate palladium dimethylglyoximate which was then purified by dissolution in hydrochloric acid and extraction with chloroform. The solvent was evaporated and the palladium was converted into the chloride. Silver carrier was added and the silver chloride was removed. Finally palladium dimethylglyoximate was precipitated and weighed, and the beta activity of palladium-109 was counted. The supernatant liquid from the palladium dimethylglyoximate was treated with mercury(I) chloride to precipitate platinum which was then dissolved and finally precipitated as ammonium hexachloroplatinate. This precipitate was dissolved, the solution was treated

with tin(II) chloride, and the coloured constituent was extracted with ethyl acetate. The solvent was evaporated and the residue was treated with sodium nitrite to remove base metals, and the platinum was finally precipitated by mercury(I) chloride; the beta activity for platinum-197 was counted. The chemical yield for platinum was determined by measuring the absorbance of the chloro-complex. All counting rates were corrected for paralysis, background, decay, and chemical yield, which was about 80% for palladium and 50–60% for platinum.

The results obtained showed values for pentlandite which are well within the range of spectrophotometric determinations, and these methods could have been used to provide direct comparisons of results from activation and standard methods.

Ruthenium and osmium. Traces of ruthenium, osmium and uranium in materials such as chondrites, achondrites, tektites, trolite, and terrestrial rocks, *etc.*, were determined by Bate and Huizenga[88] by neutron activation techniques. After irradiation the samples were fused in sodium peroxide with the carriers $[Ru_2(OH)_2Cl_4 \cdot 7NH_3 \cdot 3H_2O]$ and K_2OsCl_6. The caustic solution was treated with ethanol to precipitate hydrated ruthenium oxide and the filtrate was treated with hydrogen sulphide to precipitate "osmium oxide". The ruthenium oxide was distilled from a sodium bismuthate suspension and collected in sodium hydroxide. Subsequent purification procedures included solvent extraction of the octavalent oxide by carbon tetrachloride, back-extraction with sodium hydroxide, precipitation by ethanol, scavenging and precipitation of gold by hydrazine hydrochloride, further scavenging with lead iodide and cadmium sulphide, and finally precipitation of ruthenium oxide and treatment of the supernatant liquid with hydrogen sulphide to recover the residual ruthenium. The combined ruthenium precipitates were again subjected to a bismuthate distillation and treatment with ethanol, and finally the ruthenium was precipitated as caesium hexachlororuthenate which was mounted on a weighed filter paper for counting.

The initial osmium precipitate was treated by distillation, solvent extraction, scavenging and precipitation as for ruthenium. The final precipitate of caesium hexachloro-osmate was mounted as for ruthenium and counted.

Recovery tests were made with known amounts of osmium and ruthenium on strips of glass fibre filter paper, buried in a matrix of powdered dunite. The mixtures were irradiated for 24 hr at a flux of 6×10^{12} neutrons . cm^{-2} . sec^{-1}. The extent of recovery was obtained by comparing the count rates of the sample, corrected for chemical yield, with those of the flux monitors simultaneously irradiated. The energy spectra for samples and flux monitors were identical, and free from extraneous activities. The activities were identified by their half-lives.

The work was carefully done, but the analytical approach involved an unduly lengthy and unnecessarily cumbersome series of techniques. The problems presented by the explanations for the good recoveries of osmium relative to those of ruthenium could be solved very readily by simple experiments, but the authors had, as is also found in the early analytical literature, some degree of misconception concerning the ease of oxidation of ruthenium to form the volatile octavalent oxide.

Meteorites

Gold and palladium. For the determination of gold and palladium in iron meteorites, Goldberg, Uchiyama and Brown[89] used the neutron activation and radiochemical methods described by Brown and Goldberg.[83] For palladium, precision at the 1 ppm level was about 10% and for gold 10–15%. A correction factor of 25% was applied to allow for the self-shadowing effect of gold in the samples.

Iridium, gold and platinum. Rushbrook and Ehmann[3] used activation methods for the determination of iridium in stone meteorites. The meteorite samples and the aluminium disk flux monitors containing an evaporated residue of standard iridium solution were irradiated for 4–6 hr at a flux of about 2×10^{12} neutrons. cm^{-2} . sec^{-1}. The chemical procedure involved addition of the irradiated sample to the iridium carrier solution, treatments with hydrochloric, nitric, hydrofluoric and sulphuric acids and *aqua regia* to dissolve all but a small residue which presumably was discarded. Iridium was taken out on an anion-exchanger, Dowex 1-X8, pretreated with cerium(IV) solution. The column was washed free from iron by 0·8*M* hydrochloric acid, and the iridium on the column was reduced to the tervalent form by hydroxylamine hydrochloride (and thereby partially eluted), and then eluted with 8·0*M* hydrochloric acid. (This process for the separation of iridium should receive a quantitative analytical examination.) The iridium eluate was treated first with peroxide and then with zinc, the excess of which was removed by treatment with acid. The iridium precipitate was separated, purified by treatment with *aqua regia*, filtered, washed with glacial acetic acid and water, dried, and weighed. The gamma-ray spectrum of the precipitate indicated the absence of impurities. The chemical yield ranged from 70 to 95%. Counts were made at the 0·316 MeV gamma-ray peak of the 74·7 d iridium-192. Positive identification was made by means of the iridium-192 gamma-ray peak at 0·47 MeV. No iridium activity was detected in the aluminium discs used for blanks.

These researches were extended by Baedecker and Ehmann[90] to include determinations of gold,

platinum, and iridium in meteoritic and terrestrial materials. The three metals were sometimes determined simultaneously in a single sample. The techniques used for sample preparation, dissolution, monitoring, irradiation, and iridium separation were previously discussed.[3]

When the three metals were determined simultaneously, they were adsorbed selectively on Dowex 2-X8 anion-exchanger, then iridium was eluted first with hydroxylamine and hydrochloric acid as previously described,[3] then gold with a solution of thiourea in dilute hydrochloric acid. The gold eluate was treated with ammonia, the gold sulphide produced was dissolved, and the gold extracted by ethyl acetate and finally precipitated by hydroquinone, purified, dried and weighed, and its activity was counted at the 0·411 MeV peak of gold-198. Platinum was not isolated chemically but was determined indirectly by counting at the 0·158 MeV peak of the 3·14 d gold-199 produced indirectly from platinum-198. Problems arose from the simultaneous production of gold-199 through double neutron capture by gold-197. Methods of avoiding the error were discussed. The preferred method involved the subtraction of the gold-198 spectrum from a gold flux monitor (which automatically included the gold-199 activity caused by the double neutron capture by gold-197, and the gold-198 Compton distribution). The total error for platinum was about ±20%. The error for gold and iridium was ±8–10%. For the latter element the 0·31, 0·47 and 0·61 MeV gamma-ray peaks of 74·37 d iridium-192 were used for counting.

Platinum, iridium and palladium. A neutron activation method for the determination of platinum, iridium and palladium in meteorites was recorded by Hamaguchi, Nakai and Kamemot.[91] The method uses a cation-exchange separation previously recorded by Stevenson *et al.*[92] and applied by Karttunen and Evans[93] to the separation of rhodium from palladium.

Solutions of the irradiated meteorite were treated with noble metal carriers and then with magnesium. The precipitate was fused with sodium peroxide and hydroxide, the cooled melt was leached with water and the residue was dissolved in hydrochloric acid. The metal constituents were oxidized with chlorine, and then platinum and iridium were precipitated as the ammonium hexachloro-salts. Palladium in the filtrate was purified by reprecipitation with dimethylglyoxime after scavenging with iron hydroxide. The chloro-salts were dissolved and treated with perchloric and nitric acids, the perchlorates were passed through a cation-exchanger, and the metals were eluted selectively. Platinum was purified by solvent extraction with ethyl acetate to remove gold and with ethyl acetate and tin(II) chloride to separate the platinum, which was finally precipitated by magnesium. Palladium, the second to be eluted from the cation-exchanger was purified by treatment with dimethylglyoxime alternating with scavenging with iron hydroxide.

Iridium in the third fraction of eluate was precipitated by magnesium. Initially the meteorites were irradiated for 2–3 d (5 hr/day) with a flux of 10^{11} neutrons . cm^{-2} . sec^{-1}. Standards were prepared by adding the noble metals to a mixture which simulated the composition of a meteorite.

ALLOYS

Gold and palladium in aluminium

For the determination of impurities in very high purity aluminium including gold and palladium, Gaittet[94] described a procedure for the separation of the two metals from tellurium by extracting gold bromide with ether and precipitating palladium with dimethylglyoxime.

Gold and platinum metals in silver

Zvyangintsev and Kulak[95] determined gold and platinum metals in refined silver by neutron activation. The isotopes used were gold-197, platinum-192 and -196, palladium-102 and -108, iridium-191 and -193. The interference from palladium-109 produced from silver was avoided by the use of fluxes of 5×10^{9}–10^{10} and 10^{11}–5×10^{13} neutrons . cm^{-2} . sec^{-1}. The activity of the isolated precipitates was compared with the activity of standards, and corrections made for chemical yield of the carrier and for self-absorption in the sample. The silver samples were irradiated in the form of thin shavings to reduce self-absorption. Irradiation of samples in the form of blocks was considered to be unsatisfactory. After irradiation, the samples and standards were dissolved in nitric acid, and carriers for each of the constituents to be determined were added in amounts of 15–20 mg. Silver was removed as the chloride, gold and copper by nitrite, palladium by dimethylglyoxime, iridium by hydrolysis to the hydrated dioxide and platinum by mercury(I) chloride. Gold was separated from copper by solvent extraction and then precipitated by sulphur dioxide. The chemical yield was determined gravimetrically. The authors sought to achieve radioactive purity by dissolving each precipitate, adding appropriate carriers, and reprecipitating. Traces of active silver were removed similarly by adding silver to the initial silver chloride filtrate and filtering off the silver chloride. Here, it may be noted that a silver chloride precipitate preferentially adsorbs palladium from solution, and because the mechanism of this phenomenon has not been established, the effect, if any, of this adsorption upon isotopic homogeneity ought to be investigated.

There is also the question of incomplete dissolution of iridium/silver alloys. To the best of the present authors' knowledge no results have been recorded to indicate that even traces of iridium can be completely dissolved by treatment of a cupelled silver alloy with nitric acid solutions. Furthermore, the technique used by the authors to determine radioactive purity may not necessarily indicate chemical purity. In any case, the authors record a precision for the method of only ±5–20%. It is noted that no comparative results were given for the chemical determination of iridium, though they were included for gold, platinum and palladium.

Gold and platinum in silicon

For the determination of 29 elements, including gold and platinum, in ultra-pure silicon Thompson *et al.*[25] applied a modification of the classical separations, and made beta and gamma activity measurements. Gold was separated by formation of gold and arsenic sulphides, followed by treatment with hydrochloric, nitric and perchloric acids, addition of potassium iodide and solvent extraction with carbon tetrachloride. Chromium(II) chloride was used to precipitate the gold. Platinum was isolated as the sulphide together with cadmium, molybdenum, mercury and tin, and finally precipitated as metal by chromium(II) chloride. The concentrations of gold were as small as 5×10^{-5} ppm, and of platinum, 9×10^{-4} ppm.

Osmium and iridium in platinum and palladium

A neutron-activation method for the determination of submicro amounts of osmium and iridium in platinum and palladium was recorded by Morris and Killick.[96] The samples were activated for 1 week with fluxes of 10^{12} neutrons.cm^{-2}.sec^{-1} for palladium and 9×10^{11} neutrons.cm^{-2}.sec^{-1} for platinum. Measured amounts of standard solutions of ammonium hexachloro-osmate and hexachloroiridate were added to 0·1 g each of platinum and palladium powder. Activity measurements were made on 30·6 hr osmium-193, 16 d osmium-191, 19 hr iridium-194 and 74 d iridium-192. All activities for osmium were measured with a Geiger-Mueller counter and for iridium with a gamma-scintillation counter, and corrected for paralysis, background and chemical yield. No figures for the chemical yield were reported. The radiochemical purity of the separated osmium and iridium was confirmed by decay measurements. The possibility of errors arising from certain conflicting nuclear processes was examined experimentally. The activating flux used for palladium was applied also to platinum in which case the corresponding flux of fast neutrons was $1{\cdot}6 \times 10^{11}$ neutrons.cm^{-2}.sec^{-1} as compared to the fast neutron flux of 5×10^{8} used initially for the platinum activation. The average result for osmium was 0·36 ppm as compared to 0·33 ppm obtained with the flux of 9×10^{11} neutrons.cm^{-2}.sec^{-1}. In the case of iridium the respective values were 0·66 ppm and 0·50 ppm. Errors from the conflicting nuclear processes could therefore be ignored. Interference from other possible nuclear reactions was shown by calculation to be negligible. The authors reported values for osmium in the range 0·08–1·06 ppm, and for iridium, 0·097–11·1 ppm. The osmium solutions were standardised by evaporation and reduction of the residue in hydrogen to produce osmium as the weighing form; the iridium solutions were standardised by hydrolytic precipitation.

After irradiation the material was dissolved in hydrochloric acid and osmium and iridium carriers were added. Osmium tetroxide was distilled from nitric acid solution and collected in a solution of sodium hydroxide and methanol. The osmium was precipitated hydrolytically, and the oxide was converted into the metal by reduction with hydrogen, and the metal was weighed to establish the chemical yield. The pot liquid was treated to remove platinum, rhodium, *etc.*, selectively by mercury(I) chloride and sodium bromide, then iridium in the filtrate was precipitated as the hydrated oxide, which was then dissolved in hydrochloric acid and fumed with perchloric acid, and the iridium was extracted by pyridine from sodium hydroxide solution. The pyridine extract was then treated to produce finally hydrated iridium(IV) oxide; the oxide was ignited to yield the metal, the activity of which was counted.

It is unfortunate that the authors did not give the chemical yield. The procedure for the determination of iridium offers new features and if analytically effective could provide useful alternative methods for iridium after removal of osmium.

Ruthenium, palladium and platinum in beryllium

Zarmyatnina *et al.*[97] mixed standard samples of palladium chloride, chloroplatinic acid and ruthenium nitrosopentachloride and irradiated them in a uniform thermal neutron flux. The samples and standards together with carriers were dissolved in hydrochloric acid and hydrogen peroxide. Ruthenium was isolated by distillation into sodium hydroxide solution, then precipitated by ethanol. Palladium and platinum were precipitated as sulphides. Palladium was separated by precipitation as the dimethylglyoximate, selective extraction with butyl phosphate, and precipitation again as

first the glyoximate and finally the sulphide. Platinum was separated by extraction with butyl phosphate and benzene and finally by precipitation of the sulphide. The weighing forms were ruthenium(IV) oxide and platinum and palladium metals. Activities were measured for ruthenium-106, palladium-109 and platinum-197. The lanthanides were also determined.

Rhodium, iridium and gold

The increasing interest in the analytical use of short-lived isotopes is made evident by a variety of publications. Anders[48] used isotopes with 5–24 sec half-lives for the determination of 18 elements including rhodium, iridium and gold. Irradiations were made at a flux of 2×10^8 neutrons.cm^{-2}.sec^{-1}. The activation analysis required less than ½ hr and for about 15 mg of gold the relative deviation was about 4%. By the subtraction of the spectrum taken 32 sec after irradiation from the spectrum taken 2 sec after irradiation, most of the longer-lived contributions were suppressed. The results were interpreted by comparing the number of counts in the photopeak ranges of the difference spectra for both samples and standards. Cumulative spectra were collected with a "rabbit" to serve as a background correction.

Iridium, platinum and gold

In a study of the radiation characteristics of the active isotopes of iridium, platinum and gold, Wilkinson[98] used conventional methods of dissolution and chemical separation. For the dissolution of iridium he used the bomb method of Wichers, Schlect and Gordon,[99] and after removing osmium, gold and platinum, precipitated iridium as the hydrated dioxide. For large amounts of iridium the ammonium chloride method was applied. Osmium was removed by distillation of the tetroxide from nitric acid and finally precipitated by magnesium. Gold was then removed by solvent extraction and precipitated by sulphur dioxide; this was followed by the extraction of platinum as the tin(II) complex and precipitation of the metal by magnesium. The final precipitates were washed with acetone and mounted as the metal for counting, or were dissolved and the resulting solutions were evaporated to yield residues which were used for counting.

Ruthenium and palladium in fission products

In a study of the fission of thorium with alpha particles Newton[100] isolated ruthenium from the products by distillation with perchloric acid and sodium bismuthate, collected the tetroxide in a solution of sodium hydroxide, and precipitated the hydrated oxide with ethanol and finally the metal with magnesium. He removed palladium with dimethylglyoxime, dissolved the glyoximate in nitric acid, made the solution ammoniacal, and precipitated silver iodide. The glyoximate was again separated from the solution, and mounted for counting.

DISCUSSION

Considered in retrospect, the research reports reviewed here suggest a few comments based on some 30 years of experience in the field of noble metal research.

Those analytical chemists who have struggled to establish experimentally the relative efficiency and the applicability of newly proposed techniques must find astonishing the apparent confidence with which the efficiency of analytical activation methods for such complex materials as ores, alloys, *etc.*, are accepted by their authors. The almost constant failure to deal adequately with the problem of efficiency relative to proved methods is especially disappointing when there frequently exist other techniques for determining trace constituents, which could be used for comparison. The need for a comparison of accuracy is sometimes met by casual references to adverse characteristics of other published chemical and physical methods, with the intention of placing the proposed method in a favourable perspective. This approach is not, of course, a characteristic only of activation methods; too often it has presented a misleading interpretation of the researches to which reference is made. Furthermore, such unfavourable comparisons, without the backing of the unmistakable mark of experience, serve only to initiate lack of confidence in the reports.

In many of the earlier activation methods the more unacceptable separatory

procedures and reagents seem often to have been used. This deficiency is particularly evident in the analytical methods for iridium and ruthenium. On the other hand, in the more recent reports of activation methods, a number of new reagents for both the separation and determination of noble metals has been proposed and results for known separatory processes have been provided which indicate the advisability of re-examining some of the classical analytical methods. A case in point is the report[69] that iridium may be volatilized from perchloric acid solutions.

It is emphasized again that for a wide variety of purposes, involving the detection and determination of submicrogram traces, the activation techniques now available will meet a fast growing need that, in general, is not met by any other existing analytical technique. Indeed, Herr and Woolfe[79] have proposed that terms indicating a new dimension of purity will now be required and it is suggested that "nuclear pure" must be added to distinguish from "chemically pure" and "spectrally pure." It is to be hoped that each of these terms will be more clearly defined.

Résumé—On passe en revue de façon critique, jusqu'en décembre 1965, les méthodes par activation de neutrons pour les sept métaux nobles. Les méthodes traitent de la détermination d'impuretés à l'état de traces dans chaque métal noble ainsi que de la détermination de traces de métaux nobles dans des milieux tels que substances organiques, produits de fission et autres solutions, minerais, alliages, minéraux, silice et métaux de base. On met en évidence la nécessité de preuves confirmatoires dans le cas de matériaux complexes comme les minerais.

Zusammenfassung—Es wird eine kritische Übersicht über Neutronenaktivierungsmethoden zur Bestimmung der sieben Edelmetalle bis Dezember 1965 gegeben. Die Methoden befassen sich mit der Bestimmung von Spurenverunreinigungen in jedem Edelmetall sowie mit Edelmetallspuren in Medien wie organischem Material, Lösungen von Spaltprodukten und anderen Lösungen, Erzen, Legierungen, Mineralien, Kieselerde und unedlen Metallen. Es wird Nachdruck auf die Feststellung gelegt, daß bei so kompliziert zusammengesetzten Substanzen wie Erzen zusätzliche Informationen notwendig sind.

A NEW OXIDIMETRIC REAGENT: POTASSIUM DICHROMATE IN A STRONG PHOSPHORIC ACID MEDIUM—VII*

PHOTOMETRIC TITRATION OF VANADIUM(IV) AND OF CERIUM(III) ALONE AND IN MIXTURES WITH IRON(II)

G. GOPALA RAO and P. KANTA RAO
Department of Chemistry, Andhra University, Waltair, India

(*Received* 19 *October* 1964. *Revised* 14 *February* 1966. *Accepted* 15 *March* 1966).

Summary—Vanadium(IV) can be accurately titrated with potassium dichromate in media containing phosphoric acid of 3–12*M* concentration: the change in absorption of vanadium(IV) is followed in the region 660 mμ using a red filter. It is more convenient to carry out the titration in 3*M* phosphoric acid because at higher concentrations chloride, nitrate, cerium(III) and manganese(II) may interfere. Photometric titration is more convenient than potentiometric because the former can be made in a 3*M* phosphoric acid medium, whereas the latter is possible only in 12*M* phosphoric acid. The simultaneous differential photometric titration of iron(II) and vanadium(IV) is also possible. Conditions have been found for the photometric titration of cerium(III) and of cerium(III) plus iron(II). The titration is carried out (at 450 mμ or with a blue filter) in about 10.5*M* phosphoric acid. Application of the method to a cerium mineral is considered.

GODDU AND HUME[1] titrated vanadium(IV) with potassium permanganate photometrically at 525 mμ. The relative error was 0·5–1·0%. Chromium(III) interfered when the ratio chromium(III): vanadium(IV) exceeded 10; tungsten(VI) also interfered. Gopala Rao and Kanta Rao[2,3] titrated vanadium(IV) and cerium(III) potentiometrically with potassium dichromate in phosphoric acid medium. We have now investigated the same titrations with a photometric end-point.

EXPERIMENTAL

Reagents

Cerium(IV) solution, 0·1*M*. Prepared in 1*M* sulphuric acid from *Pro Analysi* cerium(IV) sulphate and standardised as previously described.[3]

Cerium(III) solution, 0·1*M*. Prepared in 1*M* sulphuric acid and standardised.[3]

Vanadium(IV) solution, 0·1*M*. Prepared in 0·5*M* sulphuric acid and standardised as described previously.[3]

Vanadium(V) solution, 0·1*M*. Prepared from analytical reagent grade ammonium vanadate (B.D.H. Ltd., England), by heating with a slight excess of analytical reagent grade sodium carbonate until ammonia is completely driven off, and then dissolving the product in water. The solution was standardised against a standard solution of iron(II) sulphate with barium diphenylamine sulphonate as indicator.

Potassium dichromate solutions. Prepared from *Pro Analysi* grade potassium dichromate (E. Merck, Germany) in the required concentrations of phosphoric acid.

Syrupy phosphoric acid. Pro Analysi grade phosphoric (E. Merck, Germany) was purified as previously described.[4] For determination of the absorption spectrum of cerium(IV) and chromium(VI) neither syrupy phosphoric acid of *Pro Analysi* grade nor analytical reagent grade acid was satisfactory because of the presence of traces of reducing impurities which react rapidly with cerium(IV) and chromium(VI).

Absorption spectra

Solutions of vanadium(IV), vanadium(V), cerium(IV) and potassium dichromate in various concentrations of phosphoric acid were prepared, and their absorption spectra measured. A Hilger Uvispek spectrophotometer with 1-cm glass cells was used. The absorption spectra are shown in Figs.1–4. Cerium(III) in phosphoric acid (12*M*) shows no absorption over the range of wavelengths

* Part VI: *Talanta*, 1966, **13**, 1335.

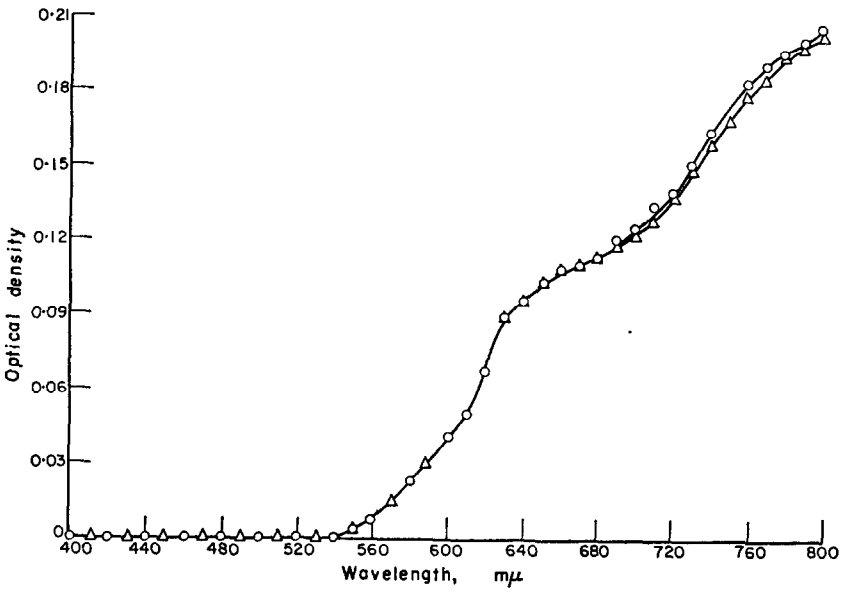

FIG. 1.—Effect of phosphoric acid concentration on the absorption spectrum of 0·01*M* vanadium(IV):
⊙—⊙ 1·5*M* H_3PO_4,
△—△ 3·0*M* H_3PO_4.

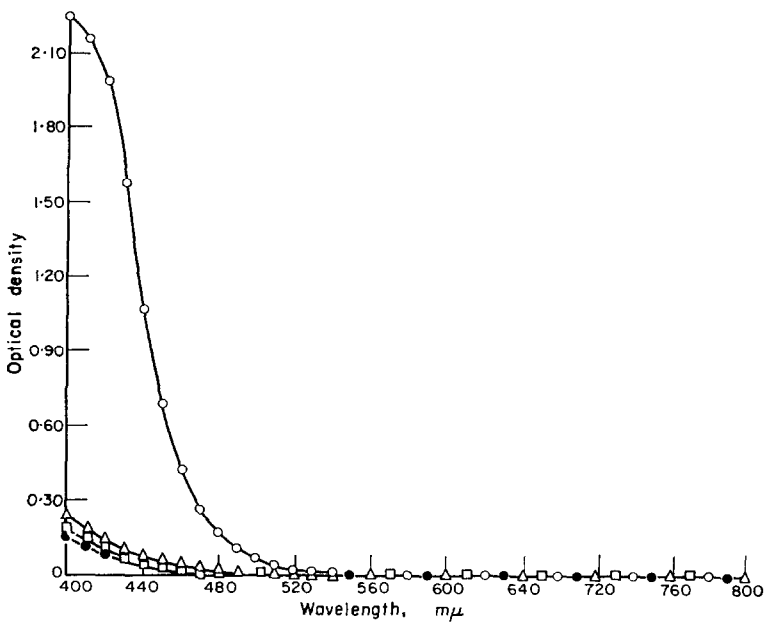

FIG. 2.—Effect of phosphoric acid concentration on the absorption spectrum of 0·01*M* vanadium(V):
⊙—⊙ 10·5*M* H_3PO_4,
△—△ 4·5*M* H_3PO_4,
⊡—⊡ 3·0*M* H_3PO_4,
●—● 1·5*M* H_3PO_4.

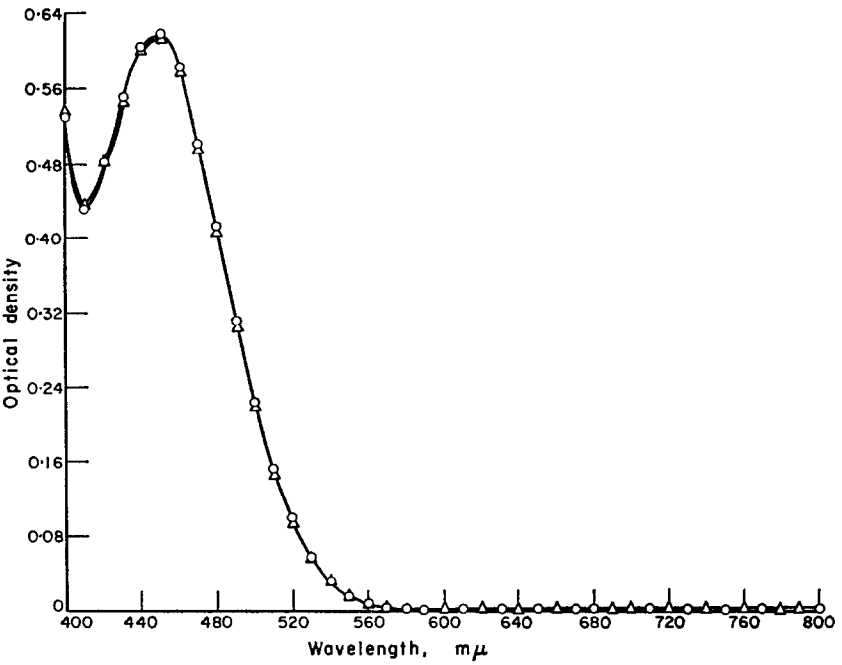

FIG. 3.—Effect of phosphoric acid concentration on the absorption spectrum of 0·0033*M* chromium(VI)
○—⊙ 4·5*M* H_3PO_4,
△—△ 12·0*M* H_3PO_4.

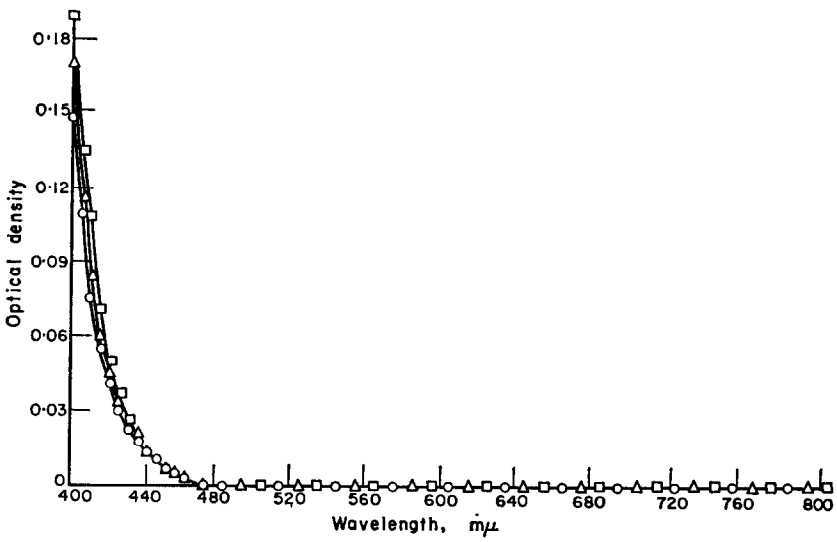

FIG. 4.—Effect of phosphoric acid concentration on the absorption spectrum of 0·01*M* cerium(IV):
⊡—⊡ 9·0*M* H_3PO_4,
△—△ 10·5*M* H_3PO_4,
○—⊙ 12·0*M* H_3PO_4.

covered. From these absorption spectra and those already published for vanadium(IV)[5] and chromium(III),[4] the best wavelengths for the spectrophotometric titration of vanadium(IV) and cerium(III) can be selected. For the titration of iron(II) and vanadium(IV) in the same solution, or iron(II) and cerium(III), advantage can be taken of the large difference in the molar absorptivity between chromium(III) and vanadium(IV) at 660 mμ and between chromium(III) and chromium(VI) at 450 mμ, to yield separate end-points for the iron(II) oxidation and the oxidation of the other reductant present.

Rate of reaction

To find the concentration of phosphoric acid at which a rapid oxidation of vanadium(IV) or cerium(III) occurs, we measured at different time intervals the absorbance of a mixture of vanadium(IV) or cerium(III) with an equivalent amount of potassium dichromate at a suitable wavelength. The results are given in Table I. At 660 mμ the initial absorbance is due to vanadium(IV) and the final absorbance to chromium(III). At 450 mμ the absorbance of chromium(VI) decreases as reaction proceeds.

TABLE I.—EFFECT OF PHOSPHORIC ACID CONCENTRATION ON TIME NEEDED TO COMPLETE REACTION BETWEEN CHROMIUM(VI) AND VANADIUM(IV) OR CERIUM(III)

	Time needed, *min*								
Phosphoric acid concentration, *M*	0·75	1·5	3·0	4·5	6·0	7·5	9·0	10·5	12·0
Vanadium(IV)	7	3	2	2	1	1	1	1	1
Cerium(III)	—	—	—	—	—	40	10	1	1

If the phosphoric acid concentration is higher than 7*M*, then ions such as manganese(II), cerium(III) and nitrate interfere with the vanadium titration. For this reason 3*M* phosphoric acid is used as the titration medium for vanadium(IV) and the spectrophotometer readings are taken 3 min after each addition of the titrant.

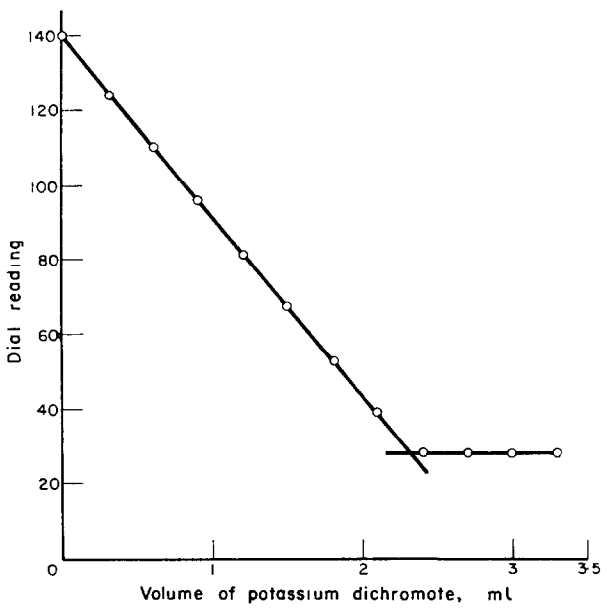

FIG. 5.—Photometric titration of vanadium(IV) (16·44 mg) with 0·2*N* potassium dichromate in a 3*M* phosphoric acid medium.

Procedure for vanadium

Take 2–10 ml of vanadium(IV) solution (containing 10–50 mg of vanadium) in an optical cell (a convenient size is 2 × 4 × 8 cm), add 10 ml of syrupy phosphoric acid, and dilute to 40 ml with water. Arrange an inlet tube so that it is immersed in the solution at one corner of the cell, out of the light-path. Pass carbon dioxide through the solution to mix it and maintain an inert atmosphere above it, and stop the passage of gas before taking a reading of the absorbance. Titrate photometrically at 660 mμ (or with a red filter), adding 0·2*N* potassium dichromate from a microburette, and taking readings 3 min after each addition. Plot absorbance (corrected for dilution) against volume of titrant added. The absorbance decreases as vanadium(IV) is oxidised, and becomes constant at the end-point. A typical curve is shown in Fig. 5, and typical results in Table II. The maximum relative error is 0·7%.

TABLE II.—PHOTOMETRIC TITRATION OF VANADIUM(IV) WITH POTASSIUM DICHROMATE IN A 3*M* PHOSPHORIC ACID MEDIUM

Vanadium(IV), *mg*	
Taken	Found
12·35	12·28
16·44	16·50
23·01	23·13
25·61	25·48
29·13	29·32
35·76	36·01
43·30	43·40
50·71	50·94

Interferences

Iron(II), arsenic(III), antimony(III), uranium(IV) and molybdenum(V) are also oxidised by potassium dichromate under the conditions proposed for the photometric titration of vanadium(IV). However, a separate equivalence point can be obtained from the photometric titration curve when iron(II) is present with vanadium(IV) (see later). Large amounts of chloride and nitrate do not interfere. Iron(III), cerium(III), manganese(II), cobalt(II), nickel(II), molybdenum(VI), uranium(VI), chromium(III) and zinc(II) do not interfere (see Table III). Tungsten(VI) interferes under the conditions proposed for the photometric titration of vanadium(IV), which forms a coloured solution with tungsten(VI). This interference can be eliminated if the photometric titration is carried out in a phosphoric acid medium of 7·5*M* or above. The photometric method of titration is advantageous compared with the potentiometric one because chloride, nitrate, cerium(III) and manganese(II) ions do not interfere.

Procedure for iron(II) and vanadium(IV)

Use the same apparatus as before but pass carbon dioxide through the sample solution for 10 min *before* adding the phosphoric acid; this is done to remove oxygen dissolved in the sample solution. Titrate and plot the results as before. There is an initial increase in absorbance as a result of production of chromium(III) in the preferential oxidation of iron(II), followed by a decrease as the vanadium(IV) is oxidised: the absorbance finally becomes constant. The first point of intersection (Fig. 6) corresponds to the end-point for iron(II) and the second to that for vanadium(IV). Typical results are shown in Table IV and a titration curve in Fig. 6. The maximum relative error is 0·7% for both species.

Procedure for cerium(III)

Take 1–7 ml of cerium(III) solution (containing 15–100 mg of cerium) in the optical cell, add 30–33 ml of purified 90% syrupy phosphoric acid, and dilute to 40 ml with water. Stir with carbon dioxide as already described, and titrate with 0·1*N* potassium dichromate photometrically at 450 mμ (or with a blue filter). Measure the absorbance 1 min after each addition of titrant, and apply a correction for dilution. Some typical results are shown in Table V and a titration curve in Fig. 7. The maximum relative error is 0·6%. The absorbance of the chromium(III) and cerium(IV) increases slowly up to the end-point, and then there is a steep rise in absorbance, from the addition of excess of chromium(VI).

TABLE III.

Interferences

Iron(II), vanadium(IV), manganese(II), arsenic(III), antimony(III), uranium(IV) and molybdenum(V) are also oxidised by potassium dichromate under the conditions proposed for the photometric titration of cerium(III). However, a separate equivalence point can be obtained from the titration curve when iron(II) is present with cerium(III) (see later). Fluoride, which forms a precipitate with cerium(III), also interferes. Chromium(III) interferes slightly if the titration is started immediately after adding phosphoric acid because any chromium(III) salt other than phosphate has some absorption in the region where chromium(VI) also absorbs; moreover this absorption of chromium(III) does not remain constant but changes with time because of increasing complexation with phosphoric acid. If the mixture of salts and phosphoric acid is kept for 2 hr equilibration of phosphoric acid with chromium(III) is almost complete and the titration with potassium dichromate can then be started without any interference from chromium(III). Although cobalt(II), nickel(II), molybdenum(VI), uranium(VI) and cerium(IV) have some absorption in the same region as chromium(VI), they do not interfere because this absorption remains constant throughout the experiment. Thallium(I) and large quantities of chloride do not interfere. The non-interference of chloride is an advantage of the photometric method over the potentiometric titration. Nitrate slowly oxidises cerium(III) in a strong phosphoric acid medium and interferes. Sulphuric acid does not interfere even up to a concentration of 1*N*. Iron(III), thallium(I), copper(II), zinc(II), tungsten(VI), thorium(IV), *etc.*, do not interfere (Table VI).

† Interferes.

Procedure for iron(II) and cerium(III)

Perform the titration as described for cerium(III) alone. The iron(II) is preferentially oxidised, and the absorbance increases slowly, the absorbing species being the chromium(III) produced. When the iron has all been oxidised the absorbance increases slightly more rapidly [chromium(III) and cerium(IV)] until after the cerium end-point, when the excess of chromium(VI) absorbs strongly. Because of the low molar absorptivity of the chromium(III) and cerium(IV) the first end-point is difficult to interpret (Fig. 8), and errors made here affect both the iron and the cerium results, the errors being in opposite directions. Consequently the relative error (as is evident from the typical results in Table VII) is rather large, about 2%. A better accuracy can be attained by determining the total titre photometrically by the method described, and titrating the iron(II) separately with potassium dichromate in 0·5*M* sulphuric acid, using barium diphenylamine sulphonate as indicator. Under these conditions the cerium(III) is not titrated, and its titre is found by difference. Results obtained in this way are shown in Table VIII; the relative errors here are 0·4% for iron and 1·0% for cerium.

Analysis of cerium in a mineral

Digest about 10 g of sample (*e.g.*, monazite sand) in a porcelain evaporating dish with 25 ml of concentrated sulphuric acid on a sand-bath until most of the sulphuric acid is evaporated. Cool, leach the mass with 1*M* sulphuric acid, filter and dilute to 250 ml in a volumetric flask. Withdraw 8-ml portions and titrate them by the procedure described for cerium(III). The rare earths and thorium do not interfere. Typical results for a monazite sand from Travancore are shown in Table IX.

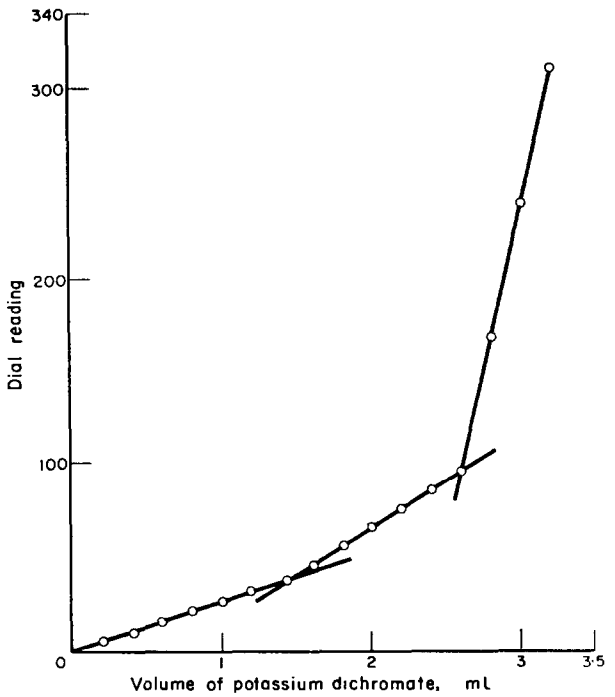

FIG. 8.—Photometric titration of a mixture of iron(II) (15·74 mg) and cerium(III) (33·29 mg) with 0·2*N* potassium dichromate in a 10·5*M* phosphoric acid medium.

The method now developed for the photometric titration of cerium(III) is more convenient than the method of Bricker and Loeffler.[8] These workers employed cobalt(III) sulphate for the photometric titration of cerium(III) in a 1*M* sulphuric acid medium using silver nitrate as catalyst, and measured the absorbance at 400 mμ [cerium(IV)] or at 610 mμ [cobalt(III)]. Cobalt(III) sulphate is difficult

to prepare and is unstable in aqueous solution at room temperature. Further, the dichromate method now proposed by us is subject to fewer interferences. Chromium(III), chloride, acetic acid and oxalic acid do not interfere in the dichromate method, whereas they interfere in the cobalt(III) method. The photometric titration of cerium(III) in a neutral pyrophosphate medium with potassium permanganate proposed by Marple, Przybylowicz and Hume[9] requires close control of pH (5·5–7·0). If the pH is high, basic salts may precipitate and if it is low the stoichiometry of the reaction is altered because of incomplete stabilisation of the reduced manganese in the tervalent state. Moreover, this method is subject to more interferences than the dichromate method proposed by us.

Acknowledgement—One of us (P. K. R) desires to thank the Council of Scientific and Industrial Research (India) for the award of a Research Fellowship.

Zusammenfassung—Vanadium(IV) kann mit Kaliumdichromat in Medien, die 3–12*M* Phosphorsäure enthalten, genau titriert werden: bei Gebrauch eines Rotfilters wird die Änderung der Absorption von Vanadium(IV) im Bereich von 660 nm verfolgt. Es ist bequemer, die Titration in 3 M Phosphorsäure auszuführen, da bei höherne Konzentrationen Chlorid, Nitrat, Cer(III) und Mangan(II) stören können. Photometrische Titration ist bequemer als potentiometrische, da erstere in 3*M* Phosphorsäure stattfinden kann, letztere dagegen nur in 12*M* Phosphorsäure möglich ist. Die gleichzeitige differenzphotometrische Titration von Eisen(II) und Vanadium(IV) ist auch möglich. Die Bedingungen für die photometrische Titration von Cer(III) und Cer(III) plus Eisen(II) wurden gefunden. Die Titration wird (bei 450 nm oder mit Blaufilter) in etwa 10,5*M* Phosphorsäure durchgeführt. Die Anwending der Vorschrift auf ein Cermineral wird erörtert.

Résumé—On peut doser avec précision le vanadium(IV) au moyen de bichromate de potassium dans des milieux contenant de l'acide phosphorique à la concentration 3–12*M*: on suit la variation d'absorption du vanadium(IV) dans la région 660 mμ en utilisant un filtre rouge. Il est plus convenable de mener le dosage en acide phosphorique 3*M* car, aux plus fortes concentrations, chlorure, nitrate, cérium(III) et manganèse(II) peuvent interférer. Le dosage photométrique convient mieux que le dosage potentiométrique car le premier peut être effectué en milieu acide phosphorique 3*M*, alors que le second n'est possible

qu'en acide phosphorique 12*M*. Le dosage photométrique différentiel simultané du fer(II) et du vanadium(IV) est également possible. On a trouvé des conditions de dosage photométrique du cérium(III) et de cérium(III) plus fer(II). Le dosage est mené (à 450 mμ ou avec un filtre bleu) en acide phosphorique environ 10,5*M*. On considère l'application de la méthode à un minéral du cérium.

SEPARATION OF STRONTIUM FROM LARGE AMOUNTS OF CALCIUM, WITH APPLICATION TO RADIOSTRONTIUM ANALYSIS

VICTOR E. NOSHKIN and NORMAN S. MOTT
Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, U.S.A.

(*Received* 4 *February* 1966. *Accepted* 30 *May* 1966)

Summary—The elution first of calcium and then of strontium by complex formation with cyclohexanediaminetetra-acetic acid (CyDTA) after sorption on ion-exchange columns, is shown to require careful control of pH and the concentrations of CyDTA and NH_4^+. A procedure is described for volumetric analysis of calcium and strontium, and for use of this separation procedure before determination of ^{90}Sr in sea-water. Careful choice of reagents and materials is shown to be necessary for use of such a method in determination of trace amounts of radiostrontium.

THE chemical separation of strontium from sea-water is complicated by the high concentration of calcium, which has a close chemical similarity to strontium. Numerous precipitation, extraction or ion-exchange procedures have been described for the separation or determination of strontium in materials containing calcium.[1–18] Of these, most are not suitable for treatment of large volumes of sea-water; those which have been devised specifically for this purpose[1,12–14,16,17] are all time-consuming, of only moderate efficiency, and involve some steps which are potentially hazardous.

In searching for an improved method of collecting fallout ^{90}Sr from large volumes of sea-water, we have developed an ion-exchange procedure using the complexing agent cyclohexanediaminetetra-acetic (CyDTA) to separate calcium from strontium. The procedure is free from hazardous chemicals, and is much less laborious than others we have used.

Wade and Seim[4] have discussed the reaction between a metal ion and the complexing agent EDTA. They have indicated that the system $M^{2+} + H_2Y^{2-} = MY^{2-} + 2H^+$ is dependent on the hydrogen ion concentration. As the acidity of a solution is increased, the concentration of the metal-EDTA complex will decrease; the concentration of the complex at any pH depends on its stability constant. On this basis, procedures using cation-exchange resins have been proposed for separation of calcium from strontium, followed by strontium determination by instrumental or chemical means.[3–8,11] A resin will in general favour retention of ionic species of smallest ionic radius (for a mixture of hydrated ions with the same charge); strontium can be retained and calcium eluted if a proper choice of conditions and complexing agent is made (the calcium complex is considerably more stable than the strontium complex).

The logarithms of the stability constants of the calcium and strontium complexes with EDTA are 10·59 and 8·63, respectively.[19] Comparable values for the stability constants with CyDTA, quoting from unpublished data, are 12·3 and 10·0.[19] The ratios between the stability constants of calcium and strontium with EDTA or CyDTA

are approximately the same, but the higher absolute values with CyDTA indicate that these complexes will compete more successfully with the resin than do the EDTA complexes. In ion-exchange complexing-agent elutions, we have found very important the combined effect of pH, concentration of complexing agent and concentration of additional cations; these three variables interact to affect the separation of calcium from strontium.

The procedure described is being used both for separation of strontium from as much as 55 l. of sea-water, and for the separate determination of strontium and calcium in mixed carbonate precipitates. In the measurement of ^{90}Sr at the low concentrations typical of deep ocean water, careful choice of reagents and materials is essential to minimize blank corrections.

EXPERIMENTAL

Resin capacity

Reagents and equipment. Dowex 50-X12 (50–100 mesh) cation-exchange resin washed with six 50-ml portions of 6*M* hydrochloric acid, then with water followed by 10% ammonium chloride solution until the washings were neutral, finally with water until tests showed no chloride present. Calcium acetate solution, 10% w/w, adjusted to pH 4·7 with ammonia and acetic acid. Glass column: 1·2 × 20 cm fitted with a glass-wool plug and teflon stop-cock.

Procedure. The washed resin was filtered under suction and dried in an oven at 70° for 10 min. Then 3·6 g of the resin were slurried with water and transferred to the column. The calcium acetate solution was percolated through the column at a rate of 1 drop/2 sec. After breakthrough occurred, as indicated by testing the effluent with sodium carbonate, the column was washed with water and the calcium stripped from the column with 3*M* hydrochloric acid, precipitated as calcium carbonate, collected, and weighed to determine the resin capacity. This was 60 mg of calcium per g of dried resin.

Conditions for strontium elution

Reagents and equipment. Strontium chloride solution containing 11 mg of strontium per ml; ^{85}Sr tracer added to bring the specific activity of the solution to 500 cpm ^{85}Sr/mg Sr. CyDTA, 0.038*M*, prepared by dissolving 13.1 g of CyDTA in 300 ml of 1*M* ammonia and diluting to 1 l. Radiometer pH meter. Sodium iodide well-type scintillation counter. Ion-exchange columns prepared as already described.

Procedure

Elution of strontium at pH 6·7. Aliquots of the tagged strontium solution (5 ml) were sorbed on each of 4 columns. The CyDTA solution was adjusted to pH 6·7 with ammonia and acetic acid, and diluted and adjusted to give CyDTA concentrations of 0·028 and 0·018*M* with ammonium ion concentration 0·3*M*. Ammonium acetate, 0·3*M*, was adjusted to pH 6·7. Each of these solutions was used to elute strontium; 5-ml fractions of effluent, collected serially, were counted to obtain the elution curves shown in Fig. 1. The 0·028*M* CyDTA was the most efficient eluent.

Ammonium ion effect at pH 6·7 *and* 5·1. Solutions of 0·028*M* CyDTA were prepared, 1·1, 0·3 and 0·04*M* in ammonium ion at pH 6·7; 150 ml of each solution were passed through a column loaded with 5 ml of tagged strontium solution. The effluent was analysed for ^{85}Sr as before. The results are shown in Fig. 2. The experiment was repeated with solutions of 0·028*M* CyDTA, 0·2, 0·4, 0·8, 1·2, 1·6 and 2·0*M* in ammonium ion, and at pH 5·1. The results are shown in Fig. 3.

Effect of pH. The effect of varying the pH while keeping the CyDTA and ammonia concentrations constant at 0·028*M* and 0·3*M* respectively, is shown in Fig. 4.

From these results it is evident that at pH 6·7 the minimum ammonium ion concentration necessary for elution of strontium lies between 0·04 and 0·3*M*. At pH 5·1 the ammonium ion concentration must be below 0·4*M* to retain strontium on the column. With 0·028*M* CyDTA and 0·3*M* ammonium ion, complete retention of strontium on the column was observed at pH 5·0–5·5; partial elution occurred at pH 5·5–6·2, and at pH 6·2 strontium was completely eluted. Calcium was completely removed from the column by 0·028*M* CyDTA that was 0·3*M* in ammonium ion and at pH 5·1, and no detectable ^{85}Sr was present in the eluate.

Column loading characteristics

Some solutions containing 4·5, 8·5, 12·5 and 20·5 mg Sr/ml at pH 4·5 were passed at 7 ml/min through columns containing 3·6 g of resin, to find the concentration that gave maximum uptake. The best uptake occurred when the strontium concentration did not exceed 8·5 mg/ml.

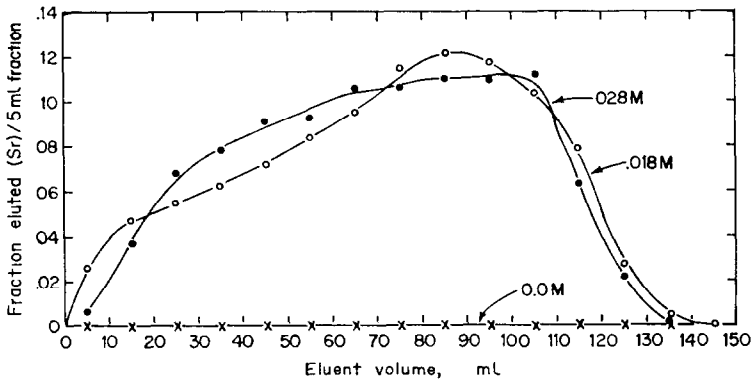

FIG. 1.—Strontium elution curves for 0·3*M* NH_4^+ at pH 6·7 and various CyDTA concentrations.

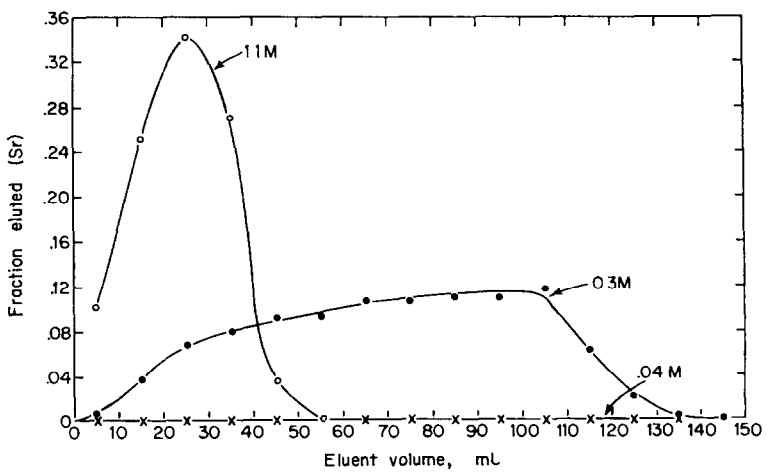

FIG. 2.—Strontium elution curves for 0·0286*M* CyDTA at pH 6·7 and various ammonium ion concentrations.

Sea-water samples

Separation of ^{90}Sr *from 500 ml of sea-water.* Fill a 1·2 × 55 cm glass column to a height of 31 cm with pretreated Dowex 50 resin (7·5 g of dry resin). Convert the resin to the ammonium ion form with 1*M* ammonium chloride and rinse it with water. With constant stirring acidify the sea-water sample to pH 1·0 with hydrochloric acid and add 100 mg of carrier strontium, and other desired carriers. Stir for several hr to ensure radiochemical equilibration. Adjust the sea-water to pH 7 with ammonia solution. Precipitate strontium, calcium, magnesium, barium and other interfering cations by adding sodium carbonate. Separate the strontium and much of the calcium by procedures described elsewhere.[1] Precipitate the mixed strontium-calcium carbonates; dry, weigh and dissolve them in a minimum amount of hydrochloric acid. Dilute the solution to give a concentration equivalent to 14 mg of the mixed carbonates per ml, and buffer to pH 4·7 with ammonia and acetic acid, maintaining the ammonium ion concentration in the final solution at 0·4*M*. Pass this solution through the column at 1 drop/2 sec; wash the column with 100 ml of water, and then at the same flow-rate elute calcium with a solution of 0·03*M* CyDTA and 0·4*M* ammonium ion buffered to pH 5·1. Test the effluent periodically with a saturated solution of oxalic acid. When no further precipitation is observed, stop the elution. Elute strontium with 0·03*M* CyDTA and 0·4*M* ammonium ion buffered to pH 6·7. Follow the course of elution by adding oxalate to each 10-ml portion, discontinuing

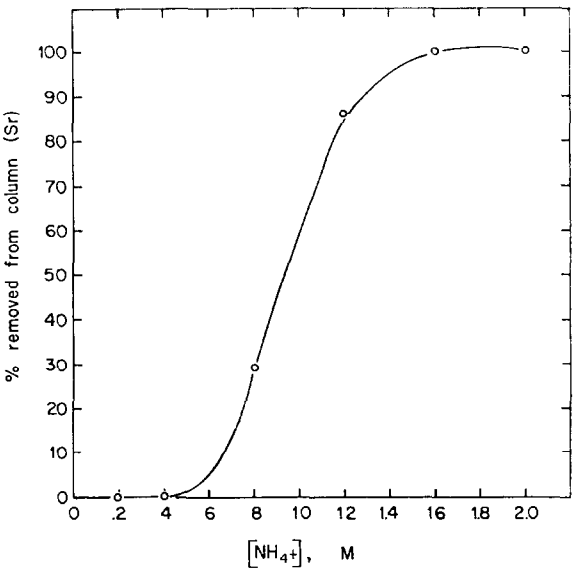

FIG. 3.—Elution of 55·8 mg of strontium with 150 ml of 0·028*M* CyDTA at pH 5·1 and various ammonium ion concentrations.

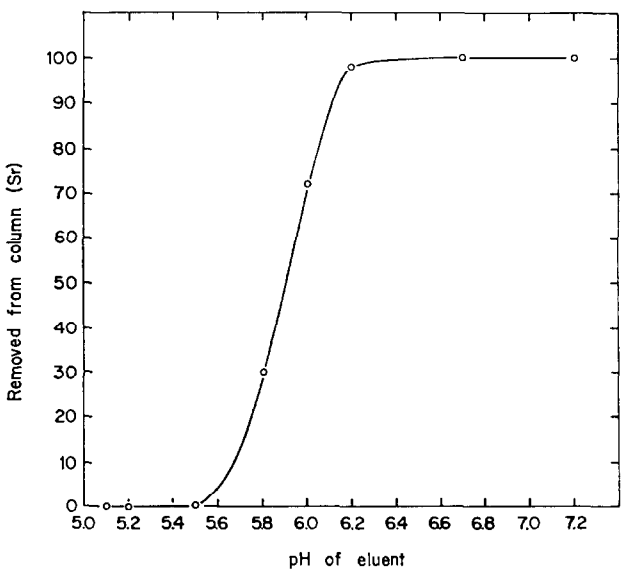

FIG. 4.—Effect of pH of eluent on elution of 55·8 mg of strontium with 150 ml of 0·028*M* CyDTA and 0·3*M* NH_4^+.

elution when no further precipitation is evident. Convert all the strontium oxalate into the carbonate and weigh it to determine recovery.

Separation of ^{90}Sr from 55 l. of sea-water. Prepare a 7 × 39 cm column with 1 lb of pretreated Dowex 50-X12 (50–100 mesh). Follow the procedure for ^{90}Sr in sea-water, described by Sugihara *et al.*[1] through the precipitation of mixed carbonates in the presence of EDTA. Weigh this precipitate, dissolve it in the minimum of hydrochloric acid needed and dilute with distilled water to a concentration of 14 mg of the mixed carbonates per ml; adjust the pH to 4·7 with ammonia and acetic acid, maintaining the ammonium ion concentration at 0·4*M* in the final solution. In routine operation, this results in volumes of about 2 l. Pass the solution through the resin column at 3 ml/min, rinse the column (500 ml of water) and strip calcium with the eluent described above (at 3 ml/min), checking the effluent periodically with oxalate (typically, 4–6 l. of effluent are needed for complete calcium elution). Next strip the strontium with the eluent described for 500-ml sea-water samples but at a flow-rate of 3 ml/min. If the stripping is not to be monitored or allowed to proceed overnight, 3*M* hydrochloric acid should be used as the stripping solution. If CyDTA is allowed to elute strontium unchecked, a large excess of it will be present in the effluent. The precipitation of strontium from this solution will be difficult and a loss in recovery evident. Precipitate strontium oxalate to determine recovery.

Separation and determination of strontium and calcium from their mixed carbonates. Dissolve the mixed carbonates in the minimum of hydrochloric acid needed, heat to expel carbon dioxide, and dilute to a known weight or volume. Remove an aliquot, adjust it to pH 9 with ammonia and titrate with standardized CyDTA (using Phthalein Purple indicator) to determine the total concentration of bivalent cations present. Load another aliquot onto a precleaned Dowex 50-X12 (50–100 mesh) column. The capacity of the column should exceed the sum of the calcium and strontium in the aliquot taken. Measure a volume of standardized CyDTA solution (pH 5·1, 0·4*M* in ammonium ion), corresponding to more than the total metal ion concentration on the column; pass it through the column at 3 ml/min, and follow it with two washes of water, each of about 1 column-volume. Determine calcium by titrating the excess of CyDTA in the combined eluent and washings with a standard calcium solution, using Phthalein Purple indicator. Then elute strontium as described above, again using a measured volume of CyDTA in excess of the strontium present, followed by two 1-column-volume water washes. Determine strontium by back-titration of the excess of CyDTA, as for calcium. A check is available in that the sum of the calcium and strontium found should equal the sum of calcium and strontium titrated in the first aliquot taken.

Determination of ^{90}Sr radiochemical blanks. Since this procedure was to be used for the determination of very low concentrations of ^{90}Sr in sea-water, reagent blanks were run to assess their radioactive contamination. Commercial cation-exchange resins have been shown[20] to contain small amounts of ^{90}Sr within the resin lattice, and these traces are not entirely removable by any continuous elution process. Slow release of strongly bound impurities during the interval between resin purification and use has also been noted.[21]

By the procedure outlined above for separation from 55 l. of sea-water, samples of commercial calcium and strontium salts were loaded on to columns and separated as shown in Table I. The eluted strontium in each case was weighed as carbonate to determine recovery, and then dissolved in 1*M* hydrochloric acid. After 15 days, iron(III) hydroxide was precipitated from this solution, dried, mounted and its beta-activity determined with a low-background detector. The net activity (Fig. 5) decreased with a 64·5 hr half-life, typical of the ^{90}Sr daughter, ^{90}Y.

The counting results (Table I) show that both calcium and strontium carbonates contain varying amounts of ^{90}Sr, whereas strontium chloride (at least the lot tested) is free of this isotope. Sample CB5 shows that some ^{90}Sr can be eluted from a large capacity Dowex 50-X12 column, even after precleaning as outlined above.

DISCUSSION

It appears that by careful choice of resins, carriers and other reagents, essentially no ^{90}Sr blank should be obtained with procedures proposed. Resin preparation and cleaning probably should be done with both hydrochloric and nitric acids; the fact that the distribution coefficient of barium is substantially lower in the nitric acid/cation-exchanger system than in the corresponding hydrochloric acid system,[22] suggests that the retention of ^{90}Sr on the resin may be reduced by nitric acid washing.

For routine analysis of ^{90}Sr in large numbers of samples containing large amounts of calcium, this separation method is an improvement in terms of speed, convenience and amount of sample manipulation, over the more conventional strontium–calcium separations by use of large quantities of fuming nitric acid.

‡ Chemical yield for this run was low because of accidental loss of sample. The *dpm* figure was calculated from a nett count-rate of 0·030 ± 0·015 cpm.

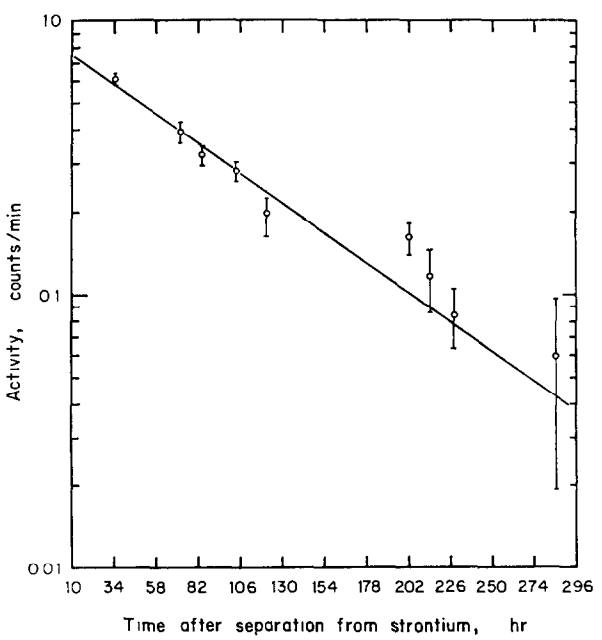

FIG. 5.—Decay curve of iron(III) hydroxide precipitate from a blank strontium solution (CB-2, Table I). Uncertainties indicated are $\pm\sigma$, from counting statistics only.

The average recovery of strontium from 500 ml of sea-water by CyDTA elution was found to be 75% for 50 samples; the 25% loss appeared to occur, indiscriminately, either before or after the elution chemistry.

More than 50 samples of mixed strontium and calcium carbonates (Sr:Ca ratio ranging from 0·1 to 0·8) have been analysed for strontium as described. The error associated directly and indirectly with the strontium determination in each sample averaged ±0·65% over the 50 samples.

Acknowledgements—The authors are indebted to Dr. V. T. Bowen for his helpful suggestions in the planning and operation of this work and to Miss S. Kite for aid in many of the analyses. This work was supported at the Woods Hole Oceanographic Institution by the United States Atomic Energy Commission under Contracts AT(30-1)-2174 and AT(30-1)13145; this is report number AT(30-1)-2174-32 and AT(30-1)-3145-3. This is contribution number 1841 from the Woods Hole Oceanographic Institution.

Zusammenfassung—Es wird gezeigt, daß die aufeinanderfolgende Elution von Calcium und Strontium durch Komplexbildung mit Cyclohexandiamintetraessigsäure (CyDTA) nach Sorption an Ionenaustauschersäulen genaue Kontrolle des pH und der Konzentrationen von CyDTA und NH_4^+ erfordert. Es wird ein Verfahren zur volumetrischen Bestimmung von Calcium und Strontium beschrieben mit Anwendung dieser Trennmethode vor der Bestimmung von ^{90}Sr in Meerwasser. Es wird gezeigt, daß sorgfältige Auswahl der Reagentien notwendig ist, um mit einer derartigen Methode Spuren von Radiostrontium zu bestimmen.

Résumé—On montre que l'élution du calcium puis du strontium par formation de complexe avec l'acide cyclohexanediaminotétracétique (CyDTA) après sorption sur colonnes échangeuses d'ions nécessite un contrôle minutieux du pH et des concentrations de CyDTA et NH_4^+. On décrit une technique pour l'analyse volumétrique du calcium et du strontium et pour l'emploi de cette méthode de séparation avant dosage de ^{90}Sr dans l'eau de mer. On montre qu'un choix minutieux des réactifs et des produits est nécessaire pour l'emploi d'une telle méthode dans le dosage du radiostrontium à l'état de traces.

DETERMINATION OF RHENIUM IN MOLYBDENITE BY NEUTRON-ACTIVATION ANALYSIS*

KIKUO TERADA, YUKIO YOSHIMURA, SUSUMU OSAKI and TOSHIYASU KIBA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Japan

(*Received* 30 *May* 1966. *Accepted* 10 *August* 1966)

Summary—A neutron-activation method is described for the determination of rhenium in molybdenite. Radiochemical separation by a carrier technique was carried out very rapidly by means of successive liquid–liquid extraction processes. The recovery of rhenium, which was determined by a spectrophotometric method, was about 93%. About 10 samples could be analysed within 6 hr in parallel runs.

RHENIUM is an element of very low cosmic and terrestrial abundance. The distribution of the element in natural sources can be studied only by a very sensitive analytical method; of the techniques readily available neutron-activation analysis seems to be the most adequate. Neutron-activation analysis has been applied to the determination of rhenium in meteorites,[1,2] igneous rocks,[3] and minerals.[4,5] Various methods of radiochemical separation have been used in the procedures for rhenium, *viz.*, distillation,[6,7] precipitation,[8–12] ion-exchange chromatography[13–16] and liquid–liquid extraction.[17–21] Liquid–liquid extraction seems to be the most useful method because of its simplicity and rapidity. In some minerals such as molybdenite, rhenium occurs in association with a large amount of molybdenum. Therefore, in the activation-analysis of such molybdenum-rich minerals, ^{99}Mo is formed in an excessive amount after irradiation of ^{98}Mo (which occurs to the extent of 23·75% in nature) with a thermal neutron flux, and it must be completely removed from rhenium. Moreover, ^{99m}Tc and ^{99}Tc may be produced by β-decay of the ^{99}Mo with its half-life of 66·0 hr, so these should also be excluded. A number of studies have been made on the separation of rhenium from molybdenum and technetium, but it is still difficult to separate the former by liquid–liquid extraction.

Nuclear data

Nuclear data for the thermal neutron activation of rhenium have been summarized by Morris and Fifield.[3]

Rhenium analysis in the present work was based on the nuclides ^{186}Re and ^{188}Re which have half-lives, sufficiently long to survive both the transit time from the reactor site and the time required for chemical processing. It is assumed that their isotopic abundance is the same in all rhenium samples used. Although analyses based on ^{188}Re may suffer some interference[3] from a second order reaction of ^{186}W, 100 ppm of ^{186}W (abundance 28·4%) will produce an activity equivalent to less than 4×10^{-7} ppm of rhenium in an hour. Therefore, this interference may be ignored in the present work.

* Part of the work was performed at the Research Reactor Institute, Kyoto University, and the paper was read at the 9th Symposium in Radiochemistry, Chemical Society of Japan, at Hiroshima, 12 October 1965.

EXPERIMENTAL

Reagents

Standard rhenium solution: 0·1 g of 99·94% pure rhenium was dissolved in 1 ml of conc. nitric acid by heating on a water-bath, and the solution was neutralized with sodium hydroxide solution and diluted to 100 ml with distilled water. This stock solution was standardized gravimetrically via tetraphenylarsonium perrhenate and diluted to a suitable concentration for the standard sample and the carrier solution.

Radioactive rhenium solution: Rhenium-186 was prepared by neutron irradiation of rhenium metal and dissolved in the same way as the non-radioactive rhenium.

Molybdenum solution: Molybdenum trioxide was crystallized from ammonium molybdate solution treated with conc. hydrochloric acid, and was filtered off, washed, and heated at 600° for 5 hr in an electric furnace. Its purity was found to be 99·96% by reductimetric analysis. Forty g of it were dissolved in a small volume of 1N sodium hydroxide solution, and diluted to 500 ml with distilled water. This solution contained 54 mg of molybdenum/ml.

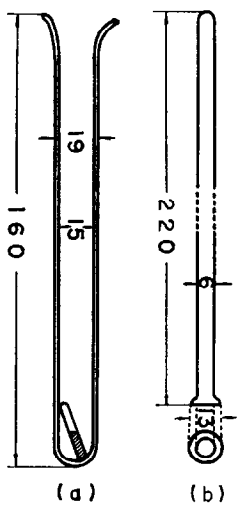

FIG. 1.—(a) Test-tube thickened at bottom; (b) Glass rod with flattened end.

Radioactive molybdenum solution: Molybdenum-99 was prepared by neutron irradiation of the molybdenum trioxide, and a solution of the product was made in the same way as the non-radioactive solution.

Apparatus

A Hitachi EPU-2A type spectrophotometer with 10-mm glass cells, a Horiba Model M-3 glass electrode pH meter, and a γ-ray scintillation counter (Kobe Kogyo Co.) consisting of a PS-400 scintillation probe (SG-78W, 1¾ in. dia. × 2 in. NaI(Tl) crystal) and an SA-230 "1000" scaler, were used. A 50-ml, spindle-shaped separating funnel and an Iwaki shaking-machine, type KM, were used.

Irradiation

A sample of about 0·1 g of the finely-ground molybdenite (about 100-mesh) was accurately weighed and sealed in a clean silica tube (4-mm bore). In a similar tube a standard was prepared by weighing about 0·01 ml of 100 ppm standard rhenium solution on to about 0·1 g of finely powdered quartz in the tube, drying, and sealing. Samples and standards were wrapped in aluminium foil, packed with cotton in a polyethylene capsule, and irradiated with a thermal neutron flux of 4×10^{12} n.cm^{-2}.sec^{-1} for periods of 1 hr in the nuclear reactor KUR, Research Reactor Institute, Kyoto University.

Radiochemical separation

After irradiation, the samples and standards were left to "cool" for 30 min and then assayed radiochemically for ^{186}Re and ^{188}Re. The silica tubes were removed from the capsule and foil, and transferred to a test-tube with a thickened bottom. The silica tubes were broken with a glass rod as shown in Fig. 1. Then 1 ml of conc. nitric acid was added in the glass tube and the solution was

heated in a boiling water-bath for 1 hr. The tubes were removed and 2 ml of Re carrier (250 ppm) and 3 ml of 10*N* sodium hydroxide were added. Any precipitate was removed by centrifugation.

The supernatant liquid was transferred to a 50-ml separating funnel; the residue was washed with 4 ml of distilled water, and the washings transferred to the separating funnel after centrifugation. Then 2 ml of 1% aqueous tetrabutylammonium hydroxide solution were added. The rhenium was extracted as perrhenate by shaking with 10 ml of methyl isobutyl ketone (MIBK) for 10 min; the lower layer was rejected and the organic extract was washed twice with 10-ml portions of 2*N* sodium hydroxide which contained 1 ml of 1% tetrabutylammonium hydroxide solution and 10% of sodium chloride.

The organic phase was then shaken for 10 min with two 10-ml portions of 0·25*M* sodium perchlorate which contained about 5% of sodium chloride. The aqueous extracts were combined in a brown-glass separating funnel and the organic (upper) layer was discarded.

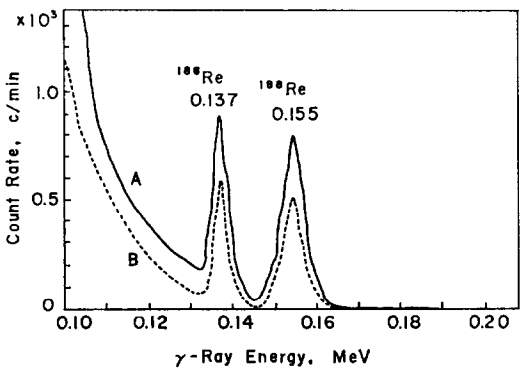

FIG. 2.—Gamma ray spectra of final solution:
A-standard; B-molybdenite sample.

Then 1 ml of conc. hydrochloric acid was added to make the final acid concentration about 0·5–0·6*N*, about 100 mg of potassium xanthate were added to the aqueous phase, and the technetium species was extracted by shaking with 10 ml of carbon tetrachloride for 30 min. The process was repeated and the organic phase discarded. Finally, the aqueous phase was washed with 5 ml of carbon tetrachloride and the organic washings were discarded.

The residual aqueous phase was transferred to a 25-ml standard flask and diluted to 25 ml with distilled water. Then 10 ml of this solution were transferred by pipette into another 25-ml standard flask, and 6 ml of conc. hydrochloric acid, 4 ml of 10% sodium thiocyanate solution and 3 ml of 20% tin(II) chloride solution were added, and the solution was diluted to 25 ml with water. After 30 min the absorbance of the coloured solution was measured at 378 mμ and the amount of rhenium calculated from a calibration curve. The standard and blank samples were treated in the same way.

Counting of the ^{186}Re *and* ^{188}Re

The final solutions were all counted with a well-type γ-ray scintillation counter. Five ml of the 25 ml of final sample solution were transferred to a polyethylene test-tube (12 mm i.d.) and counted. All activities were corrected for paralysis, background, and chemical yield, and decay measurements were made. After about 6 days the ^{188}Re activity had disappeared and subsequent decay was that theoretically expected for ^{186}Re. From the activity of samples and standards at any arbitrarily chosen time, the rhenium content of the original material could be found from the relationship:

$$\text{Weight of Re in sample} = \text{Weight of Re in standard} \times \frac{\text{Corrected counting rate of sample}}{\text{Corrected counting rate of standard}}.$$

The blank test for the powdered quartz used to make the standard gave a negligible counting rate.

Additional confirmation that ^{186}Re and ^{188}Re were the only radionuclides assayed was obtained by γ-ray spectrometry. Typical spectra are shown in Fig. 2.

RESULTS

In Table I are shown the results of the neutron-activation analysis of rhenium in two molybdenite samples from different sources in Japan. The paired values were obtained by irradiation at same time. The loss of rhenium in the dissolution and centrifugation processes was estimated to be below 0·5%.

DISCUSSION

Separation of rhenium from molybdenum by solvent extraction

Rhenium was completely separated from about 60 mg of molybdenum by solvent extraction. Maeck *et al.*[23] reported that rhenium(VII) was extracted into methyl isobutyl ketone from both acidic and alkaline solutions in the presence of tetrabutylammonium salts. According to their results, it seemed possible to separate rhenium from most other metals, including molybdenum. In the present study the alkaline MIBK system was chosen because several metal ions in the samples could be removed as their hydroxide precipitates before the extraction. Experiments were done to find the optimum conditions for extraction of rhenium, using ^{186}Re as a tracer.

Effect of the concentration of alkali on the extraction. Variation of the sodium hydroxide concentration from 0·5 to 5*M* was without effect, >99% of the rhenium (in amounts of 30–300 μg) being extracted; 2·0*M* alkali was therefore preferred. No change of the basicity of the aqueous phase occurred before or after the extraction.

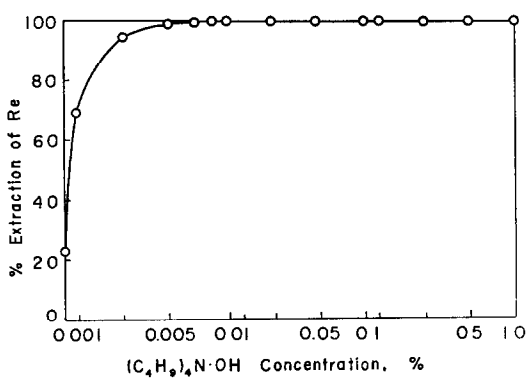

FIG. 3.—Effect of concentration of tetrabutylammonium hydroxide on the extraction of rhenium. Concentration of rhenium 50 ppm.

Effect of the tetrabutylammonium salt concentration. As shown in Fig. 3, >99% of the rhenium was extracted when the aqueous phase contained more than 0·01% of tetrabutylammonium hydroxide in 2·0*M* alkali. Rhenium was completely separated from 60 mg of molybdenum if the concentration of the reagent was in the range 0·025–1·0%.

The effect of other ions on the extraction. From the results of Maeck *et al.*, it seemed that relatively large amounts of pertechnetate, permanganate, osmium(IV), platinum(IV), gold(III) and mercury(II) ions might have some effect on the extraction of perrhenate, but, as shown in Table II, 10 mg of any of these ions was without effect.

TABLE II.—EFFECT OF OTHER IONS ON EXTRACTION OF RHENIUM WITH TETRABUTYLAMMONIUM SALTS

Ions	Added (*mg*/10 *ml*)	Recovery of Re in organic phase* (%)

Th(IV)	10	99·8
Se(IV)	10	99·9

* 50 ppm of Re were present in each run.

The amounts of these elements in ordinary rocks or minerals would not affect the extraction of rhenium.

In Table III, the effect of several anions is shown. Perchlorate and thiocyanate interfere seriously, iodide and chlorate interfere to a lesser extent. Perchlorate and thiocyanate presumably interfere by competing with perrhenate in ion-pair formation with the quaternary ammonium ions; this property can be used to good effect in the back-extraction process.

Back-extraction of rhenium into the aqueous phase. The rhenium in MIBK must be back-extracted to separate it from technetium. The results obtained with sodium

perchlorate and perchloric acid solutions of varying concentration are shown in Fig. 4. According to Gerlit,[21] perrhenate can be extracted fairly well into MIBK from acidic solution ($K_d = 3{\cdot}8$ from $2N$ sulphuric acid). The decrease in the amount of rhenium back-extracted as the concentration of perchloric acid increased, may be attributed to this behaviour.

Addition of sodium chloride was found to improve the separation of the phases. A composite reagent containing $0{\cdot}5M$ perchlorate was found satisfactory and to give >99% recovery of rhenium in two extractions.

A small amount of MIBK was often transferred with the aqueous phase and interfered in the spectrophotometric determination, but could be readily removed by back-washing the aqueous phase with carbon tetrachloride.

TABLE III.—EFFECT OF ANIONS ON EXTRACTION OF RHENIUM WITH TETRABUTYLAMMONIUM SALTS

Anions	Concentration, M	Recovery of Re in organic phase* (%)

	0·50	99·9

* 50 ppm of rhenium were present in each run.

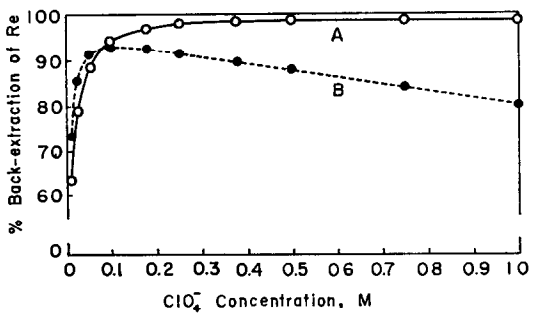

FIG. 4.—Effect of concentration of perchlorate and perchloric acid on back-extraction of rhenium.
A—Sodium perchlorate; B—Perchloric acid. Concentration of rhenium 50 ppm.

Separation of rhenium and technetium nuclides. The radionuclide 6 hr ^{99m}Tc (γ, 0·1403 MeV) may be produced during or after the neutron-irradiation of molybdenite by the following processes:

$$^{98}\text{Mo}(n, \gamma)^{99}\text{Mo} \xrightarrow[t_{\frac{1}{2}}=66\text{ hr}]{\beta^-} {}^{99m}\text{Tc}$$
$$^{98}\text{Tc}(n, \gamma)^{99m}\text{Tc}$$
$$^{99}\text{Tc}(n, n)^{99m}\text{Tc}$$
$$^{99}\text{Ru}(n, p)^{99m}\text{Tc}$$

The first process may predominate in this case, and this nuclide will certainly interfere considerably in the γ-counting of the rhenium activity.

It was observed that a considerable activity of ^{99m}Tc had been produced as expected, and remained after the molybdenum had been removed by the first extraction. Rhenium had been separated from technetium by solvent extraction[24] with xanthate into carbon tetrachloride; double extraction with rather larger amounts of xanthate (100 mg in each extraction) proved satisfactory.

Spectrophotometric determination of rhenium. This was used to determine the chemical yield of rhenium instead of the usual gravimetric method. The rhenium-tin(II)-thiocyanate complex gave absorption peaks at 378 and 420 mμ. The second peak has been used for the colorimetric determination of rhenium, but the absorbance at that wavelength varies considerably with time. The first peak was found to be useful since its absorbance obeyed Beer's law in the range of 0·0–12 ppm of rhenium. The colour of the solution was stable for at least 2 hr under the conditions recommended.[25] The error was found to be 1% over the range 1–12 ppm and 2% for about 0·5 ppm of rhenium.

Possible interferences. Morris and Fifield[3] and Morgan[5] reported possible interferences in the neutron-activation analysis of rhenium in various minerals and rocks. Most metal ions encountered in geological materials, *e.g.*, iron, manganese and chromium, could be removed by the procedure described above and the effect of these ions may be disregarded. The neutron self-shielding in the sample is insignificant because of the small size of sample used.

The mean chemical recovery of the added carrier was about 93%, and the time required for a complete radiochemical analysis of 10 samples was about 6 hr.

Acknowledgement—The authors wish to express their thanks to the Ministry of Education for financial support for this research. They are also indebted to Dr. Yoshiyuki Kiso, Research Reactor Institute, Kyoto University, for his help in the irradiation of samples, and to Mr. Teiji Okubo, Government Industrial Development Laboratory, Tokyo, for a gift of pure rhenium.

Zusammenfassung—Ein Neutronenaktivierungsverfahren zur Bestimmung von Rhenium in Molybdänit wird beschrieben. Die radiochemische Abtrennung mittels Träger wurde mit Hilfe aufeinanderfolgender flüssig-flüssig-Extraktionsprozesse sehr schnell ausgeführt. Die Ausbeute an Rhenium, das spektrophotometrisch bestimmt wurde, betrug etwa 93%. Zehn Proben konnten in sechs Stunden in nebeneinanderlaufenden Arbeitsgängen bestimmt werden.

Résumé—On décrit une méthode par activation de neutrons pour le dosage du rhénium dans la molybdénite. La séparation radiochemique par une technique par entraînement a été menée très rapidement au moyen de méthodes d'extractions successives en phase liquide. La récupération du rhénium, déterminée par une méthode spectrophotométrique, est d'environ 93%. En menant les opérations en paralléle, on peut analyser environ 10 échantillons en 6 h.

ELEKTRONISCHES RECHNEN IN DER ANALYTISCHEN CHEMIE—I

ALGOL-PROGRAMM FÜR DIE AUSWERTUNG VON MODELLANALYSEN

G. GOTTSCHALK
OSRAM Studiengesellschaft Berlin, Technische Universität Berlin

(*Eingegangen am* 14 *Juli* 1966. *Angenommen am* 3 *August* 1966)

Zusammenfassung—Ein üblicher Weg zur Ermittlung von Kenngrößen analytischer Verfahren ist die Durchführung einer Reihe von Modellanalysen. Über den Vergleich von bekannten vorgegebenen Mengen mit wiedergefundenen Mengen liefert eine geeignete Auswertung objektive ziffernmäßige Informationen über die zufälligen und systematischen Fehler in einem festgelegten Arbeitsbereich. Zeitbedarf und Schwierigkeitsgrad einer solchen Auswertung sind bei Verwendung konventioneller Rechentechniken relativ groß. So werden für eine Testreihe von 24 Modellanalysen ohne Berücksichtigung menschlich bedingter Rechenfehler mindestens 8 Std benötigt. Erfahrungsgemäß sind bei rechnerisch weniger geübten Personen oft sogar mehrere Tage erforderlich. Praktisch rechenfehlerfreie Resultate können dagegen bei elektronischer Datenverarbeitung in weniger als 5 min erhalten werden. Hierzu wird im folgenden ein Rechenprogramm in der problemorientierten Universalsprache ALGOL formuliert. Die verbleibenden vorbereitenden Arbeitsgänge sind bei dieser Form der Auswertung so einfach, daß sie von jeder Hilfskraft einwandfrei durchgeführt werden können.

VERWENDETE BEGRIFFE UND SYMBOLE (ALGOL-SYMBOLE IN KLAMMERN)

Gesamtanzahl der Testanalysen	n	(N)
Gruppenumfang	l	(—)
Laufzahlen, Einzelgrößen	i	(I)
Gruppengrößen	J	(—)
Umrechnungsfaktoren, für Einwaagen	λ_1	(L1)
für Meßwerte	λ_2	(L2)
Integralgrenzen t der t-Verteilung	t	(T)
Einwaagen an Standardsubstanz	G_1	(G[I])
Meßwerte (Auswaagen oder Volumina)	W_1	(W[I])
Vorgegebene Mengen	$[a_1]$	(VA)
Wiedergefundene Mengen	a_1	(WA)
Korrigierte wiedergefundene Mengen	$a_{\mathrm{K}i}$	(—)
Unkorrigierte Abweichungen	B_1	(—)
Zufällige Abweichungen	v_1	(ABW)
Variationskoeffizient	VK	(—)
Standardabweichung	$[s_{\mathrm{K}}]$	(SK)
Absolutkorrektur, Wert	$[U]$	(U)
Absolutkorrektur, mittlerer Fehler	$[s_{\mathrm{U}}]$	(SU)
Relativkorrektur, Wert	$[R]$	(R)
Relativkorrektur, mittlerer Fehler	$[s_{\mathrm{R}}]$	(SR)
Prüfgrößen	τ	(TAU)

EINFÜHRUNG

ALS Modellanalysen sollen im folgenden quantitative analytische Bestimmungen aus dem Bereich der Gravimetrie und Titrimetrie bezeichnet werden, bei denen der Umrechnungsfaktor λ von der Meßgröße W_1 auf die Mengengröße a_1 von vornherein bekannt ist. Neben diesen auch „chemische Analysenverfahren" genannten Methoden gibt es eine Vielzahl „physikalischer Analysenverfahren", bei denen die zunächst unbekannten Umrechnungsgrößen durch Eichmessungen erst ermittelt werden müssen.

Die Auswertung von Modellanalysen beginnt mit Berechnungen vorgegebener Mengen $[a_1]$ aus Einwaagen G_1 einer Standardsubstanz sowie wiedergefundener Mengen a_1 aus Meßgrößen W_1 (Auswaagen, Volumina) mit Hilfe bekannter Umrechnungsfaktoren λ. Danach werden im allgemeinen absolute und relative Abweichungen ermittelt. Formelmäßig ergibt sich bei n Testanalysen der n-malige Handlungsvorgang:

Vorgegebene Menge	$[a_1] = \lambda_1 \cdot G_1$	mg	
Gefundene Menge	$a_1 = \lambda_2 \cdot W_1$	mg	
Abweichung, absolut	$B_1 = a_1 - [a_1]$	mg	(1)
Abweichung, relativ	$100 \dfrac{B_1}{[a_1]}$	Rel%	

wobei Laufzahl $i = 1, 2, \ldots, n$.

Anstatt der Mengeneinheit mg können auch andere Einheiten wie μg, Gew%, Vol%, Mol% *etc.* gewählt werden oder vorkommen. Das Klammerzeichen [. . .] wird für Sollgrößen oder durch Ausgleichsrechnung definierte Größen verwendet. Modellanalysen sind nicht nur für eine vorgegebene Menge $[a_1]$ sondern stets für eine Reihe unterschiedlicher Vorgabemengen durchzuführen. Innerhalb des Bereiches der größten und kleinsten Menge liegt der getestete Arbeitsbereich.

Es ist zweckmäßig die Testreihe durch k Gruppen vom Umfang l zu strukturieren, wobei innerhalb der Gruppen gleiche Mengen $[a_1]$ vorgegeben werden. Speziell bei gleichem Gruppenumfang l gilt $n = k \cdot l$. Bei diesem Vorgehen werden die Einzelabweichungen B_1 innerhalb jeder Gruppe häufig zu einem Gruppenmittel $\bar{B}_J$ zusammengefaßt. Die zugehörigen Gruppen-Standardabweichungen s_J oder auch die Variationskoeffizienten VK_J werden sodann als ein Maß für die „Genauigkeit" des Verfahrens angesehen.

Die entsprechenden Rechenvorgänge der k-fachen Gruppenauswertung sind:

Mittelwert	$\bar{B}_J = \dfrac{1}{l} \sum_1^l B_i$	mg	
Standardabweichung	$s_J = \pm \sqrt{\left(\dfrac{1}{l-1} \sum_1^l (B_i - \bar{B}_J)^2 \right)}$	mg	(2)
Variationskoeffizient	$VK_J = \pm 100 \dfrac{s_J}{\bar{B}_J}$	Rel%	

wobei Gruppen-Lauzahl $J = 1, 2, \ldots, k$.

Die ermittelten n Einzelabweichungen B_i bzw. k Gruppenabweichungen $\bar{B}_J$ können durch zufällige Fehler und systematische Fehler bedingt sein. Daß die Resultate a_i systematisch verfälscht sind, wird nur dann erkennbar, wenn für die Abweichungen B_i bzw. $\bar{B}_J$ ein Vorzeichen + (Überbefund) oder — (Unterbefund) stark überwiegt. Über Art und effektive Größe der systematischen Fehler kann man aber bei dieser Auswertungsmethode keine Informationen-erhalten. Eine objektive Beurteilung der Leistungsfähigkeit eines analytischen Verfahrens und eine gezielte Verbesserung der arbeitstechnischen Durchführung setzt jedoch die genaue Kenntnis und damit die Möglichkeit der Ausschaltung oder zumindest rechnerischen Eliminierung systematischer Fehler voraus.

Eventuelle systematische Einflüsse lassen sich mit einer Korrekturgröße $[R]$ für relative systematische Fehler und einer Größe $[U]$ für absolute systematische Fehler fast immer weitgehend erfassen und eliminieren. Im ungünstigsten Fall wird man eine wiedergefundene Menge a_i durch beide Größen korrigieren müssen, wodurch eine korrigierte wiedergefundene Menge a_{Ki} erhalten wird.

$$a_{Ki} = [R](a_i + [U]) \qquad \text{mg} \tag{3}$$

Die gewählte Formulierung (3) hat sachlich analytische Gründe. Ein typisches Beispiel für einen solchen Korrekturausdruck findet man in der Titrimetrie im Zusammenhang des „wahren" Verbrauches V mit dem durch Faktor F und Blindwertverbrauch V_B verfälschtem Rohverbrauch V_x.

$$V = F(V_x - V_B) \qquad \text{ml.}$$

Liegen n nach (3) korrigierte wiedergefundene Mengen a_{Ki} vor, so lassen sich n korrigierte Abweichungen v_i bilden, deren Vorzeichen und numerische Größen praktisch allein vom Zufall abhängen. Eine Zusammenfassung der einzelnen v_i-Werte liefert die Verfahrens-Standardabweichung $[s_K]$, eine einzige Kenngröße der Reproduzierbarkeit, im gesamten Arbeitsbereich.

$$[s_K] = \pm \sqrt{\left(\frac{1}{f}\sum_1^n v_i^2\right)} \qquad \text{mg} \tag{4}$$

mit zufälliger Abweichung $v_i = a_{Ki} - [a_i]$ und Freiheitsgrad f aus Anzahl n der Testanalysen minus der Anzahl 2, 1 oder 0 der erforderlichen Korrekturgrößen.

Bei der nachfolgend beschriebenen Standard-Auswertemethode werden nicht nur die numerischen Werte von $[R]$, $[U]$ und $[s_K]$ sondern auch die mittleren Fehler $[s_R]$ und $[s_U]$ der Korrekturgrößen über eine modifizierte Form der Ausgleichsrechnung ermittelt. Darüber hinaus werden durch mathematisch-statistische Vergleichstests die Realität der Korrekturgrößen $[R]$ und $[U]$ sowie abschließend das gesamte Datenmaterial auf Ausreißer (grobe Fehler) überprüft.

Elektronische Datenverarbeitung

ALGOL (ALGO-rithmic L-anguage) ist eine problemorientierte Programmiersprache mit Vereinbarungen (declarations) und Anweisungen (statements) in englischer Sprache, die relativ leicht erlernbar und vom Typ der bereits sehr zahlreichen elektronischen Datenverarbeitungsanlagen mit ihren speziellen Maschinensprachen unabhängig ist. Ein in ALGOL geschriebenes Programm wird durch ein

vom Maschinentyp abhängiges ALCOR (ALGOL CONVERTER = Übersetzerprogramm) automatisch in die jeweilige Maschinensprache übersetzt und sodann gerechnet. Im allgemeinen steht bei jeder leistungsfähigen Rechenanlage ein ALCOR zur Verfügung.

Die Eingabe eines ALGOL-Programmes in den Rechner erfolgt fast ausschließlich durch Lochstreifen, die von einem Lochstreifen-Lesegerät abgetastet werden. Speziell für ALGOL vorgesehen ist der 5-Spur-Lochstreifen mit dem Codesystem ALCOR CCIT, das bis auf wenige Ausnahmem mit dem internationalen Fernschreibcode CCIT 2 übereinstimmt. Naturgemäß können auch andere Eingabemedien wie etwa der 8-Spur-Lochstreifen oder Lochkarten Verwendung finden, wenn Lesegerät und ALCOR darauf abgestimmt sind.

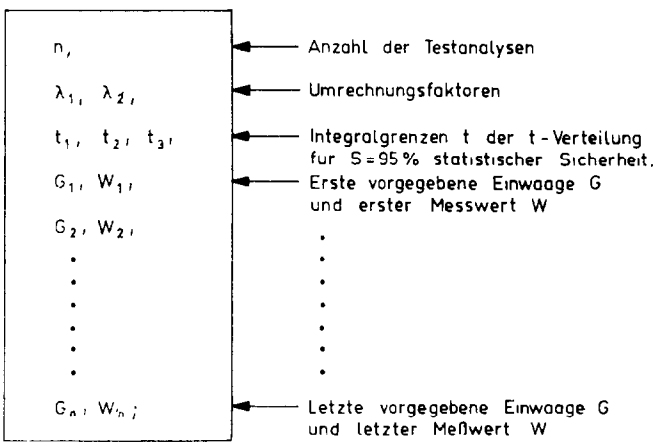

ABB. 1.—Datenliste bei Modellanalysen.

Ein ALGOL-Programm wird nur einmal geschrieben, erprobt und kann sodann in Form des Lochstreifens bei Bedarf immer wieder eingelesen werden. Bei häufiger Verwendung empfiehlt sich die maschineninterne Speicherung direkt als Maschinenprogramm, das durch einen Codenamen abgerufen werden kann. Das hier beschriebene ALGOL-Programm ist erprobt und braucht von einem Benutzer nur sorgfältig abgeschrieben und an ein Rechenzentrum gegeben zu werden. Nach dieser einmaligen Arbeit beschränkt sich seine weitere Tätigkeit auf die Auflistung seiner jeweils ermittelten Untersuchungsbefunde in programmrichtiger Reihenfolge, wie dies Abb 1 zeigt, und die Entgegennahme der Resultate.

Wenn auch für die elektronische Auswertung analytischer Daten bei Vorliegen von Programmen die Kenntnis der Programmiersprache keinesfalls erforderlich ist, so hat es sich doch als sehr vorteilhaft erwiesen, wenn ein oder mehrere Mitarbeiter die im Prinzip sehr einfache ALGOL-Programmierung beherrschen. Es gibt hierzu bereits einige gute Anleitungen, von denen eine Auswahl[1–5] im Literaturteil angeführt ist. Zur Vertiefung sei die Teilnahme an einem ALGOL-Programmierkursus in einem Rechenzentrum empfohlen.

MATHEMATISCHE STRUKTUR

Grunddaten und Ansätze

Bei der Auswertung geht man von der üblichen Minimumbedingung der Ausgleichsrechnung aus, die speziell bei Modellanalysen zu

$$\sum_{1}^{n} v_i^2 = \sum_{1}^{n} (a_{Ki} - [a_i])^2 = \text{MINIMUM} \tag{5}$$

formuliert werden muß. Die korrigierte wiedergefundene Menge wird nicht in jedem Fall durch die Beziehung (3) definiert sein. Es ist durchaus möglich, daß sich die primär errechneten Größen $[R]$ und $[U]$ nicht signifikant von den idealen Sollwerten 1 bzw. 0 unterscheiden. Unter Berücksichtigung aller Möglichkeiten müssen insgesamt 4 verschiedene Korrukturansätze und zugehörige Rechengänge programmiert und gegebenenfalls durchgerechnet werden. Hierzu gibt Tab. I eine Uebersicht.

TABELLE I.—KORREKTURANSÄTZE UND RESULTATE

	Ansatz	Rechengang	f	Resultate
I	$a_{ki} = [R](a_i + [U])$	VOLLKORREKTUR	$n-2$	$[R]$, $[U]$, $[s_k]$, $[s_R]$, $[s_U]$, v_i^*
II	$a_{ki} = a_i + [U]$	ABSOLUTKORREKTUR	$n-1$	$[R] \equiv 1$, $[U]$, $[s_k]$, —, $[s_U]$, v_i^*
III	$a_{ki} = [R] \,.\, a_i$	RELATIVKORREKTUR	$n-1$	$[R]$, $[U] \equiv 0$, $[s_k]$, $[s_R]$, —, v_i^*
IV	$a_{ki} = a_i$	KEINE KORREKTUR	n	$[R] \equiv 1$, $[U] \equiv 0$, $[s_k]$, —, —, v_i^*

v_i^* sind korrigierte Abweichungen $v_i = a_{ki} - [a_i]$, deren numerische Werte größer als ein Streubereich $[s_k] \cdot t$ (95) sind.

Der Minimumansatz (5) kann nach Einsetzen der jeweiligen a_{Ki}-Werte gemäß I, II, III und IV durch partielle Differentiation nach den Konstanten $[R]$ bzw. $[U]$ in einfache Beziehungsgleichungen überführt werden.[6] Die Ausgleichsrechnung muß jedoch stets mit einer Auswertung des Ansatzes I beginnen. Die aus 5 Grundsummen und 3 Determinanten folgenden Primärresultate sind in Tab. II zusammengestellt.

Logische Entscheidungen

Die Realität des Unterschiedes zwischen dem

$[U]$-Wert und dem idealen Sollwert NULL

$[R]$-Wert und dem idealen Sollwert EINS

ist nach dem Sollwert-t-Test[6–8] in einfacher Weise feststellbar. Man formuliert zweckmäßig 2 logische Aussagen (Boole'sche Variable) $V1$ und $V2$, die auf Grund arithmetischer Vergleiche (t-Test) nur „wahr" oder „nicht wahr" sein können.

Mit den Primärresultaten werden gebildet:

$V1$ entspricht „1. Vergleich ist wahr," d.h. „$[U]$ ist real"

$$\text{für} \quad \tau_U = \left| \frac{[U]}{[s_U]} \right| \geqq t_1 \tag{6}$$

V2 entspricht „2. Vergleich ist wahr", d.h. „[*R*] ist real"

$$\text{für} \quad \tau_R = \left| \frac{[R] - 1}{[s_R]} \right| \geqq t_1$$

V1 und *V2* ergeben den logischen Wert „nicht wahr", wenn

$$\left| \frac{[U]}{[s_U]} \right| < t_1 \quad \text{bzw.} \left| \frac{[R] - 1}{[s_R]} \right| < t_1$$

gefunden wird, was den negierten Aussagen „[*U*] ist nicht real" bzw. „[*R*] ist nicht real" entspricht. Mit t_1 sind die Integralgrenzen der *t*-Verteilung für den Freiheitsgrad $f = n - 2$ (2 Konstanten!) und einer Statistischen Sicherheit $S = 95\%$ (Level of Significance 0,05) bezeichnet. Den entsprechenden Wert entnimmt man Tabellen statistischer Zahlenwerte.[6–9] Speziell für $n = 24$ gilt $t_1 = 2{,}074$.

TABELLE II.—GRUNDSUMMEN, DETERMINANTEN, PRIMÄRRESULTATE

Grundsummen
$\mathrm{S1} = \sum_1^n a_1 = \lambda_2 \times \sum_1^n W_1$
$\mathrm{S2} = \sum_1^n a_1^2 = \lambda_2 \times \lambda_2 \times \sum_1^n (W_1 \times W_1)$
$\mathrm{S3} = \sum_1^n [a_1] = \lambda_1 \times \sum_1^n G_1$
$\mathrm{S4} = \sum_1^n [a_1]^2 = \lambda_1 \times \lambda_1 \times \sum_1^n (G_1 \times G_1)$
$\mathrm{S5} = \sum_1^n a_1 \,.\, [a_1] = \lambda_1 \times \lambda_2 \times \sum_1^n (G_1 \times W_1)$
Determinanten
$\mathrm{D} = n \times \mathrm{S2} - \mathrm{S1} \times \mathrm{S1}$
$\mathrm{D}_1 = n \times \mathrm{S5} - \mathrm{S1} \times \mathrm{S3}$
$\mathrm{D}_2 = \mathrm{S2} \times \mathrm{S3} - \mathrm{S1} \times \mathrm{S5}$
Primärrelsultate
$[R] = \frac{\mathrm{D}_1}{\mathrm{D}}$
$[U] = \frac{\mathrm{D}_2}{\mathrm{D}_1}$
$[s_k] = \sqrt{\left(\frac{1}{n-2} \sum_1^n v_1^2\right)} \quad \text{mit} \sum_1^n v_1^2 = \mathrm{S4} - [R] \times (\mathrm{S5} + [U] \times \mathrm{S3})$
$[s_R] = [s_k] \times \sqrt{\left(\frac{n}{\mathrm{D}}\right)}$
$[s_u] = [s_k] \times \sqrt{\left(\frac{\mathrm{S2} + n \times [U] \times [U]}{\mathrm{D}}\right)}$

Die logischen Werte von *V1* und *V2* bestimmen den weiteren Gang der Auswertung. Wenn *V1* UND *V2* „wahr" sind (konjunktive Verknüpfung), so ist nur der Rechengang I (Vollkorrektur) auszuführen und mit der Resultatnotierung abzuschließen. Sind jedoch *V1* ODER *V2* ODER BEIDE „nicht wahr" (disjunktive Verknüpfung), so sind nacheinander die Rechengänge II (Absolutkorrektur) und III (Relativkorrektur) auszuführen. Mit den neuberechneten Werten $[U]$, $[s_U]$ sowie $[R]$, $[s_R]$ müssen analog (6) zunächst neue Aussagen *V1* bzw. *V2* gebildet werden, wobei jedoch t_1 für $f = n - 2$ durch t_2 für $f = n - 1$ (jeweils nur 1 Konstante!) zu ersetzen ist. Speziell für $n = 24$ gilt $t_2 = 2{,}069$.

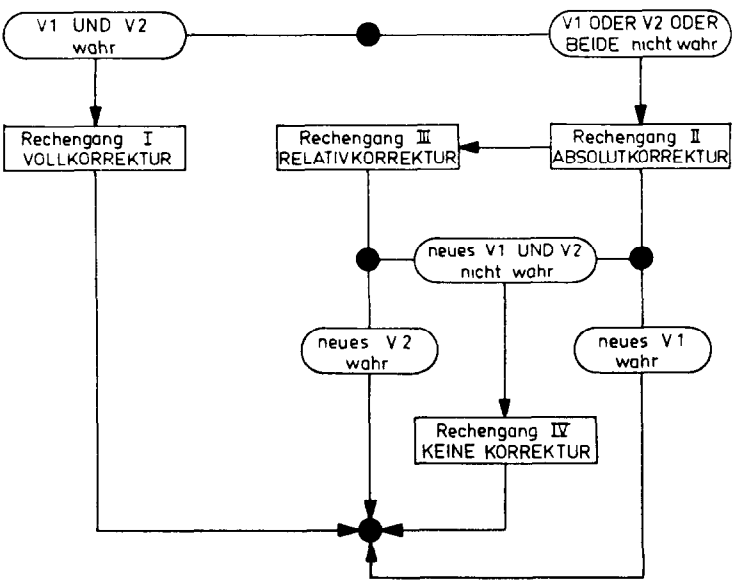

ABB. 2.—Logische Verzweigungen und Rechengänge.

Die Resultate der Rechengänge II oder III sind nur dann von Interesse, wenn *V1* bzw. *V2* als „wahr" gefunden wird. Sind beide Größen „wahr", so resultiert ein Doppelresultat. Welche der Korrekturen sodann praktisch sinnvoll ist, muß extern aus Überlegungen zum chemischen Reaktionsverlauf und zur angewandten Arbeitstechnik entschieden werden. In jedem Fall *V1* ODER *V2* ODER BEIDE „wahr" ist die Auswertung mit der entsprechenden Resultatnotierung abzuschließen.

Der Rechengang III (keine Korrektur) ist nur dann durchzuführen, wenn beide neuen Werte *V1* UND *V2* als „nicht wahr" ermittelt werden. Abb. 2 gibt nochmals einen Überblick der logischen Verzweigungen.

Rechengänge

Der Rechengang I für die Vollkorrektur muß als Basisrechnung in jedem Fall durchgeführt werden. Sofern die logischen Entscheidungen eine Vollkorrektur fordern, sind die Primärresultate nach Tab. II bereits die gesuchten Endergebnisse. Trifft dies nicht zu, so müssen die Rechengänge II und III sowie eventuell auch IV durchgeführt werden, wobei die Resultate aus einer anderen Verknüpfungsform der Grundsummen erhalten werden, wie dies Tab. III zeigt.

TABELLE III.—RESULTATE BEI DEN RECHENGÄNGEN II, III, UND IV

II Absolutkorrektur
$[R] \equiv 1$
$[U] = \frac{1}{n} \times (\mathrm{S3} - \mathrm{S1})$
$[s_k] = \sqrt{\left(\frac{1}{n-1}\sum_1^n v_i^2\right)}$ mit $\sum_1^n v_i^2 = \mathrm{S4} + \mathrm{S2} - 2 \times \mathrm{S5} + n \times [U] \times [U]$
$[s_U] = \frac{[s_k]}{\sqrt{n}}$
III Relativkorrektur
$[U] \equiv 0$
$[R] = \frac{\mathrm{S5}}{\mathrm{S2}}$
$[s_k] = \sqrt{\left(\frac{1}{n-1}\sum_1^n v_i^2\right)}$ mit $\sum_1^n v_i^2 = \mathrm{S4} - [R] \times \mathrm{S5}$
$[s_R] = \frac{[s_k]}{\sqrt{(\mathrm{S2})}}$
IV keine Korrektur
$[R] \equiv 1$ und $[U] \equiv 0$
$[s_k] = \sqrt{\left(\frac{1}{n}\sum_1^n v_i^2\right)}$ mit $\sum_1^n v_i^2 = \mathrm{S4} + \mathrm{S2} - 2 \times \mathrm{S5}$

Prüfung der korrigierten Abweichungen

Die n korrigierten Abweichungen stellen eine vom Rechengang abhängige Wertreihe dar. Bei einwandfreiem Datenmaterial dürfen diese v_i-Werte einen Streubereich $[s_K] \cdot t$ weder beliebig weit noch beliebig oft überschreiten. So sind Überschreitungsabweichungen

$$|v_i^*| \geqq [s_K] \cdot t \qquad \text{bzw.} \qquad \tau = \frac{|v_i^*|}{[s_K]} \geqq t \tag{7}$$

bei t-Werten der Statistischen Sicherheiten

$$\begin{aligned} S = 95\% &: 1 \text{ Mal unter } 20 \quad v_i\text{-Werten} \\ S = 99\% &: 1 \text{ Mal unter } 100 \quad v_i\text{-Werten} \\ S = 99{,}9\% &: 1 \text{ Mal unter } 1000 \quad v_i\text{-Werten} \end{aligned}$$

zu erwarten. Werden z.B. bei $n = 24$ Modellanalysen mehr als 2 v_i-Werte mit $|v_i^*| = [s_K] \cdot t(95)$ oder sogar solche mit $|v_i^*| = [s_K] \cdot t(99)$ bzw. $|v_i^*| = [s_K] \cdot t(99{,}9)$ gefunden, so kann auf „überzufällige" Sondereinflüsse bei den betroffenen Werten geschlossen werden. Die entsprechenden Testanalysen und sodann die gesamten Auswertungsschritte sind zu wiederholen. Erfahrungsgemäß ergibt sich eine solche Notwendigkeit relativ selten.

Im Rahmen des hier angeführten ALGOL-Programmes werden in jedem Rechengang zwar die entsprechenden n Abweichungen v_i berechnet, jedoch die Versuchsnummer i und die Abweichung nur dann ausgegeben, wenn

$$\frac{|v_i^*|}{[s_K]} \geqq t(95)$$

gefunden wird. Der weitere Vergleich ausgegebener v_i^*-Werte mit Streubereichen $[s_K]\cdot t(99)$ und $[s_K]\cdot t(99{,}9)$ hat extern zu erfolgen. Tab. IV gibt eine Zusammenstellung der t-Werte speziell für $n = 24$ Modellanalysen.

TABELLE IV.—t-WERTE BEI $n = 24$ MODELLANALYSEN

Rechengang	f	S = 95%	S = 99%	S = 99,9%
I	22	$t_1 = 2{,}074$	$t_1' = 2{,}819$	$t_1'' = 3{,}792$
II oder III	23	$t_2 = 2{,}069$	$t_2' = 2{,}807$	$t_2'' = 3{,}767$
IV	24	$t_3 = 2{,}064$	$t_3' = 2{,}797$	$t_3'' = 3{,}745$

t_1, t_2, t_3 sind Bestandteile der Datenliste (input).

Die Größe TAU $= \frac{[v_i^*]}{[s_K]}$ wird ausgedruckt und ist direkt mit t, t' oder t'' vergleichbar.

PROGRAMMIERUNG

Flußdiagramm

Abbildung 3 zeigt das vollständige Ablaufschema der Auswertung von Modellanalysen.

Die logischen Entscheidungen treten als Programmverzweigungen in Erscheinung und werden als BEDINGTE Anweisungen formuliert, wobei zwischen alternativer Formulierung

'IF' (Aussage wahr) 'THEN' .... 'ELSE' .... ;

und einseitiger Formulierung

'IF' (Aussage wahr) 'THEN' .... ;

zu unterscheiden ist. Die in abgerundete Tableaus gesetzten Aussagen wirken als „logische Filter" innerhalb der Ablauflinien.

ALGOL-Programm

Das in Tab. V zusammengestellte ALGOL-Programm ist auch ohne ALGOL-Kenntnisse verständlich, wenn man einige Besonderheiten beachtet.

Im ALCOR CCIT-Code sind nur Großbuchstaben (Fernschreib-Schriftbild) oder nur Kleinbuchstaben definiert. Das hier angeführte Programm wurde in Großbuchstaben geschrieben (siehe Zusammenfassung).

Zur Speicherplatz-Reservierung dienen Vereinbarungen (declarations), die alle im Programm verwendeten Variablennamen enthalten müssen. Je nach Variabletyp werden sie in ALGOL durch die Wortsymbole 'REAL' (Gleitkommavariable), 'INTEGER' (Ganzzahlige Variable), 'BOOLEAN' (Aussage-Variable) oder 'ARRAY'

(Variablentabelle) gekennzeichnet. Prozedurvereinbarungen (Unterprogramme) werden mit 'PROCEDURE' eingeleitet.

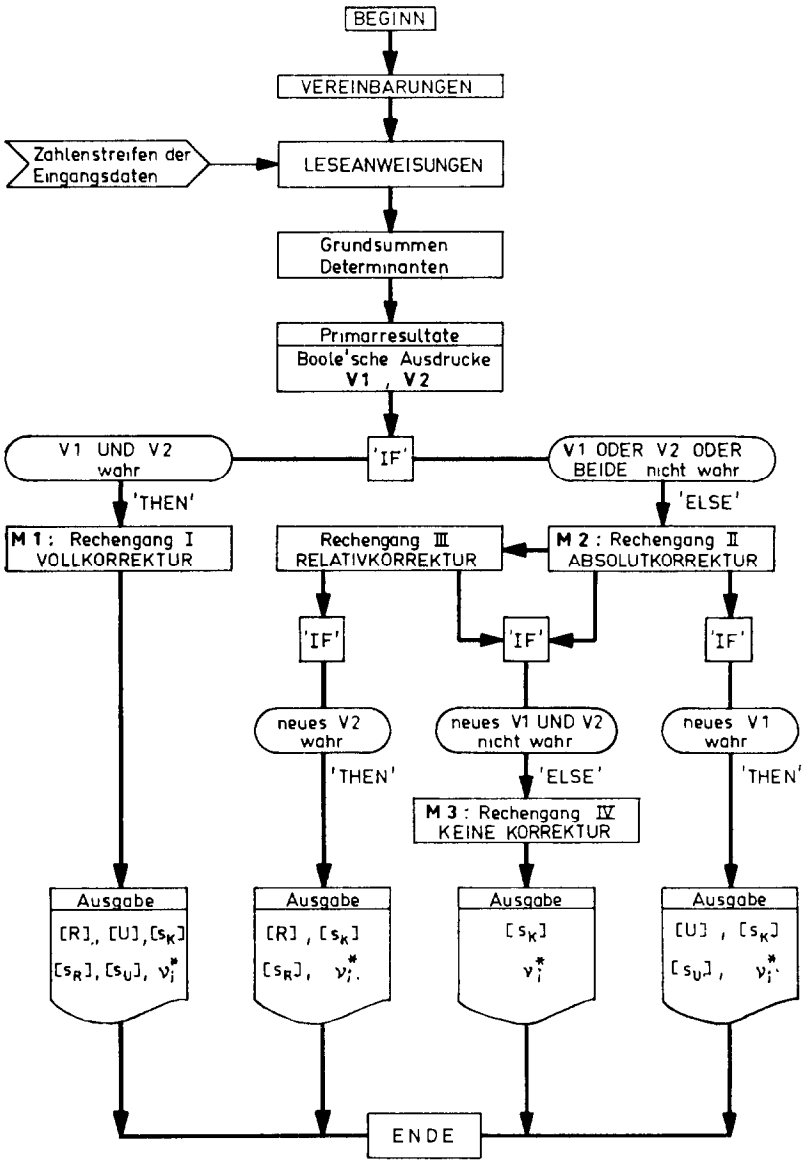

ABB. 3.—Flussdiagramm der Auswertung von Modellanalysen.

Für das arithmetische Vergleichszeichen $\geqq$ (größer und gleich) der Beziehungen (6) und (7) steht in ALGOL das Wortsymbol 'NOT LESS' (nicht kleiner als), während fur die konjunktive logische Verknüpfung von Aussagen 'AND' und für die disjunktive Verknüpfung 'OR' zu setzen ist.

Die Rechengänge werden durch Marken strukturiert und durch eine Folge von Anweisungen (statements) formuliert, wobei neben einfachen arithmetischen oder

logischen Ausdrücken (expression statements) Laufanweisungen (for statements), Sprunganweisungen (go to statements) und bedingte Anweisungen (if statements) zu unterscheiden sind.

Der Dateneingabe dient die Leseanweisung READ und der Datenausgabe die Anweisungen PRINT, WRITE und TYPE. In neueren ALCORS[5] werden diese 4 Anweisungen durch differenziertere Prozeduren ersetzt, jedoch ist hier die Entwicklung noch keineswegs abgeschlossen. Die Betriebszeichen eines ALGOL-Schreibers

Wagenrücklauf WR, Symbol <

Zeilenvorschub ZV, Symbol ≡

Zwischenraum ZW, Symbol ␣

sind im allgemeinen ohne Einfluß auf den Programmablauf. Im Rahmen einer Ausgabeanweisung WRITE ("Zeichenkette") sind sie aber zu beachten und für das Ausgabebild von Bedeutung. Im vorliegenden Programmbild sind diese Zeichen in den Zeichenketten der WRITE-Anweisungen ausdrücklich angeführt, wobei mehrfache Zwischenräume, z.B. 12 mal ␣, durch ␣12 gekennzeichnet werden.

Hinsichtlich weiterer Einzelheiten zur ALGOL-Programmierung sei auf die angeführte Literatur[1–5] verwiesen.

BEISPIELE

Nachfolgende Beispiele wurden an einer relativ kleinen und langsamen Rechenanlage ZUSE Z23 gerechnet. Der Zeitbedarf für das einmalige Einlesen des

ALGOL-Programmes beträgt 4½ Minuten. Für das Einlesen des Zahlenstreifens der Eingangsdaten sowie für Rechnung und Resultatausgabe werden je Beispiel weitere 1½ Minuten benötigt, so daß die Auswertung beider Beispiele in weniger als 8 Minuten beendet ist. Bei 1 Std Rechenzeit können mehr als 30 derartiger Modellanalysenreihen ausgewertet werden, die bei konventioneller Rechentechnik mehr als 1 Monat Arbeitszeit pro Person beanspruchen würden.

Titrimetrische Chloridbestimmung nach Mohr

Makro-Arbeitsbereich: 1,0 bis 0,05 mMol Chlorid, entsprechend 35 bis 1,8 mg Chlorid.

Modellanalysen: $k = 6$ Testgruppen mit jeweils $l = 4$ Einwaagen G_i an Standardlösung von etwa 10/7,5/5,0/2,5/1,0/0,5 Gramm, entsprechend etwa 1,0/0,75/0,50/0,25/0,10/0,5 mMol Chlorid.

Bürette: 10 ml-Normalbürette, Teilung 0,02 ml oder Kolbenbürette, Teilung 0,005 ml: Tropfengröße unter 0,03 ml.

Standardlösung: Wässerige Natriumchloridlösung (etwa 0,1M) mit $\lambda_1 = 3{,}5472$ mg Cl/Gramm Lösung; $[a_i] = \lambda_1 G_i$ mg Cl/Einwaage.

Kurzvorschrift: Maximal 50 ml mit 0,5*M* $NaHCO_3$ neutralisierte Probelösung (pH 7–8) in 300 ml Weithals-Erlenmeyerkolben +1,0 ml 0,5*M* Kaliumchromat + 50 ml Äthanol + Wasser bis Endvolumen von 100 ml. Sofort Titration mit 0,1*N* Silbernitrat-Maßlösung bis zum scharfen Umschlag von Hellgelb nach Rotbraum. Rohverbrauch V_x ml (Bereich 10 bis 0,5 ml).

Blindwerte und Faktor: 10 Blindansätze mit den verwendeten Reagentien ergaben im Mittel: $\bar{V}_B = 0{,}026$ ml; $s_B = \pm 0{,}005_3$ ml. Faktor F der Maßlösung: $F = 1{,}000$ (Herstellergarantie ±0,2 Rel%).

Titrationsergebnis: $W_i = V_i = F(V_{xi} - \bar{V}_B) = V_{xi} - 0{,}026$ ml. Die Meßgröße W_i wird extern berechnet. In Fällen $F \neq 1{,}000$ kann F in den Umrechnungsfaktor einbezogen werden. Gefundene Menge: $a_i = \lambda_2 . V_i$ mg Chlorid mit $\lambda_2 = [\mathrm{Cl}] . N$ (bzw. $F . [\mathrm{Cl}] . N$) = 3,5453 mg Cl/ml Verbrauch.

Tabelle VI gibt eine Zusammenstellung der Eingangsdaten in programmrichtiger Reihfolge,

wobei die Wertepaare G_i, V_i nach den 6 Gruppen geordnet sind, sowie das Originalbild der von der Rechenanlage ausgedruckten Resultate und Urteile.

Diskussion. Nach Auflistung der statistischen Vergleichsgrößen t_1, t_2 und t_3 werden die nach Beziehung (6) mit den Primärresultaten gebildeten Prüfgrößen τ_U und τ_R ausgegeben. Wegen $\tau_U = 1{,}967 < t_1 = 2{,}074$ d.h. „*V1* nicht wahr", und $\tau_R = 2{,}233 > t_1 = 2{,}074$ d.h. „*V2* wahr", wird die Marke M2 des Programmes angesteuert und $[U]$ bzw. $[R]$ in den Einzelrechengängen II und III erneut berechnet.

Da hierbei $\tau_U = 0{,}294 < t_2 = 2{,}069$ d.h. „neues *V1* nicht wahr", und auch $\tau_R = 1{,}043 < t_2 = 2{,}069$ d.h. „neues *V2* nicht wahr" resultiert, wird das Programm nach Ausdrucken der Urteile

UNTERSCHIED VON $[U]$ ZU NULL NICHT FESTSTELLBAR
UNTERSCHIED VON $[R]$ ZU EINS NICHT FESTSTELLBAR

bei der Marke M3 fortgesetzt. Der Rechengang IV liefert als Endresultat die Verfahrens-Standardabweichung $[s_K] = \pm 0{,}0881$ mg Chlorid entsprechend $s_V = [s_K]/\lambda_2 = \pm 0{,}025$ ml Maßlösung. Der Befund $[U] = 0$ und $[R] = 1$ beweist, daß die übliche Korrektur von Titrationsergebnissen durch gesondert ermittelte Blindwerte V_B und Faktoren F bei dem vorliegenden Verfahren ausreichend und einwandfrei ist.

Modellanalyse Nr. 8 mit $[a_1] = 26{,}46$ mg Chlorid ergab einen „überzufälligen", Abweichungswert von $v_1^* = +0{,}253$ mg Chlorid (Überbefund). Wegen $\tau = 2{,}878 > t_3' = 2{,}792$ ($S = 99\%$!) liegt der relativ seltene Fall einer „unzulässigen" Überschreitung des Streubereiches vor und die betreffende Modellanalyse wurde wiederholt, wobei $G_8 = 7{,}4817$ g, d.h. $[a_8] = 26{,}54$ mg Chlorid; $W_8 = 7{,}524$ ml, d.h. $a_8 = 26{,}68$ mg Chlorid gefunden wurde. Eine erneute Durchrechnung ergab hinsichtlich $[U]$ und $[R]$ gleiche Urteile, jedoch im Rechengang IV eine kleinere Standardabweichung von $[s_K] = \pm 0{,}0773$ mg Chlorid entsprechend $s_V = \pm 0{,}022$ ml Maßlösung.

Gravimetrische Wolframbestimmung mit 8-Oxychinolin

Makro-Arbeitsbereich:	1,0 bis 0,1 mMol Wolfram entspricht 184 bis 18,4 mg Wolfram.
Modellanalysen:	$k = 6$ Testgruppen mit jeweils $l = 4$ Einwaagen G_i an Standardlösung von etwa 10/8/6/2/1 Gramm entsprechend etwa 1,0/0,8/0,6/0,4/0,2/0,1 mMol Wolfram.
Geräte:	Fällungsregler-Kombination, Filtertiegel Schott u. Gen. 63aG4, Saugtopf u.a.m.
Standardlösung:	Natriumwolframat in 0,2*M* Natriumhydroxid (etwa 0,1*M* an Wolfram mit $\lambda_1 = 18{,}385$ mg Wolfram/Gramm Lösung; $[a_i] = \lambda_1 \cdot G_i$ mg Wolfram.
Kurzvorschrift:	Maximal 170 ml Probelösung mit höchstens 2 mMol freier Natriumhydroxid in 400 ml-Becherglas (hohe Form) + 25,0 ml 0,5*M* Oxalsäure + 10,0 ml 0,25*M* ÄDTA + 5,0 ml 2*M* Ammoniak + Wasser auf 200–210 ml, pH 2,5 ± 0,5. Unter Rühren auf 70–80° erwärmen, Lösung klar, +30,0 ml 0,1*M* Oxinlösung (1*M* an Essigsäure) schnell unter Rühren eintropfen, 5 min Rühren, dann +15,0 ml 2*M* Ammoniak innerhalb von 20–25 min aus Fällungsregler unter Rühren eintropfen. Temperatur der Lösung auf 70–80° halten. Fällung 30 min bei 70–80°C ausrühren. End-pH 5,0 ± 0,5. Noch warm über Tiegel 63aG4 filtrieren. Filtrat auffangen und mit 50° heißem Filtrat letzte Niederschlagsreste aufbringen. Nachwaschen durch Auftropfen von insgesamt 25 ml Wasser (70° warm). Bei 160°C zunächst 60 min, danach in Intervallen von 30 min konstant trocknen. (Gewichtskonstanz auf ±0,05 mg). Wägeform: $WO_2(Ox)_2$, M = 504,157. Auswaage: $A_x$mg (Bereich 500–50 mg).
Blindwerte:	4 Blindansätze mit den verwendeten Reagentien ergaben keine sichtbaren und wägbaren Fällungen, d.h. $A_B = 0{,}00$ mg.
Fällungsergebnis:	Gefundene Menge $a_i = \lambda_2 \cdot A_{xi}$ mg Wolfram mit $\lambda_2 = [W]/[WO_2(Ox)_2] = 0{,}36467$ mg W/mg Auswaage.

Tabelle VII gibt eine Zusammenstellung der Eingangsdaten in programmrichtiger Reihenfolge, wobei die Wertepaare G_i, A_i nach den 6 Gruppen geordnet sind, sowie das Originalbild der von der Rechenanlage ausgedruckten Resultate und Urteile.

Diskussion. Nach Auflistung der statistischen Vergleichsgrößen t_1, t_2 und t_3 werden die nach Beziehung (6) mit den Primärresultaten gebildeten Prüfgrößen τ_U und τ_R ausgegeben.

Wegen $\tau_U = 3{,}682 > t_1 = 2{,}074$ d.h. „*V1* wahr" und $\tau_R = 2{,}091 > t_1 = 2{,}074$ d.h. „*V2* wahr", wird die Marke M1 angesteuert. Die bereits berechneten Primärresultate

$$[R] = 1{,}00174$$

$$[U] = -0{,}346 \text{ mg W}$$

$$[s_K] = \pm 0{,}242 \text{ mg W}$$

$$[s_R] = \pm 0{,}00083$$

$$[s_U] = \pm 0{,}094 \text{ mg W}$$

werden für dieses Verfahren als maßgebende Korrekturgrößen ausgegeben. Das negative $[U]$ ist wegen $\tau_U > t_1' = 2{,}819$ ($S = 99\,\%$!) signifikant Kleiner als Null und korrigiert einen Überbefund durch Mitreißen von Verunreinigungen bei Fällungen von Wolframmengen an der unteren Grenze des Arbeitsbereiches. Wegen $\tau_R < t_1'$ ist $[R]$ nur wahrscheinlich größer als 1. $[R]$ korrigiert Unterbefunde durch Löslichkeit bei Fällungen von Wolframmengen der oberen Grenze des Arbeitsbereiches.

Das Verfahren ist in dieser Form keinesfalls optimal und es wurden weitere gezielte Untersuchungen zur Ausschaltung der systematischen Fehlerquellen durchgeführt, worauf hier jedoch nicht eingegangen werden kann.

Modellanalyse Nr. 1 ergab einen Abweichungswert $v_1^* = -0{,}508$ mg Wolfram (Unterbefund) der wegen $\tau = 2{,}102 < t_1 = 2{,}819$ jedoch zulässig ist.

Résumé—La méthode usuelle d'évaluation d'une méthode analytique consiste à mener une série d'expériences-types. Une comparaison entre la quantité prélevée et la quantité trouvée donne une information numérique objective sur le hasard et les erreurs systématiques dans le domaine particulier étudié. Si l'on utilise les méthodes ordinaires de calcul, le temps nécessité et les difficultés sont relativement importants. Une série de 24 essais peut nécessiter 8 h pour les calculs, même s'il n'y a pas d'erreur humaine dans les estimations. L'expérience montre que des opérateurs inexpérimentés peuvent avoir besoin de plusieurs jours pour les calculs. On peut obtenir des résultats exempts d'erreur en 5 mn seulement par calcul électronique. On présente un programme de calcul écrit dans le language logique universel ALGOL. Les opérations préparatoires sont si simples qu'une assistance technique n'est pas nécessaire.

Summary—The usual way of evaluating an analytical method is to carry out a series of model experiments. A comparison of the amount taken and the amount found gives objective numerical information about the random and systematic errors in the particular range studied. If conventional methods of calculation are used, the time needed and the difficulty are relatively large. A series of 24 tests may need 8 hr for the calculations, even if no human error in computation occurs. Experience shows that inexperienced operators may need several days for the calculations. Results free from error can be obtained in as little as 5 min by electronic computing. A calculation programme written in the universal logical language ALGOL is given. The preparatory operations are so simple that skilled assistance is not necessary.

THERMAL STANDARDS IN THERMOGRAVIMETRY

C. J. KEATTCH
John Laing Research & Development Ltd., Boreham Wood, Hertfordshire, England

(*Received* 28 *July* 1966. *Accepted* 14 *September* 1966)

Summary—Comparisons of thermogravimetric data from different instruments have often led to controversy because of lack of appreciation that the values are influenced by the apparatus used. Consequently, it is suggested that various compounds be employed as thermal standards for comparing data from different sources. The paper also discusses the variables to be considered when attempting to devise such standards and includes a list of suggested thermal standards covering the ranges 100–400° and 1050–1060°.

THE rapid development of thermogravimetry in recent years has meant that there is now a considerable variety of apparatus in use in many different fields of study. This equipment, whether constructed in the laboratory or available commercially, naturally varies considerably in design and performance. Comparisons of so-called decomposition temperatures and other data derived from thermogravimetric curves, have often led to controversy because of lack of appreciation that these values partly depend on the apparatus used.[1] Duval,[2] for example, states that he has been unable to find any compound which gives the same decomposition temperature on five commercial thermobalances of different makes, even though all of the heating conditions were apparently identical.

In an attempt to avoid such controversy, it is suggested that various compounds possessing suitable thermal characteristics be employed as thermal standards. This would mean that if a worker studying the thermal behaviour of a compound in a particular apparatus under a specified set of operating conditions, quotes a certain temperature as being of some consequence, this temperature would be qualified by referring it to a significant temperature on the thermogravimetric curve of a thermal standard, run under identical operating conditions. Ideally, this standard temperature should be close to the significant temperature of the compound under investigation.

Although no extensive study of suitable compounds has been previously published, the idea of thermal standards is not new and probably the substance most studied in this context is calcium oxalate monohydrate. Duval[3] used this material when adjusting thermobalances after they had been assembled, cleaned or repaired and Barcia–Goyanes[4] and Wilson[5] suggested that the extremities of the plateaux of its thermogravimetric curve be used as temperature calibration points for a thermobalance. Such use of the two extremities of the plateaux of any thermogravimetric curve is inadvisable as their position is not dependent solely on the sample.[6,7] However, Simons and Newkirk[7] have shown that if calcium oxalate monohydrate is heated in a thermobalance under carefully controlled conditions, the resultant thermogravimetric curve can be useful in assessing the performance of the thermobalance and in the interpretation of thermogravimetric measurements.

Early in 1965, Forsyth[8] suggested the use of calcium and iron(II) oxalates as

standards for the calibration of thermoanalytical equipment and subsequently[9] enlarged on this idea by using the peak temperatures of the derivative thermogravimetric curve of calcium oxalate monohydrate as calibration points.

It is intended that thermal standards should only be used to avoid controversy when differences (>25°) in critical temperatures are reported by different workers.

EXPERIMENTAL

Decomposition temperature

It is important to realise that in thermogravimetry the term "decomposition temperature" is a misnomer. Although a particular temperature may be the lowest temperature at which the start of a weight change can be observed with a certain apparatus under a given set of experimental conditions, it is not the absolute decomposition temperature below which the reaction rate suddenly becomes zero.[10]

In a thermogravimetric curve of a single stage non-isothermal reaction, there are two characteristic temperatures;[7] the initial temperature, T_i and the final temperature, T_f; T_i is defined as the lowest temperature at which the cumulative weight change reaches a magnitude that a particular thermobalance can detect, and T_f as the temperature at which the cumulative weight change first reaches its maximum value. Although T_i has no fundamental significance, it can still be a useful characteristic of a thermogravimetric curve[6] and the term "procedural decomposition temperature" has been suggested for it.[6,11]

The peak temperature of a derivative thermogravimetric curve is, again, not the decomposition temperature, a fact which has not been appreciated by some workers.[12] Although Forsyth[9] chose this temperature as his reference point, it is not necessarily the ideal point, as McAdie[13] pointed out in connexion with his attempt to establish standard materials for differential thermal analysis.

In this paper, the procedural decomposition temperature, T_i, is the parameter considered in investigation of materials suitable as thermal standards.

Materials studied

In choosing compounds as potential thermal standards it was thought desirable to use materials that were both universally and commercially available in a known state of purity. Accordingly, only chemicals conforming to the AnalaR specification were employed.

Operating details

Thermobalance. A Stanton thermobalance, Model HT-SM, was used for establishing all the reference temperatures given, except the temperatures below 100° quoted for copper(II) sulphate pentahydrate. In this instance, a modified recording system was used (see *Comments on Table II*). The thermobalance used has a sensitivity of 1 mg for each small division of the weight record chart and the sample weights were chosen accordingly (see below). A chart speed of 6 in/hr was chosen to obtain satisfactory resolution of the thermogravimetric curve. All temperatures quoted are furnace wall temperatures.

Sample container. The geometry and the material of manufacture of the sample container will profoundly affect the shape of the thermogravimetric curve.[1,14,15] A shallow platinum dish, 20 mm in diameter and 6 mm deep, was chosen for this study because this design facilitates gaseous exchange between the sample and the surrounding atmosphere.[1,15–18] Platinum was chosen because of its good thermal conductivity and lack of any known catalytic effect on the thermal decomposition of the materials studied.

Sample weight. The weight of sample chosen always gave only a thin layer at the bottom of the platinum dish. This allowed free diffusion of the gaseous products through the void space round the particles and made any temperature gradient in the sample negligible in comparison with the temperature differences being investigated. At the same time, the sample weight was sufficient to give an adequate weight change, relative to the sensitivity of the thermobalance.

State of sub-division of the sample. The effects of particle size and surface area have been widely studied[7,19–23] although it has been shown[24] that although the final temperature T_f and the rate of weight loss vary markedly with particle size, the procedural decomposition temperature T_i is not affected. In the present work, all samples with the exception of calcium carbonate (which was obtainable in analytical reagent grade only in a very finely divided form) were lightly ground so that all the material passed a No. 100 British Standard sieve. The fraction passing a No. 100 and retained on a No. 200 British Standard sieve was then used in the experiments.

Heating rate. That the heating rate can markedly influence the overall shape of a thermogravimetric curve was stressed by early workers[19,20] and the effect has subsequently been studied in a variety of applications.[21,23,25,26,27] Newkirk[6] has shown that at a given temperature the degree of decomposition is greater, the slower the heating rate. Further, the appearance of an inflexion in a thermogravimetric curve at a fast heating rate may resolve into a plateau at a slower heating rate.[28] There is therefore neither an optimum nor a standard heating rate, but in the light of past experience[27] and of other workers' results[1,6,28] a heating rate of 3°/min was considered suitable.

Gas atmosphere. The effect of the atmosphere present has also been studied and it has been found that it can be considerable.[1,7,29,30] Clearly there is no gas atmosphere suitable for all cases, and any choice is open to question. A static air atmosphere was chosen for the current investigation with a full appreciation of its possible shortcomings.

RESULTS

Since it had been decided to use the procedural decomposition temperature T_1 as the reference temperature, a variety of compounds was run on the thermobalance in order to obtain some preliminary information. Table I summarizes the results obtained. From a study of the Table and the corresponding thermogravimetric curves, it was apparent that in order to determine T_1 unambiguously, the initial rate of weight loss as recorded on the Stanton thermobalance should be not less than $2\frac{1}{2}$ mg/5 min. Appropriate compounds from Table I were selected for further study. To be suitable as a standard of this type, any potential standard compound should

(i) be stable at room temperature for at least 12 months,
(ii) give reproducibility of reference temperatures to $\pm 5°$,
(iii) give agreement between operators to $\pm 5°$ for the value of the reference temperature,
(iv) give agreement to $\pm 15°$ for different batches from the same supplier, and
(v) give reference temperatures differing by not more than 25° for samples from different suppliers.

The first requirement was satisfied because the work took about 18 months and the thermogravimetric curves of the compounds suggested as thermal standards varied little during this time. The other four requirements were covered by using samples from two different supply houses, one of which provided samples from different batches, and by having separate thermogravimetric runs carried out by two operators and the suggested reference temperatures, in almost every case, read off the same thermogravimetric curves by both operators. The results obtained are summarized in Table II.

Comments on Table II

With the exception of that for copper(II) sulphate pentahydrate, the reference temperatures below 100° are only approximate values and have been included merely as an indication of compounds which may be suitable as standards at low temperatures The suggested reference temperatures of 52–3° and 86° for copper(II) sulphate pentahydrate were obtained with a modified Stanton thermobalance which instead of recording temperature, recorded the voltage of a chromel/alumel thermocouple over the range 0–22 mV (0–530°). The overall results indicate good reproducibility of the reference temperatures and satisfactory agreement between operators. Most of the compounds gave satisfactory agreement between samples from different sources and different batches, the exceptions being sucrose, barium acetate, potassium hydrogen phthalate and sodium hydrogen tartrate.

* Initial value, averaged over 5 min immediately after procedural decomposition temperature, T_i.
† Averaged over 2½ min.

Some sucrose samples exhibit a small slow weight loss starting at about 170° but this does not interfere with the sharp increase in the rate of weight loss at 205–210°. Barium acetate gives reference temperatures which show good agreement between operators, but the variation of 40° between samples from the same supply house is not acceptable. Potassium hydrogen phthalate shows good agreement for reference temperatures of 240–250° and 365–370°, but one sample gave a further reference temperature of 565° whereas a sample from a different supply house gave an additional reference temperature of 670°. These temperatures are undoubtedly derived from the decomposition of dipotassium phthalate[31] but no explanation can be offered for their

wide divergence. They cannot, of course, be recommended as reference temperatures. Sodium hydrogen tartrate gives a useful reference temperature of 545° but, as will be seen from Table II, although this temperature is reproducible with samples from different supply houses, it is not given by all samples. Consequently its use as a thermal standard must be treated with some reserve.

McVicar is gratefully acknowledged and thanks are also due to Dr. H. G. McAdie, Ontario Research Foundation, Canada and Mr. R. S. Forsyth, AB Atomenergi, Studsvik, Sweden for useful discussions.

Zusammenfassung—Der Vergleich thermogravimetrischer Daten von verschiedenen Geräten führte oft zu Diskussionen, da der Einfluß des Geräts außer Acht gelassen wurde. Daher wird vorgeschlagen, daß verschiedene Verbindungen als thermische Standards zum Vergleich der Daten von verschiedenen Geräten herangezogen werden. Die Arbeit diskutiert auch die Variablen, die bei einem Versuch, solche Standards aufzustellen, berücksichtigt werden müssen, und enthält eine Liste vorgeschlagener thermischer Standards in den Bereichen 100–400° und 1050–1060°.

Résumé—Des comparaisons de données thermogravimétriques obtenues avec différents instruments ont souvent conduit à des controverses parce qu'on n'a pas pris en considération le fait que les valeurs sont influencées par l'appareil utilisé. En conséquence, on suggère que divers composés soient utilisés comme étalons thermiques pour comparer les données de différentes sources. Le mémoire discute également des variables à prendre en considération lorsqu'on tente d'établir de tels étalons et comprend une liste d'étalons thermiques suggérés, couvrant les domaines 100–400° et 1050–1060°.

APPLICATION OF RADIOISOTOPES IN COLUMN CHROMATOGRAPHY ON SUBSTITUTED CELLULOSES—III

THE SEPARATION OF GOLD FROM SILVER, IRON AND OTHER METALS

R. A. A. MUZZARELLI
Department of Chemistry, Faculty of Science, University of Sherbrooke, Sherbrooke, P.Q., Canada

(*Received* 1 *July* 1966. *Accepted* 19 *August* 1966)

Summary—The chromatographic behaviour of several metals has been studied on columns of natural and substituted celluloses, by using radioisotopes. It has been found that gram and nanogram amounts of gold are not adsorbed on natural cellulose, and consequently gold can be separated from nanogram amounts of silver, iron, zinc, cadmium, chromium, manganese and cobalt. Gold has a limited tendency to form complexes with the functional groups of the celluloses, but the other metals mentioned formed very stable complexes. The results have also been compared with those obtained for mercury.

THE most important studies on the chromatography of traces of metals on cellulose columns deal with the purification of mercury and uranium. Mercury is not adsorbed from ethyl ether onto natural cellulose and is not retained on substituted celluloses: apparently it cannot be adsorbed and cannot form complexing bonds with the amine, phosphate and carboxyl groups.[1] The chromatography of uranyl nitrate in ether on natural cellulose has been studied carefully,[2] and uranium has been found not to be retained on natural cellulose. On the other hand, caesium, strontium, barium, indium and antimony;[2] scandium, yttrium and the lanthanons;[3] chromium, manganese and iron;[2] cobalt;[2,4] copper and silver;[2] zinc;[1,2] and cadmium[1,2,3] are retained more or less strongly. These metals are distributed over all the metal groups of the periodic table, and at present there is no explanation of their retention on cellulose. A comparative study of the other metals might eventually confirm the hypothesis that complexes are formed, and allow the structure and the stability of the complexes of certain metals with the functional groups of the celluloses to be determined. Even before a complete theory of the chromatography of metals on celluloses can be established, however, the results available permit important separations of traces of metals and purification of macro amount of salts to be made.

The separation of gold is important for two purposes: the recovery and concentration of traces of gold from solutions containing traces of other metals, and the purification of macro amounts of gold. These operations can be of importance both in preparative and analytical chemistry. One of the most interesting fields requiring rapid separation of gold, generally on microscopic samples, is archaeology;[5] others include the analysis of cosmic dust,[6] metallurgy of gold,[7] and activation analysis of high purity materials.[8] For preparative purposes, macro amounts of gold may have to be purified before use in electronic instrumentation or after recovery from waste solutions.

Few papers on the ion-exchange chromatography of gold have been published. These include articles on ion-exchange papers in mixed solvents,[9] ion-exchange resins,[10] and papers pretreated with organic complexing agents.[11]

A booklet on the radiochemistry of gold[12] and a recent review on ion-exchange celluloses[13] contain further references: among these is the only article dealing with a kind of chromatography of gold on columns of natural cellulose.[14] Gold was adsorbed on 2 g of natural cellulose containing hydrochloric or nitric acid and this was then packed at the top of a column of cellulose, and the gold eluted with ethyl acetate. The amount of gold used was 0·0050–0·1857 g; the amounts of other metals were not indicated, their movement into the column was not specified, and no method for their recovery was given. Although the authors stated that preliminary separations of gold on columns of cellulose were carried out with ethereal solvents, they did not explain why ethyl acetate was finally adopted, and ether no longer used. Indeed, ethyl ether seems to be very useful for eluting gold from cellulose, because many compounds of gold are very soluble in it.

The present study was made in order to apply a unique simple chromatographic procedure to gram and nanogram quantities of gold, and to recover microgram and nanogram quantities of iron, silver and other transition metals, separated from gold. Moreover, the knowledge of the chromatographic behaviour of these metals may contribute to the study of the ion-exchange mechanism on substituted celluloses in ethyl ether solvents, and to the study of the complexing capacity of the different functional groups of these celluloses.

EXPERIMENTAL

Reagents

Reagent-grade chemicals and solvents were used for the preparation of all solutions.
Anhydrous ethyl ether, used as supplied.
Nitric acid (90%) 2% v/v solution ethyl ether.
Ammonium thiocyanate solution, 0·04% w/v in methanol–ethyl ether (1 + 4).
Ammonium thiocyanate solution, 5% w/v in methanol–ethyl ether (1 + 4).
Hydrochloric acid, 3*M*.
Ammonia solution, 3*M*.
Chloroauric acid, $HAuCl_4 \cdot 3H_2O$, crystals.

Cellulose powders

Whatman CF 11 (natural), DE 11 (diethylaminoethyl), AE 11 (aminoethyl), P 11 (phosphate), CM 11 (carboxymethyl), and ET 11 (epichlorohydrin triethanolamine, Ecteola).

Radioisotopes

The gold-198 and silver-110 m were supplied by the Radiochemical Centre, Amersham, England; the others by New England Nuclear Corp., Boston, Mass., U.S.A. The isotopes used are listed in Table I.

The isotope solutions were diluted with 90% nitric acid, and volumes between 10 μl and 250 μl were added to 25 ml of ethyl ether.

Radioactivity measurements

The fractions of eluate and the cellulose powders were collected in plastic bottles of uniform shape and capacity. Their radioactivity was measured by a 128-channel gamma-ray spectrometer ND-110 electronically coupled to an NaI(Tl) crystal, and compared with a standard. The mean dispersion of repeated results was 8%.

Preparation of the columns of celluloses

The columns (10 mm bore; reservoir 200 ml; Teflon stop-cock) were prepared as described earlier.[1,4] The time needed for preparing two columns and running two complete separations is 1 hr.

TABLE I.—RADIOISOTOPES USED IN CHROMATOGRAPHY

	Specific activity at time of use, $Ci.g^{-1}$	Chemical purity, %	Quantity used for each experiment, g
^{198}Au	3	n.s.	$4 \cdot 10^{-8}$
^{110m}Ag	1	n.s.	$1 \cdot 10^{-7}$
^{65}Zn	5·6	99%	$1 \cdot 10^{-8}$
^{109}Cd	carrier-free	99%	$<6 \cdot 10^{-9}$
^{51}Cr	36	99%	$5 \cdot 10^{-8}$
^{54}Mn*			$\sim 10^{-8}$
^{59}Fe	6	99%	$1 \cdot 10^{-7}$
^{60}Co	61	n.s.	$1 \cdot 10^{-8}$

* Produced from the iron solution by $^{54}Fe(n,p)^{54}Mn$.
n.s. = none stated.

Preparation of concentrated solutions of gold

Chloroauric acid crystals were kept in a desiccator and dissolved in ethyl ether just before use. The radioactive gold and the other radioisotopes were added to this solution. No precipitation of silver occurred.

Nitratoauric acid, $H\,Au(NO_3)_4$ was prepared by making auric oxide[15,16] and dissolving it in hot 90% nitric acid. One ml of this solution was added to 50 ml of ethyl ether, already containing the radioisotopes, just before the chromatography. Traces of peroxides formed by the action of nitric acid on ethyl ether, can reduce gold(III) to the metal in a short time. The solution was passed through the column at very high speed, by using compressed air, in order to avoid prolonged contact of cellulose with the nitratoauric acid. The flow-rate of 50 ml/min did not affect the retention of traces of metals.

RESULTS AND DISCUSSION

Gram or nanogram amounts of gold (as chloroauric acid) are not adsorbed on natural cellulose and pass quantitatively through the column (Fig. 1). On the other hand, substituted celluloses partially retain gold (Figs. 2–6). Ecteola cellulose (Fig. 6) gives the highest retention, though even this is incomplete. In any case gold can be quantitatively eluted by 0·04% ammonium thiocyanate solution.

Nanogram quantities of chromium, manganese and iron are completely retained on all celluloses and separated from gold. Their retention has been studied in the standard conditions chosen for cobalt,[4] and the results for iron are shown in Figs. 1 to 6. Chromium and manganese behave practically the same as cobalt.[4] The retention of nanogram amounts of iron was affected by the presence of gram amounts of chloroauric acid: iron was carried by the gold and passed through the column. This interference was overcome by using nitratoauric acid on a longer column (25 × 1 cm) instead of chloroauric acid: in these conditions the separation of gold from iron was quantitative, and the elution curves of iron were closer to those of iron when alone. Occasionally during separation of gram amounts of nitratoauric acid from iron, reduction of gold occurred at a certain extent (5–10%) on the column, and some purple of Cassius was visible. In this case it was possible to continue the regular procedure, elute the other metals, and recover the pure precipitated gold by ashing the cellulose.

Zinc and cadmium were perfectly separated from gold on the natural, phosphate, and aminoethyl celluloses, giving the elution curves already reported,[1] and their chromatography was not appreciably affected by the presence of large quantities of chloroauric or nitratoauric acids. It was also possible to separate zinc and cadmium from silver on aminoethyl and phosphate celluloses. Corresponding figures in this

FIGS. 7–12.–The chromatographic behaviour of silver on columns of cellulose. For legend see Figs. 1–6.

paper and the earlier two of this series,[1,4] can be superimposed to study the possibility of separations of nanogram amounts of the metals.

Silver was retained by all celluloses. The elution curves from the natural, carboxymethyl and phosphate celluloses, (Figs. 7, 10 and 11), have the same shape and this should mean that carboxymethyl groups and phosphate groups are not responsible for retention of silver: on these three celluloses, silver is simply adsorbed. On the contrary, celluloses containing amino groups, namely diethylaminoethyl (Fig. 8), aminoethyl (Fig. 9), and epichlorohydrin-triethanolamine (Fig. 12), retain silver much more strongly because they evidently form amino complexes, the highest strength being for diethylaminoethyl complexes, as expected. A 5% solution of ammonium thiocyanate did not elute silver, although thiocyanate is a good complexing agent for silver and has been often used to elute silver from ion-exchange resins. In fact, aqueous ammonia was needed to elute silver from diethylaminoethyl cellulose. These results again emphasise the peculiarity of the behaviour of mercury under these chromatographic conditions: mercury should form amino complexes and therefore should be retained at least by diethylaminoethyl cellulose; on the contrary it does not, so mercury can be separated from silver on all celluloses. Mercury cannot be separated quantitatively from gold, but on Ecteola cellulose about 30% of the gold passed through with the mercury, and 70% of the gold was retained (Fig. 6) free from mercury.

Antimony and copper could also be separated from gold and their behaviour will be illustrated in the next articles of this series.

Gold was obtained in ethyl ether solution after passage through cellulose columns: it was generally easy to reduce the gold to metal by exposing the nitratoauric acid to sunlight or by adding some nitric acid to the solution of chloroauric acid in ether.

CONCLUSIONS

Traces of gold can be separated from many elements by chromatography on a natural cellulose column. Gram amounts of gold can be freed from traces of metals by a simple and rapid procedure. It is interesting to note that gold behaves like mercury and uranium on natural cellulose and its chromatography is not affected by the anions present. The traces of metals collected on the cellulose column can be eluted, sometimes selectively, and subsequently analysed by neutron-activation or other physico-chemical methods. In special cases substituted celluloses can be used for particular separations. Gold tends to be retained on substituted celluloses, but at present no explanation can be given of this retention.

It is very important to note that silver forms very strong bonds with the amino groups of the substituted celluloses and the chromatographic behaviour of silver is markedly different from that of mercury, which is not retained on substituted celluloses although mercury generally forms stable amino complexes. Other transition metals such as chromium, manganese, iron and cobalt form amino complexes, and they are more or less strongly retained on substituted celluloses, but as it is known that the complexes of silver are quite different from those of cobalt, it should be interesting to elucidate the nature of the complexes of these metals with the aminoethyl, diethylaminoethyl, and triethanolamine groups of the substituted celluloses.

The study of the structures, stability constants and other parameters of these complexes seems of interest. Even though the distribution of the functional groups

on these celluloses is not thoroughly known, these modified polymers are derived from relatively simple natural polymers and have points of similarity to both sugars and proteins. The study of the selective retention of traces of metals could be of interest not only to analytical chemists but also to biochemists.

Finally, the particular ability of each type of cellulose to retain the metals shows that in common with most separations on cellulose, simple partition chromatography is not the sole mode of separation, but that strong adsorption phenomena, together with complex-formation, depending on the type of cellulose, may also be important factors.

Acknowledgement—The author expresses his appreciation to the National Research Council of Canada for financial support of this research (Grant No. 734, 1965).

Zusammenfassung—Chromatographischen Verhalten von manchen Metallen an der Cellulosesäule und modifizierten Cellulosesäulen wurde mit Radioisotoptechnik untersucht. Diese Untersuchung zeigte das der Gold im Menge von Gramm bis vierzig Nanogramme wird an der Cellulose nicht absorbiert und folglich kann doch von Silber, Eisen, Zink, Kadmium, Chrom, Mangan und Kobald abgetrent werden. Der Gold zeigt eine sehr beschränkte Tendenz zur Komplexbildung mit der Cellulose, während der andere obengenante Metalle bilden sehr stabile Komplexverbindungen. Die erlangten Resultate wurde auch auf das Quecksilber betreffenden Resultate bezichen.

Résumé—Les radioisotopes ont été appliqués à l'étude du comportement chromatographique de plusieurs métaux sur colonnes de cellulose naturelle et de celluloses substituées. On a constaté que l'or en quantités variables entre un gramme et quelques nanogrammes n'est pas adsorbé sur cellulose naturelle, et qu'il est par conséquent séparé d'avec nanogrammes d'argent, fer, zinc, cadmium, chrome, manganèse et cobalt. La tendance à former des complexes avec les groupes fonctionnels des celluloses substituées est très limitée dans le cas de l'or, tandis que les autres métaux cités forment des complexes très stables. Les résultats obtenus ont été aussi referés aux résultats concernant le mercure.

HYDROLYSIS STUDY OF ORGANIC ACID ANHYDRIDES BY DIFFERENTIAL THERMAL ANALYSIS—II

MALEIC ANHYDRIDE AND TRIMELLITIC ANHYDRIDE

J. M. ROSENFELD and C. B. MURPHY*
General Electric Company, Schenectady, N.Y., U.S.A.

(*Received* 30 *June* 1966. *Accepted* 14 *July* 1966)

Summary—Differential thermal analysis has been used to follow the hydrolysis of maleic anhydride (MA) and trimellitic anhydride (TMA). On exposure of MA to an atmosphere of 96% relative humidity, maleic acid is produced, hydrolysis being complete in 21 hr at 22°, but no hydrolysis occurs at a relative humidity of 50%. When exposed to an atmosphere of 96% relative humidity, TMA is quite stable for short periods, but hydrolyses slowly, the production of trimellitic acid being complete in 113 hr at 22°.

IN a previous paper in this series,[1] differential thermal analysis (DTA) was applied to the study of the hydrolysis of pyromellitic dianhydride. The present paper is a continuation of this work, DTA being applied to a study of the hydrolysis of two additional commercially-important anhydrides, maleic and trimellitic anhydrides.

EXPERIMENTAL

Apparatus and reagents

The apparatus employed was identical to that previously reported.[1] The maleic anhydride, a commercial product obtained from the Monsanto Chemical Company, was specified as briquettes melting at 57–60°. Maleic acid was obtained from Matheson, Coleman and Bell, and it had a melting point of 135–6°. The trimellitic anhydride, also a commercial product, was obtained from Amoco Chemicals Corp. in the form of flakes melting at 161–163·5°. Trimellitic acid, a product of the K & K Laboratories, Inc., melted over the range 218–220°. All materials were ground in an atmosphere of dry nitrogen to 10 μ average particle size.

Procedure

DTA curves were obtained from 2-mg samples of each anhydride, both as received, and after exposure to relative humidities of 96 and 50% at 22·34–23·22°. The reference material was calcined alumina. Samples were heated at 10°/min while a stream of nitrogen passed through the bedded powder sample. All DTA curves were prepared at a sensitivity of 300 μV/(6°).

RESULTS AND DISCUSSION

Figure 1 is a reproduction of the DTA curve obtained from maleic anhydride and shows two endothermic peaks. The first of these, with a maximum at *ca.* 60°, is in excellent agreement with that reported by Sandermann *et al.*[2] and with the reported melting point for the compound.[3] The second peak marks the volatilization of the anhydride, as confirmed by the observation that the sample holder was empty when the curve returned to its base line.

* Present address—Xerox Corporation, Rochester, N.Y.

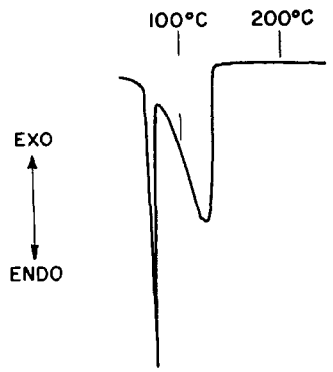

FIG. 1.—DTA curve for maleic anhydride.

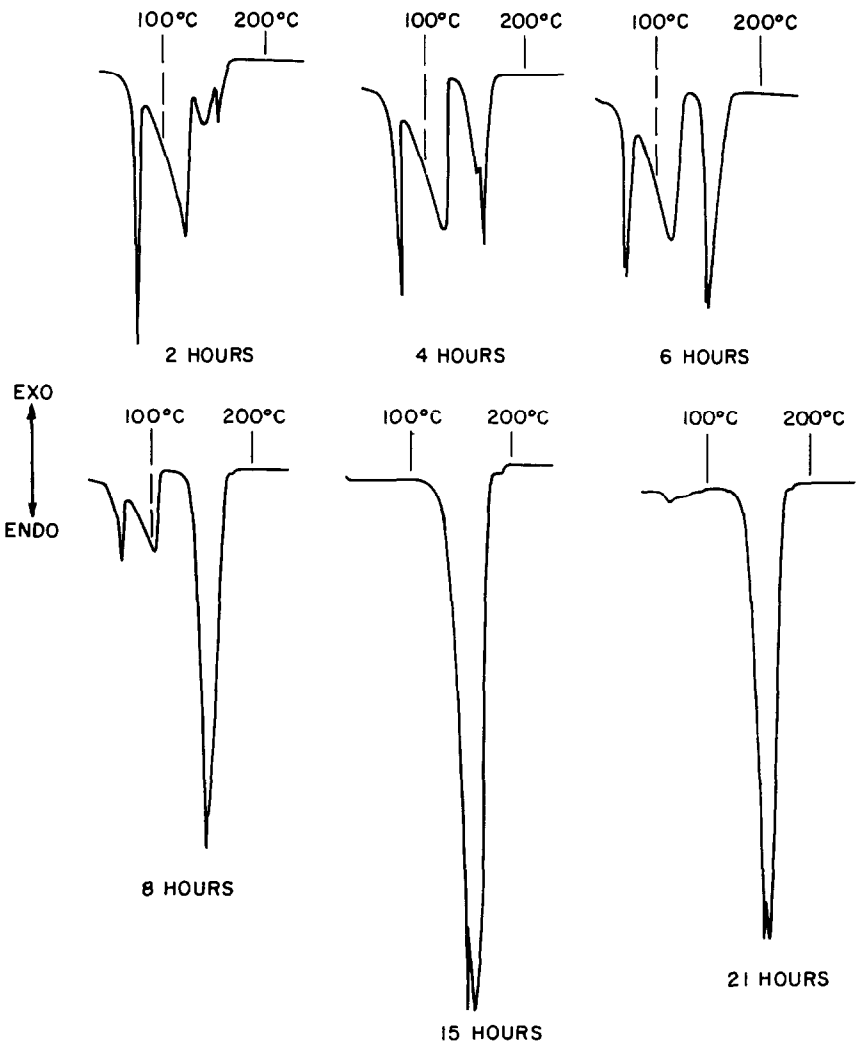

FIG. 2.—DTA curves for maleic anhydride after exposure to 96% relative humidity for various times.

DTA curves for samples of maleic anhydride exposed to 96% relative humidity for various periods of time are reproduced in Fig. 2. It is evident from these curves that the maleic anhydride peaks diminish in intensity with the length of exposure, and become virtually non-existent after 21 hr. The exposure to this atmosphere also induces two peaks at higher temperatures, which are well resolved at the short exposure times but tend to fuse into a single peak as the exposure time is extended. This sharp single endotherm corresponds well with the endotherm for maleic acid which is shown in Fig. 3. The first of the higher-temperature peaks is associated with the melting of the maleic acid, reported to be 130–131°,[3] while the second is associated with decomposition of this compound, which is reported to occur at 135°.

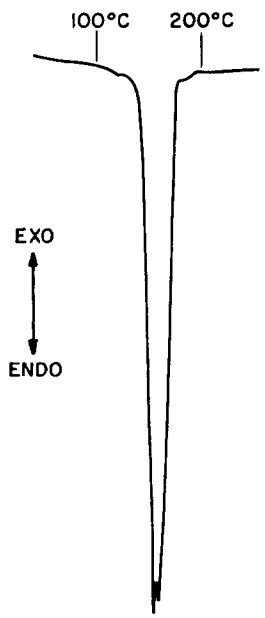
In contrast to the results obtained at 96% relative humidity, exposure of maleic anhydride to 50% relative humidity for 46 hr produced no variations from the curve for maleic anhydride.

While these results indicate that maleic anhydride can undergo hydrolysis, they also show that the material can be stored safely at 50% relative humidity at temperatures up to 22°.

Figure 4 depicts the DTA curve obtained from trimellitic anhydride, which is characterized by two endothermic peaks. The first of these, occurring at *ca.* 165°, is in good agreement with the reported melting point for this compound, 165–7°.[4] The second endotherm will be discussed subsequently.

DTA curves for 2-mg samples of trimellitic anhydride exposed to 96% relative humidity for various periods are reproduced in Fig. 5. These results are to be compared with the curve for trimellitic acid which is reproduced in Fig. 6.

It is evident from the curves that short periods of exposure to 96% relative humidity have little effect, the curve (Fig. 5*a*) being identical with that of the anhydride.



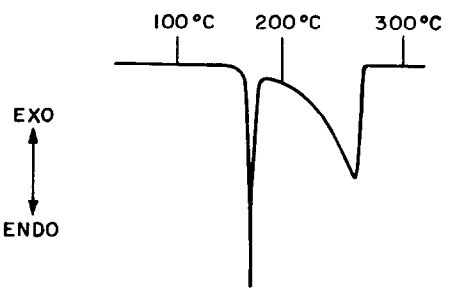


FIG. 4.—DTA curve for trimellitic anhydride.

FIG. 3.—DTA curve for maleic acid.

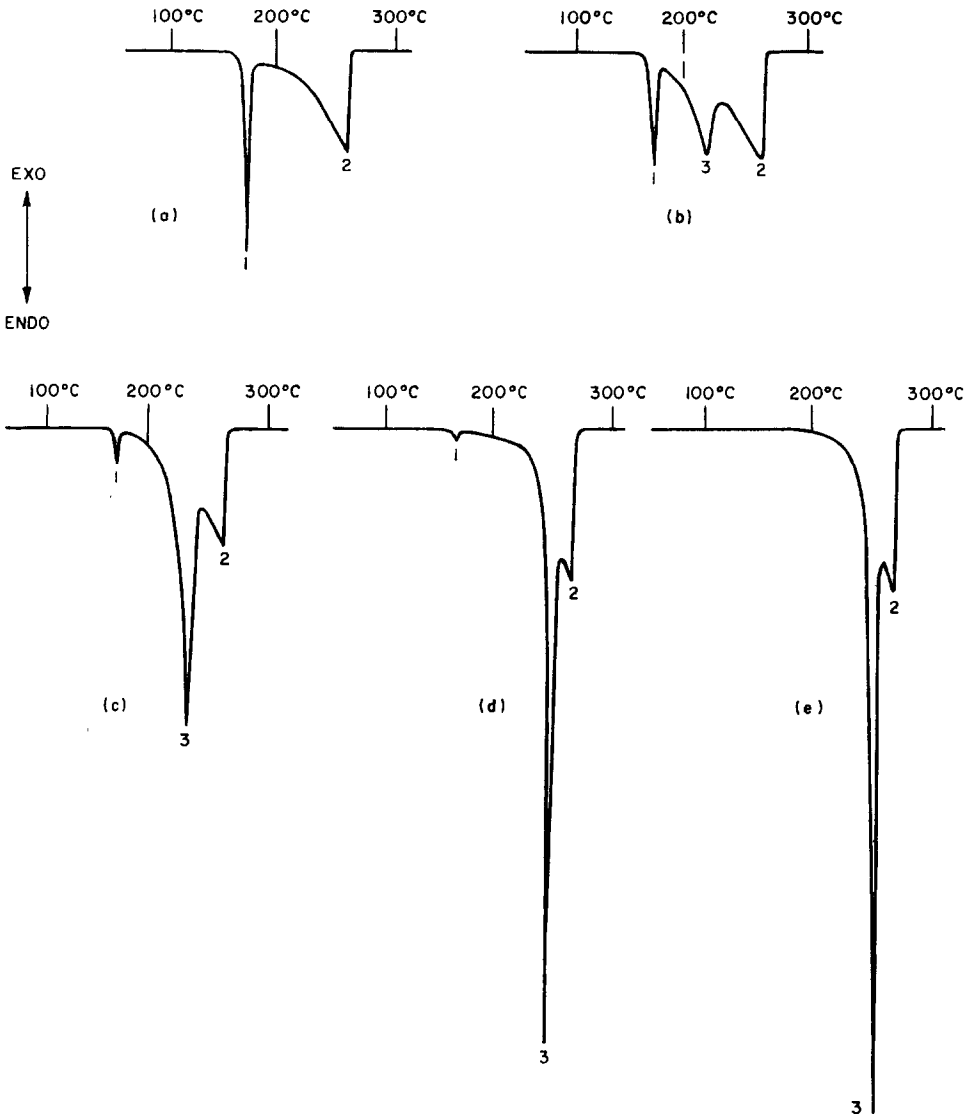

FIG. 5.—DTA curves for trimellitic anhydride after exposure to 96% relative humidity for various times.
(*a*) 7 hr; (*b*) 16 hr; (*c*) 48 hr; (*d*) 72 hr; (*e*) 113 hr.
1—Trimellitic anhydride m.p., 161°C
2—Trimellitic anhydride b.p., 240°C
3—Trimellitic acid m.p., 216°C.

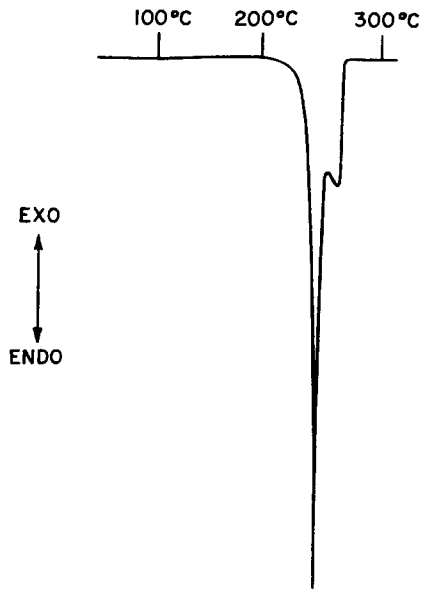

FIG. 6.—DTA curve of trimellitic acid.

However, as the exposure period increases, several changes in the curves are observed. The first of these is the decrease in intensity of the melting endotherm for trimellitic anhydride, indicating hydrolysis of the anhydride ring. This peak disappears completely after 113 hr of exposure. A third endotherm appears after 16 hr of exposure to 96% relative humidity, and becomes more intense with the extent of exposure. This endotherm occurs at the melting point of trimellitic acid, 215–217°,[5] as shown by the excellent correspondence of Figs. 5*e* and 6. The lack of better temperature correspondence in materials subjected to shorter exposure periods is assumed to be a result of melting point lowering induced by the anhydride.

The third endotherm, with a peak at 260°, appears in DTA curves for both the hydrolysed and unhydrolysed material without any significant variation. The breadth of this peak (Fig. 4), which is subdued by competitive endothermic reactions in the hydrolysed material (Figs. 5*e* and 6), would indicate volatilization similar to that experienced with maleic anhydride. As trimellitic acid is reported to decompose at its melting point,[5] this peak is assumed to result from an impurity. The significance of this peak was not investigated.

As previously indicated,[1] differential thermal analysis can be applied successfully to the determination of safe storage conditions of moisture sensitive materials. Further, the sensitivity, quantities of materials employed, and the speed of the technique would appear to offer advantages not available in other methods now employed for this purpose.

Acknowledgement—The authors are indebted to Mrs. M. B. Warner for her assistance in the preparation of the DTA curves and to Dr. E. L. Simons for his helpful discussions of this work.

Résumé—On a utilisè l'analyse thermique différentielle pour suivre l'hydrolyse de l'anhydride maléique (MA) et de l'anhydride trimellitique (TA). Lorsqu'on expose MA à une atmosphère à 96% d'humidité relative, il se forme de l'acide maléique, l'hydrolyse ètant complète en 21 h à 22°, mais il n'y a pas d'hydrolyse avec une humidité relative de 50%. Par exposition à une atmosphère à 96% d'humidité relative, TA est totalement stable pendant de courtes périodes, mais s'hydrolyse lentement, la production d'acide trimellitique étant complète en 113 h.

Zusammenfassung—Die Hydrolyse von Maleinsäureanhydrid (MA) und Trimellitsäureanhydrid (TA) wurde mittels Differential thermoanalyse verfolgt. Setzt man MA einer Atmosphäre von 96% relativer Feuchtigkeit aus, so bildet sich Maleinsäure, wobei die Hydrolyse bei 22° in 21 Stunden beendet ist; bei einer relativen Feuchtigkeit von 50% hingegen tritt keine Hydrolyse ein. In einer Atmosphäre von 96% relativer Feuchtigkeit ist TA für kurze Zeiten recht stabil, hydrolysiert aber langsam; die Bildung von Trimellitsäure ist nach 113 Stunden vollständig.

COMPLEXOMETRIC DETERMINATION OF GALLIUM WITH CALCEIN BLUE AS INDICATOR

H. N. ELSHEIMER
U.S. Geological Survey, Menlo Park, California 94025, U.S.A.

(*Received* 23 *June* 1966. *Accepted* 22 *July* 1966)

Summary—A metalfluorechromic indicator, Calcein Blue, has been used for the back-titration of milligram amounts of EDTA in presence of gallium complexes. The indicator was used in conjunction with an ultraviolet titration assembly equipped with a cadmium sulphide detector cell and a microammeter for enhanced end-point detection. The result is a convenient and rapid method with an accuracy approaching 0·1% and a relative standard deviation of about 0·4% for 10 mg of gallium.

VARIOUS indicator and titrant systems have been used for the complexometric determination of milligram amounts of gallium with EDTA. For the direct titration of gallium with EDTA, indicators such as Gallocyanine,[1] PAN,[2,3] PAR,[2] copper-PAN,[4,5] SNAZOXS,[6] 7-(1-naphthylazo)-8-hydroxyquinoline-5-sulphonic acid,[7] Pyrocatechol Violet[8] and Morin[8,9] have been used. These titrations were carried out in the pH range 1–5, and most involved heated titrand solutions.

Indirect complexometric determinations of gallium with EDTA have involved indicators such as Pyrocatechol Violet with bismuth nitrate as the titrant,[10,11] Xylenol Orange with various titrants,[12] Xylenol Orange plus Poirrier's Blue with thorium nitrate as the titrant,[13] Pyrogallol Red and Bromopyrogallol Red as indicators with bismuth nitrate as the titrant,[14] Erio Black T as indicator with zinc as the titrant,[15] SNAZOXS as indicator with copper as the titrant,[16] and diphenylcarbazone plus Methylene Blue as indicator in the presence of the vanadium-EDTA complex with zinc acetate as the titrant.[17]

There are two disadvantages of visual EDTA titrations: many EDTA complexes are coloured, making the end-point hard to observe, and often the indicator change at the end-point is not sharply defined. Use of a fluorescent indicator would eliminate at least the first of these difficulties. Of the indicators cited above, only Morin was used as a fluorescent indicator.[8] Gallium-EDTA complexes are only slightly coloured, but dissatisfaction with the highly coloured indicator used by Miner and DeGrazio[13] led to exploration of the use of fluorescent indicators, in particular, metalfluorechromic indicators. These indicators function in highly coloured solutions by forming a metal complex and at the same time undergoing a change in the intensity and sometimes the colour of fluorescence.[18] Their extreme sensitivity allows the determination of small concentrations of many metals, often without preliminary separations, and macro samples may be conveniently titrated.

The first use of a metalfluorechromic indicator, as such, was by Wilkins[18] for the indirect chelometric determination of cobalt and iron. He complexed the metals with an excess of EDTA at pH 4·0 and back-titrated with standard copper solution under ultraviolet light, using an indicator known as Calcein. The second known use

of Calcein as a metalfluorechromic indicator was also by Wilkins[19] for the back-titration of EDTA in the presence of the highly-coloured EDTA complexes of cobalt, chromium and copper. Calcein, which is a condensation product of fluorescein, iminodiacetic acid, and formaldehyde, was first used as an indicator by Diehl and Ellingboe,[20] and Tucker.[21] They used it as a visual indicator in a direct complexometric titration, and not as a metalfluorechromic indicator.

The second useful metalfluorechromic indicator was then known as Calcein W, a purified form of Calcein containing no free fluorescein to cause residual fluorescence and fuzzy end-points.[22] It was first used by Hibbs and Wilkins[23] for the indirect determination of aluminium, titanium, nickel and other constituents of their alloys and by Wilkins and Hibbs[24] for the direct determination of copper with triethylenetetramine without prior separations or the use of masking agents.

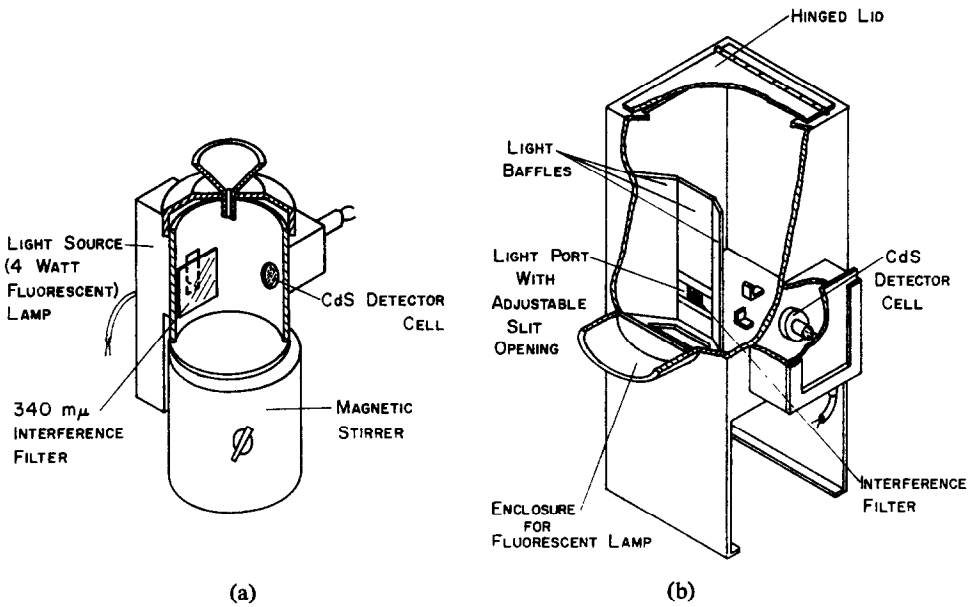

FIG. 1.—Ultraviolet titration assembly for the determination of gallium using a metalfluorechromic indicator.
(a) Original design. (b) Modified design.

A metalfluorechromic indicator somewhat different in structure, but similar in properties to Calcein W, is Calcein Blue. It is a condensation product of methyl-umbelliforone, formaldehyde and iminodiacetic acid. Calcein Blue is reported by Wilkins[25] to be superior to Calcein W for chelatometric titrations. This is because the wavelengths at which Calcein Blue is activated in acidic or basic solution are a much closer match to the wavelength of maximum output of most ultraviolet sources than are the excitation wavelengths of Calcein W. Calcein Blue was first used by Wilkins[25] for the direct determination of calcium, strontium and barium and the indirect determination of nickel and chromium mixtures without prior separations.

Because of the superiority of Calcein Blue used indirectly, it was chosen by us as an indicator for the investigation of the indirect complexometric determination of gallium. Standard copper solution was used as the titrant for the excess of EDTA.

Wilkins[26] used a titration housing of rather simple design to permit the visual detection of the fluorescent end-point. A commercial version of the equipment is available.[27] In our laboratory a titration housing was used which monitored the course of the titration by means of a microammeter connected in series with a cadmium sulphide detector cell located at right angles to the incident ultraviolet radiation. Calcein Blue fluoresces at 445 mμ, which is close to the wavelength of maximum response for cadmium sulphide detector cells. This equipment gave better end-point detection than could be obtained visually. The apparatus is shown in Fig. 1*a*, and a later modification with a more powerful ultraviolet source and better access to the titration cell and the detector cell is shown in Fig. 1*b*.

EXPERIMENTAL

Reagents

Standard 0·1M *EDTA*, prepared from disodium ethylenediaminetetra-acetate dihydrate dried according to the method of Schwarzenbach.[28]

Standard 0·025M *copper*(II), prepared from pure copper dissolved in concentrated nitric or sulphuric acid and standardized against the standard EDTA solution.

Indicators. Calcein Blue, 0·1% aqueous solution; Bromphenol Blue, 0·1% aqueous solution.

Buffer. Sodium acetate-acetic acid buffer solution, pH 4·8.

Sodium hydroxide, 6M

Hydrochloric acid, 0·5M

All chemicals were of reagent grade purity.

Apparatus

The titration assembly and its circuitry are shown in Figs. 1 and 2 respectively.

A Koch microburette, graduated in 0·01 ml divisions, and readable to 0·005 ml, was used for the titrations.

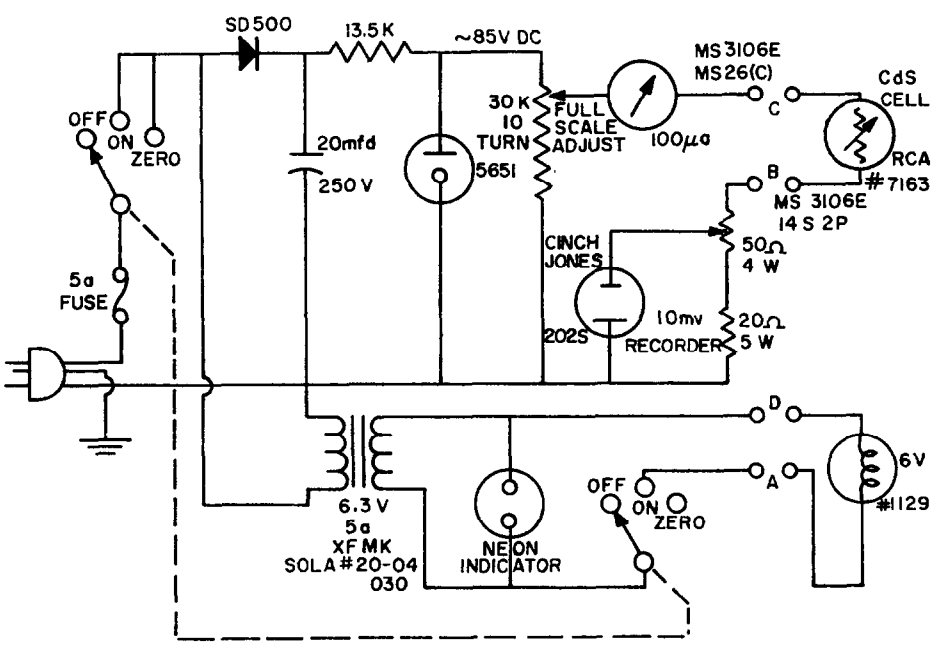

FIG. 2.—A schematic diagram of the electrical circuitry for the ultraviolet titration assembly.

Procedure

The following procedure is recommended for solutions free from interfering ions or for solutions in which the interfering ions have been suitably masked. Transfer an aliquot containing 1–20 mg of gallium into a Berzelius beaker containing 50 ml of 0·5*M* hydrochloric acid. Aliquots of 1 ml or less are desirable in order to minimize the amount of base added later. Dilute the solution to 95 ml with distilled water. If a pH meter is used, add 6*N* sodium hydroxide until the meter indicates a pH of 3·5. Otherwise, add 2 drops of Bromphenol Blue and add base until the colour of the solution just begins to change. Add 15 ml of buffer solution to bring the pH of the solution to about 4·8, then add 5 ml of 0·1*M* EDTA from an automatic-delivery pipette. Add 7 drops of Calcein Blue indicator solution and boil for 2 min. Cool to near room temperature and titrate with the 0·025*M* copper solution. Follow the course of the titration with the microammeter of the titration assembly, the microammeter being adjusted to read 100% fluorescence initially. The fluorescence initially decreases rapidly, then more slowly until the end-point is reached, when a sharp drop in fluorescence occurs.

Determine the end-point either graphically or by direct observation of the meter. A typical titration curve is shown in Fig. 3.

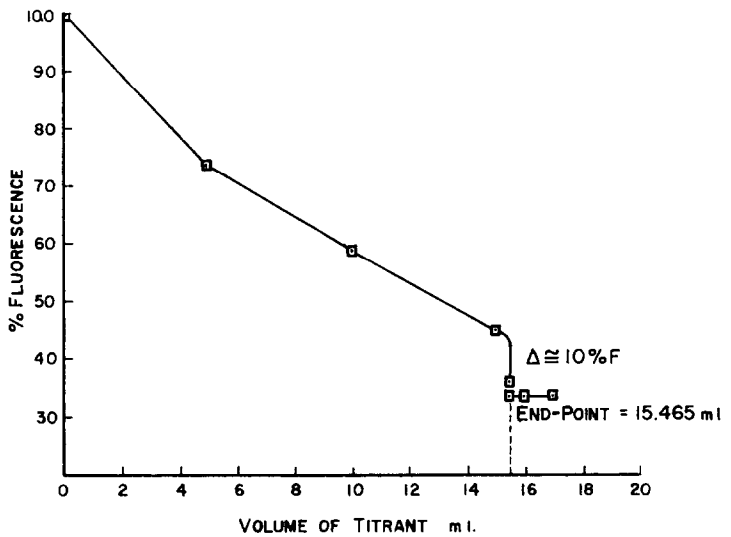

FIG. 3.—A typical titration curve for the back-titration of gallium, with Calcein Blue as indicator.

The characteristic meter response can be determined from the standardization titrations and then the end-point can be anticipated for titrations of unknown solutions. It is possible to titrate rapidly to a meter reading approximately 10–15 units greater than that at the end-point, and then titrate drop by drop until an abrupt needle deflection of 5–10 units occurs. If no significant deflection occurs with the addition of further titrant, the end-point has been reached. Normally the fluorescence will remain constant for excesses of titrant up to 1 or 2 ml.

If aliquots containing 20–100 mg of gallium are to be titrated, more 0·1*M* EDTA solution must be added and 0·05*M* copper solution should be used for the back-titration.

RESULTS AND DISCUSSION

Three series of determinations were made in order to measure the precision of the method. In Series C the accuracy was also measured. The end-points in Series A were obtained graphically and those in Series B and C were obtained visually from the behaviour of the microammeter. A summary of the results is shown in Table I.

The relative standard deviations of Series A, B and C, based on the measurement of the volume of titrant added, were 0·11%, 0·14% and 0·19% respectively. The results from Series A demonstrate the slightly greater precision obtainable from

TABLE I.—PRECISION STUDIES ON THE CALCEIN BLUE INDICATOR METHOD FOR THE COMPLEXOMETRIC DETERMINATION OF GALLIUM

Series	n	Gallium found, *mg*	Standard deviation, *mg*	Relative standard deviation, %
A	22	9·320	$0·026_8$	0·29
B	16	9·334	$0·034_8$	0·37
C	10	9·977	$0·047_1$	0·47

graphical end points. Application of the *F*-test to the data of Series A and B led to the conclusion that at the 95% confidence level there is no statistically significant difference in the precision between the two sets of data. A *t*-test showed that the difference between the mean amount of gallium in Series A and B was not significant.

The accuracy of the procedure was checked by using calibrated pipettes and carefully standardized solutions. From the mean value of standard copper solution used in Series C, the amount of gallium found experimentally was 9·98 mg. The theoretical amount of gallium present was 9·99 mg. Thus the deviation from the theoretical in this series was only 0·1%.

A convenient, rapid, precise and accurate method for the titration of gallium has been developed. The use of Calcein Blue affords a titration with a sharp end-point in contrast to some of the previous methods. The use of the apparatus described could be conveniently applied to other fluorescent titrations in lieu of direct visual observation of the end point.

The work reported was performed under U.S. Atomic Energy Commission Contract AT(29-1)-1106.

Zusammenfassung—Ein fluoreszierender Metallindikator, Calceinblau, wurde zur Rücktitration von Milligrammengen komplex an EDTA gebundenen Galliums verwendet. Der Indikator wurde in Verbindung mit einem Ultraviolett-Titrationsgerät verwendet, das mit einem Cadmiumsulfiddetektor und einem Mikroamperemeter zur verbeserten Endpunktsbestimmung ausgerüstet ist. Es resultiert ein bequemes und schnelles Verfahren mit einer Genauigkeit von fast 0,1% und einer relativen Standardabweichung von etwa 0,4% für 10 mg Gallium.

Résumé—On a utilisé un indicateur métallofluorochrome, le Bleu de Calcéine, pour le dosage en retour de EDTA en présence de sa gallium-complex en quantités de l'ordre du milligramme. On a utilisé l'indicateur en liaison avec un montage de titrage en ultra-violet équipé d'une cellule de détection au sulfure de cadmium et d'un microampéremètre pour une détection plus sensible du point de fin de dosage. Le résultat en est une méthode commode et rapide avec une précision approchant 0,1% et un écart type relatif d'environ 0,4% pour 10 mg de gallium.

FLUORESCENCE AND PHOSPHORESCENCE CHARACTERISTICS OF ANTICOAGULANTS

A NEW APPROACH TO DIRECT MEASUREMENT OF DRUGS IN WHOLE BLOOD

H. C. HOLLIFIELD and J. D. WINEFORDNER
University of Florida, Department of Chemistry, Gainesville, Florida 32601, U.S.A.

(*Received* 26 *May* 1966. *Accepted* 2 *September* 1966)

Summary—Fluorimetric and phosphorimetric excitation and emission peaks and limiting detectable concentrations and phosphorimetric decay times are given for warfarin, dicumarol, diphenandione, phenindione and tromexan. Known concentrations of warfarin, a highly fluorescent compound, and dicumarol, a highly phosphorescent compound, are directly measured in the complex biochemical system of whole blood. Excellent recoveries of warfarin and dicumarol in the concentration range of 0·1 to 10 mg% in whole blood were achieved.

FLUORIMETRY and phosphorimetry have been used previously in the analysis of drugs in biological fluids.[1–7] Both techniques require fewer sampling steps and chemical reagents for analysis than most other instrumental methods. Fluorimetry is a simpler method, is of lower cost, uses simpler instrumentation, and uses a much wider range of solvents than phosphorimetry, whereas phosphorimetry is generally more selective and sensitive than fluorimetry. The disadvantages of phosphorimetry become less important in areas where fluorimetry is not applicable. To illustrate their complementary nature, fluorimetry and phosphorimetry are used here with excellent results for the direct measurement of anticoagulants separated from whole blood. This is not to be interpreted as a proposed clinical procedure; whole blood is used here because it provides an interesting and complex biochemical medium. Warfarin, an intensely fluorescing compound when excited by a xenon source, is measured by fluorimetry. Dicumarol, although it fluoresces, exhibits stronger phosphorescence and so is measured by phosphorimetry.

The analysis of both compounds is made simpler and more accurate by the use of protein-free ethanolic filtrates of whole blood samples. Protein-free ethanolic filtrates were previously[2] used for the phosphorimetric determination of a number of sulpha drugs in serum. The ethanolic filtrate is shown here to work equally well for the phosphorimetric measurement of non-protein-bound anticoagulants in whole blood.

EXPERIMENTAL

Apparatus

Fluorescence measurements were taken with a spectrophotofluorimeter (Aminco-Bowman No. 4-8202) with a potted RCA IP28 photomultiplier tube, a 150-W xenon arc lamp and an X-Y recorder (No. 1620-814, American Instrument Co. Inc.). The same instrumentation modified with a phosphoroscope attachment (Aminco-Keirs No. C27-62140) was employed for all phosphorimetric measurements. All studies were performed at constant slit width, with the slit arrangement 4, 3, 3, 4, 3. A volumetric "repipet" apparatus was used in the preparation of all experimental samples.

Reagents

Ethanol was used as the solvent for all studies. Absolute ethanol was distilled through a 6-ft vacuum-jacketed and silvered column with a reflux ratio of 15:1. The column was packed with 3/8 in.

coil helices. Only the centre fraction of the distillate was saved, and this was checked for acceptable fluorimetric and phosphorimetric backgrounds.

Standard stock solutions of the anticoagulants were prepared by adding 50 ml of absolute ethanol to 50 mg of each of dicumarol, diphenadione, phenindione, tromexan and warfarin. Five drops of di-n-butylamine were added to each stock solution (except phenindione) to aid in the dissolution of the drugs. The di-n-butylamine did not increase the fluorescence or phosphorescence backgrounds when mixed in the same proportions with pure ethanol. Solutions used for the measurement of spectra and for analyses were prepared by dilution of the stock solutions to give the desired concentrations.

Procedure

Excitation and emission spectra were obtained for each compound (except diphenadione and phenindione, which did not fluoresce at a concentration of 1 mg/ml of ethanol) by both fluorimetry and phosphorimetry. The limiting detectable concentrations were determined by fluorimetry and by phosphorimetry, and were taken as that drug concentration which resulted in a signal twice the standard deviation of the background (blank ethanolic solution with no drugs) readings. The fluctuations were due partially to noise but mainly to variability in the source intensity signal during a series of measurements.

"Unknown"drug samples in citrated blood were prepared by mixing 8 ml of absolute ethanol, 1 ml of ethanolic solution of the specified drug (of known concentration), and 1 ml of citrated blood. A blank was prepared by adding 1 ml of citrated blood (containing no drugs) to 9 ml of absolute ethanol. If a volumetric "repipet" is used in the preparation of these 10-ml samples, the order of addition of the blood and the diluent becomes arbitrary and has no bearing on the ease or accuracy of the dilution. The mixtures were shaken for 3–5 min and then centrifuged for 5 min to separate the precipitated protein. Then 1 ml of supernatant liquid was added to 9 ml of absolute ethanol and mixed, and the relative intensity signal of fluorescence or phosphorescence was measured. The relative intensity signals of the "unknowns" were corrected by subtracting the intensity signal due to the blood (the difference between the ethanol background relative intensity signal and the intensity signal of the blood-ethanol blank) from the relative intensity signals of the "unknowns". The concentration of the "unknown" sample was determined by comparing the corrected intensity signal of the "unknown" with that of a standard solution in the same concentration range as that of the "unknown". Fluorimetry was used as the method of choice for the analysis of warfarin in whole blood at concentrations of 0·1 mg/100 ml of blood, 1·0 mg/100 ml of blood and 10 mg/100 ml of blood. Phosphorimetry was the method of choice for dicumarol when analysed by this procedure at the same concentrations as the warfarin.

A number of protein-free filtrate blanks were prepared from whole blood, and their fluorescence and phosphorescence backgrounds were measured.

RESULTS AND DISCUSSION

The primary purpose of this study is to demonstrate that fluorimetry and phosphorimetry can be used to make direct, accurate and rapid measurements of non-protein-bound drug concentrations in the complex biochemical environment of diluted whole blood. Out-dated blood-bank citrated blood was used for the preparation of all blood samples. The ethanolic protein-free filtrates prepared in the course of the analyses are in effect dilutions of the whole blood samples. These filtrates have been prepared in such a way that the concentration of non-protein-bound drug in the mixture is known exactly. Also, adding the blood to the ethanolic standard solution causes the protein to precipitate immediately, minimizing any loss of the anticoagulant due to reactions between the drugs and the unprecipitated protein. For the same reason, the mixture of the precipitate and the ethanolic supernatant liquid is centrifuged immediately after the mixture has been shaken sufficiently to ensure complete precipitation of the protein.

The background fluorescence and phosphorescence intensity signals due to the protein-free ethanolic filtrates of whole blood-bank samples were highly reproducible. The fluorimetric background signal was reproducible to $\pm 1\%$ on the second most sensitive scale of the photomultiplier microphotometer. The phosphorimetric

background signal due to the filtrate and ethanol was reproducible to ±10% on the same scale. The intensity signal of the phosphorimetric background, however, was notably smaller than that of the fluorimetric background. Consequently, slightly lower limiting detectable drug concentrations in the ethanol filtrate are obtainable by phosphorimetry than by fluorimetry when this procedure is used. These studies demonstrated that the blank luminescence backgrounds were insignificant at drug concentrations greater than 10 mg%.* At drug concentrations of 1 mg%, the luminescence background signal of the blank accounted for approximately 5% of the concentration. At 0·1 mg% concentration, the background signal due to the blank was significant and had to be considered in the calculations of the percentage of drug recovered.

In Table I, the fluorimetric and phosphorimetric excitation and emission wavelength peaks (uncorrected for instrumental response), the phosphorimetric decay times and phosphorimetric and fluorimetric limiting detectable concentrations for dicumarol, diphenadione, phenindione, tromexan and warfarin in ethanol are given. A comparison of the limiting detectable concentrations in Table I indicates that the fluorescence of warfarin is greater than that of the other anticoagulants. Except for warfarin, all of the anticoagulants used in this study had lower limiting detectable concentrations by phosphorimetric analysis than by fluorimetric analysis.

† Fluorescence not analytically useful.
¶ (m) indicates the most intense peak.
‡ Limiting detectable concentration.

The intense fluorescence of warfarin permitted measurement over a fairly large concentration range without the need of special concentration procedures. Excellent recoveries of warfarin at relatively low concentrations in the prepared blood sample (0·1 mg%) were obtained by this procedure. The intense phosphorescence of dicumarol also allowed the measurement of this anticoagulant over a wide range of concentrations. In Table II typical recoveries of these two anticoagulants from the prepared whole blood samples are given. All data are averages of triplicate measurements on standards (at all three concentrations) and on blanks. Recoveries

* 1 mg% = 1 mg/100 ml of sample.

>90% were obtained at all three concentrations, for both drugs, when the protein-free ethanolic filtrates were used. The relative standard deviation on the three measurements of each concentration of each drug was <5% in all cases. Duplicate determinations of warfarin in blood samples can be made by fluorimetry in less than 15 min. It takes a little longer, however, by phosphorimetry because several more steps are needed in the measurement procedure.

TABLE II.—TYPICAL RECOVERIES OF WARFARIN BY FLUORESCENCE AND DICUMAROL BY PHOSPHORESCENCE*

The advantages of the protein-free ethanolic filtrate for the fluorimetric and/or phosphorimetric analysis of whole blood samples are numerous. Several have been previously discussed in connection with the use of protein-free ethanolic filtrates of serum in the analysis of a number of sulpha drugs.[2] The advantages of using ethanol to deproteinize blood and as the solvent are: speed, ease of preparation, availability and low cost of solvent, low luminescent background, solubility of a large number of drugs, and the formation of a rigid clear glass at 77°K at a dilution of 1/20 (water: ethanol). It is important to note that there is no significant increase in the luminescence background signal of the protein-free ethanolic filtrates when whole blood is used in place of serum. It should also be noted that the ultimate advantage of using a protein-free ethanolic filtrate for analyses of drugs in blood, plasma or serum is that the compound of interest (in this case the anticoagulant) is separated from protein interferences, and the compound is diluted to volume in ethanol in the same step. There is then a low background when the anticoagulant in ethanol is measured directly by fluorimetry or phosphorimetry. No additional separation steps are necessary. When a non-protein-bound drug concentration is being measured the only possible loss is therefore adsorption of the drug on the surface of the precipitated protein. The same solution can be measured fluorimetrically and phosphorimetrically. Phenindione and diphenadione phosphoresce with fair sensitivity and do not fluoresce. The use of fluorimetry and phosphorimetry together should be useful for the analysis of mixtures of phenindione or diphenadione and any of the other fluorescing anticoagulants. This is possible because the fluorescing anticoagulants (especially dicumarol and warfarin) also phosphoresce. If such a mixture is first measured fluorimetrically, the concentration of the fluorescing species is determined without interference from the non-fluorescing species of the mixture (phenindione or diphenadione). Phosphorimetric analysis of the mixture yields a relative intensity

signal due to the phosphorescence of both components of the mixture. Because the concentration of one component is known from the fluorimetric analysis, the concentration of the second component is easily determined from the total phosphorescence signal.

Acknowledgement—This work was carried out as part of a study on the phosphorimetric analysis of drugs in blood and urine, supported by the U.S. Public Health Service (GM-11373-03). The authors also wish to thank the following companies who supplied several of the anticoagulants studied: Geigy Pharmaceuticals (tromexan), The Upjohn Company (diphenadione) and Walker Laboratories (phenindione).

Résumé—On donne les maximums d'excitation et d'émission fluorimétriques et phosphorimétriques, les concentrations limites décelables et les temps d'affaiblissement phosphorimétrique pour la warfarine, le dicoumarol, la diphénandione, la phénindione et le tromexane. Des concentrations connues de warfarine, un composé fortement fluorescent, et de dicoumarol, un composé fortement phosphorescent, sont mesurées directement dans le système biochimique complexe du sang total. On a obtenu des récupérations excellentes en warfarine et dicoumarol dans le domaine de concentrations de 0,1 à 10 mg% dans le sang total.

Zusammenfassung—Anregungs- und Emissionsmaxima von Fluoreszenz und Phosphoreszenz sowie Nachweisgrenzen und Phosphoreszenzabklingdauern von Warfarin, Dicumarol, Diphenandion, Phenindion und Tromexan werden angegeben. Bekannte Konzentrationen von Warfarin, einer intensiv fluoreszierenden, und Dicumarol, einer stark phosphoreszierenden Substanz, wurden direkt in einem komplizierten biochemischen System, nämlich Vollblut, gemessen. Es wurden ausgezeichnete Ausbeuten an Warfarin und Dicumarol im Konzentrationsbereich 0,1 bis 10 mg-% in Vollblut erreicht.

SUBSTOICHIOMETRIC SEPARATION IN ACTIVATION ANALYSIS

EXTRACTION OF CO-ORDINATIVELY-UNSOLVATED SALTS

I. P. ALIMARIN and G. A. PEREZHOGIN

(*Received* 19 *January* 1966. *Accepted* 2 *August* 1966)

Summary—The necessary conditions have been examined for the use of extraction of coordinatively-unsolvated salts for substoichiometric separations in activation analysis, especially the influence of interfering ions and of the concentration of the carrier. A study has been made of the substoichiometric extraction of halide ions, oxyanions and anionic metal complexes by means of the tetraphenylarsonium ion into chloroform and dichloroethane, and of the extraction of alkali metal ions into nitrobenzene with tetraphenylborate. Substoichiometric extraction can be combined with neutron-activation analysis for the determination of traces of iodine, caesium, rubidium, manganese, rhenium, chromium, thallium, gold, gallium and tantalum.

NOT long ago, Růžička and Starý[1] suggested a new method of separation in activation analysis, called substoichiometric separation. For this purpose[2,3] the extraction of chelate compounds is very satisfactory, but it is limited to those metals which form stable chelates. The extraction of co-ordinatively unsolvated salts (*i.e.*, those containing large ions[4]) extends the range of the method, because the element to be determined can be present in either the cationic or the anionic part of the salt extracted.[5,6]

The necessary conditions for satisfactory substoichiometric separation by extraction of unsolvated salts can be derived in two ways if the ions in the salt have the same degree of charge. We can use the extraction constant K_{AB} for the system

$$A + B \rightleftharpoons (AB)_0; \qquad K_{AB} = [AB]_0/[A][B] \tag{1}$$

where $[AB]_0$ is the equilibrium concentration of the ion-pair $(AB)_0$ extracted into the organic phase, and [A] and [B] are the equilibrium concentrations of the two ions in the aqueous phase, and use it in conjunction with the initial concentrations of the reagent and the carrier of the element to be determined.[6] Alternatively, we can use the equations for the distribution ratio for the reagent, E_A,[5] which relate it to the original concentration of reagent C_A and carrier C_B,

$$E_A = K_{AB}[B] \approx K_{AB}(C_B - C_A) \tag{2}$$

and satisfy the requirement that at least 99% of the reagent added should be extracted,

$$E_A \geqslant 99\, v/v_0 \tag{3}$$

where v and v_0 are the volumes of the aqueous and organic phases respectively. Solution of equations (2) and (3) gives the value of the extraction constant:

$$\log K_{AB} \geqslant 2 + \log(v/v_0) - \log(C_B - C_A). \tag{4}$$

If the ions constituting the salt do not bear the same degree of charge, the conditions for substoichiometric separation to be satisfactory are more complicated.

It is understood that the roles of A and B may be reversed. The significance of the extraction constant K_{AB} depends on the size, charge and structure of the ions, the nature of the solvent, and on other factors.[4,7] The solvent must be little soluble in water, acid, or alkali, and must itself not be able to extract the element to be determined, unless the reagent is present.

TABLE I.—SOLUBILITY OF TETRAPHENYLARSONIUM SALTS IN CHLOROFORM AND 1,2-DICHLOROETHANE

Salt	Solubility, M	
	Chloroform	1,2-dichloroethane
$R_4AsAuCl_4$	$4{\cdot}4 \times 10^{-3}$	$>2{\cdot}8 \times 10^{-2}$
R_4AsReO_4	$1{\cdot}1 \times 10^{-3}$	$6{\cdot}1 \times 10^{-3}$
R_4AsMnO_4	$0{\cdot}7 \times 10^{-3}$	$3{\cdot}1 \times 10^{-3}$
R_4AsClO_4	$0{\cdot}8 \times 10^{-3}$	$1{\cdot}1 \times 10^{-2}$
R_4AsI	0·2	—
$(R_4As)_2Cr_2O_7$	—	$>3{\cdot}5 \times 10^{-2}$

Concentration of the carrier

In activation analysis, the concentration of carrier to be used is chosen arbitrarily. The upper limit is set by the solubility of the extracted species, and hence if $C_B = 2C_A$ the concentration of B is determined by the condition

$$C_B \leqslant 2S_{AB}v_0/v \tag{5}$$

where S_{AB} is the solubility of AB in the organic phase. In Table I the solubilities of some tetraphenylarsonium salts in chloroform and 1,2-dichloroethane are quoted.

The lower limit depends on K_{AB} and v/v_0; if $C_B = 2C_A$, then

$$\log C_B \geqslant 2{\cdot}3 + \log(v/v_0) - \log K_{AB}. \tag{6}$$

Thus rhenium(VII) for example, can be extracted substoichiometrically as its tetraphenylarsonium salt into chloroform over the concentration range $4 \times 10^{-4}M$ to $2 \times 10^{-3}M$ if $v = v_0$ and $C_B = 2C_A$. In principle, a specific amount of carrier can be isolated even when the rhenium concentration is less than $4 \times 10^{-4}M$, but the concentration of carrier must be controlled precisely, whereas at concentrations of rhenium carrier greater than $2 \times 10^{-4}M$ a change in the volume of the aqueous phase and loss of part of the carrier does not substantially influence the chemical yield. A wider range of carrier concentrations can be extracted with 1,2-dichloroethane ($a'b'$ in Fig. 1), and so this solvent is preferred.

The effect of interfering ions

Significant interference can be expected primarily from ions with the same charge as the carrier. The concentrations of the interfering ions (including any complexing ions) must not exceed a predetermined fraction of the concentrations of the reagent and of the carrier of the element to be determined, and can be derived by substituting

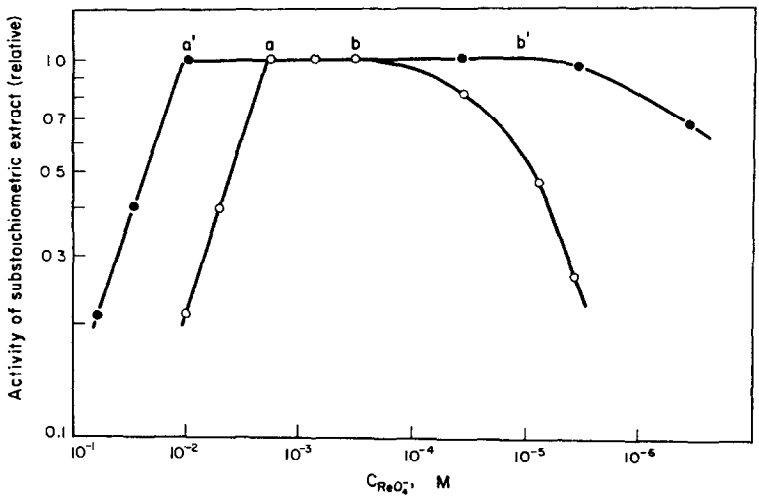

FIG. 1.—The influence of rhenium concentration on the substoichiometric extraction of perrhenate with tetraphenylarsonium chloride (50% stoichiometry).
○ with chloroform
● with 1,2-dichloroethane

the initial concentrations of the carrier and of the interfering ion (B′) into the ratio of the extraction constants for the two species:

$$\frac{K_{AB}}{K_{AB'}} = \frac{[AB]_0[B']}{[B][AB']_0}. \tag{7}$$

To maintain the condition of substoichiometric separation it is necessary that

$$[AB]_0 v_0 > 0{\cdot}99\, C_A v \tag{8}$$

$$[B]v < C_B v - 0{\cdot}99\, C_A v \tag{9}$$

$$[AB']_0 v_0 < 0{\cdot}01\, C_A v \tag{10}$$

$$[B']v > C_{B'} v - 0{\cdot}01\, C_A v. \tag{11}$$

By combining equations (7) to (11) we obtain the value for the threshold concentration of the interfering ion:

$$C_{B'} < 0{\cdot}01 \left[\frac{K_{AB} \cdot C_B}{K_{AB'} \cdot 0{\cdot}99} - \left(\frac{K_{AB}}{K_{AB'}} - 1 \right) C_A \right]. \tag{12}$$

If $C_B = 2C_A$, this simplifies to

$$C_{B'} < 0{\cdot}005 \left(\frac{K_{AB}}{K_{AB'}} + 1 \right) C_B. \tag{13}$$

It is obvious from equation (12) that if the carrier ion and the interfering ion have the same charge, then to give an adequate separation their exchange constant, *i.e.*,

$K_{AB}/K_{AB'}$, must be greater than 100. The exchange constant can be found experimentally from the equation:[8]

$$E_B = \frac{K_{AB}}{K_{AB'}} \cdot \frac{[AB']_0}{[B']} \tag{14}$$

where E_B is the distribution ratio of B when $C_B \ll C_A$ and $C_{B'} > C_A$.

In Fig. 2 the influence of chloride, nitrate, and perchlorate on the extraction of perrhenate as its tetraphenylarsonium salt into 1,2-dichloroethane is shown.

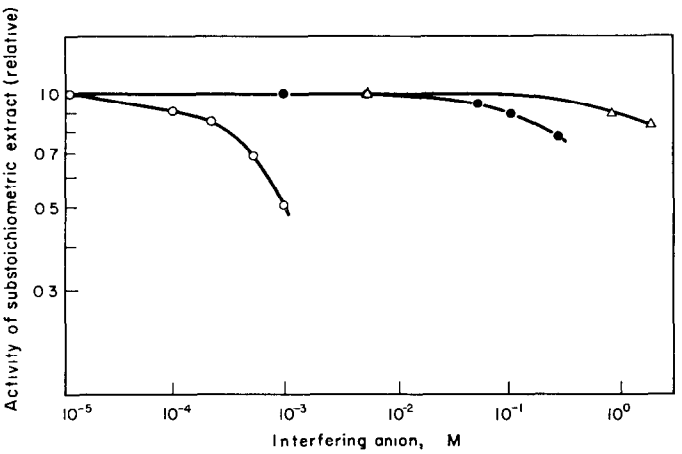

FIG. 2.—The influence of interfering anions on the substoichiometric extraction of rhenium(VII) with tetraphenylarsonium chloride into 1,2-dichloroethane ($10^{-3}M$ perrhenate, 50% stoichiometry).

● nitrate
△ chloride (chloroform extraction)

Selectivity

When co-ordinatively-unsolvated salts are extracted with an excess of the reagent, the distribution ratio is proportional to the extraction constant and the equilibrium concentration of the reagent in the aqueous phase:[8]

$$E_B = K_{AB}[A]$$

and

$$E_{B'} = K_{AB'}[A]. \tag{15}$$

If $K_{AB} > K_{AB'} \gg [A]^{-1}$ then both ions are being extracted quantitatively, and the degree of separation, β, is unity ($\beta = [AB]_0 C_{B'}/[AB']_0 C_B$). If, however, B is being extracted substoichiometrically, the degree of separation β_s will be much greater than unity; it can be shown that when $C_B = 2C_A$ and the conditions of equation (12) are fulfilled, then

$$\beta_s = (K_{AB} + K_{AB'})/2K_{AB'}. \tag{16}$$

It is seen that β_s changes from 1/2 when $K_{AB}/K_{AB'} \ll 1$, to $K_{AB}/2K_{AB'}$ when $K_{AB}/K_{AB'} \gg 1$.

SUBSTOICHIOMETRIC SEPARATIONS OF TETRAPHENYLARSONIUM SALTS

The extraction of large anions with tetraphenylarsonium cations (R_4As^+) as the reagent has been well studied. It is known[9] that ions such as I^-, NO_3^-, CN^-, SCN^-, MnO_4^-, TeO_4^-, ReO_4^-, ClO_3^-, ClO_4^-, and $Cr_2O_7^{2-}$ are easily extracted into chloroform with R_4As^+, whereas Br^-, Cl^-, BrO_3^-, IO_3^-, and IO_4^- are less well extracted, and the majority of the multi-charged oxyanions such as SO_4^{2-}, CrO_4^{2-}, MoO_4^{2-}, WO_4^{2-}, and PO_4^{3-} are very badly extracted. Examples are also known of the extraction of anionic

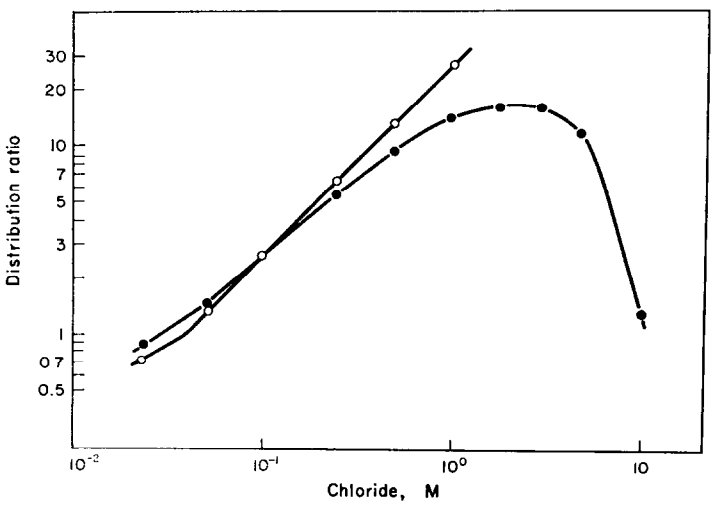

FIG. 3.—The influence of the concentration of potassium chloride and hydrochloric acid on the extraction of tetraphenylarsonium chloride with chloroform.
○ potassium chloride
● hydrochloric acid

metal complexes (halides, cyanides, thiocyanates, *etc.*) with R_4As^+ and other large cations. For example, Ueno[10] studied the extraction of 53 elements with tetraphenylarsonium chloride into chloroform from various concentrations of hydrochloric acid.

Halides

Tribalat[8] says the extraction constant of tetraphenylarsonium chloride into chloroform is 200. This value was obtained from the solubility of the reagent in water and chloroform. We have investigated the dependence of the distribution ratio of this reagent on the chloride concentration, the initial concentration of the reagent being $5 \times 10^{-4}M$ in the aqueous phase (Fig. 3). Over the range 0·045–0·9M potassium chloride there is a linear relationship with a slope of 30. In hydrochloric acid medium the distribution ratio passes through a maximum when the hydrochloric acid is about 3·5M. The distribution ratio for the reagent in the water-chloroform system is about 0·2 and is independent of pH over the range 0·1–12.[9]

In Table II results are given for the extraction of tetraphenylarsonium iodide from chloride or bromide solutions. The iodide distribution was determined radiometrically by means of ^{131}I. The exchange constants were calculated from equation

(14). It is clear that K_{R_4AsI} is much higher than K_{R_4AsCl} and K_{R_4AsBr} and that the difference is accentuated when 1,2-dichloroethane is used as solvent. The value of K_{R_4AsI} is about 10^5 for the chloroform system, and the extraction of iodide with a deficit of the tetraphenylarsonium reagent satisfies the conditions of equation (1) for substoichiometric separation if $v = v_0$ and $C_{I^-} > 2 \times 10^{-3}M$. The high solubility of tetraphenylarsonium iodide in chloroform (Table I) allows an iodide concentration higher than $10^{-2}M$ to be used. In this case the concentrations of bromide and chloride must not exceed $0{\cdot}01M$ and $0{\cdot}15M$ respectively [Table II and equation (13)].

TABLE II.—EXTRACTION OF ^{131}I FROM SOLUTIONS CONTAINING CHLORIDE OR BROMIDE AND SUBSTOICHIOMETRIC AMOUNTS OF TETRAPHENYLARSONIUM IONS

Solvent	Anion B′	Equilibrium concentration of B′ in the aqueous phase, M	Equilibrium concentration of R_4AsB' in the organic phase, M	Distribution ratio of iodide	Exchange constant
Chloroform	Cl^-	1·0	$1{\cdot}8 \times 10^{-3}$	5·4	3×10^3
	Br^-	0·2	$1{\cdot}5 \times 10^{-3}$	1·5	2×10^2
1,2-dichloroethane	Cl^-	1·0	$1{\cdot}8 \times 10^{-3}$	11	6×10^3

In an acidic medium there will be interference from metals such as bismuth, gold, mercury, *etc.*, which form anionic iodide complexes. The total concentration of such metals must not exceed $10^{-4}M$. Apparently the extraction constants of the R_4As^+ salts of these complexes (especially if they are singly-charged) are higher than the extraction constant for the iodide itself, and consequently trace quantities of these metals will be extracted quantitatively and may interfere radiometrically. The interference can be eliminated either by a preliminary conversion of the iodide into iodine which is then extracted with chloroform, or by a preliminary preferential extraction of the halo-complexes with an amount of R_4As^+ that is not more than a tenth of the amount to be used for extracting the iodide.

Oxyanions

In Table III are given results for the extraction of tetraphenylarsonium perrhenate into chloroform and 1,2-dichloroethane from solutions containing chloride, nitrate, thiocyanate, perchlorate, permanganate and dichromate. The distribution ratio of the rhenium was determined by means of ^{186}Re. Similar experiments were carried out with ^{99m}Tc from perrhenate solution. The exchange constants $K_{R_4AsTcO_4}/K_{R_4AsReO_4}$ were 1·7 and 2·5 for chloroform and 1,2-dichloroethane respectively.

The order of extractability into chloroform as tetraphenylarsonium salts is

$$MnO_4^- > TcO_4^- > ReO_4^- > ClO_4^- > (I^-, SCN^-, Cr_2O_7^{2-}) \gg NO_3^- > Br^- > Cl^-.$$

From Table III it is clear that manganese(VII), rhenium(VII), and chromium(VI) can be substoichiometrically separated by extraction of their tetraphenylarsonium salts into chloroform or 1,2-dichloroethane.

Manganese has been substoichiometrically separated after oxidation of manganese(II) to manganese(VII) by sodium bismuthate in sulphuric acid medium,

following a preliminary separation of the manganese from interfering elements and reducing agents by precipitation as the hydroxide or manganese(IV) oxide.[11] Similar conditions are used for the separation of chromium(VI).

Technetium, formed by the reaction sequence $^{98}Mo(n,\gamma)^{99}Mo \xrightarrow{\beta} {}^{99m}Tc$, does not interfere with the substoichiometric separation of rhenium, because equation (13) always holds if the amount of technetium present is too small to be weighed, but ^{99m}Tc coextracted with rhenium (according to equation (16) and Table III) does interfere with measurement of ^{186}Re on a gamma-spectrometer because the γ-radiation energies of the two isotopes are very close (about 0·14 MeV).

The difference in redox potential of rhenium(VII) and technetium(VII) was made use of for their separation. In Fig. 4 is shown the effect of tin(II), added as sodium stannite, on the extraction of technetium and rhenium as their tetraphenylarsonium salts into chloroform or 1,2-dichloroethane from 0·3*M* sulphuric acid. A similar separation occurs from alkaline medium.

Anionic complexes of metals

Anions such as $AuCl_4^-$, $TlCl_4^-$, $FeCl_4^-$, $GaCl_4^-$ and $SbCl_6^-$, are easily extracted from hydrochloric acid solution as their R_4As^+ salts. Doubly-charged complex

△ Fe:Au 1500:1

anions of this kind are very poorly extracted. The extent of formation of these ions depends markedly on the hydrochloric acid concentration, which explains why iron does not hinder the substoichiometric extraction of gold when the concentration of hydrochloric acid is $<1M$, even when the ratio of iron to gold is 1000:1 (Fig. 5).

In Table IV results are given for the extraction of tetraphenylarsonium tetrachloroaurate(III) into chloroform or 1,2-dichloroethane from solutions containing

thallium(I) or iron(III). The distribution coefficient was determined by means of ^{198}Au. From Table IV it can be seen that the difference in the extraction constants is negligible. For the extraction of gold, the ratio $K_{R_4AsAuCl_4}/K_{R_4AsCl}$ is about $1{\cdot}5 \times 10^6$, *i.e.*, it is possible to separate gold, thallium, iron and gallium from hydrochloric acid solution substoichiometrically by this method.

The extraction of the anionic fluoride, bromide, iodide, cyanide and thiocyanate complexes is apparently suitable for the substoichiometric separation of such metals as tantalum, bismuth, molybdenum(V) and tungsten(V), sometimes with ions smaller than the tetraphenylarsonium ion. The thiocyanate complex of gold, for

example, can be extracted into 1,2-dichloroethane with the triphenylguanidine ion. Increase in the anionic radius, however, decreases the effect of anionic charge on selectivity of separation, and the permissible concentrations of complexing anions which themselves are easily extractable (such as iodide and thiocyanate) are limited according to equation (4).

SUBSTOICHIOMETRIC SEPARATIONS OF SIMPLE AND COMPLEX CATIONS

It is known that the alkali metal cations can be extracted into nitrobenzene as compounds with tetraphenylborate or dipicrylamine anions, or other large anions. Some results are given in Table V. The distribution coefficient was determined by means of ^{134}Cs. The extraction constant for caesium tetraphenylborate exceeds 10^6. It seems possible to separate thallium(I), caesium, rubidium, and possibly potassium, substoichiometrically by extraction of the tetraphenylborates. Small or multiply-charged cations are not extracted. Such ions may be extracted, however, in the form of their cationic complexes with certain chelating agents such as 2,2'-dipyridyl or 1,10-phenanthroline which form complexes with metals such as copper(I) and iron(II). In that case it is best to use as counter-ions large anions with the same degree of charge as the cation concerned.[7]

CONCLUSION

We have already used substoichiometric separation by extraction of coordinatively-unsolvated salts for the neutron activation determination of traces of gold[5] and manganese[11] in high purity metals, and of gold[12] and rhenium[13] in rocks and meteorites. This new method of separation of these elements in neutron activation analysis is much simpler and quicker than any used previously. The method seems extremely promising for the separation of iodine, caesium, rubidium, thallium, chromium, tantalum, and other metals.

Zusammenfassung—Die notwendigen Bedingungen zur Extraktion koordinativ nicht solvatisierter Salze zu unterstochiometrischen Trennungen in der Aktivierungsanalyse wurden untersucht, speziell der Einfluß störender Ionen und der Trägerkonzentration. Die unterstochiometrische Extraktion von Halogenidionen, Oxyanionen und anionischen Metallkomplexen mittels Tetraphenylarsoniumionen in Chloroform und Dichloräthan wurde studiert sowie die Extraktion von Alkalimetallionen mit Tetraphenyloborat in Nitrobenzol. Die unterstochiometrische Extraktion kann mit der Neutronenaktivierungsanalyse bei der Bestimmung von Spurenmengen Jod, Caesium, Rubidium, Mangan, Rhenium, Chrom, Thallium, Gold, Gallium und Tantal kombiniert werden.

Résumé—On a examiné les conditions qui sont nécessaires à l'usage de l'extraction de sels non solvatés par coordination pour les séparations substoechiométriques dans l'analyse par activation, essentiellement les influences des ions gênants et de la concentration du porteur. On a effectué une étude sur l'extraction substoechiométrique des ions halogénures, des oxyanions et des complexes métalliques anioniques au moyen d'ion tétraphénylarsonium en chloroforme et dichloréthane, et sur l'extraction des ions alcalins métaliques en nitrobenzène au moyen de tétraphénylborate. On peut combiner l'extraction substoechiométrique avec l'analyse par activation de neutrons pour le dosage de traces d'iode, caesium, rubidium, manganèse, rhénium, chrome, thallium, or, gallium et tantale.

SHORT COMMUNICATIONS

Purification des colorants thiaziniques, Azur A, Azur B, Azur C, par une méthode de partage

(*Reçu le* 20 *Juil.* 1966. *Accepté le* 7 *Septembre* 1966)

LES méthodes de préparation des dérivés *N*-méthylés des colorants thiaziniques tel que l'Azur C (*N*-monométhyl thionine), l'Azur A (*N,N'*-diméthyl thionine) ou l'Azur B (*N,N'*-triméthyl thionine) conduisent inévitablement à des mélanges de thionines plus ou moins méthylés. La séparation des constituants du mélange est délicate car tous ces colorants ont pratiquement les mêmes propriétés physiques et chimiques et de plus, ils peuvent facilement perdre un ou plusieurs groupements méthyles.

Une méthode de séparation par chromatographie a été proposée par Taylor,[1] mais ce procédé met en jeu des solvants qui peuvent modifier la réactivité des colorants. Par ailleurs, elle n'est commode que pour séparer des quantités de colorants de l'ordre de la micromole.

A la suite d'une étude sur les propriétés acide-base des thiazines en milieu basique, nous avons remarqué qu'il était possible de séparer sélectivement ces colorants par une méthode de partage entre la solution aqueuse et un solvant organique non miscible à l'eau.

En solution aqueuse basique, la thionine et les azurs donnent lieu à un équilibre acide-base que l'on peut écrire de la façon suivante:

$$TH^+ + H_2O \rightleftharpoons T + H_3O^+$$

en désignant par TH^+ la forme ionique, et T la forme moléculaire du colorant. Nous avons déterminé, par spectroscopie, la constante de dissociation acide, $K_1 = [T][H^+]/[TH^+]$, de ces équilibres pour les différentes thionines et nous avons obtenu les résultats suivants:

	Thionine	Azur C	Azur A	Azur B
pK_1	11,0	11,5	11,8	12,1

La forme TH^+ est soluble dans l'eau et insoluble dans les solvants organiques non polaires alors que la forme moléculaire T se partage entre l'eau et les solvants organiques selon un équilibre de la forme $T_{aq} \rightleftarrows T_{org}$ dont la constante $K_2 = T_{org}/T_{aq}$ est d'autant plus grande que le colorant est plus méthylé. Le coefficient d'extraction K se met alors sous la forme:

$$K = \frac{[T_{org}]}{[T_{aq}] + [TH_{aq}^+]} = \frac{K_1 K_2}{K_1 + [H^+]}$$

A un pH donné, et pour un même solvant organique, ce coefficient dépend de la nature du colorant. Ainsi, en solution aqueuse tamponnée à pH 10 par un mélange d'acide acétique $10^{-2}M$, d'acide borique $10^{-2}M$, d'acide phosphorique $10^{-2}M$ et de soude en présence de tétrachlorure de carbone, nous avons mesuré les coefficients d'extraction suivants, à la température ambiante:

Thionine: 0,80 Azur A: 12

Azur C : 1,9 Azur B: 9,2

Ces valeurs permettent de calculer K_2 et le coefficient d'extraction pour d'autres valeurs du pH.

Le bleu de méthylène est le colorant le plus facile à éliminer d'un mélange de *N*-méthyl thionines car il n'a pas de forme moléculaire neutre. Lorsqu'on agite quelques minutes une solution de colorants, dont le pH est fixé à 11, en présence de tétrachlorure de carbone ou de benzene, le bleu de méthylène reste dans la phase aqueuse. Les azurs passent dans la phase organique sous leur forme moléculaire. Il est aisé par la suite de les reprendre par l'eau.

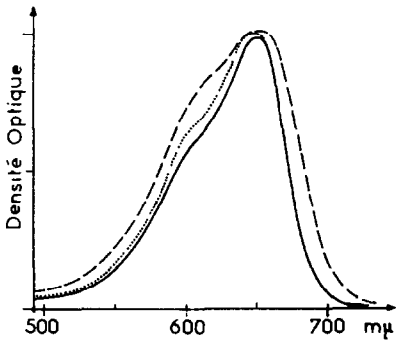

FIG. 1.—Azur B en solution aqueuse à pH 4,5.
– – – – Produit commerical
. . . . . Après un partage
————Après deux partages

En choisissant judicieusement le pH des solutions aqueuses et la phase à conserver après partage, on peut, suivant les cas, soit séparer les constituants d'un mélange d'azurs, soit purifier le colorant commercial.

Prenons par exemple, le cas de l'Azur B qui est généralement souillé de bleu de méthylène, d'Azur C et de thionine. Le spectre du colorant commercial dissous dans l'eau est donné sur la figure ci-jointe. Après un premier partage entre la solution aqueuse, dont le pH était initialement fixé à 10 par la soude, et du tétrachlorure de carbone, on obtient le spectre tracé en pointillé et après un deuxième partage, dans les mêmes conditions le spectre en trait plein.

En bon accord avec l'expérience, le calcul montre qu'après deux extractions le pourcentage d'Azur C, s'il était initialement de 10%, n'est plus que de 1%, le rendement en Azur B étant de 25%. Lorsque le taux d'impureté atteint cette valeur, les extractions suivantes ne modifient plus ni la forme de la bande, ni la position du maximum d'absorption.

En conclusion, le procédé de séparation des colorants thiaziniques par partage entre deux solvants non miscibles est rapide et satisfaisant lorsqu'il s'agit de purifier 10 à 20 micromoles de colorant. La purification de colorants en quantitiés plus importantes que celles auxquelles nous nous sommes interessés est encore possible, mais elle necessite la manipulation de volumes importants de solvant car solubilité des formes moléculaires est faible.

Enfin, il faut signaler que la solution aqueuse contient encore, outre le colorant, une certaine quantité de solvant non polaire. On peut l'éliminer par une filtration sur gel Sephadex.

JACQUES JOUSSOT-DUBIEN

Résumé—On a séparé les uns des autres, ainsi que de la thionine et du bleu de méthylène, des dérivés N-méthylés de la thionine au moyen d'extraction en tétrachlorure de carbone à partir d'une solution aqueuse tamponnée au pH approprié pour chaque composé. On peut utiliser la méthode pour purifier les colorants.

Summary—Some *N*-methylated derivatives of thionine have been separated from thionine, Methylene Blue, and each other by solvent extraction into carbon tetrachloride from an aqueous solution buffered to the pH appropriate for each compound. The method can be used to purify the dyes.

Zusammenfassung—Einige N-methylierte Derivate von Thionin wurden von Thionin selbst, Methylenblau und untereinander durch Extraktion aus einer wäßrigen, am für die jeweilige Substanz geeigneten pH gepufferten Lösung in Tetrachlorkohlenstoff getrennt. Die Methode kann zur Reinigung der Farbstoffe dienen.

Azo dyes from 2-amino-1,3,4-thiodiazole

(*Received* 7 *October* 1966. *Accepted* 9 *October* 1966)

2-AMINO-1,3,4-THIODIAZOLE is similar to 2-aminothiazole, in that it can be diazotized with nitrous acid.[1] The colorimetric properties of the thiodiazolylazo dyes have not been studied except for the β-naphthol compound which has been used as an acid-base indicator.[2] Substituted thiodiazolylazo compounds have also been investigated both academically and as commercial dyestuffs.[3,4]

EXPERIMENTAL

Preparation of reagents

Thiosemicarbazide was treated with formic acid to give 2-formamido-1,3,4-thiodiazole,[5] which was then heated with hydrochloric acid to produce the amine. 2-Amino-1,3,4-thiodiazole was more water-soluble than 2-aminothiazole but on diazotization gave lower yields of the dyestuffs. Thiodiazolylazo dyes from resorcinol (TdAR), *p*-cresol (TdA*p*C) and β-naphthol (TdANβ) were prepared.

RESULTS AND DISCUSSION

TdAR is a yellow dye, orange in alkali, which gives red-brown complexes with many metal ions. TdA*p*C was very similar to thiazolylazo-*p*-cresol (TA*p*C) giving colour changes from yellow to blue on chelation, whereas TdANβ was paler than thiazolylazo-β-naphthol (TANβ). These three thiodiazolylazo dyes all gave greenish complexes with iron and ruthenium. TdAR, TdANβ, and TdA*p*C were not obtained in a very pure state, but were definitely less sensitive towards all metals than the thiazolylazo dyes. This is probably due to the lower basicity of the nitrogen atom of the thiodiazole ring. In a similar manner, the extra nitrogen atom present in 8-hydroxycinnoline causes it to form weaker complexes than 8-hydroxyquinoline.[6] Since the thiodiazolylazo dyes also produce duller colour changes than their thiazole and triazole analogues, they were inferior in all respects.

Semimicro method for the determination of linalol in coriander oil

(*Received* 7 *July* 1965. *Revised* 10 *December* 1965. *Accepted* 3 *May* 1966)

THE determination of linalol is a problem in the analysis of essential oils. The methods used are those suggested for the determination of tertiary alcohols. These determinations require from 6 hr to 4 days[1] for their completion and involve the use of special reagents.[2,3] In addition, large samples (10 g) are needed. Semimicro methods[4] and colorimetric methods[5] also need special reagents and apparatus.

Linalol gives a green colour when sodium nitrite solution and hydrochloric acid are added to the essential oil that contains it.[6] This reaction can be used for the determination of linalol.

EXPERIMENTAL

Reagents

Linalol was obtained from coriander oil by saponification with 10% potassium hydroxide solution. The product was redistilled three times under reduced pressure (13 mm Hg). The gas chromatogram indicated a purity of 99·5%. It had the following properties:

$$n_D^{20} = 1{\cdot}4629, \quad \alpha_D^{20} = 11{\cdot}5°, \quad d_{20}^{20} = 0{\cdot}8679, \quad \text{b.p.} = 84\text{–}86°/13 \text{ mm}$$

Aqueous sodium nitrate solution, 50%.
Hydrochloric acid, 25%.
Anhydrous sodium sulphate, dried at 200°.

Specificity of the reaction

Gorjaev and Pliva[6] recommend this reaction for qualitative identification of linalol in essential oils, but we find that other compounds give the same colour. Table I shows the results obtained by treating toluene solutions of the most common components of essential oils with sodium nitrite and hydrochloric acid.

TABLE I.—REACTION OF SOME COMPONENTS OF ESSENTIAL OILS WITH NITROUS ACID

Compound	Colour produced	Compound	Colour produced
Linalol	green	Eugenol	none
Linalol acetate	green	Borneol	none
Geraniol	green	Menthol	none
Geraniol acetate	green	Menthone	none
Dipentene	green	Menthol acetate	none
Terpineol	green	α-Pinene	none
Terpineol acetate	green	β-Pinene	none
Citronellol	green	Δ^3-Carene	none
Citronellal	green	Hydroxycitronellal	none
Nerol	green	Sclareol	none
Indole	red	Ionone	none
Nonyl alcohol	none	Thymol	none
Decyl alcohol	none	Anethole	none
		Vanillin	none

Standardisation

A stock solution of linalol was prepared by dissolving 4 g of it in 100 ml of toluene. Different volumes of this solution (0–5·00 ml) were diluted with toluene to 5·00 ml. To each solution was added 1·00 ml of sodium nitrite solution and 1·00 ml of hydrochloric acid. The mixtures were shaken for 5–10 sec and left in the dark for 1–2 min. When reaction was complete (3 min) the toluene layer was separated and 2–3 g of sodium sulphate were added. After 3 min, the toluene was decanted, and its absorbance against a reagent blank was measured at 680 nm. The absorption spectrum of the solution is shown in Fig. 1(a), and a calibration curve in Fig. 1(b).

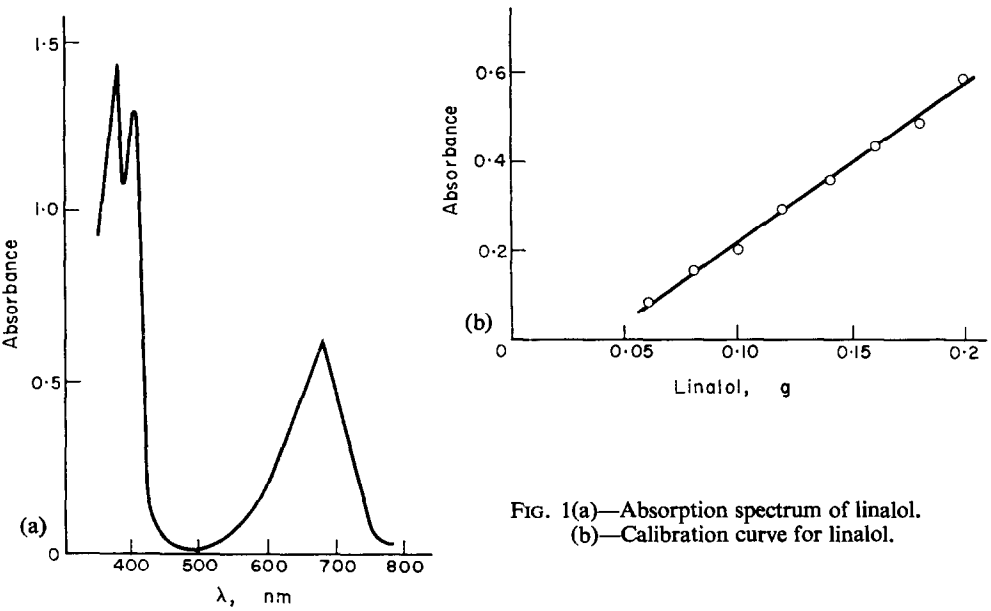

FIG. 1(a)—Absorption spectrum of linalol.
(b)—Calibration curve for linalol.

Procedure

A sample of 0·15–0·2 g of essential oil was dissolved in 5 ml of toluene, and treated as described under *Standardisation*. Different quantities of rectified and raw coriander oil were analysed. The results are given in Tables II and III.

TABLE II.—RECTIFIED CORIANDER OIL

Oil,	Linalol found,		Deviation from mean,
g	*g*	%	%
0·1277	0·1120	87·8	−0·8
0·1287	0·1152	90·3	+0·7
0·1547	0·1375	89·0	+0·4
0·1737	0·1530	89·2	+0·6
0·1787	0·1550	87·0	−1·6

TABLE III.—RAW CORIANDER OIL

Oil,	Linalol found,		Deviation from mean,
g	*g*	%	%
0·1257	0·0785	62·5	−0·4
0·1300	0·0847	65·2	+2·3
0·1682	0·1045	62·3	−0·6
0·1699	0·1045	61·6	−1·3

DISCUSSION

Coriander oil contains mainly linalol and linalol acetate. Gerianol acetate and dipentene are present in low concentration.[7] By this method all compounds giving a green colour are calculated as linalol. The green colour is photo-sensitive but persists in the dark for several days. Pure benzene and toluene also give an initial green colour but this fades rapidly, and does not interfere with determinations made after 5 min.

The amount of nitrous acid is critical for the determination. The hydroxyl group is not involved in the formation of the green compound, since acetates also give a green colour. In order to verify this we analysed coriander oil and its esterified products. Samples were formylated by the method of Glichitch and acetylated by the standard method.[8] The method adopted by British Standards[9] and

the Holness procedure[10] are better than the Grasse method but we preferred the latter in order to establish whether the dehydration hinders the determination of linalol. All three products were analysed, and the quantity of linalol calculated. The results (Table IV) show that the formylated and acetylated oils contain almost the theoretical quantities of linalol. The dehydration which takes place during the esterification does not hinder the determination.

TABLE IV.—ANALYSIS OF THE ESTERIFIED ESSENTIAL OILS

	Linalol, %	
	found	theoretical
After formylation	75·5	76·1
	75·0	76·1
After acetylation	71·0	71·3
	72·2	71·3

CONCLUSION

The new method is rapid and requires very small quantities of the essential oil. The reaction is not specific for linalol but if other active components are present in low concentration the results are satisfactory. The error is lower than that for the method of Glichitch provided that the absorbance lies in the range 0·15–0·45.

Summary—Linalol has been determined colorimetrically in essential oils by means of the green colour developed in the presence of nitrous acid. Geraniol, dipentene, terpineol, citronellol and citral also give a green colour, and are therefore calculated as linalol by this method, but the error is small if they are present in small concentrations.

Zusammenfassung—Linalool wurde in ätherischen Ölen mit Hilfe der grünen Farbe, die es in Gegenwart salpetriger Säure entwickelt, kolorimetrisch bestimmt. Geraniol, Dipenten, Terpineol, Citronellol und Citral geben auch eine grüne Farbe und werden deshalb bei dieser Methode als Linalool mitberechnet, aber der Fehler ist gering, wenn sie in geringen Konzentrationen vorhanden sind.

Résumé—On a dosé colorimétriquement le linalol dans les huiles essentielles au moyen de la coloration verte qu'il développe en présence d'acide nitreux. Le géraniol, le dipentène, le terpinéol, le citronellol et le citral donnent également une coloration verte et sont par conséquent calculés en tant que linalol par cette méthode, mais l'erreur est petite s'ils sont présents à de faibles concentrations.

Photo-induced oxidation of some organic carbonyl compounds by vanadium(V)

(*Received* 11 *May* 1966. *Accepted* 23 *August* 1966)

WE have previously described[1-6] some applications of vanadium(V) in quantitative organic analysis. These oxidation reactions are slow at room temperature and require heating, with resultant loss of the more volatile organic substances. Renz[7] reported in 1921 that mixtures of vanadium(V) and some organic substances are photo-sensitive and that on exposure to sunlight carbon dioxide is evolved, but no quantitative examination of these reactions has been recorded. We have now observed that oxidation of several carbonyl compounds with vanadium(V) may be effected smoothly and rapidly at room temperature by illuminating the reaction mixtures with visible light. The reactions are quantitative and stoichiometrically resemble these effected by heating.

EXPERIMENTAL

Reagents

Vanadium(V) solution, 0·1*N*. The required amount of sodium metavanadate (Merck) was dissolved in the minimum of sulphuric acid necessary, and diluted to the required volume. The solution was standardized with a standard iron(II) solution, *N*-phenylanthranilic acid being used as indicator.

Carbonyl compounds. Pyruvic and levulinic acid solutions, 0·01*M*, were prepared by appropriate dilution of more concentrated solutions that had been standardized alkalimetrically. The solutions were checked by a permanganate titration. Acetaldehyde solution, 0·2*M*, was prepared, standardized iodometrically, and diluted to 0·05*M*. Isobutyraldehyde, crotonaldehyde and acetylacetone solutions, 0·01*M*, were prepared by diluting the pure reagent to the volume required.

Procedure

The reaction mixtures consisted of an aliquot of vanadate solution containing sufficient sulphuric acid to give the desired final acid concentration, and an aliquot of the solution of the compound under study, diluted to a total volume of 50 ml. The reaction vessels were 250-ml pyrex iodine flasks.

The reaction mixtures were exposed to the radiation of a 1000-W tungsten-filament lamp at a distance of about 18 in. At intervals of time, the mixtures were diluted and titrated with standard iron(II) solution to determine the amount of oxidant consumed. A constant minimum consumption of iron(II) solution was taken as indication of the completion of the reaction. A blank was run simultaneously.

The oxidation was studied at different total concentrations of the oxidant (0·01–0·08*N*), sulphuric acid (5·4–9*F*) and the organic compound (0·001–0·0005*M*) and the optimum conditions were found for the quantitative oxidation.

RESULTS

In Table I are presented the results obtained under optimum conditions. Pyruvic acid reacts much faster than the other compounds tested.

TABLE I

Reaction mixture			Consumption of vanadate, *eq/mole*	Time needed to complete reaction, *min*
Sample, *ml*	Vanadate, *ml*	Conc. sulphuric acid, *ml*		
0·01*M* Pyruvic acid, 5	0·01*N*, 20	15	2·00	10
0·01*M* Levulinic acid, 5	0·2*N*, 20	25	12·0	40
0·05*M* Acetaldehyde, 3·5	0·2*N*, 20	25	8·05	30
0·01*M* Isobutyraldehyde, 5	0·2*N*, 20	25	4·00	120
0·01*M* Crotonaldehyde, 2·5	0·1*N*, 20	20	10·0	30
0·01*M* Acetylacetone, 5	0·1*N*, 20	30	7·95	30

DISCUSSION

Pyruvic acid undergoes fast oxidation with acid vanadate solution, consuming 2 equivalents of the oxidant per mole of acid. This suggests that pyruvic acid is oxidized to acetic acid directly, without intermediate formation of acetaldehyde, which would cause a higher consumption of oxidant (see below). Probably the absence of hydrogen on the α-carbon atom in pyruvic acid prevents the formation of acetaldehyde and is also responsible for the fast oxidation. The method gives quite accurate results and can be used to estimate pyruvic acid in the presence of formic and acetic acids.

The oxidation of levulinic acid, a γ-keto acid, is slower than that of an α-keto acid. The 12 equivalents of oxidant consumed per mole of acid suggest that during oxidation a mole each of formic and acetic acids and water are formed, with evolution of two moles of carbon dioxide. Thus a molecule of levulinic acid is probably first oxidized to a molecule each of acetic and malonic acids. The former resists further oxidation whereas the latter readily undergoes oxidation to formic acid, carbon dioxide and water. This view is supported by the fact that 6 equivalents of oxidant are consumed per mole of malonic acid, in agreement with the proposed mechanism.

The results for the oxidation of acetaldehyde indicate that the oxidation does not yield acetic acid. Probably the aldehyde undergoes enolization followed by hydroxylation of the double bond, which promotes further oxidation to give formic acid as the end product. The mechanism of the reaction has been discussed earlier.[5]

Isobutyraldehyde undergoes slower oxidation than acetaldehyde, consuming 4 equivalents of the oxidant per mole of the aldehyde. This suggests that the oxidation takes place with the formation of a molecule each of acetone and formic acid, in agreement with the observations of Jones and Waters.[8]

Acetylacetone and crotonaldehyde consume 8 and 10 equivalents, respectively, of the oxidant per mole of the compound, which suggests the formation of a mole each of acetic and formic acids and carbon dioxide in the case of crotonaldehyde and two moles of acetic acid and a mole of carbon dioxide with acetylacetone.

All this suggests that during oxidation C—C bond fission takes place. Such oxidations, involving the elimination of a carbon atom should proceed by enolization followed by hydroxylation of the double bond so produced. The hydroxylated product then undergoes oxidation resulting in C—C bond cleavage. The fact that the overall reaction is facilitated by an increase in acid concentration supports these conclusions, as the intermediate steps are known to be acid catalysed.[9] These observations are in good agreement with those of Jones and Waters, who have demonstrated that C—C bond fission occurs in oxidations with vanadium(V).[10]

The presence of various end-products in the reaction mixture after completion of oxidation was confirmed by qualitative tests. A quantitative determination was, however, not always successful, *e.g.*, recovery of formic acid never exceeded 50%, probably because of decomposition in the presence of conc. sulphuric acid, and the recovery of carbon dioxide and acetic acid was only about 90%.

Summary—The oxidation of pyruvic acid, levulinic acid, acetaldehyde, isobutyraldehyde and acetylacetone by vanadium(V) in aqueous solution on illumination with visible light is described. Pyruvic acid undergoes oxidation much more rapidly than does levulinic acid; both give acetic acid. Acetaldehyde is more rapidly oxidized than is isobutyraldehyde, the former giving formic acid, and the latter, formic acid and acetone. Acetylacetone is converted into acetic acid. The oxidations are rapid and quantitative and may be used for the estimation of these carbonyl compounds.

Résumé—On décrit l'oxydation de l'acide pyruvique, de l'acide lévulinique, de l'acétaldéhyde, de l'isobutyraldéhyde et de l'acétylacétone par le vanadium (V), en solution aqueuse irradiée en lumière visible. L'acide pyruvique subit l'oxydation beaucoup plus rapidement que l'acide lévulinique; tous deux fournissent de l'acide acétique. L'acétaldéhyde s'oxyde plus rapidement que l'isobutyraldéhyde, le premier donnant de l'acide formique et le second de l'acide formique et de l'acétone. L'acétylacétone est convertie en acide acétique. Les oxydations sont rapides et quantitatives et l'on peut les utiliser pour l'estimation de ces composés carbonylés.

Zusammenfassung—Die Oxydation von Brenztrauben- und Lävulinsäure, Acetaldehyd, Isobutyraldehyd und Acetylaceton durch Vanadium(V) in wäßriger Lösung bei Bestrahlung mit sichtbarem Licht wird beschrieben. Brenztraubensäure wird viel schneller oxydiert als Lävulinsäure; beide liefern Essigsäure. Acetaldehyd wird schneller als Isobutyraldehyd oxydiert; ersterer bildet Ameisensäure, letzterer Ameisensäure und Aceton. Acetylaceton gibt Essigsäure als Produkt. Die Oxydationen gehen schnell und quantitativ und können zur Bestimmung dieser Carbonylverbindungen herangezogen werden.

Amalgam exchange separation of radiothallium

(*Received* 23 *May* 1966. *Accepted* 9 *August* 1966)

AMALGAM exchange is a rapid and selective method which may be used for the separation of various elements. Although this technique was first used in 1936 by Lewis and McDonald[1] for enriching lithium isotopes, only recently has it been applied to the radiochemical separation of various elements. The method has been used for the radiochemical separation of cadmium,[2] zinc[3] and indium.[4] Limited studies on the amalgam exchange of strontium and thallium have also been reported.[5] The procedure developed in this investigation is rapid and selective and may be used to separate short-lived isotopes such as thallium-202, and determine their activities.

EXPERIMENTAL

Apparatus

Standard radiochemical equipment was used throughout this work. Beta-activity of thallium-204 was counted with an end-window Geiger tube of the halogen-quenched type which was mounted in a vertical lead shield.

Reagents

Thallium-204 was obtained from the Isotopes Division of Oak Ridge National Laboratory. The desired activity was obtained by dilution of the tracer with 0·1*M* nitric acid.

Ethylenediamine, 85% solution in water.

Mercury, reagent-grade (base metals 1×10^{-4}%, foreign metals 5×10^{-4}%).

Nitrogen gas, water-pumped, stored in tank.

Thallium metal, 99+%, Amend Drug and Chemical Co., New York.

Thallium amalgam, 3%; 0·88 g of thallium metal was cleaned with 0·1*M* nitric acid and mixed with 2 ml (27·2 g) of mercury in a test-tube. The amalgam was kept under distilled water and oxygen was removed from the system by purging with nitrogen.

Preliminary experiments

Radiothallium solution was mixed with various reagents, flushed with nitrogen to remove oxygen

Amalgam exchange separation of radiothallium

(*Received* 23 *May* 1966. *Accepted* 9 *August* 1966)

AMALGAM exchange is a rapid and selective method which may be used for the separation of various elements. Although this technique was first used in 1936 by Lewis and McDonald[1] for enriching lithium isotopes, only recently has it been applied to the radiochemical separation of various elements. The method has been used for the radiochemical separation of cadmium,[2] zinc[3] and indium.[4] Limited studies on the amalgam exchange of strontium and thallium have also been reported.[5] The procedure developed in this investigation is rapid and selective and may be used to separate short-lived isotopes such as thallium-202, and determine their activities.

EXPERIMENTAL

Apparatus

Standard radiochemical equipment was used throughout this work. Beta-activity of thallium-204 was counted with an end-window Geiger tube of the halogen-quenched type which was mounted in a vertical lead shield.

Reagents

Thallium-204 was obtained from the Isotopes Division of Oak Ridge National Laboratory. The desired activity was obtained by dilution of the tracer with 0·1*M* nitric acid.

Ethylenediamine, 85% solution in water.

Mercury, reagent-grade (base metals 1×10^{-4}%, foreign metals 5×10^{-4}%).

Nitrogen gas, water-pumped, stored in tank.

Thallium metal, 99+%, Amend Drug and Chemical Co., New York.

Thallium amalgam, 3%; 0·88 g of thallium metal was cleaned with 0·1*M* nitric acid and mixed with 2 ml (27·2 g) of mercury in a test-tube. The amalgam was kept under distilled water and oxygen was removed from the system by purging with nitrogen.

Preliminary experiments

Radiothallium solution was mixed with various reagents, flushed with nitrogen to remove oxygen

and then shaken with thallium amalgam. Portions of the aqueous phase were than removed and their activity measured to determine the amount of exchange that had occurred. The amalgam phase was then separated and shaken with a back-extractant, and the amount of radiothallium extracted into the aqueous phase was measured by counting its activity. Anions, complexing agents and pH exert definite effects on the efficiency of the exchange steps. Several anions and complexing agents were investigated to obtain maximum efficiency in the amalgamation step. Fluoride, nitrate, sulphate and perchlorate were the anions investigated. Ethylenediamine (EDA), triethanolamine (TEA), phenylethylamine (PEA), EDTA, hyamine perchlorate and ammonia were tried as complexing agents. The results of this investigation are summarized in Table I. The degree of exchange observed in the presence of PEA, TEA, and EDA is almost identical. Hyamine perchlorate inhibits the exchange step. The ethylenediamine and fluoride systems were selected for extensive study.

TABLE I

Anion or complexing agent	^{204}Tl added, *cpm*	Total activity in aqueous phase *cpm*	Exchange into the amalgam, %
0·1*M* Hyamine perchlorate	22450	20500	8·5
PEA, 2·5%	22450	1350	94·0
TEA, 2·5%	22450	1335	94·0
EDA, 2·5%	22450	1360	93·9
0·1*M* EDTA	22450	2980	86·7
0·25*M* Ammonia	22450	3475	84·6
0·25*M* Fluoride	8890	336	96·2
0·25*M* Sulphate	8890	1323	85·1
0·25*M* Perchlorate	8890	567	93·6
0·25*M* Nitrate	8890	600	93·2

It was found that dilution of the amalgam by the addition of 1 ml of mercury to 100 μl of amalgam increases the efficiency considerably. With undiluted amalgam, the back-extraction step had an efficiency of approximately 20%, but with the diluted amalgam the efficiency rose to 97%. Various acids were studied in the back-extraction. A summary of this investigation is given in Table II.

TABLE II.—EFFECT OF VARIOUS ACIDS ON BACK-EXTRACTION

Exchange system	^{204}Tl exchanged into amalgam, %	Back-extractant	^{204}Tl back-extracted into amalgam, %
500 μl tracer + 100 μl EDA + 100 μl 3% amalgam + 500 μl 0·1*M* NH_4OH	91·7 92·2	Co^{2+}, 2 ml Co^{2+}, 2 ml + 1 ml 6*M* HCl	21·7 16·0
500 μl tracer + 200 μl EDA + 500 μl 0·1*M* NH_4OH + 200 μl 3% amalgam	93·2 92·9 93·5	Co^{2+}, 2 ml + 2 ml 0·5*M* HNO_3 Co^{2+}, 2 ml + 1 ml 1*M* CH_3COOH Co^{2+}, 2 ml + 1 ml 1*M* $HClO_4$	19·0 20·2 13·7
Amalgam diluted with 1 ml of mercury before back-extraction			
500 μl tracer + 200 μl EDA + 500 μl 0·1*M* NH_4OH + 200 μl 3% amalgam	92·9 93·2 93·7	Co^{2+}, 2 ml + 1 ml 1*M* $HClO_4$ Co^{2+}, 2 ml + 1 ml 0·5*M* HNO- Co^{2+}, 2 ml + 1 ml 1*M* CH_3COOH	88·7 97·0 97·3

The effect of pH on the amalgamation step was studied and a summary of the results is given in Table III. It is observed that the exchange is not greatly affected by the change in pH except when nitric acid is present. In this case, it is possible that the thallium in the amalgam is oxidized by the nitric acid and extracted, and so the efficiency of isotopic exchange is lowered. A pH above 3 is preferred.

TABLE III.—EFFECT OF pH

System	pH	Exchange into amalgam, %
200 μl tracer + 100 μl 3% amalgam		
1 ml 4M HNO_3 + 3 ml 1M NaF	0	88·7
1 ml 0·4M HNO_3 + 3 ml 1M NaF	1	93·6

Amalgam exchange procedure for thallium-204

On the basis of the preceding studies, the following procedure was devised for the amalgam exchange separation of thallium-204.

Amalgam exchange step: 500 μl of thallium-204 tracer were mixed with 500 μl of 0·1M ammonia in a test-tube, and 100 μl of 85% ethylenediamine or 3 ml of 1M sodium fluoride were added. If EDA was added, the solution was diluted to 4·0 ml with distilled water. Nitrogen was passed through the sample to remove oxygen. Then 100 μl of freshly prepared 3% amalgam were added, and the test-tube was stoppered tightly and shaken vigorously for 5 min. Then 500 μl of the supernatant liquid were transferred to a planchette, dried and counted for 5 min. The per cent activity exchanged into the amalgam was calculated. A standard was also counted under the same conditions.

Back-extraction step: the supernatant liquid was removed by syringe micro-pipette and the amalgam was washed with 1 ml of distilled water. The amalgam was dried with a Kleenex tissue and the amalgam bead transferred into another test-tube containing 1 ml of mercury, 3 ml of cobalt nitrate solution (50 mg of Co/ml) and 1 ml of 0·5M nitric acid. The diluted amalgam was shaken with the aqueous solution for 4 min. The supernatant liquid was transferred into a fresh test-tube and the amalgam was washed with 1 ml of 0·1M nitric acid which was then added to the aqueous phase already separated; 500 μl of this solution were transferred to a planchette, dried and counted for 5 min. For short-lived isotopes, a shorter mixing time may be chosen. The efficiencies of extraction from the amalgam and of overall separation were calculated.

RESULTS

The procedure with ethylenediamine and sodium fluoride as the complexing agents was carried through and the results are given in Table IV.

The minimum time needed for this procedure is about 7 min and the recoveries are about 90%. This procedure, therefore, satisfies the need for a rapid, efficient and simple radiochemical separation for thallium isotopes.

Summary—A method is presented for the rapid separation of radiothallium. The solution is made basic by addition of ammonia, then sodium fluoride and ethylenediamine are added and the mixture is shaken with 3% thallium amalgam. A rapid exchange takes place and the bulk of the activity is concentrated in the amalgam. The amalgam is diluted with clean mercury and shaken with acidic cobalt nitrate solution which back-extracts thallium. About 90% of the thallium activity is recovered.

Résumé—On présente une méthode pour la séparation rapide du radiothallium. La solution est alcalinisée par addition d'ammoniaque, puis on ajoute du fluorure de sodium et de l'éthylènediamine et agite le mélange avec de l'amalgame de thallium à 3%. Il se produit un échange rapide et la majeure partie de l'activité est concentrée dans l'amalgame. On dilue l'amalgame au moyen de mercure propre et l'agite avec une solution acide de nitrate de cobalt qui réextrait le thallium. On récupère environ 90% de l'activité du thallium.

Zusammenfassung—Ein Verfahren zur schnellen Abtrennung von Radiothallium wird angegeben. Die Lösung wird durch Ammoniakzusatz basisch gemacht, Natriumfluorid und Äthylendiamin zugesetzt und mit 3%-igem Thalliumamalgam geschüttelt. Es findet ein rascher Austausch statt, nach dem der Hauptteil der Aktivität sich im Amalgam befindet. Das Amalgam wird mit reinem Quecksilber verdünnt und mit sauberer Kobaltnitratlösung geschüttelt, die das Thallium wieder extrahiert. Etwa 90% der Thallium-Aktivität werden wiedergewonnen.

ANNOTATION

High frequency titration methods in the investigation of complex formation

(*Received* 28 *March* 1966. *Accepted* 2 *June* 1966)

HARA and West[1] were the first to use high frequency titration (HFT) for the investigation of complex formation when they studied the reaction of EDTA with the lanthanides and certain rare metals. Pungor and Zapp[2] repeated this work and extended it to other reactions; they considered that the method had its limitations, particularly if the change in conductivity was very small near the end-point of the titration. We have found that the HFT method gives valuable information about the processes of complex formation in solutions, if the titration is carried out under conditions that give the steepest characteristic curve with the equipment used. Under these conditions break points are obtained on the titration curve at certain molar ratios of metal and complexing agent, and correspond to sharp changes in the electrical conductivity of the solution as a result of such reactions as displacement of metal ions from their EDTA complexes by addition of protons. This application of HFT must be supplemented by a parallel study based on preparative work and physico-chemical methods such as potentiometry, chromatography, optical activity, *etc.*

EXPERIMENTAL

Two variations of HFT are used in the investigation of complexes in solution. In the first, solutions of complexing agent and a salt of the metal are mixed in various molar ratios and the hydrogen ions released in the complex-formation are titrated with sodium hydroxide; the composition of the most stable complex is found from the number of protons released per metal ion. In the other method a solution of a salt of the metal is titrated with a solution of the complexing agent. and the breaks in the curve give the compositions of all the complexes formed. In our investigations we have used high frequency equipment types BY–IA and BY–2A;[3,4] automatic recording of the HFT curves is particularly useful. A very important function of HFT is for rapid assessment of the chelating properties of newly synthesised complexing agents.

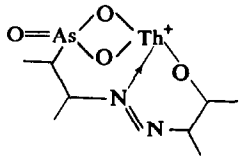
RESULTS AND DISCUSSION

Thorium complexes

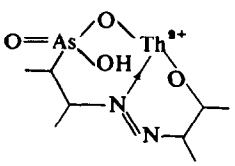
The reaction of thorium nitrate with a series of complexones has been investigated by HFT methods supplemented by preparative and potentiometric studies.[5] Except for the reaction with EDTA, thorium forms stable 1:1 complexes with 4-, 5- and 6-membered rings (at pH 9) with these reagents. With nitrilotriacetic acid (NTA) and uramildiacetic acid, thorium forms 1:2 complexes at pH 8. The reaction of thorium with a series of complexones containing from one to five carboxyl groups—hexamethylenediaminetetra-acetic acid (HMDTA), ethylenediamineoxyphenylacetic acid, oxyphenylethylenediaminediacetic acid, oxyethylethylenediaminetriacetic acid, and diethyl triaminepenta-acetic acid—has been investigated.[6] The reaction with HMDTA was studied to investigate the effect of steric factors (increase in polymethylene chain length and distance between iminodiacetic acid groups) on the stability of thorium complexes with complexones. Direct titration of thorium nitrate with HMDTA showed that a 1:1 complex was formed, and titration with sodium hydroxide showed that two protons were released per thorium ion, indicating the reaction $H_2X^{2-} + Th^{4+} \rightleftharpoons ThX + 2H^+$. The product is insoluble and is precipitated.[7] HFT has also been used to clarify the structure of the complex carbonates of thorium.[8] It had earlier been found that the most characteristic type of these compounds was the hydrated form, *e.g.*, $M_6Th(CO_3)_5 \cdot H_2O$, where M is a univalent ion. In such compounds the carbonate groups are bound to the thorium through the oxygen atom, but the number of carbonate groups bound to the central atom was uncertain. This problem was especially interesting in connection with the ammonium carbonate complex, which is characterised by its instability. HFT curves for potassium, sodium and ammonium carbonate solutions with thorium nitrate show two breaks. The first corresponds to the formation of the soluble carbonato complex

with a molar ratio of 1:4 for $Th:CO_3^{2-}$, and the second corresponds to precipitation of thorium carbonate when $Th:CO_3^{2-}$ is 1:2. The complex anion is therefore assigned the structure $Th(CO_3)_4^{4-}$ with coordination number 8 for the thorium.

Spectroscopic studies show that in arsenazo III complexes only one of the functional groups is involved in complex-formation, the other being left free as a result of a reduction of its reactivity by an inductive effect when the first group has formed a chemical bond with a cation.[9,10] In dilute acid solution (~0·1*M* hydrochloric acid), when thorium is present in excess the arsenazo III (R) complex is ThR, and at higher acidities (>1*M*) ThR_2 is formed with arsenazo III in excess. The spectrophotometric titration curves, however, do not give unambiguous evidence for these complexes, but the HFT curves for 10^{-3}–$10^{-4}M$ thorium nitrate and arsenazo III (titrated in both directions) show clearly that these formulae are correct. The formulae (I) and (II) shown for the ThR and ThR_2 are confirmed[9] by HFT determination of the number of protons released in formation of the complexes—3 for ThR and 4 for ThR_2. The proton of the sulphonic acid grouping is preferentially titrated first and takes no part in the complex formation.



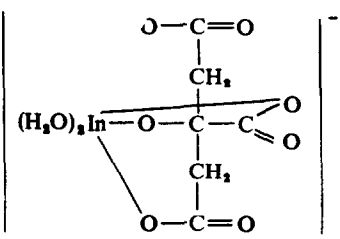
(I)



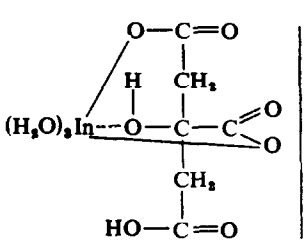
(II)

Indium complexes

By high frequency and potentiometric titration of various mixtures of indium(III) and citric acid by a solution of an alkali metal salt it has been shown that the indium citrate complex is a 1:1 complex.[12] When indium(III) chloride is titrated with sodium citrate, however, a binuclear complex In_2Cit is formed, which resembles those found for other metals with oxy-acids.[13–15] These results, taken in conjunction with those from ion-exchange and preparative work, show that when indium citrate complexes are formed both hydroxyl and carboxyl groups participate. If the coordination number of indium is taken as 6, then structures (III) and (IV) can be proposed for the 1:1 complex at pH 1–2 and pH 7·1 respectively.



(III)



(IV)

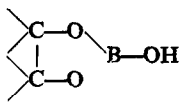
HFT studies have been made of the reaction of indium(III) with various complexones. With EDTA, DCTA (1,2-diaminocyclohexane-tetra-acetic acid) and HMDTA, indium forms 1:1 complexes.[16] From the stereochemistry of these complexes it would be expected that the stabilities would be in the order InDCTA > InEDTA > InHMDTA. The sharpness of the HFT peaks changes in just this order, and indicates that there is a definite relationship between the character of the peak on the HFT curve and the stability of the complex, but further study of this is required. HFT shows that indium forms two complexes with NTA—InNTA and $In(NTA)_2$.[16] Similar behaviour has been observed for indium and oxyethyliminodiacetic acid, and confirmed by potentiometric titration.

Plutonium complexes

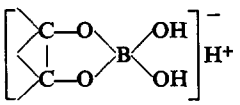
The reaction of plutonium(V) and EDTA has been studied[17] and the two breaks on the titration curve indicate the formation of the complexes PuEDTA and $Pu(EDTA)_2$. The results obtained have been combined with potentiometric data to yield (by Bjerrum's method) the stability constant for PuEDTA ($\log K = 12{\cdot}9 \pm 0{\cdot}1$).

Boron complexes

HFT has recently been used to investigate the reaction of hydroxystearinic acids (HSA) with boric acid in alcoholic solutions.[18] It was found that 1:1 complexes were formed with di-, tri- and tetrahydroxystearinic acids (m.p. 96°, 111° and 135° respectively) and a 1:2 complex (m.p. 160°) was also formed with tetrahydroxystearinic acid. Together with the results of low frequency conductivity measurements, these data confirm that a complex of the type (V) exists in solution. When the tetrahydroxystearinic borate complex was titrated (HFT) with sodium hydroxide in alcoholic solution, however, a complex of the type (VI) was found.



(V)



(VI)

These results indicate the HFT can be used to investigate the composition and structure of high molecular weight acids and polyalcohols in non-aqueous solvents or in mixed solvents.

Analytical applications

HFT can be used to locate the end-point in complexometric titrations, as for example in the titration of thorium with HMDTA. As HMDTA does not react with lanthanides at pH 4, it can be used for the determination of thorium in the presence of these elements (in ratios of La:Th up to 5) by the HFT method.[6]

At low enough pH (~1·5) NTA forms a stable complex with indium and does not react with zinc, cadmium, aluminium, nickel and cobalt. As shown in Table I, this allows indium to be determined in the presence of these elements. Similar results are obtained with DCTA.[19]

TABLE I.—HFT TITRATION OF INDIUM WITH NTA

Indium taken, *mg*	Other elements, *mg*					Indium found, *mg*	Error %
	Zn	Cd	Al	Ni	Co		
5·74						5·74	0
5·74	6·54	11·2	2·70	5·87	5·89	5·74	0
11·5	6·54	11·2	2·70	5·87	5·89	11·4	1
11·5	13·1	22·4	5·4	11·7	11·8	11·4	1

Complexometric high frequency titration is also used to determine yttrium oxide in mixtures of it with dysprosium or other lanthanide oxides. The average error is 5% relative, partly because an indirect method is used. A known weight of the oxide mixture is dissolved and titrated (HFT) with EDTA. The yttrium oxide content (X%) is then calculated from the formula

$$X = \frac{M_1(M_2A - 2a)}{2(M_2 - M_1)a} \times 100$$

where M_1 and M_2 are the formula weights of Y_2O_3 and the other lanthanide sesquioxide respectively, a is the weight of oxide mixture (in mg), and A is the number of mmoles of EDTA required to titrate the metals in that weight of oxide.

Inert electrolytes lower the accuracy of interpretation of the HFT curves,[20] but in spite of this limitation the technique is a promising one for the investigation of complex formation in solution and for the development of analytical methods, especially if its advantages and the possibility of automating it are taken into account.

Summary—High frequency titration is a valuable tool in the study of complex formation in solutions, and the breaks in the titration curves can be used, in conjunction with the results of other physical methods, to determine the composition of the complexes formed. High frequency titration and other methods have been used to study the complexes formed by thorium, indium, plutonium(V) and boron with various complexing agents, and to develop methods for the determination of thorium and yttrium in rare earth mixtures, and of indium in the presence of zinc, cadmium, aluminium, nickel and cobalt.

Zusammenfassung—Die Hochfrequenztitration ist wertvoll bei der Untersuchung der Komplexbildung in Lösungen und die Stufen in den Titrationskurven können zusammen mit den Ergebnissen anderer physikalischer Methoden zur Ermittlung der Zusammensetzung der gebildeten Komplexe dienen. Die Hochfrequenztitration und andere Methoden wurden zur Untersuchung der Komplexe aus Thorium, Indium, Plutonium(V) und Bor mit verschiedenen Komplexbildnern verwendet und damit Vorschriften zur Bestimmung von Thorium und Yttrium in Gemischen seltener Erden und von Indium neben Zink, Cadmium, Aluminium, Nickel und Kobalt entwickelt.

Résumé—Le titrage en haute fréquence est un outil de grand intérêt dans l'étude de la formation de complexes en solutions, et l'on peut utiliser les brisures des courbes de dosage, conjointement aux résultats d'autres méthodes physiques, pour déterminer la composition des complexes formés. On a utilisé le titrage en haute fréquence et d'autres méthodes pour étudier les complexes formés par le thorium, l'indium, le plutonium (V) et le bore avec divers agents complexants, et pour développer des méthodes de dosage du thorium et de l'yttrium dans des mélanges de terres rares, et de l'indium en présence de zinc, cadmium, aluminium, nickel et cobalt.

PRELIMINARY COMMUNICATIONS

Application of the drop method to the study of nucleation of sparingly soluble chelates

(*Received* 10 *August* 1966. *Accepted* 14 *August* 1966)

PROGRESS in the study of nucleation from solution was slow until the advent of the drop method. This ingenious and elegant technique was devised by Vonnegut[1] to eliminate the effect of heterogeneous catalysts, *e.g.*, dust particles, glass walls, *etc.*, on nucleation processes. If a liquid is subdivided into discrete droplets of small enough volume, the heterogeneous matter present in the original volume of liquid will presumably be confined to a small fraction of the droplets. Nucleation of material in these droplets will occur as a heterogeneous process, whereas nucleation in the rest of the droplets will be governed only by the molecular characteristics of the pure material. The drop method has apparently only been used in conjunction with supercooling methods for obtaining supersaturated solutions, and has been applied in this manner with success to the study of the self-nucleation of a variety of compounds; polymers,[2,3] water,[4] tin[5] and n-alkanes.[6] Only limited success, however, has been achieved in the nucleation of salts from aqueous solution, *e.g.*, potassium nitrate[7] and ammonium iodide.[8] Supercooling is not generally a satisfactory method of producing supersaturated aqueous solutions of sparingly soluble species, however, because of the low solubility and the small working range of supercooling attainable. In fact, Melia[9] has stated that, "A new method of producing supersaturation in droplets (other than supercooling which sets a lower temperature limit of 0° and hence a supercooling limit of about 100°) would represent a major technical advance, . . . ".

This paper describes a new application of precipitation from homogeneous solution (PFHS) as a method of generating supersaturated solutions of sparingly soluble chelates, which may be combined effectively with drop techniques. In this combined technique, a PFHS reaction is started and some of the reaction medium is immediately emulsified into small droplets suspended in a suitable oil. The emulsion is then transferred to a microscope stage cell and observed either visually or photographically to study nucleation and growth processes as a function of time. To obtain critical supersaturations, kinetic rates, *etc.*, it is necessary to know the rate of production of nucleating material in the generation process. The kinetics of PFHS processes of nickel dimethylglyoxime and other chelates have been studied in great detail by Gordon *et al.*[10,11] and this work is being utilised in the analysis of nucleation experiments. Some of the experimental details of the combined technique and a description of a typical drop experiment are given below.

EXPERIMENTAL

The dispersion medium

An oil dispersion medium was needed that would not dissolve the reactants or products and that would be suitable for the preparation of reasonably stable, non-opaque, water-in-oil emulsions. Many oils were examined, *e.g.*, silicones, fluorocarbons, *etc.* The oils that seemed most suitable were Nujol (Saybolt viscosity 360–390 at 100°F, s.g. 0·880–0·900 at 60°F) and light mineral oil (Fisher Scientific Co., Saybolt viscosity 125–135).

Emulsification methods

An emulsification process was required that would produce monodisperse drops in a short time without introducing large temperature changes. Several methods were examined, *e.g.*, ultrasonic dispersion, syringe, aerosol spraying and mechanical mixing (various devices). The best results were obtained with a biological microhomogeniser.

Observation system

The system used was a Bausch and Lomb "Dynazoom" microscope fitted with polariser and analyser. A suitable cell for holding the emulsion in the light path was made by fixing a Teflon washer

on a microscope slide. Photographic techniques (still and cine) were used to obtain a large number of photographs of a large number of drops over long periods of time.

The effect of polarised light on nickel dimethylglyoximate

The use of crossed polarisers in the microscope led to some interesting observations on the properties of nickel dimethylglyoximate. A normal PFHS of nickel dimethylglyoximate was carried out with biacetyl monoxime as starting material. About 2 ml of this solution were placed in a Littman microscope cell on the stage. The solution was viewed under dark field conditions. The first crystals were blue and as the crystals grew larger they became red in the middle and remained blue at either end. Rotation of the sample caused extinction of these colours to occur at 90° intervals. These colours are polarisation colours and were determined by the quartz wedge technique to be second order blue and red. A birefringence-polarisation colour table was used (assuming approximate values for the birefringence of nickel dimethylglyoximate) to show that the red parts of the crystal were about twice the thickness of the blue parts.

A typical drop experiment

A PFHS reaction to generate nickel dimethylglyoximate was started by adding 10 ml of a solution $1{\cdot}25 \times 10^{-3}M$ in nickel and $1 \times 10^{-1}M$ in hydroxylamine hydrochloride (pH 7·1) to 10 ml of $2{\cdot}5 \times 10^{-2}M$ biacetyl monoxime. A small amount, 0·5 ml, of this mixture was quickly transferred to a microhomogeniser vessel which had been filled with Nujol. The whole mixture was emulsified by stirring at 14,000 rpm for 20 sec. The water-in-oil emulsion was quickly poured into a 50-ml measuring cylinder and allowed to stand. The cylinder was used as a very rough fractionating column in order to achieve removal of the larger drops. Part of the emulsion (2–3 drops) from near the top of the cylinder was transferred to the slide cell on the microscope stage.

About 100–200 drops were brought into the field (magnification 100–200 ×) and observed for 3–4 hr. After 18 min blue crystals were observed in a few of the drops and after 35 min many drops contained crystals. Drops which sank to the bottom of the cell and spread out on the glass (even in the presence of oil) produced crystals immediately. Photographs were taken at various times to complete a record of the number of drops containing crystals. The normal "beaker" reaction produced a nickel dimethylglyoximate precipitate in 3–4 min; the addition of oil had no effect on this reaction.

DISCUSSION

The results from the preliminary experiments indicate that PFHS techniques may be combined effectively with drop methods. The supersaturations of nickel dimethylglyoximate obtained were large (of the order of 10^3 or 10^4 times the equilibrium solubility) compared with those previously obtained in non-drop studies.[11] A much more detailed study of the system is now being carried out. The technique will be extended to a study of the nucleation of a series of metal aliphatic dioximates to obtain correlations between nucleation data and the structural characteristics of dioximates.

Precipitation from homogeneous solution applied to the drop technique for the study of nucleation

(*Received* 15 *September* 1966. *Accepted* 23 *September* 1966).

MELIA, in his review on crystal nucleation from aqueous solution, pointed out the advantages of the droplet technique, first proposed by Vonnegut,[1] in the study of the nucleation process.[2] He also stated that methods of producing supersaturation within the droplets other than by supercooling, if devised, would be a "major technical advance", and that techniques need to be developed which would permit the observation of the number of secondary nuclei produced from a parent nucleus. The techniques of precipitation from homogeneous solution (PFHS) and high-speed motion picture photomicrography coupled with the droplet technique could possibly be used to produce the necessary supersaturation and to observe nucleation and crystal growth. Preliminary studies on the dispersion of water droplets in various oils and the application of PFHS to the droplet technique were therefore initiated. Some results of these preliminary studies are reported in this communication.

EXPERIMENTAL

Apparatus

A model MPS Lumex polarizing microscope (Fisher Scientific) was used throughout this investigation. The aqueous solutions were dispersed in the various oils by means of an osterizer (John Oster Manufacturing Company, Racine, Wisconsin) modified so that the total volume of the air-tight mixing chamber was about 125 ml.

Reagents

Except for the oils, all chemicals were of reagent grade quality.

Procedure

About 10 ml of a freshly-prepared PFHS reaction mixture (the conditions of which were adjusted so that a turbidity was observed about 7 min after mixing) were placed in the osterizer and enough mineral oil added so that all air was excluded from the system when the cap was in place. The osterizer was immediately turned on and allowed to operate for about 30 sec (5000 rpm). Two drops of the resulting oil-water mixture were removed from the osterizer and placed on a "hanging-drop" slide. The slide was then mounted on the stage of the polarizing microscope. With a magnification of 100–400 × and crossed polarizers, approximately 100 droplets were observed during an experiment.

RESULTS AND DISCUSSION

Initial experiments employing various lubricating, silicone and mineral oils indicated that a mixture of equal parts of air-free light and heavy mineral oils provided the best medium for dispersing the PFHS reaction mixtures. In this mixture most of the droplets remained dispersed for the 2–3 hr observation period.

About 10 ml of a freshly-prepared PFHS reaction mixture (the conditions of which were adjusted so that a turbidity was observed about 7 min after mixing) were placed in the osterizer and enough mineral oil added so that all air was excluded from the system when the cap was in place. The osterizer was immediately turned on and allowed to operate for about 30 sec (5000 rpm). Two drops of the resulting oil-water mixture were removed from the osterizer and placed on a "hanging-drop" slide. The slide was then mounted on the stage of the polarizing microscope. With a magnification of 100–400 × and crossed polarizers, approximately 100 droplets were observed during an experiment.

RESULTS AND DISCUSSION

Initial experiments employing various lubricating, silicone and mineral oils indicated that a mixture of equal parts of air-free light and heavy mineral oils provided the best medium for dispersing the PFHS reaction mixtures. In this mixture most of the droplets remained dispersed for the 2–3 hr observation period.

The following PFHS reactions have been successfully coupled with the droplet technique: nickel(II)—salicylaldehyde—hydroxylamine, nickel(II)—cyclohexanedione—hydroxylamine, nickel-(II)—cycloheptanedione—hydroxylamine, palladium(II)—cyclohexanedione—hydroxylamine, and palladium(II)—cycloheptanedione—hydroxylamine. In the case of the nickel(II)—salicylaldehyde—hydroxylamine system, supersaturations of about 1000 times the equilibrium solubility were attained before nucleation was observed.

It is apparent from these preliminary experiments that PFHS reactions can be coupled with the droplet technique for study of the nucleation process. Presently, a more detailed study of these systems is being carried out and a high-speed motion picture camera is being adapted for microscopic work.

LETTER TO THE EDITOR

Remarks on hexamminecobalt(III) carbonatoberyllate

SIR,

Monk and Exelby[1] have corroborated the conclusion reached by us[2] that the precipitate formed by the action of hexamminecobalt(III) chloride on a solution of the carbonato complex of beryllium has the composition proposed by Sen Gupta[3] and not that put forward by Pirtea.[4]

On the other hand they consider that this precipitate cannot be used for precise quantitative determination of beryllium, on the grounds that it consists of a mixture of the deca- and dodeca-hydrates described by Sen Gupta, the ratio of the two depending on the history of the precipitate. They state that if not too high an accuracy is required, the compound is suitable as a weighing form if it is kept for a long period at a relative humidity of 32–80%. For precise determination, they prefer to take advantage of the 2:1 mole ratio of beryllium to cobalt and determine the cobalt as a means of evaluating the amount of beryllium in the precipitate.

Monk and Exelby also state that "to prevent possible dehydration of the precipitate, the precipitate was not washed with absolute ethanol", but present no evidence that such an effect would occur. We consider that it would not, since in our experience, gathered over many years, washing with absolute (or 96%) ethanol or anhydrous acetone removes only the mother liquor, and the subsequent washing with ether and drying under suction from a water-pump removes only the wash-liquids. We are quite sure that no water of crystallisation is lost in the process, no matter how much ethanol is used or how long the precipitate is kept under reduced pressure.

We consider that keeping the precipitate at a relative humidity of 32–80% until it has reached constant weight is likely to be a protracted business, and moreover is unreliable as the wash-liquid used (60% aqueous ethanol) is not removed by this treatment, which may account for these authors having found more than 10 molecules of water of crystallisation in the formula. They are also mistaken in supposing that we and Pirtea used a desiccant (which they further presumed was "slow in action"). The precipitate was kept in an empty desiccator under a moderate vacuum. Although Pirtea suggested 15 min as the duration of the drying, we have found that longer periods make no difference, and that repetition of the process does not alter the weight of the precipitate (within the limits of accuracy of the weighing).

If the precipitate is washed with alcohol and ether and then kept under a moderate vacuum, it can be used as a good weighing form for beryllium. It contains 10 molecules of water per unit formula, and the conversion factor to beryllium is 0·0395. We have not found the dodecahydrate described by Sen Gupta.

Monk and Exelby's method of determining the beryllium through the cobalt content of the precipitate is fully justified in theory. It has been proposed[5] that the precipitate can be dissolved and the cobalt(III) reduced in alkaline solution. The cobalt(II) is then titrated with EDTA with Murexide as indicator. We have tried this method, but used Xylenol Orange as indicator and titrated at pH 4·5–5·0. The results were completely satisfactory, but somewhat less accurate than the gravimetric results; we think this is because of the increased number of operations needed and hence the number of sources of error. We would, however, recommend this method for the determination of small amounts of beryllium (<1 mg) and for routine macro determinations. An advantage is that the precipitate can be washed with a dilute ammonium carbonate solution and the washing with alcohol and ether is unnecessary.

We consider that the complexometric method proposed by Monk and Exelby[6] gives very accurate results, and would be very suitable for referee work, though it is perhaps rather more complicated than one would wish for routine analysis.

GEGENSTROMIONOPHORESE—II*

EXPERIMENTELLE UNTERSUCHUNGEN

W. PREETZ und H. L. PFEIFER
Institut für Analytische Chemie und Radiochemie der Universität des Saarlandes, Saarbrücken, Deutschland

(*Eingegangen am* 14 *April* 1966. *Angenommen am* 18 *Juli* 1966)

Zusammenfassung—Durch Anwendung neuer Apparaturen gelingt es, Prinzip und Verlauf der Gegenstromionophorese unter Verwendung anionischer Modellsubstanzen zu bestätigen. In Übereinstimmung mit der Theorie richten sich die Anionen von der Anode zur Kathode hin nach fallender Beweglichkeit aus. Zur Ausbildung des stationären Zustandes müssen bei der Anionentrennung Gegenstrom- und Anodenelektrolyt Anionen größerer, Ablauf- und Kathodenlösung Anionen kleinerer Beweglichkeit als das Trenngemisch enthalten. Feldstärkemessungen in einer Kammer mit kapillarem Trennspalt beweisen, daß die Feldstärke im stationären Zustand nicht gleichmäßig abfällt, sondern daß an den Grenzen benachbarter Zonen unterschiedlicher Ionenbeweglichkeiten sprunghafte Änderungen auftreten. Die Ausbildung dieses Feldstärkeprofils ist für die erhaltenen scharfen Trennungen verantwortlich. Durch Vergleich gemessener Feldstärkequotienten mit berechneten Beweglichkeitsquotienten wird die Berechnung unbekannter Ionenbeweglichkeiten möglich. Die sich in den Zonen einstellenden Konzentrationen werden durch die Beweglichkeiten der beteiligten Ionen und die Konzentration der Gegenstromlösung bestimmt.

IN der vorangehenden Mitteilung[1] wurden auf Grund theoretischer Betrachtungen allgemeine Bedingungen abgeleitet, die bei der Gegenstromionophorese zur Einstellung stationärer Verhältnisse führen und die automatische Steuerung des Trennvorganges ermöglichen.

Die vorliegende Arbeit dient der experimentellen Prüfung. Durch Trennungen von Modellsubstanzen, Messung des Feldstärkeverlaufs im Trennsystem und Bestimmung der Konzentrationsverhältnisse in eigens dazu entwickelten Apparaturen werden die wesentlichen Annahmen über den Verlauf von Gegenstromtrennungen experimentell bestätigt. Darüberhinaus wird die Trennung chemisch sehr ähnlicher Gemischtligandkomplexionen mit dem neuen Verfahren durchgeführt.

APPARATUREN FÜR DIE GEGENSTROMIONOPHORESE

Für die qualitative Beobachtung von Modelltrennungen und zur orientierenden Bestimmung der Einflüsse verschiedener Versuchsparameter dient eine einfache Gegenstromapparatur mit einer Trennkapillare.

Zur quantitativen Messung der Feldstärke- und Konzentrationsverhältnisse während des Trennvorgangs wird eine Meßkammer beschrieben, die den Zugang von außen zum Trennsystem gestattet.

Das Trennrohr

Beim Bau des Gegenstromtrennrohrs sind folgende Gesichtspunkte zu berücksichtigen:
(a) Verwendbarkeit von Kapillaren verschiedener Länge und verschiedenen Durchmessers.

* Mitteilung I: *Talanta* 1966, **13**, 1649.

(b) Genaue Regulierbarkeit der Gegenstromgeschwindigkeit.
(c) Bequeme Zuführung des Trenngemisches.
(d) Intensive Kühlung.
(e) Einfache Reinigung und Spülung.

Das Trennrohr Abb. 1 besteht aus einer Trennkapillare (1), an deren Enden zwei Aufweitungen (6 und 7) von 6 cm Länge und 1 cm Durchmesser angeschmolzen sind. Beide tragen Glasaufsätze (0,5 cm Durchmesser und 3 cm Länge), die mit den Elektrodentrögen (5 cm Höhe und 5 cm Durchmesser) verbunden sind. In den Glasaufsätzen befinden sich Steinwollediaphragmen. Durch das

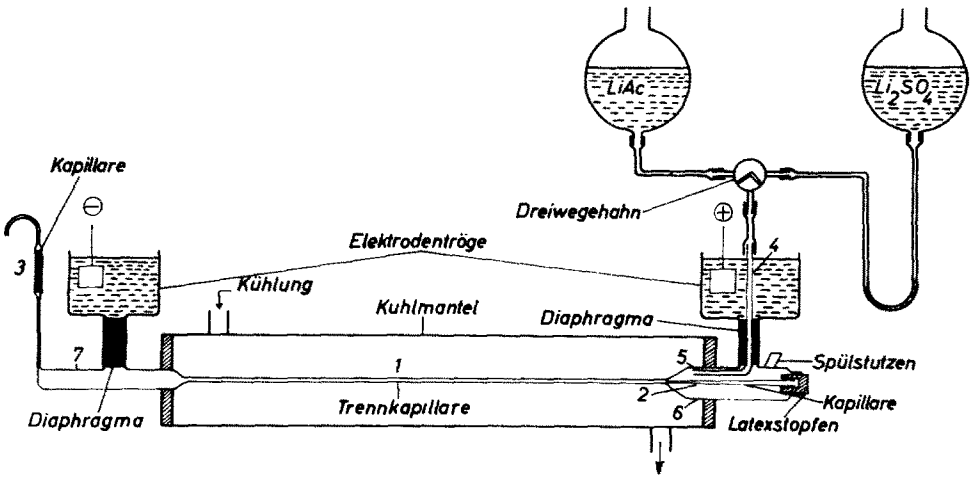

ABB. 1.—Schematischer Längsschnitt des Trennrohrs.

Anodendiaphragma führt eine Glasröhre (4) mit aufgesetztem Polyäthylenschlauch (5) in das aufgeweitete Glasrohr (6) bis kurz vor den Ansatz der Trennkapillare. Sie dient der Zufuhr der Elektrolytlösung (Lithiumacetat und-sulfat) die aus zwei Niveaugefäßen über einen Dreiwegehahn getrennt in das Trennrohr gelangen.

Die Aufweitung (7) unter der Kathode mündet in einem Kapillaraufsatz (0,1 cm Durchmesser) über den ein Polyäthylenschlauch mit einer feinen Kapillare (3) zur Regulierung der Gegenstromgeschwindigkeit gestülpt ist.

Die Zuführung des Trenngemisches erfolgt über eine weitere Kapillare (2) von ungefähr 6 cm Länge, die etwa 0,2 cm in die Trennkapillare hineinreicht. Gehalten wird sie von einem zur Hälfte angebohrten Latexstopfen, der gleichzeitig die Öffnung des Trennrohres abschließt. Somit gelangt das Trenngemisch unmittelbar in die Trennkapillare, wodurch Vermischung weitgehend ausgeschlossen wird.

Zur Abführung der Jouleschen Wärme einerseits und zur Aufrechterhaltung konstanter Temperaturverhältnisse in der Trennkapillare andererseits ist diese von einem Kühlmantel umgeben, durch den ein Glycerin-Wassergemisch von 0° aus einem Kryomaten gepumpt wird.

Die Anordung der zu trennenden Ionen nach steigender Beweglichkeit bereits vor Versuchsbeginn bewirkt eine Verkürzung der Trenndauer. Bei der Anionentrennung füllt man deshalb das Trennrohr zunächst blasenfrei mit Lithiumacetat-lösung. Mit Hilfe einer Injektionsspritze wird dann eine gewählte Menge der Trennlösung durch den Latexstopfen und die Zuflußkapillare (2) in die Trennkapillare (1) gedrückt. Anschließend spült man den Raum unterhalb der Anode durch Öffnen des Spülstutzens gut mit der Gegenstromlösung (Lithiumsulfat) aus.

Die Regulierkapillare (3) wird durch Ausziehen eines dickwandigen Glasrohres hergestellt. Ihre Auslaufgeschwindigkeit muß so groß sein, daß bei einer Niveaudifferenz zwischen der Gegenstromlösung und dem Ausfluß von etwa 40 bis 60 cm die Strömungsgeschwindigkeit in der Trennkapillare gerade die elektrolytische Wanderung der Ionen kompensiert. Durch Heben oder Senken des Niveaugefäßes kann die Gegenstromgeschwindigkeit reproduzierbar und in weiten Grenzen variiert werden.

Zur Vermeidung von Ionenverarmung, wählt man die Lösungen, in den Elektrodentrögen grundsätzlich konzentrierter als in der Trennkapillare, insbesondere, wenn von einer Elektrodenspülung während der Trennung abgesehen wird. Als Anodenlösung dient im allgemeinen 0,025–0,05 m Lithiumhydroxid, als Kathodenlösung ein Puffergemisch, das je 0,05 m an Lithiumacetat und Essigsäure ist.

Um die Apparatur von eventuell gebildeten Zersetzungs- und Hydrolyseprodukten bequem reinigen zu können, besteht sie aus mehreren Einzelteilen, die von Polyäthylenschläuchen zusammengehalten werden. Diese Aufgliederung hat den Vorteil, daß man die Trennkapillaren schnell auswechseln kann. Besonders haben sich Kapillaren von 20 cm Länge und 0,08 cm Durchmesser bewährt. Bei der meistens angelegten Gleichspannung von 3000 V entspricht das einer mittleren Feldstärke von 150 V/cm.

Meßkammer

Die Meßkammer ist grundsätzlich dem Trennrohr entsprechend aufgebaut, Abb. 2.

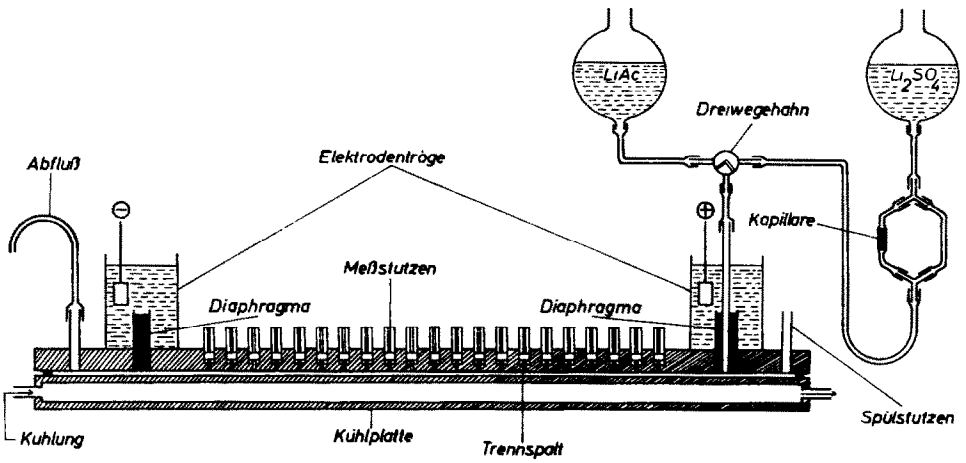

ABB. 2.—Schematischer Längsschnitt der Meßkammer.

Zwischen zwei 30 cm langen und 10 cm breiten Glasplatten werden zwei weiche Gummistreifen parallel zu einander ausgelegt, so daß sie einen Trennspalt bilden. Die obere Platte ist so beschaffen, daß sie während der Trennung mit Eis gekühlt werden kann; die untere ist an ein Kühlsystem angeschlossen (Glycerin-Wasser-Gemisch von 0°). Beide Platten werden von drei Kunststoffklammern zusammengehalten.

Im Abstand von 2 bzw. 3 cm von den Plattenenden entfernt, sind auf die obere Platte zwei Elektrodentröge geklebt, die über Bohrungen mit dem Trennspalt in Verbindung stehen. In diese Bohrungen werden PVC-Hülsen mit Steinwolldiaphragmen eingelassen.

Vier Glasröhren durch die Anodendiaphragmen führend, besorgen die Elektrolytzufuhr. Zwischen Plattenende und Anodentrog befinden sich zwei 0,4 cm Bohrungen mit PVC-Hülsen. Sie dienen als Spülstutzen. Hinter dem Kathodentrog bilden weitere sechs PVC-Hülsen in 0,35 cm Bohrungen den Auslauf der Kammer. Auslauf- und Spülbohrungen einschließend, grenzen zwei weitere Gummistreifen, senkrecht zu den beiden ersten angeordnet, den Trennspalt ab.

Die Gegenstromgeschwindigkeit wird mit einer Kapillare (Dosierkapillare) gesteuert, die in einer Schlauchverzweigung der Zuführung des Gegenstromelektrolyten befestigt ist.

Konzentrations- und Feldstärkemessungen erlauben 21 Meßstutzen, die im Abstand von je 1 cm zwischen den Elektrodentrögen liegen. Sie werden im folgenden näher beschrieben.

An eine Bohrung von 0,75 cm Höhe und 0,35 cm Durchmesser schließt sich eine engere Bohrung von 0,15 cm Durchmesser und 0,25 cm Höhe an, so daß die engere Bohrung im Trennspalt endet. Auf diese Art entsteht ein Absatz in der gesamten Bohrung. Darauf liegt ein 0,1 cm hohes PVC-Führungsplättchen mit einer 0,1 cm Bohrung. Eine 0,3 cm dicke Latexscheibe wird von einer fest an der oberen Bohrung anliegenden PVC-Hülse gegen das Führungsplättchen gedrückt. PVC-Hülse und Führungsplättchen haben die Aufgabe, eine Nadelelektrode, die durch die Latexscheibe gestochen wird, stets an der gleichen Stelle in den Trennspalt einzuführen, so daß bei Feldstärkemessungen der Abstand zwischen den einzelnen Meßstutzen als annähernd konstant angesehen werden kann. Die Latexscheibe verhindert den Zugang der Elektrolytlösungen an die Oberfläche der Glasplatte.

Wie im Trennrohr werden auch hier die Anionen bereits vor der eigentlichen Trennung nach steigender Beweglichkeit im Trennspalt angeordnet. Die Trennlösung wird mit einer Injektionsspritze durch einen der Meßstutzen direkt in den Trennspalt gedrückt.

Vor Anlegen der Spannung wird der direkte Weg des Gegenstromzulaufs geschlossen, so daß die

Regulierung der Gegenstromgeschwindigkeit über die Dosierkapillare und das Niveaugefäß mit der Gegenstromlösung erfolgen kann.

Der Anodentrog enthält im allgemeinen 0,5 m Lithiumhydroxid der Kathodentrog 0,5 m Lithiumacetat-Pufferlösung.

Die Trenndauer ist auf Grund der niedrigeren Feldstärken (*ca.* 80 V/cm) entsprechend höher als im Trennrohr.

Im Gegensatz zum Trennrohr kann man in dieser Apparatur den Verlauf der Trennung bis zur Einstellung stationärer Verhältnisse durch Feldstärkenmessungen verfolgen. Ebenso ist es möglich, dem Trennspalt durch die Meßstutzen Proben zu entmehmen, die der Klärung der Konzentrationsverhältnisse nach beendeter Trennung dienen.

Die Verwendung einer Abdeckplatte mit einer größeren Zahl im Abstand von 0,3 cm festeingelassener dünner Platindrähte zur Feldstärkemessung hat sich nicht bewährt, weil durch Polarisationselektrolyse gebildete kleine Gasbläschen im Trennspalt zu erheblichen Störungen Anlaß geben.

QUALITATIVE UNTERSUCHUNGEN AM TRENNROHR

Die auf Grund theoretischer Überlegungen gewonnenen Vorstellungen über den Ablauf und die Steuerung von Gegenstromtrennungen werden unter Verwendung von Modellsubstanzen experimentell geprüft. Für die visuelle, qualitative Beobachtung des Entmischungsvorgangs im Trennrohr und die Ausbildung des stationären Zustandes mit scharf abgegrenzten Zonen eignen sich besonders gefärbte Ionen mit großen Beweglichkeitsunterschieden, wie z.B. gelbe $[IrCl_6]^{2-}$-, blaue $[IrBr_6]^{2-}$-, violette MnO_4^--Ionen u.a.. Weiterhin werden durch Variation apparativer Parameter die günstigsten Bedingungen für eine hohe Trennschärfe bestimmt.

Zeitlicher Verlauf einer Trennung

Ein Gemisch mit $[IrCl_6]^{2-}$-und $[IrBr_6]^{2-}$-Ionen wird in der Trennkapillare zwischen Lösungen aus Lithiumacetat nahe der Kathode und Lithiumsulfat nahe der Anode angeordnet, Abb. 3*a*.

Bereits 3 Minuten nach Einschalten des Gegenstroms (Lithiumsulfatlösung) und der Hochspannung (3000 V) beginnt sich eine Front des Trenngemisches gegen die Ac^--Ionen auszubilden. Nach etwa 7 Minuten (Abb. 3*d*) besteht zwischen den blauen $[IrBr_6]^{2-}$-Ionen und dem Acetatbereich eine scharfe Grenze. Nach 9 Minuten ist die Trennung der gelben $[IrCl_6]^{2-}$-Ionen und der SO_4^{2-} -Ionen soweit fortgeschritten, daß sich zwischen beiden Ionenarten eine Grenze abzuzeichnen beginnt, die nach 12 Minuten ausgeprägt ist. Gleichzeitig schreitet die Trennung der Komplexionen fort, und die Entmischung ist nach *ca.* 15 Minuten beendet.

Die mit Abb. 3*g* wiedergegebene stationäre Anordnung der Zonen bleibt bei konstanten Versuchsbedingungen beliebig lange erhalten. Wird der Versuch unterbrochen, so vermischen sich die scharfen Grenzen durch Diffusion und Konvektion sehr schnell. Es genügt jedoch eine Trenndauer von wenigen Minuten, um die stationären Verhältnisse wiederherzustellen.

Änderungen der angelegten Spannung um 10% und mehr bzw. der Gegenstromgeschwindigkeit durch Heben oder Senken des Niveaugefäßes mit der Gegenstromlösung (Abb. 1) führen zu einer langsamen gleichmäßigen Verschiebung der Zonen um eine bestimmte Strecke in Richtung Anode oder Kathode bis wieder stationäre Verhältnisse erreicht sind. Bei solchen Wanderungen der Grenzschichten leidet die Trennschärfe nicht. Diese Beobachtungen bestätigen somit die Ausführungen über die Steuerung von Gegenstromtrennungen (I. Mitteilung, Abb. 2).

Einfluß der Konzentration des Gegenstromelektrolyten

Entsprechend der allgemeinen Arbeitstechnik wird ein Gemisch aus $[IrCl_6]^{2-}$- und $[IrBr_6]^{2-}$-Ionen, eingegrenzt zwischen Ac^-- und SO_4^{2-}-Ionen, getrennt. Die Gegenstromgeschwindigkeit wird so eingestellt, daß sich beide Komplexzonen nach Erreichen stationärer Verhältnisse etwa in Rohrmitte befinden, Abb. 4*a*.

Die Konzentration des Gegenstromelektrolyten wird schrittweise von zunächst 0,01 m (Abb. 4*a*) über 0,0075 m (Abb. 4*b*) und 0,005 m (Abb. 4*c*) auf 0,0025 m (Abb. 4*d*) erniedrigt.

Dazu wird nach gleichzeitiger Unterbrechung des elektrischen Stroms und des Gegenstroms die Gegenstromlösung im Niveaugefäß (Abb. 1) gegen die verdünntere ausgetauscht und der Raum vor der Trennkapillare unterhalb der Anode bei geöffnetem Spülstutzen quantitativ mit der neuen Lösung gefüllt. Die Lösung in der Trennkapillare wird von diesem Spülvorgang nicht betroffen. Bereits kurze Zeit nach Fortsetzung des Versuches erscheinen die Komplexzonen wieder scharf und zunächst in der ursprünglichen Länge. Sobald jedoch die verdünntere Lösung durch den Gegenstrom das

Abb. 5.—Abhängigkeit der Trennschärfe vom Kapillardurchmesser.

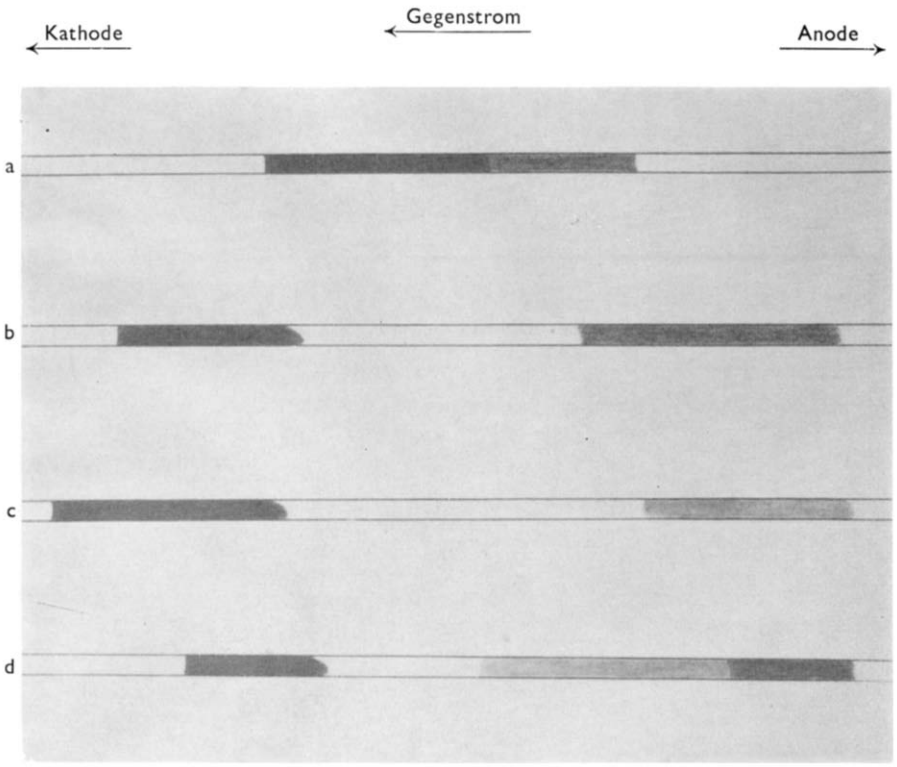

Abb. 6.—Mehrstofftrennungen.

Gebiet der Komplexzonen erreicht hat, dehnen sich die beiden Zonen um ein bestimmtes Stück aus und behalten dann wieder konstante Längen bei.

Die Abb. 4 zeigt anschaulich, daß durch die Änderung der Konzentration der Gegenstromlösung die Trennschärfe nicht beeinträchtigt wird, daß sich aber die Zonen im Trennrohr bei den einzelnen Verdünnungsschritten um die Hälfte, das Doppelte und Vierfache der ursprünglichen Länge ausdehnen.

Wie erwartet (I. Mitteilung, Gl. 16) besteht demnach eine direkte Proportionalität zwischen den Konzentrationen des Trenngemisches und des Gegenstromelektrolyten.

Abhängig keit der Trennschärfe vom Kapillardurchmesser

Um einheitliche Versuchsbedingungen zu gewährleisten und die vergleichende Beobachtung der Trennschärfen zu ermöglichen, werden drei Trennrohre verschiedenen Durchmessers zu einer Apparatur zusammengefaßt.

In einem Kühlmantel ausreichender Weite sind Kapillaren von 0,3; 0,15; 0,08 cm Durchmesser parallel zu einander eingesetzt. Die Stromzufuhr erfolgt über eine verzweigte Leitung von einem Hochspannungsgleichrichter aus. Wegen der höheren elektrischen Stromstärken bedingt durch die größeren Querschnitte der Kapillaren und der damit verbundenen Wärmeentwicklung, wird die übliche Spannung von 3000 V auf 2500 V erniedrigt.

Abb. 5 zeigt den stationären Zustand der Trennung eines $[IrBr_6]^{2-}/[IrCl_6]^{2-}$-Gemisches, wie er sich nach etwa einstündiger Trenndauer eingestellt hat.

Während in der engsten Kapillare bereits nach 15 Minuten eine exakte Trennung vorliegt (Abb. 5*c*), kommt es in der mittleren nur langsam zu einer Anreicherung der Komponenten (Abb. 5*b*). Einzelne Zonen sind nicht mehr zu erkennen. In der dicksten Kapillare wird der Hexabromokomplex mit dem Gegenstrom spiralförmig in den Acetatbereich hineingewirbelt (Abb. 5*a*).

Die Ursache für die schlechte Trennung in Kapillaren größeren Durchmessers ist in der bei allen ionophoretischen Trennungen auftretenden Konvektion zu suchen. Durch die gleichmäßig über den gesamten Querschnitt der Kapillare entstehende Joulesche Wärme baut sich von ihrer Mittelachse in Richtung zur gekühlten Außenwand ein Temperaturgradient auf. Die dadurch entstehenden Dichteunterschiede erzeugen bei der waagerechten Anordnung der Apparatur senkrecht zur Strömungsrichtung eine Thermokonvektion, die zur Ausbildung spiralförmiger Wirbel führt.

MEHRSTOFFTRENNUNGEN

Am Beispiel von Ionen, die sich in ihren Beweglichkeiten stärker unterscheiden, werden zunächst allgemeine Gesichtspunkte für Mehrstofftrennungen aufgezeigt.

Trennung von Ionen mit größeren Beweglichkeitsunterschieden

Durch die Trennung einer Anzahl Ionen wird qualitativ demonstriert, wie Trennschärfe, Trennzeit der einzelnen Ionen und die Gesamttrennzeit von Mehrkomponentengemischen zusammenhängen.

Abbildung 6 zeigt die stationären Zustände für die Trenngemische *a* bis *d*. In Tab. I sind die Ionen in ihrer Reihenfolge von der Kathode in Richtung Anode aufgeführt. Tabelle II enthält die Gesamttrennzeiten und die Trennzeiten für einzelne Ionenpaare. Aus Abb. 6 ergibt sich für die Beweglichkeiten der getrennten Ionen folgende qualitative Reihe:

$$Ac^- < [IrBr_6]^{2-} < BrO_3^- < [IrCl_6]^{2-} < MnO_4^- < SO_4^{2-}$$

Den Trennzeiten für die einzelnen Ionenpaare (Tab. II) ist zu entnehmen, daß die Differenz der Ionenbeweglichkeiten zwischen $[IrCl_6]^{2-}$ und BrO_3^- größer sein muß als z.B. zwischen $[IrBr_6]^{2-}$ und BrO_3^-. Der Vergleich der Trennschärfen ergibt, daß

diese um so exakter werden, je mehr sich die einzelnen Ionenpaare in ihren Beweglichkeiten unterscheiden, d.h. je kürzer die Trennzeiten sind.

Allgemein gilt für Mehrstofftrennungen die Regel, daß die Dauer der gesamten Trennung der Zeit entspricht, in der sich benachbarte Ionen mit der geringsten Beweglichkeitsdifferenz entmischen.

Wie Abb. 6 anschaulich zeigt, ist es vorteilhaft, farblose Ionen, in diesem Fall BrO_3^-, durch "Indikatorionen" zu markieren, indem man die farblose Zone durch kleine Gebiete gefärbter Ionen abgrenzt.

TABELLE I.—FOLGE DER IONEN IM STATIONÄREN ZUSTAND

Trennung von Ionen sehr ähnlicher Beweglichkeit

Während die bisher beschriebenen Trennungen im wesentlichen Modellfälle darstellen, ist die Trennung von Gemischtligandkomplexionen des Ir(IV), $[IrCl_xBr_{6-x}]^{2-}$ ($x = 0, 1, \ldots, 6$), ein Beispiel für die Trennung chemisch sehr ähnlicher Ionen.

Ein Lösungsgemisch mit allen Gliedern dieser homologen Komplexreihe wird zwischen Ac^-- und SO_4^{2-}-Ionen der Gegenstromtrennung unterworfen. Es stellt sich sehr schnell ein quasistationärer Zustand ein. Die Gemischtligandkomplexionen bilden zunächst eine gegen den Ac^-- und SO_4^{2-}-Bereich scharf abgegrenzte annähernd homogene Zone. Die Subfraktionierung, d.h. die Entmischung in sieben Zonen mit den einzelnen Gemischtligandkomplexionen vollzieht sich nur sehr langsam und führt nach etwa zwei Stunden zu dem endgültigen stationären Zustand.

Die Reihenfolge der Gemischtligandkomplexionen ist dieselbe wie bei der Hochspannungspapierionophorese. Die Beweglichkeitsabnahme erfolgt schrittweise bei Austausch von Chlorid gegen Bromid und dürfte für benachbarte Gemischtligandkomplexionen ungefähr 1,5 bis 2% betragen.

In Trennkapillaren von 0,08 cm Durchmesser und bei mittleren Feldstärken um 150 V/cm bilden sich zwischen den Zonen mit den einzelnen Gemischtligandkomplexionen noch scharfe Grenzen aus.

Es ist somit zu erwarten, daß auch Ionen noch größerer Ähnlichkeit wie z.B. Stereoisomere und gewisse Isotope nach diesem Prinzip mit der beschriebenen Versuchsanordnung bei ausreichend langer Versuchsdauer getrennt werden können.

UNTERSUCHUNGEN AN DER MESSKAMMER

Die Untersuchungen an der Meßkammer (Abb. 2) dienen der quantitativen experimentellen Prüfung der in der I-Mitteilung formulierten Zusammenhänge zwischen Ionenbeweglichkeit, Feldstärke- und Konzentrationsverlauf längs des Trennweges.

Feldstärkemessungen

Im Gegensatz zum Trennrohr kann man an der Meßkammer die Einstellung stationärer Verhältnisse messend verfolgen.

Im einfachsten Fall legt man Lithiumacetatlösung vor, der man mit der

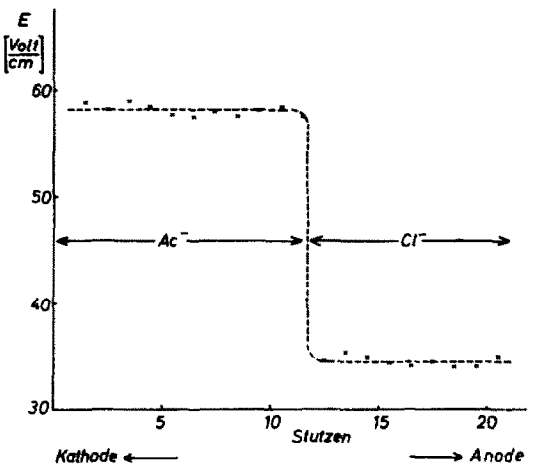

ABB. 7.—Feldstärkeverlauf für die Trennung Ac^-/Cl^-. Gegenstromlösung: 0,018 m LiCl; Spannung: 1200 V.

Gegenströmung z.B. Lithiumchloridlösung folgen läßt. Gemäß den allgemeinen Steuerbedingungen (1. Mitteilung, Abb. 2) kann man durch Variation der Gegenstromgeschwindigkeit, die entstehende Grenzschicht zwischen Ac^- und Cl^--Ionen an jeder Stelle der Meßkammer fixieren. Wegen der großen Beweglichkeitsunterschiede zwischen diesen Ionen stellt sich innerhalb weniger Minuten der stationäre Zustand ein.

Die Messung der Spannung zwischen jeweils benachbarten Stutzen an der Meßkammer (Abb. 2) mit einem möglichst stromlos messenden Voltmeter ergibt den Feldstärkeverlauf im Trennspalt. Er ist für die aneinander grenzenden Ac^-- und Cl^--Zonen in Abb. 7 graphisch dargestellt.

Die Feldstärke bleibt innerhalb einer Zone konstant und fällt an der Grenze zur nächsten scharf ab. Der Ersatz des Kations, z.B. Lithium gegen Kalium ist auf den Feldstärkeverlauf ohne Einfluß.

Bringt man entsprechend den Versuchen am Trennrohr ein Gemisch mit $[IrBr_6]^{2-}$- und $[IrCl_6]^{2-}$-Ionen zwischen Zonen mit Acetat und Sulfat, so stellt sich auch in der Meßkammer ein stationärer Zustand der Trennung ein. Das Ergebnis der Feldstärkemessung veranschaulicht Abb. 8.

Innerhalb der einzelnen Zonen ist die Feldstärke konstant, an den Grenzschichten

treten mehr oder weniger große Sprünge auf. Sie sind um so größer, je mehr sich die benachbarten Ionen in ihren Beweglichkeiten unterscheiden.

Die Meßstutzen verändern geringfügig den Querschnitt des Trennspaltes und beeinträchtigen dadurch etwas die scharfe Ausbildung der Fronten im stationären Zustand. Aus dem Feldstärkeverlauf der Abb. 8 ist ersichtlich, daß solche Störungen um so mehr in Erscheinung treten, je geringer die Feldstärkesprünge sind.

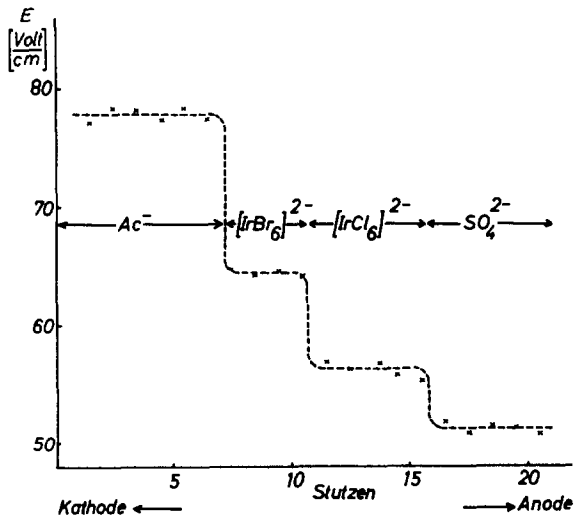

ABB. 8.—Feldstärkeverlauf für die Trennung $Ac^-/[IrBr_6]^{2-}/[IrCl_6]^{2-}/SO_4^{2-}$.

Obwohl die Meßkammer wegen apparativer Unzulänglichkeit für die Messung kleiner Feldstärkedifferenzen nicht geeignet ist, beweisen jedoch die Messungen bei Trennungen mit Ionen größerer Beweglichkeitsunterschiede die theoretischen Annahmen über den Feldstärkeverlauf, wie ein Vergleich der Abb. 8 mit Abb. 1 der 1. Mitteilung eindrucksvoll zeigt.

Störungen des normalen Feldstärkeprofils

Wichtigste Voraussetzung für die Messung reproduzierbarer Werte für die Feldstärke ist die Einstellung stationärer Verhältnisse. Diese sind mitunter nur scheinbar erreicht.

Die Trennkammer wird mit 0,01 m Lithiumsulfatgegenstromlösung bei 1600 V betrieben. Der Kathodenraum ist mit einer Lösung, die je 0,05 m an Lithiumacetat und Essigsäure ist, gefüllt. Im Anodentrog befindet sich 0,025 m Lithiumhydroxidlösung. Die Werte für die Feldstärken, wie sie nach einer Stunde (E_1) und nach fünf Stunden (E_2) gemessen werden, zeigt die Abb. 9.

Obwohl an der Apparatur keine Veränderungen vorgenommen wurden, weist Abb. 9 völlig verschiedene Feldstärkeverhältnisse für die beiden Messungen auf.

Die Erklärung liegt im Fehlen stationärer Verhältnisse. Da die Elektrodenlösungen nicht erneuert werden, hat sich ihre Zusammensetzung im Laufe des Experiments entscheidend verändert. Die Kathodenlösung ist nur noch schwach sauer.

Wesentlich für den Effekt sind jedoch die Vorgänge an der Anode. Aus der

ursprünglich alkalischen Anodenlösung wandern ständig Li^+-Ionen ab und SO_4^{2-}-Ionen zu. Außerdem entstehen anodisch H^+-Ionen, die am Anfang sofort durch die OH^--Ionen neutralisiert werden. In dem Maße, wie die Anodenlösung an Li^+-Ionen verarmt, nimmt ihre Konzentration an H^+-Ionen zu, bis sie schließlich sauer reagiert. Der Kationenstrom wird nach einer gewissen Zeit nicht mehr allein durch die Li^+-Ionen, sondern in erster Linie durch die schnelleren H^+-Ionen bewirkt. Im SO_4^{2-}-Bereich nimmt dementsprechend die Leitfähigkeit zu und die Feldstärke ab. Im

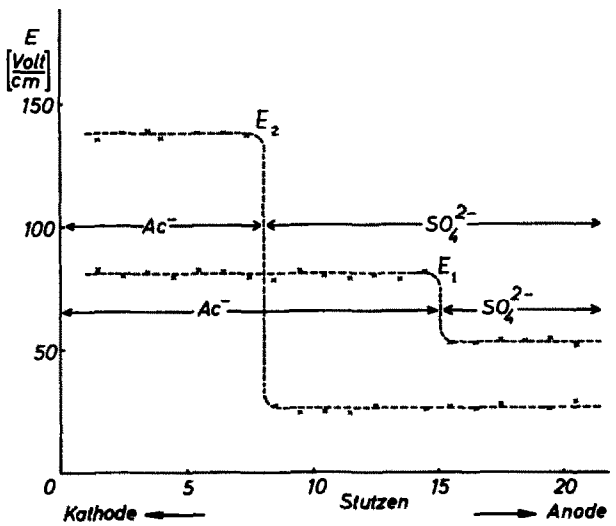

Abb. 9.—Anomaler Feldstärkeverlauf bei nichstationären Verhältnissen.

Ac^--Bereich treten dagegen die H^+-Ionen mit den Ac^--Ionen zu wenig dissoziierter Essigsäure zusammen. Es werden also Anionen weggefangen, die von der Kathode her nachwandern müssen, so daß sich eine Zone geringer Leitfähigkeit, d.h. hoher Feldstärke ausbildet.

Auch die kathodisch entstandenen und nicht neutralisierten OH^--Ionen stören. Bedingt durch ihre hohe Beweglichkeit wandern sie dem Gegenstrom entgegen und treffen auf die Komplexionen. Ir(IV)-Verbindungen werden jedoch im alkalischen Bereich leicht zu Ir(III)-Verbindungen reduziert, die leicht hydrolisieren.

Berechnung von Ionenbeweglichkeiten

Mit Hilfe der Beziehung

$$\frac{E_1}{E_2} = \frac{u_2}{u_1} \quad \text{(I. Mitteilung, Gl. 2)}$$

läßt sich eine unbekannte Ionenbeweglichkeit, z.B. u_2, aus einer bekannten, u_1, und dem Verhältnis der Feldstärken E_1/E_2, die sich im stationären Zustand in den Zonen zweier Ionenarten einstellen, berechnen.

Wie im vorangegangenen Kapitel beschrieben, ist für eine Anzahl Trennungen der Feldstärkeverlauf im Trennspalt gemessen worden. Erwartungsgemäß ergibt sich bei

Verwendung verdünnter Lösungen in allen Fällen unabhängig von der Feldstärke und der Art der Kationen im stationären Zustand für bestimmte Anionen stets das gleiche Feldstärkeverhältnis. Innerhalb der Meßgenauigkeit stimmen die Ergebnisse mit den Literaturwerten überein.

Aus den Feldstärkeverhältnissen, die sich zwischen Ac^-- bzw. SO_4^{2-}-Ionen einerseits und $[IrBr_6]^{2-}$- und $[IrCl_6]^{2-}$-Komplexionen andererseits bei etwa 0° und *ca.* 0,01 n Lösungen einstellen, ergeben sich für diese Temperatur und Konzentration für die beiden Komplexionen folgende Beweglichkeiten:

$$u_{[IrCl_6]^{2-}} = 3{,}01 \cdot 10^{-4}\ [cm^2 \cdot V^{-1} \cdot sec^{-1}]$$

$$u_{[IrBr_6]^{2-}} = 2{,}63 \cdot 10^{-4}\ [cm^2 \cdot V^{-1} \cdot sec^{-1}]$$

Außer durch apparative Unzulänglichkeiten der einfachen Meßkammer werden Fehler durch die unterschiedliche Feldstärke in den einzelnen Zonen verursacht. Im Gebiet hoher Feldstärke, z.B. im Ac^--Bereich, entsteht mehr Joulesche Wärme pro Volumeneinheit als z.B. in der SO_4^{2-}-Zone. Deshalb ist mit gewissen Temperaturunterschieden, die die Ionenbeweglichkeit beeinflussen, zwischen den Zonen zu rechnen. Weitere Schwierigkeiten bereitet die stromlose Messung hoher Potentialdifferenzen.

Konzentrationsbestimmungen

Die Konzentrationsbestimmungen an der Meßkammer (Abb. 2) werden parallel zu den Feldstärkemessungen vorgenommen. Sie dienen der Bestätigung, daß sich nach Erreichen stationärer Verhältnisse die Konzentrationen der einzelnen Zonen entsprechend der Kohlrauschbeziehung und der Gl. 16 der 1. Mitteilung verhalten.

Entsprechend der allgemeinen Arbeitsweise stellt man bei Vorlage von Ac^--Ionen und mit Cl^-- bzw. SO_4^{2-}-Ionen in der Gegenstromlösung stationäre Verhältnisse ein, so daß die zur Kathode hin liegende Hälfte des Trennspalts mit Ac^--Ionen, die andere mit den Anionen der größeren Beweglichkeit besetzt ist. Der Ablauf der Gegenstromlösung wird bei stationärem Betrieb stundenweise aufgefangen. Die qualitative Analyse ergibt, daß es sich dabei um verdünnte Acetatlösungen handelt, in denen keine Anionen aus dem Gegenstromzulauf nachzuweisen sind.

Die Probenahme aus dem Trennspalt der Meßkammer geschieht sofort nach Abschalten des Versuchs, indem mit einer Injektionsspritze, deren Nadel durch die Meßstutzen gestoßen wird, aus den beiden getrennten Zonen etwa je 0,5 ml Lösung angesaugt werden. Je nach der verwendeten Gegenstromlösung handelt es sich bei den Proben um verdünnte wäßrige Lösungen von Lithiumchlorid bzw. Kaliumchlorid in der ersten Zone und um Lithiumacetat bzw. Kaliumacetat in der zweiten Zone. Die Konzentrationsbestimmungen erfolgen gravimetrisch nach Umwandlung in die Sulfate, die zur Trockne eingedampft, bei schwacher Rotglut geglüht und anschließend auf einer Mikrowaage ausgewogen werden.

Die Analysen zeigen, daß die Konzentration von Gegenstromzulauf und erster Zone sowie Gegenstromablauf und letzter Zone nicht, wie berechnet,[1] übereinstimmen. Die Konzentration in der ersten Zone liegt bis 10% höher als die des Gegenstromzulaufs. Dafür dürften u.a. in erster Linie elektroosmotische Strömungen verantwortlich sein.

Die Konzentrationen der beiden Zonen (Cl) und (Ac) im Trennspalt verhalten sich jedoch entsprechend der Beziehung:

$$\frac{c_{(Cl)}}{c_{(Ac)}} = \frac{u_{M(Ac)} + u_{Ac}}{u_{M(Cl)} + u_{Cl}} \cdot \frac{u_{Cl}}{u_{Ac}} \quad \text{(I. Mitteilung, Gl. 16)}$$

Bei Verwendung von Lithiumsulfat-, Lithiumchlorid-, Kaliumsulfat- und Kaliumchlorid-gegenstromlösungen verschiedener Konzentrationen ergeben sich für die Konzentrationsverhältnisse zwischen den Zonen im Trennspalt stets die von der obigen Beziehung geforderten Werte. Wie erwartet, wird der Konzentrationssprung zwischen den Zonen beim Austausch von K^+- gegen Li^+-Ionen erheblich kleiner.

Die vorliegende Arbeit wurde im Institut für Analytische Chemie und Radiochemie der Universität des Saarlandes durchgeführt. Wir danken dem Direktor des Instituts, Herrn Prof. Dr. E. Blasius, für Unterstützung und Diskussion und der Deutschen Forschungsgemeinschaft, dem Bundesminister für Wissenschaftliche Forschung sowie der Wissenschaftlichen Gesellschaft der Universität des Saarlandes für die Bereitstellung von Mitteln und Apparaturen.

Summary—By use of a new apparatus it has been possible to confirm the principle and course of countercurrent ionophoresis, by applying it to model anionic substances. Qualitative investigation showed that the anions were arranged between the anode and cathode according to their mobilities. For the formation of a stationary state the anions in the anode and countercurrent electrolytes must have greater mobility, and the anions of the effluent and cathode electrolytes a lower mobility, than the anions in the mixture to be separated. Field intensity measurements in a chamber with a capillary separation gap show that there is a sharp change in the field intensity at the boundaries of the stationary zones, and this intensity profile is responsible for the sharp separations obtained. By comparison of field intensity factors and known mobilities it is possible to calculate other ionic mobilities. The concentrations of ions in the zones can be calculated from the ionic mobilities and the concentration of the countercurrent solution.

Résumé—Par l'emploi d'un nouvel appareil, on a pu confirmer le principe et le développement de l'ionophorèse à contre-courant, en l'appliquant à des substances anioniques modèles. Une recherche qualitative a montré que les anions se répartissaient entre l'anode et la cathode selon leurs mobilités. Pour la formation d'un état stationnaire, les anions des électrolytes d'anode et de contre-courant doivent avoir une mobilité plus grande, et les anions des électrolytes d'écoulement et de cathode, une mobilité plus faible que les anions dans le mélange à séparer. Des mesures d'intensité de champ dans un compartiment avec un intervalle de séparation capillaire montrent qu'il y a un changement marqué dans l'intensité de champ aux séparations des zones stationnaires, et ce profil d'intensité est responsable des séparations nettes obtenues. Par comparaison des facteurs d'intensité de champ et de mobilités connues, il est possible de calculer d'autres mobilités ioniques. On peut calculer les concentrations des ions dans les zones à partir des mobilités ioniques et de la concentration de la solution de contre-courant.

CATION-EXCHANGE BEHAVIOUR OF SEVERAL ELEMENTS IN HYDROCHLORIC ACID—ORGANIC SOLVENT MEDIA

J. KORKISCH and S. S. AHLUWALIA
Analytical Institute, University of Vienna IX, Währingerstrasse 38, Austria

(*Received* 23 *June* 1966. *Accepted* 8 *September* 1966)

Summary—In the present paper the cation-exchange characteristics of 20 elements towards the strongly acidic cation-exchange resin Dowex 50X8 in media containing varying concentrations of organic solvents and aqueous hydrochloric acid were investigated. Based on the determination of the distribution coefficients of these elements in the organic solvents methanol, ethanol, n-propanol, isopropanol, methyl glycol, acetone, tetrahydrofuran, and acetic acid, the conditions most suitable for their quantitative separation are indicated and discussed.

IN comparison to the relatively large number of comparable data available for the cation-exchange behaviour of the elements in pure aqueous hydrochloric acid solutions,[1,2] no attempt has so far been made to investigate systematically the broad field of mixed aqueous—organic solvent media containing hydrochloric acid.

The exchange behaviour of lithium, sodium and potassium,[3–11] and of magnesium, calcium, strontium and barium[7,9,12,13] in methanol—hydrochloric acid media has been investigated. Some of these systems were applied to the effective separation of lithium from other alkali metals, *e.g.*, by using 90% methanol—10% 12*M* hydrochloric acid as eluent for the lithium.[9] Under these conditions the distribution coefficients of lithium and sodium for example are 2 and 41 respectively. In media containing phenol as well as methanol and hydrochloric acid, lithium was separated from sodium and potassium.[14]

Cation-exchange separations of lithium, sodium and potassium[11,15] in ethanol—hydrochloric acid media have been reported and the adsorption of indium studied.[16]

In hydrochloric acid solutions containing isopropanol, uranium was separated from large quantities of bismuth.[17]

Relatively great attention has been paid to cation-exchange studies and separations of various elements with acetone—hydrochloric acid mixtures as eluents. They have been used to fractionate lithium, sodium and potassium;[5,18] to separate calcium from copper, zinc, mercury(II), cadmium, and iron(III);[19] copper from nickel;[20] iron, copper, zinc, and lead from cobalt and manganese; these metals from the alkali metals, alkaline earths, magnesium, molybdate, sulphate and phosphate;[21] and to separate bismuth, cadmium, indium, zinc, iron(III), copper(II), uranium(VI), cobalt, gallium and manganese(II).[22,23] Acetone—hydrochloric acid solutions as eluting agents have also been employed to separate copper and zinc.[24,25] The adsorption of cerium(III) and praseodymium(III) in acetone media was studied.[26] The behaviour of the latter rare earth element was also investigated in hydrochloric acid systems containing methanol, ethanol, isopropanol, methyl ethyl ketone and glycol.[27]

Similarly in the same solvent—hydrochloric acid mixtures the adsorption behaviour of scandium was studied,[28] and a method for the separation of copper from iron with ethyl methyl ketone—hydrochloric acid as eluent was reported.[20] An effective separation of large amounts of iron(III) from cobalt, nickel and aluminium is possible by using tetrahydrofuran—hydrochloric acid mixtures as eluents.[29]

From this literature survey it is seen that cation-exchange in hydrochloric acid—organic solvent media has received attention only with respect to the solution of specific separation problems or has been used to study the adsorption behaviour of several metal ions in only one solvent or of only one or a small group of elements in several different organic solvents. The correlation of the various adsorption data obtained in these media by the various authors is extremely difficult because cation-exchange resins of various types were used. For this reason and to obtain a more complete picture of the adsorption characteristics and separation possibilities of elements in organic solvent media, the research work presented in this paper was performed, using the most frequently employed cation-exchange resin Dowex 50 in mixtures of 8 organic solvents containing hydrochloric acid. For this purpose the effect of increasing concentration of organic solvent from 0 to 90% in solutions with a constant overall acidity of 0·6*M* hydrochloric acid, and the effect of acidity ranging from 0·15 to 1·2*M* overall acidity at the constant concentration of organic solvent of 90%, were investigated by measuring the distribution coefficients in these media. From the distribution coefficients thus obtained, the possibilities of separating the elements investigated from one another are indicated and discussed.

EXPERIMENTAL

Reagents

Ion-exchange resin. The air-dried strongly acidic cation-exchanger Dowex 50X8 (100–200 mesh, hydrogen form) was used for the batch experiments.

Standard solutions. Exactly weighed amounts of Mg, Ca, UO_2(II), Mn(II), Co, Ni, Cu(II), Zn, Cd, Pb, Fe(III), Al, Ga, In, Bi, Th, Zr, Ce(III), V(V) and Mo(VI) as chlorides were dissolved in 6*M* or 12*M* hydrochloric acid to give solutions containing 5 mg of the element/ml.

Solvents. The reagent-grade pure organic solvents used were: methanol, ethanol, n-propanol, isopropanol, methyl glycol, acetic acid, tetrahydrofuran and acetone.

Determination of the various elements

Most of the elements investigated (in amounts exceeding *ca.* 100 μg) were determined titrimetrically, by suitable chelatometric methods with EDTA (disodium salt) as the titrant. Uranium was determined fluorometrically[30] and microgram quantities of the other elements were determined spectrophotometrically.[31]

Determination of distribution coefficients

The weight distribution coefficient is defined by the equation:

$$K_d = \frac{\mu\text{g of element/g of resin}}{\mu\text{g of element/ml of solution}}.$$

The method employed for determining the distribution coefficients of the elements in the various mixtures was the batch equilibrium method (batch method). Each equilibrium experiment was performed with 20 ml of a mixture consisting of 0–90% of the organic solvent, 10% of hydrochloric acid, and water up to 100%, and containing 5 mg of the element in question. To this mixture 1 g of resin was added and the solution was agitated on a shaking machine for 12 hr, then the resin was filtered off and the element determined in the filtrate. The experimental error of the measurements of the distribution coefficients was usually ±5–10% for low K_d-values (below 100), but for high values an error of 10–20% was frequently observed.

RESULTS AND DISCUSSION

In Tables I—XVII the metal ions are arranged in the same order. The distribution coefficients of cerium and thorium were in all cases larger than 2×10^3 and were not determined exactly. In those cases in which results are not given, experimental difficulties were encountered (*e.g.*, in the case of lead and aluminium the solubility was often too small).

Aliphatic Alcohol Media

In Tables I–IV, IX–XII, the distribution coefficients measured in hydrochloric acid—aliphatic alcohol mixtures (methanol, ethanol, n-propanol and isopropanol) are shown.

Uranium(VI), thorium(IV), zirconium(IV) and cerium(III)

It is seen that in all cases the adsorption of uranium is less than that of thorium. With increasing concentration of the aliphatic alcohol the uranium adsorption decreases, while that of thorium remains virtually constant so that a separation of uranium from thorium is possible. Cerium and zirconium show a behaviour similar to thorium. Thus these elements can be separated from uranium but not from thorium. It is to be expected that other lanthanide ions will behave very similarly to cerium.

When the concentration of hydrochloric acid is increased, the adsorption of uranium decreases considerably while the adsorption of thorium, cerium and zirconium is only slightly affected by a change in the acidity of the hydrochloric acid—aliphatic alcohol mixtures. Therefore a ready separation of uranium from thorium, cerium and zirconium is possible at 0·6*M* or higher overall acidities of the mixtures.

Molybdenum(VI) and vanadium(V)

These show identical behaviour in methanol, ethanol and isopropanol, but in n-propanol—hydrochloric acid media a separation of molybdenum from vanadium should be possible because molybdenum is much less strongly adsorbed than vanadium.

Both molybdenum and vanadium are practically non-adsorbable from 90% alcoholic media, so no separation is possible in this way in any of the alcohols.

Iron(III), aluminium(III), gallium(III), indium(III) and bismuth(III)

At all concentrations of aliphatic alcohols investigated indium is practically not retained by the resin except from 60% isopropanol, from which it is retained slightly. A similar behaviour is shown by bismuth although in some cases rather irregular variations of its K_d values occur.

In all hydrochloric acid—aliphatic alcohol mixtures gallium shows maximum adsorption at 60% of alcohol and then the distribution coefficient decreases considerably when the alcohol concentration is increased to 90%.

Aluminium is in all cases strongly adsorbed at practically all alcohol concentrations, with 80% alcohol mixtures a separation of aluminium from gallium and indium in all four aliphatic alcohols is possible.

In practically all media the K_d-value of iron(III) decreases with an increase in the concentration of the organic component of the mixtures.

An increase in the acid concentration does not change the adsorbability of aluminium appreciably. It is strongly adsorbed at all hydrochloric acid concentrations (at an overall acidity of 1·2*M* hydrochloric acid, the solubility of aluminium chloride is very small so that no measurements of the distribution coefficients were possible under these conditions).

Because indium is not adsorbed over the acidity range from 0·15 to 1·2*M* hydrochloric acid and the adsorption of iron(III) decreases very strongly with increasing acidity, a separation of iron or indium from aluminium can be performed in all four aliphatic alcohols.

Magnesium(II), calcium(II) and lead(II)

When the alcohol concentration is increased the adsorption of these ions shows only a slight increase. A simple separation of the first two is not possible because of the similarity of their distribution coefficients. Thus a fractionation of these metal ions would only be possible by means of elution chromatography.

TABLE VII.—DISTRIBUTION COEFFICIENTS IN 0·6*M* HYDROCHLORIC ACID IN AQUEOUS TETRAHYDROFURAN

Ion	Tetrahydrofuran concentration, %					
	0	20	40	60	80	90
UO_2(II)	40	77	76	77	11	<1
Th(IV)	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$

Ce(III)	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$
Mo(VI)	~2	~2	~2	~2	~2	~2
V(V)	5	~5	~5	~5	4	3
Fe(III)	84	166	134	17	~1	~1
Al(III)	186	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$
Ga(III)	242	268	704	39	8	~1
In(III)	1	<1	<1	<1	<1	<1
Bi(III)	<1	<1	<1	<1	<1	<1
Mg(II)	33	38	60	109	159	179
Ca(II)	74	188	207	281	422	655
Pb(II)	~1	16	10	4	<1	<1
Zn(II)	39	24	10	<1	<1	<1
Cd(II)	6	<1	<1	<1	<1	<1
Cu(II)	32	34	41	29	<1	<1
Mn(II)	80	184	274	292	355	176
Co(II)	44	52	69	138	108	6
Ni(II)	46	52	95	172	227	113

With an increase in acidity, the K_d-values of calcium and magnesium which are greater than 2×10^3 decrease slightly. As in the case of the 0·6*M* hydrochloric acid—aliphatic alcohol mixtures a separation of these two elements from each other would also be rather difficult at lower or higher concentrations of this acid.

A similar adsorption behaviour is observed in the case of lead although its distribution coefficient is in all cases smaller than that of the alkaline earth ions.

Zinc(II) and cadmium(II)

The adsorption of zinc from methanol, ethanol and n-propanol decreases when the concentration of the organic component in the mixtures is increased. If the amount of alcohol is 80% or higher, zinc is not retained at all by the resin. From the isopropanol—hydrochloric acid mixtures zinc is adsorbed to the same extent at all alcohol concentrations.

In methanol, ethanol and isopropanol media the adsorption of cadmium decreases with an increase of the alcohol concentration while in n-propanol no change of the

distribution coefficient of cadmium by variation of the alcohol content of the mixtures is observed.

Separations of zinc from cadmium should be possible in all four hydrochloric acid—alcohol systems. The best separation can very probably be obtained when using as eluent a hydrochloric acid—isopropanol mixture containing a high percentage of this alcohol.

At higher hydrochloric acid concentrations both elements are only very weakly adsorbed so that separations in such mixtures are not readily possible.

Co(II)	44	56	80	169	77	<1
Ni(II)	46	55	111	220	250	227

Copper(II) and manganese(II)

The adsorption of copper increases slightly as the concentration of aliphatic alcohol increases to 80%, whereafter it decreases. The adsorption of manganese increases in methanol, ethanol and isopropanol mixtures. A separation of copper from manganese is easily possible in hydrochloric acid—isopropanol mixtures.

When the concentration of hydrochloric acid increases the adsorption of copper decreases rapidly while that of manganese does not show pronounced variations.

A separation of copper from manganese is possible in media of higher hydrochloric acid concentrations containing methanol, n-propanol or isopropanol. From ethanol solutions both elements are retained by the resin to about the same extent so that no separations are possible.

Cobalt(II) and nickel(II)

In virtually all cases cobalt and nickel show the same adsorption behaviour and their K_d-values increase with increasing concentration of aliphatic alcohol. Because the K_d-value of iron(III) decreases when the concentration of the organic components of the mixtures is increased, a separation of cobalt and nickel from iron is possible in

methanol, ethanol and n-propanol. From an isopropanol medium all three elements are adsorbed to about the same extent.

When the concentration of hydrochloric acid is increased cobalt and nickel are decreasingly adsorbed from all four alcohols. A separation of these two elements from iron is possible when the hydrochloric acid concentration is 0·6*M* or higher.

Methyl Glycol Media

The results of measurements of the distribution coefficients of the various elements in hydrochloric acid—methyl glycol media are shown in Tables V and XIII.

Uranium(VI), thorium(IV), zirconium(IV) and cerium(III)

The behaviour of these elements with increasing methyl glycol concentration is virtually the same as that observed in the hydrochloric acid—aliphatic alcohol mixtures. A fractionation of thorium, zirconium and cerium is not possible but these three elements can be separated as a group from uranium. While the adsorption behaviour of uranium in media containing up to 80% methyl glycol is very similar to that observed in the aliphatic alcohols a further increase in methyl glycol concentration decreases the K_d-value of uranium considerably. This is in accordance with observations made earlier with respect to its adsorption behaviour towards the strongly basic anion-exchange resin Dowex 1 on which it is exceptionally strongly adsorbed from a mixture consisting of 90% methyl glycol and 10% 6*M* hydrochloric acid,[32,33] *i.e.*, in such a medium it forms a very stable anionic chloro-complex and hence is not retained by Dowex 50.

Molybdenum(VI) and vanadium(V)

These two elements show an adsorption behaviour similar to that observed in methanol, ethanol and n-propanol media and a separation of molybdenum from vanadium is impossible.

Iron(III), aluminium(III), gallium(III), indium(III) and bismuth(III)

As in the aliphatic alcohol media the adsorption of iron(III) decreases considerably at high methyl glycol concentrations. Aluminium is strongly adsorbed at all concentrations of this organic solvent. The same applies to gallium up to concentrations of 60% methyl glycol, whereafter the adsorption decreases. Indium is not taken up by

TABLE XIV.—DISTRIBUTION COEFFICIENTS IN 90% ACETIC ACID MIXTURES CONTAINING 10% OF HYDROCHLORIC ACID OF VARIED MOLARITY

Ni(II)	>10^3	>10^3	>10^3	25	20

the resin at any methyl glycol concentration. A methyl glycol concentration of 70% seems to be the best medium to effect a separation of aluminium, gallium and indium. In contrast to its behaviour in the aliphatic alcohols bismuth is rather strongly retained by the resin, especially at higher concentrations of methyl glycol.

Magnesium (II), calcium (II), lead (II), zinc (II), cadmium (II), copper (II) and manganese (II)

These elements show in hydrochloric acid—methyl glycol media a behaviour which is similar to that observed in the aliphatic alcohols. A separation of copper from manganese can be effected in 90% methyl glycol.

Cobalt (II) and nickel (II)

In methyl glycol—hydrochloric acid solutions cobalt and nickel show about the same behaviour as in methanol, ethanol and n-propanol media, and can be separated from iron(III). Their separation together with aluminium, bismuth, manganese, calcium and magnesium from iron can also be effected.

At lower hydrochloric acid concentrations the behaviour of cobalt and nickel is virtually the same as in the methanol media of comparable acidity. There exists however, the possibility of separating cobalt from nickel when the acidity is increased above 0·9*M* hydrochloric acid. Furthermore a separation of iron from cobalt can be effected.

Acetone and Tetrahydrofuran Media

In Tables VII, VIII, XV and XVI are shown the results of determinations of the distribution coefficients of the various metal ions in acetone and tetrahydrofuran media containing hydrochloric acid. The elements show a similar behaviour in both organic solvents.

TABLE XVII.—DISTRIBUTION COEFFICIENTS IN HYDROCHLORIC ACID OF VARIED MOLARITY

Ni(II)	369	177	46	20	18

Uranium (VI), thorium (IV), zirconium (IV) and cerium (III)

Thorium, cerium and zirconium show the same behaviour as in the organic solvent media discussed before. The adsorption of uranium decreases with increasing concentration of the organic component. A separation of thorium, cerium and zirconium from uranium is possible at higher concentrations of acetone or tetrahydrofuran, while thorium, cerium and zirconium cannot be fractionated at any concentrations of these two solvents.

At higher hydrochloric acid concentrations uranium is practically not adsorbed whereas thorium, cerium and zirconium are still strongly retained and hence their separation from uranium is easily possible.

Other elements

Vanadium, molybdenum, aluminium, gallium, indium, calcium, magnesium, zinc, cadmium, lead, copper and manganese show a behaviour similar to that observed in the media discussed earlier.

With tetrahydrofuran as the organic component of the mixtures a good separation of copper from manganese is possible at a tetrahydrofuran concentration of 90%. A similar separation can be effected when the acetone concentration is 80%.

A complete separation of iron(III), cobalt and nickel is possible by using in succession 80% tetrahydrofuran—20% 3*M* hydrochloric acid and 90% tetrahydrofuran—10% 6*M* hydrochloric acid mixtures as eluents. From a column of Dowex 50 the first eluent removes the iron(III) and then cobalt is removed by the second eluent, leaving nickel on the resin.[29]

At lower hydrochloric acid concentrations separations of the following pairs of metal ions can also be carried out: in both solvents: aluminium—indium, aluminium—iron, cobalt—nickel and iron—nickel.

A separation of uranium from large amounts of bismuth can be effected by using a mixture of isopropanol and aqueous hydrochloric acid.[34]

Acetic Acid Media

The results of measurements of distribution coefficients of the elements in acetic acid media containing hydrochloric acid are shown in Tables VI and XIV. A comparison of these with those representing the systems discussed before shows that the behaviour of the elements in acetic acid is very similar to that in the other organic solvents so that no detailed discussion will be presented.

Water Media

In Table XVII the behaviour of the elements in pure aqueous solutions containing varying concentrations of hydrochloric acid is shown. In these systems fewer possibilities exist for the separation of the various metal ions from one another than in the media containing organic solvents. That this is generally true has been amply demonstrated[35] and can in several cases be explained theoretically by the CIESE-effect.[29,36,37]

Résumé—On a étudié, dans le présent mémoire, les caractéristiques d'échange cationique de 20 éléments vis-à-vis de la résine cationique fortement acide Dowex 50X8 dans des milieux contenant des concentrations variables de solvants organiques et d'acide chlorhydrique aqueux. En se basant sur la détermination des coefficients de partage de ces éléments dans les solvants organiques méthanol, éthanol, n-propanol, isopropanol, méthylglycol, acétone, tétrahydrofuran et acide acétique, on indique les conditions les plus convenables pour leur séparation quantitative et en discute.

Zusammenfassung—In dieser Arbeit wurden die Kationenaustauscheigenschaften von 20 Elementen am stark sauren Kationenaustauscharz Dowex 50X8 untersucht in Medien, die organische Lösungsmittelen. und wäßrige Salzsäure in verschiedenen Konzentrationen enthielten. Auf Grund der Bestimmung der Verteilungskoeffizienten dieser Elemente in den organischen Lösungsmitteln Methanol, Äthanol, n-Propanol, Isopropanol, Methylglycol, Aceton, Tetrahydrofuran und Essigsäure werden die besten Bedingungen für ihre quantitative Trennung angegeben und diskutiert.

(*Received* 2 *June* 1966. *Accepted* 8 *August* 1966)

Summary—The uranyl ion forms only 1:1 chelates with 4-(2-thiazolylazo)resorcinol (TAR) in solution, $UO_2(TAR)H^+$ being formed below pH 3 and $UO_2(TAR)$ above pH 3·5. The latter complex may also be precipitated at pH > 3. The quantitative formation of $UO_2(TAR)$ at pH 7·5–7·8 in solutions containing a small excess of reagent and some triethanolamine as buffer can be used for the sensitive spectrophotometric determination of uranium. Several interfering ions can be masked with a mixture of sodium fluoride, cyclohexanediaminetetraacetic acid and 5-sulphosalicylic acid. TAR is slightly less sensitive than 4-(2-pyridylazo)resorcinol as a reagent for uranium but is more selective.

THE *o*-substituted azo-dyes and bisazo-dyes are among the most sensitive reagents for spectrophotometric determination of uranium in aqueous solution. Heterocyclic azo-dyes with an aromatic nucleus containing a nitrogen atom *ortho* to the azo group also react with the uranyl ion with great sensitivity over a wide range of pH. Of the pyridylazo dyes, the most common, 1-(2-pyridylazo)-2-naphthol (PAN) and 4-(2-pyridylazo)resorcinol (PAR),[1–10] have been used frequently for the spectrophotometric determination of uranium, and their complexation equilibria have been widely studied. PAR is soluble in water and so are its metal chelates, which gives it an advantage over PAN, the metal chelates of which are usually extracted into organic solvents.

Little information is available about the reaction of uranyl ion with thiazolylazo dyes, except for 1-(2-thiazolylazo)-2-hydroxy-4-dimethylaminobenzene,[11] 2-(2-thiazolylazo)-1-hydroxy-5-diethylaminobenzene[12] and 4-(2-thiazolylazo)resorcinol (TAR).[13] Because of its similarity to PAR, TAR aroused our interest in it as a possible analytical and complex-forming reagent. Its reaction with the uranyl ion is described in detail in this paper, and it is shown that TAR is a very useful reagent for the spectrophotometric determination of uranium.

EXPERIMENTAL

Reagents

Uranyl nitrate solution. A stock solution was made by dissolving 49·8 g of uranyl hexahydrate in 100 ml of 1*M* perchloric acid and diluting the solution to 1 l. It was standardized gravimetrically

via triuranium octaoxide, and contained 23·83 mg of uranium/ml. To prevent hydrolysis, the perchloric acid concentration must not fall below 0·1*M*.

TAR. A sample from Lachema, Brno, was recrystallized twice from ethanol in the presence of activated carbon, and dried over calcium chloride hemihydrate to constant weight. The purity of the sample was checked by elemental analysis, ash determination, and potentiometric titration in dimethylformamide–hydrochloric acid medium with chromous chloride.[14] Reagent solutions in ethanol or in dimethylformamide were used, but the concentrations of these solvents in the final solutions never exceeded 4 and 30% v/v respectively.

Control of pH. The pH was adjusted by addition of dilute sodium hydroxide, ammonia, or perchloric acid solutions, and buffers were used only in the determination of uranium. The ionic strength was kept constant at 0·1 by addition of sodium perchlorate.

All chemicals used were analytically pure.

Apparatus

Spectrophotometer. Model SF-4 (USSR) with 1 cm cells.

pH *Meter.* Radiometer PHM 3k, precision ±0·02 pH units.

THE REACTION OF THE URANYL ION AND TAR

At pH $\leqslant$ 3 a soluble red uranyl chelate is formed; the colour of the reagent is yellowish orange in these conditions. At pH $>$ 3·5 the colour of the chelate solution is red-violet, and is intensified by a small excess of ligand or a large excess of metal ion.

The chelating equilibria and the composition and stability of the chelates were studied spectrophotometrically by graphical and numerical analysis of pH–absorbance curves for solutions containing various ratios of metal ion and ligand,[15,16] by the method of continuous variations,[17] by the slope-ratio method,[18] and the mole-ratio method at selected pH values.[19]

All the results in this paper are for solutions containing not more than 4% v/v of ethanol; this amount of ethanol does not affect the results. The pH_k values are valid for 30% v/v dimethylformamide solution and have not been recalculated for true hydronium concentration.

Acid–base equilibria of TAR

The concentrations of the ligand species present in solution (H_3R^+, H_2R, HR^-, R^{2-}) are determined by the acid dissociation constants $pK_{a1} = 0{\cdot}96$, $pK_{a2} = 6{\cdot}23$, $pK_{a3} = 9{\cdot}44$.[20] Only the first two proved to be important, and the wavelengths of maximum absorption were 488 mμ for H_3R^+ and 410–440 mμ for H_2R. The molar absorptivities of these species at 530 mμ were $1{\cdot}15 \times 10^4$ and $2{\cdot}4 \times 10^2$ mole^{-1}. cm^2 respectively.

Absorption spectra of the uranyl chelates

The absorption curves for solutions containing an excess of metal ion, and for equimolar mixtures of the reagents, at pH $<$ 5, have a maximum at 530 mμ and an isosbestic point at 470–475 mμ (Figs. 1 and 2). An additional inflexion in the spectrum of the chelate corresponds to deformation of the ligand absorption maximum at 440 mμ and is similar to that previously found for metal chelates of TAR.[20] For solutions with a small (1- to 5-fold) excess of reagent, the absorption maximum of the chelate is shifted to 540–545 mμ at pH $>$ 5 (after correction for the absorbance due to the free ligand).

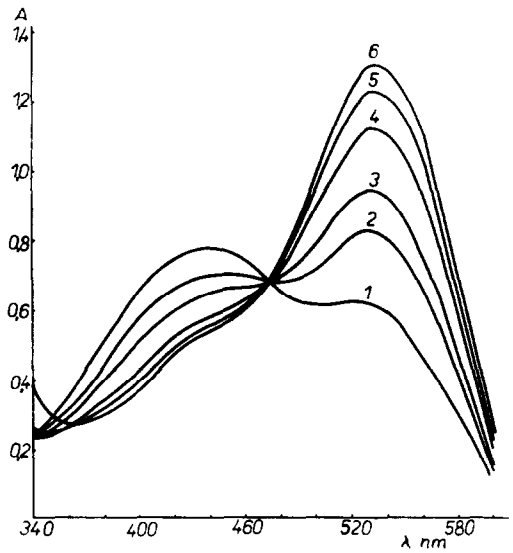

FIG. 1.—Absorption spectra for UO_2^{2+} and TAR in 4% aqueous ethanol.
$C_M = 5{\cdot}0 \times 10^{-5}M$; $C_R = 5{\cdot}0 \times 10^{-5}M$
pH: *1*—2·03; *2*—2·32; *3*—2·55; *4*—3·08; *5*—3·55; *6*—3·98.

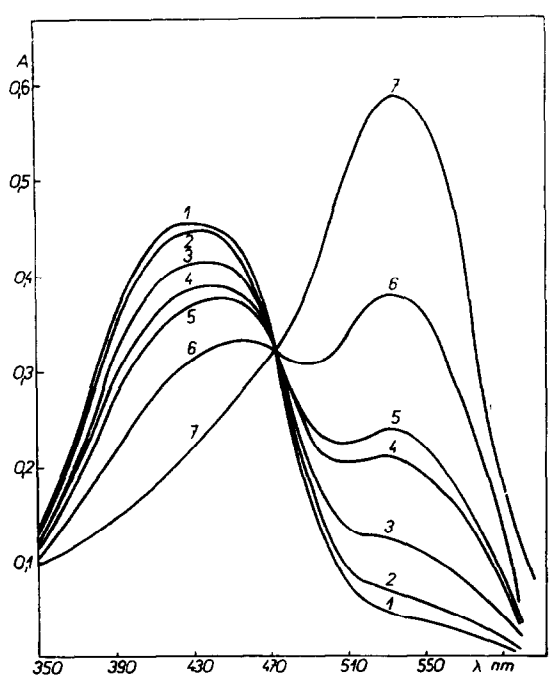

FIG. 2.—Absorption spectra for equimolar UO_2^{2+} and TAR in 20% aqueous ethanol.
$C_M = C_R = 2{\cdot}5 \times 10^{-5}M$
pH_k: *1*—3·26; *2*—3·45; *3*—3·94; *4*—4·10; *5*—4·29; *6*—4·42; *7*—5·65.

pH-Absorbance curves and their interpretation

Previous experience with TAR complexes of metal ions[20] led to the assumption that only 1:1 and 1:2 chelates need be taken into account in interpreting the pH-absorbance curves.

Solutions containing metal ion in excess at pH $\leqslant$ 3·5. Plots of absorbance *vs.* pH give curves which are shifted towards lower pH values as the concentration ratio of metal ion to reagent is increased, and the length of the linear portion of the curves is simultaneously decreased. The curves show a distinct change of slope with increase

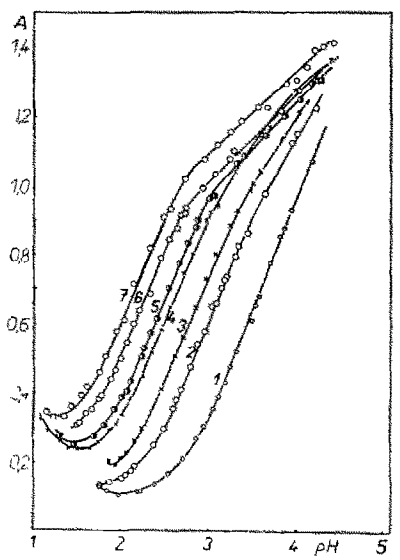

FIG. 3.—pH-Absorbance curves for TAR solutions with excess of UO_2^{2+}, measured at 530 mμ, in 4% aqueous ethanol.
$C_R = 5 \times 10^{-6} M$; C_M/C_R: *1*—4; *2*—10; *3*—16; *4*—25; *5*—50; *6*—80; *7*—100.

in pH if the concentration ratio is high (Fig. 3). It is suggested that above pH 3 the H_3R^+ and H_2R forms of the reagent react according to the equilibria

$$UO_2^{2+} + H_3R^+ \leftrightharpoons UO_2RH^+ + 2H^+ \quad \text{(I)}$$

$$UO_2^{2+} + H_2R \leftrightharpoons UO_2RH + H^+. \quad \text{(II)}$$

To check this suggestion, the curves were analysed graphically by means of the transformations $C_R/A = f[H]^n$ and $\log X = f(\log C_M, \text{pH})$, where C_R and C_M are the analytical concentrations of reagent and metal ion respectively, A is the absorbance and [H] is the hydrogen ion concentration. In addition, the molar absorptivity of the complex and the equilibrium constant were calculated from two points on the curve (absorbances A_1 and A_2) by means of the following set of equations, where ε_{1H} is the molar absorptivity of the complex, ε_{R1} and ε_{R2} are the molar absorptivities of the species H_3R^+ and H_2R respectively, M represents UO_2, the constants are defined by the equations, and the charges are omitted.

H_2R *and* H_3R^+ *are present but only* H_3R^+ *reacts, by equilibrium* (I)

$$k_{12} = \frac{[MRH][H]^2}{[M][H_3R]}$$

$$C_M = [M] + [MRH] \sim [M]$$

$$C_R = [H_3R] + [H_2R] + [MRH]$$

$$A = \varepsilon_{1H}[MRH] + \varepsilon_{R1}[H_3R] + \varepsilon_{R2}[H_2R]$$

$$k_{12} = \frac{a[H]^2}{C_M(\varepsilon_{1H}C_R - A)} \tag{1}$$

$$\varepsilon_{1H} = \frac{a_1[H]^2 A_2 - a_2[H]_1^2 A_1}{C_R(a_1[H]_1^2 - a_2[H]_2^2)} \tag{2}$$

$$C_R/A = \frac{1}{\varepsilon_{1H}} + \frac{a[H]^2}{AC_M k_{12}\varepsilon_{1H}} \tag{3}$$

$$\log \frac{a}{\varepsilon_{1H}C_R - A} = \log k_{12} + \log C_M + 2\text{pH} \tag{4}$$

$$a_n = A_n(1 + K_{a1}[H]_n - C_R(\varepsilon_{R1} + \varepsilon_{R2}K_{a1}/[H]_n). \tag{5}$$

H_2R *and* H_3R^+ *are present but only* H_2R *reacts, according to equilibrium* (II)

$$k_{11} = \frac{[MRH][H]}{[M][H_2R]} = \frac{a[H]}{C_M(\varepsilon_{1H}C_R - A)} \tag{6}$$

$$\varepsilon_{1H} = \frac{a_1[H]_1 A_2 - a_2[H]_2 A_1}{C_R(a_1[H]_1 - a_2[H]_2)} \tag{7}$$

$$C_R/A = \frac{1}{\varepsilon_{1H}} + \frac{a[H]}{AC_M k_{11}\varepsilon_{1H}} \tag{8}$$

$$\log \frac{A - A_0}{\varepsilon_{1H}C_R - A} = \log C_M + \text{pH} + \log k_{11} \tag{9}$$

$$A_0 = \frac{C_R(\varepsilon_{R1}[H] + \varepsilon_{R2}K_{a1})}{[H] + K_{a1}}. \tag{10}$$

H_2R *only is present*

$$C_R = [MRH] + [H_2R]$$

$$A = \varepsilon_{R2}[H_2R] + \varepsilon_{1R}[MRH]$$

$$C_R/A = \frac{1}{\varepsilon_{1H}} + \frac{(A - \varepsilon_{R2}C_R)[H]}{AC_M k_{11}\varepsilon_{1H}} \tag{11}$$

$$\log \frac{A - \varepsilon_{R2}C_R}{\varepsilon_{1H}C_R - A} = \log C_M + \log k_{11} + \text{pH}. \tag{12}$$

The values for ε_{1H} and k_{11} calculated from equations (6) and (7) agree well with other values for these constants (Table I), and confirm that equilibrium (II) occurs at pH $\geqslant$ 1·82 and $C_M = 5 \times 10^{-3}M$. The splitting off of one proton was further confirmed by the straight line obtained for equations (8) and (9) when the value of ε_{1H} calculated from equation (6) (Fig. 4) was used. When equilibrium (I) was considered, the dispersion of values of k_{12} calculated from equation (1) was larger

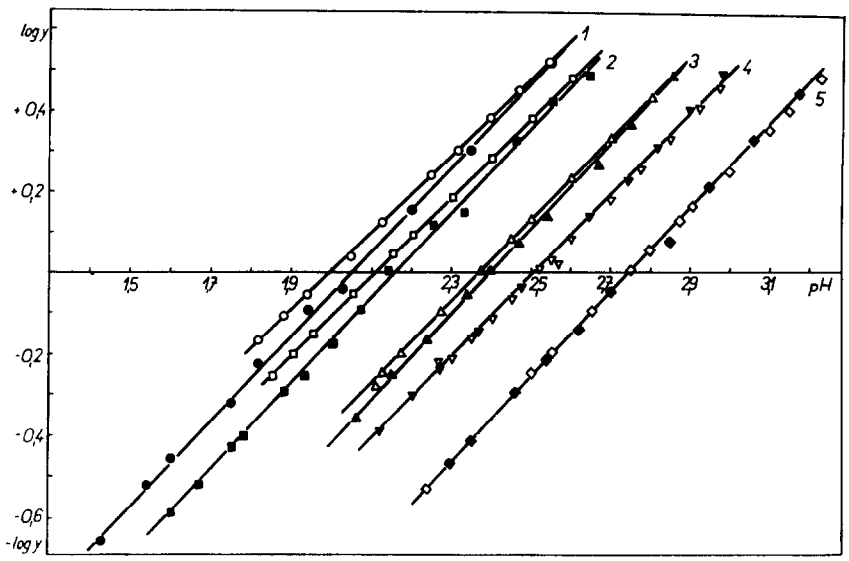

FIG. 4.—Analysis of linear portions of pH-absorbance curves.
$C_R = 5 \times 10^{-5}M$; C_M/C_R: *1*—100; *2*—80; *3*—50; *4*—25; *5*—16
Open points: $y = \log [(A - \varepsilon_{R_2}C_R)/(\varepsilon_{1H}C_R - A)]$
Filled points: $y = \log (A - A_0)/(\varepsilon_{1H}C_R - A)$ where
$A_0 = C_R(\varepsilon_{R1}[H] + \varepsilon_{R_2}K_{a1})/([H] + K_{a1})$.

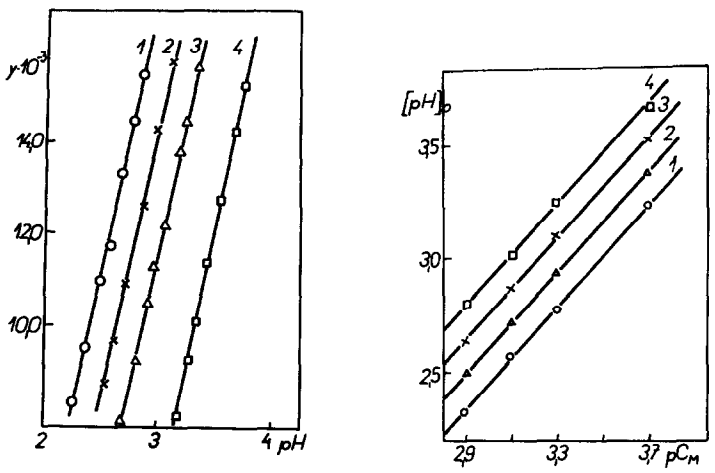
($k_{12} = 0{\cdot}07$–$0{\cdot}21$ for $C_M = 2{\cdot}5 \times 10^{-3} - 5 \times 10^{-3}M$ and $C_R = 5 \times 10^{-5}M$). The existence of H_3R^+ can be neglected at pH > 2·5 and $C_M < 2{\cdot}5 \times 10^{-3}M$ in the interpretation of the pH-absorbance curves. The points on the straight lines for the log functions calculated from equation (11) coincide well with those obtained from equation (9) (Fig. 4). For $C_M > 2{\cdot}5 \times 10^{-3}M$ the deviation of both lines increases rapidly.

By comparison of the family of pH-absorbance curves for various C_M-values, put in the form $pH = f(A - \varepsilon_{R2}C_R)/C_R$ or $pH = \log (A - A_0)/(\varepsilon_{1H}C_M - A)$, a linear plot (Fig. 5a) can be derived for corresponding solutions with equal values of the apparent molar absorptivity:

$$pH_{0i} = (-\log C_M)m/x + \text{constant} \qquad (12)$$

where pH_{0i} represents the pH values for corresponding solutions, m is the number of metal ions bond in the chelate and x is the number of protons split off during chelation.

The results (Fig. 5b) confirm the loss of one proton and the formation of mononuclear MRH at pH 2–3·5, C_M $2{\cdot}9 \times 10^{-3}$–$3{\cdot}7 \times 10^{-3}M$ and C_R $5 \times 10^{-5}M$ (*i.e.*,



(a) (b)

FIG. 5a.—The pH dependence of the apparent molar absorptivity of the uranyl-TAR complex in 4% aqueous ethanol.
$C_R = 5 \times 10^{-5} M$; C_M/C_R: *1*—25; *2*—16; *3*—10; *4*—4 $y = (A - \varepsilon_{R_2} C)/C_R$
FIG. 5b.—Plot of pH $= f(-\log C_M)$ for the corresponding solutions.
$x = (A - \varepsilon_{R_2} C_R)/C_R$.

over the linear lower part of the pH-absorbance curves). In the upper part of the pH-absorbance curves a different equilibrium exists which under certain conditions corresponds to

$$UO_2RH^+ \leftrightharpoons UO_2R + H^+ \qquad \text{(III)}$$

and the equations

$$k_1' = \frac{[MR][H]}{[MRH]}$$

$$C_M \sim [M]$$

$$C_R = [MRH] + [MR]$$

$$A = \varepsilon_{1H}[MRH] + \varepsilon_1[MR]$$

$$k_1' = \frac{(A - \varepsilon_{1H}C_R)[H]}{\varepsilon_1 C_R - A} \qquad (13)$$

$$C_R/A = \frac{1}{\varepsilon_1} + \frac{(A - \varepsilon_{1H}C_R)[H]}{Ak_1'\varepsilon_1} \qquad (14)$$

$$A = \varepsilon_1 C_R - \frac{(A - \varepsilon_1 C_R)[H]}{k_1'} \qquad (15)$$

$$\log \frac{A - \varepsilon_{1H}C_R}{\varepsilon_1 C_R - A} = npH + \log k_1' \qquad (16)$$

where ε, is the molar absorptivity of MR.

For the calculation of ε_1 and k_1' the values of ε_{1H} calculated for the equilibrium (II) postulated as existing for the lower part of the pH curves were used for solutions with

the same concentration of metal ion. The graphical transformations (14) and (15) were most useful for calculating ε_1 simply, and equations (13) and (16) were used for calculation of k_1' (Fig. 6). Consistent values of ε_1 and k_1' were obtained only over limited ranges of pH and metal ion concentration (see Table I): C_R $5 \times 10^{-5}M$; pH 3·40–4·08, C_M $5 \times 10^{-3}M$; pH 3·70–4·50, C_M $4 \times 10^{-3}M$; pH 3·85–4·70, C_M $2{\cdot}5 \times 10^{-3}M$.

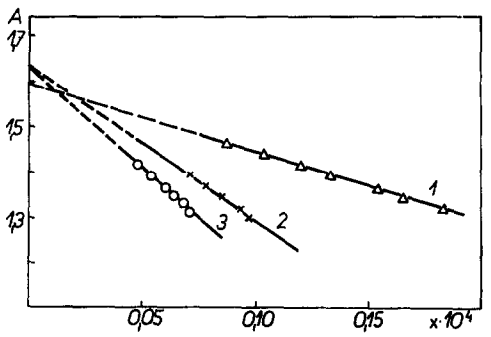


FIG. 6.—Plot of A *vs.* $\varepsilon_1 C_R - (A - \varepsilon_{1H} C_R)[H]/k_1'$ for the second linear portion of the pH-absorbance curves.
$C_R = 5 \times 10^{-5}M$; C_M/C_R: *1*—100; *2*—80; *3*—50.

Below these ranges, MRH is also often present and causes a large deviation in the calculated values, *e.g.*, at pH $< 2{\cdot}7$ and $C_M/C_R = 100$, the value for ε_1, $2{\cdot}33 \times 10^4$, was practically the same as that of ε_{1H}, and a negative value was obtained for k_1', which could have no physical significance. In such a case formation of MRH according to equilibrium (II) must predominate.

Equimolar solutions and solutions with excess of ligand. The pH-absorbance curves for solutions with C_M $2{\cdot}5 \times 10^{-5}$ and C_R $2{\cdot}5 \times 10^{-4}$–$7{\cdot}5 \times 10^{-4}$ were shifted towards lower pH values as the ligand concentration increased, but generally reached a horizontal at pH values >5. Measurements were made at 570 mμ to reduce the absorbance due to the excess of ligand, and corrections were applied for this absorbance. Because of the limited solubility of the ligand in ethanolic medium, 30% v/v aqueous dimethylformamide was used as solvent. From the linear parts of the curves for C_R/C_M ratios of 10, 20 and 30, it was confirmed that equilibrium (II) took place. For this purpose the equations used were

$$C_M = [M] + [MRH]$$

$$C_R = [H_2R] + [MRH] \sim [H_2R]$$

$$C_M/A = \frac{1}{\varepsilon_{1H}} + \frac{[H]}{\varepsilon_{1H} k_{11} C_R} \tag{17}$$

$$\log \frac{A}{\varepsilon_{1H} C_M - A} = \text{pH} + \log C_R + \log k_{11}. \tag{18}$$

The molar absorptivity calculated from the intercept on the graph of equation (17) was used to obtain $\log k_{11}$ from equation (17), Fig. 7. The values of ε_{1H} obtained

agreed well with those for solutions containing excess of metal ion, when the conversion factor $A_{530}/A_{570} = 1{\cdot}08$ was applied.

The higher values of k_{11} were partly influenced by the dimethylformamide present. The MR complex was formed to a negligible extent under the given conditions.

The shape and position of the pH-absorbance curves for nearly equimolar solutions

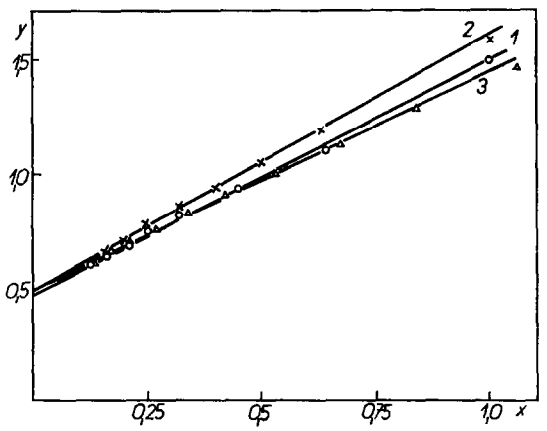

FIG. 7.—Graphical analysis of the rising portion of pH-absorbance curves according to equation (17).
30% aqueous dimethylformamide; 570 mμ
$C_M = 2{\cdot}5 \times 10^{-5}M$; C_R/C_M: *1*—10; *2*—20; *3*—30.

($C_R/C_M \leqslant 6$) were similar to those for a large excess of ligand but the absorbance was about twice as great (Fig. 8). This indicated the existence of the MR species, formed according to the equilibria

$$M + H_2R \leftrightharpoons MR + 2H^+ \quad \text{(IV)}$$

$$M + HR^- \leftrightharpoons MR + H^+ \quad \text{(V)}$$

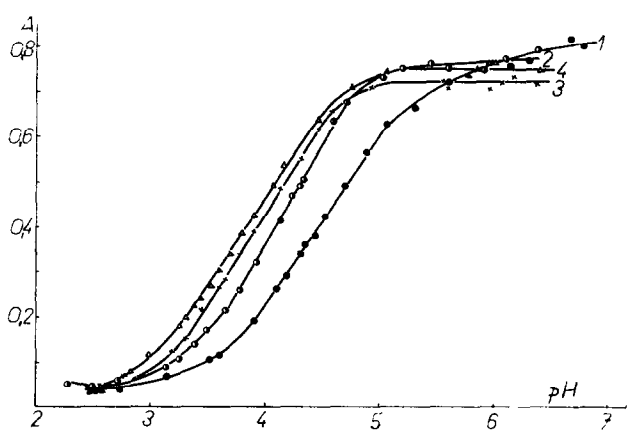

FIG. 8.—pH-Absorbance curves for uranyl-TAR solutions in 8% aqueous ethanol/4% aqueous dimethylformamide.
$C_M = 2{\cdot}5 \times 10^{-5}M$; C_R/C_M: *1*—1; *2*—2; *3*—4; *4*—6.

at pH > 4. The large dispersion of the results for $\varepsilon_1(1{\cdot}15 \times 10^4 - 46{\cdot}1 \times 10^4)$ provides further evidence for the existence of a mixture of MRH and MR species under these conditions.

Other evidence for the 1:1 *complex*

Continuous variation, slope-ratio and mole-ratio plots (Figs. 9, 10, 11) all indicated the existence of a 1:1 complex over the pH range 3·5–7·8. The mole-ratio plot for solutions at pH < 3·3 no longer shows a break on the curves, but this is taken as

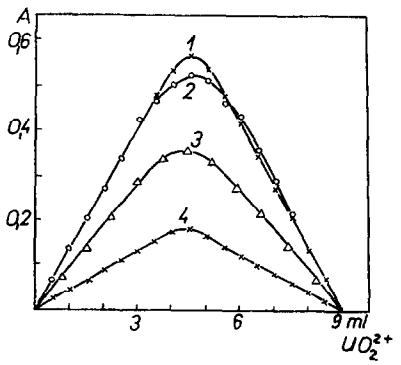

FIG. 9.—Job curves for equimolar solutions of UO_2^{2+} and TAR at 530 mμ.
$C_M = 4{\cdot}5 \times 10^{-5}M$; pH: *1*—7·8 (no buffer); *2*—6·00 (0·2*M* triethanolamine)
$C_M = 3{\cdot}0 \times 10^{-5}M$; pH: *3*—7·8 (no buffer); *4*—6·02 (0·2*M* triethanolamine).

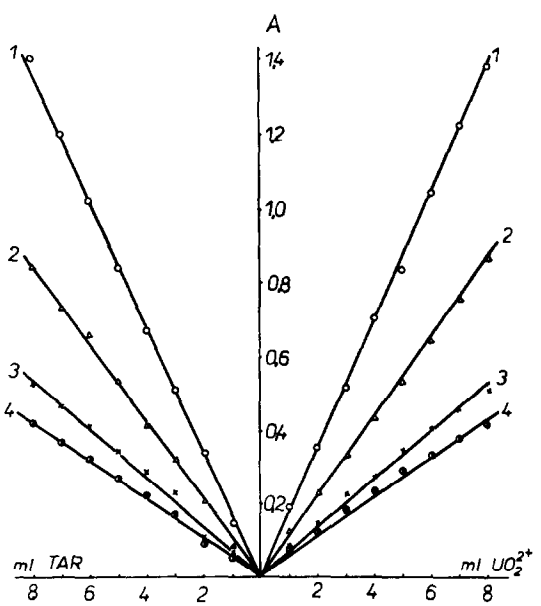

FIG. 10.—Slope ratio plots.

pH 6·95: *3*—570 mμ; *4*—530 mμ.

evidence of another form of 1:1 complex with a higher absorptivity (occurring when $C_R/C_M > 1$) rather than of the presence of a higher complex.

A green–violet crystalline product was obtained by treating 100 ml of $1{\cdot}25 \times 10^{-3}M$ uranyl nitrate in $1M$ perchloric acid with 50 ml of $1{\cdot}25 \times 10^{-2}M$ TAR in ethanol, and adding $1M$ ammonia dropwise with continuous stirring. The precipitate which appeared at pH 3 was filtered off on a sintered glass crucible, washed with small amounts of ethanol and water, and dried over calcium chloride hemihydrate in a vacuum desiccator. The solid was analysed (found: C 19·6%; H 2·0%; N 7·5%; U 44·1%; H_2O 7·5%; calculated for $UO_2R.2H_2O$: C 20·5%; H 1·7%; N 8·0%; U 45·2%; H_2O 6·8%) and the ratios U:C and U:N were 1:8·8 and 1:2·9, compared with 1:9 and 1:3 expected theoretically. The compound strongly adsorbs water, so the water content is always higher than the theoretical value. There was no evidence for the formation of a 1:2 complex in the solid state.

*Constants for the uranyl-*TAR *chelate*

We may summarize the various equilibrium constants for the system:

$$k_{11} = [MRH][H]/[M][H_2R]$$

$$k_{12} = [MRH][H]^2/[M][H_3R]$$

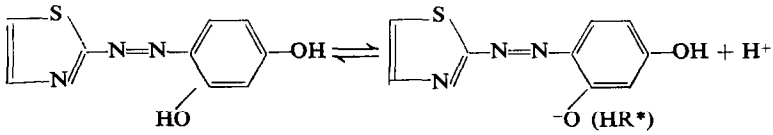
$$k_1' = [MR][H]/[MRH]$$

$$k_{12} = k_{11}.K_{a1}$$

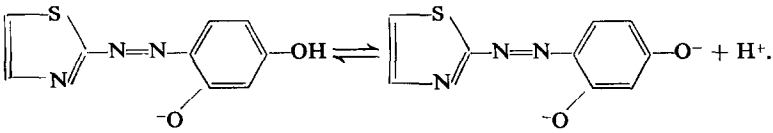
$$K_{1H} = [MRH]/[M][HR^*] = k_{11}/K_{a2}^*$$

$$K_1 = [MR]/[M][R] = k_1'K_{1H}/K_{a3}^*$$

where K_{a2}* is the dissociation constant for the hypothetical dissociation



and K_{a3}* is the dissociation constant for the hypothetical dissociation



These hypothetical constants are required for the evaluation of K_{1H} and K_1 because in the formation of the complex MRH the proton of the *o*-hydroxy group is displaced, whereas it is the *p*-hydroxy group that dissociates first in the absence of a complex-forming cation. It is not possible to measure the values of these "reversed" dissociation constants, and for simplicity it is assumed[21,22] that they have the same values as the normal constants, *i.e.*, $pK_{a2}^* = pK_{a3}$ and $pK_{a3}^* = pK_{a2}$.

The values for particular equilibrium constants and absorptivities are given in Table I. There is good agreement between the values obtained by different methods. The values for the other constants then become: $\log k_{12} = -0{\cdot}65$; $\log K_{1H} = 9{\cdot}8$; $\log K_1 = 11{\cdot}35$.

TABLE I.—MOLAR ABSORPTIVITIES AND EQUILIBRIUM CONSTANTS

MRH $\varepsilon_{1H} \times 10^{-4}$	MR $\varepsilon_1 \times 10^{-4}$	$\log k_{11}$	$\log k_1'$
2·4; 2·3 (7)	$3{\cdot}4_5$; 3·4; 3·3 (14)	0·28 (6)	−4·5 (13)
$2{\cdot}4_5$; 2·3; $2{\cdot}3_4$; 2·4 (10)	3·3 (15)	0·30 (11)	−4·5 (16)
2·3 (17)	3·3*	$0{\cdot}28_6$ (9)	
	$3{\cdot}3_5$†	0·34; 0·40 (18)‡	

Numbers in brackets are those of the equations used.

The results for equations (6), (9), (11), (13) and (16) are the means of 3, 5, 5, 4 and 4 values respectively, for various excesses of ligand and metal ion.

Absorbances were corrected for the absorbance of excess of ligand.

* Calculated by $\varepsilon_1 = A/C_R$ or $\varepsilon_1 = A/C_M$ from Job plots at pH > 6 with excess of ligand or metal ion (mean of 9 values).

† From linear plots of $A = f(C_R)$ for solutions with excess of metal ion at pH 6·95 (slope ratio method).

‡ Values obtained for solutions in 30% v/v aqueous dimethylformamide.

The agreement of the values for the molar absorptivity calculated from Job plots, slope-ratio plots, pH-absorbance curves and equations (14) and (15) is further evidence that only the MR species is formed at pH > 6, and not MR_2.

SPECTROPHOTOMETRIC DETERMINATION OF URANIUM

Of the 1:1 chelates formed under various conditions, the UO_2R complex is the most suitable for spectrophotometric use. Although this complex is the sole species formed at pH > 5 if the ligand is present in excess, pH 7·5–8 was chosen because at this pH the complex is formed quantitatively in the presence of only a small excess of ligand and several interfering ions can be masked.

Reaction conditions

Sodium acetate, triethanolamine, tris(hydroxymethyl)aminomethane and urotropine were used as buffers, for the pH range 6–8. None of them influenced the absorbance of the chelate when they were present in 0·2–0·4*M* concentration. For further work 0·1*M* triethanolamine was used; a 1*M* stock solution was adjusted to pH 7·5–8 by addition of perchloric acid.

For determination of 20–120 μg of uranium, 5 ml of $4 \times 10^{-4}M$ TAR in 96% ethanol or 0·1*M* ammonia were used. If the ammoniacal reagent was used, a few drops of 0·1*M* perchloric acid were added until the red colour of the solution changed to yellow, and then 5 ml of 96% ethanol were added to keep the reagent in solution.

Variation of the ionic strength over the range 0·1–0·3 (by addition of sodium perchlorate) was without influence on the absorbance. The absorbance increases slightly in the first 60 min and then begins to decrease. The optimal time for measuring the absorbance is 0–10 min after the solution has been prepared. Beer's law is obeyed over the range 0·4–4·8 ppm of uranium at pH 3–8 in the absence of a buffer or at pH > 6 in the presence of 0·2*M* triethanolamine, 0·04*M* urotropine or 0·02*M* sodium acetate.

The molar absorptivity calculated from several points on the calibration curve was $3{\cdot}30 \times 10^4$ (mean of 9 values), in good agreement with the values given in Table I.

Influence of masking agents

Table II shows the effect of various common masking agents. Carbonate and oxalate were found to interfere strongly. Fluoride, cyclohexanediaminetetra-acetic

TABLE II.—EFFECT OF SOME MASKING AGENTS ON THE DETERMINATION OF 60 μg OF URANIUM

Masking agent	Concentration ratio agent/uranium	Relative error in determination, %
EDTA	20	−2·0
CHDTA	3000	−0·8
Sodium fluoride	5000	+3·0
5-Sulphosalicyclic acid	3100	−3·0
Sodium thiosulphate	16000	−0·7
Sodium acetate	6000	+3·3
Potassium sodium tartrate	400	−5·8
Diammonium hydrogen phosphate	420	+2·8
Hydrogen peroxide	4200	−4·4

acid (CHDTA) and 5-sulphosalicylic acid are very useful masking agents for a number of interfering ions, and the mixture of them recommended by Florence and Farrar[9] was used in this work. Even when a large excess of this mixture was added there was less than 3% change in the absorbance of the uranyl–TAR complex. The mixture used contained 25 g of cyclohexanediaminetetra-acetic acid, 2·5 g of sodium fluoride and 65 g of 5-sulphosalicyclic acid dissolved in water to give a solution which was neutralized with ammonia (1 + 1), filtered, adjusted to pH 7·5–8 with dilute ammonia, and diluted to 1l.

Procedure

To the slightly acid sample solution (in a 50 ml volumetric flask) containing 20–120 μg of uranium add 10 ml of masking mixture, 5–6 drops of phenolphthalein

TABLE III.—DETERMINATION OF 60 μg OF URANIUM IN THE PRESENCE OF VARIOUS IONS

Salt added	Concentration of metal ion, *mg/ml*	Relative error of determination, %
$Al(NO_3)_3$	0·111	+1·3
$MnSO_4$	0·130	+0·7

Na_2MoO_4	2·70	−4·4
Na_2WO_4	0·488	−2·8

and first ammonia until a pink colour appears and then just enough 1*M* perchloric acid to discharge the colour. Then add 5 ml of $4{\cdot}0 \times 10^{-4}M$ TAR in 96% ethanol, and 5 ml of 1*M* triethanolamine buffer, pH 7·5–7·8. Dilute the mixture to the mark, mix, and measure the absorbance within 10 min in 1-cm cells at 530–545 mμ against a reagent blank of the same composition and pH. The sensitivity is 0·072 μg/cm^2 for an absorbance of 0·01, and the relative error is less than 2%.

Effect of various ions

Table III shows the effect of various ions on the determination of uranium by the procedure given.

Acknowledgement—Thanks are due to V. Svoboda who supplied the sample of TAR.

Zusammenfassung—Das Uranylion bildet nur 1:1-Chelate mit 4-(2-Thiazolylazo)resorcin (TAR) in Lösung, $UO_2(TAR)H^+$ bei pH < 3 und $UO_2(TAR)$ bei pH > 3,5. Der zuletzt genannte Komplex kann auch bei pH > 3 gefällt werden. Die quantitative Bildung von $UO_2(TAR)$ bei pH 7,5–7,8 in Lösungen, die einen kleinen Reagensüberschuß und Triäthanolamin als Puffer enthalten, kann zu empfindlicher spektrophotometrischer Bestimmung von Uran dienen. Mehrere störende Ionen können mit einer Mischung von Natriumfluorid, Cyclohexandiamintetraessigsäure und 5-Sulfosalicylsäure maskiert werden. TAR ist als Uranreagens etwas weniger empfindlich als 4-(2-Pyridylazo)resorcin, aber selektiver.

Résumé—L'ion uranyle ne forme que des chélates 1:1 avec le 4-(2-thiazolylazo) résorcinol (TAR) en solution, $UO_2(TAR)H^+$ se formant en-dessous de pH 3 et $UO_2(TAR)$ au-dessus de pH 3,5. Le dernier complexe peut aussi être précipité à pH 3. On peut utiliser la formation

quantitative de UO_2(TAR) à pH 7,5–7,8 en solutions contenant un faible excès de réactif et un peu de triéthanolamine comme tampon pour le dosage spectrophotométrique sensible de l'uranium. On peut dissimuler différents ions gênants par un mélange de fluorure de sodium, acide cyclohexanediaminotétracétique et acide 5-sulfosalicylique. Le TAR, en tant que réactif de l'uranium, est légèrement moins sensible que le 4-(2-pyridylazo) résorcinol, mais il est plus sélectif.

DETERMINATION OF ALUMINA FILM THICKNESS BY ALPHA PARTICLE SCATTERING

MAX PEISACH, DARRELL O. POOLE* and HERMANN F. RÖHM†
Southern Universities Nuclear Institute, P.O. Box 17,
Faure, C.P., South Africa

(*Received* 7 *July* 1966. *Accepted* 28 *September* 1966)

Summary—The scattering of accelerated alpha particles has been used to determine the surface oxide film thickness of anodized aluminium. The measurements were based on determining the difference between the energy of an alpha particle cattered from the surface oxide layer and that from the underlying metal. Films ranging in thickness from 10 to 130 μg/cm^2 were analysed non-destructively with a relative standard deviation of 3·5%. The average time for an analysis was 30 min with an incident beam current of up to about 1 μA.

PREVIOUS work[1] has shown that use may be made of semiconductor detectors to measure the energy spectrum of elastically scattered alpha particles for qualitative and quantitative analysis of surface films. The method was applied to the measurement of surface concentrations of heavy metals deposited on backing materials with lower atomic number.[2] This work extends the technique to the determination of surface concentrations of light elements. Oxide films have been analysed on aluminium.

Theory

The Rutherford differential scattering cross section, $d\sigma/d\Omega$ for single scatter of a charged particle through a centre-of-mass angle θ, moving with non-relativistic velocities, is given[3] by

$$\frac{d\sigma}{d\Omega} = \frac{b^2}{16 \sin^4 \theta/2} \text{ cm}^2 \text{ . atom}^{-1} \text{ . steradian}^{-1}, \quad (1)$$

where b, the distance of closest approach, is given by

$$b = \frac{Z_1 Z_2 e^2}{E} \text{ cm}. \quad (2)$$

Z_1 and Z_2 are respectively the atomic numbers of the bombarding charged particle and the target nucleus, e is the electronic charge and E the incident energy of the charged particle.

After scatter, the energy of the scattered particle, E', is given by

$$\frac{E'}{E} = 1 - 2(1 - \cos \theta) \frac{M_1 M_2}{(M_1 + M_2)^2} \quad (3)$$

where M_1 and M_2 respectively are the masses of the incident and target nuclei.

When scattering occurs within the target material, the particle will lose energy by

* South African Atomic Energy Board, Isotope Unit. Present address: Mount Sinai Hospital, Miami Beach, Florida, U.S.A.
† Dept. of Chemistry, University of Stellenbosch, Stellenbosch, C.P., South Africa.

ionization and excitation along its inward and outward paths, and by scattering at a particular depth i. The energy of the particle at the detector, E_{di}, is given by

$$E_{di} = [E - \Delta E_i]\left[1 - 2(1 - \cos\theta_i)\frac{M_1 M_2}{(M_1 + M_2)^2}\right] - \Delta E_i' \tag{4}$$

where the energy ΔE_i lost along the inward path length S_{1i} and $\Delta E_i'$ along the outward path length S_{2i} are obtained from

$$\Delta E_i = \int_0^{S_{1i}} \frac{dE}{dx}\, ds \quad \text{and} \quad \Delta E_i' = \int_0^{S_{2i}} \frac{dE'}{dx}\, ds. \tag{5}$$

When a charged particle beam is scattered off a monolayer target containing two components with nuclidic masses ${}^1M_2$ and ${}^2M_2$ in fractional concentrations n_1 and n_2 atoms/cm^2 respectively, the energy spectrum of the scattered particles measured at a selected laboratory angle θ_L will consist of two normal distributions about energies E_1' and E_2' respectively, provided the difference between these two energies is appreciably greater than the resolution of the detecting system which determines the width of each peak. The energies E_1' and E_2' may be obtained from equation (3) in which the corresponding centre-of-mass angle is used. The centre-of-mass angle is given by

$$\theta = \theta_L + \arcsin\left(\frac{M_1}{M_2}\sin\theta_L\right). \tag{6}$$

The area under each peak, and consequently the peak height, is proportional to the product of the fractional concentration of the component and its scattering cross-section.

With a thick target, each layer may be considered to yield a similar set of peaks in the energy spectrum of the scattered particle, but the energy is degraded according to equation (4). Any observed spectrum will consist of the sum of the spectra of the layers and should provide information about the atomic mass M_2 and the number of atoms per unit area of beam (n) of each constituent element.

Selection of experimental conditions

One of the factors determining resolution is the variation of the scattered energy E' with unit increase in M_2. The mass sensitivity, $S(M_1)$, can be obtained by differentiating equation (3) with respect to M_2 at a constant value of the scattering angle for each type of bombarding particle M_1.
Thus

$$S(M_1) = \frac{\partial}{\partial M_2}\left(\frac{E'}{E}\right)_{\theta_L} = \frac{2M_1(1 - \cos\theta)(M_2 - M_1)}{(M_1 + M_2)^3} + \frac{2M_1 \sin\theta \tan(\theta - \theta_L)}{(M_1 + M_2)^2} \tag{7}$$

for constant laboratory angle θ_L. Curves for the mass sensitivity with respect to protons, alpha particles and nitrogen ions are given in Fig. 1 for $\theta_L = 135°$. From this figure it is clear that alpha particles give the best resolution in the analysis of alumina films.

The criterion for selecting a suitable scattering angle was that the energy difference between particles scattered from aluminium and from oxygen should be as great as possible. Figure 2 shows the variation of E'/E with laboratory angle for aluminium

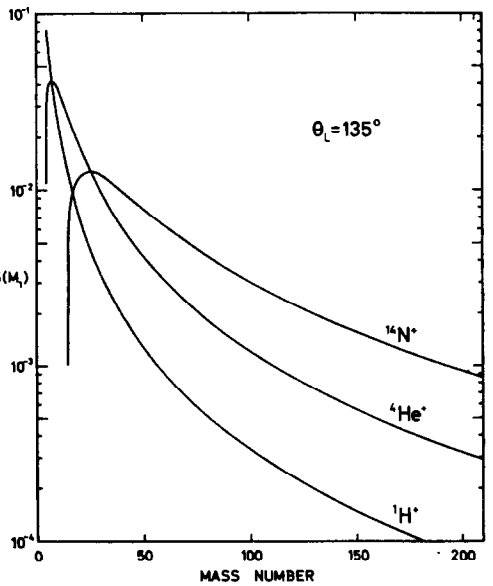

FIG. 1.—Mass sensitivity for protons, alpha particles and nitrogen ions scattered through a laboratory angle of 135°.

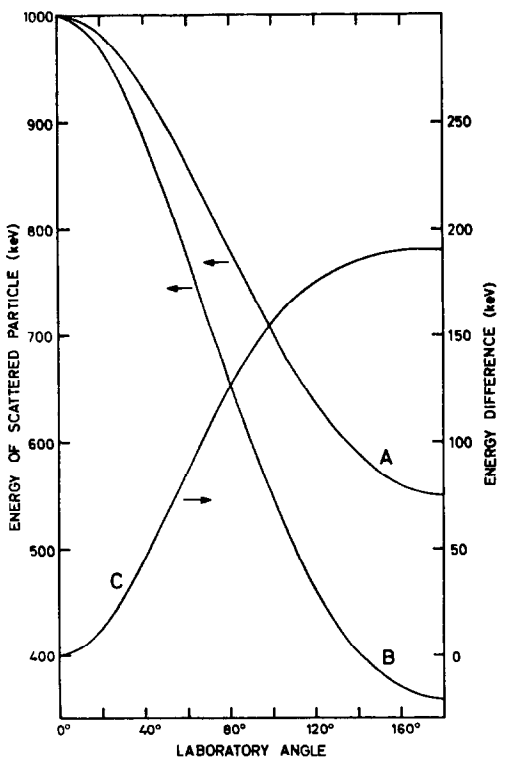

FIG. 2.—Effect of variation of scattering angle on the energy of the alpha particles scattered from aluminium (A), oxygen (B) and the difference between them (C). Incident energy = 1·00 MeV

and for oxygen. In the same figure, the energy difference between particles scattered from aluminium and oxygen at the same depth is shown as a function of the scattering angle for an incident beam of 1 MeV. Although the energy difference increases, there is relatively little change for angles greater than 135°. Accordingly this angle was selected.

The bombarding energy was chosen on the criterion that the rate of energy loss of the alpha particles should be as large as possible, within the alumina, so that penetration into the aluminium metal should be minimized. The lower the energy E, the lower the penetration, but the Van de Graaff accelerator could not give a stable beam much below 0·6 MeV. However, at this energy, the separation between E_1' and E_2' was not sufficiently large. The energy was thus stepped up to 1 MeV as a compromise between better resolution and poorer penetration properties.

EXPERIMENTAL

Apparatus

The 5·5 MeV Van de Graaff accelerator at the Southern Universities Nuclear Institute provided the beam of singly charged helium-4 ions of 1 MeV with energy spread of ± 1 keV. In all cases the incident beam was collimated to a cross-sectional area of 5×10^{-3} cm². With currents of up to 1 μA no vaporization could be detected from the targets, because of the refractory nature of alumina. When gold was used for calibration, lower currents were used to prevent gold volatilization.

The scattering chamber with the collimation for the incident beam was the same as described previously.[2] The detector assembly consisted of a surface barrier silicon solid state detector[4] with an active area of 0·2 cm², mounted 12·7 cm from the point of scatter. When required, collimators could be inserted in the scattered beam to reduce background from multiply scattered alpha particles.

The target assembly allowed for two 17 mm metal plates to be mounted for analysis. An aperture between them enabled the beam to be passed directly to a Faraday cup for current measurement. The entire target assembly was insulated and connected to a current integrator.[5]

Measurement and resolution

Pulses from the solid state detector were amplified and transmitted to a multichannel analyser on which the entire observed spectrum was recorded. The resolution of the detector, as measured by the full width at half the height of the spectrum peak obtained from the 5·48 MeV alpha particles from americium-241 was never more than 55 keV.

Calibration of the measuring system

The scattering of alpha particles at $\theta_L = 135°$ was measured for gold, aluminium and carbon. On adjustment of the scattering angle to centre-of-mass co-ordinates, the three energies obtained from equation (3) gave a straight line calibration. With thick targets the inflection point of the plateau edge in the spectrum was taken as E'.

Preparation of alumina targets

Alumina films of different thicknesses were prepared by anodizing one side of an aluminium foil in 3% w/v triammonium citrate at voltages ranging from 20 to 280 V. The foils were washed in water and stored in vacuum desiccators till required.

Standardization of film thicknesses

Previous work[6–10] has shown that the thickness of alumina formed during anodization is a linear function of the voltage. The mean value of the proportionality constant was accepted as 0·478 μg of alumina/V. As a check on the alumina film thickness, the oxygen content of anodized films was determined by helium-3 activation and measurement of the induced fluorine-18 activity.[11]

RESULTS AND DISCUSSION

Energy spectra of alpha particles scattered from untreated aluminium and from anodized aluminium with thin and thick layers of oxide are shown in Fig. 3. As was expected, the energy spectrum for a thin oxide layer showed a single plateau, caused

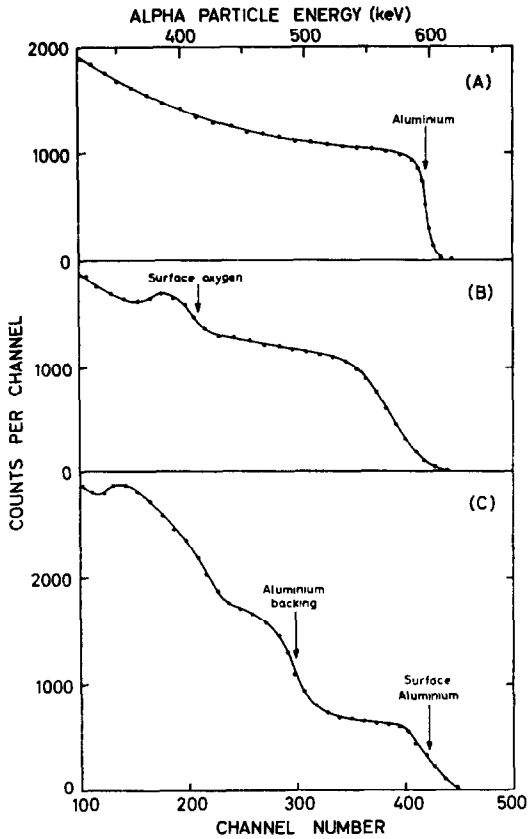

FIG. 3.—Energy spectra of alpha particles scattered from untreated aluminium (A), and from anodised aluminium with thin (B) and thick (C) layers of oxide. $\theta_L = 135°$, $E = 1{\cdot}00$ MeV, counted for 30 min.

by alpha particles scattered from a thick layer of aluminium, with a broadened peak corresponding to a much thinner layer of oxygen, superimposed on the plateau. It was found that the calculated value of E' for oxygen (0·417 MeV) agreed with the maximum energy of particles scattered from oxygen (as measured by the inflection point of the protruding peak in the spectrum). However, the inflection point of the plateau was found to be at a somewhat lower energy than that calculated for E' for aluminium (0·598 MeV). Examination of the same spectrum showed that the leading edge of the spectrum did not fall to zero as rapidly as was the case with unanodized aluminium foil. With increasing target thickness the difference between the measured and the calculated energies corresponding to aluminium increased. At the same time the number of counts recorded in the leading edge of the spectrum increased with thickness until the leading edge resolved into another plateau, the energy of the inflection point of which corresponded exactly to the energy of alpha particles scattered from surface layers of aluminium. An example of a spectrum with three plateaux is shown in Fig. 3C.

The inflection point of the edge of the intermediate step in the energy spectrum

corresponding to an energy intermediate between that of oxygen and aluminium, was found to vary with the thickness of alumina and was displaced to lower energies with increasing thickness of the alumina. If the energy measured from scatter occurring from aluminium in the last layer of alumina is E_{d1} [see equation (4)], then the maximum energy measured from scatter at the surface of the aluminium metal, $E_{d(1+1)}$, is related to $(S_1 + S_2)$, the total path length of the alpha particle in alumina. The difference between the energy of a particle scattered from a surface atom of aluminium in alumina and $E_{d(1+1)}$, represents the total energy loss of the particle in alumina. Thus the energy $E_{d(1+1)}$, corresponding to the inflection point of the intermediate plateau can serve as a measure of alumina thickness.

The crystal structure of aluminium metal is cubic close packed with a unit cell of 4·04 Å and an average distance between aluminium atoms[13] of 2·86 Å. In the case of γ-alumina, the unit cell[12] is 7·90 Å with oxygen atoms in cubic close packing. The 24 aluminium atoms are randomly situated in 8 of the 64 sites which have oxygen tetrahedrally arranged around them and 16 of the 32 sites where oxygen is octahedrally arranged. The shortest distance between two octahedrally surrounded aluminium atoms is about 2·8 Å, while between tetrahedrally and octahedrally surrounded ones it is 3·1 Å and between tetrahedrally surrounded atoms, about 3·4 Å. The overall effect is that the average distance between aluminium atoms in alumina is appreciably greater than in aluminium metal. The difference in intensity of the alpha particles scattered from within the alumina and those from the aluminium metal, and hence the appearance of the intermediate plateau in the energy spectrum, is attributed to the increased concentration of aluminium atoms per unit area of the beam.

Recent work[14–17] has indicated that energetic ions could penetrate ordered crystalline structures along favoured crystallographic directions without appreciable loss of energy. Thus, for an alumina layer which is deposited as an ordered crystal and on which the alpha particle irradiation beam is incident in precisely the favoured direction, scattering data could lead to a low result. However, as anodization is unlikely to lead to ordered crystals and because the thickness of the film is obtained from the difference in energy between particles scattered from *surface* aluminium atoms of alumina and *surface* aluminium atoms from the underlying metal, this effect can be neglected. Alternatively, penetration of the underlying metal by channelling would result in a small change of the number of particles scattered from *within* the aluminium, which would again have little bearing on the analysis.

A calibration curve of the maximum energy of an alpha particle scattered from the aluminium metal as a function of alumina thickness is given in Fig. 4. The energy error flags shown in Fig. 4 refer to the errors involved in determining the inflection point in the spectrum, while the thickness error flags refer to the standardization errors from the determination of oxygen by helium-3 activation.

The results of a typical series of analyses are shown in Table I. The values of the known thickness in the table were obtained from activation analysis. The precision of the method as given by the relative standard deviation was found to be 3·5%, while the statistical scatter of results and the mean error indicated no bias. It should be noted that the relative standard deviation included errors from activation analysis, the results of which were assumed to be absolute for purposes of calculation. Because the precision of the standardization by activation analysis[11] or by the variation of film thickness with the anodizing voltage[6–10] is about the same as the value of 3·5% found

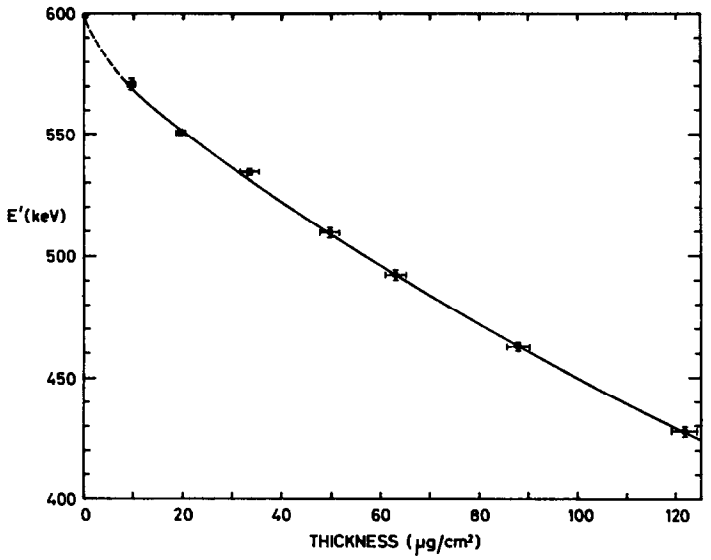

FIG. 4.—The variation of the maximum energy of alpha particles scattered from aluminium metal with thickness of alumina film.

TABLE I.—SOME ANALYSES OF ALUMINA LAYERS ON ALUMINIUM

Sample number	*E, keV*	Thickness, $\mu g/cm^2$			Relative error, %
		Found	Known	Difference	
1	559	15·54	14·34	+1·20	+8·37
2	557	16·83	16·73	+0·10	+5·98
3	549	21·84	22·94	−1·10	−4·80
4	543	25·62	26·29	−0·67	−2·55
5	539	28·49	29·64	−1·15	−3·88
6	520	41·78	41·11	+0·67	+1·63
7	502	55·45	54·01	+1·44	+2·67
8	497	59·37	57·84	+1·53	+2·65
9	490	65·25	67·40	−2·15	−3·19
10	480	73·04	72·18	+0·86	+1·19
11	476	76·48	77·44	−0·96	−1·24
12	438	110·75	110·42	+0·33	+0·30

Mean error +0·00833 $\mu g/cm^2$
Mean relative error +0·59%
Relative standard deviation ±3·5%

here, it may be deduced that the method of alpha particle scattering is, at worst, as precise as these two methods.

Applications

The method of alpha particle scattering affords a convenient method for measuring oxide films on aluminium from 10 to about 150 $\mu g/cm^2$ by the technique of determining the energy lost by the incident and scattered particles passing through the film. The method may be extended to thin films of light elements on metals and heavy elements. For thicker films the incident energy of the alpha particle may be increased,

thus increasing the range of applicability of the method without appreciable loss of sensitivity.

In corrosion studies the oxide film on iron may be measured *in situ*, without having to float the oxide film off the underlying metal.[18] Alternatively films of iron oxide floated off corroded surfaces may be analysed for homogeneity.

Résumé—On a utilisé la diffusion des particules alpha accélérées pour déterminer l'épaisseur du film superficiel d'oxyde sur l'aluminium oxydé anodiquement. Les mesures sont basées sur la détermination de la différence entre l'énergie d'une particule alpha diffusée par la couche d'oxyde superficiel et celle d'une particule diffusée par le métal sous-jacent. On a analysé de façon non destructive des films d'épaisseur comprise entre 10 et 130 $\mu g/cm^2$ avec un écart type relatif de 3,5%. Le temps moyen nécessité par une analyse est de 30 min, avec une intensité de faisceau incident allant jusqu'à 1 μA environ.

Zusammenfassung—Die Streuung beschleunigter Alphateilchen wurde benutzt, um die Dicke des Oxydfilms auf der Oberfläche anodisch oxydierten Aluminiums zu bestimmen. Die Messungen beruhten auf der Bestimmung der Differenz der Energie eines Alphateilchens, das einerseits an der oberflächlichen Oxydschicht, andererseits am darunterliegenden Metall gestreut wurde. Filme der Dicke 10–130 $\mu g/cm^2$ wurden zerstörungsfrei mit einer relativen Standardabweichung von 3,5% analysiert. Die durchschnittliche Zeit für eine Analyse betrug 30 min mit einer Stromstärke des auftreffenden Strahls bis etwa 1 μA.

ANALYSIS OF ZONE-MELTED ULTRA-PURE ORGANIC COMPOUNDS*

A NEW QUANTITATIVE DIFFERENTIAL THERMAL ANALYSIS METHOD

ROBERT FRIEDENBERG

(*Received* 24 *January* 1966. *Revised* 20 *July* 1966. *Accepted* 9 *September* 1966)

Summary—A method for the rapid quantitative determination of impurities in ultra-pure organic compounds is described. It is based on the difference in slopes of the curves obtained when the difference in temperature between the sample and a reference shield is plotted against time. The results are compared with those obtained by thermal analysis.

IN the past, differential thermal analysis (DTA) has been used qualitatively to evaluate the purity of samples by comparison of the DTA curves for the materials in various states of purity.[1,2] Such evaluations have relied heavily on the theory of dynamic methods of thermal analysis. These methods are not based on the changes occurring during phase transitions or chemical reactions (as other applications of DTA are often based) but rather on Newton's law of heating and cooling, applied to the premelting phase of a solid or to the cooling molten phase. The influence of impurities on the premelting phase may be related to the equations associated with the lowering of the melting point. It can easily be shown from two fundamental equations that not only the lowering of the melting point but also all temperatures in the premelting phase are proportionately affected by the concentration of the impurity, which may be measured by DTA methods.

Herington[1] has recently developed two procedures; a quantitative thermal analysis procedure and a very rapid qualitative DTA method. In the latter, he uses a copper block, alongside the sample, to act as a "shield" or temperature reference. When the temperature difference between sample and shield is plotted against time for a series of samples of different purity, the slopes of the curves give a rough estimate of the purity. We have adapted Herington's method to permit the determination of impurities in ultra-pure organic substances. Methods for increasing the sensitivity of thermal analysis methods have been published separately[3] and only those parts needed for standardizing the DTA procedure will be given here. The theory and experiments for both the premelting and the cooling phases have been completed; as the theory and procedures are similar for both phases only the premelting phase will be considered here.

THEORY

The slope of the curve of the temperature difference between shield and sample plotted against time can be related to the mole % of impurity by the equation

$$\frac{\Delta(\Delta T_1)}{\Delta(\Delta T_2)} = \frac{Gn_1}{n_1 + n_2} \tag{1}$$

where $\Delta(\Delta T_1)$ and $\Delta(\Delta T_2)$ are the slopes of the temperature difference curves of two samples, G is a constant to be theoretically derived, n_1 is the mole % of impurity in the original sample, and n_2 is the mole % of impurity added to obtain the second sample. The method is a mathematical refinement of Herington's procedure,[1] making it quantitative. Herington's final equation[1] is used as a starting point:

$$\frac{\Delta T_1}{\Delta T_2} = \frac{n_1}{n_1 + n_2}. \tag{2}$$

Let $\Delta T_1 = (T_B - T_A)$, $\Delta T_2 = (T_D - T_C)$, $\Delta(\Delta T_1) = [(T_{AS} - T_A) - (T_{BS} - T_B)]$ and $\Delta(\Delta T_2) = [(T_{CS} - T_C) - (T_{DS} - T_D)]$, where T_A and T_B are the temperatures of sample 1 at times A and B respectively, T_{AS} and T_{BS} are the corresponding temperatures of shield 1, and T_C *etc.*, refer similarly to sample 2.

Then

$$\Delta(\Delta T_1) = (T_B - T_A) - (T_{BS} - T_{AS}) = \Delta T_1 - \Delta T_{1S} \tag{3}$$

and

$$\Delta(\Delta T_2) = (T_D - T_C) - (T_{DS} - T_{CS}) = \Delta T_2 - \Delta T_{2S}. \tag{4}$$

If plots of ΔT_1 against ΔT_{1S} and of ΔT_2 against ΔT_{2S} are linear and pass through the origin, then

$$\Delta T_1 = K_1 \Delta T_{1S};\ \Delta T_2 = K_2 \Delta T_{2S} \tag{5}$$

where K_1 and K_2 are the slopes of these plots. Substitution of equation (5) in equation (3) yields

$$\Delta(\Delta T_1) = \Delta T_1 - \Delta T_1/K_1 \tag{6}$$

and similarly

$$\Delta(\Delta T_2) = \Delta T_2 - \Delta T_2/K_2. \tag{7}$$

Then

$$\frac{\Delta(\Delta T_1)}{\Delta(\Delta T_2)} = \frac{K_2}{K_1}\frac{\Delta T_1}{\Delta T_2}\frac{(K_1 - 1)}{(K_2 - 1)} \tag{8}$$

and substitution from equation (2) gives

$$\frac{\Delta(\Delta T_1)}{\Delta(\Delta T_2)} = \frac{K_2}{K_1}\frac{(K_1 - 1)}{(K_2 - 1)}\frac{n_1}{(n_1 + n_2)} \tag{9}$$

which yields equation (1) if

$$G = K_2(K_1 - 1)/K_1(K_2 - 1). \tag{10}$$

EXPERIMENTAL

Apparatus

A Leeds and Northrup (L & N) 9835–B stabilized d.c. microvolt amplifier and a Speedomax H continuously adjustable Azar recorder were used for the DTA measurements. The microvolt amplifier is a null-balance instrument suitable for measuring the voltage output of thermocouples. It can be used as a preamplifier in combination with the recorder to give increased sensitivity over long or short test periods.

The recorder provides any desired span of e.m.f. measurement from 0·67 to 100 mV, with a zero shift of up to 50 mV. Figures 1–3 shows the instrumentation. The thermocouples were made from 30-gauge iron–constantan wire, silver-soldered. The furnace was made from a quart Dewar flask surrounded by vermiculite in a large drum. The top of the furnace was sealed with two sheets of asbestos which had holes for the thermocouple leads and the platinum resistance thermometer. A

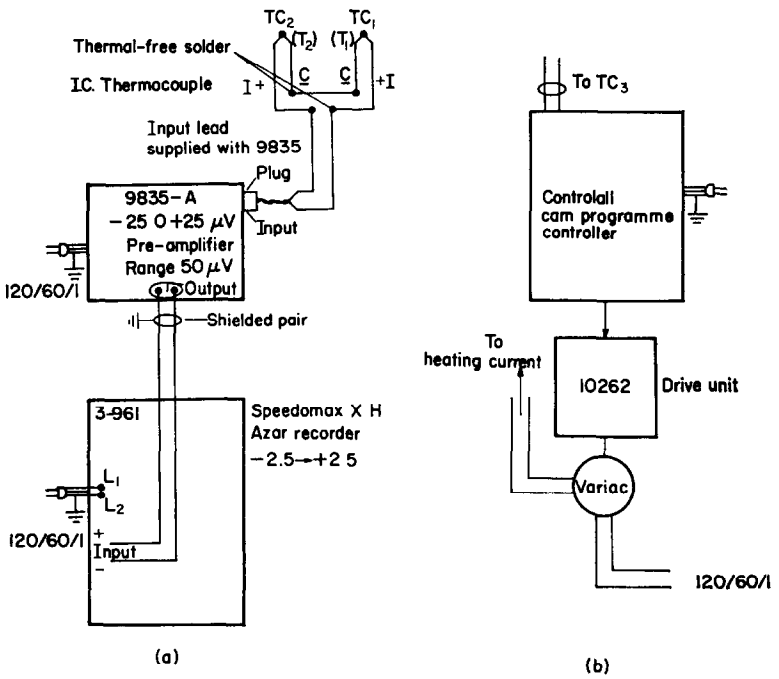

FIG. 1.—(a) Temperature difference measurement.
(b) Controlall and drive unit.

copper cone was used as the reference shield and was placed in a conical heating mantle which served as the heat source. The sample was carefully placed in a test-tube resting on the metal shield, and contained the platinum thermometer and a thermocouple. The other thermocouple was attached to the copper shield.

A controlled constant heating rate in the furnace is essential. Herington used a heating rate of 0·2°/min until the sample was 10° below its melting point.[1] We used a rate of 0·016°/min with an equilibration time of 5 hr. To accomplish this rigorously and check the thermocouple readings, elaborate equipment was used, but not all of it need be used once the system has been standardized. For automatic temperature control, Leeds and Northrup current-adjusting controls were used in conjunction with a saturable-core reactor. These controls supplied *proportional*, *reset*, and *rate* actions for stepless regulation of electric power for precise control of the furnace. A block diagram is given in Fig. 3. The recorder monitored the shield temperature, and deviation from the set temperature was transmitted as an error signal to the current-adjusting control unit which then made an automatic correction. A Leeds and Northrup Controlall assembly (Cat. No. 10171-15) was used for this purpose. Details of its operation can be obtained from the manufacturers, or Friedenberg's work.[4]

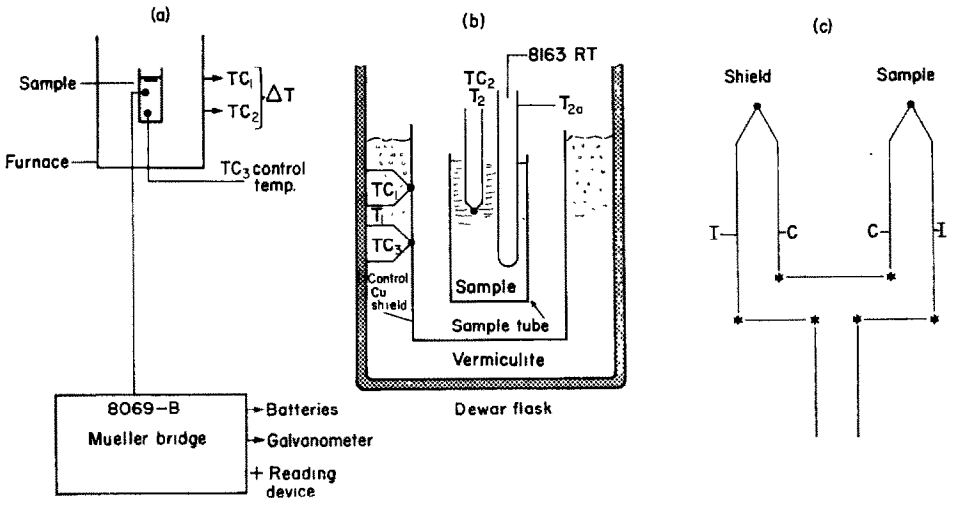

FIG. 2.—(a) Absolute temperature measurement. (b) DTA measurements. (c) Iron–constantan thermocouples for temperature difference measurements. TC_1—thermocouple to shield; TC_2—thermocouple to sample; TC_3—thermocouple to Controlall furnace; 8163 RT_1—platinum resistance thermometer; *L & N thermal-free solder at junctions; I—iron; C—constantan.

The performance of the equipment and of the DTA method was independently checked with a Mueller temperature bridge platinum resistance thermometer (N.B.S. certified) which yielded absolute temperature measurements to a high degree of accuracy.

Procedures

The calculation of impurity concentrations by this DTA method involves three quantities: (*a*) $\Delta(\Delta T_1)$, (*b*) $\Delta(\Delta T_2)$, and (*c*) G. The determination of each will be considered in turn.

(*a*) Milligram samples are adequate provided the thermocouple junction can be completely immersed in the sample. The recorder automatically plots the temperature difference between sample and shield against time. Although all our experiments were run for 24–48 hr to verify that the slope of the curve was constant, the slope can be measured from any 15- to 30-min section of the premelting heating curve (Fig. 4).

The measurement of differences in temperature is well-known for its sensitivity and accuracy.[5] According to the manufacturers the equipment described here is capable, with some modifications, of measuring temperature differences of 10^{-8} deg. In our experiments the maximum sensitivity of measurement was 10^{-6} deg, but the precision and accuracy were limited by the precision of the chart recorder. Other limiting factors are the heat transfer properties of the system at the point of measurement, and the standardization procedure used to measure the absolute value of the temperature, but these were negligible in comparison.*

For routine work a sensitivity of 0·01° may be used and three temperature readings suffice to give the slope of the DTA curve. For the ultra-purity determinations reported here a higher sensitivity (0·00001°) was used, and the slope was obtained by the method of least squares from 25–50 readings. Repeating a run under the same conditions always yielded an identical recording. If the rate of heating was increased above 0·05°/min the curves were no longer linear, and this may account for the non-linearity of the curves in Herington's qualitative DTA tracings.

(*b*) The procedure is repeated for the same sample after addition to it of a known quantity of a known substance. The impurity added to naphthalene was benzoic acid. Choice of an impurity to add should be based on the ability of the impurity to form eutectics rather than solid solutions, *e.g.*, benzoic acid rather than β-naphthol. The sample (50 g) is weighed, the impurity is added, and the mixture is melted, mixed well, cooled and reweighed. Weighings should be done as accurately as possible. When 6 successive additions of impurity were made, with a heating run for each, the results gave identical initial concentrations of impurity, so a single addition is sufficient.

* Heat transfer tests were made by Prof. W. H. Hilding, Department of Mechanical Engineering, University of Connecticut.

FIG. 3.—(a) Block diagram of Controlall.
(b) Block diagram of apparatus.

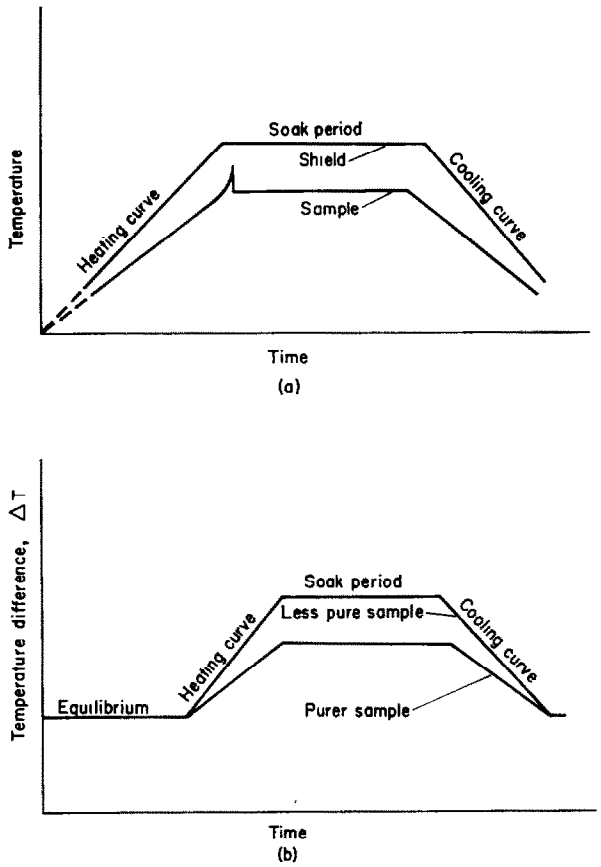

FIG. 4.—(a) Time–temperature curves of shield and sample.
(b) Time–temperature difference curves for two samples of different purity.

(*c*) The proportionality constant G is dependent on external factors associated with the equipment and on the nature of the substance being analysed. The external factors include the heating rate, the characteristics of the shield, the size and insulating properties of the furnace, *etc.* If the instrumentation is not changed, the external factors are constant, and G will then vary for each substance according to equation (10). For the highest accuracy to be achieved, G must be known as accurately as possible, and data from thermal analysis measurements must therefore be used initially to establish the value of G for each substance. This was done with a platinum resistance thermometer (sensitivity 0·00002°) certified by the National Bureau of Standards. Because the readings were taken manually and the conversion of resistance readings into temperature was tedious, a limited number of points was used. As a check, plots were made of sample temperature *vs.* shield temperature. All gave straight lines passing through the origin, as they must if the method is to be valid—see equation (5).

If G is calculated with arbitrary values of K_1 and K_2 it is found to be a singular function for values of K_1 and K_2 that are less than unity (Fig. 5). The experimental values $K_1 = 0{\cdot}99788$ and $K_2 = 0{\cdot}99810$ obtained from thermal analysis measurements would therefore give a singular value for G. Once G has been determined for a given substance any number of samples of any purity can be analysed by this DTA method, rapidly, automatically and accurately.

RESULTS AND DISCUSSION

Table I lists the results of thermal analysis[3] and DTA measurements of the same samples of naphthalene. Each value represents a separate sample, each of which had a minimum of three additions of impurity made to it in the DTA work. The

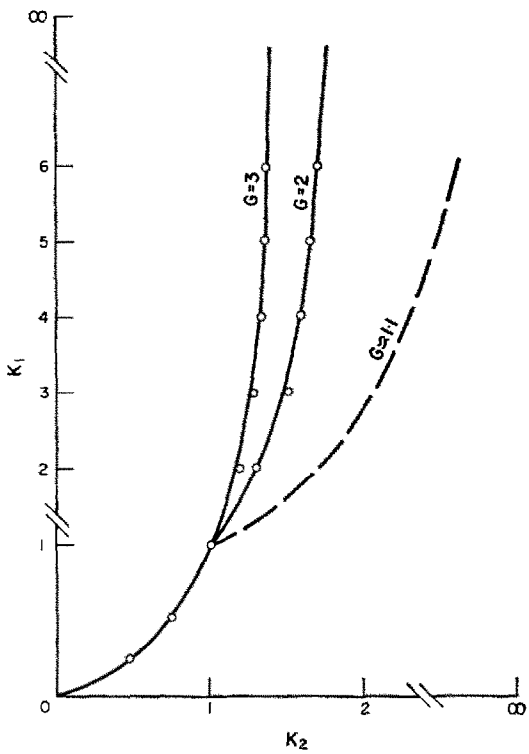

FIG. 5.—Relationship of calibration constant G and slopes K_1 and K_2 [equation (10)].

TABLE I.—DTA AND THERMAL ANALYSIS MEASUREMENTS FOR NAPHTHALENE

Sample	Impurity	
	Thermal analysis *mole%*	DTA *mole%*
Commercial Fisher reagent grade	2·699	2·780
Commercial Baker & Adams reagent grade		1·327
Zone-refined, 1 pass	0·06040	0·06038
	0·06335	0·04557
		0·09581
Zone-refined, 30 passes	$0·00094_7$	$0·00078_8$
	$0·00056_2$	

difference in the results for the commercial samples is explained by the fact that the methods were devised for determination of trace amounts of impurity in ultra-pure materials, and that at higher concentrations the mole fraction of the original impurity plays a dominant role. In the samples purified by zone-refining, the concentration of impurity added to the original sample during the determination is large compared to the original concentration of impurity. The reverse holds for the commercial samples. The results for the zone-refined samples are of a consistent order of magnitude for both methods. The relative error naturally increases as the amount of impurity decreases.

The limiting error is the error in measuring the slope of the differential temperature curves. If a recorder is used the error is likely to be between 1 and 5 parts per 1000. Resistance thermometry does not appear to give much improvement in precision.

This new method provides a rapid automatic technique for purity determinations. Except for mass spectrometry, methods currently available are tedious and lack the necessary sensitivity and accuracy. They have been evaluated elsewhere.[3,4,6] The new method does have some disadvantages, however. Misunderstandings most often arise in distinguishing between the slopes of thermal analysis curves (the rate of change of temperature) and of DTA curves (the rate of change of the difference in temperature between sample and reference). Since the standardization of the method is based on thermal analysis measurements of K_1 and K_2 to give G, and the principles of the two kinds of measurement are quite similar, the disadvantages inherent in cryoscopic methods are apparent here too. The use of mole % as a unit necessitated by measurement of a colligative property is a particular disadvantage. Other methods which yield weight % are more useful but so far lack the necessary accuracy and sensitivity.

The standardization procedure for determining K_1 and K_2 is tedious and is the main disadvantage of the method. For naphthalene K_1 and K_2 are very close to unity and the measurements must be made as accurately as possible, preferably to 5 significant figures; approximations cannot be used. It is possible, however, that other methods of standardization might be used.[4,6,7] The main advantage of standardization by thermal analysis measurements is that G can be evaluated.

The usefulness of these ultra-purity measurements cannot be minimized.[8,9] Numerous theoretical applications to the zone-refining of organic compounds may be verified in practice[7,10] and ultra-purity data obtained for pharmaceuticals.

Zusammenfassung—Ein Verfahren zur raschen quantitativen Bestimmung von Verunreinigungen in ultrareinen organischen Verbindungen wird beschrieben. Es beruht auf dem Unterschied der Steigungen der Kurven, die man erhält, wenn man die Temperaturdifferenz zwischen Probe und einem zum Vergleich dienenden Schild gegen die Zeit aufträgt. Die Ergebnisse werden mit denen der thermischen Analyse verglichen.

Résumé—On décrit une méthode de détermination quantitative rapide des impuretés dans des composés organiques ultra-purs. Elle est basée sur la différence des pentes des courbes obtenues lorsqu'on enregistre la différence de température entre l'échantillon et une référence en fonction du temps. On compare les résultats à ceux obtenus par l'analyse thermique.

RAPID ANALYSIS OF PLATING BATHS BY A DIRECT-READING THERMOMETRIC METHOD

I. SAJÓ and B. SIPOS
Research Institute for Ferrous Metallurgy, Budapest XI, Fehérvári ut 130, Hungary

(*Received* 28 *March* 1966. *Revised* 21 *July* 1966. *Accepted* 9 *August* 1966)

Summary—Methods are described for the rapid analysis of plating baths by measurement of the heat evolved in a reaction between the reagent and the component to be determined. The novel feature of the method is the use of reagents which have zero heat of mixing, so that the temperature scale can be directly calibrated in concentration units for a particular determination. A determination takes only 5 min and the precision is equal to that of the classical methods. Procedures are given for the analysis of nickel and chromium plating baths.

PRINCIPLE OF THE METHOD

THE heat change accompanying chemical reactions is proportional to the quantity of reaction products formed. Direct thermometric analysis is based on this principle. An excess of reagent is added to the sample solution; the amount of product formed and the heat change will then be dependent only on the quantity of the component to be determined.

It is difficult to measure the heat of reactions proceeding in solution, but if the experimental conditions are suitably chosen the heat and temperature changes can be made proportional to the amount of component determined.[1–5] The reagent must react selectively with the desired component; with the aid of a calibration curve the temperature change resulting from the reaction can then be translated into a concentration. The calibration curve will not usually pass through the origin, because the heat of reaction will be accompanied by heat from other sources (heat of mixing, dilution, *etc.*) which causes a displacement of the curve.[5–7]

If the calibration curve can be made to pass through the origin, and the influence of the environment can be eliminated, the temperature scale can be calibrated in concentration units, giving the novel method of direct-reading thermometric analysis.

If the calibration curve passes through the origin, the relationship

$$c_m = K\Delta T \tag{1}$$

exists, where c_m is the concentration of the component to be determined (in mole $l.^{-1}$), K is a proportionality constant, and ΔT is the temperature change in °C. The value of K may be calculated from constants characteristic of the system:

$$-QN_m = C\Delta T \tag{2}$$

where Q is the heat of reaction (kcal $mole^{-1}$), N_m is the number of moles of reacting component, and C is the heat capacity of the system (kcal deg^{-1}).

Then

$$c_m = \frac{N_m}{V} = -\frac{C\Delta T}{QV} \tag{3}$$

where V is the volume of the sample solution (in litres), and if C, Q and V are kept constant,

$$K = -\frac{C}{QV} \tag{4}$$

The conditions for this are given below. Any other desired concentration unit may be obtained by means of a conversion factor.

The heat capacity of the system consists of several components:

$$C = C_S + C_R + C_E \tag{5}$$

where C_S, C_R and C_E are the heat capacities of the sample solution, the reagent solution and the apparatus, respectively. If the specific heats of the solutions are known, we can write

$$C_S = V\bar{c}_S\rho_S \tag{6}$$

and

$$C_R = V_R\bar{c}_R\rho_R \tag{7}$$

where $\bar{c}_S$ and $\bar{c}_R$ are the specific heats, V and V_R the volumes, and ρ_S and ρ_R the densities of the sample and reagent solutions respectively. Substituting into equation (3) we have

$$c_m = -\left[\frac{\bar{c}_S\rho_S}{Q} + \frac{V_R\bar{c}_R\rho_R}{QV} + \frac{\bar{c}_E}{QV}\right]\Delta T. \tag{8}$$

From equation (8) it is evident that analytically useful results can only be obtained if all the terms in the bracket are kept constant. This condition is fulfilled if (*a*) the sample solutions and reagent solutions are prepared strictly according to the prescribed procedure, (*b*) the prescribed volumes of solutions are always used, (*c*) the same apparatus or apparatus of the same heat capacity is always used, and (*d*) the reaction chosen always proceeds unequivocally, *i.e.*, the same end products are obtained from the same starting materials.

If these conditions are fulfilled, equation (1) correctly describes the relationship between the concentration of the component to be determined and the temperature change in the solution, provided that no subsidiary reactions occur that are accompanied by temperature changes.

Influence of subsidiary reactions

The subsidiary reactions may be of two kinds—those which cause a temperature change proportional to the amount of the component to be determined, and those which are accompanied by a temperature change independent of the concentration of the component in question.

Subsidiary reactions of the first kind are usually secondary reactions following the chief reaction. The products of the chief reaction react further with some component of the reaction mixture; for instance iron(III) produced in citric acid medium from iron(II) forms a complex with the citrate. The secondary reactions themselves

do not affect the determination if they proceed rapidly and quantitatively, because in this case the relationship between the concentration of the component sought and the temperature change remains linear and only the slope of the calibration curve (*i.e.*, the value of K) varies.

In some subsidiary reactions, however, the heat change (and hence the temperature change) is independent of the concentration of the component to be determined. Such subsidiary reactions occur in the mixing of the sample solution and the reagent solution. For instance, the degree of dissociation or hydration of the dissolved substances changes and the process of mixing is accompanied by cooling or heating according to the direction of the process. In such a case the calibration curve will

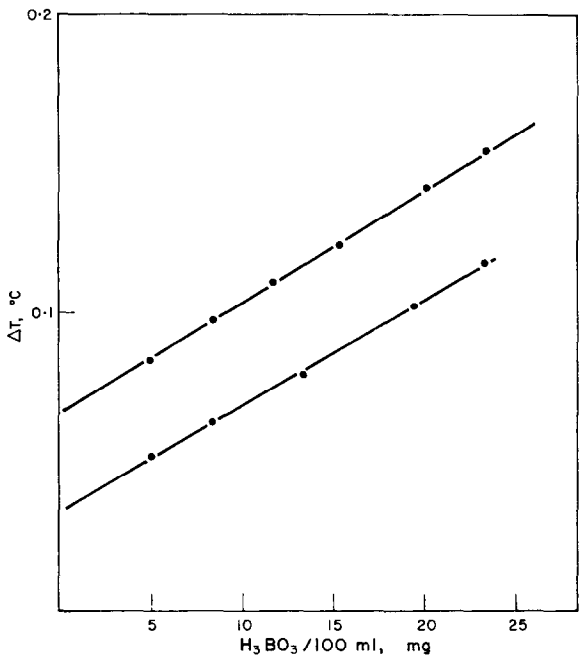

FIG. 1.—Calibration curves for boric acid with addition of 1 or 2 ml of 40% hydrofluoric acid (sample volume 200 ml).

not pass through the origin but will be vertically displaced by a constant amount if the volumes of reagents used are always the same and if the heat of mixing is independent of the concentration of the component sought. In Fig. 1 calibration curves for the boric acid content of nickel baths are shown which have been obtained with various volumes of reagent (1 or 2 ml of 40% hydrofluoric acid). Obviously a small variation of the amount of added reagent causes a sensible change in the heat of dilution and a corresponding displacement of the calibration curve; this is another reason why the reagent should be added in precisely measured quantities. Ideally the heat of mixing is zero; in this case the calibration curve starts from the origin, and it is easy to calibrate the scale of the sensing instrument directly in concentration units.

The prime aim is therefore to obtain a calibration curve starting from the origin. This can be achieved either by adding a non-reacting substance which has a heat of mixing equal and opposite to that of the component causing the side-effect (chemical compensation) or by using a centre-zero scale on the sensing instrument and off-setting the scale to cancel the contribution of the heat of mixing (instrumental compensation). Figure 2 shows the calibration curve for boric acid obtained by adding 2 or 3 ml of hydrofluoric acid with urea added as compensating reagent; the values fall on a single straight line, contrary to Fig. 1.

However, it is more advantageous to use reagents with zero heat of mixing, since the amount of added reagent may then be varied within wider limits, and the same scale zero can be used for each component. The volume of reagent is not critical, because the total volume is very large compared with the reagent volume.

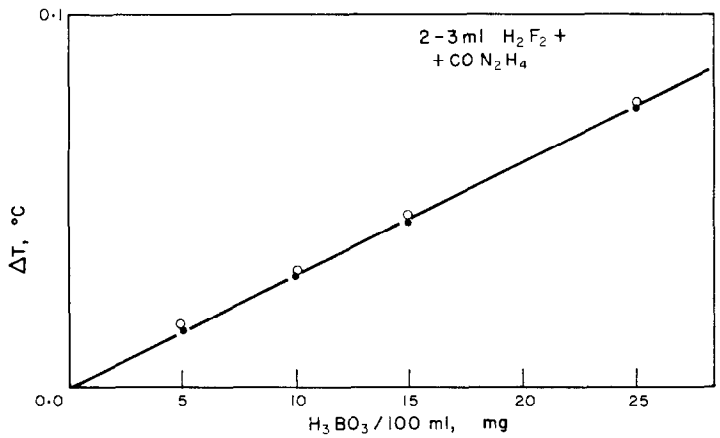

FIG. 2.—Calibration curve for boric acid with addition of 2 or 3 ml of hydrofluoric acid reagent with zero heat of mixing (sample volume 200 ml).

Only two points are really needed on the calibration curve; one of these is the origin. The parameters of the Wheatstone bridge or the shunt of the galvanometer may be adjusted from the analysis of a standard sample of known composition, so that the scale reads directly in the desired concentration units.

Eliminating the influence of the environment

In our calculations so far we have neglected the heat exchange between the system and its environment ($\Delta T'$). This exchange is the resultant of two processes with different rates, namely conduction and evaporation (effects caused by stirring and heat radiation may be neglected). Therefore

$$\Delta T' = t \cdot [\Delta T_1'/\Delta t + \Delta T_2'/\Delta t] \tag{9}$$

where t is the time necessary for the reaction, $\Delta T_1'/\Delta t$ the rate of the temperature change caused by conduction, and $\Delta T_2'/\Delta t$ the rate of the temperature change caused by evaporation.

The value of $\Delta T'$ should be as low as possible. If the temperature of the sample solution is lower than the temperature of the environment the solution will be heated by conduction and cooled by evaporation. At some temperature the rates of heating and cooling must be equal and then the two processes will compensate each other.

It is rather difficult, however, to find this temperature. Therefore in practice the starting temperature is adjusted so as to give only an approximate compensation of $\Delta T_1'/\Delta t$ by $\Delta T_2'/\Delta t$. It is sufficient if the difference in temperature between the sample solution and the environment is adjusted to a few tenths of a degree, which is easily done. We have found that if the temperature of the sample solution is about 0·5° lower than that of the environment the value of $\Delta T'/t$ will lie between 10^{-4} and 10^{-5} deg sec^{-1} which is negligible for fast reactions. The value of $\Delta T'/t$ will of course depend on the composition of the sample solution.

If the temperature of the sample solution is adjusted to make $\Delta T'/t$ negative, the heat transfer to the environment may be compensated by electrically heating the sample solution, and this balances the environmental heat loss for a relatively lengthy period (1–2 min). In this way a quasi-isothermal, quasi-adiabatic system can be established.

Because the temperature coefficients of the two heat-exchange processes will not be the same, the change in temperature of the solution caused by the reaction should affect $\Delta T'/t$, but in practice the effect is negligible because the calibration curve obtained under the same conditions provides an automatic compensation.

The heat exchange with the environment may, then, be neglected in practice, especially if the reaction time is short. The reaction should therefore proceed as rapidly as possible, and in precipitation reactions crystal seeds are often added to the solution to increase the rate of precipitation (*e.g.*, determination of sulphur).

PRACTICAL METHODS OF DETERMINATION

In direct-reading thermometry the same amount of reagent is always added to the sample solution in one batch, and there must be a surplus of reagent even if the component to be determined is present in the highest possible concentration. The surplus permits the use of reactions which are still incomplete at the equivalence point (*e.g.*, formation of complexes of low stability or of precipitates with high solubility) since it displaces the equilibrium in the required direction. Sluggish reactions can also be used because the heat transfer to the environment is negligible for periods of 1–2 min.[5–8]

It is very important to have all solutions at the same temperature before mixing them, especially if the expected temperature change is small or if the volume of the reagent solution is much larger than the volume of the sample solution; in such cases the results may be rather dubious if the temperature difference between the two solutions is a few hundredths of a degree. This is best done by having both reagents in the same vessel, but separated from each other. When their temperatures are the same they can be mixed. A thermostat is not needed, because the sample solution acts as thermostat for the reagent solution (see Fig. 3). This apparatus is very simple and suitable for plant determinations.[6,8]

If a concentrated reagent solution is used, its volume is small compared to the volume of the sample solution, and the solutions come to thermal equilibrium within 2–3 min even if the original temperature difference is as high as 3°.[6] Large sample

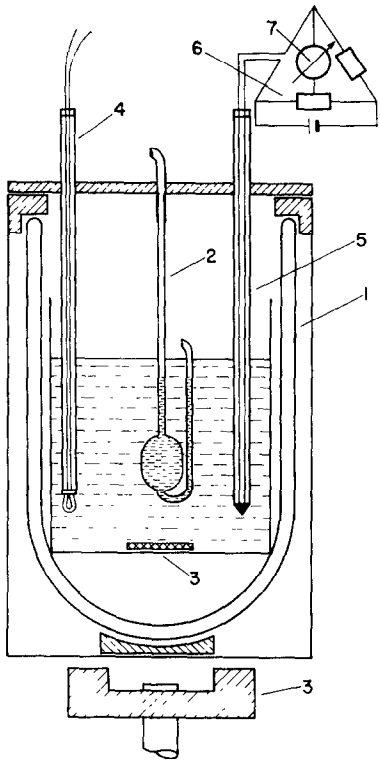

FIG. 3.—Schematic drawing of the apparatus: 1—Dewar vessel; 2—submersible pipette; 3—magnetic stirrer; 4—heater; 5—thermistor; 6—Wheatstone bridge; 7—galvanometer.

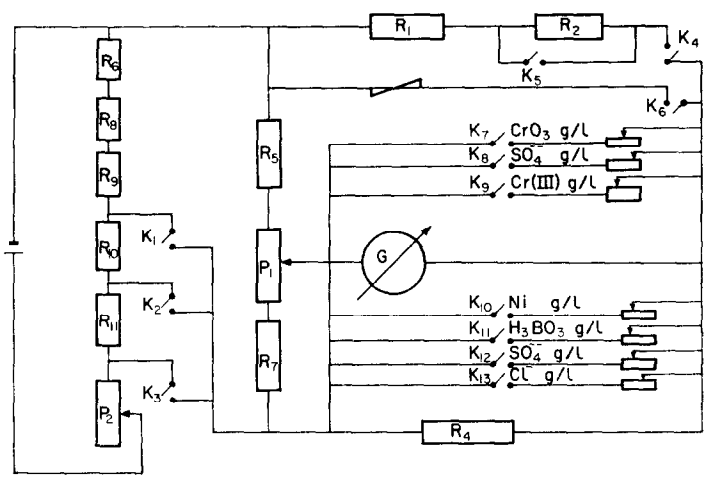

FIG. 4.—Schematic circuit diagram of the Wheatstone bridge.

volumes should be used to give a high heat inertia and low sensitivity to temperature variations in the environment.[6]

EXPERIMENTAL

Apparatus

The apparatus is shown in Fig. 3 and consists of a Dewar vessel, a submersible pipette,[8] a stirrer, a heater, a thermistor, a Wheatstone bridge and a galvanometer or digital voltmeter. The schematic circuit diagram of the Wheatstone bridge is shown in Fig. 4. A moving scale galvanometer with a sensitivity of 10^{-9}A and a scale divided into 1000 parts, or a digital voltmeter with a sensitivity of 10 mA was used as the reading instrument.[9] Suitable resistances can be used in conjunction with the galvanometer or digital voltmeter to give a scale calibrated in the desired concentration units.

Procedure

Transfer by pipette the prescribed amount of the plating bath sample into a 200-ml standard flask, add the reagents necessary for the particular determination, and dilute to the mark with distilled water. Adjust the temperature of the sample solution to 0·5° below the temperature of the environment. Put the sample solution in the Dewar flask. Fill the submersible pipette to the mark with the reagent (with zero heat of mixing). Rinse off the reagent surplus from the outside of the pipette and introduce the pipette into the sample solution (the reagent may also be introduced in a platinum crucible instead of in the pipette). Put the heater, thermistor and stirrer into the sample solution. Switch on the stirrer and allow a pause of 2 min for equilibration.

Then switch the measuring bridge to the most sensitive stage (0·2°/1000 scale divisions) and compensate with potentiometer P1 to bring the galvanometer pointer to about 100 scale divisions; observe the heat exchange between the sample solution and the environment for about 30 sec. If the starting temperature of the sample solution has been correctly adjusted the temperature of the solution will fall by about 0–30 scale divisions in 30 sec. Compensate the cooling of the solution by switching on the heater and adjusting its resistance until the temperature of the sample solution remains practically constant for periods of about a minute.

Introduce the shunt for direct reading of the concentration in g/l, and compensate the bridge by potentiometer P1 to bring the galvanometer pointer to zero on the scale. Transfer the reagent from the submersible pipette into the sample solution with the aid of a rubber bulb. At the end of the reaction, which is shown by the instrument pointer stopping, read off the concentration of the component sought.

The necessary resistance values of the shunts are obtained by use of model solutions which contain known concentrations of the components to be determined. The shunt should be chosen so that the scale is fully utilized, *e.g.*, for an expected content of 10–100 g/l the full scale deflection should correspond to 100 g/l. The shunt resistance values may be adjusted easily if continuously variable resistances are used as shunts. A model solution of known composition is used and the shunt is varied until the scale reading gives directly the concentration of the component present in the model solution. All the usual types of analytical reaction can be used.[10]

RAPID ANALYSIS OF NICKEL BATHS

Nickel

Reagents

Sodium tartrate solution. Dissolve 1 kg of tartaric acid in distilled water, dilute to 2 l. and add 3 l. of 30% sodium hydroxide solution.

Model nickel bath. This contains 400 g of nickel sulphate heptahydrate, 30 g of boric acid and 30 g of sodium chloride per l.

Potassium cyanide solution with zero heat of mixing. Dissolve 500 g of potassium cyanide in 100 ml of water and 100 ml of 30% sodium hydroxide solution. Add 515 ml of glycerine to the solution. *Control of the reagent:* dilute 50 ml of the sodium tartrate solution to the mark in a 200-ml standard flask. Transfer the solution to the apparatus and add 8 ml of the potassium cyanide solution. If the solution cools or gets warmer, adjust the cyanide solution by addition of a few ml of glycerine or a few g of potassium cyanide and test again. Repeat the adjustment until the heat of mixing practically disappears.

Method

Take 2 ml of the nickel sample in a 200-ml standard flask and add 50 ml of distilled water and—with vigorous stirring—50 ml of sodium tartrate solution. Dilute to the mark with distilled water,

and analyse the solution with 8 ml of the potassium cyanide solution as reagent. The results of the analysis of baths with various nickel contents are shown in Table I.

TABLE I.

Number	Nickel content: EDTA titration g/l	Thermometric method g/l	Difference g/l

7	10·1	10·2	+0·1

Boric Acid

Reagents

Hydrochloric acid (s.g. 1·12).

Sulphuric acid (s.g. 1·6).

Hydrofluoric acid with zero heat of mixing. Dissolve 34 g of carbamide in 205 ml of 40% hydrofluoric acid. *Control of the reagent:* dilute 20 ml of hydrochloric acid (s.g. 1·12) and 50 ml of sulphuric acid (s.g. 1·6) to the mark in a 200-ml standard flask with distilled water. Transfer the mixture to the apparatus and add 5 ml of the hydrofluoric acid reagent from a platinum crucible. If the sample solution cools or gets warmer, add hydrofluoric acid or carbamide to the reagent until on repetition of the control the heat of mixing practically disappears.

Method

Take 20 ml of the nickel bath in a 200-ml standard flask, add 20 ml of hydrochloric acid (s.g. 1·12) and 50 ml of sulphuric acid (s.g. 1·6), dilute to the mark with distilled water and transfer to the apparatus. Add 5 ml of the hydrofluoric acid reagent from a platinum crucible. Table II shows typical results.

TABLE II.

Number	Boric acid content: Added g/l	Thermometric method g/l	Difference g/l
1	10·0	10·3	+0·3
2	17·0	17·5	+0·5

5	33·0	33·6	+0·6
6	41·0	41·1	+0·1
7	45·2	45·0	−0·2

Sulphate

Reagents

Hydrochloric acid (s.g. 1·12).

Barium sulphate suspension. Suspend 100 g of barium sulphate in 400 ml of distilled water.

Precipitating reagent with zero heat of mixing. Dissolve 39·5 g of barium chloride in 155 ml of distilled water and add 30·5 ml of hydrochloric acid (s.g. 1·12) to the solution. *Control of the reagent:* take 20 ml of hydrochloric acid (s.g. 1·12) in a 200-ml standard flask, add 5 ml of barium sulphate suspension and dilute to the mark with distilled water. Transfer the solution to the apparatus and add 10 ml of precipitating reagent. If the solution cools or gets warmer, add a few ml of hydrochloric acid or a few g of barium chloride until on repetition of the control the heat of mixing practically disappears.

Method

Take 5 ml of the bath in a 200-ml standard flask, add 20 ml of hydrochloric acid (s.g. 1·12) and 5 ml of barium sulphate suspension, and dilute to the mark with distilled water. Analyse with 10 ml of the precipitating reagent. Typical results are shown in Table III.

Chloride

Reagents

Nitric acid (s.g. 1·2).

Precipitating reagent with zero heat of mixing. Dissolve 240 g of silver nitrate in 400 ml of water; add 96 ml of 96% ethanol and 50 ml of nitric acid (s.g. 1·2) to 380 ml of the solution. *Control of the reagent:* dilute 15 ml of nitric acid (s.g. 1·2) to the mark in a 200-ml standard flask with distilled water. According to the general working procedure add 5 ml of reagent. If the sample solution gets warmer or cooler, adjust the reagent with a few g of silver nitrate or a few ml of alcohol.

Method

Take 20 ml of the plating bath in a 200-ml standard flask, add 15 ml of nitric acid (s.g. 1·2) and dilute to the mark. Then add 5 ml of silver nitrate solution as reagent according to the general working procedure. Some results are shown in Table IV.

RAPID ANALYSIS OF CHROMIUM BATHS

Chromic Acid

Reagents

Sulphuric acid (s.g. 1·6).

Model chromium bath. This contains 400 g of chromic acid, 10 g of chromium(III) chloride and 20 g of sulphuric acid per l.

Iron(II) sulphate solution with zero heat of mixing. Dissolve 200 g of iron(II) sulphateheptahydrate in 440 ml of distilled water. Add 150 ml of sulphuric acid (s.g. 1·6) to the solution. *Control of the reagent:* dilute 50 ml of sulphuric acid (s.g. 1·6) to 200 ml with distilled water and add 5 ml of iron(II) sulphate solution according to the general working procedure. If the sample solution cools or gets warmer, adjust the reagent with a few ml of sulphuric acid or a few g of iron(II) sulphate heptahydrate.

Method

Transfer 10 ml of the chromium bath to a 100-ml standard flask and dilute to the mark with distilled water. Transfer 5 ml of the diluted solution to a 200-ml standard flask, add 50 ml of sulphuric acid (s.g. 1·6) and dilute to the mark with water. According to the general working procedure add 5 ml of iron(II) sulphate reagent. The results obtained for the chromic acid contents of various chromium baths are shown in Table V.

TABLE V.

6	158·1	158·0	−0·1

Chromium(III)

Reagents

Sodium hydroxide, 30% solution.

Potassium permanganate solution with zero heat of mixing. Add 30 ml of 28% sodium chloride solution and 0·2 ml of 30% sodium hydroxide solution to 70 ml of cold saturated potassium permanganate solution. *Control of the reagent:* dilute 30 ml of 30% sodium hydroxide solution to 200 ml with distilled water. According to the general working procedure add 5 ml of reagent. If the solution gets warmer or cooler, adjust the reagent with a few ml of sodium chloride or potassium permanganate solution.

Method

Transfer 10 ml of the chromium bath to a 200-ml standard flask, add 30 ml of 30% sodium hydroxide solution and dilute to the mark with distilled water. According to the general working procedure add 5 ml of potassium permanganate reagent. Table VI shows typical results.

TABLE VI.

Number	Chromium(III) content: Volumetric method *g/l*	Chromium(III) content: Thermometric method *g/l*	Difference *g/l*
1	3·92	3·98	+0·06
2	3·63	3·71	+0·08
3	2·94	2·90	−0·04

5	1·35	1·40	+0·05
6	0·67	0·68	+0·01

Sulphate

The sulphate content of chromium baths is determined on the same principle as described in the determination of the sulphate content of nickel baths. It must be remembered, however, that the results obtained for the sulphate content show a negative error dependent on the chromic acid content and therefore the results must be corrected for the chromic acid content.

Since the sulphate content of chromium baths is much lower than that of nickel baths the determination must be performed with larger samples and the value of the shunt calibrated for sulphate content is adjusted with a sulphuric acid solution of known concentration so as to obtain the sulphate content of the solution directly in g/l even for these larger samples.

Method

Take a 20-ml sample of the chromium bath and perform the analysis according to the procedure for determining the sulphate content of nickel baths. Correct the results according to the chromium content of the bath. For every g of chromic acid present per litre, increase the determined sulphate content by 0·05 g/l.

Some results obtained in the analysis of chromium baths with different sulphate contents are shown in Table VII.

TABLE VII.

Zusammenfassung—Methoden zur Schnellanalyse von Plattierungsbädern werden beschrieben, bei denen die in einer Reaktion zwischen Reagens und zu bestimmender Verbindung entwickelte Wärme gemessen wird. Neu ist an der Methode, daß Reagentien ohne Mischungswärme verwendet werden, so daß die Temperaturskala für eine besondere Bestimmung direkt in Konzentrationseinheiten geeicht werden kann. Eine Bestimmung dauert nur fünf Minuten und die Genauigkeit ist dieselbe wie bei den klassischen Methoden. Vorschriften zur Analyse von Vernickelungs und Verchromungsbädern werden angegeben.

Résumé—On décrit des méthodes pour l'analyse rapide des bains de galvanoplastie par mesure de la chaleur dégagée dans une réaction entre le rèactif et le composant à déterminer. Le nouveau caractère de la méthode réside dans l'emploi de réactifs dont la chaleur de mélange est nulle, de sorte que l'échelle de température peut être directement étalonnée en unités de concentration pour une détermination particulière. Une détermination ne nécessite que 5 mn et la précision est égale à celle des méthodes classiques. On donne des techniques d'analyse de bains de nickelage et chromage.

IMPROVED METHOD FOR THE CONSTANT-CURRENT POTENTIOMETRIC DETERMINATION OF PLUTONIUM

CHARLES E. PIETRI and ALBERT W. WENZEL
U.S. Atomic Energy Commission, New Brunswick, N.J.

(*Received* 10 *August* 1966. *Accepted* 25 *October* 1966)

Summary—A highly precise method is described for the determination of plutonium by constant-current potentiometric titration with primary standard potassium dichromate. The relative standard deviation is 0·04% or better.

THE precise constant-current potentiometric titration of plutonium with National Bureau of Standards primary standard potassium dichromate as titrant[1] has been used successfully for several years at this laboratory. In order to obtain acceptable precision (relative standard deviation <0·1%) with 100 mg samples, a weight burette was used to titrate 99% of the plutonium content, and a microburette was used to complete the determination. With the increasing availability of plutonium, larger samples can now be used to minimize the weighing and titration errors. Accordingly, the potentiometric titration has been modified so that 250–450 mg of plutonium are determined by a direct weight titration with a more concentrated titrant, to give results with a relative standard deviation of about 0·04% or better. The method may be used for the titration of smaller samples, with somewhat less precision (~0·10%).

EXPERIMENTAL

Apparatus

Weight burette. A 30-ml Friedman–LaMer-type burette with Teflon stop-cock is used. The tip of the burette is drawn out to a fine opening and silicone-treated.

Titration apparatus. This equipment has been described previously.[1] The gold electrodes (35 × 5 × 1 mm) are cut from polished gold sheet and gold-soldered to platinum rods (1–2 mm diameter). The gold electrodes are immersed to a depth of about 15 mm in the solution to be titrated. No special care or pretreatment of these electrodes is required except for occasional wiping with acetone to remove any surface organic films.

Reagents

Sulphuric acid, 1*N*, reagent grade.

Potassium dichromate solution, 3 mg of potassium dichromate per g of solution.[1]

Procedure

Dissolve the plutonium metal or compound by standard methods.[2] If organic material, *e.g.*, from ion-exchange or solvent extraction procedures, is suspected to be present, it must be removed by fuming with a nitric–sulphuric acid mixture to which a small amount of perchloric acid (<0·5 ml) has been added. Solutions containing chloride, fluoride, nitrate or perchlorate must be heated to incipient dryness with sulphuric acid several times. Dissolve the residue in a minimum amount of 1*N* sulphuric acid and cool.

Pour the plutonium(IV) solution into the Jones reductor. Using air pressure from a rubber bulb at the top of the reductor, force the plutonium solution through the reductor at a flow-rate of about 20–30 ml/min. Rinse the sample beaker several times with 1*N* sulphuric acid, adding the washings to the reductor. Wash the reductor at least twice with 15-ml portions of 1*N* sulphuric acid. Collect the reduced plutonium(III) in a 150-ml beaker containing a Teflon-coated magnetic stirring bar.

Complete the reduction step in about 5 min to avoid possible air-oxidation of plutonium(III). Collect up to 75 ml of solution for titration.

Rapidly set up the titration apparatus and adjust the magnetic stirrer so that it agitates without spattering or introducing air into the solution. Add the titrant from a weight burette containing about 30 ml of the dichromate solution, until the blue colour of the sample just changes to pale green-brown.

Adjust the pH meter to read 700 mV and quickly add the titrant in 5-drop portions until the potential of the system reverses. Continue the titration until the potential has changed by 10 mV and then add the titrant dropwise until the first potential change of greater than 10 mV occurs. Weigh the burette and continue the titration, recording the change in potential and weighing each increment (about 10 mg) of titrant added. Continue the titration past the end-point until the addition of one drop of titrant changes the potential by 10 mV or less. The end-point is obtained in the usual way by a derivative plot or is accurately calculated by Yan's method[8] as modified for weight titrations. The end-point break usually starts at 580–680 mV.

RESULTS

National Bureau of Standards plutonium metal sample No. 949 and the proposed primary standard compounds, plutonium sulphate tetrahydrate,[4] anhydrous plutonium sulphate[5] and dicaesium plutonium hexachloride,[6] were used for evaluation of the method. Table I shows that acceptable results are obtained with these materials.

TABLE I.—DETERMINATION OF PLUTONIUM BY CONSTANT-CURRENT POTENTIOMETRY WITH NBS POTASSIUM DICHROMATE

Sample	Weight taken, *g*	Plutonium given, %	Plutonium found, %**	Relative standard deviation, %
Pu metal (NBS949)	0·3	99·93*†	99·93	0·02
$Pu(SO_4)_2 \cdot 4H_2O$	0·9	47·51‡	47·53	0·04
$Pu(SO_4)_2$	0·7	55·45‡	55·44	0·02
Cs_2PuCl_6	1·0	33·33†¶	33·32	0·03

* Certified value, corrected for ^{241}Am growth.
† Relative standard deviation 0·03%.
‡ Theoretical value.
¶ Analysed value, Dow Chemical Co.
** Mean of 4 results.

Determination of plutonium in over 50 samples of plutonium sulphate tetrahydrate, made at intervals during several years, has indicated a relative standard deviation of 0·04% for the method.

DISCUSSION

The fine tip of the burette allows delivery of the titrant in drops weighing 10–30 mg. The drops from the silicone-treated tip are relatively reproducible in size and are easily dispensed. Weight increments of about 10 mg of titrant (equivalent to about 0·15 mg of plutonium) will usually provide a potential change of at least 100 mV at the end-point. Larger increments up to about 30 mg provide potential changes greater than 400 mV.

Meter readings for potential changes of 10 mV or less are stable almost immediately after dropwise addition of titrant, but near the end-point may require about 10 sec to reach a stable value. The potential change at the end-point, 100–400 mV, may take as long as 3 min for completion. Stable potential readings are indicated by a drift of less than 10 mV in 10 sec.

The final titration in the earlier method[1] required 4*N* sulphuric acid for a sharp end-point, probably because of the very small increments of dichromate (0·01 mg) added. The present method uses from 3 to 9 times as much dichromate in each increment added near the end-point and apparently requires only 1*N* sulphuric acid for a satisfactory end-point. The use of 1*N* sulphuric acid reduces the amount of "gassing" in the Jones reductor and makes the reduction step faster, especially when large plutonium samples are used.

The tip of the burette need not be capped at any time. The silicone treatment prevents titrant from adhering to the outside of the tip during the titration, and prevents loss by evaporation. There is less than a 2-mg change in the weight of the loaded burette during 24 hr.

Cations such as those of Cr, Fe, Mo, Ti, U, V and W which are reduced in a Jones reductor, interfere, but repeated analysis of the same plutonium material by this method over a period of several years has indicated no significant interference from americium as has been suspected in ceric sulphate titrations.[6] A correction for these interfering cations may be applied, or better, they may be removed by anion-exchange methods.[7] It must be realized that applying corrections for certain elements such as uranium and chromium which are reduced in a Jones reductor to a mixture of oxidation states, *e.g.*, U(III)-U(IV), Cr(II)–Cr(III), may introduce significant errors in the plutonium value if the concentration of the interfering element is high enough. When nitric acid anion-exchange procedures are used to remove impurities, organic material (apparently leached from the resin) causes positive errors if it is not destroyed before the titration. The errors have been found to be consistent for particular brands (or grades) of anion-exchange resin.[8] Results high by 0·28 % were obtained with one brand of standard Dowex-1 resin, but the results were high by only 0·05% when AG-1 resin[9] (a specially purified, treated and graded form of Dowex-1) was used. This interference can be reduced or entirely eliminated by fuming the samples with a nitric–sulphuric–perchloric acid mixture. Treatment with nitric or sulphuric acid, alone or mixed, did not remove the organic matter even after repeated fumings.

Résumé—On décrit une méthode hautement précise de dosage du plutonium par titrage potentiométrique à intensité constante avec pour étalon primaire le bichromate de potassium. L'écart type relatif est de 0,04%, ou meilleur.

Zusammenfassung—Es wird eine sehr genaue Methode zur Bestimmung von Plutonium durch potentiometrische Titration bei konstantem Strom mit dem primären Standard Kaliumdichromat beschrieben. Die relative Standardabweichung ist 0,04% oder besser.

AN EXPERIMENTAL EVALUATION OF NEUTRON ACTIVATION, WET ASSAY AND FIRE ASSAY METHODS OF DETERMINING GOLD IN ORES

A. CHOW and F. E. BEAMISH
Department of Chemistry, University of Toronto, Toronto 5, Canada

(*Received* 22 *September* 1966. *Accepted* 8 *October* 1966)

Summary—The errors associated with fire assay, wet extraction and neutron activation methods are evaluated, the accuracy and precision of these methods are compared, and a method of determining chemical recovery in the activation determination of gold in ores and concentrates is presented.

THE gold content of ores has been estimated by fire assay and cupellation since at least the 16th century. Recently, wet methods of extracting gold have been recorded and neutron activation has been developed into a potentially useful method of determination. However, very little has been recorded to permit an evaluation of the various methods for determining gold in ores, or to allow assessment of the efficiency of fire assay and wet extraction for the separation and collection of microgram amounts of gold. The purpose of the present research was to remedy this situation.

EXPERIMENTAL

Apparatus

William and Wilson 20 kW electric furnace.
Beckman Model B spectrophotometer.
Sartorius MPR 5/2 microbalance.
Nuclear Chicago Model 410A single channel spectrometer and Model 422 well-type scintillation detector.
Cupels and assay crucibles supplied by A. P. Green Fire Brick Co. (Weston, Ontario, Canada).

Reagents

Gold foil (Johnson Matthey).
Gold, precipitated powder (Fisher purified).
Silver, precipitated powder (Fisher certified reagent).
Lead foil (Matheson, Coleman and Bell reagent).
All acids and other chemicals used were commercially pure reagent grade except the hydrobromic acid which was the colourless fraction obtained by distillation of reagent grade acid.

Standard gold solutions

Approximately 1 g of gold foil was dissolved in *aqua regia* and nitrous oxides were removed by repeated evaporations with hydrochloric acid in the presence of a few milligrams of sodium chloride. The solution was filtered and the residue ignited, dissolved by the same procedure and added to the original filtrate. The final solution was diluted to 1 l. with 0·12*M* hydrochloric acid. Dilute gold solutions were prepared by dilution with 0·12*M* hydrochloric acid. The concentrated stock solution was standardized with hydroquinone.[1]

Standard methods used for determining gold

Gravimetric. After annealing at 700° for a few minutes, the gold residue was transferred directly to the balance pan by tweezers or by careful brushing. Alternatively, the residue was collected by filtration, the filter paper and contents were placed in a tared crucible and the sample heated to constant weight at 700°. A blank was necessary to correct for the filter ash. With some samples, the gold was dissolved in *aqua regia* and then precipitated from the solution and determined by hydroquinone.[1]

Titrimetric. The iodometric technique[8] was used to determine 0·2–25 mg of gold.

Spectrophotometric. The direct bromoaurate procedure[2] is one of the simplest colorimetric methods available for gold and was used to determine 10–500 μg of gold which had been isolated from interfering elements. The bromoaurate was formed in 0·8M hydrobromic acid and the absorbance measured at 380 mμ.

For amounts of gold from 1–10 μg, the Methyl Violet procedure[3] was applied. The absorbance of the coloured species was measured at 600 mμ.

THE FIRE ASSAY

The long use of the fire assay has encouraged the belief that it is precise and accurate under all circumstances. This assumption has been supported by the authors of a few reports who proposed to determine the accuracy of the fire assay, but provided only a comparison of the efficiency of different assay procedures and perhaps of the various assayers. Despite the lack of experimental justification for the use of the classical assay and the uncertainty of the chemistry of the interactions of the flux constituents, the technique is the most universally used method for the estimation of gold in ores.

We have tried to obtain a realistic appraisal of the fire assay procedures for both milligram and microgram amounts of gold.

The fire assay of standard gold samples

Both the normal and the nitre assay methods were evaluated by using standard gold samples. The fluxes used were A and B respectively (Table I).

Each set of samples was prepared from a mixture of the flux with the appropriate amount of a blank ore. For the normal assay, the blank ore was pure silica, and for the nitre assay, it consisted of a mixture of silica and iron, copper and nickel sulphides. After thorough mixing of the blank ore with the flux, samples were weighed and transferred to an assay crucible, and salted individually with a known amount of gold. Some samples were salted with milligram amounts of pure gold powder and then thoroughly mixed on a cellophane sheet. Others were salted with either milligram or microgram amounts of gold added as a standard solution of gold chloride. These samples were dried overnight at 85°, cooled, stirred gently to break up any large lumps, and then mixed.

The crucibles containing the samples were placed in the furnace at 1040° and heated to 1150° as quickly as possible (usually 45–60 min). After 30 min at 1150°, the crucibles were removed and the samples poured into a conical iron mould in which they were allowed to cool. The slag could be separated from the lead button by gentle tapping with a small hammer.

The lead buttons were cupelled, the silver beads parted, and the gold was determined either by direct weighing of the gold residue or by the bromoaurate colorimetric method, depending on the amount of gold added to the assay sample. In all cases, blank corrections were applied.

The values for the normal fire assay show that an average of 99% or more of the gold was recovered for milligram amounts and 97% or more for microgram amounts of gold added. Equally complete recovery was obtained from samples salted with gold powder or with a gold solution. Similar recovery of gold was obtained with the nitre assay.

Although the values show excellent precision and accuracy, it was found that precise results can be expected for ore samples only if the gold can be rendered as readily amenable to collection as with the standard samples. This is sometimes extremely difficult to achieve, but with many ores a proper choice of flux can be made.

The cupellation and parting of gold standards

The cupellation and parting methods were evaluated by using artificial lead buttons (~23 g in weight) containing gold and silver. Weighed amounts of the pure metal powders were placed in a lead foil boat and the boat folded carefully to avoid loss during handling. Other artificial buttons were prepared by evaporation (at 85°) of an aliquot of gold chloride solution in a boat made of lead foil. The volume and the acidity of the solution were kept to a minimum to limit the corrosion of the lead and prevent possible losses of solution. After the addition of silver powder, the lead was folded into a $\frac{3}{4}$ in. cube.

Magnesia cupels were preheated in the furnace to 982° and the lead buttons were added quickly to prevent "freezing." After "opening" for 5 min at this temperature, the draught was opened and the sample "driven" for 25–30 min. The draught was then closed, and after a "finishing" time of 5 min the cupels were withdrawn from the furnace gradually, to prevent "splitting".

Two parting procedures were used. For milligram amounts of gold, the bead was parted with

5–10 ml of hot 5*M* nitric acid in a glazed porcelain crucible. The solution was decanted and the residue washed thoroughly. After annealing, the gold was weighed directly. For milligram and microgram amounts of gold, the bead was parted in a small beaker and the residue filtered off on a 7-cm Whatman No. 42 filter paper. For milligram amounts, the filter was placed in a tared crucible, charred, and heated at 700° to constant weight. With microgram amounts, the filter was returned to the parting beaker and the paper removed by heating at 450° for several hr. After cooling, the gold was dissolved and then determined by the bromoaurate method. Blanks were done with all procedures. Occasionally silver chloride formed because of hydrochloric acid fumes, and the samples were then washed with aqueous ammonia (1 + 1) and then with water.

The losses resulting from the decantation procedure depended on the skill of the operator. With coherent residues, losses were minimal but with scattered residues the probability of losses was greatly increased. Losses of gold by dissolution in the nitric acid or by passage of very fine particles through the filter were evaluated by fire assay of the evaporated filtrate, using flux A with 15 g of silica. The maximum amount of gold found in the filtrate was 0·3% of the gold added.

The recovery of gold from artificial buttons containing milligram amounts of gold powder was usually 99·5% or better. Losses during decantation cause low values and incomplete parting causes high values. Varying proportions of gold and silver do not affect the recovery. Samples which were parted a second time showed no significant loss in weight.

For buttons containing gold added as a solution the recovery was greater than 97% for microgram amounts but only 90–95% for milligrams amounts of gold. When the gold chloride solution was added to the lead boats, gold was precipitated very rapidly. Rapid precipitation encourages the formation of very fine particles and there were indications that these gold particles could be absorbed if they came into contact with the cupel surface before they were alloyed with lead. The more complete recovery of the smaller amounts of gold supports this suggestion. Further evidence was obtained by cupelling artificial buttons prepared from a constant amount of gold solution and varying amounts of lead. The losses were larger with decreasing proportions of lead.

To verify that the loss of gold was into the cupel, a fire assay of the used cupels was made, using flux E. The gold recovered was 90% of that lost during cupellation.

In an attempt to avoid the losses experienced when using gold solutions, the gold was precipitated before its addition to the lead boat. Lead powder and sulphur dioxide did not give improved results but silver powder gave quite an accurate and consistent gold recovery. Varying amounts of silver gave equal accuracy and 50 mg were sufficient for complete recovery of 20 mg of gold. The gold chloride solution was placed in a small beaker and silver powder was added. After 2 hr of heating on a steam-bath, the contents of the beaker were transferred to a lead boat, with careful washing. The solution was evaporated and the boat was folded and cupelled as before.

These cupellation and parting experiments showed that there was complete recovery of gold by the procedures described but the loss of gold to the cupel when using artificial buttons prepared with gold solutions is quite significant, because standards for spectrographic and other procedures are often prepared in this manner. Though the losses are negligible for a few micrograms, they can be considerable for larger amounts and unless some corrective measure such as prior precipitation is taken, the buttons used for standards are best prepared by adding gold metal to lead foil or by doing the complete fire assay.

Sampling

The precision and accuracy of any method depends on the effectiveness of the sampling procedure. The ore sample received in the laboratory usually weighed less than 100 lb and was crushed and ground to 100–200 mesh. The ore was split by hand riffling and two of the portions accepted if their weights differed by less than 1%; otherwise the portions were recombined and the process repeated.

When the sample weight had been reduced to a convenient amount, the ore was placed on a large cellophane sheet and rolled thoroughly by lifting alternate corners of the sheet, taking care to avoid losses because of too vigorous rolling. The ore was spread evenly on the cellophane and the surface marked into 1 in. squares. The sample required for an assay was obtained by taking a small segment from each square, making sure that each segment extended down to the surface of the cellophane.

It is apparent that true homogeneity is impossible unless the gold is a dissolved constituent in the

* Gold concentration was determined by the bromoaurate method.

entire ore body. Since gold commonly occurs as the native metal or as a constituent of a particular mineral, real homogeneity is not obtainable by any physical procedure. The apparent homogeneity depends on the physical nature of the noble metal, the size of the ore particles and the size of sample taken for analysis. The use of the assay ton (approximately 29 g) for the fire assay, taken from a well-mixed sample, often provides apparent homogeneity.

The determination of gold in ores by fire assay

Several gold ores were obtained from the Mining Department (University of Toronto) and those were crushed, ground and sampled as described. Two gold ore concentrates were similarly treated. Each sample was designated by a number and the originating mine was known in most cases. In addition a nickel ore, flotation concentrate and matte were also treated as described. The gold ores and concentrates were composed mainly of silicates and the nickel samples mainly of sulphides. For all samples the whole of the crushed ore passed through a 100-mesh screen and 90–100% passed through a 200-mesh screen.

The gold concentrates and ores were assayed, using flux A, by the methods previously discussed. Blanks were made by substituting an appropriate amount of silica for the ore, but these contributed only a minor amount to the gold value. The gold concentrations were determined by direct weighing of the gold residue or by dissolution and the use of either the hydroquinone precipitation or the bromoaurate colorimetric procedure. The values obtained for these ores are recorded in Table II.

The nickel matte and concentrate required nitre assays and flux B was used for the matte and fluxes B, C and D were used for the concentrate. The assay was conducted as described for the standard gold samples. Blanks were provided by an appropriate amount of the following mixture: silica 12 g, iron sulphide 12 g, copper and nickel sulphides 3 g of each. Gold was determined by the bromoaurate colorimetric procedure.

Preliminary assays of the nickel concentrate gave unexpectedly high spectrophotometric values. An examination of the ultraviolet and visible spectra showed two distinct peaks in the 0·8*M* hydrobromic acid solutions, at 295 mμ and 370 mμ. These peaks corresponded to those for lead and bismuth respectively, and the bismuth peak effectively masked the bromoaurate peak at 380 mμ. The presence of microgram amounts of lead and bismuth was confirmed by several spot tests.

The presence of a small amount of lead in the silver bead is not unexpected, but normally this is removed as the nitrate during the parting procedure. Trace amounts of bismuth in the litharge are probably collected in the lead button during the nitre assay, although this was not observed for the normal assay. The supposition that the bismuth originated in the litharge is supported by the observation that interference from bismuth was observed with blanks prepared as described and even with blanks consisting only of flour and flux.

The separation of gold from bismuth and lead was easily achieved by extraction of the bromoaurate from 0·8*M* hydrobromic acid by ethyl acetate.[3] The gold was completely recovered and could be determined as the bromoaurate after evaporation of the ethyl acetate, destruction of any organic residue, and dissolution of the gold.

The values obtained for the determination of gold in the nickel matte and concentrates are recorded in Table III. The values for the gold concentrates and the nickel samples show the homogeneity achievable by the sampling method described. The results for the gold ores sampled in the same way, show that the homogeneity of these samples is quite varied, the results for some showing similar precision to those for the gold concentrates, while others show considerably larger variations.

The variations in precision emphasize that any assay of an ore is very dependent on the degree of homogeneity within the sample. It is apparent that no assay result should be accepted without some knowledge of the methods used to obtain homogeneity and that no range of acceptability may be proposed without a series of values being obtained for the particular ore.

WET EXTRACTION

Wet extraction is a term used to describe any method in which the desired constituent is concentrated into a liquid medium. This process has the advantage that the chemistry of the resulting solution can be predicted with reasonable certainty. On the other hand, the fire assay, which concentrates the gold into a solid medium, presents difficulty because of a lack of knowledge of the components of the ore and of the products occurring during the assay process.

The most common methods of commercial wet extraction of gold from ores are amalgamation and cyanidation. The recovery of gold by these methods varies with the character of the ore and the physical conditions of the extraction. For the analysis of gold in ores, a more complete extraction is required and usually involves some acid treatment. *Aqua regia* is commonly favoured as an extractant and the gold is then isolated by solvent extraction or by precipitation.

Most methods for the wet extraction of gold and its determination are designed to be field tests and thus give semi-quantitative values at best. No research report has verified the completeness of the extraction process or the efficiency of the other processes used for the purification or the gold prior to its determination. For this reason, several extraction methods were investigated for both milligram and microgram amounts of gold, and the values obtained for several gold ores by these methods were compared with values obtained by its fire assay.

EXPERIMENTAL

The wet extraction of gold

Several techniques were used to extract gold from an ore. The completeness of the extraction was evaluated by fire assaying the ore residue. The residue was mixed with an appropriate amount of flux A and with enough silica to compensate for the portion of the ore which was dissolved. The fire assay was carried out as described previously and the gold content of the residue determined by the bromoaurate method.

Extraction methods for gold

Several 15-g ore concentrate samples were treated in plastic beakers with 25 ml of hydrofluoric acid. The solution was evaporated by heating on a steam-bath and the process was repeated. The residue was dissolved in hydrochloric acid and the solution was evaporated to dryness several times to ensure removal of hydrofluoric acid. The residue was dissolved in 25 ml of *aqua regia* and the solution was diluted with 25 ml of water and filtered through Whatman No. 42 filter paper, the beaker and paper being carefully washed. The filter paper and the small amount of residue in it were fire assayed, with proper adjustment of the flour content of the flux to allow for the reducing effect of the filter paper. By comparison with the fire assay values, the extraction of gold was 99·7–99·9% complete.

A few samples of 7·5 g and 3·75 g of ore concentrate were hydrogenated in porcelain boats for 4 hr at 650° in a Vycor tube and then chlorinated for 4 hr at 700° with a slow stream of chlorine. Other samples were treated by chlorination only. Each of the samples was treated individually and after cooling, was transferred to a beaker. The inside of the Vycor tube was washed with hydrochloric acid and the washings added to the same beaker. The porcelain boat was washed free of any residue and removed from the beaker. The contents of the beaker were evaporated and then treated with 25 ml of *aqua regia*. After dilution with 25 ml of water, the contents of the beaker were filtered through Whatman No. 42 or No. 541 filter paper, and the residue was thoroughly washed. The paper and the residue were dried and then fire assayed. The extraction by hydrogenation and chlorination or by chlorination alone was calculated to be 99% complete.

Several 15-g gold ore concentrate samples were treated with 30 ml of *aqua regia* for 24 hr on a steam-bath with occasional stirring. After dilution with water, the samples were filtered through Whatman No. 42 or No. 541 filter paper, and the residual gold determined by fire assay. This extraction of gold was 99·5% complete.

The *aqua regia* extraction was repeated with the available gold ores and in this case the residue was dried in the original beaker and then treated again with *aqua regia*. The gold remaining in the residue and the gold found in the evaporated second extract were determined by fire assay. For the

gold ores which contained 100–600 μg of gold per sample, the first extraction was 98·0–99·5% complete and the final undissolved residue contained a maximum of 0·5% of the original gold.

Although the chlorination procedure gave acceptable results, it was more time-consuming than the methods involving *aqua regia* and hydrofluoric acid, and also required more extensive equipment, especially if a large number of samples were to be handled. The *aqua regia* extraction could be done with a minimum of equipment and supervision and was generally 99% efficient in a single treatment. Treatment of the ore with hydrofluoric acid removed silica and permitted a more efficient dissolution of gold. Since only negligible amounts of residue remained after the hydrofluoric acid and *aqua regia* treatments, the extraction of gold was quite complete.

The procedures described above were evaluated only for the completeness of the removal of gold from ores and not for the total recovery of the precious metal.

The separation of gold from base metals

The extraction of gold from an ore by the methods described is accompanied by simultaneous extraction of base metals. The isolation of gold by precipitation and by most solvent extraction methods is subject to interference from these base metals.

For the recovery of small amounts of gold from solutions, and for the separation of gold from most of the other elements, the co-precipitation of gold with tellurium has frequently been used.[3–6]

Nitrous oxides were removed from the *aqua regia* extract of a gold ore concentrate by evaporating it nearly to dryness several times after addition of a few ml of hydrochloric acid. The solution was diluted to 50 ml and adjusted to be 2·4–3·6*M* in hydrochloric acid; then 1–2 ml of 2% tellurous acid solution were added. The solution was heated to boiling, and 10 ml of 15% hydrazine hydrochloride solution and 40 ml of a saturated solution of sulphur dioxide were added, which caused the formation of a dark precipitate. The precipitate was also formed by bubbling sulphur dioxide through a sample solution heated on a steam-bath. The sample was digested by continued heating. The coagulated precipitate was quite coarse and easily filtered off on medium porosity sintered glass crucibles or Whatman No. 42 filter paper.

The filtrates from several ore samples treated in this way were fire assayed and indicated that the loss of gold to the filtrate was 0·1–0·3%.

Separation of gold from tellurium

The tellurium co-precipitation of gold provides a fast and efficient method for separating gold from the base metals. Unfortunately, it is difficult to determine gold in the presence of tellurium and a complete separation is often required.

The most common method of removing tellurium is to volatilize it by heating the precipitate at 600–700° in air, but it was found that an interfering residue was left which could not be removed even by prolonged heating. Since small amounts of tellurium interfere with the bromoaurate method, a more complete separation was required.

Tellurium forms a volatile hydride and it was found that hydrogenation of the precipitate for 12 hr at 650–750° successfully removed the tellurium. A shorter hydrogenation (2–3 hr) was sufficient if the bulk of the tellurium was volatilized by an initial 5-hr heating in air. Gold does not form a volatile hydride under these conditions.

The hydroquinone precipitation of gold in the presence of tellurium was developed by Seath and Beamish[6] for milligram amounts of gold. No previous report deals with the separation of microgram amounts of gold with this procedure.

The tellurium-gold precipitate was collected in a sintered glass crucible, washed thoroughly with hot water, and dissolved in *aqua regia*. The solution and washings were transferred to a beaker and evaporated to dryness after the addition of 2 ml of 2% sodium chloride solution. Any nitrous oxides were removed by alternate evaporation and addition of a few drops of hydrochloric acid. The residue was dissolved in 40 ml of 1·2*M* hydrochloric acid the and solution was heated to a gentle boil, a small piece of filter paper being used to prevent "bumping". From a small dropping tube, 1 ml of 5% hydroquinone solution was added slowly to the solution to initiate the reduction, and then 5 ml of the hydroquinone solution were added by a Mohr pipette to complete the precipitation. The solution was boiled for 30 min to coagulate the precipitate, cooled and filtered through a 7-cm Whatman No. 42 filter paper. The beaker was carefully cleaned with small pieces of filter paper as "policeman." The filter and extra paper was folded and ignited in a porcelain crucible.

The collection and separation of gold

The collection of gold by co-precipitation with tellurium and the separation of gold from tellurium by either the hydrogenation or hydroquinone methods was evaluated by the use of standard gold solutions. Standard samples containing 10 μg–1 mg of gold were treated as described after addition of 30 mg of tellurium. The combined procedures gave a recovery of about 94% for microgram amounts of gold and 98% for milligram amounts.

The wet determination of gold was evaluated by using various amounts of a gold ore concentrate

already analysed by fire assay. The results show a recovery of 80% or more for 10 μg and 95–98% for larger amounts of gold.

The wet determination of gold ores

The gold content of the five gold ores and one gold ore concentrate was determined by the wet procedure outlined. The values obtained are reported in Table IV. They are quite similar to those obtained by the fire assay, and so is the precision. Only by chance was homogeneity obtained and the degree to which it occurs may be measured by the precision of the values obtained by either the fire assay or the wet method.

DISCUSSION

The wet extraction method provides an alternative to the fire assay which is especially useful in those cases when the fire assay values are in doubt. While the fire assay requires the use of a special assay furnace and associated equipment, the wet method may be carried out with normal laboratory equipment. The fire assay procedures may be carried out rapidly and with little attention but the wet method does not have these advantages. The wet extraction, however, requires less knowledge of the ore composition, whereas the influence of the nature of the noble metal minerals is one of the questionable aspects of the fire assay. Because the mechanically mixed components are not known with any certainty, the claim has occasionally been made that the fire assay is ineffective for particular ores. Wet extraction is always effective.

NEUTRON ACTIVATION ANALYSIS

Neutron activation analysis techniques are most frequently applied for submicrogram amounts of constituents, and in this range, no tool of comparable value exists. While this high sensitivity is an outstanding advantage, it is also important that errors arising from contamination during processing should be eliminated. After irradiation,

only the radioactive constituent is determined and thus milligram amounts of inactive constituent may be added to serve as a carrier for the trace amount of radioactive material. The carrier permits the use of conventional techniques, and if complete isotopic exchange can be assumed, the chemical yield can be used to correct for any losses of active constituent during the procedure. The nuclear properties of a radioactive isotope such as half-life, beta energy and gamma energy provide for its unequivocal identification.

The major disadvantages of activation analysis are the need for irradiation facilities and the fact that the method makes no distinction between different oxidation states.

Many of the problems arising in activation analysis are the result of an uncritical acceptance of the chemical yield as an alternative to acceptable chemical methods. In addition, the problem of securing a representative sample of the size required for activation analysis increases the difficulty of obtaining results comparable to those of ordinary chemical methods in concentration ranges where both may be applied. This is a particularly important factor in the determination of gold and other noble metals in ores, particularly when, as usual, the homogeneity of the sample is in doubt.

Various explanations have been offered for the lack of precision of some activation methods and for the discrepancies between the values obtained by some activation procedures and by other medthods for the determination of gold in ores, but no acceptable evaluation of the neutron activation method for gold ores has been recorded.

EXPERIMENTAL

Activation of gold standards

The precision of the activation analysis technique developed was evaluated by the use of gold standards. These samples, containing 0·05–5 μg of gold were prepared by evaporating weighed amounts of standard gold solution in 3–5 mm quartz tubes. The tubes were sealed by fusing with an oxygen torch, and were wrapped in aluminium foil and placed in an aluminium irradiation capsule. The samples were irradiated in the McMaster Reactor (Hamilton, Ontario, Canada) at a flux of approximately 5×10^{12} n/cm^2/sec for 3–12 hr.

The irradiated samples were transferred from the capsule to individual plastic beakers and treated by the procedure described below for ore samples. The results showed that an average deviation of 2–8% may be expected.

The similarity of the specific activity for varying amounts of gold indicates that there is no self-shielding problem with microgram amounts of gold.

Activation analysis of gold in ores

The activation analysis technique only permits the use of a small sample, usually less than 0·5 g, so the preparation and sampling of an ore is very important. The degree of homogeneity is likely to be much larger with small samples than with 30-g samples.

To provide as much uniformity as possible, the sample for analysis was removed from 30 g of the ore, treated as described for the fire assay but marked into $\frac{1}{2}$ in. squares on the cellophane. The samples were added to tared quartz vials which were centrifuged to pack most of the ore in the bottom. Any residual powder in the upper portion of the vial, which might be lost on sealing, was removed with a small piece of filter paper. The vial was re-weighed and then sealed. Each set of ore samples together with at least one standard was placed in an aluminium capsule and irradiated for 3–12 hr.

The nickel ores as well as the gold ores could be completely dissolved in a mixture of nitric and hydrofluoric acids (1 + 3). These dissolved irradiated samples were filtered and the filter was washed thoroughly. Examination of the paper with a multi-channel gamma spectrometer showed only minor amounts of activity of various energies similar to those of the sample solution, which suggests that some solution was retained on the paper.

The sample vials were opened in a glove-box after irradiation, and most of the material removed by gentle tapping. Attempts were made to ensure complete removal of sample by washing the vial with several portions of acid. Although this technique has been generally used, it seemed to be subject to error. To eliminate the possibility of loss during opening and discarding the vials, they were

placed in 50-ml polypropylene beakers and dissolved in hydrofluoric acid. After the removal of the silica, an aliquot of a standard gold solution was added to each sample and the solution was evaporated to dryness. The residue was treated twice with 10 ml of nitric and hydrofluoric acids (1 + 3) and thrice with 10 ml of *aqua regia*, with evaporation to dryness after each addition. The residue was dissolved in 5 ml of *aqua regia* and 1 ml of 5% sodium chloride solution was added. Nitrous oxides were removed by evaporating the solution to a small volume several times after the addition of a few drops of hydrochloric acid. This sample solution was diluted to 25 ml with 3*M* hydrochloric acid. Then 50 mg of tellurium (as tellurous acid solution) were added and sulphur dioxide was bubbled through the solution until the tellurium was precipitated and coagulated. The presence of nitrous oxides interfered with and delayed the precipitation, but prolonged treatment with sulphur dioxide eventually produced elemental tellurium. The solution was filtered through a sintered glass crucible and the beaker and crucible were washed thoroughly. The filtration was done in a fume hood or with the operator wearing a proper gas-mask, because of the risk from prolonged exposure to the sulphur dioxide fumes. The gas could have been boiled out, but the plastic beakers did not permit boiling, and the delay might have led to considerable decay of the radioactivity. Fire assay showed the filtrates to contain less than 1% of the total gold activity.

The tellurium precipitates from several nickel concentrate samples were examined with a gamma scintillation multi-channel analyser and were found to contain radioactive isotopes of gold, antimony and selenium. The samples required separation because the activity of selenium interfered with that of gold and because the inactive tellurium prevented the determination of chemical yield.

Although preliminary trials showed that gold could be separated radiochemically pure from antimony and selenium by ethyl acetate extraction of the bromoaurate, the partial extraction of tellurium prevented a yield determination. The hydroquinone precipitation provided a separation of gold from selenium, tellurium and antimony. The tellurium precipitate was dissolved in *aqua regia* and the crucible washed clean. The sample and washings were treated as described earlier for the separation of gold from tellurium (p. 7). The filtrates from this separation were examined and showed that varying amounts of gold were lost because of incomplete precipitation. A longer digestion period of 1 hour or more gave more consistent and complete separation. The filtrates from nickel concentrate samples contained radioactive selenium and antimony but those from gold ores showed only negligible amounts of activity.

The gold residue was dissolved in a few drops of *aqua regia*, sodium chloride was added and nitrous oxides were removed by evaporations. The final solution in a few drops of hydrochloric acid was diluted to 25 ml with 0·8*M* hydrobromic acid. One aliquot of this solution was used to determine the bromoaurate concentration spectrophotometrically at 380 mμ, and another to determine the activity of the gold-198 with a well-type, single channel, gamma scintillation counter. The range of energies counted was 0·39–0·43 MeV with the peak for gold occurring at 0·41 MeV. The gamma spectrum and a half-life measurement both showed that the gold was radiochemically pure.

The chemical yield was calculated for each sample and used to correct for losses during the procedure. The recovery of gold was 90–100% for those samples given a longer digestion period to precipitate gold, but varied more widely for the others. The losses of gold may be the result of the remote handling procedures required for radioactive materials; the use of tongs, rubber gloves, *etc.*, does not promote accurate manipulation. The plastic beakers used for the ore dissolution show a tendency to retain some activity although they have no observable preference for gold. The losses to the beaker are dependent on the condition of the inner surfaces and probably beakers should be discarded after use to avoid any carry-over of active materials and to provide more uniform conditions.

The amount of gold was calculated by comparison of the activity of samples and standards, corrected for the chemical yield. The values obtained for several gold ores and nickel ores are recorded in Table V.

The results for gold ore No. 294 show reasonable consistency and quite good agreement with values obtained by other methods. However, the precision given by the activation analysis techniques for other gold ores is very poor. Values of 0·2–1·3 oz/ton for the same ore indicate the magnitude of the problem of sample homogeneity in the determination of gold. The values obtained for gold in the nickel matte, concentrate and ore indicate that the gold is considerably more homogeneously distributed in these samples.

The neutron activation analysis technique which was developed avoided losses due to incomplete removal of sample from the irradiation vial or to incomplete dissolution of the sample. Only small amounts of gold were lost because of incomplete co-precipitation with tellurium or by hydroquinone and these losses could be corrected for on the basis of the chemical yield. Isotopic homogeneity was encouraged by the similar treatment given the carrier and the active gold. No appreciable losses of radioactive gold were observed and the chemical yield indicates only small losses of the carrier gold. The similarity of the specific activity for different amounts of irradiated gold sample indicated that there was no self-shielding effect for the amounts of gold used and that quite probably isotopic homogeneity had been obtained. The effect of the matrix could not be properly evaluated because

* Average gold content ± the average deviation.

of the variations occurring with the ore samples, but irradiation of ore samples salted with a gold standard indicated no major variations.

The activation procedure described required approximately three days for completion although as many as 30 samples were done at one time. The procedure could be shortened if a better method of separating gold and tellurium could be devised. The separation would be unnecessary if there was no selenium in the sample and if the chemical yield was 100%. The technique could also be made more rapid by eliminating the dissolution of the quartz vial although this might be a source of error. The replacement of filtration by the use of the centrifuge would reduce the time required for filtration and for the subsequent treatment. While each change in technique would decrease the time required for a determination, most of those suggested would also increase the losses of gold, but if the chemical yield could correct for these losses, the revised procedure could be used. Without a careful examination no variation can be unconditionally recommended.

The activation analysis procedure as outlined gives a radiochemically pure sample with a high yield and provides accurate and precise values for materials for which representative irradiation samples can be taken.

CONCLUSIONS

The amount of gold in ores may be estimated by fire assay, wet extraction or neutron activation by the procedures described.

The fire assay is the fastest and most efficient method for multiple and routine analysis of ores, but requires considerable equipment and a flux suitable for the individual ore. This technique may be used with large amounts of ore and thus is relatively insensitive to the homogeneity of the gold distribution in the ore. For milligram and microgram amounts of gold, the losses by each of the procedures of the fire assay were found to be negligible. This method remains the least understood on a theoretical basis and considerable improvement in the existing techniques for devising a flux and for predicting losses might be expected if this knowledge was forthcoming.

The wet extraction may be used with a variety of sizes of sample and permits a laboratory, without special equipment, to determine gold in ores. Although the ores used for the evaluation of the method may have given fortuitously good results, suitable variations of the dissolution technique should provide similar results. The method which was developed could be improved by a more efficient technique of separating gold from tellurium or by methods of determination which tolerate large amounts of tellurium. Although the procedures are time-consuming, many samples

can be treated simultaneously and only negligible losses are involved for milligram and microgram amounts of gold. The wet extraction provides an alternative method for ores which present unusual collection problems for the fire assay.

The neutron activation analysis technique involved a series of treatments of the irradiated sample similar to those used in the wet extraction method. The methods were proved to be quite efficient by the use of radioactive samples. The values obtained for a variety of ores indicated the difficulty in obtaining a representative sample of the small size required. The advantage of the method was shown by the determination of less than 0·005 μg of gold. In addition, the activation technique gave accurate values for gold in a sample for which the fire assay gave erroneous results because of an interference with the colorimetric method. If the limitations imposed by inhomogeneity of the sample are taken into account, neutron activation may be used for a wide variety of gold materials,

The results of this work indicate the accuracy and precision obtainable with each procedure and emphasize the serious effect of the inhomogeneity of distribution of gold.

Zusammenfassung—Die Fehler, die bei Flammenproben-, nassen Extraktions- und Neutronenaktivierungsmethoden auftreten, werden ermittelt, die Richtigkeit und Genauigkeit dieser Methoden verglichen und eine Methode zur Bestimmung der chemischen Ausbeute bei der Aktivierungsanalyse von Gold in Erzen und Konzentraten angegeben.

Résumé—On évalue les erreurs liées aux méthodes de dosage par grillage, extraction par voie humide et activation de neutrons, compare la justesse et la précision de ces méthodes, et présente une méthode pour déterminer le rendement chimique dans le dosage par activation de l'or dans les minerais et concentrats.

USE OF THENOYLTRIFLUOROACETONE FOR THE DETERMINATION OF MANGANESE BY ACTIVATION ANALYSIS

FRANTIŠEK KUKULA, BLAŽENA MUDROVÁ and MILOSLAV KŘIVÁNEK
Nuclear Research Institute, Czechoslovak Academy of Sciences, Řež by Prague, Czechoslovakia

(*Received* 13 *July* 1966. *Accepted* 16 *September* 1966)

Summary—A new procedure for the substoichiometric extraction of bivalent manganese by thenoyltrifluoroacetone into ethyl acetate has been developed and used in activation analysis. The value of the extraction constant has been found to be $3{\cdot}1 \times 10^{-6}$; the pH range in which the extraction can be performed is 7·8–9·2. The influence of oxalate, citrate, tartrate, fluoride and cyanide ions has been studied. A selective substoichiometric extraction of manganese in the presence of Zr, Hf, Nb, Th, Fe and Sc is possible at pH 8–8·5, tartrate and fluoride being used as masking agents. Copper and cobalt can be screened by ammonia and cyanide respectively. The method has been used for the determination of manganese in biological materials, potassium fluoride and zirconium.

ACTIVATION analysis has been widely used for the determination of manganese because the cross-section and half-life of its isotopes make the determination highly sensitive. In some simple cases the determination can be performed non-destructively. However, in most cases manganese has to be separated before the activity is counted. In general, use is made of the precipitation of manganese dioxide for the separation and isolation of manganese.[1,2,3] Extraction of tetraphenylarsonium permanganate has been used[4] for the determination of ^{56}Mn in ^{56}Cr. The substoichiometric extraction of tetraphenylarsonium (or tetraphenylphosphonium) permanganates has been suggested by Růžička and Zeman.[5] However, a preliminary extraction of manganese with sodium diethyldithiocarbamate into chloroform is recommended by these authors. A simple method for the substoichiometric extraction of manganese thenoyltrifluoroacetonate into ethyl acetate and its use in activation analysis is suggested here.

EXPERIMENTAL

Apparatus

Gamma-spectrometer, 200-channel, Intertechnique SAI 332 (Intertechnique, Versailles, France) with NaI(Tl) crystal 1 × 1·5 in.

Decadic scaler (ZVIL Plzeň, Czechoslovakia) with well-type NaI(Tl) crystal 1 × 1·5 in. Multoscop pH-meter (Labora n.p., Czechoslovakia) with a combined electrode (Metrohm, Herisau, Switzerland).

Reagents

Manganese carrier solution. An aqueous solution of manganese(II) sulphate, containing 1 mg of manganese/ml. A part of this solution was labelled with carrier-free ^{52}Mn.

Standard manganese solution. Prepared by diluting the carrier solution to give a final concentration of 0·022 μg of manganese/ml.

Buffer solution. Ammonium acetate solution, 20%—ammonia.

Masking solutions. Sodium tartrate solution, 10%. Potassium fluoride solution, 20%.

Thenoyltrifluoroacetone (TTA). Ethanolic solution of TTA, 0·11*M*. Ethyl acetate solution of TTA, 0·2*M*. Ethyl acetate was purified according to the method described in the literature.[6] All reagents used were *pro analysi* or pure reagent grade.

Irradiation

All irradiations were carried out at a neutron flux of about $7{\cdot}5 \times 10^{12}$ neutrons.cm^{-2}.sec^{-1} for 2 hr. Polythene capsules containing samples and sealed capsules holding 4 ml of standard solution were irradiated in the same irradiation can.

Determination of the extraction constant

Five ml of aqueous carrier-free solution of ^{52}Mn were adjusted to the required pH with hydrochloric acid or potassium hydroxide. The ionic strength was adjusted to 1 by addition of potassium chloride. The solution was extracted with 5 ml of 0·2*M* TTA in ethyl acetate. After the extraction the pH was measured again and aliquots of the aqueous and organic phases were taken for activity counting. The extraction curve is shown in Fig. 1. The extraction constant was calculated from the

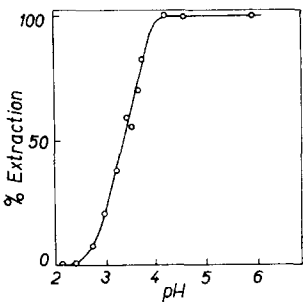

FIG. 1.—Extraction of carrier-free ^{52}Mn by 0·2*M* TTA in ethyl acetate, as a function of pH.

values of the distribution ratio ranging from 0·1 to 10 according to the relationship

$$K = q\frac{[H^+]^2}{[HTTA]^2}$$

where q is the distribution ratio.

Development of procedure

The pH region in which optimum substoichiometric extraction can be performed was estimated first. Two ml of the carrier solution (labelled with ^{52}Mn) were diluted to 30 ml, the pH was adjusted with acetic acid or ammonia and 0·5 ml of ethanolic TTA solution was added. At higher pH values, about 10 mg of hydroxylamine hydrochloride were added to prevent oxidation of manganese(II). The solution was extracted with 10 ml of ethyl acetate for 2–3 min. The time required to complete the extraction was found experimentally. The activity of the aqueous phase was determined by means of a well-type scintillation crystal. The pH region (7·8–9·2) over which the extraction is complete is illustrated in Fig. 2.

The reproducibility of the substoichiometric extraction was verified both by extractive radiometric titration of a carrier solution (labelled with ^{52}Mn) with TTA and by titration of TTA with the labelled carrier solution. The titration procedure was the same as that described earlier.[7] An example of the latter titration at pH 8·5 is shown in Fig. 3.

Influence of masking reagents

Extractive radiometric titrations were used for the study of the influence of masking agents such as tartaric acid, oxalic acid, citric acid, fluoride and cyanide on the substoichiometric extraction of manganese with TTA. The results are presented in Table I. The influence of zirconium, hafnium, thorium, iron, scandium, antimony, copper and cobalt in the presence of the masking agents was studied in the same way.

Procedure

Irradiated material was dissolved as follows: potassium fluoride in water, ash from biological samples in hydrochloric acid, zirconium and aluminium in a mixture of hydrofluoric and nitric acids. Two ml of carrier solution, 3 ml of 10% tartaric acid solution, 3 ml of 20% potassium fluoride

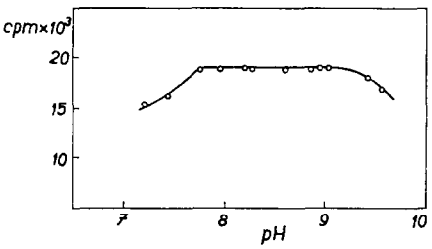

FIG. 2.—The substoichiometric extraction of manganese(II)-thenoyltrifluoroacetate, as a function of pH.

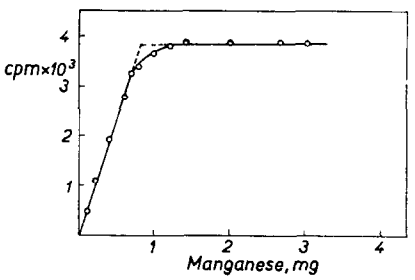

FIG. 3.—Radiometric titration of TTA with manganese(II) at pH *ca.* 8·5.

TABLE I.—THE INFLUENCE OF MASKING REAGENTS ON THE SUBSTOICHIOMETRIC EXTRACTION OF MANGANESE

Masking reagent	Amount of reagent (*mg*) required to decrease the extent of extraction by	
	1%	5%
Citric acid	75	100
Tartaric acid	650	800
Oxalic acid	200	250
Potassium cyanide	160	190
Potassium fluoride	>5000	

solution and 10 mg of hydroxylamine hydrochloride were added successively and the pH was adjusted to 8–8·5; 0·5 ml of ethanolic solution of TTA was added (corresponding to about 70% of the manganese content) and the solution was extracted for 2–3 min with 10 ml of ethyl acetate. After separation of the phases, the γ-spectrum of the organic phase was measured with a 200-channel analyser. The same procedure was performed with the standard sample. By comparison of the areas under the 0·84 MeV photopeak of the sample and the standard, the manganese content was determined.[8]

RESULTS AND DISCUSSION

TTA has been successfully used for the colorimetric[9] and flame photometric[10] determination of manganese. According to De and Rahaman[9] the region of complete extraction of manganese thenoyltrifluoroacetonate with a mixture of benzene and acetone begins at pH 6·7. Cobalt(II) and EDTA interfere with the colorimetric determination. Iron, zirconium and thorium are first extracted from a citrate medium. The

majority of metallic ions can be masked by a mixture of tartaric and hydrofluoric acids according to Johnson and Lott,[10] but cyanides show a slight interference.

The region of complete extraction has been found to be within the pH range 7·8–9·2. In the presence of ammonium acetate no manganese(II) hydroxide is precipitated at pH 9·5 even after 5 hr. However, a reducing reagent, such as hydroxylamine hydrochloride must be added to prevent the oxidation of manganese(II) to manganese(III). The extraction equilibrium is attained within 2–3 min. The influence of oxalic, tartaric and citric acids, fluoride and cyanide on the substoichiometric extraction is summarized in Table I. The error exceeds 5% only if the concentration

TABLE II.—THE DETERMINATION OF MANGANESE (MEAN VALUES FROM THREE DETERMINATIONS)

Sample	Manganese found (mean of 3 determinations)	
	μg	ppm
Zirconium (pure)	$5·9 \times 10^{-3}$	$5·8 \times 10^{-3}$
Aluminium (zone-refined)	$6·0 \times 10^{-4}$	$1·05 \times 10^{-2}$
Biological material (fish)	2·24	40·0*
Potassium fluoride	$2·7 \times 10^{-3}$	0·1

* Relative to ash content.

of cyanide is greater than 5·5 mg/ml. On the other hand, manganese thenoyltrifluoroacetonate is not back-extracted by cyanide. Use was made of these results for the selective determination of manganese in the presence of elements with higher extraction constants.[11] Manganese can be selectively extracted from a tartrate or fluoride

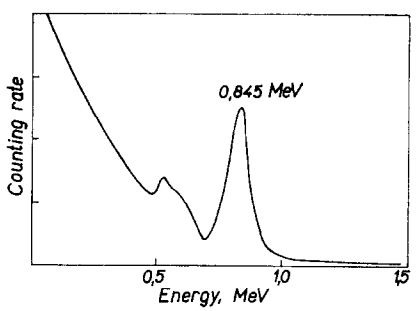

FIG. 4.—The γ-spectrum of ^{56}Mn after separation from potassium fluoride by TTA.

medium at pH 8–8·5 even in the presence of zirconium, hafnium, niobium, thorium, iron, scandium and antimony. Ammonia prevents copper and cobalt from being extracted. These ions can also readily be removed from the organic phase by a 1% cyanide solution. Carrier-free lead and thallium interfere neither with the determination of the chemical yield nor with the γ-spectrometric determination of manganese (both being pure β-emitters).

The extraction constant has been found to be $3·1 \times 10^{-6}$ (the mean value of 8 independent extractions with ethyl acetate). The recently published value[12] of the extraction constant for a mixture of benzene and acetone is 3×10^{-7}.

In Table II results are shown for analyses of potassium fluoride, zirconium and ash from fish.

The γ-spectrum of the TTA–Mn extract is shown in Fig. 4. The method described in the present communication was also used for the determination of the manganese concentration in the target, water, and reagents used in the production of ^{52}Mn by the ^{52}Cr(d, 2n)^{52}Mn nuclear reaction. These results will be published elsewhere.[13]

The method is very simple and no preliminary separations are required. The time necessary for carrying out the chemical treatment depends mainly on the time required for the dissolution. The separation itself (including the adjustment of the pH) takes less than 10 min. The maximum sensitivity attainable (5×10^{-11} g) is in agreement with other published results.[14]

Résumé—On a élaboré et utilisé dans l'analyse par activation une nouvelle méthode pour l'extraction substoechiométrique du manganèse bivalent par la thénoyltrifluoracétone en acétate d'éthyle. On a trouvé que la valeur de la constante d'extraction est de $3{,}1 \times 10^{-6}$; on peut effectuer l'extraction aux pH compris entre 7,8 et 9,2. On a étudié l'influence des ions oxalate, citrate, tartrate, fluorure et cyanure. Une extraction substoechiométrique sélective du manganèse en présence de Zr, Hf, Nb, Th, Fe et Sc est possible à pH 8–8,5, le tartrate et le fluorure étant utilisés comme agents de dissimulation. Le cuivre et le cobalt peuvent être masqués par l'ammoniaque et le cyanure respectivement. On a utilisé la méthode pour le dosage du manganèse dans les matériaux biologiques, le fluorure de potassium et le zirconium.

Zusammenfassung—Eine neue Vorschrift zur substöchiometrischen Extraktion von zweiwertigem Mangan durch Thenoyltrifluoraceton in Essigester wurde entwickelt und bei der Aktivierungsanalyse verwendet. Die Extraktionskonstante wurde zu $3{,}1 \cdot 10^{-6}$ ermittelt. Die Extraktion kann im pH-Bereich 7,8–9,2 vorgenommen werden. Der Einfluß von Oxalat, Citrat, Tartrat, Fluorid und Cyanid wurde untersucht. Mit Tartrat und Fluorid als Maskierungsmitteln läßt sich Mangan selektiv substöchiometrisch in Gegenwart von Zr, Hf, Nb, Th, Fe und Sc bei pH 8–8,5 extrahieren. Kupfer und Kobalt können durch Ammoniak bzw. Cyanid maskiert werden. Die Methode wurde zur Bestimmung von Mangan in biologischen Materialien, Kaliumfluorid und Zirkonium verwendet.

INORGANIC POLAROGRAPHY IN ORGANIC SOLVENTS—II

POLAROGRAPHIC EXAMINATION OF THE MOLYBDENUM(V) THIOCYANATE COMPLEX IN DIETHYL ETHER

B. K. AFGHAN and R. M. DAGNALL
Chemistry Department, Imperial College, London S.W.7., England

(*Received* 20 *June* 1966. *Accepted* 1 *November* 1966)

Summary—A procedure involving the solvent extraction of molybdenum(V) thiocyanate into diethyl ether followed by a direct polarographic examination of the organic phase offers a selective method for the determination of molybdenum down to 0·5 ppm. Only molybdenum, amongst 21 elements examined, is observed to give a reduction wave under the recommended conditions. The method is evaluated with respect to various experimental factors and is applied to the determination of molybdenum in mild and alloy steels.

THE previous communication in this series[1] showed some of the advantages to be obtained by carrying out a polarographic examination of an organic phase following solvent extraction. The extraction system described below, when used in conjunction with polarography, has an enhanced selectivity. This arises because, although certain species are reduced at a dropping mercury electrode in aqueous solution, they do not necessarily give polarographic waves in an organic solvent. The direct application of polarography to the examination of a diethyl ether phase used for solvent extraction of metal-thiocyanate complexes has been found to give a selective method for the determination of molybdenum(V).

The method has been tested on a number of B.C.S. mild and alloy standard steels, and has many advantages over others previously described. For instance, the method used by Haight,[2] although sensitive, depends on the use of a catalytic wave and measurements are made from a non-linear calibration curve. In addition, the careful control of experimental conditions and the absence of certain anions is essential. A method devised by Wolfson[3] for molybdenum in nickel alloys used a citric acid–sulphuric acid supporting electrolyte, but is interfered with by large amounts of iron and copper. Parry and Yakubic[4] described a method suitable for steels, using a tartrate supporting electrolyte. However, only synthetic mixtures were examined and even then only after removal of iron and chromium. The method evolved by Stackelberg *et al.*[5] can only be used after the chemical separation of molybdenum from all the other alloying elements.

Other potentially useful polarographic reduction waves for molybdenum involve the use of either a non-linear calibration curve,[6] a catalytic wave[7] or the extensive removal of other elements.[8,9]

The most widely used method for determining molybdenum is a spectrophotometric one,[10] by means of the red colour produced with thiocyanate. However, we have found that interference is given in certain instances; for example the high chromium

content (5·03%) of the alloy steel B.S.C. No. 241/1 produces an intense green colour under the recommended conditions and interferes in the spectrophotometric method.

EXPERIMENTAL

The apparatus used was an Elliot Polarograph Model 200 with a dropping mercury electrode. Unless otherwise stated the operating conditions were as follows: rate of potential increase 0·5 V/100 sec, drop time 3·4 sec, height of mercury reservoir 60 cm, mercury flow-rate 2·2636 mg/sec, temperature *ca.* 18°, no damping or counter current. An internal mercury pool anode was used and de-aeration was achieved by bubbling nitrogen through a 5-ml sample for 2 min. Provided this time is not exceeded, there is a negligible reduction in volume.

A mercury seal was used instead of the more usual water seal to prevent re-absorption of oxygen. All chemicals were analytical grade unless otherwise stated.

Preliminary polarographic investigation

The solvent extraction procedure followed was as described by Morrison and Freiser.[11] The aqueous phase (25 ml) was made 10^{-3} *M* in metal ions, *ca.* 0·5*M* in hydrochloric acid and *ca.* 2*M* in ammonium thiocyanate (by addition of 2·5 ml of a saturated aqueous solution). Extraction was carried out with 15 ml of diethyl ether (G.P.R.*) and the resulting organic phase, after the addition of 5 ml of a 0·5*M* lithium chloride (G.P.R.) solution in methanol (G.P.R.), was diluted to 25 ml with methanol. This solution was de-aerated with oxygen-free nitrogen and polarographed, the instrument sensitivity being 10 μA/full scale deflection. The efficiency of the extraction was checked by examining the aqueous phase.

Table I shows the half-wave potentials of the reduction waves in the organic phase (column 5) together with those obtained in an aqueous phase before and after complex formation (columns 2 and 3 respectively). All the metal ions known to be extracted under these conditions were examined.

Most of the metal ions examined, and their thiocyanate complexes, give polarographic waves in acidic aqueous solution. However, in the organic phase only those due to Fe(III) and Mo(V) and Mo(VI) are produced. The thiocyanate complexes of Ga, In, Sn(IV) and U(VI) are not reduced in the organic phase, although they give waves in aqueous solution and are certainly extracted to some extent (*ca.* 70%, 70%, 99% and 40% respectively).[11] Consequently, the direct application of polarography to the organic phase gives a greater degree of selectivity. It can be seen from Table I that the reduction waves for some metal-thiocyanate complexes in aqueous solution (column 3) occur at more positive potentials than those for the corresponding aquo- or chloro- complexes (column 2), *e.g.*, As(III), Bi, Ga, Mo(V), Mo(VI), Sb(III), Sn(IV), Ti(IV), U(VI) and V(V). This effect can be used to advantage with an element such as gallium which does not give a reduction wave in acidic aqueous solution. It can also be used to obtain a separation of the reduction waves for mixtures of metal ions, *e.g.*, Bi and Sb(III), As(III) and Mo(V) or Mo(VI). In addition, the three Mo(V) reduction waves in acidic aqueous solution are ill-defined and the individual wave-heights are very small. As a result, they are of no use either for theoretical or analytical purposes. However, the extracted thiocyanate complex gives a well defined wave with a diffusion current approximately equal to the sum of the three waves in aqueous solution. Without information on parameters of the Ilkovic equation for the aqueous and non-aqueous systems, it is difficult to make a sound theoretical interpretation of this phenomenon, but from the analytical point of view the summation into a single, much larger, wave is highly advantageous.

The available potential range under these conditions was 0·0–0·9 V *vs.* mercury

* General purpose reagent.

pool and was controlled by the anodic dissolution of mercury and the catalytic reduction of hydrogen. The cell resistance was approximately 500 Ω so that the iR drop was negligible in these experiments.

The addition of ascorbic acid to the aqueous phase reduces Fe(III) to Fe(II) and was found to render the combination of techniques specific for Mo(V).

The following experimental variables and their effects on the molybdenum(V) thiocyanate reduction were examined.

Organic solvents

An aqueous solution of the molybdenum(V) thiocyanate complex was equilibrated, as above, with a number of organic solvents, *viz.*, diethyl ether, isobutyl methyl ketone, amyl acetate, toluene, chloroform and carbon tetrachloride. Only the first three solvents extracted the complex and gave solutions yielding polarographic reduction waves. Isobutyl methyl ketone also extracted 65% of copper(I) and (II) which gave rise to a wave with $E_{\frac{1}{2}}$ −0·3 V *vs.* mercury pool. All efforts to prevent the extraction of copper, and its reduction, by the addition of complexing agents were unsuccessful. Amyl acetate did not extract copper, but did extract tin(II) quantitatively. In the presence of molybdenum an additional wave with $E_{\frac{1}{2}}$ −0·45 V was given and the molybdenum(V) wave had a very large maximum which could not be suppressed. As with copper, it was not possible to prevent the extraction of tin(II) whilst allowing the extraction of molybdenum(V). In the absence of molybdenum, no wave for tin(II) was observed in the organic phase, although examination of the aqueous phase showed it had been extracted quantitatively. The height of the tin(II) wave and the molybdenum maximum both increased with increasing concentrations of tin(II).

Both solvents extracted iron(III) quantitatively, but not iron(II) and thus diethyl ether was selected for further investigation because of its greater selectivity.

Hydrochloric acid concentration

The concentration was varied between 5*M* and 0·001*M* and its effect on the extraction and half-wave potential of the molybdenum(V) thiocyanate complex was evaluated. The polarographic wave moved towards more positive potentials with increasing acid concentrations until, at acid concentrations above 1*M*, the wave was indistinguishable from that due to the anodic dissolution of mercury. At concentrations $\leq$0·01*M*, the efficiency of the extraction decreased to 20% or less. An acid concentration of *ca.* 0·1*M* was selected as being the most suitable and under these conditions the reduction wave occurred at −0·13 V.

Thiocyanate concentration

The reduction wave characteristics were found to be independent of the thiocyanate concentration provided it was between 1 and 4*M*. Low concentrations, $<$*ca.* 0·05*M*, gave incomplete extraction and high concentrations, $>$*ca.* 7*M*, moved the wave to more positive potentials so that it became difficult to distinguish from the anodic wave due to the dissolution of mercury.

The other experimental parameters, *viz.* drop-time, distance between electrodes, mercury pressure, supporting electrolytes and deoxygenation were as found in the previous communication.[1]

GENERAL METHOD

Reagents

Standard $10^{-3}M$ ammonium molybdate solution was prepared by dissolving 0·1766 g of analytical grade ammonium molybdate $[(NH_4)_6Mo_7O_{24}.4H_2O]$ in distilled water and diluting to 1 l. Other reagents were as described under *Preliminary polarographic investigation.*

Procedure

Add 2·5–15 ml of $10^{-3}M$ molybdenum solution to a 100 ml separating funnel, followed by 2·5 ml of 1*M* hydrochloric acid, 1–2 g of ascorbic acid and 5 ml of saturated ammonium thiocyanate solution. Dilute to *ca.* 25 ml with distilled water and extract with 15 ml of diethyl ether. Transfer the organic phase to a 25 ml volumetric flask, add 5 ml of 0·5*M* lithium chloride in methanol and dilute to volume with methanol. Deoxygenate an aliquot (5 ml) of this solution with a fast stream of oxygen-free nitrogen for 2 min and polarograph it from zero to −0·5 V *vs.* mercury pool with an instrument sensitivity of 5 μA/full scale deflection. Measure the height of the wave of $E_{\frac{1}{2}}$ −0·13 V.

A graph of wave-height against concentration of molybdenum is a straight line from 10–60 ppm, which is a suitable working range for the procedure given. The relative standard deviation from the analysis of nine solutions, each $4 \times 10^{-4}M$ in molybdenum, was 2·3%.

Extractions have been carried out from 500 ml of aqueous phase (pre-saturated with diethyl ether) containing the same amounts of molybdenum as used for the calibration curve. An exactly similar calibration curve was obtained and the overall sensitivity was increased to cover the range 0·5–3·0 ppm.

Interferences

The effect of those ions listed in Table I, together with Cd(II) and Cr(VI), was determined. The tests were carried out with a 10-fold molar excess of these ions in a solution $4 \times 10^{-4}M$ in molybdenum(V) taken through the recommended extraction procedure. The height and position of the reduction wave was not altered by any of these ions. The aqueous phase was also made 0·1*M* in hydrochloric, nitric, sulphuric and perchloric acids. Again, no difference was noted.

Analysis of steel

In view of the great selectivity obtained by the combination of solvent extraction and polarography, it was decided to try the method for the determination of molybdenum in mild and alloy steels.

Procedure

Dissolve a suitable weight (0·1–1 g) of the steel, containing not less than 250 μg of molybdenum in 10 ml of concentrated hydrochloric acid in a 100-ml beaker, warming to assist dissolution. Evaporate the solution almost to dryness (avoid baking) and re-dissolve the residue in 10 ml of 0·5*M* hydrochloric acid. If a large amount of tungsten is present, add sufficient citric acid solution to obtain complete dissolution. Transfer the solution to a 250-ml separating funnel and dilute to *ca.* 40 ml. Add 1–2 g of ascorbic acid and 10 ml of aqueous saturated ammonium thiocyanate solution, and finish as described above under *General procedure*.

TABLE II.—DETERMINATION OF MOLYBDENUM IN B.C.S. STEELS

Sample No.	Type of steel	Found, %	Certified value, %	Spread in certificate values, %
273	mild steel	0·045 0·041 0·040	$0{\cdot}04_5$	0·041–0·046
275	mild steel	0·100 0·101	$0{\cdot}09_5$	0·092–0·100
320	mild steel	0·208 0·217	0·22	0·21–0·22
321	mild steel	0·069 0·068 0·065	0·068	0·064–0·072
323	mild steel	0·105 0·104 0·111	0·100	0·095–0·105
325	mild steel	0·167 0·167	0·16	0·15–0·16
219/2	alloy steel	0·421 0·439	0·43	0·40–0·45
241/1	alloy steel	0·511 0·516	0·52	0·51–0·52

A calibration curve obtained by taking 1 g of electrolytic iron with standard molybdenum aliquots through the procedure was the same as the one obtained without iron present.

The results of the analysis of some British Chemical Standards mild and alloy steels are shown in Table II.

Résumé—Une technique comportant l'extraction par solvant du thiocyanate de molybdène (V) en éther-diéthylique suivie d'un examen polarographique direct de la phase organique offre une méthode sélective de dosage du molybdène jusqu'à 0,5 ppm. Parmi les 21 éléments examinés, on a observé que seul le molybdène donne une vague de réduction dans les conditions recommandées. On évalue la méthode en ce qui concerne divers facteurs expérimentaux et l'applique au dosage du molybdène dans l'acier doux et les alliages d'acier.

Zusammenfassung—Ein Verfahren, bei dem Molybdän (V)-rhodanid in Diäthyläther extrahiert und die organische Phase dann direkt polarographisch untersucht wird, bietet eine selektive Methode zur Bestimmung von Molybdän bis herunter zu 0,5 ppm. Unter 21 untersuchten Elementen gibt nur Molybdän unter den empfohlenen Bedingungen eine Reduktionsstufe. Die Methode wird bezüglich mehrerer experimenteller Variabler optimiert und auf die Bestimmung von Molybdän in kohlenstoffarmen und legierten Stählen angewandt.

DETERMINATION OF LOW CONCENTRATIONS OF HYDROGEN HALIDES AND HALOGENS IN THE GAS PHASE

REMOVAL FROM A MIXTURE OF GASES AND QUANTITATIVE ESTIMATION

LESLIE BATT and FRANK R. CRUICKSHANK
Chemistry Department, University of Aberdeen, Old Aberdeen, Scotland

(*Received* 29 *April* 1966. *Revised* 18 *August* 1966. *Accepted* 8 *October* 1966)

Summary—A method has been developed for the removal of hydrogen chloride, and mixtures of bromine and hydrogen bromide, from gaseous mixtures by absorption on various solids. The efficiency of removal of bromine and hydrogen bromide has been determined and the substances have been estimated potentiometrically. The technique is extended to include the other halogens and hydrogen halides.

SMALL quantities of hydrogen halides or halogens (~0·3 mole %) are often produced in gaseous reactions (for example in the decomposition of hot radicals produced by the flash photolysis of halomethanes[1]) or used as traps for organic free radicals.[2] Halogens may be estimated spectrophotometrically,[2,3] but this is not feasible for hydrogen halides. It is sometimes necessary to remove these substances from a gaseous reaction mixture prior to condensing the products and reactants in a liquid-nitrogen trap. Acetone, for example, reacts in the presence of hydrogen halides in the condensed phase to give polymers.[2]

The present work is concerned primarily with a method for the efficient removal of hydrogen chloride and mixtures of bromine and hydrogen bromide and secondarily with their quantitative estimation. These compounds are being used as radical traps in organic free radical studies.[4] The technique is extended to include methods for the isolation and estimation of the other halogens and hydrogen halides.

EXPERIMENTAL

Absorption efficiency

Hydrogen chloride, hydrogen bromide (Matheson), and carbon dioxide (prepared from crushed solid) were dried by passage through "drierite" (B.D.H.) and purified by bulb-to-bulb distillation. Bromine (May & Baker) was thoroughly degassed and similarly purified. The auramine (B.D.H.) used contained some of the hydrochloride which was reduced to a low level by repeated extraction with ethanol in a Soxhlet extractor, followed by recrystallization (five times) from ethanol. 1-Amino-anthraquinone (Hopkins & Williams) was used as received. All the other absorbents were obtained from B.D.H. The apparatus has been described in detail elsewhere.[5]

Various mixtures of carbon dioxide, hydrogen bromide and bromine, or carbon dioxide and hydrogen chloride, were expanded from a 300-ml cylindrical vessel through an absorption trap (Fig. 1) and any residual gas was removed by an automatic Töpler pump and measured in the gas burette. This provided a method for estimating the efficiencies of the various absorbents for removing hydrogen chloride, hydrogen bromode or bromine. The absorbents used are listed in Table I or referred to in the discussion.

Potentiometric titration of halide

A method used in this department was adapted to the micro-scale. The titration cell consisted of a wide-necked conical flask in which the solution was stirred magnetically. The cathode was a length

of silver wire, 2 mm in diameter, surrounded by a 1-cm diameter plastic tube pierced with several 3-mm diameter holes. The anode was a platinum wire sealed into the capillary tip of an Agla micrometer syringe. The tip dipped into the halide solution to complete the cell $(Ag/Ag^{+}(a_1)\|Ag^{+}(a_2)/Ag/Pt)$. The initial voltage of the cell depends on the silver nitrate concentrations but was usually ~400 mV. The voltage was measured on a Tinsley potentiometer (type 3184D) *via* a simple electrometer (Fig. 2) based on a Mullard ME1400 valve enclosed in an airtight box dried with silica gel. The L.T. supply was 4·4 V and the H.T. supply was 45 V. The arrangement is a little unusual in that the cell produces reverse bias on the control grid. The electrometer was checked for linearity with a Mullard dual-beam oscilloscope. The output voltage was adjusted to 1400 mV and 10 ml of ethanol were added to the halide solution at the beginning of each titration to improve the end-point.

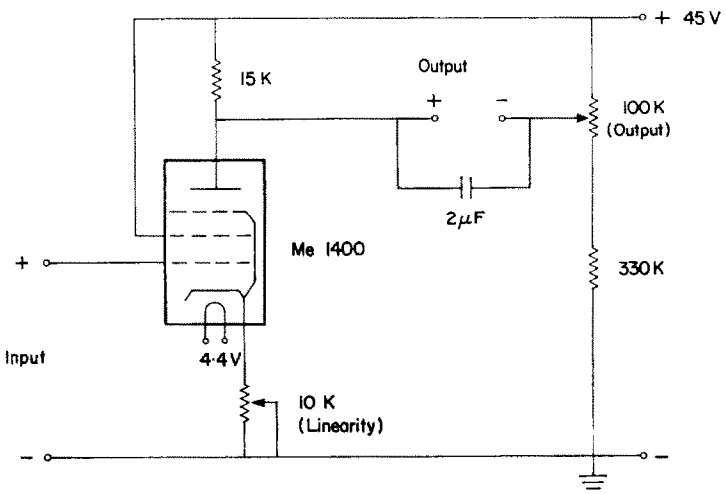

FIG. 2.—Circuit for the potentiometric titration.

Preparation of sample for titration

With auramine (for HX only). A column of purified auramine 2·5 cm long and 1 cm diameter was sufficient to absorb several mmoles of halide. The auramine was pushed out of the U-tube and any residue washed out with 10 ml of acetone, followed by 20 ml of de-ionized water, and was then hydrolysed by addition of 1 pellet of sodium hydroxide and boiling for 12 hr. This resulted in the production of ammonia and Michler's ketone, the solution changing from yellow to almost colourless. The cooled mixture was washed with four 50 ml portions of benzene, which removed most of the ketone. The colourless aqueous solution was made acid to litmus by addition of dilute nitric acid and titrated with 0·05*M* silver nitrate.

With sodium carbonate–oxine–soda-lime (for hydrogen chloride or hydrogen bromide–bromine mixtures). The surface area of the sodium carbonate in the column (8 cm long and 1 cm diameter) was increased by mixing it with glass wool, which minimized the amount of sodium carbonate used. This column was followed by a column of soda-lime 2·5 cm long and 1 cm diameter which had been degassed thoroughly by being kept at 80° under vacuum for 2 hr. The columns (see Fig. 1) were separated from each other by glass wool and connected by ground glass joints. During a run, the entire U-tube was maintained at 80° by placing it in a water-bath. The columns in the order stated, removed hydrogen bromide, bromine and carbon dioxide respectively. The sodium carbonate was dissolved in enough dilute nitric acid to give a solution just acid to litmus, 10 ml of ethanol were added and the halide was titrated.

DISCUSSION

Table I summarizes the results for the isolation of hydrogen chloride, hydrogen bromide or hydrogen bromide + bromide by absorption on various solids. Anthraquinone, phenanthrene, fluorescein and calcium carbonate were useless as absorbents. Copper, magnesium, naphthalene and 1-amino-anthraquinone absorbed only small amounts of gas.

By far the most efficient absorbent was auramine,[2] but it is not selective in its absorption properties, being equally efficient for hydrogen bromide, bromine and t-butyl hypobromite.[4] The mechanism for the absorption of HX is presumably *via* salt formation. There are three possible positions where this may occur in the auramine molecule and probably all three are involved. This would explain the high efficiency of auramine. The absorption efficiency increases if the temperature is raised to 80°. In addition to indiscriminate absorption of hydrogen bromide and bromine, auramine had the disadvantage that it was impossible to estimate the absorbed halide because of erratic cell voltages caused by organic compounds in the solution. Michler's

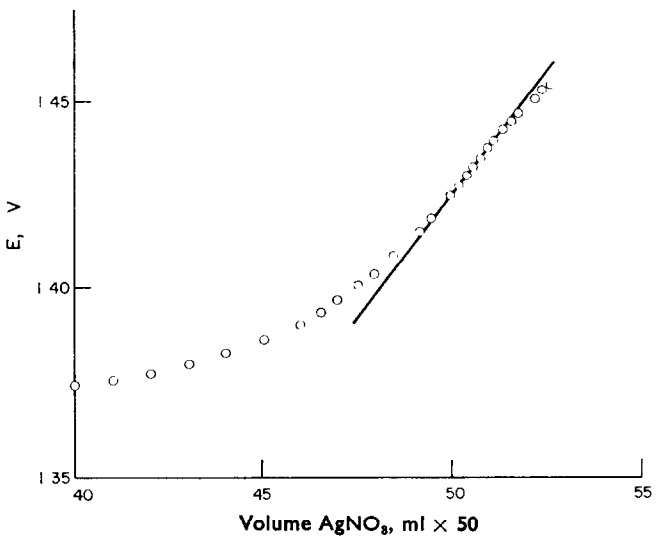

FIG. 3.—Typical curve for potentiometric titration of halide.

ketone is slightly soluble in water, and its presence is shown by the production of a yellow colour on acidification. Addition of Nonex 501 minimized the variation in cell voltage.

The sodium carbonate–oxine system was much more convenient because the carbonate selectively absorbed hydrogen bromide, gave a blank titre of only 0·2 μmole of halide and provided accurate, reproducible titrations. Accuracy was checked by the estimation of weighed, dried samples ($\sim$60 μmole) of analytical reagent grade potassium bromide and potassium chloride (B.D.H.) Smooth titration curves were obtained (Fig. 3) of which the point of inflection was taken as the end-point. Differential plots were unsatisfactory, but the end-point was readily found as the mid-point of the steepest slope.

The hydrogen chloride from hydrogen chloride–carbon dioxide mixtures (1:8) was determined by the potentiometric method to better than 1%. When hydrogen chloride or hydrogen bromide reacts with sodium carbonate, about 30% of their volume of carbon dioxide is produced and with large amounts of them, water can be detected. With gaseous mixtures of hydrogen bromide and bromine, diluted with carbon dioxide (1:8), analysis of hydrogen bromide was reproducible within $\pm$6% but it was impossible to estimate bromine. Oxine, although a selective absorbent for

bromine, was subject to the same analytical difficulties as auramine. Direct weighing proved unsuccessful because of the relatively high vapour pressure of the oxine and consequent loss by sublimation. A large scale oxygen flask determination of the bromine might be successful. Since the mixture passes through the sodium carbonate first, the bromine probably interferes with the hydrogen bromide analysis *via* the equilibrium

$$Br_2 + H_2O \rightleftarrows HBr + HOBr,$$

and hence accounts for the 6% error. The carbon dioxide produced was removed with 100% efficiency by soda-lime.

Thus small amounts of hydrogen chloride, hydrogen bromide and hydrogen iodide may be absorbed efficiently on columns of sodium carbonate backed by a column of soda-lime, and estimated within 1%. Tests with hydrogen fluoride have not been carried out although a solution of hydrogen fluoride produces the same colour with auramine, so that there is every indication that auramine will also be effective for hydrogen fluoride. Mixtures of hydrogen bromide and bromine can be selectively absorbed on columns of sodium carbonate, oxine and soda-lime used in that order. It should be possible to adapt this system for other halogen/hydrogen halide mixtures, the halogens being estimated spectrophotometrically as indicated earlier. It has been shown that fluorine reacts quantitatively with calcium oxide, the liberated oxygen giving a quantitative measure of the fluorine absorbed.[8]

Acknowledgements—The authors are indebted to Dr. B. Chamberlain (Pilkington Bros., Latham, Lancs) for helpful discussions about the potentiometric titration set-up. One of us (F.R.C.) gratefully acknowledges the receipt of a Carnegie Scholarship from the Carnegie Trust for the Universities of Scotland.

Zusammenfassung—Es wurde eine Methode entwickelt zur Entfernung von Chlorwasserstoff und Mischungen von Brom und Bromwasserstoff aus Gasgemischen durch Adsorption an verschiedenen Festkorpern. Der Wirkungsgrad der Entfernung von Brom und Bromwasserstoff wurde ermittelt und die Substanzen potentiometrisch bestimmt. Das Verfahren wird auf die anderen Halogene und Halogenwasserstoffe ausgedehnt.

Résumé—On a élaboré une méthode pour éliminer l'acide chlorhydrique et des mélanges de brome et d'acide bromhydrique de mélanges gazeux par adsorption sur divers solides. On a déterminé le pouvoir d'élimination pour le brome et l'acide bromhydrique et estimé potentiométriquement ces substances. On a étendu la technique pour y inclure les autres halogènes et acides halogènhydriques.

POLAROGRAPHY OF LEAD ITACONATE COMPLEXES

TSAI-TEH LAI, SHOU-NAN CHEN and EYIH LIN
Analytical Chemistry Laboratory, Cheng Kung University, Tainan, Taiwan, China

Summary—The complexation of lead ions with itaconic acid (H_2A) has been studied polarographically at 30°. At $pH < pK_1$, the complex species $Pb(HA)^+$ was identified. At $pK_1 < pH < pK_2$ and $pH > pK_2$ the formation of Pb(A) and $Pb(A)_2^{2-}$ respectively, was confirmed. The dissociation constant of $Pb(A)_2^{2-}$ was found to be $8{\cdot}3 \times 10^{-5}$. The electrode reactions were established.

(*Received* 2 *September* 1966. *Accepted* 24 *October* 1966)

THE polarographic behaviour of the complexes of lead with formic acid and tartaric acid has been studied by Hershenson *et al.*,[1] and Iwase,[2] respectively. The complexes of lead with glutamic acid,[3] glycollic acid and malonic acid[4] have been investigated polarographically.

Although the polarography of the uranyl itaconate system has been investigated,[5] the lead itaconate system has not been studied previously. This work was undertaken to present a complete picture of the polarographic behaviour of this system.

EXPERIMENTAL

Apparatus

All polarograms were obtained with a Fisher Elecdropode. The applied potential was measured accurately with Leeds and Northrup Student Potentiometer. A modified H-type cell, containing a saturated calomel reference electrode separated from the solution compartment by a fine sintered-glass disk and a potassium chloride–agar plug, was used. The cell was immersed in a water thermostat at 30° ± 0·01°. Dissolved oxygen was displaced from the polarographic solutions by hydrogen, which was scrubbed by passage through an alkaline solution of sodium pyrogallate. The capillary characteristics of the dropping mercury electrode were: $m = 1{\cdot}685$ mg/sec and $t = 4{\cdot}53$ sec/drop at 71·4 cm height of mercury in 0·3*M* potassium nitrate solution at an applied potential of −0·45 V.

The pH was adjusted with nitric acid or carbonate-free potassium hydroxide solution, and measured with a Toa Electronics HM-5A pH meter.

Chemicals

The stock solution of 0·01*M* lead nitrate was standardized complexometrically with standard EDTA solution.[6] The itaconic acid was of c.p. grade and its solution was standardized against carbonate-free sodium hydroxide solution which had itself been standardized with potassium hydrogen phthalate from the National Bureau of Standards.

Potassium nitrate solution was used as supporting electrolyte. A maximum suppressor was not used, as no maxima were observed.

RESULTS AND DISCUSSION

Nature of the reduction

As can be observed from Fig. 1, the half-wave potential of the simple lead ion in 0·3*M* potassium nitrate solution at pH 3·20 is −0·396V *vs.* S.C.E.; the half-wave potentials are all shifted to more negative values by the complexation of lead ion with itaconic acid, and by the variation in pH value, showing that hydrogen ion is involved in the electrode reduction of the complex.

The polarographic characteristics of the lead itaconate complexes were studied systematically over the pH range 1·65–7·70 by polarographing a solution of 1·055 ×

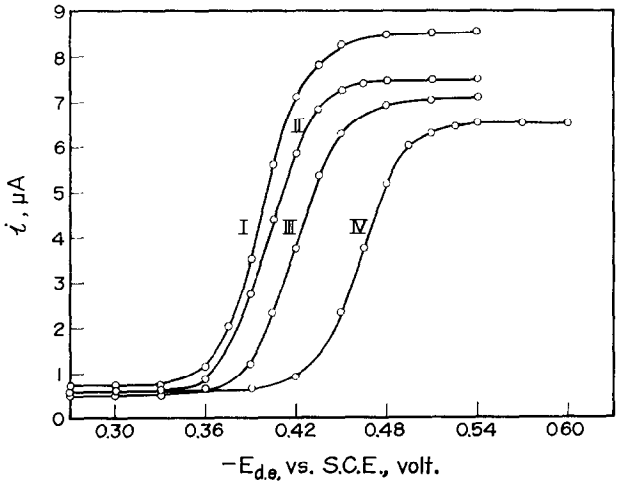

FIG. 1.—Typical polarograms.
I. $1{\cdot}055 \times 10^{-3}M$ $Pb(NO_3)_2$, $0{\cdot}3M$ KNO_3 at pH 3·20
II. plus $0{\cdot}1M$ itaconic acid at pH 3·52
III. plus $0{\cdot}3M$ itaconic acid at pH 3·25
IV. plus $0{\cdot}3M$ itaconic acid at pH 4·80.

$10^{-3}M$ lead nitrate in $0{\cdot}3M$ itaconic acid and $0{\cdot}3M$ potassium nitrate. The upper limit of pH in these measurements is restricted by the precipitation of lead ion. As shown in Table I, both the mean value of $E_{3/4} - E_{1/4}$ and the mean slope of the conventional logarithmic plots were −0·031V *vs.* S.C.E. These are in excellent agreement with the theoretical value for a reversible two-electron reduction.

The temperature coefficient of the half-wave potential is −0·63 mV/deg in the temperature range 25–40°, giving further evidence of the reversible character of the reduction. The temperature coefficient of the diffusion current is 0·16%/deg, and the value of $i_d/h^{1/2} = 0{\cdot}790 \pm 0{\cdot}037$ for the height of mercury column from 35·67 to 83·30 cm. These data demonstrated that the electrode reductions were entirely diffusion controlled processes.

Effect of pH on the half-wave potential

The dependence of half-wave potential on the pH value for solutions of $1{\cdot}055 \times 10^{-3}M$ lead nitrate in $0{\cdot}3M$ potassium nitrate and varying concentrations of itaconic acid from $0{\cdot}05M$ to $0{\cdot}80M$ is shown in Fig. 2. When the pH value is lower than 2·3, the half-wave potentials kept a constant value at −0·396V *vs.* S.C.E., which is identical with the half-wave potential of the simple lead ion. This indicates that lead does not form complexes with itaconic acid below pH 2·3. At pH values between 2·3 and 5·7, the half-wave potentials are shifted to more negative values as the pH is increased. The slopes of the straight lines increase with increasing concentration of ligand and a mean value of −0·029 was obtained for ligand concentrations between 0·3 and $0{\cdot}8M$. This shows that one hydrogen ion is involved in the electrode reduction. When the pH value is increased to higher than 5·7, which corresponds to the pK_2 of the itaconic acid,[7] the half-wave potential becomes independent of pH indicating that no hydrogen ion is involved in the reduction.

($1{\cdot}055 \times 10^{-3}M$ lead nitrate, $0{\cdot}3M$ itaconic acid and $0{\cdot}3M$ potassium nitrate).

Complex species and the half-wave potential

Itaconic acid is an unsaturated dicarboxylic acid with $pK_1 = 3{\cdot}8$ and $pK_2 = 5{\cdot}7$.[7] Since the probable ligand in the lead itaconate complex in acid solution may be either the protonated itaconate ion (HA^-) or the itaconate ion (A^{2-}), a generalized equation for the half-cell reaction of the complexes can be expressed as

$$Pb(HA)_p^{2-p} + 2e + Hg = Pb(Hg) + pHA^- \quad (1)$$

or

$$Pb(A)_p^{2-2p} + 2e + Hg = Pb(Hg) + pA^{2-}. \quad (2)$$

The half-wave potentials of equations (1) and (2) can be expressed as

$$(E_{1/2})_c = (E_{1/2})_s + \frac{0{\cdot}060}{2}\log K - \frac{0{\cdot}060}{2}\,p\log C_{H_2A} - \frac{0{\cdot}060}{2}p\log K_1 - \frac{0{\cdot}060}{2}p\log [H^+] + \frac{0{\cdot}060}{2}p\log ([H^+]^2 + K_1[H^+] + K_1K_2) \quad (3)$$

and

$$(E_{1/2})_c = (E_{1/2})_s + \frac{0{\cdot}060}{2}\log K - \frac{0{\cdot}060}{2}p\log C_{H_2A} - \frac{0{\cdot}060}{2}p\log K_1K_2 + \frac{0{\cdot}060}{2}p\log ([H^+]^2 + K_1[H^+] + K_1K_2) \quad (4)$$

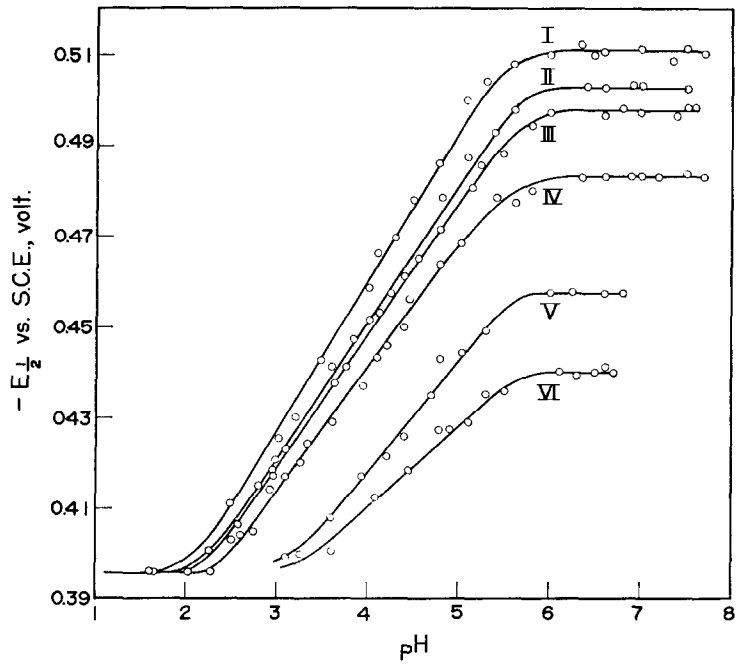

FIG. 2.—Effect of pH on the half-wave potential
$1{\cdot}055 \times 10^{-3}M$ $Pb(NO_3)_2$, $0{\cdot}3M$ KNO_3, and
I. $0{\cdot}8M$ itaconic acid IV. $0{\cdot}3M$ itaconic acid
II. $0{\cdot}6M$ itaconic acid V. $0{\cdot}1M$ itaconic acid
III. $0{\cdot}5M$ itaconic acid VI. $0{\cdot}05M$ itaconic acid.

respectively, where K is the dissociation constant of the complex, and C_{H_2A} is the analytical concentration of itaconic acid.

We may distinguish three cases according to the pH value of the solution: (*a*) $pH < pK_1$, (*b*) $pK_1 < pH < pK_2$, and (*c*) $pH > pK_2$. In these cases equation (3) simplifies to

$$(a) \qquad (E_{1/2})_c = \text{const.} - 0{\cdot}030\, p \log C_{H_2A} - 0{\cdot}030\, p\ pH \qquad (5)$$

$$(b) \qquad (E_{1/2})_c = \text{const.} - 0{\cdot}030\, p \log C_{H_2A} \qquad (6)$$

$$(c) \qquad (E_{1/2})_c = \text{const.} - 0{\cdot}030\, p \log C_{H_2A} + 0{\cdot}030\, p\ pH. \qquad (7)$$

And for the same three pH conditions equation (4) simplifies to

$$(a)' \qquad (E_{1/2})_c = \text{const.} - 0{\cdot}030\, p \log C_{H_2A} - 0{\cdot}060\, p\ pH \qquad (8)$$

$$(b)' \qquad (E_{1/2})_c = \text{const.} - 0{\cdot}030\, p \log C_{H_2A} - 0{\cdot}030\, p\ pH \qquad (9)$$

$$(c)' \qquad (E_{1/2})_c = \text{const.} - 0{\cdot}030\, p \log C_{H_2A}. \qquad (10)$$

These equations demonstrate that if the ligand is protonated, the slopes of the straight lines for the plots of $(E_{1/2})_c$ *vs.* pH are $-0{\cdot}030p$, zero and $+0{\cdot}030p$ respectively, for the three pH conditions of (*a*), (*b*) and (*c*), whereas if the ligand is deprotonated, the slopes are $-0{\cdot}060\,p$, $-0{\cdot}030\,p$ and zero.

It is obvious from Fig. 2 that the plots of $(E_{1/2})_c$ *vs.* pH break at pH 5·7 ($= pK_2$) and the mean slope of the straight lines is $-0{\cdot}029$ up to the pH value 5·7. When the pH value is greater than 5·7, the slope is zero.

Equations (5) and (9) show that the plots of $(E_{1/2})_c$ *vs.* pH have the same slope of $-0{\cdot}030\ p$. This behaviour can be correlated with the fact that there was no break point observed at pH 3·8 (= pK_1) in Fig. 2, and provides evidence that the ligand species is HA^- at pH $<$ pK_1 and is A^{2-} at pK_1 < pH < pK_2.

Therefore, it was concluded that for condition (*a*), pH < pK_1, the complex species must be $Pb(HA)_p^{2-p}$, corresponding to equation (5) in which $p = 1$; for (*b*), pK_1 < pH < pK_2, the complex species must be $Pb(A)_p^{2-2p}$, corresponding to equation (9) in which $p = 1$; and for (*c*), pH > pK_2, the complex species must be $Pb(A)_p^{2-2p}$, corresponding to equation (10) in which $p = 2$ (as will be shown in the next section).

Effect of ligand concentration on the half-wave potential

The co-ordination number in lead itaconate complexes was determined by a plot of half-wave potential *vs.* logarithm of ligand concentration as shown in Fig. 3. At pH < 5·7 the mean reciprocal slope of the straight lines is 0·036, corresponding to a metal–ligand ratio of 1:1. This result agreed completely with that of the section mentioned above. On the other hand at pH > 5·7, the mean reciprocal slope is 0·061, yielding the metal–ligand ratio 1:2.

Basing on the foregoing data and discussion, the complex species and electrode reactions can be formulated as

$$Pb(HA)^+ + H^+ + 2e + Hg = Pb(Hg) + H_2A \qquad pH < pK_1$$
$$Pb(A) + H^+ + 2e + Hg = Pb(Hg) + HA^- \qquad pK_1 < pH < pK_2$$
$$Pb(A)_2^{2-} + 2e + Hg = Pb(Hg) + 2A^{2-} \qquad pH > pK_2.$$

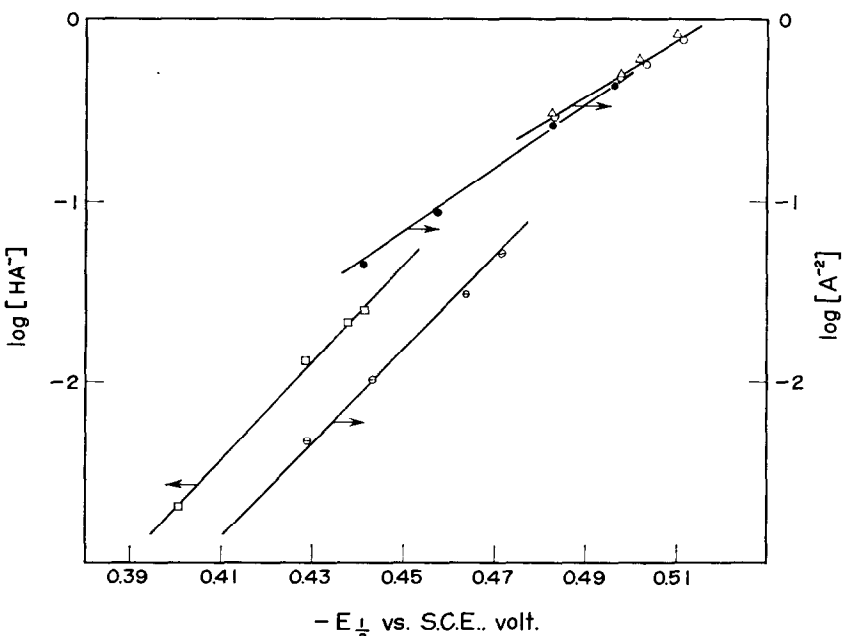

FIG. 3.—Variation of half-wave potential with ligand concentration.
□ pH 3·60 ○ pH 7·00
⊖ pH 4·80 △ pH 7·50
● pH 6·60

Dissociation constant of complex

As shown in Fig. 3, when the pH value is greater than pK_2, the complexes have an almost constant co-ordination number of 1·96, 2·17 and 2·17 at pH 6·60, 7·00 and 7·50, respectively. Applying equation (4) and $(E_{1/2})_s = -0{\cdot}396$V *vs.* S.C.E. (curve I in Fig. 1), the concentration dissociation constant of $Pb(A)_2^{2-}$ was found to be $8{\cdot}3 \times 10^{-5}$ mole^1 l.$^{-2}$ (see Table II).

FREE RADICAL OXIDATION OF DIHYDRIC PHENOLS WITH DIPHENYLPICRYLHYDRAZYL

GEORGE H. SCHENK and DANIEL J. BROWN
Department of Chemistry, Wayne State University, Detroit 2, Michigan, U.S.A.

(*Received* 29 *August* 1966. *Accepted* 7 *October* 1966)

Summary—A spectrophotometric study has been made of the reactions between the free radical 2,2-diphenyl-1-picrylhydrazyl (DPPH) and the three dihydric phenols. It has been shown that water affects the rate of all three reactions and the stoichiometry of the DPPH-catechol (pyrocatechol) reaction. Because of the differences in the rate of oxidation in absolute ethanol, it is possible to determine selectively either hydroquinone or catechol in the presence of resorcinol.

THE purple free radical diphenylpicrylhydrazyl (DPPH) has a great potential as an analytical reagent for readily oxidized organic compounds. This has been demonstrated in a limited fashion for mercaptans[1] and phenols[1] and in an elegant fashion for amines[2] and phenols.[3] The phenol-DPPH reaction is kinetically second-order;[3] it has been proposed[4] that a hydrogen atom is abstracted in a slow step from phenols by DPPH (written below as DPPH· to indicate the unpaired electron). The products are a phenoxy radical (ArO·) and yellow diphenylpicrylhydrazine (DPPH:H):

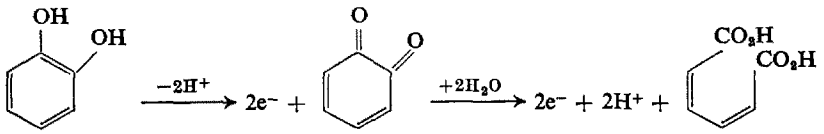
$$\text{DPPH}\cdot + \text{ArOH} \xrightarrow{\text{slow}} \text{DPPH:H} + \text{ArO}\cdot .$$

The analytical technique employed by Blois[1] is based on the measurement of the decrease in absorbance of the 517 mμ peak of DPPH after reaction. The calibration curve is thus a plot of the absorbance of the unchanged DPPH *vs.* the concentration of phenol or mercaptan. In contrast, Papariello and Janish[2,3] plotted the difference (ΔA) between the absorbance values of a DPPH blank and an amine-DPPH mixture *vs.* the amine concentration.

Other workers have studied the kinetics and stoichiometry of DPPH reactions, and many of these papers have been reviewed by Papariello and Janish.[2] In particular, McGowan and Powell[5] have studied the kinetics of certain amine and phenol-DPPH reactions and the effect of certain constituents[6] on phenol-DPPH reactions. Venker and Herzmann[7] found rapid reactions in acetone between DPPH and phenols having at least 2 hydroxyl groups, but no reaction with DPPH and compounds such as resorcinol, phloroglucinol, and phenol. However, Hogg, Lohmann and Russell[4] found that DPPH slowly abstracts an average of 2 hydrogen atoms from monohydric phenols.

The results reported below indicate that water exerts a marked influence on the rate and type of oxidation reaction occurring with catechol (pyrocatechol), hydroquinone and resorcinol. In particular, it appears that catechol and possibly hydroquinone can react with from two to four molecules of DPPH; *i.e.*, undergo 2- or 4-electron oxidations, depending on whether the solvent is anhydrous or not. An

analogy for the 4-electron oxidation of catechol has been reported[8] for the aqueous periodate cleavage of catechol and its ethers:



A 2·7-electron oxidation of hydroquinone by the 2,4,6-tri(t-butyl)phenoxy free radical has also been reported.[9]

EXPERIMENTAL

Apparatus

A transistor-regulated model Bausch and Lomb Spectronic 20 Colorimeter was used for the spectrophotometric measurements. A Beckman model DB spectrophotometer was used in checking the purity of the hydroquinone solutions.

Reagents

2,2-Diphenyl-1-picrylhydrazyl (DPPH) and 1,1-diphenyl-2-picrylhydrazine (DPPH-H) were obtained from Eastman (White Label grade) and were used as received.

Ethanolic solutions of $1 \times 10^{-4}M$ DPPH and $1 \times 10^{-4}M$ DPPH-H were prepared by stirring solvent and solute for 30–45 min. These solutions were then diluted to prepare the reagents used in the study.

Hydroquinone was Eastman White Label grade. Catechol (pyrocatechol) was a Matheson reagent, and resorcinol was Baker and Adamson U.S.P. grade. All $2{\cdot}5 \times 10^{-4}M$ alcoholic phenol solutions were prepared by dilution of a solution of 11·0 mg/100 ml of the appropriate phenol. Whenever absolute ethanol was used as solvent, it was first dried over "Drierite" for at least 24 hr.

Procedure

Time studies of the DPPH-dihydroxyphenol reactions in absolute and 95% ethanol were made by adding 25 ml of $1 \times 10^{-4}M$ DPPH to 2 ml of $2{\cdot}5 \times 10^{-4}M$ solution of the respective phenol, and diluting to 50 ml with the appropriate solvent. (For resorcinol, 5 ml of a $2{\cdot}5 \times 10^{-4}M$ solution were added.) Absorbance readings were taken at 540 mμ at appropriate times, a $5 \times 10^{-5}M$ solution of DPPH-H being used to set 100% transmission. All reaction mixtures were kept in the dark between readings to avoid the slow photochemical reduction of the DPPH to DPPH-H which occurs in sunlight and at 520 mμ.[10]

The amount of 2-electron reaction occurring in the time studies was determined by multiplying the per cent decrease in absorbance by the initial radical concentration and then dividing by twice the molar concentration of the particular phenol.

Linearity of the calibration curves[1] in absolute and 95% ethanol was investigated by adding 25 ml of $1{\cdot}28 \times 10^{-4}M$ DPPH to appropriate aliquots of $2{\cdot}5 \times 10^{-4}M$ solutions of each phenol, diluting to 50 ml with the appropriate solvent, and measuring the absorbance at 540 mμ after about 1 hr of reaction under room lighting.

The interference of resorcinol in the determination of catechol and hydroquinone in absolute ethanol was studied by adding various amounts of $1 \times 10^{-3}M$ resorcinol to 1 ml of $2{\cdot}5 \times 10^{-4}M$ catechol or hydroquinone, then adding the $1 \times 10^{-4}M$ DPPH solution, as in the time studies above. Absorbance readings were taken at 540 mμ after 50 min (catechol) and 140 min (hydroquinone) reaction.

Spectrophotometric measurements were always made at 540 mμ to avoid the interference from DPPH-H encountered at 520 mμ on the Spectronic 20. (The absorption peak is at 517 mμ.)

RESULTS AND DISCUSSION

The relative rates of three selected DPPH-phenol reactions are shown in Fig. 1. It is obvious that the water in 95% ethanol makes the rate of the 2-electron oxidation of catechol to *o*-benzoquinone faster than the rate of this oxidation in absolute ethanol. It is also apparent that water permits reaction between DPPH and resorcinol although Venker and Herzmann[7,11] report that no such reaction occurs in dry acetone.

After a very rapid 2-electron oxidation of catechol, a slower oxidation reaction occurs. The main reaction is presumably the 2-electron oxidation of *o*-benzoquinone to *cis,cis*-muconic acid observed with aqueous periodate by Adler and Magnusson.[8]

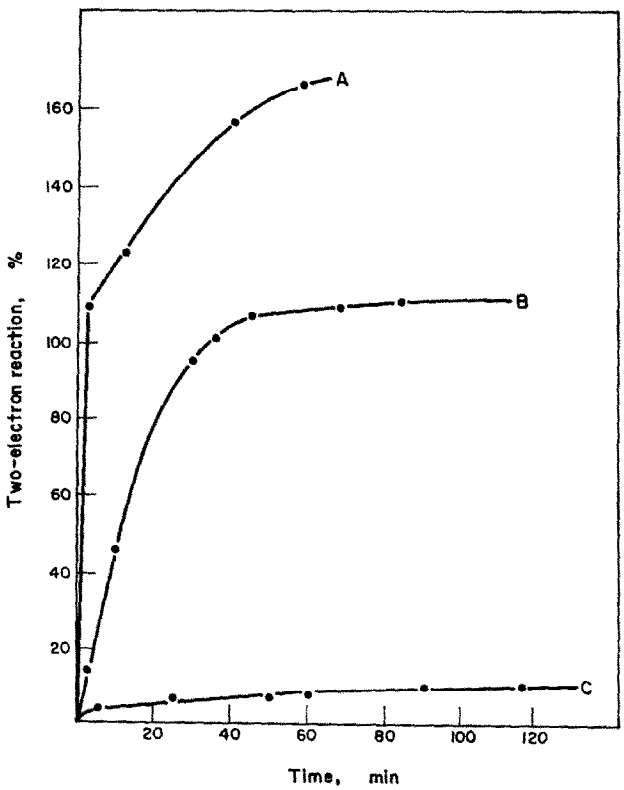


FIG. 1.—Relative rates of DPPH-dihydric phenol reactions.
A 8:1 DPPH:catechol in 95% ethanol
B 5:1 DPPH:catechol in absolute ethanol
C 1:1 DPPH:resorcinol in 95% ethanol.

As indicated in Table I, however, the reaction of DPPH and catechol in 95% ethanol does not terminate at a point corresponding to a 4-electron oxidation, but proceeds well beyond that point. As Adler and Magnusson note, this is probably a side reaction involving an oxidizing agent (DPPH) and decomposition of *o*-benzoquinone. This side-reaction must involve more than two electrons. It is difficult to follow this reaction accurately after the first hour or two because DPPH decomposes with time, and the presence of DPPH-H inhibits this decomposition.[12]

Table I indicates that in absolute ethanol resorcinol reacts at a negligible rate with DPPH, but that hydroquinone and catechol both react with about 2 molecules of DPPH. (The 109% result for catechol may be the result of a trace of water in the absolute ethanol or the result of an impurity in the catechol.) In contrast, resorcinol is readily oxidized by DPPH in the method of Papariello and Janish.[3] Catechol would also be oxidized to *cis,cis*-muconic acid in their procedure. The same would

TABLE I.—RATES OF DIHYDRIC PHENOL-DPPH REACTIONS

* Measured using 4·0 μmole of DPPH.

be true for the aqueous ethanol procedure of Blois,[1] who apparently studied only the stoichiometry of the DPPH-hydroquinone reaction.

Using Blois's technique, we found that both catechol and hydroquinone in 95% ethanol give straight line calibration curves after 60–80 min reaction time. In absolute ethanol, results from catechol deviate somewhat from Beer's law to give a curved calibration graph; a straight line was found for hydroquinone, however.

TABLE II.—DETERMINATION OF CATECHOL AND HYDROQUINONE IN THE PRESENCE OF RESORCINOL ABSOLUTE ETHANOL SOLVENT, $5 \times 10^{-5}M$ DPPH

Mole ratio of resorcinol to hydroquinone or catechol	Compound determined*†	Present, *M*	Found, *M*
0·4:1	Hydroquinone	2.5×10^{-5}	2.35×10^{-5}
2:1	Hydroquinone	1.5×10^{-5}	1.47×10^{-5}
8:1	Hydroquinone	0.5×10^{-5}	0.51×10^{-5}
8:1	Catechol(pyrocatechol)	0.5×10^{-5}	0.5×10^{-5}
12:1	Catechol(pyrocatechol)	0.5×10^{-5}	0.51×10^{-5}
20:1	Catechol(pyrocatechol)	0.5×10^{-5}	0.52×10^{-5}
32:1	Catechol(pyrocatechol)	0.5×10^{-5}	0.53×10^{-5}

* The ranges of the calibration curves are $0.25–2.5 \times 10^{-5}M$ for hydroquinone† and $0.25–2.5 \times 10^{-5}M$ for catechol.†

† The reaction times are 140 min for hydroquinone and 50 min for catechol.

Because resorcinol reacts at a negligible rate with DPPH in absolute ethanol, we investigated the determination of catechol and hydroquinone in the presence of resorcinol, using DPPH and Blois's technique. The results are shown in Table II. It is possible to determine either of these phenols spectrophotometrically in the presence of much larger molar quantities of resorcinol. This is only possible because of the large difference in their relative rates of reaction with DPPH in absolute ethanol, a difference that is not found in 95% ethanol. This selective determination is not possible using either the aqueous ethanol reagent of Blois or the aqueous methanol reagent of Papariello and Janish because resorcinol would then react at an appreciable rate.

Zusammenfassung—Die Reaktionen zwischen dem freien Radikal 2,2-Diphenyl-1-pikrylhydrazyl (DPPH) und den drei zweiwertigen Phenolen wurden spektrophotometrisen untersucht. Es wurde gezeigt, daß sich Wasser auf die Geschwindigkeit aller drei Reaktionen und die Stochiometrie der DPPH-Brenzkatechinreaktion auswirkt. Wegen der Unterschiede in der Oxydationsgeschwindigkeit in absolutem Äthanol ist es möglich, wahlweise entweder Hydrochinon oder Brenzkatechin in Gegenwart von Resorcin zu bestimmen.

Résumé—On a effectué une étude spectrophotométrique des réactions entre le radical libre 2,2-diphényl 1-picrylhydrazyle (DPPH) et les trois diphénols. On a montré que l'eau modifie la vitesse des trois réactions et la stoechiométrie de la réaction DPPH-pyrocatéchol. Par suite des différences entre les vitesses d'oxydation en éthanol absolu, il est possible de doser sélectivement l'hydroquinone ou le pyrocatéchol en présence de résorcinol.

SHORT COMMUNICATIONS

Precise determination of uranium in pure uranium and uranium compounds by constant-current coulomeric titration

(*Received* 28 *April* 1966. *Accepted* 8 *October* 1966)

RECENTLY Pszonicki[1] described a procedure for the precise determination of uranium in pure uranium compounds, based on the reduction of uranium(VI) in concentrated hydrochloric acid solution, by means of metallic aluminium in the presence of cadmium ions, to uranium(III) which is oxidized to uranium(IV) by protons on the addition of concentrated phosphoric acid. A weighed amount of solid potassium dichromate, sufficient to oxidize all but a few mg of the uranium(IV), is added and the remaining unoxidized material is titrated with a standard solution of potassium dichromate potentiometrically.

To avoid the use of any standard solutions, the last step of this procedure has been modified by adding a small excess of solid potassium dichromate to the uranium(IV) solution and determining the excess by constant-current coulometry. An additional advantage of this new procedure is that in titrating from higher to lower potential values the potential change at the equivalence point is better defined, changing from about 840 to about 670 mV. It was found also that four evaporations with hydrochloric acid to destroy any nitric acid present in the simple solution as recommended by Pszonicki are not absolutely necessary. Evaporation of the acid used to dissolve the sample, followed by only one further evaporation with hydrochloric acid, is sufficient for satisfactory analytical results to be obtained.

EXPERIMENTAL

Apparatus

pH-Meter: Radiometer, type PHM-22r with platinum electrode type P-101 and saturated calomel electrode type K-101.

Constant-current coulometer: Metrohm, type E211, with generating platinum-platinum electrodes with diaphragm, type EA-224.

Magnetic stirrer: Metrohm, type E 349A, with inert plastic covered stirring bars.

Conical flasks, 1000-ml with normal socket joints NS 29/32 and splash heads.[1]

Reagents

Hydrochloric acid, s.g. 1·19
Nitric acid, s.g. 1·40
Ortho-phosphoric acid, s.g. 1·71
Hydrochloric acid, 1*M*
Cadmium chloride (cryst.) 50% aqueous solution
Iron(III) chloride (cryst.), 25% aqueous solution
Aluminium wire, BDH AnalaR, 0·7 mm diameter
Potassium dichromate, NBS Standard No. 136 b

Water twice distilled from quartz. All reagents are of analytical reagent grade.

Preparation of the samples

Preparation of U_3O_8 *samples.* Ignite the sample for 1 hr at 850–880° and cool in a desiccator. Weigh a sample (5·8–5·9 g) with an accuracy of ±0·01 mg. Transfer the sample carefully to a 1000-ml Erlenmeyer flask with a standard taper neck, using 20–30 ml of 1*M* hydrochloric acid for washing out the weighing bottle and the funnel; add 20 ml of concentrated hydrochloric and 1 ml of concentrated nitric acids, and fit the flask with a splash head.[1] Warm the flask at first gently on a hot-plate, swirling occasionally, until the sample dissolves; then boil the solution without removing the splash head and evaporate it almost to dryness. Next remove the flask from the hot-plate for a short time to allow the contents to cool and suck the condensate from the splash head into the flask. Evaporate the solution again almost to dryness, remove the flask from the heat, add through the splash head 20 ml of concentrated hydrochloric acid and suck it into the flask by cooling. Evaporate again almost to dryness and repeat the addition of hydrochloric acid (30 ml) through the splash

head, dipping the flask into cold water to accelerate the suction so as to give better washing of the walls of the flask.

Preparation of uranium metal, UO_2 *and* UO_3 *samples.* Use the procedure already described,[1] modified as above.

Procedure

Weigh, with an accuracy of ±0·01 mg, an amount of solid potassium dichromate (previously dried at 105° and cooled in a desiccator) 2–3 mg more than the theoretical quantity needed for the oxidation of the sample.

To the sample prepared as described above, add 1 ml of 50% cadmium chloride solution and 0·75 g of aluminium wire cut into pieces about 5 cm long. Put the flask, closed by the splash head, on a hot plate at low heat and warm until the solution turns deep red. Wash the splash head with a few ml of 1*M* hydrochloric acid to suck down the small quantity of green condensate and warm until the aluminium wire is completely dissolved. Remove the flask from the plate and add through the splash head 15 ml of concentrated phosphoric acid followed by a few ml of 1*M* hydrochloric acid. Hydrogen is evolved and the solution turns green. Boil for 1 min to drive off hydrogen, wash the splash head with a few ml of 1*M* hydrochloric acid and cool to room temperature with cold water. Remove the splash head, add 100 ml of 25% iron(III) chloride solution, mix well to dissolve the gelatinous precipitate and dilute with 100 ml of 1*M* hydrochloric acid, mixing well again. Add the weighed potassium dichromate, stir until dissolved and transfer the solution to a 600-ml beaker. Introduce the indicating and generating electrodes and the magnetic stirring bar.

Reduce the excess of potassium dichromate using a current of 10 mA and rapid stirring. The potential of the platinum electrode at the beginning of the titration is about 900 mV *vs.* S.C.E. and remains almost unchanged throughout the whole titration period. As the end-point approaches, titrate at first in intervals of 5 sec and later of 2 sec. At least 3 min is necessary to obtain a constant value of the potential.

For the blank determination, put 20 ml of hydrochloric acid in a 1000-ml conical flask fitted with the splash head, and go through all stages of the analysis; after addition of iron(III) chloride solution and 1*M* hydrochloric acid, add 2–3 mg of potassium dichromate, weighed to ±0·01 mg, and titrate as described above. However, owing to the absence of uranium, dissolution of the aluminium in the blank determination is much slower. It was found that the blank value is mainly due to the iron(II) content of the iron(III) chloride solution; for routine determinations it is sufficient to prepare the blank by mixing 30 ml of conc. hydrochloric acid, 15 ml of syrupy phosphoric acid, 100 ml of iron(III) chloride solution and 100 ml of 1*M* hydrochloric acid, adding 2–3 mg $K_2Cr_2O_7$ weighed to ±0·01 mg, and titrating as described.

All weighings must be reduced to vacuum.

General remarks

(a) After a few titrations the platinum indicating electrode may become poisoned; to regenerate it, oxidize the electrode anodically in a 1*M* sulphuric acid solution for a period of at least 30 min, electrolysing with current from a 6-V battery.

(b) In analysing some samples of U_3O_8 it was not possible to obtain a permanent deep-red colour of uranium(III) at the reduction stage. Before the final dissolution of aluminium, the solution

TABLE I.—ANALYSIS OF U_3O_8 SAMPLES

U_3O_8 % NBS 950a	U_3O_8 % (from UO_3)
99·941	100·014
99·941	100·010
99·939	100·014
99·944	100·015
99·945	100·015
99·942 ± 0·003%	100·014 ± 0·003%

turned from red to brown and green. It was found that amounts of nickel and/or cobalt greater than a total of 10 ppm in the sample are responsible for this. The analytical results obtained are, however, unaffected, as was proved by the analysis of known U_3O_8 samples to which 40 ppm of nickel plus cobalt had been added.

RESULTS

The precision of the method for single determination is better than $\pm 0{\cdot}01\%$. Table I shows the results of analysis of NBS U_3O_8 sample No. 950a (certified value $99{\cdot}94 \pm 0{\cdot}02\%$) and a sample of U_3O_8 obtained by ignition of very pure UO_2.

The value obtained for the NBS 950a standard is in good agreement with the value of $99{\cdot}946 \pm 0{\cdot}003\%$ previously obtained.[1] In all cases the limits shown are at the 95% confidence levels for the average.

JERZY MALINOWSKI

Summary—A procedure is described for very precise determination of uranium in high-purity uranium and uranium compounds. Uranium(VI) is reduced in a concentrated hydrochloric acid solution by metallic aluminium in the presence of cadmium ions to uranium(III). This is oxidized to uranium(IV) by protons on addition of an excess of orthophosphoric acid, and then oxidized to uranium(VI) by adding a weighed quantity of potassium dichromate in small excess. The excess of potassium dichromate is determined by constant-current coulometry. The coefficient of variation does not exceed 0·003%.

Résumé—Une description est faite de la méthode très précise de dosage d'uranium dans l'uranium et les composés d'uranium de très haute pureté. On réduit l'uranium(VI) dans une solution forte à l'acide chlorhydrique par l'aluminium métallique en présence d'ions de cadmium vers l'uranium(III). Après oxidation vers l'uranium(IV) par addition d'un excès de l'acide ortho-phosphorique, on oxidise l'uranium(IV) vers l'uranium(VI) par addition d'un excès pesé du dichromate de potassium. On détermine l'excès du dichromate de potassium par coulométrie à courant constant. Le coefficient de variation n'excède pas 0,003%.

Zusammenfassung—Es wird eine hochprezise Methode der Uranbestimmung in reinem Uran und Uranpräparaten beschrieben. Uran(VI) wird in einer stark salzsauren Lösung mit Aluminiummetall in Gegenwart von Cadmiumionen zu Uran(III) reduziert. Durch Zugabe von orto-Phosphorsäure wird Uran(III) zu Uran(IV) oxydiert. Jetzt wird Uran(IV) durch ein genau abgewogenes Überschuss von Kaliumdichromat zu Uran(VI) oxydiert. Der Überschuss an Kaliumdichromat wird durch Culometrie mit konstantem Strom bestimmt. Variationskoeffizient des Verfahrens 0,003%.

Contributions to the basic problems of complexometry—XXII
Determination of thorium and scandium in the presence of each other

(*Received* 28 *September* 1966. *Accepted* 24 *October* 1966)

THE complexometric determination of thorium and scandium in their mixtures was recently described by us.[1] The method is based on the titration of both metals with EDTA at pH 2·5–4 and a subsequent exchange reaction between the thorium–EDTA complex and triethylenetetraminehexa-acetic acid (TTHA) according to the equation:

$$\text{Th–EDTA} + \text{TTHA} = \text{Th–TTHA} + \text{EDTA}. \quad (1)$$

Scandium does not react. Determination of the liberated EDTA and of the excess of TTHA by titration with a zinc solution occurs smoothly according to the equations:

$$\text{EDTA} + \text{Zn} = \text{Zn–EDTA} \quad (2)$$

$$\text{TTHA} + 2\text{Zn} = \text{Zn}_2\text{–TTHA}. \quad (3)$$

The calculation of the amount of thorium and scandium is very simple and is described in the paper cited.

We have now found an easier way to determine thorium in the presence of scandium. The thorium–TTHA complex does not react with phosphate and therefore thorium is not displaced from this complex by zinc; scandium, however, reacts quantitatively. Such a determination is possible only with TTHA, and not with EDTA: thorium and scandium are displaced from their EDTA complexes by zinc in the presence of phosphate, as happens also with the light lanthanides.[2]

EXPERIMENTAL

Reagents

1,2-Diaminocyclohexanetetra-acetic acid (DCTA), 0·05*M*, prepared by dissolving 17·63 g of it in 150 ml of hot 1*M* sodium hydroxide, cooling, and diluting to 1 l. The solution is standardized with 0·05*M* zinc solution.

TTHA, 0·05*M*, prepared by mixing 24·72 g of it with 150 ml of hot distilled water, adding 1*M* sodium hydroxide and diluting to 1 l. The solution is standardized with 0·05*M* zinc.

Solutions, 0·05*M*, of thorium and scandium were prepared from the nitrates, and of zinc from the metal.

Disodium hydrogen phosphate solution, 1*M*, was prepared by dissolving 35·82 g of it in distilled water, acidifying it to pH 4–5 with 1*M* nitric acid, and diluting to 1 l. Other reagents included a 0·2% aqueous solution of Xylenol Orange and a 20% solution of urotropine.

Procedure

Determination of the sum of thorium and scandium. Titrate an aliquot of the solution at pH 2·5–4 and a temperature of 50° with 0·05*M* DCTA, using Xylenol Orange as the indicator.[1]

Determination of scandium. To a second aliquot add an excess of 0·05*M* TTHA, enough urotropine solution to adjust the pH to 5–5·5, 10–20 ml of 1*M* phosphate, and a few drops of Xylenol Orange. Titrate the solution slowly at room temperature with 0·05*M* zinc solution till the colour changes from yellow to intense red violet. The TTHA consumed corresponds to the amount of thorium. The amount of scandium is calculated by difference from the results of both titrations. Some results are summarized in Table I.

Remarks. The use of two aliquots is necessary. It is not possible, for example, to determine the sum of thorium and scandium by back-titration of the excess of TTHA with zinc, because the colour change is sluggish. (Scandium is slightly displaced from its TTHA complex and immediately hydrolysed.)

Before the end-point, titration with zinc must be carried out slowly, because the last traces of scandium are also displaced slowly from its TTHA complex. The final red violet colour is stable, but fades slightly after 5 min. During the titration a precipitate of scandium phosphate appears, but does not affect the sharpness of the end-point.

DISCUSSION

This method forms part of our systematic study of the common type-reactions:

$$Me_1Y + X + Me_2 = Me_2Y + Me_1X$$

where Y is the anion of EDTA, DCTA, diethylenetriaminepenta-acetic acid (DTPA), 2,3-diaminopropanetetra-acetic acid (MEDTA) or β-hydroxyethylethylenediamine-triacetic acid (HEDTA), where Me_1 = Th, Sc, Y, rare earths, Al, Ti, Cr, Fe, Ga, In, *etc.*, X = a complex-forming, precipitating or extracting reagent such as PO_4^{3-}, $P_2O_7^{4-}$ or F^-, and Me_2 is an ion such as Zn, Pb, Cu or Mn that is used as the titrant.

We have found that these displacement reactions can lead to new and unexpected possibilities in the analytical chemistry of the rare earths (such as their individual determination) or of other combinations of elements which are difficult to analyse in a simple way.

Analytical Laboratory R. PŘIBIL
J. Heyrovský Polarographic Institute, ČSAV V. VESELÝ
Prague 1, *Jilská* 16, *Czechoslovakia* J. HORÁČEK

Summary—A new method for the determination of thorium and scandium in the presence of each other is presented. Two aliquots of the solution are necessary. In one the sum of thorium and scandium is determined by direct titration with DCTA. In the second, thorium and scandium are treated with an excess of TTHA, phosphate is added, and zinc is used to titrate the excess of TTHA and to displace the scandium from its TTHA complex.

Résumé—On présente une nouvelle méthode de dosage du thorium et du scandium en présence l'un de l'autre. Deux parties aliquotes de la solution sont nécessaires. Dans l'une, on détermine la somme du thorium et du scandium par dosage direct au moyen de DCTA. Dans la seconde, on traite le thorium et le scandium par un excès de TTHA, ajoute du phosphate et utilise le zinc pour titrer l'excès de TTHA et déplacer le scandium de son complexe avec le TTHA.

Zusammenfassung—Zur Bestimmung von Thorium und Scandium nebeneinander wird eine neue Methode angegeben. Zwei Teile der Lösung sind notwendig. Im einen wird die Summe von Thorium und Scandium durch direkte Titration mit DCTA bestimmt. Im zweiten werden Thorium und Scandium mit einem Überschuß TTHA versetzt, Phosphat zugegeben und mittels Zink der Überschuß an TTHA titriert und Scandium aus seinem TTHA-Komplex verdrängt.

TALANTA REVIEW

PROCESS GAS CHROMATOGRAPHY

C. S. F. PINE
Imperial Chemical Industries Ltd., Heavy Organic Chemicals Division, Billingham, Co. Durham, England

(*Received* 25 *July* 1966. *Accepted* 15 *September* 1966)

Summary—The history of process gas chromatography is described briefly, followed by a description of the essential details of process gas chromatograph systems. The economics of process analysers are contrasted with those of laboratory instruments, and the application of process analysers to automatic control systems, process control computers and data loggers or chemical plant is discussed. The paper concludes with a discussion of likely future trends in the subject.

INTRODUCTION

GAS chromatography, since its discovery some 14 years ago[1] has become a widely used analytical method for the analysis of chemicals and petroleum products. During this time there has been parallel development of fully automatically operated chromatographs in the oil and chemical industries and later by instrument companies. The purpose of these instruments is to analyse process streams continuously to obtain analysis data for process control purposes. In many cases the process operator uses the recorded analysis data to reset process conditions to achieve a desired end. In a smaller but growing number of cases, chromatographs are part of conventional automatic process control systems. Also, process chromatographs are now increasingly being used in feeding analytical data automatically to digital computers which are being used to control and optimize the operation of chemical plants. Process chromatographs are now being used extensively in process research work at the pilot plant stage. Often the data are fed automatically to data loggers.

Since the purpose of the process chromatograph is process control, the emphasis is on relatively high speeds of analysis (repetitive analyses every 10 min and less are now typical). This must be achieved with high reliability for long periods of automatic and largely unattended operation. It must be emphasized that satisfactory results have been achieved only by considerable technical effort by the user. If he does not provide this he may well be disappointed by the results he gets. If he does provide it, chromatographs do give high reliability and good results.

The objectives of this paper are threefold. First, it is intended to describe the significant features of process gas chromatograph equipment. Secondly, it is intended to comment critically on the performance of many commercially available process chromatographs. Thirdly, it is intended to describe the capabilities and use of process chromatographs.

It is worth while pointing out first that process chromatographs are expensive in comparison to laboratory instruments. The cost of a laboratory instrument is typically £600–800 (excluding recorder). The cost of a fully automatic process chromatograph can be as low as about £1,000 for an instrument suitable for simple

* For reprints of this Review see the Publisher's announcement near the end of this issue.

analysis problems. This is not typical in the chemical industry, where instruments of suitable capability cost £2,500–4,000. It is significant that such prices do not usually affect the decision to install an instrument for control purposes. Where on-line analysis is required the annual return is, in many cases, higher than the initial capital cost. The economics behind on-line analyser installation are discussed in detail later in this paper. The disparity in prices between laboratory and process chromatographs has tempted many to buy a laboratory instrument and adapt it to process use. Generally the cost involved has risen rapidly to the point where there has been little difference between the final cost and that of a commercial process chromatograph. The capability and performance of the adapted laboratory instrument may often prove inferior, but in any event manpower is wasted in duplicating work that has already been done in developing the equipment.

HISTORY OF DEVELOPMENT OF PROCESS GAS CHROMATOGRAPHY

The first process chromatographs were built by their users in the chemical and petroleum industries. The first process chromatograph built by I.C.I. was installed at Billingham during 1955, for the analysis of a stream of mixed C_3 and C_4 hydrocarbon gases. Essentially the instrument consisted of a laboratory oven containing the column, thermal conductivity detector and sample injector valve. Apart from the sample injector valve it was very similar to laboratory chromatographs used at that time. The sample injector valve[2] was developed to inject reproducible volumes of gases and liquids into the chromatographic column with an error of less than $\pm 0{\cdot}1\%$. The valve was of the linear sliding plate type. It was pneumatically operated, the air signal being applied *via* a multiway solenoid valve operated from a repetitive process timer. The valve was continuously purged with a steady flow of the process gas, supplied to it from the plant. The component peaks were displayed on a potentiometric strip-chart recorder in the plant control room. The instrument was located in the plant building which was classed as a safe area according to the prevailing fire regulations, but electrical equipment containing sparking contacts was purged with nitrogen as an additional safeguard in the event of sample leakage. During the early days of chromatography similar developments were going on elsewhere with several notable results. These are described below.

The need quickly arose for equipment which would be sufficiently rugged to stand up to plant conditions, which could operate safely in hazardous areas and which could be used in automatic control systems. These developments took place within the chemical and petroleum industries. Subsequently, instrument companies were licensed to produce equipment for sale on the open market. The first of such instruments became available in 1958.

Equipment developed by Phillips Petroleum was produced for wider use by the Perkin–Elmer Corporation. The analyser oven section shown in Fig. 1 consists essentially of a heated and temperature-controlled metal mandrel on to which the columns are wound. The sample valve, column switching valve and detector are attached at one end. At the other end a separately temperature-controlled compartment contains other associated equipment including the carrier gas flow-controller. An insulating cover is fitted over the assembly. An explosion-proof cover is then fitted over the top. This equipment has been very reliable but until recently it has been suitable for straightforward analyses only. Early in the 1960's Perkin–Elmer's

interest in process gas chromatography was taken over by the Mine Safety Appliances Company (M.S.A.). This company have now extended the range of equipment they offer, most of it based on earlier developments by Phillips Petroleum.

Another main development in process gas chromatography was undertaken by the Union Carbide Company. Here the analyser oven consists of a stirred air-bath enclosure. It is essentially an insulated box containing the sample valve, columns, detector, *etc.*, which is purged with a fast flow of hot air. An example of this type of analyser (Beckman Instruments) is shown in Fig. 2. A temperature controller is used to regulate the air temperature by continuously adjusting the power to the air-heater. Analysers of this type are now being produced by Greenbrier-Bendix Instruments and Beckman Instruments in the U.S.A.

A new development by M.S.A. is the production of an analyser using the stirred air-bath enclosure principle with the feature of two separately temperature-controlled compartments. The main compartment is electrically heated and the second compartment is supplied with cold air from a Ranque-Hilsch Vortex Cooler.[3] The maximum temperature difference between the compartments is 75°. This feature makes it possible to operate columns at 0° in the cold zone and other columns at above ambient temperature. This feature greatly extends the range of stationary phases that can be used with a process chromatograph, *i.e.*, to those which are too volatile at elevated temperatures.

In England the process chromatograph came on to the market in 1958 and was made by W. G. Pye & Co. Ltd. of Cambridge. This equipment was developed in conjunction with I.C.I. at Billingham and was based on the Pye Argon Chromatograph. This instrument was equipped with a β-ray/argon detector. The development of this equipment followed a different course from that in the U.S.A., largely because many of I.C.I.'s early process chromatographic analysis problems required the use of a highly sensitive detector. At that time the hydrogen flame-ionization detector had not been discovered, but the β-ray/argon detector[4] was available and had adequate sensitivity. A process chromatograph with β-ray detector was installed on an oxygen plant at Billingham in 1957–58 to measure directly 0–3 ppm concentrations (v/v) of acetylene in oxygen. This chromatograph was home-made and is still giving excellent service. The Pye company is now producing a new range of equipment capable of using the full range of chromatograph detectors, whereas in the past it relied on the β-ray/argon detector.

Since equipment first became commercially available it has steadily improved. Complicated analyses can now be performed in comparatively short times, 10–15 min being typical. Less complicated analyses are commonly performed in less than 5 min. These short times are achieved by using 2, 3 or even 4 columns in conjunction with column switching arrangements. Typical examples will be described. The most frequent concentration range is from 0·1 % upwards, but concentrations of a few ppm are frequently determined with the hydrogen flame-ionization detector.[5,6] At present the analysis data are usually displayed on a potentiometric strip-chart recorder and interpreted by the peak height. Measurement by peak height (instead of peak area) is entirely satisfactory in most cases.

The companies mentioned above have taken most of the initiative in the field of process chromatography. Various manufacturers in Europe produce process chromatographs but these have been later developments and are not significantly different

from previously available equipment. A notable new instrument from the U.S.A. is made by the Foxboro Company. The analyser is not particularly novel in conception (it resembles the Phillips Petroleum type) but it is very well engineered and the presentation of the analysis results is particularly appropriate for process use. Other manufacturers are or until recently have been backward in this respect.

Recently, Elliott Process Automation in the U.K. have brought on to the market a low-cost instrument (Model ISC 1129 at about £1,000 without a recorder) with emphasis on the analysis of single process streams. This instrument was developed originally by the Imperial Smelting Corporation in the U.K. and is suitable for simple analyses where the use of the more sophisticated (and expensive) process chromatographs is unnecessary. This instrument in its present form has been unsuitable for most of the process chromatograph problems in the chemical industry. It has been applicable mainly to problems such as furnace gas analysis and petroleum gas analysis. However, it is now being developed for use on the more complex process streams encountered in the chemical industry. Elliott are also producing under licence another low-cost process chromatograph developed by British Petroleum and called the L.P.G. analyser. This instrument costs about £600 (excluding recorder) and has been designed specifically for measuring a single component in a process stream.

PROCESS CHROMATOGRAPH EQUIPMENT

The component parts of a process chromatograph are shown in the functional diagram, Fig. 3. For descriptive purposes, five main items are described.

1. Analyser unit (constant temperature enclosure and carrier flow control)
2. Programmer unit (including amplifier)
3. Sampling system
4. Services (including carrier gas supply and instrument air supply)
5. Data display

Although process analysers are designed to work out in the open in hazardous areas it is advisable to avoid this. The main reason is that it is much more difficult to maintain the equipment, and maintenance costs go up. The present I.C.I. method of installing process chromatographs is to install items 1–4 of the system in a temperature-controlled, clean-air force-ventilated analyser house located conveniently near to the process streams to be analysed. The analysis data are transmitted to the plant control room and displayed on recorders similar to those displaying the other measured process variables.

Analyser unit

The analyser unit consists of a temperature-controlled enclosure and contains the sample injector, columns and detector. Associated equipment which includes the carrier gas flow-controller and the temperature controller, is part of the unit, but it is contained in a separate compartment, which may or may not be temperature-controlled. The individual components of the analyser are worth consideration. They are (*a*) sample injector valves, (*b*) columns, and (*c*) detectors.

Sample injector valves. Four main types are used; linear slide valves, rotary slide valves, piston valves, and diaphragm valves.

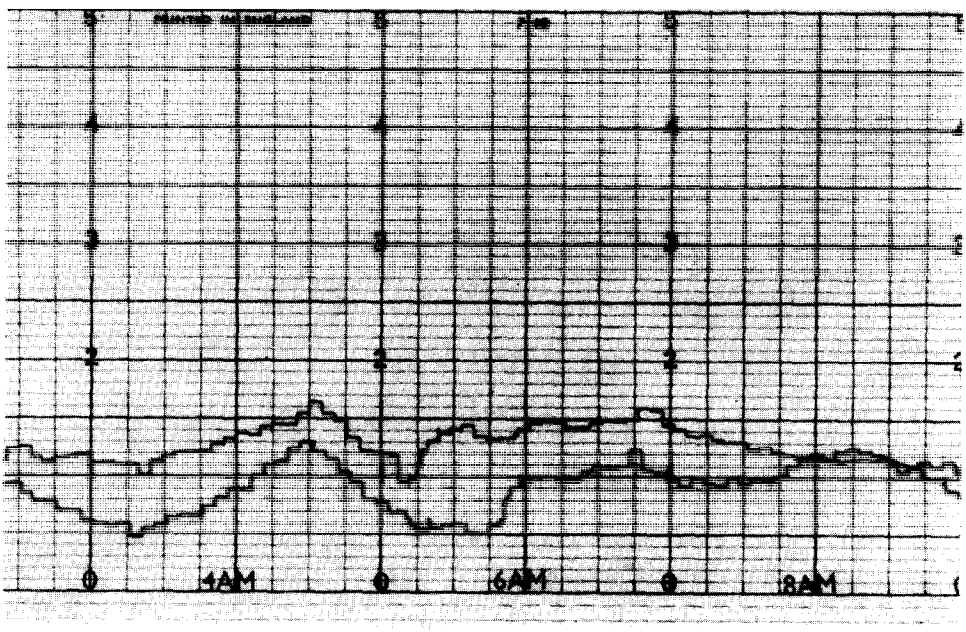

FIG. 16.—Trend output.

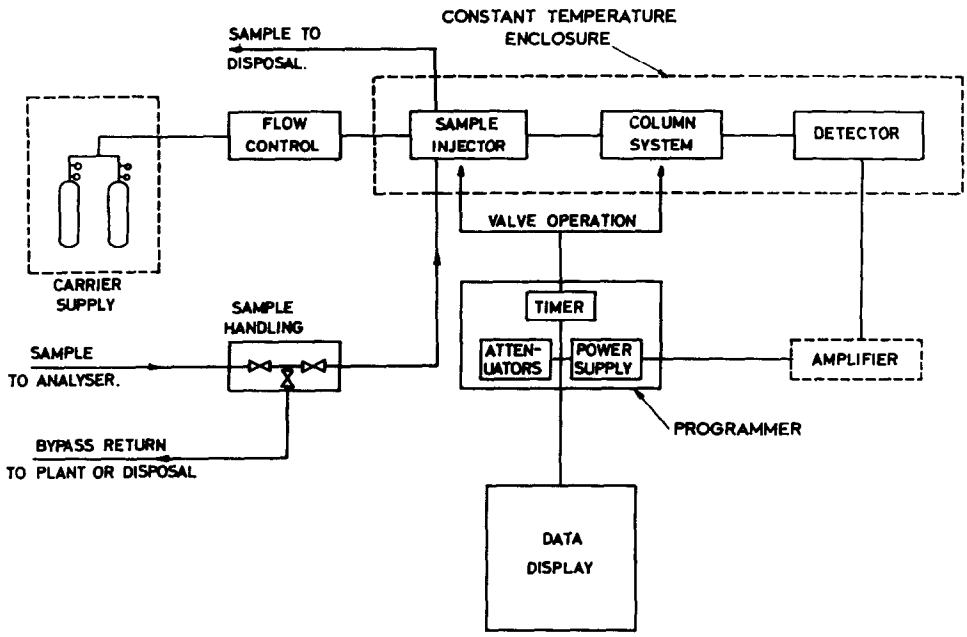

FIG. 3.—Functional diagram of a process chromatograph.

Linear slide valves. Figure 4 shows an external view of a linear slide valve. The working parts are shown in Fig. 5. A 'Fluon'* plastic insert (two examples are shown in Fig. 5) is arranged to slide linearly on the face of the metal block also shown in Fig. 5. Fluon is used because it has a very low coefficient of friction, so a surface lubricant is not required. The surfaces are flat and smooth and are loaded together by a mechanism which ensures sealing. The grooves in the Fluon insert connect various ports in the metal block. Sample injection is achieved as shown in Fig. 6(A) and 6(B). With the insert in one position the sample loop is purged with sample, and with it in the other position the carrier gas flushes the sample into the column. This valve is used in this way to inject vapour samples larger than 0·3 ml. For small volumes, a Fluon insert with grooves as in Fig. 6(C) is used. Here the sample volume is that of the centre groove in the insert. The smallest volume obtainable with this valve is about 1 μl. The sample injection action is shown in Fig. 6(C) and 6(D). This arrangement is used mainly for injecting liquid samples directly into the carrier gas stream.

Figure 7 shows another type of linear slide valve. Here a plastic insert is sandwiched between two metal blocks. The action for vapour sampling is shown in Fig. 8(a) and (b).

The linear slide valve[2] is probably the valve most widely used since its inception in 1954. Its main advantages are that it is not expensive to produce, it is very reliable and it can work at high sample pressures. A sandwich type valve can work reliably with sample pressures up to 500 psig if necessary. For example, such a valve has been used for 9 months at a sample pressure of 200 psig without deterioration. These

* Fluon is the trade mark for ICI Polytetrafluoroethylene. This material is commonly known in the U.S.A. as Teflon (a Du Pont trade mark).

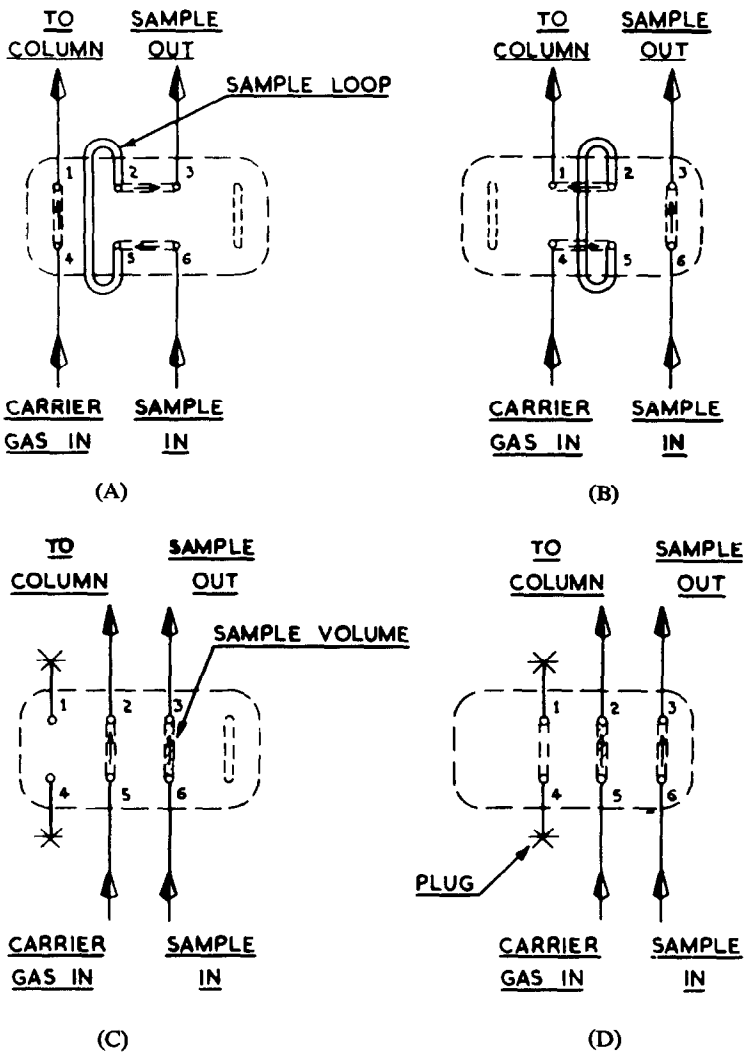

FIG. 6.—Sampling valves with external and internal sample loops.

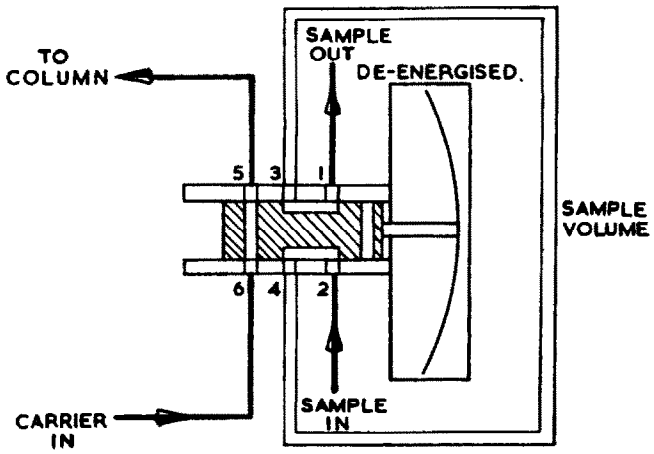
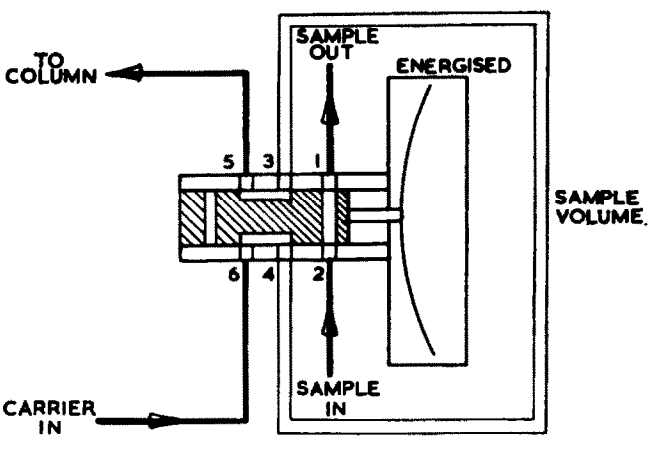
valves cost about £35 to produce, although they are generally sold at over £100. They are generally provided with six connections, but some are available with eight, so that they can be used for back-flushing as well as sample injection. These valves are all pneumatically operated. Switching of the air signal is usually achieved with a three- or four-port solenoid valve.

Rotary slide valves. In valves of this type a flat-faced insert (usually plastic), into which grooves are machined, is rotated on a flat metal surface. Ports in the surface lead to the external connections. The two surfaces are spring-loaded together. Apart from the rotary action, the operation is similar to that of a linear slide valve. These valves are less popular as they have not proved suitable for high carrier gas or sample pressures since they are generally more difficult to seal. For straightforward problems they do give good performance. They are usually electrically actuated.



(a)



(b)

FIG. 8.—Sampling action of sandwich-type slide valve.

Piston valves. A valve of this type usually consists of a cylinder with connections through the walls at intervals along the axis, together with a piston with rubber sealing rings located in grooves along it. By choice of the appropriate connections, movement of the piston between two positions effects sample injection. These valves are satisfactory for low pressure operation only, as unfortunately the rings tend to flatten and cause leakage. These valves are usually pneumatically actuated. For straightforward problems they give good performance.

Diaphragm valves. These valves are probably the best alternative to the linear slide valve. Unfortunately they are much more expensive and cost two to three

times as much as the linear slide valve. A typical example is shown in Fig. 9. Their operation is illustrated in Fig. 10. The body of the valve is a flat metal surface with 6 ports to external connections, located at the corners of a hexagon. A plastic diaphragm is fitted over the ports and held so that gas cannot leak outwards or inwards but only between the ports. A set of 6 pneumatically operated pistons is arranged, with one piston between each pair of ports. In one of the operating positions of the valve (mode 1) 3 pistons press down on the diaphragm and the other 3 pistons are raised, allowing gas to flow between the ports as shown in Fig. 10. In the other position (mode 2) the pistons previously raised are pressed down and those previously pressed down are raised.

The diaphragm valve has the advantage of very low internal volume, together with ultra high speed of operation. Failure eventually occurs owing to fatigue of the plastic diaphragm. The main disadvantages of the valve are its high cost and the extreme care required in its assembly.

Columns. The columns used in process chromatographs are packed columns very similar to those used in the laboratory, but with the following qualification. Columns are selected for high stability over long periods of operation, preferably 1–2 years but a minimum of 6 months. This precludes the use of the more volatile stationary phases often used in the laboratory, and these stability requirements have also so far prevented the use of capillary columns. These have been found to be unstable, even when the capillaries are coated with the stationary phases which are acceptable for packed columns.

Most process chromatographs use more than one column to perform the desired analysis. This is because a single column is rarely able to perform the analysis satisfactorily in an acceptable time.

Detectors. Three types are generally used: thermal conductivity (katharometer), hydrogen flame-ionization, and β-ray/argon. Other detectors are not in general use mainly because they possess disadvantages for quantitative work. A recent development by Greenbrier Instruments is to use the phosphorus pentoxide electrolytic hygrometer cell[7] in a chromatograph for the determination of water in complex process streams. Most organic compounds poison such cells if used directly. With a chromatograph the water can be separated from other components and then passed alone to the detector. The other peaks are by-passed by a suitable column switching arrangement.

Thermal conductivity. This detector is the one most widely used in process chromatographs. With it, the full-scale range of the process chromatograph corresponds to a concentration range which can be as low as 0–1000 ppm but is more often 0–5000 ppm. Four-element hot wire detectors are generally preferred. The cells used are moderate in size and are generally similar to thermal conductivity cells used in the laboratory.

Hydrogen flame-ionization.[5–8] This detector is the main alternative to the thermal conductivity cell. The detector cells have to be ruggedly constructed so that they are safe for use in plant areas, *i.e.*, they must be able to contain internal explosions and must not propagate a flame to external sources of flammable material. For this reason and also because they require an expensive amplifier, the overall cost of the equipment is £500–800 higher than for equipment with a thermal conductivity detector.

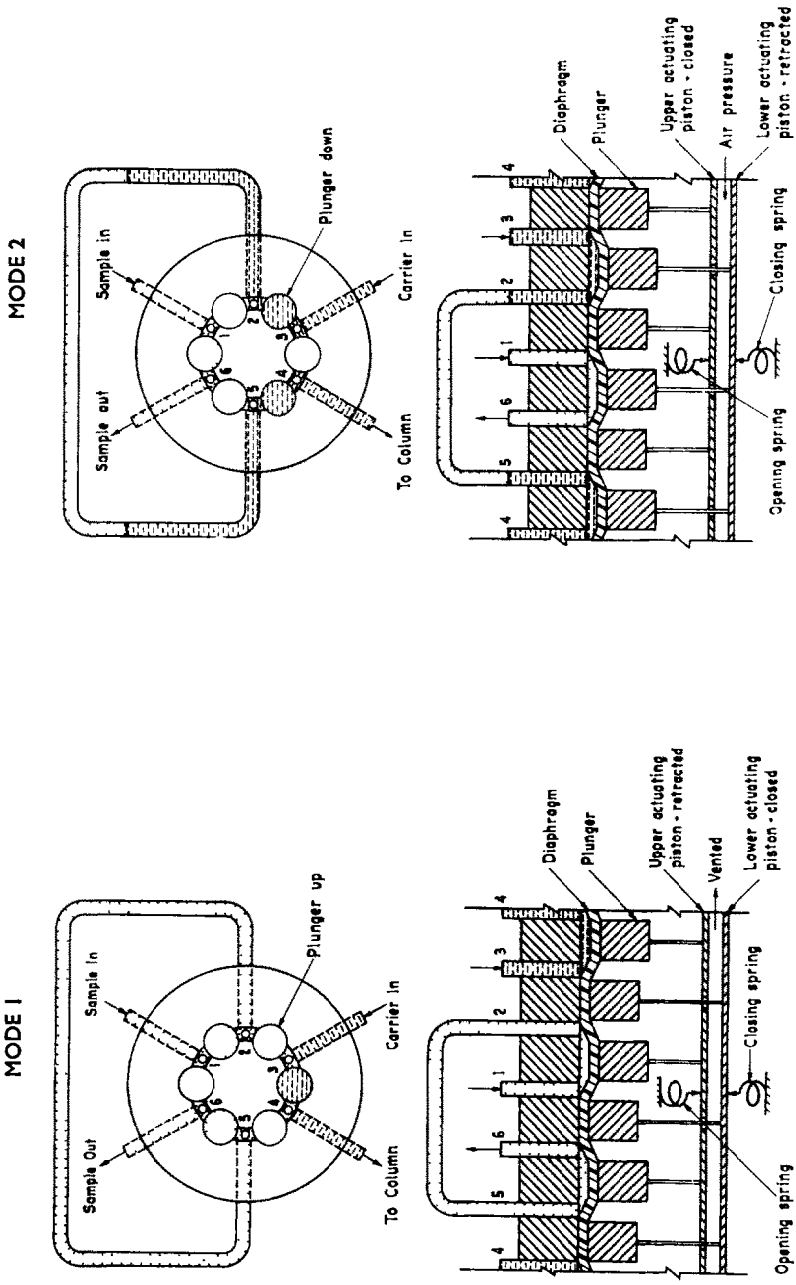


FIG. 10.—Schematic diagram of vapour sampling with a diaphragm valve.

With the hydrogen flame-ionization detector concentrations down to 0–10 ppm can be measured with full-scale deflection. This detector is used normally for those problems which cannot be tackled satisfactorily with a thermal conductivity detector.

β-Ray/argon detector. This detector was widely used in the early days of process chromatography but is much less used nowadays. This is because the hydrogen flame-ionization detecor (a later development) is more attractive for most purposes. It has a wider dynamic range of operation than the β-ray/argon detector and does not have the inconvenience of a powerful radioactive source (^{90}Sr).

Operation of the analyser unit

This is illustrated by two examples.

The first is an analysis performed by an analyser of the type shown in Fig. 1. This analyser has a thermal conductivity detector with a 16-port sample valve mounted

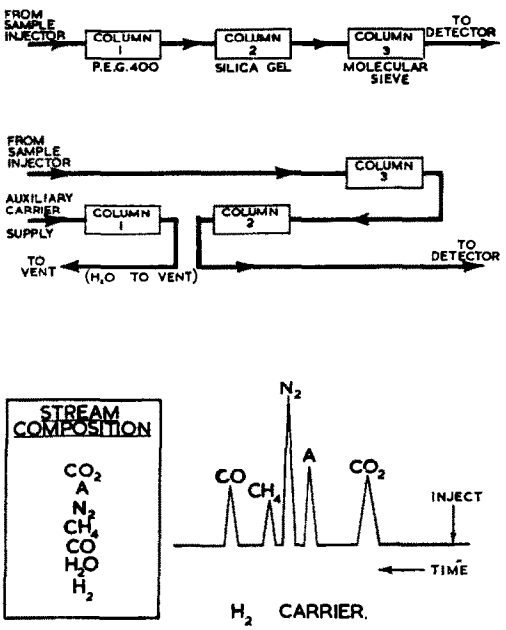

FIG. 11.—Stream analysis with column back-flush through the detector.

on the top of the heated mandrel. The valve actuator is mounted in the lower compartment and is connected to the valve *via* a shaft running through the centre of the mandrel. The flow diagram in Fig. 11 shows how the analysis is performed.

The gas stream to be analysed contains H_2, Ar, N_2, CH_4, CO, CO_2 and H_2O. It is desired to measure all components except the hydrogen and water. To achieve this, three columns are used and are connected to the 16-port valve as in Fig. 12 (CCW) and (CW). The situation before a sample is injected into the columns is shown in Fig. 12 (CW). A steady flow of sample at constant pressure purges the sampling chamber (a length of stainless steel tubing) connected to two of the valve ports. The hydrogen carrier gas is supplied to an adjacent port, and to inject a sample the valve is rotated

to give the flow path shown in Fig. 12 (CCW). Hydrogen carrier gas flushes the sample from the loop into column 1, thence into columns 2 and 3, and finally into the detector measuring cell (SENS). The action of the columns is such that column 1 holds back water but not the other components, column 2 holds back CO_2 but not the remainder. As soon as the remaining components have entered column 3, the valve is shifted to give the flow path in Fig. 12 (CW). The water in column 1 is back-purged out of

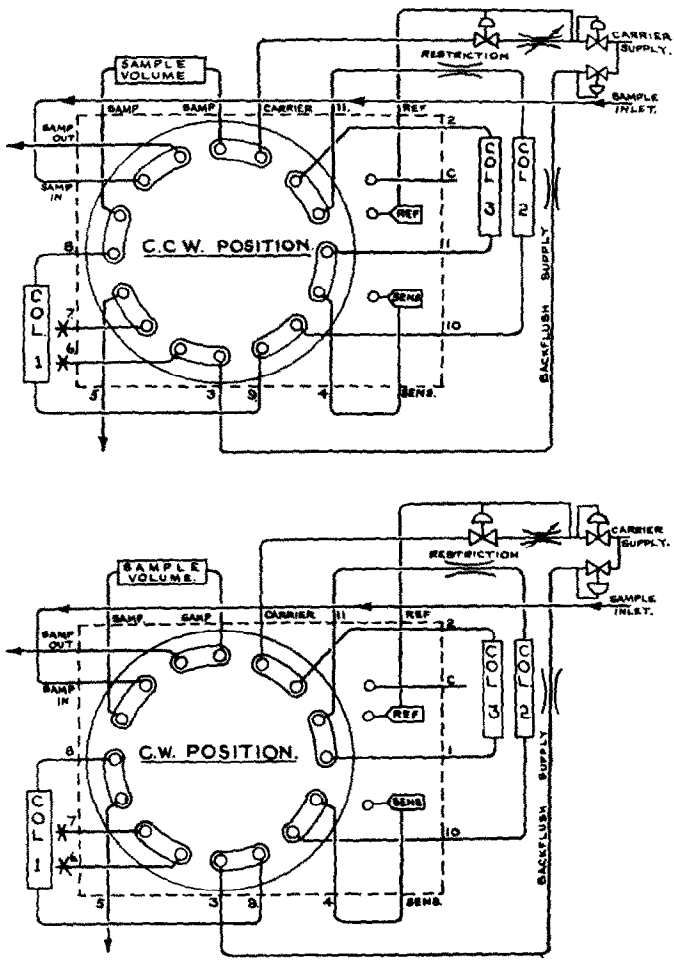

FIG. 12.—Sample injection and column flushing by means of a 16-port rotary valve.

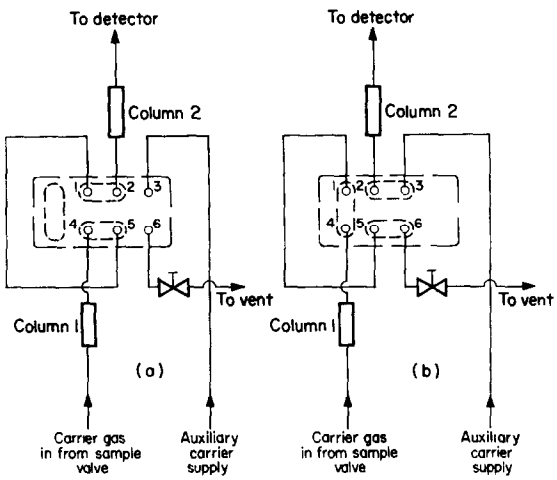
column 1 to atmosphere. The CO_2 peak is back-flushed out of column 2 straight through to the detector where it is measured. The remaining components proceed through column 3 and are separated by it. They pass through column 2 a second time, then to the detector where they are measured. The sort of trace that appears when the detector signal is fully recorded is shown in Fig. 11. The reason for using such a scheme as that in Fig. 11 is that the column material suitable for resolving Ar, N_2, CO and CH_4 (molecular sieves) absorbs CO_2 irreversibly. Thus CO_2 must not be allowed to enter column 3.



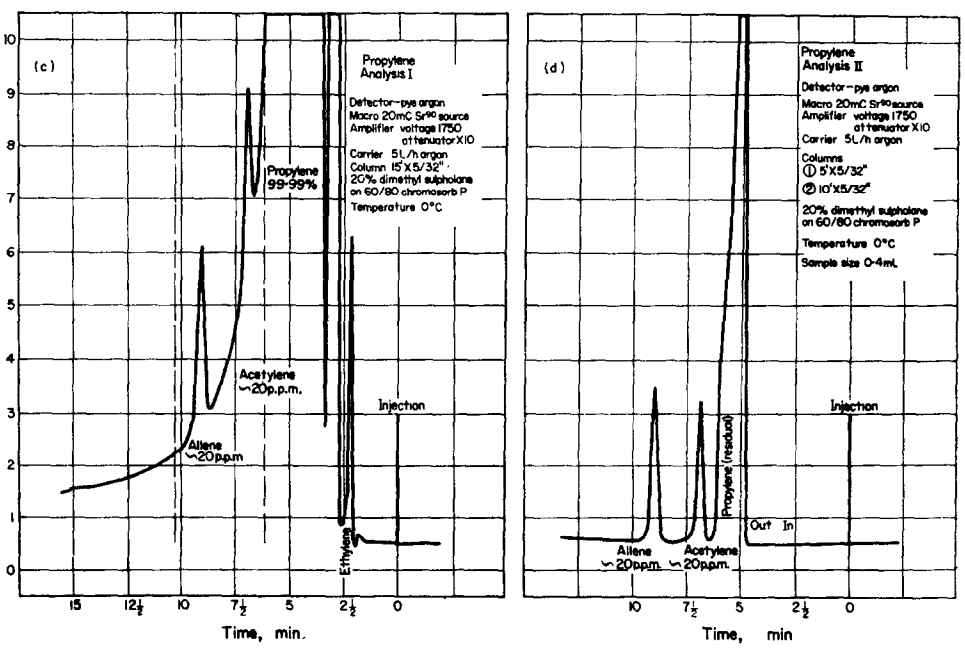


FIG. 13.—Heart-cut analysis.

The second example, of an analysis performed with a β-ray/argon ionization detector, is illustrated in Fig. 13. (This analysis could have been performed equally well with a hydrogen flame-ionization detector.) The analysis problem is the determination of acetylene and allene, each present at about 20 ppm concentration in propylene. Figure 13(c) shows what happens when the sample passes through a single column. The components of interest sit high on the "tail" of the major component. Increasing the column length does not usually help matters. Even if the required

peaks can be separated effectively from the tail, the analysis time is prolonged excessively. Measurement can be made in the laboratory fairly simply. With a process instrument it is necessary to measure the peak height from the zero-base line. This can be achieved by using two columns connected as shown in Figs. 13(a) and (b). Linear sliding plate valves are used, one for sample injection, the other for column switching. The operation is as follows.

With the valves connected as in Fig. 13(b) the sample injector valve is operated and the sample is swept into column 1. The gas emerging from column 1 is vented to atmosphere until the major part of the propylene peak has passed out of the column. The column switching valve is then shifted, Fig. 13(a), to allow that section of the tail of the propylene peak containing the acetylene and allene to pass into column 2. As soon as this section is in column 2, the valve is reversed. Column 2 then separates the two peaks from the peak of the interfering propylene as in Fig. 13(d). The method is known as "heart-cut analysis." A method similar to this was first reported in 1958.[9]

Programmer unit

The programmer by definition controls the operation of a process chromatograph. Since a gas chromatograhic analysis is not a continuous operation but a batchwise process, the essential part of the programmer is an automatic process timer. This timer must initiate at the correct and precisely defined times the series of operations required in the analysis. Also it must repeat this analysis cycle continually. In practice analyses are performed with cycle times ranging typically from 1–40 min. The functions controlled by the timer are; (*a*) sample injection valve operation, (*b*) column switching valve operation, (*c*) automatic zeroing of the detector output, (*d*) processing of the detector output, (*e*) control of the analysis data display and, (*f*) automatic selection of different process streams (where it is desired to analyse in rotation more than one process stream). The programmer usually also contains the power supplies for the detector, and means of signal amplification and attenuation. A typical programmer is shown in Fig. 14.

Process timers. At present these are electromechanical in construction. The commonest type and one which is very reliable consists of an a.c. mains frequency synchronous motor driving a cam shaft *via* gears. The cams (up to 12 in number) are adjustable, and operate microswitches. These switches are used to initiate the various operations, usually *via* hermetically sealed relays. The cycle time of the timer is changed by changing the gearing between motor and shaft. These timers, although reliable, are tedious to set up and adjust. To get over this adjustment problem, other timers use a large diameter disc or endless belt driven at constant speed instead of a small diameter cam. Pins are attached to the disc or belt at positions corresponding to the times an event is to occur. The pins operate a microswitch as they pass it and the switching operation causes a stepping switch (uniselector) to step on one position. The operations are wired through the stepping switch in the correct order. At the end of the sequence of operations in the analysis, the stepping switch is reset by a larger sized pin operating a separate switch. Another variation on this principle is to use a rotating disc with light sources on one side and photocells on the other. Holes punched into the disc are used to permit light to pass through the disc to the photocells at the selected times, and the photocells are used to initiate the desired operations.

Sample and column valve switching. Most process chromatographs now use sample and column switching valves which are pneumatically operated *via* electric solenoid valves actuated electrically from the programmer.

Automatic zeroing. The output signal of a chromatograph detector is subject to random drifts which can become troublesome over periods of several hours. Thus it is standard practice to correct these drifts automatically once per analysis cycle. This is usually done in one of two ways.

1. With the aid of a servo amplifier and a servo motor. The motor is used to drive a potentiometer in the detector signal circuit until the output of the circuit (fed to the amplifier) is restored to zero.

2. A high gain amplifier is connected at the output of the detector, and feeds back its output signal to the detector circuit. The feedback signal is then stored on a capacitor and this corrects any out-of-balance signal from the detector for the rest of the analysis.

Automatic zeroing must always be performed at that part of the analysis cycle when only pure carrier gas is passing through the detector.

Processing of the detector output and control of the data display. The simplest method of recording chromatograph data is as peaks on a strip-chart recorder. Normally the signal is fed to the recorder *via* an attenuator which can be set so that the full scale range on the recorder is equivalent to a convenient figure, *e.g.*, 0–10% concentration by volume. Where more than one peak is measured each peak is allotted its own attenuator. This is necessary as the peak height sensitivity of substances varies greatly. The function of the timer in the programmer is to switch the required attenuators in at the desired times.

More sophisticated instruments store the peak values in memory circuits so that the values can be presented as continuous signals for use for automatic control purposes or fed to loggers or computers for further processing. These more sophisticated forms of data processing are now coming into common use. The function of the programmer is to ensure that the peak signals are correctly stored in the memory circuits.

Automatic selection of process streams. Process chromatographs are often used for multiple stream analysis, *i.e.*, a succession of process streams is analysed in turn by the same instrument. This is usually only possible where the streams are similar in character, *e.g.*, the feeds and products from a group of reactors all producing the same product. The programmer is fitted with a stream selector unit. This may be part of the programmer itself or it may be a separate box. The function of the stream selector is to connect in turn the process streams (usually by energizing electric solenoid valves) to the instrument sample line. The selector is usually a stepping switch, which is stepped on by the process timer in the programmer. The solenoids are wired through the switch.

Sampling system

Any process analyser working continuously on the analysis of a process stream has to be supplied with a fresh and usually steady flow of sample. In all cases a properly engineered sample handling system has to be designed and erected on the plant to provide the analyser with a sample automatically. Owing to the wide range

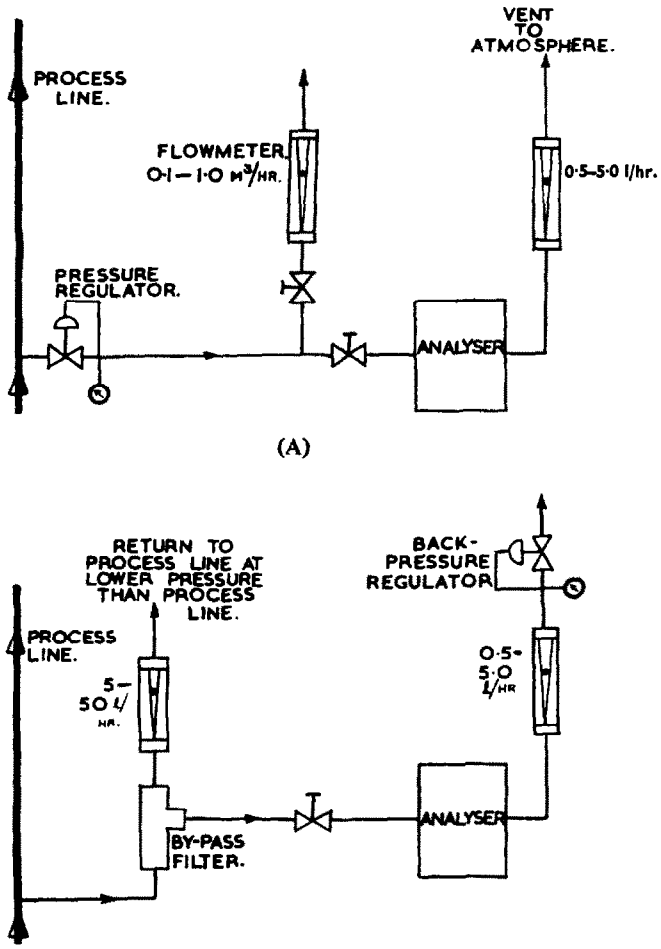

FIG. 15.—Simple sampling arrangements.

of conditions existing in chemical and petroleum processes, sampling system requirements differ considerably.

The individual problems of sampling systems for process analysers are sufficient to justify a separate review. The importance of the subject cannot be overemphasized, and the following points should be borne in mind.

Supplying a continuous sample to an analyser is generally not a difficult task when the sample is a clean liquid or gas under pressure. Figure 15(A) shows a typical system for liquid sampling and Fig. (15)B one for a gas system. Since the analyser may be located up to 200 ft away from the process line, by-passes are used to reduce the lag time from process line to analyser to less than 1 min. Unless the line length is very long, a line of $\frac{1}{4}$ in. outside diameter and $\frac{5}{32}$ in. bore is usually satisfactory.

Difficult problems frequently arise, and in such circumstances a small plant (processing unit) may have to be built to obtain a satisfactory sample. Two examples illustrate this.

(*a*) The process stream is a hot condensible vapour at sub-atmospheric pressure. It contains catalyst dust and inert gases. The analyser requires a cool clean liquid sample under pressure. A processing unit has to be built which removes catalyst dust, condenses the vapour to liquid and removes the inert gases. The liquid is pumped to the analyser. The sample lag-time must be kept below 1 min.

(*b*) The process stream is a hot vapour containing hydrogen, light hydrocarbon gases, gasoline, heavy fuel oil vapour, coke, tars and water vapour. The analyser has to measure the relative proportions of the light hydrocarbons. A processing unit has to be built to remove most of the gasoline and water, and all of the fuel oil, coke and tars, and to supply a clean gas sample to the analyser. If the "heavy" materials are not removed, they would choke the analyser sample lines in a few minutes. The gasoline and water must be condensed out so that the sample entering the analyser is not a mixture of gas and liquid.

In process analysis the objective is rarely to analyse for all the components of the process stream but to determine one or a small number of the components. This can greatly simplify the analyser. In the case of gas chromatography it permits analysis of components present in substances which are themselves not amenable to analysis by gas chromatography *e.g.*, determination of volatile hydrocarbons in solutions containing dissolved polymers and other solids.

Column switching methods are now used extensively to remove unwanted volatile components from a sample being analysed by gas chromatography. Removal of water by such a method was described above. All such methods are really internal sample handling within the analyser.

Sample handling equipment is supplied by manufacturers of process chromatographs. The important thing for the customer is to provide very precise information on his process stream to the instrument manufacturer, if he wishes to obtain satisfactory operation. Many a process chromatograph has earned itself a bad reputation owing to sampling difficulties. Examination of the situation has revealed that the chromatograph itself has worked very well. Unfortunately, an inadequately designed sampling system has not supplied an uninterrupted sample flow to the analyser.

Hard-won experience has convinced the author that detailed design of sampling systems should be done by the user of the analyser and not by the instrument manufacturer. Even where systems are supplied by chemical plant contractors the customer should carefully scrutinize the proposed systems.

Services

Design of the supply of services to process chromatographs is extremely important if reliable operation is required. Two items need particular care, the carrier gas supply and the air supply.

Carrier gas. The supply of carrier gas entering a process chromatograph should be continuous, and pure, dry, and free from organic impurities. Pure gas is usually supplied from cylinders. In the U.K. hydrogen is most commonly used for thermal conductivity detectors and nitrogen for hydrogen flame-ionization detectors. Cylinder gas contains variable amounts of water vapour, often >100 ppm. If this water is not removed, an unstable baseline can result, and damage may occur in the analytical columns, particularly when activated solids are used as column packings. The water

is commonly removed by passing the gas from the cylinder through a drier vessel containing activated molecular sieve pellets.

A molecular sieve drier will also remove many organic materials which might accidentally get into the system. Where flame-ionization detectors are used, all pipework leading from the carrier cylinders to the analyser must be scrupulously clean and free from adsorbed organic substances. Pipework is usually cleaned *in situ*. The first step is solvent washing with methanol and/or benzene. Then the pipe wall is heated along its length with a blow torch and at the same time is purged with a dry inert gas—usually nitrogen from a cylinder. The supply of carrier gas should be uninterrupted. This is achieved by using a pair of cylinders as shown in Fig. 3. Both cylinders are connected to the analyser at the same time, but the pressure-reducing regulators on the cylinders are adjusted so that their output pressures are different by about 5–10 psig. The net effect is for the cylinder with the higher output pressure to deliver gas to the analyser, and the higher pressure prevents the other cylinder regulator from delivering gas. Eventually the pressure in the first cylinder falls to the lower set pressure and the second cylinder then takes over. This prevents failure of the gas supply, say in the middle of the night. An empty cylinder is replaced by the daily maintenance staff on the first morning it is noted to be empty. A further precaution is advisable with carrier gas supplies, in the event of inadvertent failure owing to the onset of leakage (at a pipe joint for instance). It is now normal practice to provide a pressure switch in the carrier line to cut the power supply to the programmer in the event of carrier gas failure. It has the advantages of preventing the burn-out of expensive filaments in thermal conductivity detectors owing to diffusion of air into the detector, and the flooding of columns with sample, which could ruin them.

Air supply. Most, but not all, process chromatographs require a supply of air. The reason for this is historical in that for many years the bulk of chemical and petroleum process instrumentation has been pneumatic. Thus an air supply has been conveniently available and has been used to advantage. The crucial problem which arises here is with hydrogen flame-ionization detectors. These require a flow of air to support combustion, and this air must be hydrocarbon-free. Thus rules out use of air supplies which originate from oil-lubricated compressors. Instrument-grade air used at I.C.I. is oil-free and can be used directly, although a molecular sieve trap is used as an added precaution. The user should examine the nature of his air supply, and if it is not oil-free he must seek another source. Cylinders require frequent replacement, as the normal consumption of a flame detector (20–30 l/hr) will soon empty one. The best solution is a small oil-free air compressor. These are not expensive.

Data display

The satisfactory presentation of the analytical measurements is the most important part of the process chromatograph installation for the process operator. The analysis measurements should be presented similarly to other process measurements such as flow, pressure, level, *etc.*, *e.g.*, as in Fig. 16. The example chosen shows a section of the chart from a standard 2-pen 4-in. pneumatic strip chart recorder. The process stream is analysed for two components. The measured values of each component are stored in the chromatograph programmer. At the same time the stored signal is displayed on the recorder. Each component peak height is changed to the latest value during each subsequent analysis.

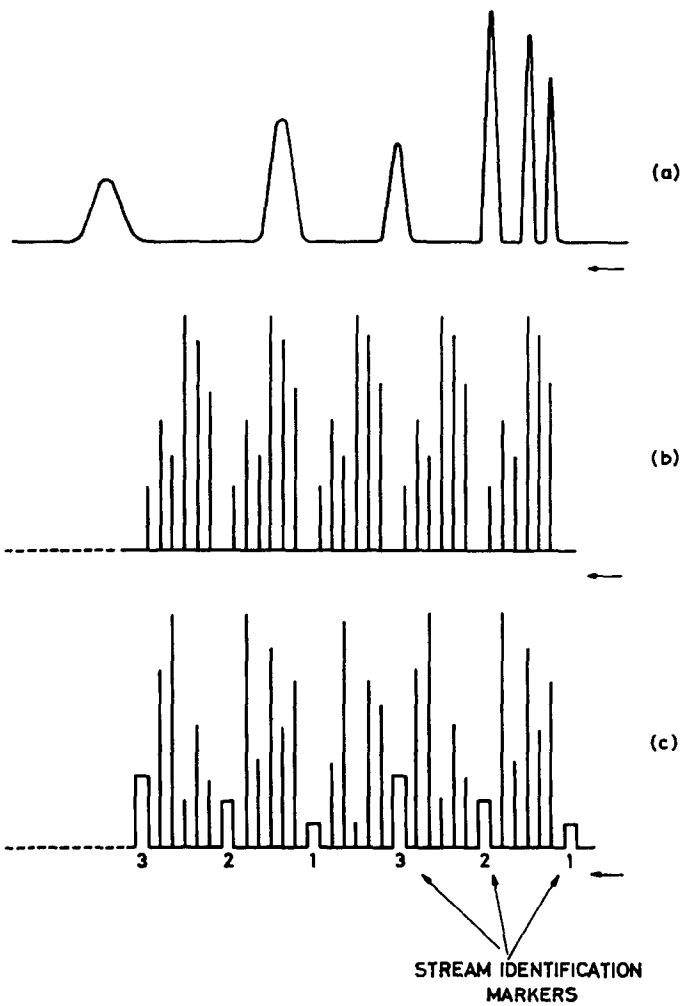

FIG. 17.—Process chromatograph data presentation.

The presentation in Fig. 16 is commonly called "trend" presentation. Each component measured is assigned its own recorder pen. When all the pens are in the same recorder, they have different colours. Thus the process operator can follow the concentration trends easily. The signals are also in a form which is standard in automatic process control systems.

As a process chromatograph is not a continuous analyser but a repetitive batch type of analyser, problems arise in obtaining a display of the kind in Fig. 16. In the laboratory all the user needs is an output on a strip chart recorder as in Fig. 17(a). This is not much use to the process operator who would have to abstract all the peak values from the chart and does not have the time to handle long accumulated lengths of chart. Moreover, with this kind of presentation he cannot easily follow the concentration trends. In the laboratory a chromatograph operator generally measures

the areas of the peaks to obtain the measured values. However, in most cases, measurement with a process chromatograph is made on a peak-height basis. This is possible since under the stable conditions under which process chromatographs operate, the height of a peak is (in most cases) entirely suitable as a direct and accurate ($\pm 1\%$ of full scale) measurement of concentration. Area measurement has been found to be unnecessary in most cases.

Since peak height measurement is satisfactory, the output of Fig. 17(a) is often transformed to that in Fig. 17(b) to avoid excessive usage of recorder chart. This is done by halting the chart drive of the recorder whilst a peak is emerging. With the aid of a time-delay circuit, the chart is advanced a fixed distance between peaks. This form of presentation is called "bar-graph." Its main disadvantage is readily apparent when considered from the process operator's point of view. When the analysis is for more than two peaks, it is very difficult to follow individual component trends. It becomes impossible to do so at a glance when the analyser is used to analyse more than one process stream and all the analysis data are put on one recorder. In such cases the streams are identified by a rectangular marker as in Fig. 17(c).

Bar-graph presentation is suitable if only one or two components are measured in a process stream. Otherwise it is virtually useless. This view is based on the experience of a large number of plant managers and process operators. The only virtue of bar-graph presentation is its low cost. Trend presentation is more expensive, although as a result of recent developments by chromatograph manufacturers, the cost differential has narrowed considerably. It normally does not add more than 10% to the cost of the equipment and in our view this is well justified.

Trend presentation equipment

Various techniques are used for transforming a peak as in Fig. 17(a) to the trend form in Fig. 16. Three basic methods are used: (*a*) phase sensitivity peak pickers, (*b*) diode-capacitor systems, and (*c*) pneumatic peak picking.

Phase sensitive peak pickers. These utilize the electromechanical-servomechanism in conventional potentiometric recorders. For their operation these peak pickers use the property of the change in phase of the a.c. signal which drives the recorder pen motor. The upscale and downscale pen drive signals are opposite in phase. A phase-sensitive circuit is used to detect the change of phase. The output of this circuit is used to permit the pen to drive upscale to the peak maximum but it disconnects the drive motor as soon as the pen starts downscale. The recorder pen is thus held at the peak maximum. The pen is held for a sufficient time (a few seconds) whilst the peak signal is transferred to an auxiliary storage circuit, *e.g.*, a servo-potentiometer, or after conversion into a 3–15 psig air signal it is stored as a pressure in an isolated line.

Our experience with phase sensitive peak pickers is not good; they should be avoided wherever possible. Generally they are difficult to adjust and to keep adjusted satisfactorily.

Diode capacitor systems. In this type of system, the mV output signal from the chromatograph is amplified to give a peak signal of 50 or 100 V maximum value. This is then passed to a diode-capacitor network which allows a capacitor to charge up to the peak value through the diode. The diode back-biases on the tail on the peak, leaving the peak height signal stored on the capacitor. The large signal voltage is necessary to minimize errors due to the nature of a diode's characteristic when only a

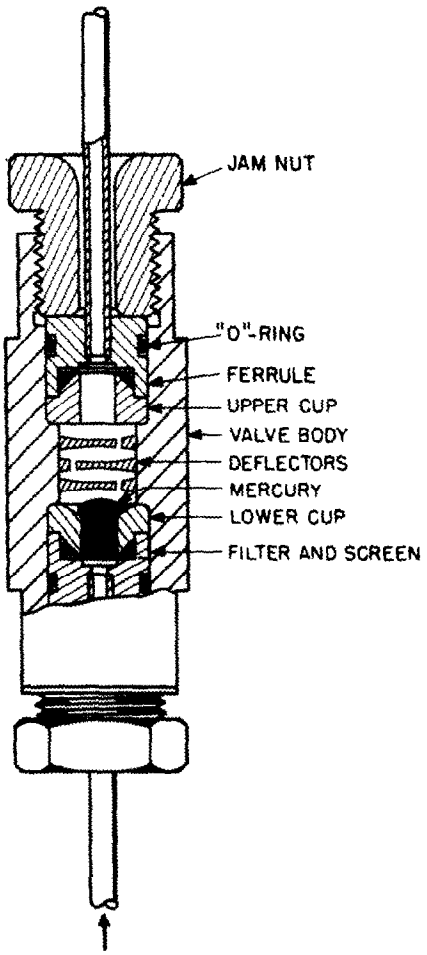

FIG. 18.—Foxboro mercury check valve—construction.

small voltage is applied to it. The peak signal may then be transferred to a second capacitor, leaving the first capacitor ready for the next peak. More sophisticated circuitry based on this principle may be used, usually incorporating integrating amplifier circuits. Generally a diode-capacitor system works very well, and is recommended.

Pneumatic peak picking. A recent development by the Foxboro Company is particularly interesting. Here the electrical signal from the chromatograph is converted into a standard 3–15 psig pneumatic signal by standard process control equipment. The air signal is fed to a novel mercury check-valve consisting of a pool of mercury on a porous metal disc in a cylinder, see Fig. 18. The action is described in Fig. 19. As a peak signal increases from zero the air signal pressure increases from 3 psig. Air bubbles upward through the mercury pool into the chamber above until the pressure has reached that equivalent to the peak maximum. Then the pressure below the pool falls, but, surface tension prevents air from above the mercury pool from seeping back. At this point the peak signal is locked into a pneumatic recorder channel with the aid

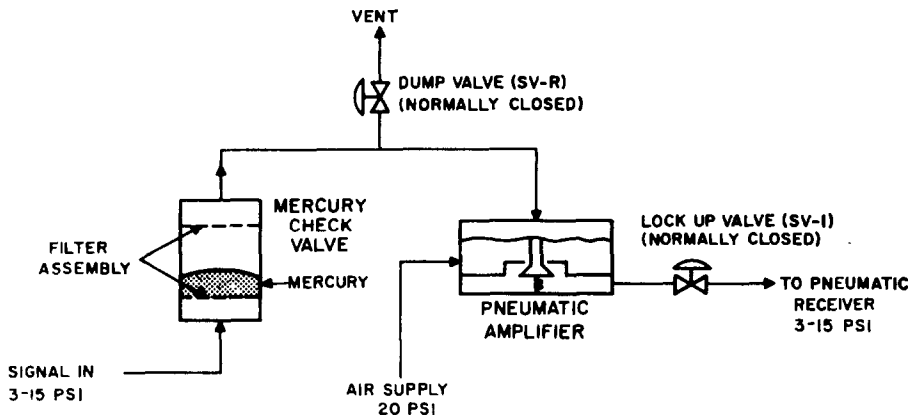

FIG. 19.—Foxboro mercury check valve—operation.

of a leak-free solenoid valve. Owing to the limited air capacity of the system a 1:1 pneumatic amplifier is used as a boost. Another solenoid valve is then used to "dump" the air pressure above the mercury and thus reset the system in time for the next peak. The performance of this system has proved to be very good.

ECONOMICS OF PROCESS ANALYSIS

The intention in installing process analysers (automatic on-line analysers including chromatographs) on running plant, is not necessarily to replace routine shift laboratory analyses and thus economize on personnel, though this may be a bonus. The main reason for installing automatic analysers is that they can do *some* analyses much more economically than shift laboratories can. In many cases it is physically impossible to run and control sections of plant without on-line analysers. This is becoming more so as chemical processes become more and more sophisticated. Furthermore the availability of process analysers makes it possible to design plants more economically, usually by elimination of intermediate storage, and to reduce considerably the periods of production of material that is not of the specified composition or quality.

Process analysers have, of course, to be justified on economic grounds and in these days of sophisticated processes and large scale plant this is easier to do. For instance, chromatographs costing as much as £5,000–6,000 can often be justified.

There are four main reasons for using process analysers in process control.

(*a*) They may be essential for running a plant. In such cases the cost of analysers (several thousands of pounds) is rarely a factor in the decision to build plants (costing several millions).

(*b*) They may be almost essential for running a plant. This situation is best illustrated by a typical example. If the concentration of a key component in a process stream from the bottoms product of a distillation column rises above a critical level it severely upsets subsequent distillation stages in the plant. Such changes in concentration can take place in 20–30 min, making laboratory analysers an ineffective and uneconomic form of control. The quality of the final product can be upset beyond selling specification and the upset in the plant can take at least 24 hr to correct. Thus a day's production is lost, involving loss of profit, and the off-specification product has

to be reprocessed at extra cost. Large-scale plants these days usually produce well over 100 tons of product per day and the value is often in the region of £100 per ton. From this it can be seen that £5,000 for a process analyser is not an excessive price to pay for an instrument. In one recent case it was estimated that a chromatograph costing £4,000 paid for itself in the first weekend it was installed on a plant. This instrument is now regarded as essential.

(*c*) Availability of an on-line analyser may make it possible to design the plant or parts of it more economically. Expensive large storage vessels and tanks may be eliminated and the net capital saving can be large.

(*d*) Improvement in plant running efficiency may be achieved but the case for installing on economic grounds is less easy to prepare. The decision is made only after an exhaustive investigation of the process concerned. The capital cost of the analyser has to be offset by the return based on improved efficiency achieved with the aid of the analyser. A typical situation is the closer control of a distillation column, where economy in operation is achieved by reduced use of steam in the reboiler. The analyser sets the minimum steam flow to achieve the desired composition of the product. This situation arises where conventional control of a column to achieve the desired composition (usually achieved by temperature control) is inadequate.

PROCESS ANALYSERS APPLIED TO AUTOMATIC PROCESS CONTROL

Process analysers are used in automatic control systems for two main reasons. First, they are used if they are essential for controlling stream composition. Secondly, they are used to enable the plant to run at higher efficiency even though they are not required for basic control. Applying process analysers to process control is a highly specialized subject which easily justifies a separate paper. However, a typical situation encountered in practice is illustrated in Fig. 20.

The essential conditions in the bottom part of a distillation column are controlled as shown in Fig. 20(A). Heat in the reboiler is supplied by hot "Thermex"* flowing through it and the flow is controlled by a standard arrangement of a flow-meter, control valve and flow-recorder-controller (FRC). Linked to this is a temperature-recorder-controller (TRC) which monitors temperature several plates up the column. The output of the TRC adjusts the flow setting of the FRC so that a Thermex flow is obtained to give the desired temperature in the column. With the desired column temperature and composition of feed of material to the column, the composition of the bottoms product from the column comes within specified limits. This assumes a number of factors are satisfied, including constant composition of the feed. Unfortunately, if this is not so, merely controlling the column temperature may be inadequate to hold the bottoms product composition to the desired figure. In many cases, however, temperature control is adequate to ensure desired product composition even with feed composition changes.

One example of this type where temperature control is inadequate is now described. It was found that with the situation described above, changes in feed composition, in particular the concentration of one component of a multicomponent mixture, resulted in similar fluctuations in composition of the component in the bottoms product. It

* "Thermex" is an I.C.I. trademark for a high-temperature heat-exchange fluid consisting of a mixture of diphenyl oxide and diphenyl.

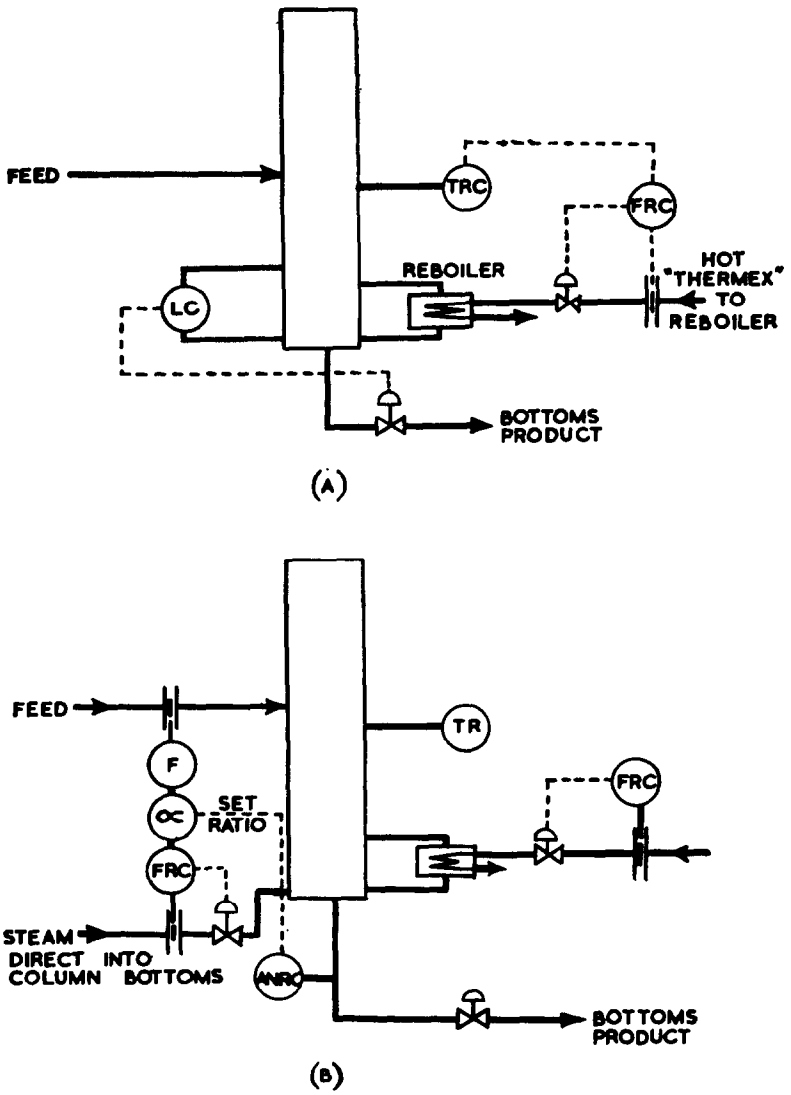

FIG. 20.—Distillation column control.

was very important to hold the level of this component below a certain figure, otherwise severe difficulties were encountered in later stages of the plant. A process chromatograph was installed to monitor the composition of this component on the tray immediately above the bottom of the column. Experiments revealed that the column could be controlled more easily with the system as shown in Fig. 20(B). The flow of Thermex to the reboiler was held constant with the FRC, and the TRC was disconnected from the FRC. Thus the heat flow to the reboiler was held constant. A flow of steam was injected directly into the liquid in the bottom of the column. The effect of this was to lower the boiling point of the liquid and strip off the low boiling unwanted component. The steam flow was controlled with a flow controller FRC and the flow

related directly to the flow of the feed to the column, by a ratio controller (α). Thus if the feed flow rises the steam flow is caused to rise in a pre-set ratio. This system on its own was not adequate to compensate for changes in the composition of the feed, but it was found that if the ratio setting was altered manually in accordance with the observed concentration indicated by the chromatograph, entirely satisfactory control of the composition of the bottoms product could be obtained. The next step was to link the chromatograph output directly into the column control system. This was done by first converting the chromatograph output into the form of a continuous trend signal as described above. The type of signal used was the standard 3–15 psig pneumatic signal used in process control. This was fed to a standard process recorder controller (denoted ANRC) whose output was proportional to the difference between the measured concentration and the desired concentration. This output signal was connected to the ratio controller and used to continuously adjust the ratio between the steam and feed flows. After initial adjustment of the opening conditions and system gain, this system has proved to be entirely satisfactory.

The considerations in applying an analyser in control as in Fig. 20 are principally effectiveness, reliability and operator convenience. The effectiveness of analysers in such situations has been clearly demonstrated. The method of connection is arrived at by thorough system study on the basis of practical results. Reliability is a problem for the instrument engineer and various safety mechanisms are built into equipment to reduce the probability and effects of failure. Operator convenience is achieved mainly by displaying the results in a form compatible with the other process variables he is familar with.

APPLICATION WITH PROCESS DIGITAL COMPUTERS AND DATA LOGGERS

At the same time as process analysers are being used in conjunction with full scale production plants and pilot plants, computers and data loggers are being used to collect data automatically from these analysers. The systems commonly in use at present are illustrated below.

Production Plant → Optimizing computers with conventional automatic control systems
Production Plant → Direct digital control computers

Pilot Plant → On-line data logging equipment → Off-line processing by digital computer

The scope in applying process analysers in automatic control systems is immense. The chromatograph raises special considerations in that the measurement is discrete and made at regular intervals. For control purposes the signal must be as in Fig. 16. The interval between analyses and the delay times in the sampling system must be significantly shorter than the time in which significant changes in the process occur.

If computing or logging equipment is available, the versatility of process analysers can be exploited considerably. The output from analysers can be logged in the "raw" form and printed out in the desired form, *e.g.*, measurements which normally emerge from the analyser expressed as mole% can be printed out as weight %, the computer performing all the calculations. The possibilities are considerable.

The process chromatograph produces its information in a discrete form instead of a

continuous signal. This creates a problem for computing and logging equipment. It is usually tackled in one of the following ways.

Priority interrupt system. As soon as a chromatographic peak emerges the peak value is held by a peak picker (as described earlier). At the same time a separate circuit signals the computer that a peak value is ready to be logged. The computer then stops its previous duty and logs the peak value. The logging operation takes a very short time indeed, usually between 1 and 5 sec. The process is repeated for subsequent peaks. Peaks are identified by the computer either by allocating each peak a separate digital identifying signal which is transmitted from the chromatograph's programmer to the computer, or by letting the computer count up the peaks from the start of the analysis, only a definite known number being selected.

Ordinate sampling. The computer samples the output of the chromatograph detector at regular intervals—say every 1/10 sec. Peak areas and maximum heights are computed by the computer. Start of analysis and peak identification signals are provided separately by the chromatograph programmer. This method is used only where the computer has sufficient spare time.

At present priority interrupt is the most common method. Where trend presentation is available for all peaks of interest, then the priority interrupt method is not required. The peaks can be logged at a time convenient to both the computer and chromatograph.

A recent problem at I.C.I. illustrates the power of a computer. A chromatograph has to analyse 10 similar streams (9 process streams + 1 calibration check stream) in turn and measure 16 components in each stream. The chromatograph measures each component as a mole % concentration. The information required is the amount of each component relative to a key component with the results expressed on a w/w basis. The computer takes all the chromatograph data in, computes the required results, and prints them out as required. At the same time it automatically checks the calibration of the chromatograph by checking its output when analysing a sample of known composition. It corrects the data for calibration errors and checks correct functioning of other parts of the equipment. Additional digital inputs to the computer are provided for this purpose.

INSTALLATION OF A PROCESS CHROMATOGRAPH

The purpose of this section is to emphasize that a process chromatograph is not just an instrument which is placed in a plant area and expected to work, but a complete analytical system. For the system to function correctly it must be correctly designed, installed and maintained. The stages of installation are tabulated below.

(*a*) Initial requirements defined in consultation with the process management.
(*b*) Feasibility of the analyses determined. Information obtained by customer from his own resources and/or the instrument manufacturer. Absolutely all details on process stream(s) composition must be obtained without any omissions of seemingly trivial information.
(*c*) Initial decision to purchase.
(*d*) Specification of analyser, sampling system, services, housing of equipment.
(*e*) Enquiries for the analyser to potential supplier(s) and for the sampling system if to be obtained from the same supplier.
(*f*) Final decision to purchase.

(*g*) Ordering of equipment.
(*h*) Acceptance (after tests and calibration in supplier's factory).
(*i*) Delivery followed by proving trials in laboratory to ensure smooth running of equipment and eliminate unsuspected faults.
(*j*) Installation on site and start-up.
(*k*) Calibration.
(*l*) Maintenance.

Satisfactory results are only obtained if thorough attention is paid to all these stages. The list may seem rather formal and pedantic, but hard-won experience convinces most users of these instruments of the necessity for care at all stages of the installation.

If correct attention is given at the right time a process chromatograph can give excellent results and work reliably. Once the system has reached the maintenance stage the subsequent time and cost required are very low, provided the quality of the maintenance is high.

Typical operating and maintenance costs for a process chromatograph, capital cost £2,500–3,500, (including calibration checking) are estimated as follows.

	£
Personnel costs per analyser per year	150–250
Services and materials (carrier gas, electricity, *etc.*)	100
Total per year	250–350

These costs must be taken only as a typical average. Simple straightforward installations can cost less than the minimum stated. More complex installations can cost considerably more. The user can either employ skilled maintenance personnel—most companies do this—or rely on the manufacturer of the equipment to provide service. At present in the U.K. only one manufacturer provides this service adequately. Perhaps it is significant that this chromatograph manufacturer is the only one who also supplies the full range of conventional process instrumentation.

FUTURE TRENDS IN PROCESS GAS CHROMATOGRAPHY

It appears that gas chromatography is a strongly growing field in the realm of automatic process analysis. It is relevant to consider where changes should take place and what trends are likely.

Reliability

This is the key to acceptance of process chromatographs by plant operating personnel. Regrettably, until recently process chromatographs as received from instrument manufacturers have not been sufficiently reliable. The user has usually been involved in modifications to equipment to make it reliable. Faults have been widespread in type. Typical examples include—unsealed relays whose contacts go open circuit, low quality solenoid valves which overheat and burn out, sample/column switching valves which are prone to sticking owing to use of unsuitable materials.

Fortunately, the reliability of process chromatographs is now recognised by manufacturers as a principal factor in their acceptability to customers.

Speed of analysis

At present, analysis times of 5–15 min are typical and in many cases are adequate. In an increasing number of cases 1–5 min is required where chromatographs are to be connected in automatic control systems. It is envisaged that analysis times of 1–2 min will be regarded as necessary in 5–10 years' time.

Present day instruments are just about adequate for analysers taking 1–5 minutes, but only just so for the shorter times. The limitations of current equipment lie principally in the following parts of the equipment.

Columns. The time factor here is principally determined by the complexity of the sample and by the column size. In the past, columns were generously large and often still are. Smaller-bore packed columns (1/16 in. bore or less) are now becoming more common and are beginning to supersede 1/8 in. bore or larger columns typically used for slower analyses. The disadvantage of using smaller-bore columns is the need to use smaller samples. Where thermal conductivity detectors are used these have to have low internal volume and fast response. Capillary columns have proved disappointing so far owing to their short life. For the immediate future an intermediate between the capillary column and the packed column appears to be the solution for high speed analysis.

Sample and column switching valves. At present the sample and column switching valves have to perform about 50,000 operations per year when performing an analysis every 10 min. The valves described earlier in the paper can achieve this task without failure. Some of these valves do not last much longer than a year, however, without needing overhaul.

For higher speeds of analysis (*e.g.*, one a minute) a valve will have to have a minimum of life of 500,000 operations. This kind of life can be achieved, but careful design is required.

The diaphragm type of valve, if properly assembled, is capable of giving the required life. So is the linear sliding plate type of valve, provided the grade of the Fluon plastic insert material is correctly chosen and considerable attention is paid to the surface finish of the working parts.

In our experience the filled type of PTFE plastics are unsuitable for use as inserts in linear slide valves unless the filler material is graphite. There is a tendency for the filler material to be desorbed from the insert and deposited on the metal faces of the valves, gradually building up and eventually causing valve seizure. In some cases the sample has attacked the filler material and leakage has resulted. Generally speaking pure PTFE polymer is preferred as the insert material. The surface finish must be excellent. A criticism of liquid sampling valves with PTFE inserts is that they give poor reproducibility owing to distortion of the plastic under pressure. This is overcome by using a metal insert sandwiched between metal plates coated with a PTFE layer.

Pneumatic actuation of valves, as used at present, should be adequate even with the higher speeds of operation envisaged in the near future.

Programming and data handling. For higher speeds of analysis coupled with high reliability, it will be necessary to eliminate many electromechanical components from the present equipment. The new equipment will make use extensively of electronic digital techniques in switching and timing of events in the analysis. Signal handling

will have to be all-electronic with the elimination wherever possible of slow servo-balancing potentiometric recorders. Pneumatic peak picking will be too slow, although for control purposes where a pneumatic signal is required for a control valve, the electrical signal will be transduced locally near the valve. Trend presentation of the data will be essential and where process computers are used the chromatograph programming will be performed by the computer.

Temperature programming

This technique is used in the laboratory to advantage in speeding up and improving analyses. It is not used in process chromatography except in rare cases and even then as a last resort. The main problems which arise are "ghosting" and baseline correction as well as the problem of the reliability of the programming device. Ghosting is the appearance of spurious peaks owing to the desorption of stationary phase from the column, caused by repeated cycles of temperature increase and decrease. Baseline drifts are troublesome as most detectors, when connected to columns, are sensitive to temperature and flow changes. Compensation is difficult to achieve satisfactorily.

It is our opinion that the use of temperature programming techniques in process chromatography will not be widespread owing to the above-mentioned difficulties. If it is necessary to analyse samples having a wide boiling range it is probably better to use two chromatographs, one for the "light ends", the other for the "heavy ends." It appears that carrier gas flow programming may prove to be more suitable with process chromatographs.

Detectors

As stated earlier, the detectors used most frequently at present are the thermal conductivity and hydrogen flame-ionization detectors. These are likely to continue as the most widely used detectors. However, there is a tendency towards the use and development of detectors which are highly specific towards certain substances. For instance, the phosphorus pentoxide electrolytic hygrometer cell[7] is used for determination of water in process streams. Other detectors include the piezoelectric quartz detector[8] which is coated so that it can respond to selected materials. Ionization detectors of various types may also be developed to give selective responses.

Zusammenfassung—Die Geschichte der Prozeß-Gaschromatographie wird kurz beschrieben. Dann werden die wesentlichen Bestandteile von Systemen zur Prozeß-Gaschromatographie erläutert. Die Wirtschaftlichkeit von Prozeß-Analysengeräten wird mit der von Laboratoriumsgeräten verglichen, und die Anwendung von Prozeß-Analysengeräten bei automatischen Regelgeräten, Rechenanlager zur Verfahrenskontrolle, Datenspeichern oder im chemischen Betrieb wird diskutiert. Die Arbeit schließt mit einer Erörterung wahrscheinlicher Zukunftsentwicklungen auf diesem Gebiet.

Résumé—L'historie de la chromatographie en phase vapeur industrielle est brièvement décrite, et suivie par une description des détails essentiels des systèmes de chromatographes en phase vapeur industriels. On met en opposition les économies des analyseurs industriels et des instruments de laboratoire, et l'on discute de l'application des analyseurs industriels aux systèmes de contrôle automatique, aux calculateurs de contrôles industriels et aux enregistreurs numériques ou aux installations chimiques. Le mémoire conclut par une discussion sur les tendances futures vraisemblables dans ce domaine.

PRECIPITATION OF NICKEL SALICYLALDOXIMATE FROM HOMOGENEOUS SOLUTION

B. S. KRISHNA RAO and O. E. HILEMAN, JR.
Department of Chemistry, McMaster University, Hamilton, Ontario, Canada

(*Received* 27 *June* 1966. *Accepted* 19 *August* 1966)

Summary—The reaction between hydroxylamine and salicylaldehyde in the presence of nickel ions has been made the basis of the precipitation of nickel salicylaldoximate from homogeneous solution. Conditions for quantitative precipitation of nickel when present alone or with such metal ions as Fe^{3+}, Cr^{3+}, Al^{3+}, Zn^{2+}, Mn^{2+} and Cd^{2+} are described. The recommended procedure is shown to be useful in the analysis of a steel sample.

THE advantages of precipitation from homogeneous solution (PFHS) over the conventional precipitation techniques have been recognized and demonstrated with great success in recent years. Methods have been suggested for the preparation, *in situ*, of such reagents as dimethylglyoxime,[1] 8-hydroxyquinoline,[2] cupferron,[3] 8-hydroxyquinaldine,[4] and others,[5] thus modifying the well-established gravimetric procedures for the analysis of several metals. The compact crystalline precipitates formed by PFHS are generally purer and easier to handle analytically.

Salicylaldoxime was first reported by Ephraim[6] as a reagent for the detection and determination of copper and nickel. Since then the use of this reagent has been extended to the detection or determination of iron, zinc, bismuth, copper, cadmium, and lead.[7,8] However, only copper has received much attention, and procedures have been worked out for its determination either by direct weighing of the copper salicylaldoximate[9] or by extraction of the chelate into n-amyl acetate and measurement of the absorbance of the solution.[10] An indirect method, reported by Flagg and Furmann,[8] is based on the decomposition of the chelate by excess of iron(III) in hydrochloric acid and titration of the resultant iron(II). Only one study on the determination of nickel with salicylaldoxime has been reported.[9] Vogel[11] has suggested that a few metals such as silver, lead and mercury do not interfere in the determination of nickel, but that there is marked interference by iron, cobalt and copper.

Pietrzak and Gordon[12] have shown that copper salicylaldoximate can be precipitated from homogeneous solution, and that the chelate thus obtained is easy to filter off. Surprisingly, however, the determination of copper by this method was found to be less satisfactory than the conventional procedure.

The present study was undertaken to examine the precipitation of nickel salicylaldoximate by PFHS and to use the procedure for the determination of nickel in a steel sample.

EXPERIMENTAL

Reagents

Metal ion solutions. Solutions of appropriate amounts of metal salts were made in distilled water, filtered and diluted. The nickel solution was standardized by precipitation of nickel dimethylglyoximate by the procedure of Salesin and Gordon.[1]

Salicylaldehdye. About 4·0 g of the reagent were stirred into 1 l. of distilled water. Complete dissolution was ensured by stirring for about 6 hr. The solution was stable for at least 48 hr.

All other chemicals were reagent grade. The pH measurements were made with a Radiometer pH meter, and a filtered ammonia solution (1 + 2) was used for pH adjustments.

Procedure

Place an aliquot of solution, containing 2–75 mg of nickel, in a 400-ml beaker, add ammonium chloride (1–2 g) and an 8-fold excess of a hydroxylamine hydrochloride solution. Adjust the pH to 5·9–6·8 with the ammonia solution. Add a few ml of the salicylaldehyde solution and wait until a turbidity appears. Then add enough salicylaldehyde solution to make the total aldehyde concentration 3–15 times the stoichiometric requirement. Let the solution stand for about 4 hr at room temperature and then filter, using a medium porosity sintered glass crucible, wash the precipitate with distilled water and dry it at 105–110° to constant weight.

Separation of nickel from other metals

The sequence of addition of the reagents is the same as that given above except that tartaric acid (2·0 g) must be added before the pH is adjusted. The amounts of hydroxylamine and salicylaldehyde have to be increased proportionately, taking into account the consumption of the reagent by the cations of metals such as zinc, cadmium, manganese, vanadium, chromium and iron, which form soluble complexes with it. However, in the presence of large amounts of iron (~100 mg), the procedure must be further modified: the reaction time should be at least 14–16 hr; the amount of salicylaldehyde must be in 20- to 25-fold excess of the theoretical amount and can be added all at once; about 3 g of tartaric acid should be added; the hydroxylamine hydrochloride must be in 200-fold excess of the stoichiometric requirement.

Analysis of filtrates for nickel

A few representative filtrates were taken and evaporated almost to dryness. The organic content of the residue was destroyed by repeated addition of nitric acid and evaporation to dryness. The residue was then dissolved in distilled water and the nickel content was determined colorimetrically.[18] In all cases the amount of nickel was found to be $<0{\cdot}04$ mg.

RESULTS

The results obtained by use of these procedures are shown in Figs. 1 and 2, and Tables I–IV. For comparison, a few determinations were carried out by Riley's

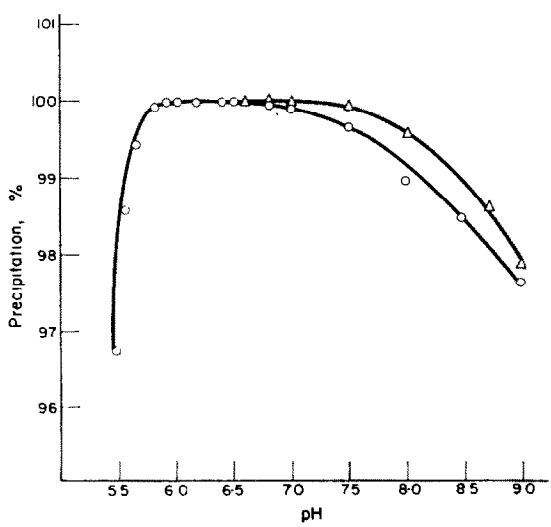

FIG. 1.—Effect of pH on precipitation of nickel salicylaldoximate.

† Conventional procedure, time of standing, 16 hr.

method.[9] He suggested that an excess of reagent should be added and the solution stirred to coagulate the precipitate. In the present work a two-fold excess of the reagent was added to the metal solution at pH 6·0–6·5. The solution was stirred and then allowed to stand for 3 hr before filtration. The results are presented in Table I.

The behaviour of iron in this system deserves special mention. Citric acid, EDTA and tartaric acid were tried as masking reagents. Tartaric acid was found to be suitable, but citric acid and EDTA prevented the precipitation of nickel salicylaldoximate. However, with the procedure outlined above, the amounts of tartaric acid and hydroxylamine hydrochloride must be kept within certain limits to give quantitative precipitation of nickel. Amounts of tartaric acid below a minimum value gave positive errors and impure precipitates. Large amounts of tartaric acid gave pure precipitates but low recoveries of nickel. Large excesses of hydroxylamine hydrochloride were required for quantitative recovery. Some of the results of these experiments are collected in Table III.

Analysis of a steel sample for nickel

About 1·0 g of the steel (NBS No. 121b) was dissolved in the usual way and diluted to 500·0 ml. Aliquots (25 or 50 ml) were transferred into 400-ml beakers. Tartaric acid (3·0–3·5 g), hydroxylamine hydrochloride (2·5 or 5·0 g, according to the aliquot) and ammonium chloride (2·0 g) were added to each and the pH was adjusted (6·0–6·5) with dilute ammonia solution. Enough aqueous solution of salicylaldehyde to give a 20- to 25-fold excess was then added. The mixture was set aside for 14–16 hr before filtration. Some results obtained by this procedure are shown in Table IV.

DISCUSSION

This study has shown the expected superiority in the quality of the precipitates obtained by the PFHS method and has established a set of experimental conditions under which the recovery of nickel is quantitative. The procedure suggested, however, failed to achieve a successful separation of nickel from copper. (Copper salicylaldoximate is known to be precipitated in varying amounts from solutions over a wide range of pH.) Cobalt also seriously interferes, but this was not investigated in detail. The precipitation of zinc and cadmium was found to begin at pH 6·5. When nickel was precipitated at pH 6·0–6·3 there was no co-precipitation of these elements. In the presence of tartaric acid zinc did not co-precipitate even at pH 7·0. Hence the use of tartaric acid was recommended. However, when cadmium was present, tartaric acid could not be used because the cadmium tartrate complex is sparingly soluble.

In the procedure of Salesin and Gordon for the determination of nickel, the generating reaction was found to be extremely slow (24 hr standing time required) in the presence of iron. In the present case it was found that large excesses of iron and tartaric acid also retarded the precipitation of nickel. However, it was shown that a proper combination of the amounts of tartaric acid and hydroxylamine hydrochloride did produce a successful separation of nickel from large amounts of iron, within a reasonable reaction time.

Acknowledgement—The authors acknowledge the partial assistance of the National Research Council of Canada in supporting this investigation.

Zusammenfassung—Die Reaktion zwischen Hydroxylamin und Salicylaldehyd in Gegenwart von Nickelionen wurde zur Fällung von Nickelsalicylaldoximat aus homogener Lösung verwendet. Die Arbeitsbedingungen zur quantitativen Fällung von Nickel allein oder neben Metallionen wie Fe^{3+}, Cu^{2+}, Al^{3+}, Zn^{2+}, Mn^{2+} und Cd^{2+} werden beschrieben. Die empfohlene Vorschrift erweist sich bei der Analyse einer Stahlprobe als nützlich.

Résumé—La réaction entre l'hydroxylamine et el salicylaldéhyde en présence d'ions nickel a été prise comme base pour la précipitation du salicylaldoximate de nickel à partir d'une solution homogène. On décrit les conditions de précipitation quantitative du nickel seul ou en présence d'ions tels que Fe^{3+}, Cr^{3+}, Al^{3+}, Zn^{2+}, Mn^{2+} et Cd^{2+}. On montre que la technique recommandée est utile pour l'analyse d'un échantillon d'acier.

L'APPLICATION DES RADIOISOTOPES A LA CHROMATOGRAPHIE SUR COLONNES DE CELLULOSES SUBSTITUEES—IV*

L'ANALYSE DU MERCURE ET DU ZINC DANS LE BISMUTH

R. A. A. MUZZARELLI et G. MARCOTRIGIANO†
Département de chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, P.Q., Canada

(*Reçu le* 21 *Octobre* 1966. *Accepté le* 17 *Novembre* 1966)

Résumé—Les radioisotopes ont été appliqués à l'étude du comportement chromatographique de quelques nanogrammes de bismuth sur cellobiose, cellulose et sept celluloses substituées. Toutes les celluloses en éther éthylique adsorbent le bismuth pourvu qu'il soit sous forme de nitrate et qu'un excess d'acide nitrique ne soit pas présent. Le bismuth a été élué à l'aide de thiocyanate en méthanol–éther, ou d'acide chlorhydrique en méthanol, suivant la force de rétention montrée par les différents groupes fonctionnels de la cellulose. Une méthode simple de séparation du mercure d'avec le bismuth en différents rapports est presentée.

CETTE étude a été conduite pour définir le comportement chromatographique du bismuth sur colonnes de celluloses substituées. Les seules indications au sujet de l'adsorption du bismuth sur celluloses sont contenues dans une monographie qui traite la purification de l'uranium d'avec de nombreux métaux parmi lesquels le bismuth qui serait retenu sur cellulose naturelle en éther-acide nitrique.[1]

Comme le comportement de l'arsenic et de l'antimoine a déjà été étudié dans les mêmes conditions,[2,3] les données concernant le bismuth s'ajouteraient à celles disponibles et fourniraient des indications intéressantes sur les possibilités de séparation de l'arsenic et de l'antimoine d'avec le bismuth.

L'étude du bismuth dans les conditions choisies pour l'étude du mercure et du zinc[4] devrait permettre de sélectionner les celluloses qui retiennent particulièrement bien le bismuth, et d'établir les conditions expérimentales favorables à la séparation d'avec le mercure et le zinc.

La détermination du mercure dans le bismuth à haute pureté a été l'objet d'une publication récente[5] qui a été suivie d'une publication sur la détermination du zinc dans le bismuth.[6] La méthode présentée était basée sur plusieurs opérations, parmi lesquelles la distillation finale du mercure et la formation d'un amalgame sur une feuille d'argent. Puisque la méthode radiochimique demandait soit l'introduction d'une quantité de mercure ou de zinc comme entraîneurs, soit l'analyse par spectrométrie gamma, les auteurs cités se sont vus obligés à irradier l'échantillon de bismuth avant même de commencer les manipulations chimiques. Aucune indication n'a été donnée sur la radioactivité de l'échantillon de bismuth après plusieurs jours d'irradiation, mais il faut penser que, comme le ^{209}Bi a une section efficace de 0·015

* Part III—*Talanta*, 1967, **14**, 85.

† Adresse permanente: Istituto di Chimica Generale e Inorganica, Università di Modena, Modena, Italie.

barns pour les neutrons du spectre du réacteur,[7] une certaine quantité de bismuth ait subi les réactions suivantes:

$$^{209}\text{Bi (n, } \gamma) \, ^{210}\text{Bi} \xrightarrow[5 \text{ jours}]{\beta^-}$$

$$^{209}\text{Bi (n, } \gamma) \, ^{210}\text{Bi isomère} \xrightarrow[\sim 10^6 \text{ ans}]{\alpha}$$

On doit par conséquent admettre que l'irradiation préalable de l'échantillon à analyser, oblige à manipuler un échantillon radioactif, et que la méthode présente des aspects désavantageux, tels que perte de temps pour laisser décroître une partie de l'activité, télémanipulation, déchets radioactifs.

Au contraire, une méthode basée sur l'activation neutronique des traces de mercure ou de zinc déjà séparées d'avec la matrice de bismuth est plus simple, ne demande pas les précautions demandées par un échantillon radioactif, et évite les interférences qui pourraient provenir de l'activation d'autres impuretés éventuellement présentes dans le bismuth. En d'autres mots, l'activation neutronique doit être la dernière opération à exécuter.

Deux nouvelles celluloses substituées, précisément la sulfoéthyle et la para-aminobenzyle, sont devenues disponibles et ont été prises en considération avec le cellobiose. Ce dernier étant le dimère du glucose, il est intéressant de le comparer avec la cellulose naturelle, car les différences de capacité d'adsorption seraient imputables au fait que le cellobiose est une molécule de petites dimensions, tandis que la cellulose est une macromolécule.

PARTIE EXPERIMENTALE

Solutions

Les produits chimiques et les solvants étaient de degré analytique et ils ont été utilisés sans traitement ultérieur. Les solutions utilisées sont les suivantes.

(*a*) Ether éthylique anhydre.
(*b*) Acide nitrique 90% (2 ml) dissous en éther éthylique (98 ml).
(*c*) Thiocyanate d'ammonium (40 mg) dissous en méthanol (20 ml) plus éther éthylique (80 ml).
(*d*) Thiocyanate d'ammonium (5 g) dissous en méthanol (20 ml) plus éther éthylique (80 ml).
Acide chlorhydrique 0,5, 1,5 et 5*M* dans le méthanol.

Celluloses

Cellulose Whatman CF 11, en poudre, non substituée.
Cellulose Whatman DE 11, en poudre, diéthylaminoéthyle.
Cellulose Whatman AE 11, en poudre, aminoéthyle.
Cellulose Whatman P 11, en poudre, phosphate.
Cellulose Whatman CM 11, en poudre, carboxyméthyle.
Cellulose Whatman ET 11, en poudre, epichlorohydrine triéthanolamine—Ecteola.
Cellobiose Sigma CB, en poudre, (glucose-β-glucoside).
Cellulose Bio-Rad SE, sulfoéthyle.
Cellulose Bio-Rad PAB, en poudre, *p*-aminobenzyle.

Radioisotopes

Le bismuth-207 a été fourni par Science and Engineering Corp, Pittsburgh, Pa, U.S.A. et ses caractéristiques étaient les suivantes: radioactivité 29,0 μC/ml; activité spécifique: carrier-free; pureté radiochimique > 99%. Une fraction de 250 μl de cette solution a été diluée en 10 ml d'acide nitrique 90%. Une fraction de 50 μl de cette dernière solution a été prélevée pour chaque expérience. Les autres radioisotopes correspondaient à ceux qui ont été utilisés dans les autres Parties de cette étude.[2-4]

Mesures de radioactivité

Les fractions d'élution ainsi que les celluloses ont été recueillies en bouteilles de plastique de capacité et dimensions uniformes. Leur radioactivité a été mesurée à l'aide d'un spectromètre gamma à 128 canaux ND-110, couplé électroniquement à un cristal de NaI(Tl), et comparée à un étalon. La dispersion moyenne des résultats des déterminations quantitatives était de 8%.

Préparation des colonnes de celluloses

Les colonnes et le mode opératoire étaient les mêmes que décrits dans la Partie précédente.[4] Les dimensions des colonnes de cellulose étaient 15 cm × 1 cm, et le temps pour compléter deux chromatographies était une heure.

Préparation des solutions à haute concentration de bismuth et de mercure

Du trichlorure anhydre de bismuth a été dissous, et l'hydroxyde a été précipité, filtré et séché. L'hydroxyde de bismuth (0·21 g) a été dissous dans 250 μl de la solution de ^{207}Bi en l'acide nitrique 90%; 100 μl de la solution résultante ont été prélevés pour chaque expérience. La quantité d'hydroxyde de bismuth a été calculée de façon à neutraliser presque tout l'acide nitrique, et à en laisser l'excès nécessaire pour tenir le bismuth en solution dans l'éther. Ces solutions ont été préparées au moment de l'utilisation.

La solution de mercure a été préparée en dissolvant 5 g de chlorure mercurique dans 100 ml d'éther éthylique.

DISCUSSION DES RESULTATS

Les courbes d'élution représentées en Figs. 1, 2, 8, 9 montrent que les celluloses où le bismuth est quantitativement retenu sont la cellulose naturelle CF, la diéthylaminoéthyle DE, la sulfoéthyle SE et la *p*-aminobenzyle PAB, quand la colonne de cellulose est préparée dans l'éther éthylique. Le cellobiose retient aussi quantitativement le bismuth (Fig. 7).

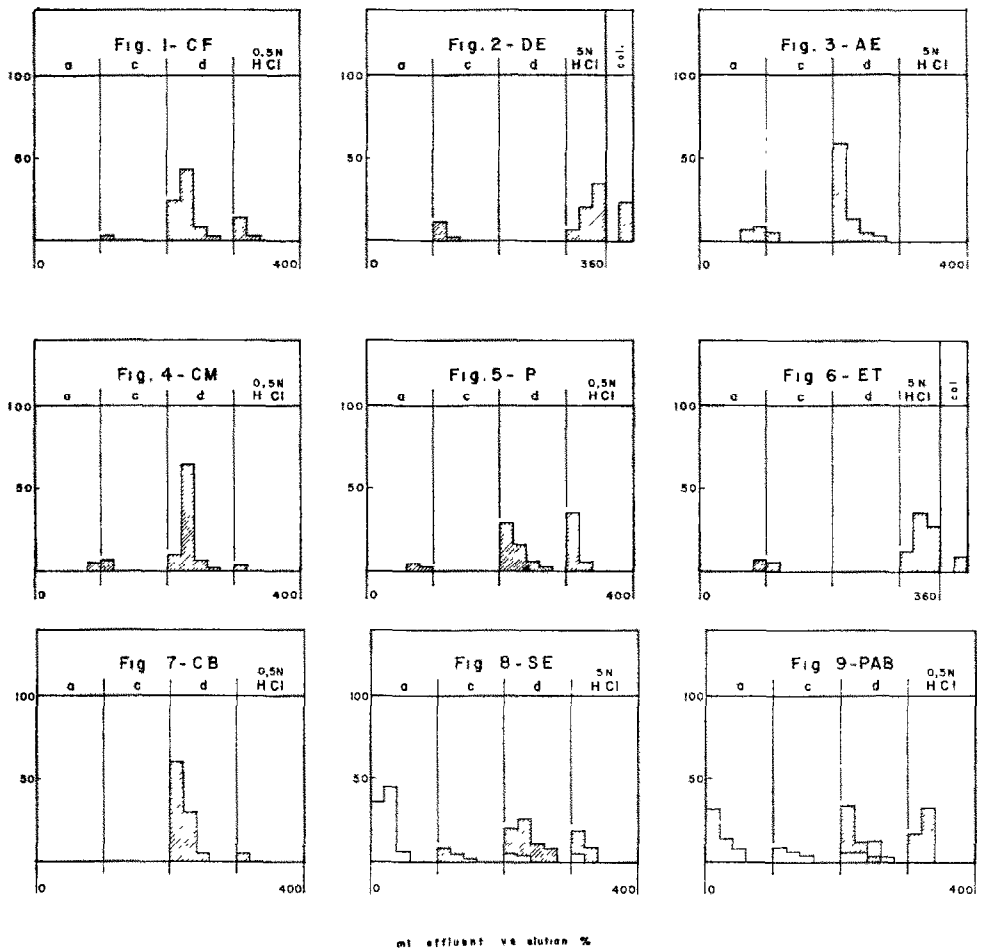
Les autres celluloses AE, CM, P, ET (Figs. 3, 4, 5, 6) laissent passer seulement une petite quantité de bismuth pendant le lavage avec l'éther éthylique, tandis que la quantité la plus importante est fortement adsorbée et peut être éluée avec la solution concentrée (*d*) de thiocyanate ou celle de l'acide chlorhydrique dans le méthanol, sauf pour la cellulose Ecteola ET sur laquelle reste le 10% du bismuth.

La cellulose Ecteola ainsi que la diéthylaminoéthyle adsorbent particulièrement bien le bismuth à tel point que l'acide chlorhydrique 5*M* n'a pas la capacité d'éluer le bismuth quantitativement. Les autres celluloses aminées, au contraire, retiennent le bismuth moins fortement, comme on peut le remarquer à la Fig. 3 pour l'aminoéthyle à partir de laquelle le bismuth est élué avec la solution de thiocyanate (*d*), et à la Fig. 9 pour la *p*-aminobenzyle où l'élution quantitative demande de l'acide chlorhydrique 0,5*M*, c'est-à-dire à concentration nettement inférieure à celle demandée pour l'élution partielle qu'on peut obtenir sur ET et DE.

On a observé que quand l'acide nitrique était neutralisé par l'hydroxyde de bismuth, c'est-à-dire quand on utilisait la solution à grande concentration de bismuth décrite plus haut, la présence du bismuth n'était plus détectée dans les fractions d'éther de lavage (*a*) et de solution (*c*) d'élution provenant des colonnes AE, CM, P et ET. Seulement la solution concentrée de thiocyanate (*d*) et encore mieux l'acide chlorhydrique 0,5*M* pouvaient réaliser l'élution du bismuth.

Sur la base de ces résultats, on a constaté que le bismuth se sépare d'avec le mercure sur toutes les six premières celluloses, à condition de prendre un minimum d'acide nitrique quand on utilise les celluloses AE, CM, P et ET.

Ces résultats ont été étendus à la séparation d'une quantité macroscopique de

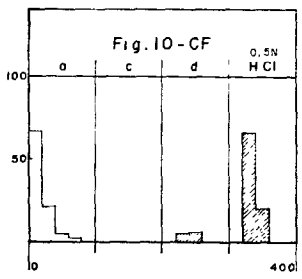


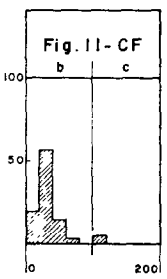
FIGS. 1–9.—Le comportement chromatographique des traces de bismuth sur celluloses et cellobiose.

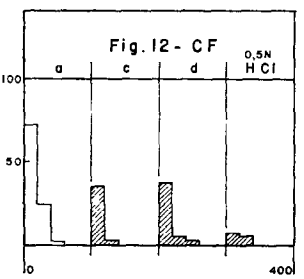
(Solution de bismuth en acide nitrique dilué en éther) Les Figs. 8 et 9 présentent aussi le comportement des traces de mercure.

bismuth d'avec des traces de mercure. Du ^{203}Hg a été additionné à la solution à haute concentration de bismuth, et la chromatographie de cette solution a été réalisée comme décrit. La séparation très nette des traces de mercure d'avec le bismuth est représentée en Fig. 10 pour la cellulose naturelle; la même Figure montre aussi comment l'adsorption du bismuth change quand l'acide nitrique est presque neutralisé (comparez Figs. 1 et 10).

La raison pour laquelle un petit pourcentage de bismuth était élué en avance par rapport à la plus grande partie de bismuth, quand l'acide nitrique n'était pas neutralisé, a été étudiée. On a remarqué que le nitrate de bismuth est très soluble dans l'acide nitrique et on a alors supposé que le responsable de l'absence d'adsorption d'une partie de bismuth était l'acide nitrique introduit dans l'éther au moment de la préparation de la solution de ^{207}Bi. Pour confirmer cette hypothèse, des colonnes de







ml effluent vs elution %

FIGS. 10.—La séparation de quelques nanogrammes de mercure d'avec 84 mg d'hydroxyde de bismuth, sur colonne de cellulose naturelle en éther éthylique.

FIG. 11.—Le comportement chromatographique de 10 mg de trichlorure de bismuth anhydre sur colonne de cellulose naturelle en éther-acide nitrique 2% [solution (*b*)].

FIG. 12.—La séparation de quelques nanogrammes de bismuth d'avec 1 g de chlorure mercurique en 20 ml d'éther éthylique, sur colonne de cellulose naturelle.

cellulose naturelle ont été préparées dans un mélange ether–acide nitrique 2% et le lavage a été effectué avec la même solution (*b*): on a constaté que le bismuth n'était plus retenu sur cellulose CF. La même chose se vérifiait quand on soumettait à la chromatographie une solution de trichlorure de bismuth dans l'éther pur: ce composé est en effet très soluble dans l'éther (Fig. 11). Il en résultait donc que la grande solubilité du nitrate de bismuth dans l'acide nitrique et du chlorure dans l'éther jouaient un rôle extrêmement important dans le phénomène d'adsorption et que les élutions pouvaient être corrigées en calculant la quantité limite d'acide nitrique dans l'éther, et en évitant le chlorure, comme on a fait.

La méthode de chromatographie sur colonnes de cellulose qui a été développée pour la purification du bismuth, se prête aussi à la purification du mercure d'avec traces de bismuth: par example 20 ml d'éther contenant un gramme de chlorure mercurique et 10 μl de solution de ^{203}Hg avec 50 μl de solution de ^{207}Bi ont été soumis à la chromatographie sur une colonne de cellulose naturelle dans l'éther et le bismuth a été séparé quantitativement d'avec le mercure. Les courbes d'élution de la Fig. 12 montrent qu'il convient d'effectuer le lavage du mercure avec 100 ml d'éther éthylique pur, et ensuite l'élution des traces de bismuth avec environ 50 ml d'acide chlorhydrique 0,5*M* dans le méthanol. Ce résultat s'ajoute à ceux qui sont déjà publiés sur la purification du mercure d'avec de nombreuses impuretés par la même méthode. La superposition de la Fig. 10 de cet article et de la Fig. 1 de la deuxième Partie de cette étude[4] permet de constater que le bismuth peut être purifié des traces de mercure et de zinc au moyen d'une seule opération, et que les trois métaux peuvent être élués sélectivement.

CONCLUSION

La conclusion immédiate de cette étude est que le bismuth et le mercure en tous les rapports de quantité peuvent être séparés réciproquement par chromatographie sur celluloses CF, DE, AE, CM, P et ET.

Si on est intéressé à la détermination des traces de mercure et de zinc dans le

bismuth, au niveau du ppm, la méthode présentée permet de recueillir les traces de mercure en solution dans l'éther: cette solution se prête bien à tous les traitements analytiques ultérieurs. La solution peut aussi être rapidement concentrée sans réchauffement et, après les traitements opportuns, être soumise à l'irradiation neutronique, pour une détermination quantitative du mercure par spectrométrie gamma. Les avantages sont la rapidité, la simplicité, les réactifs très courants et la manipulation de substances non irradiées pendant tout le cours de la séparation. Pour la détermination de traces de mercure dans le bismuth au niveau du ppb* une plus longue colonne pourrait être utilisée.

La solution qui sert à éluer le zinc peut être aussi concentrée et soumise à irradiation neutronique: elle contient en effet seulement du thiocyanate d'ammonium qui ne donne par d'interférences par activation neutronique.

Si par contre, on est intéressé à la détermination de traces de bismuth dans le mercure au niveau du ppb,* la méthode demeure valide et aussi simple que décrite. Il convient de faire le lavage du mercure avec de l'éther éthylique pur, et réaliser par la suite l'élution du bismuth avec de l'acide chlorhydrique 0,5*M* en méthanol.

Pour ce qui concerne les applications analytiques et technologiques la méthode peut être donc comparée bien favorablement avec celles qui sont disponibles.[5,6]

Le comportement des traces de bismuth en chromatographie sur celluloses dans les conditions préfixées est aussi intéressant pour plusieurs autres points de vue.

(a) Le comportement du bismuth est différent de ceux de l'arsenic et de l'antimoine et il n'y a pas d'évolution progressive avec le nombre atomique; le bismuth peut être séparé facilement d'avec l'antimoine par chromatographie sur celluloses.[3]

(b) La solubilité de certains sels se confirme être un facteur important en chromatographie sur celluloses.

(c) La purification de l'uranium d'avec des traces de bismuth sur cellulose naturelle devra se faire en conditions contrôlées, spécialement en ce qui concerne la concentration d'acide nitrique dans l'éther. Une fois que le comportement de l'uranium sur celluloses substituées sera connu, il sera éventuellement possible de réaliser la purification de l'uranium d'avec le bismuth sur l'une ou l'autre des celluloses substituées.

(d) Les celluloses aminées adsorbent le bismuth fortement et dans l'ordre suivant: DE, ET, PAB, AE. Il est intéressant de noter aussi qu'un pourcentage significatif du mercure est adsorbé sur PAB, et SE. (Figs. 8 et 9).

Chaque cellulose substituée présente une différente capacité pour la retention du bismuth, qui dépend évidemment du groupe fonctionnel. Le cellobiose donne des courbes d'élution qui ne différent pas d'une façon significative de celles de la cellulose naturelle.

Summary—The chromatographic behaviour of nanogram amounts of bismuth has been studied by radioisotope techniques on cellobiose, cellulose and seven substituted celluloses. All celluloses in ethyl ether adsorb bismuth, provided that it is as nitrate, and that excess of nitric acid is avoided. Bismuth can be eluted with thiocyanate in ether–methanol or with hydrochloric acid in methanol, depending on the retention strength of the various functional groups of celluloses. A very simple method of separation of bismuth from mercury over a wide range of concentration is presented.

* b = 10^9

Zusammenfassung—Das chromatographische Verhalten von Nanogrammengen Wismut wurde mit einer Radioisotopentechnik an Cellobiose, Cellulose und sieben substituierten Cellulosen studiert. Alle Cellulosen adsorbieren in Äthyläther als Nitrat vorliegendes Wismut, wenn ein Überschuß an Salpetersäure vermieden wird. Wismut kann mit Rhodanid in Äther-Methanol oder mit Salzsäure in Methanol eluiert werden, was vom Retentionsvermögen der verschiedenen funktionellen Gruppen abhängt. Eine sehr einfache Methode wird gezeigt, Wismut von Quecksilber in einem weiten Bereich von Konzentrationsverhältnissen zu trennen.

DETERMINATION OF THORIUM, SCANDIUM AND SOME LANTHANIDES IN THE PRESENCE OF EACH OTHER

RUDOLF PŘIBIL and JAN HORÁČEK
Laboratory for Analytical Chemistry, J. Heyrovský Polarographic Institute, ČSAV, Prague I, Jilská 16, Czechoslovakia

(*Received* 24 *May* 1966. *Accepted* 7 *September* 1966)

Summary—A new method is described for the determination of thorium, scandium, and the sum of light lanthanides, in the presence of each other. The method is based on the titration of thorium plus scandium with DCTA (1,2-diaminocyclohexanetetra-acetic acid) at pH 2·5–3·5, with Xylenol Orange as indicator. After addition of TTHA (triethylenetetraminehexa-acetic acid) the thorium-DCTA complex is converted into the thorium-TTHA complex according to the equation Th-DCTA + TTHA = TH-TTHA + DCTA. Simultaneously, free lanthanum, cerium, praseodymium and neodymium react with TTHA. The excess of TTHA and the liberated DCTA are then determined by titrations with zinc and with lanthanum solutions according to the equations DCTA + TTHA + 3Zn = Zn-DCTA + Zn_2-TTHA and DCTA + TTHA + 2La = La-DCTA + La-TTHA. From the results, the amounts of thorium and scandium, and the sum of the lanthanide concentrations, can easily be calculated. Further possibilities, *e.g.*, determination of heavier lanthanides, are briefly discussed.

IN a previous paper[1] we have described consecutive titrations of thorium and lanthanum with diethylenetriaminepenta-acetic acid (DTPA) or triethylenetetraminehexa-acetic acid (TTHA). Both methods are based on the titration of thorium at pH 2·5–3·0 and of lanthanum at pH 5·0–5·5, Xylenol Orange being used as indicator. It has been claimed that such consecutive titrations cannot be performed with EDTA or 1,2-diamino-cyclohexanetetra-acetic acid (DCTA) because the thorium complexes react with the indicator above pH 4. The method with DTPA has been utilized by Gupta and Powell[2] for the determination of other rare earths. On the other hand the determination of thorium in the presence of scandium cannot be performed with an EDTA titration because their stability constants with EDTA are very close ($\log K_{ThY} = 23{\cdot}3$, $\log K_{ScY} = 23{\cdot}1$). We have found[3] that the thorium-EDTA complex reacts quantitatively with TTHA at pH 5 after short boiling, forming a thorium-TTHA complex, but the scandium-EDTA complex does not react at all. The TTHA consumed and the EDTA liberated

$$\text{Th-EDTA} + \text{TTHA} = \text{Th-TTHA} + \text{EDTA} \qquad (1)$$

can be determined by a back-titration with zinc, Xylenol Orange being used as indicator, and the amounts of thorium and scandium are easily calculated.[3]

It would be of great interest if such determinations could also be carried out in the presence of some of the lanthanides. At first we encountered some difficulties.

* Part XXII: *Talanta*, 1966, **14**, 266.

When we titrated the sum of thorium and scandium in the presence of lanthanum, the results were very good, but the subsequent determination of lanthanum with TTHA could only be performed by boiling the solution for a short time, after adding urotropine, in which case the liberated EDTA [see reaction (1)] reacted partly with the lanthanum and the reaction with TTHA was not quantitative. It seemed that such a problem could not be solved properly. Fortunately we have found that DCTA behaves differently—displaced from its thorium complex it does not react with lanthanum in the presence of TTHA. The determinations are therefore based on the following reactions.

(*a*) Determination of thorium + scandium with DCTA at pH 2·5–3·0:

$$x\text{Th} + y\text{Sc} + (x + y)\text{DCTA} = x\text{Th-DCTA} + y\text{Sc-DCTA}. \quad (2)$$

(*b*) Determination of thorium + lanthanum by reaction with an excess of TTHA at pH 5·0–5·5:

$$x\text{Th-DCTA} + z\text{La} + (x + z)\text{TTHA} = x\text{Th-TTHA} + z\text{La-TTHA} + x\text{DCTA}. \quad (3)$$

The total amount of DCTA and TTHA is known. In a mixture they can easily be determined by titrating two aliquots with lanthanum and with zinc solutions:

$$x\text{DCTA} + w\text{TTHA} + (x + 2w)\text{Zn} = x\text{Zn-DCTA} + w\text{Zn}_2\text{-TTHA} \quad (4)$$

$$x\text{DCTA} + w\text{TTHA} + (x + w)\text{La} = x\text{La-DCTA} + w\text{La-TTHA}. \quad (5)$$

EXPERIMENTAL

Reagents

DCTA, 0·05*M*, was prepared by dissolving 17·63 g of it in 150 ml of hot 1*M* sodium hydroxide. cooling, and diluting to 1 l. The solution was standardized by complexometric titration with 0·05*M* zinc solution.

TTHA, 0·05*M*, was prepared by dissolving 24·72 g of it in 150 ml of hot water, neutralizing with 1*M* sodium hydroxide, cooling, diluting to 1 l. and standardizing as above.

For preparing 0·05*M* solutions of thorium, scandium and lanthanum, the nitrates were used. Zinc solution, 0·05*M*, was prepared from metallic zinc. Solutions of other rare earths (Ce, Pr, Nd, Sm and Ho) were prepared by dissolution of their oxides in hydrochloric acid, and were 0·05*M*. The concentrations of all solutions were checked by complexometric analysis. A 0·2% Xylenol Orange solution and reagent grade urotropine were also used.

Procedure

Take two aliquots of the dissolved sample containing not more than 500 mg of thorium, scandium and lanthanide oxides, adjust both solutions to pH 2·5–3·0, add a few drops of Xylenol Orange solution, and titrate with 0·05*M* DCTA till the red colour changes to clear yellow (consumption, *a* ml). Adjust the pH to 5·0–5·5 with solid urotropine (red colour reappears), add 0·05*M* TTHA in excess—more than sufficient for thorium and lanthanum (*b* ml)—and boil the solution for 3 min. The red solution must turn yellow. Then cool and titrate one solution with 0·05*M* zinc (*c* ml) and the other with 0·05*M* lanthanum (*d* ml). The colour change of both end-points, from yellow to intense red, is very sharp. Then thorium is given by $(2d - c)$, scandium by $(a + c - 2d)$, and the lanthanide by $(b - d)$ if all the titrants are equimolar.

Some results for thorium, scandium and lanthanum are summarized in Table I and those for thorium, scandium and/or cerium, praseodymium and neodymium are included in Table II.

Remarks

In titrations with zinc solutions, the red colour at the end-point reverts after some time (5 min) to yellow, owing to the reaction:

$$\underset{\text{(red)}}{\text{La-TTHA} + \text{Zn-DCTA} + \text{ZnXO}} = \underset{\text{(yellow)}}{\text{La-DCTA} + \text{Zn}_2\text{-TTHA} + \text{XO}} \quad (6)$$

(where XO is the anion of Xylenol Orange). It is also possible to use only one aliquot if we mask all the zinc by the addition of 1,10-phenanthroline[4] after the zinc titration, and repeat the titration with lanthanum solution.

TABLE I.—DETERMINATION OF THORIUM, SCANDIUM AND LANTHANUM

DISCUSSION

The proposed method offers good results for the combination thorium, scandium, lanthanide (where lanthanide = La, Ce, Pr, Nd). Further rare earths can be determined as well, even when they do not react quantitatively according to equation (3) and are always partially bound with DCTA. In such cases their determination according to reaction (5) gives satisfactory results, but the calculation shows a negative error for the thorium and a corresponding positive error for the scandium. These errors increase with increasing stability constants of the respective lanthanide-DCTA complexes, which are responsible for the interfering reaction:

$$\text{Ln-TTHA} + \text{DCTA} = \text{Ln-DCTA} + \text{TTHA}. \qquad (7)$$

The last two results in Table II for samarium and holmium illustrate this situation quite well. The whole problem is being systematically investigated.

Zusammenfassung—Es wird eine neue Methode zur gleichzeitigen Bestimmung von Thorium, Scandium und der Summe der leichten Lanthaniden beschrieben. Die Methode beruht auf der Titration von Thorium plus Scandium mit DCTA (1,2-Diaminocyclohexantetraessigsäure) bei pH 2,5–3,5, mit Xylenolorange als Indikator. Nach Zugabe von TTHA (Triäthylentetraminhexaessigsäure) wird der Thorium-DCTA-Komplex in den Thorium-TTHA-Komplex übergeführt gemäß der Gleichung Th-DCTA + TTHA = Th-TTHA + DCTA. Gleichzeitig reagieren das freie Lanthan, Cer, Praseodym und Neodym mit TTHA. Der Überschuß an TTHA und das freigewordene DCTA werden dann durch Titration mit Zink-und mit Lanthanlösungen gemäß den Gleichungen DCTA + TTHA + 3Zn = Zn-DCTA + Zn_2TTHA und DCTA + TTHA + 2La = La-DCTA + La-TTHA bestimmt. Aus den Ergebnissen können die Thorium- und Scandiummengen sowie die Summe der Lanthanidenkonzentrationen leicht berechnet werden. Weitere Möglichkeiten, zum Beispiel die Bestimmung schwererer Lanthaniden, werden kurz diskutiert.

Résumé—On décrit une nouvelle méthode de dosage du thorium, du scandium et de la somme des lanthanides légers, en présence les uns des autres. La méthode est basée sur le dosage de thorium plus scandium au moyen de DCTA (acide 1,2-diaminocyclohexanetétracétique) à pH 2,5–3,5 avec le xylénol orangé pour indicateur. Aprés addition de TTHA (acide triéthylènetétraminohexacétique), on convertit le complexe thorium-DCTA en complexe thorium-TTHA selon l'équation Th-DCTA + TTHA = Th-TTHA + DCTA. Simultanément, les lanthane, cérium, praséodyme et néodyme libres réagissent avec le TTHA. L'excès de TTHA et le DCTA libéré sont alors dosés par titrages avec des solutions de zinc et de lanthane selon l'équation DCTA + TTHA + 3Zn = Zn-DCTA + Zn_2-TTHA et DCTA + TTHA + 2La = La-DCTA + La-TTHA. Des résultats, on peut aisément calculer les quantités de thorium et de scandium et la somme des concentrations en lanthanides. On discute brièvement d'autres possibilités, par exemple le dosage de lanthanides plus lourds.

RADIOCHEMISCHE TRENNUNGEN MIT HILFE DER RINGOFENMETHODE—I

DAS SYSTEM $^{137}Cs/^{137m}Ba$

D. KLOCKOW
Chemisches Laboratorium der Universität Freiburg i. Br.,

(*Eingegangen am* 5 *August* 1966. *Angenommen am* 1 *November* 1966)

Zusammenfassung—Die Anwendung der Ringofenmethode auf radiochemische Trennungen wird am Beispiel des "Mutter-Tochter"-Paares $^{137}Cs/^{137m}Ba$ erläutert. Auf Rundfiltern, welche mit schwerlöslichen Hexacyanoferraten(II) bzw. mit Salzen von Heteropolysäuren imprägniert sind, kann das ^{137m}Ba in etwa 2 min vom ^{137}Cs getrennt und nach Wiedereinstellung des radioaktiven Gleichgewichtes immer wieder "abgemolken" werden. Die erzielten ^{137m} Ba-Ausbeuten liegen bei den Hexacyanoferrat-Papieren zwischen 80 und 100%, bei den Molybdato- und Wolframatophosphat-Papieren zwischen 50 und 70%. Die Dekontaminationsfaktoren erreichen Werte von 10^3 bis 10^5. Die Halbwertszeit des abgetrennten ^{137m}Ba wurde aus den Versuchsdaten zu 2,570 ± 0,006 min errechnet.

TRENNUNGEN von Submikrogrammengen an Kationen oder Anionen lassen sich mit Hilfe der Ringofenmethode nach Weisz[1] einfach und schnell ausführen. Diese Eigenschaften sowie die Tatsache, daß die abgetrennten Substanzen an einem definierten Ort, nämlich in einem scharfen Ring von 22 mm Durchmesser, wieder konzentriert werden, haben dazu geführt, daß das Verfahren bereits verschiedentlich auf radiochemische Probleme angewendet wurde. So trennten Weisz und Scott[2] radioaktiv markiertes Sulfat, Jodid und Phosphat voneinander, während Hilton und Reed die Abtrennung von $^{137}Cs/^{137m}Ba$[3,4] sowie von $^{99}Mo/^{99m}Tc$[5] aus bestrahltem Uran beschreiben. Weiterhin wurde die Ringofentechnik zur Analyse von Gemischen langlebiger Uranspaltprodukte herangezogen.[6,7]

Von besonderem Interesse sind derartige leicht und schnell durchzuführenden Trennungen in solchen Fällen, in denen kurzlebige Radioisotopen von ihren Mutternukliden abgetrennt und identifiziert werden sollen. Hierbei ist es von Vorteil, wenn das Mutternuklid so fixiert werden kann, daß sich die "Tochter" in bestimmten Zeitabständen immer wieder "abmelken" läßt. Im folgenden wird gezeigt, wie Trennungen dieser Art beim "Mutter-Tochter"-Paar $^{137}Cs/^{137m}Ba$ bequem mit Hilfe der Ringofenmethode durchgeführt werden können.

Die Trennoperationen erfolgen auf Rundfiltern, welche mit anorganischen Ionenaustauschern, nämlich schwerlöslichen Hexacyanoferraten(II) und Salzen von Heteropolysäuren imprägniert sind. Diese Verbindungen sind dafür bekannt, daß sie bevorzugt Kationen der Ladung +1 sorbieren und eine besondere Selektivität für Cs^+ aufweisen. Als Beispiele hierfür seien einige Arbeiten aufgeführt, in welchen die selektive Sorption von Cs^+ an Kobalthexacyanoferrat(II),[8,9] Berliner Blau,[10] Vanadium(IV)-hexacyanoferrat(II),[11] Ammonium-molybdato- und wolframato-phosphat[12–14] sowie an Thallium-wolframatophosphat[15] untersucht wird bzw. radiochemisch-analytische Anwendung findet.

EXPERIMENTELLER TEIL

Herstellung der Filterpapiere

Kobalthexacyanoferrat(II)-Papiere. Rundfilter MN 2260 von 5,5 cm Durchmesser (Hersteller: Macherey, Nagel u. Co., Düren) werden mit einer 2%igen $K_4[Fe(CN)_6]\cdot 3\,H_2O$-Lösung getränkt und auf Filterpapier abgepreßt. Anschließend taucht man die Papiere 10–15 sec in eine Kobaltchlorid-Lösung, welche 0,5% Kobalt enthält, preßt sie wiederum ab und legt sie *ca.* 1 Std. in dest. Wasser, wobei dieses alle 10 min erneuert wird. Zum Schluß werden die Rundfilter mit dest. Wasser abgespült und auf Filterpapier an der Luft getrocknet.

Berliner Blau-Papiere. Die wie oben mit Kaliumhexacyanoferrat(II) imprägnierten Rundfilter werden 15–30 sec in eine salzsaure (pH ≈ 1) Eisen(III)chlorid-Lösung mit 0,5% Eisen getaucht, abgepreßt und zunächst 2 mal je 15 min in 1 n Salpetersäure gebadet. Anschließend wässert man die Papiere 1 Std. in dest. Wasser und behandelt sie weiter wie oben.

Kupferhexacyanoferrat-Papiere. Die mit einer 2%igen $K_4[Fe(CN)_6]\cdot 3\,H_2O$-Lösung getränkten Rundfilter werden 1–1½ min in eine Kupfer(II)chlorid-Lösung mit 0,5% Kupfer gelegt (Papiere dabei nicht bewegen!), abgeklatscht, 1 Std. in dest. Wasser gebadet, abgespült und an der Luft getrocknet.

Vanadiumhexacyanoferrat-Papiere. Als Reagentien dienen eine 2%ige $K_4[Fe(CN)_6]\cdot 3\,H_2O$-Lösung und eine Vanadium(IV)sulfat-Lösung mit 0,5% Vanadium. Zur Fällung werden die mit Hexacyanoferrat imprägnierten Rundfilter etwa 30 sec in die Vanadium(IV)-Lösung getaucht. Die Papiere werden weiterbehandelt wie oben.

Thalliummolybdatophosphat-Papiere. Rundfilter MN 2260 werden mit einer 4%igen Lösung von Molybdatophosphorsäure (E. Merck AG, Darmstadt) getränkt, auf Filtrierpapier abgepreßt, 15–30 sec in einer 1n salpetersauren Thalliumacetat-Lösung mit 0,5% Thallium gebadet und wiederum abgepreßt. Man legt die Papiere anschließend 10 min in 0,5n Salpetersäure, spült sie kurz mit dest. Wasser ab und läßt sie auf Filterpapier an der Luft trocknen. Die gelben Thalliummolybdatophosphat-Papiere sollten im Dunkeln aufbewahrt werden, da sie sich am Licht allmählich nach Blau verfärben.

Thalliumwolframatophosphat-Papiere. Die Imprägnierung erfolgt analog der Herstellung der Thalliummolybdatophosphat-Papiere unter Anwendung einer 4%igen Lösung von Wolframatophosphorsäure (E. Merck AG, Darmstadt).

Ammoniumwolframatophosphat-Papiere. Als Reagentien dienen eine 4%ige Wolframatophosphorsäure-Lösung und eine 1n salpetersaure 2%ige Ammoniumnitrat-Lösung. Zur Fällung werden die mit der Heteropolysäure imprägnierten Rundfilter ½–1 min in die Ammoniumnitrat-Lösung getaucht. Die Papiere werden wie oben mit 0,5n Salpetersäure und Wasser gewaschen.

Durchführung der Versuche

Die Experimente wurden mit zwei schwach salzsauren ^{137}Cs-Lösungen durchgeführt. Lösung I besaß eine spez. Aktivität von 9 μC/ml bei einer Trägerkonzentration von 0,02 mg CsCl/ml, Lösung II eine spez. Aktivität von 440 μC/ml bei einer Trägerkonzentration von 0,065 mg CsCl/ml.

Auf den Hexacyanoferrat-Papieren erfolgten die Trennungen mit 0,05n Salzsäure oder mit einer 0,05n salzsauren Bariumchlorid-Lösung mit 0,1% Barium, auf den Molybdato- und Wolframatophosphat-Papieren mit einer 0,1n salpetersauren 0,1m Ammoniumnitrat-Lösung.

Im Zentrum eines imprägnierten Rundfilters wurden 6 × 5 μl der ^{137}Cs-Lösung I (nach jeder 5 μl-Portion trocknen) oder 1 μl der Lösung II aufgetragen, sodaß sich auf dem Filter 0,27 μC bzw. 0,44 μC ^{137}Cs mit 0,6 μg bzw. 0,065 μg CsCl-Träger befanden. Auf dem Ringofen wurde dann in der üblichen Weise mit 120–150 μl der entsprechenden Waschlösung das ^{137m}Ba aus dem zentralen Cs-Tüpfelfleck abgetrennt und im Ring konzentriert. Unmittelbar nach der Trennoperation und dem Trocknen des Rundfilters wurde aus dem Zentrum desselben ein Scheibchen von 17 mm Durchmesser (mit dem Cs-Tüpfelfleck in der Mitte) herausgeschnitten (vgl. Abb. 1). Das restliche Filter mit dem im Ring konzentrierten ^{137m}Ba gelangte sofort zur Aktivitätsmessung.

Die eigentlichen Trennoperationen erforderten 2–2½ min Zeit, das Trocknen und Ausschneiden ½–1 min. Es konnte demnach etwa 2 min nach der Trennung mit der Messung begonnen werden, wenn man die Mitte zwischen Beginn und Ende des Auswaschens als den Zeitpunkt (t = 0) der Abtrennung des ^{137m}Ba vom ^{137}Cs betrachtet. Die γ-Messungen wurden mit einem NaJ(Tl)-Kristall (Frieseke u. Hoepfner, FH 421/Z 4), β-Messungen (zur Ermittlung des Dekontaminationsfaktors) mit einem Endfensterzählrohr (FHZ 15a) durchgeführt. Abbildung 2 zeigt den Abfall der Aktivität von ^{137m}Ba, welches auf Berliner Blau-Papier vom Mutternuklid ^{137}Cs abgetrennt wurde.

Aus dem 17 mm-Scheibchen mit dem Cs-Tüpfelfleck wurde 35–40 min nach der 1. Trennung ^{137m}Ba erneut "abgemolken". Hierbei wurde nach einer bereits früher beschriebenen Technik[6] das Filterscheibchen auf die Mitte eines neuen imprägnierten Rundfilters gepreßt und das ^{137m}Ba mit der geeigneten Lösung in die Ringzone gewaschen. Da hierbei Teile des ^{137}Cs (1–5% bei den

Hexacyanoferrat-Papieren, 5–10% bei den Molybdato- und Wolframatophosphat-Papieren) aus dem Filterscheibchen mit in das untere Rundfilter übergingen, mußte aus dessen Zentrum vor Beginn der Messung ebenfalls ein Scheibchen, und zwar mit 18 mm Durchmesser, ausgeschnitten werden (vgl. Abb. 1). Dieses Scheibchen enthielt die gesamte störende ^{137}Cs-Aktivität. Das "Abmelken" wurde bei jedem Versuch bis zu 3 mal durchgeführt.

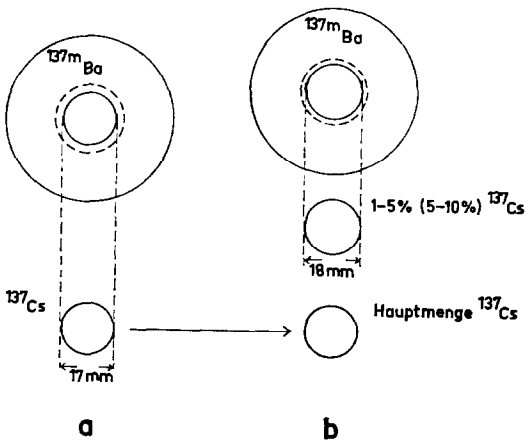

ABB. 1.—Verteilung von Mutter- und Tochternuklid auf dem Rundfilter. (a) 1. Abtrennung. (b) "Abmelken" aus dem 17mm-Scheibchen.

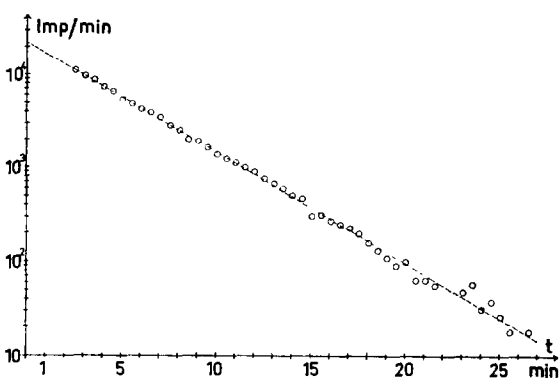

ABB. 2.—^{137m}Ba-Abfall.

ERGEBNISSE UND DISKUSSION

Als Kriterien für die Brauchbarkeit der beschriebenen Trennungen wurden die ^{137m}Ba-Ausbeute, der Dekontaminationsfaktor und die Halbwertszeit des abgetrennten ^{137m}Ba herangezogen.

Die Ausbeute wurde aus der auf den Zeitpunkt $t = 0$ extrapolierten Anfangsaktivität des ^{137m}Ba ermittelt, der Dekontaminationsfaktor durch β-Messung von Filterscheibchen und Ring (etwa 35 min nach der Trennung) und die Halbwertszeit rein rechnerisch nach der auf kurzlebige Strahler mit Vorteil anwendbaren sog. "Quotientenmethode" (vgl. z.B. bei G. Böhler[16]). Bei diesem Verfahren benötigt man als bekannte Größen nur die Impulszahl zu einem bestimmten Zeitpunkt t nach Beginn der Messung (im vorliegenden Fall nach 3 min), die Gesamtimpulszahl bis

zum völligen Abklingen der Aktivität (im vorliegenden Fall nach 35 min) und die Nullrate.

Es zeigte sich, daß man auf den Hexacyanoferrat-Papieren ^{137m}Ba-Ausbeuten zwischen 80 und 100% erreicht, wenn man die Trennungen mit der 0,05n salzsauren Bariumchlorid-Lösung durchführt. Arbeitet man mit 0,05n Salzsäure allein, trennt man also praktisch trägerfrei, dann erzielt man die gleichen Ausbeuten nur auf den Berliner Blau-Papieren. Die Dekontaminationsfaktoren liegen im allgemeinen bei den 1. Abtrennungen zwischen $5 \cdot 10^2$ und 10^3, beim folgenden "Abmelken" aus den 17 mm-Scheibchen jedoch zwischen 10^3 und 10^5.

Ähnlich lagen die Verhältnisse bei der Untersuchung der Thallium- und Ammoniumwolframatophosphat-Papiere. Die ^{137m}Ba-Ausbeuten beim "Abmelken" aus den 17mm-Scheibchen erreichten jedoch nur 50–70%. Als weniger brauchbar für ^{137}Cs-^{137m}Ba-Trennungen erwiesen sich die Thalliummolybdatophosphat-Papiere, da hiermit bei zwar hohen Ausbeuten stets nur Dekontaminationsfaktoren $<10^3$ erreicht werden konnten. Berechnungen der Halbwertszeit von ^{137m}Ba nach der erwähnten "Quotientenmethode" wurden nur bei denjenigen Versuchen durchgeführt, bei denen das Tochternuklid mit Dekontaminationsfaktoren $>10^3$ vom Mutternuklid abgetrennt werden konnte.

Folgende Ergebnisse wurden gefunden:

2,581 ± 0,014 min	2,557 ± 0,008 min
2,556 ± 0,012 min	2,573 ± 0,015 min
2,585 ± 0,017 min	2,563 ± 0,011 min
2,577 ± 0,015 min	2,574 ± 0,009 min
2,522 ± 0,022 min	2,578 ± 0,011 min
2,589 ± 0,012 min	2,559 ± 0,015 min
2,539 ± 0,014 min	2,574 ± 0,006 min
2,627 ± 0,012 min	2,549 ± 0,008 min
2,629 ± 0,013 min	2,530 ± 0,006 min
2,579 ± 0,007 min	2,552 ± 0,007 min

Aus diesen 20 Ergebnissen ließ sich für die Halbwertszeit von ^{137m}Ba der Mittelwert 2,570 ± 0,006 min errechnen, der eine gute Übereinstimmung mit dem genauesten bisher bekannten Wert von 2,554 ± 0,003 min[8] aufweist. Das geschilderte Verfahren zeigt, wie mit Hilfe der Ringofenmethode radiochemische Trennungen schnell und einfach durchgeführt werden können. Hierbei soll das System ^{137}Cs/^{137m}Ba nur als Beispiel für weitere "Mutter-Tochter"-Paare oder Nuklidgemische dienen. Auch dann, wenn im Hinblick auf die Halbwertszeit der abgetrennten Isotopen schnelle Trennungen nicht unbedingt erforderlich sind, dürfte die angegebene Arbeitsweise von Vorteil sein. Man führt alle Operationen auf einem festen Trägermaterial aus und hat die getrennten Nuklide stets in einer definierten Geometrie (zentraler Tüpfelfleck bzw. Ringzone) vorliegen.

Summary—The application of the ring-oven method to radiochemical separations is exemplified by separation of the mother-daughter pair ^{137}Cs/^{137m}Ba. The ^{137m}Ba can be separated from ^{137}Cs in about 2 min on a filter circle impregnated with an insoluble ferrocyanide or heteropoly acid salt, and after re-establishment of radioactive equilibrium can be "milked off" again. The yield of ^{137m}Ba obtained is 80–100% for the ferrocyanide-impregnated paper and 50–70% for a paper impregnated with a phosphomolybdate or tungstomolybdate. The decontamination factor ranges from 10^3 to 10^5. The half-life of the separated ^{137m}Ba was calculated to be 2.570 ± 0.006 min.

Résumé—L'application de la méthode du four annulaire aux séparations radiochimiques est illustrée par la séparation de la paire de filiation $^{137}Cs/^{137m}Ba$. On peut séparer le ^{137m}Ba du ^{137}Cs en 2 mn environ sur un cercle de papier filtre imprégné par un ferrocyanure insoluble ou par un sel d'hétéropolyacide et, après rétablissement de l'équilibre radioactif, traiter de nouveau. Le rendement obtenu en ^{137m}Ba est de 80–100%, pour le papier imprégné de ferrocyanure, et de 50–70% pour un papier imprégné de phosphomolybdate ou de tungstomolybdate. Le facteur de décontamination va de 10^3 à 10^5. On a calculé que la période du ^{137m}Ba séparé est de 2,570 ± 0,006 mn.

RADIOCHEMICAL SEPARATION OF LEAD BY AMALGAM EXCHANGE

IQBAL H. QURESHI and FAZAL I. NAGI
Atomic Energy Centre, Ferozepur Road, Lahore, Pakistan

(*Received* 9 *August* 1966. *Accepted* 25 *November* 1966)

Summary—An amalgam exchange technique has been used for the rapid radiochemical separation of lead. A number of variables which affect the exchange were studied and a lead yield of 88·5% was obtained. At room temperature the procedure requires about 13 min, whereas at 40° it can be completed in about 9 min. Radioactive tracers of 16 different elements were used to check the selectivity of this procedure, which has also been applied for the separation of ^{212}Pb from thorium nitrate solution.

PREVIOUS work on isotopic exchange between a dilute amalgam of a metal and its ions in aqueous solution has proved very useful for radiochemical separations of cadmium,[1] indium,[2] strontium,[3] bismuth,[4] and thallium.[5] In the amalgam exchange technique, a simple procedure gives excellent decontamination which is much better than that obtained previously. These studies show that the heterogeneous isotopic exchange reactions are rapid and selective and can be employed for rapid radiochemical separations. A preliminary communication[6] indicated that the amalgam exchange technique can also be applied to the radiochemical separation of lead. The aim of the present investigation is to develop an optimum procedure for the separation of radio-lead by this technique.

The separation is carried out in two steps. In the first step a dilute lead amalgam is made to contact an aqueous solution containing radioactive isotopes of lead, in order to selectively exchange radioactive lead with the inactive lead in the amalgam. The exchange reaction may be represented by

$$Pb(Hg) + \overset{*}{Pb}^{2+} \rightleftharpoons \overset{*}{Pb}(Hg) + Pb^{2+}$$

where the asterisk denotes radioisotopes of lead. In the second step the amalgam containing radio-lead is removed and contacted with a solution of copper(II) nitrate or lead nitrate to strip the element from the mercury into the aqueous phase.

EXPERIMENTAL

Apparatus

The separations were made in one-ounce square-bottomed flint glass bottles with polyethylene insert caps. The bottles were clamped in a mechanical shaker (Wrist-Action shaker, Burrell Corp., Pittsburg, Pa., U.S.A.), to which an extension arm of 9 in. was connected to give additional radial action. For high temperature studies the bottles were agitated in a thermostatically controlled tank.

Gross gamma ray measurements were made with a Baird Atomic Model 810 scintillation well counter, and gamma ray spectrum measurements with a 3 in. × 3 in. NaI(Tl) crystal coupled with a Nuclear Data 512 channel analyser. A Tracerlab Geiger tube TGC-1 was used for beta activity measurements.

Reagents

Mercury: triply distilled, CENCO, U.S.A., further purified by washing with dilute nitric acid, followed by rinsing with distilled water.

Lead metal: C.P., City Chemical Co., New York, U.S.A.

Thorium nitrate: Reagent grade, May & Baker Ltd., England.

All radioisotopes used as tracers were obtained from the Radiochemical Centre, Amersham, England and from the Union Carbide Nuclear Company, Oak Ridge, Tenn., U.S.A.

The lead-212 tracer was prepared from thorium in equilibrium with its decay products, by adsorbing the lead, bismuth, thallium and polonium on a column of De-Acidite FF (100–200 mesh) anion-exchange resin. After the column had been washed with 2*M* hydrochloric acid, the lead-212 was eluted with distilled water.[7]

Preparation of lead amalgam

The lead metal was washed with 2*M* nitric acid until etched, washed with distilled water and dried. The appropriate weight of lead was added to 20 g of purified mercury stored under 0·1*M* nitric acid, heated and stirred.

Exchange procedure

Lead-212 tracer was added to 4 ml of 1*M* hydrochloric acid solution for yield determination and interference studies. Radioactive tracers (10^5–10^6 cpm) of contaminating ions plus 1 μg of inactive lead were used for decontamination studies. Lead amalgam (200 μl $\sim$ 2·6 g) containing 2% lead by weight was added and the mixture was mechanically agitated for 3 min. A 200 μl aliquot was removed for counting and the aqueous phase was removed by suction. The amalgam was transferred to another bottle and washed twice with distilled water. The amalgam was then transferred to a bottle containing 2 ml of copper(II) nitrate solution in 1*M* nitric acid (25 mg of copper per ml) and agitated for 8 min. A 500 μl aliquot of the aqueous layer containing the separated lead isotopes was counted in a scintillation well-counter. The procedure requires about 13 min at room temperature and gives a yield of about 88·5%.

Separation of lead-212 from thorium nitrate

Lead amalgam (2%, 200 μl) was added to 5 ml of 50% thorium nitrate solution in 1*M* hydrochloric acid and agitated for 2 min at 40°. The aqueous layer was removed by suction and the amalgam was transferred to another bottle and washed twice with distilled water. The amalgam was then mixed with 2 ml of lead nitrate solution in 1*M* nitric acid (100 mg of lead per ml) and agitated for 5 min at 40°. The solution containing separated lead-212 was transferred to a new bottle and 10 μg of thallium carrier were added. Then 200 μl of 2% thallium amalgam were added and the mixture agitated for one min at 40° to remove thallium from the solution. Total time of separation is about 12 min, and a yield of about 66% is obtained.

DISCUSSION AND RESULTS

In the search for a suitable exchange medium, the amalgam was agitated in various systems. In general, the acid media were found to permit maximum exchange. With 2% lead amalgam and a 3-min contact time exchange yields of 93·2%, 90·1% and 86·3% were obtained for 1*M* solutions of hydrochloric acid, hydrobromic acid and nitric acid. When the amalgam was agitated in 1*M* sulphuric acid, a white turbidity due to the formation of lead sulphate was observed. Further experiments with different concentrations of hydrochloric acid showed that maximum exchange is obtained in 0·7–1·5*M* hydrochloric acid media, and 1*M* hydrochloric was therefore selected as the exchange medium.

In order to determine the optimum separation procedure several preliminary experiments were performed in which a number of factors which affect the exchange such as the concentration of lead in the amalgam and in the aqueous phase, the agitation time and the effect of temperature were studied and optimized.

As the amount of lead in the amalgam was gradually increased from 0·1 to 2% the exchange yield rapidly increased from 58·5% to 93·2%. Further increase in the concentration of lead amalgam did not show any significant increase in the yield. Studies made with different volumes of a 2% lead amalgam gave the best yields with 200 μl portions of the amalgam.

Because for high exchange it is necessary that the concentration of lead in the amalgam should be much greater than its concentration in the aqueous phase,

experiments were carried out to determine the maximum usable aqueous concentration of lead. In these experiments the aqueous concentration of lead was varied, the lead concentration in the amalgam being kept at 2%. It was found that above an aqueous concentration of 125 μg of lead per ml the exchange starts decreasing. Further studies showed that the exchange decreased if more than 5 ml of aqueous phase were used, and the optimum ratio of the volumes of aqueous phase and amalgam is 25.

The exchange yield depends upon the duration of agitation, increases rapidly with increasing agitation time and begins to level off at 3–4 min. On prolonged agitation, the exchange gradually decreases, probably because of oxidation of lead from the amalgam by air trapped in the bottle above the solution. The results are shown in Table I.

TABLE I.—DEPENDENCE OF LEAD YIELD ON AGITATION TIME AND TEMPERATURE*

Agitation time, *min*	Initial exchange, %		Back-exchange in copper nitrate system, %		Back-exchange in lead nitrate system, %	
	24°C	40°C	24°C	40°C	24°C	40°C
1	54·8	92·4	—	81·4	—	38·8
2	85·5	96·8	69·7	94·6	42·6	50·4
3	93·2	97·9	80·3	96·8	50·8	61·5
4	96·4	97·6	—	—	—	—
5	97·8	96·8	88·5	98·3	65·3	72
6	96·9	—	—	—	—	—
7	—	—	93·1	98·4	70·6	—
8	96·4	96·2	95·0	—	71·0	72
10	96	—	96·0	—	72·0	—

* In these experiments 200 μl of 2% lead amalgam were used. The back-extracting solutions contained 25 mg of copper or 100 mg of lead per ml.

In the initial exchange most of the radioactivity is transferred to the amalgam in a short time. The next step is then to reclaim this activity from the amalgam into an aqueous solution by selectively stripping the element. Of the several solutions tried for back-exchange, only lead nitrate and copper nitrate solutions in 1*M* nitric acid were efficient. The back-exchange increases with increasing concentrations of lead and copper in the solutions and above a certain concentration no more increase is observed. Therefore, solutions containing 100 mg of lead or 25 mg of copper per ml of 1*M* nitric acid were chosen as back-extractants. With 8-min agitation back-exchange yields of 72% and 95% respectively were obtained when lead nitrate and copper nitrate were used.

The dependence of back-exchange yield on the duration of agitation is shown in Table I. With increasing agitation time the yield increases and starts leveling off at 7–8 min agitation. Therefore, in the optimum separation procedure a 3-min agitation for the initial exchange and an 8-min agitation for the back-exchange were used.

Both the initial and the back-exchange reactions were studied at 40°. The results are given in Table I. The exchange reactions proceed somewhat faster at high temperature and a relatively shorter time is required to attain equilibrium. Thus at 40° the agitation times for the initial and the back-exchange can be reduced to 2 and 5 min respectively.

In the interference studies it was found that the exchange yield is not affected by

alkalies in concentrations up to 1*M*. Acids such as sulphuric, phosphoric and oxalic below 0·1*M* concentrations do not interfere whereas sulphites and oxidizing agents do interfere in the exchange. It is therefore necessary that the oxidizing agents should be reduced to their lowest oxidation state before the amalgam exchange.

Decontamination

The selectivity of this method was checked by making decontamination studies with radioactive tracers of a number of elements representative of the periodic table. The results are summarized in Table II. The elements have been listed in the order

TABLE II.—SEPARATION OF LEAD AND CONTAMINANTS*

of their reduction potentials and the data have been subdivided to show the selectivity in the amalgam exchange step and in the back-extraction step. It is observed that the elements above lead (in Table II), with the exception of thallium and cadmium, do not contaminate the initial exchange step within the sensitivity of the experiments *i.e.*, with the amount of tracer used (10^5–10^6 cpm), whereas the other elements do contaminate the initial exchange step, probably because their ions are reduced by lead amalgam. With the exception of bismuth these activities remain in the amalgam and are not extracted when copper(II) nitrate solution is used for selective removal of lead from the amalgam. Bismuth, however, is extracted together with lead and causes considerable contamination. Several unsuccessful attempts were made to reduce this contamination by bismuth. It was finally reduced to less than 0·001% when lead nitrate solution was used for back-extraction; this exchanges with the lead without oxidizing bismuth from the amalgam. Although the back-exchange yield is only 72% with lead nitrate solution, it gives very good separation of lead from bismuth.

The simple amalgam exchange procedure was applied to the separation of lead-212 from thorium nitrate. The gamma-ray spectrum of the separated sample showed only about 3% contamination by thallium-208. To reduce this contamination an additional step was added. The separated sample was agitated with a 2% thallium amalgam for 1–2 min to exchange thallium selectively from the solution. By this treatment the contamination by thallium was reduced to less than 1%.

The amalgam exchange technique for the radiochemical separation of lead is simple and rapid and appears to have useful potential for the separation of short-lived isotopes of lead. The yield can be further increased by shaking longer, and the time of separation can be reduced by performing the exchange at high temperatures. Although very small amounts of lead can be separated by this technique, the final sample counted contains a large amount of inactive lead, and self-absorption corrections may be necessary if beta-counting is used.

Acknowledgements—Some of the preliminary experiments were performed by S. Mahmud Ahmad. This work was supported in part by the U.S. National Bureau of Standards, under International Research Grant Programme, Contract No. NBS(G)-46.

Zusammenfassung—Ein Amalgam-Austauschverfahren wurde zur schnellen radiochemischen Abtrennung von Blei benutzt. Eine Anzahl Variabler, die den Austausch beeinflussen, wurde studiert und eine Bleiausbeute von 88,5% erzielt. Bei Zimmertemperatur dauert das Verfahren etwa 13 min, während es bei 40° in etwa 9 min beendigt werden kann. Radioaktive Tracer von 16 verschiedenen Elementen wurden benutzt, um die Selektivität des Verfahrens zu prüfen, das auch zur Abtrennung von ^{212}Pb aus Thoriumnitratlösung angewandt wurde.

Résumé—On a utilisé une technique d'échange par amalgame pour la séparation radiochimique rapide du plomb. On a étudié un certain nombre de variables qui affectent l'échange et obtenu un rendement en plomb de 88,5%. A température ordinaire, la technique nécessite environ 13 mn, alors qu'à 40° elle peut être réalisée en 9 mn environ. On a utilisé les traceurs radioactifs de 16 éléments différents pour vérifier la sélectivité de cette méthode, qu'on a aussi appliquée à la séparation du ^{212}Pb d'une solution de nitrate de thorium.

THE REACTION OF URANYL IONS WITH 4-(2-PYRIDYLAZO)RESORCINOL

L. SOMMER, V. M. IVANOV* and H. NOVOTNÁ
Department of Analytical Chemistry of the J. E. Purkyně-University, Brno, Czechoslovakia

(*Received* 1 *August* 1966. *Accepted* 16 *October* 1966)

Summary—The uranyl ion and 4-(2-pyridylazo)resorcinol (PAR) form only 1:1 chelates in solutions of pH < 8·5, $UO_2(PAR)H^+$ being formed at pH > 3 and $UO_2(PAR)$ at pH > 5·5. Equilibrium constants and spectrophotometric data for both chelates are given. Solid, non-stoichiometric crystalline species in which the mole ratio of PAR to uranium is more than 1:1 are precipitated up to pH 6. The medium of 0·1–0·2*M* triethanolamine at pH 8 recommended by other workers proved satisfactory for the sensitive spectrophotometric determination of uranium, as did pH 3·6 in the presence of < 0·1*M* formate or 20–30% v/v dimethylformamide.

4-(2-PYRIDYLAZO)RESORCINOL (PAR) has been shown to be a sensitive reagent for uranium, and several methods for the spectrophotometric determination of uranium at pH 7–8 have been proposed.[1–3] However, there is disagreement concerning the complexation equilibria. Geary *et al.*,[1] from their potentiometric studies, proposed the formation of a 1:2-chelate at pH 8. Others have assumed a 1:1 species in alkaline medium.[2,3] Because the resolution of these differences is of particular interest for practical spectrophotometry the complexation of the uranium ion with PAR was studied anew by suitable spectrophotometric methods.

EXPERIMENTAL

The preparation of solutions of uranium, the experimental conditions and the apparatus used have been described previously;[4] only reagents not described earlier are listed below.

Reagents

4-(2-Pyridylazo)resorcinol (PAR). Samples used were products of Lachema, Brno or Chemapol, Prague. The purity was always checked by descending paper chromatography with methanol–acetic acid–water (6:3:1), n-butanol–ammonia–water (5:1:5) or pyridine–pentanol–ammonia (5:5:1) on Whatman No. 1 or No. 4 paper, by elemental analysis, and by titration with chromous chloride.[4] The content of the active dye was never lower than 85%. The calculated amounts were dissolved in water or dimethylformamide. The ionic strength was usually adjusted to 0·1, and the pH was regulated by addition of 0·1 and 0·5*M* sodium hydroxide, ammonia or perchloric acid. In special cases buffers were used, *e.g.*, 0·1*M* triethanolamine (pH 8 and 7·7) or 0·1*M* tris(hydroxymethyl)aminomethane (pH 8·05).

Spectrophotometric methods used for solutions

The complexation equilibria, the composition and the molar absorptivities of the chelates were studied by the various spectrophotometric methods used previously.[4–6]

RESULTS AND DISCUSSION

Acid-base equilibria of PAR

The concentrations of the ligand species present in solution (H_3R^+, H_2R, HR^- and R^{2-}) are determined by the acid dissociation constants, $pK_{a1} = 3{\cdot}1$ (2·64), $pK_{a2} =$

* On leave of absence from Department of Analytical Chemistry of the M. V. Lomonosov University, Moscow, U.S.S.R.

5·6 (5·9), $pK_{a3} = 11·9$ where the figures in brackets are for 30% v/v dimethylformamide media.[9] Only the first three proved to be important. The molar absorptivities of H_3R^+, H_2R and HR^- respectively, at 510 mμ and (in brackets) at 470 mμ, are $3·7 \times 10^3$ ($1·84 \times 10^4$), $2·5 \times 10^3$ ($1·95 \times 10^4$) and $7·8 \times 10^2$. The absorption maxima in water, 30% v/v dimethylformamide and 90% dimethylformamide occur at 395, 430–444 and 441–8 mμ respectively for H_3R^+; 385, 388 and 389 mμ for H_2R; and 413, 413 and 394 mμ for HR^-.

Reaction with uranyl ions

PAR-solutions turn orange or dark red at pH > 3 in the presence of uranyl ions. At pH 4·5–6 the chelate formed partly precipitates or forms colloidal solutions, especially when excess of ligand is present, but at pH > 6 the solutions are clear. However, a red-violet solid layer floats on the surface of the liquid and can only be dissolved by addition of ethanol or dimethylformamide. The sensitivity is pD = 7·0 at pH 5–6 (pD = −log [dilution limit]) referred to 1 ml of solution. Uranium(IV) reacts similarly at pH > 4·5.

Spectra of the uranyl chelate solutions

The spectra of the uranyl chelates were measured for solutions containing various concentrations of components and at different pH so that in turn H_3R^+ (λ_{max} 395 mμ), H_2R (λ_{max} 385 mμ) or HR^- (λ_{max} 413 mμ) were co-ordinated (Fig. 1). Some experimental results are given in Table I.

TABLE I.—WAVELENGTH MAXIMA AND ISOSBESTIC POINTS FOR URANIUM(VI)-PAR

pH	C_M, M	C_R, M	λ_{max}, mμ	Isosbestic point, mμ
1·8–3·3	$5·37 \times 10^{-3}$	$5·55 \times 10^{-5}$	500	470
33·2–10·2	$3·38 \times 10^{-5}$	$3·38 \times 10^{-5}$	525	460
6·45–10·5	$1·35 \times 10^{-5}$	$6·76 \times 10^{-5}$	525–30	455
7·68	$(1·0–7·5) \times 10^{-5}$	$1·25 \times 10^{-4}$	525	455
2·14–3·14	$1·0 \times 10^{-3}$	$5·0 \times 10^{-5}$	500*	473

* 4% v/v dimethylformamide.

The interference of the protonated form H_3R^+ shifts the absorbance curves for solutions with metal ion excess from the isosbestic point, at pH < 1·8. The curves have a deformed maximum or inflexion point of lower intensity belonging to the H_2R-form of the ligand at 390–400 mμ besides the regular chelate maximum at 500 mμ, even when the chelate is quantitatively formed at pH > 3. This was explained earlier by the formation of a protonated MRH-chelate where the *p*-hydroxy proton is not dissociated.[9] These two different species have absorption maxima at 510 and 526–535 mμ respectively in 30% v/v dimethylformamide.

pH–Absorbance curves and their interpretation

Solutions with excess of metal ion. S-shaped curves with a straight line portion between pH 1·90 and 2·93 when $C_R = 5 \times 10^{-5} M$ and $C_M/C_R = 20–100$ are characteristic of a single chelate equilibrium. The chelate formation is evidently shifted to

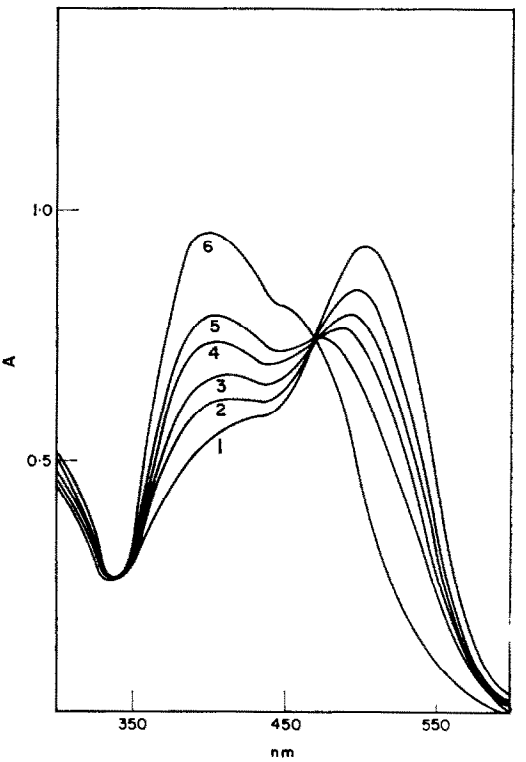

FIG. 1(a).—Absorption curves of PAR solutions in the presence of excess of uranium(VI).
$C_M = 5{\cdot}368 \times 10^{-5}M$; $C_R = 5{\cdot}55 \times 10^{-5}M$; pH: *1*—3·27; *2*—2·98; *3*—2·70; *4*—2·53; *5*—2·41; *6*—1·84.

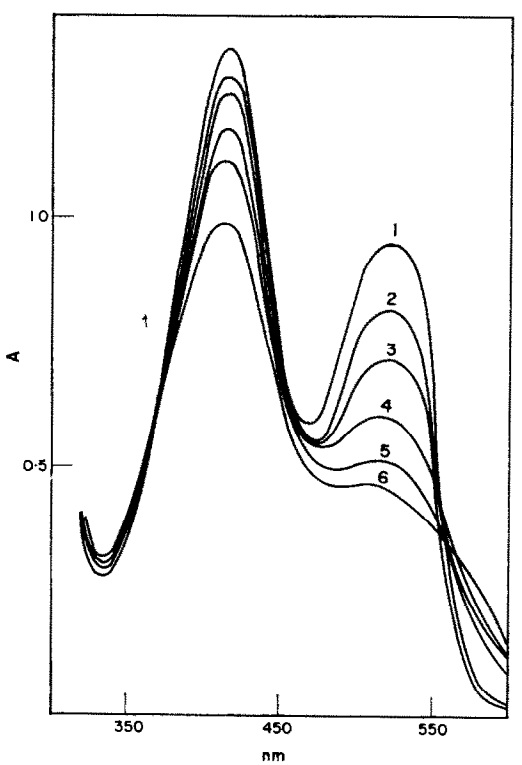

FIG. 1(b).—Absorption curves of uranyl(VI) solutions in the presence of excess of PAR.
$C_R = 6{\cdot}76 \times 10^{-5}M$, $C_M = 1{\cdot}352 \times 10^{-5}M$; pH: *1*—8·10; *2*—9·00; *3*—6·73; *4*—6·45; *5*—6·20; *6*—6·05.

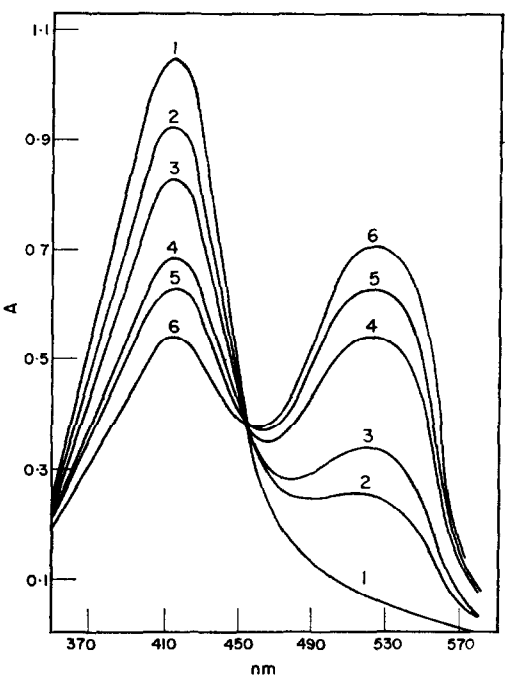

FIG. 1(d).—Absorption curves of PAR solutions with increasing uranyl(VI) concentrations at pH 7·68 (0·5-cm cells). $C_R = 1{\cdot}25 \times 10^{-4}M$. *1*—PAR only; *2*—$C_M = 1{\cdot}10^{-5}M$; *3*—$C_M = 1{\cdot}5 \times 10^{-5}M$; *4*—$C_M = 2{\cdot}5 \times 10^{-5}M$; *5*—$C_M = 3{\cdot}0 \times 10^{-5}M$; *6*—$C_M = 7{\cdot}5 \times 10^{-5}M$.

lower pH values with the increasing metal ion or ligand concentration (Fig. 2). The following equilibria were examined to see if they explained the chelation at pH < 3:

$$UO_2^{2+} + H_3R^+ \rightleftharpoons UO_2RH^+ + 2H^+ \quad (A)$$

$$UO_2^{2+} + H_2R \rightleftharpoons UO_2RH^+ + H^+. \quad (B)$$

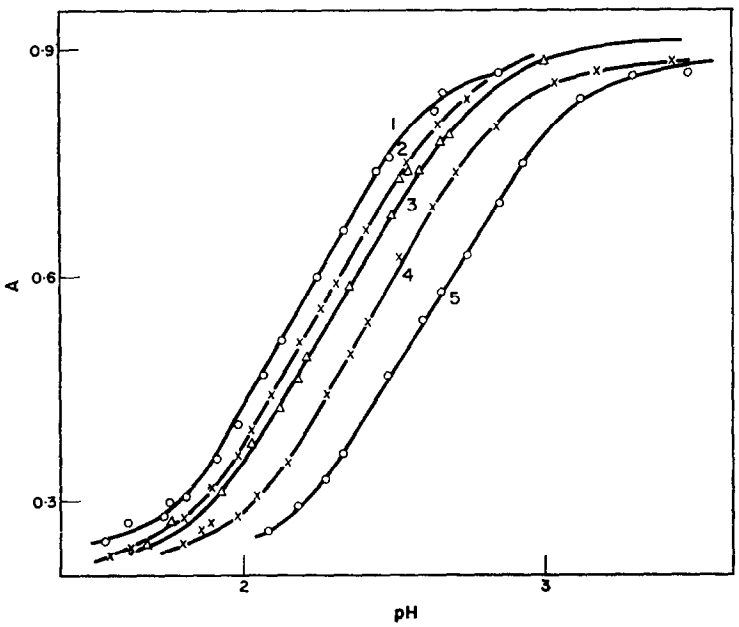

FIG. 2.—Absorbance-pH plots for PAR solutions with increasing uranyl(VI) concentrations at 510 mμ.
$C_R = 5{\cdot}10^{-5}M$, C_M: *1*—$5 \times 10^{-5}M$; *2*—$4 \times 10^{-5}M$; *3*—$3 \times 10^{-5}M$; *4*—$2 \times 10^{-5}M$; *5*—$1 \times 10^{-5}M$.

The following basic equations are valid for the interpretations of the ascending part of the curves, taking into account the partial dissociation of the ligand.

$$C_M \sim [M]$$

$$C_R = [MRH] + [H_3R](1 + K_{a1}/[H]) \text{ or } [MRH] + [H_2R](1 + [H]/K_{a1})$$

$$A = \varepsilon_{1H}[MRH] + [H_3R](\varepsilon_{R1} + \varepsilon_{R2}K_{a1}/[H]) \text{ or}$$

$$\varepsilon_{1H}[MRH] + [H_2R](\varepsilon_{R1}[H]/K_{a1} + \varepsilon_{R2})$$

$$A_{0R} = \varepsilon_{R1}C_R + \varepsilon_{R2}C_RK_{a1}/[H] \text{ for equilibrium (A) and}$$

$$\varepsilon_{R2}C_R + \varepsilon_{R1}C_R[H]/K_{a1} \text{ for equilibrium (B)}$$

$$A_{01} = \varepsilon_{1H}C_R$$

$$k_{12} = [MRH][H]^2/[M][H_3R] \text{ for equilibrium (A) and}$$

$$k_{11} = [MRH][H]/[M][H_2R] \text{ for equilibrium (B).}$$

$$C_R/A = \frac{1}{\varepsilon_{1H}} + \frac{\{A(1 + K_{a1}/[H]) - A_{0R}\}[H]^2}{Ak_{12}\varepsilon_{1H}C_M} \quad (1)$$

for equilibrium (A) and

$$C_R/A = \frac{1}{\varepsilon_{1H}} + \frac{\{A(1 + [H]/K_{a1}) - A_{0R}\}[H]}{Ak_{11}\varepsilon_{1H}C_M} \tag{2}$$

for equilibrium (B).

Similarly, for equilibrium (A) and (B) respectively, we have

$$\log\left\{\frac{A(1 + K_{a1}/[H] - A_{0R}}{A_{01} - A}\right\} = \log C_M + \log k_{12} + 2pH \tag{3}$$

and

$$\log\left\{\frac{A(1 + [H]/K_{a1}) - A_{0R}}{A_{01} - A}\right\} = \log C_M + \log k_{11} + pH \tag{4}$$

where ε is the molar absorptivity of the species indicated by the subscript (1H = MRH; R1 = H_3R^+, R2 = H_2R). Charges are omitted. The existence of equilibria

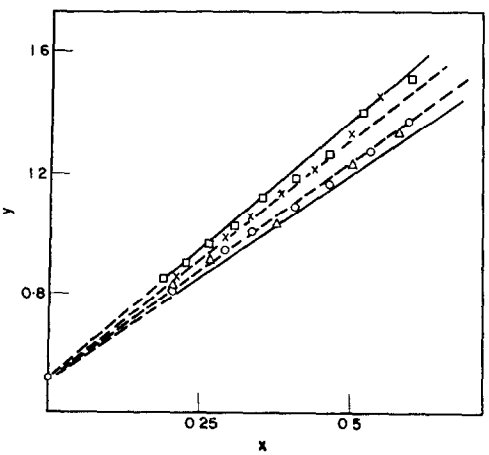

FIG. 3.—Analysis of the linear portions of the pH-absorbance plots, according to equation (1).

$$x = \frac{\{A(1 + K_{a1}/[H]) - A_{0R}\}[H]^2 \times 10^{-3}}{A}; \quad y = \frac{C_R \times 10^{-5}}{A - A_{0R}}.$$

$C_R = 5 \times 10^{-5}M$; C_M/C_R: $\Delta = 100$; $\circ = 60$; $\times = 40$; $\square = 20$; 510 mμ.

(A) and (B) was confirmed by the linearity of transformations (1) and (2). Equilibrium (A) predominates between pH 2 and 2·6 for $C_M/C_R = 20$–100. The number of protons lost during chelation was also confirmed by application of equations (3) and (4) (Figs. 3 and 4). The pH curves show the influence of hydrolysis at pH > 3·5. Further complex formation for solutions containing a small metal ion excess takes place at pH 4–5·5 in the presence of 30% v/v dimethylformamide, but the details of the equilibrium are not given here. The mononuclear character of the 1:1-complex formed at pH < 3 was proved by the linearity of transformation (5), derived from (1):

$$\frac{C_R}{A - A_{0R}} = \frac{1}{\varepsilon_{1H} - \bar{\varepsilon}_R} + \frac{1}{\gamma_1(\varepsilon_{1H} - \bar{\varepsilon}_R)\{C_M - m(A - A_{0R})/(\varepsilon_{1H} - \bar{\varepsilon}_R)\}^m} \tag{5}$$

where m is the number of metal ions in the complex, $\bar{\varepsilon}_R$ is the apparent molar absorptivity for the ligand irrespective of the species present, and γ_1 is the apparent stability

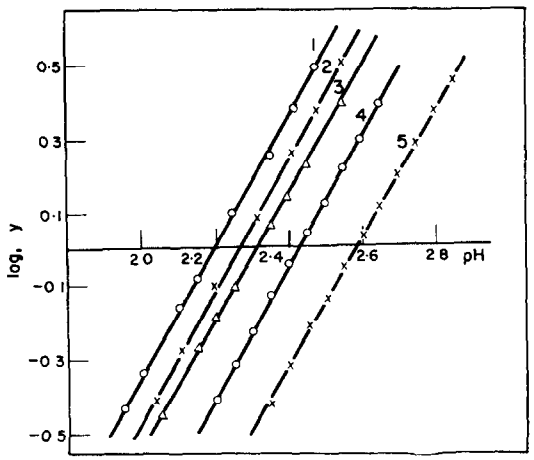

FIG. 4.—Logarithmic plots according to equation (3).

$y = \log \dfrac{A(1 + K_{a1}/[H]) - A_{0R}}{A_{01} - A}$. Working conditions as in Fig. 3.

constant for MRH. The plot $C_R/(A - A_{01}) = f(1/C_M)^m$ was only linear when $m = 1$, pH = 2·1, $C_R = 1{\cdot}22 \times 10^{-4}M$ and $C_M = 10^{-3}$–$10^{-2{\cdot}3}M$. From the value of ε_{1H} determined from equation (5), m can be calculated by means of equation (6):

$$\log \frac{A(1 + K_{a1}/[H] - A_{0R}}{A_{01} - A} = m \log C_M + \log \gamma_1. \qquad (6)$$

The value of m obtained was 0·8 (Fig. 5) and this shows that oligonuclear complexes are not formed in this pH region.

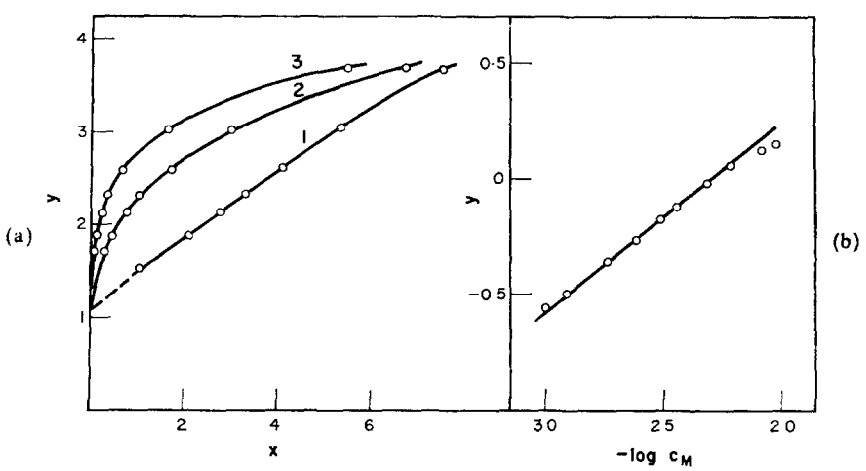

FIG. 5.—Analysis of the $A = f(C_M)$ curve at pH = 2·10, $C_R = 1{\cdot}22 \times 10^{-4}M$, $\lambda = 520$ mμ.

(a) According to equation (5); $y = C_R \times 10^4/(A - A_{0R})$; $x = 1/(C_M{}^m)$ (approximated curves); *1*—$m = 1$; *2*—$m = 2$; *3*—$m = 3$.

(b) According to equation (6); $y = \log \dfrac{A(1 + K_{A1}/[H]) - A_{0R}}{A_{01} - A}$.

Solutions with excess of ligand

The formation of two optically different uranyl(VI) chelates, one at pH < 4 and the other at pH > 6 is clearly shown from the pH–absorbance curves for aqueous equimolar solutions and solution with ligand excess (Fig. 6).

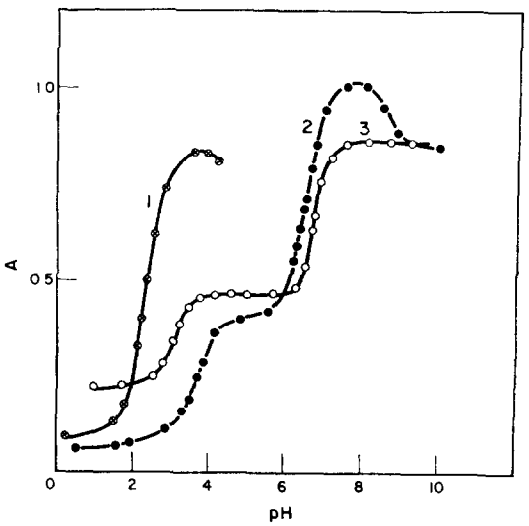

FIG. 6.—pH-Absorbance plots for UO_2-solutions with various concentrations of PAR, at 520 mμ.
1—$C_R = 5{\cdot}15 \times 10^{-5}M$, $C_M = 5{\cdot}15 \times 10^{-3}M$; *2*—$C_R = C_M = 3{\cdot}38 \times 10^{-5}M$; *3*—$C_R = 1{\cdot}35 \times 10^{-4}M$; $C_M = 1{\cdot}35 \times 10^{-5}M$.

Between pH 4 and 6·5 formation of a solid species or of colloidal solutions gives rise to erratic results, but the trouble is avoided by working with 30% v/v dimethylformamide.

The absorbance of the solutions containing excess of reagent was always corrected for absorbance of the surplus reagent at 500–530 mμ, the amount consumed in chelation being taken into account.

The pH–absorbance curve at pH < 3 (Fig. 7) shows the formation of UO_2RH^+, according to equilibria (A) and (B). This chelate coexists with a further chelate which is formed quantitatively at pH $> 7{\cdot}8$–8.

For solutions with excess of ligand the basic equations and transformations follow:

$$C_R \sim [H_2R] + [H_3R^+]$$
$$C_M = [M] + [MRH]$$
$$\Delta A = \varepsilon_{1H}[MRH].$$

When equilibrium (A) is valid,

$$C_M/\Delta A = \frac{1}{\varepsilon_{1H}} + \frac{[H]^2\Delta A(1 + 1/K_{a1}[H])}{[H_3R]k_{12}\varepsilon_{1H}}. \tag{7}$$

When equilibrium (B) is valid,

$$C_M/\Delta A = \frac{1}{\varepsilon_{1H}} + \frac{[H]\Delta A(1 + K_{a1}[H])}{[H_2R]k_{11}\varepsilon_{1H}}. \tag{8}$$

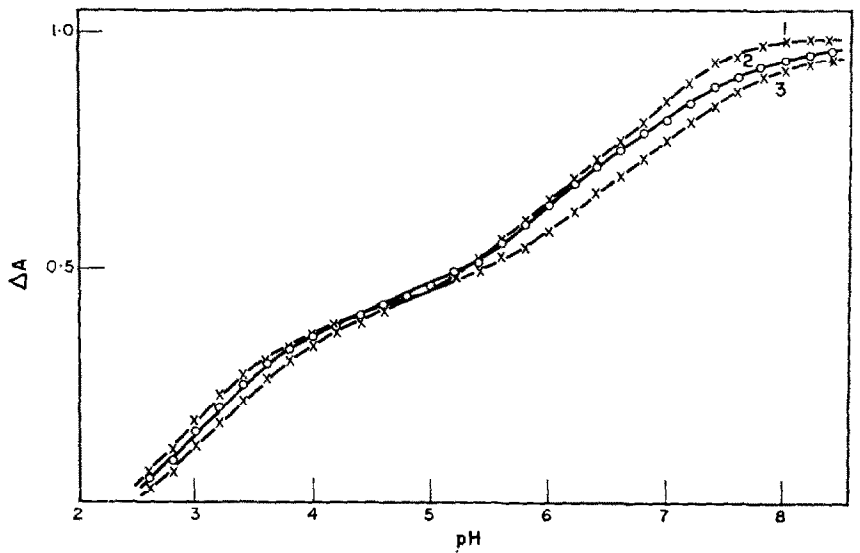

FIG. 7.—pH-Absorbance plots for UO_2^{2+} solutions with various excesses of PAR in the presence of 30% v/v dimethylformamide.
510 mμ; $C_M = 2{\cdot}5 \times 10^{-5}M$; C_R/C_M: *1*—6·37; *2*—12·75; *3*—19·12. The absorbance of the ligand is subtracted.

We also have

$$\log\left\{\frac{\Delta A}{A_{01} - \Delta A}\right\} = \log\{[H]^2(1 + 1/K_{a1}[H])\} + \log[H_3R] + \log k_{12}. \qquad (9)$$

In the second formation region at pH > 6 the principal equilibria must be selected from the following:

$$MRH + H_2R \rightleftharpoons M(RH)_2 + H^+ \qquad (C)$$

$$MR + HR^- \rightleftharpoons MR_2 + H^+ \qquad (D)$$

$$MRH \rightleftharpoons MR + H^+ \qquad (E)$$

$$MRH + HR^- \rightleftharpoons MR_2 + 2H^+ \qquad (F)$$

$$2MRH \rightleftharpoons MR_2 + M^{2+} + 2H^+. \qquad (G)$$

It is difficult to distinguish the equilibria involving ligand from those such as (E) and (G) in solutions with excess of ligand. However, the parts of the pH curves at pH 5·5–7 are slightly shifted to higher pH values with increasing ligand concentration. Further, only 1:1-chelates were found at pH < 8·5 by Job's method and the tangent ratio plots (*vide infra*). Hence no further ligand is co-ordinated to the UO_2RH^+ chelate at pH > 6 and only the equilibria (E) and (G) need to be considered.

The splitting off of one proton according to equations (10), (11) and (12) and the equilibrium (E) was proved by the constant values of the molar absorptivities and the equilibrium constant, K_{Ra1}, obtained when these equations were used for results from solutions with $C_M = 2{\cdot}5 \times 10^{-5}M$, $C_R/C_M = 6$–19 in 30% v/v dimethylformamide, or with $C_M = 2{\cdot}5 \times 10^{-5}M$, $C_R = 2{\cdot}00 \times 10^{-4}M$ in aqueous solutions and over the

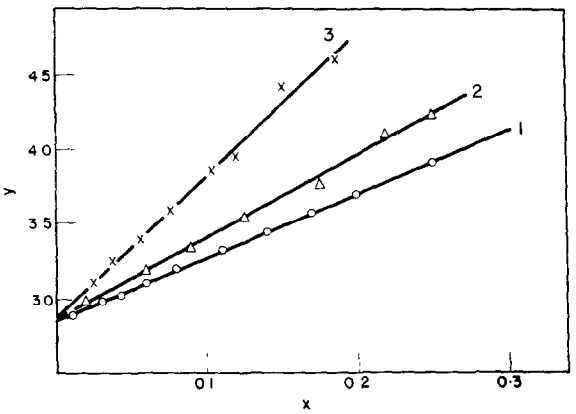

FIG. 8.—Analysis of the second linear portions of the pH-absorbance plots in Fig. 7, according to equation (11).

$y = C_M \times 10^5/\Delta A$; $x = \frac{(\Delta A - \varepsilon_{1H}C_M)[H]}{\Delta A}$; C_R/C_M: *1*—6·37; *2*—12·75; *3*—19·12.

wavelength range 510–520 mμ (Figs. 8 and 9).

$$C_M = [MRH] + [MR]$$

$$A = \varepsilon_{1H}[MRH] + \varepsilon_1[MR]$$

$$K_{kal} = [MR][H]/[MRH]$$

$$C_M/\Delta A = \frac{1}{\varepsilon_{1H}} - \frac{(\varepsilon_1 C_M - \Delta A)K_{kal}}{[H]\Delta A\varepsilon_{1H}} \tag{10}$$

$$C_M/\Delta A = \frac{1}{\varepsilon_{1H}} + \frac{(\Delta A - \varepsilon_{1H}C_M)[H]}{\varepsilon_1 \Delta A K_{kal}} \tag{11}$$

$$\log \frac{\Delta A - \varepsilon_{1H}C_M}{\varepsilon_1 C_M - \Delta A} = pH + \log K_{kal} \tag{12}$$

where ε_1 is the molar absorptivity of the UO_2-PAR complex. The value of ε_{1H} calculated from the intercept of (10), using for ε_1 the value obtained from the horizontal line of the pH curve, agreed well with the value found for solutions with metal ion excess when equation (1) was used. Similarly the same value of ε_1 was obtained from equation (11) when the value of ε_{1H} calculated from equation (1) for solutions with metal ion excess was used. Values of ε_1 and K_{kal} were also calculated for various points of the pH-curve between pH 5·8–7 when this value of ε_{1H} was used in equations (13) and (14):

$$\varepsilon_1 = \frac{a_1\Delta A_2 - a_2\Delta A_1}{C_M(a_1 - a_2)} \tag{13}$$

where $a = (A - \varepsilon_1 C_M)[H]$,

$$K_{kal} = \frac{(A - \varepsilon_{1H}C_M)[H]}{\varepsilon_1 C_M - \Delta A}. \tag{14}$$

The values for ε_1 and K_{kal} agreed well with those found from equations (10), (11) and (12). This agreement is proof that equilibrium (E) predominates.

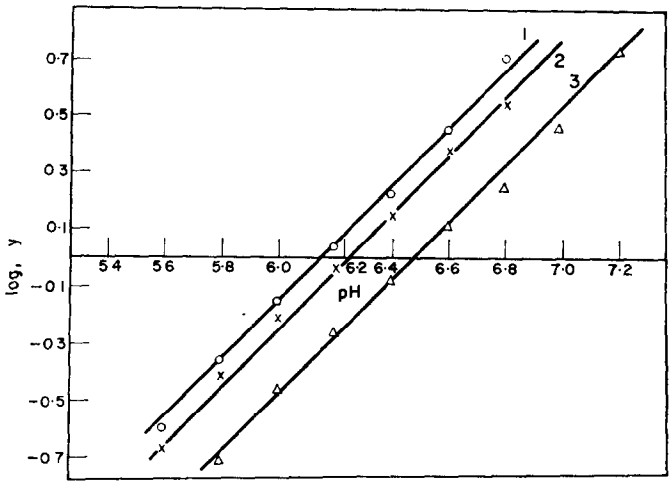

FIG. 9.—Logarithmic plots according to equation (12) for the second linear portions of the pH-absorbance curves in Fig. 7.

$$y = \frac{\Delta A - \varepsilon_{1H} C_M}{\varepsilon_1 C_M - \Delta A}\ ;\quad C_R/C_M\text{: } 1\text{—}6{\cdot}37;\ 2\text{—}12{\cdot}75;\ 3\text{—}19{\cdot}12.$$

No explanation is given for the shift of the linear logarithmic plots (12) to higher pH values with increasing ligand concentration. It seems that the formation of the MRH-complex is preferred and the transition (E) delayed when the concentration of the ligand is increased.

Note: For calculations the absorbance of the total concentration of reagent $C_R = [H_2R] + [HR^-]$ was always subtracted from the measured absorbance, the concentration of ligand bound in chelates being neglected.

Other evidence for the 1:1 *complex*

Continuous variation and slope-ratio plots (Figs. 10 and 11) indicated the existence of a 1:1 complex over the pH range 3·1–8.

Molar absorptivities and constants of the UO_2-chelates

The results calculated by various methods are summarized in Tables II and III for both chelates. The following additional constants were defined to characterize both uranyl-chelates:

$$k_{12} = [MRH][H]^2/[M][H_3R] = k_{11}K_{a1}$$
$$K_{1H} = [MRH]/[M][HR^*] = k_{12}/K_{a2}{}^*K_{a1} = k_{11}/K_{a2}{}^* = k_{11}/K_{a3}$$
$$K_{kal} = [MR][H]/[MRH]$$
$$K_1 = [MR]/[M][R] = K_{kal}K_{1H}/K_{a3}{}^* = K_{kal}K_{1H}/K_{a2}.$$

For an explanation of the equivalence of $K_{a2}{}^*$ with K_{a3}, and of $K_{a3}{}^*$ with K_{a2} see Sommer and Ivanov.[4]

The protonated UO_2RH^+ is a little bit more stable than the normal UO_2R. Of the values of constants given by Geary *et al.*[11] only that of $\log K_1 = 12{\cdot}5$ agrees with $\log K_{1H}$ found here. Since no 1:2-complex with uranium(VI) exists, the values given for $\log K_2 = 8{\cdot}4$ for water or 9·6 for 50% v/v water-dioxane are rather confusing and differ seriously from the value of $\log K_{kal} = 6{\cdot}3$ found in this study.

The nature of the solid products

To a 1M perchloric acid solution containing 100 μg of uranyl ion and 50 ml of $1{\cdot}25 \times 10^{-2}M$ PAR, 0·5M ammonia was added dropwise (the ratio UO_2:PAR was 5:7). The solution was carefully shaken and left for some hours in a dark place. Two slightly different crystalline solids were precipitated at pH 1·84 and pH 3·35. They were filtered off on sintered glass, washed with a little ethanol and water and then dried over silica gel in a vacuum desiccator. The hues of the dry solids are quite different—deep red and dark brown-red. The solids were analysed (found for precipitate obtained at pH 1·84: C 35·0%; H 3·0%; N 10·3%; U 24·9%; H_2O 7·1%, and for precipitate obtained at pH 3·35: C, 30·8%; H 3·5%; N 9·7%; U 36·1%); the elemental ratios found were U:N = 1:7 and 1:4·6, U:C = 1·28 and 1:17, respectively. The compounds are evidently of variable or non-stoichiometric composition, but that there is more than one ligand molecule per uranium atom in the solid state seems to be proved. The amount of ligand in the solid species possibly decreases as the pH of precipitation is raised.

Comments on the spectrophotometric determination of uranium with PAR

The methods due to Geary *et al.*,[1] Busev and Ivanov,[2] and Florence and Farrar[3] at pH 8 result in the quantitative formation of UO_2(PAR), which has a high molar absorptivity. The very useful mixture of 1,2-diaminocyclohexanetetra-acetic acid, fluoride and 5-sulphosalicylic acid for masking interfering ions increases the selectivity of the reaction at pH 8. The working conditions and triethanolamine buffer recommended by Florence and Farrar[3] can be fully endorsed.

Sometimes the presence of 0·1–0·2*M* triethanolamine alone guarantees good buffering capacity at pH 8 and partial masking of a number of univalent ions. The minimal ligand excess during the work should correspond to $C_R/C_M = 8$. The absorbance is fairly independent of the order of mixing the components and of the ionic strength of the solution and is little influenced by the buffer up to 0·2*M* concentration. The Lambert-Beer law is obeyed up to 7·5 ppm of uranium(VI) and the spectrophotometric sensitivity is 0·006 $\mu g/cm^2$ for $A = 0{\cdot}01$ at 530 mμ.

Determination at pH 3·6

In this case the quantitative formation of protonated UO_2(PAR)H^+ forms the basis of the method. In the presence of $\geqslant 20\%$ v/v dimethylformamide or of formate as buffer no precipitation occurs and the Lambert-Beer law is obeyed up to 12·3 ppm of uranium(VI). Increasing concentration of formate decreases the absorbance of the solution at 530 mμ (Fig. 12); hence its concentration must be the same for the sample and standards. A minimal reagent ratio of $C_R/C_M = 8$–10 and a formate

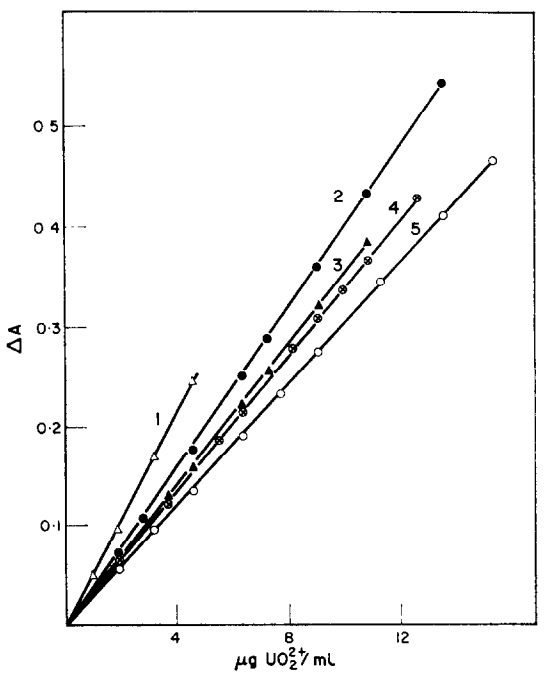

FIG. 12.—Calibration curves at pH 3·60.
$C_R = 3{\cdot}24 \times 10^{-4}M$, $\lambda = 530$ mμ. *1*—without buffer; *2*—20% v/v dimethylformamide; *3*—0·06*M* formate; *4*—0·08*M* formate; *5*—0·1*M* formate.

TABLE IV.—INTERFERENCES OF SOME SUBSTANCES IN THE DETERMINATION OF URANIUM(VI)

Substance	pH 3·6*		pH 8·0†	
	Taken, *ppm*	Error, %	Taken, *ppm*	Error, %
Bicarbonate	1186	−5·0	30·5	−5·0
Acetate	163	+4·0	8·2	+5·0

Oxalate	1	−6·6	138	−5·0
EDTA	114	−5·0	59·5	−5·8
Th(IV)	3	+5·0	3	+4·9
Y(III)	19	+5·0	0·05	+5·0
La(III), Ce(III), Pr(III), Nd(III)	75–80	+5·0	0·1–0·05	+5·0

* 7·75 ppm uranium, $C_R = 1{\cdot}935 \times 10^{-4}M$, 0·1*M* formate.
† 2·9 ppm uranium, $C_R = 9{\cdot}68 \times 10^{-5}M$, 0·1*M* triethanolamine.

concentration of not more than 0·1 *M* are recommended. Inert salts do not influence the absorbance even in high concentrations. The spectrophotometric sensitivity is 0·027 μg/cm^2 for $A = 0{\cdot}01$ at 530 mμ in the presence of 0·1*M* formate buffer. The sensitivity is only a quarter of that at pH 8 but the higher selectivity is advantageous. The interference of rare earths and a number of anions decreases. The influence of some interfering substances is summarized in Table IV. Beryllium does not interfere at pH 3·6 even in large amounts.

Zusammenfassung—Das Uranylion bildet mit 4-(2-Pyridylazo)resorcin (PAR) nur 1:1-Chelate in Lösungen mit pH <8,5, und zwar UO_2-(PAR)H$^+$ bei pH >3 und UO_2(PAR) bei pH >5,5. Es werden Gleichgewichtskonstanten und spektrophotometrische Daten für beide Chelate angegeben. Feste, nichtstöchiometrische kristalline Spezies, in welchen das Molverhältnis von PAR zu Uran höher als 1:1 ist, werden bis pH 6 gefällt. 0,1–0,2 M Triäthanolamin, das von anderen Autoren bei pH 8 empfohlen wird, erwies sich als zufriedenstellend für die empfindliche spektrophotometrische Bestimmung von Uran, ferner bei pH, 3,6 in Gegenwart von ≤0,1 M Formiat oder 20–30 Volum-% Dimethylformamid.

Résumé—L'ion uranyle et le 4-(2-pyridylazo) résorcinol (PAR) ne forment que des chélates 1:1 en solutions de pH < 8,5 UO_2(PAR)H$^+$ se formant à pH > 3 et UO_2(PAR) à pH > 5,5. On fournit les constantes d'équilibre et les données spectrophotométriques pour les deux chélates. Des espèces cristallines solides, non stoechiométriques, dans lesquelles le rapport molaire PAR-uranium est plus que 1:1 sont précipitées jusqu'à pH 6. Le milieu triéthanolamine 0,1–0,2*M* à pH 8 recommandé par d'autres auteurs s'est révélé satisfaisant pour le dosage spectrophotométrique sensible de l'uranium, ainsi que le milieu pH 3,6 en présence de formiate <0,1*M* ou de diméthylformamide 20–30% v/v.

DETERMINATION OF TERTIARY AMINES AND SALTS OF ORGANIC ACIDS IN ACETIC ACID BY CATALYTIC THERMOMETRIC TITRATION

VILIM J. VAJGAND and FERENC F. GAÁL
Institute of Chemistry, Faculty of Science, University of Belgrade, Studentski trg 16, Yugoslavia

(*Received* 20 *April* 1966. *Accepted* 12 *October* 1966)

Summary—A new method of determination of tertiary amines and salts of organic acids in acetic acid solution, to which about 2% of water and 8% acetic anhydride are added, is described. After the equivalence point, the excess of perchloric acid catalyses the exothermic reaction of water with acetic anhydride. The end-point is determined from the graph of temperature against volume of added titrant. If a slightly soluble compound is produced during the titration, the precision of the new method is superior to that of the potentiometric method.

IT is known that by the hydrolysis of acetic anhydride a considerable amount of heat is liberated, but that the process is slow. However, strong acids accelerate this hydrolysis.[1] This reaction was successfully applied by Greathouse *et al.*[2] for the determination of acetic anhydride and water in glacial acetic acid by thermometric titration. Keily and Hume[3] determined by thermometric titration different weak organic bases and salts of organic and inorganic acids by titrating them with perchloric acid in glacial acetic acid. The titration system should not contain at the same time water and acetic anhydride, since these two components, though reacting only slowly before the equivalence point, start a violent reaction after reaching that point in the presence of a slight excess of perchloric acid as catalyst. A sudden and uncontrolled increase in temperature after the equivalence point makes thermometric titration of bases impossible, even if the differential method is applied. Temperature changes at the titration end-point are slight (less than 0·1°), and the titration curve is of the usual shape, *i.e.*, it rises linearly to the equivalence point, and then it drops, also linearly.

As has been seen, the reaction between water and acetic anhydride is a disadvantage for thermometric titrations in glacial acetic acid. On the basis of this reaction we have, however, been able to develop a new procedure based on the following principles: the base is titrated in glacial acetic acid containing a certain amount of water and acetic anhydride, with a perchloric acid solution in glacial acetic acid. The reaction between water and acetic anhydride is slow till the equivalence point, but after it, with the first excess of perchloric acid, it shows a sudden acceleration. A particular problem was the determination of the titration end-point, and we developed three methods for determining it: from the intersection of two straight lines, from the intersection of a straight line and a curve, or by means of a calibration curve.

The method is based on the titration of bases with perchloric acid, which acts as a catalyst in the water-acetic anhydride, and it should, therefore, be classified as a

"catalymetric" titration.[4] Because the titration end-point is determined from the increase in temperature, as in thermometric titrations, we propose the name catalytic-thermometric titration for this type of analysis. On a similar principle Vaughan and Swithenbank[5] determined weak acids in acetone, by titrating them with a 1*M* solution of potassium hydroxide in isopropanol. At the end-point, the free potassium hydroxide caused polymerization of the acetone, giving a large temperature rise.

EXPERIMENTAL

As solvent we used glacial acetic acid (C. Erba, s.g. 1·051 and Oswiecim zaklady chemiczni, s.g. 1·049–1·060) mixed with acetic anhydride (C. Erba, s.g. 1·08), in the ratio 12:1. The 0·25*M* solution of perchloric acid (Kemika *p.a.*, s.g. 1·07) in glacial acetic acid was standardized potentiometrically with sodium acetate, a Radiometer pH meter type pH M 22 m being used. For potentiometric determination of the substances used, as well as for the standardization of perchloric acid, a glass electrode was used coupled with a mercury/mercury(I) acetate electrode.[6] When halogen acid salts of organic bases were titrated, a 3% mercuric acetate solution was added. Because of the expansion of the glacial acetic acid as the temperature rose during titration, the necessary corrections to the molarity of the titrant were always made.[7] Titrations were made by means of a calibrated Metrohm piston burette, type E 274, 20-ml capacity, scale graduated to 0·02 ml. Temperature was measured with either a thermometer or a thermistor.

For thermometric operations the 50-ml beakers used were lined on the outside with tinfoil and placed in 100-ml beakers, and these were then placed in 400-ml beakers which were lined on the inside with filter paper and had a perforated cork insulator at the bottom. The solutions were stirred magnetically. Experiments were also carried out in Dewar vessels, though the results obtained when using ordinary glass beakers were satisfactory.

RESULTS AND DISCUSSION

The solvent selected contained 8% of acetic anhydride and 2% of water. The mechanism of the exothermic reaction between water and acetic anhydride is not yet definitely known.[8] We measured the reaction rate as a function of the quantity of perchloric acid added as catalyst at the initial temperatures of 22° and 28°, by following temperature changes in the reaction mixture (total volume 26 ml). The results obtained at 28° are shown in Fig. 1. The graph obtained at 22° is of similar shape, but the reaction rate is lower.

If, on the basis of the values from Fig. 1, a graph is plotted of temperature rise against the amount of perchloric acid present, the function is linear if temperature readings are taken less than 2 min after each addition of reagent, independent of the initial temperature of the solution. Therefore, if the addition of perchloric acid is made at equal intervals of time, the increase in temperature must be exponential in character, even if the exponential effect of temperature on the reaction rate is left out of account. This is evident if the temperature changes during titration are plotted either on ordinary or semi-log paper (Figs. 2a and 2b). When plotted on ordinary paper, the temperature curve rises linearly to the equivalence point, and then exponentially if the readings are taken at 1-min intervals after addition of the titrant. If, however, the temperature changes are plotted logarithmically, the values before the equivalence point lie on a curve, and on a straight line after it. The equivalence point is easily determined from the intersection of the lines.

To determine the end-point from a graph plotted on ordinary paper, we developed the following procedure. The titration is carried out by adding equal amounts of titrant at equal intervals of time to the solution titrated, and reading the temperature at a given time after adding the titrant, *e.g.*, 1 min. The equivalence point is reached when there is a sudden temperature rise. Then yet another point is determined in the same manner, while the subsequent reading is taken at half the time interval. Thus

three more points are obtained after the equivalence point. By connecting the points two straight lines are obtained, the intersection of which is the titration end-point (Fig. 2a). The figures circled represent the values after which no more titrant is added. Temperature readings can also be started when 75% of the base has been titrated. To determine the end-point precisely from the graph on ordinary paper, it is imperative to know the maximum temperature rise caused by 0.10 ml of 0.25*M* perchloric acid at the working temperature. These maximum temperature changes for a total volume

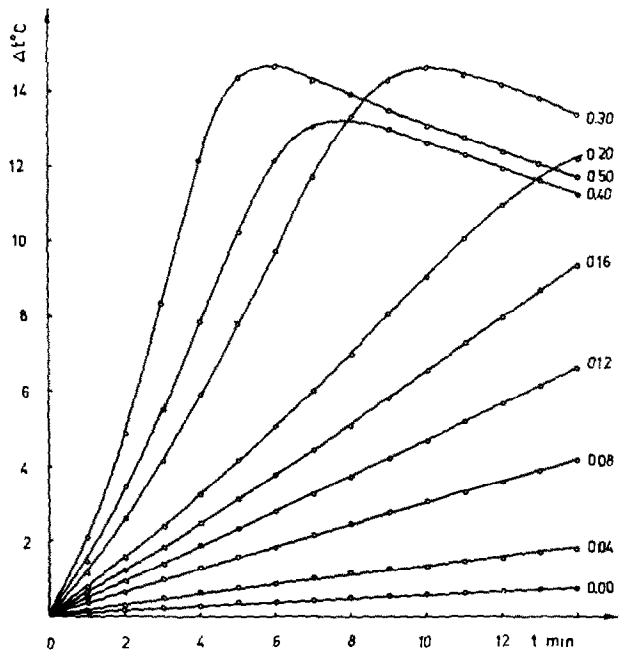

FIG. 1.—Changes in rate of reaction of water and acetic anhydride with change in concentration of perchloric acid, at 28°C.

of 26 ml at different initial temperatures are shown in Fig. 3. The end-point can be determined without this function being known, but if the temperature rise after the end-point is too large or too small, this function can be used to resolve the dilemma of whether the temperature measured is to be taken as the first or the second point used to obtain the straight line after the equivalence point.

The end-point can also be determined by means of a calibration curve based on the data given in Fig. 1. The product of the temperature change and the total volume of solution is plotted against the volume of perchloric acid added. Straight lines are obtained, the slopes of which depend on the initial temperature and the time at which the temperature readings are taken. The titration is continued until the first increase in temperature after the equivalence point. Temperature readings are taken every minute, but no more perchoric acid is added to the solution. The effect of the catalyst in the water–perchloric acid–acetic anhydride system is proportional to its amount, and so this excess of perchloric acid can be determined from the calibration curve. The results and average deviation obtained by the first two methods (Figs. 2a and 2b)

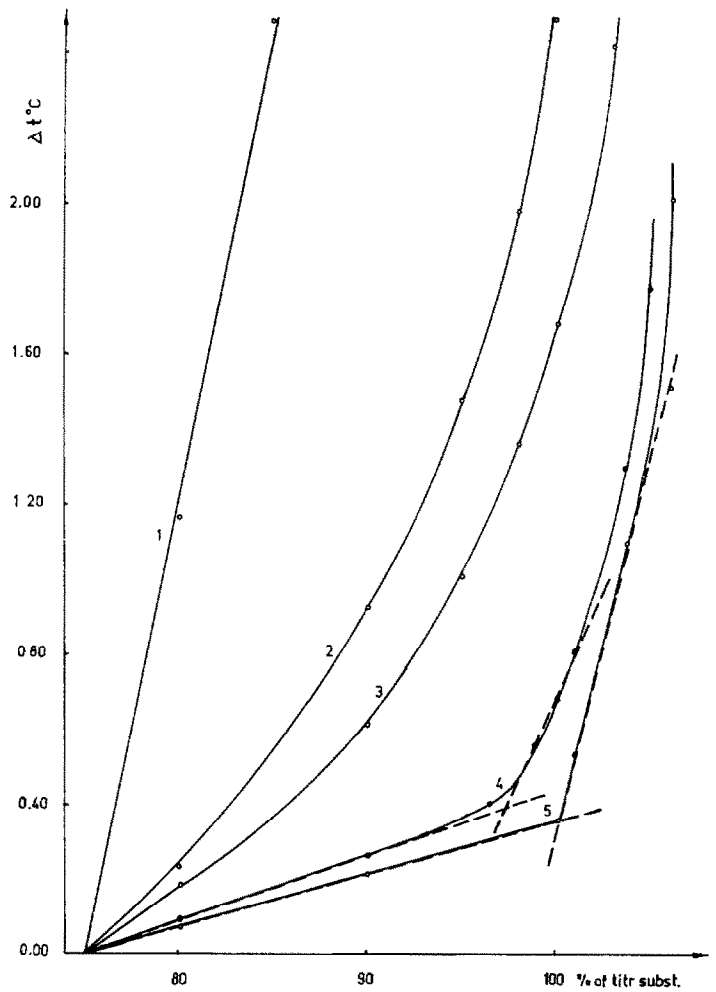

FIG. 4.—Catalytic thermometric titration curves for bases of different strengths: *1* — caffeine; *2* — 2-methyl-5-nitro-imidazole; *3* —novalgin; *4* —antipyrine; *5* — potassium biphthalate.

are in good agreement with those achieved potentiometrically, but in the calibration curve method the deviations are considerable.[9]

By the catalytic thermometric method described, the determinations of bases are improved as the potential change around the equivalence point increases. Very weak bases, such as caffeine or 2-methyl-5-nitro-imidazole, cannot be determined under these conditions, since their basicity is already so weak that the catalytic reaction takes place in preference to neutralization. Titration curves for such bases, plotted on ordinary paper, are given in Fig. 4. As can be seen, antipyrine cannot be determined precisely (the error amounts to −2·8%), whereas with potassium biphthalate a pronounced rise in temperature appears immediately after the disappearance of the base from the solution, *i.e.*, the end-point is identical with the equivalence point. The results of determinations by this method are much more reproducible than those

obtained potentiometrically, if the substances titrated give precipitates with perchloric acid. This can be seen from Table I, where results and average deviations are given for determinations by both methods. The concentrations of the bases ranged from $2{\cdot}5 \times 10^{-2}$ to $5{\cdot}7 \times 10^{-2}N$, and the quantities taken were from 0·63 to 1·4 mequiv. Even lower concentrations can be titrated by this method.[9]

In comparison to the results obtained by various electrochemical methods developed earlier and described in previous papers, [10–13] it can be seen that the new method gives high accuracy and reproducibility.

Acknowledgement—We express our gratitude to the Pharmaceutical Industry "Galenika", Beograd for supplying us with the samples of the substances investigated.

Zusammenfassung—Es wird eine neue Methode beschrieben, tertiäre Amine und Salze organischer Säuren in Essigsäurelösung, welcher etwa 2% Wasser und 8% Acetanhydrid zugefügt werden, zu bestimmen Nach Erreichen des Äquivalenzpunktes katalysiert die überschüssige Perchlorsäure die exotherme Reaktion von Wasser mit Acetanhydrid. Der Endpunkt wird durch die graphische Darstellung der Temperatur gegen das Volumen des zugefügten Titranten bestimmt. Falls sich während der Titration eine schwerlösliche Verbindung bildet, ist die Genauigkeit der neuen Methode der potentiometrischen überlegen.

Résumé—On décrit une nouvelle méthode de dosage des amines tertiaires et des sels d'acides organiques en solution dans l'acide acétique auquel on ajoute environ 2% d'eau et 8% d'anhydride acétique. Au-delà du point d'équivalence, l'excès d'acide perchlorique catalyse la réaction exothermique de l'eau avec l'anhydride acétique. Le point de fin de dosage est déterminé à partir de la courbe de la température en fonction de volume d'agent de titrage ajouté. Si, lors du dosage, il se forme un composé faiblement soluble, la précision de la nouvelle méthode est supérieure à la méthode potentiométrique.

HYDROXYTRIAZENES—A REVIEW OF A NEW CLASS OF CHELATING AGENTS

D. N. PUROHIT*
Laboratory of Analytical Chemistry, Polarographic Institute of J. Heyrovský, ČSAV, Jilská-16, Praha-1, Czechoslovakia

(*Received* 22 *September* 1966. *Accepted* 1 *November* 1966)

Summary—A review of the applications of hydroxytriazenes as chelating agents in analytical chemistry.

THE new class of organic reagents, hydroxytriazenes, is of comparatively recent origin. This review gives a survey of analytical applications of this potentially useful class of organic reagents.

Since the syntheses of hydroxytriazenes by Bamberger[1] and others,[2] the complexing ability of these compounds has been examined by Elkins and Hunter.[3] They reported that these compounds form well defined crystalline complexes with Cu(II), Ni(II), Co(II), Co(III), Fe(II) and Fe(III), but Sogani and Bhattacharya[4] first evaluated their analytical usefulness. Sogani and co-workers later prepared a large number of these compounds and discussed and described their analytical use.[5–8]

Two methods have been reported for the preparation of these compounds:

(i) by the action of phenylhydrazine or substituted phenylhydrazine[1] on aliphatic or aromatic nitro or nitroso compounds

(ii) by the coupling reaction of diazo compounds[4] with alkyl or aryl-substituted hydroxylamines.

The latter method seems to have been preferred. These compounds possess the common functional grouping —N(OH)—N=N—.

Ultraviolet and infrared absorption studies of a large number of hydroxytriazenes have been made and an intramolecular hydrogen-bonded structure has been assigned.[9] In the case of 3-hydroxy-1,3-diphenyl triazene, an intramolecular hydrogen-bonded structure and its tautomeric forms have been postulated[10] on the basis of its acid dissociation constant and ultraviolet absorption. Tautomerism is also reflected in the synthesis of both the *O*- and *N*- ethers.[11]

3-*Hydroxyl*-1,3-*diphenyltriazene*

This is a light yellow compound, m.p. 119–120°. Its spectral characteristics in alcohol are: λ_{max} 238 and 348 mμ; log ε 4·186 and 4·328 respectively. It is stable towards heat, light, and air, and can be preserved indefinitely. Many of its complexes are granular, insoluble in water, thermally stable, of definite composition, and suitable for direct weighing. The reagent is not very soluble in water but the excess of the reagent can be removed easily either by washing with dilute alcohol or by

* Present address: Department of Inorganic Chemistry, University of Copenhagen, Universitetsparken, 5, Copenhagen.

heating the weakly acidic solution to hydrolyse it to water soluble products. The washings can be checked for presence of reagent by addition of a drop of sodium hydroxide solution. If alcohol has been used an intense yellow colour appears, and a blue colour if the reagent was hydrolysed. Below pH 3 the reagent precipitates only Cu(II), Pd(II), Fe(III), V(IV), Ti(IV), and molybdate. Only the first two are stable if the acidic reaction medium is heated.

Estimation of palladium. A granular yellowish green palladium(II) complex is quantitatively precipitated between pH 1·6 and 8. It is soluble in acetone, chloroform, carbon tetrachloride and benzene, and crystallizes from acetone as silky yellowish brown needles, m.p. 252°. Spectral characteristics in alcohol are λ_{max} 255 and 413 mμ with log ε 4·585 and 4·384 respectively.

In estimations the pH is kept between 2 and 3 (hydrochloric acid and sodium acetate) and a 20–25% excess of the reagent is added. Palladium can be estimated in the presence of Ni, Co(II), Zn, Al, Cr(III), Cd, Mn(II), Sb(III), Bi(III), As(III) Be, UO_2(II), Fe(III), Zr, Ce(IV), and nitrate. In separations from Ce(IV) and Zr(IV), no sodium acetate or sodium potassium tartrate should be added, the pH being adjusted by dilution only, as prolonged heating in the presence of buffering agents causes a turbidity and high results. Au(III), Ag(I), and Os(IV), interfere by being reduced to the metallic state by the reagent. Pt(IV) even in 10-fold times excess does not interfere. Separation from Rh(IV), Ru(III), Ir(III), Th, Sn(IV), Pb, Ti, molybdate, fluoride, and phosphate has also been described. No actual separation of palladium from alkali or alkaline earth metals has been carried out but none of these elements forms a precipitate with the reagent, so they should be separable. The reagent is said to be superior to dimethylglyoxime.

Estimation of copper. A granular chocolate brown copper complex is completely precipitated between pH 1·9 and 7 with a slight excess of the reagent. The complex is highly soluble in benzene, chloroform, and carbon tetrachloride, fairly soluble in ether and acetone, and only slightly soluble in alcohol. It crystallizes from acetone as brown silky needles, m.p. 193°. Spectral characteristics in alcohol are: λ_{max} at 247, 283 and 362 mμ, log ε 4·563, 4·132, and 4·572 respectively.

Estimations are carried out between pH 2·3 and 3·0 to facilitate hydrolysis of excess of reagent and increase specificity. Cu(II) (13–17 mg) has been determined in the presence of 50 mg of Ni, Zn, Mn(II), Cd, Bi(III), Al, Cr(III), Hg(II), As(III), Pb, Sb(III), Zr, UO_2(II), Ce(IV), Th, Be, Co(II), Fe(II), Fe(III), Ti, Sn(IV), nitrate phosphate, fluoride, tungstate, and molybdate. Ag(I), Au(III), and Os(IV) interfere by reduction to the metallic state by the reagent, but this reaction may be prevented by addition of cyanide. Copper cannot be estimated in the presence of palladium, and cannot be separated quantitatively from V(V), and V(IV), because of their partial coprecipitation.

The reagent has been reported[12] to be superior to all the copper reagents described in the literature, including salicylaldoxime and α-benzoinoxime.

Estimation of nickel. Nickel is precipitated quantitatively between pH 4·4 and 7·0. The deep yellow complex has solubility properties similar to those of the copper complex, and crystallizes from acetone as bright yellow needles, m.p. 209°. Spectral characteristics in alcohol are λ_{max} 248, 320 and 410 mμ and log ε 4·455, 4·391, and 4·199 respectively. Nickel has been estimated between pH 5·0 and 5·5 in the presence of Zn, Mn(II), Cd, Mg, As(III), Be, phosphate and fluoride.

Reaction with titanium. The reagent precipitates titanium quantitatively,[12] but the complex is substantially soluble when the concentration of alcohol in the reaction medium is above 5%. The complex also decomposes if the medium is heated above 55°, and is therefore unsuitable for direct weighing.

Vanadium complex. Dutta and Lahiry[13,14] have made a detailed structural study of V(V) and V(IV) complexes of 3-hydroxy-1,3-diphenyltriazine. With the aid of X-ray powder patterns, IR spectra, molecular weights, and magnetic moments they have given a convincing proof that V(V) and V(IV) form the same complex with the reagent, *i.e.*, first V(V) is reduced to V(IV) by the reagent and then V(IV) forms the complex. Reactions of the complexes with pyridine have also been described. A preparative study of V(IV) and V(V) complexes of a number of hydroxytriazines[15] has been reported and reactions of the complexes with pyridine and picoline were also carried out, but so far no attempt has been made to estimate vanadium in either oxidation state with this reagent.

Copper and cadmium separation. Recently the reagent has been used fori dentification and separation of copper and cadmium by Poonia and Gupta.[16]

Electrochemical reduction and polarographic behaviour of 3-hydroxy-1,3-diphenyltriazine. The reduction process for the reagent is reported to be irreversible, with half-wave potential dependent on concentration, *e.g.*, at pH 2·18, $E_{1/2}$ varies from −0·723 to −0·685 V as concentration varies from 0·3 to 0·1 × $10^{-3}M$. A different reduction mechanism at different pH values has been suggested, but the ultimate reduction products have been reported to be the same, *i.e.*, aniline and phenylhydrazine. A polarographic method has been recommended for the detection and estimation of 3-hydroxy-1,3-diphenyltriazene.[17]

3-*Hydroxy*-1-(p-*chlorophenyl*)-3-*phenyltriazene*

This is a light greenish yellow compound, m.p. 140°. Spectral characteristics in alcoholic solution are λ_{max} 235, 281, and 350 mμ, log ε 3·991, 3·874, and 4·183 respectively.

Estimation of titanium.[12] This reagent precipitates titanium quantitatively as a bright orange complex, which is stable up to 100° in an aqueous acidic reaction medium. The optimum pH was found to be between 2·2 and 2·5. The complex crystallizes from alcohol as bright yellow crystals, m.p. 146°. With this reagent, Ti (10 mg) has been estimated in the presence of 50 mg each of Zn, Mn(II), Cd, Co(II), Ni, Hg(II), As(III), UO_2(II), Th, Mg, Cr(III), and Al. The complex is not, however, of definite composition and has to be ignited to titanium dioxide before weighing. Zr, Ce(IV), Cu(II), Pd(II), Fe(II), Fe(III), Mo(VI) and V(V), interfere because of coprecipitation. Phosphate and tungstate precipitate the corresponding titanium salts and hence interfere in the determination.

The reagent however compares well with other reagents for titanium and is superior to the related compounds, cupferron and *N*-benzoylphenylhydroxylamine.

The reagent offers no advantage over the parent compound of the series for the estimation of palladium, copper, and nickel.

3-*Hydroxy*-1-(o-*nitrophenyl*)-3-*phenyltriazene*[18]

This is an orange red compound, m.p. 150°, reported as a qualitative reagent for detection of nickel and zinc in the presence of Fe(II), Fe(III), Al and Mn(II).

With zinc at pH 5–6 it forms a red precipitate (dilution limit 1 in 3×10^4) and with nickel a violet precipitate (dilution limit 1 in $5{\cdot}2 \times 10^4$). It has been used for the colorimetric determination of zinc in ores.[19]

3-Hydroxy-1-(p-nitrophenyl)-3-phenyltriazene

The compound is greenish yellow, insoluble in water, soluble in alcohol, acetone and toluene and gives a yellow solution. With strong alkali a red colour develops. The reagent has been reported by Pochinok *et al.*[20,21] for the detection and colorimetric determination of magnesium. In alkaline solution the colour changes from yellow to orange to red between pH 11 and 12. A 0·05% solution of the reagent is prepared in alcohol and 2–3 ml of this solution are added to 100 ml of 1% sodium hydroxide solution for further use. With magnesium in neutral or weakly acidic medium it develops a rose-violet or blue-violet colour depending on the concentration of magnesium. The detection limit is 1 ppm. If the magnesium concentration is greater than 0·05 mg/ml, precipitation takes place. Alkali metals, alkaline earths, and lead do not interfere. Cations of the third and fourth analytical groups, which are precipitated by sodium hydroxide, do interfere and should be removed. The most intense colour is with magnesium, stable for 1 hr, is reported to be obtained with a reagent containing 2 g of borax 0·6 g of sodium hydroxide, 100 ml of water and 3 ml of a 0·05% alcoholic solution of the reagent.

3-Hydroxy-1-(p-sulphophenyl, sodium salt)-3-phenyltriazene

This is a light yellow water-soluble compound and forms water-soluble complexes. The solid starts decomposing at 157°, and the acid has a pK value of 9·99. Spectral characteristics are λ_{max} 235 and 345 mμ; log ε 4·178 and 4·441 respectively. It has been used as a colorimetric reagent for various metal ions.

Palladium. Sogani and Bhattacharya[22] were the first to synthesize this compound and to report it as a colorimetric reagent for palladium. A spectrophotometric and conductometric study of the palladium complex has been made by Durgapal and Sogani.[23] The composition of the complex is reported to be PdR_2 (where R is the anion of the reagent). Maximum absorbance is at 413 mμ, but to avoid interference the reagent wavelength of 420 and 430 mμ have been used. The sensitivity of the colour reaction is reported to be 0·05 ppm, and the identification limit as 0·05 μg of palladium in 0·15 ml of solution. The optimum pH range for maximum absorbance is between 1·7 and 4·4, but 2·5–3 is preferred. Colour development is instantaneous and maximum colour development is ensured with a 3-fold excess of reagent. Beer's law is obeyed over the concentration range 0·2–5 ppm. From 25° to 85° there is no change in absorbance. Palladium has been estimated in the presence of Cu(II), Ni, Fe(III), Co(II), Pt(IV), Rh(IV), Ir(III) and Ru(III). The reagent is claimed to be superior to other spectrophotometric reagents for palladium.

Iron. With Fe(III) it forms a bluish black water-soluble complex with absorption peaks at 520 and 650 mμ, in the pH range 2–4·3. The composition FeR_3 has been established by conductometric and spectrophotometric methods.[24] Both methods have indicated that FeR and FeR_2 are also formed. The sensitivity was found to be 0·2 ppm, and the identification limit 0·1 μg of iron in 0·15 ml of solution. Colour development is instantaneous, with maximum colour development ensured with a 4-fold excess of reagent, and Beer's law is obeyed from 1–20 ppm. Iron(III) has been

estimated[25] in the presence of Co(II), Ni, Zn, Mn(II) and Fe(II), and the possibility of its determination in the presence of various other metal ions has been discussed.

Molybdenum. Molybdenum(VI) forms[26,27] an orange yellow water-soluble complex with the reagent in the pH range 2·8–3·7 with an absorption peak at 416 mμ. Its composition is reported to be $(MoO)R_3$. Colour development is not instantaneous but takes about 20 min, reaching a maximum with a 6-fold excess of reagent. The kinetics of this reaction were studied and the reaction found to be first-order, with specific reaction rate constant 0·1606. The sensitivity is reported to be 0·2 ppm, and Beer's law is obeyed from 1·5 to 25 ppm. Molybdenum has been estimated in the presence of the commonly associated diverse ions Cu(II), Ni, Zn, Mn(II), Co(II), UO_2(II), Ca, and W(VI).

The reagent is said to compare well with thioacetic acid, and is superior to it in having greater tolerance for W(VI).

Titanium. Titanium[28] forms a bright yellow complex with the reagent in the pH range 1·9–3·3 with an absorption peak at 405 mμ. Spectrophotometric studies suggest a 3:1 ratio of ligand to metal. Colour development is instantaneous, but a 16-fold excess of reagent is needed for maximum absorbance. To avoid reagent interference, the absorbance is measured at 425 mμ. Beer's law is obeyed from 0·3 to 2·5 ppm. Titanium has been estimated in the presence of Zn, Mn(II), Ni, Co(II), Cd, Hg(II), Mg, Be, Al and Cr(III). Cu(II), Fe(II), Fe(III), Pd(II), vanadate, phosphate, tartrate, fluoride, and tungstate interfere.

Copper, nickel, and cobalt. Spectrophotometric and conductometric studies on the complexes of copper,[29] nickel,[30] and cobalt,[31] have been reported. Copper forms a pale yellow complex with an absorption peak at 405 mμ. It is formed instantaneous and maximum absorbance occurs between pH 4·4 and 6·2. The composition is reported to be CuR_2. The yellow nickel complex has an absorption peak at 420 mμ. Optimum pH range is 3·8–5·9 and the composition is NiR_2. In this pH range the selectivity of the reagent is fairly low, so it is not very useful for the colorimetric estimation of nickel. Cobalt forms a brown complex of composition CoR_3 with an absorption peak at 390 mμ and a plateau from 450–485 mμ. The optimum pH range is 4·3–5·9 and Beer's law is obeyed over the range 0·8–10 ppm. Colour development is instantaneous and reaches a maximum for a 1:6 ratio of cobalt to reagent. Conductometric measurements suggest the formation of CoR and CoR_2 as well as CoR_3.

Fluoride, phosphate, oxalate, citrate and tartrate. The fading of the bluish black colour of the iron complex when fluoride ions are added is made the basis of an indirect spectrophotometric determination of fluoride,[32] in the concentration range 0·5–40 ppm.

The same principle has been utilized[33] for determining oxalate, phosphate, citrate and tartrate in acidic medium. Linear calibration curves are obtained only over a limited concentration range.

Metal indicator for complexometric determination of iron(III). It has recently been reported that the reagent is a good metal indicator for the direct complexometric determination of iron.[34] The colour change at the end-point from bluish black to lemon yellow or colourless is very sharp and conspicuous. Many ions do not interfere. Iron in solids, ores, cement, and dolomite has been determined complexometrically with this indicator.[35]

3-Hydroxy-1-phenyl-3-methyltriazene

This is a white compound, m.p. 69°, highly soluble in alcohol and alcohol-water mixtures. With iron(III) it forms a greenish blue water-soluble complex with absorption peaks at 400, 490 and 625 mμ, the last of which is suitable for the colorimetric determination of iron. The optimum pH range is 3·1–4·5, and Beer's law is obeyed over the range 1–10 ppm. The composition of the complex is FeR_3 and the sensitivity is 0·2 ppm. No superiority over other reagents is claimed.

Other hydroxytriazenes

3-Hydroxy-1-*p*-tolyl-3-phenyltriazene[6](I), 3-hydroxy-1-*p*-tolyl-3-methyltriazene[7](II) and 3-hydroxy-1,3-*p*-ditolyltriazene[8](III) have also been reported as reagents for palladium and copper. Compounds (I) and (III) have more favourable conversion factors than the parent compound (3-hydroxyl-1,3-diphenyltriazene). It is reported[5] that complexes formed by 3-hydroxyl-1-*o*-chlorophenyl-3-phenyltriazene and 3-hydroxy-1-*p*-carboxyphenyl-3-phenyltriazene were gelatinous in nature and not useful for analytical purposes. Hydroxytriazenes prepared from diazo anthroquinones and phenylhydroxylamine, and their colour reactions with some metals, have been reported.[37] A new hydroxytriazene, *p*-(3-hydroxy-3-phenyltriazeno)-phenyltrimethylammonium chloride has recently been reported; it is water soluble and gives coloured water-soluble complexes.[38]

Ionization constants of hydroxytriazenes and stabilities of their metal chelates

Hydroxytriazenes are very weak acids. Most of these triazenes give a yellow colour with alkali. In the case of 3-hydroxy-1,3-diphenyltriazene, for example, an absorption peak at 348 mμ in neutral or acidic medium is shifted to 393 mμ in alkaline medium. Different workers[17,39,40] have reported different values for pK, using the same spectrophotometric method. The ionization constants for a large number of hydroxytriazenes have been reported and the effect of substitution on pK values discussed.[40,41]

Stability constants of palladium, copper, nickel, zinc, and manganese chelates of various hydroxytriazenes have been determined in a 70% v/v dioxan–water mixture by Dugar[41] and Purohit *et al.*[42] The effect of substitution on the stabilities of metal chelates has also been discussed and described[43–45] and a linear correlation between pK and $\log \beta_1$ and $\log \beta_2$ has been established. The stability sequence is reported to be

$$Pd > Cu > Ni > Zn > Mn.$$

ELEKTRONISCHES RECHNEN IN DER ANALYTISCHEN CHEMIE—II*

ALGOL-PROGRAMM FÜR DIE EINFACHE VARIANZANALYSE

G. GOTTSCHALK
OSRAM Studiengesellschaft Berlin, Technische Universität Berlin

(*Eingegangen am* 9 *September* 1966. *Angenommen am* 14 *November* 1966)

Zusammenfassung—Innere Homogenität und Gesamt-Homogenität eines gruppenweise angefallenen Datenmaterials läßt sich durch die mathematisch-statistische Methode der einfachen Varianzanalyse objektiv prüfen und sicherstellen. Die bisher bekannte varianzanalytische Datenauswertung wird durch den von Nalimov vorgeschlagenen *r*-Test erweitert, wodurch auch die innere Homogenität der Einzeldaten in jeder Gruppe beurteilt werden kann. Erst der varianzanalytisch geführte Nachweis einer Homogenität gewährleistet die einwandfreie Zusammenfassung einer Vielzahl von Einzelinformationen auf die 2 für ein Untersuchungsproblem charakteristischen Kenndaten, Gesamt-Mittelwert $\bar{x}$ und die totale Varianz s^2 bzw. Standardabweichung s. Die einfache Varianzanalyse weist zwar keine schwierigen Rechenoperationen auf, ist aber bei mehr als 50 Einzeldaten bereits sehr zeitraubend und anfällig für Rechenfehler. Bei konventioneller Rechentechnik werden z.B. für 10 Gruppen mit insgesamt 100 Einzeldaten 3 bis 6 Stunden je Person benötigt, während bei elektronischer Datenverarbeitung die Resultate in weniger als 5 min anfallen. Ein geeignetes ALGOL-Programm wird mitgeteilt. Am Beispiel des Vergleiches der Resultate flammenphotometrischer Natriumbestimmungen aus 7 Laboratorien für eine gleichartige vorgegebene Glasprobe wird eine der wichtigsten Anwendungsmöglichkeiten der einfachen Varianzanalyse in der analytischen Chemie ausführlicher behandelt.

VERWENDETE BEGRIFFE UND SYMBOLE (ALGOL-SYMBOLE IN KLAMMERN)

Gesamtzahl der Untersuchungen	n (N)
Anzahl der Gruppen	k (K)
Gruppenumfänge	l_J (L)
Laufzahlen, für Gruppen	J (J)
für Einzelwerte innerhalb der Gruppen	i (I)
Einzelwerte innerhalb der Gruppen	x_i (X[I])
Gruppen-Mittelwert	$\bar{x}_J$ (XM)
Gruppen-Varianz (Standardabweichung s_J)	s_J^2 (V)
Gesamt-Mittelwert	$\bar{\bar{x}}$ (GXM)
Varianz zwischen den Gruppen	VZ (VZ)
Mittlere Varianz innerhalb der Gruppen	VI (VI)
Totale Varianz (Gesamt-Standardabweichung s)	s^2 (GV)
Integralgrenzen r der r-Verteilung für $S = 95\%$	r_J (R)
Vergleichsgröße zum r-Test	τ (TAU)
Vergleichsgröße zum F-Test	θ^2 (—)

* Teil I—*Talanta*, 1967, **14**, 61.

EINFÜHRUNG

Problemstellung

Im Rahmen der Untersuchung von Objekten und Vorgängen werden häufig mehrere Gruppen gleichartiger Untersuchungsbefunde erhalten. Zur einwandfreien Beurteilung und Zuordnung der Tatbestände und Einflüsse ist die Klärung der Frage unerläßlich, ob die Daten insgesamt einer gemeinsamen Grundgesamtheit mit definiertem Lage- und Streuungsparameter angehören oder ob die Kenndaten der k einzelnen Gruppen sich voneinander durch überzufällige Abweichungen unterscheiden. Man spricht in diesem Zusammenhang von der Homogenität bzw. Inhomogenität das Datenmaterials. Eine objektive Entscheidung ermöglicht die mathematisch-statistische Methode der Varianzanalyse.

Bei inhomogenem Datenmaterial können Gesamt-Mittelwert $\bar{x}$ und totale Varianz s^2 oder Standardabweichung s systematisch verfälscht sein und dürfen daher nicht als umfassende Kenngrößen zu dem betreffenden Problem interpretiert werden. Durch Weglassen von Gruppen mit stark abweichenden Gruppen-Kenndaten $\bar{x}_J$ und s_J und erneute varianzanalytische Durchrechnung des restlichen Datenmaterials kann eine Homogenisierung für einen Datenrest und eine Separierung von „Ausreißer"-Gruppen erreicht werden. Die mit diesem Vorgehen zwangsläufig verbundene Verkleinerung der Gruppenanzahl k und der Gesamtanzahl n der Einzeldaten bedeutet aber auch stets einen Verlust an Aussage-Sicherheit. Daher ist die weitere varianzanalytische Aufschlüsselung eines Rest-Datenmaterials mit weniger als $n/2$ Einzeldaten kaum mehr sinnvoll.

Unter den zahlreichen Möglichkeiten für die Anwendung der Varianzanalyse seien im folgenden nur einige genannt.

Zusammenfassung chronologisch angefallener Prüfbefunde (Zeiteinfluß)

Beispiel: Ermittlung der Jahres-Kenndaten aus $k = 12$ Monats-Kenndaten.

Mengenverteilungen (Prozeß- oder Herstellungseinfluß)

Beispiel: Homogenität der Verteilung eines bestimmten Stoffes nach definierten Mischprozessen bzw. Herstellbedingungen.

Trendreihen (Einflußanalyse für verschiedene Parameter)

Beispiel: Konstanz oder Änderung der Resultate von Analysengruppen bei systematischer Variation eines Zustandsparameters wie Temperatur, Druck, Volumen oder auch Konzentration zugesetzter Stoffe *etc.*

Zuverlässigkeitstest für Prüfverfahren

Beispiel: Resultatvergleich von verschiedenen Laboratorien auf der Basis einer vorgegebenen Prüfsubstanz. Für diesen wichtigen Anwendungsbereich wird abschließend ein typisches Beispiel durchgerechnet und diskutiert.

Eine Datengruppe besteht aus l_J Einzeldaten x_i in Form von gleichartigen Analysenbefunden oder auch physikalischen Merkmalsgrößen, die im allgemeinen zu einem Niveauwert $\bar{x}_J$ und einem Streuungswert s_J^2 bzw. s_J zusammengefaßt

werden können. Für k Gruppen ist danach ein k-maliger Berechnungsgang, wie folgt, durchzuführen:

$$\begin{aligned} &\text{Gruppen-Mittelwert} \qquad \bar{x}_J = \frac{1}{l_J} \sum_{1}^{l} x_i \\ &\text{Gruppen-Varianz} \qquad s_J^2 = \frac{1}{l_J - 1} \sum_{1} (x_i - \bar{x}_J)^2 \end{aligned} \tag{1}$$

wobei $i = 1, 2, \ldots, l$ Laufzahl der Einzelwerte in einer Gruppe
$J = 1, 2, \ldots, k$ Laufzahl der Gruppen (Gruppen-Nummern)
Abbildung 1 gibt einem Überblick für ein Datenmaterial von $k = 5$ Gruppen mit verschiedenem Umfang.

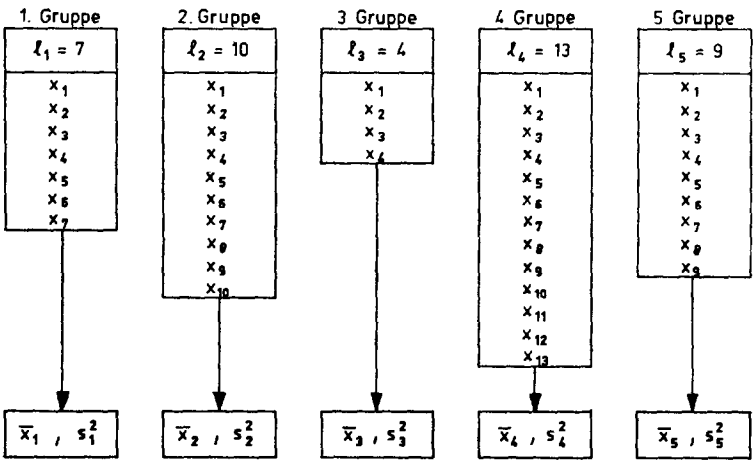

ABB. 1.—Einzeldaten, Mittelwerte und Varianzen für ein Beispiel mit $k = 5$ Gruppen.

Ein spezieller Sonderfall liegt vor, wenn zwar die Gruppen-Kenndaten l_J, $\bar{x}_J$, s_J bekannt, die Einzelwerte x_i jedoch nicht mehr zugänglich sind. Die varianzanalytische Zusammenfassung solcher Daten ist problematisch, da die oft starke Rundung der Gruppen-Kenndaten zu einer beträchtlichen Verfälschung des Endurteils führen kann. Nur bei hinreichend großer Ziffernzahl in der Angabe von $\bar{x}_J$ und s_J wird man auch für die Durchrechnung des Sonderfalles zuverlässige Endresultate erwarten dürfen. Besser ist aber in jedem Fall die Angabe und Verrechnung der Einzeldaten x_i einer jeden Gruppe. Weitere Einzelheiten zu den zweckmäßigsten Rechengängen und Datenprüfungen bringt das Kapitel über die mathematische Struktur der einfachen Varianzanalyse.

Elektronische Datenverarbeitung

Wie bereits bei der Arbeit I (Modellanalysen) werden für den Normalfall und den Sonderfall der Varianzsanalyse Rechenprogramme in der problemorientierten Universalsprache ALGOL (ALGO-rithmic L-anguage) unter Verwendung der für das Codesystem ALCOR CCIT zulässigen Zeichen formuliert. Bei Vorliegen der Programme beschränkt sich auch hier die weitere Tätigkeit des Benutzers auf die Auflistung der Untersuchungsbefunde in programmrichtiger Reihenfolge, wie dies Abb. 2 zeigt.

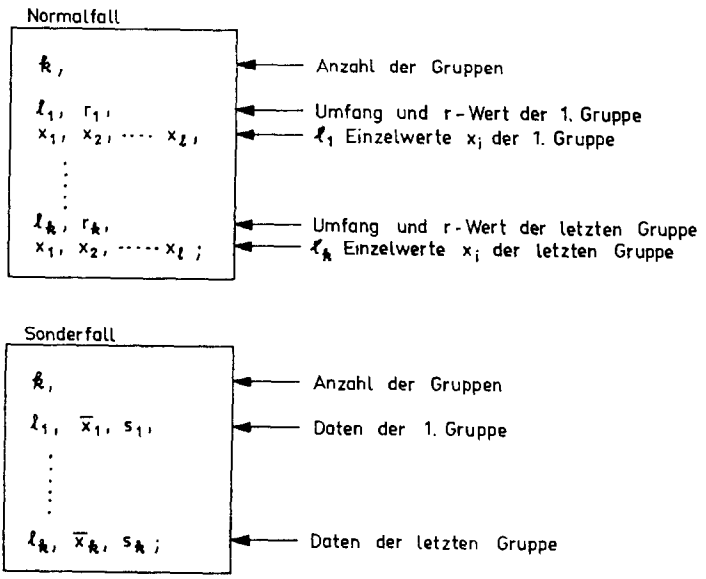

ABB. 2.—Datenlisten bei einfachen Varianzanalysen.

Weitere Einzelheiten über den Gebrauch von ALGOL siehe Arbeit I und die dort angeführte ALGOL-Literatur.

MATHEMATISCHE STRUKTUR

Rechengänge

Bei der k-maligen Gruppenrechnung ermittelt man zweckmäßig zunächst die Gruppensummen S_J der Einzelwerte x_i und QS_J der Einzelwert-quadrate x_i^2, woraus in einfacher Weise die Gruppen-Kenndaten $\bar{x}_J$, s_J^2 bzw. s_J berechnet werden können, soweit sie nicht im Sonderfall bereits vorgegeben sind. Tabelle I zeigt die Rechengänge der Gruppenrechnung.

Wie noch gezeigt wird, läßt sich die „innere" Homogenität der Daten x_i innerhalb einer jeden Gruppe durch die mathematisch-statistische Prüfmethode des r-Testes sicherstellen.

TABELLE I.—GRÖSSEN DER GRUPPENRECHNUNG

Größen		Normalfall	Sonderfall
Summe der Einzelwerte S_J =		$\sum_1^l x_i$	$l_J \cdot \bar{x}_J$
Summe der Einzelwert-Quadrate QS_J =		$\sum_1^l x_i^2$	$(l_J - 1) \cdot s_J^2 + \bar{x}_J \cdot S_J$
Mittelwert	$\bar{x}_J = XM_J$ =	$\frac{1}{l_J} \cdot S_J$	vorgegeben
Varianz	$s_J^2 = V_J$ =	$\frac{1}{l_J - 1} \{QS_J - \bar{x}_J \cdot S_J\}$	$s_J \cdot s_J$
(bzw. Standardabweichung s_J)			s_J vorgegeben

Das gesamte Datenmaterial der k-Gruppen wird danach zu einem übergeordneten Niveauwert $\bar{\bar{x}}$ und 3 Streuungswerten VZ, VI und s^2 zusammengefaßt, wobei die k Gruppensummenpaare S_J, QS_J, die Mittelwerte $\bar{x}_J$ und die Gruppenumfänge l_J in diese Gesamtrechnung eingehen, wie Tab. II zeigt.

TABELLE II.—GRÖSSEN DER GESAMTRECHNUNG

Summen	
Gesamt-Anzahl	$n = \mathrm{N} = \sum_1^l l_J$
Gesamtsumme der Einzelwerte	$GS = \sum_1^l \left\{ \sum_1^l x_i \right\} = \sum_1^l S_J$
Gesamtsumme der Einzelwert-Quadrate	$GQS = \sum_1^k \left\{ \sum_1^l x_i^2 \right\} = \sum_1^k QS_J$
Gesamtsumme des Produktes aus Gruppenmittel mal Gruppensumme	$GSQ = \sum_1^k l_J \cdot \bar{x}_J^2 = \sum_1^k \bar{x}_J \cdot S_J$
Endresultate	
Gesamt-Mittelwert	$\bar{\bar{x}} = \mathrm{GXM} = \frac{1}{n} \sum_1^k S_J = \frac{1}{n} GS$
Varianz zwischen den Gruppen	$\mathrm{VZ} = \frac{1}{k-1} \sum_1^k l_J (\bar{x}_J - \bar{\bar{x}})^2 = \frac{1}{k-1} \{GSQ - \bar{\bar{x}} \cdot GS\}$
Mittlere Varianz innerhalb der Gruppen	$\mathrm{VI} = \frac{1}{n-k} \sum_1^k (l_J - 1) \cdot s_J^2 = \frac{1}{n-k} \{GQS - GSQ\}$
Totale Varianz (bzw. Standardabweichung s)	$s^2 = \mathrm{GV} = \frac{1}{n-1} \{(k-1) \cdot \mathrm{VZ} + (n-k) \cdot \mathrm{VI}\}$
	$= \frac{1}{n-1} \{GQS - \bar{\bar{x}} \cdot GS\}$

Zur Prüfung des gesamten Datenmaterials auf Homogenität wird abschließend ein F-Test durchgeführt.

Prüfung der Gruppen-Homogenität durch den t-*Test*

Die Gruppen-Kenndaten $\bar{x}_J$ und s_J bzw. s_J^2 sind nur dann einwandfreie Gruppengrößen, wenn keiner der Einzelwerte x_i innerhalb der betreffenden Gruppe extrem weit vom Mittelwert abweicht. Die „innere" Homogenität der Gruppendaten x_i kann durch den r-Test[1,2] überprüft und sichergestellt werden. Hierzu bildet man für den kleinsten und größten x_i-Wert und eventuellen weiteren stark vom Mittelwert abweichenden x_i-Werten die Prüfgröße:

$$\tau_i = \frac{|x_i - \bar{x}_J|}{s_J} \sqrt{\frac{l_J}{l_J - 1}} \tag{2}$$

Mit den Integralgrenzen r der r-Verteilung wird τ_i verglichen, wobei für die jeweilige numerische Größe von $r = r_J$ der vom Gruppenumfang l_J abhängige Freiheitsgrad $f = l_J - 2$ und die Statistische Sicherheit $S = 95\%$ oder $S = 99\%$ (Level of significance 0,05 bzw. 0,01) maßgebend ist. Als Funktion von f und S ist r tabelliert.[1,2] Theoretisch kann $\tau_i \geqq r(95)$ 1-Mal unter 20 Werten x_i und $\tau_i \geqq r(99)$ sogar nur 1-Mal unter 100 Werten erwartet werden. Die Gruppendaten sind praktisch als in sich homogen zu beurteilen, wenn bei $l_J = 10$ bis 20 1-Mal, bei $l_J = 21$ bis 40 2-Mal, bei $l_J = 41$ bis 60 3-Mal Prüfgrößen $\tau_i \geqq r(95)$ gefunden werden. Praktisch ist $\tau_i \geqq r(99)$ 1-Mal für $l_J = 50$ bis 100 zulässig.

Für $l_J = 10$ entnimmt man z.B. der Tabelle für $f = 8$ die r-Werte:

$$r(95) = 1{,}895 \qquad \text{und} \qquad r(99) = 2{,}294$$

Eine homogene Datengruppe liegt in diesem Fall dann vor, wenn höchstens 1-Mal $\tau_i \geqq r(95) = 1{,}895$ vorkommt. Bei mehreren Befunden $\tau_i \geqq r(95)$ oder sogar solche mit $\tau_i \geqq r(99)$ sind die betreffenden x_i-Werte als „Ausreißer" einzustufen. Die varianzanalytischen Berechnungen müssen sodann unter Fortlassen der Ausreißer wiederholt werden. Darüber hinaus sollte man bemüht sein, die Ursachen für Ausreißer aufzudecken. Der r-Test setzt die Kenntnis der Einzelwerte x_i voraus. Liegen im Sonderfall nur die Gruppendaten l_J, $\bar{x}_J$, s_J vor, so kann auf innere Homogenität nicht geprüft werden, wodurch eine erhöhte Gefahr der systematischen Resultatverfälschung resultiert.

Für die Praxis ist eine umgeformte Beziehung (2) einfacher zu handhaben. Mit $\tau_i \geqq r_J$ folgt:

$$| x_i - \bar{x}_J | \geqq r_J \cdot s_J \sqrt{\frac{l_J - 1}{l_J}} = r_J \sqrt{\frac{(l_J - 1) \cdot V_J}{l_J}} = PG \tag{3}$$

Wenn der absolute Differenzbetrag $(x_i - \bar{x}_J)$ gleich oder größer als eine aus l_J, $r_J(S)$, s_J bzw. V_J gebildeten Prüfgröße PG ist, so liegt eine Überschreitung der vorgegebenen r-Grenze vor. Das Normalprogramm enthält den r-Test und druckt für externe Vergleiche die Versuchsnummer i = I, den betreffenden Wert x_i = X[I], die Größe τ_i = TAU und den Wert r_J = R[J] aus, wenn die $r(95)$- Grenze überschritten wird.

Prüfung der Gesamt-Homogenität durch den F-*Test*

Die Homogenität des gesamten Datenmaterials wird durch einen F-Test[1–4] geprüft und beurteilt. Die einfache Prüfgröße

$$\theta^2 = \frac{VZ}{VI} \tag{4}$$

ist hierzu lediglich mit den Integralgrenzen F der F-Verteilung für die Freiheitsgrade

$$\text{von } VZ, \text{ d.h. } f_1 = k - 1 \text{ und}$$

$$\text{von } VI, \text{ d.h. } f_2 = n - k$$

sowie vorgegebenen Statistischen Sicherheiten $S = 95/99/99{,}9\%$ (Level of significance 0,05/0,01/0,001) zu vergleichen.

Die F-Werte sind als Funktion von f_1, f_2 und S tabelliert,[1–4] doch muß eventuell

interpoliert werden. Wegen $F \leqq 1$ zeigt eine Prüfgröße $\theta^2 \leqq 1$ auch ohne Vergleich mit den F-Werten stets ein streng homogenes Datenmaterial an. In allen Fällen $\theta^2 > 1$ urteilt man zweckmäßig, wie folgt:[2]

$$\theta^2 < F(95): \quad \text{streng homogen}$$

$$F(95) \leqq \theta^2 < F(99): \quad \text{homogen}$$

$$F(99) \leqq \theta^2 < F(99{,}9): \quad \text{nahezu homogen}$$

$$\theta^2 \geqq F(99{,}9): \quad \text{inhomogen}$$

Nur für $\theta^2 < F(99{,}9)$, bei strengen Maßstäben sogar für $\theta^2 < F(95)$, stellen Mittelwert $\bar{x}$, totale Varianz s^2 bzw. Standardabweichung s eine zulässige auf nur 2 Kenndaten konzentrierte Information zu dem betreffenden Problem dar.

In einem inhomogenen Datenmaterial sind dagegen überzufällige Einflüsse wirksam. Wie bereits in der Einführung beschrieben, kann durch Fortlassen von Gruppen mit stark abweichenden Gruppenkenndaten $\bar{x}_J$, s_J^2 bzw. s_J und erneute Rechnung eine Homogenität der Restdaten und eine Separierung von Ausreißer-Gruppen erreicht werden.

Im nachfolgend angeführten Normal- und Sonderprogramm wird lediglich θ^2 berechnet und ausgedruckt, während der Vergleich mit F-Werten extern erfolgen muß. Dies erspart in vielen Fällen eine zeitraubende Interpolationsrechnung für nicht tabellierte F-Werte und ermöglicht eine eventuelle andere Abstufung des Urteils.

PROGRAMMIERUNG

Flußdiagramm

Abbildung 3 zeigt das vollständige Ablaufschema der einfachen Varianzanalyse für den Normalfall. Die Gruppenrechnung wird nur 1-Mal formuliert und so dann in einem k-maligen Zyklus durchgeführt. Dieses Vorgehen erspart die Indizierung durch die Gruppen-Nummer J. Es kann $l_J = \mathrm{L}$, $r_J = \mathrm{R}$ und $x_{iJ} = \mathrm{X[I]}$ gesetzt werden. Die richtige Auflistung der Eingangsdaten für den Normalfall zeigt Abb. 2.

Im Sonderfall der einfachen Varianzanalyse mit vorgegebenen Gruppendaten $l_J, \bar{x}_J, s_J$ beschränkt sich der k-Zyklus auf das Einlesen dieser Größen, wobei auch hier $l_J = \mathrm{L}$, $\bar{x}_J = \mathrm{XM}$, $s_J = SJ$ gesetzt werden kann. Es sei ausdrücklich darauf hingewiesen, daß die elektronische Rechnung für den Sonderfall gegenüber einer konventionellen Rechentechnik nur dann merkliche zeitliche und sonstige Vorteile besitzt, wenn mindestens 10 Gruppen zusammenzufassen sind.

ALGOL-Programm

Die relativ kurzen und einfachen ALGOL-Programme für den Normalfall und den Sonderfall sind in den Tabellen III und IV zusammengestellt.

Die Programme sind erprobt und brauchen von einem Benutzer nur sorgfältig abgeschrieben und an ein Rechenzentrum gegeben zu werden: Die zukünftige Arbeit beschränkt sich sodann auf die Auflistung der Befunde in programmrichtiger Reihenfolge nach Abb. 2.

Weitere Hinweise zur ALGOL-Programmierung wurden in Arbeit I gebracht, in der auch ausführlichere ALGOL-Literatur angegeben wird.

```

BEISPIEL

Das nachfolgende Beispiel wurde an einer relativ kleinen und langsamen Rechenanlage ZUSE 23 gerechnet. Der Zeitbedarf für das einmalige Einlesen des ALGOL-Programmes beträgt für den Normalfall 2 Minuten und für den Sonderfall 1 Minute. Für das Einlesen des Zahlenstreifens der Eingangsdaten sowie für Rechnung und Resultatausgabe werden weitere 3 bzw. 1,5 Minuten benötigt. Das direkte Ausdrucken der Resultate in Klarschrift beansprucht bei den hier formulierten Programmen etwa 75 % der Zeit, da bei der Z 23 die Rechenvorgänge während des Druckvorganges unterbrochen werden. Bei einer größeren Anzahl zu verarbeitender Zahlenstreifen ist es daher vorteilhafter, die Resultate nicht in Klarschrift sondern zunächst in der

sehr viel schnelleren Lochstreifenform ausgeben zu lassen. Die Lochstreifen können später über einen ALGOL-Schreiber in beliebig viele Klarschriftexemplare umgesetzt werden.

Zielsetzung: Überprüfung der Zuverlässigkeit und Ermittlung der Standardabweichung eines flammenphotometrischen Prüfverfahrens für Natriumgehalte zwischen 1,0 bis 2,0 Gew% in einem häufig verwendeten Glastyp.

Teilnehmer: 7 Laboratorien.

Vorbereitung: Durch eine neutrale, hinsichtlich der Auswertung federführende Institution wird eine 1000-g Großprobe eines typischen Glases auf eine Korngröße von weniger als 60 μ vermahlen und sorgfältig homogenisiert. Jedem Laboratorium wird eine Kleinprobe von 20 g in gut verschlossener Kunststoff-Pulverflasche übersandt.

Auflagen: Jedes Laboratorium (Gruppe) hat mindestens $l_J = 6$ flammenphotometrische Bestimmungen durchzuführen, wobei der erforderliche Abrauchprozeß je Bestimmung mit Einwaagen im Bereich $G = 100$ bis 500 mg erfolgen soll. Eine Probenteilung des gelösten Rückstandes wird ebenso wie Arbeitstechnik und

benutztes Gerät freigestellt. Von den Laboratorien sind die Einzelergebnisse $x_i = H_i$ in Gew% Na auf 2 Stellen nach dem Komma sowie die jeweils verwendeten Arbeitsvorschriften (Einwaagen, Reagentien, Aufschlußtechnik, Probenteilung, Art des Gerätes) mitzuteilen.

Die erhaltene Resultatmatrix zeigt Tab. V, die allen beteiligten Laboratorien mit den Ergebnissen der varianzanalytischen Auswertung nach Abschluß der Untersuchungen zugestellt wird. Sind an dem Versuch Laboratorien verschiedener Firmen, Institute oder sonstige Untersuchungsstellen beteiligt, so ist aus gewichtigen sachlichen und psychologischen Gründen von der neutralen Stelle unbedingt eine anonyme Aufschlüsselung und Bewertung durchzuführen. Hierzu werden den beteiligten Laboratorien willkürlich Gruppennummern zugeordnet. Jedes Laboratorium erhält neben den Endunterlagen nur seine eigene Nummer, nicht aber die Nummern der anderen Laboratorien. Bei diesem Vorgehen wird man gewisse berechtigte Vorurteile gegen solche für den Fortschritt der analytischen Prüftechnik sehr wertvolle Ringsversuche vermeiden können. Neben den Einzelresultaten H_i enthält Tab. V auch die aus Tabellen[1,2] entnommenen r-Werte für $S = 95$ und 99% Statistischer Sicherheit.

Die Daten der Tab. V wurden nach Abb. 2 aufgelistet und unter Verwendung des Normal-Programmes durchgerechnet. Tabelle VI zeigt das erhaltene Resultatbild in Klarschrift.

1. Urteil: Wichtigste Größe ist zunächst das gefundene $\theta^2 = 14{,}807$. F-Werte mit dem Freiheitsgrad $f_1 = 6$ und $f_2 = 43$ sind im allgemeinen nicht tabelliert. Doch zeigt bereits der benachbarte Wert

$$F\{f_1 = 6, f_2' = 40,\ S = 99{,}9\%\} = 4{,}73 < \theta^2$$

daß das gesamte Datenmaterial als eindeutig inhomogen zu beurteilen ist. Die Tabelle der Gruppendaten wird nicht durch Ausgabe von r-Testwerten unterbrochen, so daß alle Gruppen in sich homogen sind. Gruppe 3 weist mit $\bar{H}_3 = 1{,}482$ Gew% Na den Kleinsten und Gruppe 5 mit $\bar{H}_5 = 1{,}715$ Gew% Na den höchsten Gruppen-Mittelwert auf.

Abb. 4.—Histogramm der absoluten Häufigkeiten für die Klassenbreite $\Delta H = 0{,}05$ Gew.% Na.

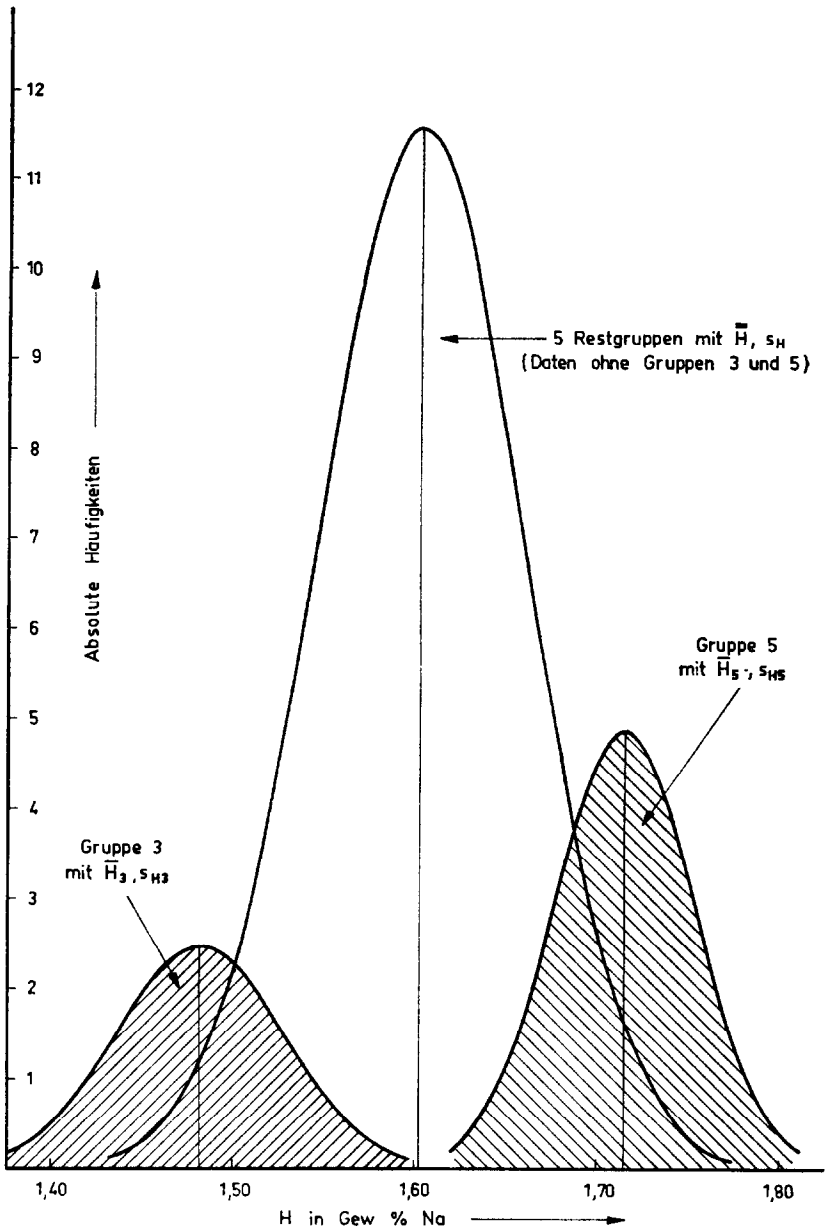

ABB. 5.—Homogener Datenrest und Ausreißer-Gruppen als Normalverteilungen mit Schätzwerten H, s_H.

Auf Grund des 1. Urteils wurden erneute Rechnungen unter Fortlassen der Gruppe 3 bzw. der Gruppe 5 bzw. der Gruppen 3 und 5 durchgeführt. Tabelle VII zeigt die Teile: Prüfgrößen und Endresultate der betreffenden Klarschriftbilder. Die Gruppen-Kenndaten bleiben naturgemäß unverändert.

Zwischenurteile: Ohne Gruppe 3 wird $\theta^2 = 8{,}891$ ($f_1 = 5$, $f_2 = 38$) und ohne Gruppe 5 $\theta^2 = 6{,}381$ ($f_1 = 5$, $f_2 = 34$) erhalten. Bereits der Näherungswert

$$F\{f_1 = 5, f_2' = 30, S = 99{,}9\,\%\} = 5{,}53 < \theta^2$$

zeigt, daß das jeweilige Restmaterial nach wie vor inhomogen ist. Der kleinere θ^2-Wert bei Fortlassen der Gruppe 5 läßt darauf schließen, daß Gruppe 5 einen größeren Einfluß hinsichtlich der Inhomogenität besitzt als Gruppe 3.

Endurteil: Ohne Gruppe 3 und 5 resultiert

$$\theta^2 = 1{,}546 < F\{f_1 = 4, f_2 = 29, S = 95\,\%\} = 2{,}70$$

das heißt ein „streng homogenes" Datenmaterial mit den Gesamt-Kenndaten:

$$\begin{aligned} \bar{\bar{H}} &= \ \ 1{,}602 \text{ Gew\% Na} \\ s_H &= \pm 0{,}057 \text{ Gew\% Na} \\ (VK &= \pm 3{,}54 \ \text{Rel\%}) \end{aligned}$$

Den Einfluß der Inhomogenität erkennt man an den bisherigen Gesamtdaten:

alle Gruppen: $\bar{\bar{H}} = \ \ 1{,}610$ Gew% Na, $s_H = \pm 0{,}083$ Gew% Na, (VK $= \pm 5{,}18$ Rel%)

ohne Gruppe 3: $\bar{\bar{H}} = \ \ 1{,}628$ Gew% Na, $s_H = \pm 0{,}071$ Gew% Na, (VK $= \pm 4{,}38$ Rel%)

ohne Gruppe 5: $\bar{\bar{H}} = \ \ 1{,}584$ Gew% Na, $s_H = \pm 0{,}070$ Gew% Na, (VK $= \pm 4{,}41$ Rel%)

Die Resultate der Laboratorien 3 und 5 mit

$$\bar{H}_3 = 1{,}482 \text{ bzw. } \bar{H}_5 = 1{,}715 \text{ Gew\% Na}$$

sind nach der varianzanalytischen Aufschlüsselung eindeutig zu niedrig bzw. zu hoch.

Abschließend zeigen die Abbildungen 4 und 5 die Verteilung der absoluten Häufigkeiten und die mit den Schätzwerten $\bar{H}$ und s_H resultierenden Normalverteilungen.

Summary—The homogeneity within and between groups of data can be objectively tested and established by a simple analysis of variance. The analysis of variance methods already known can be extended by means of the *r*-test proposed by Nalimov, whereby the homogeneity of single values in each group can be assessed. Only the proof of homogeneity obtained by analysis of variance guarantees the unequivocal interpretation of a large number of single results from the two characteristic

parameters—the variance s^2 (or the standard deviation s) and the mean value $\bar{\bar{x}}$. Certainly simple analysis of variance requires no difficult calculations, but, even with only 50 results to be used, is time-consuming and subject to arithmetical slips. For example, by conventional calculation methods 3–6 hr are needed for one person to handle groups containing 100 results, whereas the results can be obtained in 5 min with an electronic computer. A suitable ALGOL programme is given, and as an example of use of this potentially important application of analysis of variance, a detailed comparison is made of the flame photometric determination of sodium in a homogeneous glass sample by 7 laboratories.

Résumé—On peut objectivement examiner et établir l'homogénéité à l'intérieur et entre des groupes de données par une analyse simple de la variance. Les méthodes d'analyse de variance déjà connues peuvent être étendues au moyen de l'essai-*r* proposé par Nalimov, par lequel l'homogénéité de valeurs isolées de chaque groupe peut être appréciée. Seule la preuve d'homogénéité obtenue par l'analyse de la variance garantit l'interprétation non équivoque d'un grand nombre de résultats simples à partir des deux paramètres caractéristiques de la variance, s^2 (ou l'écart type s) et la valeur moyenne $\bar{\bar{x}}$. L'analyse simple de la variance n'exige certainement pas de calculs difficiles mais, même avec seulement 50 résultats à utiliser, elle prend beaucoup de temps et est sujette à des erreurs arithmétiques par inadvertance. Par exemple, par les méthodes de calcul ordinaires, une personne nécessite 3–6 h pour traiter des groupes contenant 100 résultats, alors que les résultats peuvent être obtenus en 5 mn avec un calculateur électronique. On donne un programme ALGOL appropriéet, comme exemple d'emploi de cette application potentiellement importante de l'analyse de la variance, on procède à une comparaison détaillée du dosage photométrique de flamme du sodium dans un échantillon de verre homogène effectué par 7 laboratoires.

PURITY DETERMINATIONS BY DIFFERENTIAL THERMAL ANALYSIS*

P. B. BOWMAN† and L. B. ROGERS®
Department of Chemistry, Purdue University, Lafayette, Indiana 47907, U.S.A.

(*Received* 16 *February* 1966. *Revised* 30 *June* 1966. *Accepted* 9 *November* 1966)

Summary—Measurement of the melting-point depression of impure samples was compared with a differential method that involved running the impure sample against a pure sample of the same material. Samples of highly purified benzophenone to which had been added known quantities of 4-methylbenzophenone were studied. The area under the curve was proportional to the difference in purity between the sample and reference material over the range studied, 0·3–2·0 mole % with a standard deviation of 0·10 mole %, an uncertainty only half as large as one obtained by the melting-point depression method with the same apparatus.

THERE is no shortage of methods capable of determining low levels of one component in another. When the impurity is similar to the major component, the most common method of analysis is based on melting-point depression.[1] In a study at the National Bureau of Standards,[2] 0·004 mole % of heptane in benzene was determined with a standard deviation of 0·0004 mole % by use of freezing and melting curves. That approach is very sensitive but also extremely slow and tedious, requiring 4 hr or more for analysis of a single sample.

The work described in this paper was begun in the hope that the application of a differential thermal technique[3,4] might shorten the time required without appreciable loss in sensitivity.‡ Our results fell far short of the desired sensitivity but did prove to be more precise than the method based upon visual observation of the melting-point depression. This paper reports the results of our comparison of two methods of purity determination by differential thermal techniques. One method involved a conventional differential thermal analysis (DTA) technique to determine the melting-point depression. The second method used the area under a curve obtained by comparing the temperature of the sample with that of an active reference sample of pure material.[3] Highly purified benzophenone diluted with carborundum was used as the reference material; benzophenone mixed with known quantities of 4-methylbenzophenone and diluted with carborundum was used as the sample. The resulting curve had a second-derivative shape, the area of which depended on the degree of overlap of the sample and reference transitions, which in turn depended on the difference in purity of the sample and reference materials.

EXPERIMENTAL

Apparatus

The DTA instrument used in this work was similar to that of Barrall and Rogers,[4] except that a more convenient method of thermocouple mounting was devised which permitted the thermocouples

* Taken in part from the Ph.D. thesis of P. B. Bowman, Purdue University, Lafayette, Indiana, August, 1965.

† Present Address: The Upjohn Company, Kalamazoo, Michigan 49001.

‡ After submission of this manuscript, a similar procedure was reported based on use of a Perkin–Elmer Differential Scanning Calorimeter. See A. P. Gray, Thermal Analysis Newsletter, No 5. Perkin–Elmer Corporation, Norwalk, Connecticut, 1966.

to be removed from the cells without breaking the connections to the amplifier leads at the Jones terminal board. The thermocouple was mounted in an aluminium plug which served to centre it in the sample compartment. The plug was held in place by a brass compression fitting which also sealed the cell compartment. The thermocouple leads from the block to the terminal board, and all connections on the board itself, were wrapped in glass wool.

The thermocouples were Chromel/Alumel Part No. 900301 from the Instrument Products Division of E. I. DuPont de Nemours and Co., Inc. and were designed for use with the DuPont 900 DTA instrument. These thermocouples were sealed in the plugs with ceramic cement.

Two thermocouple arrangements, both with the cold junction in an ice-bath, were used in this study. For melting-point depression experiments, which involved direct measurement of temperature, the thermocouple in the sample cell was used in the circuits for both temperature and differential temperature measurements.[5] With that arrangement, the abscissa was the temperature of the sample, and there was very little variation of peak shape with purity.

For the differential measurements against pure benzophenone, one thermocouple pair detected the difference in sample and reference temperatures, while a second pair measured the block temperature. The hot junction of the latter temperature-sensing pair was located in pure carborundum in a third cell compartment. For that configuration, the abscissa of the recorder trace was the temperature of the block, and endotherms for the sample and reference cells had the same shape although the deflections were in opposite directions. Using that thermocouple arrangement, the shape of the endotherm depended on the purity of the sample. The melting of a high purity sample was completed in a narrow temperature range and had a deep endotherm. The less pure samples melted over wider temperature ranges with correspondingly shallower endotherms.

The block was non-inductively wrapped with 18-gauge asbestos-insulated nichrome wire. A 1-pint Dewar flask was placed round the block during runs. The block temperature was controlled with an F and M model 40 Linear Temperature Programmer. All runs were performed at a heating rate of 2·9°/min. The differential temperature signal was amplified by a Leeds and Northrup 9835B Stabilized d.c. (zero centre) Microvolt Indicating Amplifier. Part of the temperature signal was bucked out (backed off) by a bridge-type bucking source.[6] The remainder was fed to another Leeds and Northrup amplifier. The thermograms were recorded on a Mosley Model 135 AM X-Y Recorder (18 × 25 cm). Power for the recorder and amplifiers was first fed to a Sola type CVN-1 constant-voltage transformer.

The usual sensitivity of the ΔT axis was 2·5 μV/cm (3·5° full scale), and that of the T axis was 20 μV/cm (12·5° full scale). Any 12·5° range could be selected by varying the output of the bucking source.

For the differential experiments against pure benzophenone, matching of thermal characteristics of the sample and reference cells was extremely important. Cells were constructed from 8 mm lengths of 6 mm diameter spectroscopic graphite electrodes, a lathe being used to drill holes in them 5 mm in diameter and 7 mm deep. Between runs, the cells were leached in boiling acetone for 10 min and then dried in a vacuum oven at 140° for 30 min.

Reagents

Carborundum (500-mesh) from the Carborundum Company was used as the diluent, and was prepared according to Barrall and Rogers.[4] No attempt was made to size the material except that, during the washing steps, the fines, which were slower to settle, were decanted with the wash liquid.

Reagent grade benzophenone, obtained from Columbia Organic Chemicals Company, Inc., was recrystallized three times from ligroin which had been distilled from calcium hydride. This material (designated *3RR*) was used as the reference for "active reference" runs. It was assumed to be pure within the sensitivity of this work. Eastman White Label 4-methylbenzophenone, recrystallized once from ligroin, was used as the impurity for the preparation of samples.

Samples were prepared by weighing out 10 g of benzophenone (*3RR*) and adding a weighed portion of 4-methylbenzophenone to provide the desired level of impurity. The mixture was melted in a vacuum oven at 50°, then removed and frozen quickly in a dry ice–acetone bath. After solidification, the samples were ground in a mortar and then in a Wiggle Bug mixer. Finally, the samples were mixed by repeated coning and quartering and stored in a desiccator in the dark until used.

Procedures

The sample was diluted by dissolving it in enough reagent grade diethyl ether to make a thick slurry with the carborundum, ground in a mullite mortar until the ether had evaporated, and then dried in a vacuum oven at 40°. To establish that no segregation of the impurity had occurred, a few samples were prepared by grinding the carborundum with the dry sample. An F test on the variances of the melting points of samples prepared by the two methods showed no significant difference.

The amount of thermally active material in a sample was checked by ignition in a muffle furnace.

Porcelain combustion boats were filled with the same weight of sample used in a DTA run. Weight loss was calculated after ignition to constant weight.

All runs were performed in the following manner: a pair of clean graphite cells (matched to within 1% by weight) were weighed, then filled with 0·1200 ± 0·0005 g of sample. The cells were tapped 25 times on the desk top to ensure even packing before being placed in the furnace. Thermocouples were cleaned between runs by rinsing three times with acetone and burning it off. The cell compartments were then sealed, a Dewar flask was placed round the block, glass wool was wrapped around the leads, and the programmer was started. The temperature amplifier was set in the "linear" mode to display the temperature signal on the meter of the amplifier. When the output from the pair of temperature thermocouples equalled the potential set on the bucking source, the amplifier was switched to the "recorder" mode, and the recorder itself was turned on.

This procedure was followed for both the "regular" DTA runs against the inert reference, carborundum, and the "active reference" runs against *3RR* benzophenone on carborundum. Three samples of each composition were run in triplicate so that a total of nine measurements was made for each procedure.

In the regular method, the melting point was measured at the intersection of the extensions of the baseline and the steepest part of the descending edge of the endotherm,[8] the appropriate thermocouple arrangement being used.

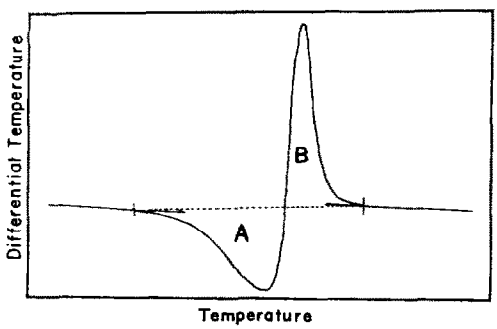

FIG. 1.—Differential thermogram obtained when a sample containing 1·01% of 4-methylbenzophenone was run against *3RR* benzophenone.

The other thermocouple arrangement was employed in the active reference method, for which a typical curve is shown in Fig. 1. For measurement of the total area, a line (shown as a dashed line in the figure) was drawn between the point of first deviation from baseline and the point of return to baseline. A polar planimeter was used to measure the area enclosed by the dashed line and the part of the curve that fell below it (Area A). A corresponding measurement was made for area B and the two areas were summed. (An attempt to use only the area of the lower portion of the curve for calibration proved impractical. A small error in establishing the baseline caused a large error in one direction. Use of the areas of both the upper and lower portions largely cancelled the errors.) The total area of a single thermogram could be reproduced with a relative standard deviation of 1%. Areas for curves resulting from repeated runs of a single portion of a sample had a relative standard deviation of 5%; areas of curves for different portions of the same sample had a relative standard deviation of 8%.

In order to estimate the area generated by mismatch of the sample and the reference cells or of the respective thermocouples, a blank was run with equal weights of *3 RR* benzophenone on carborundum in both cells. The areas under these curves were large for the first run, but for subsequent runs decreased to less than the difference in area for replicates of the differential run. The first run of either a blank or a sample gave a much larger area than later runs did. Since the thermocouples measured the temperature at a *point* in the sample, settling of the sample would have a pronounced effect on the differential signal. As a result, the first run was always disregarded and the next three used.

DISCUSSION

Melting-point depression measurements

The experimental values in the second column of Table I illustrate the capability of the instrument for determining melting points. If twice the standard deviation of the melting-point measurement was arbitrarily taken as the limit of detection, differences of less than 0·42 mole %impurity could not be detected. Comparison of

experimental melting points with theoretical melting points, calculated by the classical melting-point depression formula[7] and listed in columns three and four, indicates that the method would be useful in its present form for many of the melting-point determinations that are made. If the temperature range displayed on the recorder could have been reduced by increasing the amplification of the temperature signal, the precision of the measurements could, in principle, have been improved. However, surges in the temperature signal as the programmer cycle switched on and off were already detectable so that further expansion of the temperature axis was not feasible. Another major contribution to the uncertainty in the melting-point measurements was the spread of the endotherm due to the presence of the diluent. Use of small, pure (undiluted) samples in an instrument having a continuous programmer such as the one recently described by Barrall *et al.*[5] should make better measurements possible and, thereby, make the approach more attractive.

Active reference procedure

This procedure was carried out in two different ways. In one, the amount of active material mixed with the carborundum was adjusted, by trial and error, for the reference and each of the samples until 1g of each mixture gave very nearly the same endothermal area when measured against pure carborundum. This was done so as to match very closely the thermal behaviour of the samples. In the other, a 1-g sample of each mixture was made up to contain very nearly the same proportion by weight of active material. The latter approach was obviously faster and easier to apply.

Columns five to seven of Table I show results obtained by the first method of preparation of carborundum mixtures for analysis; columns eight and nine show results obtained by use of the second method. In both cases, samples were run against an appropriate reference of *3RR* benzophenone. For both, a straight line could be drawn through the points. For the first set, the slope of the line, as determined by regression analysis, was 2·31 in^2/mole % of impurity, and the intercept was −0·17. The standard deviation calculated by the method of least squares was 0·26. A second calibration curve prepared from a new set of samples had a slope of 2·28 in^2/mole % of impurity. The limit of detection, taken as twice the standard deviation was 0·28 mole %. The upper limit was not established experimentally, but was indicated in preliminary experiments by a decrease in slope that became a plateau when there was no overlap of the two endotherms. It should be possible to expand the range of the method by using a reference of known impurity content.

When the second method was used, the slope obtained for the least-squares line was 2·57 in^2/mole % of impurity, with an intercept of −0·20. When the slope was calculated for the same sensitivity as that used for the other procedure, the value obtained was 5·31 in^2/mole % of impurity. The relative standard deviation of an area measurement (8 % for triplicate samples) was the same as that obtained with area matching. However, the procedure was more direct in that it avoided the secondary dilutions required for area matching and, therefore, saved time. It should be noted that, in preparing the samples, a surprisingly consistent loss of 2 % of active material was observed as a result of homogenizing the samples by grinding. For example, although 0·7660 ± 0·0005 g of active material was added to 12·000 ± 0·001 g of carborundum, ignition analyses on 5-g portions generally showed 5·89 ± 0·05 % active material present. Finally, it should be noted that the slightly greater areas

(for a 0·120-g sample) obtained by the weight-matched procedure were the result of using a heavier loading than in the area-matched runs.

The active reference procedure had two limitations. First, the desirability of matching the thermal properties of the samples rather closely required the use of relatively high dilutions and correspondingly high amplifications, with some sacrifice of precision. Second, the on-off cycling of the programmer produced small deviations from linearity in heating rate, to which the active reference method was extremely sensitive, particularly at high amplification. New calorimetric DTA apparatus[8] using a proportional programmer, described since this work was started, would minimize that limitation and permit the use of undiluted samples, thereby increasing the sensitivity further. The convenience and speed of this method would also be improved.

The precision of the active reference method, $\pm 0{\cdot}28$ mole %, was significantly better (at the 95% confidence level) than the 0·42 mole % of the melting point-depression procedure, as each was performed in this study. It should be noted, however, that the methods were studied under nearly identical conditions which were farthest from optimum for the melting-point depression method. However, even under these conditions, the melting-point measurements with a precision of $\pm 0{\cdot}1°$ compared very favourably with classical capillary melting-point measurements which, without special precautions, have a precision of about $\pm 0{\cdot}5°$.[9] The active reference method eliminates the need for precise temperature calibration, but the greater care required in weighing out a fixed amount of active material for dilution with carborundum offsets that advantage to some extent.

Acknowledgements—We wish to thank Dr. E. M. Barrall II, of the Chevron Research Corporation, for several helpful discussions. One of us, P. B. B., was supported in part by a Union Carbide Fellowship and in part by U.S. Atomic Energy Commission Contract No. AT(11-1)-1222.

Zusammenfassung—Die Messung der Schmelzpunktsdepression unreiner Proben wurde mit einer Differenzmethode verglichen, bei der die unreine Probe gegen eine reine Probe desselben Materials gemessen wurde. Es wurden Proben aus hoch gereinigtem Benzophenon untersucht, denen bekannte Mengen 4-Methylbenzophenon zugesetzt waren. Die Fläche unter der Kurve war proportional der Reinheitsdifferenz zwischen Probe und Bezugsmaterial im Bereich von 0,3 bis 2,0 Mol-% mit einer Standardabweichung von 0,10 Mol-%. Diese Unsicherheit ist nur halb so groß wie die bei der Schmelzpunktsdepressionsmethode mit derselben Apparatur.

Résumé—La mesure de la dépression du point de fusion d'échantillons impurs a été comparée à une méthode différentielle comprenant le traitement de l'échantillon impur parallèlement à un échantillon pur du même produit. On a étudié des échantillons de benzophénone hautement purifiée à laquelle on a ajouté des quantités connues de 4-méthylbenzophénone. L'aire de la courbe est proportionnelle à la différence de pureté entre l'échantillon et la substance de référence dans le domaine étudié, 0,3–2,0 moles % avec un écart type de 0,10 mole %, une incertitude qui n'est que la moitié de celle obtenue par la méthode de dépression du point de fusion avec le même appareil.

ANALYTICAL CHEMISTRY OF CYCLAMATES: A REVIEW

M. L. RICHARDSON*
John & E. Sturge Limited, Lifford Chemical Works, Kings Norton, Birmingham, 30, U.K.

(*Received* 29 *August* 1966. *Accepted* 17 *November* 1966)

Summary—The analytical chemistry of cyclamates is reviewed, the emphasis being on methods of assay, tests for impurities and methods of determination in food and drug products.

INTRODUCTION

ALTHOUGH a variety of chemicals other than carbohydrates have a sweet taste, only two synthetic sweetening agents are safe for use in beverages, drugs and food; cyclamates and saccharin.

Saccharin, discovered in 1879, has been commercially available since 1900. Its properties and those of the various saccharin salts and derivatives have been reviewed.[1,2]

Cyclamate, discovered in 1937, became available in 1950. Since then several articles describing the use[3,4] and properties[5] of cyclamate have been published. Cyclamate is the generic name for cyclohexylsulphamates. The sodium and calcium salts and the free acids are commercially available.

This paper reviews the methods which are used for the analysis of cyclamates and include methods of assaying, tests for impurities and the determination of cyclamate in food and drug preparations.

METHODS OF ASSAY

One of the earliest official methods of assaying cyclamate materials is given in the United States Pharmacopoeia;[6] the nitrogen content of calcium cyclamate is determined by Kjeldahl's method.

The National Formulary XI[7] recommends the assay of sodium cyclamate by treatment of an acidified solution of sodium cyclamate with an excess of nitrous acid in the presence of excess of barium chloride and then the weighing of the precipitated barium sulphate.

The First Addendum to the British Pharmacopoeia 1963[8] describes a variety of procedures for the assay of cyclamate materials. In calcium cyclamate, the calcium is determined by titration with EDTA and the cyclamate by a nitrogen determination similar to that described above.[6] Cyclamic acid is determined by titration with standard alkali, and the sodium salt by non-aqueous titration (acetic/perchloric acid) of the cation.

Perhaps the best procedure for the assay of cyclamate is that described in the National Formulary XII.[9] The calcium and sodium salts are titrated with nitrous acid, either a starch/iodide external indicator being used or an electrometric detection of the end-point similar to that described in the General Procedures of the British Pharmacopoeia 1963.[10] In the writer's opinion the best method for the assay of

* Present address: S. Z. Wick & Sons Ltd., Falcon Street, Oldham, Lancs., U.K.

cyclamate materials is that based on the titration with nitrous acid, as this is the only procedure which directly determines the active grouping (—$NHSO_3^-$).

TESTS FOR IMPURITIES

Acidity or alkalinity[8]

The B.P. 1963 Addendum 1964 describes a simple pH determination in a 10% w/v aqueous solution of the calcium or sodium salt.

Sulphate[8]

This is carried out by the usual turbidimetric procedure.

Water[8]

In the case of the calcium salt dihydrate, the water is best determined by the Karl Fischer method. For the sodium salt and the free acid, oven-drying at 105° is quite adequate.

Sulphated ash (cyclamic acid only)[8]

This is determined in the conventional manner by ashing in the presence of sulphuric acid in a platinum dish.

Heavy metals[6,9]

These are determined by the United States Official methods, *i.e.*, by reaction with sulphide under mildly acidic conditions.

Cyclohexylamine

The Ministry of Health Statutory Instruments,[11] describe an inadequate test based on the reaction of cyclohexylamine, or other amine present, with an excess of sodium carbonate in warm water to produce ammonia. The test states that "no distinct odour of ammonia" should be observed. We have found this test to be sensitive only to about 1200 ppm of cyclohexylamine.

For the sodium salt and cyclamic acid we have devised a simple test based on the reaction of Nessler's reagent with the amine to give a white precipitate, which can be estimated turbidimetrically. This procedure is sensitive to about 500 ppm of cyclohexylamine.

We have also confirmed Morris's[12] findings that the cyclohexylamine can be extracted from an alkaline solution of the cyclamate material with benzene; the resulting benzene solution, after acidification, reacts with picryl chloride to form an intensely yellow coloured picrylamine which can be measured spectrophotometrically (λ_{max} 418 mμ). This procedure, which offers the most sensitive procedure for cyclohexylamine in cyclamate materials, is sensitive to 50 ppm of cyclohexylamine, but is relatively lengthy.

DETERMINATION OF CYCLAMATES IN FOOD AND DRUGS

Ion-exchange procedures

Komoda and Takeshita,[13] have separated saccharin, cyclamic acid and dulcin from food by adsorption onto Amberlite CG400 Type 1, Cl form. The cyclamic acid and the saccharin are then eluted with oxalic acid and alcohol. The eluate is neutralized and examined by paper chromatography, as described below.

Asano *et al.*[14] have used a similar system. They used Amberlite CG46 (Cl form)

for the sorption, and eluted cyclamic acid with 0·1*M* hydrochloric acid. They then titrated the cyclamic acid with nitrous acid and determined the sulphate nephelometrically.

These methods are rather lengthy and in many cases can be superseded by the titrimetric, gravimetric, spectrophotometric and gas chromatographic techniques described below, especially the first.

Yamaguchi[15] has described a useful procedure for the separation of sulphamic and cyclamic acids on Amberlite IRA-400 and IR46, with methanol and 0·05*M* hydrochloric acid as eluting agents.

Paper and thin-layer chromatography

Mitchell has proposed a method based on paper chromatography.[16] Cyclamic acid, saccharin and dulcin in foodstuffs are extracted with ethyl acetate after acidification with sulphuric acid. The solvent is evaporated off and the residue dissolved in ammoniacal 50% aqueous ethanol is applied to the paper. Separation is completed by ascending chromatography with a mobile phase of acetone–ethyl acetate–ammonia (8:1:1). Cyclamic acid and saccharin give white spots when sprayed first with 0·005*M* silver nitrate in ammoniacal ethanol and then with 0·0005*M* pyrogallol in ethanol. We have used this system for thin-layer chromatography on cellulose and found it to be satisfactory.

Ko *et al.*[17] separated the sweetening agents by paper chromatography with a mobile phase of n-butanol–10% ammonia (4:1) and a spray reagent consisting of a dilute nitric acid solution containing pyrogallol and silver nitrate for the detection of cyclamic acid. Komada and Takeshita[13] used a similar procedure, but favoured a mobile phase of isoamyl alcohol–pyridine–water, which gave less interference from food preservatives such as salicyclic, benzoic and sorbic acids.

Salo *et al.*[18] and Salo and Salminen[19] favour a stationary phase of 10% acetylated cellulose containing 40% of polyamide for thin-layer chromatography. They use Shell Sol A (an isomeric mixture of methyl benzenes)–isopropanol–glacial acetic acid–formic acid (45:6:7:2) as the mobile phase, and locate the sweetening agents with Rhodamine B. We have successfully used this procedure with Rhodamine B as internal locating agent.

Ichibagase and Kojima[20] recommend mobile phases of ethyl acetate–glacial acetic acid–water (4:1:2) or ethyl acetate–formic acid–water (4:1:2) or ethyl acetate–ethanol–glacial acetic acid–water (4:2:1:2). For location they hydrolyse cyclamic acid to cyclohexylamine with hydrogen peroxide and finally spray with quinhydrone to give a violet spot.

Kamp[21] used silica gel G thin-layer plates and a mobile phase of either acetone–10% ammonia (90:10) or acetone–10% ammonia–ethyl acetate (80:10:10) and subsequently sprayed these plates with Mitchell's reagent.[16]

We have examined these systems and found that Salo's[18,19] give very clean chromatograms. We have also satisfactorily used a mobile phase of n-butanol–glacial acetic acid–water (4:1:5) (upper phase only) with 0·015% w/v Bromophenol Blue as locating agent, and a mobile phase of ethanol–ammonia (s.g. 0·880)–water (20:4:1) with 0·040% w/v Bromocresol Green as locating agent, on cellulose thin-layer plates. In general we have found that locating agents containing silver

nitrate[13,16,17,21] are not completely satisfactory and it is suggested that it may be preferable to incorporate this reagent in the thin layer itself.

All these procedures have the shortcoming that if cations are present, spots will be obtained not only for cyclamic acid but also for the salt.

Titrimetric methods

Vercillo and Manzone[22] treated the salts of cyclamic acid with excess of nitrous acid and then titrated the liberated sulphate with standard barium solution, tetrahydroxyquinone being used as indicator, after removal of calcium by ion-exchange.

The National Formulary XII[9] describes a simple titrimetric procedure for the determination of the cyclamate content of compound calcium cyclamate and calcium saccharin tablets. Cyclamate is titrated in acid solution with sodium nitrite, starch-iodide being used as an external indicator.

Richardson and Luton[23] have described a similar procedure for cyclamate in comminuted and other fruit drinks, but detect the end-point electrometrically. It has proved one of the most satisfactory and simple techniques for the determination of cyclamate in food and drugs. It is usually only necessary to acidify the sample with mineral acid and titrate electrometrically with sodium nitrite solution. This method has been successfully used for the determination of cyclamate in sauces. For the determination of cyclamate in biscuits a simple water extraction, before titration, proved to be adequate. In the case of a drug preparation (an expectorant) containing a substantial quantity of a thickening agent, it was found desirable to acidify the drug preparation to pH $< 0{\cdot}6$, extract with chloroform (preferably in a continuous liquid–liquid extractor) evaporate off the chloroform, dissolve the residue containing the cyclamate in dilute mineral acid, and titrate it.

Gravimetric determination

This is the oldest method of analysis for cyclamate; it is generally reliable but is time consuming.

The United States Pharmacopoeia XVI[6] gives a gravimetric procedure for the determination of the cyclamate content of compound calcium cyclamate and calcium saccharin solution and tablets. The cyclamate is treated with an excess of nitrous acid in the presence of excess of barium chloride and the barium sulphate formed is filtered off, dried and weighed.

Wilson[24] and Cox[25] have used similar procedures for the determination of sodium cyclamate in canned fruit and similar products.

Wilson[26] has described a lengthy procedure for determining sodium cyclamate in sugar-free beverages. The beverage is first neutralized and then evaporated to dryness. The sodium salt is extracted with hot ethanol, which is then evaporated off and the residue is dissolved in water. The cations are removed by ion-exchange, and the effluent is evaporated to dryness and the residue is first extracted with chloroform, and then dried and weighed as cyclamic acid. The analysis is finally checked by the barium sulphate method. If pectin is present it is removed before the determination by alcoholic precipitation.

Knelhofer and Aumann[27] recommend a procedure for the determination of cyclamates in wine. The wine is made alkaline with sodium hydroxide and then just acidified with hydrochloric acid (Methyl Orange as indicator) and then oxidized

with hydrogen peroxide. The resulting sulphamic acid is hydrolysed to sulphate which is then precipitated, filtered off and weighed as barium sulphate.

Giodano and Pennati[28] have confirmed that cyclamate in wines can be identified by paper chromatography by Mitchell's[16] procedure, but have noted that the procedures of Wilson[24] and Cox[25] are not possible owing to interference by sulphur dioxide, which is always present in wines. They recommend removing the effect of the sulphur dioxide by first boiling the wine with hydrochloric acid, then adding excess of barium chloride, boiling again, filtering off any barium sulphate and other insoluble materials and finally treating with sodium nitrite, reheating, filtering off the precipitated barium sulphate, igniting and weighing. This procedure has the great advantage that any turbidity arising from interaction of the sodium nitrite with colouring matter, leaves no residue on ignition and hence does not interfere.

Mihashi and Kobayashi[29] have described a procedure in which the cyclamic acid is separated by solvent extraction with ether or ethyl acetate after acidification. The solvent is evaporated off and the extracted cyclamic acid is treated with hydrochloric acid and sodium nitrite. The resulting sulphate is then precipitated with an excess of standard barium chloride and the excess of barium is titrated with standard EDTA. They indicate that the method is suitable for drug preparations, carbonated beverages (not containing sulphur dioxide), *etc.* but it is not suitable for foodstuffs containing antiseptics.

Both this procedure and that of Wilson[26] suffer from the objection that unless the pH of the mixture is less than 0·6 (*q.v.* Beck[5]) then the extraction of the cyclamic acid is unlikely to be quantitative.

Infrared spectroscopy

Oba *et al.*[30] recommend infrared spectroscopy for the determination of cyclamic acid in the presence of carbohydrates, *etc.* They carried out the determination by the potassium bromide disc technique without isolation of the acid. The absorption band at 800 cm^{-1}, characteristic of cyclamic acid, was used and the measurements were made by the base-line method in order to overcome the absorption by saccharin and dulcin at this frequency. When lactose was used as the vehicle, the differential method was applied. The results gave errors of up to 10% so that, even if complex calculations involving matrix algebra were applied, it is unlikely that the method could be widely used quantitatively for the determination of cyclamate in complex mixtures in food and drug preparations.

Colorimetry

Gianferrara[31] extracted cyclamic acid from acidified beverages with petroleum ether and evaporated the extract to dryness. The extract was dissolved in propylene glycol–ethanol (6:4) solvent mixture and warmed, and a drop of hydrogen peroxide was added, followed by two drops of a 1% benzene solution of chloranil; the violet colour produced was measured spectrophotometrically; the calibration curve was linear.

Kojima and Tchibagase[32] treated sodium cyclamate with hydrochloric acid and hydrogen peroxide and allowed the solution to digest at 100° for 2 hr. Sodium hydroxide and manganese dioxide were added and the mixture was stirred, diluted with water and centrifuged. Atkins and Poutin buffer and ethanolic quinhydrone

solution were added to an aliquot of the supernatant liquid. The mixture was heated at 60° for 10 min and then allowed to cool to room temperature; a 10% solution of acetic acid in chloroform was added and the solution was thoroughly mixed. The chloroform phase was separated and its absorbance at 355 mμ was measured.

A second procedure consists of treating the cyclamic acid with hydrogen peroxide and hydrochloric acid for 1–5 hr at 100°, neutralizing the cooled mixture with sodium hydroxide, adjusting the pH to 12 and heating with quinhydrone in ethanol, extracting with chloroform and measuring the absorbance at 495 mμ.

They report that dulcin, putrifying amines and colouring materials, *etc.* interfere, but can be removed by preliminary treatment with ion-exchange resin and/or solvent extraction.

Ichikawa *et al.*[33] have hydrolysed sodium cyclamate with hydrochloric acid and hydrogen peroxide to form cyclohexylamine. When the cyclohexylamine content is less than 0·025% the amine is extracted into chloroform and treated with quinhydrone or 1,4-benzoquinone in ethanol, and kept at 50° for 2 hr to give 2-(cyclohexylamine)-1,4-benzoquinone which can be measured spectrophotometrically.

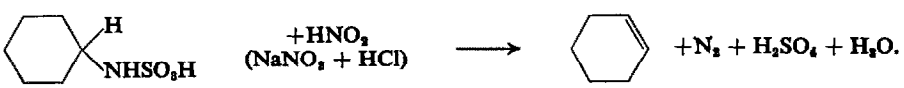
When the concentration of cyclohexylamine is greater than 0·25%, manganese dioxide is added to decompose excess of hydrogen peroxide, the pH is adjusted to 9·0, a solution of quinhydrone in ethanol is added and the mixture is kept at 50° for 15 min. It is then extracted with chloroform to give 2,5-bis(cyclohexylamine)-1,4-benzoquinone which can then be measured spectrophotometrically.

In our experience colorimetric procedures are tedious and usually do not give very accurate results, especially for the determination of cyclamate in complex food and drug products.

Gas chromatography

Rees[34] has described a gas chromatographic procedure for the determination of cyclamate in fruit drinks.

The procedure is based on the reaction with nitrite:—



The cyclohexene formed is extracted and then determined by gas chromatography on a silicone oil column. Richardson and Luton[35] have examined and modified this procedure by ensuring that the pH of extraction is in accordance with Beck's[5] recommendations and by using sulphuric acid in place of hydrochloric acid in order to avoid the formation of monochlorocyclohexane. They recommended a polyethylene glycol 400 column and found that in addition to cyclohexene they could detect the presence of substantial quantities of cyclohexanol and cyclohexanone; monochlorocyclohexane was also detected if hydrochloric acid was used.

Gas chromatography, although a reliable technique for determining cyclamate in fruit drinks is, by comparison with the simple titration procedure,[23] rather time-consuming, and requires more expensive equipment and manipulative skill.

Acknowledgements—The author wishes to thank the Directors of John & E. Sturge Limited for permission to publish this paper and to thank Mr. A. W. Leek and Mr. P. E. Luton for carrying out much of the experimental work.

Résumé—On passe en revue la chimie analytique des cyclamates, en insistant sur les méthodes de détermination, les essais pour impuretés et les méthodes de dosage dans les produits alimentaires et pharmaceutiques.

Zusammenfassung—Es wird eine Übersicht über die analytische Chemie von Cyclamaten gegeben, wobei besonderes Gewicht auf die Nachweismethoden, Reinheitsprüfung und die Bestimmung in Lebensmitteln und Drogen gelegt wird.

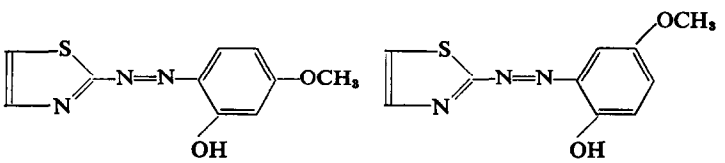
2-(2-THIAZOLYLAZO)-4-METHOXYPHENOL AND 2-(2-THIAZOLYLAZO)-5-METHOXYPHENOL AS METAL-ION INDICATORS

V. CHROMÝ and L. SOMMER
Lachema, Research Institute of Pure Chemicals, Brno, and Department of Analytical Chemistry of the J. E. Purkyně-University, Brno, Czechoslovakia

(*Received* 7 *September* 1966. *Accepted* 14 *October* 1966)

Summary—2-(2-Thiazolylazo)-5-methoxyphenol (TAMR) and 2-(2-thiazolylazo)-4-methoxyphenol (TAMH) are shown to be good indicators for the titration of many metal ions with EDTA. TAMH is better and more widely applicable than TAMR. The acid dissociation constants have been determined by spectrophotometry. The effect of pH on the absorbance of the indicators and metal-indicator complexes is reported.

2-(2-THIAZOLYLAZO)-5-METHOXYPHENOL (TAMR) and 2-(2-thiazolylazo)-4-methoxyphenol (TAMH) resemble 4-(2-thiazolylazo)resorcinol (TAR) in their properties as metal-ion indicators. TAMH, and a family of thiazolylazo dyes, has been prepared by Kawase,[1] who has also studied its complexes with some bivalent metal ions[2,3] and cobalt(III).[4] We showed that TAMH especially was more useful than TAR when used for high-precision EDTA-titrations of a number of metal ions. This study is concerned with the behaviour of these compounds as metal-ion indicators.



EXPERIMENTAL

Reagents

2-(2-Thiazolylazo)-5-methoxyphenol (TAMR) and 2-(2-thiazolylazo)-4-methoxyphenol (TAMH). Prepared by Svoboda and Bendová[15] and purchased from Lachema, Brno or Chemapol, Prague. TAMH in the form of bright dark-green crystals, and TAMR, a brown crystalline powder, are sparingly soluble in ether, dioxane and water, but very soluble in dimethylformamide, methanol, ethanol, acetone and chloroform, giving red and yellow-orange solutions respectively. Doubly recrystallized from hot ethanol, the samples contained 99–100% of active dye.

The purity of the dyes was checked by descending paper chromatography with 80% v/v aqueous ethanol as eluent, by elemental analysis, and by determination of the inorganic sulphate in the ashed material (<0·1%). Solutions, 0·1*M* or 0·1%, of TAMH and TAMR in methanol were generally used, but solutions in 0·2*M* ammonia are suitable. Traces of heavy metal ions were masked by 1 drop of 0·05*M* EDTA solution.

pH-Control. The pH was adjusted with dilute perchloric acid or sodium hydroxide for the spectrophotometric measurements. For qualitative studies the following buffer solutions were used: sodium acetate/hydrochloric acid (pH 2–5), hexamethylenetetramine/nitric acid (pH 5–6·5) or tris(hydroxymethyl)aminomethane/hydrochloric acid (pH 7–9).

For EDTA-titrations, hexamethylenetetramine buffer (0·1*M* with respect to base) of pH 6 and acetate buffer (0·79*M* with respect to base trihydrate) of pH 4·5.

Acidities below pH 1 were calculated from the perchloric acid concentrations corrected by the appropriate activity coefficients,[6] or were expressed by the H_0 function.[7,8]

Ionic strength. For spectrophotometric studies an ionic strength of 0·1 was maintained with sodium perchlorate.

Metal nitrate solutions. Standardized chelometrically by obvious procedures. All chemicals were of analytical grade.

EDTA, 0·025M and 0·05M solutions. Standardized by lead chloride with Xylenol Orange as indicator.[9]

Apparatus

A CF-4 spectrophotometer (Optica, Milano) with 10-mm and 50-mm silica cells. Radiometer PHM 28 pH meter.

RESULTS AND DISCUSSION

Acid-base equilibria of TAMH and TAMR

Three optically different forms exist in solution, depending on the pH. For TAMH the solutions are orange-red at pH < 1, yellow at pH 1–7 and violet at pH 7·5–8, the colours being due to the forms H_2R^+, HR and R^- respectively. For TAMR the corresponding forms are red at pH < 2, yellow at pH 2–5·5 and red at pH > 5·5. The spectra show isosbestic points corresponding to these transitions (Figs. 1 and 2).

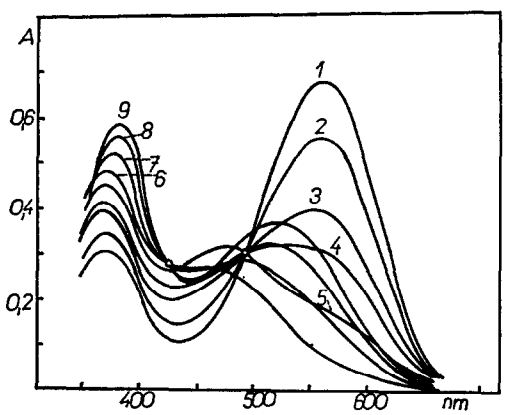


FIG. 1.—Dependence of absorption spectra of TAMH on pH.

$C_R = 5·0 \times 10^{-5}M$, in 0·5% v/v methanol.
pH: *1*—10·80; *2*—8·10; *3*—8·11; *4*—7·59; *5*—7·35; *6*—0·81; *7*—0·42; *8*—0·14; *9*—H_0 = −0·33.

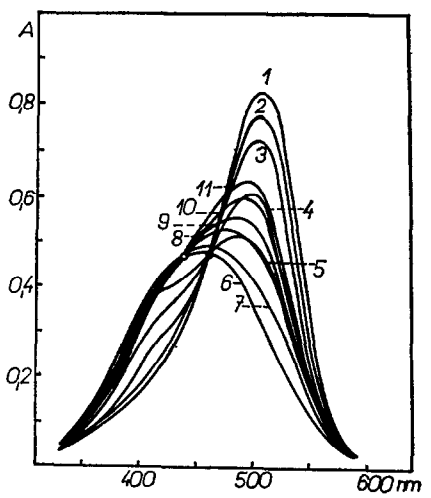

FIG. 2.—Dependence of absorption spectra of TAMR on pH.

$C_R = 3 \times 10^{-5}M$, in 0·5% v/v methanol.
pH: *1*—10·80; *2*—8·50; *3*—8·05; *4*—7·31; *5*—6·83; *6*—1·42; *7*—1·01; *8*—0·81; *9*—0·64; *10*—0·42; *11*—0·14.

The molar absorptivities for the various forms were calculated from the horizontal lines of pH–absorbance plots and graphically from plots of $C_R/A = f\{[H]\}$ and from equations (1) and (2),[10] or the logarithmic form [equation (3)],[11] which were used to calculate the dissociation constants. The calculations were made from the absorbances at 510 and 550 mμ for TAMH and 410 and 500 mμ for TAMR.

If the acid dissociation constants are given by

$$K_{a1} = \frac{[HR][H^+]}{[H_2R]} \text{ and } K_{a2} = \frac{[R^-][H^+]}{[HR]},$$

then for the second step only:

$$\frac{C_R}{A} = \frac{1}{\varepsilon_R} + \frac{[H](A - \varepsilon_{HR}C_R)}{A\varepsilon_R K_{a_2}} \quad (1)$$

$$\frac{C_R}{A} = \frac{1}{\varepsilon_{RH}} + \frac{(A - \varepsilon_R C_R)K_{a_2}}{A[H]\varepsilon_{RH}} \quad (2)$$

$$\log \frac{A - \varepsilon_{HR}C_R}{\varepsilon_R C_R - A} = \text{pH} + \log K_{a_2} \quad (3)$$

where A is the total absorbance, C_R the analytical concentration of indicator and ε_x is the molar absorptivity of species x. The constants determined for both indicators are shown in Table I.

TABLE I.—SUMMARY OF OPTICAL AND ACID DISSOCIATION CONSTANTS FOR TAMH AND TAMR

The yellow form is the most suitable for titrations so the useful pH ranges for TAMH and TAMR are 1·5–6 and 2·0–5 respectively (Figs. 3 and 4). They have the advantage of a simple dissociation scheme compared to TAR. However, the reactions with ions at pH > 7 are often difficult to observe owing to the considerable increase in absorbance of the indicator anion; horizontal parts of the pH–absorbance plots, which indicate quantitative formation of a particular metal complex, are sometimes obtained with difficulty.

Analytical reactions of TAMH and TAMR

TAMH reacts with a number of metal ions giving green, blue-green or blue complexes (Fig. 5); TAMR forms red or red-orange ones under similar conditions (Fig. 6). They can usually be destroyed by EDTA and are extractable into polar solvents such as isoamylol or ethyl acetate. There is little difference in the analytical behaviour of the reagents, although with TAMH the colour change in the presence of metal ions is slightly better; both, but especially TAMR, resemble TAR.

When $C_R = C_M = 10^{-3}$–$10^{-4}M$ the following ions react with TAMH and TAMR:
pH < 2·5; Cu(II), Zr(IV), Bi(III), UO_2(VI), Pd(II), Tl(III), Hg(II), Ti(IV), V(V), V(IV), Nb(V) in the presence of tartrate, Ta(V) in the presence of oxalate;
pH 2·5–6; Zn(II), Cd(II), Hg(II), Sc(III), In(III), Ga(III), Y(III), La(III), lanthanides, Th(IV), Ti(IV), Fe(III), Ni(II), Co(II), Pb(II), Ta(V) in the presence of oxalate;
pH 6–9; Ca(II), Al(III), Sn(IV), Cr(III) (all after boiling), Mo(VI), W(VI), Sb(III), Mn(III).

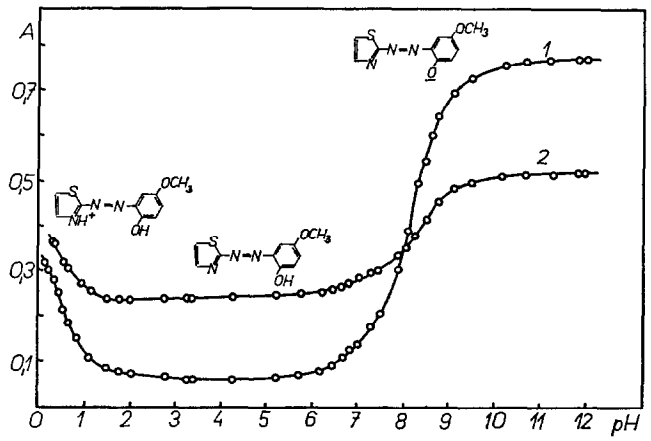

FIG. 3.—pH-Absorbance plots of TAMH.
$C_R = 5 \times 10^{-5} M$, in 0·5% v/v methanol;
1—550 mμ; *2*—510 mμ.

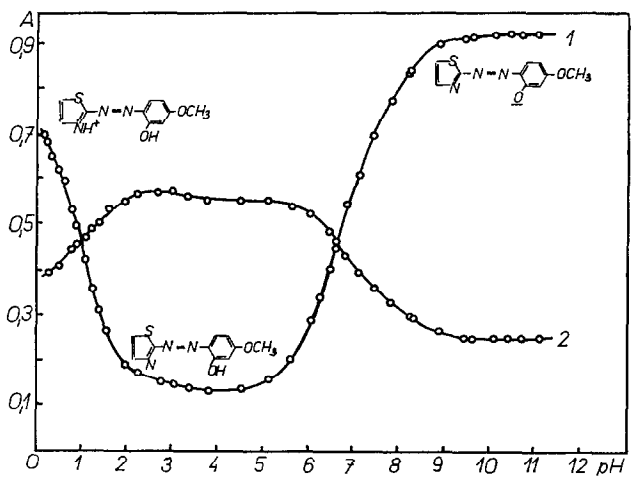

FIG. 4.—pH-Absorbance plots of TAMR.
$C_R = 3 \times 10^{-5} M$, in 0·5% v/v methanol.
1—500 mμ; *2*—410 mμ.

However, Mg(II), Sr(II), Ba(II), Al(III), Sn(IV), As(III), Sb(III), Cr(III), Mo(VI), W(VI), Se(IV), Te(IV) and platinum metals with the exception of Pd(II), do not give distinct colour changes. Cerium(IV) oxidizes the indicators and Sn(II) and Ti(III) reduce them.

It is evident that the sensitivity of the reactions strongly depends on pH. The maximal sensitivity and the corresponding pH values for reactions with several ions are given in Table II.

Metal complexes formation with TAMH and TAMR

pH-Absorbance plots at selected wavelengths, and absorption curves for equimolar solutions or for solutions containing excess of metal ion ($C_M/C_R \sim 50$) give

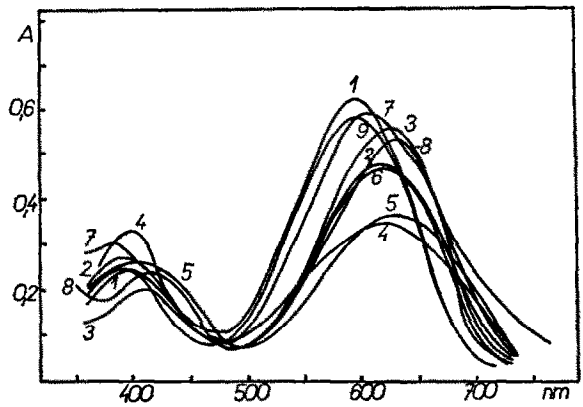

FIG. 5.—Absorption spectra of TAMH chelates with various metal ions.
$C_R = 4 \times 10^{-5}M$, $C_M = 2 \times 10^{-3}M$.
1—Zn(II), pH 7·60; *2*—Pb(II), pH 5·81; *3*—Hg(II), pH 6·0;
4—Co(II), pH 6·72; *5*—Bi(III), pH 2·20; *6*—In(III), pH 3·58
7—Ni(II), pH 7·10; *8*—Cu(II), pH 6·20; *9*—Cd(II), pH 7·70.

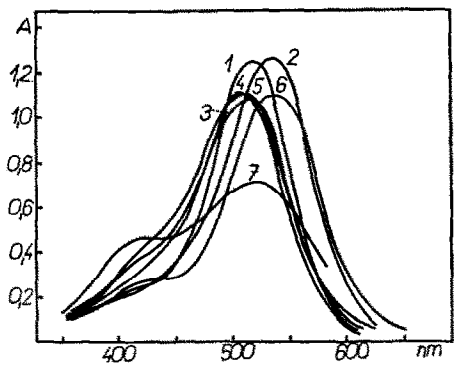

FIG. 6.—Absorption spectra of TAMR chelates with various metal ions.
$C_R = 4 \times 10^{-5}M$, $C_M = 2 \times 10^{-3}M$.
1—Ni(II), pH 7·45; *2*—Cu(II), pH 6·20; *3*—Zn(II), pH 7·40;
4—Cd(II), pH 7·70; *5*—Co(II), pH 8·11; *6*—Hg(II), pH 6·38;
7—Pb(II), pH 6·52.

evidence of the formation of 1:1 complexes with TAMH and TAMR. If the concentrations of metal ion and reagent are fixed the complexes with TAMH are formed at lower pH than those with TAMR (Figs. 7 and 8). Typical absorption curves for some metal complexes with TAMH and TAMR have already been shown in Figs. 5 and 6. The complexation equilibrium:

$$M^{n+} + HR \rightleftharpoons MR^{(n-1)+} + H^+$$

in solutions containing excess of metal ion can be characterized by pH-dependent absorption curves; to conserve space, only those for the systems of copper(II)-TAMH and copper(II)-TAMR are shown (Figs. 9 and 10). In general, sharp isosbestic points are found. The diffuse inflexion at 420 mμ in the TAMR system is similar to those of the MRH complexes of TAR and 4-(2-pyridylazo)resorcinol (PAR). A

TABLE II.—MAXIMAL SENSITIVITY OF SOME REACTIONS OF TAMH AND TAMR WITH METAL IONS

	TAMH		TAMR	
	pD*	pH	pD*	pH
Cu(II)	6·7	4·5–7·0	6·7	6·0
Zn(II)	7·0	7·0	7·3	7·0
Cd(II)	6·6	6·0	5·8	7·0
Pd(II)	5·9	6·0	5·6	6·0
Ni(II)	7·0	6·0	7·0	7·0
Co(II)	6·7	6·0	6·7	7·0
Hg(II)	6·2	6·0	6·6	6·0
Bi(III)	6·2	3·0	5·8	3·0
In(III)	5·6	4·5	5·8	5·3
Ga(III)	5·4	5·3	6·1	5·3
Tl(III)	6·0	5·3	5·7	5·3
Lanthanides	6·1–6·5	7–8	5·8–5·9	7–8

* Sensitivity values correspond to 1 ml of solution containing 1 drop of $10^{-3}M$ reagent and 0·8 ml of suitable buffer solution; pD = −log (dilution limit).

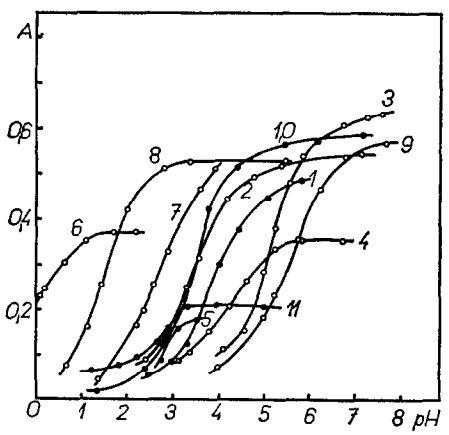

FIG. 7.—pH-Absorbance plots of TAMH solutions in the presence of excess of metal ion.

$C_R = 4 \times 10^{-5}M$, $C_M = 2 \times 10^{-3}M$:
1—Pb(II), 618 mμ; *2*—Hg(II), 628 mμ; *3*—Zn(II), 594 mμ;
4—Co(II), 518 mμ; *5*—Ga(III), 613 mμ; *6*—Bi(III), 632 mμ;
7—In(III), 618 mμ; *8*—Cu(II), 631 mμ; *9*—Cd(II), 598 mμ;
10—Ni(II), 608 mμ; *11*—Tl(III), 626 mμ; $C_R = C_M = 4 \times 10^{-5}M$.

large absorbance due to the ligand, at 425–430 mμ, was only found for the lead(II)–TAMR system at pH 6·52, where formation of the ligand anion and hydrolysis of lead(II) are significant. No sharp isosbestic point was found for this system.

The part of the spectrum of the TAMH complexes below 500 mμ shows the strong influence of the cationic field on the dye spectrum. Optical data for some metal complexes of TAMH and TAMR are shown in Table III.

The difference in λ_{max} between the HR-form of the indicator and its metal complex is greater for TAMH (126–164 mμ) than for TAMR (90–120 mμ). The shift is large enough for both to function as metal-ion indicators.

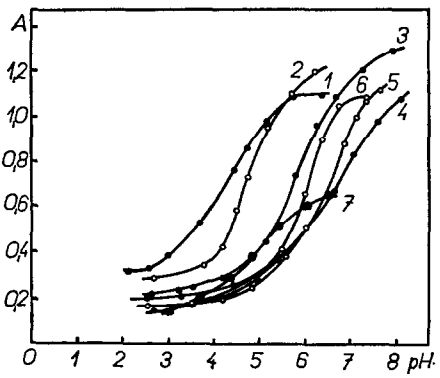

FIG. 8.—pH-Absorbance plots of TAMR solutions in the presence of excess of metal ion.
$C_R = 4 \times 10^{-5} M$, $C_M = 2 \times 10^{-3} M$:
1—Hg(II), 537 mμ; *2*—Cu(II), 535 mμ; *3*—Ni(II), 520 mμ;
4—Co(II), 511 mμ; *5*—Cd(II), 508 mμ; *6*—Zn(II), 513 mμ;
7—Pb(II), 538 mμ.

TAMH and TAMR as metal-ion indicators in EDTA-titrations

Both indicators are suitable for the EDTA-titration of Cu(II), In(III), Bi(III), Tl(III), Hg(II), Cd(II), Zn(II), Pb(II), Ni(II) and Co(II).

TAMH is generally preferred because the complex formation takes place at lower pH and there is a marked colour change from blue, blue-green or green to yellow or yellow-orange at the equivalence point. The difference in colour between the H_2R^+-form of TAMR and its metal complexes, especially those of bismuth(III) and thallium-(III), which are preferentially titrated at pH 1–2, is not great.

The following determinations have been investigated.

Determination of copper(II) and indium(III). Add 6–8 drops of 0·1% methanolic solution of TAMH and 20 ml of buffer (pH 4·5) to 100 ml of sample solution containing 3–30 mg of copper(II) or 6–35 mg of indium(III) and titrate the solution with 0·05*M* EDTA. The colour change at the equivalence point is from blue-green to yellow, passing through light green, and occurs with 1–2 drops of titrating solution.

When TAMR is used a buffer of pH 6·0 is preferable and the colour change is then from red to bright yellow. At higher concentrations of copper(II) the colour change is less distinct. This indicator is not recommended for indium(III) titration.

Determination of bismuth(III) and thallium(III). The titration of bismuth(III) (10·5–63 mg) is carried out at pH 1·5–2 in solutions containing nitrate. When TAMH is used there is a sharp colour change from green to yellow-orange at the equivalence point, but with TAMR there is a less suitable change from red to yellow-orange.

Carefully neutralize the thallium(III) (34–135 mg) solution with 10% ammonia until a precipitate just appears and then add 20 ml of 1*M* chloroacetic acid and a few drops of indicator solution. The equivalence point is indicated by a sharp colour change green to yellow over one drop of 0·05*M* EDTA when TAMH is used. With TAMR the colour change from brick red to yellow-orange is not quite so sharp.

Determination of mercury(II), cadmium(II), zinc(II) and lead(II). Add 20 ml of buffer (pH 6) and 6–8 drops of indicator solution to 100 ml of metal-ion solution. A very distinct colour change is obtained with both indicators at the equivalence point, *i.e.*, from blue-green to yellow (yellow-orange) when TAMH is used or from red to yellow in the presence of TAMR, over a wide range of metal-ion concentrations.

Determination of nickel(II) and cobalt(II). Add 20 ml of buffer (pH 6) and 6–8 drops of indicator solution to 100 ml of metal-ion solution containing 3–30 mg of metal ion. Heat the solution to 50–60° for nickel(II) or 60–70° for cobalt(II) and instantly titrate with 0·05*M* EDTA. A reasonably sharp colour change is observed at the equivalence point; from blue through violet to yellowish orange with TAMH and from red to yellow with TAMR.

Precision

The precision of the titrations of various metal ions at different concentrations is given in Table IV. The results were evaluated according to the procedure of Dean and Dixon[12] from 6 titrations per metal and for 95% probability.

Acknowledgement—The authors are indebted for the pure indicator samples to Ing. V. Svoboda and Ing. L. Bendová and appreciate the interest shown by Ing. V. Svoboda.

Zusammenfassung—2-(2-Thiazolazo)-5-methoxyphenol (TAMR) und 2-(2-Thiazolazo-34-methoxyphenol (TAMH) bewehren sich als gute Metallindicatore bei den ÄDTA-Titrationen, wobei TAMH einige Vorteile zeigt. Die analytische Reaktionsfähigkeit gegen Metallionen und der pH-Einfluss auf die Extinktion der Indikatorlösungen und deren Chelate mit einigen Metallen werden studiert und die Dissoziationskonstanten der Indicatore sowie auch optische Angaben für einige Metallchelate werden angeführt.

Résumé—2-(2-Thiazolylazo)-5-methoxyphénol (TAMR) et 2-(2-Thiazolylazo)-4-methoxyphénol (TAMH) s'est revelé comme indicateurs des ions métallique au cours des titrations par EDTA où TAMH s'est montré plus advantageux. L'influence du pH sur la densité optique des solutions des indicateurs et leur chelates métallique st les qualités analytiques des ces deux indicateurs sont étudié et les constants de dissociation des indicateurs et les donnés optiques des quelques chelates métalliques sont présentés.

Summary—A scheme for the isolation of subpicogram to microgram amounts of thorium from bone and soft tissue samples is described. Thorium is first collected by co-precipitation with iron(III) hydroxide and then adsorbed by a cation-exchange resin column from a concentrated hydrochloric acid solution of the precipitate. A double precipitation is necessary for bone samples whereas a single precipitation suffices for liver samples. The thorium is eluted from the column with an ammonium carbonate solution which is then evaporated to dryness to effect the isolation. Good recoveries of thorium from bone samples are obtained.

NUMEROUS studies have been made on the distribution and excretion of thorium compounds; these have been ably summarized by Boecker.[1] The quantity of thorium distributed over the body varies with the mode of administration and the form in which the material is injected. Mobilization usually occurs soon after administration but in many cases the amount distributed is very small, the bulk of that added remaining at the original site. The two principal sites of deposition of the mobile material are the liver and the skeleton.

Studies with animals can be carried out rather easily with the aid of γ-active thorium-234. However, in cases of exposure to the stable isotope, and more specifically in the case of those patients to whom thorotrast had been administered, the problem of measuring thorium levels is not simple.

Because thorium phosphate is one of the few acid-insoluble phosphates, the element must be separated from phosphate before any of the colorimetric or fluorimetric methods may be used for measurement. In biological samples, it would be expected that separation from bone would present the greatest difficulty. It was the purpose of this work to develop a separation scheme to isolate the smallest measurable quantities of thorium from relatively large amounts of bone with the expectation that the same scheme would be applicable to any other biological sample. The quantitative estimation of the thorium could then be made by any of the numerous methods available, for all interfering ions would have been eliminated

In this work thorium-234 (UX_1) was used without added carrier for the smallest quantities of thorium. In testing the suitability of the separation scheme for a subsequent colorimetric estimation, sufficient carrier thorium was added to the radioisotope, and the final recoveries were measured both by radioactivity and colorimetry. Menis *et al.*[2] have used both cation- and anion-exchange columns for eliminating interferences in their spectrophotometric determination of thorium. Their work is

* This paper is based on work performed under contract with the United States Atomic Energy Commission at the University of Rochester Atomic Energy Project, Rochester, New York, U.S.A.

not strictly comparable with that described here because the levels of the impurities (5 mg of phosphate, 1 mg of iron) are very different from those encountered in samples of bone and liver.

EXPERIMENTAL

Apparatus

Radioactivity measurements were made on a Radiation Instrument Development Laboratory Model 49–51 counter with a sodium iodide crystal well. A Beckman DU quartz spectrophotometer was used for spectrophotometric measurements.

Materials

Thorium-234. The radioisotope ^{234}Th (UX_1) was prepared as needed by the method of Berman *et al.*[3] Approximately 60 g of UO_3 were dissolved in 150 ml of conc. hydrochloric acid and poured through 350 g of Amberlite XE-117 resin in a column 3·5 × 100 cm. The radioisotope was stripped whenever needed by passing 750 ml of 9·6*M* hydrochloric acid (4 + 1 conc. acid and water) through the column, evaporating off the acid and igniting the residue at 450°. The stock solution of the isotope was prepared by dissolving the residue in 100 ml of nitric acid (1 + 1).

Biological samples. Pre-ashed beef bone and several different kinds of fresh liver were used for samples. A standard quantity of 10 g of bone ash was spiked with an appropriate quantity of thorium and placed in a muffle furnace for 5 hr at 600°. Liver samples were spiked, dried at a low temperature and gradually brought up to the final temperature of 600°.

Iron(III) chloride solution. Conc. hydrochloric acid (1 ml) was added to 1 g of iron(III) chloride hexahydrate and diluted to 100 ml. Analytical grade reagents and deionized water were used.

Procedure for bone

Dry-ash the bone at 600° overnight. Dissolve 10 g of the ash in about 200 ml of 6*M* hydrochloric acid (1 + 1 conc. acid and deionized water) with heating. Add 10 ml of iron(III) chloride solution. Add concentrated ammonia solution until the pH is between 3·15 and 3·4 and collect the precipitate on a Whatman No. 40 filter paper. No washing is necessary. Dissolve the precipitate by pouring about 150 ml of 6*M* hydrochloric acid through the filter paper and collect the solution in the original beaker. Adjust the pH of the solution to 3·3 with 40% sodium hydroxide solution and repeat the collection and dissolution of the precipitate with 6*M* hydrochloric acid, collecting the solution again in the original beaker.

Pass the hydrochloric acid solution through a prepared cation-exchange resin column at a rate of about 15 drops per min. Wash the column successively with 150 ml of 6*M* hydrochloric acid and 150 ml of 20% ammonium chloride solution. Elute the thorium from the column with 75 ml of 20% ammonium carbonate solution. Cover the beaker with a ribbed watch glass and evaporate the carbonate solution to dryness. Add 1 ml of conc. sulphuric acid and heat until all the acid is expelled. Place the beaker in a muffle furnace at 450° for 1 hr, cool it, add about 5 ml of dilute nitric acid (previously made up to pH 2·0) and warm the beaker. Transfer the contents to a 10-ml volumetric flask with the pH 2·0 nitric acid solution. Take an appropriate aliquot for analysis.

Procedure for liver and soft tissue

Quantities of about 10 g have been treated. Dry the sample in a platinum dish and gradually increase the temperature to 600°. Heat for at least 5 hr. Dissolve the residue in 100 ml of 6*M* hydrochloric acid, heating if necessary. Add 10 ml of iron(III) chloride solution and adjust the pH to 3·3 with 40% sodium hydroxide. Collect the precipitate on a Whatman No. 40 filter paper, dissolve the precipitate with 6*M* hydrochloric acid and continue with the cation-exchange as in the procedure for bone.

Preparation of column

The column used was of borosilicate glass 15 mm in diameter and 450 mm long with a 10-mm coarse sintered glass disk and a Teflon stop-cock. An enlarged section was attached to the top end of the column so that a substantial amount of solution could be poured in at one time. Approximately 25 g of air-dried Dowex 50-X8 resin (50–100 mesh) was added to some deionized water and poured into the column. The column was back-washed with deionized water to remove all air bubbles, and the following solutions were passed through successively.

(1) 25 ml of 20% ammonium carbonate solution
(2) 100 ml of 20% ammonium chloride solution
(3) 100 ml of dilute hydrochloric acid (10 ml of conc. acid/100 ml)

(4) 100 ml of hydrochloric and nitric acids (50 ml of conc. hydrochloric acid and 2 ml of conc. nitric acid /100 ml)
(5) 100 ml of 6*M* HCl (1 + 1 mixture of conc. acid and deionized water).

DISCUSSION

It might be expected that quadrivalent thorium would be strongly absorbed by a cation-exchange resin[4], but thorium-234 was removed only to the extent of 50% by a 30-g Dowex 50-X8 resin column from a 6*M* hydrochloric acid solution of 10 g of bone ash. Attempts to use a nitric acid solution with an anion-exchange resin column were equally unsuccessful, and it was necessary to use a preliminary separation step to remove the bulk of the phosphate. Precipitation of thorium along with a collecting precipitate was the method chosen, and ordinary filtration was used although centrifugation would have been equally satisfactory. A double precipitation was necessary for bone samples because the first precipitate contained sufficient phosphate to cause interference with the cation-exchange separation (40 to 50% not retained by the column). Even in the case of liver, a single preliminary precipitation was necessary before the cation-exchange column could be used. The conditions used for the liver were exactly the same as for the second precipitation in the case of bone samples.

The preliminary separation

The object of the preliminary separation is to separate the thorium from the bulk of the phosphate. Sill and co-workers[5] have reported the successful use of barium sulphate to collect the thorium from as much as 2 g of bone in solution even in strongly acidic media. In the present work, all the separations were based on 10-g bone ash samples, and the acidity was very much a factor in the quantity of thorium collected by barium sulphate. The addition of 4 ml of 0·2*M* barium chloride to the bone dissolved in 150 ml of 6*M* hydrochloric acid, followed by the addition of sulphate resulted in the collection of only 2·5% of the thorium at the tracer level. The addition of 3 ml of 2*M* sulphuric acid to precipitate some calcium sulphate from the acidic bone-solution resulted in the collection of about 2% of the thorium. When the bone solution was partially neutralized by the addition of concentrated ammonia solution until a calcium phosphate precipitate just persisted (pH 1·88) and then the barium chloride solution and sodium sulphate solution were added successively, 97·3% of the thorium was collected. However, the barium sulphate collection was not suitable for the subsequent ion-exchange separation because of its insolubility in acid.

Attempts to use a limited amount of calcium phosphate precipitate as a collector were not satisfactory because of the difficulty in controlling the amount of precipitate. The addition of iron(III) and the adjustment of the pH to a definite value proved to be the best solution. The control of pH is essential because exceeding the upper limit results in the precipitation of a large amount of calcium phosphate which increases the bulk considerably. Too low a pH gives poor collection. The first precipitation carries sufficient phosphate to interfere with the ion-exchange absorption of the thorium, so double precipitation is necessary. Recovery of carrier-free thorium-234 from both collection steps was essentially complete. A single preliminary collection for liver adequately removed the excess of phosphate.

Final separation

Sorption of thorium on a cation-exchange resin (Dowex 50-X8) from a fairly concentrated hydrochloric acid solution was used for the final stage of the separation

because thorium is almost selectively removed under these conditions. Complexing agents which would reduce the charge of quadrivalent thorium should be absent. None of the usual cations found in biological materials would be retained on a cation-exchange resin in the presence of 6*M* hydrochloric acid. Iron(III), for example forms a negatively charged chloride complex. Phosphate, which forms complexes with thorium, would be expected to be almost completely in the form of undissociated phosphoric acid, but the quantity from 10 g of bone ash is sufficient to interfere with the ion-exchange step, and has to be reduced as already described. The optimum quantity of resin was determined from the study of the retention of thorium in the presence of that concentration of phosphate still in solution after the preliminary separation. The thorium from a solution containing 4 ml of 85% phosphoric acid (equivalent to the quantity of phosphate in 10 g of bone ash) was first collected by 40 mg of iron precipitated at pH 3·3. The precipitate was separated and dissolved in 6*M* hydrochloric acid, and the solution was poured through columns containing different amounts of resin. The results are shown in the Table I. For the routine procedure a 25-g column was used.

TABLE I.—RETENTION OF THORIUM ON ION-EXCHANGE COLUMNS OF VARYING SIZE

Weight of resin, g	Th passed through, %
5	32
10	8·4
15	3·4
20	0·5

For stripping the thorium from the column, 20% ammonium carbonate solution as described by Chernikhov *et al.*[6] was used. The rate of elution seemed quite variable but in general most of the activity was removed from the column in the first 50 ml. Table II shows 3 separate elution patterns. The eluate was collected in 25-ml portions.

TABLE II.—ELUTION OF THORIUM BY AMMONIUM CARBONATE

Portion	Eluted, %		
	Run 1	Run 2	Run 3
1	84·1	86·8	48·3
2	5·1	11·6	49·6
3	7·0	0·3	0·8
4	0·1	—	—
Total	96·3	98·7	98·7

The use of ammonium carbonate for elution is very desirable because it is completely eliminated during the evaporation process. Ammonium chloride solution was used to remove the acid from the column before the addition of the carbonate solution because it too could be eliminated by low-temperature heating. Sulphuric acid was added before the final heating in order to convert the thorium into the sulphate form which is stable at 450° and easily soluble. The final heating temperature of 450° was sufficient to eliminate traces of organic matter eluted from the column and also permit the use of borosilicate beakers.

With the separation scheme employed, only thorium should be isolated from biological samples. Radioactivity measurements showed essentially complete recovery. As a final check to see whether the separation scheme would produce samples suitable for some chemical method, a series of bone samples was spiked with both radioactive thorium and stable thorium. The colorimetric method using Morin, as described by Fletcher and Milkey,[7] was employed as a check on the radioactivity measurement, The recoveries measured by the two methods are shown in Table III. It was noticed

TABLE III.—RECOVERY OF THORIUM FROM BONE

Sample No.	Recovery, %	
	Radioactivity	Colorimetric
1	99·2	97·1
2	101·7	100·7
3	99·9	99·3
4	99·2	98·2

that the colorimetric method gave high results if the hydroxylamine were omitted. This was attributed to the presence of traces of iron introduced with reagents added after the separation.

Since the thorium is finally isolated in a soluble form, the final measurements may be made by any method. This is in contrast to schemes which use an insoluble collecting agent such as barium sulphate which requires an alkaline solution of a complexing agent for dissolution. The measurement must then be made under alkaline conditions.

Résumé—On décrit un schéma d'isolement de quantités de thorium allant du subpicogramme au microgramme à partir d'os et de tissus mous. On recueille d'abord le thorium par coprécipitation avec l'hydroxyde de fer(III), puis l'adsorbe sur une colonne de résine échangeuse de cations à partir d'une solution du précipité dans l'acide chlorhydrique concentré. Une double précipitation est nécessaire pour les échantillons d'os alors qu'une précipitation simple suffit pour les échantillons de foie. Le thorium est élué de la colonne par une solution de carbonate d'ammonium que l'on évapore alors à sec pour effectuer l'isolement. On obtient de bonnes récupérations de thorium à partir des échantillons d'os.

Zusammenfassung—Ein Verfahren zur Isolierung von Subpicogrammbis Mikrogrammengen Thorium aus Proben von Knochen- und Weichteilgewebe wird beschrieben. Zuerst wird das Thorium durch Mitfällung mit Eisen(III)-hydroxid gesammelt und anschließend aus einer Lösung des Niederschlages in konzentrierter Salzsäure an einer Säule aus Kationenaustauscherharz adsorbiert. Für Knochenproben ist zweimalige Fällung notwendig, für Proben aus Leber genügt eine. Das Thorium wird von der Säule mit einer Ammoncarbonatlösung eluiert, die zur Isolierung zur Trockne eingedampft wird. Bei Knochenproben werden gute Thoriumausbeuten erzielt.

DISSOCIATION CONSTANTS AND ULTRAVIOLET SPECTRA OF THE CONJUGATE ACIDS OF OXIMES

PAUL R. ELLEFSEN*® and LOUIS GORDON†
Department of Chemistry, Case Institute of Technology
Cleveland, Ohio 44106, U.S.A.

(*Received* 18 *August* 1966. *Accepted* 1 *October* 1966)

Summary—A spectrophotometric method was used to determine the acid dissociation constants of the conjugate acids of dimethylglyoxime and biacetyl monoxime. The dissociation constant, the acidity function and the absorbance of a mixture of protonated and unprotonated oxime were utilized to obtain the ultraviolet spectra of the protonated oxime.

Two semiquantitative determinations of the dissociation constant of the conjugate acid of dimethylglyoxine have been previously reported. Banks and Anderson[1] studied several dioximes, including dimethylglyoxime, and concluded that all the dissociation constants were approximately the same and of the order of 100 in 75% dioxane–25% water mixtures. Freiser[2] reported pK_A for dimethylglyoxime to be less than 2, *i.e.*, K_A to be greater than 0·01. No similar investigation for biacetyl monoxime has been reported.

Oximes, such as dimethylglyoxime and biacetyl monoxime, are very weak bases and decompose in acid solution.[3] Because of this, the present study utilizes a modified spectrophotometric technique to obtain more accurate results for the dissociation constants of the conjugate acids of dimethylglyoxime and biacetyl monoxime. In addition, the ultraviolet spectra of these acids have been determined.

EXPERIMENTAL

Reagents

Dimethylglyoxime (Baker analysed) was dried in a desiccator over calcium chloride and used without further purification.

Biacetyl monoxime (Matheson, Coleman and Bell) was sublimed thrice at 35° and 1 mm Hg pressure.

All other chemicals used were reagent grade.

Apparatus

All spectrophotometric measurements were made on a Cary Model 14 instrument equipped with a thermostatic cell compartment (±0·1°).

Procedure

A 3-ml portion of hydrochloric acid of known strength was transferred to a 1-cm cell by pipette. This solution was brought to constant temperature and then 0·04807 ml of a solution of either biacetyl monoxime in water or of dimethylglyoxime in ethanol was added by means of a Hamilton microlitre syringe equipped with a Chaney adapter. The absorbance was measured at a fixed wavelength at intervals of time. About 15 sec elapsed between the addition of oxime and the first recording of the absorbance. The absorbance plot was extrapolated to zero time so as to yield the absorbance of the equilibrium mixture of the undecomposed protonated and unprotonated forms of the oxime.

* Present address: Department of Chemistry, Hanover College, Hanover, Indiana.

RESULTS AND DISCUSSION

The procedure described was used at 50-Å intervals over the wavelength range 2100–2700 Å, and the ultraviolet spectrum of dimethylglyoxime in hydrochloric acid of various concentrations was obtained. A plot of the extinction coefficient, ε_S, of the solution *vs.* wavelength is shown in Fig. 1;

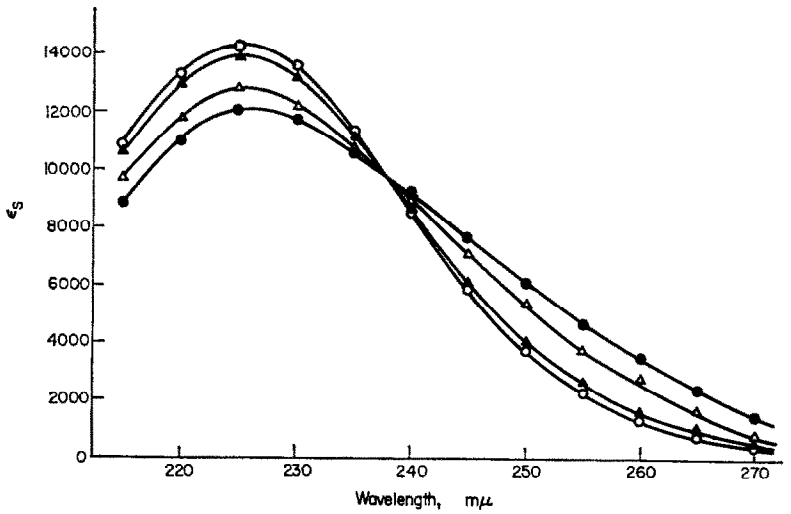

FIG. 1.—Effect of hydrochloric acid concentration on the absorption spectra of dimethylglyoxime between 210 and 270 mμ, at 25·0°C.
Isosbestic point 237·6 mμ; $\varepsilon_{237.6} = 10{,}120$.
[HCl], *M*: ○—0·0; ▲—0·406; △—1·218; ●—1·624.

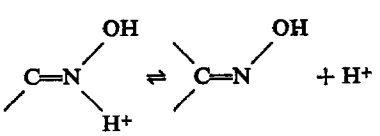
$$\varepsilon_S = \frac{A_0}{[HD]_t} \tag{1}$$

where A_0 = absorbance extrapolated to zero time
$[HD]_t$ = dimethylglyoxime initially added = $[HD] + [HDH^+]$
HD = dimethylglyoxime
HDH^+ = protonated dimethylglyoxime

Figure 2 shows a plot of ε_S *vs.* wavelength in the range 2300–2500 Å obtained in a similar way with biacetyl monoxime in hydrochloric acid of various concentrations. Both figures show very good isosbestic points indicating that the extinction coefficients of both the protonated and unprotonated oximes are not a function of solvent composition. Hence, a spectrophotometric method can be used to give accurate results for the concentrations of protonated and unprotonated oximes.

Only the method used to determine the acid dissociation constant of biacetyl monoxime will be described; the method employed for dimethylglyoxime is identical.

The acid dissociation constant for the reaction



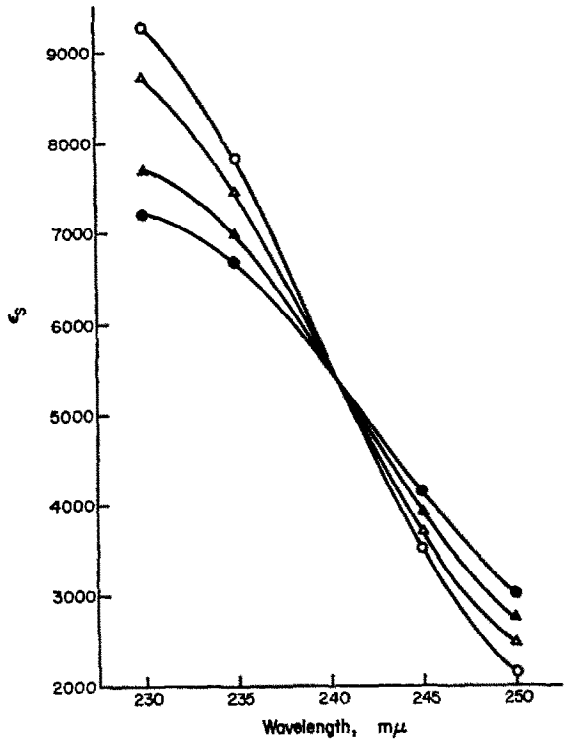


FIG. 2.—Effect of hydrochloric acid concentration on the absorption spectrum of biacetyl monoxime between 230 and 250 mμ at 25·0°C.
Isosbestic point 240·8 mμ
[HCl], *M*: ●—10·07; ▲—7·55; △—2·52; ○—0·00.

in the case of biacetyl monoxime is given by

$$K_A^{HMH^+} = \frac{a_{H^+}a_{HM}}{a_{HMH^+}} = \frac{h_0[HM]}{[HMH^+]}, \qquad (2)$$

where a denotes the activity of the species indicated by the subscript. It is readily seen that a plot of the ratio, $[HMH^+]/[HM]$ *vs.* h_0, the acidity function, should result in a straight line whose slope is the dissociation constant, $K_A^{HMH^+}$.[4]

Acidity functions were used because of the high ionic strengths involved. The values of h_0 used[5] are shown in Tables I and II.

The values of $[HMH^+]/[HM]$ were obtained from equations (3) and (4) as follows:

$$A_0 = A_{HM} + A_{HMH^+} = \varepsilon_{HM}[HM] + \varepsilon_{HMH^+}[HMH^+] \qquad (3)$$

$$[HM]_1 = [HM] + [HMH^+] \qquad (4)$$

$$\varepsilon_S = \frac{A_0}{[HM]_1}. \qquad (5)$$

The value of ε_{HM} was determined in neutral solution where decomposition does not take place and there is no significant protonation. The value of ε_{HMH^+} was obtained by plotting ε_S *vs.* h_0 and extrapolating to infinite h_0. At infinite h_0, *i.e.*, infinite concentration of hydrochloric acid, all of the biacetyl monoxime will be in the protonated form and hence ε_S becomes ε_{HMH^+}. Figure 3 shows an example of the extrapolation

from which it can be seen that ε_S asymptotically approaches a limiting value. In effect, equation (3) becomes

$$\varepsilon_S = \frac{A_{HMH^+}}{[HMH^+]} = \varepsilon_{HMH^+}. \tag{6}$$

At 20, 25 and 30°, the values of ε_{HMH^+} were found to be 6070, 6120 and 6110 respectively. The values of [HM] and [HMH⁺] were then calculated from equations (3) and (4) and the ratio [HMH⁺]/[HM] was obtained. The results for biacetyl monoxime are shown in Table II and for dimethylglyoxime in Table I.

The plot of [HMH⁺]/[HM] *vs.* h_0 results in a straight line except at very high values of [HMH⁺]/[HM], as shown by the typical example in Fig. 4. It is difficult to obtain highly accurate values of A_0 at high acid concentrations where there is a concomitant increase in the rate of decomposition of the oximes; errors in A_0 result in errors in the values of ε_{HMH^+} and of [HMH⁺]/[HM]. The errors involved in the extrapolation are not large; ε_S will be reasonably accurate even at high acid concentrations and thus ε_{HMH^+} should be reasonably accurate. However, small errors in

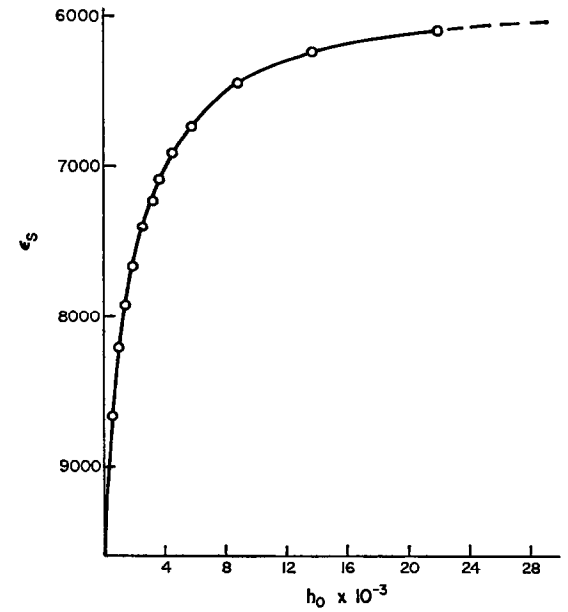

FIG. 3.—Molar absorptivity of biacetyl monoxime as a function of the acidity, at 2·0°C. $\varepsilon^{2275}_{HMH^+} = 6070.$

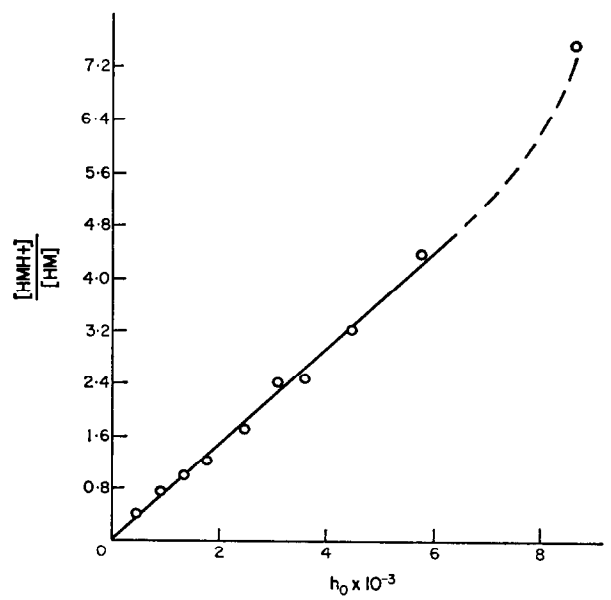

FIG. 4.—The dissociation constant of biacetyl monoxime at 30·0°C.

$$K_A^{HMH^+} = \frac{h_0[HM]}{[HMH^+]} = 1380.$$

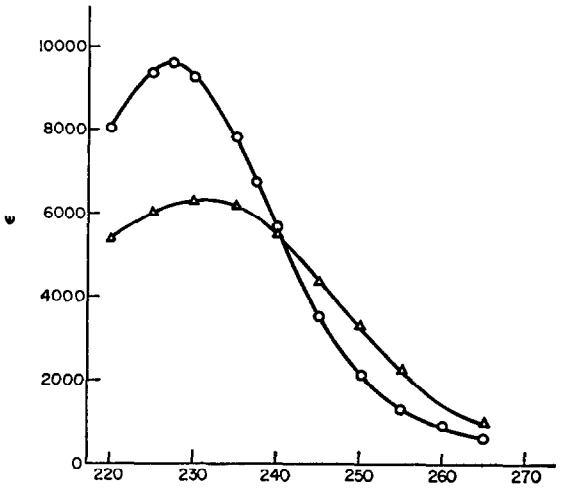

FIG. 5.—The ultraviolet absorption spectra of protonated and unprotonated biacetyl monoxime.
○—HM; λ_{max} 227·5 mμ; ε_{max} 9650
△—HMH^+; λ_{max} 231·0 mμ; ε_{max} 6300.

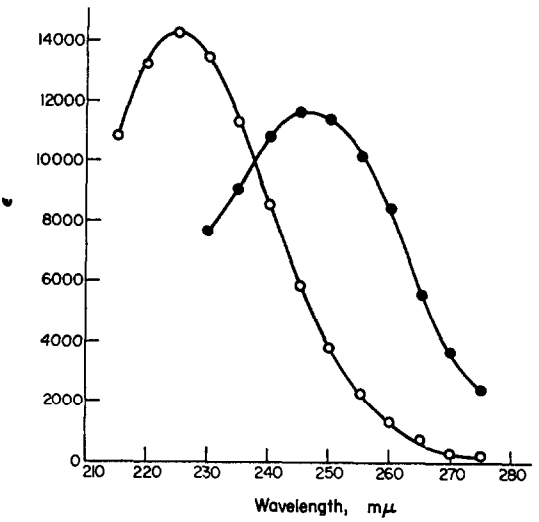

FIG. 6.—The ultraviolet absorption spectra of protonated and unprotonated dimethylglyoxime.
○—HD; λ_{max} 225·0 mμ; ε_{max} 14100
●—HDH^+; λ_{max} 246·0 mμ; ε_{max} 10800.

A_0 will produce large errors in [HMH^+]/[HM] when this ratio is very large, and when the acid concentration is high, because the error in A_0 will approach or exceed the value of A_{HM} as A_{HM} becomes very small. Hence, the straight-line portion of a plot, as shown in Fig. 4, was always obtained by ignoring the [HMH^+]/[HM] values for high acid concentrations.

TABLE III.—THE DISSOCIATION CONSTANTS $K_A^{HDH^+}$ AND $K_A^{HMH^+}$

Temperature, °C	$K_A^{HDH^+}$	$K_A^{HMH^+}$
30·0	8·69	1380
25·0	8·67	1440
20·0	8·72	1490

The values obtained for the dissociation constants, $K_A^{HMH^+}$ and $K_A^{HDH^+}$, are given in Table III. (The values of ε_{HDH^+} were found to be 11830 and 4900 at 2550 Å and 2250 Å respectively.)

A value of ε_{HMH^+} at any given wavelength can be obtained from the dissociation constant, equations (2), (3) and (4), and a single value of ε_S obtained at the same wavelength. Values of ε_{HMH^+} were thus calculated at 50-Å intervals for the region 2200–2650 Å. The calculated spectrum for protonated biacetyl monoxime is shown in Fig. 5 along with the spectrum of the unprotonated monoxime. The same procedure was used to obtain the spectrum for protonated dimethylglyoxime in the region 2300–2750 Å, and the results are shown in Fig. 6. A red shift of 210 Å is observed on protonation of dimethylglyoxime, and a red shift of 35 Å for biacetyl monoxime. This red shift has been observed previously in the protonation of other more basic Schiff's bases.[3,6]

Acknowledgement—The authors acknowledge the partial assistance of the United States Atomic Energy Commission in supporting this investigation, under Contract AT(11-1)582.

Résumé—On a utilisé une méthode spectrophotométrique pour déterminer les constantes de dissociation acide des acides conjugués de la diméthylglyoxime et de la diacétyl monoxime. On a utilisé la constante de dissociation, la fonction d'acidité et l'absorption d'un mélange d'oxime protonée et non protonée pour obtenir le spectre ultra-violet de l'oxime protonée.

Zusammenfassung—Die Säuredissoziationskonstanten der konjugierten Säuren von Dimethylglyoxim und Biacetylmonoxim wurden spektrophotometrisch gemessen. Die Dissoziationskonstante, die Aciditätsfunktion und die Extinktion einer Mischung von protoniertem und nicht protoniertem Oxim wurden benutzt, um die Ultraviolettspektren des protonierten Oxims zu erhalten.

DETERMINATION OF ALUMINIUM AND SODIUM IN TUNGSTEN BY NON-DESTRUCTIVE ACTIVATION ANALYSIS

P. QUITTNER, A. SIMONITS and A. ELEK
Central Research Institute for Physics, Budapest, Hungary

(*Received* 26 *August* 1966. *Accepted* 3 *November* 1966)

Summary—The sodium and aluminium content of tungsten has been measured by thermal neutron activation analysis. The concentration of aluminium was evaluated from the 1·78 MeV, and that of sodium from the 2·76 MeV full energy peaks. The minimum detectable concentrations of impurities were 0·04 μg of aluminium and 0·07 μg of sodium per 100 mg of tungsten.

TUNGSTEN is known to be a poor matrix for activation analysis. The reactions induced by thermal neutrons in natural tungsten are listed in Table I.[1,2] Owing to ^{187}W interference, the sensitivity of the non-destructive method is inadequate for elements

TABLE I.—INTERFERING (n, γ) REACTIONS IN TUNGSTEN

Natural stable isotopes	Abundance %	Isotopic cross-section *barn*,	Species	Half-life	Decay	Stable final product
^{180}W	0·14	20	^{181}W	140 d	k, β^-, γ	^{181}Ta stable
^{184}W	30·7	2	^{185m}W	1·8 min	IT	^{185}Re stable
			^{185}W	73 d	β^-	
^{186}W	28·7	34	^{187}W	24 h	β^-, γ	^{187}Re stable

which do not emit γ-rays with energy above 1 MeV. The non-destructive method was used by Corth for the determination of 0·1–10% of tantalum in tungsten and for sodium by Reuland and Voight.[3,4] In the tungsten samples analysed by the authors the concentration of aluminium was found to be 3–5 $\times$ 10^{-4} %, that of sodium 2–8 $\times$ 10^{-4} %.

EXPERIMENTAL

Irradiations were carried out in the VVRSz-type reactor with 5 $\times$ 10^{12} n/cm^2/sec thermal neutron flux. The cadmium ratio, as measured in aluminium, was 1:30 at the site of exposure, which was connected to the measuring equipment by means of a pneumatic tube system.[5] The helical tungsten samples, 80–100 mg in weight were kept in danamide (polyamide) holders during the exposure. For the activity measurement the irradiated holders were replaced by nonactivated ones. For samples of this size the attenuation of the neutron flux in tungsten is less than 1% and its effect can be neglected. Solutions of aluminium nitrate (0·1% Al) and sodium sulphate (0·5% Na) dropped onto Düren 640 m 5·5-cm filter paper (0·02 mg ash content) were used as standards, and the measured values were corrected for the impurities present in the filter paper.

An NaI crystal, 3 in. $\times$ 3 in. (Nuclear Enterprises 12/IA-4/12 Integral Assembly) and an NTA-256 type multichannel analyser and a single channel analyser were used for the activity measurements. In order to reduce the pile-up of signals due to the high tungsten activity, the signal width of the photomultiplier was reduced from 18 μsec to 1·5 μsec by decreasing the plate load resistance. Even so, the superimposed tungsten background was still too high in the region of the 2·76 MeV photopeak of sodium. To overcome this, the distance between sample and detector was increased (the individual activity counts decrease linearly with the solid angle, whereas the pile-up counts

decrease at least with the square of the solid angle) and a lead shield was inserted between sample and detector (the higher energy gamma intensity of the measured activity is decreased less by the shield than is that of the tungsten radiation, and the pile-up is known to be proportional at least to the second order of the transmission probability). By variation of the distance from sample to detector and of the thickness of lead, the ratio of the measured activity to the total interfering activity can be increased so as to render the tungsten pile-up comparable to the natural background count. Under the given experimental conditions a 20-cm sample–detector distance and 1·5 cm of lead was enough to provide a good aluminium to tungsten pile-up ratio. To reduce the natural background, the measurements were performed in an iron box with a wall 15 cm thick lined with lead, cadmium and copper plates.

RESULTS

Aluminium

The nuclear reaction

$$^{27}\mathrm{Al}(n, \gamma)^{28}\mathrm{Al} \xrightarrow[\beta-]{t_{1/2} = 2{\cdot}27 \text{ min}} {}^{28}\mathrm{Si} + \gamma$$

with 0·23 barn cross-section for thermal neutrons was used for the determination of aluminium. The measurement covered the 1·775 MeV gamma activity from ^{28}Si.[1,2] Calculations made from the available cross-section[6] and fast neutron flux data have shown that the chance of ^{28}Al production by the fast neutron induced ^{28}Si(n, p)^{28}Al and ^{31}P(n, α)^{28}Al is negligible, considering that 60 μg of silicon or 170 μg of phosphorus contamination would be necessary to produce as much ^{28}Al as 1 μg of aluminium. Though either of these high contaminations seemed improbable, parallel irradiations were performed with a cadmium filter. The check proved that the total ^{28}Al activity originated from ^{27}Al.

Both the samples and standards were irradiated for 60 sec. On termination of the irradiation 10 sec were needed to take the sample to the measuring equipment and 40 sec to replace the sample holder before the start of the activity measurement. In serial analysis, for maximum statistical accuracy the counts in the aluminium full energy peak area were taken on a single channel analyser for 200 sec,[7] at two 100-sec intervals to check the half-life. After the total decay of the aluminium activity, which takes 20 min, the tungsten and other background activities could be established. The aluminium concentration was evaluated from the sample and standard full energy peak counts. The method was checked by measuring the half-life and the pulse-height spectrum of both the sample and the standard on the multichannel analyser. In Fig. 1a the spectrum of a 90-mg tungsten sample containing 0·4 μg of aluminium, and the background of the tungsten after the decay of the aluminium, are shown, while in Fig. 1b the spectrum of this sample is shown with that of a 10-μg aluminium standard corrected for background. In Fig. 2 is shown the decrease with time of the aluminium photopeak counts, corrected for background in the tungsten sample. The value of the half-life thus obtained is in agreement with the 2·27 min half-life of the ^{28}Al activity.

The results were also checked by performing the measurement described above with measured amounts of 1–10 μg of aluminium juxtaposed to the samples. The result of the activity measurement showed in each case the total measured aluminium concentration to be equal to the sum of the amount already found in the tungsten and the juxtaposed amount of aluminium.

Since the standards and samples were not irradiated simultaneously, the time behaviour of the reactor flux had to be checked. The reproducibility of the measurements was tested also by reactivating the tungsten samples after several days. For

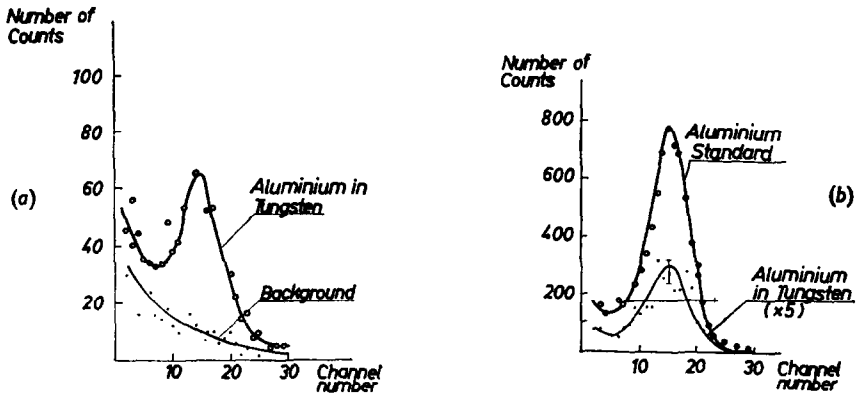

FIG. 1.—(a) Spectra of a 90-mg tungsten sample, containing 0·4 μg of aluminium, and of the background of the tungsten after decay of the aluminium. (b) Spectra of the same sample and of a 10-μg aluminium standard corrected for background.

tungsten samples containing 4–6 ppm of aluminium (0·3–0·5 μg) the results were found to be reproducible within the 10% statistical variation in the number of counts.

The maximum obtainable sensitivity for the non-destructive method is determined by the background count. In the present case it was equivalent to 0·1 μg of aluminium. If the minimum detectable amount is defined such that the counts due to the activity

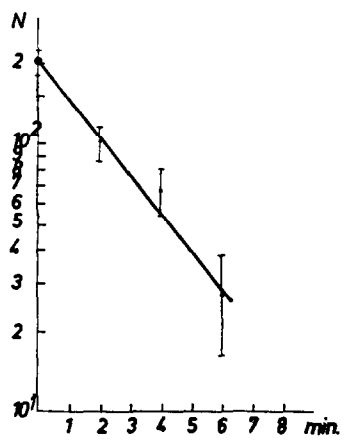

FIG. 2.—The decay of the aluminium full energy peak in a 90-mg tungsten sample containing 0·4 μg of aluminium.

of the element to be determined should exceed the experimental error of the background count (taken as three times the standard deviation) the method permits the quantitative determination of 0·04 μg of aluminium in 100 mg of tungsten.

Sodium

For the determination of sodium, the tungsten samples were irradiated for 200 sec. The activity measurement was based on the 15 hr half-life ^{24}Na produced by the ^{23}Na(n, γ)^{24}Na reaction (0·505 barn reaction cross-section).[1,2] No inconvenient interference was caused by the fast neutrons. Since the analysis is sensitive for even small

amounts of sample (20–100 mg), the method can be applied to cover both elements even if the inhomogeneity of the contaminants along the tungsten filament must also be known. For the identification of sodium, the 2·76 MeV full energy peak was used because the 1·38 MeV peak was considerably masked by the pile-up of the tungsten activity. The samples were measured twice, each time for 2500 sec, to check the

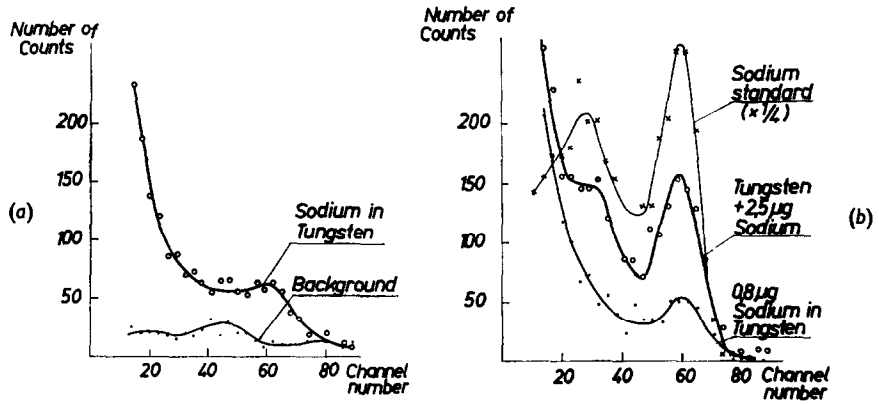

FIG. 3.—(a) Spectra of an 88-mg tungsten sample containing 0·8 μg of sodium and of the background. (b) Spectra of the same sample, alone and with 2·5 μg of sodium juxtaposed, and of a 20-μg sodium standard.

half-life. The spectrum and background are plotted in Fig. 3a for an 88-mg tungsten sample containing 0·8 μg of sodium. The spectra of an 88-mg tungsten sample, of 2·5 μg of sodium juxtaposed to the tungsten and corrected for background, and of a 20-μg sodium standard are shown in Fig. 3b. The results were checked by the same measurements as for aluminium.

The background counts are equivalent to 0·2 μg of sodium and the minimum detectable quantity is 0·07 μg of sodium, if a 1-hr count is used.

Zusammenfassung—Es wurde der Natrium- und Aluminiumgehalt von Wolfram durch thermische Neutronenaktivierungsanalyse bestimmt. Die Aluminiumkonzentration wurde aus der Full-Energy-Peak von 1,78 MeV, die von Sodium aus der von 2,76 MeV berechnet. Minimal nachweisbare Konzentration der Verunreinigung erwies sich als 0,04 μg für Aluminium und 0,07 μg für Natrium.

Résumé—L'aluminium et le sodium ont été dosés dans le tungstène au moyen de l'analyse par activation par neutrons thermiques. Les concentrations sont évaluées du pic de 1,78 MeV pour l'aluminium et du pic de 2,76 MeV pour le sodium. La détectabilité minime est 0,04 μg d'aluminium et 0,07 μg de sodium par 100 mg de tungstène.

CHARACTERIZATION AND ANALYSIS OF WAXES BY DIFFERENTIAL THERMAL ANALYSIS

B. R. CURRELL
Department of Chemistry, Northern Polytechnic, Holloway Road, London, N.7, U.K.
and
B. ROBINSON
Chiswick Products Ltd., P.O. Box 26, Burlington Lane,
Chiswick, London, W.4, U.K.

(*Received* 15 *September* 1966)

Summary—The characterization of waxes by differential thermal analysis is described. An endothermic peak at 475–480° is characteristic of microcrystalline and polyethylene waxes, and measurement of its area provides a method for the estimation of these waxes in mixtures.

RECENT interest in the characterization of paraffin and microcrystalline waxes and in the analysis of mixtures of these waxes is typified by the papers by Ferris,[1] Fox,[2] Templin[3] and Ludwig.[4] Lange and Jochinke[5] have applied differential thermal analysis (DTA) to a study of the melting and solidification of waxes (temperature range 20–140°) and suggest that these curves may be used to characterize a wax and in many cases to determine the components of a mixture. We have similarly applied DTA but, in our case, in the range 20–600°.

From our studies of the melting curves we draw the same general conclusions as Lange and Jochinke and suggest that, to a possibly limited extent, these curves may be used to characterize a wax. The melting curves do not give unequivocal criteria for distinguishing between microcrystalline and polyethylene waxes and paraffin waxes, but there is a tendency for most microcrystalline and polyethylene waxes to be characterized by a single melting endotherm (Fig. 2), whereas the paraffin waxes show at least two endotherms (Fig. 1). Exceptions to this tendency are the Superla 165/170° and Jasber 180/185° waxes (*e* and *h*, Fig. 2) and the 140/145° *ex* Assam and the 56/58° German Zeitz waxes (*f* and *j*, Fig. 1). The additional peaks in the paraffin wax traces may be due to the crystalline transition orthorhombic → hexagonal which Ludwig detected by infrared spectra.

DTA in the extended temperature range up to 600° does, however, provide a ready means of distinguishing between microcrystalline and polyethylene waxes and paraffin waxes. At the higher temperatures all the paraffin waxes showed broad diffuse peaks which returned to baseline before 460°. In contrast, a sharp peak at 475–480° is characteristic of all the microcrystalline and polyethylene waxes which we have examined. This peak may be used to identify the presence of a microcrystalline or polyethylene wax in a mixture and also to give a quantitative estimation of the amount present; thus Table I shows the results obtained by measuring the area of this peak and relating it to the amount of microwax C700 in an artificial mixture of this microwax and the paraffin wax 135/140° *ex* Stanlow Refinery. The DTA trace of the mixture containing 50·0% of microwax is reproduced in Fig. 3.

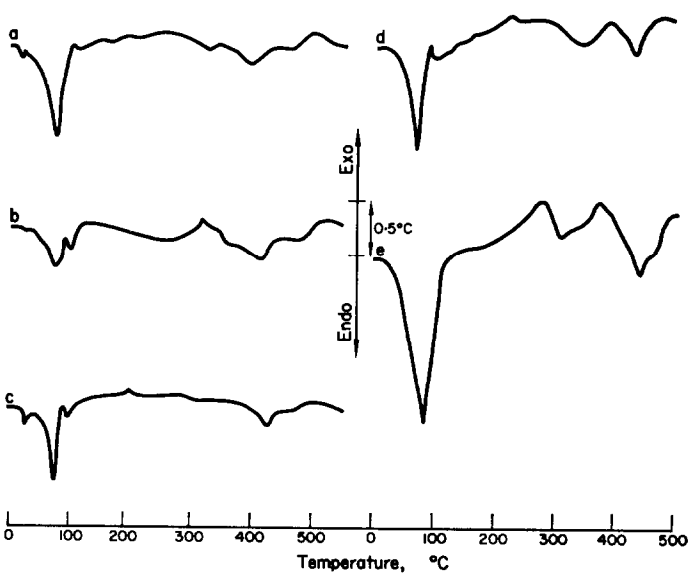

FIG. 4.—DTA curves of waxes.
a Hoechst Wax L; *b*, Hoechst Wax OM; *c*, Candelilla Wax; *d*, Beeswax; *e*, Carnauba Flake.

To provide a comparison the DTA traces of some other waxes are included (Fig. 4). These include the natural waxes Beeswax, Candelilla and Carnauba Flake and the synthetic Hoechst waxes L and OM.

These results are preliminary; a full evaluation of the limitations of this method of analysing wax mixtures will be carried out when we have finished a programme of work designed to define the limitations of DTA as a quantitative method; factors to be taken into account will include variations in the size and thermal conductivity of the samples, heating rate, crucible design and methods of packing.

EXPERIMENTAL

The apparatus used was the American Instrument Co. DTA instrument. The sample (~100 mg) and reference material (calcined alumina) were contained in inconel cups, the bases of which rested on chromel-alumel thermocouples; the cups were supported in an inconel block. Differential temperature was plotted against block temperature on an Aminco X–Y recorder. All runs were carried out at a heating rate of 8°/min.

To obtain maximum reproducibility in the quantitative experiments the same components, *i.e.*, cups, block and furnace, were used throughout. The pair of cups used were chosen to be as nearly as possible of the same weight.

Acknowledgements—We wish to acknowledge the generosity of the American Instrument Co. in providing the DTA equipment on loan, and also the experimental assistance given by Mr. P. Stevenson, who carried out many of the runs.

Zusammenfassung—Die Charakterisierung von Wachsen durch Differentialthermoanalyse wird beschrieben. Ein endothermer Peak bei 475–480° ist charakteristisch für mikrokristalline und Polyäthylenwachse; Messung seiner Fläche bietet eine Methode zur Bestimmung dieser Wachse in Gemischen.

Résumé—On décrit la caractérisation de cires par analyse thermique différentielle. Un pic endothermique à 475–480° est caractéristique de cires microcristallines et polyéthyléniques et la mesure de son aire fournit une méthode d'estimation de ces cires dans des mélanges.

TITRIMETRISCHE GOLDBESTIMMUNG MIT ASCORBINSÄURE UNTER VISUELLER ENDPUNKTSINDIKATION

G. RÁDY und L. ERDEY
Institut für Allgemeine Chemie, Technische Universität, Budapest XI

(*Eingegangen am* 9 *August* 1966. *Angenommen am* 1 *November* 1966)

Zusammenfassung—Es wurde eine reduktometrische Methode zur Gold(III) bestimmung mit Ascorbinsäure mit visueller Indikation ausgearbeitet. Den Endpunkt zeigt das Verschwinden der orangenen Farbe des Tetrabromoaurat(III). Störende Ionen werden durch Extraktion mit Äthylacetat abgetrennt und anschliessend Gold(III) nach Zusatz von Kaliumbromid in der organischen Phase titriert. Das entstehende farblose Dibromoaurat(I) kann nach Zusatz von Variaminblau als Indikator zu metallischem Gold weitertitriert werden, das sich als feine Schicht an der Grenze der Phasen abscheidet und die Indikation nicht stört.

UNTER den titrimetrischen Goldbestimmungsmethoden[1,2] findet man nur wenige, bei denen Gold(III)ionen unmittelbar und mit visueller Endpunktsindikation erfaßt werden. Bei einer dieser Methoden[3] dient das Verschwinden der gelben Farbe des Tetrachloroaurat(III)ions, bei einer anderen,[4] das des braunen Tetrabromoaurats(III) nach Einwirkung der reduzierenden Maßlösung zur Wahrnehmung des Endpunkts. Gold(III) wird in beiden Fällen zu Gold(I) reduziert. Infolge der schwachen Farbe des Chlorokomplexes gibt die erste Methode in verdünnten Lösungen keine zuverlässigen Ergebnisse. Ein Nachteil der zweiten Methode liegt darin, daß bei mindestens 95° titriert werden muß. In der Praxis hat keines dieser Verfahren besondere Bedeutung. Milazzo[5] schlug eine Titration mit Hydrochinon mit *o*-Dianisidin als Indikator vor. Die Bildung von kolloidalem Gold stört jedoch oft das Wahrnehmen der Farbänderung des Indikators.

Nachdem wir eine potentiometrische Methode zur Titration von Gold(III) mit Ascorbinsäure[2] ausgearbeitet hatten, wurde eine visuelle Endpunktsindikation angestrebt.

Die Versuchsbedingungen wurden schon bei der potentiometrischen Bestimmung eingehend untersucht. Gold(III)ionen können in 0,01-und 0,001m Lösungen im pH-Bereich von 1,6 bis 3,00 gut titriert werden, sofern die Chloridkonzentration nicht mehr als 1m beträgt. Gearbeitet wird bei ungefähr 50°, da hier einerseits die Reduktion schneller verläuft, andererseits die bei der Oxydation der Ascorbinsäure entstehende Dehydroascorbinsäure noch keinen meßbaren Fehler verursacht.

EXPERIMENTELLER TEIL

Lösungen und Reagenzien

Gold(III)chlorid—Stammlösung, 0,1n. Metallisches Gold wird in Königswasser gelöst, die Lösung mehrmals eingedampft. Vor Verdünnung wird soviel Salzsäure zugesetzt, daß sich die Wasserstoffionenkonzentration der Lösung zwischen 0,5n und 0,1n bewegt. Der Goldgehalt wird gravimetrisch sowohl durch Reduktion mit Eisen(II)sulfat, wie mit Ascorbinsäure bestimmt. Durch entsprechende Verdünnung 0,01- und 0,001n Lösungen werden bereitet.

Ascorbinsäuremasslösung 0,1n. Ascorbinsäure (8,9 g) werden in dest. Wasser gelöst, mit 100 mg ÄDTA als Stabilisator versetzt und mit Wasser auf 1 l. ergänzt. Das benutzte dest. Wasser soll in einer Glasapparatur destilliert werden.[6] Der Gehalt der Lösung wird mit Kaliumjodat gegen Variaminblau bestimmt.[7,8] Durch Verdünnung werden 0,01- und 0,002n Lösungen bereitet. Der Faktor der verdünnten Lösungen wird täglich zweimal, vor und nach den Bestimmungen ermittelt. Es genügt jedoch den Wirkungswert von 0,01n Ascorbinsäurelösungen täglich einmal zu kontrollieren, sofern die Lösung in Flaschen mit Glasstopfen vom Licht geschützt aufbewahrt wird. Über die Wirkungswertänderung von 0,01n Ascorbinsäurelösungen wurde schon früher eingehend berichtet.[8]

Wäßrige Kaliumbromidlösung, 10%*ige*

Äthylacetat analysenrein

Variaminblau Indikator. Zehn g des unter dem Namen Variaminblau B als Farbstoff dienenden Handelsproduktes werden in 200 ml heissem Wasser gelöst, die Lösung mit 0,4 g Ascorbinsäure und 1,5 g Aktivkohle versetzt und heiß filtriert. Zum farblosen oder höchstens schwach gelben Filtrat werden 50 ml gesättigte Natriumchlorid-Lösung gegeben. Nach Abkühlen filtriert man die ausgeschiedenen weissen Nadelkristalle, wäscht mit kaltem Wasser und trocknet im Vakuum bei Zimmertemperatur. Der gereinigte Indikator wird in gut schliessender Flasche aufbewahrt. Vom Indikator bereitet man entweder eine 0,5% ige wäßrige Lösung, die fünf Tage lang brauchbar ist, oder man verreibt ihn mit Natriumchlorid im Verhältnis 1:100 und benutzt ihn in dieser unbegrenzt haltbaren festen Form.

TITRATION VON GOLD(III)IONEN IN GEGENWART VON KALIUMBROMID

Die farblose oder schwach gelbe Gold(III)chloridlösung wird nach Bromidzusatz je nach dem Goldgehalt orange bzw. rötlichbraun. Diese Farbe entwickelt sich rasch, die Stabilität des entsprechenden Komplexes ist bei niedrigem pH hoch. Mit zunehmender Chloridkonzentration nimmt zwar die Farbintensität der Lösung ab, dies stört aber nur bei der photometrischen Bestimmung. Das Redoxpotential des Chlorokomplexes liegt höher als das des Bromokomplexes; dementsprechend reagiert zuerst der Chlorokomplex mit der Maßlösung. Beim Verschwinden der Farbe des Bromokomplexes liegen demnach keine meßbaren Mengen von Gold(III)-ionen mehr in der Lösung vor.

Das Normalredoxpotential des farbigen Tetrabromoaurat(III)-komplexes beträgt +0,87 V. Mit geeigneten Reduktionsmitteln, z.B. Ascorbinsäure läßt sich die Verbindung leicht in farbloses instabiles Dibromoaurat(I) überführen. Sowohl bei Einwirkung von überschüssigem Reduktionsmittel, wie auch durch Disproportionierung wird metallisches Gold gebildet. Somit tritt in der auf Farblosigkeit titrierten Lösung allmählich wieder eine Farbvertiefung ein. Da aber die Disproportionierung unter dem gegebenen Bedingungen erst nach 5–10 Minuten merklich wird, kann Ascorbinsäure zur Titration verwendet werden.

Man gibt 5–20 ml der ungefähr 0,003m Gold(III)ionenlösung in einen 100-ml Titrierkolben, setzt 5 ml 10%ige Kaliumbromid-Lösung hinzu und ergänzt mit Wasser auf 40 ml. Die so vorbereitete braunrote Lösung vom pH-Wert 1–1,5 titriert man bei Zimmertemperatur mit 0,01n Ascorbinsäure bis Farblosigkeit. Die Ergebnisse sind in Tab. I. dargestellt.

Die Titration ist in 0,3–0,1m salzsaurer Lösung und bei Zimmertemperatur am genauesten. In 1m salzsaurer Lösung liegt die Genauigkeit noch innerhalb ±3% sofern bei 40–50° gearbeitet wird.

An Fremdionen stören Cadmium-, Blei-, Arsen-, Aluminium-, Zink-, Calzium-, Barium- und Alkaliionen in Mengen von *ca.* 200 mg nicht. Bei Silbermengen unter 50 mg stört der entstehende Niederschlag die Endpunktsindikation nicht. Quecksilber(II)ionen stören ebenfalls nicht, nur ist in ihrer Gegenwart eine 3–5 fache Menge von Kaliumbromid zuzusetzen.

Farbige Ionen wie Platin(IV), Kupfer(II), Kobalt, Nickel, Chrom(III), Eisen(III) stören, da der Endpunkt nicht sichtbar ist. Es stören weiterhin Oxydationsmittel, die Bromid zu Brom oxydieren oder deren Redoxpotential positiver ist als das des Golds und die deshalb Maßlösung verbrauchen. In diesen Fällen muß das Gold vorher abgetrennt werden.

EXTRAKTION VON GOLD(III)-IONEN MIT ÄTHYLACETAT UND TITRATION IN DER ORGANISCHEN PHASE

Die Extraktion mit Äthylacetat in salzsaurer Lösung bietet eine gute Trennung des Golds von den störenden Metallionen. Demgegenüber können in bromwasserstoffsaurer Lösung störende Ionen mitextrahiert werden, z.B. Eisen(III)bromid. In der organischen Phase wird das Gold ohne weiteres reduktometrisch mit visueller Indikation erfaßt.

Die beste Extraktion erfolgt bei 5% Salzsäuregehalt; höhere Konzentrationen sind für die anschliessende Titration ungünstig. Die besten Titrierergebnisse werden erzielt, wenn aus 0,5–1m salzsaurer Lösung extrahiert wird.

Die zu bestimmende Lösung wird in einen 100 ml Scheidetrichter gegeben, wenn nötig mit 20 ml Wasser ergänzt und mit soviel Salzsäure versetzt, daß sich die Säurekonzentration der Lösung zwischen 0,5–1m einstellt. Dann gibt man 20 ml Äthylacetat hinzu und schüttelt kräftig 1 Minute durch. Nachdem sich die zwei Phasen getrennt haben, läßt man die wäßrige Phase in einen zweiten Scheidetrichter ab und wiederholt die Extraktion mit 10, dann mit 5 ml Äthylacetat. Trennen sich die zwei Phasen nur langsam, so ist die wäßrige Lösung nicht genügend sauer; dann sind noch 1–2 ml 1m Salzsäure zuzusetzen.

Die Äthylacetat-Phasen sammelt man in einem mit Glasstopfen versehenen 100-ml Erlenmeyer-Kolben. Nötigenfalls wäscht man vorher die gesammelten Phasen im Scheidetrichter mit 1m Salzsäure. Dann setzt man 10 ml 10%ige Kaliumbromidlösung hinzu, und titriert mit 0,01n Ascorbinsäurelösung unter kräftigem Zusammenschütteln der beiden Phasen solange, bis im durchfallenden Licht die Emulsion milchartig weiß wird. 1 ml 0,01n Ascorbinsäurelösung entspricht 985 μg Gold. Am Ende der Titration liegt quantitativ der Dibromoaurat(I) Komplex vor.

Die auf die beschriebene Weise titrierte Lösung wird nach Zusatz von Variaminblau durch Bildung der oxydierten Form des Indikators ß. Titriert man weiter mit Ascorbinsäure, so werden zuerst die in der wäßrigen Phase anwesenden Gold(I)ionen zu elementarem Gold reduziert. Zeitweise verschwindet die blaue Farbe. Sie erscheint erneut nach Vermischen der beiden Phasen, wenn ein Teil der Gold(I)ionen von der organischen wieder in die wäßrige Phase übergeht. Es ist solange zu titrieren bis der Indikator nach grau umschlägt und auch nach Zusammenschütteln der Phasen nicht wieder blau wird. Das entstehende Gold befindet sich als dünne Schicht an der Grenze der beiden Phasen und stört die Indikation nicht. Wenn man in reinwäßriger Lösung mit Ascorbinsäure zu kolloidalem elementaren Gold titriert, stört dieses die Endpunktsindikation.

TABELLE II.—TITRATION VON GOLD(III)-IONEN NACH ÄTHYLACETAT EXTRAKTION MIT 0,01n ASCORBINSÄURE

(a) In Gegenwart von Br^- ionen bis$[AuBr_2]^-$
(b) Dann weitertitriert in Gegenwart von Variaminblau bis Metallgold.

In Tab. II sind die Ergebnisse dargestellt. Sie zeigen, daß nach Extraktion des Tetrachloroaurat(III) mit Äthylacetat Gold sowohl im Gegenwart von Kaliumbromid, als von Variaminblau gut titrierbar ist. Im ersten Fall beträgt das Äquivalentgewicht Mol/2. Bei Fortführung der Titration in Gegenwart von Variaminblau läßt sich das erste Ergebnis gut kontrollieren. Das Äquivalentgewicht beträgt bei der Variaminblautitration Mol/3.

Goldmengen von ungefähr 500 μg können aus salzsaurer Lösung in Gegenwart von Platin, Kupfer, Selen, Tellur, Blei usw. mit Äthylacetat extrahiert und mit 0,002n Ascorbinsäure gegen Variaminblau mit einem Fehler von 2–5 % titriert werden.

Summary—A reductometric method for the determination of gold(III) with ascorbic acid has been developed. The end-point is given by the disappearance of the orange colour of the tetrabromoaurate(III) ion. Interfering ions may be separated by extraction with ethyl acetate and then the gold(III) titrated in the organic phase after the addition of potassium bromide. The colourless dibromoaurate(I) which is formed can be further reduced to metallic gold (Variamine Blue used as indicator) in which case the gold precipitates as a thin layer at the boundary of the phases, and does not interfere with the indicator.

Résumé—On a élaboré une méthode réductométrique de dosage de l'or (III) au moyen d'acide ascorbique. Le point de fin de dosage est donné par la disparition de la coloration orangée de l'ion tétrabromoaurate (III). On peut séparer les ions gênants par extraction à l'acétate d'éthyle et doser alors l'or (III) dans le phase organique après addition de bromure de potassium. Le dibromoaurate (I) incolore qui se forme peute encore être réduit à l'état d'or métallique (le Bleu Variamine étant utilisé comme indicateur), auquel cas l'or précipite à l'état de couche mince à la séparation des phases, et n'interfère pas avec l'indicateur.

SHORT COMMUNICATIONS

Assay for 9-acridanone in urban atmosphere by thin-layer chromatography fluorimetric procedures

(*Received* 20 *September* 1966. *Accepted* 28 *October* 1966)

In a previous paper the column and thin-layer chromatographic separation of polynuclear ring-carbonyl compounds was described.[1] These methods were applied to the development of a group of methods for the analysis of the carcinogen, 7*H*-benz(de)anthracen-7-one, in urban atmospheres.[2] These earlier investigations indicated that other ring-carbonyl compounds are present in urban atmospheres. This paper represents proof that 9-acridanone is a constituent of polluted urban atmospheres. Several methods involving two-dimensional thin-layer chromatography and fluorimetry are presented for the assay of this compound.

EXPERIMENTAL*

Reagents and apparatus

Solvents were obtained in the purest grades and were distilled if there was any evidence of interfering impurities. 9-Acridanone was obtained from K and K Laboratories, Plainview, New York, and crystallized to a constant melting point.

Spectrophotofluorimetry. An Aminco-Bowman spectrophotofluorimeter with 0·1- and 1-ml cells was used with the following settings: sensitivity 50, slit arrangement No. 2, and phototube RCA type IP 21. The fluorescence spectra of spots on thin-layer chromatograms were obtained by use of an Aminco solid-sample accessory.[1,3]

Procedure

A 1–2 mg sample of a benzene-soluble extract of airborne particulates was separated two-dimensionally on aluminia—cellulose (2:1). Some of the developing solvents used in the alternative separation methods were toluene-methanol (9:1, v/v) followed by dimethylformamide—water (35:65), and toluene—ether (7:3) followed by dimethylformamide—water (35:65). In another method alumina was used as the adsorbent with ethyl acetate—cyclohexane (1:1) as the developer in both dimensions. 9-Acridanone (0·5 to 1 μg) was run with each one-dimensional separation. The two-dimensional separation took about 3–4 hr. The appropriate spots were scraped from the plate. Standards and the unknown were eluted from the adsorbent with methanol—trifluoroacetic acid (4:1). Three min of shaking were required. The elution took about 10 min. The solutions of the standards and the unknown were evaporated and then diluted to an appropriate volume (0·1–1 ml) with methanol—trifluoroacetic acid (4:1). The excitation and emission spectra of the standards and unknown were determined. Analysis was at F 390/450. The whole operation took 3·5–4·5 hr.

The calculations are based on the equation

$$\mu\text{g of 9-acridanone/g of benzene-soluble fraction} = \frac{1000 \cdot W_s \cdot R_x}{W_{bs} \cdot R_s}$$

where the final volumes of standard and unknown are identical and $W_s = \mu$g of standard 9-acridanone, R_x = product of meter multiplier and transmittance readings obtained for unknown, R_s = product of meter multiplier and transmittance readings obtained for standard, and W_{bs} = weight (in mg) of benzene-soluble fraction placed on plate.

DISCUSSION

The greatest loss of 9-acridanone resulted when the compound was eluted from the plate following development. The variations in adsorbent or developer had little effect on the recovery (Table I).

* Mention of commercial products does not constitute endorsement by the Public Health Service.

TABLE I.—RECOVERY OF 9-ACRIDANONE FROM THE PLATE AFTER DEVELOPMENT

Adsorbent	Developer	Recovery %	Average recovery %
1. Al_2O_3–cellulose (2:1)	Toluene–methanol (9:1)	55, 61, 68, 71, 66	64
2. Al_2O_3–cellulose (2:1)	Dimethylformamide–water (35:65)	62, 64, 63, 70, 66, 62, 61, 60, 74	65
3. Al_2O_3–cellulose (2:1)	Toluene–ether (7:3)	58, 61, 50, 73	61
4. Al_2O_3	Ethyl acetate–cyclohexane (1:1)	60, 65, 69, 69, 60, 62, 60, 58	63

The type of separation obtained and the large assortment of other fluorescent spots present on the chromatogram are depicted in Fig. 1. All samples were assayed in acidic methanol. In this solution 9-acridanone was present as the neutral compound in the ground state (as shown by the fluorescence excitation spectrum) and as the cationic salt in the excited state (as shown by the fluorescence emission spectrum) (Fig. 2). The advantage of this type of analysis is the large wavelength separation between the fluorescence excitation wavelength maximum at 390 mμ and the emission wavelength maximum at 455 mμ. Because of this wide separation, scatter is less of a problem and the analysis is performed more readily.

The characterization of 9-acridanone was based on the R_f values of standard and unknown being identical in the various adsorbents and developers studied. In addition the extract of the unknown spot gave fluorescence spectra identical to those of 9-acridanone in the various solvents (Fig. 2).

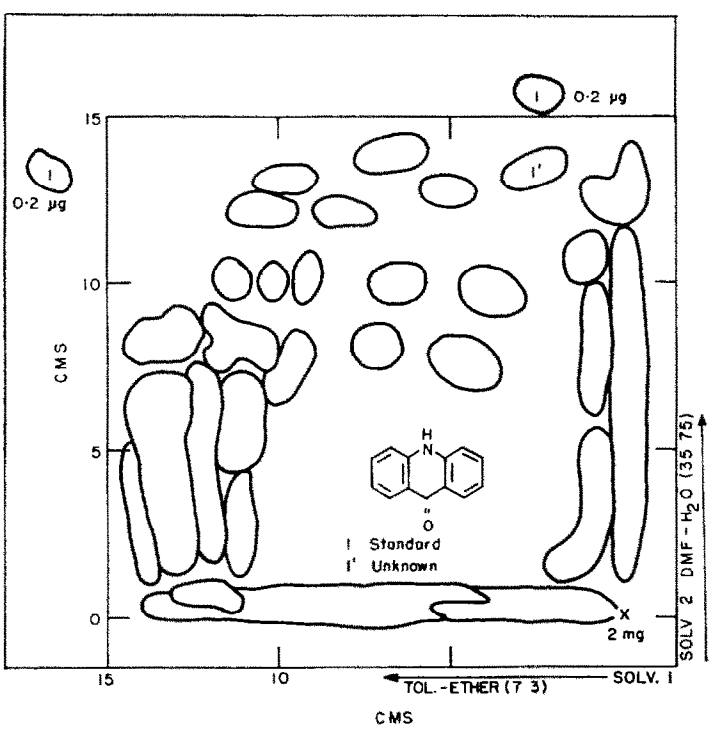

FIG. 1.—Two-dimensional thin-layer chromatogram on alumina-cellulose (2:1), toluene–ether (7:3) in first direction and dimethylformamide–water (35:65) in second direction. 9-Acridanone (0·2 μg) run in each direction: 2 mg of benzene–soluble fraction of airborne particulates separated.

TABLE II.—COMPARISON OF METHODS OF ASSAY FOR 9-ACRIDANONE IN A COMPOSITE URBAN ATMOSPHERIC SAMPLE

Separation method*	Benzene solution μg/g	Mean	Airborne particulate sample μg/g	ng/m³ of air
1. 1 → 2	40, 40, 35, 40	40	3	0·4
2. 3 → 2	40, 30, 40, 40	40	3	0·4
3. 4 → 4	60, 20, 50	40	3	0·4
4. 1 → 2†	60, 50, 40, 30	45	4	0·5

* See Table I.
† Direct spectrophotofluorimetric assay[1,3] after treatment of spot with 5 μl of trifluoroacetic acid, F 390/460.

A composite airborne particulate sample was analysed with the help of two-dimensional thin-layer chromatography and fluorimetry either after elution or directly from the plate (Table II). Several different development methods were compared. The alumina—cellulose elution methods gave the best results; the direct fluorimetric method gave the most variable results. Either of the two alumina—cellulose elution methods is recommended for the analysis of 9-acridanone in urban atmospheres and in air pollution source effluents. Approximately 0·4 ng of 9-acridanone is present in each cubic metre of urban atmosphere.

Summary—9-Acridanone has been found in urban atmospheres. Four two-dimensional thin-layer chromatographic methods have been described for the assay of this compound in urban atmospheres and in air pollution source effluents. Fluorimetric assay was done either directly on the plate or after elution. The best method involved two-dimensional separation on alumina-cellulose followed by elution and fluorimetric analysis of the acidic methanol solution. Urban atmospheres contain approximately 0·4 ng of 9-acridanone/m³ of air.

Résumé—On a trouvé la 9-acridanone dans les atmosphères urbaines. On a décrit quatre méthodes de chromatographie en couche mince bidimensionnelle pour la détermination du composé dans les atmosphères urbaines et les dégagements des sources de pollution de l'air. On a effectué le dosage fluorescimétrique soit directement sur la plaque, soit après élution. La meilleure méthode comprend la séparation bidimensionnelle sur alumine-cellulose suivie d'élution et de l'analyse fluorescimétrique de la solution méthanolique acide. Les atmosphères urbaines contiennent approximativement 0,4 ng de 9-acridanone par m³ d'air.

Zusammenfassung—In städtischen Atmosphären wurde 9-Acridanon gefunden. Vier zweidimensionale dünnschichtchromatographische Methoden wurden zum Nachweis der Verbindung in städtischen Atmosphären und in Emissionen aus Quellen der Luftverunreinigung beschrieben. Der fluorimetrische Nachweis wurde entweder direkt auf der Platte oder nach Elution geführt. Beim besten Verfahren wurde zweidimensional auf Aluminiumoxyd/Zellulose getrennt, eluiert und die saure Methanollösung fluorimetrisch analysiert. Stadtatmosphären enthalten ungefähr 0,4 ng 9-Acridanon pro m³ Luft.

Determination of scandium in wolframite and in the residues obtained after the extraction of tungsten

(*Received* 5 *August* 1966. *Accepted* 30 *November* 1966)

WOLFRAMITE contains about 0·01–0·05% of scandium. During the extraction of tungsten by the carbonate process, this scandium is enriched to about 0·03 to 0·1% in the residue, which contains mostly iron and manganese.

In the course of our investigations on the extraction of scandium from wolframite residues, it became necessary to determine the scandium content of wolframite and its residues. Though several methods are known[1–6] for the estimation of scandium very little information is available for its determination in low grade ores. The method recommended by Schoeller and Powell[7] for determination of scandium in wolfram is very tedious and involves a large number of steps. Therefore an alternative method was developed which is comparatively quick and simple and was found to be quite reliable.

Separation of scandium from iron and manganese by solvent extraction with tri-butyl phosphate (TBP)

Two of the major constituents present in wolframite residues after the removal of tungsten are iron and manganese. Preliminary experiments indicated that extraction of scandium by TBP from hydrochloric acid is complete only if the acid concentration exceeds 8*M*. Under these conditions extraction of iron also is complete, whereas only a small fraction of manganese is transferred to the organic phase (K_d values for Fe, Sc and Mn are 400, 24 and 0·2 respectively). From 2*M* hydrochloric acid the extraction of scandium is very low ($K_d < 0{\cdot}005$) whereas that of iron is sufficiently high ($K_d > 7$) to give fairly good separation from scandium.

Synthetic mixtures of iron(III), manganese(II) and scandium were prepared by taking known amounts of stock solutions and the hydrochloric acid concentration of each was adjusted to 8*M*. Each solution was shaken twice with an equal volume of TBP which had been pre-equilibrated with 8*M* hydrochloric acid. Two extractions are necessary to extract all the iron, because of its high concentration in the aqueous phase. Most of the iron is extracted in the first step and the extraction of scandium is completed only after all the iron has been removed. The two extracts are mixed and the scandium is back-extracted with an equal volume of 2*M* hydrochloric acid. It should be emphasized here that if the scandium is not back-extracted within an hour or so, recovery is incomplete. An appreciable amount of iron is also back-extracted, but most of it is removed by extraction with TBP pre-equilibrated with 2*M* hydrochloric acid (the volume used being half that of the aqueous phase). The scandium in the aqueous phase is precipitated from the hot solution by addition of ammonia solution in the presence of excess of ammonium chloride.* To reduce the manganese content still further, this step is repeated, after dissolution of the hydroxide in the minimum amount of hydrochloric acid. The precipitate is finally filtered off, dissolved in 25–50 ml of conc. hydrochloric acid and extracted with TBP, and the scandium is back-extracted with 2*M* hydrochloric acid as before. This solution is free from iron but contains traces of manganese from which it is finally freed by precipitation with ammonia in the presence of ammonium chloride, and the product is ignited to the oxide. The oxide thus obtained is found spectrographically to be 99·9% pure (Fe = 0·010%, Mn = 0·005%).

Results obtained by this procedure are summarized in Table I. It can be seen that the relative error increases with decrease in scandium content in the mixture. Also, when the amount of scandium is small the error is considerably higher, mainly because of the unfavourable gravimetric factor. Therefore the minimum amount of scandium should be 20–30 mg.

* There are some contradictory observations regarding the completion of precipitation of scandium as hydroxide by ammonia. Fisher and Bock[8] observed complete precipitation of scandium with ammonia in the absence of ammonium carbonate, whereas Vickery[9] has found low recoveries even with ammonia free from carbon dioxide. Our results, however, show that in the concentration range 20–200 mg of Sc_2O_3 per 100 ml the precipitation of scandium is more than 99·5% complete by ammonia free from carbon dioxide, even in the presence of a 50 to 100-fold excess of ammonium chloride. The ammonia precipitation method has also been used by Alimarin and Shen Han Si[3] for standardization of scandium solution.

TABLE I.—ESTIMATION OF SCANDIUM IN PRESENCE OF IRON AND MANGANESE

Sc_2O_3 taken, *mg*	Fe_2O_3 added, *g*	MnO added, *g*	Sc_2O_3 found, *mg*	% Error
100	2·0	—	101·0	+1·0
100	4·0	—	98·8	−1·2
50	2·0	—	48·6	−2·8
50	4·0	—	48·8	−2·4
50	6·0	—	48·4	−3·2
100	—	1·26	100·4	+0·4
50	—	0·63	49·7	−0·6

50	—	1·89	48·6	−2·8
50	4·0	0·63	48·2	−3·6
30	4·0	0·63	28·6	−4·6
20	4·0	0·63	18·8	−6·0

Total volume of solutions: 100 ml.

Determination of scandium in wolframite and ore-residues

Mix about 100 g* of the finely ground ore (−200 mesh) intimately with 50 g of anhydrous sodium carbonate, 15 g of sodium nitrate and 10 g of sodium chloride and heat the mixture to 500–550° for 1 hr in a mild steel crucible. (These are the optimum conditions for the extraction of tungsten from wolframite.[8]) Digest the cooled mass with 300 ml of water for about 30 min and filter. Wash the residue thrice with 100 ml of hot water by decantation. Digest the residue with 200 ml of conc. hydrochloric acid for about an hour on a hot-plate, and then filter. Bring the volume of the solution to 200 ml by addition of conc. hydrochloric acid (to replace acid lost during the digestion and make the final acidity of the solution about 8*M*). Extract the scandium with TBP and estimate it as oxide by the procedure described above. In the case of ore-residues obtained after the extraction of tungsten, the same procedure is adopted after direct treatment of the residue with conc. hydrochloric acid.

In a typical analysis of a sample of wolframite obtained from Rajasthan, India, 30 mg of scandium oxide were obtained from 100 g of the ore, corresponding to a scandium content of 0·030%. The same sample gave a scandium content of 0·028% on analysis by the method of Schoeller and Powell.

Acknowledgements—The authors wish to thank Dr. Jagdish Shankar, Chemistry Division, Atomic Energy Establishment Trombay, for his keen interest and useful suggestions and also Dr. N. A. Narasimham, Spectroscopy Division, for spectrographic analyses of some of the samples.

T. R. BHAT

Summary—The separation of scandium from iron and manganese by extraction with TBP from hydrochloric acid was studied in detail and this method was applied to the estimation of scandium in wolframite and its residues. The method consists of the extraction of tungsten from the wolframite with sodium carbonate, dissolution of the residue in hydrochloric acid and preferential extraction of iron and scandium from hydrochloric acid, stripping of the scandium with 8 *M* hydrochloric acid and re-extraction of accompanying iron with fresh TBP, precipitation of scandium with ammonia in presence of ammonium chloride, and final purification of the scandium by TBP extraction.

* The amount of the ore to be taken depends on its scandium content. The error will be more than 6% if the total scandium content of the sample used is less than 25 mg.

Résumé—On a étudié en détail la séparation du scandium du fer et du manganèse par extraction au TBP à partir d'acide chlorhydrique, et cette méthode a été appliquée à l'estimation du scandium dans la wolframite et ses résidus. La méthode consiste en l'extraction du tungstène de la wolframite par le carbonate de sodium, la dissolution du résidu en acide chlorhydrique et l'extraction préférentielle du fer et du scandium de l'acide chlorhydrique, l'élimination du scandium par l'acide chlorhydrique 8 M et la réextraction du fer qui l'accompagne par du TBP frais, la précipitation du scandium à l'ammoniaque en présence de chlorure d'ammonium et la purification finale du scandium par extraction au TBP.

Zusammenfassung—Die Abtrennung von Scandium von Eisen und Mangan durch Extraktion mit TBP aus salzsaurem Medium wurde im Detail untersucht und die Methode zur Bestimmung von Scandium in Wolframit und seinen Rückständen angewandt. Die Methode besteht aus der Extraktion von Wolfram aus dem Wolframit mit Natriumcarbonat, Auflösen des Rückstandes in Salzsäure und bevorzugte Extraktion von Eisen und Scandium aus der Salzsäure, Rückextraktion des Scandiums mit 8 M Salzsäure und Rückextraktion des begleitenden Eisens mit frischem TBP, Fällung von Scandium mit Ammoniak in Gegenwart von Ammonchlorid und schließlich Reinigung des Scandiums durch TBP-Extraktion.

PRELIMINARY COMMUNICATIONS

Precipitation from homogeneous solution by photochemical action. Determination of thorium

(*Received* 3 *November* 1966. *Accepted* 10 *November* 1966)

ALTHOUGH precipitation from homogeneous solution is a well established method in analytical chemistry, the application of a photochemical reaction to produce the precipitating reagent and yield quantitative results is novel. Yen and Yang[1] reported a method for the precipition of tantalum selenite from homogeneous solution which was based on the indirect catalytic destruction of the masking ion, oxalate, by photochemically produced bromine. Their method was not quantitative nor did it involve the direct production of the precipitating ion by photochemical action.

The advantages of photochemical methods lie in the temperature-independent control of the experimental parameters (light intensity, time of exposure, nature of the radiation). In principle, any absorbing substance or ion which can be reduced or oxidized photochemically is potentially useful for photochemical precipitation methods. In practice, the wavelength region in which such photochemical redox reactions usually take place is the ultraviolet where radiation sources are readily available. Therefore, other absorbers of ultraviolet radiation should be absent so that the radiation is absorbed primarily by the ion or substance undergoing the desired photochemical change.

Thorium iodate has been precipitated from homogeneous solution by Stine and Gordon[2] who reduced periodate chemically by reaction with ethyleneglycol acetate (2-hydroxyethyl acetate). The photochemical reduction of periodate to iodate has been described by Head.[3,4] Aqueous solutions of metaperiodate show an absorption band in the ultraviolet with a maximum at 2200 Å ($\varepsilon = 9{\cdot}8 \times 10^3$ l. mole^{-1} cm^{-1}) and an absorptivity of $1{\cdot}8 \times 10^3$ l. mole^{-1} cm^{-1} at 2537 Å.

Previous methods for the precipitation of thorium iodate, such as that of Meyer and Speter,[5] made use of dilute nitric acid solution. In the photochemical method, the presence of nitrate is undesirable because of its ultraviolet absorption, and perchloric acid should therefore be used.

EXPERIMENTAL

A low-pressure mercury resonance lamp with a quartz envelope (Nester Faust Co.) was used. Approximately 85–90% of the output of the lamp is at 2537 Å.

Reagent grade thorium nitrate monohydrate was dissolved in water and heated with a slight excess of reagent grade perchloric acid (70–72%) until fumes of perchloric acid appeared. The mass was cooled, more perchloric acid was added, and the fuming was repeated. The residue was dissolved in water and diluted to yield a solution containing approximately 1·6 g of perchloric acid per 100 ml of solution. Thorium was determined by the method given by Vogel,[6] but with the following more specific conditions: a solution containing about 100 mg of thorium was mixed with 225 ml of water and 5 ml of conc. hydrochloric acid and heated to boiling. Hot 10% oxalic acid dihydrate solution (55 ml) was added slowly with constant stirring. The solution was digested for 2 hr below the boiling point, then kept at room temperature overnight. The precipitate of thorium was filtered off on medium retention ashless filter paper and washed with 150–200 ml of a solution which contained 2·5 g of oxalic acid and 3·5 ml of conc. hydrochloric acid per 100 ml. The filter paper and precipitate were dried, ashed and ignited in an electric muffle furnace at 700–800° to yield thorium dioxide.

Water (60 ml) and 60% perchloric acid (10 ml) were placed in a 10 × 5 cm crystallizing dish. Reagent grade sodium periodate (4 g) was added and the solution was stirred until the solid had dissolved. Thorium perchlorate solution containing 35–180 mg of thorium was added and the dish was placed under the ultraviolet lamp in a reproducible position. Aluminium foil covered the upper surface of the lamp in order to serve as a reflector and as protection for the operator. A 4-hr exposure was found to be adequate for these experimental conditions. The contents of the dish were transferred to a 400-ml beaker and the dish was rinsed into the beaker with 50 ml of water. The contents of the beaker were allowed to cool for 15 min and were filtered through American S and S

* 12-hr digestion.

No. 589 blue label filter paper (high retentivity). The precipitate was dissolved off the filter paper with 100 ml of 1*M* hydrochloric acid and the same solution was used for dissolving any precipitate adhering to the crystallizing dish. The iodate was reduced to iodide by adding solid sodium sulphite (reagent grade) until the iodine colour was discharged. The solution was heated to 60–70° and filtered ammonia solution was added until the solution contained a slight excess. The resulting thorium hydroxide was filtered off on American S and S No. 589 white label filter paper (medium retentivity) and washed with water until the excess of ammonia was removed. The precipitate was dissolved in 150 ml 0·5*M* hydrochloric acid and the solution was collected in a 600-ml beaker. The solution was diluted to approximately 250 ml and the thorium was determined by the oxalate procedure given above.

RESULTS AND DISCUSSION

Results are summarized in Table I. The over-all standard deviation (20 results) was 0·2 mg. The precipitates obtained by this method were dense and crystalline. In contrast, voluminous and very gelatinous precipitates are obtained by the direct precipitation of thorium by iodate. The volume of precipitate, after settling, was only about a tenth of that obtained by the conventional method. Photomicrographs of the precipitates obtained by these two methods also indicate a pronounced difference in the density of the precipitates.

The final determination of thorium by the oxalate method was adopted with a view to separating thorium from zirconium, iron and titanium, which frequently accompany thorium in its ores and which are also precipitated as the iodates. With small amounts of thorium longer digestion periods were required for complete precipitation of thorium oxalate.

The amount of sodium periodate required by this method is much lower than that required in the method of Stine and Gordon.[3] Furthermore, that procedure cannot be regarded as pure precipitation from homogeneous solution because of the necessity of adding 2 g of potassium iodate at the end for complete precipitation of the thorium iodate.

When attempts were made to carry out the final determination by precipitating thorium hydroxide and igniting it to thorium dioxide, high results were obtained, probably because of coprecipitation of the sodium salts present. In addition, the ignited residues were slightly brownish in colour, indicating the presence of an impurity.

Summary—Thorium was precipitated from homogeneous solution by photochemical reduction of periodate to iodate in a solution containing thorium and perchloric acid, by means of a 2537 Å low-pressure mercury vapour lamp. For weighing, the precipitate was redissolved, precipitated once as thorium hydroxide, and finally as thorium oxalate, which was ignited to thorium dioxide. Quantitative results were obtained in the range 35–180 mg of thorium.

Résumé—On a précipité le thorium d'une solution homogène par réduction photochimique du periodate en iodate dans une solution contenant du thorium et de l'acide perchlorique, au moyen d'une lampe à vapeur de mercure à basse tension à 2537 Å. Pour la pesée, le

précipité est redissous, précipité une fois à l'état d'hydroxyde de thorium, et finalement à l'état d'oxalate de thorium qui est calciné en bioxyde de thorium. On a obtenu des résultats quantitatifs dans le domaine allant de 35 à 180 mg de thorium.

Zusammenfassung—Thorium wurde aus homogener, Thorium und Überchlorsäure enthaltender Lösung gefällt durch photochemische Reduktion von Perjodat zu Jodat bei 2537 Å mit Hilfe einer Niederdruck-Quecksilberdampflampe. Zum Auswiegen wurde der Niederschlag wieder gelöst, einmal als Thoriumhydroxyd und zuletzt als Thoriumoxalat gefällt; dieses wurde zu Thoriumdioxyd verglüht. Quantitative Ergebnisse wurden im Bereich 35–180 mg Thorium erzielt.

Neutron absorptiometric titration

(*Received* 23 *May* 1966. *Revised* 1 *November* 1966. *Accepted* 10 *November* 1966)

MEINKE[1] studied the possibility of utilizing the absorption of neutrons for the determination of non-absorbing elements (which have an insignificant thermal neutron cross-section) and called the technique "indirect neutron absorptiometry".

We propose to use this principle in titrimetric analysis for the determination of the end-point ("neutron absorptiometric titration"). In this titration the effective component of the titrant (or of the solution titrated) must contain an element with a large absorption cross-section for thermal neutrons, and the titration products must be separable from the initial components as another phase (precipitation or dissolution; extraction into a non-miscible solvent and so on). For instance, in titrations based on precipitate formation, measurement is made of the absorption of thermal neutrons in the liquid separated from the precipitate. If the titrant contains an element with a large thermal neutron absorption cross-section (*e.g.*, cadmium) the measured value of the neutron absorption up to the end-point will be insignificant, because the added effective component is bound in the precipitate and the neutron absorption measurements are made on the liquid residue but will increase after the end-point is reached, as excess of the neutron-absorbing titrant is added. The end-point can easily be determined graphically.

This titration can be carried out both in a discontinuous or in a continuous (automatic) manner. The liquid sample is placed between the neutron-source and the neutron-detector.

Three methods of titration can be applied.[2]

Filtration method. After the addition of a certain amount of titrant, the supernatant liquid is filtered by suction into the measuring cuvette, which is placed between the neutron source and the neutron detector, and the neutron radiation is measured. This liquid is returned to the bulk solution, another portion of titrant is added, and the whole process is repeated. The time required for the titration is 30–40 min.

Centrifugation method. Identical amounts of the test solution are transferred into several centrifuge tubes, various amounts of the titrant are added, and the solutions are then diluted to the same volume with distilled water. The precipitate formed is then sedimented by centrifuging. The absorption of neutrons in the supernatant liquids is measured in the measuring cuvette. The time required for the titration is about 25 min.

Neutron absorptiometric titration

(*Received* 23 *May* 1966. *Revised* 1 *November* 1966. *Accepted* 10 *November* 1966)

MEINKE[1] studied the possibility of utilizing the absorption of neutrons for the determination of non-absorbing elements (which have an insignificant thermal neutron cross-section) and called the technique "indirect neutron absorptiometry".

We propose to use this principle in titrimetric analysis for the determination of the end-point ("neutron absorptiometric titration"). In this titration the effective component of the titrant (or of the solution titrated) must contain an element with a large absorption cross-section for thermal neutrons, and the titration products must be separable from the initial components as another phase (precipitation or dissolution; extraction into a non-miscible solvent and so on). For instance, in titrations based on precipitate formation, measurement is made of the absorption of thermal neutrons in the liquid separated from the precipitate. If the titrant contains an element with a large thermal neutron absorption cross-section (*e.g.*, cadmium) the measured value of the neutron absorption up to the end-point will be insignificant, because the added effective component is bound in the precipitate and the neutron absorption measurements are made on the liquid residue but will increase after the end-point is reached, as excess of the neutron-absorbing titrant is added. The end-point can easily be determined graphically.

This titration can be carried out both in a discontinuous or in a continuous (automatic) manner. The liquid sample is placed between the neutron-source and the neutron-detector.

Three methods of titration can be applied.[2]

Filtration method. After the addition of a certain amount of titrant, the supernatant liquid is filtered by suction into the measuring cuvette, which is placed between the neutron source and the neutron detector, and the neutron radiation is measured. This liquid is returned to the bulk solution, another portion of titrant is added, and the whole process is repeated. The time required for the titration is 30–40 min.

Centrifugation method. Identical amounts of the test solution are transferred into several centrifuge tubes, various amounts of the titrant are added, and the solutions are then diluted to the same volume with distilled water. The precipitate formed is then sedimented by centrifuging. The absorption of neutrons in the supernatant liquids is measured in the measuring cuvette. The time required for the titration is about 25 min.

Automatic titration. The titrant is added to the test solution at a steady rate, and a precipitate is formed. The supernatant liquid is pumped through a filter plate in the titration flask, into the measuring cuvette, and back again into the titration flask, by a laboratory micro-pump. The neutron-detector is attached to a rate-meter and the count rate indicated is continuously registered by an appropriate recording device. The automatic apparatus reduces the time required for the titration to 5–8 min.[8]

Preliminary experiments have been carried out with a plutonium-beryllium source ($5{\cdot}5 \times 10^6$ n/sec) and a neutron scintillation detector. In our first experiments sulphide ions were titrated with 1*M* cadmium nitrate by the centrifugation method. The ratio C_1/C_2, where C_1 and C_2 are the respective neutron count rates for water and supernatant liquid in the cuvette, was plotted against volume of titrant added. The end-point was indicated by the break in the titration curve. In such a way 48 mg of sulphide were determined with an error of $\pm 0{\cdot}5$ mg.

The sensitivity and accuracy of the determination depend on the geometry of the measurement system, on the neutron flux, and on the properties of the neutron detector.

Further experiments are being done on titrations based on precipitate formation, the titrants being cadmium nitrate ($\sigma_{Cd} = 2550$ barns) for determination of fluoride, sulphide and oxalate; sodium tetraphenylborate ($\sigma_B = 750$ barns) for determination of thallium, potassium, rubidium and caesium; and potassium iodomercurate ($\sigma_{Hg} = 380$ barns) for determination of alkaloids (σ is the neutron absorption cross-section of the species indicated by subscript).

The titration method based on absorption of neutron radiation offers the advantage over the methods of radiometric titration applied so far, of using a sealed source of radiation, and is thus less hazardous. Neutron absorptiometric titration also extends the field of applicability of neutron-absorptiometric determinations.

Preliminary results indicate that the idea of neutron absorptiometric titration has considerable potential for the determination of many elements.

Summary—A method is outlined for detection of two-phase titration end-points by means of an abrupt change in the neutron-absorption characteristics of one of the phases. One of the components of the precipitate must have a large neutron absorption cross-section, and the disappearance or appearance of neutron absorption by the supernatant liquid from the precipitation reaction then marks the completion of precipitation.

Résumé—On donne un aperçu d'une méthode pour la détection des points de fin de titrage dans les dosages à deux phases au moyen d'un changement brusque des caractéristiques de l'absorption neutronique de l'une des phases. L'un des composants du précipité doit avoir un important profil d'absorption neutronique et la disparition ou l'apparition de l'absorption neutronique par le liquide surnageant de la réaction de précipitation marque alors la fin de la précipitation.

Zusammenfassung—Es wird eine Methode zur Endpunktsbestimmung in Zweiphasentitrationen durch jähen Wechsel in der Neutronenabsorptionscharakteristik einer der Phasen skizziert. Eine der Komponenten des Niederschlags muß einen großen Neutronenabsorptionsquerschnitt haben; Verschwinden oder Auftreten von Neutronenabsorption in der Flüssigkeit über dem Niederschlag zeigt dann das Ende der Fällung an.

KINETICS AND MECHANISM OF THE REACTION BETWEEN BIACETYL AND HYDROXYLAMINE IN ACID SOLUTION

PAUL R. ELLEFSEN* and LOUIS GORDON†
Department of Chemistry, Case Institute of Technology, Cleveland, Ohio 44106, U.S.A.

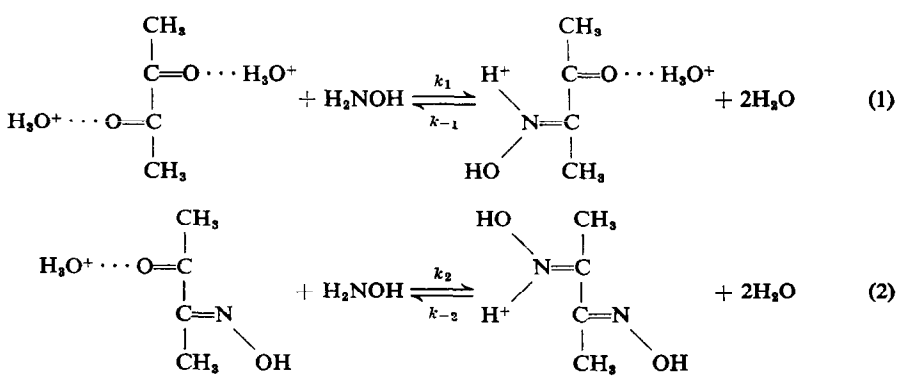
(*Received* 18 *August* 1966. *Accepted* 1 *October* 1966)

Summary—The kinetics and mechanism of formation of dimethylglyoxime from biacetyl and hydroxylamine in acid solution have been studied. Unprotonated hydroxylamine was found to react with the hydrogen-bonded carbonyl group to give the conjugate acid of the oxime. Detectable quantities of carbinolamine intermediates were not found in the acid concentration range studied.

THE kinetics and mechanism of oxime, semi-carbazone and, in general, Schiff's base formation have been the subject of many investigations. A comprehensive series of papers on Schiff's base formation was initiated in 1959 by Jencks[1] who studied the kinetics and mechanism involved over a wide acid concentration range. The variation in rate-determining steps in the reaction sequence explained many of the previous inconsistent results.

Hileman and Gordon[2] studied the kinetics and mechanism of the reaction of biacetyl and hydroxylamine at pH 7·0. Their results showed that this system generated dimethylglyoxime in accordance with the model proposed by Cordes and Jencks[3] for this pH.

The present investigation is concerned with the kinetics and mechanism of the reaction of biacetyl and hydroxylamine in hydrochloric acid solution. On the basis of the Jencks model the expected sequence for the reaction of biacetyl with hydroxylamine in acid solution should be:



Free hydroxylamine should react reversibly with the hydrogen-bonded carbonyl group to give the conjugate acid of the Schiff's base. Hileman and Gordon[2] showed that in neutral solution the decomposition of a carbinolamine intermediate is the

* Present address: Department of Chemistry, Hanover College, Hanover, Indiana.

rate-determining step; because of acid catalysis, the decomposition of this intermediate should be very fast in acid solution, and its concentration very small.

EXPERIMENTAL

Apparatus

All spectrophotometric measurements were carried out on a Cary model No. 14 recording spectrophotometer equipped with a thermostatic cell compartment (±0·05°).

Chemicals

Hydroxylamine hydrochloride (Baker analysed reagent) was purified by recrystallization from 95% ethanol. After filtration the residual ethanol was removed by air-drying with an aspirator. Water was removed by drying over calcium chloride in a desiccator. The purified hydroxylamine hydrochloride was found to be 99·9% pure by indirect titration.[4]

Biacetyl monoxime (Matheson, Coleman and Bell) was triply sublimed at 35° and approximately 1 mm Hg pressure.

PFHS-grade biacetyl obtained from Burdick and Jackson Laboratories, Muskegon, Michigan, was used without further purification.

Dimethylglyoxime (Baker analysed) was dried in a desiccator over calcium chloride and also used without further purification.

Procedure for kinetic studies

A spectrophotometric cell containing a solution of hydrochloric acid and all the other reagents except one was brought to constant temperature. Then 0·04807 ml of a solution of the last reagent necessary to start the reaction was added from a Hamilton microlitre syringe. The absorbance was measured at a set wavelength at various times after the addition of the last reagent.

THEORY

HD = dimethylglyoxime
HDH^+ = protonated dimethylglyoxime
HM = biacetyl monoxime
HMH^+ = protonated biacetyl monoxime
Hx = hydroxylamine
HxH^+ = protonated hydroxylamine
B = biacetyl
$B(OH)_2$ = hydrated biacetyl

The hydration constant K_h, for biacetyl is given by

$$K_h = \frac{a_{B(OH)_2}}{a_B}. \tag{3}$$

Mass balance shows that

$$[Y]_T = [Y] + [YH^+] \tag{4}$$

where $[Y]_T$ is the total concentration of the various Y species and Y = HD, HM or Hx; $YH^+ = HDH^+$, HMH^+ or HxH^+. Similarly

$$[B]_T = [B] + [B(OH)_2]. \tag{5}$$

The apparent equilibrium constants for equations (1) and (2) are

$$K_1' = \frac{[HM]_T}{[B]_T[Hx]_T} = \frac{k_1'}{k_{-1}'} \tag{6}$$

$$K_2' = \frac{[HD]_T}{[HM]_T[Hx]_T} = \frac{k_2'}{k_{-2}'} \tag{7}$$

$$[B] = \frac{A^{4065}}{\varepsilon_B^{4065}} \tag{8}$$

where A^{4065} denotes the absorbance of B at 4065 Å and ε_B^{4065} its molar absorbtivity; only biacetyl absorbs in the visible.

The absorbance A is given by

$$A = \varepsilon_{HM}[HM] + \varepsilon_{HD}[HD]_T \tag{9}$$

where the ε values are the molar absorptivities of the species indicated by the subscripts.

$$[HM]_i = [HM] + [HD]_T \tag{10}$$

where the subscript i denotes the initial value.

Similarly

$$[Hx]_T = [Hx]_i - [HM] \tag{11}$$

$$[HM] = \frac{A_{HM}}{\varepsilon_{HM}^{2275}}. \tag{12}$$

The acid dissociation constant is given by

$$K_A^Y = h_0 \frac{[Y]}{[YH^+]} \tag{13}$$

where Y = HD, HM or Hx; correspondingly $YH^+ = HDH^+$, HMH^+ or HxH^+.

$$A = \varepsilon_{HD}[HD] + \varepsilon_{HDH^+}[HDH^+] \tag{14}$$

$$[HD]_i = [HD] + [HDH^+]. \tag{15}$$

The thermodynamic equilibrium constants for equations (1) and (2) are

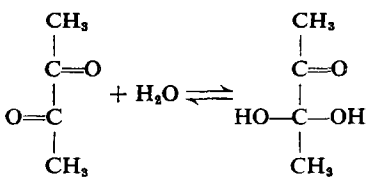
$$K_1 = \frac{a_{HMH^+}}{a_B a_{Hx} a_{H^+}} \tag{16}$$

$$K_2 = \frac{a_{HDH^+}}{a_{HM} a_{Hx} a_{H^+}} \tag{17}$$

RESULTS

Hydration

It is known that biacetyl is hydrated[5,6,7] in aqueous solution:



(18)

The method employed here to determine the extent of hydration is that described by Bell and McDougall.[6] The extinction coefficient of the visible band for biacetyl

employed in this study is 20·3. This is the average of the extinction coefficients of the visible band found by Foster[8] in a series of non-aqueous polar solvents.

As shown in Fig. 1, plotting the extinction coefficient of the visible peak for biacetyl versus 1/[HCl] and extrapolating to infinite hydrochloric acid concentration (where the water concentration is zero and hydration cannot occur) results in a value

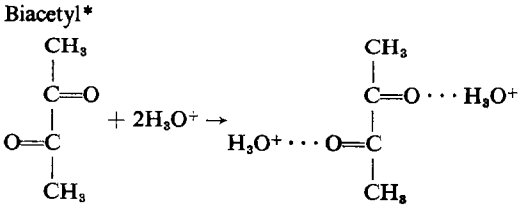
Biacetyl*



(23)

The acid dissociation constants of the conjugate acids of biacetyl monoxime and dimethylglyoxime, determined by Ellefsen and Gordon,[9] show that at concentrations of hydrochloric acid below about 1M, the extent of protonation of biacetyl monoxime is very small. However, the extent of protonation of dimethylglyoxime in 0·101–0·812M hydrochloric acid is significant. Therefore, in order to simplify determination of the concentration of dimethylglyoxime, absorbance measurements used in determining the kinetics for dimethylglyoxime were carried out at 2376 Å, the isosbestic point for dimethylglyoxime (*cf.* Ellefsen and Gordon[9] for the ultraviolet spectra of HD, HDH^+, HM, and HMH^+).

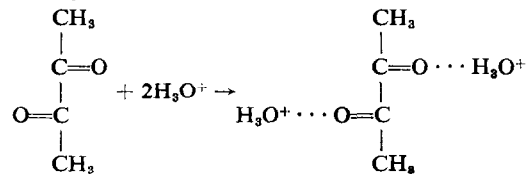
(22)

Biacetyl*



(23)

The acid dissociation constants of the conjugate acids of biacetyl monoxime and dimethylglyoxime, determined by Ellefsen and Gordon,[9] show that at concentrations of hydrochloric acid below about 1M, the extent of protonation of biacetyl monoxime is very small. However, the extent of protonation of dimethylglyoxime in 0·101–0·812M hydrochloric acid is significant. Therefore, in order to simplify determination of the concentration of dimethylglyoxime, absorbance measurements used in determining the kinetics for dimethylglyoxime were carried out at 2376 Å, the isosbestic point for dimethylglyoxime (*cf.* Ellefsen and Gordon[9] for the ultraviolet spectra of HD, HDH^+, HM, and HMH^+).

Rate and equilibrium constants

All rate and equilibrium constants were first calculated from values of HD_T, HM_T, Hx_T, and B_T as indicated in equations (4)–(7). The trends observed in these constants as the acid concentration is varied are used to determine the reaction mechanism. A preliminary value of K_1' at 25·0° and in 0·406M HCl was obtained by spectrophotometrically following first the decomposition of dimethylglyoxime, and

* These reactions are considered to be essentially irreversible.

second, the decomposition of biacetyl monoxime until equilibrium had been obtained.

From measurements of the absorbance at 4065 Å and 2550 Å, the concentrations of biacetyl, hydroxylamine, biacetyl monoxime and dimethylglyxoime were calculated from equation (8) and the equations below;[10] no detectable quantities of carbinolamine intermediates were found to be present:

$$A^{2550} = \varepsilon_{HM}[HM] + \varepsilon[HD]_T$$

where ε is the extinction coefficient of the mixture of HD and HDH^+ in 0·406M hydrochloric acid and is constant at constant acid concentration,

$$[B] + [HM] + [HD]_T = [B]_i + [HM]_i + [HD]_i = \text{known constant}$$

$$[Hx]_T + [HM] + 2[HD]_T = [Hx]_i + [HM]_i + 2[HD]_i = \text{known constant.}$$

It was found that at equilibrium only biacetyl, hydroxylamine and biacetyl monoxime remained in solution in detectable quantities; the calculations indicated the absence of dimethylglyoxime in both cases. The preliminary values of K_1' were calculated to be $3{\cdot}9 \times 10^3$ and $3{\cdot}5 \times 10^3$ l. mole^{-1} respectively.

Determination of the equilibrium and rate constants K_2', k_2' and k_{-2}' was carried out by treating excess of hydroxylamine with biacetyl monoxime under conditions such that the formation of dimethylglyoxime took place by a pseudo first-order reversible reaction sequence. The reaction was followed at 2376 Å and the conditions employed are shown in Table II; measurements were also carried out in 2·00M

potassium chloride to correspond with a concomitant study involving the precipitation of palladium dimethylglyoximate. Under the conditions used, the decomposition of biacetyl monoxime into biacetyl and hydroxylamine was negligible. The absorbance was measured at intervals of time until equilibrium was obtained. The concentrations of biacetyl monoxime and dimethylglyoxime at various times as well as at equilibrium were calculated from equations (9) and (10), and the equilibrium and rate constants were calculated from a reversible first-order rate equation. The results are also shown in Table II.

The determination of the equilibrium and rate constants K_1', k_1' and k_{-1}' was carried out by letting $6{\cdot}696 \times 10^{-6}M$ hydroxylamine react with $3{\cdot}566 \times 10^{-4}M$ biacetyl. Under these conditions, practically no dimethylglyoxime is formed and the

formation of biacetyl monoxime takes place by a pseudo first-order reversible reaction. The formation of biacetyl monoxime was followed at 2275 Å. The constants K_1', k_1' and k_{-1}' were calculated from a first-order reversible rate law and equations (11) and (12). The results of these determinations are shown in Table III.

Several independent checks were made on the magnitude of the equilibrium and rate constants determined by these methods. For example, it was found that the decomposition of dimethylglyoxime in 0·406*M* hydrochloric acid at 25·0° takes place by an irreversible first-order rate law. The rate constant k_{-2}' was found to be 0·0234 min^{-1}. This compares favorably with 0·0239 min^{-1} determined by the previous procedure (*cf.* Table II).

Values of K_1', k_1' and k_{-1}' were also obtained by following the decomposition of biacetyl monoxime at 2275 Å in 0·406*M* hydrochloric acid at 25·0°. The equilibrium and rate constants were calculated from first- and second-order reversible rate laws. Values of K_1', k_1' and k_{-1}' calculated by this method are $5{\cdot}27 \times 10^3$ l. $mole^{-1}$, 10·3 l. $mole^{-1}$. min^{-1} and $1{\cdot}96 \times 10^{-3}$ min^{-1} respectively. The values obtained by the previous procedure were $4{\cdot}65 \times 10^3$ l. $mole^{-1}$, 9·39 l. $mole^{-1}$. min^{-1} and $2{\cdot}04 \times 10^{-3}$ min^{-1} (*cf.* Table III).

TABLE III.—K_1', k_1' AND k_{-1}' AT 25·0°C AS A FUNCTION OF ACID CONCENTRATION

[HCl], *M*	$K_1' \times 10^{-3}$, *l. mole*$^{-1}$	k_1', *l. mole*$^{-1}$. *min*$^{-1}$	$k_{-1}' \times 10^3$, *min*$^{-1}$
		[KCl] = 0	
0·812	2·23 ± 0·12	7·85 ± 0·25	3·53 ± 0·09
0·609	2·91 ± 0·02	8·29 ± 0·15	2·91 ± 0·06
0·406	4·65 ± 0·06	9·38 ± 0·15	2·04 ± 0·01
0·203	9·17 ± 0·44	11·2 ± 0·4	1·24 ± 0·05
0·101	15·3 ± 0·8	13.3 ± 0·1	0·869 ± 0·038
		[KCl] = 2·00*M*	
0·812	1·08 ± 0·04	6·49 ± 0·47	5·94 ± 0·49
0·609	1·52 ± 0·04	7·47 ± 0·08	4·97 ± 0·19
0·406	2·18 ± 0·06	7·61 ± 0·19	3·53 ± 0·04
0·203	4·75 ± 0·01	9·92 ± 0·13	2·11 ± 0·02
0·101	9·44 ± 0·17	12·1 ± 0·00	1·29 ± 0·02

All the results shown are the average of three determinations.

It was found that the values of the rate and equilibrium constants for the reaction of biacetyl with hydroxylamine and the reaction of biacetyl monoxime with hydroxylamine were unchanged upon determination at a different wavelength; change in the initial concentrations of reactants had no effect on the rate or equilibrium constants in any of the methods.

Acidity functions

In the ensuing discussion, acidity functions[11] play a role, so values of the acidity functions were determined for the solutions in which equilibrium and rate constants were measured. Dimethylglyoxime was used as an indicator.

The absorbance at 2550 Å of an equilibrium mixture of undecomposed protonated and unprotonated dimethylglyoxime (obtained by extrapolation of the decomposition back to zero time) was measured in each of the solutions represented in columns 3, 4 and 5 of Table IV. This value and equations (13), (14) and (15) were then used to

calculate h_0. The results are shown in Table IV. For the solutions used in the determination of K_1', k_1' and k_{-1}', the effect of the hydroxylamine and biacetyl on the acidity function can be neglected because of their low concentrations; thus, the values shown in the second column of Table IV were taken directly from the literature.[11]

TABLE IV.—THE ACIDITY FUNCTIONS

[HCl], M	h_0			
	a		b	
	[KCl] = 0	[KCl] = 2M	[KCl] = 0	[KCl] = 2M
0·812	1·18	1·30	2·18	3·37
0·609	0·804	0·772	1·60	2·11
0·406	0·483	0·535	0·988	1·24
0·203	0·234	0·259	0·499	0·553
0·101	0·113	0·149	0·235	0·300

$a = h_0$ values for the solutions used for calculation of K_1, k_1 and k_{-1}.
$b = h_0$ values for the solutions used for calculation of K_2, k_2 and k_{-2}.
$h_0 = \frac{f_B a_{H^+}}{f_{BH^+}}$ where f_{BH^+} and f_B = activity coefficients of the bases BH^+ and B.

DISCUSSION

Enolization of biacetyl

The enol content of biacetyl in aqueous solution has been measured by Schwarzenbach and Witwer.[12] They found that the enol content was $5{\cdot}6 \times 10^{-3}$ %; this enolization is therefore neglected in this study.

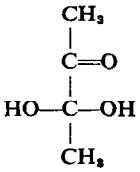
Enolization of biacetyl monoxime

As shown in Fig. 3, the extinction coefficient of the carbonyl absorption-peak of biacetyl monoxime dissolved in dioxane is 26·7. This value is approximately that which would be expected for the n-π^* transition of a carbonyl group and indicates little if any enolization in dioxane. If there is no extensive enolization in dioxane, then there will not be any in acid aqueous solution because it is known that the extent of enolization decreases as the polarity of the solvent increases.[13,14] Therefore, the enolization of biacetyl monoxime, like that of biacetyl, has been neglected.

Hydration of biacetyl

The hydration of biacetyl has been represented as taking place on only one carbonyl group. Hydration of the second carbonyl group would not be expected because $B(OH)_2$ does not possess an electron-withdrawing group adjacent to its carbonyl group, a requirement for a "hydratable" carbonyl.[15,16]

As shown in Fig. 2, little change in the extinction coefficient of the ultraviolet band of biacetyl takes place in hydrochloric acid of various concentrations, in contrast to the visible band of biacetyl.[10] The reason is that the new carbonyl compound



will have an absorption band in the ultraviolet at approximately the same point as that for biacetyl with approximately the same extinction coefficient, but will not absorb in the visible.[17] If the second carbonyl group on biacetyl was hydrated extensively, a decrease in the intensity of the ultraviolet band for biacetyl would be expected as the solvent became more polar, as well as a decrease in the visible band. This is not observed.

Hydration of biacetyl monoxime

Only some indirect evidence is available indicating that the carbonyl group of biacetyl monoxime is not appreciably hydrated. As shown by Ellefsen and Gordon,[9] a very good isosbestic point is observed for biacetyl monoxime in 0-10*M* hydrochloric acid solution. If hydration were occurring, unprotonated and protonated hydrated biacetyl monoxime, in addition to unprotonated and protonated unhydrated biacetyl monoxime, would be present. A good isosbestic point would not be observed if this were the case, because the hydration equilibrium would be expected to shift considerably, as was the case for biacetyl. Therefore, only the two unhydrated species, HM and HMH^+, must be present to an appreciable degree.

Carbinolamine intermediates

In their study of the reaction of hydroxylamine with biacetyl at pH 7, Hileman and Gordon[2] found that carbinolamine intermediates were the predominant species during much of the reaction sequence. The Jencks model predicts that the decomposition of these intermediates is acid-catalyzed. Therefore, in strongly acid solution, their decomposition would be expected to be very fast and their concentrations should remain very small. This has been found in this study. The rate constants k_1', k_{-1}', k_2' and k_{-2}' were calculated in all cases over the entire range of the reaction sequence. It was found that "constant" rate constants were obtained from zero time to the time when equilibrium had been obtained. The isosbestic points observed by Ellefsen and Gordon for biacetyl monoxime and dimethylglyoxime show that only protonated and unprotonated oxime are present at zero time. Therefore, if carbinolamine intermediates were to form to any appreciable degree in the formation or decomposition of dimethylglyoxime or biacetyl monoxime, a change in the rate constant with time would be observed. Additional evidence for lack of appreciable quantities of carbinolamine intermediates is the fact that the same rate constants were obtained by following the reactions at different wavelengths.

Spectrophotometric work has shown that the hydration of biacetyl is very fast. The protonation of hydroxylamine, dimethylglyoxime and biacetyl monoxime will also be very fast. Therefore, the rate-determining steps in oxime formation in this study will be the attack of hydroxylamine on the carbonyl group and the rate-determining step in the decomposition will be the attack of water on the oxime.

Mechanisms for the formation or the decomposition of dimethylgyloxime and biacetyl monoxime can now be proposed by analysis of the results shown in Tables II and III. All the subsequent equations are derived in terms of acidity functions.

Mechanism for the decomposition of oxime

Consideration of the variation of the activity coefficients of positively charged, neutral and hydrogen bonded species in solutions of high ionic strengths (0·101–0·812*M* hydrochloric acid) is necessary in the following discussion. In no case,

however, are the absolute values of the activity coefficients known and, for this reason, they are incorporated in the final rate and equilibrium constants.

Upon consideration of the size and charge of the ions HxH^+, HDH^+ or HMH^+, it would be expected that the activity coefficients would decrease with increase in hydrochloric acid concentration from 0·101 to 0·812*M*. The activity coefficient of neutral species such as Hx would not be expected to change greatly with this change in ionic strength. It is not obvious whether the activity coefficient of a hydrogen bonded carbonyl group would act like that of a neutral species or a positive species. However, it is sufficient to know that it will either remain constant or decrease with the specified increase in ionic strength.

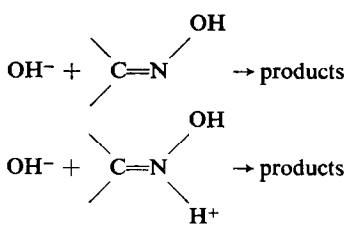
If the decomposition of dimethylglyoxime and biacetyl monoxime takes place by the attack of water on the neutral oxime molecule, the rate constants k_{-1}' and k_{-2}' would contain the activity coefficients of the neutral species HM and HD; for example, one would find for the decomposition of biacetyl monoxime that

$$\frac{-\mathrm{dHM}}{\mathrm{d}t} = k_n a_{\mathrm{HM}} \qquad (a_{\mathrm{H_2O}} \text{ is constant and included in } k_n) \tag{24}$$

or

$$\frac{-\mathrm{dHM}}{\mathrm{d}t} = k_{-1}'[\mathrm{HM}] \qquad (\text{where } k_{-1}' = k_n f_{\mathrm{HM}}). \tag{25}$$

The rate constant k_{-1}' would not be expected to change much with change in acid concentration because the activity coefficient f_{HM} would not change much. However, as seen from Table III, k_{-1}' increases rapidly with increase in acid concentration, indicating a more complicated mechanism. Likewise the following mechanisms would not be consistent with the experimental results because k_{-1}' or k_{-2}' would decrease with increase in acid concentration.



The Cordes and Jencks model[3] predicts the attack of water on the conjugate acid of the oxime. For this mechanism, the following relationships can be derived[9] from equations (4) and (13) [using HD and HDH^+ gives equation (26); using HM and HMH^+ gives equation (27)]. See equations (1) and (2) for definitions of k_{-1} and k_{-2}.

$$k_{-2}' = k_{-2} f_{\mathrm{HDH^+}} \frac{h_0}{K_{\mathrm{A}}^{\mathrm{HDH^+}} + h_0} \tag{26}$$

$$k_{-1}' = k_{-1} f_{\mathrm{HMH^+}} \frac{h_0}{K_{\mathrm{A}}^{\mathrm{HMH^+}}} \tag{27}$$

The terms $k_{-1} f_{\mathrm{HMH^+}}$ and $k_{-2} f_{\mathrm{HDH^+}}$ were calculated from the values of k_{-1}' and k_{-2}' shown in Tables II and III, the acid dissociation constants[9] and the values of h_0 shown

TABLE V.—RATE AND EQUILIBRIUM CONSTANTS FOR THE REACTION OF BIACETYL MONOXIME WITH HYDROXYLAMINE AT 25·0°C

[HCl], M	$K_2\frac{f_{HM}f_{HxH^+}}{f_{HDH^+}}$ $l.\ mole^{-1}$	$k_2 f_{HM} f_{HxH^+}$ $l.\ mole^{-1}\ .\ min^{-1}$	$k_{-2}f_{HDH^+}$ min^{-1}

0·406	$4·8 \times 10^5$	$10·5 \times 10^4$	0·23
0·203	$5·0 \times 10^5$	$12·5 \times 10^4$	0·26
0·101	$4·3 \times 10^5$	$14·1 \times 10^4$	0·33
	[KCl] = 2·00M		
0·812	$2·8 \times 10^5$	$6·3 \times 10^4$	0·22
0·609	$2·6 \times 10^5$	$7·2 \times 10^4$	0·28
0·406	$2·7 \times 10^5$	$8·9 \times 10^4$	0·36
0·203	$2·6 \times 10^5$	$12·0 \times 10^4$	0·46
0·101	$2·8 \times 10^5$	$13·0 \times 10^4$	0·47

in Table IV. The results shown in column 4 of Tables V and VI show that these terms behave as predicted, *i.e.*, they decrease with increase in acid concentration. This mechanism for the decomposition of dimethylglyoxime and biacetyl monoxime also explains their stability in neutral solution where no significant protonation takes place.

Mechanism for the formation of the oxime

Protonated hydroxylamine is unreactive toward carbonyl groups[1]; further, it is also known that carbonyl groups are extremely weak bases.[18] Therefore, as pointed out by Cordes and Jencks,[3] the mechanism of formation of an oxime cannot be the attack of unprotonated hydroxylamine on a protonated carbonyl group because the rate constant for this reaction would be larger than that for a diffusion-controlled system.

If the formation of dimethylglyoxime were due to the attack of unprotonated hydroxylamine on a neutral carbonyl group, the following equation would apply to

TABLE VI.—RATE AND EQUILIBRIUM CONSTANTS FOR THE REACTION OF BIACETYL WITH HYDROXYLAMINE AT 25·0°C

[HCl], M	$K_1\frac{f_B f_{HxH^+}}{f_{HMH^+}}$ $l.\ mole^{-1}$	$k_1 f_{HxH^+} f_B$ $l.\ mole^{-1}\ .\ min^{-1}$	$k_{-1}f_{HMH^+}$ min^{-1}
	[KCl] = 0		
0·812	$5·7 \times 10^6$	$2·5 \times 10^7$	4·3
0·609	$5·1 \times 10^6$	$2·6 \times 10^7$	5·2
0·406	$5·1 \times 10^6$	$3·1 \times 10^7$	6·1
0·203	$5·0 \times 10^6$	$3·8 \times 10^7$	7·6
0·101	$4·1 \times 10^6$	$4·6 \times 10^7$	11·1
	[KCl] = 2·00M		
0·812	$2·5 \times 10^6$	$1·9 \times 10^7$	7·6
0·609	$2·6 \times 10^6$	$2·4 \times 10^7$	9·3
0·406	$2·7 \times 10^6$	$2·5 \times 10^7$	9·5
0·203	$3·1 \times 10^6$	$3·6 \times 10^7$	11·7
0·101	$3·6 \times 10^6$	$4·5 \times 10^7$	12·5

the reaction of biacetyl monoxime with hydroxylamine:

$$\frac{\mathrm{dHDH^+}}{\mathrm{d}t} = k_m a_{Hx} a_{HM} = k_2'[HM][HxH^+] \tag{28}$$

where

$$k_2' = \frac{k_m f_{Hx} f_{HM} K_A^{HxH^+}}{h_0}. \tag{29}$$

The activity coefficients f_{Hx} and f_{HM} would not be expected to change much with increase in acid concentration and therefore k_2' at a hydrochloric acid concentration of 0·101*M* would be about 10 times the value for k_2' with 0·812*M* hydrochloric acid (*cf.* Table II). This is not observed.

Campbell and Edward[18] have shown that the strength of the hydrogen bond on the carbonyl group in aliphatic ketones increases as the polarity of the solvent is increased. In the present case, the solvent polarity is increased by increase in the concentration of hydrochloric acid. It would be expected that the carbon atom in the carbonyl group would be more reactive toward hydroxylamine as the hydrogen bond became stronger. Therefore, it is assumed that the reactivity of biacetyl to hydroxylamine is proportional to $a_B a_{H^+}$ and the reactivity of biacetyl monoxime to hydroxylamine is proportional to $a_{HM} a_{H^+}$. In the reaction of biacetyl with hydroxylamine, there are two forms of biacetyl with which hydroxylamine can react. However, hydroxylamine will probably react preferentially with unhydrated biacetyl because, as shown by Cordes and Jencks,[19] a nitrogen base will react fastest with those carbonyl groups which have the more strongly electron-withdrawing groups adjacent to them.

From these relationships and equations (3) and (13) (Y and YH^+ = Hx and HxH^+), the following relationships can be derived[9]:

$$k_1' = k_1 \frac{f_B f_{HxH^+} K_A^{HxH^+}}{1 + \dfrac{K_h f_B}{f_{B(OH)_2}}} \tag{30}$$

$$k_2' = k_2 f_{HxH^+} f_{HM} K_A^{HxH^+}. \tag{31}$$

The values of k_1, k_2, $K_h f_B / f_{B(OH)_2}$ and $K_A^{HxH^+}$ are known (the value of $K_A^{HxH^+}$ used is that determined by Bissot, Parry and Campbell[20]). Therefore, the terms shown in column 3 of Tables V and VI can be obtained.

The activity coefficient of HxH^+ would be expected to decrease with increase in acid concentration and the activity coefficients of B and HM would be expected either to remain unchanged or to decrease with this change in acid concentration. If this is so, the terms in column 3 of Tables V and VI would be expected to decrease with increase in acid concentration; this is observed.

The equilibrium constants corresponding to the proposed mechanism are those shown in equations (16) and (17). The following equilibrium equations were derived for this mechanism:

$$K_1' = K_1 \frac{(f_B f_{HxH^+}) K_A^{HxH^+} K_A^{HMH^+}}{(f_{HMH^+}) h_0 \left(1 + \dfrac{K_H f_B}{f_{B(OH)_2}}\right)} \tag{32}$$

$$K_2' = K_2 \frac{(f_{HM} f_{HxH^+}) K_A^{HxH^+} (K_A^{HDH^+} + h_0)}{(f_{HDH^+}) h_0}. \tag{33}$$

By use of these equations, the terms shown in column 2 of Tables V and VI were obtained from the values of K_2' and K_1' in Tables II and III. It will be noted that in the absence and presence of potassium chloride, these terms are almost unchanged as the hydrochloric acid concentration is varied. If it is assumed that the ratio of the activity coefficient of HxH^+ to the activity coefficient of the conjugate acid of biacetyl monoxime in the term shown in column 2 of Table V and to the conjugate acid of dimethylglyoxime in the term shown in column 2 of Table VI is approximately unity for all of the acid concentrations considered, then the hydrogen bonded species HM and B must act like a neutral species, the activity coefficients remaining approximately unchanged.

It is seen that $k_{-2}f_{HDH^+}$ is smaller than $k_{-1}f_{HMH^+}$ and $k_1f_{HxH^+}f_B$ greater than $k_2f_{HxH^+}f_{HM}$ at any given acid concentration. This is attributed primarily to steric hindrance of attack by water and hydroxylamine.

Thus, with the exception of the interpretation of the nature of the reaction of hydroxylamine with the hydrogen bonded carbonyl group, the kinetics and mechanism of formation of dimethylglyoxime in acid solution are those predicted on the basis of Cordes and Jencks's model.[3]

Acknowledgement—The authors acknowledge the partial assistance of the United States Atomic Energy Commission in supporting this investigation, under Contract AT(11-1)-582.

Zusammenfassung—Kinetik und Mechanismus der Bildung von Dimethylglyoxim aus Biacetyl und Hydroxylamin in saurer Lösung wurden untersucht. Es wurde gefunden, daß nicht protoniertes Hydroxylamin mit der an einer Wasserstoffbrücke beteiligten Carbonylgruppe zur konjugierten Säure des Oxims reagiert. Im untersuchten Bereich an Säurekonzentrationen wurden keine nachweisbaren Mengen von Carbinolamin-Zwischenstufen gefunden.

Résumé—On a étudié la cinétique et le mécanisme de formation de la diméthylglyoxime à partir du diacétyle et de l'hydroxylamine en solution acide. On a trouvé que l'hydroxylamine non protonée réagit avec le groupe carbonyle à liaison hydrogène pour donner l'acide conjugué de l'oxime. On n'a pas trouvé de quantités décelables d'intermédiaires de la carbinolamine dans le domaine de concentration acide étudié.

COMPLEXATION OF ALUMINIUM, YTTRIUM, LANTHANUM AND LANTHANIDES WITH 4-(2-PYRIDYLAZO)RESORCINOL (PAR)*

L. SOMMER and H. NOVOTNÁ
Department of Analytical Chemistry of the J. E. Purkyně-University, Brno, Czechoslovakia

(*Received* 15 *August* 1966. *Accepted* 3 *October* 1966)

Summary—The sensitive reactions between 4-(2-pyridylazo)resorcinol (PAR) and yttrium, lanthanum and the lanthanides can be used for the spectrophotometric determination of these elements. The method has no advantage over other methods for the determination of aluminium and lanthanum. Only M(PAR)H and M(PAR) complexes are formed in solutions where the molarity of the metal ion is greater than or nearly equal to the molarity of the ligand at pH $< 7{\cdot}5$. If there is molar excess of PAR, 1:2 complexes may be formed but this is certain only for the yttrium-PAR system. Errors in analysis may result from the simultaneous occurrence of optically different complexes; close control of pH and reagent concentration is essential. Optical and equilibrium data are given for the systems investigated.

4-(2-PYRIDYLAZO)RESORCINOL (PAR) is used as a metal-ion indicator, with ions of the elements of group IIIA of the periodic system and with aluminium, to give intensely red soluble complexes in slightly acidic medium. The sensitivity of the reactions, with the exception of that with aluminium, is high, as is shown by the values of pD at pH 6·4–6·6: scandium 7·4, yttrium 6·6, lanthanum 6·0, cerium 7·3, praseodymium 6·5, samarium 6·9, erbium 7·4, aluminium 5·9. PAR has been used as an indicator for the spectrophotometric EDTA titration of erbium at pH 8·0–8·8, and, more recently, as a reagent for the spectrophotometric determination of lanthanum and cerium,[2] or of the sum of rare earths elements in neutral or slightly alkaline medium.[3,4]

It is generally assumed[3] that the composition of the complexes formed under these conditions is M:R = 1:2. This was not considered strange, because such complexes are sometimes formed with PAR in alkaline medium when there is a slight excess of PAR and when the formation is not hindered by hydrolysis. For lanthanum(III) and cerium(III) these complexes were also prepared in solid state.[2]

In this paper the complexation of aluminium, yttrium, lanthanum and lanthanides with PAR is studied in detail. No evidence for 1:2 complexes with the exception of that of yttrium can be found at pH $< 7{\cdot}5$. Thus the "normal" MR complex (H_2R = PAR) prevails under the conditions described earlier for the spectrophotometric determination of these elements. Results obtained by the method of continuous variations must be carefully evaluated for these systems.

EXPERIMENTAL

Only reagents and apparatus not described previously are listed.

Reagents

Metal-ion solutions. All chemicals used were analytically pure. Standard solutions of yttrium, lanthanide and lanthanum perchlorates, and aluminium and praseodymium nitrates were prepared

* See also: *Talanta*, 1966, **13**, 667; 1967, **14**, 171.

from the spectrally pure oxides (Johnson and Matthey). The solutions were standardized gravimetrically when the oxides dissolved were not well-defined.

Control of pH. The pH of solutions was regulated by addition of suitable amounts of 0·1, 0·5 and 2*M* ammonia or perchloric acid, and the ionic strength was adjusted to 0·1 by addition of sodium perchlorate.

Procedure for complexation studies

In the case of PAR the formation of MRH, MR, $M(RH)_2$ and MR_2 complexes and equilibria involving H_2R, HR^- and H_3R^+, where H_2R is electrically neutral PAR, is considered.

The pH-absorbance curves for equimolar solutions and solutions containing an excess of metal ion were interpreted by the help of the $C_R/A = f[H]^n$ transformations previously derived, or corresponding logarithmic plots.[5–7]

The true equilibrium is confirmed by the linearity of a suitable transformation and the number of protons split off. The molar absorptivities and stability constants of the complexes were found graphically.

Occasionally the method of continuous variations[8] was also used.

RESULTS AND DISCUSSION

Complexation of aluminium

Absorption curves for solutions at pH 3·66–4·9 when $C_M \geqslant C_R$ (Figs. 1 and 2) have isosbestic points. The measurements at pH >4·9 are complicated by hydrolysis. The limiting wavelength of maximum absorption and isosbestic point occur at 495 and 435 mμ respectively when $C_M = 3{\cdot}99 \times 10^{-3}M$ and $C_R = 3{\cdot}99 \times 10^{-5}M$ and at 490 and 430 mμ when $C_M = C_R = 5{\cdot}87 \times 10^{-5}M$ (C_M and C_R are the analytical concentrations of the metal and reagent, respectively).

Job's method indicates a 1:1 Al(PAR) complex (Fig. 3); curves at pH > 6 are unobtainable because of hydrolysis.

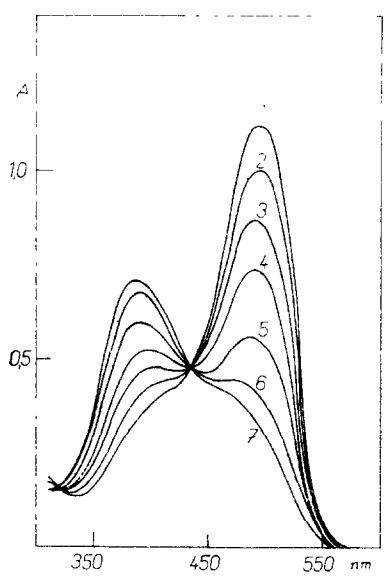

FIG. 1.—Absorption spectra for PAR-solutions with excess of aluminium. $C_R = 3{\cdot}99 \times 10^{-5}M$; $C_M = 3{\cdot}99 \times 10^{-3}M$. pH: *1*—4·39; *2*—4·28; *3*—4·19; *4*—4·10; *5*—3·98; *6*—3·79; *7*—3·66.

Absorbance-pH plots indicate rapid formation of a complex of limited stability over a narrow pH region at pH >3·5 for solutions with excess of aluminium ($C_M/C_R = 100$). In equimolar solutions with $C_M = C_R = 5{\cdot}87 \times 10^{-5}M$ this complex is only formed at pH >4·5 and the absorbance decreases with increase in pH because of hydrolysis at pH >5 (Fig. 4).

The splitting off of two protons during complexation was proved for solutions with an excess of aluminium by the linearity of the transformation (1) for $n = 2$ (Fig. 5):

$$C_R/A = \frac{1}{\varepsilon_1} + \frac{(A - \varepsilon_{R2}C_R)[H]^n}{\varepsilon_1 k_{1n} C_M} \tag{1}$$

(the ligand is present solely as H_2R in solution over the pH region studied).*

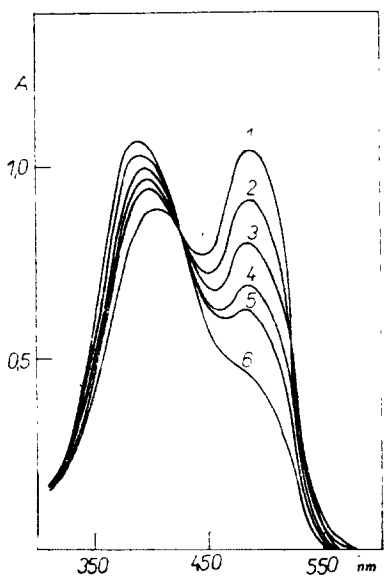

FIG. 2.—Absorption spectra for equimolar PAR and aluminium solutions. $C_R = C_M = 5{\cdot}871 \times 10^{-5}M$. pH: *1*—5·08; *2*—5·04; *3*—5·01; *4*—4·90; *5*—4·80; *6*—4·65.

This conclusion was confirmed by the corresponding log plot (2):

$$\log \frac{A - A_{0R}}{A_{01} - A} = n\text{pH} + \log C_M + \log k_{1n} \tag{2}$$

where $A_{01} = \varepsilon_1 C_R$ and $A_{0R} = \varepsilon_{R2} C_R$, *cf.* Fig. 6.

Because a 1:1 complex is evidently formed, one of the following equilibria must be valid:

$$Al^{3+} + H_2R \rightleftharpoons AlR^+ + 2H^+ \tag{A}$$

$$Al^{3+} + H_2R \rightleftharpoons Al(RH)(OH)^+ + 2H^+. \tag{B}$$

* Symbols have the same meaning as in earlier papers in this series. The definitions and values of the constants are summarized towards the end of this paper.

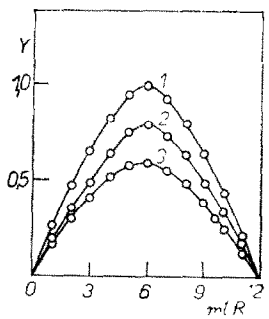

FIG. 3.—Job curves of equimolar PAR and aluminium solutions at 500 mμ. $C_{total} = 1{\cdot}068 \times 10^{-4}M$. pH: *1*—5·50; *2*—5·25; *3*—5·10.

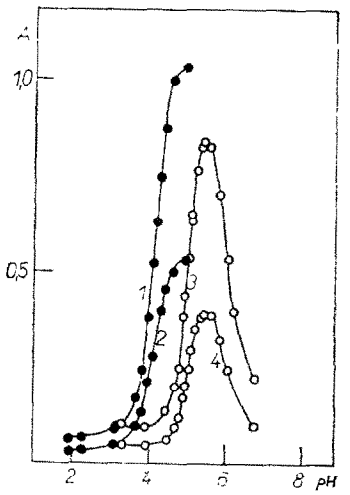

FIG. 4.—pH-Absorbance curves for PAR and aluminium solutions. $C_R = 3{\cdot}99 \times 10^{-5}M$; $C_M = 3{\cdot}989 \times 10^{-3}M$: *1*—520 mμ; *2*—530 mμ. $C_R = C_M = 5{\cdot}571 \times 10^{-5}M$: *3*—520 mμ; *4*—530 mμ.

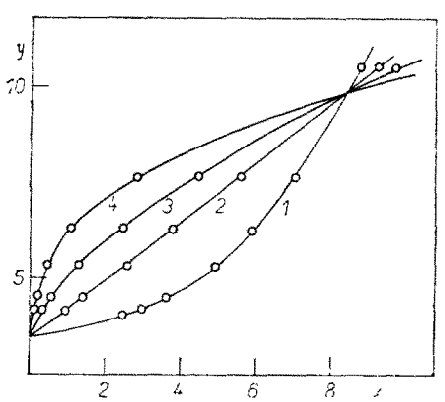

FIG. 5.—Analysis of Fig. 4, curve 1, according to equation (1). $y = C_R \times 10^5/A$; $x = (A - \varepsilon_{R2}C_R)\,[H]^n/A$: *1*—$n = 1$; $x \times 10^5$: *2*—$n = 2$; $x \times 10^9$: *3*—$n = 3$; $x \times 10^{13}$: *4*—$n = 4$; $x \times 10^{17}$.

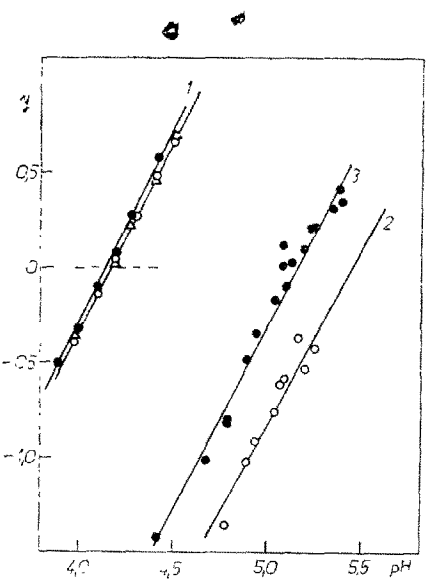

FIG. 6.—Log plots based on Fig. 4. *1*—according to equation (2); ● 500 mμ; ○ 520 mμ; △ 510 mμ. *2* and *3*—according to equation (4): 520 mμ and 530 mμ. $y = \log (A - A_{0R})/(A_{01} - A)$ or $(A - A_{0R})/(A_{01} - A)^2$.

Two protons are split off in equimolar solutions ($5 \times 10^{-5}M$) at pH < 5·4, where the H_2R form of the ligand predominates. This follows from the linearity of the transformation (3) and the logarithmic plot (4) (Fig. 6).

$$\frac{C_R}{A} = \frac{1}{\varepsilon_1} + \frac{[H]}{A\varepsilon_1}\sqrt{\frac{(\varepsilon_1 - \varepsilon_{R2})(A - \varepsilon_{R2}C_R)}{\kappa_{12}}} \tag{3}$$

$$\log \frac{A - \varepsilon_{R2}C_R}{(\varepsilon_1 C_R - A)^2} = 2\,\mathrm{pH} + \log \kappa_{12} - \log(\varepsilon_1 - \varepsilon_{R2})\,. \tag{4}$$

Thus equilibrium (A) is again established as the operative one. Moreover the values of molar absorptivity of the AlR^+ complex calculated from the intercepts of (1) and (3) are higher than is usual for an MRH-complex and closer to those expected for MR complexes (Table I).

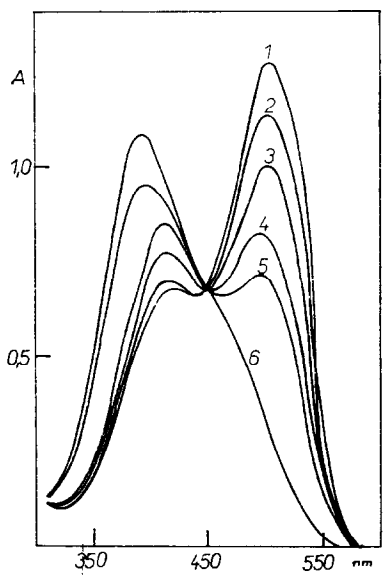

FIG. 7.—Absorption spectra for PAR-solutions with excess of yttrium. C_R = $5{\cdot}83 \times 10^{-5}M$; $C_M = 3{\cdot}54 \times 10^{-3}M$. pH: *1*—6·27; *2*—6·07; *3*—5·76; *4*—5·45; *5*—4·96; *6*—3·28.

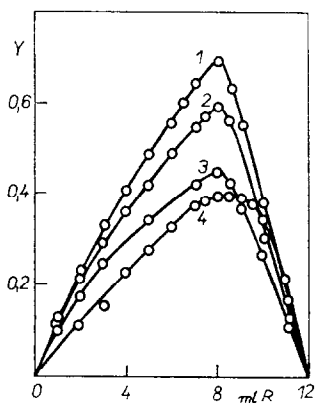

FIG. 8.—Job curves for equimolar PAR and yttrium solutions. $C_{total} = 7{\cdot}48 \times 10^{-5}M$; 500 mμ. pH: *1*—6·00; *2*—5·90; *3*—5·75; *4*—8·10 ($C_{total} = 8{\cdot}80 \times 10^{-6}M$; 0·008*M* triethanolamine).

Complexation of yttrium

Absorption curves have $\lambda_{max} = 500$ mμ at pH 6·07 and 490 mμ at pH < 6 and an isosbestic point at 450 mμ for solutions with an excess of metal ion between pH 3·28 and 6·27 (Fig. 7). The maximum of the curves for equimolar solutions is shifted to 510 mμ at pH 6·6.

Job curves suggest a $Y(PAR)_2$ complex between pH 5·5 and 8 (Fig. 8). At lower pH values the curves are deformed and the mole ratio M:R decreases. At pH > 6 the measurements are very difficult in equimolar solutions, owing to rapid fading of the colour.

A mutual transition of at least two complexes is shown from the pH-absorbance curves for solutions with excess of metal ion present (Fig. 9). One proton is evidently split off during complexation at pH < 5 according to the linearity of transformation (1) for $n = 1$, and the corresponding logarithmic plot (2) (Fig. 10, Fig. 11, curve 1).

Only equilibrium (C) need be considered in solutions containing excess of metal ion at pH 3·6–4·4:

$$Y^3 + H_2R \rightleftharpoons YRH^2 + H^+. \qquad (C)$$

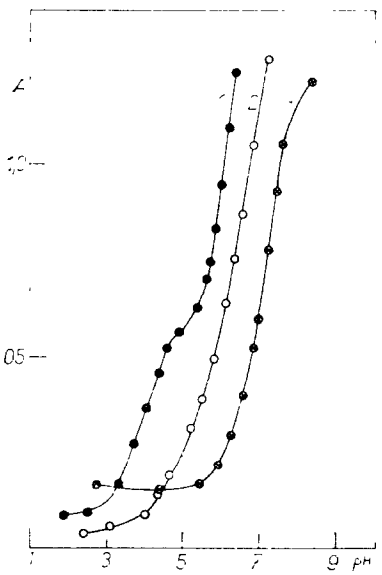

FIG. 9.—pH-absorbance plots for PAR and yttrium solutions. *1*—$C_R = 5{\cdot}83 \times 10^{-5}M$; $C_M = 3{\cdot}54 \times 10^{-3}M$; *2*—$C_R = C_M = 3{\cdot}97 \times 10^{-5}M$; *3*—$C_R = 5{\cdot}10 \times 10^{-5}M$; $C_M = 5{\cdot}10 \times 10^{-6}M$. $\lambda = 530$–520 mμ.

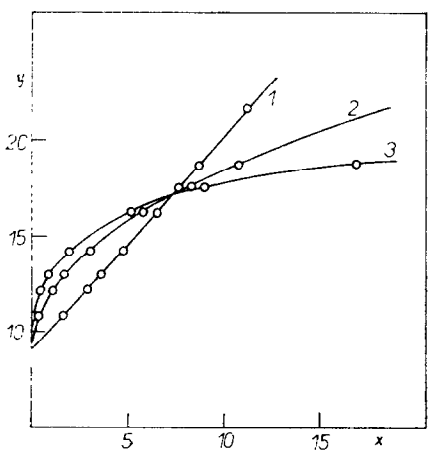

FIG. 10.—Graphical analysis of Fig. 9, curve 1, according to equation (1). $y = C_R \times 10^5/A$, $x = (A - \varepsilon_{R_2}C_R)[H]^n/A$. *1*—$n = 1$; $x \times 10^5$: *2*—$n = 2$; $x \times 10^9$: *3*—$n = 3$; $x \times 10^{13}$.

The splitting off of one proton between pH 5·8 and 6·4 was assumed to be due to a mutual transition of two complexes, according to (D), rather than to the formation of $Y(RH)_2^+$.

$$YRH^{2+} \rightleftharpoons YR^+ + H^+. \qquad (D)$$

The linearity of transformation (5) agrees well with this assumption, and the precise value of $n = 1$ follows from the logarithmic plot (6) (Fig. 11).

$$\frac{C_R}{A} = \frac{1}{\varepsilon_1} + \frac{(A - \varepsilon_{1H}C_R)[H]}{A}\,\frac{1}{K_{kal}\varepsilon_1} \qquad (5)$$

$$\log\frac{A - \varepsilon_{1H}C_R}{\varepsilon_1 C_R - A} = pH + \log K_{kal}. \qquad (6)$$

For $\lambda < 520$ mμ and at pH < 5·6 or >7 other equilibria were indicated by the larger scattering of points for the plot of equation (5).

For equimolar solutions (*cf.* Fig. 9) linearity is only obtained with transformation

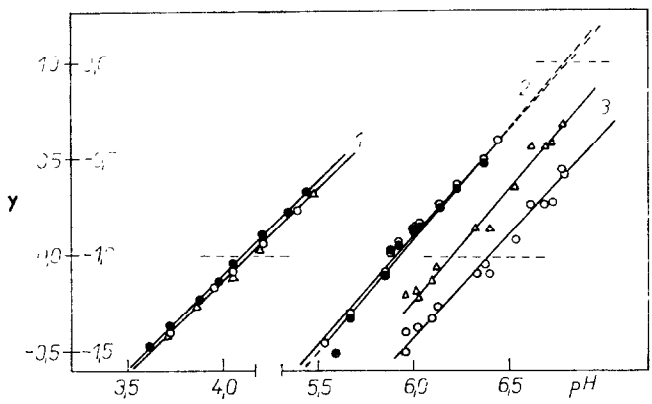

FIG. 11.—Logarithmic analysis of the pH-absorbance plots.
1—according to equation (2): ○ 520 mμ; △ 510 mμ; ● 530 mμ. *2*—according to equation (6): ○ 520 mμ ; ● 530 mμ (right-hand *y*-scale). *3*—according to equation (8): 520 mμ; *4*—530mμ. $y = \log (A - A_{0R})/(A_{01} - A)$, $\log (A - A_{01})/(A_{02} - A)$, and $\log (A - A_{0R})/(A_{01} - A)^2$ respectively.

(7), derived for 1:1 complex formation with loss of one proton, and in logarithmic transformation (8) from which $n = 1$ was found for 520–530 mμ.

$$\frac{C_R}{A} = \frac{1}{\varepsilon_1} + \frac{\sqrt{[H](A - \varepsilon_{R3}C_R)}}{A}\frac{1}{\varepsilon_1}\sqrt{\frac{\varepsilon_1 - \varepsilon_{R3}}{\kappa_{11}}} \tag{7}$$

$$\log\frac{A - \varepsilon_{RX}C_R}{(\varepsilon_1 C_R - A)^2} = n\text{pH} + \log\kappa_{1n} - \log(\varepsilon_1 - \varepsilon_{RX}). \tag{8}$$

Hence the equilibrium (E) obtains for equimolar solutions at pH 5·9–7·2:

$$Y^{3+} + HR^- \rightleftharpoons YR^+ + H^+. \tag{E}$$

Complexation of lanthanum

The formation of complexes in solutions where $C_M \geqslant C_R$ is greatly disturbed by the hydrolysis of lanthanum.

The absorption curves have λ_{max} 510 mμ at pH > 7 and an isosbestic point at 455 mμ between pH 6·22 and 7·35 for solutions with $C_M/C_R = 10$, (Fig. 12).

The graphical analysis of the pH-absorbance plots for solutions with slight excess of metal ion coincides with the formation of a 1:1 complex only between pH 6 and 7. The HR^- anion is practically the only form of ligand in solution under these conditions. The transformation (9) is linear, showing the splitting off of one proton:

$$\frac{C_R}{A} = \frac{1}{\varepsilon_1} + \frac{(A - \varepsilon_3 C_R)[H]}{A\kappa_{11}\varepsilon_1} \tag{9}$$

(Figs. 13, 14).

A straight line with slope $n = 0{\cdot}9$ was found for the logarithmic transformation (2) at 510–530 mμ and pH 6·0–6·5 (Fig. 15).

Higher values for n were found at pH > 6·6 and the formation of a further complex cannot be excluded. The use of Job's method is hindered by hydrolysis. Only the equilibrium (F) can be proved with certainty in this case:

$$La^{3+} + HR^- \rightleftharpoons LaR^+ + H^+. \tag{F}$$

Complexation of lanthanides

Absorption curves have a limiting maximum at 500 mμ and an isosbestic point at 445 mμ for pH 6·3–6·5 and for $C_M/C_R = 100$ for praseodymium, neodymium, samarium, dysprosium, erbium and ytterbium (Fig. 16).

The pH-absorbance plots indicate the presence of at least two red complexes in solutions containing excess of metal ion (Fig. 17), one at pH < 4, the other between pH 4 and 6.

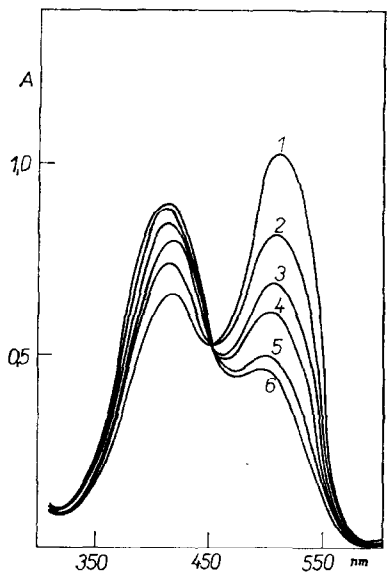

FIG. 12.—Absorbance curves for PAR-solutions with excess of lanthanum. $C_R = 4{\cdot}30 \times 10^{-5}M$, $C_M = 7{\cdot}30 \times 10^{-4}M$ pH: *1*—7·35; *2*—7·06; *3*—6·80; *4*—6·70; *5*—6·29; *6*—6·22.

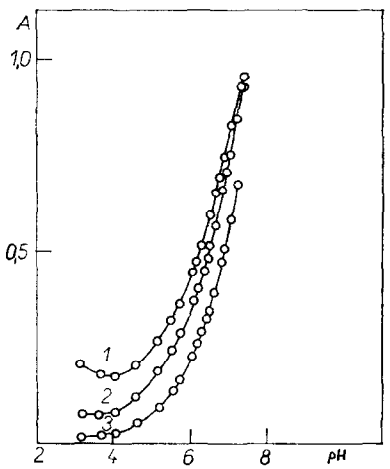

FIG. 13.—pH-Absorbance plot for PAR solutions with excess of lanthanum. $C_R = 4{\cdot}30 \times 10^{-5}M$, $C_M = 4{\cdot}30 \times 10^{-4}M$. *1*—500 m$\mu$; *2*—520 m$\mu$; *3*—540 m$\mu$.

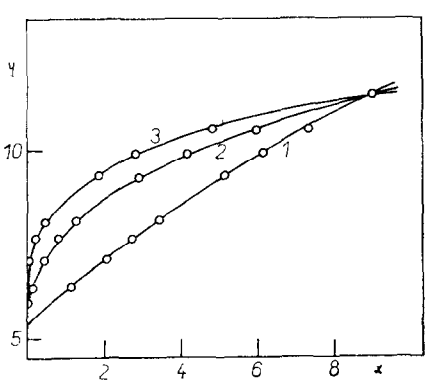

FIG. 14.—Graphical analysis of pH-absorbance plot (at 510 mμ, same conditions as Fig. 13) according to equation (9). $y = C_R 1 \times 0^5 A$, $x = (A - \varepsilon_{R3})[H]^n/A$. *1*—$n = 1$; $\times x 10^7$: *2*—$n = 2$; $x \times 10^{13}$: *3*—$n = 3$; $x \times 10^{19}$.

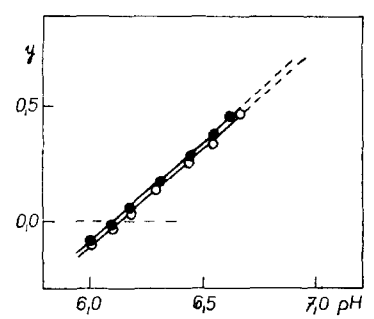

FIG. 15.—Logarathmic plots according to equation (2), for same conditions as for Fig. 13. ○ 510 mμ, ● 520 mμ $A_{0R} = \varepsilon_{R3}C_R$, $A_{01} = \varepsilon_1 C_R$.

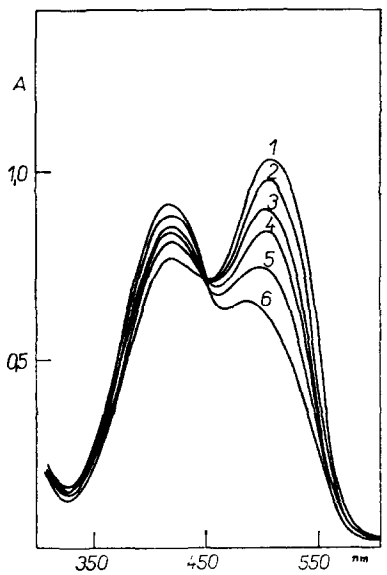

FIG. 16.—Absorption curves for PAR solutions with excess of praseodymium. $C_R = 5{\cdot}59 \times 10^{-5}M$, $C_M = 5{\cdot}59 \times 10^{-3}M$. pH: *1*—6·48; *2*—6·36; *3*—6·23; *4*—6·10; *5*—5·82; *6*—4·97.

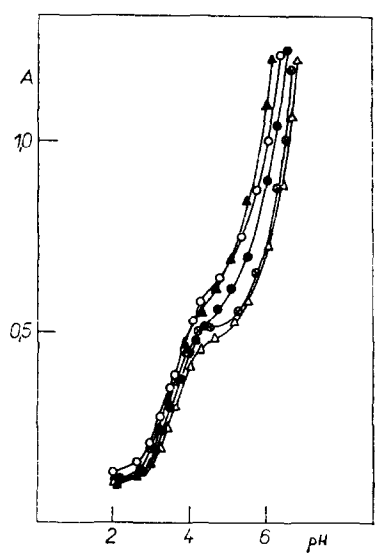

FIG 17.—pH-Absorbance plots (520 mμ) for PAR solutions with lanthanide ions in excess.

○ Er^{3+}: $C_R = 5{\cdot}01 \times 10^{-5}M$, $C_M = 2{\cdot}64 \times 10^{-3}M$
▲ Yb^{3+}: $C_R = 5{\cdot}27 \times 10^{-5}M$, $C_M = 1{\cdot}51 \times 10^{-3}M$
⊕ Sm^{3+}: $C_R = 5{\cdot}27 \times 10^{-5}M$, $C_M = 1{\cdot}92 \times 10^{-3}M$
● Dy^{3+}: $C_R = 5{\cdot}27 \times 10^{-5}M$, $C_M = 1{\cdot}98 \times 10^{-5}M$
△ Nd^{3+}: $C_R = 5{\cdot}27 \times 10^{-5}M$, $C_M = 1{\cdot}84 \times 10^{-3}M$

It was assumed that all the lanthanides would react with PAR similarly, but that slight differences in the stabilities of individual complexes would influence the position and shape of pH-absorbance plots.

One proton is split off during complexation between pH 3·15 and 4·2. The transformation (10), derived on the assumption of the partial existence of the protonated ligand, H_3R^+, over the pH range studied, has a linearity only for $n = 1$ as proved for praseodymium and samarium (Fig. 18):

$$\frac{C_R}{A} = \frac{1}{\varepsilon_{1H}} + \frac{A(1 + [H]/K_{a1}) - A_{0R}}{AC_M\varepsilon_{1H}k_{11}}[H] \qquad (10)$$

where

$$A_{0R} = \varepsilon_{R1}C_R\frac{[H]}{K_{a1}} - \varepsilon_{R2}C_R.$$

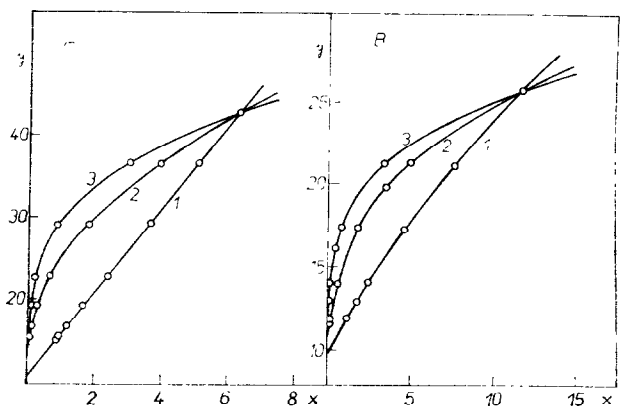

FIG. 18.—Graphical analysis of the first part of pH absorbance plots (at 520 mμ) for praseodymium and samarium solutions in excess (*cf.* Fig. 17) according to equation (10). $y = C_R \times 10^5/A$; $x = \{A(1 + [H]/K_{a1}) - A_{0R}\}[H]^n/A$. A: Pr^{3+}; B: Sm^{3+}. *1*—$n = 1$; $x \times 10^4$: *2*—$n = 2$; $x \times 10^7$: *3*—$n = 3$; $x \times 10^{10}$.

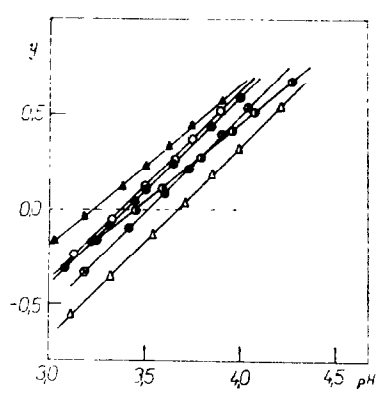

FIG. 19.—Logarithmic analysis of the pH-absorbance plots for lanthanide solutions (*cf.* Fig. 17, first part) according to equation (11).
▲ Sm^{3+}; ○ Dy^{3+}; ● Yb^{3+}; ◑ Er^{3+}; ⊕ Nd^{3+}; △ Pr^{3+}.

Slopes approaching unity ($n = 0{\cdot}8-1{\cdot}0$) were found when the logarithmic function (1) was plotted for solutions containing excess of various lanthanide ions (Fig. 19):

$$\log \frac{A(1 + [H]/K_{a1})}{A_{01} - A} = pH + \log C_M + \log k_{11} \qquad (11)$$

where $A_{01} = \varepsilon_{1H} C_R$.

Absorbances at 510–530 mμ and molar absorptivities calculated from equation (10) were used. Deviations in the erbium system are probably caused by a further complex formed under the same conditions, pH > 4.

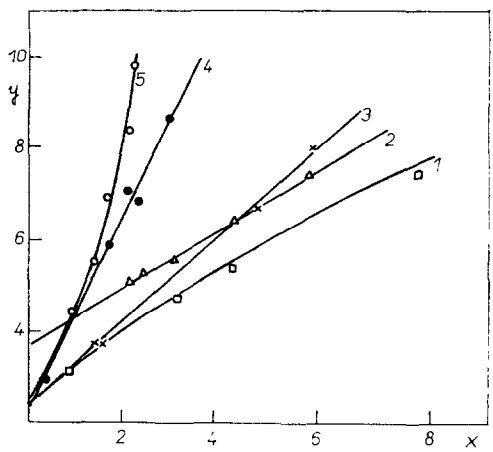

FIG. 20.—Graphical analysis of the second part of pH-absorbance plots (at 530 mμ; *cf.* Fig. 17) according to equation (5).
1—Yb^{3+}; *2*—Er^{3+}; *3*—Dy^{3+}; *4*—Sm^{3+}; *5*—Nd^{3+}; $y = C_R \times 10^5/A$, $x = (A - A_{01})[H] \times 10^7/A$.

Analysis of the pH-absorbance curves by equations (5) and (6) for reactions over the pH range 5·4–7·2, the wavelength of absorption being $\geqslant$ 530 mμ, showed that one proton was split off during complexation (Figs. 20, 21). Thus for solutions of PAR containing a slight excess of lanthanide ion, equilibrium (6) was proved when pH < 4 and (H) when pH > 5·4:

$$M^{3+} + H_2R \rightleftharpoons MRH^{2+} + H^+ \qquad (G)$$

$$MRH^{2+} \rightleftharpoons MR^+ + H^+. \qquad (H)$$

In equimolar solutions ($7{\cdot}45 \times 10^{-5} M$) equilibrium (I) is valid as indicated by the pH-absorbance plot for praseodymium (Fig. 22).

$$M^{3+} + HR^{--} \rightleftharpoons MR^+ + H^+ \qquad (I)$$

The transformation (7) and the logarithmic plot (8) are linear giving a value of $n = 1{\cdot}1$ between pH 6·5 and 7·4 (Fig. 23).

The complex formed at pH 6·5–7·0 was shown by Job's method at 520 mμ and $C_{total} = 1{\cdot}490 \times 10^{-4} M$, to have a mole ratio of 1:1 (Fig. 24). In the praseodymium system the maximum of the Job curves at 520 mμ is shifted to a higher mole fraction of PAR, *i.e.*, 0·56–0·71 at pH 8, ($C_{total} = 1{\cdot}486 \times 10^{-4} M$) in the presence of 0·01 M

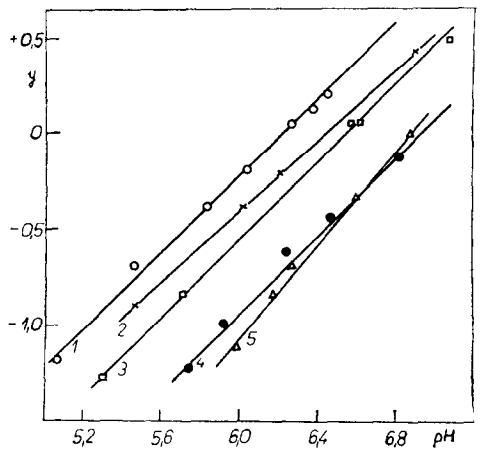

FIG. 21.—Logarithmic analysis of the second part of pH-absorbance plots (at 530 mμ; *cf.* Fig. 17) according to equation (11).
$y = \log (A - A_{01})/(A_{02} - A)$. *1*—$Dy^{3+}$; *2*—$Yb^{3+}$; *3*—$Er^{3+}$; *4*—$Sm^{3+}$; *5*—$Nd^{3+}$.

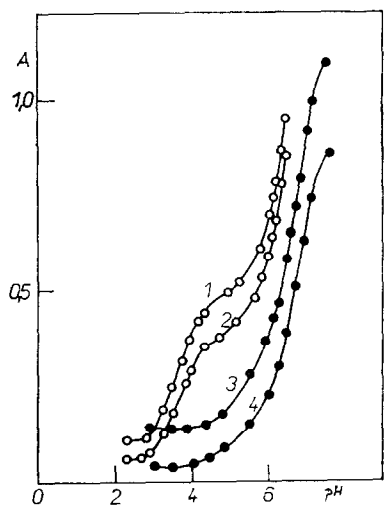

FIG. 22.—pH-Absorbance plot for PAR solutions with praseodymium.
$C_R = 5{\cdot}59 \times 10^{-5}M$, $C_R = 5{\cdot}59 \times 10^{-3}M$: *1*—520 mμ; *2*—530 mμ.
$C_M = C_R = 7{\cdot}45 \times 10^{-5}M$; *3*—520 mμ; *4*—540 mμ.

triethanolamine. The absorbance decreases rapidly with time, the part of the curves where metal ion is in excess is deformed and the maximum is also continuously shifted. This suggests the influence of hydrolysis rather than a 1:2 complex as suggested earlier.

As no evidence was found for a 1:2 lanthanide-PAR complex in solutions the assumption of Munshi and Dey[3] could not be substantiated.

Optical and equilibrium constants

The molar absorptivities calculated in various ways are collected in Tables I and II. The values of molar absorptivities for the MR complex sometimes lack high

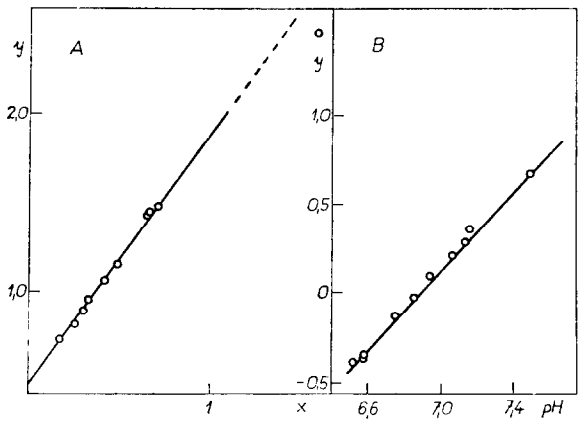

FIG. 23.—Graphical analysis of the equimolar pH-absorbance plot for praseodymium and PAR solutions (*cf.* Fig. 22).

* κ_{12}, † κ_{11}.

precision. For lanthanides the values for 510–520 mμ were not calculated because of the high errors involved. The following equilibrium and stability constants were evaluated:

$$k_{11} = [MRH][H]/[M][H_2R] \qquad K_{1H} = [MRH]/[M][RH^*]$$
$$\kappa_{12} = [MR][H]^2/[M][H_2R] \qquad K_1 = [MR]/[M][R]$$
$$\kappa_{11} = [MR][H]/[M][HR^*] \qquad K_{kal} = [MR][H]/[MRH]$$

where HR* is the hypothethetical anion derived if the *o*-hydroxy group dissociates first. Some further relations between particular constants are valid:

$$K_{1H} = k_{11}/K_{a2}^*$$
$$K_1 = K_{kal} \cdot K_{1H}/K_{a3}^*$$
$$K_1 = \kappa_{12}/K_{a2}K_{a3} = \kappa_{11}/K_{a3}^*$$

where $K_{a2}^* = K_{a3}$ and $K_{a3}^* = K_{a2}$ (see *Talanta*, 1967, **14**, 182).

The equilibrium constants were calculated from the intercepts of the logarithmic plots (2, 4, 6, 8, 11). The data are summarized in Table II.

With the exception of aluminium, the Group III B elements form more stable PAR complexes than the Group III A elements do.[9–12] The same is true for the complex binding tendency of these metals ($\log k_{11}$, $\log k_{12}$, $\log \kappa_{12}$, $\log \kappa_{11}$).

Little difference in stability was found between corresponding protonated and "normal" complexes but a considerable increase in absorptivity for the latter complexes was observed. The "normal" species seem to be slightly less stable. There is no simple relation between complex stability and atomic number or radius of the lanthanides; however, as expected, the stabilities do not differ considerably.

The "normal" MR complex is only suitable for the spectrophotometric determination of yttrium and lanthanides in slightly acid, neutral and alkaline medium. Care must be taken to ensure that only this complex is formed in solution because variable proportions of the protonated and "normal" complexes greatly affect the results. Moreover the 1:2 complex formed in solutions containing excess of ligand also influences the apparent molar absorptivity and the sensitivity of the method.

Hence the working conditions (pH, excess of ligand, metal ion concentration region, the ionic strength and the buffering substances) must be carefully maintained for the standard and sample solutions, otherwise confusing results are obtained.

PAR has no advantage as a colorimetric reagent for aluminium and lanthanum.

Acknowledgement—We are indebted to Dr. M. Hniličková for helpful discussions.

Zusammenfassung—Die empfindlichen Reaktionen zwischen 4-(2-Pyridylazo)resorcin (PAR) und Yttrium, Lanthan und den Lanthaniden können zur spektrophotometrischen Bestimmung dieser Elemente benutzt werden. Die Methode hat keine Vorteile gegenüber anderen Methoden zur Bestimmung von Aluminium und Lanthan. Nur M(PAR)H- und M(PAR)-Komplexe werden in Lösungen gebildet, in denen die Molarität des Ions größer oder gleich der Molarität des Liganden bei pH < 7,5 ist. Wenn molarer Überschuß an PAR besteht, konnen 1:2-Komplexe gebildet werden, aber sicher ist das nur für das Yttrium-PAR-System. Fehler in der Analyse können vom gleichzeitigen Vorhandensein optisch verschiedener Komplexe herrühren. Eingehende Kontrolle von pH und Konzentration des Reagens ist wichtig. Es werden optische und Gleichgewichtsdaten für die untersuchten Systeme angegeben.

Résumé—On peut utiliser les réactions sensibles entre le 4-(2-pyridylazo) résorcinol (PAR) et l'yttrium, le lanthane et les lanthanides pour le dosage spectrophotométrique de ces éléments. La méthode n'offre pas d'avantages par rapport aux autres pour les dosages de l'aluminium et du lanthane. Seuls les complexes M (PAR) H et M (PAR) se forment dans des solutions où la molarité de l'ion metallique est supérieure ou égale à la molarité du ligand à pH $< 7{,}5$. S'il y a un excès molaire de PAR, des complexes 1:2 peuvent se former, mais ceci n'est certain que pour le système yttrium-PAR. Des erreurs d'analyse peuvent résulter de la présence simultanée de complexes optiquement différents; un contrôle serré du pH et de la concentration en réactif est essentiel. On fournit des données optiques et sur l'équilibre pour les systèmes étudiés.

SPECTROPHOTOMETRIC DETERMINATION OF SCANDIUM WITH BROMOPYROGALLOL RED

TSUNEO SHIMIZU
Department of Chemistry, Faculty of Liberal Arts and Education,
Gunma University, Maebashi, Gunma, Japan

(*Received* 8 *September* 1966. *Accepted* 29 *November* 1966)

Summary—A highly sensitive spectrophotometric method for scandium with Bromopyrogallol Red is described; microgram amounts of scandium can be determined by measurement at 610 mμ and pH 6·1. The molar absorptivity is $2{\cdot}4 \times 10^4$ at 610 mμ. Formation of a 1:1 complex of scandium with Bromopyrogallol Red is confirmed. Common cations interfere, but can be separated completely by three successive ion-exchange steps, so the method can be applied to the determination of traces of scandium in silicate rocks. Results are quoted for scandium in several types of igneous rocks.

FOR the spectrophotometric determination of scandium, Sandell[1] in 1959 considered two reagents, Alizarin Red S and 8-quinolinol, and also described a method using Morin. Recently, many other organic reagents have been used for the spectrophotometric determination of scandium. All these reagents are more sensitive than Alizarin Red S and 8-quinolinol but are not selective.

Jeníčková, Suk and Malát[2] proposed Bromopyrogallol Red, (5,5′-dibromopyrogallol sulphophthalein), as a metal indicator for complexometric titration of the rare earth elements. The reagent has since been applied to the spectrophotometric determination of a number of elements such as indium,[3] niobium,[4] silver[5] and uranium.[6]

The present author has found that Bromopyrogallol Red is a very sensitive colorimetric reagent for scandium. For comparison, the molar absorptivities of various scandium complexes are listed in Table I. Bromopyrogallol Red is not, however, as selective as other colorimetric reagents for scandium, and a preliminary separation must be made. This can be done by ion-exchange. The method is useful for determining traces of scandium in silicate rocks.

EXPERIMENTAL

Apparatus

A Shimazu Model QR-50 spectrophotometer with 1-cm cells was used for all absorbance measurements, and a Toa-denpa Model HM-5A pH meter with glass and calomel electrodes for pH measurement.

Reagents

Bromopyrogallol Red solution. 0·05% in 50% v/v aqueous ethanol.

Scandium stock solution. An appropriate amount of scandium oxide (99·9% purity) was dissolved in a minimum amount of diluted sulphuric acid, and the solution was evaporated to dryness. The residue was taken up in 100 ml of 0·05*M* sulphuric acid. The strength of the solution was determined by titration with 0·01*M* EDTA solution previously standardized against zinc metal of primary standard quality. The stock solution contained 0·860 mg of scandium per ml and was used after appropriate dilution.

Acetate buffer solution. 10 ml of 1*M* acetic acid were mixed with 320 ml of 1*M* sodium acetate to give a pH of 6·1.

Cation-exchange column (I). Five g of Dowex 50W-X8, 100–200 mesh (hydrogen form) were slurried with water to form a column 10 cm long and 1 cm in diameter.

Anion-exchange column (II). Ten g of Dowex 1-X8, 100–200 mesh, (sulphate form) were formed into a column 18 × 1 cm. Before use the column was washed with several column volumes of 0·1 *M* ammonium sulphate–0·025*M* sulphuric acid solution.

Anion-exchange column (III). Two g of Dowex 1-X8, 100–200 mesh, (chloride form) were formed into a column 3 × 1 cm. The column was pretreated with 6*M* hydrochloric acid before use.

All other reagents used were guaranteed reagent grade.

Procedure

Transfer to a 25 ml volumetric flask 10 ml of dilute sulphuric acid solution containing between 3 and 70 μg of scandium. Add 3 ml of the Bromopyrogallol Red solution and 5 ml of acetate buffer solution. Dilute to the mark with water, mix, and measure the absorbance of the solution at 610 mμ against a reagent blank. The final pH should be 6·1.

Construct a calibration curve covering the range 5–70 μg of scandium.

TABLE I.—COMPARISON OF SENSITIVITY OF COLORIMETRIC REAGENTS FOR SCANDIUM

Reagents	Molar absorptivity	Reference
Alizarin Red S	$4·8 \times 10^3$ (at 520 mμ)	1
8-Quinolinol	$7·5 \times 10^3$ (at 378 mμ)	1
Tiron	$8·1 \times 10^3$ (at 310 mμ)	7
5,7-Dichloro-8-quinolinol	$1·0 \times 10^4$ (at 397 mμ)	8
Anthrarufin-2,6-disulphonic acid	$1·1 \times 10^4$ (at 495 mμ)	9
Chlorophosphonazo-III	$1·2 \times 10^4$ (at 690 mμ)	10
Quercetin	$1·3 \times 10^4$ (at 435 mμ)	11
4-(2-Pyridylazo)-resorcinol	$1·5 \times 10^4$ (at 520 mμ)	12
Arsenazo	$1·7 \times 10^4$ (at 570 mμ)	13
Eriochrome Cyanine R	$1·9 \times 10^4$ (at 535 mμ)	14
Xylenol Orange	$2·4 \times 10^4$ (at 553 mμ)	15
Bromopyrogallol Red	$2·4 \times 10^4$ (at 610 mμ)	
Pontachrome Azure Blue B	$3·4 \times 10^4$ (at 610 mμ)	16

COLOUR REACTIONS OF SCANDIUM AND OTHER IONS

Absorption spectrum

The absorption spectrum of the solution was measured against a reagent blank at pH 6·1, and is shown in Fig. 1.

Effect of acidity

Acidity has a considerable effect on the absorbance of the complex at 610 mμ, as illustrated in Fig. 2. The maximum absorbance of the complex remains nearly constant in the pH range 5·0–6·5. Buffers of acetic acid–sodium acetate, hydrochloric acid–potassium chloride, and ammonia–ammonium chloride, were used to cover the pH ranges 2·7–6·1, 1·0–2·4, and 6·9–9·2 respectively.

Effect of reagent concentration

In order to study the effect of reagent concentration on the absorbance, 38·2 μg of scandium were added to solutions containing varying amounts of Bromopyrogallol Red solution and diluted to 25 ml, the total acetate concentration being kept constant. The reagent concentration had no effect on the absorbance when more than 2 ml of 0·05% Bromopyrogallol Red solution were present. The use of 3 ml of the reagent solution is recommended.

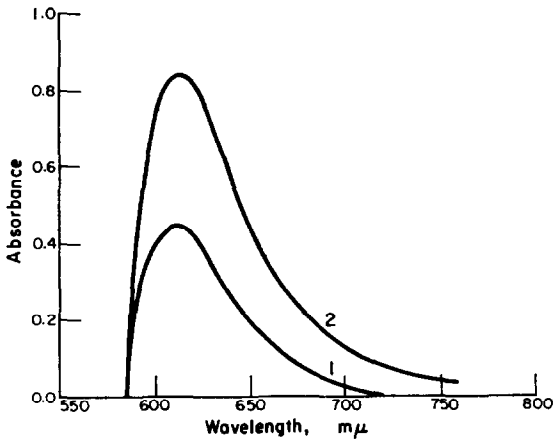

FIG. 1.—Absorption spectra for scandium–Bromopyrogallol Red complex at pH 6·1.
(1) Reagent ($1{\cdot}59 \times 10^{-6}$ mole) plus Sc (19·1 μg) per 25 ml, *vs.* reagent blank.
(2) Reagent ($1{\cdot}59 \times 10^{-6}$ mole) plus Sc (38·2 μg) per 25 ml, *vs.* reagent blank.

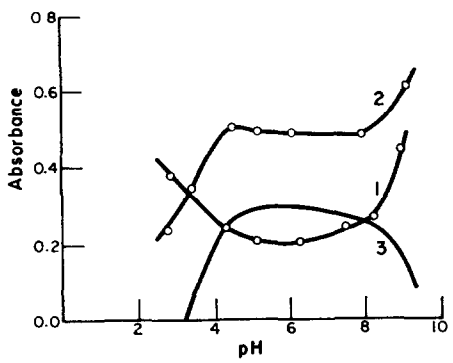

FIG. 2.—Effect of acidity on scandium–Bromopyrogallol Red complex at 610 mμ.
(1) Reagent blank ($1{\cdot}05 \times 10^{-6}$ mole/25 ml) *vs.* water.
(2) Reagent ($1{\cdot}05 \times 10^{-6}$ mole) plus Sc (14·3 μg) per 25 ml, *vs.* water.
(3) Reagent ($1{\cdot}05 \times 10^{-6}$ mole) plus Sc (14·3 μg) per 25 ml, *vs.* reagent blank.

Effect of buffer solution

At pH 6·1, the absorbance of the complex decreased very slightly as the concentration of acetate buffer increased. With increasing volumes of 4, 6, 8, and 10 ml of acetate buffer solution, the absorbance due to 19·1 μg of scandium decreased slightly, having the values 0·399, 0·395, 0·384, and 0·380 respectively. An addition of 5 ml of acetate buffer solution was chosen.

Stability of the coloured solution

The scandium–Bromopyrogallol Red complex formed almost instantly at pH 6·1 and the absorbance remained constant for at least 24 hr.

Conformity to Beer's law

The relationship between the absorbance of the scandium–Bromopyrogallol Red complex and the scandium concentration was examined by varying the scandium

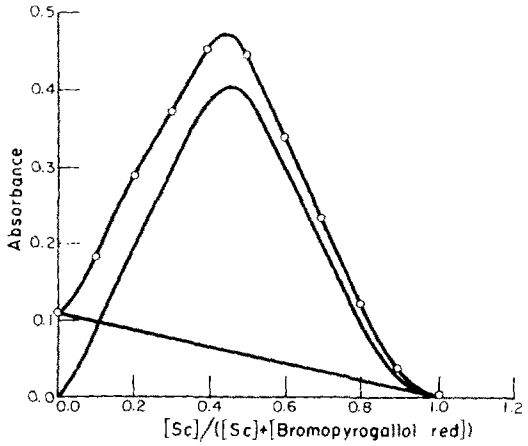

FIG. 3.—Continuous variation plots for scandium–Bromopyrogallol Red complex at pH 6·1 and 610 mμ.

TABLE II.—EFFECT OF DIVERSE IONS ON DETERMINATION OF 28·7 μg OF SCANDIUM

Ion	Amount added, *mg*	Sc found, *μg*

Chloride	93·7	19·3

concentration and measuring the absorbance at 610 mμ and pH 6·1. Conformity to Beer's law was found in the range 0·12–2·40 ppm of scandium. The molar absorptivity for scandium at 610 mμ was $2{\cdot}4 \times 10^4$.

Composition of the scandium–Bromopyrogallol Red complex

To estimate the empirical formula of the complex species formed under the present conditions, Job's method[17] of continuous variation and the slope-ratio method[18] were used, at pH 6·1 and 610 mμ. Figure 3 shows that the combining ratio of bromopyrogallol red to the scandium can be regarded as 1:1, and this was confirmed by the slope-ratio method.

Effect of diverse ions

The interference of many ions in the determination of scandium was studied under the conditions used in the procedure above. The results are summarized in Table II. Many common cations seriously interfere, but 0·1 mg of arsenic(III), bismuth(III),

TABLE III.—DETERMINATION OF SCANDIUM IN ROCK SAMPLES

Samples	Scandium content, *ppm*	
	Bromopyrogallol Red method	Arsenazo method[21]
Basalt	35·1, 36·8, 37·1 (mean 36·3 ± 1·1)	34·7 ± 1·2 (mean of 8)

Basalt composite	19·1, 21·6, 23·9 (mean 21·5 ± 2·4)	
Gabbro composite	18·8, 19·9 (mean 19·3)	
Diabase composite	17·7	
Andesite composite	14·3	
Composite of granite and granodiolite	6·2, 6·4, 6·6 (mean 6·4 ± 0·2)	

calcium, cobalt(II), magnesium and tungsten(VI) do not interfere. Sulphate, borate, nitrate and perchlorate do not interfere, but phosphate, thiocyanate, tartrate and large amounts of chloride must be absent. Because of the many interferences involved, a preliminary separation is necessary. In the following section a general procedure, including the preliminary separation by three ion-exchange steps, is given for the determination of scandium in silicate rocks. Although there have been reported several excellent ion-exchange systems for scandium, none of these appears to give complete enough separation for the subsequent photometric determination of scandium. A combination of the three ion-exchange steps allows the subsequent determination of scandium in complex matrix materials.

DETERMINATION OF SCANDIUM IN SILICATE ROCKS

Decompose a rock sample, weighing about 0·5 g, with a perchloric acid–hydrofluoric acid mixture and evaporate the solution to dryness. Dissolve the residue with dilute hydrochloric acid. Add a slight excess of 1:1 ammonia solution to the hot solution, filter off the precipitate and dissolve it with 20 ml of 3*M* hydrochloric acid. Load the solution on to the cation-exchange column (I) and wash the column with 10 ml of water, and then with 20 ml of 0·3*M* ammonium sulphate–0·025*M* sulphuric acid solution. Strip the scandium with 15 ml of the same eluent at a flow-rate of 0·7 ml/min. Add 30 ml of 0·025*M* sulphuric acid to the effluent. Load the solution on to the anion-exchange column (II). Remove foreign ions by elution with 45 ml of 0·1*M* ammonium sulphate–0·025*M* sulphuric acid solution and elute the scandium with a further 130 ml of the same solution. Add 10 mg of iron(III) to the effluent and precipitate iron(III) hydroxide with ammonia solution. Filter off the precipitate and dissolve it in 10 ml of 6*M* hydrochloric acid. Pass the solution through the anion-exchange

column (III). Wash the column with 6*M* hydrochloric acid. Collect all the hydrochloric acid solution and evaporate it to dryness. Dissolve the residue in 1 ml of 0·1*M* sulphuric acid and dilute to 10 ml with water. Continue as described in *Procedure*.

The separation by cation-exchange has been reported by Kuroda, Nakagomi and Ishida.[19] Most anions and metal ions listed in Table II can be separated effectively from scandium, except thorium and beryllium, which, however, are easily separated on the anion-exchange column (II).[20] The volume of effluent from column (II) is large, so the scandium should be concentrated before the photometric determination. The iron(III) hydroxide precipitate carries the scandium quantitatively from the sulphate solution. Anion-exchange column (III) serves as a trap for iron(III), yielding a good separation of scandium and iron.

The procedure described was applied to several types of rock samples. The results are quoted in Table III. Errors quoted are standard deviations. For comparison the values obtained by an arsenazo method previously reported[21] are also listed for the same three samples. There are no significant differences between the averages obtained by both methods. The Bromopyrogallol Red method is sufficiently sensitive to be applied to silicic rocks less abundant in scandium without large amounts of sample being needed.

Acknowledgement—The author is greatly indebted to Professor H. Hamaguchi, University of Tokyo, and Professor R. Kuroda, University of Chiba, for many helpful discussions and suggestions during this study.

Zusammenfassung—Es wird eine hochempfindliche spektrophotometrische Methode zur Bestimmung von Scandium mit Brompyrogallolrot beschrieben; Mikrogrammengen Scandium können durch Messung bei 610 nm und pH 6,1 bestimmt werden. Der molare Extinktionskoeffizient beträgt $2{,}4 \cdot 10^4$ bei 610 nm. Die Bildung eines 1:1-Komplexes von Scandium mit Brompyrogallolrot wird bestätigt. Die normalerweise vorkommenden Kationen stören, können aber durch drei aufeinanderfolgende Ionenaustausch-Schritte vollständig abgetrennt werden, sodaß die Methode zur Bestimmung von Scandiumspuren in Silikatgesteinen angewandt werden kann. Es werden Ergebnisse von Scandiumbestimmungen in verschiedenen Arten von vulkanischen Gesteinen angegeben.

Résumé—On décrit une méthode spectrophotométrique hautement sensible pour doser le scandium au Rouge de Bromopyrogallol; on peut doser des quantités de scandium de l'ordre du microgramme par mesure à 610 mμ et pH 6,1. Le coefficient d'absorption moléculaire est de $2{,}4 \times 10^4$ à 610 mμ. On confirme la formation d'un complexe 1:1 du scandium avec le Rouge de Bromopyrogallol. Les cations communs gênent mais peuvent être complètement séparés par trois étapes successives d'échange d'ions, de sorte que la méthode peut être appliquée au dosage de traces de scandium dans les roches aux silicates. On note des résultats pour le scandium dans différentes roches ignées.

STUDY OF BERYLLIUM OXINATE BY THE HOMOGENEOUS PRECIPITATION METHOD

M. N. SASTRI and T. P. PRASAD
Department of Chemistry, Andhra University, Waltair, South India

(*Received* 8 *August* 1966. *Accepted* 10 *November* 1966)

Summary—Beryllium oxinate has been precipitated from homogeneous solutions and the nature of the complex has been studied by thermogravimetric, infrared and X-ray methods. A structural formula has been proposed on the basis of the results.

THERE is controversy regarding the formation of the beryllium oxinate complex. Niessner,[1] from the reported quantitative separation[2] of aluminium from beryllium concluded that beryllium forms no complex with oxine. Rao *et al.*[3] reported precipitation of beryllium from aqueous solutions as the insoluble complex for which they gave the formula $Be(C_9H_6NO)_2$. On the other hand, Motojima[4] proposed the formula $Be_2O(C_9H_6NO)_2 \cdot 2H_2O$ for the complex he obtained. In a recent paper Magee and Gordon[5] pointed out that if a minimum radius ratio of 0·225 is the lower limit for a tetrahedral metal oxinate structure then ions of radius less than 0·32 Å would not be expected to form oxinates, so beryllium, with an ionic radius 0·31 Å, might be expected not to form a complex with oxine.

A detailed study on the formation of the beryllium oxinate complex was therefore undertaken. As precipitation from homogeneous solution is expected to give relatively pure compounds, this technique was used for the precipitation of the complex, which was then examined by thermogravimetric and infrared methods.

EXPERIMENTAL

Reagents

Beryllium nitrate solution was prepared from analytical grade material and standardized by the gravimetric ammonia method. The following solutions were also prepared from analytical grade reagents.

5% Oxine in acetone.
10% Urea in water.
10% Ammonium chloride in water.
0·1*N* Standard potassium bromate–potassium bromide mixture.
1% Triethanolamine (w/v) in water.

Apparatus

Cambridge pH-meter.

Stanton Model TR-1 thermobalance with sensitivity 1 mg, chart speed 6 in/hr, heating rate 4°/min.

Phillips 114·6-mm X-ray camera, with CuKα radiation.

Procedure for precipitation of the complex

Metal oxinates may be precipitated from homogeneous solution by three methods: (*a*) the urea hydrolysis method in which the pH of the solution is slowly raised until the desired pH is obtained;[6] (*b*) the mixed solvent method in which the mixture containing the metal and oxine dissolved in a solvent mixture such as acetone–water, adjusted to a predetermined pH, is slowly heated to 50–60° to volatilize the acetone with resulting gradual precipitation of the metal oxinate;[7] (*c*) the hydrolysis of 8-acetoxyquinoline to generate the reagent *in situ* for the precipitation of the complex.[8] Of these methods, only the first two methods are applicable in the case of beryllium, because in the third

method the acetic acid liberated either prevents the precipitation of beryllium oxinate or leads to low values.

Urea hydrolysis method. To a solution containing not more than 7·0 mg of beryllium are added 350 mg of oxine (7·0 ml of 5% solution), 500 mg of ammonium chloride and 4 g of urea. The volume of the solution is adjusted to 50 ml with distilled water. The solution is mixed thoroughly, and heated in a water-bath at 90°. Precipitation starts in 30–40 min (initial pH 3·5) and is complete in another 30–40 min. The precipitate is filtered off from the hot solution and washed with hot water followed by a few ml of acetone, and is then dried at 80° for 2 hr.

Mixed solvent method. To the solution containing not more than 9·0 mg of beryllium are added 7·0 ml of oxine solution, 25 ml of acetone and 10 ml of triethanolamine. The solution is mixed thoroughly, and heated on a water-bath at 60°. As the acetone evaporates, beryllium oxinate is slowly precipitated. At this stage the volume of the solution has been reduced to about 25 ml, and is diluted to 50 ml with hot water (80°). The temperature of the water-bath is now raised to 90° and maintained at this temperature until a clear orange yellow supernatant liquid is obtained (about 30 min). The precipitate is collected and dried as before.

Analysis of precipitates

The carbon and hydrogen contents of the precipitate were determined by microanalytical methods. The beryllium content was determined by igniting a known weight of the dried precipitate and weighing the beryllium oxide. The oxine content was estimated volumetrically with standard potassium bromate–potassium bromide solution. The values found were: C = 61·7%; H = 4·4%; Be = 4·96%; Oxine = 82·1%. Theoretical values for $Be(C_9H_6NO)_2$: C = 72·71%; H = 4·07%; Be = 3·03%; Oxine = 97·0%; for $Be_2O(C_9H_6NO)_2 \cdot 2H_2O$: C = 60·34%; H = 4·5%; Be = 5·03%; Oxine = 81·0%.

The molecular weight could not be determined by the conventional methods because of the insolubility of the precipitate in any of the common organic solvents.

RESULTS AND DISCUSSION

The beryllium oxinate precipitate obtained by either of the procedures described is a bright yellow crystalline solid and conforms to the formula suggested by Motojima[4] but not to the formula suggested by Rao *et al.*[3] The precipitate is insoluble in any of the common organic solvents—chloroform, acetone or alcohol, and exhibits a bright yellow fluorescence under ultraviolet light. The complex melts with decomposition at 290 ± 2°.

At least twice the theoretical amount of oxine is necessary for the precipitation of the complex. In the case of urea hydrolysis the precipitation starts at a pH of 5·5–6·0 and is complete at pH 7·0, whereas in the case of the mixed solvent method the final pH lies in the region 7·5–8·0. The interference of acetic acid and the need for a large excess of the reagent for the precipitation of the complex were probably responsible for the observation of earlier workers that beryllium forms no complex with oxine.

Pyrolysis of precipitate

When the complex is heated in an ignition tube, it melts, forming a brown to yellow-red solution, and needle-shaped crystals condense on the cooler parts of the tube along with some droplets of water. These crystals melt sharply at 76°, which corresponds to the melting point of oxine. This indicates that water and oxine are liberated from the complex on heating.

The differential thermogravimetric curve (Fig. 1) of the complex dried to constant weight at 80° indicates that the complex is stable up to 180° with three prominent regions of weight loss at 300°, 400° and 570°. In addition, a slow but significant weight loss occurs in the region 180–270° preceding the peak 300°. The decomposition is complete at 690° with no subsequent weight loss.

The loss in the region 180–270° corresponds to one molecule of water; the total

loss after ignition is 86·9%, giving the value for the loss of oxine (complete volatilization) as 81·9%. This agrees reasonably with the theoretical value for the oxine content. However, only one water molecule is accounted for (the total loss up to 300°, corresponding to the first peak, is more than that required for two molecules of water). It may be recalled that Charles,[9] in his studies with barium oxinate tetrahydrate, observed

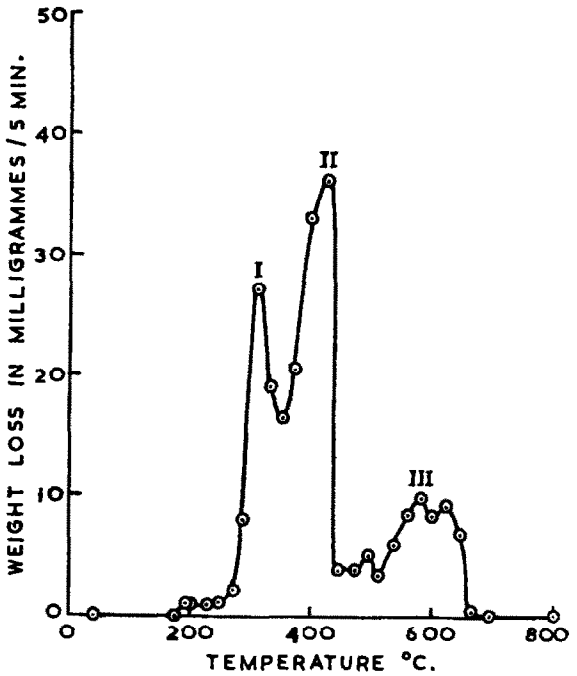

FIG. 1.—Differential thermogravimetric curve of the oxinate obtained by PFHS.

that oxine was liberated during pyrolysis, and his pyrolysis data accounted for only two molecules of water. This was explained as arising from solid-state hydrolysis of the complex.

The pyrolysis of beryllium oxinate can also be explained similarly. The loss of weight up to 270° arises from the loss of one molecule of water from the compound:

$$Be_2O(C_9H_6NO)_2{\cdot}2H_2O \rightarrow \underset{(A)}{Be_2O(C_9H_6NO)_2{\cdot}H_2O} + H_2O. \qquad (1)$$

The high temperature required for this reaction (180–270°) indicates that the water is strongly bound.

The compound *A* thus formed is unstable, as the co-ordination sphere of beryllium is disturbed, and solid-state hydrolysis occurs according to the equation

$$Be_2O(C_9H_6NO)_2{\cdot}H_2O \rightarrow \underset{(B)}{Be_2O(C_9H_6NO)OH} + C_9H_7NO. \qquad (2)$$

The intermediate compound *B* formed is very unstable and decomposes rapidly according to the reaction:

$$Be_2O(C_9H_6NO)OH \rightarrow 2BeO + \text{oxine(decomposed)}. \qquad (3)$$

Peak I thus arises from reaction (2), where the oxine liberated is volatilized. Peak II represents the reaction (3) where the intermediate compound *B* decomposes. However, these reactions could not be assessed quantitatively as the peaks overlap and the intermediate compounds cannot be isolated because of their high instability, as indicated by the position of the trough on the differential curve.[10] Peak III consequently represents the oxidation of carbonaceous matter formed during the decomposition of the precipitate.

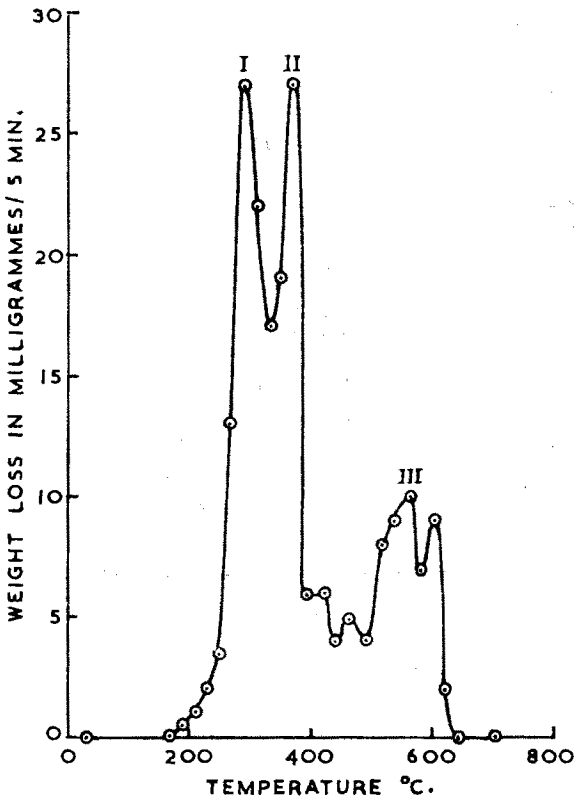

FIG. 2.—Differential thermogravimetric curve of the oxinate obtained by Motojima's method.

From the foregoing discussion it is evident that the beryllium oxinate precipitated from homogeneous solution has the same molecular formula as that suggested by Motojima.[4] This is further illustrated by the differential curve of the compound prepared according to the procedure suggested by him (Fig. 2) and dried at 80°.

Infrared study

The infrared spectrum of the complex is given in Fig. 3. The infrared spectra of oxinates are generally similar having a characteristic peak[11] around 1100 cm^{-1}. In the case of beryllium oxinate this peak occurs at 1108 cm^{-1}. The absence of the peak at 710 cm^{-1} characteristic of the oxine indicates the absence of free oxine in the complex.

The spectrum of beryllium oxinate shows strong bands in the 1000–790 cm^{-1} region, indicating that the metal–oxygen bond is strong and that the water molecules form

strong co-ordination bonds with beryllium.[12] The spectrum also shows bands at 3600 cm^{-1} (OH-stretching of water) and 1600 cm^{-1} (H—O—H bending) which are to be expected on the basis of the suggested formula.

In addition, the spectrum shows a characteristic absorption at 946 cm^{-1}. Such characteristic absorptions were also noted in the case of a few other oxinate complexes of metals. Thus Charles *et al.*[11] found that uranyl oxinate has a characteristic peak

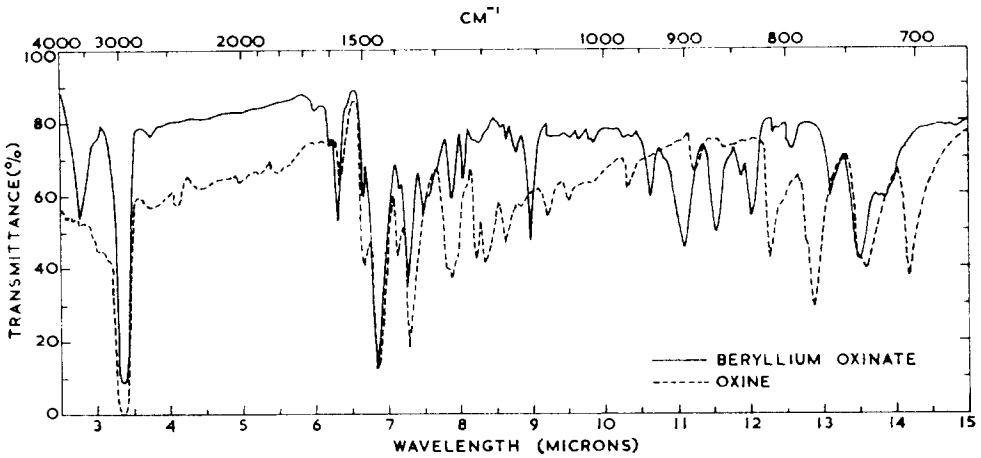

FIG. 3.—Infrared spectrum of the oxinate.

at 892 cm^{-1} and assigned it to the UO_2 group. Magee and Martin[13] found that niobium and tantalum oxinates exhibit characteristic peaks at 921, 914 and 904 cm^{-1}. The niobium peak at 921 cm^{-1} was attributed by them to the NbO group. Assuming that the tantalum peak at 914 cm^{-1} is due to the TaO group, the 927 cm^{-1} peak[13] of molybdenum to the MoO_2 group and the 946 cm^{-1} peak of beryllium to the BeO group, a straight-line relation is obtained when the peak position in the 10·5-μ region is plotted against the first ionization potential of the metal (Fig. 4); the peak position is expressed in microns for convenience. It is interesting to note that Be, Nb, Ta, U, and Mo, the complexes of which contain Be_2O, NbO, TaO, UO_2 and MoO_2, fall very nearly on a straight line while Co and Mn, whose oxinates do not have metal–oxygen linkages, fall outside it.

X-ray examination

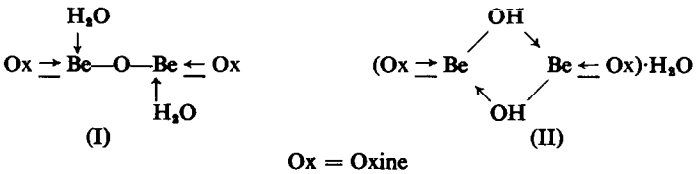
X-ray examination showed that the beryllium oxinate complex is orthorhombic with the unit cell dimensions $a = 9{\cdot}42$ Å, $b = 12{\cdot}5$ Å and $c = 14{\cdot}32$ Å. The density measured by weighing in air and in benzene is 1·361 g/cm^3. The density calculated for 4 molecules of $Be_2O(C_9H_6ON)_2{\cdot}2H_2O$ per unit cell is 1·409 g/cm^3.

Analytical applications

The procedures described for the precipitation of the beryllium oxinate complex have been found to give excellent values for the gravimetric determination of beryllium in the 1·5–9·0 mg range.

Conclusion

These studies clearly show that beryllium forms a complex of well defined composition, $Be_2O(C_9H_6NO)_2 \cdot 2H_2O$. Two structural formulae are possible for this compound:



Ox = Oxine

Evidence for the existence of beryllium compounds containing hydroxyl bridges[14] and the preferential removal of one molecule of water during pyrolysis lend support for structure II. However, the fact that the complex is stable up to 180° and that the loss of water occurs over a wide range of temperature (heating the compound at 160° for

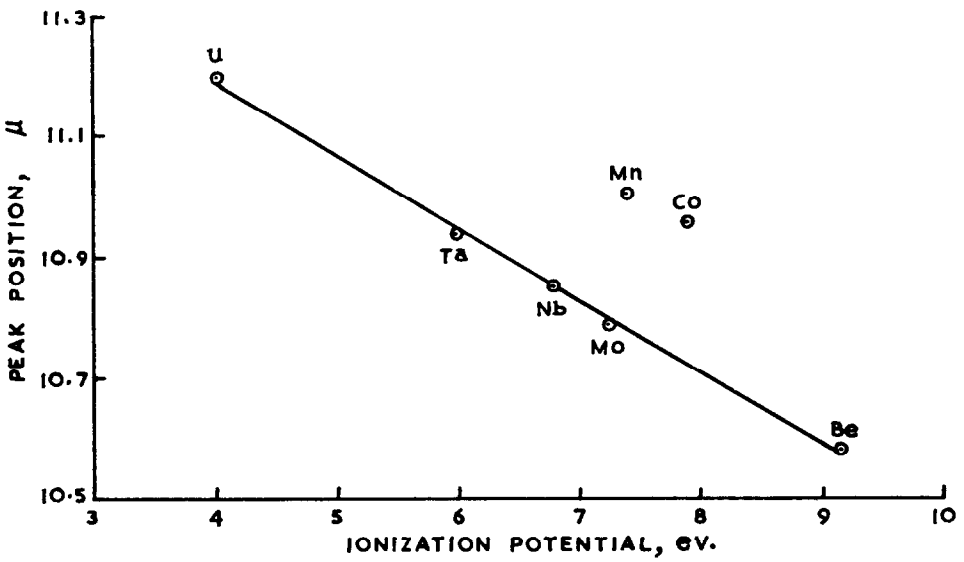


FIG. 4.—Relation between peak position (in the 10–11 μ region) *vs.* first ionization potential of the metal.

2 hr resulted in less than 2% weight loss) shows that the water present is more strongly bound than lattice water. It may further be seen that the liberation of oxine (Peak I) occurs immediately after the loss of one molecule of water without a complex being formed that is free from lattice water, as normally expected. This can be explained if water is present in the co-ordination sphere, which will be disturbed with consequent decomposition when the water is removed. The bands in the region 1000–790 cm^{-1} in addition to those at 3600 cm^{-1} (OH-stretching) and 1600 cm^{-1} (H—O—H bending) which are assigned to the wagging, rocking and twisting motions of water present in the coordination sphere[12] are clearly indicated in the infrared spectrum. The available evidence therefore appears to favour structure I.

APPLICATION OF RADIOISOTOPES IN COLUMN CHROMATOGRAPHY ON SUBSTITUTED CELLULOSES—VI*

THE SEPARATION OF ANTIMONY FROM MANGANESE, IRON AND OTHER METALS

R. A. A. MUZZARELLI and G. MARCOTRIGIANO†
Department of Chemistry, Faculty of Science, University of Sherbrooke, Sherbrooke, P.Q., Canada

(*Received* 10 *October* 1966. *Accepted* 15 *November* 1966)

Summary—The chromatographic behaviour of nanogram amounts of antimony in ethyl ether medium was studied by radioisotope techniques on cellobiose, cellulose and seven substituted celluloses. It was found that antimony is strongly retained and can be separated from macro amounts of manganese, iron, gold, uranium, mercury, arsenic and several other metals. Antimony could be quantitatively recovered by elution from natural cellulose and cellobiose. The method can be applied in several analytical problems concerning the separation of traces of antimony.

INFORMATION on the chromatographic behaviour of antimony on natural cellulose was first given when uranyl nitrate was purified from numerous trace elements by chromatography: it was observed that antimony was retained on a cellulose column.[1] Traces of antimony have been eluted from a cellulose column by means of a mixture of acetone and concentrated hydrochloric acid after the separation of large amounts of uranium,[2] and antimony has been separated from germanium and eluted from a narrow column of natural cellulose.[3]

One of the most important separations of small amounts of antimony from a matrix is that of antimony from cast iron. This has been done by co-precipitation of antimony on manganese dioxide formed from permanganate and manganese(II);[4] several ions interfere, particularly iron(III). The antimony separated must then be determined by those methods with which manganese does not interfere. Practically the same method has been recently applied to the determination of traces of antimony in marine water, but the antimony was subsequently separated from manganese and interfering elements by solvent extraction.[5] More recently antimony has been separated by isotopic exchange.[6] The influence of iron, manganese and arsenic was not examined, and the method was limited to a narrow range of amounts of metals, required addition of antimony as carrier, and was subject to several interferences.

A method which offered a rapid separation of antimony from iron and other metals, with few interferences, and which allowed recovery of traces of antimony without chemical or isotopic dilution would be more widely applicable.

* Part V—International symposium on physical methods of separation, Amsterdam, 1967; *Anal. Chim. Acta*, May 1967.

† Permanent address: Istituto di Chimica Generale e Inorganica, Università di Modena, Modena, Italy.

The strong retention of antimony on natural cellulose[2] indicated that it was possible to separate traces of antimony from a number of elements. Natural and substituted celluloses have been examined to establish which metals disturb the retention of antimony, and to find the best conditions of quantitative elution.

EXPERIMENTAL

Solutions

Reagent-grade chemicals and solvents were used for the preparation of all solutions, without further treatment. The following solutions were prepared:

(*a*) anhydrous ethyl ether
(*b*) 2 ml of 90% nitric acid in 98 ml of ethyl ether
(*c*) 40 mg of ammonium thiocyanate in 20 ml of methanol plus 80 ml of ethyl ether
(*d*) 5 g of ammonium thiocyanate in 20 ml of methanol plus 80 ml of ethyl ether.

Concentrated hydrochloric acid, 0·5, 1·5 and 5*M* in methanol.
Aqueous nitric acid, 0·5, 1·5 and 5*M*.
Solutions (5% w/v) of iron(III) chloride hexahydrate, mercury(II) chloride and chloroauric acid trihydrate in solution (*b*).

Celluloses

Cellulose Whatman CF 11, powder, natural.
Cellulose Whatman DE 11, powder, diethylaminoethyl.
Cellulose Whatman AE 11, powder, aminoethyl.
Cellulose Whatman P 11, powder, phosphate.
Cellulose Whatman CM 11, powder, carboxymethyl.
Cellulose Whatman ET 11, powder, epichlorohydrin triethanolamine, Ecteola.
Cellobiose Sigma CB, powder, (glucose-β-glucoside).
Cellulose Bio-Rad SE, powder, sulphoethyl.
Cellulose Bio-Rad PAB, powder, para-aminobenzyl.

Radioisotopes

Antimony-125 solution, carrier-free, was provided by New England Nuclear Corp., Boston, Mass., U.S.A. Its concentration was ~0·3 mg/ml and 10 μl of it were diluted with 10 ml of 90% nitric acid. Aliquots of 100 μl of this solution, corresponding to 30 mg of antimony, were used for each experiment.

The other radioisotopes used are listed in earlier parts of this series.[7–9]

Procedures

The eluted aliquots and the cellulose powders were collected in plastic bottles of uniform shape and capacity. Their radioactivity was measured by a 128-channel gamma-ray spectrometer, ND-110, electronically coupled to an NaI(Tl) crystal, and compared with a standard. The average deviation of results was 8%.

The columns (15 × 1 cm; Teflon stop-cock) were prepared as described earlier[7,8] and operated under pressure to give a flow-rate of about 20 ml/min. The time needed for preparing two columns and doing two complete runs was one hour.

RESULTS AND DISCUSSION

All the celluloses examined collect antimony from ether–nitric acid mixtures, and further washing with this solution is without eluting effect.

Solutions (*c*) and (*d*) do not elute antimony, nor does a 2% solution of potassium hydrogen tartrate. A solution of oxalic acid in 0·5*M* hydrochloric acid gives the same elution curves as 0·5*M* hydrochloric acid alone.

Solutions of hydrochloric acid in methanol and of nitric acid in water elute antimony; pure water and pure methanol do not, so the acids are the necessary eluting agents. Aqueous hydrochloric acid is also convenient but the methanol solutions cause less swelling of the celluloses, though a slight applied pressure is needed.

Table I shows the extent of elution of antimony from natural and substituted celluloses with aqueous nitric acid. Cellulose phosphate very strongly retains antimony and there is little elution. There is a remarkable similarity in the elution of antimony from amino-celluloses and from natural cellulose. The amino-substituted celluloses were decolorized when treated with dilute nitric acid, suggesting that the amino groups were probably destroyed and the properties of these celluloses were altered. Antimony was quantitatively recovered from Ecteola cellulose.

TABLE I.—ELUTION OF ANTIMONY FROM VARIOUS CELLULOSES BY NITRIC ACID*

Total		100	104	98	107	100	108

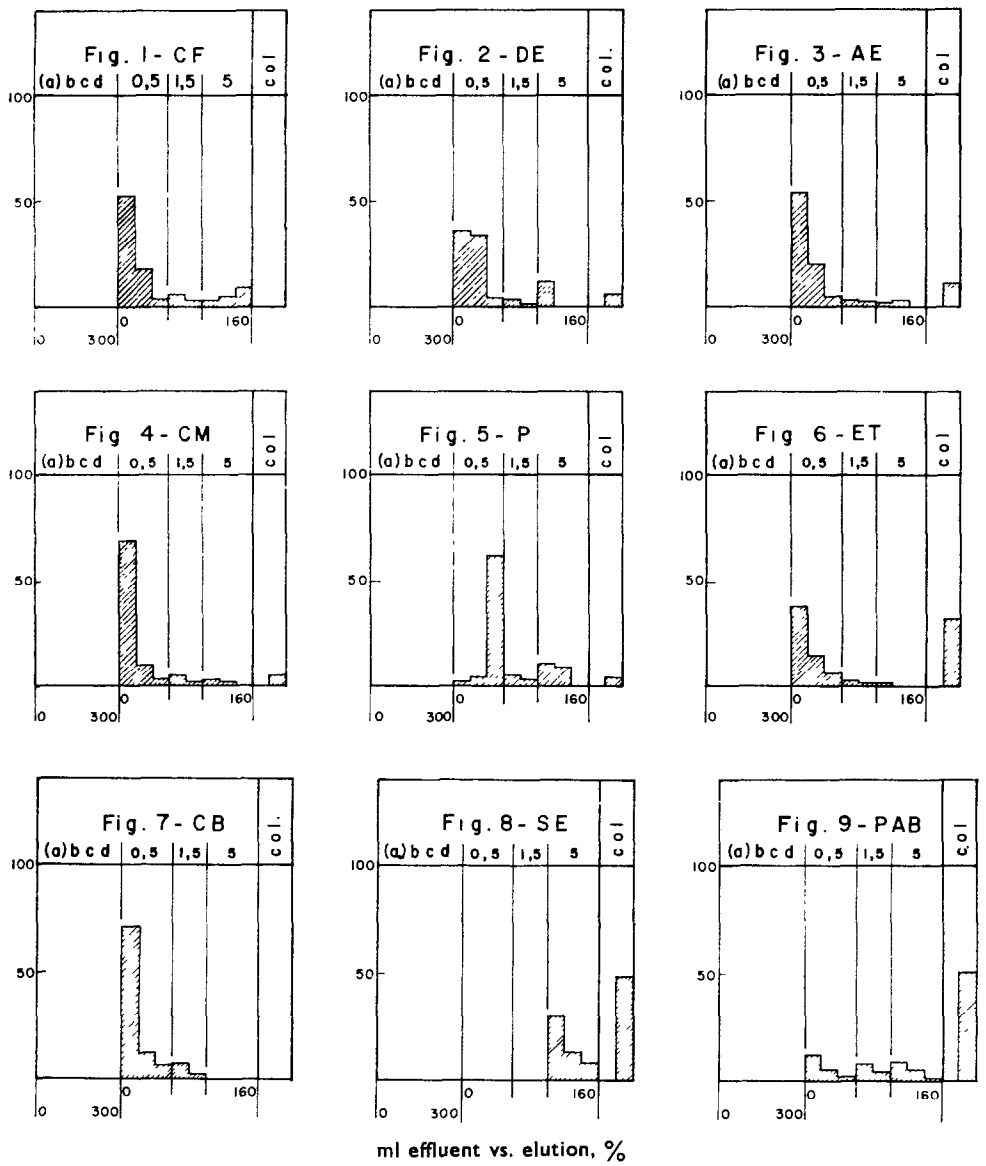
* After passage of 100 ml each of solutions (*a*), (*b*) and (*c*).
† 20-ml fractions.

The elution of antimony with hydrochloric acid in methanol is shown in Figs. 1–9, and is generally delayed for the substituted celluloses relative to the elution from natural cellulose, particularly for cellulose phosphate and the amino-substituted celluloses, confirming the general trend that substituted celluloses adsorb cations more strongly than natural cellulose does.

Antimony was completely recovered from natural cellulose, and in yields varying from 90 to 96% from the substituted celluloses except for ET, SE and PAB celluloses where 32%, 50% and 42% of antimony respectively were still retained after passage of the eluting solutions.

Because natural cellulose allows the most complete elution of antimony and retains transition metals relatively less strongly than substituted celluloses, it was used for examining the possible separation of antimony from other metals. Traces of antimony were separated from traces of iron on natural cellulose: ethyl ether containing traces of iron and antimony was passed at a high flow-rate through the column and both metal ions remained at the top. Iron was subsequently eluted with diluted thiocyanate solution (*c*) and antimony was eluted with hydrochloric acid (Fig. 10) Comparison of Figs. 3, 4 and 6 with Figs. 3, 4 and 6 of Part III of this series[8] shows that this separation can also be done on AE, CM, ET, SE and PAB celluloses, even though the elution of antimony would not be quantitative.

Antimony was also separated on CF cellulose from nanograms of silver, zinc, chromium and cobalt and from micrograms of manganese, all of which were eluted



FIGS. 1–9.—The chromatographic behaviour of 30 nanograms of antimony on natural and substituted celluloses and cellobiose in ethyl ether-nitric acid mixture, eluted with 0·5, 1·5 and 5*M* hydrochloric acid in methanol.

with solution (*c*),[8] and from copper.[9] Nanogram amounts of antimony were also separated from mercuric chloride, chloroauric acid and uranyl nitrate, gram amounts of which did not affect the adsorption of the antimony on cellulose. The small amounts of these retained by the column could be washed off with solutions (*a*) or (*b*). Similar results were obtained with gram amounts of iron(III) chloride, the excess of which passed through the column, and the retained fraction was eluted with thiocyanate solution. Thiocyanate was then washed off the column with methanol and antimony was quantitatively eluted as described. The same procedure

could be applied to macro amounts of the other elements mentioned, the limiting factor being the solubility of their nitrates or chlorides in ethyl ether.

It is noteworthy that large quantities of chloroauric acid and of the other chlorides used do not elute antimony, even though hydrochloric acid does.

CONCLUSIONS

Antimony is very strongly adsorbed on natural cellulose, and even more strongly on substituted celluloses, particularly cellulose phosphate. Arsenic is not adsorbed on celluloses from ether-nitric acid mixture,[9] though bismuth is retained and generally can be eluted with thiocyanate solutions. There is no progressive variation of chromatographic behaviour within Group VA and no physico-chemical parameter can be found at present to explain this.

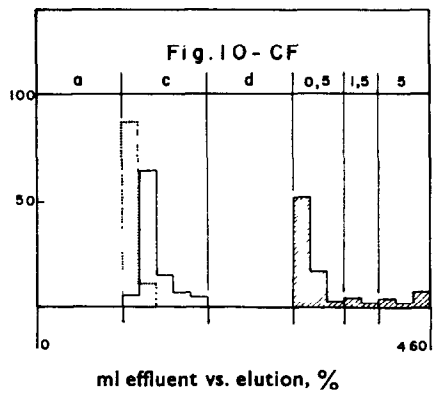


FIG. 10.—The chromatographic separation of 30 nanograms of antimony (shaded area) from gram amounts of iron (. . . .) and manganese (—) on natural cellulose.

As only a few other elements are strongly adsorbed, *e.g.*, barium and caesium,[2] antimony can be separated from a large number of elements by chromatography on any convenient cellulose.

The separations reported here can be applied in several important analytical problems: adsorption chromatography on columns of cellulose is easy and rapid to perform, is practically independent of certain parameters such as temperature, and large samples can be treated and purified.

Acknowledgement—This research was conducted under Grant No A-2507 attributed by the National Research Council of Canada to R. A. A. Muzzarelli who gratefully expresses his appreciation.

Résumé—Le comportement chromatographique de nanogrammes d'antimoine en éther éthylique a été étudié à l'aide de radioisotopes sur cellobiose, cellulose et sept celluloses substituées; il a été trouvé que l'antimoine est fortement adsorbé et peut être séparé d'avec quantités de l'ordre du gramme de manganèse, fer, or, uranium, mercure, arsenic et quelques autres éléments. L'antimoine pût être élué quantitivement de la cellulose naturelle et du cellobiose. La méthode est applicable à certains problèmes de chimie analytique concernant les traces d'antimoine.

Zusammenfassung—Chromatographischen Verhalten von Nanogrammenge Antimon an der Cellobiosesäule, Cellulosesäule und sieben modifizierten Cellulosesäulen wurde mit Radioisotoptechnik untersucht. Antimon ist sehr stark adsorbiert und deshalb konnte ohne Schwierigkeiten von Grammengen Gold, Eisen, Mangan, Uranium, Quecksilber, Arsen, und von anderen Metallen abgetrent werden. Antimon wurde von der natürliche Cellulose und Cellobiose vollständig ausgespült. Diese Methode kann man für Antimonspurenbestimmung in analytischen Chemie angewendet werden.

EXTRACTION AND SPECTROPHOTOMETRIC DETERMINATION OF VANADIUM(V) WITH 8-HYDROXYQUINOLINE

N. KURMAIAH, D. SATYANARAYANA and V. PANDU RANGA RAO®
Chemistry Department, Andhra University, Waltair, India

(*Received* 12 *July* 1966. *Accepted* 14 *October* 1966)

Summary—The extraction and spectrophotometric determination of vanadium (V) with oxine is investigated at higher acidities than described previously. Under these conditions, n-butanol and other alcohols are found to exert a synergic effect on the extraction of vanadium into benzene. In the presence of alcohol only a 6-fold ligand excess is needed for quantitative extraction in a single operation, the acidity of the aqueous medium being 0·05*M* with respect to sulphuric or phosphoric acid. The interference of iron(III) in the spectrophotometric determination of vanadium is suppressed by the addition of pyrophosphate. Beer's law is obeyed up to 14·0 μg of vanadium/ml and the sensitivity is 0·008 μg of vanadium/cm^2 at 390 mμ. The composition of the extracted species is found to be vanadium:oxine:n-butanol = 1:2:2.

SEVERAL authors have investigated the separation and photometric determination of vanadium(V) based on the extraction of the blue-black complex of vanadium(V) with oxine, formed at pH 3–5, into organic solvents such as chloroform,[1–7] benzene,[8] carbon tetrachloride,[9] isoamyl alcohol,[10–12] amyl acetate[11,12] and chlorohydrocarbons.[13] These methods require repeated extractions for quantitative recovery, complicated and sometimes cumbersome operations for the elimination of the interference of foreign ions, notably iron(III), a lengthy equilibration, a narrow range of pH and a high concentration of the ligand. Further, no thorough investigation has been made of the nature and composition of the extracted species.

The procedure described below allows the rapid separation and determination of vanadium and offers several advantages in that almost quantitative recovery (average 99·1 %) of vanadium can be achieved in a single extraction even with a 1-min equilibration. A 6-fold excess of ligand is sufficient for quantitative extraction and the colour of the organic phase is quite stable.

EXPERIMENTAL

Apparatus

The absorbance measurements were made on a Beckman Model DU spectrophotometer, in 1-cm Corex cells.

Reagents

Oxine solution. Analytical reagent grade (B.D.H.) 8-hydroxyquinoline dissolved in analytical reagent grade (thiophene-free) benzene.

Vanadium(V) solution, 0·01*M*. Guaranteed reagent grade (Merck) ammonium metavanadate dissolved in doubly distilled water, and standardized with standard iron(II) solution.

n-Butanol and other alcohols were purified by distillation. All other chemicals used were of analytical reagent grade.

Procedure for investigation of the extraction

Equilibrate 25·0 ml of an aqueous solution of vanadium(V) at the required acidity for 1 min with 25·0 ml of the solvent containing the requisite amount of oxine. Separate the phases and reduce the

vanadium(V) in the organic phase to vanadium(IV) by shaking it with sulphite solution in the presence of 1·0*M* sulphuric acid and back-extract into water. Oxidize the vanadium(IV) to vanadium(V) with permanganate and titrate it potentiometrically with iron(II) solution.[14]

Effect of acidity

Favourable extraction is achieved from sulphuric and phosphoric acid media. The results in Table I show the extraction of vanadium(V) into benzene from both these media at various acidities, in the presence and absence of n-butanol.

TABLE I.—EFFECT OF ACIDITY

Acidity, *M*	Extraction, %			
	Sulphuric acid		Phosphoric acid	
	20% n-Butanol in benzene	Pure benzene	20% n-Butanol in benzene	Pure benzene
0·005	98·8	84·1	37·5	37·5
0·050	98·9	47·8	99·0	72·4
0·125	60·4	5·5	98·4	60·5
0·250	29·1	nil	94·7	24·5
0·500	11·7	nil	64·3	nil
1·000	nil	nil	16·6	nil

Aqueous phase contains 50 μmole of vanadium(V).
Organic phase contains 500 μmole of oxine.

Quantitative recovery is achieved from 0·005–0·05*M* sulphuric acid and 0·05–0·125*M* phosphoric acid. Alcohol exerts a synergic effect on the extraction.

Effect of the concentration of n-butanol in the organic phase

For quantitative recovery of vanadium with benzene, the organic phase should contain 20% of n-butanol, the acidity of the aqueous phase being 0·05*M* with respect to either sulphuric or phosphoric acid. Other alcohols such as n-amyl alcohol and benzyl alcohol behave similarly.

Effect of oxine concentration

Table II gives the results of the study of the effect of oxine concentration on the extraction into pure benzene and into benzene containing 20% of n-butanol. Whereas in the presence of n-butanol,

TABLE II.—EFFECT OF OXINE CONCENTRATION

[Oxine] / [Vanadium(V)]	Extraction, %	
	Benzene	20% n-Butanol in benzene
1	nil	20·8
5	9·0	90·0
6	20·0	98·9
10	47·8	98·9
30	93·9	98·9
40	97·5	98·9
50	97·8	98·9
60	97·8	98·9

Aqueous phase—0·05*M* with respect to sulphuric acid, and containing 50 μmole of vanadium(V).

only a 6-fold excess of ligand is needed to give quantitative recovery, a 50-fold excess is needed with pure benzene as solvent.

Effect of time of equilibration and volume of the organic phase

Maximum extraction is achieved even with 1 min equilibration provided equal volumes of aqueous and organic phases are used. If the volume of the organic phase is less than that of the aqueous phase, the degree of extraction is reduced.

Procedure for spectrophotometric determination

Mix an aliquot of vanadium(V) solution containing up to 14·0 μg of vanadium/ml with enough sulphuric or phosphoric acid to give an overall acidity of 0·05*M* on dilution to 25·0 ml with redistilled water. Add 5·0 ml of 0·1*M* oxine solution in benzene, 5·0 ml of n-butanol and 15·0 ml of benzene,

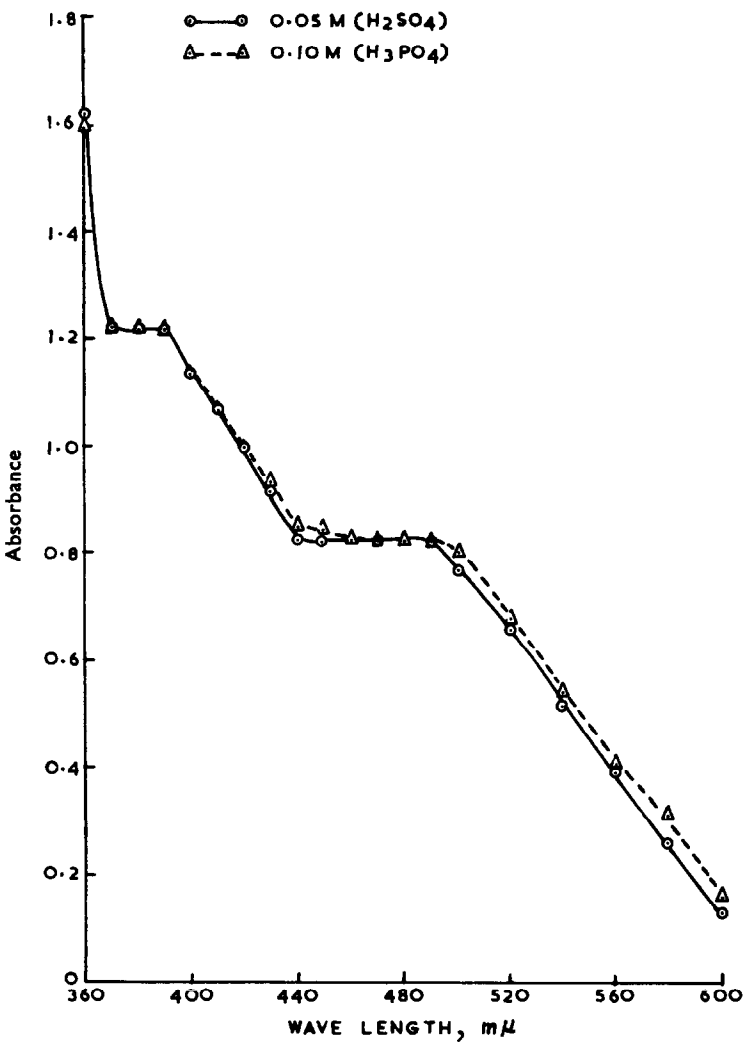

FIG. 1.—Absorption spectrum of vanadium(V)–oxine complex extracted into 20% n-butanol in benzene.
Vanadium(V) = 2·0 × 10^{-4}*M*.

and shake for 1 min. Separate the organic phase, dry it over anhydrous sodium sulphate, and measure its absorbance at either 390 mμ or 480 mμ against 20% n-butanol solution in benzene.

The absorption spectra of the red vanadium(V)–oxine complex extracted from 0·05*M* sulphuric and 0·10*M* phosphoric acids into 20% n-butanol solution in benzene are given in Fig. 1. They are

similar to those obtained by earlier workers[13,15] under different experimental conditions. Identical spectra are obtained with other alcohols such as n-amyl alcohol or methanol in place of n-butanol. The red colour is stable for more than 6 hr whereas the colour of the extract in the absence of any alcohol fades very rapidly, indicating that the complex decomposes. The recovery of vanadium is shown in Table III.

TABLE III.—RECOVERY OF VANADIUM

Vanadium(V) taken, *mmole*	Vanadium(V) recovered, %
0·025	98·5
0·050	98·7
0·075	99·0
0·100	99·2
0·125	99·5
0·150	99·5
0·200	99·2

Benzene phase contains 1·50 mmole of oxine and 20% of n-butanol.

Sensitivity of the colour reaction

The molar absorptivities at 390 and 480 mμ are $6{\cdot}02 \times 10^3$ and $3{\cdot}95 \times 10^3$ respectively, the sensitivities[16] being 0·008 μg and 0·013 μg of vanadium/cm^2 respectively at these wavelengths.

Interferences

Al, Be, Cd, Ce(III), Co(II), Cr(III), Mg, Mn(II), Ni, Th, U(VI), V(IV) and Zn, even when present in 1000-fold excess, are without effect on the extraction and photometric determination of vanadium(V). Although Cu(II), Mo(VI), and W(VI) give coloured extractable precipitates under the experimental conditions they do not interfere with the recovery of vanadium. In the photometric determination their tolerance limits are Cu(II) 0·6 mg, Mo(VI) 1·0 mg, and W(VI) 0·9 mg per 0·13 mg of vanadium. Fe(III) also gives an extractable coloured product but its interference is completely suppressed by addition of excess of pyrophosphate. Citrate, fluoride, pyrophosphate, phosphate and tartrate do not interfere but the extraction is markedly inhibited by oxalate and EDTA. Reagents which reduce vanadium(V) to lower oxidation states should be absent.

Composition of the extracted species

The composition of the extracted species is determined by plotting log (distribution ratio) *vs.* log (reagent concentration) in the presence and absence of alcohol. The amount of vanadium(V) taken in all the experiments was 50 μmole. It can be seen that in the absence of alcohol the ratio of vanadium(V) to oxine in the extracted species is 1:2 (Fig. 2). Even when the aqueous phase is 0·125*M* with respect to phosphoric acid, the same ratio is obtained. With a constant concentration of alcohol (20% v/v) in the organic phase the log (*D*) *vs.* log [oxine] curve (Fig. 3) shows two straight line portions with slopes of 1 and 2, indicating that at low concentrations of oxine the species contains vanadium and oxine in the ratio 1:1, and at higher concentrations the ratio is 1:2. With a constant concentration of oxine, (0·02*M* in the organic phase) the dependence of extraction on the concentration of n-butanol was investigated, the acidity of the aqueous phase being kept at 0·25*M* with respect to sulphuric acid. The log (*D*) *vs.* log [n-butanol] curve (Fig. 4) shows two straight line portions with slopes of 1 and 2 indicating the existence of a 1:1 vanadium:n-butanol species at low alcohol concentrations and a 1:2 species at high alcohol concentrations. Similar results are obtained for phosphoric acid medium, the acidity being 0·5*M*.

Job's method[17]

The method of continuous variations was adapted for the two phase system.[18] Equimolar solutions (0·01*M*) of vanadum(V) in the aqueous phase and of oxine in 20% n-butanol in benzene were prepared. These two solutions were mixed in such proportions that in each system the total concentration of vanadium(V) and oxine was the same ($4{\cdot}0 \times 10^{-3}M$) and the mole fraction of vanadium varied from 0–1·0, the aqueous phase being kept 0·05*M* in sulphuric acid or 0·25*M* in phosphoric acid. After equilibration for 1 min, the organic phase was separated and dried over anhydrous sodium sulphate,

and its absorbance was measured. The curves at 390 and 480 mμ are given in Fig. 5 and indicate that the extracted species from both acid media contain vanadium and oxine in a 1:2 ratio.

Slope-ratio method[18,19]

In this method, the concentration of one component was kept at $4{\cdot}0 \times 10^{-3}M$ while that of the other was varied from $1{\cdot}0 \times 10^{-4}M$ to $6{\cdot}0 \times 10^{-4}M$. The results are presented in Fig. 6 in which curves A_1 and B_1 refer to the absorbances at 390 and 480 mμ when the oxine concentration was kept constant, and A_2 and B_2 are the corresponding curves for a constant concentration of vanadium.

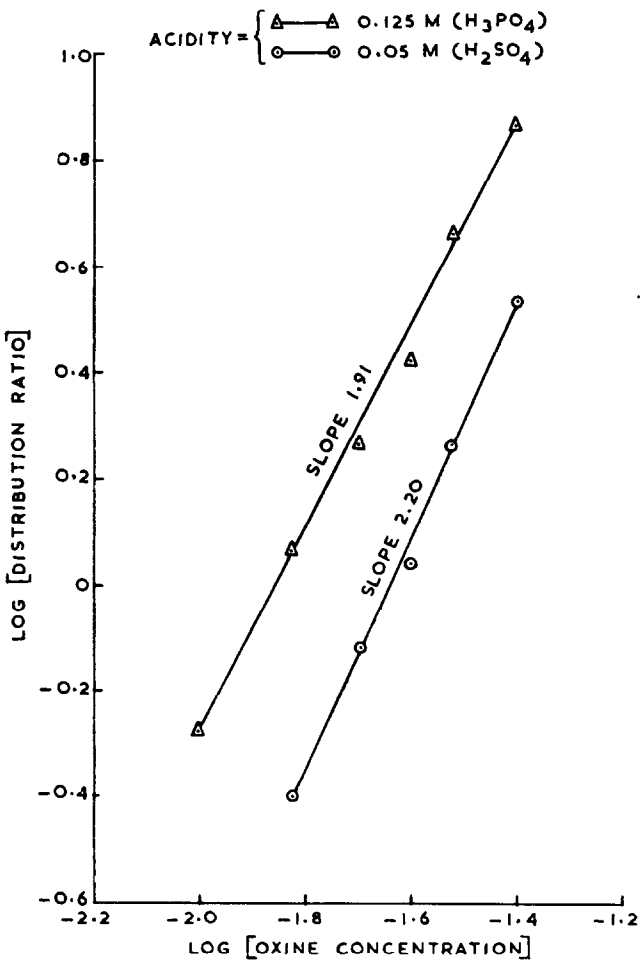

FIG. 2.—Nature of the vanadium(V)–oxine species extracted.

The slope-ratios A_1/A_2 and B_1/B_2 are 2·29 and 2·3 respectively, confirming that the mole ratio of vanadium:oxine in the species is 1:2. The same value is obtained when the extraction is carried out from an aqueous phase $0{\cdot}25M$ with respect to phosphoric acid.

DISCUSSION

Under the experimental conditions, vanadium(V) in solution exists as univalent VO_2^+.[20,21] Since only neutral species are extracted into organic solvents, it is probable that first a 1:1 chelate is formed between vanadium(V) and oxine. This chelate adds another oxine molecule by replacement of water, thus rendering it hydrophobic and

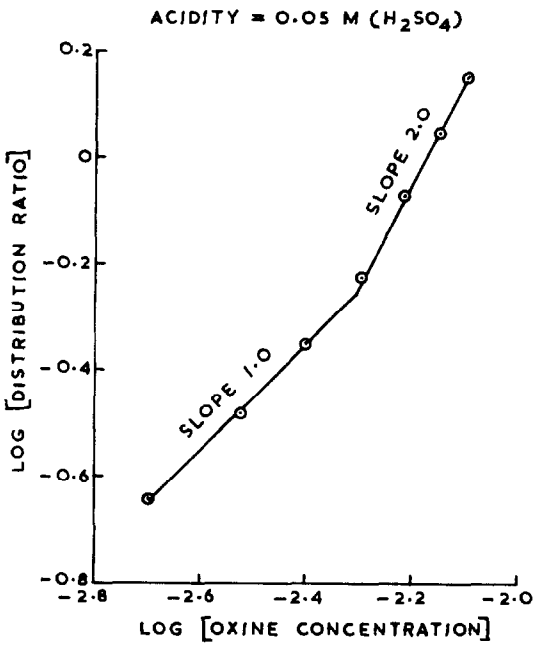

FIG. 3.—Nature of the extracted vanadium(V)–oxine–n-butanol species.

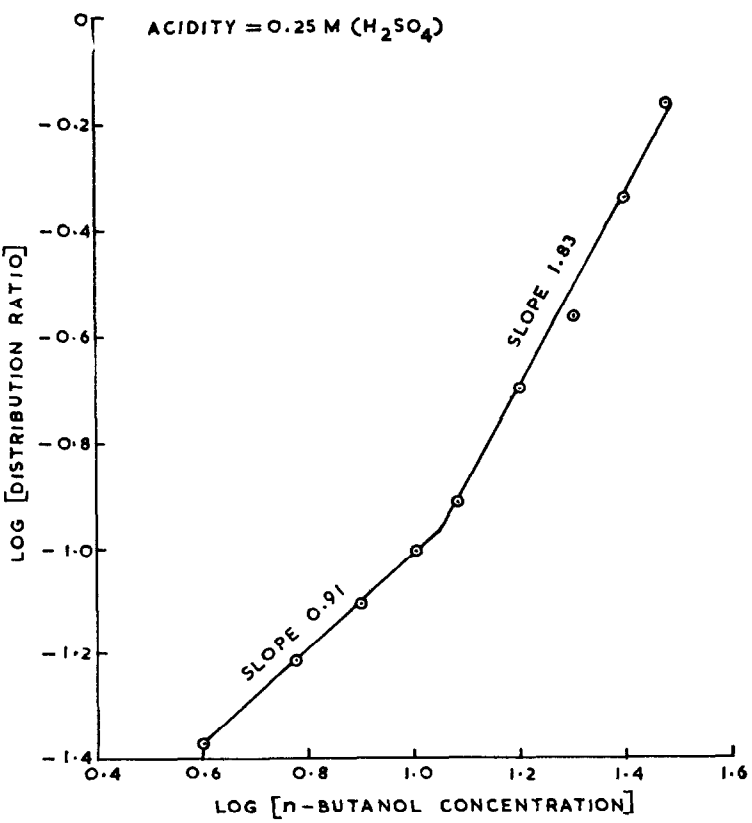

FIG. 4.—Nature of the vanadium(V)–oxine–n-butanol species extracted.

soluble in organic solvents as in the case of magnesium[22] and strontium.[23] This accounts for the fact that in the absence of alcohol no extraction is observed at very low concentrations of oxine where there is not enough oxine to form the adduct. However, recovery is quantitative when the concentration of oxine is about 50 times that of the vanadium and under these conditions the log-log plots indicate that the

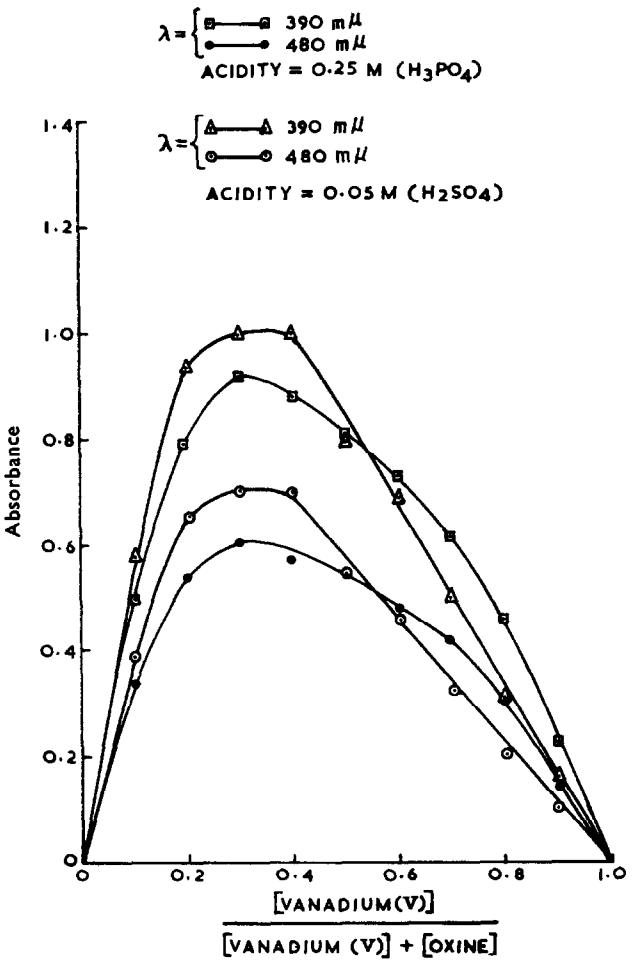

FIG. 5.—Nature of the vanadium(V)–oxine species extracted: Job's method.

composition of the extracted species is 1:2 vanadium:oxine (Fig. 2). However, in the presence of an alcohol, even at a low concentration of oxine, some recovery of vanadium is observed. Under these conditions evidence for a 1:1 vanadium:oxine species is given by the log–log plot, although at higher concentrations of oxine a 1:2 species is also indicated (Fig. 3). This explains the mechanism of the synergic effect of alcohol. The formation of a 1:2 vanadium:oxine species is also indicated by the spectrophotometric methods (Figs. 5 and 6). The log–log plot (Fig. 4) shows that either one or two molecules of n-butanol are associated with each species extracted, depending on the concentration of the n-butanol. In view of the fact that in routine extraction work,

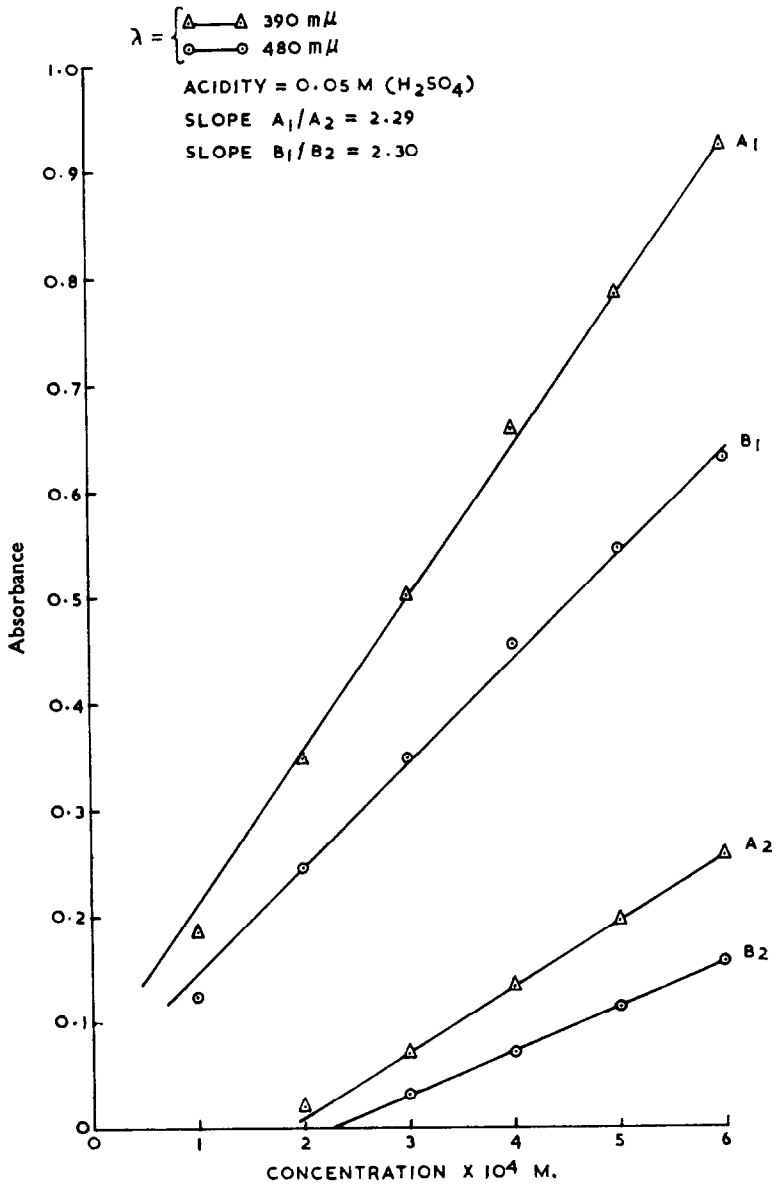

FIG. 6.—Nature of the vanadium(V)–oxine species extracted: slope-ratio method.

sufficiently high concentrations of oxine and n-butanol will be used, it may be concluded that the predominant species extracted has a 1:2:2 ratio of vanadium:oxine:n-butanol.

Zusammenfassung—Die Extraktion und spektrophotometrische Bestimmung von Vanadium(V) mit Oxin wird bei höheren Aciditäten als den früher beschriebenen untersucht. Unter diesen Bedingungen wurde gefunden, daß n-Butanol und andere Alkohole einen synergistischen Einfluß auf die Extraktion von Vanadium in Benzol

ausüben. In Gegenwart von Alkohol wird nur ein 6-facher Ligandenüberschuß zur quantitativen Extraktion in einem einzigen Arbeitsgang benötigt, wenn die Acidität des wäßrigen Mediums 0,05 M bezüglich Schwefeloder Phosphorsäure ist. Störendes Eisen(III) wird bei der spektrophotometrischen Bestimmung von Vanadium durch Beigabe von Pyrophosphat unterdrückt. Das Beersche Gesetz gilt bis zu 14,0 μg Vanadium pro ml, die Empfindlichkeit ist 0,008 μg Vanadium pro cm^2 bei 390 nm. Die Zusammensetzung der extrahierten Spezies wurde als Vanadium: Oxin: n-Butanol = 1:2:2 gefunden.

Résumé—On étudie l'extraction et le dosage spectrophotométrique du vanadium(V) par l'oxine à des acidités plus fortes que celles décrites antérieurement. On a trouvé que, dans ces conditions, le n-butanol et d'autres alcools exercent un effect synergique sur l'extraction du vanadium en benzène. L'extraction quantitative en une seule opération ne nécessite, en présence d'alcool, qu'un excès de ligand égal à 6 fois la théorie, le milieu aqueux étant 0,05 *M* en acide sulfurique ou phosphorique. On supprime l'interférence du fer(III) dans le dosage spectrophotométrique du vanadium par l'addition de pyrophosphate. La loi de BEER est respectée jusqu'à 14,0 μg de vanadium/cm^3 et la sensibilité est de 0,008 μ de vanadium/cm^2 à 390 mμ. On a trouvé que la composition de l'espèce extraite est vanadium:oxine:n-butanol = 1:2:2.

SIMULTANEOUS ESTIMATION OF COPPER, ZINC, CADMIUM AND MERCURY IN BIOLOGICAL MATERIAL BY NEUTRON ACTIVATION ANALYSIS

H. D. LIVINGSTON, HAMILTON SMITH and NIKOLA STOJANOVIC*
Department of Forensic Medicine, The University, Glasgow, Scotland

(*Received* 27 *July* 1966. *Accepted* 3 *November* 1966)

Summary—Simultaneous determination of copper, zinc, cadmium and mercury with high sensitivity is possible by neutron activation analysis. After irradiation, the samples are digested and an initial separation of the four elements made by means of an ion-exchange resin. The elements in the separated fractions are then treated to give radiochemical purity, precipitated, and their activities measured. A purely instrumental technique for the analysis of zinc in samples of biological material is also described. The samples are irradiated for a week and after the activity has decayed for about three months it is measured on a gamma-spectrometer.

ALTHOUGH activation analysis methods are available separately for the determination of copper, zinc, cadmium and mercury, their determination together has not previously been described. This paper gives details for separating these elements and measuring their activity.

EXPERIMENTAL

Isotopes used

Of the isotopes produced by irradiation of copper, zinc, cadmium and mercury with thermal neutrons, some are not useful for analytical purposes, because of unsuitable half-lives or low activation cross-sections. The useful isotopes are 12·8-hr ^{64}Cu, 245-day ^{65}Zn, 57-min ^{69}Zn, 13·8-hr ^{69m}Zn, 53-hr ^{115}Cd, 43-day ^{115m}Cd, 2·4-hr ^{117}Cd, 65-hr ^{197}Hg, 24-hr ^{197m}Hg, and 47-day ^{203}Hg.

Some of these isotopes can be produced by reactions other than (n, γ), *e.g.*,

$$^{64}\text{Zn(n, p)}^{64}\text{Cu}$$
$$^{72}\text{Ge(n, }\alpha)^{69/69m}\text{Zn}$$
$$^{63}\text{Cu(n, }\gamma)^{64}\text{Cu} \xrightarrow{\beta^-} {}^{64}\text{Zn(n, }\gamma)^{65}\text{Zn}$$
$$^{115}\text{In(n, p)}^{115/115m}\text{Cd}$$
$$^{120}\text{Sn(n, }\alpha)^{117}\text{Cd}$$
$$\text{and } ^{203}\text{Tl(n, p)}^{203}\text{Hg}$$

There is no other apparent source of production of $^{197/197m}$Hg. The contributions from these reactions to the induced activity are insignificant unless the matrix contains large amounts of the parent elements, and can be ignored for biological materials.

Irradiation of samples

Irradiations are carried out with a thermal neutron flux of 10^{12} n cm^{-2} sec^{-1}. The duration of irradiation depends on which isotopes are used for the analysis. Different sensitivities and radiochemical contaminants arise from the use of various times of irradiation. With short irradiation the resultant activity, due to short-lived isotopes, decays rapidly and limits the time available for chemical separation. If a longer irradiation is used to produce the isotopes with long half-lives, more time is available for the chemical separation and many more samples can be handled; a further advantage is that direct access to a reactor near the laboratory is not essential.

* Present address: Veterinarski Fakultet, Department of Chemistry, Bulevar J.N.A. 18, Belgrade.

Three irradiation times are used: 1 hr for ^{69}Zn and ^{117}Cd: 1 day for ^{64}Cu, ^{69m}Zn and ^{115}Cd: 1 week for ^{64}Cu, ^{69m}Zn, ^{65}Zn, ^{115}Cd, ^{197}Hg, ^{197m}Hg and ^{203}Hg.

Preparation of samples

The materials dealt with are enamel sections from human teeth and tissue samples from post-mortem examinations. The amount of handling before irradiation is minimized to prevent contamination of the samples. The tissue samples are vacuum dried and stored in clean polyethylene envelopes. The enamel samples are obtained from teeth rinsed with distilled water and sectioned with a cutting disc. No contamination was found from this disc. For the 1-hr irradiation the samples are weighed into small clean polyethylene envelopes and packed for irradiation in $\frac{1}{4}$ in. diameter polyethylene containers along with zinc and cadmium standards. For the longer irradiations the samples are weighed and wrapped in aluminium foil and packed, with standards, in an aluminium irradiation can.

Preparation of standards

For the short irradiations standards are prepared from dilute aqueous solutions of high purity zinc and cadmium. A small volume of standard solution, containing 1–10 μg of the element, is evaporated on a piece of polyethylene sheet (previously cleaned with conc. nitric acid and distilled water) under an infrared lamp. For the 1-day irradiations standard solution is weighed into clean silica ampoules which are then carefully heat-sealed. After irradiation, the ampoules are opened and the contents washed into volumetric flasks and diluted appropriately. An aliquot of the diluted standard is used for comparison with the samples and is processed and counted in a similar manner. For 1-week irradiations, high purity solid standards are used in sub-milligram amounts. The amount of cadmium standard irradiated is kept as small as possible to avoid the effect of self-shielding, which could cause the specific activity induced in the standard to be lower than that induced in a very minute amount of the element in the samples.

Reagents

Where possible, analytical grade reagents are used. The anion-exchange resin is the strongly basic Amberlite IRA-400 (Cl form), used in 1-cm columns packed with a 7-cm length of resin.

The ammonium reineckate solution is not very stable and is prepared frequently.

Procedure

Place the irradiated samples and standard in 25-ml conical-bottomed flasks with 6-in. necks. Add 10 mg of copper, zinc, cadmium and mercury carriers to each flask. Digest the samples with 2 ml of a mixture of 16*M* nitric acid and 18*M* sulphuric acid (1 + 1). When dissolution is complete and all the nitric acid has been removed, dilute the solutions to 36 ml with 0·5*M* hydrochloric acid.

If mercury is not to be determined, decompose the samples as described or dissolve them, together with carrier, by heating with 3 ml of 16*M* nitric acid in 100-ml beakers, evaporate the solutions to dryness, add 1 ml of 11*M* hydrochloric acid and again take them to dryness. Dissolve the residues in 0·5*M* hydrochloric acid. Add 5 drops of 10% ammonium dihydrogen phosphate solution to the solution from the digestion stage. Precipitate zirconyl phosphate by adding 8 drops of 10% zirconyl chloride octahydrate solution and centrifuge it. Sulphuric and hydrochloric acids in concentrations less than 1*N* do not interfere significantly with the precipitation.

Transfer the 0·5*M* hydrochloric acid solution of the sample (from the digestion or the phosphate scavenge step) to a gravity-operated reservoir on top of the ion-exchange column, pass it through, and wash the column with 25 ml of 0·12*M* hydrochloric acid containing 10% w/v of sodium chloride. Elute the copper with 20 ml of 0·5*M* hydrochloric acid followed by 20 ml of 0·12*M* hydrochloric acid containing 10% w/v of sodium chloride. Elute the zinc (with some cadmium and mercury—see discussion below) at a flow-rate of 3 ml/min with 40 ml of 2*M* sodium hydroxide containing 2% w/v of sodium chloride. Elute the cadmium with a little mercury and the rest of the zinc by means of 50 ml of 1*M* nitric acid at a flow-rate of 3 ml/min. Strip the residual mercury from the column with 5% w/v ethylenediamine solution. Treat each of the four eluates as described below.

Copper. The hydrochloric acid eluate contains many other radioactive species besides copper, and Nixon and Smith's separation procedure[1] should be used. This entails precipitation of copper(I) thiocyanate in the presence of hold-back carriers, a scavenging step with hydrous iron(III) oxide, reprecipitation of copper(I) thiocyanate, and final precipitation of copper quinaldinate which is used as the weighing form for calculating chemical yield and also for the activity determination with an end-window Geiger counter.

Zinc. Make the eluate just acid by addition of concentrated hydrochloric acid, and add 0·5 ml of 10 % w/v iron(III) chloride solution as iron carrier. Add 3 ml of 5*M* sodium hydroxide, heat the

mixture on a water-bath, and centrifuge off the hydrous iron(III) oxide. Filter the supernatant liquid to ensure removal of all iron, neutralize it with glacial acetic acid to the phenolphthalein end-point and add another 1 ml of acetic acid. Heat the solution on a water-bath and precipitate the zinc by addition of 2% quinaldinic acid solution. Wash the precipitate once with water and once with acetone and slurry it onto a weighed aluminium planchet with acetone. Dry it under an infrared lamp at 100°, weigh the precipitate as $Zn(C_{10}H_6O_2N)_2H_2O$ and measure its activity with an end-window Geiger counter.

Cadmium. Make the cadmium effluent alkaline with 5*M* sodium hydroxide and centrifuge off the cadmium hydroxide. Dissolve the precipitate in 1 ml of concentrated hydrochloric acid, dilute the solution to 20 ml and add 5 ml of 5% thiourea solution and 8 ml of a solution of ammonium reineckate (saturated at 18°) containing 1% of urea. Wash the precipitated cadmium reineckate with 1% thiourea solution and absolute alcohol. Slurry it onto a weighed aluminium planchet with absolute alcohol, dry it under an infrared lamp, weigh it as $Cd[SC(NH_2)_2][Cr(NH_3)_2(SCN)_4]_2$ and count its activity with an end-window tube.

Mercury. Add 1 ml of 10% sodium iodide solution and 1 ml of 10% copper sulphate solution to the mercury eluate to precipitate the copper ethylenediamine—mercuric iodide complex,[2] wash the precipitate with water and isopropanol, transfer it to a stainless steel planchet, dry it at 90°, weigh it, and measure its activity with a sodium iodide (Tl) crystal and pulse-height analyser. For greatest sensitivity use the 78 keV photopeak of ^{197}Hg.

Count rates. All count-rates are corrected for background, decay and chemical recovery, and the metal content calculated in the usual way from the activity of sample and standard.

Instrumental method for zinc only

Some samples can be analysed for zinc by irradiating them (together with a standard) for a week at a flux of 10^{12}n cm^{-2} sec^{-1}, letting short-lived activities decay during 100 days, and then measuring the activity of the 1·12 MeV ^{65}Zn photopeak with a pulse-height analyser (3 in. sodium iodide (Tl) crystal, analyser window set to 1·00–1·25 MeV).

RESULTS AND DISCUSSION

Phosphate scavenge

Phosphorus is one of the major interfering contaminants in work with biological materials and any separation procedure must be tested to ensure that this interference is not present.

Experiments with ^{32}P tracer showed that no ^{32}P activity could be detected in the zinc quinaldinate precipitates, but it was found in the hydrochloric acid fraction first eluted from the ion-exchange column. However, decay measurements made on zinc quinaldinate precipitates separated from tissue samples irradiated for 24 hr indicate the presence of 14·2-day ^{32}P. It appears that because of the high phosphorus content of the samples being analysed, the amount of ^{32}P activity induced in the sample is many times greater than that used in the tracer experiments. A small fraction of this activity comes through the separation and consequently it is necessary to introduce the phosphate scavenge step before the ion-exchange procedure, if the irradiation time is 24 hr or longer. It is not necessary for samples of less than 10 mg irradiated for 1 hr.

Ion-exchange separation

The separation used is based on that reported by Kallmann, Steele and Chu[3] for the separation of zinc and cadmium. Tracer experiments show that zinc, cadmium and mercury are retained on the column, but cations and non-adsorbable anions are washed through.

Copper. As described by Kraus and Nelson,[4] bivalent copper is not retained on the resin from dilute solutions of hydrochloric acid. By use of ^{64}Cu tracer and zinc,

cadmium and copper carrier, it can be demonstrated that the copper is not retained on the resin but passes through in the hydrochloric acid fractions. The results are shown in Table I. No copper activity appears in the zinc or cadmium precipitates subsequently obtained.

Zinc. Zinc is eluted from the column by displacement of the chloro-complex of zinc and formation of the tetrahydroxozincate ion. Only amphoteric elements capable of forming alkali-soluble salts will be eluted with this fraction. Many other elements displaced from the resin by hydroxide form insoluble hydroxides or oxides. In the case of mercury and cadmium this can be seen by the formation of a yellow band of mercuric oxide or a grey band of cadmium hydroxide on the resin.

Some cadmium and mercury escape from the column. Kallman, Steele and Chu,[3] however, did not find cadmium in their zinc fractions when separating 1 g each of zinc and cadmium by this ion-exchange technique.

Tracer experiments with ^{115}Cd have been made to determine the behaviour of the cadmium in the ion-exchange procedure. This isotope has a daughter ^{115m}In with a half-life of 4·5 hr. The ^{115m}In activity is not adsorbed on the column, and this is in accordance with Kraus and Nelson's results for the adsorption of indium on Dowex 1 resins from hydrochloric acid solutions.[4] Counting was, therefore, delayed overnight to allow parent/daughter equilibration. The zinc fractions were acidified with concentrated hydrochloric acid on collection, to prevent possible mechanical loss of cadmium as cadmium hydroxide. The results are given in Table I. It can be seen that a total of about 5% of cadmium tracer is found in the zinc fraction. In addition, γ-spectrometry revealed the presence of cadmium activity in the final zinc quinaldinate precipitate if the iron hydroxide scavenge was omitted during analysis of tissues containing significant amounts of cadmium.

Similarly it is found that mercury escapes from the column with the zinc fraction. A typical experiment showed about 20% of the mercury tracer being eluted with the zinc (Table I). It is thought that these two effects are due to the retention mechanism for the cadmium and mercury.

Kallman, Steele and Chu[3] note that the mechanism of cadmium retention by the resin has not been established. They suggest that the presence of sodium chloride has some effect. The slight leakage of cadmium and mercury from the resin on elution with sodium hydroxide (Table I) leads to a suggestion of the manner in which these elements are retained.

This would probably also apply to other elements held on the resin and capable of forming insoluble oxides and hydroxides. When zinc is eluted with alkali in the presence of cadmium tracer and carrier, no activity is detected in the effluent fractions with a Geiger liquid-counter. When the fractions are made acid with hydrochloric acid, 4–5% of the cadmium tracer used is detected with the zinc fraction (Table I). It is probable that, in the alkaline medium, the cadmium is adsorbed on the walls of the collecting tube as cadmium hydroxide and is not transferred to the counting tube. When the fraction is made acid, the cadmium is dissolved and is transferred and counted. This problem does not arise in the case of zinc elution in the presence of mercury tracer and carrier as the eluted fractions are counted directly in a scintillation well crystal without being transferred from the collecting tube.

It is suggested that the retention of the cadmium and mercury bands on the resin is a mechanical retention of the insoluble hydroxide and oxide respectively. The

leakage from the column may be attributed to small particles of precipitate being separated from the main bulk of precipitate and washed down through the resin.

Cadmium. It was expected that mercury would contaminate the cadmium fraction but under the elution conditions the mercury is very difficult to remove from the resin and only about 5% of the tracer was found in the cadmium fraction (Table I).

Mercury. Kraus and Nelson[5] report that mercury is difficult to elute from an anion-exchange resin, on which it is adsorbed as its chloro-complex. Various solutions (Table II) were used in an attempt to remove the mercury from the resin after the cadmium elution.

The mercury carrier is precipitated on the column as mercury(II) oxide during zinc elution and is not eluted with 1*M* nitric acid although mercury(II) oxide dissolves readily in this concentration of acid and tracer experiments show that mercury is not retained on the resin when added to it in the nitrate form.

The reason for the ease of mercury elution with ethylenediamine is thought to be

the formation of the cationic species $Hg(OH)(en)_2^+$, $Hg(en)_2^{2+}$ or $Hg(en)_3^{2+}$, which are not held on an anion-exchange resin. As most complexing agents produce a negatively charged complex they would not elute mercury from this type of resin.

Final processing

Each of the solutions from the column requires to be further processed to give complete radiochemical purity and to prepare the element in a form suitable for making recovery estimations.

Copper. The radiochemical purity of the quinaldinate and the accuracy of the analysis are already established but these were checked again as follows. A series of copper quinaldinate precipitates prepared from activated biological tissue were checked exhaustively by γ-spectrometry and decay measurements, but all showed the activity present to be due exclusively to ^{64}Cu. A series of samples of a biological standard* were analysed and gave answers of 4·5, 4·5 and 4·9 ppm which compare well with the known value of 4·4 ppm and a range of 4·1–4·5 ppm obtained by the method of Nixon and Smith.[1]

Zinc. Of the elements adsorbable in the resin from dilute hydrochloric acid solutions, Cd, Zn, Ag, Pb, Hg(II), Pd(II), Pt(II) and Fe(III) are capable of forming quinaldinates. Of these, only zinc and lead form an alkali-soluble salt and hence are separated from the rest of these elements on elution of the zinc fraction. Under the activation conditions lead does not interfere but as noted before, there is a leakage of cadmium and mercury into the alkaline eluate. To eliminate this contamination, it is necessary to introduce a scavenging step before the final precipitation. The scheme used results in complete radiochemical purity, as can be shown by γ-spectrometry and decay studies.

A series of standard solutions was analysed to check the accuracy of the method and gave values which agreed with the calculated value within 5% for all the samples. Samples of the biological standard gave values of 34, 32 and 27 ppm which compare closely with the known value of 30 ppm.

Cadmium. Of the elements held on the resin with cadmium by formation of insoluble oxides or hydroxides, only Ag, Hg(II), Tl and Bi are precipitated with cadmium by Reinecke's salt. As shown in Table I, only about 5% of the mercury is eluted with the cadmium and it has not been found as a contaminant in the samples analysed in this work. It may well prove to be a contaminant in analysis of material relatively rich in mercury. If silver, mercury or thallium should prove to be a problem, they can be removed by a suitable silver chloride scavenge before the reineckate precipitation. Because of its poor activation characteristics, bismuth does not interfere in analysis of most biological materials.

A series of standard solutions was analysed to check the accuracy of the method and gave values which agreed with the calculated value within 5% in all the samples. Samples of the biological standard gave analysis values of 0·67, 0·63 and 0·60 ppm. No known figures are available for comparison. The precipitates were radiochemically pure.

Mercury. As shown in Table I, the chemical recovery of mercury may be as low as 60% because of losses during the separation procedure.

* Due to H. J. M. Bowen, Department of Chemistry, University of Reading, England.

The radiochemical purity of the final precipitates was determined by γ-spectrometry and only mercury activity was found to be present. A series of analyses of the biological standard gave values of 0·24, 0·21 and 0·24 ppm. Samples analysed by a method specific for mercury[2] gave values in the range 0·21–0·26 ppm.

Instrumental zinc analysis

Figure 1 shows the γ-spectra of a 40-mg sample of human tooth enamel, 9 and 100 days after the end of a 1-week irradiation. After 9 days the principal features of the spectrum are the ^{65}Zn photopeak at 1·12 MeV, the ^{24}Na photopeak at 1·37 MeV,

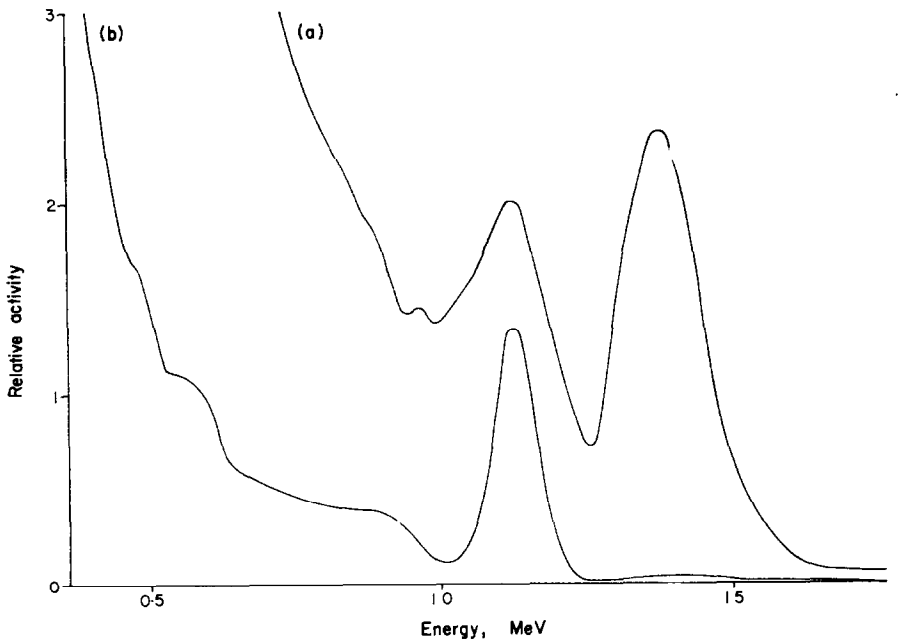

FIG. 1.—γ-Spectra of irradiated tooth enamel.
(a) 9 days after irradiation
(b) 100 days after irradiation

and the gross ^{32}P bremsstrahlung at the lower (<1 MeV) end of the spectrum. After 100 days the ^{24}Na photopeak ($t_{\frac{1}{2}}$ = 15·0 hr) has disappeared and the brehmsstrahlung effect from the ^{32}P ($t_{\frac{1}{2}}$ = 14·2 days) is greatly reduced. The spectrum above 0·5 MeV is essentially that of ^{65}Zn ($t_{\frac{1}{2}}$ = 245 days) and the 1·12 MeV photopeak is used for the zinc estimation.

As a check on the accuracy of the instrumental method a batch of samples (sections of the inner enamel cut from sound extracted human teeth) was analysed by the 1-hr irradiation method described and another batch was analysed by the instrumental method. A comparison of the results obtained is given in Table III. The weight of sample used is in the range 10–30 mg. The results show a good comparison of the two methods with reasonable agreement between the mean and median values. The spread of results is greater for the batch analysed by the instrumental method but this is not unexpected since more samples were analysed by this method.

TABLE III.—COMPARISON OF ZINC CONTENT OF INNER ENAMEL SECTIONS BY TWO METHODS OF ANALYSIS

	Zinc, *ppm*	
	Chemical method	Instrumental method
No. of samples analysed	16	60
Range	110–435	58–584
Mean value	255	236
Median value	224	209

Sensitivity

The sensitivities vary according to the experimental condition chosen. The major factors are the neutron flux and the irradiation time, which in turn depends on the isotope used. The limit of sensitivity is taken to be the amount of element needed to give a count-rate equal to the background count-rate of the detection instrument. The results are shown in Table IV.

TABLE IV.—TRACE ELEMENT SENSITIVITIES (μg)

Condition	Sensitivity at a neutron flux of 10^{12} n cm^{-2} sec^{-1}			
	Copper	Zinc	Cadmium	Mercury
1-hr irradiation	not used	0·01	0·1	not used
1-day irradiation	0·0005	0·1	0·01	not used
1-week irradiation	0·0005	0·1	0·001	0·0005
Instrumental analysis	—	1·0	—	—

As can be seen from the table, the choice of irradiation period affects the sensitivity attainable for both zinc and cadmium. For maximum sensitivity of analysis for zinc a short irradiation of $\frac{1}{2}$–2 hr is required. Maximum sensitivity for cadmium analysis is obtained by irradiating for a week, to give ^{115}Cd. The instrumental method of zinc analysis will often prove adequate for zinc determination in biological material. It has the advantage that a large number of samples may be analysed at a time since the long-lived ^{65}Zn eliminates the problem of completing the analysis in a short time interval. From our experience in zinc analysis of dry human tissue from various organs the amount of zinc in a 50-mg sample will be in the range 1–20 μg, which is readily detectable by this method.

Acknowledgements—The authors thank the Scottish Research Reactor Centre for use of laboratory and short irradiation facilities. They further thank Professor Gilbert Forbes, Dr. J. M. A. Lenihan and Dr. G. S. Nixon for support and encouragement during the course of this work. H. D. Livingston thanks the Scottish Hospitals Endowment Research Trust for financial support.

Zusammenfassung—Die gleichzeitige Bestimmung von Kupfer, Zink, Cadmium und Quecksilber mit hoher Empfindlichkeit ist möglich durch Neutronenaktivierungsanalyse. Nach Bestrahlung werden die Proben aufgeschlossen und mit Hilfe eines Ionenaustauschharzes die vier Elemente grob getrennt. Die Elemente in den abgetrennten Fraktionen werden dann radiochemisch gereinigt, gefällt und ihre Aktivitäten gemessen. Es wird auch ein rein instrumetalles Verfahren zur Bestimmung von Zink in Proben biologischen Materials beschrieben. Die Proben werden eine Woche lang bestrahlt. Nach dreimonatigem Abklingen der Aktivität wird sie an einem Gamma-Spektrometer gemessen.

Résumé—Le dosage simultané du cuivre, du zinc, du cadmium et du mercure avec une sensibilité élevée est possible par analyse par activation de neutrons. Après irradiation, les échantillons sont digérés et l'on effectue une séparation initiale des quatre éléments au moyen d'une résine échangeuse d'ions. On traite alors les éléments dans les fractions séparées pour avoir la pureté radiochimique, les précipite et mesure leurs activités. On décrit aussi une technique purement instrumentale pour l'analyse du zinc dans des échantillons de produits biologiques. On irradie les échantillons pendant une semaine et après affaiblissement de l'activité pendant environ trois mois, on la mesure avec un spectromètre gamma.

VARIAMINE BLUE AS A GRAVIMETRIC REAGENT

DETERMINATION OF TUNGSTEN

L. ERDEY, I. BUZÁS and K. VIGH

Institute for General Chemistry, Technical University, Budapest XI, Hungary

(*Received* 2 *August* 1966. *Accepted* 2 *November* 1966)

Summary—Tungsten can be precipitated by a solution of Variamine Blue at pH 5. The precipitate is ignited to constant weight at a temperature above 600° and weighed as tungsten trioxide. The method can be used for the determination of tungsten in alloy steels.

AMONG gravimetric methods for the determination of tungsten the one using precipitation in the form of tungstic acid ($WO_3 \cdot H_2O$) seems to be the simplest. Tungstic acid precipitated from acid solution, however, partly dissolves in water. Although the solubility can be reduced by dehydrating the precipitate at 120°, 1–3% of the precipitate dissolves on being washed with dilute acid. Tungstic acid dissolved this way cannot be precipitated again by repeated evaporation, and so low results are obtained by this method.[1]

Quantitative precipitation can be achieved, however, if the tungsten is precipitated in the form of the tungstate of an alkaloid or amine.[1–11] These precipitates are not of stoichiometric composition, and probably consist of tungstic acid binding variable amounts of organic reagent by adsorption. Precipitates formed with organic reagents have a favourable morphology and can be fairly easily ignited to tungsten trioxide.

Variamine Blue base* was found to be a suitable reagent for the quantitative precipitation of tungsten. Besides being an excellent redox indicator and colorimetric reagent,[12] it has been successfully used in qualitative analysis as a spot-test reagent.[13]

We found in our spot-test experiments that Variamine Blue produced an amorphous, greyish white precipitate with tungstate ions. This precipitate was soluble in dilute acids, so the detection could only be carried out in nearly neutral media. The detection limit was 1·8 μg, in a 1:544,000 dilution, and the sensitivity exponent p_D was 5·7. Molybdenum ions interfere by forming a precipitate of similar colour. The sensitivity of the reagent for molybdenum is one order of magnitude lower than that for tungstate ions, so that small amounts of molybdenum do not interfere.

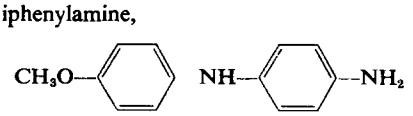
EXPERIMENTAL

Reagents

Sodium tungstate solution 0·02*M*, was prepared from analytical grade reagent (hydrated), and was standardized by the mercury(I) tungstate and benzidine tungstate gravimetric methods.

Variamine Blue solution was prepared by rubbing 1 g of reagent with 10 ml of 0·1*M* acetic acid, diluting to 100 ml with water and filtering through a G4 sintered glass crucible. This reagent can be used for 1–2 days, but it is advisable to prepare it freshly before use.

* 4-Amino-4′-methoxy-diphenylamine,



Optimum pH for precipitation

The pH of the nearly neutral stock solutions was varied between 0·3 and 6·0 by adding hydrochloric acid or acetic acid and the degree of precipitation was determined. The results are presented in Table I. Quantitative precipitation occurs at pH 5. At lower pH values tungsten is only partly precipitated, and the precipitate formed at pH 6 is very fine, and difficult to filter. The error of 2·5% is due to the fact that some of the precipitate passed through the filter. The precipitate formed at pH 5 is voluminous, settles quickly and is easy to filter.

TABLE I.—EFFECT OF VARIATION OF pH ON THE PRECIPITATION

True value, WO_3, *mg*	pH	Obtained, WO_3, *mg*	Deviation, %
92·4	0·3	82·9	−10·2
	1·0	83·1	−10·0
	3·0	90·3	−2·2
	4·0	91·6	−0·8
	5·0	92·4	±0·0
	6·0	86·0	−2·5

Solubility of the precipitate

Variamine Blue tungstate was precipitated from solutions at pH 4 and 5, filtered off on a G4 sintered glass crucible, washed with 0·01*M* acetic acid, and dried by sucking air through it for about 2 hr. The dry precipitate was agitated in 100 ml of 0·01*M* acetic acid at 26° for 4 hr and the solubility of the precipitate was determined by measuring the Variamine Blue concentration of the solution photometrically.

The calibration curve for the determination was prepared as follows: known amounts of 0·01*M* iron(III) chloride solution were added to solutions of Variamine Blue of known concentration, at a suitable pH. The optical densities of the solutions were measured with a Pulfrich photometer, an S57 filter being used. The amount of Variamine Blue due to the dissolution of the precipitate, and hence the solubility, was determined by measuring the optical density under the same conditions. The solubility in 0·01*M* acetic acid is $3·5 \times 10^{-5}$ mole/l if the precipitation is carried out at pH 5, and $8·5 \times 10^{-5}$ mole/l. for the precipitate produced at pH 4.

Temperature of precipitation

Table II shows the effect of temperature on the precipitation. The weights of the precipitates obtained at different temperatures are similar, but whereas the precipitate is formed instantaneously in a voluminous flaky form at room temperature and can be filtered off after 15 min settling, the one obtained at 50° is at first colloidal, and can only be filtered off after cooling with frequent stirring. It is difficult and tedious to transfer to the filter the traces of precipitate adhering to the wall of the beaker. These disadvantages are even more marked if the precipitation is carried out at the boiling point.

TABLE II.—EFFECT OF TEMPERATURE ON THE PRECIPITATION

True value, *mg*	WO_3 obtained by precipitation at		
	Room temperature *mg*	50° *mg*	100° *mg*
92·4	92·5	92·6	92·9

Heating of the precipitate

The Variamine Blue tungstate precipitate cannot be dried to constant weight. One might assume on the basis of the thermoanalytical curves of the precipitate (see Fig. 1) that a weighable precipitate, possibly of constant weight, can be obtained by drying between 110 and 200°. The weights of precipitates dried at the same temperature in this range were the same, but those of precipitates dried at different temperatures differed markedly, as is shown in Table III. The results obtained after drying at room temperature by passing air through the precipitate were also different.

Even if a precipitate of constant weight could be obtained by drying in a certain temperature range, it would not be reasonable to use a conversion factor calculated from the formula weight obtained by

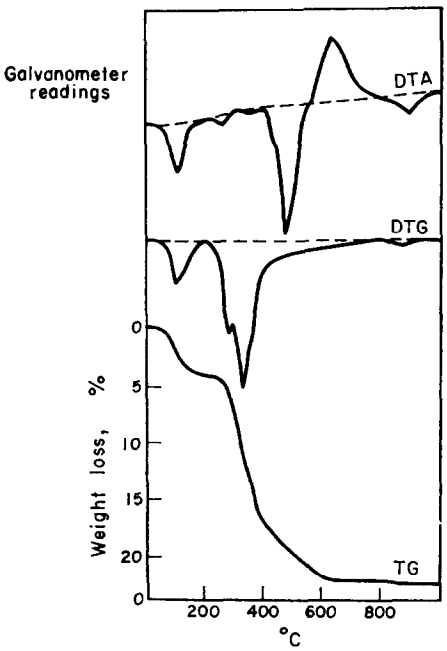


FIG. 1.—Thermogravimetric curves for the tungsten–Variamine Blue complex.

TABLE III.—DRYING OF THE PRECIPITATE

Temperature, °C	Weight of precipitate, *mg*			Mean, *mg*
Air suction (room temperature)	155·0	152·0	151·8	152·9
110	151·7	151·2	151·1	151·3
150	149·0	149·2	148·4	148·8
200	143·8	144·5	144·1	144·1

elementary analysis. Presumably, Variamine Blue tungstate, like other amine tungstates, is an adsorption compound of variable composition and loose structure. This is also shown by the infrared spectroscopic data. The infrared spectrum of the precipitate was nearly the same as that of Variamine Blue itself, which suggests that no molecular bonding exists between the constituents.

Collecting the precipitate on filter paper and igniting it at temperatures above 600° gives reproducible and accurate results. Table IV, presenting results obtained for various amounts of precipitate, shows the reproducibility of the method.

The accuracy and standard deviation of the measurements were determined on the basis of six parallel measurements. In the case of precipitate weights of 92·4 mg the deviation from the mean was found to be +0·2%, while the standard deviation was 0·16 mg, i.e. the coefficient of variation was 0·2%.

Among foreign ions, halides, sulphates, nitrates, thiocyanates and silicates of alkali metals, and copper, arsenic(III), cobalt(II), nickel, aluminium, zinc, manganese and ammonium ions do not interfere with the determination.

Heavy metal ions, such as silver, lead and mercury(I), and also calcium and barium ions, produce a precipitate with tungsten and interfere with the determination.

TABLE IV.—PRECIPITATION OF VARIOUS AMOUNTS OF TUNGSTEN

WO_3				
True value, *mg*	Found, *mg*	Mean, *mg*	Deviation, *mg*	*%*
45·8	45·2 45·7 45·2	45·4	−0·4	−0·9
92·4	92·7 92·3 92·3	92·4	0·0	0·0
231·0	230·9 231·6 231·2	231·3	+0·3	+0·1

Oxidizing agents also interfere, because no precipitate is formed in their presence; such are iron(III), chromium(VI) and cerium(IV) ions. Molybdate ions give a precipitate with Variamine Blue. The effect of iron(III) can be eliminated by reduction with ascorbic acid or masking with EDTA, but molybdenum must be separated before precipitation. Phosphate and chromium(III) also interfere.

Procedure

Add to the nearly neutral or neutralized solution containing 40–200 mg of tungsten, 10 ml of 0·1*M* acetic acid and dilute to about 100 ml with water. After adding 20–30 ml of Variamine Blue reagent solution, stir the quickly settling, flaky precipitate several times with a glass rod, then filter it off on a medium porosity filter paper after about 15 min standing. Wash with a solution consisting of 100 ml of 0·1*M* acetic acid and 10 ml of Variamine Blue reagent solution mixed and diluted to 300 ml with water. After washing, ignite the precipitate in a porcelain or platinum crucible to constant weight at 600–700°, and weigh the tungsten trioxide obtained.

PRACTICAL APPLICATION OF THE METHOD

The procedure has been utilized for the determination of tungsten in steel. The acid solution of the steel sample was passed through an ion-exchange column and tungsten was eluted and then precipitated with Variamine Blue.

Wilkins's method was used for the separation by ion-exchange,[14,15] as it was worked out for the determination of components of alloy steels. Strongly basic Dowex I resin, in a polythene tube, was converted into the chloride form with hydrochloric acid, and then washed with 2·5% hydrofluoric acid solution.

The sample was dissolved in a mixture of hydrofluoric, hydrochloric and nitric acids, the solution was evaporated to dryness, and the solid residue was dissolved in hydrofluoric acid, diluted with water and washed into the column with 2·5% hydrofluoric acid solution. Iron, cobalt, nickel, chromium, manganese, aluminium and copper were contained in the eluate. Titanium, tungsten, molybdenum and tantalum were bound on the column. First titanium was eluted, with 8*M* hydrochloric acid, then tungsten, with a solution consisting of 10 ml of 40% hydrofluoric acid and 60 ml of conc. hydrochloric acid mixed and diluted to 100 ml with water.

Sulphuric acid was added, and the solution was evaporated to fumes of sulphur trioxide, to remove fluoride. The solution was then diluted with water, neutralized with ammonia solution, and the pH adjusted by addition of an acetic acid—acetate buffer solution of pH 5. The precipitation was effected by the method described above. The precipitate was then filtered off, washed, and ignited and weighed as tungsten trioxide. The tungsten content of a steel sample containing 17·4% of tungsten was found to be 17·6 % by our method.

Our method has the advantage over others using other organic reagents, that the precipitate has favourable morphologic properties and can be filtered off shortly

after the precipitation. The Variamine Blue precipitate can be fairly easily converted into pure yellow tungsten trioxide, by igniting at above 600°.

Zusammenfassung—Wolfram kann durch eine Lösung von Variaminblau bei pH 5 gefällt werden. Der Niederschlag wird bei einer Temperatur oberhalb 600° bis zur Gewichtskonstanz geglüht und als Wolframtrioxyd gewogen. Die Methode kann zur Bestimmung von Wolfram in legierten Stählen verwendet werden.

Résumé—On peur précipiter le tungstène par une solution de Bleu Variamine à pH 5. Le précipité est calciné à poids constant à une température supérieure à 600° et pesé à l'état de trioxyde de tungstène. On peut utiliser la méthode pour le dosage du tungstène dans des alliages d'acier.

SHORT COMMUNICATIONS

Radiometric determination of submicrogram amounts of mercury

(*Received* 4 *July* 1966. *Accepted* 8 *October* 1966)

EXCHANGE reactions between a metal to be determined and a complex of another metal with lower stability or extraction constant are often used in analytical chemistry. With the use of radioisotopes the sensitivity of determinations of this type can be greatly increased.

In the present paper a radiometric method for the determination of mercury by exchange with silver–110m dithizonate is described. From the extraction constants of the metal dithizonates[1,2] it follows that silver is completely exchanged by mercury according to the reaction:

$$2\ {}^{110m}Ag(HDz)_{(org)} + Hg^{2+} = Hg(HDz)_{2(org)} + 2\ {}^{110m}Ag^{+}.$$

Preliminary experiments showed that equilibrium for this reaction is reached within 1 min. The amount of mercury present can be found from the decrease in the radioactivity of the silver–110m dithizonate in the organic phase or from the increase in the radioactivity of the silver–110m cations in the aqueous phase.

General procedure

To 8 ml of the test solution (pH 1-2) containing 0·01–0·10μg of mercury, add 1 ml of 5% urea solution and 1 ml of 10M acetic acid (previously purified by dithizone extraction). Transfer the solution into a separating funnel, and add 1·00 ml of $10^{-6}M$ silver–110m dithizonate in carbon tetrachloride.* Shake the funnel for 2–3 min, transfer 0·50 ml of the organic phase into an aluminium planchette, evaporate to dryness and measure the activity with a Geiger-Müller counter. A typical calibration curve is linear and has a slope of -1400 cpm silver activity/10^{-8} g of mercury/ml.

For determination of mercury in amounts ten times as great, use $10^{-5}M$ silver–110m dithizonate. The specific activity of silver–110m available permits the determination of mercury down to 5×10^{-10} g/ml with sufficient precision. The method is rather selective; only palladium, gold, silver and large amounts of copper and bismuth interfere, and these must be removed.

Procedure in the presence of palladium, copper and bismuth

To 8 ml of the test solution in 1M sulphuric acid, containing 0·1–1·0μg of mercury and 20 times as much palladium or 100 times as much copper and bismuth, add 1 ml of 0·01M 8-hydroxyquinoline solution in 10M acetic acid. Extract palladium (and partially copper and bismuth) as the 8-hydroxyquinolinate several 5 ml portions of chloroform. To the aqueous phase, still containing all the mercury, add 1·00 ml of $10^{-5}M$ silver–110m dithizonate in carbon tetrachloride, and test the solution as previously described. The amount of mercury is found from the calibration curve.

Procedure in the presence of silver

To 8 ml of the test solution (pH 1–3) containing 10–100 times as much silver as mercury, add 1 ml of 5% urea solution, 1 ml of 10M acetic acid and 1·3 g of solid sodium chloride (the total concentration of chloride ions is then about 12·5%). Extract the mercury quantitatively with an excess of dithizone solution in carbon tetrachloride (for 0·1–1·0μg of mercury use 2·00 ml of $10^{-5}M$ dithizone solution), leaving the silver completely in the aqueous phase. Transfer 1·00 ml of the organic extract into another separating funnel, and shake it for 2 min with an excess of silver–110m nitrate solution containing 0·5% of urea and 1M acetic acid. Transfer 0·50 ml of the organic extract to a planchette, evaporate it to dryness and measure the activity with a Geiger-Müller counter. The amount of mercury in the test sample is determined from a calibration curve prepared under the same conditions as before.

* This solution is prepared by shaking $10^{-6}M$ dithizone solution in carbon tetrachloride with an excess of silver–110m nitrate solution containing 0·5% of urea and 1M acetic acid. Thus prepared, and kept in the dark, the solution is stable for at least two days.

TABLE I.—DETERMINATION OF MERCURY IN THE PRESENCE OF FOREIGN METALS

Mercury taken, μg	Foreign metals present, μg	Mercury found, μg	Error, %
0·100	—	0·103	3
0·100	10 Cu	0·102	2
0·100	10 Bi	0·102	2
0·100	2 Pd	0·100	0
0·200	—	0·198	−1
0·200	20 Cu	0·205	2·5
0·200	20 Bi	0·213	6
0·200	4 Pd	0·208	4
0·300	—	0·304	1
0·300	30 Cu	0·302	1
0·300	30 Bi	0·299	0
0·300	6 Pd	0·303	1
0·400	—	0·405	1
0·400	40 Cu	0·405	1
0·400	40 Bi	0·394	1·5
0·400	8 Pd	0·396	−1
0·500	—	0·493	−1
0·500	50 Cu	0·489	−2
0·500	50 Bi	0·504	1
0·500	10 Pd	0·506	1

The procedure described is very simple and rapid. It permits the determination of as little as 5×10^{-10} g of mercury/ml with high selectivity (only gold interferes). Methods of this type are especially suitable when a radioisotope of high specific activity of the element to be determined is not available. Some typical results are shown in Table I.

Summary—A radiometric method for the determination of submicrogram amounts of mercury (down to 5×10^{-10} g/ml) is described. The method is based on the exchange reaction between mercury and silver–110m dithizonate. Only palladium, gold, silver, and large amounts of copper and bismuth interfere in the determination, and must be removed.

Zusammenfassung—Es wird eine radiometrische Methode zur Bestimmung von Submikrogrammengen Quecksilber (bis herunter zu $5 . 10^{-10}$ g/ml) beschrieben. Die Methode beruht auf der Austauschreaktion zwischen Quecksilber und Silber–110m-Dithizonat. Nur Palladium, Gold, Silber und große Mengen Kupfer und Wismut stören bei der Bestimmung und müssen entfernt werden.

Résumé—On décrit une méthode radiométrique de dosage de quantités de mercure inférieures au microgramme (jusqu'à 5×10^{-10} g/ml). La méthode est basée sur la réaction d'échange entre le mercure et le dithizonate d'argent–110m. Seuls le palladium, l'or, l'argent, et de fortes quantités de cuivre et de bismuth gênent le dosage et doivent être éliminées.

Extractive photometric determination of thorium with arsenazo DAL

(*Received* 10 *October* 1966. *Accepted* 28 *November* 1966)

ARSENAZO III, (3,6-bis(2'-arsonophenylazo)-4,5-dihydroxy-2,7-naphthalenedisulphonic acid) is a well known photometric reagent, employed for determination of actinides, lanthanides, zirconium, hafnium, yttrium and scandium.[1] The methods with arsenazo III are usually used for homogeneous aqueous/non-aqueous solutions, because of the hydrophilic sulphonic groups in the reagent molecule. An extractive modification is based on the blocking of the hydrophilic character of the sulphonic acid groups by salt formation with *sym*-diphenylguanidine.[2-4] A considerable disadvantage of this procedure is the contamination of the aqueous phase by the excess of *sym*-diphenylguanidine, which makes it difficult to use without a preliminary removal of the *sym*-diphenylguanidine. This disadvantage can be eliminated by blocking the hydrophilic character of the sulphonic groups by sulphonamide formation. Arsenazo DAL, *i.e.*, the dianilide of 3,6-bis(2'-arsonophenylazo)-4,5-dihydroxy-2,7-naphthalenedisulphonic acid forms extractable metal chelates with the same elements as arsenazo III. The reagent can be used for the determination of thorium, DCTA being used as masking agent.

EXPERIMENTAL

Preparation of the reagent solution

Dissolve 93 mg of arsenazo DAL[5] in about 250 ml of 0·1*M* sodium hydroxide. Add 1000 ml of n-butanol and about 250 ml of 0·5*M* hydrochloric acid. Shake for 1–2 min and then separate the

* Extraction with tri-iso-octylamine was used.

layers. Wash the butanol phase 3–4 times with 250 ml of water until the pH of the aqueous phase is 5–6. The reagent is used directly after washing.

A 0·01*M* solution of the diammonium salt of DCTA (1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetra-acetic acid) is prepared by dissolving 3·46 g of DCTA in 200 ml of 0·1*M* ammonia and diluting to 1 l. with water.

Procedure

Dissolve a sample containing 1–25 μg of thorium in hydrochloric acid of such concentration as to yield 1·2*M* acid after dilution to 10 ml. Add 5 ml of 0·01*M* diammonium-DCTA and dilute with water to 10 ml. Add 10·0 ml of the reagent solution and shake vigorously for 3–5 min. After clarification of the butanol phase, place an appropriate volume of it in a 1-cm cell and measure the absorbance at 654 mμ against a reagent blank.

RESULTS AND DISCUSSION

Typical results for several samples are summarized in Table I. Amounts of 30–50 μmole of other metal ions such as copper(II), beryllium, magnesium, calcium, strontium, barium, zinc, cadmium, mercury(II), scandium, yttrium, lanthanides, aluminium, gallium, indium, thallium(III), titanium(IV), zirconium, hafnium, germanium, tin(IV), lead(II), vanadium(V), niobium(V), bismuth, chromium(III), molybdenum(VI), tungsten(VI), uranium(VI), manganese(II), iron(III), cobalt(II), nickel, ruthenium(IV) and palladium(II) do not interfere. In addition, 1-mmole amounts of alkali metal cations and common anions, such as chloride, bromide, nitrate, sulphate, perchlorate, acetate, EDTA, citrate, and tartrate, do not interfere.

Larger amounts, 1–4 mmole of uranium(VI), vanadium(V), niobium(V), cobalt(II), copper(II), iron(III), chromium(VI), molybdenum(VI), zinc and cadmium, can be removed by extraction from 7*M* hydrochloric acid with three 20-ml portions of 20% w/v solution of tri-iso-octylamine in xylene. The excess of acid is evaporated before the determination of thorium.

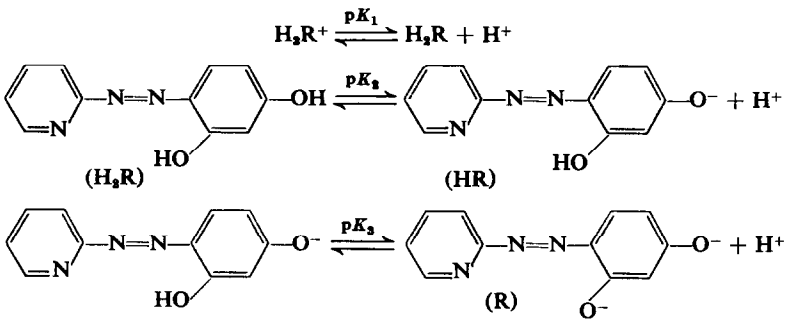
ANNOTATION

The stability constants of TAR and PAR complexes

(*Received* 1 *November* 1966. *Accepted* 20 *December* 1966)

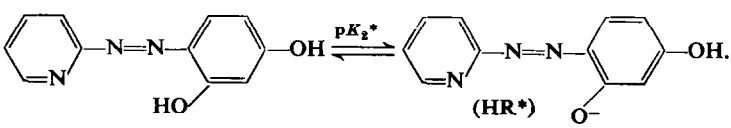
THE reagent 4-(2-pyridylazo)resorcinol (PAR) dissociates according to the reaction scheme



and 4-(2-thiazolylazo)resorcinol (TAR) behaves similarly. When these reagents form metal complexes, however, the complexes are formed at a pH too low for dissociation of a proton from the hydroxy group *para* to the azo group, and a proton is displaced from the *o*-hydroxy group although this proton would normally be the last to dissociate. The proton of the *o*-hydroxy group in the free reagent is involved in internal hydrogen bonding with the azo group, and so is normally less labile than the *p*-hydroxy group proton. In order to derive a stability constant for the complex formed between a metal ion M and the reagent, it is necessary to measure the equilibrium constant for the reaction

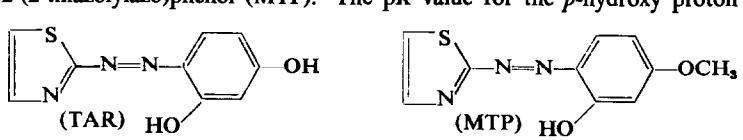
$$M + H_2R \rightleftharpoons MRH^* + H$$

where MRH* represents the complex, and then to ascribe a dissociation constant pK_2^* to the proton of the *o*-hydroxy group for the hypothetical situation in which it is assumed to be dissociated before the proton of the *p*-hydroxy group:



Most workers[1-3] have taken the view that this dissociation constant should be taken as equal to the dissociation constant that this group has *after* dissociation of the *p*-hydroxy proton (*i.e.*, $pK_2^* = pK_3$) but others[4] have taken the view that the dissociation constants should be interchanged (*i.e.*, $pK_2^* = pK_2$). Neither view is "correct", because it is impossible to assess the magnitude of the effect of the hydrogen bonding, but on balance it seems preferable to take pK_2^* as equal to pK_2, for the following reasons: (*a*) the contribution of internal hydrogen bonding to increase in p*K* for the *o*-hydroxy proton would be expected to be small compared with the inductive effect of the dissociated *p*-hydroxy group, and (*b*) there seems to be no reason why, in the absence of the hydrogen bonding effect, the *o*-hydroxy group should not be as least as acidic as the *p*-hydroxy group.

Support for this view comes from consideration of the dissociation constants for TAR and for 5-methoxy-2-(2-thiazolylazo)phenol (MTP). The p*K* value for the *p*-hydroxy proton in TAR in



aqueous medium is 6·2, and for the *o*-hydroxy proton in MTP is 6·7.[5] If we assume that the inductive effect of the methoxy group is very nearly that of the hydroxyl group, then the difference in the pK's would give a value of about 0·7 kcal/mole for the internal hydrogen bonding. This value may be compared with the 2 kcal/mole found by Franc[6] for the internal hydrogen bond in 2-methylresorcinol. It should be pointed out here that a change of 1 kcal/mole in ΔG is equivalent to a change of about 0·7 in pK.

It may be argued that the acidity of the *p*-hydroxy group is enhanced by resonance in the conjugated system (leading to a quinonoid structure for the resorcinol moiety), but this immediately leads to the difficulty that this resonance is not possible for the methoxy derivative, yet the acidity of the *o*-hydroxy group of MTP is not much less than that of the *p*-hydroxy group of TAR. This substantiates the view that the decisive factor is the hydrogen bonding and that the strength of the hydrogen bond is probably not more than 2 kcal/mole and may well be less than 1 kcal/mole.

It would be instructive to prepare the compounds 5-methoxy-2-(2-pyridylazo)phenol and 2-(2-thiazolylazo)resorcinol, and to measure the dissociation constants for the hydroxy group protons. The results should give a better estimate of pK_2* for PAR and TAR. Until this has been done, the best value to use for pK_2* would be pK_2 for the corresponding 5-methoxy compound.

At present, with two sets of conventions, it is necessary to perform a calculation to compare different sets of results. It will, of course, always be the case that the stability constants obtained will be artificial, but the difference between the "true" and reported values could be minimized by using the most realistic value for the estimate of pK_2*. As things stand, values for the stability constants obtained by Stanley and Cheney's method of calculation will be greater than those obtained by Sommer and Hniličková's method, by a factor of K_2/K_3 for the reagent concerned.

ROBERT A. CHALMERS

Summary—A discussion is given of the problem of ascribing dissociation constants in the hypothetical situation in which the protons of the hydroxy groups of TAR and PAR dissociate in the reverse of the normal order, and it is suggested that the *o*-hydroxy group should be regarded as intrinsically as acidic as the *p*-hydroxy group, and that the change in pK due to the internal hydrogen bonding is probably less than one unit.

Zusammenfassung—Das Problem der Zuordnung von Dissoziationskonstanten wird in der hypothetischen Situation diskutiert, in der die Hydroxylprotonen von PAR und TAR in umgekehrter Reihenfolge wie üblich dissoziieren. Es wird vorgeschlagen, die *o*-Hydroxylgruppe als im wesentlichen ebenso sauer wie die *p*-Hydroxylgruppe zu betrachten; die pK-Änderung auf Grund der inneren Wasserstoffbrücke kann möglicherweise kleiner als eine Einheit sein.

Résumé—On présente une discussion sur le problème de l'attribution de constantes de dissociation dans la situation hypothétique où les protons des groupements hydroxy des TAR et PAR se dissocient de façon inverse de l'ordre normal, et l'on suggère que le groupement *o*-hydroxy devrait être considéré comme intrinsèquement aussi acide que le groupement *p*-hydroxy, et que le changement de pK dû à la liaison hydrogène interne est probablement inférieur à une unité.

SEPARATION OF TIN FROM OTHER ELEMENTS BY PARTITION CHROMATOGRAPHY*

JAMES S. FRITZ and GARY L. LATWESEN
Institute for Atomic Research and Department of Chemistry,
Iowa State University, Ames, Iowa, U.S.A.

(*Received* 21 *November* 1966. *Accepted* 13 *January* 1967)

Summary—Tin(IV) is separated quantitatively from many other metal ions by reversed-phase chromatography on a column of solid support impregnated with an organic liquid. When aqueous 8*M* hydrochloric acid is used as the eluent, tin(IV) is retained on a column impregnated with methyl isobutyl ketone and is separated quantitatively from bismuth(III), cadmium(II), copper(II), lead(II), mercury(II) and zinc(II). For the separation of tin(IV) and molybdenum(VI) the aqueous eluting phase is 1*M* hydrochloric acid–3*M* sulphuric acid. A column impregnated with isopropyl ether quantitatively retains antimony(V) from 8*M* hydrochloric acid and permits tin(IV) to be eluted rapidly.

METHODS for the analytical separation of tin from other elements include precipitation, volatilization and distillation, ion-exchange, electro-deposition and solvent extraction. These methods have their virtues but also have certain shortcomings and limitations. The object of the present research is to examine some solvent extraction methods with the goal of adapting these to useful separations of tin from other metal ions by column partition chromatography.

It has been known for some time that tin(IV) is partially extracted from aqueous hydrochloric acid solutions into ethyl ether,[1] but little use has been made of this information because the extraction is not quantitative. Orlandini *et al.*[2] studied the extraction of tin and other metal ions from aqueous hydrochloric acid into 2-ethylhexanol. Goto, Kakita and Furukawa[3] gave data for extraction of various metal ions from aqueous hydrochloric acid into methyl isobutyl ketone (MIBK), and Maeck *et al.*[4] studied the effect of quaternary ammonium salts on extractions into MIBK.

In the present research, data are given for the MIBK batch extraction of tin(IV) from hydrochloric, hydrochloric–hydrofluoric and hydrochloric–sulphuric acid solutions. Based on these results methods are developed for quantitative separation of tin(IV) from other metal ions by reversed-phase partition chromatography. These methods separate tin(IV) from most other metal ions that frequently occur with tin and are reasonably quick and easy to carry out.

EXPERIMENTAL

Apparatus and materials

The columns used were prepared by the following method. A perforated Teflon disc (Fischer and Porter Co.) was supported on the end of a Pyrex tube by means of a Teflon straight union reducer tube fitting (Beckman Instruments, Inc.). A straight bore stop-cock with a Teflon plug was connected to the lower end of the Teflon tube fitting.

* Work was performed at the Ames Laboratory of the U.S Atomic Energy Commission. Contribution No. 1994.

Columns of any length could be prepared easily by cutting off the glass tubing at the proper length. The flow-rate was regulated by means of compressed air. A one-hole rubber stopper with a short piece of glass tubing through it was inserted at the top of the column. One end of the glass tubing was then connected to a compressed-air line. In most cases only a small amount of air pressure was required to maintain a sufficient flow-rate.

The solvents methyl isobutyl ketone (MIBK) and isopropyl ether (IPE) were Eastman White Label and were distilled before use.

Teflon-6, a hard polyfluoroethylene, was obtained as a pre-sieved 160–170 mesh or 60–70 mesh powder from Analytical Engineering Laboratories, Hamden, Connecticut. Before use the powder was washed with 6*M* hydrochloric acid and acetone and then air-dried.

Chromosorb W was obtained as the 80–100 mesh fraction from Johns-Manville Corp. It was washed with 6*M* hydrochloric acid and acetone. It was air-dried and then refluxed with dichlorodimethylsilane in carbon tetrachloride and methanol to obtain a product that was more useful for reversed-phase chromatography.

All aqueous eluents were prepared in the proper acid concentration and were equilibrated with equal volumes of the organic phase by shaking for at least 1 min in separatory funnels.

In general, metal ion stock solutions were prepared in aqueous hydrochloric acid and aliquots were taken for standardization. Tin(IV) fluoride was prepared by dissolving tin metal in hydrofluoric and nitric acids. Test portions of fluoride solutions were taken by weight rather than by volume.

Column preparation

Column supports were first slurried in a portion of equilibrated organic solvent and allowed to remain in contact with the organic solvent for several hours to assure complete saturation. The slurry was then transferred to the chromatographic column, and a porous Teflon disc was placed on top of it to prevent the top of the support from being disturbed during addition of sample or eluent. A sufficient amount of equilibrated acid was passed through the column to displace any interstitial organic solvent on the column. An amount of equilibrated acid equivalent to the interstitial column volume, V_m, was sufficient for this purpose. This step was important because any excess of organic phase could bleed off the column during elution and carry with it a portion of the solute intended to remain on the column. The organic phase was run down to the level of the top of the column before the equilibrated acid was added.

The equilibrated acid was run down to the level of the top of the column and the sample was then added to the column by pipette. The sample was carefully sorbed onto the column by lowering the liquid level to the top of the support and then washing the sides of the column with three consecutive portions of equilibrated aqueous eluent, each time running off liquid to lower the level to the top of the column before the next portion was added. The column was then treated with the appropriate equilibrated aqueous eluent, and the solute extracted into the stationary phase was then washed off the column with equilibrated organic eluent of the same type as that used as the stationary phase. By this procedure the column was reconditioned with the organic phase at the same time as the elution was taking place, thereby replacing any of the organic stationary phase that might have been lost during the preceding elution. After repetition of the step of forcing enough equilibrated acid through the column to remove the interstitial organic phase, the column was ready to be used again and was in exactly the same condition as it was originally.

Methods of analysis

Tin(IV) was determined by the following procedure. The solution was acidified with hydrochloric acid to a pH of 1 or less to prevent the tin(IV) from hydrolysing. Then 2 g of sodium chloride and a moderate excess of EDTA were added and the solution was boiled for 5 min. The solution was then cooled to approximately 50° and buffered to pH 3 5 with ammonium acetate. With NAS as indicator (Naphthyl Azoxine S)[7] the solution was then titrated just past the end-point with a standard copper solution and then titrated back to the red end-point with EDTA. The second end-point was sharper than the first, thereby justifying the double back-titration.

When large amounts of hydrochloric acid were present in the tin sample most of it was neutralized with sodium hydroxide before the solution was buffered In this case no additional sodium chloride was added.

If organic solvents were present in the tin sample, they were first removed by evaporation. A small amount of sulphuric acid was added to the sample to prevent volatilization of tin(IV) chloride. Small amounts of MIBK or IPE in the sample did not interfere with the titration.

When hydrofluoric acid was present, it was first removed by fuming with sulphuric acid in a platinum evaporating dish. The residue was then dissolved in 6*M* hydrochloric acid and transferred to a 250-ml beaker for analysis

Antimony(III) was determined by titration with standard potassium bromate, using α-naphthoflavone as indicator.[5] Antimony(V) was determined by the same procedure after reduction with sulphurous acid and boiling.

Mercury(II) was determined by titration with thioglycerol, using the thio analogue of Michler's ketone as indicator.[6] If an organic phase was present, it was rendered soluble by the addition of methanol; the final titration was performed in an aqueous methanol solution containing up to 50% v/v of methanol.

Cadmium, copper, lead and zinc ions were determined by titration at pH 5·5 with EDTA, NAS being used as indicator.[7] Bismuth was titrated directly at pH 2 with EDTA, Xylenol Orange being used as indicator. Molybdenum was determined gravimetrically as the 8-hydroxyquinolinate.[8]

Distribution ratios

Distribution ratios were obtained by shaking 20 ml of the aqueous phase containing a known amount of solute with 20 ml of the equilibrated organic phase. After equilibration in a separatory funnel, the phases were separated and one or the other (or both) was analysed for solute content. Because the phases were not pre-equilibrated, volume corrections were made where necessary.

RESULTS AND DISCUSSION

Distribution ratios

The degree of extraction and the distribution ratios for extraction of antimony(III) and (V), molybdenum(VI) and tin(IV) from aqueous hydrochloric acid into methyl isobutyl ketone (MIBK) are shown in Fig. 1. From approximately 6–8*M* hydrochloric acid, for all but antimony(III) there is a high degree of extraction. In Table I,

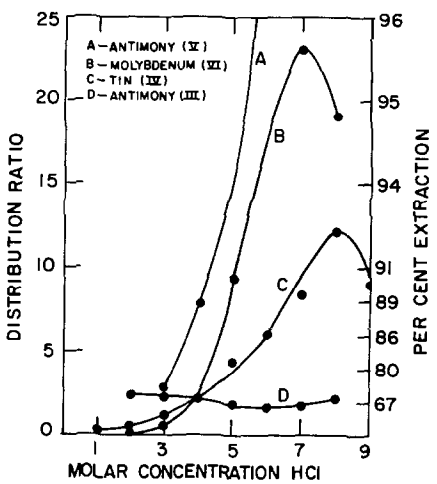

FIG. 1.—Distribution ratios for extraction of some metal ions from aqueous hydrochloric acid into MIBK.

data are given for batch extraction of several other elements known to form chlorocomplexes. These data indicate that a multistage partition technique should successfully separate tin(IV), antimony(V) and molybdenum(VI) from the other elements studied, as well as from a number of other metal ions known not to form chlorocomplexes readily or to be extracted into ketone solvents.

The effect of hydrofluoric and sulphuric acids on the extraction of tin(IV) and molybdenum(VI) from aqueous hydrochloric acid into MIBK was also studied (Table II). The data indicate that at relatively low concentrations of hydrochloric acid the extractabilities of both tin(IV) and molybdenum(VI) increase rapidly as the concentration of sulphuric acid is increased, and the extractability of tin increases

TABLE I —DISTRIBUTION RATIOS OF METAL IONS BETWEEN EQUILIBRATED MIBK AND HYDROCHLORIC ACID

Metal ion	Distribution ratio [HCl], *M*							
	1	2	3	4	5	6	7	8
Bi(III)	0 22	—	0 10	—	0 016	—	0 007	0 038
Cd(II)	—	0 014	—	—	0 06	—	—	0·95

Zn(II)	—	0 035	—	—	0 04	—	—	0·26

faster than that of molybdenum. Addition of hydrofluoric acid to the hydrochloric acid system lowers the extractability of both tin and molybdenum, by reducing the concentration of extractable chloro-complexes and increasing the concentration of non-extractable fluoro-complexes. The distribution ratios in Table II also show that the extraction of tin(IV) containing no chloride is negligible from 1–10*M* hydrofluoric acid. This is apparently in gross disagreement with one published report[9] claiming essentially 100% extraction of tin(IV) from hydrofluoric acid into another oxygenated organic solvent (ethyl ether).

Edwards and Voigt[10] studied the extraction of antimony(III) and (V) from aqueous hydrochloric acid into di-isopropyl ether. They found a distribution ratio of approximately 200 for antimony(V) from 6·5–8*M* hydrochloric acid; they reported the extraction of antimony(III) to be negligible under the same conditions. We obtained

a distribution ratio of 41 for extraction of antimony(V) from 8*M* hydrochloric acid into di-isopropyl ether, and distribution ratios of 0·006 for tin(IV), 3·3 for arsenic(III) and 0·12 for molybdenum(VI) under the same conditions. It has been shown by ultraviolet spectroscopy that solvated $HSbCl_6$ is the species extracted from 6*M* hydrochloric acid into di-isopropyl ether.[11]

Column separations

Theory. Separation of two substances by batch type solvent extraction requires that one substance be quantitatively extracted while the extraction of the other under the same conditions is essentially nil. Separations based on partition chromatography,

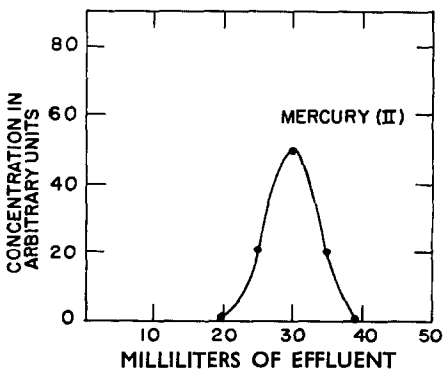

FIG. 2.—Curve for elution of 400 μmole of mercury(II) with 8*M* hydrochloric acid from a 25 × 1·3 cm Teflon-6 (160–170 mesh) column containing 12 ml of MIBK.

however, are feasible whenever there is merely a reasonable *difference* in the extractabilities of the two substances. Several successful separations of metal ions by reversed-phase partition chromatography have been reported by various workers.[12–14] In our work a special Teflon-6 was used to retain MIBK as the stationary phase, while an aqueous phase was used to introduce the sample and as the eluent to separate the substances on a column. Chromosorb W, treated with dichlorodimethylsilane to make it retain MIBK in preference to the aqueous phase, was also used but was found to be somewhat inferior to the Teflon-6.

If a separation proceeds by pure partition chromatography (*i.e.*, there is no adsorption or ion-exchange interaction between the solutes and the solid support), it can be shown that the following relationships exist between the batch distribution ratio, D, and the retention volume, V_r, when a solute is eluted from a column.

$$V_r = DV_s + V_m$$

where V_r is the retention volume, *i.e.*, the volume of eluent required for the eluted solute to reach its maximum concentration in the effluent; D is the batch distribution ratio for extraction of the solute from the aqueous to the organic phase; V_s is the volume of the stationary liquid phase (MIBK, for example); V_m is the volume of the mobile phase in the column (*i.e.*, the interstitial volume); all volumes are expressed in the same units (usually ml).

To test this equation, a sample of mercury(II) was eluted with 8*M* hydrochloric acid from a 25 × 1·3 cm column of 160–170 mesh Teflon-6 impregnated with MIBK (see Fig. 2). In this experiment $D = 1{\cdot}39$, $V_s = 10{\cdot}5$ ml and $V_m = 12$ ml. The

calculated V_r is 26·5 ml which is in reasonably good agreement with the experimental V_r of 30·0 ml. In this experiment the number of theoretical plates in the column was calculated from the relationship, $N = 8(V_r/\beta)^2$, where N is the number of theoretical plates and β is the width of the elution curve (in ml) at the concentration $c = c_{max}/e = (0{\cdot}368)c_{max}$. In this case N was found to equal 72 theoretical plates, corresponding to an HETP of about 3·5 mm.

Separation of tin(IV) and molybdenum(VI). The distribution ratios given in Table II indicate that the greatest separation factor for tin and molybdenum occurs where the sulphuric acid is 3*M* and the hydrochloric acid concentration ranges from 0·5 to

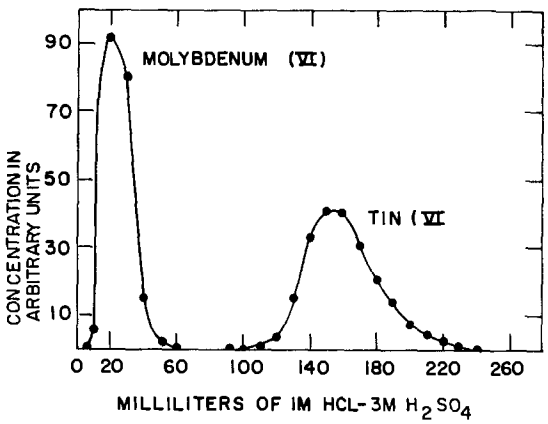

FIG. 3. Elution of 400 μmole each of molybdenum(VI) and tin(IV) from a 40 × 1 1 cm column of dichlorodimethylsilane-treated Chromosorb W impregnated with MIBK.

TABLE III.—SEPARATION OF TIN AND MOLYBDENUM

Metal ion	Added, *mmole*	Found, *mmole*	Error, %
Mo(VI)	0 3196	0·3203	+0 2
	0·3196	0 3186	−0 3
Sn(IV)	0·4498	0 4511	+0 3
	0 4498	0 4509	+0·2
	0·4498	0 4489	−0·2

1*M*. An eluent of 1*M* hydrochloric acid–3*M* sulphuric acid and a MIBK stationary phase was used for the separation. With this eluent a separation factor of 11 is obtained, and the distribution ratio of tin(IV) is sufficiently high for tin(IV) to be held on the column while the molybdenum(VI) is eluted.

An elution curve for the separation of approximately 400 μmole of tin and 400 μmole of molybdenum on a 40 × 1·1 cm column of 80–100 mesh Chromosorb W is given in Fig. 3. Results for quantitative separations are given in Table III.

Separation of tin(IV) from bismuth(III), cadmium(II), copper(II), mercury(II), lead(II) or zinc(II). A comparison of the distribution ratios for the metal ions given in Table I and those given in Fig. 2 for tin(IV) indicates the possibility of separating tin(IV) from every metal ion listed in Table I by reversed-phase chromatography with MIBK as the stationary phase and 8*M* hydrochloric acid as the mobile phase.

Although slightly more favourable separation factors can in some cases be obtained at somewhat lower acid concentrations, the equilibrium between the phases is more rapid at 8*M* hydrochloric acid than it is in the range from 3*M* to 7·5*M* acid.

For quantitative separations a 25 × 1·3 cm column of 160–170 mesh Teflon-6 impregnated with MIBK is employed. The less extracted element is eluted with 30 ml of 8*M* hydrochloric acid at a flow-rate of 2–3 ml/min. Mercury(II) has a higher distribution ratio ($D = 1{\cdot}39$) causing it to be held on the column longer; mercury is eluted in the 15–45 ml effluent fraction. After the elution with 8*M* hydrochloric acid is completed, tin(IV) is washed off the column with 20 ml of MIBK at 4–5 ml/min

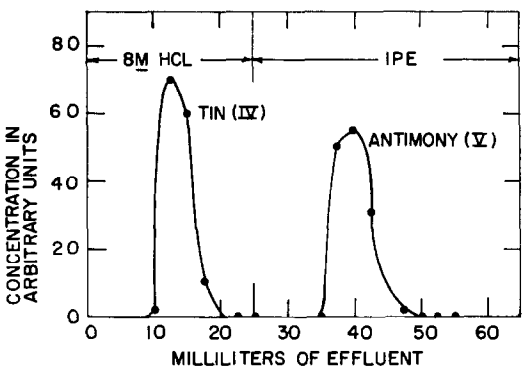

FIG. 4.—Elution of 400 μmole each of tin(IV) and antimony(V) with 8*M* hydrochloric acid from a 18 × 1·3 cm column of 160–170 mesh Teflon-6 impregnated with MIBK.

flow-rate. The column is now ready for the next sample. Quantitative results were obtained for the separation of binary mixtures of tin(IV) and each of the following: bismuth(III), cadmium(II), copper(II), lead(II), mercury(II) and zinc(II).

TABLE IV.—SEPARATION OF TIN AND ANTIMONY

Metal	Added, *mmole*	Found, *mmole*	Error, %
Sb(V)	0 3666	0 3666	+0 0
	0·3666	0 3656	−0 3
	0 3666	0 3681	+0 4
Sn(IV)	0 3911	0 3916	+0 1
	0·3911	0 3903	−0 2

Separation of tin(IV) and antimony(V). The distribution ratios of 41 and 0·006 for antimony(V) and tin(IV), respectively, from 8*M* hydrochloric acid into isopropyl ether indicate that a very effective separation should be possible by reversed-phase chromatography. Elution curves for the separation of approximately 400 μmole each of tin and antimony are given in Fig. 4. After complete elution of the tin(IV) with 8*M* hydrochloric acid, the antimony(V) is eluted with 30 ml of equilibrated isopropyl ether at a flow-rate of 5 ml/min. Continued elution with 8*M* hydrochloric acid would cause the antimony to appear after 50 ml of effluent had been collected. Quantitative results for separations are given in Table IV.

Zusammenfassung—Zinn(IV) wird durch Chromatographie mit umgekehrten Phasen auf einer Saule aus einem festen Trager, der mit einem organischen Losungsmittel beladen ist quantitativ von vielen anderen Metallionen getrennt. Mit waßriger 8*M* Salzsaure als Elutionsmittel wird Zinn(IV) auf einer mit Methylisobutylketon impragnierten Saule zuruckgehalten und quantitativ von Wismit(III), Cadmium(II), Kupfer(II), Blei(II), Quecksilber(II) und Zink(II) getrennt. Zur Trennung von Zinn(IV) und Molybdan(VI) dient als waßrige Elutionsphase 1*M* Salzsaure-3*M* Schwefelsäure. Eine mit Isopropylather beladene Saule halt Antimon(V) aus 8*M* Salzsaure quantitativ zuruck und gestattet rasche Elution von Zinn(IV).

Résumé—On sépare quantitativement l'étain (IV) de nombreux autres ions métalliques par chromatographie à phases inversées sur une colonne de support solide imprégnéd'un liquide organique. Lorsqu'on utilise l'acide chlorhydrique aqueux 8*M* comme éluant, l'étain (IV) est retenu sur une colonne imprégnée de méthylisobutylcétone et séparé quantitativement de bismuth (III), cadmium (II), cuivre (II), plomb (II), mercure (II) et zinc (II). Pour la séparation de l'étain (IV) et du molybdène(VI), la phase aqueuse éluante est l'acidechlorhydrique 1*M*-acide sulfurique 3*M*. Une colonne imprégnée d'éther isopropylique retient quantitativement l'antimoine (V) de l'acide chlorhydrique 8*M* et permet à l'étain (IV) d'être rapidement élué.

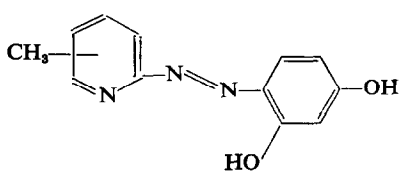
STERIC HINDRANCE EFFECTS IN THE USE OF HETEROCYCLIC AZODYESTUFFS AS SPECTROPHOTOMETRIC REAGENTS

W. J. GEARY® and F. BOTTOMLEY
Department of Chemistry and Metallurgy, Lanchester College of Technology, Coventry, England

(*Received* 14 *November* 1966. *Accepted* 9 *January* 1967)

Summary—The heterocyclic azo dyestuffs 4-(*n*-methyl-2-pyridylazo)-resorcinol (where $n = 3', 4', 5', 6'$) have been prepared, and their possible use as spectrophotometric reagents investigated. The dyestuffs are shown to function analogously to the parent ligand 4-(2'-pyridylazo) resorcinol (PAR) in giving red complexes with the ions Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} and UO_2^{2+}. Steric effects resulting from the position of the methyl group in the heterocyclic ring are shown to occur in relation both to the spectra of the dyestuffs themselves and to the sensitivity of their reactions with the metal ions.

SINCE the introduction of the reagent 1-(2'-pyridylazo)-2-naphthol (PAN) as a spectrophotometric reagent,[1] and the subsequent introduction[2] of the analogous compound 4-(2'-pyridylazo)resorcinol (PAR), the use of both of these reagents and of other heterocyclic azo dyestuffs for spectrophotometric purposes has now developed to the stage where analytical procedures for some 15 elements have been published. However, most of these methods are based on the determination of specified metals (see, *e.g.*, refs. 3–6), and there have been relatively few direct attempts to investigate the spectrophotometric sensitivity in terms of the structure of the reagent or the thermodynamic stability of the complexes formed.[7–9] As part of a programme to investigate such correlations we have prepared the methyl homologues of PAR (ligands I–IV), in which the methyl substituent is respectively in the 3-, 4-, 5-, and 6-positions of the heterocyclic ring. The spectra of the dyestuffs, and of their com-



I : 3-Me-PAR
II : 4-Me-PAR
III : 5-Me-PAR
IV : 6-Me-PAR

plexes with a series of bivalent metal ions have been obtained over a wide pH range. The absorbance–concentration curves have been investigated, and the spectrophotometric sensitivities of the reagents for the metal ions have been calculated.

EXPERIMENTAL

Preparation of ligands

Heterocyclic azo dyestuffs are usually obtained by the method of Tschitschibabin.[10,11] In this investigation it was found most convenient to prepare the ligands in the free base form rather than as the disodium salt. The appropriate 2-amino-methylpyridine (12 g) was dissolved in absolute ethanol (20 ml) and to this solution was added a solution of clean metallic sodium (2·4 g) in absolute ethanol (40 ml) followed by isoamyl nitrite (15·2 ml, 12 g). The solution was heated under reflux for 3-4 hr,

and the brown diazonium salt thus prepared was used directly without isolation. Resorcinol (14 g) was dissolved in water (20 ml), and to the solution was added the well-cooled suspension of the diazonium salt. The latter was always added to the resorcinol to prevent possible coupling of two molecules of diazonium salt with one of resorcinol. The resultant solution was allowed to stand for 48 hr, during which time the colour changed from the light brown of the diazonium salt to the dark brown-red of the dyestuff. The reaction mixture was diluted to 2 l. with water (it was found that if the alcohol content was greater than 5% the products were difficult to isolate), and then acidified to pH 4 5 with hydrochloric acid (8*M*). The flocculent precipitate so obtained was allowed to stand overnight, filtered, and thoroughly washed with water, in which resorcinol, the methylaminopyridines, and any sodium chloride formed in the acidification are soluble. Finally, after air-drying, the products were thoroughly washed with dry ether to remove any isoamyl nitrite. Analytical results are given in Table I.

6-Me-PAR	62 3	4 9	18 2	162
Calc for Me-PAR	62 86	4 85	18 32	

Spectral measurements

All spectral measurements were made in matched 1-cm silica cells at room temperature, a Unicam SP 500 spectrophotometer being used. The range 340–520 mμ was covered in 5-mμ increments for the ligand spectra, and 450–620 mμ for the spectra of the complexes.

Reagents

All reagents were of reagent grade quality; sodium perchlorate was recrystallized before use. Because of the extremely high spectrophotometric sensitivity of the dyestuffs for metal ions, it was necessary to redistil distilled water from an all-glass still before use.

Procedures

Ligand spectra. Stock solutions of the dyestuffs (40 μg/ml) were prepared by direct weighing, known volumes of sodium hydroxide being added as required for dissolution of the free dye form. For 3-Me-PAR this concentration was found to be too low and an 80 μg/ml stock solution was used. Solutions for optical measurement were prepared by diluting 10 ml of the stock solution to 50 ml in graduated flasks, together with the appropriate quantities of buffer solutions (Clarke and Lubs[12], Sorenson and Walbum[13]) and sodium perchlorate to bring the ionic strength to 0 1. Measurements were made against blank solutions containing no dyestuffs over the pH range 1 6–12·5 at intervals of 0·6 pH unit. The pH was checked with a Cambridge pH-meter.

Spectra of complexes. The spectra were obtained for solutions prepared by mixing 10 ml of metal solution (10·00 μg M/ml), 2 ml of dyestuff solution (500 μg/ml) and 30 ml of buffer solution, and diluting to 50 ml in graduated flasks. The pH range covered was 5–10, and the ionic strength was 0·1. The solutions were measured against optical blanks prepared in the same fashion, but omitting the metal ion For the spectra of the uranyl complexes, which had a lower molar absorptivity, the overall uranyl concentration was increased five fold. Measurements were made 20 min after preparing the solutions, except in the case of the uranium complexes, for which it was found that the absorbance increased with time. After 24 hr it was found to be constant, and hence the uranium solutions were allowed to stand for this length of time before measurement. Random checks showed no detectable change in absorbance of the complexes over a period of 72 hr.

RESULTS AND DISCUSSION

Ligand spectra

Typical results are shown for 5-Me-PAR in Fig. 1. It is seen that it is possible to recognize the peaks due to each of the chromophoric species, namely the protonated dye H_3R^+, the free dye H_2R, and the anionic forms HR^- and $R^{=}$. The wavelengths of maximum absorption, and molar absorptivities are given in Table II. At the

* From ref. 2.
† Absorbance/μg/ml.
‡ From linear part of plot.

It was found that for all complexes between the dyestuffs and nickel and zinc at pH values below 7·0 the complexes precipitated, and hence the absorbance could not be measured. For the uranium complexes there was no significant absorption in the visible region at pH less than 8·0.

Beer's law plots were obtained for all metal ions and dyestuffs used, at the pH and λ_{max} given in Table III. The stock solutions for this procedure were: dyestuff — 500 μg/ml, metal ion —10 μg/ml, except uranium — 50 μg/ml. The solutions had the compositions:

3-Me-PAR: 1 ml of dye solution + x ml of metal-ion solution (x = 0·2–1 0 ml, in increments of 0·2 ml) + 30 ml of buffer, diluted to 50 ml.

4- and *5-Me-PAR*: 2 ml of dye solution + x ml of metal-ion solution (x = 1·0–5 0 ml, in increments of 0 5 ml) + 30 ml of buffer, diluted to 50 ml.

6-Me-PAR: 2 ml of solution + x ml of metal-ion solution (x = 1·0–5 0 ml, in increments of 0 5 ml) + 30 ml of buffer, diluted to 50 ml.

All solutions were measured against a blank containing the appropriate quantity of buffer and dyestuff.

The Beer's law plots are linear over the concentration range given for 3-, 4-, and 5-Me-PAR, and for 6-Me-PAR are very shallow curves.

Acid dissociation constants

There have been many attempts to use spectral data for calculation of pK_a values of dissociable ligands, mainly based on the methods of Dyrssen,[14] Irving,[15] and Schwarzenbach.[16] However, these are normally applicable to systems with two widely separated dissociations; in the systems described here, there are at least three dissociations:

$$\text{protonated} \rightleftharpoons \text{free dye} \rightleftharpoons \text{mono-anionic} \rightleftharpoons \text{di-anionic}$$

with the possibility of further protonation in the most strongly acidic solutions. Although each of these species is recognizable from the spectra obtained, accurate pK_a values were not obtained, because of the complexity of the equilibria involved. Nevertheless, it is apparent from the range of pH values for which each species is present that $pK_{NH} \sim 3$, $pK_{(OH)_1} \sim 6$, and $pK_{(OH)_2} \sim 11$, in accordance with previous values for PAR and PAN,[7,9] but the values for 3-Me-PAR are about 1·5 units higher. It is well-known that in *o*-hydroxy azo dyestuffs there is intramolecular hydrogen bonding between the OH group and the adjacent azo nitrogen, giving a five-membered ring. This is considered[7,17] to account in part for the *p*-hydroxy group ionizing before the hydroxy group in PAR. There should be a greater spectral shift when the hydrogen-bonded OH group ionizes than for the *p*-OH ionization. Comparison of the measured shifts (Table IV) shows beyond doubt that the *p*-OH-group does ionize first, the shifts for the *o*-OH ionization being some 3–4 times as large. The intensities

TABLE IV.—BATHOCHROMIC SHIFTS IN SPECTRA OF DYESTUFFS

	3-Me-PAR mμ	4-Me-PAR mμ	5-Me-PAR mμ	6-Me-PAR mμ	PAR[9] mμ
Free dye → protonated	0	8	30	11	12
Free dye → mono-anionic	18	25	30	19	32
Mono-anionic → di-anionic	67	63	70	71	70

of the bands for all the dyestuffs are consistent, the order being mono-anionic > free dye ~ protonated; the di-anionic form does not fall into a regular pattern, probably because of the difficulty in obtaining the dyestuffs exclusively in this form. Intensities are uniformly lowest for the 3-methyl isomer, for which consideration of molecular models shows that there is considerable steric hindrance to the *trans* planar form

(methyl group *trans* to *o*-hydroxy) required for maximum delocalization and hence greatest intensity.

Consideration of the metal-dyestuff spectra shows a number of very interesting points. The order of molar absorptivities noted in the spectra of the dyestuffs alone is retained, the low values for 3-Me-PAR undoubtedly again being steric in origin. The complexes of 4-Me-PAR and 5-Me-PAR obey Beer's law over a much wider range of concentration than those of the other two isomers, the values for the 4- and 5-methyl isomers being close to those obtained for PAR. However, since these ligands are less easy to prepare than PAR, there does not seem to be any virtue in using these reagents instead of PAR for spectrophotometry. For 6-Me-PAR there is no measurable complex with the uranyl ion, presumably because of steric interactions, although with the other complexes the effect of the methyl group in the 6 position is small. The concentration range over which Beer's law applies exactly to the complexes of this ligand is rather restricted, though the very high sensitivity with zinc may well have analytical applications.

We are now engaged in the determination of the solution stoichiometries of the complexes of these ligands. Use of the mole ratio method has previously given unusual results with azo dyestuffs, apparent mole ratios of up to 4:1 dyestuff:metal being obtained for PAR,[2] in contrast to the potentiometric data which indicate only 1:1 and 2:1 complexes.[8,9] Other workers have obtained values of 8:1,[18] 15:1,[19] and in one case over 50:1.[20] With the ligands at present under investigation, apparent stoichiometries approaching 4:1 are obtained, and it appears that for complete colour formation a considerable excess of dyestuff is required.

Zusammenfassung—Die heterocyclischen Azofarbstoffe 4-(*n*-Methyl-2′-pyridylazo)resorcin (mit $n = 3',4',5',6'$) wurden dargestellt und ihre Anwendungsmoglichkeit als spektrophotometrische Reagentien gepruft. Es wird gezeigt, daß die Farbstoffe analog wirken wie ihre Muttersubstanz 4-(2′-pyridylazo)resorcin (PAR): sie geben rote Komplexe mit den Ionen Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} und UO_2^{2+}. Auf der Lage der Methylgruppe im heterocyclischen Ring beruhende sterische Effekte manifestieren sich sowohl in den Spektren der Farbstoffe selbst als auch in der Empfindlichkeit ihrer Reaktionen mit den Metallionen.

Résumé—On a préparé les colorants azo hétérocycliques 4-(*n*-méthyl 2′-pyridylazo) résorcinol (où $n = 3', 4', 5', 6'$) et étudié leurs possibilités d'emploi comme réactifs spectrophotométriques. On montre que ces colorants ont un comportement analogue à celui du ligand apparenté 4-(2′-pyridylazo) résorcinol (PAR) en donnant des complexes rouges avec les ions Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} et UO_2^{2+}. On montre que des effets stériques résultant de la position du groupe méthyle sur le noyau hétérocyclique se manifestent en relation tant avec les spectres des colorants eux-mêmes qu'avec la sensibilité de leurs réactions avec les ions métal liques.

EXTRACTION OF REDUCED MOLYBDOSILICIC ACID AND ITS APPLICATION TO THE DETERMINATION OF TRACES OF SILICON

YACHIYO KAKITA and HIDEHIRO GOTO
Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan.

(*Received* 13 *June* 1966. *Revised* 10 *December* 1966. *Accepted* 7 *January* 1967)

Summary—It is difficult to find satisfactory organic solvents for the extraction of reduced molybdosilicic acid, but extraction is possible with isoamyl or isobutyl alcohol if the acid concentration of the aqueous solution is increased before the extraction, the best results being obtained by extraction with isoamyl alcohol from 3·5–4·5*N* sulphuric acid medium. This makes the reduced molybdosilicic acid method much more sensitive and permits the determination of microgram amounts of silicon in various kinds of high-purity metals.

THE reduced molybdosilicic acid method is very often used for the micro-determination of silicon but the reduced molybdosilicic acid is not extracted easily into organic solvents. Reduced molybdophosphoric acid, however, is easily extracted by organic solvents and can be separated in this way from reduced molybdosilicic acid, and phosphorus determined.[1] It has been reported that reduced molybdosilicic acid can be extracted into chloroform after addition of oxy-ethylated fatty amines to the aqueous solution.[2,3] We have found that reduced molybdosilicic acid can be extracted easily with isoamyl alcohol if the acid concentration of the aqueous layer is increased. Optimal conditions for the extraction have been established, and the method applied to the determination of microgram amounts of silicon.

EXPERIMENTAL

Solvent extraction of reduced molybdosilicic acid

Molybdosilicic acid can be reduced in various ways. We used reduction with iron(II) with hydrofluoric acid present to avoid the effect of phosphorus and arsenic, because these two methods have been generally used in the Japanese Industrial Standard Methods.[4]

Reagents

Standard silicon solution. After preliminary drying at 110° for about 1 hr, 0 2140 g of pure silicon dioxide was mixed with 1 g of anhydrous sodium carbonate, fused in a platinum crucible, and dissolved in water to make 500 ml of solution containing 200 μg of silicon per ml. This stock solution was diluted accurately 100-fold.

Hydrogen peroxide solution, 100-volume (1 + 1) and (1 + 29).

Sulphuric acid, 5, 12, 15 and 18*N*.

Ammonium paramolybdate tetrahydrate solution, 10% w/v.

Hydrofluoric acid (10 + 48).

Iron (II) ammonium sulphate solution, 15% w/v in sulphuric acid (1 + 9).

Tin (II) chloride solution, 10% w/v in 5*N* sulphuric acid, freshly prepared.

All reagents were stored in polyethylene bottles.

Procedure

A solution containing silicon was placed in a polyethylene separatory-funnel together with 1·7 ml of 5*N* sulphuric acid and was diluted to 25 ml Then 6 ml of ammonium molybdate solution were added and the mixture was allowed to stand at room temperature for 5 min.[4] After the addition of

7 ml of hydrofluoric acid (10 + 48), 5 ml of iron(II) ammonium sulphate solution were added within 30 sec and the solution was mixed. The colour produced is stable and constant from 30 sec to 1 hr after the addition of iron(II)[4]. After a few minutes, 1 ml of tin(II) chloride solution was added and mixed, and then 20 ml of 12*N* sulphuric acid were added. The solution was next shaken for about 30 sec with 10 ml of isoamyl alcohol to extract the reduced molybdosilicic acid. The organic phase was transferred to a dry test-tube, and then, after any water in it had become deposited on the wall of the tube, was transferred to a cuvette and its absorbance at 800 mμ was measured and corrected for the reagent blank. The absorption spectrum is shown in Fig. 1. Beer's law is obeyed, and the molar absorptivity is $18{\cdot}5 \times 10^3$. The calibration curve must be checked for each new batch of reagents.

Choice of solvent

The reduced molybdosilicic acid could not be extracted with benzene, chloroform or dichloroethane; it could be extracted with methyl isobutyl ketone but the colour was unstable. Extraction

III—Blank plus 1 μg of silicon/ml of extract

with either isoamyl or isobutyl alcohol gave a colour stable for about 50 min, but the separation of the phases was more rapid with isoamyl alcohol, and this alcohol was therefore used subsequently.

Equilibrium time

It was found that shaking for 20 sec is sufficient to yield a constant absorbance for a fixed amount of silicon, and the extraction time was therefore set at 30–50 sec. If the shaking time is too long, the separation of the phases is slow and there tends to be more water in the organic phase.

Effect of acidity on the extraction and reduction

Reduced molybdosilicic acid cannot be extracted at the acidity needed for the reduction but it can be extracted easily with isoamyl alcohol if the acidity of the solution is increased. The optimal acidity range was determined by varying the amount of acid added; to avoid generation of heat, 12 or 15*N* sulphuric acid was added and the aqueous-phase was diluted to about 60 ml. Table I shows that the optimal acidity for extraction is 3·5–4·5*N* sulphuric acid.

Table II shows the effect of acidity on the reduction reaction, and shows that initial addition of 1·2–2·5 ml of 5*N* sulphuric acid does not affect the absorbance.

Effect of iron(III)

Iron(II) is used as the reducing agent and therefore the presence of iron(III) cannot be avoided. If the method is used for steel analysis, large amounts of iron(III) will be present. A solution containing 10 μg of silicon was carried through the procedure after the addition of 0·05 and 0·10 g of iron(III) sulphate. The absorbance was extremely low and it was observed that the blue colour became slightly pale on the addition of sulphuric acid before extraction. This was considered to be due to oxidation of the reduced molybdosilicic acid by iron(III) when the acidity was increased. Attempts to reduce the iron(III) to iron(II) showed that tin(II) chloride was the most suitable reductant.

The results in Table III indicate that this source of interference can be almost completely removed by reduction of the iron(III) with tin(II).

Iron(III) has another effect however, it is generally regarded as interfering in the production of the initial, unreduced, form of the heteropoly acid. The usual practice is to increase the amount of ammonium molybdate to prevent this interference. The effect of varying the amount of ammonium molybdate and iron(III) was studied, and the results are shown in Fig 2.

The effect of about 0 06 g of iron on the initial heteropoly acid formation can be prevented by the addition of 6 ml of 10% ammonium molybdate solution. This volume must be increased if iron is present in larger amount and the presence of 0 1 g of iron requires 12 ml of the molybdate solution.

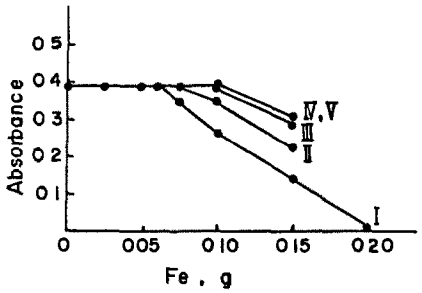

FIG. 2.—Interaction of iron(III) and ammonium molybdate in determining absorbance of 6 μg of silicon.
Ammonium molybdate solution added. I—6 ml, II—8 ml; III—10 ml; IV—11 ml; V—12 ml.

Effect of various ions

Sodium. Since sodium hydroxide is often used for the dissolution of the sample and for the neutralization of the sample solution, the effect of sodium sulphate formed from it was examined. As shown in Table IV, the presence of sodium sulphate up to 3 g (equivalent to 1 7 g of sodium hydroxide) had almost no effect.

Other ions. As shown in Table V, many of the ions examined showed no effect when present in amounts up to 125 mg (the maximum added) but some had a large effect even when present in small amount. Some of the ions are precipitated as their hydroxides or sulphates, and the amount actually present in the solution will be much lower than the amount shown. The extraction procedure has the advantage that the presence of precipitates does not affect the determination of silicon. As might be expected, the interference of germanium is positive and very large and cannot be prevented by the addition of hydrofluoric acid.

DETERMINATION OF MICROGRAM AMOUNTS OF SILICON

In iron and steel

Procedure. To 0·2 g of the sample, in a polyethylene beaker, add 8 ml of 5*N* sulphuric acid and 5 ml of hydrogen peroxide (1 + 1) and warm the beaker in a water-bath to effect dissolution. Continue the heating to decompose the excess of hydrogen peroxide and add 1*N* potassium permanganate dropwise until a faint pink colour persists. Decompose the excess of permanganate by dropwise addition of hydrogen peroxide (1 + 29), and heat the solution in a water-bath to decompose the excess of peroxide. Cool the solution and transfer it to a 100-ml standard flask, dilute it to the mark with water and mix it thoroughly. Transfer 25 ml of this solution by pipette to a polyethylene separatory-funnel, add 6 ml of ammonium molybdate solution (12 ml for a 0·4-g sample) and carry out the procedure described. The decomposition of hydrogen peroxide is difficult in the blank test and it is advisable to add exactly the same amount (about 20 mg) of iron with a low silicon content, to both the sample and the blank.

Calibration curve. Dissolve several 0·2-g pieces of iron with a low silicon content (or portions of an iron salt from which silicon has been removed) in 7 ml of 5*N* sulphuric acid and 5 ml of hydrogen peroxide (1 + 1), decompose the excess of peroxide, oxidize each of the solutions, and cool and transfer them to 100-ml standard flasks. To each of these solutions add a different amount of standard silicon solution, in the range 0–20 ml (0–40 μg of silicon), dilute them to the mark with water and mix. Take 25 ml of each solution through the procedure and plot the absorbance against the amount of silicon.

In manganese

Procedure. To 0·2 g of the sample, in a polyethylene beaker, add 5 ml of water and 8 ml of 5*N* sulphuric acid (10 ml for 0·4 g of sample). When the reaction has subsided, warm the beaker on a

water-bath to complete the dissolution. Add 1*N* potassium permanganate dropwise until a faint pink colour persists, transfer the solution to a 100-ml standard flask and dilute it to the mark with water. Transfer exactly 25 ml of this solution to a polyethylene separatory-funnel, add 6 ml of ammonium molybdate solution, and apply the extraction procedure as before.

Calibration curve. Place 0–20 ml volumes of standard silicon solution (0–40 μg of silicon) in 100-ml standard flasks, add 6 ml of 5*N* sulphuric acid to each, and dilute to the mark with water. Take 25-ml portions of these solutions through the procedure and plot absorbance *vs.* amount of silicon.

In magnesium

Procedure. To 0·2 g of the sample, in a polyethylene beaker, add 10 ml of water, 2 ml of saturated boric acid solution, and then 8 ml of 5*N* sulphuric acid (add an extra 1·5 ml of acid for each extra 0 1 g of sample) in small portions. The boric acid does not affect the final extraction or the results. When the reaction has subsided heat the beaker in a water-bath to complete the dissolution. Apply the permanganate oxidation and the rest of the procedure as described for manganese.

In aluminium

High-purity aluminium is difficult to dissolve in acid and sodium hydroxide is used as solvent. However, a large quantity of sodium hydroxide is one of the main sources of a high blank value and also affects the colour produced. Consequently, the amount of sodium hydroxide added was minimized, although this necessitated a longer time for the dissolution.

Procedure. Dissolve 0 2 g of the sample in 5 ml of 5*N* sodium hydroxide and 5 ml of water in a polyethylene beaker by letting the mixture stand overnight at room temperature. If necessary, warm the beaker to complete the dissolution. Add 12 ml of 5*N* sulphuric acid and warm in a water-bath to dissolve the aluminium hydroxide formed. Continue as for magnesium

In sodium hydroxide

Procedure. To 0 5 g of sodium hydroxide in a polyethylene beaker, add 8 ml of 5*N* sulphuric acid (add another 1 ml for each extra 0·2 g of sodium hydroxide) and carry through the procedure for magnesium. The maximum permissible size of sample is about 1·5 g.

RESULTS AND DISCUSSION

To check the precision and bias of results, samples of steel, iron, manganese, magnesium, magnesium alloys, aluminium and sodium hydroxide were analysed by the proposed methods.

The within-batch standard deviation of blank determinations was 0·13 μg of silicon. Thus,[5,6] the limit of detection was approximately 0·3 μg of silicon, *i.e.*, 0·00015% silicon in a 0·2-g sample.

Each sample (except sodium hydroxide) was also analysed by an independent method (gravimetric or absorptiometric). The silicon contents of these samples varied from 0·0003 to 0·012%, and in no case did the results of the two methods differ by more than 0·005% for the same sample; the differences were usually much smaller. The coefficients of variation ranged from 2 to 8%. Some typical results are given in Table VI.

Reduced molybdosilicic acid is shown to be completely extractable with isoamyl alcohol if the acid concentration is high enough. This means that the sensitivity of the method can be increased. By the normal non-extractive method the lowest limit

TABLE VI

Sample	Si% (Mean of six results)	Standard deviation, %	Coefficient of variation, %
Steel	0 00225	0·000083	3·7
Iron (electrolytic)	0 00055	0·000046	8 3
Manganese (electrolytic)	0·00138	0·000054	3·9
Magnesium (high-purity)	0·00212	0·000075	3·5
Magnox	0·00360	0·000055	1·5
Aluminium	0·00542	0·000079	1·5

Sodium hydroxide	0 00196	0 000062	3 2

for the determination of silicon is about 0·002% in a 0·2 g sample. This can be lowered to about 0·0002% by the method proposed here, but the blank values tend to become larger. Since the blank value is generally due to the reagents and water used, water and reagents yielding the smallest possible blank values must be selected, and a correction applied for the blank. If samples are dissolved in glass beakers there is a very high blank value due to the glass, the values often become inconstant, and the determination itself becomes impossible. For this reason a polyethylene beaker must be used.

Zusammenfassung—Es ist schwierig, zur Extraktion reduzierter Molybdokieselsaure ausreichende organische Losungsmittel zu finden. Die Extraktion mit Isoamyl- oder Isobutylalkohol ist jedoch moglich, wenn die Saurekonzentration der waßrigen Losung vor der Extraktion erhoht wird. Die besten Ergebnisse erhält man durch Extraktion mit Isoamylalkohol aus 3,5–4,5*N* schwefelsaurer Lösung. Dadurch wird die Analysenmethode mit reduzierter Molybdokieselsaure viel empfindlicher und gestattet die Bestimmung von Mikrogrammengen Silicium in verschiedenen Arten hochreiner Metalle.

Résumé—Il est difficile de trouver des solvants organiques satisfaisants pour l'extraction de l'acide molybdosilicique réduit, mais l'extraction est possible avec les alcools isoamylique ou isobutylique si la concentration en acide de la solution aqueuse est augmentée avant l'extraction, les meilleurs résultats étant obtenus par extraction à l'alcool isoamylique à partir d'un milieu 3,5–4,5*N* en acide sulfurique. Ceci rend la méthode à l'acide molybdosilicique réduit beaucoup plus sensible et permet le dosage de quantités de silicium de l'ordre du microgramme dans diverses espèces de métaux de haute pureté.

STUDIES IN ATOMIC-FLUORESCENCE SPECTROSCOPY—III*

MICROWAVE-EXCITED ELECTRODELESS DISCHARGE TUBES AS SPECTRAL SOURCES FOR ATOMIC-FLUORESCENCE AND ATOMIC-ABSORPTION SPECTROSCOPY

R. M. DAGNALL, K. C. THOMPSON and T. S. WEST®
Chemistry Department, Imperial College, London S.W.7, England

(*Received* 23 *December* 1966 *Accepted* 14 *January* 1966)

Summary—Details are given for the production and operation of microwave-excited electrodeless discharge tubes for use as sources in atomic-fluorescence and atomic-absorption spectroscopy. Special reference is made to the tubes for selenium and tellurium and their spectral characteristics are fully discussed. Optimum conditions are given for producing suitably intense and stable sources.

HOLLOW-CATHODE lamps have been used almost exclusively as spectral sources in atomic-absorption spectroscopy since the introduction of the technique by Walsh.[1] Although they have served their purpose well, they possess a number of undesirable features. They have only a relatively short "shelf-life", they are expensive, especially if a large number of elements is to be examined, and they require a "warm-up" period before use. Also, hollow-cathode lamps are difficult to produce for some elements, and for others the intensity is too low to give a sufficiently sensitive determination or a wide enough working range. The recent introduction of multi-cathode and high intensity lamps overcomes some of these problems, but only at the expense of others; for example selective volatilization of the more volatile elements and increased cost. Lastly, the necessary equipment required to produce hollow-cathode lamps means that the average user must rely largely on commercially available lamps.

Spectral discharge lamps have also been recommended,[2] but there is only a limited number commercially available and these sources are often self-reversed to an appreciable extent. The application of a continuous source[3] is also possible, but only in conjunction with a high resolution monochromator.

For the purpose of atomic-fluorescence spectroscopy, intense sources are required because the analytical signal varies linearly with the source intensity at the wavelength of excitation. Spectral discharge lamps and a xenon arc (continuous) source have been used by both Winefordner *et al.*[4,5] and ourselves.[6,7] However, the spectral discharge lamps suffer from the disadvantages outlined above, and the intensity of a continuous source at any one wavelength, especially in the ultraviolet region, is very low. The use of electrodeless discharge tubes excited by microwaves would seem to be an obvious solution to spectral source problems in both atomic-absorption and atomic-fluorescence spectroscopy. They are known to give very sharp and intense spectral lines and they can be easily made with the minimum of equipment. Some

commercially available tubes have been used by Winefordner *et al.*[8] for atomic-fluorescence studies and Goodfellow[9] has made some measurements using an experimental type of microwave discharge source powered by a 2450 Mc/s magnetron unit. The production of some selected electrodeless discharge tubes for spectroscopic standardization experiments has been recently described by Steers.[10] However, up till the present time, the production of independent electrodeless discharge tubes solely for use as sources for atomic-absorption or atomic-fluorescence does not appear to have been discussed.

This communication surveys the essential steps that must be taken to produce electrodeless discharge tubes which are suitable as sources for both atomic-absorption and atomic-fluorescence spectroscopy. The development of two tubes, for selenium and for tellurium, is discussed in detail.

PREPARATION OF ELECTRODELESS DISCHARGE TUBES

The discharge tubes were made from transparent quartz tubing (Jencons Ltd.) of 8 mm internal diameter and 1 1 mm wall thickness. The vacuum line used was very simple and consisted of a two-stage rotary pump, a cold-trap, a means of introducing argon from a gas bulb, six B-10 outlets and a vacuostat (10^{-2}–10 torr), *cf.* Fig. 1.

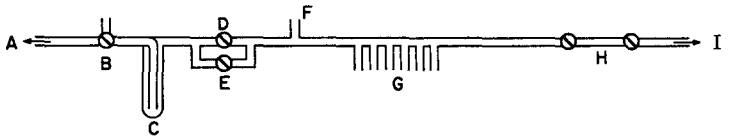

FIG. 1.—Vacuum line for preparation of microwave-excited source tubes.

C	Cold-trap	D	Two-way tap
E	Capillary leak	F	Vacuostat gauge
G	B10 connections	H	Two-way taps
	I Argon bulb.		

A 15–20 cm length of quartz tubing was sealed at one end and a constriction made between 1 and 7 cm from this end to give a tube from 1 to 7 cm in length. The tubing was then connected to a B-10 glass socket with medium-pressure tubing and the whole was attached to one of the outlets on the vacuum line and pumped down to a pressure of approximately 0·1 mm Hg. Argon was then introduced into the system after which it was again pumped down to a similar pressure. The quartz tube was then heated to just below its melting point for about 5 min, during which time argon was again introduced into the system and pumped out.

This procedure was found to be adequate for degassing the quartz. Other workers[11,12] have degassed their apparatus for up to 8 hr, but this was normally for the purpose of obtaining very "pure" spectra.

The tube was allowed to cool under vacuum and was then removed from the line. Between 5 and 20 mg of the required substance or substances were introduced into the tube which was then reconnected to the vacuum line.

The amount of substance used was found not to be critical, but too large a quantity sometimes caused plating-out during running.

The tube was evacuated as before, flushed out with argon and re-evacuated to a pressure of about 0·1 mm Hg. Gentle heat, depending on the volatility of the substance, was then applied to the tube to drive off any moisture or occluded gases in the substances used. The system was flushed twice more with argon and finally a given pressure of argon, depending on the substances used, was introduced into the vacuum system and the constriction was sealed by means of an oxy-propane hand torch.

In some instances tubes were sealed under as low a pressure as could be achieved whilst being continuously pumped. By such techniques, well over 150 tubes have been prepared for over 30 elements, *viz.*, Ag, Al, Ar, As, Bi, Cd, Co, Cr, Cu, Fe, Ga, Ge, H, Hg, I, In, Mg, Mo, N, Nb, Ni, P, Pb, S, Sb, Se, Sn, Te, Ti, Tl, V, Zn, Zr.

The following paragraphs describe in detail the preparation of discharge tubes for selenium and tellurium. Excitation of the tubes is achieved with a "Microtron 200" high-frequency generator and a

model 214.L. discharge cavity (Electro-Medical Supplies). The output frequency is 2450 ± 25 Mc/s (12·5 cm) at up to 200 W and the discharge cavity has external dimensions of approximately 2·5 cm diameter and 6 cm length with variable coupling at right-angles to the longitudinal axis of the cavity. The coaxial input connector is integral with cooling air inlets and the tuning stub is in line with the axis of the cavity. Initiation of the discharge is obtained with a Tesla coil vacuum-tester.

DISCHARGE TUBE CHARACTERISTICS

Selenium

Selenium tubes were made by introducing *ca.* 10 mg of analytical-grade selenium powder into the tubes and sealing off under various pressures of argon between 0·1 and 5·0 mm Hg. The selenium lines appeared to increase in intensity with decreasing argon pressure. The most intense selenium source used in this study was made by sealing whilst pumping, giving a final argon pressure of *ca.* 0·1 mm Hg. If the pressure was higher than 1 mm Hg the selenium lines were relatively weak and often the light blue selenium discharge would change over to a purple argon discharge with considerable reduction in the selenium line intensity. This particular tube required slight warming before initiation with the Tesla coil vacuum-tester, and was initially "run in" for about 2 hr. It is essential that all discharge tubes be "run in" because their characteristics can alter radically during the first hour of life. The tube required careful tuning and had to be moderately cooled to obtain a steady intense output. After continuous running of the selenium tube at 40 W for over 2 hr its stability was comparable with that of a hollow-cathode lamp, once the tuning and the cooling rate had been carefully adjusted.

All the expected selenium lines were observed during its operation and all of them were very sharp. The relative intensities of the ground state and intercombination lines observed, expressed as the ratio of the line intensity to that of the 1961 Å line, are shown in Table I.

These intensities can only be taken as an approximate guide because the values given are slightly dependent on the scanning rate of the Unicam SP 900A recorder unit. The relative intensity of the 1961 Å line increases with cooling. This suggests that, if the tube were run at too high a temperature or at energies >40 W, self-reversal of the resonance line might occur. On the other hand, when the tube was cooled too rapidly the discharge was extinguished. Uncooled tubes were not examined because the cavity tended to overheat. The apparently low intensity of the 1961 Å line is due to the characteristics of the 9601B photomultiplier used. This photomultiplier has a Corning U.V. glass window which has a very low transmission below

TABLE I.—EMISSION LINES FROM SELENIUM SOURCE

Line, *A*	Relative intensity	
	Slight cooling	Moderate cooling
1961 (*R*)	1	1
2040 (*R*)	5	2 5
2063 (*R*)	12	2
2075 (*I*)	3	5 0
2165 (*I*)	8	2·3

R ≡ Resonance; *I* ≡ Intercombination.

2000 Å. This illustrates one advantage of atomic-fluorescence measurements over atomic-absorption. Although the photomultiplier is very insensitive to the exciting radiation at 1961 Å or to emission at the same line, measurement may be made of the fluorescence at the 2040 Å "direct" line where a much increased response is given. This arises despite the suspected lower output of the source at 2040 Å. The selenium tube also emitted the mercury spectrum because of the diffusion of mercury from the vacuostat gauge throughout the vacuum system. Although it was found virtually impossible to eliminate this contamination completely, no resulting interference was observed.

Selenium tubes were made ranging from *ca.* 1·5 to 5·0 cm in length. The optimum length of tube for the cavity appears to be 3·5 cm. The smaller tubes were completely enclosed by the cavity and these developed hot-spots (selenium is a semiconductor) with the result that the output was neither very stable nor intense. The larger tubes did not reach a high enough running temperature to give a sufficient vapor pressure of selenium. The 3·5-cm tube was operated in such a manner that 1 cm of the tube protruded above the cavity and the selenium was sublimed to the top of the tube before operation, by heating gently with a Bunsen burner. This tube gave a steady, intense output. No information is at present available on tube-life because none of the tubes made to date has failed, even after *ca.* 50 hr of operation.

Tellurium

Tubes containing only tellurium metal were found to be unsatisfactory because they had to be run at high energies (*ca.* 75 W) and at relatively high temperatures owing to the involatility of tellurium. This resulted in a rather unstable output with eventual darkening of the quartz envelope.

A tube containing a trace of mercury plus tellurium gave a stable output but of low intensity. However, a tube containing tellurium and iodine (about 5 mg of each) which was sealed under continuous pumping (final argon pressure *ca.* 0·1 mm Hg) and run with slight cooling, gave a stable intense output at 30 W after an initial running-in period of 1 hr. The running-in period was necessary to allow complete reaction of tellurium and iodine under these low-pressure conditions.

All the expected tellurium lines were observed and, as with the selenium tube, were very sharp. Table II shows the intensities of the tellurium resonance and intercombination lines observed, relative to the intensity of the 2143 Å line. The iodine spectrum was also present in the form of a continuum with an intense line at 2062 Å.

As with selenium, the relative intensities are somewhat dependent on the rate of

TABLE II.—EMISSION LINES FROM TELLURIUM SOURCE

Line, Å	Relative intensity (slight cooling)
2143 (*R*)	1
2383 (*R*)	2 5
2386 (*R*)	4
2259 (*I*)	10
2531 (*I*)	1 3

recorder scanning and on the cooling rate. An increase in the operating power did not increase the line intensity appreciably, but merely led to instability.

The optimum tube length was found to be about 4 cm and the tube was best operated with about 1·5 cm protruding above the top of the cavity. After some 25 hr of intermittent running there has been no deterioration in output or stability.

Acknowledgements—We are grateful to the Science Research Council for the award of a research studentship to one of us (K. C. T.) and to I.C.I. Ltd for the award of a grant for the purchase of the Unicam SP 900A spectrometer used in these studies.

Résumé—On donne des détails sur la production et la manipulation de tubes à décharge sans électrodes excités par micro-ondes pour leur emploi comme sources dans la spectroscopie de fluorescence atomique et d'absorption atomique. On mentionne particulièrement les tubes pour le sélénium et le tellurium et discute de façon approfondie de leurs caractéristiques spectrales. On donne les conditions optimales pour la production de sources convenablement intenses et stables.

Zusammenfassung—Es werden Einzelheiten uber Herstellung und Arbeitsweise von mit Mikrowellen erregten elektrodenlosen Entladungsrohren als Lichtquellen bei der Atomfluoreszenz- und Atomabsorptionsspektroskopie mitgeteilt. Es wird besonders auf Selen- und Tellur-Rohren eingegangen und deren spektrale Eigenschaften voll durchdiskutiert. Die optimalen Bedingungen zur Herstellung geeignet intensiver und stabiler Lichtquellen werden angegeben.

STUDIES IN ATOMIC-FLUORESCENCE SPECTROSCOPY—IV*

THE ATOMIC-FLUORESCENCE SPECTROSCOPIC DETERMINATION OF SELENIUM AND TELLURIUM

R. M. DAGNALL, K. C. THOMPSON and T. S. WEST®
Chemistry Department, Imperial College, London S.W.7, England

(*Received* 23 *December* 1966. *Accepted* 14 *January* 1967)

Summary—Selenium and tellurium are determined down to 0·25 and 0·12 p.p.m. respectively by measuring the atomic-fluorescence signals at 2040 Å and 2143 Å respectively. Other possible wavelengths of measurement are considered in detail and the effects of some extraneous ions are examined. Microwave-excited electrodeless discharge tubes are used as spectral sources and intensity measurements are made with a Unicam SP 900A atomic-absorption/flame-emission spectrophotometer. Atomic-absorption measurements are also made with the same sources and spectrophotometer. The advantages of atomic-fluorescence methods and the use of electrodeless discharge tubes are discussed.

IN comparison with that for other elements, the volume of literature available on the flame-spectrophotometric determination of selenium and tellurium is relatively small. Rann and Hambly have determined selenium by atomic-absorption spectroscopy, using a hollow-cathode lamp and an electrodeless discharge tube operated at 15 Mc/s.[1] The limit of detection at 1961 Å was 1 ppm. A determination using a continuous source[2] and a medium quartz spectrograph gave limits of detection for selenium (2040 Å) and tellurium (2143 Å) of 5 and 0·5 ppm respectively. In addition to these, Dean[3] has described a flame-emission method for tellurium, using an oxy-acetylene flame. The tellurium(IV)–diethyldithiocarbamate complex was extracted into carbon tetrachloride, evaporated to dryness and redissolved in methyl isobutyl ketone to enhance the flame temperature. The limit of detection was 2 ppm.

This communication describes the determination of selenium and tellurium by atomic-fluorescence and atomic-absorption spectroscopy under conditions which do not require a hot flame, a high-resolution monochromator or hollow-cathode lamps. The oxidation state of the selenium and tellurium is unimportant and a preliminary extraction into organic solvents is unnecessary.

Spectral characteristics

The general theory of atomic-fluorescence has been described by Winefordner,[4] together with the determination of zinc, cadmium and mercury. The resonance lines of these elements originate from a $^1S_0$ ground state which is a singlet. However, for sulphur, selenium, tellurium and polonium[5] the ground state $^3P_2$ is part of the triplet $^3P_2$ $^3P_1$ $^3P_0$ (*cf.* Fig. 1) The separation of these states is very small (*cf.* Table I) and in tellurium and polonium the ^3P terms are partially inverted.

* Part III—R. M. Dagnall, K. C. Thompson and T. S. West, *Talanta*, 1967, **14**, 551.

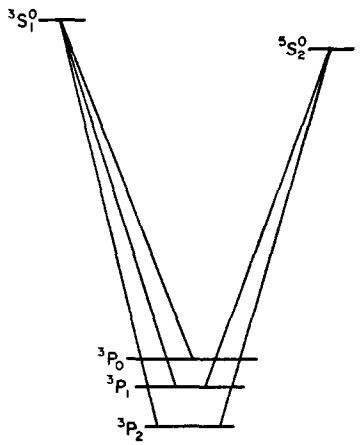

FIG. 1—Simplified Grotian diagram for S, Se, Te.

TABLE I.—SEPARATION OF GROUND STATES

Element	Interval, cm^{-1} $^3P_2 - {}^3P_1$	$^3P_1 - {}^3P_0$
S	398	174
Se	1989	545
Te	4751	−44
Po	16831	−9317

(1 eV = 8066 cm^{-1})

TABLE II —SPECTRAL RESONANCE LINES

Element	Transition, Å $^3P_2 \rightarrow {}^3S_1^0$	$^3P_1 \rightarrow {}^3S_1^0$	$^3P_0 \rightarrow {}^3S_1^0$
S	1807	1820	1826
Se	1961	2040	2063
Te	2143	2386	2383
Po	2450	4170	3003

Table II shows the spectral resonance lines which can be used for fluorescence measurements. It was found that the intercombination lines ($^3P_2 \rightarrow {}^5S_2^0$ and $^3P_1 \rightarrow {}^5S_2^0$) gave no appreciable absorption or fluorescence for any of these elements (*cf.* zinc, cadmium and mercury).

The resonance lines for sulphur lie in the vacuum-ultraviolet outside the range of the monochromator of the instrument used. For this reason it was not possible to make any fluorescence or absorption measurements for sulphur in the present study. With selenium, the 1961 Å and 2040 Å lines both absorb strongly whilst the 2063 Å line absorbs only very weakly. The 1961 Å line emanating from the ground state absorbs about 5 times as strongly as the line emanating from the $^3P_1$ state which lies 0·25 eV above the ground state. For tellurium the resonance line at 2143 Å absorbs almost 10 times as strongly as the lines at 2386 and 2383 Å. The $^3P_0$ and $^3P_1$ states lie 0·6 eV above the $^3P_2$ ground state

Atomic fluorescence was observed for selenium and tellurium for all three lines emanating from the $^3S_1$ state. However only very slight fluorescence was obtained for the intercombination lines for tellurium and none at all for those of selenium. The fluorescence for the transition from the $^3S_1$ excited state to the $^3P_{0,1,2}$ states is probably due to direct-line fluorescence; that is, excitation with the lines at 1961 and 2143 Å for selenium and tellurium respectively, with emission of selenium lines at 2040 and 2063 Å and of tellurium lines at 2386 and 2383 Å. Resonance fluorescence (excitation and emission wavelengths the same) is a possibility since some of the atoms could be thermally excited to the metastable $^3P_1$ and $^3P_0$ states. However, as the resonance lines for selenium and tellurium respectively absorb 5 and 10 times as strongly as the next highest states, and the energy gaps between the ground states and the next highest states of selenium and tellurium are 0·25 and 0·60 eV respectively, direct-line fluorescence seems much more probable. This aspect was not examined further because a monochromomator placed in front of the source would give a signal too weak to measure.

EXPERIMENTAL

Apparatus

The apparatus used consisted of a Unicam SP 900A atomic-absorption/flame-emission spectrophotometer coupled to a Honeywell-Brown 0–10 mV recorder. A description of its use for atomic-fluorescence measurements has been given elsewhere.[6] Electrodeless discharge tubes were prepared and used as sources and the discharge was maintained with a "Microtron 200" high-frequency generator and a model 214.L. discharge cavity (Electro-Medical Supplies).[7] The "emission" mode of operation of the Unicam SP 900A was used for all fluorescence measurements since this pulses the flame emission at 100 c/s in phase with the a.c. amplifier of the SP 900A. This does, however, result in the recognition by the detector of all radiation effects in the flame at the selected waveband. For this reason it would be better to modulate the light from the source mechanically or electronically before it enters the flame and to use the SP 900A in its "absorption" mode so that continuous radiation from the flame is not recorded by the detector/amplifier system. The basic instrumental arrangement for atomic-fluorescence measurements is shown diagrammatically in Fig. 2.

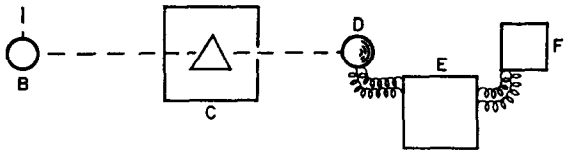

FIG. 2—Experimental arrangement for atomic-fluorescence measurements
A—Source B—Flame
C—Monochromator D—Photomultiplier
E—Amplifier F—Recorder

Stock solutions

Selenium solution (1250 *ppm*). Analytical-reagent grade selenium metal (1·250 g) was dissolved in 20 ml of a mixture of concentrated nitric and hydrochloric acids (1 + 1) and diluted to about 500 ml with distilled water. A slight excess of ammonia was then added and the whole was diluted to 1 l.

Tellurium solution (1250 *ppm*). Made up with analytical-reagent grade tellurium metal as for the selenium solution.

Both solutions were then diluted as required.

Atomic-Fluorescence Measurements

An air–propane flame was used because of its low background emission[6] and the discharge cavity was placed *ca.* 8 cm from the flame at right-angles to the optical axis of the analysing monochromator. Slit-widths ranging from 0 5 to 2 0 mm were used. The excitation sources were not chopped and so

any flame background had to be subtracted arithmetically from the readings obtained. A slightly fuel-rich flame was used and the distance from the top of the propane emission-burner head to the centre of the analysing monochromomator slit was *ca.* 3 cm. The atomic-fluorescence intensity was virtually independent of flame composition and position of measurement in the flame for both selenium and tellurium.

Selenium

The discharge tube was operated at 40 W with moderate cooling and fluorescence measurements were taken at the resonance lines (1961, 2040 and 2063 Å) and the intercombination lines (2075 and 2165 Å), with a 12·5-ppm solution of selenium. The recorder readings due to the fluorescence emission are shown in Table III together with the relative line intensities.

TABLE III.—FLUORESCENCE INTENSITIES FOR SELENIUM

Wavelength, *Å*	Recorder reading	Relative line intensity (source)
1961	42	1
2040	63	5
2063	33	12
2075	1	3
2165	0	8

The 1961 Å resonance line is the strongest fluorescing line, but because the photomultiplier used (EMI 9601B) is very insensitive below about 2000 Å, the 2040 Å line gives the higher readings. The latter wavelength was used for further measurements.

Linear calibration curves were obtained over the range 0·25–125 ppm of selenium, with a slit-width of $<2{\cdot}0$ mm. More concentrated solutions were not examined. The limit of detection (signal to noise ratio unity) was 0·15 ppm and the limit of measurement was considered to be *ca.* 0·25 ppm (*i.e.*, twice the background signal).

Tellurium

The discharge tube was run at 30 W with very slight cooling and measurements were taken (Table IV) for a 12·5-ppm solution of tellurium.

TABLE IV.—FLUORESCENCE INTENSITIES FOR TELLURIUM

Wavelength, *Å*	Recorder reading	Relative line intensity (source)
2143	44	1
2383	60	2 5
2386		4
2259	2 5	10
2531	0	1 3

With analysing-monochromator slit-widths ranging from 0·5 to 2·00 mm, the 2383 and 2386 Å lines could not be resolved. The relative intensity readings were taken with a slit-width of *ca.* 0 005 mm.

The resonance line at 2143 Å was selected for further measurements because the flame background at this wavelength was much less than that at 2383 and 2386 Å. With a photomultiplier more sensitive in the ultraviolet, the 2143 Å line would probably give increased sensitivity.

Linear calibration curves were obtained with a slit-width of <2 0 mm over the concentration range 0 12–125 ppm of tellurium. Again, more concentrated solutions were not examined. The limit of detection was about 0 05 ppm and the limit of determination was 0·12 ppm.

Interferences

The effect of a 100-fold molar excess of the following selected range of cations was investigated on both selenium and tellurium: Ag, Al, Co(II), Cu(II), Fe(II), Hg(II), Mg, Na, NH_4, Pb, Sb(III) and Zn. In addition, the effect of a similar excess of selenium on tellurium and *vice versa* was examined. The results are summarized in Table V. All solutions were acidified with 2*M* nitric acid to prevent any precipitation. Sodium gave about a 20% increase in the fluorescence signal and this was found

TABLE V.—INTERFERENCE EFFECTS WITH ATOMIC-FLUORESCENCE SPECTROSCOPY

Element	Intensity of signal		Difference, %	
	Se	Te	Se	Te
—	75	75	—	—
Ag^{+}	76	79	+1	+4
Al^{3+}	79	76 5	+5	+2
Co^{2+}	76	72	+1	−4
Cu^{2+}	76 5	74	+2	−1
Fe^{2+}	75	75	0	0
Hg^{2+}	73 5	79	−2	+5
Mg^{2+}	78	77	+4	+3
Na^{+}	94	95	+20	+22
NH_4^{+}	75	75	0	0
Pb^{2+}	77	76 5	+3	+2
Se^{4+}	—	75	—	0
Sb^{3+}	74	75	−1	0
Te^{4+}	75	—	0	—
Zn^{2+}	75	73	0	−3

to be because of intense light emission from the flame and a slight light-leak in the monochromator. This increased signal was given at all wavelengths. All other elements produced signal differences of less than 5%.

Atomic-Absorption Measurements

The "absorption" mode of operation was now used and the electrodeless discharge tubes were placed in approximately the same position as hollow-cathode lamps would be in for absorption studies. The source was thus chopped at 100 c/s. A 7-cm long air–propane flame was used.

Selenium

The discharge tube was run at 30 W with moderate cooling and placed so that it was slightly out of focus at the entrance slit, in order to reduce the amount of light passing through the flame

The 1961 Å resonance line absorbed most strongly, the 2040 Å line absorbed about a fifth as much, and the 2063 Å line absorbed still less. The intercombination lines at 2075 and 2164 Å did not absorb at all. The limit of detection (for 1% absorbance) was 1 ppm, using the 1961 Å line. Linear calibration curves were obtained from 5–100 ppm of selenium. The range could be extended beyond this if desired.

Moderate cooling of the discharge tube was found to be essential as the absorbance decreased by a factor of about 3 if the tube was not cooled, and also the calibration graph curved towards the concentration axis. Over-cooling gave a very unstable tube and the discharge tended to be extinguished.

The absorption at the 1961 Å line was similar in air–propane and air–acetylene flames. Both of these flames absorbed *ca.* 70% of the radiation at 1961 Å. Atomic absorption occurs more strongly in air–acetylene than in air–propane flames because this line does not emanate from the ground state, but a state 0·25 eV above it.

Tellurium

The discharge tube was run at 20 W with very slight cooling and was arranged in the same way as the selenium discharge tube.

The 2143 Å resonance line absorbed most strongly and the 2383 and 2386 Å lines absorbed only about a tenth as much. The intercombination line at 2259 Å absorbed only slightly and the other intercombination line at 2531 Å did not absorb at all.

The limit of detection (for 1% absorbance) was 1 ppm with the 2143 Å line, and linear calibration curves were obtained over the range 5–100 ppm.

DISCUSSION

These studies show the advantages to be obtained by measuring the fluorescence emission instead of the absorption. Table VI compares the sensitivities of the two methods, with the same instrument and the same spectral sources for selenium and tellurium.

TABLE VI.—SENSITIVITIES FOR Se AND Te BY ATOMIC-FLUORESCENCE AND ATOMIC-ABSORPTION SPECTROSCOPY

	AFS		AAS	
	Se	Te	Se	Te
Limit of determination, *ppm*	0 25	0 12	5	5
Limit of detection, *ppm*	0 15	0 05	1	1

The sensitivities of these atomic-fluorescence methods are about 10 times greater than those of the atomic-absorption methods. Improvements in the detector response would have produced a still greater increase in sensitivity *e.g.*, a further factor of 10 is quite possible.

The examination of selected extraneous ions in the atomic-fluorescence studies also shows that the method is at least as free from inter-element effects as atomic-absorption spectroscopy.

The application of electrodeless discharge tubes as spectral sources means that the atomic-fluorescence method need not be restricted by the commercial availability of intense sources of excitation, a criticism once levelled at this technique. These sources, as well as fulfilling the essential requirements of high intensity and stability, possess the advantages of ease of manufacture and low cost. Also, from our somewhat limited experience, it would appear that they have a long "shelf-life". The selenium tube, for example, was not used for approximately 3 months, but it immediately gave the same output on operation as when last used. This also indicates the reproducibility of the source intensity. We have no reason to suspect that most other tubes should not behave in a similar manner. Such properties mean that electrodeless discharge tubes could also be used to advantage in atomic-absorption spectroscopy instead of hollow-cathode lamps, which are generally far from ideal.

As with hollow multi-cathode lamps, it should be similarly possible to obtain spectra of a number of different elements in the same tube. This has already been achieved in many instances because of impurities in the major compound or element, *e.g.*, iron in niobium, and mercury from the vacuum line. Because the spectral intensity is more dependent on the volatility of the element or compound than on its actual concentration, the impurity spectral lines in many instances may be as strong as those of the major constituent. Very intense continuous sources can also be made quickly and easily by introducing hydrogen, xenon, sulphur, iodine, *etc.* into the tubes. Electrodeless discharge tubes of these and other types should also find considerable application as spectral sources in solution spectrofluorimetry and other photo-techniques where intensity is one of the major requirements.

Summary—The corrosive behaviour of caesium has been attributed in part to the presence of a non-metallic impurity such as oxygen. A photon-activation method for determining oxygen and carbon in caesium is described. Scintillation coincidence-counting and pulse-height discrimination are used to count the gamma-ray activity resulting from annihilation of the positrons emitted. Variation of beam energy has been investigated in order to obtain optimum irradiation conditions. In the samples analysed and under the conditions used, less than 100 ppm of oxygen and carbon can be detected. Results are compared with those from other methods.

THE development of high-temperature hydraulic fluids and thermionic propulsion systems has resulted in considerable investigations of alkali metals. The importance of this class of metals is attributed largely to their excellent properties as a heat transfer medium, a hydraulic fluid, and as a low ionization potential propellant.[1] However, their highly corrosive attack on most materials is a major deterrent to their use.

Experimental evidence, compiled within the last few years, indicates that the presence of impurities, even in trace amounts, often has a significant adverse effect on the properties of the alkali metals.[2] The corrosive behaviour of caesium, and of the other alkali metals, has been ascribed in part to the presence of oxygen as trace impurity. Current handling techniques are not sufficient to preclude occurrence of such impurities. In studies of methods of overcoming the corrosion problem, there is a need to correlate the effect of impurities in an alkali metal with the deterioration of the system. This report concerns the analytical technique for the determination of oxygen in caesium.

Most of the impurities commonly found in caesium are non-metallic, because of its extreme reactivity with air. In addition to the Kjeldahl method for nitrogen determination, chemical methods have been developed for the determination of non-metallic impurities in alkali metals. In the past, the amalgamation,[3] Wurtz reaction[4] and gas fusion methods[5] have been the principal techniques used for oxygen in alkali metals. Combustion methods for carbon determination have also been

* This work was presented in part at the Ninth Conference on Analytical Chemistry in Nuclear Technology in October, 1965 at Gatlinburg, Tennessee.

† Present address: General Telephone & Electronics Laboratories, Bayside, N.Y., U.S.A.

‡ Present address: Boston University Medical School, Boston, Mass., U.S.A.

§ Present address. McDonnell Aircraft Corp., St. Louis, Missouri, U.S.A.

used. All of these methods require the complete quantitative removal and recovery of the impurities, as otherwise serious errors may occur.

Recently, the more attractive radioactivation methods have been examined. These are non-destructive and do not require removal of the element. In the fast neutron reaction, neutrons produced by a generator or accelerator are used to bombard the sample. Nitrogen-16 is produced. Measurement of the 7-sec half-life nitrogen-16 requires the immediate analyis of the sample after irradiation. A rapid transfer system is mandatory for trace amounts of oxygen. Normally only one element can be determined at a time, and large sample sizes are sometimes required. Reactions induced by helium-3 have also proved popular.[6] This method is quite promising, but the limit of penetration of the helium beam confines use of this method essentially to surface studies.

Because of the disadvantages mentioned above, photon activation analysis was investigated for the analysis of caesium. Although oxygen was the impurity of interest the possibility of determining carbon and nitrogen was also examined.

Photon activation

The determination of oxygen, nitrogen and carbon by radioactivation, with photons produced by a betatron, was shown to be possible by Basile, Hure, Leveque and Schuhl in 1954.[7] Beard, Johnson and Bradshaw[8] have claimed that less than 10 ppm of oxygen can be detected in beryllium. Englemann[9] has also demonstrated the feasibility of this technique in the analysis of beryllium, calcium and boron.

Interaction of a bremsstrahlung beam of a betatron with matter may produce radioactivity through the following reaction (γ, n), (γ, p), (γ, np), $(\gamma, 2n)$, *etc.* In addition, certain elements can undergo (γ, γ') reactions and produce nuclear isomers through isomeric transition.[10] The principal reaction depends upon the target material and photon energy. For oxygen, carbon and nitrogen, and a photon energy between 20 and 30 MeV, the (γ, n) reaction is predominant. The isotopes produced by this reaction, especially for elements of low atomic number are generally positron emitters which produce annihilation radiation.

The photon-activation method was used in our analysis of caesium. The impurity of interest is mainly oxygen; however, carbon was also detected. Nitrogen was not found. This was probably due to the lack of reactivity of caesium with nitrogen under ordinary conditions.

The radioisotopes produced by the (γ, n) reaction of oxygen and carbon are oxygen-15 and carbon-11. Both are positron emitters.

EXPERIMENTAL

Chemicals

Oxygen standard. Distilled water was used as the standard for oxygen.

Caesium. The extreme reactivity of caesium with the atmosphere made it necessary to load the samples in a vacuum dry box under an atmosphere of purified helium. In addition, unique handling techniques were developed for transferring the caesium, after irradiation, to another container for counting with little loss in time and without the reactive metal igniting. Some samples were deliberately contaminated before loading in order to provide a range of concentration of impurity.

Apparatus

Radiation. The samples were irradiated at between 20 and 30 MeV in the X-ray beam of a Brown-Boveri betatron located at Montefiore Hospital, Bronx, New York. The samples and standards were bombarded in the same positions for equivalent times. A holder was fabricated to ensure

identical geometrical position each time. About 1 min was taken to place the sample in the counter.

Counting. Scintillation coincidence-counting and pulse-height discrimination were used in counting the γ-ray activity resulting from the annihilation reaction of the positrons. Two thallium-activated sodium iodide crystals, 2 in. in diameter and 3 in. long, were used to detect the 0·51 MeV annihilation photons. The crystals were mounted on photomultipliers, the pulses from which were amplified; the output from a transistorized dual pulse-height analyser was fed into a coincidence discriminator with a 1-μsec resolving time. A transistorized high-speed scaler recorded the output. The windows of the pulse-height analyser were adjusted for 0·51 MeV energy, sodium-22 being used as a calibration source.

Procedure

The glass ampoules were quickly broken after irradiation and the caesium transferred with a syringe under a protective layer of paraffin oil to a polyethylene container for counting. The paraffin oil was necessary in order to prevent the caesium from igniting in air. The transfer of caesium eliminated container blanks which are normally found in oxygen analysis. The entire operation of removing the caesium and placing it in the counter took about 1 min. The exact amount of caesium transferred was obtained by weighing the polyethylene containers after counting.

The irradiation time and beam energy selected depend on the host material and the impurities present. Since our principal interest in caesium is detecting oxygen, fairly short irradiation times were used.

Irradiation at about 25 MeV exceeds the threshold for (γ, n) and (γ, γ') reactions. The short

TABLE I.—IMPURITIES DETECTED IN CAESIUM BY EMISSION SPECTROGRAPHIC ANALYSIS

irradiations will not induce contribution of long-lived isotopes to the total activity. Likewise isotopes with very short half-lives will decay almost completely before counting is started. The only isotopes to be considered are those whose half-lives fall within the time interval of interest.

All of the radioactivity produced is assumed to be the result of the contribution of each isotope. Since oxygen is the major impurity of interest, irradiations of 2–8 min were used. The short half-life of oxygen-15 (2·1 min) makes it resolvable from the other isotopes present. The concentration of metallic impurities found in typical samples by emission spectroscopy is shown in Table I. In addition to the detected impurities, silicon and chlorine are also assumed to be present.

RESULTS AND DISCUSSION

Sensitivity

The counting rate to be expected from a known amount of oxygen in an irradiated sample can be computed. If we assume a 5 mbarn (γ, n) cross-section[11] for oxygen at 35 MeV at a photon flux of 10^9 photons/cm^2/sec, we can calculate the expected activity from the equation

$$A = \frac{M}{N}\theta\phi\sigma(1 - e^{-\lambda_0 t}) \qquad (1)$$

where

A = disintegrations/sec/g of oxygen
N = Avogadro's number
M = atomic weight of oxygen = 16
σ = (γ, n) cross-section for oxygen at 35 MeV = 5×10^{-27} cm^2
θ = isotopic abundance of ^{16}O
ϕ = photon flux at 35 MeV gamma-energy = 10^9 photons/cm^2/sec
λ_0 = decay constant for ^{15}O = 0·330
t = irradiation time (assume saturation or infinite irradiation).

Substitution in equation (1) gives $A = 1{\cdot}2 \times 10^7$ disintegrations/min/g of oxygen. Assuming 30% efficiency for the counting equipment, $A = 3{\cdot}6 \times 10^6$ cpm. In one experiment, 1 g of oxygen in the form of water gave $1{\cdot}4 \times 10^6$ cpm. These calculations are only used to compare theoretically expected counts with the experimental activity observed in our work. In practice, counting rates of unknowns were run against standards for precise results. However, this calculation indicates that theoretically it is possible to determine oxygen below 10 ppm if no interfering reactions occur.

Optimum conditions

In order to determine the optimum irradiation conditions to be used, a series of experiments was carried out. Duplicate samples of caesium loaded at the same time were irradiated for 2 min at beam energies ranging from 25 to 35 MeV. Counting times were the same for all samples. One-gram quantities of water were also irradiated under the same conditions as the caesium. A plot of activity *vs.* energy is shown in Fig. 1.

It can be seen from the plot, that from 25 MeV to about 27 MeV the induced radioactivity in the caesium samples increases proportionally. However, at approximately 28 MeV and above, the activity increases much more than expected. Possibly, some other reactions are occurring such as (γ, 2n) (γn, p), *etc.* In the water sample the induced activity increased steadily with irradiation energy up to 27 MeV. Above 27 MeV the rate of increase in activity was less. Consequently it was decided to irradiate with energies below 28 MeV in order to decrease the amount of induced extraneous activity.

Analysis of caesium

Two methods of analysing the results were used—algebraic and graphical.

Mathematical. Samples of caesium were prepared and irradiated in the betatron at 25 MeV. The counting rate observed at any time after the conclusion of the irradiation can be expressed as

$$A(t) = A_0 e^{-\lambda_c t} + A_c e^{-\lambda_c t} \tag{2}$$

where

λ_0 = decay constant for oxygen
λ_c = decay constant for carbon
$A(t)$ = measured activity at time t
A_0 = activity of oxygen at time = 0
A_c = activity of carbon at time = 0.

All of the activity is assumed to be contributed by oxygen and carbon only, since nitrogen was not detected. Chemical analysis of caesium for nitrogen also failed to detect any appreciable quantity of nitrogen. With the irradiation times employed and concentration present, nitrogen would not contribute any measurable activity and hence its contribution was neglected. The contribution of other metallic impurities is small, due to the concentration present, the half-lives and the abundance, as seen in Table II.

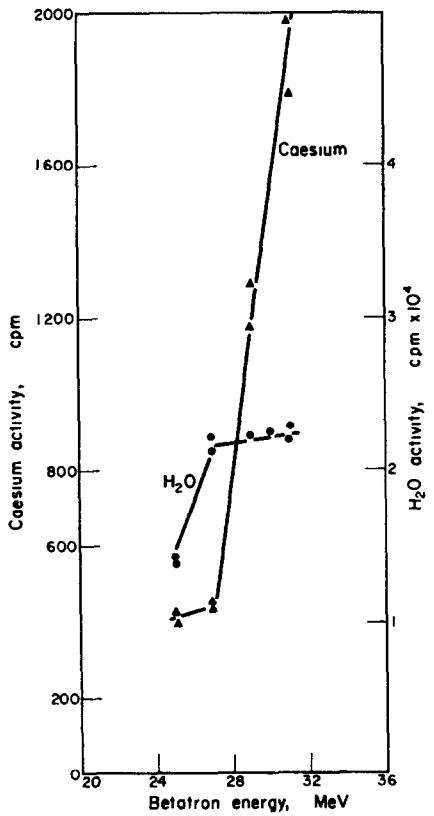

FIG. 1.—Activity *vs.* betatron energy.

By choosing two sufficiently separated observation times, two useful simultaneous equations are obtained. Since oxygen-15 and carbon-11 are detected in the samples, 2 min and 20 min are taken as the time intervals. The decay constants for oxygen-15 and carbon-11 are 0·330 and 0·0338 min^{-1} respectively.

For example, a sample of caesium weighing 2·103 g was prepared and irradiated at 25 MeV in the betatron. The activity at 2 min and 20 min is substituted in equations (2); solution of the resulting equations gives the coefficients $A_0 = 14$ cpm and $A_c = 28$ cpm. These coefficients represent the activity of each component at zero time. The total activity in cpm is then obtained by substituting A_0 and A_c in equation (2). The plot of this expression is shown in Fig. 2 as a solid line. The contributions of oxygen and carbon are shown as broken line curves.

One sample of distilled water weighing 1·034 g was used as the standard for oxygen. It was irradiated for 2 min under geometrical conditions identical with those

TABLE II.—PROPERTIES OF IMPURITIES IN CAESIUM UNDERGOING REACTIONS WITH PHOTONS*

Stable isotope	Abundance, %	Positron-emitting isotope	Half-life

* (γ, n) unless otherwise noted.
† (γ, γ'), metastable isotope does not emit positrons.

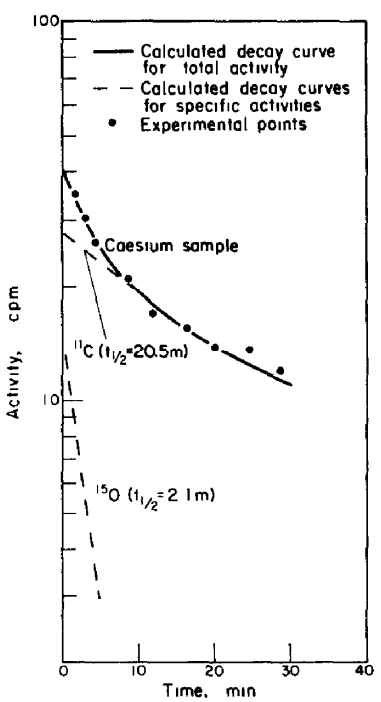

FIG. 2.—Decay of activities in caesium after photon irradiation for 8 min

used for the caesium. The count-rate for an infinite irradiation was 7×10^4 cpm. The oxygen concentration in the unknown sample of caesium was found by normalizing for differences in weight, density and bombarding intensity between the standard and the unknown. The amount of oxygen found was 0·0058%.

A similar procedure was used for carbon. A 1-g sample of polyethylene was irradiated under the same conditions for 2 min. The amount of carbon found was 0·0019%.

Graphical. A graphical method was also used for resolving some of the composite decay curves. Results obtained were in agreement with those obtained algebraically.

Accuracy. Because of the difficulty in adding precise amounts of oxygen to caesium, a chemical method[12] using a liquid ammonia extraction apparatus was used as a check. Duplicate samples of caesium were loaded at the same time in the dry box and analysis by both methods was carried out. Results are shown in Table III.

TABLE III.—COMPARISON OF ACTIVATION AND CHEMICAL METHODS

Caesium sample	Carbon	Oxygen		Beam energy, *MeV*
	Photon activation, *ppm*	Photon activation, *ppm*	Chemical method, *ppm*	
1D	342	1142	1180	35
7M	75	247	224	35
8M	150	497	469	35

14D	—	27	18	25
15M	—	20	24	25
16M	—	17	22	25

Some samples were deliberately contaminated in order to give a range of oxygen and carbon values.

Samples of caesium were analysed for oxygen at the request of the U.S. Air Force. Two types of samples were submitted. The Air Force designated these samples as "high" and "low" oxygen. The results are shown in Table IV together with those from other laboratories.

TABLE IV.—ANALYSIS OF AIR FORCE SAMPLES

	"Low"	"High"
Republic	25 ± 6*	55 ± 8*
Lab A	11 ± 5	56 ± 5
Lab B	10 ± 5	96 ± 5

* Sample weights were 2·0–2·4 g.

DISCUSSION

Photon activation analysis appears promising for the determination of trace impurities in suitable materials. Oxygen determination in caesium was emphasized at

the time because of the discrepancies that existed in the various analytical methods. Carbon was detected in the samples analysed, but nitrogen was not found. The detection of oxygen and carbon is probably due to the extreme reactivity of caesium with oxygen, carbon dioxide and water vapour in the air.

The decision to classify nitrogen as an undetectable trace contaminant was made after considerable evaluation. Nitrogen does not react with caesium under normal conditions, and hence if it is present it is in very low concentrations.[13] The supplier of caesium claims that less than 5 ppm of nitrogen is present. A modified Kjeldahl method of analysis was performed and less than 3 ppm of nitrogen was found. Computer analysis also indicated the absence of any contribution of nitrogen activity to the total activity measured after activation.

The nitrogen activity expected can be estimated from the concentration found by chemical analysis and the estimated cross-section reported by Johns, Horsley, Haslam, and Quinton.[14]

The (γ, n) cross-section for nitrogen is approximately one-third that of oxygen and carbon—about 1·7 mbarn at 35 MeV. The activity expected for 1 g of nitrogen at 25% saturation, calculated from equation (1), is $5{\cdot}4 \times 10^5$ cpm. For 1 μg of nitrogen, the activity contributed is negligible.

In the present work, some interfering activity was encountered for low levels of oxygen when irradiation energies above 28 MeV were used. It appears that this interfering activity is due to some reaction other than (γ, n). Irradiations at 35 MeV were initially used for determinations at higher levels of oxygen, with no interference. However, when lower levels of oxygen were determined, the background activity was sufficient to cause interference. The results in Table IV shows irradiations performed at both 25 and 35 MeV. For low oxygen values, irradiations below 28 MeV were used; but lowering the beam energy also decreases the photon flux, and hence reduces the activity. Deviation from the calculated decay curve occurs after 20 min. This is probably due to other impurities present and to the large statistical variation arising from the low number of counts. Even with the reduced flux, less than 100 ppm of oxygen and carbon in caesium have been determined.

Under the experimental conditions used, the accuracy of the method for low levels of oxygen is estimated to be $\pm 25\%$ with a precision of about 10%. These values are based upon the experimental variables and agreement of results found for the experiments performed. Results for oxygen compare favourably with a chemical method and with those of several other laboratories.

Acknowledgement—The authors thank Mr. G. Zackaropoulos for operating the betatron, Mr. W. Shelby for performing the emission spectrographic analysis, and Mr. C. D. Houston of Wright-Patterson Air Force Base for supplying samples.

Zusammenfassung—Das korrosive Verhalten von Caesium wurde zum Teil einer nicht metallischen Verunreinigung wie Sauerstoff zugeschrieben. Eine Photonenaktivierungsmethode zur Bestimmung von Sauerstoff und Kohlenstoff in Caesium wird beschrieben. Mit Szintillations-Koinzidenzzählung und Impulshöhendiskriminierung wird die aus der Zerstrahlung der emittierten Positronen herruhrende Gamma-Aktivität gezahlt. Um die besten Bestrahlungsbedingungen zuerhalten, wurde die Veranderung der Bestrahlungsenergie untersucht. Unter den verwendeten Bedingungen lassen sich in den untersuchten Proben weniger als 100 ppm Sauerstoff und Kohlenstoff nachweisen. Die Ergebnisse werden mit denen anderer Methoden vergleichen.

Résumé—On attribué pour partie le comportement corrosif du caesium à la présence d'une impureté non métallique comme l'oxygène. On décrit une méthode par activation de photons pour le dosage de l'oxygène et du carbone dans le caesium. On utilise les comptages par scintillation en coïncidence et d'impulsion avec discrimination pour compter l'activité des rayons gamma résultant de la destruction des positrons émis. On a étudié la variation de l'énergie du faisceau afin d'obtenir les conditions d'irradiation optimales. Dans les échantillons analysés, et avec les conditions utilisées, on peut détecter moins de 100 ppm d'oxygène et de carbone. On compare les résultats à ceux d'autres méthodes.

RAPID MICROCHEMICAL METHOD FOR THE DETERMINATION OF MAGNESIUM IN BIOLOGICAL FLUIDS

U. P. S. CHAUHAN
Institute of Nuclear Medicine and Allied Sciences, Delhi-7, India
and

R and D Cell, Patel Chest Institute, Delhi-7, India

(*Received* 28 *April* 1966. *Accepted* 18 *November* 1966)

Summary—A photometric method for the determination of magnesium in the presence of up to 50-fold excess of calcium is described. A magnesium–Azovan Blue lake is formed, stabilized with polyvinyl alcohol, and the absorbance is measured (Kodak No. 7 filter). The method has been used to determine magnesium in sera.

MUCH significance has recently been attached to the study of magnesium metabolism in living organisms. The two major spectrophotometric methods for the determination of magnesium are (*a*) the Titan Yellow method[1] and (*b*) the Eriochrome Black T method.[2] The first of these dyes forms a pink lake and the other a true complex with magnesium in alkaline medium. Both are subject to interference by calcium in the determination of magnesium in biological fluids.[3–8] The separation of calcium by precipitation leads to negative errors because of co-precipitation and adsorption of magnesium.[9,10]

A new colorimetric method free from interference by other alkaline earth ions is desirable. The method described here, based on Evans (Azovan) Blue, is shown to be satisfactory for the determination of magnesium in biological fluids.

EXPERIMENTAL

Reagents

Sulphuric acid, 0·33*M*.

Sodium tungstate solution, 10% w/v.

Titan Yellow solution, 0·05% w/v. Place in an amber bottle and store in a refrigerator. The solution is stable for a week.

Azovan Blue 0·04% w/v. A B.D.H. (laboratory reagent grade) sample was used. This solution is stable at room temperature for at least a month. This solution may have to be diluted if a spectrophotometer is used instead of an absorptiometer.

Polyvinyl alcohol (PVA). Dissolve 50 mg of PVA in 50 ml of water by warming to 65° with constant stirring. Dilute the solution to 100 ml, filter, and store in a refrigerator.

Polyethylene glycol solution, 0·1%.

Polypropylene glycol solution, 0·1%.

Methyl cellulose solution, 0·05%. Prepare in the same way as the solution of PVA.

Standard magnesium solution, 0·5 g/l. Dissolve 0·5125 g of magnesium sulphate heptahydrate in water and dilute to 100 ml. Dilute this stock solution to give a working standard solution containing 10 μg of magnesium per ml.

Sodium hydroxide solution, 4*M*.

All the reagents were obtained either from Merck or B.D.H. and except where stated were of analytical reagent grade. Distilled water was used throughout.

Apparatus

A Spekker absorptiometer was used for colorimetric measurements

Standard curves for magnesium with Titan Yellow and Azovan Blue

Place 5 portions of working standard solution containing 2–10 μg of magnesium in test-tubes and dilute each to 3 ml. Add 1 ml of the sodium tungstate solution and 1 ml of 0·33*M* sulphuric acid to each tube. Mix the contents thoroughly and transfer 2–5 ml portions from each tube to another set of 5 test-tubes. Add 1 ml of polyvinyl alcohol solution and 0·5 ml of dye solution to all the tubes and mix the contents. Slowly add down the side of the tube 1·0 ml of 4*M* sodium hydroxide and mix gently. Five minutes after addition of the alkali measure the absorbance in a 1-cm cell against a blank solution. Use Kodak filters Nos. 5 (550 mμ) and 7 (610 mμ) for Titan Yellow and Azovan Blue respectively. The Azovan Blue colour is quite stable for up to 6 hr. Standard curves for magnesium with both dyes are shown in Fig. 1.

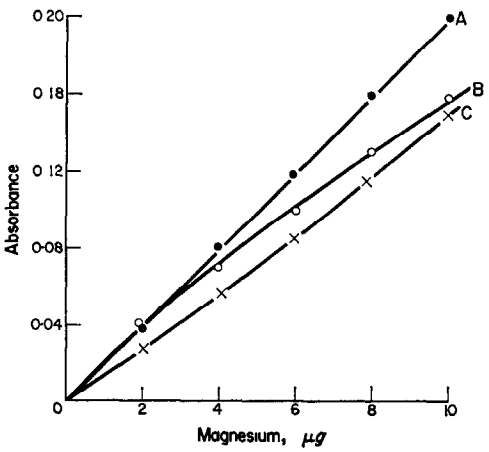

FIG. 1.—Standard curves for determination of magnesium with Azovan Blue and Titan Yellow.

A—Azovan Blue, Kodak Filter No. 7
B—Azovan Blue, Kodak Filter No. 8
C—Titan Yellow

Procedure for the determination of magnesium in serum and spinal fluid

Separate serum from the clot as soon as possible to avoid the migration of magnesium from red blood corpuscles to the serum. Place 0·5 ml of serum or spinal fluid in a test-tube, and dilute it to 3 ml with distilled water. Add 1 ml of sodium tungstate solution and 1 ml of 0·33*M* sulphuric acid. Mix well and then centrifuge. Take 2·5 ml of the supernatant fluid and complete the colour development in the way described above. Develop an aqueous standard for each batch of sera.

RESULTS AND DISCUSSION

Recovery was tested by the addition of known amounts of magnesium to the serum, and found to be at least 85%.

Gum-ghatti, polyvinyl alcohol (PVA), polyethylene glycol (PEG), polypropylene glycol and methylcellulose in the concentration range 0·05–1% were examined as potential stabilizers of the magnesium lake. PVA, methylcellulose and PEG stabilized the lake for more than an hour, but in the present investigation 0·05% PVA solution was used.

The lake forms only at high pH. To determine the optimum conditions, the colour was developed at different concentrations of alkali (Table I). The concentration of sodium hydroxide between 2 and 10*M* does not affect the sensitivity. However, 4*M* sodium hydroxide was found to be most suitable because at higher concentrations of alkali bubbles form in the solution and the viscosity increases, and at lower concentrations the results are not reproducible. The absorbance of the lake was measured

TABLE I.—ABSORBANCE OF Mg-DYE LAKE IN PRESENCE OF VARIOUS CONCENTRATIONS OF ALKALI SOLUTIONS

NaOH, *M*	Drum reading	
	5 μg Mg	10 μg Mg
2	0·10	0 17
4	0 105	0·185
6	0·10	0·23
8	0·115	0·23
10	0 11	0 22

against a blank with different filters. Beer's law is obeyed and the greatest absorbance is obtained when a Kodak filter No. 7 is used.

To determine the amount of dye required per μg of magnesium, dye solutions of different concentrations were used. The results are shown in Fig. 2, from which it is

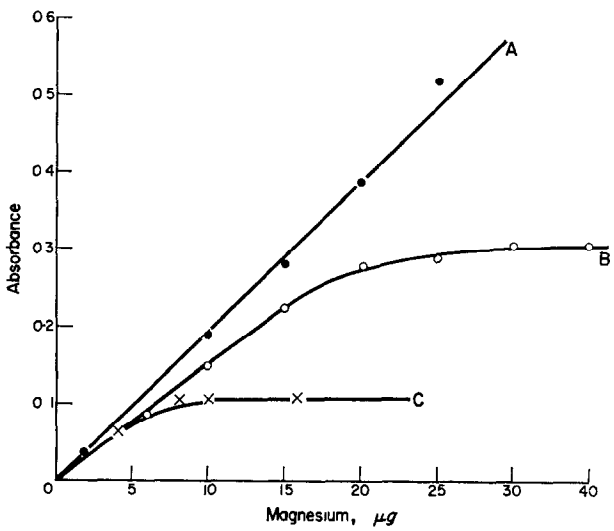

FIG. 2.—Standard curves for determination of magnesium with varying concentrations of Azovan Blue.
A—Azovan Blue 40 mg/ml
B—Azovan Blue 20 mg/ml
C—Azovan Blue 10 mg/ml

concluded that about 6·7 μg of dye per μg of magnesium is the optimum ratio and that the mole ratio of magnesium to dye in the lake is 6:1. The molar absorptivity is $2{\cdot}4 \times 10^3$ cm^2. mmole^{-1}. The sensitivity with Azovan Blue is greater than that with Titan Yellow.

Most biological materials contain a variety of cations of which only calcium may be expected to interfere under the conditions of the reaction. Magnesium and calcium react with many azo dyes in alkaline medium through either two *o,o'*-hydroxyl groups or one *o*-hydroxyl and one *o*-carboxyl group.[11] The advantageous feature of this dye is that it is less subject to calcium interference than other azo dyes which have been proposed for the determination of magnesium (Table II).

A calcium/magnesium ratio of 50 does not affect the determination of magnesium by the Azovan Blue method, but a ratio of 10 is the maximum tolerable in the Titan Yellow method.

TABLE II —ABSORBANCE OF Mg-DYE LAKE IN PRESENCE OF CONSTANT AMOUNT OF MAGNESIUM AND DIFFERENT AMOUNTS OF CALCIUM

10	500	0 20	0 36

TABLE III.—DETERMINATION OF MAGNESIUM IN 100-ml SERUM SAMPLES BY THE TITAN YELLOW AND AZOVAN BLUE METHODS

Magnesium found, *mg* %		
Azovan Blue	Titan Yellow	Difference, %
2 42	2 32	+4
2 40	2 40	—
1 76	1·76	—
2 02	2 02	—
1 06	1 06	—
2 17	2 22	−2
2 19	2 22	−1
2 00	1 96	+2
1·85	1 96	−5
2 30	2 12	+7

Magnesium in 10 serum samples was determined by both methods (Table III). The results are in good agreement with each other. In cerebrospinal fluid samples, the magnesium content was found to vary from 1·0 to 3·4 mg/100 ml. It has been reported that the Titan Yellow method, used here for comparison, yields results on serum 10–15% higher than those obtained by the magnesium ammonium phosphate method.[12] It has been pointed out[4,13,14] that the presence of calcium intensifies the colour of the magnesium Titan Yellow lake, although it has been claimed[15–20] that calcium in the concentrations found in serum does not interfere. The results in Table II show that the colour of the Titan Yellow is only increased if the calcium concentration is ten times that of the magnesium. Thus, calcium would not be expected to interfere in the determination of magnesium in serum.

Acknowledgement—The authors are indebted to Dr. T. A. Venkatasubramanium, Department of Biochemistry, Patel Chest Institute and Dr. B. C. Ray Sarkar, Institute of Nuclear Medicine and Allied Sciences, for their keen interest and encouragement. The thanks of the authors are also due to Lt. Col. S. K. Mazumdar, Officer-in-Charge, Institute of Nuclear Medicine and Allied Sciences, for providing facilities.

Résumé—On décrit une méthode photométrique pour le dosage du magnésium en présence d'une quantité jusqu'à 50 fois supérieure de calcium. Il se forme une laque magnésium—Bleu Azovan, stabilisée à l'alcool polyvinylique, et l'on mesure l'absorption (filtre Kodak no 7). On a utilisé la méthode pour doser le magnésium dans les sérums.

Zusammenfassung—Ein photometrisches Verfahren zur Bestimmung von Magnesium neben bis zu 50-fachem Überschuß an Calcium wird beschrieben. Es wird ein Farblack aus Magnesium und Azovanblau gebildet, mit Polyvinylalkohol stabilisiert und die Extinktion gemessen (Kodak-Filter Nr. 7). Die Methode wurde auf die Bestimmung von Magnesium in Seren angewandt.

APPLICABILITY OF THE QUASI-ADIABATIC ENTHALPIMETRIC METHOD FOR THE STUDY OF CHEMICAL KINETICS

PAOLO PAPOFF and PIER GIORGIO ZAMBONIN
Istituto Chimica Analitica, Università di Bari, Italy

(*Received* 22 *June* 1966. *Revised* 25 *October* 1966. *Accepted* 31 *December* 1966)

Summary—The thermal quasi-adiabatic method and the non-adiabatic one are compared for the study of chemical kinetics. With thermistors as temperature-sensitive elements, and a very simple apparatus, moderately fast reactions (with $t_{1/2}$ down to 2 sec) and consecutive reactions can be followed, and mixtures analysed with good accuracy. The reproducibility is satisfactory over a wide range of experimental conditions. The calculation of the kinetic parameters, for both first- and second-order kinetics is very simple and requires no calibration of the system. Application of the technique to the study of the alkaline hydrolysis of some alkyl acetates is described.

THE analysis of a mixture of two constituents with similar chemical properties is often difficult by traditional chemical or physical methods, but is easily achieved kinetically if the compounds react at sufficiently different rates with the same reagent. This method of analysis has been so greatly developed in recent years, especially for mixtures of organic compounds,[1–3] as to suggest the utility of setting up a kinetic technique which offers the advantages of (*a*) permitting use of different solvents without the loss of accuracy, (*b*) extensive application to many important chemical reactions in a rate-range often difficult to deal with, (*c*) rapidity, and (*d*) inexpensive and simple instrumentation, mostly readily available in the laboratory. The enthalpimetric method, in which the temperature changes of a system during a reaction under quasi-adiabatic conditions are measured with thermistors is particularly useful, and permits the rate constants of relatively fast reactions to be measured with a precision of $\pm 1\%$, and an accuracy presumably of the same order. This paper describes the conditions and limits of applicability of the method both in chemical kinetics and analytical chemistry.

The study of chemical kinetics through enthalpimetry has been pursued by various authors, principally with non-adiabatic conditions, using either a single reaction cell[4–9] or two cells for differential measurements.[10,11] Under these experimental conditions, by appropriately modifying the characteristics of the cell–thermostat separator one can follow relatively slow reactions[9] as well as relatively fast ones with $t_{1/2}$ down to 0·2 sec.[7]* The corresponding time–temperature curves are similar to those of two consecutive reactions and have a maximum, the quantity of heat playing the part of the intermediate compound. For first-order reactions, fairly good values of rate constants can be obtained from the values of time[4,6] or temperature[6–8] corresponding to the maximum. In the other cases different points in the ΔT *vs.* t curves must be used,[4,5,9–11] with a complicated and lengthy calculation.

* With the flow method, thermocouples being used to measure the temperature, very fast kinetics have been followed.[12]

Because of the method of calculus used in these methods, it is necessary to measure the ΔT value for the same reaction in adiabatic conditions, the exact relationship between temperature and the electrical quantity measured, and also the heat contribution due to the mixing of the reagents and the Newton heat–exchange constant.

It must finally be emphasized that the sign and magnitude of the heat of mixing, and the time lag corresponding to the mixing, greatly affect the accuracy of the results, limiting the applicability of the enthalpimetric method. At any rate, it cannot be usefully employed for the kinetic analysis of a mixture. The authors cited claim a precision of 5–10%, though for slow reactions (observation times of about an hour), Becker obtained a precision of 2–3%.[9] Recently, Walisch and Becker[14] have devised an experimental technique based on the use of the Peltier battery; they follow the kinetics of an exothermic reaction at a strictly constant temperature through control of the energy required by the Peltier battery to compensate for the heat of the reaction.

Wyatt[13] has described a method which is essentially adiabatic; the loss of heat from the reaction vessel to the environment was balanced, before and during the reaction, by means of a small heater. In our work, since the initial difference of temperature between the cell and the thermostatic bath was kept essentially zero, there was no need to compensate for heat loss and the use of thermistors instead of thermocouples simplified the instrumentation.

Calculation of the kinetic data for quasi-adiabatic conditions

The kinetic constant can be calculated graphically through a plot of V *vs.* t, where V is the signal of the unbalanced bridge containing the thermistor in one arm, and is proportional within certain limits[15] to ΔT.

Figure 1 shows an example of the curve recorded for a first-order reaction. In this, the line b—drawn tangentially to the experimental curve for times corresponding practically to 100% reaction—is parallel to the curve a recorded before the addition of the reactant (the slope of a depends on the mechanical agitation), and the distance d represents the heat of dilution.

The distances h of the points of the experimental curve c from the straight line b are proportional to the amount of unreacted substance $(a–x)$. The value of k is obtained directly from the slope of a plot of log h *vs.* t (curve e). The intercept for $t = 0$ allows computation of the value of h^0 in the case in which the experimental curve does not allow easy measurement of the contribution due to the heat of mixing (chemical reaction rate fast compared to mixing rate). The value of ΔH of reaction can be obtained from the value of h^0 by calibration of the system. Second-order kinetics can be treated in the same way. In this case the $(a–x)$ value is given by the corresponding value of $\left(\frac{(h^0 - h}{h^0}\right)a$; h^0 is generally obtained directly from the experimental V *vs.* t curve. When this cannot be done (because there is not a clear distinction between the heat of mixing and the heat of reaction) the heat of mixing is measured in a separate test. The activation energy can be obtained from a plot of log k against $1/T$ where T is the absolute temperature.

Analysis of a mixture

The law governing the reaction of a mixture of two compounds A and B simultaneously reacting with the same reagent with first-order kinetics is obtained by

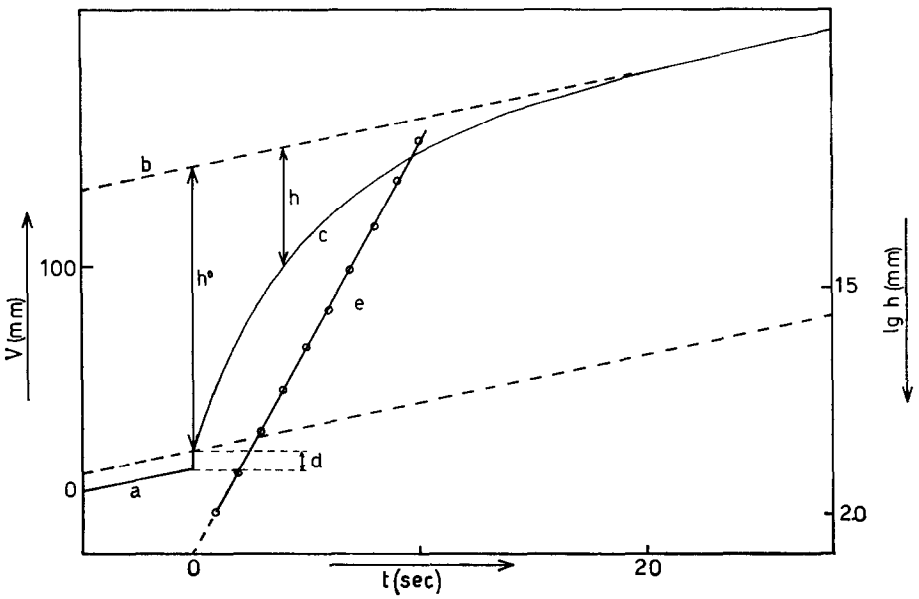

FIG. 1.—Example of quasi-adiabatic curve recorded during the hydrolysis of 0·012*M* methyl acetate with 0·50*M* NaOH at 32°C.
The intercept of log *h* (curve *e*) at $t = 0$ gives a value of $h^0 = 122$ mm; the value calculated directly from curve *c* is 125 mm. The curves are identified in the text.

combining the relationship valid for each of the individual components. Using the symbols from Fig. 1:

$$h_A = h_A^0 \,.\, \exp(-k_A t)$$

$$h_B = h_B^0 \,.\, \exp(k_B t).$$

Then

$$h = h_A + h_B = h_A^0 \,.\, \exp(-k_A t) + h_B^0 \,.\, \exp(-k_B t). \qquad (1)$$

The experimental curve *V vs. t* or ΔT *vs. t* which is obtained is of the type shown in Fig. 2. If the values of k_A and k_B are different enough, a plot of log *h vs. t* gives a curve of the type *a* in Fig. 2, from which it is possible to calculate the amount of A and B in the mixture. From curve *a* the value of log h_B^0 can be extrapolated when [A] has become negligible with respect to [B]. Under these conditions, equation (1) is reduced to:

$$\log h = \log h_B^0 - 2{\cdot}3 \,.\, k_B t. \qquad (2)$$

Once h_B^0 is known, the value of h_A^0 can be obtained from h^0 on the experimental curve. When this cannot be done, one can obtain h_A^0 by plotting log $(h - h_B)$ *vs. t* and extrapolating to $t = 0$ (curve *c* of Fig. 2).

The composition of the mixture can be obtained from the values of h_A^0 and h_B^0 by using either the values of ΔH and that of the calorimetric constant or an experimental relation between *h* and *c*.

A very quick method for finding the values of h_A^0 and h_B^0 is that of using only one point of the experimental curve in addition to the value of h^0.[3]

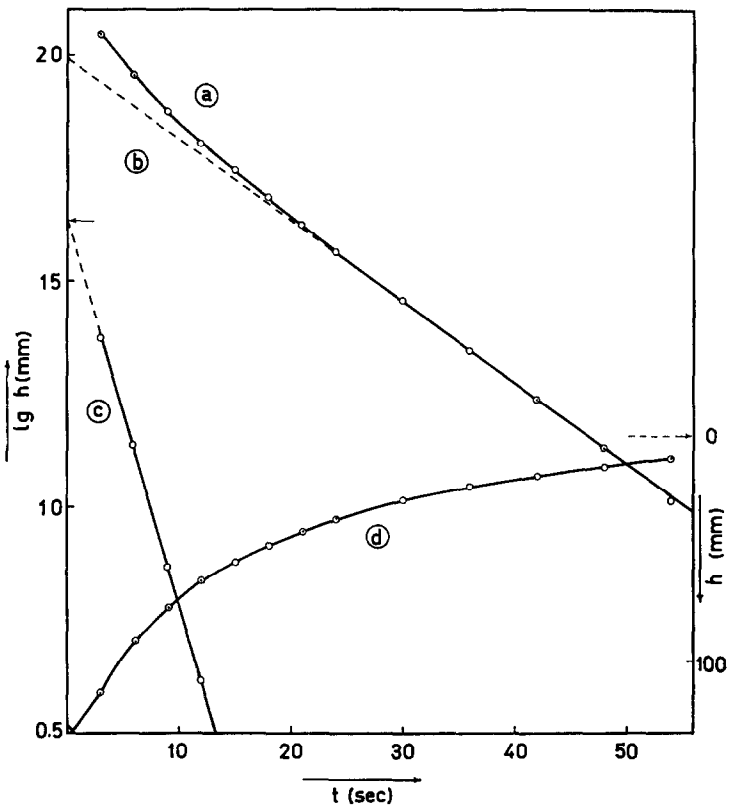

FIG. 2.—Kinetic analysis of a mixture of methyl acetate (0·424 mmole) and isopropyl acetate (0·848 mmole).
(*a*) Log h [$= \log(h_{Me} + h_{isoPr})$] *vs.* t.
(*b*) Extrapolation of curve (a) to give h^0_{isoPr} as the intercept, corresponding to $h_{Me} \ll h_{isoPr}$.
(*c*) Log $(h - h_{isoPr})$ *vs.* t. The intercept gives the value of h^0_{Me}.
(*d*) Experimental values for h *vs.* t.

From equation (1) divided by h^0 we have

$$\frac{h}{h^0} = \frac{h_A{}^0}{h^0}\,[\exp(-k_A t) - \exp(-k_B t)] + \exp(-k_B t)$$

and for a given value of t·

$$h_A{}^0 = \frac{h - Dh^0}{C}$$

where:

$$C = \exp(-k_A t) - \exp(-k_B t); \qquad D = \exp(-k_B t).$$

C and D are constant for a given mixture, once temperature and time have been fixed. The choice of the most suitable time value is made on the basis of the values of k_A and k_B:

$$t_{optimum} = \frac{2{\cdot}3 \log(k_A/k_B)}{k_A - k_B}.$$

If for any reason one cannot follow the reaction to its completion—in which case the value of h^0 would not be known—then $h_A{}^0$ and $h_B{}^0$ can be computed by using two points of the experimental curve.

EXPERIMENTAL

Apparatus

The apparatus has already been described.[15] The reaction cell, which consists of a vessel with insulated walls, has on its top an insulating cover through which are inserted a stirrer, a small heating resistor (for adjusting the initial temperature), a thermistor, and a phial-breaker (or a syringe needle). The thickness and the thermal capacity of the reaction cell and the equipment contained therein are kept as low as possible in order to achieve a rapid thermal equilibration of the calorimetric system during the reaction, which is particularly necessary for the study of fast reactions. The cell is immersed in a thermostatic bath regulated to $\pm 0{\cdot}01°$. The inertia of the calorimetric system in reaching thermal equilibrium under certain conditions of mechanical agitation may be estimated by causing an instantaneous thermal event (*e.g.*, rapid injection of a few drops of a substance having a high heat of dilution) and recording the temperature change.

If a Dewar vessel with very thin walls (*e.g.*, the lightest commercial thermos has a wall thickness of about 0·5 mm) or an externally insulated metallic vessel with moderately rapid stirring (2000 rpm) is used, the response time (99% of complete change) can be less than a second. Under these conditions, kinetics for reactions with $t_{1/2}$ down to about 2 sec can be followed with an error of 1%.

For kinetics with observation times greater than several minutes, the temperature of the thermostatic bath is continuously adjusted to follow that of the reaction cell to $\pm 0{\cdot}01°$, by the use of a Wheatstone bridge with two fixed arms and two thermistors with identical characteristics, one immersed in the reaction cell and the other in the thermostatic bath. When appropriately amplified, the signal from the unbalanced bridge controls the temperature of the thermostatic bath through a proportional device.[16] With observation times of about 10 min, this device gives a reproducibility of 1%.

The thermistors (thin glass probe, fast response, 2K type) were supplied by Fenwal Electronics Inc. The voltage supply for the bridge was a 1·5-V battery. The output of the bridge (0–3 mV) was recorded on a potentiometric recorder (1-sec, 1, 2 or 5 mV f.s.d.) manufactured by Texas Instruments Inc.

Reagents

The ethyl, methyl, and isopropyl acetates were purified by standard procedures.

RESULTS AND DISCUSSION

To check the range of applicability of the equipment, measurements were made of the hydrolysis of some esters of acetic acid for which abundant rate-data exist in the literature.

Tables I–III show our data along with those of other authors, with an indication of the experimental method used in each case. It may be noted that with one exception,[6] the experimental conditions used by the other authors led to rates smaller by one or more orders of magnitude. In the same range of sodium hydroxide concentrations the best agreement was found with the data of Becker,[9] there being a rather substantial (15–20%) disagreement with those of the other authors. Such a difference might be due to an insufficiently reliable titrimetric method in the case of such fast reactions, or to insufficient accuracy of the non-adiabatic enthalpimetric method based only on the measurement of the maximum of the $\Delta T/$ *vs.* t plot. We used sodium hydroxide concentrations ranging from 0·01 to 1M and in order to get sufficiently high reaction rates, the experiments at lower concentrations were run with correspondingly higher concentrations of esters (up to 0·8M). It has been verified, however, that the second order rate constant is independent of the ester concentration.

The data show that the second-order specific rate has k_{II} increasing somewhat with increasing concentration of alkali; this increase is considerably greater than

might be due to experimental errors. The variation of k_{II} with concentration of alkali is not linear, however, but levels off with increasing alkali concentration.

That this behaviour can hardly be a simple salt effect is shown by the data in Table V, for ester-hydrolysis reactions in solutions with varying salt concentrations. The effect is that of *decreasing* the reaction rate in an approximately logarithmic fashion as is expected for a reaction between a neutral molecule and an ion.[17] The slope in the plot of log k *vs.* [NaCl] for the hydrolysis of ethyl acetate is in agreement with the value found by Edith Schade.[18]

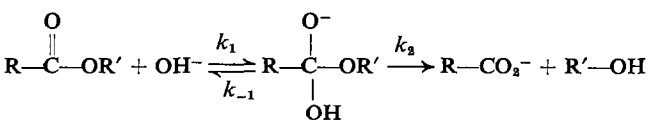
0·731	0·192 ± 1%	1·485	0 112 ± 0·5%		

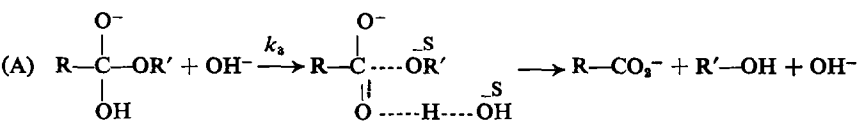
The paucity of experimental data does not permit us to put forward a proven mechanistic interpretation of the effect of high concentrations of alkali, but a mechanism can be suggested.

It is well known that the saponification of esters proceeds through addition of OH^- to the carbonyl group leading to a tetrahedral intermediate which can either decompose to alcohol and carboxylic acid or revert to starting material.[19]

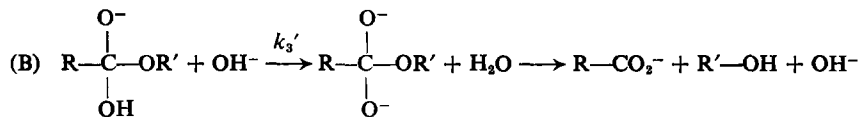


I

The fact that ^{18}O-exchange between the aqueous solvent and the carbonyl group of the unreacted ester takes place at a rate comparable to the saponification rate, clearly indicated that the decomposition steps of intermediate **I** effectively compete with each other (*i.e.*, k_{-1} and k_2 are of the same order of magnitude). Under such circumstances, an additional contribution to the rate may be expected in more concentrated alkali. This would be a base-promoted proton abstraction from **I** leading to products in a single concerted step (A), or by way of a second intermediate, **II**, which in turn may either yield the products or revert to **I**.



I



II

This hypothesis is not unreasonable in view of the following.

(*a*) Ester hydrolysis is known to undergo general base catalysis,[20] an observation requiring an explanation similar to that offered here.

(*b*) A third-order contribution, second-order in $[OH^-]$, has been found by Taft[21] in the alkaline hydrolysis of trifluoroacetanilide and has been explained on the same basis. Actually, Taft proposed the formation of a doubly-charged anion as a second intermediate (mechanism B). It is clear, however, that the concerted process A alternatively proposed here would be indistinguishable from B on the basis of the facts now available.

(*c*) Finally, as the data of Tables I–III show, the increase of k_{II} with increasing hydroxyl ion concentration becomes greater in the order: methoxide < ethoxide < isopropoxide, *i.e.*, in the inverse order of mobility of the leaving group*; the contribution that this additional path makes to the total rate is expected to become relatively more important the "harder" the leaving group since the "spontaneous" decomposition path of intermediate **I** (k_2) becomes relatively less important.

We feel that the rationalization offered here is a working hypothesis more than an explanation, and much more experimentation is needed in order to provide it with a sound factual basis.

To examine the possibility of using the apparatus for kinetic chemical analysis, we studied the model system of methyl acetate and isopropyl acetate at different ratios of ester concentration. The results, calculated in accordance with the preceding paragraph, are reported in Table VI; they show the applicability of the method for the rapid analysis of mixtures or, similarly, for the study of consecutive reactions.

In this case, too, the contribution due to the heat of dilution (and thus to the stirring speed) does not have a critical influence on the accuracy. For the experiment reported in Fig. 2, for example, the mixture of esters was purposely introduced at a temperature lower than that of the solution. In addition, the stirring speed used was only 1500 rpm. Examination of curve *d* in Fig. 2 shows that there was an initial drop in temperature quickly compensated for by the development of the heat of reaction. This low stirring speed allows a reading of the first useful point only after 3 sec, when about 40% of the more reactive compound has already reacted; in addition, the negative thermal contribution during the mixing makes the height h^0 indeterminate. In each

* That the order of leaving group mobility is $MeO^- > EtO^- >$ iso-PrO^- seems reasonable on the basis of the inductive effect of alkyl groups. It is also experimentally supported by the fact that in the ^{18}O experiments the ratio k_{ex}/k_{hydr} increases when going from ethyl to isopropyl esters.

TABLE VI.—KINETIC DIFFERENTIAL ANALYSIS FOR THE MODEL SYSTEM ISOPROPYL ACETATE/METHYL ACETATE

case, the value of the heights h relative to each of the components—obtained through extrapolation of the curves a and b—was in excellent agreement with the theoretical data.

CONCLUSION

The quasi-adiabatic thermal method represents a powerful tool for the study of moderately fast reactions ($t_{1/2}$ down to 2 sec). Consecutive reactions or differential kinetic analysis can be followed with good accuracy and reproducibility, and the results are not critically affected by changes in the experimental conditions.

Zusammenfassung—Die quasiadiabatische und die nichtadiabatische thermometrische Methode werden hinsichtlich ihrer Anwendung auf die chemische Kinetik verglichen. Mit Thermistoren als Temperaturfühlern und einer sehr einfachen Apparatur konnen ziemlich schnelle Reaktionen (mit Halbwertszeiten bis herunter zu 2 sec) und Folgereaktionen verfolgt sowie Mischungen mit guter Genauigkeit analysiert werden. Die Reproduzierbarkeit ist in einem weiten Bereich experimenteller Bedingungen zufriedenstellend. Die Berechnung der kinetischen Parameter ist für erste und zweite Ordnung sehr einfach und erfordert keine Eichung des Systems. Die Anwendung des Verfahrens auf die alkalische Hydrolyse einiger Alkylacetate wird beschrieben.

Résumé—On compare les méthodes thermiques quasi-adiabatique et non-adiabatique pour l'étude des cinétiques chimiques. Avec des thermistors pour éléments sensibles à la température et un appareil très simple, on peut suivre des réactions modérément rapides (avec $t_{1/2}$ descendant jusqu'à 2 sec) et des réactions consécutives et analyser des mélanges avec une bonne précision. La reproductibilité est satisfaisante dans un large domaine de conditions expérimentales. Le calcul des paramètres cinétiques, pour les cinétiques d'ordre un et deux, est très simple et ne nécessite pas d'étalonnage du système. On décrit l'application de la technique à l'étude de l'hydrolyse alcaline de quelques acétates d'alkyle.

1-HYDROXY-ETHYLIDENE-1,1-DIPHOSPHONIC ACID AS A TITRIMETRIC AGENT

R. PŘIBIL and V. VESELÝ
Laboratory for Analytical Chemistry, J. Heyrovský Polarographic Institute, Czechoslovak Academy of Sciences, Prague 1, Jilská 16, Czechoslovakia

(*Received* 22 *November* 1966. *Accepted* 12 *December* 1966)

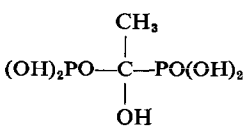
Summary—1-Hydroxy-ethylidene-1,1-diphosphonic acid (HEDPHA) has been proposed as a highly selective titrimetric reagent for thorium. In the presence of 1,2-diaminocyclohexanetetra-acetic acid (DCTA) a soluble binuclear ternary complex, $Th_2(DCTA)_2(HEDPHA)$, is formed. The determination of thorium is carried out in a slightly acidic medium, buffered with urotropine, with 0·025*M* HEDPHA, and Xylenol Orange as indicator. DCTA masks all bivalent metals, rare earths, scandium, yttrium, bismuth, iron, gallium and indium. Only zirconium, titanium, aluminium and large amounts of thallium(III) interfere.

IN ONE of our previous papers[1] we paid attention to the determination of light lanthanides in the presence of erbium, thulium and ytterbium. The method is based on the displacement reaction:

$$LnY^- + Zn^{2+} + PO_4^{3-} = ZnY^{2-} + LaPO_4 \qquad (1)$$

where Ln = La, Ce, Pr, Nd; Y = anion of EDTA. These titrations are performed in urotropine-buffered medium at pH 5–5·5 with Xylenol Orange as indicator. Reaction (1) is quantitative and fast enough for analytical purposes only for light lanthanides. Some other rare earths react slowly with phosphate but erbium, thulium and ytterbium do not react at all. Recently our study has been extended to other titrants (DCTA, DTPA, TTHA, *etc.**) and other complex-forming agents such as pyrophosphate and fluoride. From our experiments we obtained a very different picture about the reaction (1). For example the thorium complex of TTHA does not react with phosphate during the zinc titration, whereas the scandium complex does.[2] DTPA complexes of rare earths are not displaced during the zinc titration in the presence of phosphates. On the contrary, all rare earths can be determined by back-titration of DTPA with zinc even in the presence of phosphates.[3] TTHA complexes of lanthanum, cerium and praseodymium are displaced very slowly or not at all by zinc according to reaction (1), whereas the heavier lanthanides are displaced quantitatively. Details will be published soon.

The complex-forming properties of 1-hydroxy-ethylidene-1,1-diphosphonic acid (HEDPHA), which might have been expected to act in a way similar to orthophosphate, are described below.



HEDPHA

The free acid behaves as a dibasic acid when titrated to the Methyl Red end-point and as a tribasic acid when titrated to the phenolphthalein end-point. Its efficiency

* DCTA = 1,2-diaminocyclohexane-*N,N,N′,N′*-tetra-acetic acid
DTPA = diethylenetriamine-*N,N,N′,N′,N″*-penta-acetic acid
TTHA = triethylenetetramine-*N,N,N′,N″,N‴,N‴*-hexa-acetic acid.

in masking bivalent cations from Xylenol Orange is very low, but aluminium, iron(III) and titanium are masked completely, though in their presence poor end-points are obtained in the titration of bivalent metals such as zinc and lead. The complexes of iron(III) with EDTA and DCTA do not react with HEDPHA, but the corresponding aluminium and titanium complexes do to some extent. In acidic medium it precipitates thorium, scandium and rare earths. The precipitation of thorium and scandium can be followed with Xylenol Orange as indicator; the precipitation of scandium gives a very sharp end-point.

It is well-known that thorium EDTA or DCTA complexes, even in the presence of excess of complexing agents react at above pH 4 with various metallochromic indicators such as Xylenol Orange or Methylthymol Blue, to give a ternary complex ThY-X which is red in colour, displacing hydroxide ion from the complex ThOHY, which is formed at this pH in the absence of suitable ligands ($\log K^{OH}_{ThOHY} = 7$).

In preliminary experiments we have titrated solutions of Th-EDTA or Th-DCTA (prepared by titration of thorium with EDTA or DCTA at pH 2·5–3·5) with HEDPHA solution, Xylenol Orange being used as indicator. The solutions were well buffered with urotropine before the start of the titration. All the solutions remained clear without any traces of cloudiness and the end-point with Xylenol Orange was sufficiently sharp provided that the titration was performed slowly and with intense stirring. The consumption of HEDPHA was exactly half a mole for one mole of thorium. This is not in agreement with the direct titration of thorium in acidic medium (without EDTA or DCTA) in which a precipitate of 1:1 composition is formed. We have also found that the complexing agent is not liberated at all from the Th-EDTA or Th-DCTA complex during the titration with HEDPHA. This difference in behaviour indicates that the complexing agent takes part in this titration. We assume that a binuclear ternary complex of the structure (I) is formed according to the reaction:

$$2ThY + H_4CP_2O_5 = Th_2Y_2(CP_2O_5)^{4-} + 4H^+ \qquad (2)$$

or

$$2ThY + CP_2O_5^{4-} = Th_2Y_2(CP_2O_5)^{4-} \qquad (3)$$

where CP_2O_5 is an anion of HEDPHA

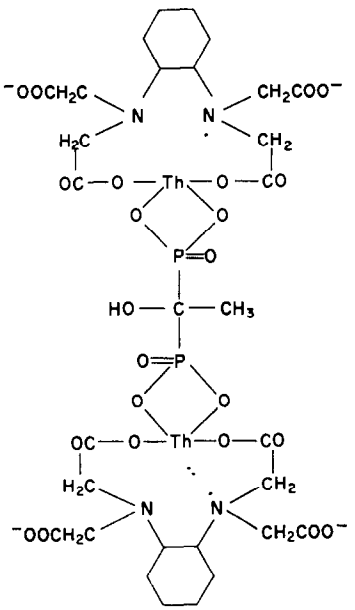
The existence of such a complex has been confirmed by acid-base titrations of mixtures of thorium–EDTA (or –DCTA) complex and HEDPHA in the ratio 2 ThY : 1 HEDPHA. It is analogous to the binuclear Xylenol Orange complex,[6] $Th_2Y_2(XO)_2$, whose existence is indicated by spectrophotometric and biamperometric titrations.

Our findings prove also the existence of a ternary complex of thorium with Xylenol Orange at above pH 4. At the end-point (colour change from red-violet to yellow or orange-yellow) such a reaction might exist:

$$2ThY\text{–}XO + CP_2O_5 = Th_2Y_2(CP_2O_5) + 2XO \qquad (4)$$

red violet yellow

(charges are omitted).



(I)

These findings led to a study of the experimental conditions which would enable thorium to be determined titrimetrically with HEDPHA in the presence of DCTA or EDTA which would serve as a masking agent for other elements.

EXPERIMENTAL

Reagents

Thorium nitrate solution, 0·05*M*. Dissolve 27·66 g of $Th(NO_3)_4.4H_2O$ in 100 ml of 1*M* nitric acid and dilute to 1 l.

DCTA, 0·05*M*. Dissolve 17·8 g of 1,2-diaminocyclohexanetetra-acetic acid in 100–120 ml of 1*M* sodium hydroxide with slight warming. Allow to cool and dilute to 1 l.

DTPA, 0·05*M*. Dissolve 19·65 g of diethylenetriaminepenta-acetic acid in 100–120 ml of 1*M* sodium hydroxide with slight warming. Allow to cool and dilute to 1 l.

Zinc nitrate solution, 0·05*M*. Dissolve 2·2685 g of metallic zinc in 40 ml of nitric acid (1 + 1) and dilute to 1 l.

HEDPHA, 0·025*M*. Dissolve 5·5–5·8 g of 1-hydroxyethylidene-1,1-diphosphonic acid in 100 ml of water. Adjust the pH of the solution with 1*M* sodium hydroxide to 4·5–5 (indicator paper) and dilute to 1 l. The sample used (Albright and Wilson) contained 7·74% of water (determined by drying to constant weight at 110°).

Urotropine solution, 20%.

Nitric acid, approx 1*M*.

Sodium hydroxide, approx 1*M*.

Xylenol Orange solution, 0·5% *aqueous*.

Standardization of the solutions

Zinc nitrate solution (0·05*M*) serves as a standard. Solutions of DCTA and DTPA are standardized complexometrically with zinc, at pH 5–5·5, (urotropine buffer), Xylenol Orange being used as indicator. The thorium nitrate is standardized by DCTA titration at pH 3, with Xylenol Orange as indicator. HEDPHA is standardized as follows. Place 5 ml of 0·05*M* thorium nitrate in a 250-ml beaker, add 6–7 ml of 0·05*M* DCTA and dilute to 100–120 ml. Add a few drops of Xylenol Orange, buffer the solution with urotropine solution to give a red-violet colour and add a further 10 ml. Titrate this solution with 0·025*M* HEDPHA from red-violet to orange-yellow. Calculate the titre according to the relationship 1 ml 0·05*M* $Th(NO_3)_4 \equiv$ 1 ml 0·025*M* HEDPHA.

Solutions (0·05*M*) of various metals, *viz.*, various rare earths, Fe, Bi, Zr, Al, Ga, In, Tl(III), Ti, Sc, Y, Ni, Cu, Cd, Zn), were prepared from reagent grade chemicals and standardized complexometrically.

Procedures

Determination of thorium, preliminary experiments. From 5 to 10 ml of 0·05*M* solution of thorium nitrate were diluted to 100–120 ml and the pH adjusted to 2·5–3 5 with 1*M* nitric acid or 1*M* ammonia solution or urotropine solution. A few drops of Xylenol Orange were added and the solution titrated with 0·05*M* EDTA or DCTA from red-violet to lemon-yellow and a small excess of the titrant was added. Then urotropine was added to give a red-violet colour, and then 10 ml extra were added The resulting pH of the solution was 5–6. This solution was slowly titrated with 0·025*M* HEDPHA from red to orange-yellow. The end-points were sufficiently sharp and corresponded to accurate consumption, *i.e.*, 1 ml 0·025*M* HEDPHA ≡ 1 ml 0·05*M* $Th(NO_3)_4$ (from the first titration).

Similar titrations have been carried out with varying amounts of excess of DCTA. It is found that up to a 9-fold excess of DCTA does not influence the end-point and accuracy provided that not more than 120 mg of it is present. The results are summarized in Table I.

Xylenol Orange is suitable for this titration, but with Methylthymol Blue the colour change comes before the end point.

Determination of thorium in the presence of other metals. Preliminary experiments showed that EDTA is not suitable for masking. Some EDTA-complexes reacted slightly with HEDPHA and the results were higher for thorium than expected. For this reason DCTA, which forms more stable complexes than EDTA, has been used for all experiments. Because the end-point of HEDPHA

* Vague end-point, too much La present

titrations is sharpest if not too great an excess of free DCTA is present, the amount of other elements present has to be known. Their complexometric determination with EDTA or DCTA is impossible, because thorium interferes forming a coloured complex with Xylenol Orange (see above), but DTPA can be used.[4] Therefore for the determination of thorium two aliquots of the sample solution are necessary.

(*a*) *Determination of the sum of metals.* Add to a suitable aliquot an excess of 0·05*M* DTPA, dilute to 100–120 ml, add a few drops of Xylenol Orange, adjust the pH to 5–5 5 with urotropine and titrate with 0 05*M* zinc nitrate from lemon-yellow to red-violet.

(*b*) *Determination of thorium.* To the second aliquot in a beaker add the same volume of 0·05*M* DCTA as the DTPA consumed in titration *a* and then 1–3 ml in excess. Dilute to 100–120 ml, add Xylenol Orange and then urotropine till a red colour appears. To ensure good buffer capacity add 10 ml of urotropine in excess. Stir magnetically and titrate slowly with 0 025*M* HEDPHA from red to orange-yellow.

RESULTS

As can be seen from Table II a number of metals do not interfere, because they are firmly bound with DCTA. Only zirconium, titanium, aluminium and large amounts of thallium (III) interfere. Because of the partial reaction with HEDPHA the EDTA and DCTA complexes of these metals, the end-points are very indistinct and the titrations fail completely.

Acknowledgement—One of us (R. P.) expresses his heartiest thanks to Dr. A. F. Childs, Head of Research Department, Albright and Wilson (Mfg) Ltd., Oldbury, Birmingham, for the warm reception during his stay in Birmingham and for the gift of HEDPHA and other chemicals.

Zusammenfassung—1-Hydroxyathyliden-1, 1-diphosphonsäure (HEDPHA) wurde als hochselektives titrimetrisches Reagens für Thorium vorgeschlagen. In Gegenwart von 1,2-Diaminocyclohexantetraessigsäure (DCTA) wird ein löslicher zweikerniger ternarer Komplex $Th_2(DCTA)_2(HEDPHA)$ gebildet. Die Thoriumbestimmung wird in schwach saurem, mit Urotropin gepuffertem Medium mit 0,025*M* HEDPHA und Xylenolorange als Indikator ausgeführt. DCTA maskiert alle zweiwertigen Metalle, seltene Erden, Scandium, Yttrium, Wismut, Eisen, Gallium und Indium. Nur Zirkonium, Titan, Aluminium und große Mengen Thallium(III) stören.

Résumé—On a proposé l'acide 1-hydroxy éthylidène 1,1-diphosphonique (HEDPHA) comme réactif titrimétrique hautement sélectif du thorium. En presence d'acide 1,2-diaminocyclohexane tétracétique (DCTA), il se forme un complexe binucléaire ternaire soluble, $Th_2(DCTA)_2$-(HEDPHA). Le dosage du thorium est mené en milieu légèrement acide, tamponné à l'urotropine, avec HEDPHA 0,025*M* en présence de Xylénol Orangé comme indicateur. Le DCTA dissimule tous les métaux bivalents, les terres rares, le scandium, l'yttrium, le bismuth, le fer, le gallium et l'indium. Seuls le zirconium, le titane, l'aluminium et de fortes quantités de thallium(III) gênent.

DETERMINATION OF MICROGRAM QUANTITIES OF TIN(IV) BY A COMBINED ION-EXCHANGE/X-RAY FLUORESCENCE TECHNIQUE

B. R. CHAMBERLAIN and R. J. LEECH
Pilkington Brothers Limited, Research and Development Laboratory, Lathom, Ormskirk, Lancashire, U.K.

(*Received* 21 *November* 1966. *Accepted* 14 *December* 1966)

Summary—A method is described for the analysis of microgram quantities of tin in dilute hydrofluoric acid. The tin is extracted onto anion-exchange resin loaded paper discs by a very simple technique and the papers are examined by X-ray fluorescence spectrography. The solutions are obtained by the dissolution of tin-containing glasses, and the normal glass-forming elements do not interfere. The method is intended for the determination of 1–20 μg of tin but may be used for up to at least 250 μg; 5 μg can be determined with a precision of $\pm 10\%$

A METHOD was required for the determination of microgram amounts of tin in small quantities of 1% hydrofluoric acid. These solutions were obtained by etching tin-containing glasses. Attempts at the direct analysis of these solutions by X-ray fluorescence spectrography failed because of inadequate sensitivity. It was thought that a concentration or separation technique could be applied to increase the sensitivity to a satisfactory level. Among the methods considered were: the ring oven technique; extraction of tin into an organic solvent followed by evaporation; extraction onto an ion-exchange membrane or paper.

The third method was thought to be the simplest and cleanest. This technique has been used by other workers for the determination of trace quantities of many metals. Cation-exchange membranes and papers have been used with success for concentrating impurities in tungsten and molybdenum after separation from the major constituents.[1–5] The impurities (aluminium, calcium, chromium, cobalt, copper, iron, lead, manganese, nickel and zinc) dissolved in hydrochloric acid at pH 2, were collected by passing the solution through the ion-exchange paper a number of times in order to achieve equilibrium. The overall precision of the method was $\pm 10\%$.

Information on the use of anion-exchange membranes and papers is less comprehensive and to some extent conflicting. Lytle, Dye and Seim,[6] when investigating the uptake of molybdenum, zinc, gallium, copper, cobalt, iron, tin and bismuth, found that in no case was the transfer quantitative and that they were unable to obtain reproducible results. The membranes had been immersed in the solutions and agitated for some hours. Minns,[7] however, describes the successful extractions of chromium as chromate, and mercury and platinum as chloride complexes, by a filtration technique. Link and co-workers[8] were also able to separate mercury by a similar procedure and attained a precision of $\pm 25\%$ at the 1-μg level. A liquid anion-exchanger[9] has been used for the estimation of trace quantities of uranium.

EXPERIMENTAL

Apparatus

Beakers. Squat 100-ml polypropylene beakers (5 cm diameter, 6 cm high).

X-ray fluorescence. Philips PW1540 Universal all-vacuum spectrograph Tube: chromium target operated at 48 kV, 18 mA. Analysing line: SnLα (3 60 Å). Analysing crystal: LiF ($2d = 4{\cdot}028$ Å). Detector: flow proportional counter using argon–methane P10 mixture and pulse-height analyser. Collimator: coarse (480 μ). Exposure time· 50 sec.

Reagents

Hydrochloric acid (analytical reagent grade).

Ion-exchange paper. Rohm and Haas SB-2 anion-exchange paper. Cut circles of this paper with a circular punch of the correct diameter ($1\frac{5}{16}$ in.) to fit the standard sample holder of the spectrograph.

Tin solution. Dissolve 1·000 g of analytical reagent grade tin in 100 ml of hydrochloric acid (1 + 1) and fully oxidize it by passing chlorine or oxygen through the solution. Boil to expel excess of gas, cool, add 300 ml of concentrated hydrochloric acid and make to 1 l. with deionized water. Dilute this solution as required, always maintaining the acid concentration at 4*M* to prevent hydrolysis.

Procedure

Place in the beaker 10 ml of the 1% hydrofluoric acid containing the tin. Add 11 ml of concentrated hydrochloric acid and 4 ml of deionized water, making the solution 6*M* with respect to hydrochloric acid, then immerse a circle of anion-exchange paper in it for 18 hr Carefully remove the paper with acid-resistant tweezers and dry it for 2 hr in a fan oven at 45–50°. Mount the paper in the sample holder of the spectrograph by means of a rubber O-ring Fully evacuate the spectrograph and compare all samples with a single reference in order to obtain the ratio $I_{sample}/I_{reference}$ for each sample. Compare these ratios with the calibration graph obtained from standard tin solutions processed in a like manner

DISCUSSION

SB-2 ion-exchange paper, manufactured by Rohm and Haas, contains Amberlite IRA-400 anion-exchange resin which owes its activity to strongly basic quaternary ammonium groups. Dowex-1 is an equivalent resin and has been used by Nelson, Rush and Krauss[10] in their extensive investigations into the effect of hydrochloric and hydrofluoric acids on the distribution coefficients of many elements. The results quoted by Nelson *et al.* indicate that the optimum hydrochloric acid concentration for the extraction of tin(IV), in which form the tin is present, is 4*M*. Hydrochloric acid was chosen for the present work in preference to hydrofluoric acid because it is less obnoxious.

Filtration of the solutions through the papers and suspension of the papers in the agitated solutions were considered but were never put into operation because the procedure above was found to be so successful. A few preliminary experiments showed that a suitable quantity of solution in which to immerse the paper was 25 ml in a standard 100-ml squat beaker. It was also found that 25 ml could be employed in a 250-ml squat beaker but not in a 100-ml tall beaker. It seemed that the uptake of tin was some function of the depth of solution above the paper, and that if the depth were too great the uptake was low. The nature of this function was not investigated since it was such an easy matter to standardize the procedure. It was also found that the tin counts on the two sides of the paper were different; the mean value was taken.

It must be emphasized that although the papers are cut to fit snugly in the sample holder, the whole paper is not scanned by the X-ray beam. Clearly the conditions of uptake must be such that the tin is reproducibly distributed over each of the two surfaces of the paper. In order to establish this, papers were immersed in 50-μg standards in 4*M* hydrochloric acid, as recommended by Nelson *et al.* and removed at different times From Fig. 1 it can be seen that the averaged count from the papers

alters by a relatively small amount during an extended immersion. On the other hand the distribution of the tin alters markedly. Initially the top surfaces bear much more tin. This difference decreases until, after about 60 hr, the two surfaces are equivalent. After this the top surface still appears to lose tin and the lower to gain it. It would appear that the optimum immersion time is probably about 60 hr but this is not exactly an ideal time for a rapid analytical method. Eighteen hours may be regarded as a convenient overnight period and tests of reproducibility showed that satisfactory results could be obtained in this time. The standard deviation for ten 50-μg samples was found to be 1·7 μg and it is inferred that a reproducible

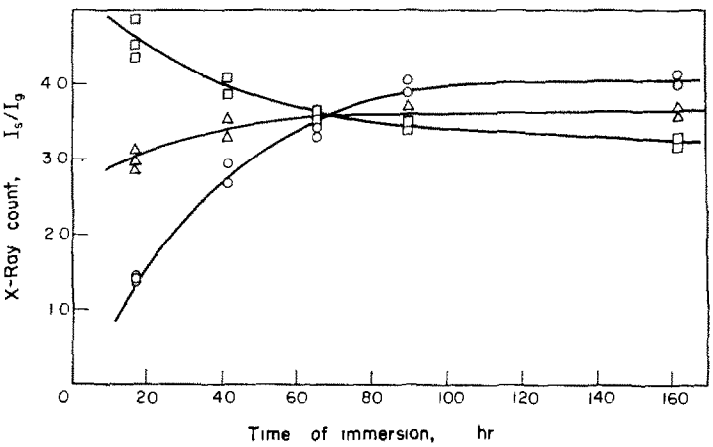

FIG. 1.—Distribution of the tin on the paper.
□—Top surface; ○—bottom surface; △—mean.

distribution over the surfaces is achieved. Measurement of one of these samples ten times indicated the standard deviation of the spectrographic measurements to be 0·7 μg.

The optimum concentration of hydrochloric acid was determined for three ranges of solutions: hydrochloric acid alone, hydrochloric acid/0·4% hydrofluoric acid (*i.e.*, 10 ml of 1% hydrofluoric acid diluted to 25 ml as in procedure), and hydrochloric acid/1% hydrofluoric acid. It can be seen from Fig. 2 that if the concentration is taken to be 6*M* then relatively wide limits may be tolerated for the concentration of hydrofluoric acid. It was found that the concentration of hydrochloric acid could not be raised above 8*M* without seriously affecting the mechanical strength of the paper.

One further point was investigated, namely the efficiency of extraction. Circles of paper were immersed in 50-μg standards for 18 hr. These papers were removed and replaced by fresh ones, which were also left for 18 hr. The process was repeated twice more. A simple extrapolation of the results shows that about 70–75% of the tin is extracted. That about 30% of the tin remains in solution is probably a major contributing factor favouring reproducibility. There is no reason to suppose that a dynamic equilibrium does not exist between solution and paper and, if the reaction is allowed full rein for sufficiently long, a uniform distribution should result. The satisfactory standard deviations indicate that 18 hr are sufficiently long to establish this over each surface

Some solutions may contain as much as 2 mg of dissolved glass; it was shown that up to 10 mg produced no noticeable interference.

Tin may also be extracted from 1–10*M* hydrofluoric acid, but silicon is also extracted and causes some interference in the measurement. Thus, besides being a particularly unpleasant reagent, hydrofluoric acid is in fact detrimental to the analysis.

Elements of medium atomic number have two spectra, K and L, which are suitable for analytical purposes. Unfortunately the K spectrum of tin, although the more intense, is masked by the very high background radiation due to the scattered continuum from the tube. On the other hand, the SnLα wavelength (3·6 Å)

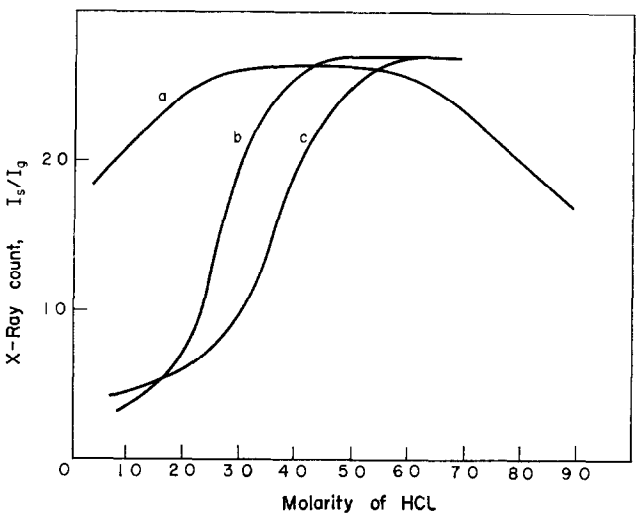

FIG. 2.—Effect of HCl concentration on tin uptake.
(*a*) No HF; (*b*) 0·4% HF; (*c*) 1 0% HF.

is appreciably absorbed by air so that either a hydrogen, helium or vacuum path is essential for maximum intensity.

Ion-exchange papers are more suitable than membranes for use in a totally evacuated system because of their greater mechanical strength and their ability to withstand drying without ill-effect. They also exhibit, in common with membranes[11,12] and filter papers,[13] the property of producing low background counts.

As temperature changes cause expansion of the analysing crystal, this and other less obvious factors can be responsible for a drift in intensity measurements during a series of analyses at this level. All samples were therefore compared to a reference (one side of a 50-μg standard) and the ratio $I_{\text{sample}}/I_{\text{reference}}$ was used throughout.

The calibration graph exhibits a slight upward curve from 0–25 μg but is then linear to at least 250 μg. The standard deviations computed at three levels, 3 μg, 7·5 μg and 15 μg, were 0·21, 0·29 and 0·42 μg respectively. The determination limit for simulated solutions is 0·2 μg but for practical solutions it is probably about 0·5–1 μg.

Résumé—On décrit une méthode pour l'analyse de quantités d'étain de l'ordre du microgramme dans l'acide fluorhydrique dilué. On extrait l'étain sur des disques de papier chargés de résine échangeuse d'anions par une technique très simple et examine les papiers par spectrographie de fluoresence aux rayons X. On obtient les solutions

par dissolution de verres contenant de l'étain, et les éléments normaux constitutifs du verre n'interfèrent pas. La méthode a pour but la détermination de 1–20 μg d'étain mais peut être utilisée jusqu'à 250 μg au moins; on peut doser 5 μg avec une précision de $\pm 10\%$.

Zusammenfassung—Ein Verfahren zur Bestimmung von Mikrogrammengen Zinn in verdunnter Flußsaure wird beschrieben. Zinn wird sehr einfach in mit Anionenaustauscherhatz beladene Papierscheiben extrahiert und die Papiere rontgenfluoreszenzspektrographisch untersucht. Die Lösungen entstehen beim Auflosen zinnhaltiger Glaser; die üblichen glasbildenden Elemente sören nicht. Das Verfahren ist entworfen zur Bestimmung von 1–20 μg Zinn, kann aber bis wenigstens 250 μg gebraucht werden; 5 μg konnen mit einer Genauigkeit von $\pm 10\%$ bestimmt werden.

SHORT COMMUNICATIONS

Spectrophotometric determination of Channel Black in small arms propellants

(*Received* 2 *November* 1966. *Accepted* 31 *December* 1966)

CHANNEL BLACK is frequently added to small arms propellants to act as an opacifying agent. It is preferred to other carbon blacks for this purpose because it has a very small particle size (about 9–17 mμ).

Channel black in small arms propellants is usually determined by dissolving the sample in nitric acid or a mixture of potassium hydroxide and hydrogen peroxide, followed by filtration through a Gooch crucible, drying at 120–130°, weighing, igniting at 600–650°, and calculating the loss in weight to be Channel Black.[1,2,3] This method is inaccurate because Channel Black may be attacked by the dissolution agent, lost as a colloid, or contaminated with other insoluble materials, and because the asbestos may change in weight between weighings. A spectrophotometric method has been proposed that depends on the black colour obtained when the propellant is dissolved in a mixture of acetone and acetic acid.[1] This method is subject to many errors, since the colour is due to a suspension. Also, the brand of Channel Black used in the preparation of the calibration curve must be the same as in the sample.

This laboratory has developed a spectrophotometric method that makes use of the yellow colour obtained when Channel Black is dissolved by boiling with nitric acid for 3 hr.

EXPERIMENTAL

Apparatus and reagents

Treated asbestos. Asbestos fibre, washed twice with hydrochloric acid, was filtered off and stored under water.[4]

Spectrophotometer. A Beckman Model B was used, with 1 00-cm cells.

Filter crucibles. No 4A sintered crucibles by Coors.

Method

Prepare a filter crucible by pouring into it a fairly thick suspension of treated asbestos in water, applying suction until the water has drained, and then repeating the treatment with another portion of asbestos, so as to form a pad ¼-in. thick. Wash it with water and ignite it in a muffle at 800° for 40 min.

Transfer 5 g of the propellant to a 250-ml beaker and add 60 ml of morpholine. If the propellant is finely divided, cool the morpholine in an ice-bath before adding it, in order to prevent a possibly vigorous reaction Cover with a watch-glass, insert a stirring rod, and warm on an electric hot-plate under a hood with occasional stirring until the sample is in solution (15–30 min). Heat to incipient boiling (white fumes will appear) and filter *while hot* through the filtering crucible. Wash the beaker and crucible with hot morpholine, then wash well with acetone and hot water. Empty the suction flask and add about 200 ml of tap water (to act as a trap for the hydrogen chloride evolved in the next step). Wash with hot hydrochloric acid (about 80°) and then with hot water.

Detach the pad from the crucible, and transfer the pad and crucible to a 500-ml tall-form beaker (with a lip). Add 145 ml of nitric acid, cover with a tightly fitting watch-glass, heat to boiling, and boil gently for 3 hr, swirling the solution occasionally. The volume at the end of the boiling period should be 50–70 ml. If the volume after 2 hr is greater then 80 ml, remove the watch-glass (there is no danger of loss from the tall-form beaker).

Dilute to about 175 ml with water, filter through a Whatman No 42 filter paper into a 250-ml standard flask, washing with nitric acid (1 + 9), cool the filtrate to room temperature and dilute to the mark with water and mix. Measure the absorbance at 400 mμ against water

A calibration curve may be prepared by treating approximately 10, 15, 20 and 25-mg portions (weighed to 0 1 mg) of Channel Black with morpholine and proceeding as in the method.

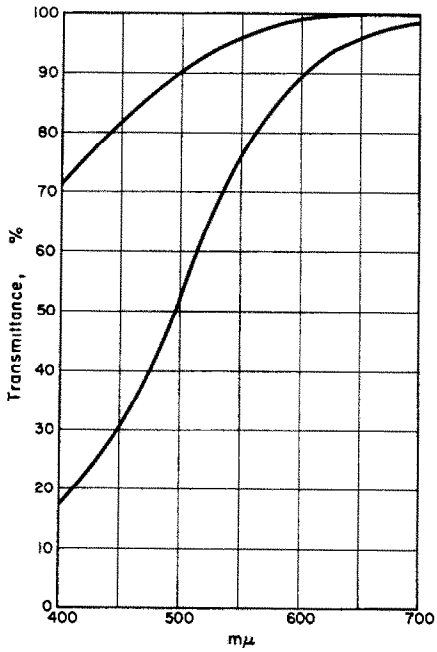

FIG. 1.—Transmission spectrum of coloured oxidation product.

RESULTS AND DISCUSSION

During the initial boiling of the nitric acid with the Channel Black, the colour may seem more intense because of the nitrogen dioxide produced. Once developed the colour is very stable and does not change on standing overnight. The transmission spectrum over the range 400–700 mμ is shown in Fig. 1. Measurement of the absorbance at 400 mμ would seem satisfactory. Beer's law is obeyed. The sensitivity is not very high, so a 5-g sample is used, giving a lower sampling error. Any sample of Channel Black can be used in preparing the calibration curve. The curves obtained with 5 different samples (Carbolac 1, Carbolac 2, Royal Spectra, Spheron 6, and Monarch 74) did not differ significantly.

The colour is due to polycarboxylic acids with cyclic nuclei. Ruof, Entel, and Howard[5] studied the colour but not from an analytical point of view. They refluxed 200 g of Channel Black with nitric acid for 11 days and found that the molecular weight of the resultant yellow carboxylic acid, determined ebullioscopically in acetone, was about 484 and that there were 6 2 carboxyl groups per molecule of carboxylic acid. The mechanism of formation of polycarboxylic acids from Channel Black involves the oxidation by the nitric acid of the peripheral rings of the polyaromatic structure of the Channel Black.

Morpholine was used by us because it was the only solvent that would dissolve 5 g of a nitrocellulose-base propellant and permit a fairly rapid filtration. The maximum sample size that could be used with 60 ml of acetone without clogging the filter was 1 g. It was found necessary to wash the carbon black, after the morpholine filtration, with acetone to remove residual nitrocellulose and other organic contaminants, then with hot water to remove soluble salts (nitrates, perchlorates, sulphates, *etc.*), and finally with hot hydrochloric acid to remove organic lead salts, barium chromate, nitroguanidine, and other materials. Organic lead salts cause slightly high results if not removed, and barium chromate causes very high results.

A sintered porcelain crucible of fine porosity containing an asbestos pad is used for the filtration. A Gooch crucible is not satisfactory since it will not retain Channel Black completely. The filter crucible containing the pad must be ignited at 800° for 40 min before use, in order to remove organic matter in the asbestos that would react with nitric acid.

The results obtained for Channel Black in two propellants (Table I) showed satisfactory precision. The recoveries from synthetic samples prepared with 5 different Channel Blacks (Table II) were also satisfactory.

Summary—A spectrophotometric method is proposed for the determination of Channel Black in small arms propellants. The Channel Black is separated from the nitrocellulose and other organic compounds by dissolution of the propellant in morpholine and filtration through a sintered porcelain crucible containing an asbestos mat. The Channel Black is then dissolved by treating the mat and crucible with boiling nitric acid for 3 hr, the solution is filtered, and the yellow colour is measured The colour is due to polycarboxylic acids with cyclic nuclei. The range of the method is from 0 to 0 5% of Channel Black.

Résumé—On propose une méthode spectrophotométrique de dosage du noir de charbon dans les poudres propulsives des armes portatives. On sépare le noir de charbon de la nitrocellulose et autres composés organiques par dissolution de la poudre dans la morpholine et filtration à travers un creuset en porcelaine frittée contenant une couche d'amiante Le noir de charbon est alors dissous par traitement de la couche d'amiante et du creuset à l'acide nitrique bouillant pendant 3 h, la solution est filtrée et l'on mesure la coloration jaune. La coloration est dûe à des acides polycarboxyliques à noyaux cycliques. La méthode est utilisable pour des teneurs en noir de charbon allant de 0 à 0,5%.

Zusammenfassung—Eine spektrophotometrische Methode zur Bestimmung von Kanalruß in Handfeuerwaffen-Munition wird vorgeschlagen Der Kanalruß wird von der Nirtocellulose und anderen organischen Verbindungen durch Losen des Sprengstoffs in Morpholin und Filtration durch einen Porzellanfiltertiegel mit Asbestschicht getrennt. Der Kanalruß wird dann durch dreistundige Behandlung von Asbestschicht und Tiegel mit kochender Salpetersaure gelost, die Losung filtriert und die gelbe Farbung gemessen. Die Farbe kommt von cyclischen Polycarbonsauren. Die Methode funktioniert von 0 bis 0,5% Kanalruß.

Synthetic and analytical studies on colour reagents—IX

The reactions of phthaleinazo compounds with the alkaline earths

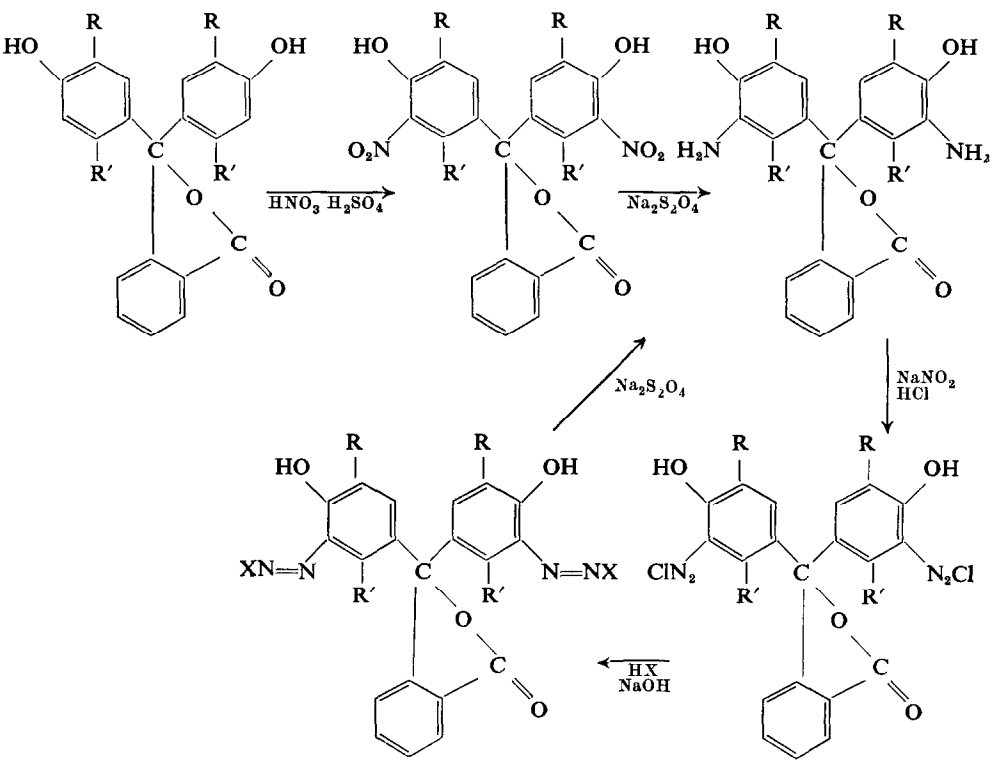
(*Received* 21 *October* 1966. *Accepted* 10 *January* 1967)

IT IS well known that *o,o'*-dihydroxyazo compounds react with the alkaline earths to form stable coloured chelates in alkaline media. To find more sensitive reagents for these elements, a series of phthaleinazo compounds was synthesized, and the limiting concentrations for the detection of magnesium, calcium, strontium and barium were determined.

EXPERIMENTAL

Synthesis of reagents

Phenolphthalein, Cresolphthalein, Thymolphthalein, Phenol Red, Cresol Red and Thymol Blue were used as starting materials and the syntheses were carried out as follows:



Sulphonphthalein derivatives were also synthesized in the same manner, except for nitration.

Nitration. Phthaleins were nitrated by Gatterman's method[1] (Cresolphthalein can also be nitrated by Bayer's method[2]). As sulphonphthaleins cannot be nitrated by Demont's method[3] the following procedure was used. The sulphonphthalein was dissolved in concentrated sulphuric acid, cooled to 0°, and the calculated amount of potassium nitrate, dissolved in concentrated sulphuric acid, was added dropwise

Reduction. The theoretical amount of sodium hydrosulphite was added little by little to the dinitro compound in alkaline solution. The colour of the solution turned from orange through green to blue.

The blue colour indicated the completion of the reaction. The blue solution was acidified with hydrochloric acid and filtered to remove unreacted dinitro compound. The filtrate was neutralized with ammonia solution to precipitate the diamino compound.

Diazotization and coupling. The diamino compound was dissolved in concentrated hydrochloric acid below 0°, and concentrated sodium nitrite solution was added dropwise. Diazotization of the two amino groups was judged to be complete from the amount of nitrite consumed. As the diamino derivatives of sulphonphthaleins are unstable, the compounds could not be prepared in the pure solid state, and the solution obtained by the reduction was directly diazotized without any purification The diazotized solution was added dropwise into a strongly alkaline solution containing chromotropic acid, R-acid, or 2-hydroxy-3-naphthoic acid, below 0°. After standing overnight at room temperature, the solution was acidified with concentrated hydrochloric acid to precipitate the phthaleinazo compound. (If the product is not precipitated, it may be salted out, or used directly in the solution as it is)

Determination of limiting concentrations

Magnesium, calcium, strontium and barium solutions were prepared from magnesium nitrate, calcium chloride, strontium nitrate and barium chloride, respectively. The concentrations were 0 1 μg/ml for magnesium and calcium and 1·0 μg/ml for strontium and barium. Various pH buffer solutions were prepared from ammonia solution, ammonium chloride and sodium hydroxide, in the range pH 8 5–13 5.

TABLE I.—DETECTION LIMITS FOR ALKALINE EARTHS (μg/ml) AT pH 11 3

Bis-diazo component	Coupling component	Mg^{2+}	Ca^{2+}	Sr^{2+}	Ba^{2+}	Note
Phenol-phthalein	Chromotropic acid	0·0003	0 001	0·05	0 05	
	R-acid	0 001	0 005	0 05	0 05	
	2-Hydroxy-3-naphthoic acid	0 001	0 05	0 05	0 08	pH = 13 5, acetone
Cresol-phthalein	Chromotropic acid	0 002	0 002	0 3	0 1	
	R-acid	0·001	0·005	0·3	0 1	
	2-Hydroxy-3-naphthoic acid	0 001	0 01	0 3	0 06	pH = 12·5, acetone
Phenol Red	Chromotropic acid	0 001	0 03	0 05	0 1	
	R-acid	0 002	0 05	0 5	0 3	
	2-Hydroxy-3-naphthoic acid	0 001	0 03	0 1	0 1	pH = 12·5, acetone
Cresol Red	Chromotropic acid	0·001	0 05	1	0 8	
	R-acid	0 002	0 08	1	1	
	2-Hydroxy-3-naphthoic acid	0·001	0·05	0 2	0 1	pH = 12 5
Thymol Blue	Chromotropic acid	0 001	0 1	2	0 5	
	R-acid	0 001	0 1	0 5	0 5	
	2-Hydroxy-3-naphthoic acid	0 0003	0 05	1	0 3	pH = 12 5
Plasmocorinth B		0 001	0 03	0 1	0 1	
Eriochrome Black T		0 001	0 05	1	0 5	

Four ml of a solution of suitable pH were taken in a test-tube, and a small amount of the reagent solution was added to develop the colour. If the colour was already red, due to the presence of alkaline earths as impurities in the buffer solution, the colour change was reversed by the addition of just sufficient $2 \times 10^{-4}M$ EDTA solution to mask the impurities. The solution was divided between two test-tubes, and a few drops of the alkaline earth solution were added to one, and the colour was compared with the original. At the most favourable pH (at which the colour-change from blue to red is most distinct) a suitably diluted solution of the metal ion was added drop by drop and the minimum number of drops (at least one drop) after which the colour change was just noticeable, was determined. From the number of drops the limiting concentration was calculated. The results are summarized in Table I, along with those for Eriochrome Black T and Plasmocorinth B, because they are said to be very sensitive reagents for magnesium and calcium.

DISCUSSION

From Table I, the order of decreasing sensitivity of the cations is seen to be magnesium, calcium, strontium, barium, and the sensitivity is about the same as or better than that with Plasmocorinth B and Eriochrome Black T.

The substituents of the phthalein or sulphonphthalein have little effect on the limiting concentration for the detection of the metals, but the nature of the coupling component is much more important. As a coupling component, in *o*-hydroxyazo compounds, chromotropic acid, R-acid and 2-hydroxy-3-naphthoic acid are superior to the other components used.[4-6] The limiting concentrations for these reagents are not very different from each other.

Sulphonphthalein derivatives are very soluble in water, but the syntheses are difficult, and the pure compounds are not obtainable. From a consideration of the sharp-colour change and ease of synthesis, bis (chromotropeazo)phenolphthalein is the best one.

2-Hydroxy-3-naphthoic acid derivatives differ from chromotropic acid and R-acid derivatives. The latter are blue at pH 10–13, but the former are red at pH 9·5–10 4 and blue at pH 11·3–13 5, but the chelates are blue at pH 9 5–10 4 and red at pH 11·3–13 5. At pH 10 4, the limiting concentration is 0 002 μg/ml for magnesium, 0 1 μg/ml for calcium, and 0 5 μg/ml for strontium and for barium, and these values are somewhat higher than those in Table I The addition of acetone improves the sensitivity of these reagents

Bis(chromotropeazo)phenolphthalein was found to react with thorium at pH 2, and the limiting concentration was 10 μg/ml. This compound is the most sensitive reagent for alkaline earths yet found, its higher sensitivity probably being due to its being an *o,o'*-dihydroxyazo compound, and having a larger conjugated system than a monoazo compound, and also due to the ease with which the human eye differentiates red from blue.

Summary—Some new phthaleinazo compounds—*o,o'*-dihydroxyazo compounds—have been prepared by coupling chromotropic acid, R-acid, and 2-hydroxy-3-naphthoic acid with bis-diazotized diaminophthaleins. These compounds have been found to be very sensitive colour reagents for alkaline earths in alkaline media, and in particular, bis(chromotropeazo)phenolphthalein is the most sensitive yet found.

Zusammenfassung—Einige neue Phthaleinazoverbindungen—*o,o'*-Dihydroxyazoverbindungen—wurden durch Kupplung von Chromotropsaure, R-Saure und 2-Hydroxy-3-naphthoesaure mit tetrazotierten Diaminophthaleinen dargestellt. Diese Verbindungen stellen sehr empfindliche Farbreagentien auf Erdalkalien in alkalischen Medien dar; insbesondere ist Bis(chromotropazo)phenolphthalein das empfindlichste unter den bisher bekannten Reagentien.

Résumé—On a préparé quelques nouveaux composés phtaléinazo—*o,o'*-dihydroxyazo composés—par copulation de l'acide chromotropique, de l'acide R et de l'acide 2-hydroxy 3-naphtoique avec des diaminophtaléines bis-diazotées. On a trouvé que ces composés sont des réactifs colorés très sensibles des alcalino-terreux en milieu alcalin et, en particulier, la bis (chromotropeazo) phénolphtaléine est le plus sensible trouvé jusqu'à présent.

PRELIMINARY COMMUNICATION

New method for the determination of pentachlorophenol by atomic absorption spectrophotometry

(*Received* 9 *December* 1966. *Accepted* 14 *December* 1966)

IN atomic absorption spectrophotometry, a hollow-cathode lamp which emits the spectral lines belonging to the element being determined is generally used as a light source. Because of this restriction, it has been impossible to determine organic compounds directly by atomic absorption methods.

In the course of studies on solvent extraction with cationic metal chelate[1] it was found that the anions of pentachlorophenol (PCP) could be extracted into nitrobenzene if the aqueous solution contained an excess of tris(1,10-phenanthroline)iron(II) cations, and that it was possible to determine a small amount of PCP by measuring the absorbance of the extracts spectrophotometrically. By continuous variation methods the chemical formula of the extracted species was deduced to be $[Fe(phen)_3]$ $(C_6Cl_5O)_2$.

It also appeared possible to determine the PCP by spraying the extracted nitrobenzene solution into the flame of an atomic absorption spectrophotometer with an iron hollow-cathode lamp as a light source.

The recommended procedure for obtaining the calibration curve is as follows.

Mix 5 ml of tris(1,10-phenanthroline) iron(II) sulphate solution ($2 \times 10^{-2}M$), 10 ml of $0{\cdot}3M$ phosphate buffer solution (pH 7), and varying amounts of standard PCP solution ($1{\cdot}25 \times 10^{-3}M$ 0–6 ml). Dilute the solution with water to 25 ml and shake it for 3 min with 10 0 ml of nitrobenzene. Separate the organic phase and dry it with 1 g of anhydrous sodium sulphate. Measure the atomic absorption at the 2483 Å iron line. (A Nippon Jarrell-Ash atomic absorption spectrophotometer Model AA-1 equipped with an iron hollow-cathode lamp was used in our work, together with an air–acetylene flame from a 10-cm slit burner used with an air flow-rate of 6 0 l/min and an acetylene flow-rate of 1·2 l/min.)

Under these conditions, the calibration curve was found to be linear for the range tested ($0–3 \times 10^{-4}M$) of PCP concentration in aqueous solution.

The effect of other ions is probably the same as that in the spectrophotometric method.[1]

Although several methods have recently been reported,[2–4] the method proposed here has a higher sensitivity.

Summary—A new application of atomic absorption is reported for the determination of pentachlorophenol. The method is based on solvent extraction into nitrobenzene of the ion-pair formed between tris(1,10-phenanthroline)iron(II) and the anion of pentachlorophenol, and the subsequent determination of the iron concentration in the extract by atomic absorption at the 2483 Å iron line.

Zusammenfassung—Es wird uber eine neue Anwendung der Atomabsorption zur Bestimmung von Pentachlorphenol berichtet. Die Methode beruht auf der Extraktion des Ionenpaars aus Tris(1,10-phenanthrolin)-eisen(II) und dem Anion von Pentachlorphenol in Nitrobenzol und nachfolgender Bestimmung der Eisenkonzentration im Extrakt durch Atomabsorption in der Eisenlinie bei 2483 Å.

Résumé—On rapporte une nouvelle application de l'absorption atomique pour le dosage du pentachlorophénol. La méthode est basée sur l'extraction par solvant en nitrobenzène de la paire ionique formée entre la tris(1,10-phénanthroline)fer(II) et l'anion du pentachlorophénol, et la détermination subséquente de la concentration en fer de l'extrait par absorption atomique à la raie 2483 Å du fer.

TALANTA REVIEW

PRESENT STATE OF COMPLEXOMETRY—III*†

DETERMINATION OF UNIVALENT METALS

RUDOLF PŘIBIL
Analytical Laboratory, J. Heyrovský Polarographic Institute,
Czechoslovak Academy of Sciences, Prague 1, Jilská 16, Czechoslovakia

(*Received* 3 *November* 1966. *Accepted* 14 *January* 1967

Summary—A review of the visual complexometric determination of univalent metals is presented. Because of the low complex-forming tendency, all methods are based on indirect determinations such as displacement reactions or precipitation of the univalent metal in a form which can be determined complexometrically.

GENERALLY speaking, the univalent cations of silver, mercury, thallium and the alkali metals are not suitable for complexometry, because they have very little tendency to form complexes with EDTA or other titrants. The strongest of their EDTA complexes are those of silver ($\log K_{AgY} = 7{\cdot}2$) and probably of thallium(I). For silver there are already enough methods for its volumetric determination. For thallium we prefer its complexometric determination as the tervalent cation.[1] For alkali metals, only indirect methods can be used, based generally on the isolation of the elements as insoluble double salts with other metals which can be determined complexometrically. Such methods are time-consuming and require careful control of the experimental conditions, especially if they are carried out on the micro scale. On the other hand the great importance of sodium and potassium in biological fluids (blood, serum, erythrocytes, urine, *etc.*) has brought about a considerable interest in these methods. If we take into account, for example, the difficulties in the determination of sodium or potassium in biological material we have to appreciate that even here complexometry has contributed much towards simplifying and speeding up clinical routine work.

SILVER
($\log K_{AgY} = 7{\cdot}2$)[2]

If we add EDTA solution drop by drop to silver nitrate solution a white precipitate of the silver salt appears and redissolves in excess of EDTA, forming a complex AgY^{3-}. The silver-EDTA complex is very weak and reacts with all the important reagents for silver even if EDTA is present in large excess. This is very useful not only for qualitative tests but also for gravimetric, titrimetric and colorimetric determinations

* For reprints of this review see the Advertizement on the facing page.
† Part II, *Talanta*, 1966, **13**, 1223.

with various organic reagents such as dithizone, mercaptophenylthiazole, mercaptophenylthiodiazolone, benztriazole *etc*,[3] because many interfering elements can be masked with EDTA.

Direct determination. Only two methods for the direct visual determination of silver have been published. Belcher[4] recommended *o*-cresolphthalein-complexone (Metalphthalein) as indicator. Klein and Skřivánek[5] more recently determined silver, using Thymolphthalexone as indicator. A number of metals interfere, so the methods can be used only for pure silver solutions.

Štráfelda[6] has described the potentiometric determination of silver with the use of a silver indicating electrode. The method has the same limitation as those mentioned above.

Indirect determination. Flaschka and Huditz[7] developed a method based on a displacement reaction:

$$Ni(CN)_4^{2-} + 2\,Ag^+ = 2\,Ag(CN)_2^{2-} + Ni^{2+}. \qquad (1)$$

The nickel is determined in ammonia solution with EDTA and Murexide as indicator. Despite the unfavourable equivalent (2 Ag ≡ Ni) the method gives accurate results, according to the authors, and can be used on the micro scale not only for silver but also for its insoluble salts (AgCl, AgBr, AgCNS, *etc.*) and hence for the indirect determination of halogens.[8] Gedansky and Gordon[9] used this method for milligram quantities of silver, detecting the end-point photometrically.

Another method is the so-called amalgam method. Silver reacts with various amalgams (zinc, cadmium) and the displaced metal is determined complexometrically.[10,11] This method is mainly of theoretical interest.

Small amounts of silver can be determined by the displacement reaction between silver ion and copper diethyldithiocarbamate (DDC) dissolved in carbon tetrachloride or chloroform:

$$Cu(DDC)_2 + 2Ag^+ = 2AgDDC + Cu^{2+}. \qquad (2)$$

The copper is then determined complexometrically in slightly acidic medium. This method is more selective but also suffers from an unfavourable equivalent.[12]

Interferences. As already mentioned, almost all elements interfere to such an extent that separation of the silver or its determination by another method is necessary.

Separation and masking. In many cases silver is separated automatically during the decomposition of the sample, *e.g.*, by dissolution of alloys *etc.* with nitric and hydrochloric acid. Silver does not usually interfere in the determination of other metals provided that it does not react with the indicator. In special cases it can be masked with potassium cyanide.

Practical applications. Flaschka's method has been used by Amin[13] for the determination of silver in coinage and in photographical materials.[14]

MERCURY(I)

Mercury(I) disproportionates after addition of EDTA, according to the equation:

$$Hg_2^{2+} + H_2Y^{2-} = Hg + HgY^{2-} + 2H^+. \qquad (3)$$

This reaction has been recommended instead of that with ammonia, for the microdetection of mercury(I).[15]

THALLIUM(I)

Direct determination. Only one method for thallium(I) has been published, by Foley and Pottie.[16] They followed the titration spectrophotometrically at 222 mμ, using an ammonia-ammonium chloride buffer at pH 10.

Indirect determination. Sen[17] isolated thallium(I) as insoluble $Tl_2Ag[Co(NO_2)_6]$ and after dissolution of the precipitate in nitric acid he determined the cobalt complexometrically in acetone medium with thiocyanate as indicator. The method suffers from the unfavourable equivalent and has not been applied.

LITHIUM

($\log K_{LiY} = 2{\cdot}79$)

Only indirect methods for lithium are known. De Sousa[18] precipitated the chloride of lithium chloride with silver nitrate and dissolved the silver chloride after filtration, in potassium nickel cyanide according to equation (1) and determined the nickel by EDTA titration. His method was applied to the micro-determination of 50–500 μg of lithium oxide with an error of 0·5%. Previous separation from potassium and sodium is necessary, so that this method gives no improvement on other methods for lithium.

SODIUM

($\log K_{NaY} = 1{\cdot}66$)

All methods for sodium determination are based on its isolation as a triple salt of the composition $NaMe(UO_2)_3(CH_3CO_2)_9$ where Me is a bivalent metal. The metal Me is then determined complexometrically. Flaschka[19] was the first to propose the precipitation of sodium with zinc uranyl acetate and the determination of zinc with EDTA in ammonia buffer, Eriochrome Black T being used as indicator. The uranyl ion was masked with ammonium carbonate. The same method was published five years later by Sen[20] without citation of Flaschka's paper. Holasek and Duganžić[21] improved Flaschka's method, using dithizone as the indicator for zinc, which gives a sharp end-point even in titrations with 0·001*M* EDTA.

Gagliardi and Reimers[22] have studied thoroughly other metallic acetates as reagents for sodium precipitation. According to these authors nickel and cobalt uranyl acetates are the best precipitants for the gravimetric or complexometric determination of sodium. Doležal *et al.*[23] have found magnesium uranyl acetate and cobalt uranyl acetate the best for the precipitation of sodium. They determine the uranium complexometrically after its reduction with ascorbic acid, *e.g.*, by back-titration with 0·01*M* thorium nitrate, using Xylenol Orange as indicator. Their attempts to determine both the uranium and the cobalt together (to the equivalent) were unsuccessful.

Gagliardi and Reimers[24] have also published an interesting method for sodium determination (together with potassium) based on ion-exchange with Lewatit S 100 in the magnesium form. The exchanged magnesium is determined complexometrically. In another portion of the eluate, potassium is determined by precipitation with sodium tetraphenylborate.

Interferences. According to Gagliardi and Reimers[22] sodium can be determined by precipitation as triple acetate in the presence of a large excess of calcium, magnesium, barium, manganese, cobalt, cadmium, copper, zinc and iron(II). Potassium

does not interfere when present up to a ratio of K:Na = 1·5:1. Doležal *et al.*[23] found that the precipitation of sodium with cobalt uranyl acetate is not affected by the presence of ammonium, zinc, magnesium, iron(II), calcium, strontium, barium and mercury. Lithium is coprecipitated, and potassium in an amount twice that of the sodium makes the results high.

Practical applications. Sodium has been determined in blood serum,[25] in glass,[26] in mineral waters[23] and in some pharmaceuticals such as *natrium citricum*, *natrium salicylicum* and *natrium gentisicum*.[23]

POTASSIUM

For potassium also, only indirect complexometric methods have been described, based on the isolation of slightly soluble compounds of the type $K_2Me[Co(NO_2)_6]$. The first method was introduced by Flaschka and Holasek[27] who precipitated potassium as $K_2Na[Co(NO_2)_6]$. After dissolution of the isolated precipitate in hydrochloric acid and destruction of nitrous oxides with urea, they determined the cobalt in slightly ammoniacal solution with EDTA, using Murexide as indicator. In slightly acid medium cobalt can be determined directly with the Cu-EDTA-PAN system.[28] Indirect determination by back-titration with zinc and Eriochrome Black T[29,30] can also be used under the proper conditions. The method has the same disadvantages as the classical gravimetric method—the solubility of the precipitate, and variation in the composition of the precipitate and hence in the Co:K ratio.

The same principle has been studied by Taketatsu[31] and Soibelman.[32] Sen[17] isolated potassium as the silver salt $K_2Ag[Co(NO_2)_6]$ and determined the cobalt with EDTA, using ammonium thiocyanate as indicator.

De Sousa[33] precipitated potassium as perchlorate, separated it, reduced the perchlorate to chloride, precipitated this as silver chloride, and determined silver according to reaction (1). His method is tedious and does not seem very useful.

A very promising method was proposed by Flaschka and Sadek[36] and by Sadek and Reilley.[37] The well-known reagent sodium tetraphenylborate precipitates potassium quantitatively as $K(C_6H_5)_4B$ and can be used for the gravimetric and titrimetric determination of potassium. The authors mentioned have found that the isolated potassium salt (dissolved in organic solvents) reacts with the mercury-EDTA complex and forms a white precipitate of a phenylmercury salt. The reaction proceeds according to the equation:

$$4HgY^{2-} + (C_2H_5)_4B^- + 8H_2O = H_3BO_3 + 4C_6H_5Hg^+ + 4H_2Y^{2-} + 5OH^-. \quad (4)$$

The liberated EDTA is determined complexometrically and has a very favourable conversion factor (1 mole of K corresponds to 4 moles of EDTA).

Flaschka dissolved the isolated $K(C_6H_5)_4B$ in acetone, added an excess of mercury-EDTA and back-titrated with zinc solution, using PAN indicator. Reilley[37] has found that fair results could be obtained by titrating the liberated EDTA with lead solution, using Xylenol Orange as indicator. Another modification has been proposed by Reilley[37] based on the dissolution of the potassium salt in dimethylformamide and, after addition of mercury-EDTA solution, titration of the freed EDTA with magnesium solution at pH 10, with Eriochrome Black T as indicator. The same procedure has been recommended by the author for the determination of ammonium ions. Gagliardi

and Reimers[24] have also used the tetraphenylborate method (see section on *Sodium*, above).

Interferences. The simple precipitation of potassium as a double salt cannot be carried out in the presence of ammonium, rubidium, caesium or thallium(I). The presence of other metals also interferes so that the determination of potassium is possible only in pure solutions of it or in those cases where those a condition can be simply achieved, in the analysis of blood serum for example.

Elimination of interferences. Pécar[34] studied thoroughly the influence of ammonium ions on the precipitation of potassium on the micro scale. He proposed the oxidation of ammonia with hypobromite in sodium hydroxide solution. The method has one disadvantage—sodium hydroxide always contains potassium (*e.g.*, reagent grade sodium hydroxide contains up to 0·09% of potassium) and the blank is too high for microanalysis. He recommended, together with Holasek and Lieb,[35] the masking of ammonia with formaldehyde. The method works well up to 0·02*M* concentration of ammonia and can probably be applied for the analysis of blood, urine and other biological fluids.

Practical applications. Complexometric determination of potassium has value only in the analysis of various biological materials such as blood serum, urine, *etc.*[27,28,30,34,38]

RUBIDIUM AND CAESIUM

Complexometric methods for rubidium and caesium are similar to those for potassium. Sen[17] proposed precipitation of both as $Me_2Ag[Co(NO_2)_6]\cdot H_2O$ and direct determination of the cobalt after the dissolution of the precipitate. Cygański[39] precipitated caesium as $Cs_3[Co(NO_2)_6]\cdot H_2O$, and Ciogolea[40] isolated caesium as $CsBiI_4$ and determined the bismuth complexometrically. De Sousa[41] precipitated caesium as perchlorate and converted it into chloride, which he precipitated as silver chloride. The silver was then determined according to Flaschka's method.[7]

Zusammenfassung—Es wird eine Übersicht über die visuelle komplexometrische Bestimmung einwertiger Metalle gegeben. Wegen der geringen Komplexbildungstendenz beruhen alle Methoden auf indirekten Bestimmungen wie Verdrängungsreaktionen oder Fällung des einwertigen Metalls in einer komplexometrisch bestimmbaren Form.

Résumé—On présente une revue sur le dosage complexométrique visuel des métaux monovalents. Par suite de la faible tendance à former des complexes, toutes les méthodes sont basées sur des déterminations indirectes telles que des réactions de déplacement ou la précipitation du métal monovalent sous une forme qu'on peut doser par complexométrie.

TALANTA REVIEW

PRESENT STATE OF COMPLEXOMETRY—IV*†
DETERMINATION OF RARE EARTHS

RUDOLF PŘIBIL
Analytical Laboratory, J. Heyrovský Polarographic Institute,
Czechoslovak Academy of Sciences, Prague 1, Jilská 16, Czechoslovakia

(*Received* 14 *January* 1967. *Accepted* 28 *January* 1967)

Summary—A review of the visual complexometric determination of the rare earths, scandium and yttrium with various volumetric reagents is presented. As in previous parts attention is paid to the complexometric behaviour of these metals and to the problems of interferences in their determinations. Methods for the determination of thorium, scandium and some rare earths in mixtures are described in detail. Recent developments and further possibilities in this field are discussed.

ACCORDING to Vickery, scandium and yttrium should be included in the family of rare earths as members of the IIIA group because their electronic 5*d* shell is also empty or incomplete. In addition, they usually accompany the lanthanides in natural sources such as monazite sand.

The expression "rare" does not mean that rare earths are scarcely to be found, but relates to their concentration, which is usually very low in minerals. The amount of rare earths liberated by dissolution of Florida apatite for phosphoric acid production is estimated, according to *Chemical News* (October 1966), at about 3500 tons. The price of some rare earths is still very high: 1 lb of europium costs about $1500 and 1 lb of thulium $2–4000.

Industrial use of rare earth metals and oxides is increasing, especially in electronics. For example, europium is in demand for activation of yttrium vanadate, used as a red phosphor in TV tubes, and samarium and praseodymium compounds are used as cracking catalysts in the petroleum industry. Another potential application of rare earth metals is in the processing of magnesium alloys and high-melting metals. Rare earths are very important for the production of special glasses and ceramics, and their semiconductor and superconductor properties have found wide practical utilization. Some rare earths play an important part in the development of garnets for radio masers, and have many applications in nuclear chemistry.

The complexometry of the rare earths represents only a very small part of the chemistry of rare earth complexes with polyaminopolycarboxylic acids. Great attention has been paid to the chemical and physico-chemical properties of these rare earth complexes, especially their stability constants which are important not only for complexometric determination, but also for chromatographic ion-exchange separations. The high purity of individual rare earths now on the market has been achieved

* For reprints of this Review see the Advertizement near the front of this issue.
† Part III, *Talanta*, 1967, **14**, 613.

by means of chromatography, with nitrilotriacetic acid (NTA), ethylenediaminetera-acetic acid (EDTA), or similar complex-forming compounds as eluents. It is probable that the details of these large-scale separations and purifications are kept secret, or are only partly published.

The stability constants of rare earth complexes with the most important poly-aminopolycarboxylic acids are summarized in Table I.

COMPLEXOMETRY OF THE RARE EARTHS (RE)

The volumetric determination of the rare earths was practically unknown before EDTA and related compounds were introduced in analytical chemistry. The application of EDTA and other titrants such as 1,2-diaminocyclohexanetetra-acetic acid

IMDA = Iminodiacetic acid; HIMDA = *N*-Hydroxyethyliminodiacetic acid;
NTA = Nitrilotriacetic acid; EDTA = Ethylenediaminetetra-acetic acid;
HEDTA = *N*-Hydroxyethylethylenediaminetriacetic acid;
EGTA = Ethyleneglycol-bis(2-aminoethylether)tetra-acetic acid;
DTPA = Diethylenetriaminepenta-acetic acid;
DCTA = 1,2-Diaminocyclohexanetetra-acetic acid;
PDTA = Propylenediaminetetra-acetic acid.

(DCTA), triethylenetetraminehexa-acetic acid (TTHA) and diethylenetriaminepenta-acetic acid (DTPA) brought valuable progress in the analytical chemistry of the rare earths. Even so, the chemical similarity of these elements allows accurate determination to be made only of the sum of the rare earths present or of individual ones already isolated from the others, and the analysis of their mixtures by complexometry only is impossible, with the exception of some attempts which will be described later.

Direct determinations. The first determination of rare earths was described by Flaschka.[1] He titrated them in alkaline medium at pH 8–9 with tartaric or citric acid present to prevent hydrolysis. Eriochrome Black T was used as indicator and the titration had to be performed on boiling solutions. The pH is critical, as

above pH 9 the RE-complexes with the indicator are too stable and do not react with EDTA. Flaschka described the determination of milligram amounts of yttrium, samarium, praseodymium and gadolinium. Chromazurol S as indicator for RE was proposed by Malát and Tenorová.[2] This indicator works in pyridine medium.

The stability constants of the RE-EDTA complexes are high enough for RE determination in acidic medium, for which carminic acid,[3] Brompyrogallol Red,[4] Galleine,[5] Azoxin S,[6] and Eriochrome Black T in urotropine medium[7] have been proposed as indicators. Azoarsonic acids (Arsenazo) have been thoroughly studied as indicators for these rare earth titrations.[8–10] The most important indicators for complexometry may be considered to be Xylenol Orange[11,12] and Methylthymol Blue.[13] The reaction of both indicators is very sensitive and therefore they have also been proposed as colorimetric reagents for a great number of metals, including the rare earths. Xylenol Orange has been used by Kinnunen and Wennestrand for the titration of RE.[14]

Indirect determinations. Back-titration of excess of EDTA can be performed in many ways. Such methods are most useful when difficulties in the direct titration are expected, *e.g.*, if RE and oxalates or phosphates are present together, or some metallic impurities are there which have to be masked. Only the back-titration at pH 5–6 with zinc, and Xylenol Orange as indicator, is worth mentioning.

Other volumetric reagents for RE. Under the same experimental conditions as for EDTA, RE can be determined with DCTA, DTPA and TTHA. Their advantages over EDTA in special cases will be mentioned further.

Interferences. All elements having log $K > 11$ for their EDTA complexes interfere or are co-titrated even in acidic solutions. Of anions, fluoride masks and phosphate precipitates all rare earths. Oxalate interferes only in direct titrations, because in acidic medium oxalates of the rare earths are also precipitated. Their ignition to the oxides is not necessary if we determine the RE indirectly. Misumi and Taketatsu[15] dissolve the isolated RE-oxalates in alkaline EDTA solution by warming to 60°, and titrate the excess of EDTA with magnesium sulphate solution, using Eriochrome Black T as indicator. According to the authors the pH of the titrated solution has to be correctly adjusted to 10·5. Their results have shown that the presence of 40–70 mg of oxalic acid obscures the end-point. For this reason the method is suitable only for microtitrations of rare earths (1–5 mg). A more reliable method is described by Lyle and Rahman,[16] based on the dissolution of the RE-oxalates in hydrochloric acid. After addition of an excess of EDTA, the pH is adjusted to 5–6 and the excess of EDTA is determined by zinc titration, with Xylenol Orange as indicator.

Elimination of interferences. Only a few possibilities exist for RE determination without previous masking or separation. The alkaline earths do not interfere with the determination of RE in acidic medium. On the other hand metals forming the most stable complexes with EDTA can be determined in the presence of rare earths. Successive determination of bismuth at pH 2 and neodymium or praseodymium at pH 5–6, Xylenol Orange being used as indicator, was described by Milner and Edwards.[17] The micro-determination first of scandium and then of rare earths was described by Hung Shui-Chieh and Liang Shu-Chuan,[18] who titrated 1–400 μg of scandium oxide in a small porcelain crucible at pH 1·8–2·2 with 0·05M EDTA after adding a small amount of Xylenol Orange. Consecutive microtitrations of scandium

and the rare earths are possible up to the ratio Sc_2O_3:Ln_2O_3 1:1000. Zirconium can be determined with EDTA in solutions of 0·4–0·6*M* nitric acid in the presence of all rare earths.[19]

Masking of metals. Some bivalent metals such as copper, zinc and cadmium are masked with potassium cyanide in Flaschka's method for the determination of RE.[1] In slightly acidic medium these cations are masked with 1,10-phenanthroline.[20] Thiourea can be used for selective masking of copper, and sulphosalicylic acid at pH 7–8 for masking of aluminium and iron.[9] According to these authors,[9] thorium is masked with sulphosalicylic acid at pH 5, but according to Chuan,[18] not at pH 2. Very small amounts of zirconium up to 50 μg are also masked with sulphosalicylic acid at pH 2.[18]

Masking and separation of rare earths. Only fluoride can be used for the masking of the rare earths even if they are present as EDTA-complexes. This allows for example the consecutive titration of heavy metals and iron by back-titration with zinc solution and Xylenol Orange. After determination of the total of all elements ammonium fluoride is added and the liberated EDTA is titrated with zinc solution.

For the separation of rare earths a number of methods have been proposed. Their precipitation as oxalates is the best known. Triethanolamine has been used as masking agent for iron, aluminium and bivalent metals in the precipitation of lanthanum with sodium hydroxide.[20] Various ion-exchange separation methods have also been described, but are outside the scope of this review.

Complexometry is not limited to the determination of rare earths in "pure solutions". There are many problems to be solved such as their determination in the presence of thorium, scandium, yttrium, uranium, titanium, phosphates, EDTA, and other complex-forming compounds and extraction reagents.

Determination of RE in the presence of phosphates

Phosphates interfere by forming insoluble phosphates under the conditions suitable for the complexometry of the rare earths. Usually ion-exchange is used for the separation of rare earths from phosphate. Even the indirect complexometric determination of RE with EDTA or DCTA is impossible because most of the rare earths are displaced from their complexes during the titration with the zinc solution, and precipitated again.[21] Recently we have found that only DTPA can be used for such determinations.[22] The RE-phosphates are dissolved in small volume and an excess of 0·05*M* DTPA is added with ascorbic acid or hydroxylamine hydrochloride, the pH is adjusted with ammonia and urotropine to 5–6 and the excess of DTPA is then titrated with zinc solution to the Xylenol Orange end-point. Scandium can be determined together with RE. Thorium interferes by forming an insoluble phosphate during the neutralization and dilution of the solution, even in the presence of DTPA.

Determination of RE in the presence of EDTA

Many chromatographic separation methods use either RE–EDTA complexes at various pH values or EDTA solutions of various pH values to elute individual rare earths or small groups of them from the column. In both cases, the eluate contains EDTA and one or more of its rare earth complexes, depending on the conditions of elution. Because ion-exchange techniques are used on the large scale, the determination of rare earths in EDTA solutions is very important.

Martynenko[23] proposed their precipitation, from one aliquot, as oxalates and determination as oxides. In a second aliquot he determined the free EDTA complexometrically. The total amount of EDTA present could then be calculated from the titration and from the amount of oxides found. A simpler method was described by Tereshin and Tananaev.[24] They determined all the EDTA at pH 2 with 0·04*M* iron(III) chloride, using sulphosalicylic acid as indicator. After adjusting the pH to 4·5–6 they determined all the rare earths with 0·04*M* EDTA, with Xylenol Orange as indicator. The relative error of a single determination by both procedures was ±0·7%.

Determination of RE in the presence of alkyl phosphates

Sheka and Sinyavskaya[25] have found that dialkyl hydrogen phosphates do not affect the direct titration of rare earths with 0·001*M* EDTA, Xylenol Orange being used as indicator. Yttrium in the presence of dibutylphosphate is determined by back-titration with lanthanum chloride. This method is useful after liquid-liquid extraction of small amounts of rare earths from other elements.

Determination of scandium or thorium and RE

The consecutive titration of scandium and the rare earths has been already mentioned.[18] Chernikov[26] applied the same method for the successive determination of thorium (at pH 1·2–2·5) and then the rare earths (at pH 5–6), using Xylenol Orange as indicator. According to this author the method is good up to the ratio Th:RE = 1:70, but we have never succeeded in reproducing his results. In acidic solution a neutral complex of thorium, ThY, is formed. Above pH 4, a ternary EDTA-Th-XO complex is formed, which makes further determination of rare earths impossible. Indeed, this red-violet complex exists in the presence of large amounts of EDTA or DCTA. This reaction has been used not only for the detection of thorium in the presence of scandium and rare earths[27] but also for the detection of EDTA in mixtures with other compounds (DTPA, TTHA)[28] as well as for the complexometric determination of DTPA or TTHA in the presence of EDTA.[29] This determination is carried out with thorium nitrate at pH 5–6, the titration solution being heated. The first traces of thorium added after the reaction with DTPA or TTHA is complete are bound with EDTA but then react with Xylenol Orange, giving a very good end-point. It is probable that not only a 1:1:1 complex (Th:XO:EDTA) is formed but also binuclear or more complicated complexes, as may be assumed from the existence of the $Th_2(XO)_2$ complex.[30] DCTA behaves similarly and cannot be used for the successive determination of thorium and rare earths.

DTPA and TTHA are most suitable for the titration of thorium plus RE. With both these titrants we determine thorium at pH 2·5–3·5 and then the rare earths in urotropine medium at pH 5–6, using Xylenol Orange as indicator.[31] The titration with DTPA has been used also for heavy RE by Gupta and Powell,[32] and the titration with TTHA by Mukherji.[33] Both titrations have been found reliable.

Peshkova and coworkers[34] recommended Arsenazo as indicator for the consecutive titration of thorium and rare earths, using photometric detection of the end-point, but Chernikov[18] did not succeed with the visual titration because of blocking of the Arsenazo with thorium.

Determination of thorium, scandium and light lanthanides

Successive determination of the sum (Th + Sc) and then the rare earths is possible with DTPA as described in the preceding paragraph. For the individual determination of thorium and scandium and rare earths another method has to be used. The thorium EDTA and DCTA complexes react with TTHA according to the equation:

$$\text{Th—DCTA} + \text{TTHA} = \text{Th—TTHA} + \text{DCTA}. \qquad (1)$$

This reaction is quantitative in hot solutions buffered with urotropine. The scandium DCTA and EDTA complexes do not react at all. The excess of TTHA and the liberated DCTA can be determined very easily by titration with zinc solution, with Xylenol Orange as indicator.[35] In the presence of rare earths, however, the situation is more complicated. The added TTHA reacts at pH 5–5·5 (urotropine buffer) with the free rare earths, forming 1:1 complexes. The DCTA liberated according to reaction (1) does not react with the TTHA complexes of lanthanum, cerium, praseodymium and neodymium, but the heavier rare earths are partly displaced:

$$\text{RE—TTHA} + \text{DCTA} = \text{RE—DCTA} + \text{TTHA}. \qquad (2)$$

The determination of thorium and scandium and the first four lanthanides can be carried out on two aliquots by differential back-titrations of excess of reagent with zinc and lanthanum, which form different types of complex with DCTA and TTHA.[36]

Analysis of rare earth mixtures

The simplicity of the complexometric titrations presents a great inducement to try to use them for the determination of rare earth mixtures. Consecutive titrations cannot be carried out, however, because the stability constants of the rare earth complexes are too close to each other. From the theoretical point of view the difference in the logarithm of the constants has to be at least 4–5 for consecutive titrations to be possible. Not even in the combination of the first and last members of the series (lanthanum and lutetium) is this condition fulfilled, and there is little hope of ever finding special masking agents for single rare earths or for small groups of them.

Some years ago Patrovský[37] utilized the difference in the atomic weights of yttrium (88·92) and erbium (167·27) for their determination in their mixtures. The oxalates were isolated, ignited, and weighed. The oxides were dissolved and their mixture titrated complexometrically with EDTA, Xylenol Orange being the indicator. If 0·02*M* EDTA is used the amount of the oxides present can be calculated according to the equations

$$\text{mg } Y_2O_3 = \frac{3{\cdot}824V - E}{0{\cdot}6935}; \quad \text{mg } Er_2O_3 = \frac{2{\cdot}582V - E}{0{\cdot}4094}$$

where V is the consumption of 0·02*M* EDTA in ml, and E is the weight of the isolated oxides. According to the author this method can also be used for the determination of yttrium and the sum of the yttrium earths if these are present in the sample in approximately equal amounts. The atomic weight of terbium (158·93) is compensated for by the atomic weight of lutetium (174·99) giving the value 166·96 which is close

to the atomic weight of erbium. The author used this procedure for the determination of yttrium in yttrium earths after the separation of the cerite earths by precipitation with potassium sulphate.

Recently we have studied some displacement reactions which at first sight seem very promising for the differentiation of small groups of rare earths. Only two examples will be given here from the work in progress.

The sum of all rare earths present can be determined indirectly, *e.g.*, by back-titration with zinc solution at pH 5–5·5, with Xylenol Orange as indicator. When sodium phosphate at pH 5–6 is added in certain excess to the solution, some rare earths are quantitatively displaced by zinc according to the equation:

$$LnY^{-} + Zn^{2+} + PO_4^{3-} = LnPO_4 + ZnY^{2-} \qquad (3)$$

where Ln = La, Pr, Ce, Nd, and Y = anion of EDTA.

The heavier rare earths (Sm . . . Dy) are displaced very slowly and only partly, and the highest members (Ho . . . Lu) are not displaced at all (see Table II). With the

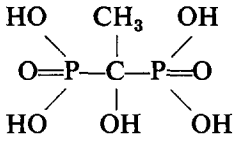
* Titrated with 0·05*M* cadmium.

aid of this displacement reaction some combinations of rare earths such as La–Tm, La–Er, Pr–Yb, Nd–Tm, Ce–Yb can be determined.[38]

Reaction (3) can be varied in many ways. For example, phosphate can be replaced by pyrophosphate or other complex-forming compounds, and EDTA by DCTA, MEDTA, HEDTA or TTHA (see Table II). However, unlike the EDTA complexes, the TTHA complexes of the light lanthanides are displaced either very slowly or

not at all by zinc in the presence of phosphate, while the higher rare earths are displaced more quickly. Unfortunately it is not possible to use this reaction because during the titration with zinc the displacement of the light lanthanides is "induced" by the faster reactions of the heavier rare earths. We have not been able so far to circumvent this difficulty.

More recently 1-hydroxy-ethylidene-1,1-diphosphonic acid (HEDPHA)—(I)—has been studied as a complex-forming reagent.



I

It forms a binuclear complex with thorium $(ThY)_2$-L, in the presence of EDTA or DCTA (where L is the anion of HEDPHA and Y the anion of EDTA or DCTA).[39]

Practical applications

Thorium and the sum of the rare earths present have been determined in monazite sands[34] and other materials.[40] Complexometric determination of rare earths in fission products[41] and in mixtures with alkaline earth oxides has been described.[42] Milner and Edwards[17] have determined neodymium and praseodymium in bismuth alloys, and Brück and Lauer[43] have determined lanthanum in aluminium alloys. A method for the determination of zirconium, thorium and lanthanum in non-silica glass has been published by Přibil and Veselý.[44]

Zussammenfassung—Es wird eine Übersicht über die visuelle komplexometrische Bestimmung von seltenen Erden, Scandium und Yttrium mit verschiedenen volumetrischen Reagentien gegeben. Wie in den früheren Teilen wird dem komplexometrischen Verhalten dieser Metalle und den Störproblemen bei ihrer Bestimmung besonderes Augenmerk geschenkt. Methoden zur Bestimmung von Thorium, Scandium und einigen seltenen Erden in Mischungen werden in Einzelheiten beschrieben. Neue Entwicklungen und zukünftige Möglichkeiten auf diesem Gebiet werden diskutiert.

Résumé—On présente une revue sur le dosage complexométrique visuel des terres rares, du scandium et de l'yttrium au moyen de divers réactifs volumétriques. Comme dans les parties précédentes, on prête attention au comportement complexométrique de ces métaux et aux problèmes des interférences dans leurs dosages. On décrit en détail des méthodes pour le dosage du thorium, du scandium et de quelques terres rares en mélanges. On discute de développements récents et de possibilités nouvelles dans ce domaine.

SOLVENT EXTRACTION AND SEPARATION OF GALLIUM(III), INDIUM(III), AND THALLIUM(III) WITH TRIBUTYLPHOSPHATE

ANIL K. DE and ASIT K. SEN
Department of Chemistry, Jadavpur University, Calcutta-32, India

(*Received* 27 *October* 1966. *Accepted* 19 *January* 1967)

Summary—A systematic study has been made of the solvent extraction behaviour of milligram amounts of gallium(III), indium(III), and thallium(III) with TBP from hydrochloric acid, and of thallium(III) from nitric acid, sulphuric acid and buffer solutions of different pH. The effect of the metal ion concentration, acid concentration, reagent concentration, salting-out agent, and diverse ions have been critically examined. A scheme for separation of gallium(III), indium(III), and thallium(III) from each other and for their determination is proposed.

A SYSTEMATIC study of the solvent extraction behaviour of gallium(III), indium(III), and thallium(III) with tributylphosphate (TBP) has been made and after a critical survey of the relevant factors, optimum conditions for the extraction have been determined.

Incomplete extraction of gallium(III) from hydrochloric acid with TBP has been reported.[1–3] The distribution ratios of indium(III) between TBP and hydrochloric acid have been measured.[4] The partial extraction of the iodo-complex of indium with TBP from nitric acid solution has been discussed.[5,6] Thallium(III) has been extracted with 50% TBP in n-decane and n-octane from aqueous sulphuric acid containing different concentrations of sodium chloride,[7] but the method is very time-consuming. Other reports include extraction of thallium with TBP from chloride, bromide and iodide solutions.[8,9] The distribution ratios of gallium(III), indium(III), thallium(I) and (III) *etc.*, extracted with TBP, as a function of hydrochloric acid concentration, have recently been reported.[10] The proposed methods for quantitative (>99%) extraction of gallium(III), indium(III) and thallium(III) with TBP from hydrochloric acid solution represent a definite improvement over the earlier methods and are more precise and rapid.

EXPERIMENTAL

Apparatus

The apparatus has been described previously.[11,12]

Reagents

Tributyl phosphate. The purification has been described previously.[11,12]

Gallium chloride solution, (5 mg of gallium/ml). Dissolve about 5 g of gallium chloride in 6*M* hydrochloric acid and make up to 500 ml with 6*M* hydrochloric acid. Standardize the solution by the oxine method.[13]

Indium chloride solution (2 mg of indium/ml). Dissolve about 2 g of indium chloride in 0·5*M*

hydrochloric acid and make up to 500 ml with 0·5*M* hydrochloric acid. Standardize the solution by the oxine method.[18]

Thallium(I) nitrate solution (10 *mg of thallium/ml*). Dissolve about 6·5 g of thallium nitrate in 1*M* nitric acid and make up to 500 ml with 1*M* nitric acid. Standardize the solution gravimetrically by the chromate method.[14]

Buffer solutions. Prepare by standard procedures: pH 2 (chloroacetate); pH 3·2 (acetate–hydrochloric acid); pH 4–6 (acetate–acetic acid).

The chemicals used were either chemically pure or reagent grade materials unless otherwise mentioned.

General procedure

The procedures were similar to those reported previously.[11,13] The following table summarizes the extraction conditions and analytical procedures.

TABLE I.—SUMMARY OF EXTRACTION CONDITIONS AND PROCEDURES

	Ga	In	Tl
Aqueous phase	Ga, 20 mg HCl, 0·35–6*M* (final) Total volume, 20 ml	In, 10 mg HCl, 0·1–9·1*M* (final) Total volume, 20 ml	Tl(I), 20 mg (oxidize with Br_2-water, warm, and cool) HCl, 0·1–6*M* (final) or HNO_3, 0·5–6*M* (final) or H_2SO_4, 0·25–5*M* (final) or buffer solution, pH 2–6. Total volume, 20 ml
Organic phase	TBP, 100%, 10 ml (acid-saturated)	TBP, 100%, 10 ml (acid-saturated)	TBP, 100%, 10 ml (acid-saturated)
Shaking period	2 min	2 min	10 min
Scrubbing (during salting-out effect and diverse ion studies)	4*M* HCl, 2 × 20 ml	6*M* HCl, 2 × 20 ml	2*M* HCl, 2 × 20 ml
Stripping agents	HCl, 0·02*M* (3 × 20 ml)	H_2O (2 × 20 ml) or tartaric acid (6·3%)–4*M* NH_3 (20 ml) followed by H_2O (20 ml).	20-vol H_2O_2 (12·5%)–3*M* NH_3 (20 ml) followed by H_2O_2 (5%)–3*M* NH_3 (20 ml)
Analysis	Complexometric titration[15]	Complexometric titration[15]	Complexometric titration[15] (decompose H_2O_2, then oxidize with Br_2-water, warm, and cool)

RESULTS AND DISCUSSION

Effect of acidity

The TBP extraction of gallium(III), indium(III), and thallium(III), as a function of hydrochloric acid concentration, was investigated. The extraction of thallium(III) was also investigated at varying concentration of nitric acid and sulphuric acid and over the pH range 2 to 6. The distribution ratio, *D*, was calculated as the ratio of the total metal ion concentrations in the organic and aqueous phases, determined by complexometric titration.[15] The results were also verified under optimum conditions of extraction by using larger amounts of the metals (20–25 mg) and checking the values by conventional gravimetric methods.

Table II and Fig. 1 show that the extraction of all three metals with 100% TBP increases with increasing acid concentration, and becomes quantitative for gallium from 2·0–6·0*M* hydrochloric acid, for indium(III) from 6·1–8·1*M* hydrochloric acid and for thallium(III) from 1·0–6·0*M* hydrochloric acid. For acid concentrations

Tl = 20·70 mg; TBP = 100%.

pH of the solution. As a safety precaution, further investigation with more concentrated sulphuric acid was avoided.

To study the effect of the metal ion concentration on extraction the amount of the metal ion was varied from 5 to 30 mg under the optimum conditions and it was found that the recommended method of extraction holds good. Varying the metal ion concentration under conditions of incomplete extraction gave almost constant values of *D* indicating the absence of polymerization in the organic phase for up to 30 mg of the metal ion.

Effect of TBP concentration

The effect of the reagent concentration was investigated by varying the concentration of TBP from 3% (0·109*M*) to 100% (3·66*M*). Benzene was used as the diluent. Table IV shows that the extraction of gallium(III), indium(III) and thallium(III) increases with increasing TBP concentration in the organic phase. The extraction of gallium(III) becomes quantitative with 20%, 25% and 100% TBP from

6*M*, 4*M* and 2*M* hydrochloric acid respectively. The extraction of gallium(III) with 20% TBP from 2*M* hydrochloric acid is poor. This indicates that though the dilution of TBP lowers the extraction of gallium(III), an increase in acid concentration increases it again. The extraction of indium(III) becomes quantitative with 100% TBP at 6*M* hydrochloric acid and dilution of the TBP lowers the extraction. The extraction of thallium(III) becomes quantitative with 15% TBP (0·549*M*) from 2*M* hydrochloric acid.

The general extraction reaction for these tervalent cations can be expressed according to Diamond and Tuck[16] as $M^{3+} + 3\ Cl^- + 3\ TBP_{(o)} \rightleftharpoons [MCl_3.(TBP)_3]_{(o)}$ and if the concentration of hydrochloric acid is high enough, the species extracted is probably $HMCl_4.3$ TBP. In the case of gallium and indium, because of the very small values of D at low TBP concentrations (<10%), attempts at log D–log C_{TBP} plots were not successful. Only with thallium were measurable values of D obtained at low TBP concentrations, and the extracted species (from 2*M* hydrochloric acid) is presumably $TlCl_3.3TBP$. The recommended optimum TBP concentrations for extraction are: gallium 20–100%; indium 100%; thallium 20–100%.

Salting-out effect

Ammonium chloride or magnesium chloride in the aqueous phase exerts a salting-out effect leading to enhanced extraction of gallium, indium or thallium.

TABLE V.—EFFECT OF AMMONIUM CHLORIDE AS SALTING-OUT AGENT

Metal ion*	Acidity	Distribution ratio, D		
		1*M* NH_4Cl†	2*M* NH_4Cl	4*M* NH_4Cl
Ga	1·2*M* HCl	110·1	Complete extraction	Complete extraction
In	1·1*M* HCl	8·4	18·0	38·3
Tl	pH 6·0 (acetate buffer)	37·8	108	Complete extraction

* Gallium = 20·10 mg; Indium = 10·89 mg; Thallium = 20·70 mg: TBP = 100%.
† The values of D in absence of NH_4Cl are 14·2 (Ga), 3·3 (In) and 1·3 (Tl).

Diverse ions

The ions examined were Ni, Mn(II), Cu(II), Co(II), Pb, Hg(II), Sn(II), Sn(IV), Pd(II), Bi, Al, Sb(III), V(V), Ag, Fe(III), U(VI), W(VI), fluoride, borate, citrate, tartrate, phosphate, thiocyanate and EDTA. Mutual interference of gallium, indium and thallium is eliminated by the separation procedure. The tolerance limit was set at 10 mg or less for ions which interfere.

The extractions were carried out according to the recommended procedure to examine the interference of ions usually associated with gallium, indium and thallium. In each experiment the organic phase, after extraction, was scrubbed with two 20-ml portions of the appropriate acid (gallium, 4*M* hydrochloric acid; indium, 6*M* hydrochloric acid; thallium, 2*M* hydrochloric acid) to remove the slightly co-extracted and entrained ions.

Gallium(III). Except for iron(III) and uranium(VI) none of the ions tested is extracted under the same conditions as gallium(III). The interference of iron(III) is eliminated by reducing to iron(II) with ascorbic acid. The trace amount of uranium(VI)

extracted is removed by scrubbing with four 20-ml portions of 4*M* hydrochloric acid. Tungsten(VI) (20 mg) remains in the aqueous phase in the presence of tartaric acid, and silver (5 mg) is not extracted from 6*M* hydrochloric acid containing ammonium persulphate. The interference of fluoride ion can be eliminated by extraction from a more acidic medium (6*M* hydrochloric acid).

Indium(III). A large number of metal ions are to some extent extracted under the the same conditions as indium(III), but many can be removed by scrubbing with two 20-ml portions of 6*M* hydrochloric acid. Among those which persist after this treatment are: copper(II), cobalt(II), tin(II) (2 mg), tin(IV), silver, antimony(III) and bismuth(III) (5 mg). They can be removed by scrubbing with four 20-ml portions of 6*M* hydrochloric acid. Palladium(II), iron(III), vanadium(V), uranium(VI) and tungsten(VI) are also extracted, but in the presence of tartaric acid vanadium(V) (10 mg) is not extracted and 2 mg of iron(III) can be tolerated if ascorbic acid is added.

Thallium(III). Only trace amounts of iron(III) and uranium(VI) are extracted under the same conditions as thallium. The interference of iron(III) is eliminated by masking with fluoride ion and that of uranium(VI) is removed by scrubbing with three 20-ml portions of 2*M* hydrochloric acid. The interference of tin(II), which tends to reduce thallium(III) to thallium(I), is eliminated by oxidizing with bromine water. Tungsten(VI) remains in the aqueous phase in the presence of tartaric acid, and silver is not extracted from 6*M* hydrochloric acid containing ammonium persulphate.

Recommended procedures

These results led to the following recommended procedures. All determinations are completed as outlined in Table I. Interfering ions should be removed or dealt with as described.

Extraction scheme for separation and estimation of gallium(III), indium(III) and thallium(III). Take in a 100-ml separating funnel, 10 ml of a solution containing about 10 mg of each of the metals and add 10 ml of 4*M* hydrochloric acid and 10 ml of 20% TBP in benzene. Shake the mixture for 10 min. Only thallium(III) is extracted. Separate the phases and keep the aqueous phase. Scrub the organic phase with 20 ml of 2*M* hydrochloric acid and add the washings to the aqueous phase. Strip thallium(III) from the organic phase and determine it as described. To the combined aqueous phases add 0·3 ml of 10% sodium chloride solution and evaporate almost to dryness. Dissolve the residue in 20 ml of 6*M* hydrochloric acid and extract for 2 min with 10 ml of 20% TBP in benzene previously saturated with 6*M* hydrochloric acid. Scrub the organic phase with three 20-ml portions of 6*M* hydrochloric acid to remove any indium. Separate the phases and strip gallium(III) from the organic phase and determine it as before.[15] Determine indium(III) in the combined aqueous phases.[15]

Typical results are shown in Table VI.

TABLE VI.—SEPARATION AND DETERMINATION OF GALLIUM, INDIUM AND THALLIUM

Taken, mg					
Ga		In		Tl	
Taken, *mg*	Found, *mg*	Taken, *mg*	Found, *mg*	Taken, *mg*	Found, *mg*
10·05	10·15	10·89	10·90	10·35	10·33
10·05	10·02	10·89	10·85	10·35	10·36
10·05	10·10	10·89	10·92	10·35	10·35

Gallium. Place an aliquot of chloride solution, containing up to 30 mg of gallium, in a 100-ml separating funnel, add 10 ml of 8*M* hydrochloric acid, and dilute to 20 ml. Shake for 2 min with 10 ml of 25% TBP in benzene previously saturated with 4*M* hydrochloric acid. Allow the phases to separate. Scrub the organic phase with 4*M* hydrochloric acid (2 × 10 ml), strip with 0·02*M* hydrochloric acid (3 × 20 ml) and determine gallium as above.

Indium. Place an aliquot of chloride solution, containing up to 30 mg of indium, in a 100-ml separating funnel, add 10 ml of concentrated hydrochloric acid and dilute to 20 ml. Extract for 2 min

with 10 ml of 100% TBP previously saturated with 6*M* hydrochloric acid. Allow the phases to separate and proceed as described in Table I.

Thallium. Place an aliquot of nitrate solution, containing up to 30 mg of thallium, in a 50-ml beaker, add a few drops of bromine water, warm to remove the excess of bromine, cool, and transfer into a 100-ml separating funnel quantitatively with 5 ml of water. Add 10 ml of 4*M* hydrochloric acid and dilute to 20 ml. Mix well and shake the aqueous phase with 10 ml of 20% TBP in benzene for 10 min. Allow the phases to separate and proceed as described before.

Zusammenfassung—Das Extraktionsverhalten von Milligrammengen Gallium(III), Indium(III) und Thallium(III) mit TBP aus Salzsäure sowie von Thallium(III) aus Salpetersäure, Schwefelsäure und Pufferlösungen verschiedenem pH wurde systematisch untersucht. Der Einfluß der Konzentrationen von Metallion, Säure, Reagens, Aussalzmittel und verschiedenen Ionen wurde kritisch geprüft. Ein Schema zur Trennung von Gallium(III), Indium(III) und Thallium(III) voneinander und für ihre Bestimmung wird vorgeschlagen.

Résumé—On a étudié systématiquement le comportement à l'extraction par le TBP de quantités de l'ordre du milligramme de gallium(III), indium(III) et thallium(III) à partir d'acide chlorhydrique et de thallium (III) à partir d'acide nitrique, d'acide sulfurique et de solutions tampons de différents pH. On a étudié de façon critique les influences des concentrations en ion métallique, acide et réactif, ainsi que celles de l'agent de relargage et de divers ions. On propose un schéma pour la séparation du gallium (III), de l'indium(III) et du thallium(III) l'un de l'autre et pour leur dosage.

DETERMINATION OF PLUTONIUM OXIDATION STATES IN DILUTE NITRIC ACID BY COMPLEMENTARY TRISTIMULUS COLORIMETRY

GARY L. SILVER
Monsanto Research Corporation, Mound Laboratory,* Miamisburg, Ohio, U.S.A.

(*Received* 22 *September* 1966. *Accepted* 30 *December* 1966)

Summary—The preparation of reference standards for use in complementary tristimulus colorimetry for plutonium is described. Plutonium(III) and (VI) are prepared by hydrazine reduction and silver(II) oxidation, respectively, of plutonium(IV). Plutonium(V) is prepared by reduction of plutonium(VI) with ascorbic or sulphurous acid. A method for computerizing tristimulus colorimetry is presented, and the technique is extended to three dimensions ("quadristimulus colorimetry").

MUCH attention was given to the determination of the oxidation states of plutonium in aqueous solutions when macro amounts of this element became available several years ago.[1,2] From time to time since then various methods have been suggested for determining the various species of plutonium in solution.[3,4] The method described in this paper is based on the work of Reilley *et al.*,[5,6] and has been extended to include four species. All the work described in this paper was performed with solutions of plutonium-238, a Beckman DK-2A spectrophotometer being used. Limitations on our facilities precluded use of all but the 238 isotope, and the techniques here described were later used to study plutonium-238 in dilute nitric acid.

DISCUSSION

The analysis of plutonium-238 in dilute nitric acid solution (0·2–1·0*M*) has been approached spectrophotometrically by the method of abbreviated complementary tristimulus colorimetry. The advantages of this technique have been described by Reilley.[6] While the multi-wavelength approach to the analysis of three-component mixtures would probably have been more accurate, the abbreviated method has been found to be rapid, convenient, and sufficiently accurate for most purposes. A spectrophotometric method is appropriate for plutonium solutions because the instrumentation is generally available and because the three principal oxidation states of plutonium [*i.e.*, plutonium(III), (IV) and (VI)] are all coloured species. For these studies the visible region of the spectrum was selected, and the range 860–420 mμ has been routinely used. This spectral region is not necessarily the best region for monitoring plutonium solutions, but was selected because of the limitations of our instrumentation.

In order to use the complementary colorimetry technique for the analysis of mixtures of Pu(III), Pu(IV), and Pu(VI), it was necessary to prepare standard solutions of these species. The preparation of plutonium in various oxidation states has been

* Operated by Monsanto Research Corporation for the U.S. Atomic Energy Commission under U.S. Government Contract No. AT-33-1-GEN-53.

examined in detail and the methods herein described, with some modification, have been adapted from standard methods.[1,2,7] Complementary colour points and C° values of Pu(III), Pu(IV), and Pu(VI) vary somewhat with the particular spectrophotometer used. Hence, values of the colour point (x, y) and C° are given to only two significant figures. Complementary colour points for Pu(III), Pu(IV), and Pu(VI) are essentially unchanged over the concentration range 0·2–1·0M nitric acid. The colour point of Pu(V) was not examined at this acidity, because of the instability of Pu(V) at this acid concentration. The terms are defined as:

$$x = \frac{A_{475}}{A_{475} + A_{525} + A_{560}}$$

$$y = \frac{A_{525}}{A_{475} + A_{525} + A_{560}}$$

C° = unit of concentration for which the colour concentration (J) is unity

where A is the absorbance at the wavelength (in mμ) indicated by subscript.

The visible spectra of the plutonium(III), (IV) and (VI) species have already been published.[1,2,9] Examination of these spectra reveals, for the tervalent and quadrivalent states, a variety of wavelengths suitable for spectrophotometric use. Unfortunately, the visible spectrum of Pu(VI) is neither as intense nor as rich as the visible spectra of the Pu(III) and Pu(IV). Spectrophotometry of PuO_2^{2+}, for these reasons, is accompanied by more difficulties than is that of the tervalent and quadrivalent species. In these studies, many of the errors encountered can be traced in part to the relative poverty of the visible spectrum of PuO_2^{2+} (*i.e.*, the absorption of light is rather weak and C° is thus rather large). Small errors in either q_{VI}° (where q_{VI}° is the "colour fraction" of Pu present as PuO_2^{2+}) or J thus result in significant errors in the calculated amount of Pu(VI). This is particularly true in solutions containing only a small amount of Pu(VI). In such cases it may be advantageous to determine the concentration of Pu(VI) by difference.

In this study, the wavelengths selected for analysis were 475, 525 and 560 mμ. Doubtless other wavelengths could also be used. The first wavelength, 475 mμ, corresponds to the maximum of a sharp peak in the spectrum of Pu(IV). Although this peak is quite sharp, and requires delicate setting of the spectrophotometer, it has been found to be useful. This wavelength corresponds to the side of an absorption band of Pu(VI). The wavelength 525 mμ was selected because it is the only other useful absorption band in the visible spectrum of Pu(VI). The wavelength 560 mμ corresponds to the top of a relatively broad absorption band of Pu(III).

A check on the accuracy of the quantities of Pu(III), Pu(IV) and Pu(VI) determined by this complementary colorimetry technique is the agreement between the total quantity of plutonium present, which with plutonium-238 is easily ascertained by alpha-counting, and the sum of the values of the three species obtained by spectrophotometry. In this respect we find our mass agreement similar to that given by Reilley and Smith.[6]

EXPERIMENTAL

Plutonium(III)

Solutions of plutonium(IV) in nitric acid were evaporated to incipient dryness (*i.e.*, to the formation of crystals), cooled and diluted with 0·2–0·5M nitric acid. As the concentration of the nitric acid

is increased, it is increasingly difficult to maintain solutions of Pu(III) free from other oxidation states. To this solution was then added a small amount of hydrazine neutralized with nitric acid, and the solution was gently boiled to reduce the plutonium to the tervalent state. Immediate measurement of the spectrum of a solution so prepared was desirable since aged solutions of tervalent plutonium-238 containing both hydrazine and nitric acid gradually become red. However, it was necessary to cool the solution before measurement because the spectrum of Pu(III) was found to be somewhat temperature-dependent.[8] The complementary colour point and unit of colour concentration of Pu(III) are (0·10, 0·07) and $C^\circ = 15{\cdot}5$ mg/ml.

Plutonium(IV)

Reference spectra of Pu(IV) were measured for solutions obtained by evaporating solutions of plutonium(IV) nitrate in nitric acid to the formation of crystals, cooling, and diluting with dilute nitric acid. During this evaporation of the solution, there is the danger that the evaporation will occur at a temperature sufficient to cause accidental denitration of the crystals resulting in oxidation to the sexivalent state:

$$Pu(NO_3)_4 \rightleftarrows PuO_2(NO_3)_2 + 2NO_2.$$

Conversely, heating at lower temperatures causes the evaporation time to become unduly lengthy. If the crystals are successfully obtained free from plutonium(VI), there is the danger of oxidation by dilute nitric acid upon dilution if the crystals have not been sufficiently cooled. More troublesome difficulties are encountered in attempting to ascertain what concentration of nitric acid should be used for dilution. If the acid is too dilute, hydrolysis of Pu(IV) is a problem, as may be the disproportionation of the quadrivalent state which begins immediately in dilute acid. Hydrolysis and precipitation do not occur if the cooled crystals are carefully dissolved in 0·5*M* nitric acid. The complexation of Pu(IV) by nitrate is such that in nitric acid that is between 0·2*M* and 1·0*M*, the fraction of $Pu(NO_3)^{3+}$ changes significantly, presumably resulting in accompanying spectral changes.[8] In this study, Pu(IV) in 0·5*M* nitric acid has generally proved satisfactory as a standard for the acidity range 0·2–1·0*M*. The problem of preparing Pu(IV) is particularly bothersome since it would be desirable to have one reference spectrum serve for a variety of nitric acid solutions. For plutonium(IV) the colour point and unit of colour concentration are approximately (0·76, 0·12) and 8·6 mg/ml.

Plutonium(VI)

Reference solutions of PuO_2^{2+} were prepared by evaporating plutonium(IV) nitrate in nitric acid to crystals and diluting with a small amount of 1*M* nitric acid. Small portions of silver(II) oxide were then added to oxidize the plutonium to the sexivalent state. When enough silver oxide had been added to impart a dark cast to the solution, oxidation was considered complete and the solution was allowed to stand in air for several hours to ensure reduction of the excess of silver(II). The solution was then diluted with 0·3*M* nitric acid. Small amounts of unreduced silver or other coloured impurities render a spectrum of PuO_2^{2+} untenable as a standard. The colour point and unit of colour concentration of Pu(VI) are approximately (0·43, 0·48) and 28 mg/ml.

Plutonium(V)

Some literature on plutonium notwithstanding,[11] the spectrum of Pu(V) proved one of the easiest reference spectra to obtain. Plutonium(V) is easily prepared from solutions of plutonyl nitrate which are silver-free. A small amount of such silver-free plutonyl nitrate was neutralized with ammonia solution (1 + 1) until one tiny drop of base turned the solution deep yellow-brown. If allowed to stand for several minutes, such neutralized solutions are likely to hydrolyse. It is necessary to neutralize the solution before reduction, however, because of the tendency of PuO_2^+ to disproportionate below pH 2 and because the reduction of PuO_2^{2+} in highly acid solution would result in reduction to the quadrivalent state. Ammonia was selected as a neutralizing agent because it forms its own buffer as the neutralization nears completion and prevents the pH from rising much above 8, thus minimizing the risk of hydrolysis. Immediately after neutralization, a 0·1*M* solution of ascorbic acid was added dropwise. This reagent, apparently not used before in the preparation of Pu(V), is both a reducing agent and an acid. Its acidic properties render it a buffer in the region of pH 4, which is ideal for the preparation of PuO_2^+. Its reducing properties also allow formation of the pink plutonium(V) species from the orange-pink plutonium(VI) species.

Numerous reagents have been used to prepare PuO_2^+, among them sulphite and iodide.[7,11] Iodine must be extracted from the solution if iodide is used as a reducing agent, and there is some evidence that sulphite solutions containing sulphate may complex Pu(V).[11] Ascorbic acid is not a good complexing agent, however, and it need not be removed from the solution before the spectrophotometric analysis. Plutonium(V) was also prepared by use of sulphur dioxide, and the spectrum

of the plutonium(V) so prepared compared favourably with that obtained when ascorbic acid was used. The colour point of Pu(V) is not used in complementary tristimulus colorimetry in these studies.

CALCULATIONS

The graphical method of tristimulus calculations of data points, although lengthy, is adequate for plutonium solutions. Methods of calculation are discussed by Flaschka.[12,13] For expediency, the tristimulus calculations were translated into Fortran II for processing on an IBM 1620 computer. The q° values were calculated by the method of the ratio of perpendiculars, as illustrated in Fig. 1. This diagram illustrates a sample calculation of q_1° based on the ratios of the perpendicular distances of the data point from the line (2–3) and of the point (1) from line (2–3) ($q_1^\circ = h_2/h_1$). The reference points were stored in the computer memory and converted to the proper co-ordinates before analysis of the data points, which were calculated from solution absorbance values used as input data.

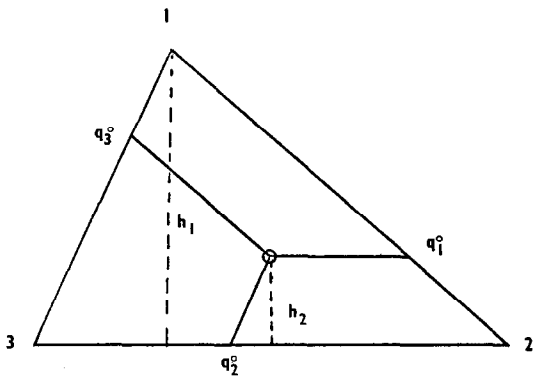

FIG. 1.—Method of calculating q_1.

In order to examine spectra for the presence of a fourth species, the method of complementary tristimulus colorimetry was expanded to three dimensions. The resulting geometric figure in which data points are located is a pyramid, the four vertices of this pyramid having been determined by the absorbance values of Pu(III), Pu(IV), Pu(V) and Pu(VI) at 475, 525, 560 and 600 mμ. In this method the ratio calculations were also performed by computer. Any two reference points serve to define one edge of the pyramid; three reference points define two vectors, the cross-product of which is a vector perpendicular to the plane defined by the three reference points. This plane is one side of the pyramid. The perpendicular distance of a data point from one of the faces of the pyramid is found by projecting the vector defined by one of the original reference points and the data point, onto the vector defined by the cross-product of the vectors derived from three reference points. Thus,

$$V(\cos\theta) = d = \frac{(A \times B) \cdot (V)}{A \times B}$$

where: A, B = vectors defined by three reference points
V = vector defined by the data point and one reference point
d = perpendicular distance of the data point from the plane defined by three reference points.

By use of the absorbance values at 475, 525 and 560 mμ as the numerator in determining the x, y, and z co-ordinates respectively, the following points and reference concentration values were obtained:

Pu(III): (0·04, 0·02, 0·48), $C^\circ = 12$ mg/ml
Pu(IV): (0·72, 0·11, 0·12), $C^\circ = 11$ mg/ml
Pu(V): (0·19, 0·24, 0·38)
Pu(VI): (0·40, 0·46, 0·10), $C^\circ = 36$ mg/ml

Acknowledgement—The author wishes to thank F. C. Fushimi and M. S. Mowchan for their thoughtful suggestions and help during the course of this work.

Zusammenfassung—Die Herstellung von Vergleichsstandards zum Gebrauch bei der komplementären Tristimulus-Kolorimetrie von Plutonium wird beschrieben. Plutonium(III) und -(VI) werden durch Reduktion von Plutonium(IV) mit Hydrazin bzw. Oxydation mit Silber(II) hergestellt, Plutonium(V) durch Reduktion von Plutonium(VI) mit Ascorbin- oder schwefliger Säure. Es wird eine Methode vorgestellt, die Ergebnisse der Tristimulus-Kolorimetrie im Computer zu verarbeiten, und das Verfahren wird auf drei Dimensionen ausgedehnt ("Quadristimulus-Kolorimetrie").

Résumé—On décrit la préparation d'étalons de référence pour l'emploi dans la colorimétrie en tristimulus complémentaire du plutonium. On prépare les plutonium(III) et (VI) par réduction à l'hydrazine et oxydation à l'argent(II), respectivement, du plutonium(IV). On prépare le plutonium(V) par réduction du plutonium(VI) aux acides ascorbique ou sulfureux. On présente une méthode pour la mise en calcul de la colorimétrie en tristimulus, et étend la technique à trois dimensions ("colorimétrie en quadristimulus").

POLAROGRAPHIC DETERMINATION OF METHYL METHACRYLATE

MILOSLAV PANTŮČEK
Public Health Station, Hradec Králové, Czechoslovakia

(*Received* 21 *October* 1966. *Accepted* 19 *January* 1967)

Summary—The permanganate oxidation of methyl methacrylate in weakly acidic solution yields methyl pyruvate. Hydroxylamine hydrochloride is used for destroying the excess of permanganate. At the same time it is consumed for oximation of the pyruvate, and the resulting oxime is determined polarographically. The reaction scheme of permanganate oxidation of methyl methacrylate is suggested and optimum working conditions are found both for permanganate oxidation and for polarographic determination. The method is used for the determination of vapours of methyl methacrylate in the air, for industrial hygiene purposes.

ANALYTICAL methods for the determination of methyl methacrylate are based on spectrophotometry in the infrared[1,2] or ultraviolet region,[1,3] gas chromatography,[4,5] polarography[6–8] and on the addition of halogens,[1,9] mercaptans[10] or mercury compounds[11] to the double bond. Indirect photometric methods are based on the photometry of the iron(III) salt of hydroxamic acid.[12] Oxidation methods are based either on the complete oxidation of the ester to carbon dioxide and water[13] with titrimetric determination of the remaining oxidation reagent, or on the fission of the double bond, the end carbon atom of the double bond yielding formaldehyde; either the remaining oxidation reagent[14] or the liberated formaldehyde[15] is then estimated.

This paper deals with the mechanism and analytical application of the permanganate oxidation of methyl methacrylate in a slightly acidic solution.

EXPERIMENTAL

Apparatus

For the polarographic determination Heyrovský's recording polarograph type V301 and reflecting galvanometer type Z9 of sensitivity $1{\cdot}4 \times 10^{-9}$ A were used. The samples were analysed under nitrogen in short cells with a needle-type SCE and Smoleř's dropping mercury electrode. The flow-rate of mercury was 0·55 mg/sec. The drop-time, measured in a $0{\cdot}64 \times 10^{-3}M$ solution of methyl pyruvate oxime, at 1·2 V and at 40·3 cm mercury height was 3·00 sec.

For the estimation of pH, a Beckmann compensation pH-meter was used.

Reagents

For the preparation of hydrochloric acid-potassium chloride buffers, 50 ml of $0{\cdot}2M$ potassium chloride were mixed with different amounts of $0{\cdot}2M$ hydrochloric acid and made up to 200 ml with distilled water.

Walpole's $0{\cdot}2M$ acetate buffer solution: different amounts of $0{\cdot}2M$ acetic acid were made up to 100 ml with $0{\cdot}2M$ sodium acetate.

The methyl pyruvate[16] and methyl acetate[17] were prepared by standard methods. The esters and pyruvic acid were freshly distilled before use.

Development of method

In most experiments, measured amounts of standardized permanganate solution and acid or buffer solution were made up with water to 4·5 ml. To this oxidation mixture 0·5 ml of standard ester

solution was added. After a definite time, the oxidation was stopped by addition of 1 ml of acid hydroxylamine hydrochloride solution and the oxime obtained was determined polarographically. The maximum on the polarographic waves was suppressed by addition of 0·05 ml of 0·5% tylose solution.

For determination of the amount of permanganate necessary for the oxidation, a titrimetric determination of unreacted permanganate[18,19] was carried out in addition to the polarographic determination of the methyl pyruvate oxime. To a series of solutions of different permanganate content (total volume 12·5 ml), 2·5 ml of 0·05*N* sulphuric acid and 10 ml of aqueous methyl methacrylate solution (25 μmole) were added. Immediately after mixing, 5 ml of each solution were measured into a separate flask. After 24 hr at 20° these 5-ml portions were analysed polarographically and to the remaining 20 ml of solution 10 ml of 0·5*M* manganese sulphate, 4 ml of 4*N* sulphuric acid, 30 ml of a saturated solution of sodium pyrophosphate, 30 ml of distilled water and 3 drops of 1% diphenylamine (in sulphuric acid) were added and they were titrated with 0·1*N* hydroquinone, standardized with dichromate. The result was calculated for 5 μmole of ester.

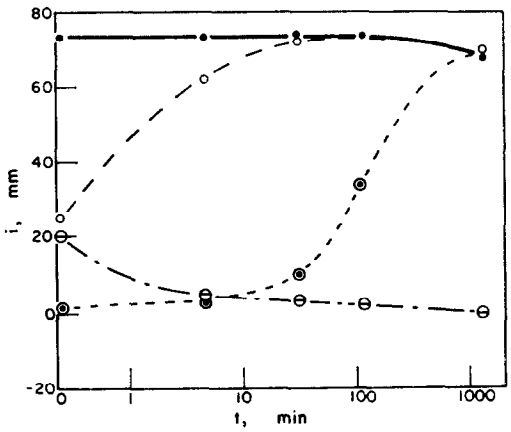

FIG. 1.—Rates of oxidation of equal amounts (0·82 mmole) of various substances. ○—methyl methacrylate (0 mm); ●—methyl pyruvate (70·7 mm); ⊙—methyl lactate (0 mm); ⊖—pyruvic acid (74·0 mm). The heights of the polarographic waves (galvanometer sensitivity 1/20) correspond to the amounts of oxime produced on oxidation at 22°C with 0·02*N* permanganate in 0·005*N* sulphuric acid. The heights of the polarographic waves of the starting material are given in brackets.

RESULTS AND DISCUSSION

The mechanism of methyl methacrylate oxidation

To explain the oxidation mechanism of methyl methacrylate in slightly acid solution (0·005*N* sulphuric acid), the end product of oxidation was isolated and identified, and the kinetics of oxidation of methyl methacrylate at low temperature, and of the oxidation of pyruvic acid, methyl pyruvate and methyl lactate were followed, for these compounds can be considered as possible products of the oxidation of methyl methacrylate.

Hydroxylamine hydrochloride in a solution of 1*M* sodium hydroxide[20] was used for the preparative oximation of methyl pyruvate. The product was extracted with ether, the ether was evaporated and the product was refined by sublimation twice at normal pressure, and dried over silica gel. The half-wave potential and the characteristic polarographic wave of this product are in accord with the properties of the oxime of the product resulting from the oxidation of methyl methacrylate. The melting point of the product is 73·3°. (Literature values: m.p. = 68–69° after crystallization from ether[21] or m.p. 71° after crystallization from benzene.[22]) Elemental

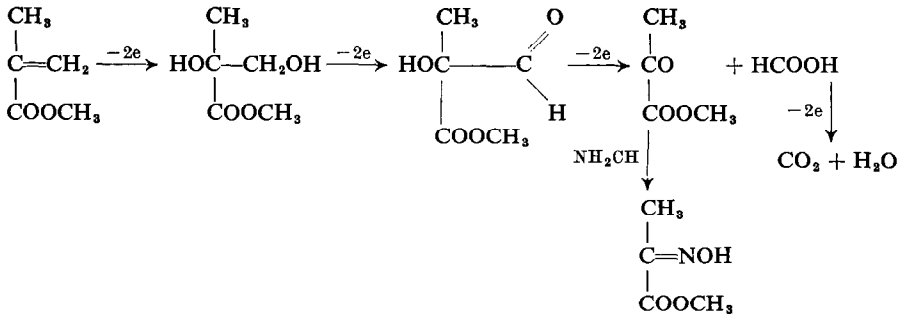
The methyl pyruvate oxime is hence the product which is electro-reduced in the polarographic determination.

From the rate of oxidation of pyruvic acid, methyl methacrylate, methyl lactate and methyl pyruvate (Fig. 1) it is evident that neither methyl lactate nor pyruvic acid is formed in considerable amounts in the course of reaction. Pyruvic acid undergoes rapid and complete oxidation, whereas methyl pyruvate resists further oxidation. This difference in reactivity can be explained in the following manner: the methacrylates

cannot form a complex with manganese(III), the intervention of which is, according to Drummond and Waters,[23] the necessary condition for fission of a double bond. When methyl lactate undergoes quantitative oxidation the velocity of the reaction is much slower.

The oxidation of methyl methacrylate to methyl pyruvate proceeds *via* a compound of which the oxime has a half-wave potential 0·3 V more negative than that of methyl pyruvate oxime (Fig. 2). The sum of the heights of the polarographic waves of this compound and of methyl pyruvate oxime varies during the oxidation only slightly. Hence, both compounds have similar diffusion coefficients, molecular weights and chemical character. It is possible that the methyl ester of 2-hydroxy-2-formylbutyric acid may be this intermediate oxidation product. The suggested reaction scheme is as follows:



The oxidation of other methacrylates (Fig. 3) and acrylates (Fig. 4) follows a similar scheme. From the oxidation of acrylates, glyoxalates result, which undergo further oxidation much more easily than pyruvates. This fact could be a basis for differentiation between pyruvates and glyoxalates or methacrylates and acrylates.

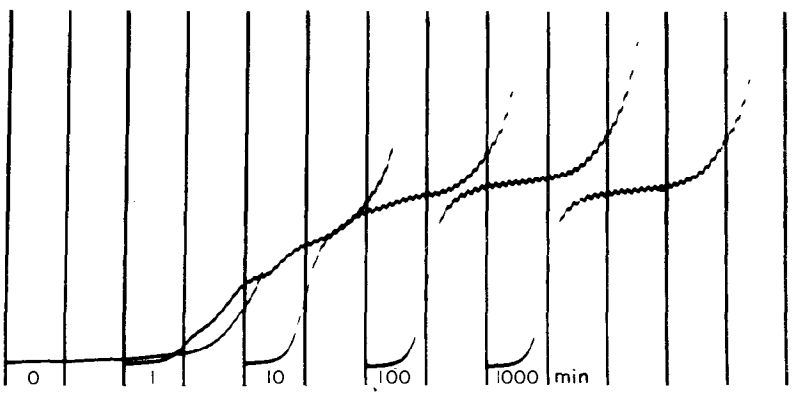


FIG. 3.—Rate of oxidation of butyl methacrylate (0·41 mmole) at 22°C. Conditions as for Fig. 1.

Optimum conditions for oxidation of methyl methacrylate

The time dependence of the effect of different permanganate excesses on methyl methacrylate at different pH values, temperatures and ionic strengths, was studied.

The optimum pH for the oxidation is 2·70 (Fig. 5) or a mineral acid concentration of 0·005*N* (Fig. 6); good results are also given by 0·1*M* acetic acid. The investigation of the rate of reaction (Fig. 7) has shown that in a more acidic solution the reaction is

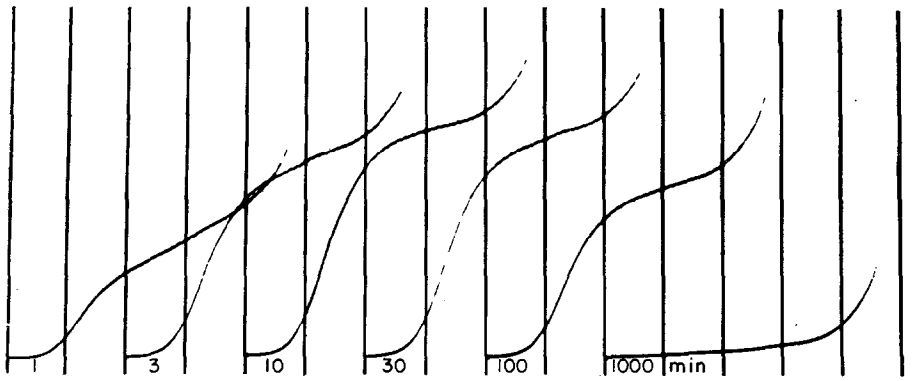

FIG. 4.—Rate of oxidation of methyl acrylate (0·82 mmole) at 22°C.
Conditions as for Fig. 2.

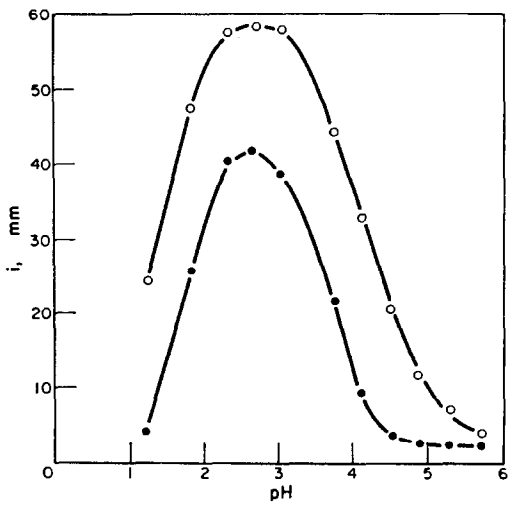

FIG. 5.—Effect of pH on degree of oxidation of methyl methacrylate (0·82 mmole) at 23°C.
The heights of the polarographic waves (sensitivity 1/20) refer to the oximes of the products obtained after 45 (○) and 75 (●) hr oxidation with 0·02*N* permanganate at various pH values. HCl/KCl buffers were used for the range of pH 1·22–3·05, and acetate buffer for pH 3·73–5·71.

not stoichiometric and further oxidation occurs. At higher pH the result is similar.

Excess of permanganate promotes further oxidation (Fig. 8). The investigation of permanganate consumption and its dependence on the volume of the added permanganate shows that the six-electron oxidation that gives rise to methyl pyruvate is followed by the two-electron oxidation of the liberated formic acid to carbon dioxide and water. Whilst the first step of the oxidation is stoichiometric, the second step needs a great excess of permanganate for its completion (Fig. 9).

Increasing the temperature of the reaction mixture accelerates not only the oxidation to the pyruvate but also the further oxidation, which is undesirable analytically (Fig. 10).

The relationship of the temperature and the time required to achieve 97–100%

conversion is presented in Fig. 11. Ionic strength within the range 0·05–0·20 has no effect on the reaction. Higher ionic strength accelerates further oxidation of pyruvate.

Polarographic determination of methyl pyruvate oxime

The determination of pyruvate can be combined with there moval of excess of oxidant. With the aid of hydroxylamine hydrochloride, the excess of permanganate is destroyed and the resulting methyl pyruvate is converted into oxime, which can be determined polarographically. The polarographic determination of pyruvate in the form of oxime is also advantageous, because it is more sensitive than

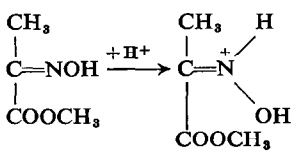
polarographic determination of the pyruvate alone. While the former compound undergoes a four-electron polarographic reduction, the latter undergoes only a two-electron reduction.

At the dropping mercury electrode, the oxime is easily reduced in the protonated form:[24–26]



Generally, oximes are very weak bases and the pK of their positive ion, according to Brønsted's theory, is less than unity.[25] For this reason, at pH >1, the kinetic current arising from the recombination of the cation contributes considerably to the total height of the polarographic wave. The dependence of the wave height on pH is represented in Fig. 12. At pH 4·4 a more negative polarographic wave appears,

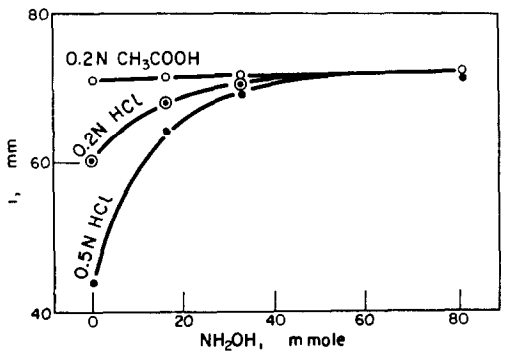


FIG. 13.—Effect of excess of hydroxylamine on limiting current for methyl pyruvate oxime (0·82 mmole) at various acidities.

caused by the reduction of uncharged molecules of the oxime. It is advantageous to work with a strongly acidic solution, where the excess of hydroxylamine does not interfere[26] and the oxime yields a simple diffusion current. To prevent the acid-catalysed hydrolysis of oxime,[26] an excess of hydroxylamine is maintained in the solution (Fig. 13). The maximum on the polarographic wave may be suppressed by gelatin[26] or tylose.[25]

Practical application

The need for a suitable method of determination of methyl methacrylate vapours in air for the purposes of industrial hygiene was the first stimulus for this work. First, it was necessary to seek a suitable method of absorption of methacrylate vapours from the air. The best absorption is given by permanganate solution, because of the immediate oxidation of absorbed ester. For this reason, the permanganate oxidation has been taken as a basis for the method.

Laboratory control of the absorption process was achieved by means of aeration of the ester from a standard solution into two absorption vessels in series. At an aeration velocity of 0·4–1·2 l/min about 3·5% of the total amount of ester passes into the second absorption vessel. At velocities of 0·08–0·20 l/min, an average of 2·8% of the total amount of ester passes into the second absorption vessel.

Interfering substances in this determination include aldehydes and ketones, and alcohols, esters and unsaturated compounds which can produce aldehydes and ketones by oxidation (Table I).

In an oxidation lasting 100 min, the presence of acetaldehyde, benzaldehyde, acetone, ethanol, and esters of acetic acid does not interfere. These compounds can only interfere by consuming some of the permanganate used to oxidize the methacrylate. The interference of acrylates and styrene can be prevented by prolonged oxidation. The oxidation of formaldehyde is very slow and hence it interferes in this determination as also does methanol, from which formaldehyde arises by oxidation.

TABLE I.—INTERFERENCE OF VARIOUS COMPOUNDS IN THE DETERMINATION OF METHYL METHACRYLATE

Compound	Amount, *μmole*	Height of interfering polarographic wave, *mm*, after *x* min oxidation					Interference after *x* min oxidation, %			$EV_{1/2}$,
	x	0	1	10	100	1000	0	100	1000	
Formaldehyde	6·34	10·0	10·0	9·5	8·0	—	15	12	—	0·64 0·89
Acetaldehyde	5·00	0	0	0	0	—	0	0	—	0·83 1·05

Butyl acrylate	2·50	0	10·0	17·0	14·0	3·0	0	54	11·6	0·34
Styrene	1·13	0	7·0	7·0	4·0	0	0	34	0	0·52
Methyl methacrylate	5·00	0	24·1	50·2	52·0	49·0	0	100	94	0·49
Butyl methacrylate	2·50	0	4·3	19·9	24·5	23·4	0	94	90	0·40

The interference is expressed as a fraction of the height of the polarographic wave for an equal molar concentration of methyl pyruvate oxime. The last column records the values of $E_{1/2}$ (*vs.* S.C.E.) of the polarographic waves of the oxidation products, in the presence of excess of hydroxylamine at pH 0·9.

Recommended procedure for the determination of vapours of methacrylate in air

Absorb the vapours of methacrylate in 5–10 ml of absorption solution (100 ml of 0·1*N* potassium permanganate and 25 ml of 0·1*N* sulphuric acid made up to 500 ml with distilled water) in an absorption vessel fitted with a fritted disc. The sampling velocity is about 1 l/min. If the absorption solution is decolorized during sampling, take a new, smaller, sample. When the sampling is finished, wait 100 min (for temperature 5–28°) and then add 1 ml of reducing solution (2·5% hydroxylamine hydrochloride in 1*M* hydrochloric acid) for every 5 ml of absorption solution. Record the polarographic curve, after the addition of 0·05 ml of 0·5% tylose for every 6 ml of the sample, in an atmosphere of nitrogen, with a saturated calomel electrode, over the range 0·2–1·0 V.

For calibration, use an aqueous solution of freshly distilled methacrylate, oxidized for 100 min with an equal volume of absorption solution containing double the designed amount of potassium permanganate and sulphuric acid.

Alternatively, the methyl pyruvate oxime alone can be used for calibration, dissolved in a mixture of the absorption and reduction solutions (5 + 1).

Acknowledgement—The author wishes to thank Dr. P. Zuman for his interest in this work and for his critical review of this manuscript.

Zusammenfassung—Die Oxidation von Methylmethacrylat mit Permanganat in schwach saurer Lösung liefert Methylpyruvat. Zur Zerstörung überschüssigen Permanganats wird Hydroxylaminhydrochlorid verwendet. Gleichzeitig wird es zur Oximierung des Pyruvats verbraucht; das entstandene Oxim wird polarographisch bestimmt. Ein Reaktionsmechanismus für die Permanganatoxidation von Methylmethacrylat wird vorgeschlagen und die optimalen Arbeitsbedingungen für Permanganatoxidation und polarographische Bestimmung angegeben. Die Methode wird zur Bestimmung von Methylmethacrylatdämpfen in der Luft zu industriehygienischen Zwecken verwendet.

Résumé—L'oxydation permanganique du méthacrylate de méthyle en solution faiblement acide donne du pyruvate de méthyle. On utilise le chlorhydrate d'hydroxylamine pour détruire l'excès de permanganate. En même temps, il est consommé pour l'oximation du pyruvate, et l'on dose polarographiquement l'oxime résultante. On suggère le schéma réactionnel de l'oxydation permanganique du méthacrylate de méthyle et l'on a trouvé les conditions de travail optimales tant pour l'oxydation permanganique que pour le dosage polarographique. On utilise la méthode pour le dosage de vapeurs de méthacrylate de méthyle dans l'air, à des fins d'hygiène industrielle.

SEPARATION OF IONS BY ALTERATION OF THE CONCENTRATION OF THE LIGAND IN A DISCONTINUOUS COUNTERCURRENT EXTRACTION SYSTEM

C. R. BOSWELL

(*Received* 29 *December* 1966. *Accepted* 1 *February* 1967)

Summary—A new technique in Craig-type liquid-liquid, discontinuous, countercurrent solvent extraction was developed. In this, the ligand concentration in the extraction train was altered at several points, causing non-equivalent changes in the extractability of the ions being separated. This allowed quantitative separation of a mixture with a minimum number of transfers, thereby keeping the solvent volume to a minimum. The technique was applied to achieve total or partial separation of a number of elements, using methyl isobutyl ketone as the solvent and hydrochloric acid as the ligand. A computer programme was developed for calculating the distribution of a solute in an extraction train operating under these conditions.

RECENTLY, Craig-type liquid-liquid, discontinuous, countercurrent* solvent extraction has been used for inorganic systems, with applications to geochemical analysis.[1–4] In many cases, good separations of the constituents of solutions of geological materials may be achieved but if the distribution coefficients of constituents between the ligand and solvent are too similar, it is virtually impossible to separate them by countercurrent distribution without an inordinate number of transfers. This difficulty can to some extent be overcome by varying the concentration or nature of the ligand in the lower phase of the extraction train so that there is relative alteration in the extraction characteristics of the species to be separated.[1] For this latter method to be other than empirical, it is necessary to know the extractability of the species and their distribution in the extraction train after a given number of transfers. The former can be obtained experimentally, but although the distribution may also be similarly obtained, it is a time-consuming operation, and there is clearly a place for some method whereby the distribution in the tubes of the extraction train may be calculated. In the case of normal liquid-liquid, discontinuous, countercurrent separation, the distribution can be predicted by the use of tables of the binomial function.[5,6] However, for varying nature or concentration of ligand, no rapid technique for calculating the distribution has hitherto been available.

It is the purpose of this paper to demonstrate further the potentialities of the variable ligand method and to show how a mathematical relationship has been derived from which the theoretical distribution can be calculated. This relationship has been programmed for a computer and has been checked by experimental studies.

* In using the term "countercurrent" for a Craig-type apparatus, we follow accepted practice though realizing that as there is only one moving phase, this term is not strictly correct.

COMPUTATION OF SOLUTE DISTRIBUTION IN AN EXTRACTION TRAIN WITH VARIABLE LIGAND CONCENTRATIONS

The mathematics governing the distribution of a solute in a discontinuous, countercurrent extraction train are relatively simple and lend themselves to the use of high-speed digital computers. This has not hitherto been necessary, owing to the ready availability of extensive tables of the binomial function[7,8] but with systems in which there is an abrupt change in extractability at some stage in the extraction train, these cannot be used.

The amount of material in tube number i after n transfers ($T_{i,n}$) is given by the expression

$$T_{i,n} = A_{i,n-1} + O_{i-1,n-1} \tag{1}$$

where $A_{i,n}$ and $O_{i,n}$ are the amounts of material in the aqueous and organic phases respectively, at equilibrium in tube i after n transfers and are given by

$$A_{i,n} = T_{i,n}\left(\frac{1}{1 + Dr}\right) \tag{2}$$

$$O_{i,n} = T_{i,n}\left(\frac{Dr}{1 + Dr}\right) \tag{3}$$

where D is the distribution coefficient of the solute and r is the ratio of the volumes of the organic and aqueous phases.

If a particular value for the initial amount of solute in the first tube of the extraction train is assumed, a theoretical countercurrent distribution can be evaluated by calculating the amounts in the aqueous and organic phases at equilibrium in each tube, calculating from equation (1) the total amount in each tube after each transfer and then recalculating the amount in the aqueous and organic layers of each tube at equilibrium from equation (2) or (3). The steps outlined above are an arithmetic analogue of the operations of equilibration and transfer followed by a second equilibration.

A programme was written for use on an IBM 1620 computer, utilizing equations (1), (2) and (3) and making it possible to calculate the distribution of a solute in an extraction train in which there are points at which there are abrupt changes in the distribution characteristics of the solute. Copies of the computer programme are available from one of the authors (C. R. Boswell).

EXPERIMENTAL

The extractabilities of a large number of metal ions from hydrochloric acid by methyl isobutyl ketone (MIBK) are known[4] and vary considerably with acid concentration. Using these data, a scheme was devised for separating a number of elements with similar extraction characteristics by altering the conditions on the extraction train.

The system involved the separation or partial separation of gold, zinc, cadmium, mercury, gallium, indium, thallium, tin, lead, arsenic, antimony, bismuth and iron by the use of counter-current distribution. The first 20 tubes of the extraction train contained $7M$ hydrochloric acid, the next 40 tubes contained $2M$ hydrochloric acid and the remaining 10 contained $0{\cdot}5M$ hydrochloric acid. The first tube of the train contained a solution of the elements mentioned, in $6M$ hydrochloric acid. This solution had previously been oxidized with chlorine gas to ensure that all elements were in their highest oxidation states. The organic phase was redistilled MIBK.

Each step of the process involved an equilibration time of 3 min and a settling time of 4 min. Previous work[4] had indicated that these times were sufficient to achieve complete equilibration of the complexes and separation of the phases.

Apparatus

The apparatus used was a 120-tube, fully automatic, discontinuous, countercurrent extraction apparatus. The individual extraction tubes were mounted on a shaking-rack, the axis of which was attached to a control unit which automatically effected the operations of shaking, settling and decantation. Individual tubes had a capacity of 20 ml for the stationary lower phase and the moving upper phase was fed into the system at the end of each cycle by means of a 20-ml dispenser attached to a 10-l. reservoir. After each shaking operation, the rack was tilted through 90° and the upper phase decanted into the next tube.

Procedure

All acid used was pre-equilibrated with MIBK. The solvent, which had been pre-equilibrated with 6*M* hydrochloric acid, was fed into the system from the reservoir, and countercurrent extraction was carried out for 70 transfers. The contents of pairs of tubes were evaporated to dryness, sodium chloride was added as carrier, and the residues were examined spectrographically in a d.c. arc, with anode excitation. All spectra were recorded on one photographic plate and the distribution of any element was found by visual observation of a sensitive spectral line of that element. Densitometric measurements were not necessary except in cases of doubt.

RESULTS AND DISCUSSION

The results are shown in Fig. 1 together with the theoretical distributions as calculated from the computer programme. In the calculations, allowance was made

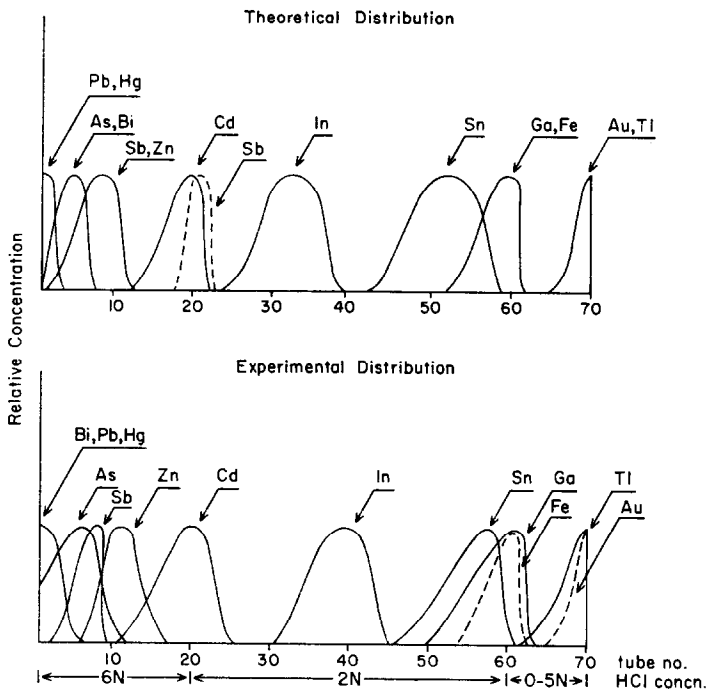

FIG. 1.—Theoretical and experimental distribution curves for certain elements after countercurrent extraction with methylisobutyl ketone with varying concentrations of hydrochloric acid in the aqueous phase.

for the two oxidation states of antimony. In the experimental work, only the peak corresponding to the species with lower extraction was found. The distribution patterns of indium and tin are displaced further along the train than expected from calculations. This is most probably due to the fact that after the solvent front, saturated with 6*M* acid, reached tube number 20, redistribution of the acid between

the two phases occurred with a consequent rise in acid concentration in the first tubes originally containing the 2*M* acid and a corresponding change in the extraction characteristics of these elements. In view of this, the agreement between the experimental and calculated distributions is very satisfactory and would indicate that movements of acid are relatively insignificant.

The results have shown that liquid-liquid, discontinuous countercurrent extraction systems in which conditions on the extraction train are altered at various stages are particularly useful in separating multicomponent mixtures, especially where the optimum conditions for separating certain components are not those for separating other components. In the case considered here, it is possible to separate quantitatively a mixture of lead, cadmium, indium, iron and gold, with only 70 equilibration stages. If the conventional system were used, a much greater number of equilibration stages would be necessary and it is doubtful whether even then a satisfactory separation of iron and gold would be attained. The saving of time and economy in solvent volume when the modified technique is used are obvious.

Acknowledgements—The authors are indebted to the New Zealand University Research Committee and the Nuffield Foundation for grants towards the establishment of a spectrographic laboratory at Massey University. They are also grateful to Chemistry Division, D.S.I.R. for the loan of a 120-tube, discontinuous, countercurrent extraction apparatus.

Zusammenfassung—Eine neue Arbeitsweise bei der diskontinuierlichen Gegenstromextraktion nach Craig wurde entwickelt. Dabei wird die Ligandenkonzentration in der Extraktionsbatterie an mehreren Punkten geändert, wobei sich ungleiche Änderungen in der Extrahierbarkeit der zu trennenden Ionen ergeben. Damit wurde quantitative Trennung einer Mischung mit einer Mindestzahl von Schritten erreicht, wobei das Lösungsmittelvolumen am Minimum gehalten wird. Das Verfahren wurde zur totalen oder teilweisen Trennung einer Reihe von Elementen mit Methylisobutylketon als Lösungsmittel und Salzsäure als Ligand verwendet. Ein Rechenprogramm zur Berechnung der Verteilung eines gelösten Stoffes auf eine unter den angegebenen Bedingungen arbeitende Extraktionsbatterie wurde erstellt.

Résumé—On a élaboré une nouvelle technique d'extraction discontinue à contre-courant, par solvant, en phase liquide, du type Craig. Dans celle-ci, la concentration en ligand dans l'ensemble d'extraction a été modifiée en différents points, causant des changements non équivalents dans l'extractibilité des ions à séparer. Ceci a permis une séparation quantitative d'un mélange avec un nombre minimal de transferts, maintenant de ce fait le volume de solvant à un minimum. On a appliqué la technique pour effectuer la séparation totale ou partielle d'un certain nombre d'éléments en utilisant la méthylisobutylcétone comme solvant et l'acide chlorhydrique comme ligand. On a élaboré un programme de computation pour calculer la distribution d'un soluté dans un ensemble d'extraction opérant dans les conditions ci-dessus.

EXTRACTION OF ANTIMONY WITH TERTIARY AMINES

A. ALIAN and W. SANAD
Analytical Chemistry Division, Atomic Energy Establishment,
Cairo, Egypt, U.A.R.

(*Received* 18 *October* 1966. *Accepted* 10 *January* 1967)

Summary—The extractability of antimony(III) and (V) with tridodecylamine from various aqueous solutions is reported. Extraction from nitric and hydrofluoric acid solutions is low, but extraction from sulphuric, hydrochloric and hydrobromic solutions is high. Antimony(III) can be separated from antimony(V) in 7*M* nitric acid or 0·64*M* hydrobromic acid. The extraction of antimony from hydrochloric acid solutions in methanol, ethanol, and acetone–water mixtures is greater than from pure aqueous solutions of the same acidity. The elements from which antimony can be separated with tertiary amines are given.

THE extraction of antimony with different organic solvents has been investigated by many authors.[1,2] The solvents studied include ethyl acetate benzene, alcohols and ethers,[3,4] organo-phosphorus solvents[5] and others.[6–10] Conditions have been determined for the isolation of antimony from other elements by these solvents and the nature of the extraction processes has also been examined.

Amine extraction of the elements has attracted the attention of chemists in the past few years because of the availability of such solvents and their high stability and selectivity, and has been well reviewed.[11,12] An analogy between extraction with amines and anion-exchange on solid resins has often been drawn. In earlier studies from this laboratory the extraction of cerium, thorium, uranium, neptunium and zirconium with tertiary amines has been investigated and the stability constants of the extraction reactions have been determined.[13–16]

The aim of the present work was to carry out a systematic study on the extractability of antimony in its two oxidation states from various acidic media with tertiary amines, and to explain the mechanism of extraction. The extraction of some other elements was also studied in order to determine the elements from which antimony can be selectively isolated with tertiary amines.

EXPERIMENTAL

Apparatus

Scintillation counter. EKCO with well crystal NaI(Tl) type.

Reagents

Antimony solutions. A mixture of antimony-122 and antimony-124 was obtained by irradiating metallic antimony of high purity in the UA-RR-1 2MW Research reactor at Inshas for 48 hr. Approximately 30 mg of irradiated antimony were dissolved by heating with the minimum amount of concentrated sulphuric acid till dissolution was complete. The solution was then heated to fumes and subsequently diluted with 6*M* hydrochloric acid. This was the stock solution of radioactive antimony(III). A stock solution of radioactive antimony(V) was prepared by heating a similar amount of irradiated antimony with a mixture of concentrated sulphuric acid and nitric acid (1 + 1) till dissolution was complete. The solution was heated till fuming and then cooled and diluted with 6*M*

hydrochloric acid. Carrier solutions of antimony(III) (0·0128*M*) and antimony(V) (0·144*M*) were prepared by dissolving suitable amounts of unirradiated metallic antimony in a similar manner.

Other ions. Suitable isotopes of iron, zinc, cobalt, silver, mercury, zirconium, scandium, cerium, caesium and chromium were obtained by irradiation. Protactinium-233 was prepared by dissolving about 5 mg of irradiated pure thorium nitrate in about 5 ml of 5*M* hydrochloric acid–1*M* lithium chloride solution, and then extracting with an equal volume of 0·3*M* trioctyl amine in benzene. Protactinium-233 was then re-extracted from the organic phase with 5 ml of 1·5*M* hydrochloric acid, and this aqueous solution was mixed with an equal volume of concentrated hydrochloric acid. The final volume of each tracer solution was selected so that 50 μl diluted to 5 ml had a measured activity of 5000–75,000 cpm.

Amine. Trilaurylamine or tridodecylamine (TDA), a high purity product of Rhone-poulenc, France, was used as a typical long-chain tertiary amine in the present study, without further purification.

Solvents. The diluents used were reagent grade xylene, toluene and benzene, and Egyptian "Sunrise" odourless kerosene.

Other chemicals and reagents were of the highest purity available.

Determination of distribution ratio

Extraction experiments were carried out by mixing 5 ml of the organic phase with 5 ml of aqueous phase to which 50 μl of tracer solution had been added, and shaking the mixture at room temperature (21 $\pm$ 4°) for about 1 hr. The layers were separated by centrifugation. Preliminary experiments showed that fluctuations of the temperature of the order indicated have no significant effect on the distribution ratios and that equilibrium is always reached in less than 1 hr. The distribution was determined by measuring the radioactivity of 3-ml aliquots of both phases after equilibration. The amine was always pre-equilibrated with acid of appropriate concentration. The concentration of acid in the aqueous solution left after extraction was determined by titration with sodium hydroxide solution. The distribution ratio (*E*) was taken to be the ratio of the activities of the tracer in the organic and aqueous phases. Because of the high reproducibility of the results, determinations were only carried out in duplicate.

RESULTS AND DISCUSSION

Extraction of antimony with xylene from nitric, hydrochloric and sulphuric acid media

The distribution of antimony between xylene and aqueous solutions of nitric, hydrochloric, and sulphuric acid was investigated. The results are shown in Table I.

TABLE I.—EFFECT OF ACIDITY ON *E* FOR Sb(III) AND Sb(V) EXTRACTED WITH XYLENE

Extraction of antimony with TDA from nitric acid

The extraction of antimony from nitric acid solutions of various concentrations has been studied for different concentrations of amine. The experimental values of *E* for

0·06*M* TDA are shown in Fig. 1. It is evident that antimony(III) is extracted much better than antimony(V). The maximum extraction of antimony(III) occurs from 8*M* nitric acid. This behaviour is identical with that for thorium, cerium(III), uranium(VI) and neptunium(IV) and (VI), and can thus be described as an anion-exchange partition:

$$m\mathrm{R_3NHX} + (m+n)\mathrm{MX}^{-m} \rightleftharpoons (\mathrm{R_3NH})_m\mathrm{MX}_{(m+n)} + m\mathrm{X}^- . \quad (1)$$

Such partition may alternatively be regarded as adduct formation between a neutral complex and the amine salt:

$$m\mathrm{R_3NHX} + \mathrm{MX_n} \rightleftharpoons (\mathrm{R_3NH})_m\mathrm{MX}_{(m+n)}. \quad (2)$$

The two equations are thermodynamically equivalent.[12]

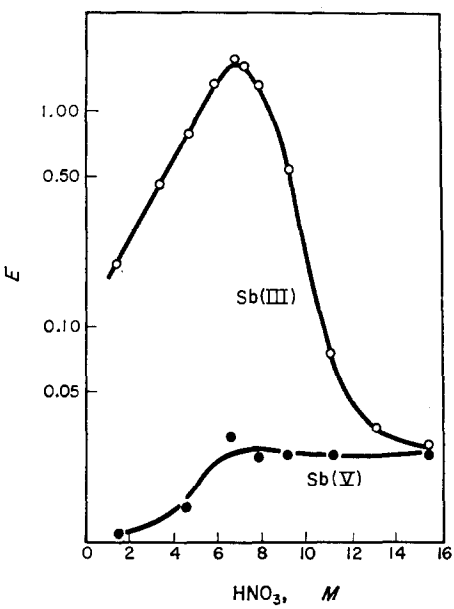

FIG. 1.—Effect of nitric acid concentration on *E* extracted by 0·06*M* TDA in xylene.

Accordingly the increase of antimony extraction with increasing nitric acid concentration can be explained by the salting out effect of the nitrate ion, while the subsequent decrease can be related either to anion competition for the available amine, or to the formation of an amine dinitrate, $\mathrm{R_3N(HNO_3)_2}$,[17] assuming that this does not interact with the metal nitrate.[12]

Such partition has been verified experimentally for the other elements and on the basis of the solvate numbers (*m*), obtained, the values of the extraction constants have been estimated.[13,14,18–20]

The decrease in *E* with increase in acid concentration is greater for antimony(III), than for the other elements mentioned. This can be attributed to the partial oxidation of antimony(III) to the less extractable antimony(V) at high nitric acid concentrations. In favour of this view is the fact that the extraction of the two oxidation states becomes the same from $\sim 15M$ nitric acid, when the oxidation is complete (Fig. 1). This interpretation was confirmed by letting antimony(III) stand with 15*M* nitric acid for about 1 hr and then determining its extractability at various nitric acid

concentrations; the values of E obtained were identical with those obtained with antimony(V).

It is clear that antimony(III) and (V) may be separated from each other by extraction of the former from about 7M nitric acid.

The values of E as a function of amine concentration for antimony(III) (Table II) did not indicate any definite extraction stoichiometry. A log–log plot of E *vs.* amine concentration for antimony(V) gives a straight line with a slope of about 1 (Fig. 2), suggesting an extractable antimony(V) complex in which the metal : amine ratio is 1 : 1.

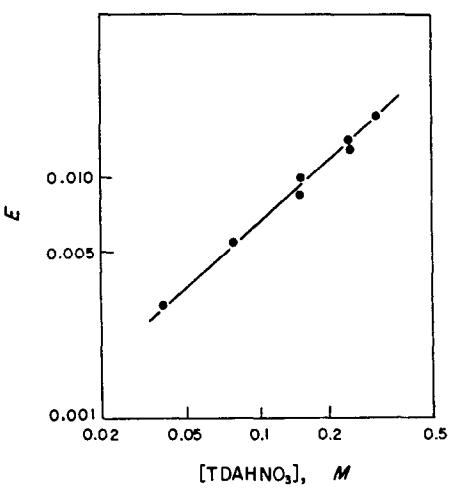

FIG. 2.—Effect of [TDA.HNO_3] on E of Sb(V) [HNO_3] = 8M.

Extraction of antimony from sulphuric acid

Both antimony(III) and (V) sulphates are efficiently extracted by TDA (Fig. 3). The extraction is much greater than with pure xylene or from nitrate medium, indicating that the amine sulphate complexes of antimony are much more stable than the amine nitrate complexes. The presence of maxima in the partition curves may be explained in the same way as for nitrate extraction.

Results on the effect of the amine sulphate concentration on E are given in Table III. No conclusions regarding the extraction mechanism can be made from these results, because both oxidation states are considerably extracted with pure xylene. The absence of extraction stoichiometry may also be related to the non-ideality of the organic phase.[12]

Extraction of antimony from hydrochloric acid

The distribution of antimony(III) and (V) as a function of hydrochloric acid concentration at fixed TDA concentration (0·06M) has been determined (Fig. 4). Maximum extraction is obtained at $\sim$ 5M hydrochloric acid for antimony(III) and at $\sim$ 7M hydrochloric acid for antimony(V). The decrease of E at higher acid molarities can be related, as with nitrate and sulphate extraction, to the formation of amine polychlorides; the formation of $R_3N(HCl)_2$ has been supported by infrared absorption[21,22] and nuclear magnetic resonance measurements.[23]

Log-log plots of E *vs.* [TDA,HCl] give straight lines with slopes of about 1 for antimony(III) and (V) (Fig. 5). This suggests the extraction of antimony monoamine complexes, $TDAH{\cdot}SBCl_4$ and $TDAH{\cdot}SbCl_6$; the formation of $[SbCl_4]^-$ and $[SbCl_6]^-$ complexes has been reported for antimony in chloride medium.[12]

The extraction of antimony chlorides has been also studied as a function of the initial metal concentration in the aqueous solution. The mean E values for extraction from 4·8 and 5·8M hydrochloric acid are shown in Tables IV and V.

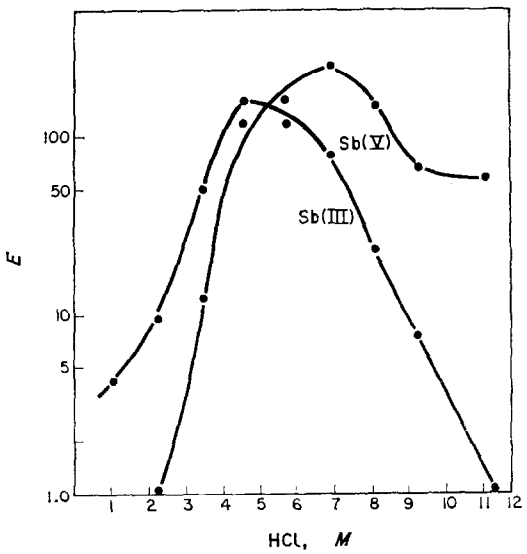

FIG. 4.—Effect of hydrochloric acid concentration on E
0·06M TDA in xylene.

For low amine concentrations the values of E decrease with increasing antimony concentration because of the decrease of the free amine concentration, while for high amine molarities extraction is almost constant and quantitative for all metal concentrations over the range studied.

Extraction of antimony from hydrobromic and hydrofluoric acids

Distribution ratios for the extraction of antimony from solutions of hydrobromic and hydrofluoric acids of varying molarity in the presence of a constant concentration of TDA are shown in Tables VI and VII.

Both antimony(III) and (V) are extracted efficiently from solutions of medium concentrations of hydrobromic acid. The extraction of both oxidation states becomes the same at high concentrations of hydrobromic acid; this is probably due to the reduction of antimony(V) to antimony(III) by hydrobromic acid. Antimony(III) and (V) may be separated by the selective extraction of antimony(III) from 0·64*M* hydrobromic acid. Antimony is extracted from hydrofluoric acid to a much lower extent, so that antimony extracted from other media may be back-extracted from the organic phase with hydrofluoric acid.

Effect of the type of diluent on the extraction of antimony

Benzene, toluene or kerosene can be used interchangeably as diluents, except for the extraction of antimony(III) from nitric acid medium (Table VIII). The slight changes in the values of E can be attributed to the differences in the values of the constants of the extraction reactions for the various diluents.[14]

TABLE VIII.—EXTRACTION OF Sb(III) AND Sb(V) WITH 0·3*M* TDA SOLUTIONS IN DIFFERENT DILUENTS

Oxidation state	Aqueous phase	Diluent	E

Effect of water-miscible organic additives on the extraction of antimony

The effect of organic additives on the extraction of antimony(V) from 1·5 *M* hydrochloric acid has been studied. These additives affected the extraction to varying degrees. Thus, E increases with increasing concentration of acetone, methanol and ethanol, whilst it decreases with increasing concentration of butanol (Fig. 6). A possible explanation of these effects is that there is a decrease in hydration as the mole fraction of water decreases and that this is accompanied by an increase in the formation of negatively charged chloride complexes of antimony *e.g.* $SbCl_6^-$. This should bring about an increase in extractability as can be seen from equation (2).

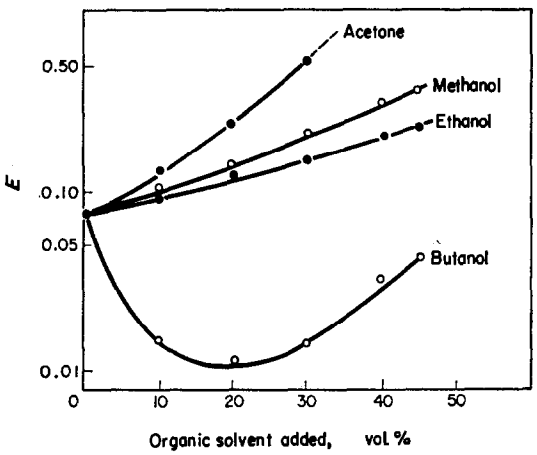

FIG. 6.—Effect of organic additives on E of Sb(V) 1·5M HCl.

TABLE IX.—EFFECT OF METHANOL ON E OF Sb(V)

Original [HCl] in aqueous phase, M*	[Methanol] in aqueous phase, % v/v	E
1·5	—	0·058
	50	0·52
1·8	—	0·14
	40	0·777
2·40	—	0·68

	10	5·95
2·85	—	2·55
	5	8·50

* TDA, 0·06M in xylene. Trace amounts of antimony.

In the case of butanol the volumes of both phases change during equilibrium because of the solubility of butanol in xylene.

From the results in Table IX it is clear that the addition of methanol in various proportions to the aqueous phase brings about a considerable increase of E.

Separation of antimony from other elements by amine extraction

The highly extractable metal nitrates such as those of uranium, thorium, neptunium and plutonium[18–20] can be easily separated from antimony(V) by extracting them with amines from nitric acid medium.

Both antimony(III) and (VI) are well extracted from sulphate, chloride and bromide media. In this part of study the extraction of a number of some other elements from a chloride medium has been investigated in order to evaluate the selectivity of amine extraction of antimony. The experimental results are presented in Table X. Appropriate radio-isotopes were used to determine E for these elements.

TABLE X.—DISTRIBUTION RATIOS OF SEVERAL ELEMENTS EXTRACTED FROM CHLORIDE MEDIUM*

* 0·075*M* TDA in xylene. Tracer metal concentration.
† Plus 2·5*M* $AlCl_3$.

From Table X it is evident that antimony, iron(III), zinc, cobalt, hafnium, protactinium, selenium, silver and mercury are well extracted with amine chlorides from 1·5*M* hydrochloric acid–2·5*M* aluminium chloride mixture. These elements can thus be extracted and separated from scandium, chromium, alkali metals, and the rare earths. Silver may be back-extracted from the organic phase with 9*M* hydrochloric acid, then cobalt with 6*M* hydrochloric acid and so on. Antimony may be stripped from the organic phase with 2–4*M* nitric acid containing a few drops of hydrogen peroxide solution as an oxidizing agent or with 3–6*M* hydrofluoric acid.

Zusammenfassung—Über die Extrahierbarkeit von Antimon(III) und -(V) mit Tridodecylamin aus verschiedenen wäßrigen Lösungen wird berichtet. Die Extraktion aus salpeter- und flußsauren Lösungen ist gering, gut jedoch aus schwefelsauren, salzsauren und bromwasserstoffsauren Lösungen. Antimon(III) kann in 7*M* Salpetersäure oder 0,64*M* Bromwasserstoffsäure von Antimon(V) getrennt werden. Die Extraktion von Antimon aus salzsauren Lösungen in Methanol, Äthanol oder Aceton-Wasser-Mischungen ist stärker als aus rein wäßrigen Lösungen derselben Acidität. Die Elemente werden angegeben, von denen Antimon mit tertiären Aminen getrennt werden kann.

Résumé—On décrit l'extractibilité de l'antimoine (III) et (V) au moyen de tridodécylamine à partir de diverses solutions aqueuses. L'extraction est faible à partir de solutions dans les acides nitrique et fluorhydrique, mais elle est élevée à partir de solutions sulfuriques, chlorhydriques et bromhydriques. On peut séparer l'antimoine (III) de l'antimoine (V) en acide nitrique 7*M* ou acide bromhydrique 0,64*M*. L'extraction de l'antimoine à partir de solutions chlorhydriques dans des mélanges méthanol, éthanol et acétone-eau est plus élevée qu'a partir de solutions aqueuses pures de même acidité. On donne les éléments dont on peut séparer l'antimoine au moyen d'amines tertiaires.

SPECTROPHOTOMETRIC DETERMINATION OF MICRO-AMOUNTS OF VANADIUM WITH 5,7-DI-IODO-8-HYDROXYQUINOLINE

C. HEITNER-WIRGUIN and M. GANCZ
Department of Inorganic and Analytical Chemistry,
The Hebrew University, Jerusalem, Israel

(*Received* 1 *August* 1966. *Accepted* 9 *January* 1967)

Summary—A precise spectrophotometric method for the determination of 2·5–25 μg of vanadium in volumes of up to 500 ml of water was developed. The method is based on the simultaneous concentration (100–1000 fold) and complexation of vanadium(V) with di-iodo-oxine in a water-immiscible phase. Interference from iron is eliminated by masking with phosphoric acid. The standard deviation evaluated was $\pm$0·04 μg for solutions containing 5 μg vanadium.

VANADIUM is one of the elements present in trace amounts in plant tissues, biological materials and soil. In plant tissues the amount of vanadium is so minute that Jackson[1] does not mention it. Mitchell *et al.*[2] and Shimp *et al.*[3] have recommended preconcentration with 8-hydroxyquinoline for the spectrochemical analysis of vanadium in soils and biological materials. Although there exist a great number of gravimetric, spectrophotometric, spectrographic and colorimetric microdetermination methods for vanadium using 8-hydroxyquinoline[4] or benzohydroxamic acid[5] as a complexing agent, a method combining concentration of minute amounts from very dilute solutions with highly sensitive determination would be of great advantage. In these methods tervalent iron interferes and has to be separated previously.

5,7-Di-iodo-8-hydroxyquinoline (di-iodo-oxine) is known to be a very sensitive reagent for the gravimetric[6] and heterometric[7] determination of vanadium. The blue-green water-insoluble vanadium di-iodo-oxine complex formed when an acetone solution of the reagent is added to an acidified vanadium solution is readily soluble in organic (water-immiscible) solvents, giving intensely coloured solutions. The colour of these solutions varies from green in chloroform to purple red in higher alcohols.

The principle of the present method is to dissolve the reagent directly in a water-immiscible organic solvent and make use of this solution simultaneously as extractant and complexing agent for vanadium.

EXPERIMENTAL

Instruments

Spectrophotometric measurements were carried out on a Perkin–Elmer Model 137 UV spectrophotometer. All the other photometric measurements were taken at the appropriate wavelength on a Beckman Model B spectrophotometer.

Reagents

An approximately 0·2% solution of 5,7-di-iodo-8-hydroxyquinoline in n-heptyl alcohol was prepared by shaking the reagent mixture for 1 hr, the undissolved reagent then being filtered off. This solution was kept in brown bottles. An aqueous solution of ammonium metavanadate was used. All the other reagents were of analytical grade. Deionized or triply distilled water was used in all experiments.

Procedure

To 500 ml of a neutral solution of vanadium(V), 4*M* phosphoric acid is added to reach the acid concentration of about 0·1*M*. If the solution also contains iron, 3 ml of 4*M* phosphoric acid are needed in addition for every 2–3 mg of iron present. Then 5 ml of the reagent solution are added (the volume needed for complete reaction with 2·5–25 μg of vanadium). The mixture is then shaken for 1 hr to ensure the complete extraction of vanadium. The phases are allowed to separate in a separating funnel and the absorbance of the pink organic extract is measured directly in 10-mm cells at 420 or 475 mμ. The measurements should be taken the same day, since fading was observed after 24 hr.

RESULTS AND DISCUSSION

The choice of the organic solvent

Di-iodo-oxine is insoluble in water and mineral solvents, but slightly soluble in organic solvents. In organic solvents the solubility order chloroform > xylene > amyl acetate > amyl alcohol > n-hexyl alcohol $\simeq$ n-heptyl alcohol > octyl alcohol was observed.

Although it would have been preferable to choose a solvent in which more concentrated reagent solutions could be prepared, this was not possible for the following reasons. Solutions of di-iodo-oxine in chloroform, amyl acetate and xylene are not stable. Chloroform solutions become pink in a few hours, and the colour deepens within a few days to dark red-brown, because of decomposition of the reagent and the liberation of iodine. The colour changes are less pronounced for xylene and amyl acetate but still occur. Amyl alcohol solutions show only a slight yellow colour, but the solvent is slightly miscible with water. Thus, when vanadium is extracted from very dilute solutions (2–5 μg of vanadium in 500 ml of aqueous solution) for which the volume of extractant should be 5–10 ml, practically no phase separation was obtainable.

n-Heptyl alcohol was chosen as the best solvent, being the least water-miscible (the volume of reagent remaining after equilibration of 5 ml of reagent and 500 ml of aqueous phase was about 4·5 ml) and also because no change of colour in the reagent was obtained even after a few weeks. This solvent is preferred to n-hexyl alcohol, mainly because of its less pronounced odour.

Choice of wavelength

Di-iodo-oxine solutions in n-heptyl alcohol have a maximum absorption at 355 mμ (Fig. 1), while in the region of 410–500 mμ, where the vanadium complex absorbs, their absorbance is negligible. This region can be used for the measurements of the vanadium complex. Optimum measurements may be carried out at 420 mμ, since at this wavelength the absorbance is about 30% higher than at 475 mμ. The molar absorptivity calculated from the measurements at 420 mμ was 6000 and that at 475 mμ was about 4800. At both wavelengths the Beer-Lambert law is obeyed for 2·5–25 μg of vanadium. For less than 2·5 μg of vanadium (0·5 μg/ml of extractant) absorbances are too low for accurate reading. If the solution contains more than 25 μg of vanadium the absorbance is too high, and an appropriate dilution is recommended. The standard deviation (20 measurements) was $\pm$0·04 μg for solutions containing 5 μg of vanadium.

The influence of the acid and its concentration

Hydrochloric, orthophosphoric and monochloroacetic acids at various concentrations were studied to establish the optimum working conditions. The results

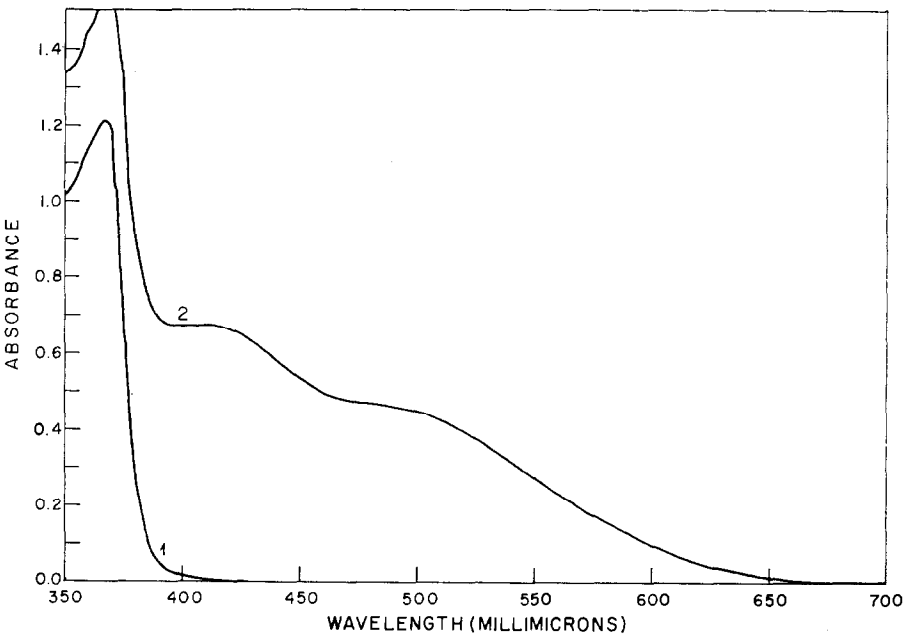

FIG. 1.—Absorption spectra of (1) di-iodo-oxine in n-heptyl-alcohol, (2) vanadium di-iodo-oxine complex in n-heptyl-alcohol.

obtained showed that both the type and concentration of the acid influence the absorbance of the complex solutions. For each acid there is an optimum concentration at which the highest absorbance of the vanadium-di-iodo-oxine complex is obtained. Above and below this concentration, the absorbance is markedly reduced. Optimum results, as may be seen from Table I, were obtained for hydrochloric acid concentration of 0·1*M*.

Extraction time

The first experiments were done with manual shaking of the mixture of vanadium and reagent solutions. It was observed that extraction was incomplete by this method,

TABLE I.—INFLUENCE OF THE ACID AND ITS CONCENTRATION ON THE ABSORBANCE OF 5 μg OF VANADIUM AS ITS DI-IODO-OXINE COMPLEX IN SOLUTIONS OF n-HEPTYL ALCOHOL

Acid	*M*	Absorbance at 420 $m\mu$	Absorbance at 475 $m\mu$
HCl	0·05	0·105	0·070
HCl	0·1	0·130	0·098
HCl	0·2	0·095	
HCl	0·6	0·065

H_3PO_4	0·1	0·110	0·070
H_3PO_4	0·2	0·105	0·072
H_3PO_4	0·7	0·045	
$ClCH_2COOH$	0·05	0·095	
$ClCH_2COOH$	0·1	0·105	0·070
$ClCH_2COOH$	0·2	0·090	0·060
$ClCH_2COOH$	0·7	0·050	

and mechanical shaking was therefore substituted. Experiments were repeated with various shaking times, and it was found that the amount of vanadium reacting with di-iodo-oxine and extracted into the organic layer depends on the shaking time, *i.e.*, for the same shaking time the same amount of vanadium complex is always extracted. It was established that 15 μg of vanadium/ml of reagent solution can be extracted within 1 hr from 500-ml portions (Table II). This is also the concentration limit for the reagent solution. When more vanadium is present, smaller volumes of the aqueous solutions should be taken (50–100 ml) and the extraction time can be reduced to 15–20 min.

TABLE II.—INFLUENCE OF EXTRACTION TIME ON THE AMOUNT OF VANADIUM EXTRACTED

Vanadium in aqueous solution μg	Vanadium extracted into 5 ml of reagent solution μg					
	15	30	45	60	90	120 *min*
2·5	2·5	2·5				
5·0	5·0	5·0

25	10	25	25			
50	10	25	50	50		
75	10	25	50	75	75	
100	10	25	50	75	75	75

Masking of interfering cations

The interference of several cations in the determination of vanadium was studied. It was found that at the above-mentioned acid concentration Ca^{2+}, Mg^{2+}, Zn^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cr^{3+}, Al^{3+}, Cd^{2+}, Fe^{2+}, Pb^{2+}, UO_2^{2+}, ZrO_2^{2+} and Cu^{2+} do not interfere, when present in concentrations a hundred times that of the vanadium. Pronounced interference occurred from tervalent iron. Iron reacts with di-iodo-oxine in strongly acid solutions to form a green water-insoluble complex that is easily extracted by the same organic solvents as vanadium. The intensely green solutions absorb at the same wavelengths as vanadium. Iron is generally present in soil or plant tissue extracts in amounts hundreds of times those of vanadium, and so this source of interference has to be removed. Experiments to separate iron on ion-exchange columns proved unsatisfactory, as difficulties arose in elution of vanadium from the column. Attempts to complex iron with fluoride were also unsuccessful. The best results were obtained when iron was masked by phosphoric acid only: substitution of phosphoric acid for part of the hydrochloric acid used for establishing the acid concentration was found to have no advantage, so that in the final procedure phosphoric acid only was added. An excess of 3 ml of 4*M* phosphoric acid over the amount required for the optimum concentration of the vanadium solution is needed for the masking of 2–3 mg of iron.

Favourable comparison may be made with other methods proposed for the photometric determination of vanadium, *viz.* that with 8-hydroxyquinoline, described by Talvitie,[3] and that given in the critical survey of methods by Bock and Gorbach,[8] in both of which iron has to be separated initially. The molar absorptivity for 8-hydroxyquinoline computed from the Beer-Lambert curve of Bock and Gorbach[8] is 3200 at

485·5 mμ. The procedure described by Talvitie is very tedious, necessitating several extractions and purification of the chloroform.

The 5,7-di-iodo-8-hydroxyquinoline method has the double advantage of not requiring initial separation of iron, and of one single extraction being sufficient for good results. Taken together with the relatively high molar absorptivity (6000 at 420 mμ), these factors make it possible to determine vanadium in samples containing only 2·5 μg of it.

Acknowledgement—This work was carried out under Grant No. FG-Is-158 of the U.S. Department of Agriculture, for which the authors are duly grateful.

Zusammenfassung—Es wurde eine genaue spektrophotometrische Methode zur Bestimmung von 2,5–25 μg Vanadium in Volumina bis 500 ml Wasser entwickelt. Die Methode beruht auf der Anreicherung (100- bis 1000-fach) und Komplexbildung von Vanadium(V) mit Dijodoxin in einer mit Wasser nicht mischbaren Phase. Die Störung durch Eisen wird durch Maskierung mit Phosphorsäure beseitigt. Für Lösungen mit 5 μg Vanadium wurde eine Stantardabweichung von $\pm$0,04 μg ermittelt.

Résumé—On a élaboré une méthode spectrophotométrique précise de dosage de 2,5–25 μg de vanadium dans des volumes d'eau allant jusqu'à 500 ml. La méthode est basée sur la concentration (100–1000 fois) et la complexation simultanées du vanadium(V) par la diiodo-oxine dans une phase non miscible à l'eau. On élimine l'interférence du fer par dissimulation à l'acide phosphorique. L'écart type estimé est de $\pm$0,04 μg pour des solutions contenant 5 μg de vanadium.

INVESTIGATION OF BIS(CARBOXYMETHYL)DITHIOCARBAMATE COMPLEXES BY THE EXTRACTION METHOD

A. HULANICKI and M. MINCZEWSKA
Department of Inorganic Chemistry, University, Warsaw, Poland

(*Received* 24 *August* 1966. *Accepted* 2 *January* 1967)

Summary—The extraction of copper, lead, cadmium, nickel and zinc dithizonates was investigated in the presence of ammonium bis(carboxymethyl)dithiocarbamate. For all metals studied, except zinc, masking of extraction was observed, depending on the amount of the dithiocarbamate in the aqueous phase. From the shift of the $pH_{1/2}$ values for dithizonate extraction, the stability constants β_2 for the metal complexes with bis(carboxymethyl)dithiocarbamate were calculated. The logarithms of the constants are 21·46, 15·45, 11·24 and 7·93 for the copper, lead, cadmium and nickel complexes respectively.

IN the course of our studies on the analytical application of dithiocarbamate complexes[1–4] we investigated the equilibria in solutions of these compounds and determined the constants which characterize these equilibria.[2,5,6]

The characteristics of a chemical compound which is used as a reagent for metal ions are defined by metal-binding functional groups and by analytical active groups which modify the properties of the metal complexes formed. The former group in the case of dithiocarbamate reagents consists of two donor sulphur atoms, but the latter may have either hydrophobic character, as in diethyldithiocarbamate, or may contain hydrophilic groups (*e.g.*, the carboxylic group present in the bis(carboxymethyl)dithiocarbamate molecule).[7] The presence of one[8,9] or two carboxymethyl groups significantly changes the properties of metal–dithiocarbamate complexes, making them readily soluble in water, but insoluble in the organic solvents commonly used in extraction. Taking these facts into account we tried to apply bis(carboxymethyl)dithiocarbamate as a selective masking reagent in dithizonate extractions and found that copper, lead, cadmium and nickel ions may be masked and do not interfere in the extraction of zinc dithizonate. In this paper we describe the determination of the stability constants of some metal–bis(carboxymethyl)dithiocarbamate complexes, from measurements based on the competition of two ligands for the same metal in the water–carbon tetrachloride system.

EXPERIMENTAL

Reagents

Solutions of Cu^{2+}, Cd^{2+}, Pb^{2+}, Zn^{2+} and Ni^{2+}, all 0·1*M*, were prepared from the nitrates or from the metals dissolved in nitric acid, and were standardized complexometrically.

Dithizone (HDz), 0·01% in carbon tetrachloride, was prepared from the purified reagent.[10] Its concentration was determined by argentometric extractive titration and checked spectrophotometrically.

Ammonium bis(carboxymethyl)-dithiocarbamate (DTC), 0·1*M* in dilute sodium hydroxide was prepared and standardized by the method previously described.[11]

Other reagents were prepared by the usual procedures and were purified by dithizone extraction.

Apparatus

Absorptiometric measurements were made with a Pulfrich photometer with photoelectric attachment (Carl Zeiss). Measurements of pH were made with a Radiometer pHM-22 instrument, with glass and calomel electrodes.

Procedure

For each metal ion two series of measurements were performed. In the first the dithizonates were extracted from non-complexing solutions in order to determine the molar absorptivities of the dithizonates and the $pH_{1/2}$ of the non-masked extraction under the given experimental conditions. In the second series, in the presence of different concentrations of bis(carboxymethyl)dithiocarbamate, the degree of extraction was determined and from the results the $pH_{1/2}$ for extraction from masked solutions was calculated.

Extraction was performed from 15 ml of aqueous solution that was 10^{-4}–$10^{-5}M$ in metal ion, $10^{-2}M$ in buffer solution (where necessary) and $0{\cdot}1M$ in potassium nitrate. In the second series the concentration of masking reagent ranged from 10^{-2} to $10^{-4}M$. The organic phase consisted of 15 ml of dithizone solution in carbon tetrachloride. Dithizone was used in approximately 10-fold excess. The equilibration time for extraction was estimated for each ion separately and ranged from 5 to 15 min. The excess of unreacted dithizone was removed by stripping twice with dilute ammonia solution of such a concentration that it did not affect the absorbance of the dithizonates even after a prolonged stripping period. Finally, the concentration of metal dithizonate in the carbon tetrachloride was determined absorptiometrically. The pH value of the aqueous layer was measured. For each masking concentration and pH the measurements were performed for several metal ion concentrations, and the absorbance of the blank was subtracted. These conditions were chosen because they most closely resemble those used in analytical separation procedures. In all experiments the temperature was maintained at $20 \pm 1°$.

RESULTS AND DISCUSSION

In the system DTC–metal ion–HDz several equilibria must be considered when quantitative results are needed. In the pH range of non-masked extraction the ions Cu^{2+}, Cd^{2+}, Pb^{2+}, Zn^{2+} and Ni^{2+} do not form hydroxo-complexes which might disturb the main reaction. When buffers were used, their concentration was less than $10^{-2}M$. The buffering substances were selected so that the logarithm of the stability constant of their complex with a given metal was not greater than 0·1. Under such conditions no interfering side-reactions need to be considered, and the total concentration of the metal in the aqueous phase is the concentration of the hydrated metal ion. The salt concentration was kept constant except for the non-masked extraction of copper dithizonate in strongly acid medium. Nevertheless the change of activity coefficients should not affect the value of the logarithm of the stability constant by more than 0·2, which is within the limits of experimental error.

The masked extractions were performed in more alkaline solutions. However, in the presence of large enough concentrations of strong masking agents the concentration of hydroxo-complexes may be neglected in comparison with that of the complexed metal ion.

Dithizone, present initially in the organic solvent, has weakly acidic properties. Its dissociation constant[12] K_{HDz} is $10^{-4{\cdot}5}$, and its distribution coefficient P_{HDz} $10^{4{\cdot}0}$ in the water–carbon tetrachloride system. When dithizone is shaken with alkaline solutions, pH > 7·5, its dissociation causes a decrease of the equilibrium dithizone concentration in the carbon tetrachloride phase, according to the equation:

$$\alpha_{HDz} = \frac{[HDz]_o}{[HDz] + [Dz^-]} = \frac{P_{HDz}}{1 + K_{HDz}/[H^+]} \qquad (1)$$

where the subscript *o* denotes the species in the organic phase. From this it follows that for dithizone $pH_{1/2}$ is 8·50. The decrease of dithizone concentration in the organic phase has a significant influence on the shape of the extraction–pH curves, which have in all cases a smaller slope than expected for a reaction involving two protons.

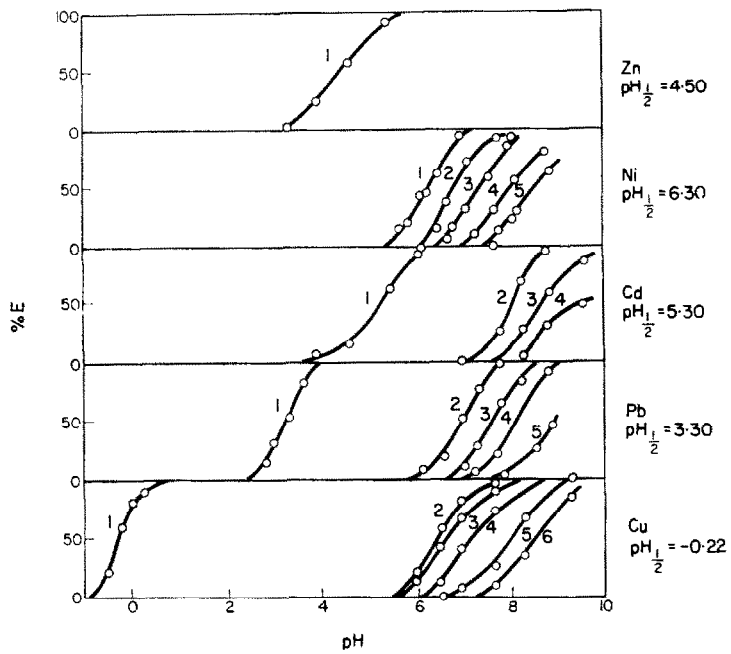

FIG. 1.—Extraction *vs.* pH curves for metal dithizonate extraction. For all metals curve (1) is for non-masked extraction.

Ni; [DTC] *2*—2×10^{-4} *M*; *3*—10^{-3} *M*; *4*—2×10^{-3} *M*; *5*—10^{-2} *M*

Cd; [DTC] *2*—10^{-3} *M*; *3*—2×10^{-3} *M*; *4*—10^{-2} *M*

Pb; [DTC] *2*—10^{-4} *M*; *3*—$3{\cdot}3 \times 10^{-4}$ *M*; *4*—10^{-3} *M*; *5*—$3{\cdot}3 \times 10^{-3}$ *M*

Cu; [DTC] *2*—6×10^{-5} *M*; *3*—2×10^{-4} *M*; *4*—6×10^{-4} *M*; *5*—2×10^{-3} *M*; *6*—6×10^{-3} *M*

In the case of a masked extraction at pH $\geqslant$ 6, the total concentration of the masking reagent may be assumed equal to the concentration of the free ligand because the estimated value of the dissociation constant is not smaller than $10^{-4{\cdot}5}$. The complete dissociation of the dithiocarbamic acid in this pH range implies a sufficient stability of the ligand, for which the half-life at pH 6 is 2 hr.[7] Further, because a large excess of the masking ligand was used, the amount bound to metal ions may be neglected. Although the formation of mixed complexes containing both competing ligands when these are of such different character is highly improbable, this possibility was checked spectrophotometrically by comparison of the spectra with those of corresponding complexes obtained in the absence of a second ligand.

Absorptiometric determinations of the amount of the dithizonate formed served as a basis for plotting the extraction–pH curves (Fig. 1). From these curves the

$pH_{1/2}$ values for non-masked and masked extraction at different bis(carboxymethyl)-dithiocarbamate concentrations were evaluated.[13,14,15] Accepting the aforementioned simplifying assumptions for the non-masked extraction

$$M^{2+} + 2(HDz)_o = (MDz_2)_o + 2H^+, \tag{2}$$

the distribution ratio is

$$D = K\frac{[HDz]_o^2}{[H]} \tag{3}$$

where K represents the extraction constant for the metal dithizonate. At $pH_{1/2}$ the distribution ratio is unity, and thus:

$$2pH_{1/2} = -\log K - 2\log [HDz]_o. \tag{4}$$

In the conditions of the masked reaction, *i.e.*, in the presence of an excess of bis-(carboxymethyl)dithiocarbamate, hydrated metal ions and complexes formed stepwise occur in the solution. The contribution of each particular species depends on the values of the stability constants β_i for the various complexes and on the concentration of free ligand (DTC), and may be described by the complexation function F:

$$F = \sum_{i=0}^{N} \beta_i [DTC]^i$$

where

$$\beta_0 = 1. \tag{5}$$

Thus, for the masked extraction the distribution ratio D^* is

$$D^* = K\frac{[HDz]_o^{*2}}{[H]^{*2}F} \tag{6}$$

where K has the same value as in equation (3), and

$$-\log K = 2\log [HDz]_o^* + 2pH_{1/2}^* - \log F \tag{7}$$

where symbols with an asterisk refer to the masked extraction. From equations (4) and (7) the value of $\log F$ may be calculated:

$$\log F = 2(pH_{1/2}^* - pH_{1/2}) + 2\log\frac{[HDz]_o^*}{[HDz]_o} \tag{8}$$

The equilibrium concentration of dithizone was calculated from its total amount and the amount bound in the metal dithizonate, taking into account the distribution ratio of dithizone at various pH values [equation (1)].

The corresponding experimental data are given in Table I. The logarithm of the complexation function calculated on this basis was plotted *vs.* the logarithm of the ligand concentration (Fig. 2). In the concentration range studied, the linear relationship at a slope of 2 indicates clearly that the dominating complex has the metal to ligand ratio 1:2. The calculated overall stability constants β_2 are also given in Table I for individual measurements. These data indicate clearly the composition of the

complexes formed. An additional proof should be obtainable from the slope of the log D *vs.* log [DTC] curve. However, in our case this method failed because the dithizone concentration changed in individual measurements owing to its dissociation, and because the excess of dithizone was not greater than ten times the concentration of the metal ion. In these experiments the extraction conditions were chosen to be as similar as possible to those used in analytical separations and therefore a larger excess was avoided. Nevertheless, considering the fact that for different concentrations of excess of dithizone the equilibrium may be established in a slightly different manner, the values of $pH_{1/2}$ seem to be the most accurate and the most reproducible measure of this equilibrium.

The values of stability of bis(carboxymethyl)dithiocarbamate complexes may be compared with the values pK_{sp} (where K_{sp} is the solubility product) of the corresponding diethyldithiocarbamate complexes, which are 29·55, 21·68, 22·03, 23·07 and 16·93 for copper, lead, cadmium, nickel and zinc respectively.[2]

It is interesting that in the case of the bis(carboxymethyl)dithiocarbamate complexes the sequence of stability of cadmium, nickel and lead complexes is different from the sequence of the solubility products of the diethyldithiocarbamates of these metals. The high stability of the lead complex may be at least partially attributed to its greater tendency to form chelates with ligand groups containing oxygen donor atoms, as for example with the carboxyl groups in bis(carboxymethyl)dithiocarbamate. This additional bonding may be responsible for the stability of the lead complex. Another factor which probably decreases the solubility of nickel diethyldithiocarbamate might be the possibility of the precipitate aging in a manner similar to that of nickel sulphide precipitates.

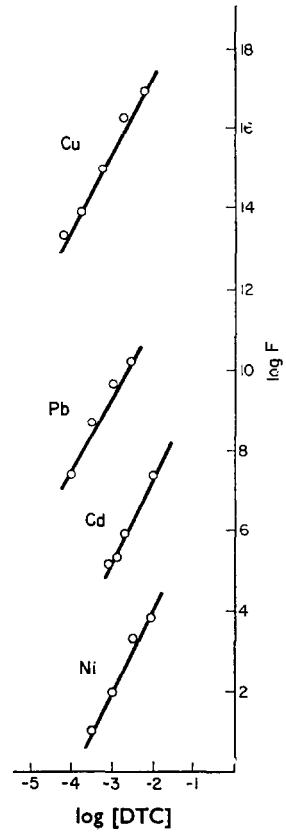

FIG. 2.—The complexation function for metal–bis(carboxymethyl)dithiocarbamate complexes.

The value of the stability constant of the copper complex may also be compared with the value of the constant determined by Janssen[16] for the 3-carboxy-cyclopentamethylenedithiocarbamate–copper complex. The logarithm of this constant is 22·4, slightly greater than in our case, which is in agreement with the statement that the introduction of the additional carboxyl group into the ligand molecule may decrease its complexing ability.

Acknowledgement—The authors are indebted to Prof. Dr. W. Kemula, Head of the Department of Inorganic Chemistry, University of Warsaw, for helpful and stimulating comments and discussions.

Zusammenfassung—Die Extraktion der Dithizonate von Kupfer, Blei, Cadmium, Nickel und Zink wurde in Gegenwart von Ammoniumbis-(carboxymethyl)dithiocarbamat untersucht. Bei allen untersuchten Metallen außer Zink wurde Maskierung der Extraktion beobachtet, je nachder Menge Dithiocarbamat in der wäßrigen Phase. Aus der Verschiebung der $pH_{1/2}$-Werte der Dithizonatextraktion wurden die Stabilitätskonstanten β_2 der Metallkomplexe mit Bis(carboxymethyl) dithiocarbamat berechnet. Die Logarithmen der Konstanten sind 21,46; 15,45; 11,24 und 7,93 für die Komplexe von Kupfer, Blei, Cadmium und Nickel.

Résumé—On a étudié l'extraction des dithizonates de cuivre, plomb, cadmium, nickel et zinc, en présence de bis(carboxyméthyl)dithiocarbamate d'ammonium. Pour tous les métaux étudiés, à l'exception du zinc, on a observé un blocage de l'extraction, dépendant de la quantité de dithiocarbamate dans la phase aqueuse. A partir du changement des valeurs du $pH_{1/2}$ pour l'extraction des dithizonates, on a calculé les constantes de stabilité β_2 pour les complexes métalliques avec le bis (carboxyméthyl)dithiocarbamate. Les logarithmes des constantes sont 21,46; 15,45; 11,24 et 7,93 pour les complexes de cuivre, plomb, cadmium et nickel respectivement.

SHORT COMMUNICATIONS

The separation of arsenic(V) and (III) by thin-layer chromatography

(*Received* 23 *November* 1966. *Accepted* 25 *January* 1967)

ANION-exchange,[1] paper electrophoresis[2] and paper chromatography,[3] as well as the classical precipitation method have been utilized for the separation of arsenic(V) and (III). These methods are effective, but take considerable time to achieve the complete separation. Thin-layer chromatography (TLC) should be very suitable on account of its simplicity, speed, efficiency of separation and sensitivity of detection. The separation of arsenic(V) and (III) by TLC in a butanol–benzene–1*M* nitric acid–1*M* hydrochloric acid (50:46:2·6:1·4) solvent system has been reported briefly. Complexity of the system and possible oxidation of arsenic(III) to (V) would hamper the utility of the method, and so would the rather long development time involved (45 min).

The present investigation was undertaken to provide simpler and more rapid TLC systems for the separation of arsenic(V) and (III), and suggests the use of an acetone–phosphoric acid mixture (50:1) as a satisfactory developing agent.

EXPERIMENTAL

Stock solutions of arsenic(III) and (V), (both 10 μg/μl) were prepared by dissolving appropriate amounts of arsenic(III) oxide and disodium hydrogen arsenate heptahydrate, in dilute sodium hydroxide solution and water respectively, and diluting with water to a definite volume. A test solution was made by mixing an equal volume of both solutions. The solvent systems used to develop the chromatograms were

A acetone–phosphoric acid (50:1)
B acetone–phosphoric acid (4:1)
C ethanol–phosphoric acid (50:1)
D butanol–phosphoric acid (50:1).

The concentration of phosphoric acid was varied over the range from 1 to 15*M* in each system except for *B*, in which the phosphoric acid was varied from 1 to 6*M* in concentration.

A commercial silica gel containing 5% of calcium sulphate was slurried with water and spread 250 μ thick on 2·5 × 20 cm^2 plates from an applicator. The plates were then air-dried overnight at room temperature. The thin-layers were spotted 25 mm from one end with one dab (about 1–2 μl) of the test solution from a glass capillary, and dried in air for 20 min. The plates were then placed in the developing chamber containing the developing solvent and allowed to stand for 20 min to permit equilibration of the atmosphere inside. Development was conducted by the ascending technique until the solvent front had risen 12 cm. Subsequently the plates were dried in air and the spots visualized by spraying first with saturated tin(II) chloride solution and then with 5% sodium thiosulphate solution. Both arsenic(III) and (V) were detected as yellow spots.

RESULTS AND DISCUSSION

In Fig. 1 the behaviour of arsenic(V) and (III) in the solvent systems *A* to *D* is illustrated. The components of the solvent move at different rates so that the organic phase advances rapidly and the aqueous phosphoric acid front moves slowly behind it. Two fronts are distinguishable in each solvent system. It is of interest to note that the phosphoric acid front always carries the arsenic(V) with it. This may be due to the formation of undissociated arsenic acid molecules, which is favoured in the presence of the much stronger phosphoric acid. In contrast, the arsenic(III) ion will react with phosphoric acid to yield $AsPO_4$,[5] which is only slightly soluble in organic solvents such as acetone and ethanol, thus remaining at or near the start of the chromatogram. As can be seen in Fig. 1b, increasing the ratio of phosphoric acid to acetone results in broadening of the spots of both arsenic(V) and (III). In addition the values of arsenic(V) decrease with increasing concentration of phosphoric acid, provided that the acetone-phosphoric acid ratio is kept constant at 4:1.

The behaviour of arsenic(V) and (III) in mixtures of ethanol and phosphoric acid is almost the same as in the acetone–phosphoric acid (50:1) solvent system (Fig. 1c). However, part of the

(*c*) Ethanol–H_3PO_4 (50:1)
(*d*) Butanol–H_3PO_4 (50:1)
– – – Phosphoric acid front

arsenic(V) is retained at the original spot, possibly because of partial reduction to arsenic(III), if the concentration of phosphoric acid is less than 6*M*.

Just as in the acetone–phosphoric acid (50:1) solvent, R_f values for arsenic(V) increase regularly with increasing concentration of phosphoric acid in the butanol–phosphoric acid system. R_f values for arsenic(III) remain constant at approximately 0·2 regardless of the phosphoric acid concentration. Greater solubility of $AsPO_4$ in butanol could account for the rather high R_f value for arsenic(III) in this system.

Other solvent systems were also tested, *e.g.*, isopropanol–phosphoric acid (50:1) with 6–15*M* acid, and acetone–benzene–15*M* phosphoric acid (20:20:1), but all without success. Based on these observations, phosphoric acid coupled with acetone or butanol should provide a satisfactory solvent for the effective separation of arsenic(V) and (III). The more concentrated the phosphoric acid, the more effective is the separation, provided the volume ratio of organic solvent to phosphoric acid is kept at 50:1. However, the time required to make the solvent front rise 12 cm, which is sufficient for good separation, depends markedly on the organic solvent used; *e.g.*, ~20 min for acetone–phosphoric acid (50:1), ~25 min for acetone–phosphoric acid (4:1), ~60 min for ethanol–phosphoric acid (50:1) and ~120 min for butanol–phosphoric acid (50:1). The solvent system acetone–15*M* phosphoric acid (50:1) may be recommended as suitable for rapid separation. Results for the practical separation of arsenic(V) and (III) in four solvent systems are illustrated in Fig. 2.

Summary—The separation of arsenic(III) and (V) can be effected by ascending chromatography on a silica gel thin-layer containing 5% of calcium sulphate. An acetone-15*M* phosphoric acid (50:1) solvent system gives the most satisfactory separation. The method is rapid, taking only 20 min to complete the separation.

Zusammenfassung—Arsenik(III) und -(V) können durch aufsteigende Chromatographie an einer 5% Calciumsulfat enthaltenden Kieselgel-Dünnschicht getrennt werden. Am besten wirkt ein Lösungsmittelsystem aus Aceton und 15*M* Phosphorsäure (50:1). Die Methode geht schnell; die Trennung ist schon nach 20 min beendet.

Résumé—On peut effectuer la séparation des arsenic(III) et (V) par chromatographie ascendante sur une couche mince de gel de silice contenant 5% de sulfate de calcium. Un système solvant acétone–acide phosphorique 15*M* (50:1) donne la séparation la plus satisfaisante. La méthode est rapide, ne nécessitant que 20 mn pour réaliser la séparation.

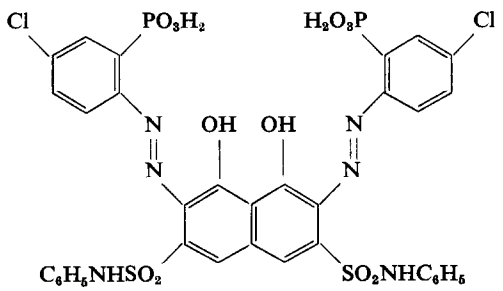
Extractive photometric determination of lanthanides and yttrium with Chlorophosphonazo DAL

(*Received* 6 *December* 1966. *Accepted* 6 *February* 1967)

THE formation of dianilides of 3,6-bisphenylazo derivatives of chromotropic acid is an advantageous way of transforming known photometric reagents, such as Arsenazo III, Chlorophosphonazo III, Sulphonazo III, *etc.*, into extractable substances.[1] Thus Chlorophosphonazo DAL, *i.e.*, the dianilide of 3,6-bis(*p*-chloro-*o*-phosphonophenylazo)-chromotropic acid (I) is a convenient extractive photo-



(I)

metric reagent for uranium (VI), uranium(IV), thorium, zirconium, hafnium, lanthanides, yttrium calcium, strontium and barium.[2] The reaction with lanthanides and yttrium is very sensitive and can be used advantageously for determination of trace amounts of these elements. It is necessary, however, to remove uranium(VI) first.

Preparation of the reagent solution

Dissolve 91 mg of Chlorophosphonazo DAL in about 250 ml of 0·1*M* sodium hydroxide. Add 1000 ml of n-butanol and about 250 ml of 0·5*M* hydrochloric acid. Shake for 2–3 min and then separate from the aqueous layer. Wash the butanol phase 3–4 times with 250 ml of water until the pH of the aqueous phase is 5–6. The concentration of reagent does not need to be accurately known, so loss of butanol in the washing procedure is unimportant. The reagent solution is stable for several months.

Procedure

Add 5 ml of a 0·01*M* solution of the diammonium salt of DCTA* for every 10 ml of sample solution. Adjust the acidity to 1·8–2·2 with 0·1*M* sodium hydroxide and 0·1*M* hydrochloric acid (use a pH meter or make the solution just acid to Methyl Red) and dilute to a convenient standard volume. Place a 10-ml aliquot of sample solution, containing 0·005–0·1 μmole of lanthanides and of yttrium, in a separatory funnel. Add 0·3 ml of 0·1*M* hydrochloric acid, 10·0 ml of the reagent solution and shake vigorously for 3–5 min. After clarification of the butanol phase, place an appropriate volume of it in a 1-cm cell and measure its absorbance at 670 mμ against a reagent blank.

Results and remarks

Typical results of lanthanide and yttrium determinations are summarized in Table I. At the recommended pH the reagent solution has maximum absorbance at 540 mμ. The absorption maxima of the lanthanide-Chlorophosphonazo DAL complexes in butanol all occur at 670 mμ and at this wavelength the net molar absorptivities are: yttrium 64500, lanthanum 53500, cerium(III) 22500, praseodymium(III) 20500, neodymium 17500, samarium(III) 29500, europium(III) 19500, gadolinium 57500, terbium 50000, dysprosium 52500, holmium 80000, erbium 64000, thulium 40000, ytterbium(III) 42000, and lutetium 38000 (all in cm^2 $mmole^{-1}$). In a 10-ml aliquot of sample solution, 20–30 μmole amounts of zirconium, hafnium, iron(III), magnesium, calcium, strontium and barium, 5 μmole amounts of fluoride, phosphate, Tiron, and chromotropic acid, or 1 mmole amounts of chloride, nitrate, perchlorate and sulphate do not interfere. Thorium interferes if 0·05 μmole is present, and so does 0·02 μmole of uranium(VI).

* Prepared by dissolving 3·46 g of DCTA in 250 ml of 0·08*M* aqueous ammonia and diluting to 1 l. with water. DCTA is 1,2-diaminacyclohexanetetra-acetic acid.

* Preliminary extraction with tri-iso-octylamine.

† Preliminary extraction of thorium with 8-hydroxyquinoline.

‡ Systematic stepwise extraction with tri-iso-octylamine, Arsenazo DAL and Chlorophosphonazo DAL, and calcium determination with Chlorophosphonazo III.

¶ Analysis of monazite sands by application of stepwise extraction with tri-iso-octylamine, Arsenazo DAL and Chlorophosphonazo DAL. The results obtained for thorium and lanthanides are compared with the Arsenazo method for thorium[6] and the gravimetric determination of the sum of the lanthanides.[5]

Larger amounts, 1–4 mmole, of uranium(VI), vanadium(V), niobium(V), cobalt(II), copper(II), lead, iron(III), chromium(VI), molybdenum(VI), zinc and cadmium, can be removed by extraction with three 20-ml portions of 20% w/v solution of tri-iso-octylamine in xylene from 7*M* hydrochloric acid. The excess of acid is evaporated before the determination of lanthanides and yttrium.

Thorium (1–3 μmole) is removed by extraction with three 10-ml portions of 1% w/v solution of 8-hydroxyquinoline in chloroform at pH 3·0–3·5. The aqueous phase may be used directly for the lanthanide and yttrium determination.

A systematic stepwise procedure, consisting of extraction with tri-iso-octylamine, followed by an extractive thorium determination by means of Arsenazo DAL,[3] determination of lanthanides and yttrium as described here, and finally calcium determination with Chlorophosphonazo III,[4] is advantageous for the determination of trace amounts of thorium, yttrium, lanthanides, and calcium in uranium, cobalt, copper, iron, zinc, cadmium, *etc.*, and for analysis of some mineral ores. Sintering

with sodium peroxide has been used for decomposition of mineral ores.[5] After the extraction of yttrium and lanthanides, the solution must be evaporated to dryness and the residue ignited at 500–600° before the calcium determination.

The precipitation of bismuth basic acetate from homogeneous solution

(*Received* 5 *January* 1967. *Accepted* 16 *February* 1967)

BISMUTH may be precipitated as its basic nitrate by urea hydrolysis in dilute nitric acid solution. Precipitation is complete at about pH 3, but in the absence of a buffer the pH rises at an uncontrollable rate at the end of precipitation to above pH 6. Formate ions exert a satisfactory buffer action, and the precipitation of bismuth basic formate by urea hydrolysis has been described.[1] However, in the presence of a large excess of formic acid some reduction to bismuth occurs, and care is necessary in igniting the precipitate since the conversion into oxide is rapid and may cause losses. Since acetate ions have a similar buffer action to formate ions the precipitation of bismuth basic acetate from homogeneous solution was studied to determine whether the method offered any advantages.

EXPERIMENTAL

All reagents were of analytical grade. A stock solution was prepared containing 10 g of bismuth per l.

Procedure

The reaction solutions containing bismuth (5·0 g), urea (50 g) and various amounts of acetic acid in a total initial volume of 550 ml were gently boiled under reflux to minimize losses due to evaporation.

with sodium peroxide has been used for decomposition of mineral ores.[5] After the extraction of yttrium and lanthanides, the solution must be evaporated to dryness and the residue ignited at 500–600° before the calcium determination.

The precipitation of bismuth basic acetate from homogeneous solution

(*Received* 5 *January* 1967. *Accepted* 16 *February* 1967)

BISMUTH may be precipitated as its basic nitrate by urea hydrolysis in dilute nitric acid solution. Precipitation is complete at about pH 3, but in the absence of a buffer the pH rises at an uncontrollable rate at the end of precipitation to above pH 6. Formate ions exert a satisfactory buffer action, and the precipitation of bismuth basic formate by urea hydrolysis has been described.[1] However, in the presence of a large excess of formic acid some reduction to bismuth occurs, and care is necessary in igniting the precipitate since the conversion into oxide is rapid and may cause losses. Since acetate ions have a similar buffer action to formate ions the precipitation of bismuth basic acetate from homogeneous solution was studied to determine whether the method offered any advantages.

EXPERIMENTAL

All reagents were of analytical grade. A stock solution was prepared containing 10 g of bismuth per l.

Procedure

The reaction solutions containing bismuth (5·0 g), urea (50 g) and various amounts of acetic acid in a total initial volume of 550 ml were gently boiled under reflux to minimize losses due to evaporation.

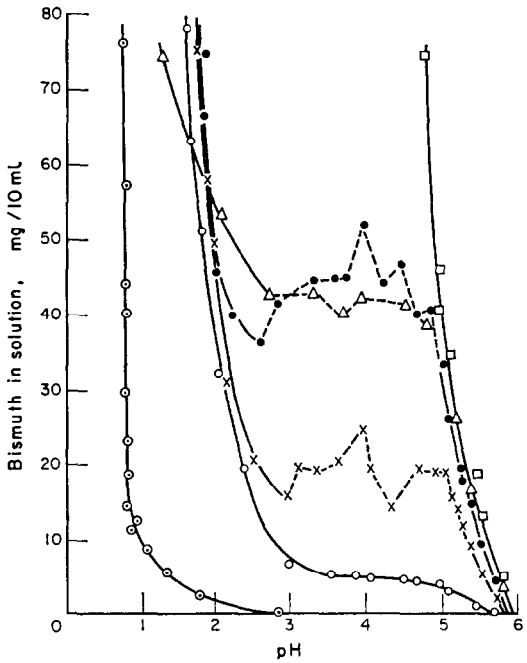

FIG. 1.—Precipitation of bismuth basic acetate.
Urea hydrolysis: ○—25 ml of acetic acid; ×—50 ml; ●—75 ml; ⊙—no acetic acid.
Addition of ammonia: △—hot solution; □—room temperature.

Samples were removed at intervals from the boiling solution, cooled to stop the hydrolysis reaction and filtered to remove precipitate particles. The pH values of the cooled samples were measured and the amount of bismuth remaining in solution was determined by titration with standard EDTA solution, Pyrocatechol Violet being used as indicator. A blank determination was carried out in the absence of acetic acid. The results are shown in Fig. 1.

For comparison purposes precipitation was also brought about by the direct addition of ammonia to reaction solutions containing bismuth (5·0 g) and acetic acid (75 ml) in an initial volume of 550 ml, both at room temperature and in boiling solution. The results are included in Fig. 1.

Determination of bismuth

Take a solution containing up to 250 mg of bismuth, add 2–4 ml of acetic acid (glacial) and 10 g of urea, dilute the solution to 300 ml and boil it. When precipitation begins add a few drops of Bromocresol Green solution and continue boiling until the indicator turns blue. Filter off the precipitate on a sintered porcelain crucible, wash it, and dry it at 120° before igniting it to bismuth oxide.

DISCUSSION

Ammonium acetate formed during the reaction provided an efficient buffer and the rate of increase of pH was easily controlled at all stages of precipitation. No reduction to metallic bismuth occurred.

Between pH 3 and 5 the results obtained in the presence of 50 ml and 75 ml of acetic acid followed a random pattern denoted in Fig. 1 by broken lines. Over this pH range the solubility of the precipitate varied widely with temperature being higher in cold solutions than in boiling solutions. When a hot solution at pH 3·5 containing some precipitate, 50 ml of acetic acid and *ca.* 2 mg of bismuth per ml was allowed to cool to room temperature, much of the precipitate in the reaction vessel redissolved and the bismuth content of the solution increased to 7 mg/ml. On re-heating of the solution, the precipitate was immediately reformed. In the experiments leading to the curves in Fig. 1 the samples removed from the boiling solutions contained precipitate particles. During cooling and filtering some of the precipitate redissolved, the amount passing into solution depending on the

amount initially present and the time taken to cool and filter. The results between pH 3 and 5 represent only approximately the amounts of bismuth in hot solution and for this reason are joined by broken lines. Above pH 5 the solubility of the precipitate was not markedly temperature dependent, and precipitation followed a smooth curve to completion.

Similar results were obtained when precipitation was brought about by the direct addition of ammonia, so the erratic behaviour was not due to the presence of urea. The solubility of the precipitate formed at pH 3·5 was tested in solutions containing the various ions present in the reaction solution at that pH. The precipitate was dissolved by acetate ions but was not affected by nitrate and ammonium ions or by urea.

The behaviour of the precipitate could be explained by the formation of acetate complexes of bismuth although it must be stressed that the existence of complexes has not been proved. Aluminium, for example, does not form a basic acetate until the solution is heated, owing to the existence of polynuclear aquo-complexes which are stable in cold solution. A similar behaviour on the part of bismuth may account for the fact that precipitation of basic acetate does not occur in cold solution till about pH 5·0, whereas in hot solution precipitation starts at about pH 2. A peculiarity of the bismuth system is the negative temperature dependence of the solubility in the pH range 3–5. This could be due to the formation of soluble acetate complexes that are unstable in hot solution, but in the absence of definite proof this must remain as a tentative explanation.

The precipitates formed by the homogeneous method were denser and more easily filtered off than those obtained by direct addition of ammonia. In the early stages of the reaction the precipitate adhered strongly to the walls of the vessel, but was more readily detached from the walls as the pH value of the solution rose above about pH 4. Microscopic examination of the precipitate showed it to consist largely of small discrete particles up to about pH 3. The precipitate obtained above pH 5 consisted of aggregates of small particles. The precipitate was readily ignited to bismuth oxide, but the conversion occurred more slowly than with bismuth basic formate and there was less danger of loss of precipitate during ignition.

When the method was applied to the determination of bismuth satisfactory recoveries were obtained (99·7–100·0%, mean value 99·9% for 5 determinations at the 250-mg level.) No difficulties were experienced in handling precipitates containing up to 0·5 g of bismuth. Attempts to separate bismuth from lead were unsuccessful owing to coprecipitation of lead. Although the use of acetate offers certain advantages over the use of formate in avoiding risk of reduction and facilitating ignition of the precipitate the method is not suitable for the determination of bismuth in the presence of lead.

Sir John Cass College
London, E.C. 3

P. F. S. CARTWRIGHT

Summary—Precipitation from homogeneous solution by urea hydrolysis has been used to investigate the conditions affecting the precipitation of bismuth basic acetate. Evidence has been found that indicates that acetate complexes may be formed. The method has been tested for the determination of bismuth, but is not suitable if lead is present.

Zusammenfassung—Die Fällung aus homogener Lösung durch Hydrolyse von Harnstoff wurde benutzt, um die Bedingungen zu erforschen, die Einfluß auf die Fällung von basischem Wismutacetat haben. Es wurden Hinweise auf Bildung von Acetatokomplexen gefunden. Die Methode wurde zur Wismutbestimmung getestet, ist aber in Gegenwart von Blei ungeeignet.

Résumé—On a utilisé la précipitation en solution homogène par hydrolyse de l'urée pour étudier les conditions affectant la précipitation de l'acétate basique de bismuth. On a trouvé des faits indiquant que des complexes acétiques peuvent se former. On a essayé la méthode pour le dosage du bismuth, mais elle ne convient pas en présence de plomb.

DETERMINATION OF TRACE AMOUNTS OF SULPHUR IN SELENIUM

BRITT-LOUISE SJÖBORG
Department of Analytical Chemistry, University of Uppsala, Uppsala, Sweden

(*Received* 24 *January* 1967. *Accepted* 12 *March* 1967)

Summary—Determination of trace amounts of sulphur as Methylene Blue after reduction of sulphate to sulphide by hydriodic and hypophosphorous acids in acetic acid solution is applied to the determination of trace amounts of sulphur in selenium after removal of the selenium by evaporation with hydrobromic acid. Samples of 100 mg or less of selenium are chosen if the sulphur content is greater than 5–10 ppm; the time required for the separation is about 1·5 hr; 100 ppm of sulphur has been determined with a coefficient of variation of 5·2%. If the sulphur content is less than 5 ppm, 1-g samples must be taken and the time required is then about 3 hr; 0·4 ppm of sulphur has been determined with a standard deviation of 0·13 ppm. The accuracy of the method seems to be well within the random error.

THE importance of trace impurity effects in semiconductor materials is well known. Though most of the trace elements of interest can be determined with a fair degree of accuracy there seems to be a lack of good methods for as common a trace impurity as sulphur. This is perhaps best illustrated by the fact that such a modern and comprehensive monograph on trace methods as Koch and Koch-Dedic's *Handbuch der Spurenanalyse* completely omits the determination of sulphur.

Very few methods for determining trace amounts of sulphur in selenium have been described. Usually the procedures recommended are based on the turbidimetric determination of sulphur as barium sulphate. Separation of the dioxides of sulphur and selenium at 800°, followed by colorimetric determination of sulphur dioxide as described by Acs and Barabas[1] seems to be rapid but has some disadvantages. None of the methods is applicable to the determination of less than 3 μg of sulphur. The separation of selenium as selenium tetrabromide by means of a mixture of hydrobromic acid and bromine has also been mentioned, but if samples of more than 1 g must be taken this procedure is very time-consuming. A brief survey of methods for the determination of trace amounts of sulphur in selenium as well as of the demands for such analyses is given by Acs and Barabas.[1]

The determination of sulphur as Methylene Blue after reduction of sulphate to sulphide by hydriodic and hypophosphorous acids in acetic acid solution[2,3] is very sensitive. If a 10-cm cell is used 5 μg of sulphur can be determined with a standard deviation of 0·10 μg and 0·1 μg of sulphur with a standard deviation less than 0·03 μg. The great sensitivity of this method should make it well suited to the present purpose. It was found that the method was not applicable in the presence of selenium; hydrogen selenide is formed and oxidized to selenium in the absorption flask in contact with air. After separation of selenium as selenium tetrabromide, however, the results obtained were good. The sensitivity of the colour reaction allows small samples to be

used and the evaporation of selenium tetrabromide takes only 3 hr at most. The following procedure was adopted.

EXPERIMENTAL

Apparatus

The separation procedure is carried out in a 50-ml round-bottomed flask with conical B24 ground-glass joint, the flask being subsequently used for the reduction. The flask is placed in a sand-bath on a hot-plate with an infrared drying lamp (250 W) above and a cylinder of glass around it to accelerate the evaporation by preventing condensation in the neck of the flask (Fig. 1).

For the reduction Gustafsson used a round-bottomed flask with a spherical ground joint and a side-tube for introduction of nitrogen. We found it more convenient to use the commercially available flasks just mentioned and to introduce the nitrogen by means of a 9 mm o.d. tube through the lower part of the condenser and ending 1·0–2·5 mm above the bottom of the flask. The flasks were selected to give the right distance between the end of the tube and the bottom. The rest of the apparatus was strictly according to Gustafsson.

The light absorption is determined with a spectrophotometer. Measured at the wavelength stated by Gustafsson, 1·0 μg of sulphur in 100 ml of solution gives an absorbance of 0·154 at 20° in a 10-cm cell.

Reagents

The reduction and colour-reaction reagents are those described by Gustafsson.

Sodium chloride solution, 0·1%.

Nitric acid, conc.

Hydrobromic acid, 48%.

Distillation of the acids is necessary to remove traces of sulphur. After one distillation in a silica apparatus nitric acid gave a blank of 10 μg of sulphur/l. and hydrobromic acid a blank of 25 μg of sulphur/l. The distilled acids are preferably stored in silica flasks, but Pyrex flasks may be used if they are first boiled for 10 min with the reducing mixture.

Recommended procedure

It is very important to clean new round-bottomed flasks thoroughly immediately before use to remove traces of sulphur that may be present. Boil the flasks with 3 ml of the reducing mixture in the reduction apparatus for about 10 min. Rinse them with distilled water and with 6*M* hydrochloric acid and again with distilled water. After this treatment the flasks are ready for use.

The figures in parentheses below refer to 1-g samples. Transfer by pipette 1 ml of 0·1% sodium chloride solution into a 50-ml round-bottomed flask. Evaporate to dryness in a drying oven at 130°. Weigh out 100 mg (1 g) of selenium and transfer it to the flask. Add 1 ml (6 ml) of nitric acid, keeping the flask in a slanting position to prevent spattering losses during the violent reaction. Evaporate to dryness in a sand-bath on a hot-plate under an infrared drying lamp and with a cylinder of glass around the flask. The sand-bath is kept as hot as possible but splashing must be avoided. Add, and evaporate to dryness after each addition, 2 × 0·5 ml (5 + 1 ml) of hydrobromic acid, 0·5 ml (1 ml) of nitric acid and 0·5 ml (1 ml) of hydrobromic acid. After this treatment, which takes about 1½ hr (3 hr), the separation is complete and all the sulphur is left as sulphate. Cool to room temperature and proceed strictly according to Gustafsson with the few exceptions mentioned above under "apparatus". It has been found that the ground joints of the round-bottomed flasks need not be greased with silicone lubricant. Instead they are wetted with a few drops of the reducing mixture and thus the flasks are more easily kept clean. The nitrogen flow-rate is kept very low at the beginning of the reduction and not until the boiling point is reached (after about a minute) is it increased to about 150 ml/min.

By this procedure sulphur has been determined in some commercial selenium samples and in some selenium samples from Bolidens Aktiebolag (Tables I–III).

DISCUSSION

Procedure

It is important to keep the blank as low as possible. The total blank is composed of the blanks for the separation and reduction procedures and the colour reaction. The colour reaction in the absence of sulphide gives a blank corresponding to 0·25 μg of

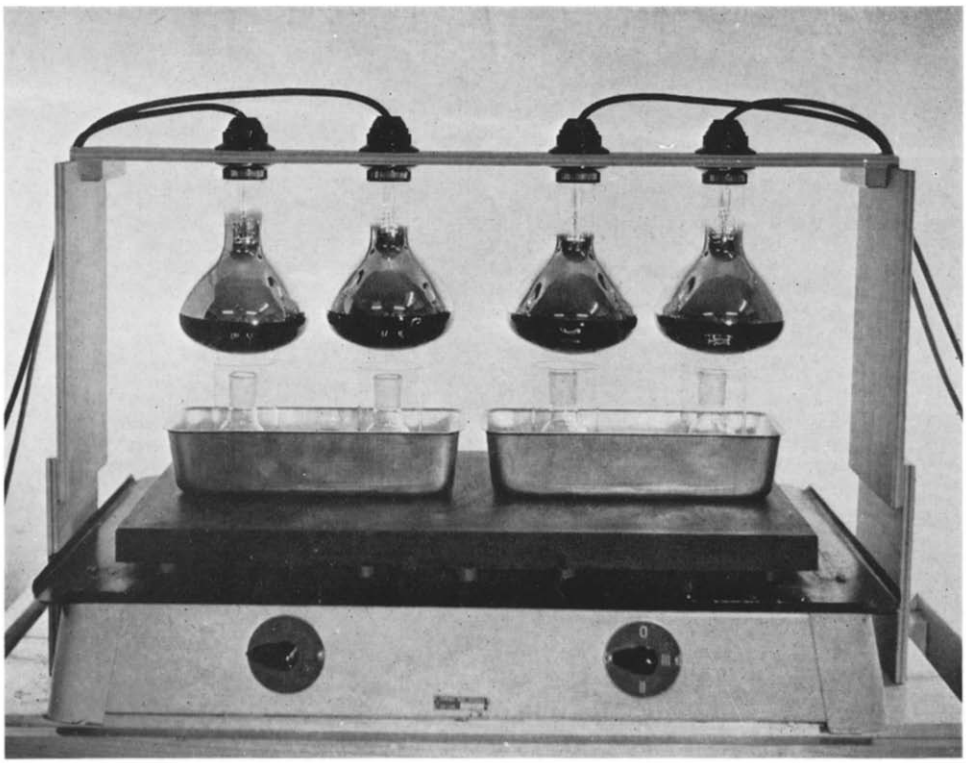

FIG. 1.—The apparatus used for the separation procedure. The equipment shown has been in use for more than a year.

sulphur. The yellow colour due to the iron(III) used as oxidant can be bleached by phosphoric acid but the absorbance at the wavelength used is unchanged. The reduction gave a blank corresponding to 0·11 μg of sulphur. The nitric and hydrobromic acids used for the separation of selenium gave blanks of about 10 and 25 μg of sulphur/l., respectively. The mean value for the total blank when working with 1-g samples thus corresponds to 0·61 μg of sulphur. The standard deviation amounts to 0·05 μg.

The blank increases with the amount of acid used for the oxidation and evaporation of selenium and also with the time required for the separation (because of the possibility of air-borne contamination with sulphur). Therefore it is necessary to use the smallest possible amounts of the acids for the separation and the procedure described above has turned out to be the best and the least time-consuming of those tried. It is also important to have a sufficiently high temperature during the evaporation of selenium tetrabromide. This is attained as described; the cylinder of glass around the flask accelerates the evaporation by preventing condensation in the neck of the flask and halves the time needed.

Sufficient sodium chloride must be added to avoid losses of sulphuric acid during the evaporation. The vapour pressure of sulphuric acid is high enough to cause losses even at steam-bath temperature.

The separation of selenium was first done with a mixture of hydrobromic acid and bromine but the same results were obtained by using hydrobromic acid only.

Cleaning

Chromic-sulphuric acid must never be used for cleaning, as traces of sulphuric acid remain in glassware even after rinsing thoroughly with 6*M* hydrochloric acid. The reduction gave a blank corresponding to 0·57–0·94 μg of sulphur if the round-bottomed flasks were cleaned with chromic-sulphuric acid, compared with the blank of 0·11 μg of sulphur obtained by boiling the flasks with the reducing mixture as mentioned under "recommended procedure".

Precision

According to Gustafsson, Beer's law is valid up to 20 μg of sulphur in 100 ml, and the standard deviation is 0·12 μg. This has been confirmed. For standards ranging from 5 μg down to 0·1 μg of sulphur the standard deviation varied from 0·10 to 0·03 μg. The precision of analysis is shown in Table I.

Accuracy

As the colour reaction is quite specific for sulphur, high systematic errors will only be obtained in the presence of sulphur impurities in reagents and glassware, but these should be compensated for by the blank.

Low results may be due to (*a*) mechanical losses on dissolving the sample, (*b*) losses as hydrogen sulphide or sulphur dioxide on dissolving the sample and (*c*) losses as sulphuric acid during the evaporations. The mechanical losses are calculated to be well within the precision of the method. To investigate the possible loss of sulphuric acid by evaporation, samples of selenium were analysed after addition of standard amounts of potassium sulphate (Table II). No losses were indicated.

1-cm cuvette.

Possible losses due to (*b*) were investigated in two ways. It seems reasonable to assume that losses of hydrogen sulphide or sulphur dioxide will be proportionally greater for the dissolution of a large sample low in sulphur than in the opposite case, as the oxidizing conditions should be better the smaller the sample. If losses occur, the analysis of a mixture of a large sample of low-sulphur selenium with a small sample of high-sulphur selenium should give a lower result than that calculated from the two sulphur contents. The results of experiments performed are given in Table III. Losses of about $0{\cdot}24 \pm 0{\cdot}17$ *μg* of sulphur are indicated at a level of 1–10 ppm of

sulphur. In other experiments the gases formed during the dissolution were passed through a solution of bromine in conc. nitric acid, and this was then analysed for sulphur by the method described. It was found to contain 1 μg of sulphur after dissolution of 1 g of selenium with a sulphur content of 614 ppm, 0·5 μg at a content of 85 ppm and $<$0·1 μg at a content of 0·4 ppm. It therefore seems that the possible losses are well within the random errors.

Acknowledgements—This work was suggested by Professor Folke Nydahl. The author wishes to thank him for the facilities placed at her disposal and for many valuable discussions. Thanks are also due to Bolidens Aktiebolag who supplied her with several selenium samples.

Zusammenfassung—Schwefelspuren lassen sich nach Reduktion von Sulfat zu Sulfid mit Jodwasserstoff- und unterphosphoriger Säure in Essigsäure als Methylenblau bestimmen. Mit dieser Methode werden Schwefelspuren in Selen bestimmt nach Entfernung des Selens durch Abrauchen mit Bromwasserstoffsäure. Als Proben werden 100 mg oder weniger Selen gewählt, wenn der Schwefelgehalt über 5–10 ppm liegt. Die Abtrennung dauert etwa 1,5 h; 100 ppm Schwefel werden einem Variationskoeffizienten von 5,2% bestimmt. Ist der Schwefelgehalt kleiner als 5 ppm, so müssen 1 g-Proben genommen werden, die Abtrennung dauert dann etwa 3 h. 0,4 ppm Schwefel wurden mit einer Standardabweichung von 0,13 ppm bestimmt. Die Genauigkeit der Methode ist anscheinend durch statistische Fehler bestimmt.

Résumé—On applique le dosage de traces de soufre à l'état de bleu de méthylène après réduction du sulfate en sulfure par les acides iodhydrique et hypophosphoreux en solution dans l'acide acétique à la détermination de traces de soufre dans le sélénium après élimination du sélénium par évaporation avec de l'acide bromhydrique. On choisit des échantillons de 100 mg ou moins si la teneur en soufre est supérieure à 5–10 ppm; le temps nécessité pour la séparation est d'environ 1,5 h; on a dosé 100 ppm de soufre avec un coefficient de variation de 5,2%. Si la teneur en soufre est inférieure à 5 ppm, il faut prendre des échantillons de 1 g et le temps nécessité est alors d'environ 3 h; on a dosé 0,4 ppm de soufre avec un écart type de 0,13 ppm. La précision de la méthode semble bien se situer à l'intérieur de l'erreur de hasard.

Summary—A general survey is given of the properties of tetrachlorogallate(III) complexes with basic dyestuffs of the triphenylmethane and diphenylnaphthylmethane class; solvents for extraction, the absorption spectra and molar absorptivities, the optimum concentrations of the dyestuffs and of hydrochloric acid, the stability of the compounds and their composition are also described. Analytical methods for the determination of traces of gallium by means of many of these complexes are suggested.

THERE are already known some compounds formed by certain inorganic complex anions (*e.g.*, $SbCl_6^-$, $AuCl_4^-$, $GaCl_4^-$ etc) with organic cations such as ammonium, oxonium, diazonium, arsonium, stilbonium, phosphonium, selenonium and sulphonium which are generally colourless. These compounds can be extracted from aqueous solution by means of various organic solvents or solvent mixtures. For analytical purposes, however, it is better to make use of coloured organic cations, which will give strongly coloured compounds with inorganic complex anions, and can be used for the determination of some elements found as traces or impurities in ores, concentrates, industrial products, *etc.*

Of the organic cations capable of forming such coloured compounds, the present paper is concerned with basic dyestuffs with two or three amino groups, taken in combination with the tetrachlorogallate(III) ion, $[GaCl_4]^-$. The dyestuffs belong to the following classes.

Diaminotriphenylmethane dyes. Malachite Green 1 (Colour Index[1] Basic Green 4/42000; *N,N,N′,N′*-tetramethyl-4,4′-diaminotriphenylcarbinol chlorhydrate); Brilliant Green (C.I. Basic Green 1/42040; *N,N,N′,N′*-tetraethyl-4,4′-diaminotriphenylcarbinol sulphate); Astrazon Blue B (C.I. Basic Blue 5/42140; 4′,4″-diethylamino-3′,3″-dimethyl-3-chlorotriphenylcarbinol chlorhydrate).

Triaminotriphenylmethane dyes. Fuchsine (C.I. Basic Violet 14/42510; 4,4′,4″-triamino-3-methyltriphenylcarbinol chlorhydrate); New Fuchsine (C.I. Basic Violet 2/42520; 4,4′,4″-triamino-3,3′,3″-trimethyltriphenylcarbinol chlorhydrate); Methyl Violet (C.I. Basic Violet 1/42535; *N,N,N′,N″*-pentamethyl-*p*-rosaniline chlorhydrate); Crystal Violet (C.I. Basic Violet 3/42555; hexamethyl-4,4′,4″-triaminotriphenylcarbinol chlorhydrate); Ethyl Violet (C.I. Basic Violet 4/42600; hexaethyl-4,4′,4″-triaminotriphenylcarbinol chlorhydrate).

Diaminodiphenylnaphthylmethane dyes. Victoria Blue (C.I. Basic Blue 11/44040; *N,N,N',N'*-tetramethyl-4,4'-diamino-*N''*-phenyl-4-naphthylaminocarbinol chlorhydrate); Fanal Blue B Supra (C.I. Basic Blue 7/42595 *N,N,N',N'*-tetraethyl-4,4'-diamino-*N''*-ethyl-4-naphthylaminocarbinol chlorhydrate).

EXPERIMENTAL

The purity of the dyestuffs was determined by reduction with titanium(III) chloride in acidic medium,[2] in accordance with the reaction

$$X_3OH + 2TiCl_3 + 2HCl = 2TiCl_4 + X_3H + H_2O.$$

The purities were: Malachite Green 94·9%; Brilliant Green 93·0%; Astrazon Blue B 38·6%; Fuchsine 81·6%; New Fuchsine 83·3%; Methyl Violet 85·7%; Crystal Violet 97·4%; Ethyl Violet 88·0%, and Victoria Blue 66·8%.

Since Methyl Violet is a mixture of methylated *p*-rosaniline (tetra-, penta- and hexa-) having the pentamethyl derivative as main component, its purity was calculated on the basis of the pentamethyl derivative; one CH_3 group more or one less influences the result only to a small extent, and one compensates for the other.

For extraction, the optimum conditions are 2 ml of 2% solution of Malachite Green, Brilliant Green, Fuchsine, New Fuchsine, Methyl Violet, Crystal Violet or Ethyl Violet, or 0·5 ml of 2% Astrazon Blue B solution, added to 1 ml of gallium solution (10 μg of gallium) in 6*M* hydrochloric acid and diluted to 5 ml final volume, which is then extracted with 5 ml of solvent (Fig. 1). The optimum concentration of hydrochloric acid is 5·5–6*M*, irrespective of the cation, as shown in Fig. 2. It is essential to form the $[GaCl_4]^-$ anion and for this 6*M* hydrochloric acid is completely satisfactory.

The complex formed by the $[GaCl_4]^-$ anion and the cations of the basic diaminotriphenylmethane dyestuffs can be extracted from 6*M* hydrochloric acid with benzene, and especially with mixtures of benzene and chlorobenzene (4:1 or 1:1) or chlorobenzene and carbon tetrachloride (4:1). Chlorobenzene cannot be used alone as extraction solvent, even though it yields a large molar absorptivity, because the separation of the two layers requires a very long time, owing to the closeness of the specific gravities of chlorobenzene (1·107) and 6*M* hydrochloric solution. If toluene is used for the extraction low absorptivities are obtained, and carbon disulphide gives very small molar absorptivities for the extracts. Carbon tetrachloride extracts none of the compounds and chloroform extracts the

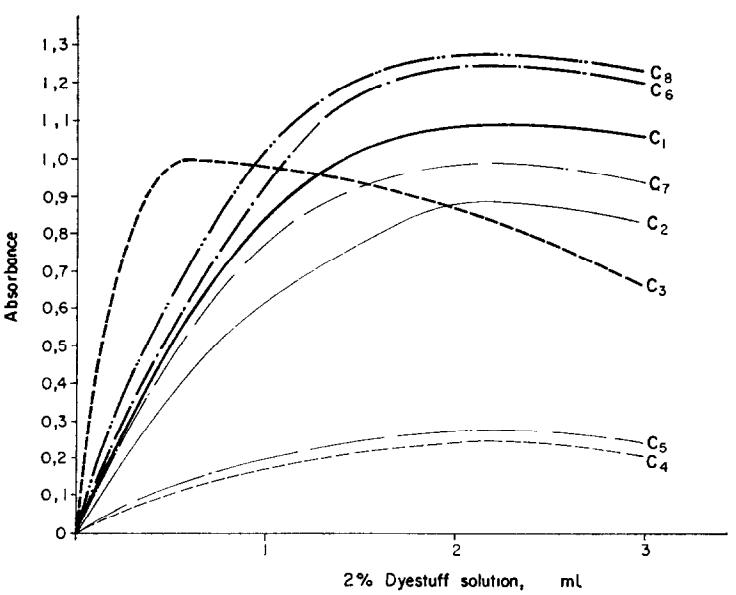

FIG. 1.—Effect of dyestuff concentration on absorbance of chlorogallate complexes. C_1—Malachite Green; C_2—Brilliant Green; C_3—Astrazon Blue; C_4—Fuchsine; C_5—New Fuchsine; C_6—Methyl Violet; C_7—Ethyl Violet; C_8—Crystal Violet.

dyestuffs as well as the $[GaCl_4]^-$ complexes. Of the complexes formed with the cations of the triaminotriphenylmethane class, those with Fuchsine and New Fuchsine are best extracted by a mixture of chloroform and cyclopentanone, and those of Methyl Violet, Crystal Violet or Ethyl Violet by chloroform alone or mixed with either acetone or acetylacetone. Benzene, toluene, carbon tetrachloride and carbon disulphide do not extract the chlorogallates of Methyl Violet, Crystal Violet and Ethyl Violet; chlorobenzene extracts them but only to a small extent. We have also tested 30 other organic solvents which, proved not to extract the chlorogallates.

The Victoria Blue chlorogallate is best extracted into benzene or a benzene–chlorobenzene mixture, and the Fanal Blue B Supra chlorogallate into chloroform–acetone or chloroform–acetylacetone mixtures. The presence of a naphthyl group instead of a phenyl group did not alter the behaviour toward organic solvents.

RESULTS

The molar absorptivities are given in Tables I, II and III, and the distribution ratios and degrees of extraction in Table IV.

For all determinations a correction was applied for a blank. Some of the molar

Chloroform–acetylacetone (6:1)	2960	2970	44600	48800	35200

absorptivities are higher than those previously obtained (J. Jankovsky[3]—48800 for Malachite Green; Kuznetsova and Tananaeva[4]—29280 for Brilliant Green; Kuznetsova and Tananaeva[5]—4200 for Methyl Violet).

By the methods of continuous variations or of series of equimolecular solutions[6–11] we have established the molar ratio of the organic cation to the $[GaCl_4]^-$ anion. The molarities studied ranged from 10^{-3} to $10^{-4}M$ and led to the conclusion that the combining ratio is 1:1.[12–14]

The distribution ratio[15] (Table IV) ranges from 2·70 for the chlorogallate of Malachite Green to 1·05 for the chlorogallate of Fuchsine, for equal volumes of organic solvent and aqueous phase; the degree of extraction varies between 87·1 and 51·2%.

CONCLUSIONS

All the compounds studied had absorption spectra with a well-defined maximum between 580 and 650 mμ (Fig. 3), in the best solvents given in Tables I–III.

The molar absorptivities are higher for the complexes with Methyl Violet and Crystal Violet, which possess methyl groups, than for those with Ethyl Violet, which has ethyl groups, and also with Malachite Green as compared with Brilliant Green. The highest molar absorptivity is obtained with Astrazon Blue B, which has methyl, ethyl and chlorine groups.

The compounds are stable in the organic phases for 6 hr for the Fuchsine and New Fuchsine complexes and 24 hr, for the others slightly decreasing thereafter. The

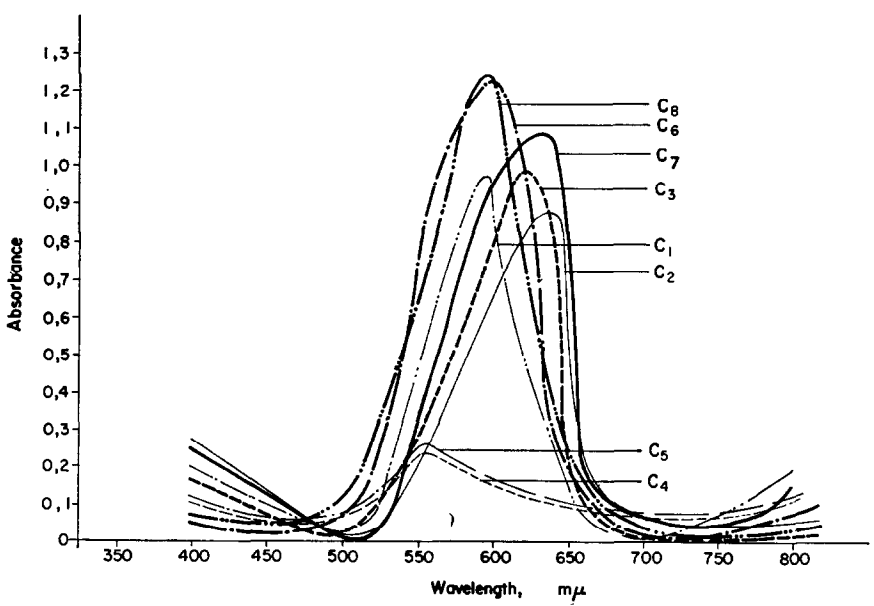

FIG. 3.—Absorption spectra of chlorogallates of various dyestuffs

absorbance of the extracts increases linearly with the gallium concentration up to 15 μg of gallium in 5 ml of aqueous solution.

New methods have been developed from this work with Crystal Violet,[16] Astrazon Blue[17] and Victoria Blue for the determination of gallium in bauxite, nepheline syenite, zinc concentrates, by-products in the zinc industry, and coal-ash, either directly in the presence of other elements, or after separation of gallium from interfering elements. The results obtained are good and the time required for analysis is shorter than for the classical oxine method.

Zusammenfassung—Es wird ein allgemeiner Überblick über die Eigenschaften von Tetrachlorogallat(III)-komplexen mit basischen Farbstoffen der Triphenylmethan- und Diphenylnaphthylmethanreihe gegeben; Losungsmittel zur Extraktion, Absorptionsspektren und Extinktionskoeffizienten, optimale Konzentrationen von Farbstoffen und Salzsäure, Stabilität und Zusammensetzung der Verbindungen werden ebenfalls abgehandelt. Es werden analytische Verfahren zur Bestimmung von Galliumspuren mit vielen dieser Komplexe vorgeschlagen.

Résumé—On présente une étude d'ensemble des propriétés des complexes du tétrachlorogallate(III) avec les colorants basiques des groupes triphénylméthane et diphénylnaphtylméthane; on décrit également des solvants d'extraction, les spectres d'absorption et les coefficients d'extinction moléculaire, les concentrations optimales des colorants et de l'acide chlorhydrique, la stabilité des composés et leur composition. On suggère des méthodes analytiques pour le dosage de traces de gallium au moyen d'un grand nombre de ces complexes.

ESTIMATION OF THE MINIMUM DETECTABLE CONCENTRATION AND OPTIMUM INSTRUMENTAL CONDITIONS IN PRECISION ABSORPTION SPECTROPHOTOMETRY OF SUBSTANCES IN THE CONDENSED PHASE

J. J. CETORELLI and J. D. WINEFORDNER
Department of Chemistry, University of Florida, Gainesville, Florida 32601, U.S.A.

(*Received* 23 *November* 1966. *Accepted* 19 *January* 1967)

Summary—An expression for the signal-to-noise ratio in precision absorption spectrophotometry of molecules in the condensed phase is derived and used to calculate the theoretical minimum detectable sample concentration, C_{mt}, and to predict the best instrumental condition for measurement. Single-beam and double-beam instruments are considered. The theoretically calculated values of C_{mt} for several organic molecules are compared with the practical minimum detectable sample concentrations, C_{mp}, which are those concentrations giving an absorbance of 0·002. As long as the source of radiation is intense, and the root-mean-square noise-to-signal ratio for incident radiation passing through the blank is known, then the expression for C_{mt} is extremely simple and easy to evaluate for any given substance whose molar absorptivity is known. The influence of instrumental parameters on the value of C_{mt} is evaluated, and only the monochromator slitwidth, the number of combined blank and sample signal measurements, and the frequency response bandwidth of the electrometer-readout system have any significant effect on the value of C_{mt} (for any given wavelength setting of the monochromator).

THE minimum detectable sample concentration in molecular absorption spectrophotometry is generally defined as that sample concentration resulting in an absorbance of 0·002.[1–3] However, it is well-known that scale-expansion techniques can be used in precision spectrophotometry,[4] to increase the sensitivity of measurement. If experimental conditions are such that the minimum detectable sample concentration is limited by the signal-to-noise ratio, then the approach of Winefordner *et al.*,[5–8] can be used to estimate the theoretical minimum detectable sample concentration and optimum instrumental conditions. Several instrumental systems for absorption spectrophotometry will be considered here, and these include: a single-beam system with a d.c. amplifier read-out (which is the system generally used for quantitative absorption spectrophotometric measurements, *e.g.*, the Beckman DU spectrophotometer), a single-beam system, chopper-modulated with a tuned a.c. amplifier (few examples of this system are used in molecular absorption spectrophotometry, although most atomic-absorption instruments are of this type), and a double-beam system with a differential or a.c. amplifier read-out.

THEORY

The theoretical minimum detectable sample concentration, C_{mt}.

The theoretical minimum detectable sample concentration, C_{mt}, has been defined[7,9–15] as that concentration producing a signal-to-noise ratio having a value

of $3\sqrt{2}/\sqrt{n}$, *i.e.*,

$$\frac{i_o - i_s}{\overline{\Delta i_T}} = \frac{3\sqrt{2}}{\sqrt{n}} \tag{1}$$

where i_o is the photo-anodic current, in amperes, due to radiation from the light source passing through the blank solution and striking the photo-cathode surface of the multiplier phototube, i_s is similarly defined for radiation which has just barely been attenuated by passage through a sample solution of minimum detectable concentration, $\overline{\Delta i_T}$ is the total root-mean-square (r.m.s.) noise due to all sources, *e.g.*, shot noise, source flicker noise, and electrometer-amplifier noise, and n is the number of pairs of blank and sample measurements. The total r.m.s. noise can be experimentally determined by measuring the peak-to-peak noise and dividing by 5.[16,17] The limiting detectable signal-to-noise ratio expression takes on additional meaning if one considers that a signal which is $3\sqrt{2}/\sqrt{n}$ times greater than the total rms noise can be measured with about 99·7% confidence (for $n \geqslant 4$).

Signal-to-noise ratio for single-beam system with d.c. amplifier read-out

The instrumental system under consideration consists of a source, *e.g.*, a hydrogen arc-lamp for the ultraviolet region or a tungsten lamp for the visible–near infrared region, a monochromator with equal entrance and exit slitwidths (*e.g.*, a Beckman DU, with suitable entrance optics), a multiplier-phototube, a d.c. electrometer-amplifier, and a read-out device, *e.g.*, a meter or recorder.

The photo-anodic currents i_o and i_s are given[5,6] by

$$i_o = \gamma k_m W s I^\circ, \tag{2}$$

and

$$i_s = \gamma k_m W s I^\circ \exp(-2{\cdot}3abC). \tag{3}$$

Near the theoretical minimum detectable sample concentration, C_{mt}, i_s is given by

$$i_s = \gamma k_m W s I^\circ(1 - 2{\cdot}3abC_{mt}). \tag{4}$$

The symbols in equations (2), (3) and (4) are defined as follows:

γ = photo-anodic sensitivity factor, in amperes produced at the anode of the photodetector per watt of light striking the photocathode
k_m = monochromator factor = $HT_t\Omega/m^2$, cm.ster
m = entrance optics factor to account for magnification of source image focused on slit
H = height of exit and entrance slit of monochromator, cm
T_t = transmittance factor of monochromator and entrance and exit optics
Ω = solid angle of incident radiation subtended by the monochromator, in steradians (usually Ω is the ratio of the effective collimator area or the area of the dispersing device, A_c, divided by the square of the focal length, F, of the collimator)
W = slitwidth of monochromator, cm
$s = R_d W$, mμ
I° = intensity of continuous source, W.cm^{-2}.ster^{-1}.mμ^{-1}
R_d = reciprocal linear dispersion of the monochromator, mμ.cm^{-1}
a = molar absorptivity, l.mole^{-1}.cm^{-1}

b = thickness of absorbing layer, cm
C = concentration of sample solution, mole.l.$^{-1}$
C_{mt} = theoretical minimum detectable sample concentration, mole.l.$^{-1}$.

By subtracting equation (4) from equation (2), the absorption signal at the theoretical minimum detectable sample concentration, C_{mt}, is given by,

$$(i_o - i_s)_{C_{mt}} = 2{\cdot}3abC_{mt}\gamma k_m WsI^\circ. \tag{5}$$

The total rms noise signal, $\overline{\Delta i_T}$, is a result of shot noise in the phototube, $\overline{\Delta i_P}$, flicker noise in the continuous source, $\overline{\Delta i_F}$, and amplifier-electrometer noise, $\overline{\Delta i_E}$. Because these noises are independent of each other, they add quadratically[5,6] and therefore $\overline{\Delta i_T}$ is given by

$$\overline{\Delta i_T} = \sqrt{\overline{\Delta i_P}^2 + \overline{\Delta i_F}^2 + \overline{\Delta i_E}^2}. \tag{6}$$

The phototube shot noise current, $\overline{\Delta i_P}$, in amperes at the anode, is given[5,6,18] by

$$\overline{\Delta i_P} = \sqrt{k_D(i_t + i_o)\Delta f}, \tag{7}$$

where:

k_D = detector factor = $2eBM$, coulombs
e = charge of electron, coulombs
B = factor to account for secondary emission of electrons in the phototube[18]
M = total gain of the phototube
i_t = thermionic emission anodic current in the phototube, in amperes (the dark current)
Δf = frequency-response bandwidth of the electrometer-amplifier–read-out system,[18] sec^{-1}.

If i_o from equation (2) is substituted into equation (7), then

$$\overline{\Delta i_P} = \sqrt{k_D(i_t + \gamma k_m WsI^\circ)\Delta f}. \tag{8}$$

The r.m.s. flicker noise signal due to flicker in the continuous source, in amperes at the photo-anode, is given[6] by

$$\overline{\Delta i_F} = \chi\sqrt{\Delta f}\, i_o = \chi\sqrt{\Delta f}\,\gamma k_m WsI^\circ \tag{9}$$

where χ is the r.m.s. fluctuation in the intensity of the source, $\overline{\Delta I^\circ}$, compared to the source intensity, I°, *i.e.*, $\chi = \overline{\Delta I^\circ}/I^\circ$ for a 1-Hz frequency-response bandwidth, and has units of sec$^{1/2}$.

The r.m.s. noise signal due to the electrometer–amplifier, in amperes at the photo-anode, is given[5] by

$$\overline{\Delta i_E} = \zeta\sqrt{\Delta f}\,(i_t + i_o) = \zeta\sqrt{\Delta f}\,(i_t + \gamma k_m WsI^\circ), \tag{10}$$

where ζ is the fraction of the total current $(i_t + i_o)$ which results in a noise for a 1-Hz frequency-response bandwidth, and has units of sec$^{1/2}$.

The total r.m.s. noise signal, in amperes at the read-out, $\overline{\Delta i_T}$, is therefore given by

$$\overline{\Delta i_T} = \{k_D\,\Delta f(i_t + \gamma k_m WsI^\circ) + \Delta f[(\chi\gamma k_m WsI^\circ)^2 + \zeta^2(i_t + \gamma k_m WsI^\circ)^2]\}^{1/2}. \tag{11}$$

The signal-to-noise expression, $(i_o - i_s)/\overline{\Delta i_T}$ at the theoretical minimum detectable

sample concentration, C_{mt}, can be found by dividing equation (5) by equation (11), and setting the quotient equal to the right hand term in equation (1).

$$\frac{3\sqrt{2}}{\sqrt{n}} = \left(\frac{i_o - i_s}{\overline{\Delta i_T}}\right)_{C_{mt}} = \frac{2 \cdot 3abC_{mt}\gamma k_m WsI^\circ}{\sqrt{\{k_D \Delta f(i_t + \gamma k_m WsI^\circ) + \Delta f[(\chi\gamma k_m WsI^\circ)^2 + \zeta^2(i_t + \gamma k_m WsI^\circ)^2]\}}}. \quad (12)$$

Signal-to-noise ratio for single-beam system with a.c. amplifier read-out

The system under consideration is assumed to be identical to the single-beam system with d.c. amplifier read-out with the exception that the light source is modulated, and an a.c. amplifier tuned to the chopper frequency is used. The equations for the absorption signal and noise are essentially identical to those derived for d.c. operation except that the source intensity is reduced by a factor t, for the decrease in source intensity due to the chopper. Usually t will be 1/2 and so the intensity of the source, which must be introduced into the signal and noise expressions, is $I^\circ/2$, where I° is the intensity of the unmodulated continuous source. In addition, since only alternating signals are amplified and the thermionic current, i_t, is a d.c. current, the electrometer noise expression, $\overline{\Delta i_E}$, does not contain i_t.

Signal-to-noise ratio for double-beam system with a.c. amplifier read-out

The system under consideration is basically the same as the single-beam a.c. system except that the optics are usually arranged to pass a double beam through the optical system, and so only one phototube is needed. Such a system provides higher accuracy than instruments that split the beam after it has passed through the optical system, and require two phototubes. When two phototubes are needed, errors result because of lack of balance due to different drift rates in the two phototubes. If the phototubes are well-matched, then either system can be dealt with by the expressions derived here. Of course, it should be pointed out that generally double-beam systems are used for qualitative studies, and single-beam systems are used for routine quantitative analyses. However, if the following conditions are met, then the expressions derived for the single-beam system with d.c. amplifier read-out will be approximately valid except that the i_t term in the electrometer noise term can be omitted: the two cells (and phototubes if two are used) must be matched or their difference compensated for; no systematic or random errors other than those already considered must arise when the beam is passing through one cell; the phototube, source flicker, and electrometer-amplifier noises must be the only ones which are significant.

Optimization of instrumental conditions

The optimum value of any instrumental parameter, X, for measuring the theoretical minimum detectable sample concentration, C_{mt}, can be found in the usual way by differentiating the expression for C_{mt} with respect to X, equating to zero, and solving

$$\frac{dC_{mt}}{dX} = 0. \quad (13)$$

The slitwidth, W. By this procedure it is found that there is no optimum slitwidth for either a single- or a double-beam system, *i.e.*, a plot of C_{mt} *vs.* W indicates that C_{mt} decreases with increasing W until a minimum plateau is reached (Fig. 1); it is assumed in this and all other cases in this paper that the spectral bandwidth of the monochromator is considerably smaller than the half-intensity width of the absorption band—this is generally the case in ultraviolet–visible absorption spectrophotometry. However, even though no optimum slitwidth exists for molecular absorption spectrometry, there is an analytically useful slitwidth, W_u, which is defined as that slitwidth above which

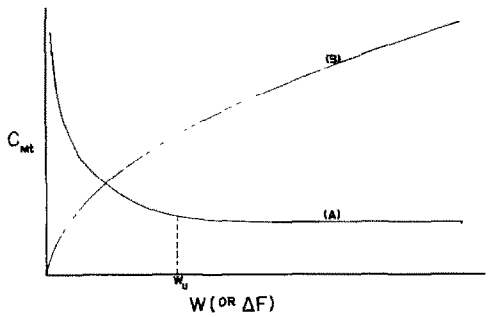

FIG. 1.—Typical plots of C_{mt} *vs.* W (Curve A) and C_{mt} *vs.* Δf (Curve B).

less than a 10% change in C_{mt} results with increase in slitwidth; it is assumed that the spectral band-width $R_d W_u$ covers only the absorption band being studied and does not exceed ~20% of the halfwidth of the absorption band.

The frequency-response bandwidth, Δf. Theoretically there is no optimum value of Δf (Fig. 1.); a plot of C_{mt} *vs.* Δf indicates that C_{mt} will decrease without limit as Δf is decreased. The frequency-response bandwidth can be decreased by use of an integration device or a time-averaging technique. However, it is seldom practical to use integration times much longer than 5 sec, because of drift in the light source or electronic system, and generally a time constant of about 1 sec is used.

Other instrumental parameters. No other instrumental parameters can be optimized in molecular absorption spectrophotometry. Indeed, of the other instrumental parameters, only phototube voltage is generally variable, and it is well-known that the signal-to-noise ratio (and hence C_{mt}) does not vary with phototube voltage as long as the voltage is sufficient to give a detectable signal and noise, and is below that at which regenerative ionization occurs in the phototube.

The theoretical minimum detectable sample concentration

Solving for C_{mt} from equation (12) results in

$$C_{mt} = \frac{1{\cdot}84\sqrt{k_D \Delta f (i_t + \gamma k_m W s I^\circ) + \Delta f [(\chi\gamma k_m W s I^\circ)^2 + \zeta^2 (i_t + \gamma k_m W s I^\circ)^2]}}{ab\gamma k_m W s I^\circ \sqrt{n}}, \tag{14}$$

for a single-beam d.c. electrometer-amplifier system. For a single- or double-beam a.c. electrometer–amplifier system, i_t drops out of the electrometer noise term in equation (14), and for the single-beam a.c. system, I° must be replaced by $I^\circ t$.

Now if the signal due to the light source is much greater than the value of i_t and if the slitwidth is set to some value near to or greater than W_u, then the shot noise term can be neglected, and the expression for C_{mt} can be greatly simplified, *i.e.*,

$$C_{mt} = \frac{1{\cdot}84\sqrt{\Delta f(\chi^2 + \zeta^2)}}{ab\sqrt{n}}. \tag{15}$$

Equation (14) can also be written as

$$C_{mt} = \frac{1{\cdot}84\overline{\Delta i_T}}{abi_0\sqrt{n}}, \tag{16}$$

where $\overline{\Delta i_T}/i_0$ is the ratio of r.m.s. noise to the signal due to radiation passing through the blank solution and is experimentally measurable. Equation (16) is very simple to evaluate and can be used even if the individual noise flicker factors χ and ζ are not known.

Practical minimum detectable sample concentration

The experimentally practical minimum detectable sample concentration, C_{mp}, can be[1–3] defined as that concentration resulting in an absorbance of 0·002, *i.e.*,

$$C_{mp} = \frac{0{\cdot}002}{ab}. \tag{17}$$

The limiting value of 0·002 is chosen on the basis of the smallest readable transmittance value on a null-type spectrophotometer. Of course, if the signal-to-noise ratio reaches the value given in equation (1) at absorbances greater than 0·002, then $C_{mt} > C_{mp}$, and the C_{mp} values will be erroneous. Usually, however, the signal-to-noise ratio will reach the value given in equation (1) at absorbances smaller than 0·002, and so $C_{mt} < C_{mp}$; in this case the sensitivity can be improved by scale expansion (as long as the conditions mentioned for C_{mt} are met).

EXPERIMENTAL

Measurement of the theoretical minimum detectable sample concentration, C_{mt}, can only be achieved experimentally if the transmittance scale is expanded electronically (precision spectrophotometry)[4] so that the transmittance reading error is negligible, and the instrumental noises are observable and significant.

Apparatus

A Beckman DU monochromator with hydrogen arc and tungsten filament lamps and power supply was used for all measurements. The Beckman amplifier system was not used. Instead, the output of a IP28 RCA multiplier phototube was fed directly into a high sensitivity electrometer (Model 610 BR, Keithley Instruments, Inc., Cleveland, Ohio). The electrometer output was detected by means of a potentiometric recorder (Model SR, E. H. Sargent and Co., Chicago, Ill.). The multiplier phototube was powered by a well-regulated power supply (Model 240, Keithley Instruments, Inc.).

The change in electronics was needed to achieve accurate measurements of signal-to-noise ratios. The separate phototube power supply set at a single voltage was used to minimize erratic phototube behaviour resulting from variations in the photo tubevoltage (the sensitivity on the null-type Beckman DU spectrophotometer is varied by changing the phototube voltage, whereas in our system the sensitivity was varied by changing the imput load resistor of the electrometer). To avoid errors due to mismatch or misalignment of the blank and sample cells, the cells used were selected to give a match within 1% on the tenfold expanded scale even when they were shifted into and out of position for measurement. The measurement electronics and hydrogen lamp used as light source were allowed to warm up for at least 1 hr before to minimize drift of the source radiance. To eliminate any small

errors due to drift in the light source, measurements of blank and sample signals were taken within 2 min of each other.

Reagents

The compounds used in this study were reagent grade and were phenanthrene,1,2-benzanthracene, and *p*-nitrophenol. Solutions of these compounds varying in concentrations from 10^{-1}–$10^{-10}M$ were prepared by successive dilution with ethanol. Absolute ethanol was distilled through a 6-ft vacuum-jacketed and silvered column with a reflux ratio of 20:1. The column was packed with 3/8-in. coil helices. Only the middle fraction was used.

RESULTS AND DISCUSSION

The values of the instrumental and spectral parameters used in equation (14) are listed in Table I. The molar absorptivities, a, for the compounds studied were calculated from the slopes of absorbance *vs.* concentration plots. The flicker factors, χ and ζ, were measured with *no* sample cell in the light beam. These values were used in equation (15) to calculate the theoretical minimum detectable sample concentrations C_{mt} [identical values of C_{mt} result from use of equation (14)]. Experimentally

TABLE I.—MEASURED VALUES OF EXPERIMENTAL PARAMETERS AND COMPARISON OF THEORETICAL (C_{mt}) AND PRACTICAL (C_{mp}) MINIMUM DETECTABLE SAMPLE CONCENTRATIONS FOR THREE ORGANIC COMPOUNDS*

Compound	λ, $m\mu$	a	γ, A/W	I°, $W/cm^2.ster.m\mu$	R_d, $m\mu/cm$	W_u, mm	C_{mt}, M	C_{mp}, M

p-Nitrophenol	312	1×10^4	$4{\cdot}1 \times 10^4$	$7{\cdot}7 \times 10^{-7}$	42·5	0·40(0·05)†	$6{\cdot}2 \times 10^{-8}$	$2{\cdot}0 \times 10^{-7}$

* Values of other measured instrumental parameters are as follows: $n = 4$; $k_m = (HT_t\Omega)/m^2 = 1{\cdot}0 \times 10^{-3}$ cm.ster; $b = 1{\cdot}00$ cm; $BM = 3{\cdot}51 \times 10^6$; $i_t = 9{\cdot}6 \times 10^{-11}$ A; $\Delta f = 1$ sec^{-1}. The evaluation of these parameters and of γ and I° is described by Cetorelli and Winefordner.[18] The values of χ and ζ were measured as described and were both approximately 5×10^{-4} sec$^{1/2}$. The value of e is $1{\cdot}6 \times 10^{-19}$ C.

† Values in parentheses are for the full intensity of the lamp. The other values were used when a neutral density filter was used to attenuate the intensity.

measured values of C_{mt} [obtained by using equation (1)] agreed with the calculated values to within $\pm 15\%$. This demonstrates that systematic and random errors due to cells and cell positioning were negligible (the major source of error is in the flicker factors, which are measured to about $\pm 15\%$).

Calculated values of C_{mt} and C_{mp} are given in Table I. The value of n, equation (1), was arbitrarily taken to be 4. Of course, if more measurements of the sample and blank signals are made, n is increased and C_{mt} will be even smaller although the rate of decrease of C_{mt} with increase in n is slow for $n > 10$. It should also be noted that the values of C_{mt} in Table I are all lower than the C_{mp} values and therefore if well-matched cells and experimental techniques are used, the theoretical minimum detectable sample concentrations can be measured confidently if scale expansion techniques are used.

It was experimentally verified that the signal-to-noise ratio (and C_{mt}) was essentially independent of the applied phototube voltage (as long as the voltage was below the point of regenerative ionization). Therefore the same signal-to-noise ratio and the same sensitivity of measurement are obtained over a wide range of applied phototube voltages. This result is of significant interest when it is realized that some instruments, *e.g.*, the Beckman DU, control the instrumental sensitivity by simply varying the phototube voltage.

It is also interesting to note that essentially the same value of W_u results for all wavelengths in the ultraviolet–visible region. This would seem to indicate that a monochromator with fixed slits, about W_u in width, would be quite ideal for quantitative spectrophotometric measurements and should be relatively inexpensive to purchase. Again it should be stressed that it is assumed that the spectral bandwidth corresponding to W_u, *i.e.*, $s = R_d W_u$, is assumed to be much smaller than the half-intensity width of the absorption band of the species being measured. Fortunately the value of W_u is near W_{min}, the minimum resolving-power slitwidth of the monochromator[19], and so good spectral resolution should also be obtained. Of course, if a more intense source were used, then W_u would be even smaller, and closer to W_{min}, and in fact C_{mt} would be independent of W_u, *i.e.*, if I° is large, then the phototube (shot) noise is insignificant compared to the other noises [see equation (15)]. It should also be noted that at high values of I°, the ratio $\overline{\Delta i_T}/i_0$ in equation (16) is constant for all wavelengths and phototube voltages. Therefore, C_{mt} for two different compounds under the same instrumental conditions is dependent *only* on the other absorptivity, a.

The smallest useful value of C_{mt} which can be used with confidence will result when the wavelength of the monochromator is adjusted to the absorption peak for which a is maximum, Δf is about 0·1 sec^{-1}, n is about 10, and the monochromator slitwidth is $\geqslant W_u$. With a given instrumental system, it is difficult to vary χ and ζ but if a more stable system were used such that χ and ζ were smaller, then C_{mt} would, of course, be smaller.

Acknowledgement—This research was carried out as a part of a study on the phosphorimetric analysis of drugs in blood and urine, supported by a grant from the U.S. Public Health Service (GM 11373–03).

Zusammenfassung—Es wird ein Ausdruck für das Signal-Rausch-Verhältnis bei der Präzisions-Absorptionsspektrophotometrie von Molekülen in kondensierter Phase abgeleitet und zur Berechnung der theoretisch nachweisbaren Mindestkonzentration und zur Ermittlung der besten apparativen Meßbedingungen verwendet. Ein- und Zweistrahlgeräte werden berücksichtigt. Die theoretisch berechneten C_{mt}-Werte mehrerer organischer Moleküle werden mit den praktischen Nachweisgrenzen C_{mp} verglichen, das sind die Konzentrationen, die die Extinktion 0,002 geben. Solange die Strahlungsquelle intensiv genug und die Wurzel aus dem mittleren Signal-Rausch-Verhältnisquadrat der durch die Referenzlösung einfallenden Strahlung bekannt ist, ist der Ausdruck für C_{mt} sehr einfach und für jede Substanz mit bekanntem Extinktionskoeffizienten leicht zu berechnen. Der Einfluß apparativer Parameter auf C_{mt} wird ermittelt; nur die Spaltbreite am Monochromator, die Anzahl der Ablesungen für Probe- und Referenz-lösung und die Frequenz-Bandbreite des elektrischen Anzeigesystems haben einen wesentlichen Einfluß auf C_{mt} (bei einer gegebenen Wellenlängen-Einstellung am Monochromator).

Résumé—Une expression pour le rapport signal-bruit dans la spectrophotométrie d'absorption de précision de molécules en phase condensée a été établie et utilisée pour calculer la concentration minimale théorique détectable de l'échantillon ainsi que pour prévoir les meilleures conditions instrumentales pour la mesure. On considère les instruments à simple et double faisceau. On compare les valeurs théoriquement calculées de C_{mt} pour différentes molécules organiques aux concentrations minimales d'échantillon pratiquement détectables C_{mp}, qui sont les concentrations donnant une absorbance de 0,002. Tant que la source de radiation est intense, et que le rapport signal-bruit efficace est connu pour la radiation incidente passant à travers le témoin, l'expression de C_{mt} est extrêmement simple et aisée à évaluer pour

n'importe quelle substance donnée dont le coefficient d'extinction molaire est connu. On évalue l'influence des paramètres instrumentaux sur la valeur de C_{mt} et seuls la largeur de la fente du monochromateur, le nombre de mesures combinées de signaux témoin et essai et la largeur de la bande de réponse de fréquence du système d'électromètre de lecture ont un effet significatif sur la valeur de C_{mt} (pour n'importe quelle position de longueur d'onde donnée du monochromateur).

INORGANIC POLAROGRAPHY IN ORGANIC SOLVENTS—III*

ANALYTICAL APPLICATIONS OF METAL–ACETYLACETONATE COMPLEXES IN TOLUENE

B. K. AFGHAN, R. M. DAGNALL and K. C. THOMPSON
Chemistry Department, Imperial College, London S.W.7

(*Received* 6 *December* 1966. *Accepted* 20 *February* 1967)

Summary—Indium and palladium are determined polarographically with a dropping mercury electrode in a toluene phase, following extraction as the acetylacetonates from aqueous solutions containing 2–10 ppm of the metals (or 0·1–0·5 ppm with a greater ratio of sample volume to solvent volume). Of 31 elements examined, only Co(III), Cr(III), Cu(II), Fe(III), In, Mo(VI), Pd and Ti(IV) gave extractable complexes with reduction waves in the available potential range. Specificity for palladium is obtained by extraction at pH 0·5, and for indium at pH 9 in the presence of cyanide and ascorbic acid as masking agents.

THERE are few successful practical applications of inorganic polarography in organic solvents, and even fewer determinations in an organic phase following solvent extraction. They include the extraction of bismuth, antimony, copper, thallium, lead and indium diethyldithiocarbamates into chloroform,[1,2] the extraction of the 8-hydroxyquinoline and salicylaldoxime complexes of copper and lead[3] and the extraction of beryllium as the acetylacetonate.[4] The base electrolytes in these determinations were added in large excesses of some other solvent medium—methyl cellosolve/water, acetic acid, and dimethylsulphoxide respectively.

There has been no systematic study of complexes in organic solvents, and no attempt to use a simple generally applicable supporting electrolyte. Such studies would undoubtedly alleviate many of the problems associated with the aqueous polarography such as resolution of waves, sensitivity limitations and the effect of solution composition on half-wave potentials and diffusion currents.

Although masking agents may improve the resolution they often give rise to difficulties by causing a further change in the solution composition. In addition, most are too unselective in their action, and some of the more useful form complexes which are insoluble in water. A solvent extraction followed by polarography overcomes most of these difficulties by providing a solution of standard composition to which only a base electrolyte need be added to increase the conductivity of the solution. Selectivity can be obtained by suitable choice of solvent system, and an increase in sensitivity is possible through the extraction step.

Previous communications in this series[5,6] have dealt with ion-association systems, and it is the purpose of this paper to discuss the analytical applications of a chelating agent—acetylacetone. The poor selectivity of its reactions, the solubility of its complexes in organic solvents, and the negative potential at which it is itself reduced at the DME,[7] suggested that a polarographic examination would be worthwhile.

* Part II—*Talanta* 1967, 14, 239.

EXPERIMENTAL

Apparatus

An Elliot Polarograph Model 200 was used, with a dropping mercury electrode. Unless otherwise stated, the following operating conditions were used: potential sweep, 0·5 V/100 sec, drop time 4·1 sec, height of mercury reservoir 70 cm, mercury flow-rate 2·42 mg/sec, temperature 18° (approx), no damping or counter-current. An internal mercury pool anode was used, and samples were de-aerated by bubbling oxygen-free nitrogen through them. A mercury seal was used to prevent re-absorption of oxygen.

Reagents

Indium. Dissolve 0·5741 g of the metal in 5 ml of concentrated hydrochloric acid, and dilute to 500 ml. The solution is $10^{-2}M$.

Palladium. Dissolve 0·8866 g of the chloride in 10 ml of concentrated hydrochloric acid, and dilute to 500 ml. This is also $10^{-2}M$.

Acetylacetone. This was purified by the method of Steinbach and Freiser[9]—shake 1 l. of general purpose grade reagent with 100 ml of dilute ammonia (1 + 10) and then with two 100-ml portions of distilled water. Distil, and collect the fraction boiling at 136°. A 0·1*M* solution in toluene was used.

Lithium chloride. A 0·5*M* solution in methanol, prepared from the dried salt.

Buffer solution pH 9.

Complexes of Co(II), Co(III), and Cr(III) were prepared according to the methods of Starý.[8]

Extractions

Equal volumes (30 ml) of 0·1*M* acetylacetone solution in toluene and of an aqueous solution containing 2 ml of $10^{-2}M$ metal ion solution and 5 ml of $10^{-2}M$ aqueous acetylacetone (to prevent precipitation of metal hydroxides) were shaken together. The pH was controlled by the addition of acetic acid or ammonia solution, and checked with a pH-meter. The aqueous and organic phases were not mutually presaturated before equilibration, as the volume changes were negligible. After being shaken for about 1 min the two phases were allowed to separate. The organic phase was then transferred to a 50-ml standard flask containing 10 ml of 0·5*M* lithium chloride in methanol, and diluted to the mark with methanol. A 5-ml portion was transferred to the polarographic cell, along with mercury for the anode-pool, and deoxygenated for 5 min. Polarograms were recorded at an instrument sensitivity of 10 μA/full-scale deflection, over the available potential range.

Toluene was chosen as solvent because chloroform is too easily reduced at the dropping mercury electrode,[5] and benzene is toxic. Otherwise the conditions are those given by Starý.[8]

RESULTS

Polarographic behaviour of various metal ions in acetylacetone-toluene-methanol solutions

Table I shows the half-wave potentials of the polarographic waves obtained in the organic and in the aqueous phases after extraction. An examination of the aqueous phase after extraction with toluene showed that Cr(III), Cu(II), Mo(VI), and Ti(IV) were incompletely extracted, in agreement with the results of other workers.[8] Many of the elements which did not give waves were nevertheless extracted to some extent, which illustrates the increase in selectivity which can be obtained by the combination of solvent extraction and polarography. Of the ions extracted under the conditions described, waves were obtained only for the following: Cu(II), Fe(III), In, Mo(VI), Pd, and Ti(IV), because the formation of the complexes of Co(III), Cr(III) and Mn(III) requires special conditions, and the extraction equilibria for these and for Mo(VI) are reached very slowly. In consequence, it was decided to investigate more fully the reduction of indium and of palladium acetylacetonates and to develop selective methods for the determination of these metals. The development of methods for the determination of Cu(II) and Fe(III) was not considered worthwhile in view of the already large number of satisfactory methods for these elements. These preliminary findings were checked by using benzene as solvent, and similar results were obtained.

Determination of Indium and Palladium

Extraction pH

A series of solutions containing the metals, and covering the pH range 0–10 were prepared, extracted, and examined as already described. The polarograms obtained showed that the extraction was quantitative over the whole range for palladium, but

only between pH 6 and 9 for indium. The half-wave potential for palladium moved to more negative potentials with decreasing pH (from −0·70 to −0·78 V) and that for indium moved to more positive potentials (from −0·92 to −0·84 V).

A pH of 0·5 was chosen for further studies on palladium because no other ion is extracted at this pH,[8] and pH 9 was selected for determinations of indium to facilitate buffering of the solutions.

Solvents

These metals were also extracted by 0·1*M* solutions of acetylacetone in amyl acetate, isobutyl methyl ketone, chloroform and ethyl acetate. With neither metal (at the pH values chosen) did any of these solvents offer any advantages over toluene. Chloroform is itself reduced, with a wave at −1·0 V which tends to obscure the indium wave, and the other solvents produced maxima on the indium wave which could not be removed by the addition of cetyltrimethylammonium bromide or Methyl Red.

Acetylacetone concentration

The concentration of the ligand in toluene was varied over the range 1–500 × $10^{-3}M$. With both metals, the extraction was slow and incomplete, yielding elongated reduction waves, when the concentration of reagent was less than $10^{-2}M$. A slight shift in half-wave potential to more negative values was also observed with increasing ligand concentration. A concentration of 0·1*M* acetylacetone in toluene was chosen as being most suitable.

The effects of other parameters such as supporting electrolyte concentration and deoxygenation have been reported elsewhere.[5]

Procedure

Indium. Transfer by pipette 1–5 ml portions of indium solution (5 × $10^{-4}M$) into 100-ml separating funnels along with 2 ml of *ca.* $10^{-2}M$ aqueous acetylacetone, 5 ml of buffer solution (pH 9) and distilled water to give a volume of about 25 ml. Add 15 ml of the toluene reagent solution and shake for 1 min. Transfer the organic phase to a 25-ml standard flask containing 5 ml of 0·5*M* lithium chloride in methanol, and dilute to the mark with methanol. Deoxygenate a 5-ml portion of this solution for 5 min and record the polarogram. The height of the wave at −0·92 V *vs.* the mercury pool anode is proportional to the concentration of indium over the range 2–10 ppm (in the original solution). The relative standard deviation (9 results) for 4 × $10^{-5}M$ indium solution was 2·7%.

Palladium. The procedure is as for indium, except that the extraction is carried out at pH 0·5, obtained by the addition of concentrated hydrochloric acid and measured by pH-meter. The height of the wave at −0·78 V is proportional to the concentration of palladium over the range 2–10 ppm.

Extractions have also been made from up to 500 ml of aqueous solution containing the same amounts of the metals. Satisfactory results were obtained with the sensitivity thus increased to cover the range 0·1–0·5 ppm in the original solution.

Interferences

At pH 0·5 only palladium is extracted. The following elements, which are wholly or partially extracted by acetylacetone at higher pH, do not interfere in the determination of indium by this method: Al, Be, Ce(IV), Co(II), Cr(III), Cu(II), Fe(III), Ga, Mn(II), Mo(VI), Nb(V), Ni, Sc, Sn(II), Ti(IV), Tl(III), U(VI), V(V), Zn, and Zr. A 50-fold amount of palladium does not interfere in the determination of indium at the 5 × $10^{-5}M$ level.

Only Cu(II), Fe(III), Ti(IV) and Pd gave reduction waves in addition to indium, but the half-wave potential of the latter is sufficiently removed from the nearest of the others [Ti(IV) at −0·80 V] for there not to be any interference unless titanium is

present in very large amounts (the limit depending on the type of polarograph and its resolution). The waves of Cu(II), Ti(IV) and Pd may be eliminated by the addition of ascorbic acid and cyanide as masking agents, before the extraction. With warming, Fe(III) is also masked, though in the cold it is extracted as its acetylacetonate.

Reversibility

Plots of log $(i/i_d - i)$ *vs.* E made from the polarograms for solutions $4 \times 10^{-4}M$ in indium and palladium, were linear, with slopes giving values of n (the number of electrons in the electrode reaction) of 0·91 and 0·81 respectively. Conductivity measurements with a Philips PR9500 conductivity bridge and a normal conductivity cell showed that the solutions had a resistivity of 630 Ω-cm.

The determinations described are not the only ones that can be made using this particular system, although they are the most useful and easily applied. For example, the determinations of Cr(III) and Co(III) are also possible provided that the slow rate of formation of the complexes is accepted and, in consequence, the longer time required to carry out an analysis. The major advantage of the system is the ease with which a minor constituent may be separated, concentrated and determined, coupled with the short time required for the determination. Previously the determination of these metals was a lengthy and involved process in even relatively simple materials, *e.g.*, in the presence of Cd, Cu, Pb and Sn,[10] or in the presence of Cd, Cu, Pb and Zn.[11]

During the course of this study, benzoylacetone was also investigated as a possible extractant, and as an alternative to acetylacetone. However, the extraction of even copper and iron was very slow and it was considered that no advantage would be gained by its use.

Zusammenfassung—Indium und Palladium werden polarographisch mit einer Quecksilbertropfelektrode in Toluollösung bestimmt nach Extraktion der Acetylacetonate aus wäßrigen Lösungen, die 2–10 ppm der Metalle enthalten (oder 0,1–0,5 ppm mit einem größeren Verhältnis von Proben- zu Lösungsmittelvolumen). Unter 31 geprüften Elementen gaben nur Co(III), Cr(III), Cu(II), Fe(III), In, Mo(VI), Pd und Ti(IV) extrahierbare Komplexe mit Reduktionsstufen im zugänglichen Potentialbereich. Spezifität für Palladium erhält man durch Extraktion bei pH 0,5 und für Indium bei pH 9 in Gegenwart von Cyanid und Ascorbinsäure als Maskierungsmittel.

Résumé—On a dosé l'indium et le palladium par polarographie en phase toluénique avec une électrode à goutte de mercure après les avoir extraits, à l'état d'acétylacétonates, de solutions aqueuses contenant 2–10 p.p.m. des métaux (ou 0,1–0,5 p.p.m. avec un plus grand volume d'échantillon par rapport au volume de solvant). Des 31 éléments examinés, seuls Co(III), Cr(III), Cu(II), Fe(III), In, Mo(VI), Pd et Ti(IV) donnent des complexes extractibles avec des vagues de réduction dans le domaine de potentiel utilisable. On obtient la spécificité pour le palladium par extraction à pH 0,5 et pour l'indium à pH 9 en présence de cyanure et d'acide ascorbique comme agents de dissimulation.

DETERMINATION OF URANIUM IN ELECTRO-REFINED PLUTONIUM BY A COMBINED ION-EXCHANGE AND X-RAY FLUORESCENCE TECHNIQUE*

J. A. HAYDEN
Analytical Development Group, Rocky Flats Division, Dow Chemical Company, P.O. Box 888, Golden, Colorado 80401, U.S.A.

(*Received* 18 *January* 1967. *Accepted* 7 *February* 1967)

Summary—Uranium is separated from plutonium by adsorption on an anion-exchange resin from a concentrated hydrochloric acid solution and is eluted from the resin, collected on a disc of cation-exchange paper, and determined by X-ray fluorescence. The lower limit of detection is 2 μg of uranium, and 50 μg may be determined with a recovery of 98% and a standard deviation of 3·2 μg. In plutonium metal, 19 ppm of uranium were found, with a standard deviation of 2 ppm (6 results).

A METHOD was required for the determination of uranium as a trace impurity in electro-refined plutonium. The total impurity content in electro-refined plutonium is not expected to exceed 100 ppm. The techniques currently available for determining impurities in plutonium include optical emission spectroscopy, polarography, spark source mass spectrometry, and wet chemistry methods. Present optical emission and polarographic techniques lack the required sensitivity for the uranium determination. Plutonium-238 interferes with the uranium-238 determination by mass spectrometry. An ultraviolet fluorescence method for determining uranium, after separation from plutonium by fluoride precipitation, has been used successfully by our chemistry laboratory.

X-ray fluorescence techniques are generally not sensitive enough for trace analysis, and had not previously been considered for use in determining low-level impurities. Recent work reported by Spano, Green, and Campbell has shown, however, that X-ray fluorescence is capable of reaching the sensitivity needed.[1–3] They determined trace impurities in tungsten by adsorbing them on SA-2 cation–exchange paper, after preliminary separation from the tungsten matrix, and so concentrating the cations in a matrix that permits quantitative detection of microgram amounts of them by X-ray fluorescence. It seemed reasonable to suppose that this approach could be used for determining trace level uranium in plutonium.

EXPERIMENTAL

Apparatus

Ion-exchange separations were made on small polyethylene columns, 0·5 in. diameter and 3 in. long, containing 2 ml of the resin. The uranium was concentrated by filtering the solution through a 1-in. diameter disc of SA-2 paper. The filtering device shown in Fig. 1 is simple to prepare and can be discarded after use. A polyethylene bottle with a 1-in. o.d. screw cap is cut in two sections. A $\frac{7}{8}$-in. hole is cut in the cap, and the resin disc is placed inside the cap. The cap is screwed on the bottle, and the inverted bottle top is placed on the severed bottom. The solution is poured into the inverted top, caught in the severed bottom and returned to the beaker for refiltering.

* U.S. Atomic Energy Commission Contract AT(29–1)–1106.

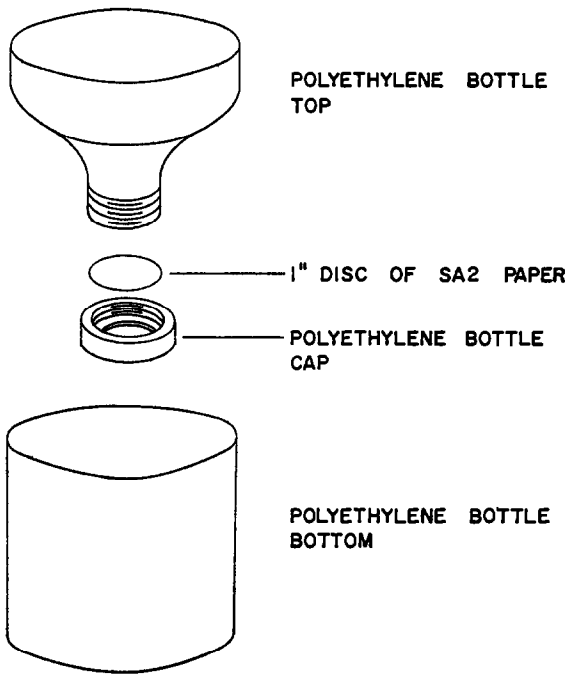

FIG. 1.—Disposable filtering device.

The loaded disc was mounted on a 1-in. i.d. pipe cap covered with 0·25 ml Mylar film and dried under an infrared lamp.

A Phillips–Norelco 100 kV constant-potential X-ray spectrograph was used to analyse the disc for its uranium content.

Reagents

Solution A. Concentrated hydrochloric acid containing 0·01 mole of ascorbic acid per l.

Solution B. A solution of pH 2 was prepared by mixing 1 ml of conc. hydrochloric acid with 1 l. of water. The pH was checked with narrow-range indicator paper.

Methanol, dried.

All reagents were chemically pure materials.

Ion-exchange resins

Anion-exchange resin. Dowex 1-X4, 100–200 mesh, was conditioned by washing with 10 column-volumes each of water, methanol, and solution A.

Cation-exchange resin. Dowex 50-X4, 100–200 mesh, was conditioned by washing with 10 column-volumes each of 3*M* hydrochloric acid, conc. hydrochloric acid, water, and solution B.

SA-2 paper (Reeve Angel Corporation, Clifton, New Jersey) is impregnated with Amberlite IR-120 cation-exchange resin in the sodium form. One-inch discs were cut from the sheets and conditioned with 20 ml each of 3*M* hydrochloric acid and water, returned to the sodium form by soaking in saturated sodium chloride solution, and finally rinsed with several ml of solution B.

Procedure

Dissolve a 1-g sample in 5 ml of conc. hydrochloric acid to which 10 mg of ascorbic acid have been added to keep plutonium in the tervalent state. Add a few drops of water to prevent precipitation of $PuCl_3$ if larger samples are dissolved. Pass the solution through the anion-exchange column. The resin adsorbs the uranium quantitatively while retaining only about 1 mg of plutonium. Wash the column with 20 ml of solution A to rinse the beaker and flush plutonium through the resin, and then with 20 ml of dry methanol. Elute the adsorbed ions with 20 ml of solution B. Pass the eluate through the cation-exchange column; both uranium and plutonium are adsorbed. Elute the cations from the column with 20 ml of solution A.

Pass this eluate through another column containing fresh Dowex 1 × 4, and use several ml of solution A to rinse the beaker and transfer the solution completely. Uranium is adsorbed and plutonium is not. Wash the resin with 20 ml of dry methanol, and again elute with 20 ml of solution B. Pass this eluate through an SA-2 cation-exchange paper disc five times to ensure complete adsorption of the uranium; the flow-rate is about 10 ml/min. Pass the eluate five times through a second disc to check that recovery is complete.

Mount the wet discs on the Mylar-covered plastic pipe caps, with the surface first contacted by the solution face down on the Mylar. Dry the discs with low heat from an infrared lamp, cover them with two layers of Mylar film, and seal with a curtain ring and tape. Check the outside surface of the Mylar film, the curtain ring and the tape for contamination before removal from the hood. Put the mounted disc in the sample chamber of the X-ray unit for analysis.

Instrument parameters are as follows:

1. Tube	Tungsten
2. Power	50 kV, 33 mA
3. Crystal	LiF
4. Detector	Scintillation, 875 V
5. PHA	Base Line 10·5 V, Window 16 V
6. Goniometer	26·14° $U_{L\alpha 1}$ 27·50° Background

Prepare a standard curve by carrying a set of standard solutions through the procedure. Plot intensity ratios (I_U/I_{bg}) *vs.* concentration on linear graph paper for the 0–300 μg range. At higher concentration ranges (1000–4000 μg) use semi-log paper. The intermediate range should be avoided for reasons that will be discussed later.

DISCUSSION

The strongest uranium line that can be excited with the 100 kV spectrograph is the first-order $L_{\alpha 1}$ line at $2\theta = 26{\cdot}14°$. The first-order plutonium $L_{\alpha 1}$ line falls at $2\theta = 24{\cdot}92°$. Since both lines are first-order, pulse height discrimination cannot be used to eliminate interference from plutonium. Prior removal of gross amounts of plutonium is necessary if microgram quantities of uranium are to be detected. Plutonium(III) can be separated from uranium(IV) by adsorption of the uranium on an ion-exchanger.

Ascorbic acid was used as the reducing agent because it effectively reduces plutonium to the tervalent state and keeps it there without introducing foreign cations into the system. The concentration of ascorbic acid was varied from 0·01 to 0·2*M* without adversely affecting the analysis. Since plutonium(III) is formed in the dissolution step, the ascorbic acid is needed primarily to prevent auto-oxidation. A 0·01*M* concentration of it was adequate.

After the uranium is loaded on the anion–exchange column the concentrated acid must be removed; this can be done with methanol. Uranium can then be eluted from the anion column and loaded onto the cation–exchange resin with a solution at pH 2. Figure 2 shows the elution curve from Dowex 1 × 4 with this element. Other techniques for eliminating the concentrated acid were investigated. Evaporation after elution of the uranium from the column was both time-consuming and inconvenient. Neutralizing the acid with dis-iopropylamine was tried in the hope that the cation formed would be too large to compete with uranium for exchange sites on the resin, so making use of the principle of ion-exclusion. Unfortunately, it did compete and the uranium exchange capacity was reduced. Washing the acid from the column with acetone was not efficient and created problems with bubble formation in the column. The best method was the methanol wash which effectively removed the acid from the column without eluting uranium or interfering with subsequent steps.

The extent of separation that can be achieved is shown in Table I. A separation factor of $10^{2{\cdot}5}$ can be obtained on the first pass through the Dowex 1 column and a separation factor of 10^5 when a double separation is used.

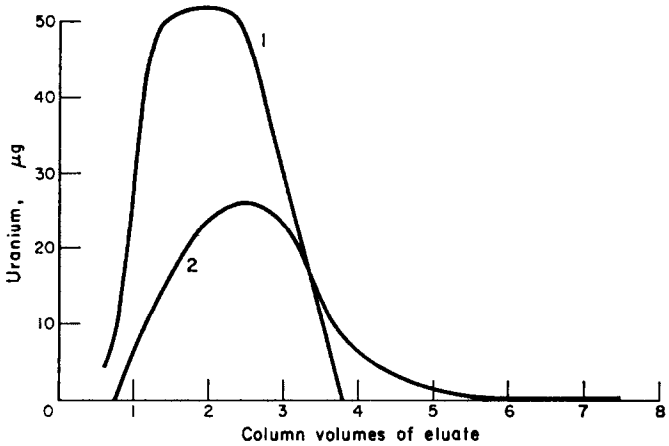

FIG. 2.—Elution curves.
1. Uranium from Dowex 1 with eluent at pH 2.
2. Uranium from Dowex 50 with conc. HCl.

TABLE I.—SEPARATION OF PLUTONIUM FROM URANIUM BY ANION-EXCHANGE IN A CHLORIDE SYSTEM

Single separation		Double separation	
Pu added, μg	Pu not separated, μg	Pu added, μg	Pu not separated, μg
$9{\cdot}45 \times 10^5$	6×10^2	$9{\cdot}39 \times 10^5$	10
$9{\cdot}51 \times 10^5$	5×10^2	$9{\cdot}45 \times 10^5$	5
$9{\cdot}33 \times 10^5$	7×10^2	$9{\cdot}61 \times 10^5$	5
$9{\cdot}56 \times 10^5$	7×10^2	$9{\cdot}96 \times 10^5$	10
$9{\cdot}76 \times 10^5$	5×10^2	$3{\cdot}96 \times 10^5$	10

For the double separation the two cations eluted from the first Dowex 1 column can be loaded on the second Dowex 1 column by evaporating the solution to incipient dryness and taking up the cations in conc. hydrochloric acid, or by loading the cations on Dowex 50 resin and eluting them with the desired volume of conc. hydrochloric acid.

The second method was selected, since the first is time-consuming and inconvenient. Figure 2 also shows the elution curve for uranium from Dowex 50 with 11·7*M* hydrochloric acid.

Ion-exchange paper

After double separation the plutonium remaining in solution (about 10 μg) is well below a level that would interfere (>300 μg), and the uranium can then be concentrated on the cation-exchange disc. The disc is the size of the X-ray beam striking the sample, weighs about 55 mg and consists of about 50% paper–50% IR 120 cation-exchange resin (Na^+).

The theoretical capacity of SA-2 paper is about 2 m-equiv/g.[1] A 1-in. disc of the paper (55 mg) should have a theoretical capacity of 0·11 m-equiv. or about 6,000 μg of

uranium(IV). The working capacity of the resin discs was established by filtering a solution containing up to 6000 μg of uranium five times through an SA-2 disc and then fives times through a fresh disc. The uranium contained on the second disc indicated the amount not adsorbed by the first.

Under the conditions used, the maximum working capacity of the 1-in. disc was about 4000 μg.

The pH of the loading solution was selected on the basis of Campbell's report[1] which indicates that below pH 1 hydrogen ion competes to some extent with metal ions

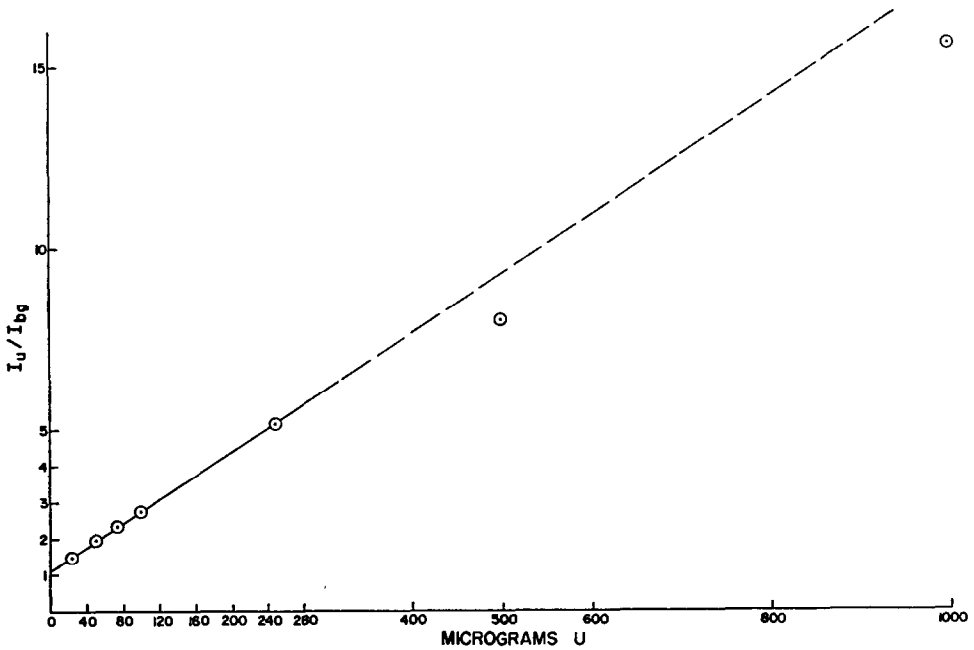

FIG. 3.—I_U/I_{bg} *vs.* amount of U—linear plot.

for available exchange sites whereas above pH 3 some metal ions tend to precipitate. He encountered no difficulty with solutions at pH 2.

Campbell[1] reported that 80% of the cation present (Co) was adsorbed during the first filtration, and quantitative adsorption was accomplished in 3–5 filtrations. Similar behaviour occurred with 100 μg of uranium, about 80% of the amount present being adsorbed at each pass; when 2000 μg of uranium were used, 96% was recovered on the first disc in five passes.

Papers were dried under low heat from an infrared lamp. Oven drying involved more handling, and the disc had a tendency to curl around the edge. Acetone will dry the disc by removing water without eluting uranium, but does not always completely remove the moisture.

The relationship between the amount of uranium on the paper and the intensity ratio (I_U/I_{bg}) varies, depending on the concentration. The relationship is directly proportional from 0–300 μg of uranium and for larger amounts is non-linear due to self-absorption of the uranium radiation (Figs. 3 and 4).

All results in this report were obtained by analysis of one side (bottom) of the disc. Uranium radiation is relatively hard and not significantly absorbed by the paper.

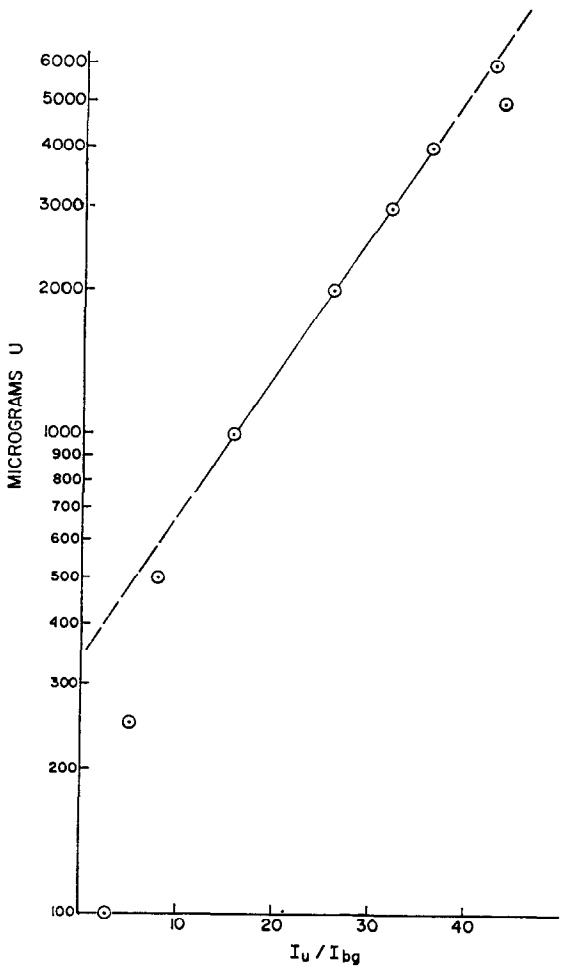

FIG. 4.—I_U/I_{bg} *vs.* amount of U—semi-logarithmic plot.

When both sides of a disc loaded with 50 μg of uranium were analysed no difference in the intensity of uranium radiation could be detected; however, for the soft radiation coming from low-atomic-number elements, absorption by the paper would be significant and placement of the disc for analysis would become a factor.

Interferences

The method is designed for ultra-pure plutonium. In such material the total content of impurities is not expected to exceed a few hundred ppm. Low concentrations of cations that might be present will not interfere with the uranium analysis. For less pure material the effect of other cations must be considered. The disposition of other cations present at the beginning of the analysis would be as follows.

The alkali metals, alkaline earths, rare earths, aluminium, nickel, yttrium and thorium are separated from uranium along with the plutonium. These thirty elements were not tested; however their adsorption characteristics on Dowex 1 X4 resin from conc. hydrochloric acid have been established by other workers.[4]

Chromium, iron, cobalt, copper, and zinc were tested qualitatively. They accompany uranium to varying degrees. If present in large amounts, they would interfere by using up exchange sites on both the anion- and cation-exchange resins. The degree of interference would have to be determined for specific concentrations.

Gallium and iron were tested, and found to be adsorbed by Dowex 1 and Dowex 50; however, they are not eluted from the cation-exchange resin with conc. hydrochloric acid. Though they do not follow uranium through the analysis, large amounts will interfere by competing with uranium for exchange sites on the resin columns. Gold was not tested but would be expected to interfere in the same manner as gallium and iron.[4,6]

Zirconium, hafnium, and neptunium were not tested, but their distribution coefficients, measured by Kraus and Nelson,[4] indicate that they would accompany uranium. Absorption of characteristic uranium radiation by these elements must be considered if the total cation content on the disc exceeds 0·005 m-equiv. (300 μg of uranium).

Three common anions, sulphate, nitrate, and fluoride, were tested to determine their effect on the analysis. In conc. hydrochloric acid, small amounts of sulphate (<0·15 m-equiv/ml) have no effect on the retention of uranium by the anion-exchange resin. The uranium solution to be passed through the SA-2 paper can be adjusted to pH 2 with sulphuric acid without hindering the uranium adsorption. Recovery of 50 μg of uranium was complete when the acidity was adjusted from pH 7 to pH 2 with sulphuric acid.

Small amounts of nitrate in conc. hydrochloric acid hinder the uranium–plutonium separation on the anion-exchanger by oxidizing plutonium(III) to the plutonium(IV). Additional ascorbic acid must be used to counteract oxidation by nitrate. Uranium (50 μg) was completely adsorbed by SA-2 paper from nitric acid solution at pH2.

Small amounts of fluoride (<0·15 m-equiv/ml) in conc. hydrochloric acid have no effect on the anion-exchange adsorption of uranium, but fluoride drastically interferes with the sorption of uranium by the cation-exchanger from pH 2 solutions. The uranium loss from the SA-2 paper was 75% when the pH was adjusted from 7 to 2 with hydrofluoric acid.

RESULTS

Six solutions, each containing 50 μg of uranium only, were carried through the entire procedure and the discs counted twice at each goniometer setting. The average values were used to calculate the amount of uranium present. The results are summarized in Table II. Precision data were obtained from six samples cut from a piece of

electro-refined plutonium. The results are listed in Table III. Accuracy data were acquired on five pieces cut from an electro-refined metal sample, which were spiked with varying amounts of uranium. The results are listed in Table IV. The minimum detectable amount, taken as three times the standard deviation of a blank sample, was 1–2 μg of uranium. The upper limit was 300 μg. Above this level self-absorption effects must be taken into account and higher uranium concentrations might best be determined by another procedure.

OTHER APPLICATIONS

The procedure could probably be used for the determination of zirconium and hafnium in plutonium. Plutonium(IV) forms an anionic nitrate complex which can be separated from elements that do not form nitrate complexes[7] by adsorbing it on an anion-exchange resin from 8*M* nitric acid. The separated elements could then be concentrated on SA-2 paper after removal of the nitric acid. The nitrate separation procedure is currently used at several AEC laboratories in conjunction with optical emission spectroscopy for determining common impurities. It could conveniently be adapted for use with ion–exchange paper and X-ray fluorescence techniques. An attempt to use the papers in infrared and ultraviolet analysis was unsuccessful.

Preliminary tests with neptunium indicated that the papers could be used in conjunction with radiochemical analysis. Gamma-emitting isotopes can be concentrated on the paper and determined with a scintillation detector. Experiments with SB-2 anion–exchange papers in conc. hydrochloric acid were moderately successful in that adsorption of the neptunium anionic chloride complex was directly proportional to the concentration of neptunium in the solution. It was not, however, quantitative.

CONCLUSION

The determination of trace amounts of uranium by X-ray fluorescence can be accomplished with good precision and accuracy. The sensitivity of X-ray fluorescence as an analytical tool is effectively extended by the technique of concentrating trace impurities on ion–exchange paper.

Acknowledgement—The author would like to thank Dr. W. J. Campbell and his coworkers at the Bureau of Mines, College Park, Maryland, for sending reports on their work with ion-exchange paper. These reports were a valuable aid in the development of this method.

Zusammenfassung—Uran wird von Plutonium getrennt durch Adsorption aus konzentriert salzsaurer Lösung an einem Anionenaustauscher und wird vom Harz eluiert, auf einer Scheibe Kationenaustauscherpapier gesammelt und durch Röntgenfluoreszenz bestimmt. Die untere Nach-weisgrenze ist 2 μg Uran; 50 μg können mit einer Ausbeute von 98% und einer Standardabweichung von 3,2 μg bestimmt werden. In metallischem Plutonium wurden 19 ppm Uran gefunden mit einer Standardabweichung von 2 ppm (6 Ergebnisse).

Résumé—L'uranium est séparé du plutonium par absorption sur une résine échangeuse d'anions à partir d'une solution en acide chlorhydrique concentré puis élué de la résine, recueilli sur une rondelle de papier échangeur de cations et dosé par fluorescence aux rayons X. La limite inférieure de détection est de 2 μg d'uranium et l'on peut doser 50 μg avec une récupération de 98% et un écart type de 3,2 μg. Dans le plutonium métallique, on a trouvé 19 p.p.m. d'uranium avec un écart type de 2 p.p.m. (6 résultats).

SPECTROPHOTOMETRIC EXTRACTIVE TITRATIONS—IV*
DETERMINATION OF ZINC IN GERMANIUM DIOXIDE AND GERMANIUM CHLORIDE

AFTANAS GALÍK
Lachema, N.C., Kaznějov, Plzeň-North, Czechoslovakia

(*Received* 5 *January* 1967. *Accepted* 13 *February* 1967)

Summary—A simple and selective determination of zinc in germanium chloride and germanium dioxide is described. The sample is dissolved in sodium potassium tartrate solution and zinc is titrated spectrophotometrically at 532 mμ with a dithizone solution in carbon tetrachloride without discarding the organic phase. Interfering ions such as Bi(III), Cu(II), Cd(II), Co(II), Ni(II), Pb(II), Sn(II), Fe(II), Fe(III), Mn(II) and Tl(I) are masked with bis(2-hydroxyethyl)dithiocarbamate. The detection limit is $3{\cdot}23 \times 10^{-5}$% of zinc and this may be lowered by taking a larger sample and by performing the analysis in a closed system. A simplified technique, consisting of the simultaneous titration of the sample and blank, is described.

IN PART III[1] the determination of silver and copper with dithizone was described. The procedure was selective because the dithizonates of these elements have extraction constants much higher than those of most other dithizonates. The present paper deals with the spectrophotometric extractive titration when the extraction constant is much less favourable *viz.*, zinc with dithizone. The conditions—pH, masking agent, wavelength, *etc.*—must be chosen so that the elements which form more stable dithizonates are not titrated at all and those that form less extractable dithizonates are titrated only partially, if at all.

It is preferable if these conditions allow the application of the procedure to the determination of zinc in germanium dioxide and germanium chloride without the separation of the matrix, because the separation procedures generally used may lead to contamination of the sample or to loss of zinc.

The dissolution of samples in sodium potassium tartrate solution was chosen because tartrate ion successfully prevents the precipitation of germanium dioxide but does not significantly affect the extraction of zinc with dithizone. Another advantage is the possibility of purifying the tartrate solution with dithizone, thus lowering the value of the blank. The limiting circumstance is that only hexagonal GeO_2 can be dissolved in this way. The use of tartrate medium determines the pH range for titration as 8–9.[2]

Bis(2-hydroxyethyl)dithiocarbamate (diethanoldithiocarbamate) was chosen as a masking agent for other metal ions which would react with dithizone. It has been used, in conjunction with cupferron to remove iron and copper, to make the determination of zinc with the dithizone single colour method very selective.[3] This method, modified by the use of sodium sulphide for stripping the excess of dithizone, was found to be the most selective of seven methods of zinc determination.[4] Thus, though it might seem that the application of spectrophotometric extractive titration

* Part III—*Talanta*, 1966, **13**, 1169.

to this determination is pointless, this technique may simplify the whole procedure, because stripping of excess of dithizone is not necessary and consequently a lower contamination hazard may be expected.

EXPERIMENTAL

The apparatus and common reagent solutions have been described previously[1,2,5]; only solutions and modifications not described earlier are listed below.

Apparatus

Titration assembly. Titrations were performed in titration cells similar to those described earlier,[5] but with the cell holder adapted for the Zeiss Universalspektrophotometer VSU—1 (Zeiss, Jena), which was used for measurement of the absorbance.

Reagents

Sodium potassium tartrate solution, 20% w/v. Purify with dithizone as described earlier.[2]

Masking solution. Add dropwise 3·5 g of carbon disulphide to 6 g of diethanolamine in 120 ml of methanol, keeping the solution cool, and dilute to 200 ml with water. Purify this solution in the same manner as the tartrate solution.

Hydrochloric acid, transistor grade.

Dithizone, 10^{-4} *to* 5×10^{-5} *M*. The solution in twice-distilled carbon tetrachloride was purified as required.[6]

Standard zinc solution. Dissolve 0·100 g of zinc in hydrochloric acid, dilute to 1 l. and then dilute this solution 50-fold immediately before use. Keep the dithizone solution in a quartz bottle, and all other solutions in polyethylene bottles.

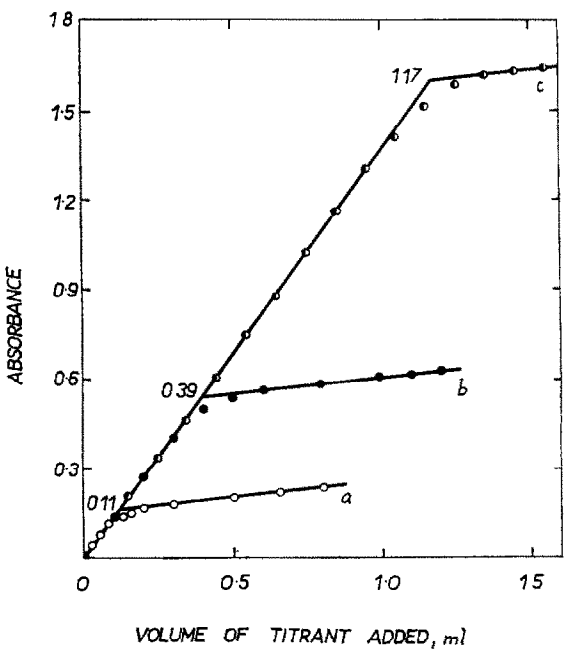

FIG. 1.—Titration of zinc with $10^{-4}M$ dithizone in CCl_4.
Curve *a*—blank titration.
Curve *b*—titration of 2-g sample of GeO_2.
Curve *c*—titration same sample as for *b*, but with 2·50 μg Zn added.

Procedure

Analysis of samples. Dissolve 2 g of the germanium dioxide or tetrachloride sample in 50 ml of sodium potassium tartrate solution in a 100-ml quartz beaker. Add 3·00 ml of the masking solution and adjust to pH 8–9 (pH paper) with few drops of ammonia solution or hydrochloric acid added from a polyethylene pipette. Transfer the solution into one of the titration cells containing 5–10 ml of

carbon tetrachloride. Titrate extractively with dithizone, using a microburette. Shake for 2 min after each addition of titrant and measure the absorbance at 532 mμ against carbon tetrachloride shaken with 50 ml of tartrate solution. Plot the absorbance *vs.* volume of dithizone added, so obtaining the titration curve. The shape of the curve is similar to that for titration of cadmium, see Part I[5] and Fig. 1. Note the consumption of dithizone, *a* ml.

Blank. Carry out the same procedure without the sample. Note the consumption of dithizone, *b* ml.

Standardization. Add 2·00 ml of standard zinc solution (4·00 μg of zinc) to 50 ml of tartrate solution in a 100-ml quartz beaker and mix for the time taken to dissolve the samples. Add 3·00 ml of the masking solution and titrate as described above. The volume of dithizone found, *c* ml, corresponds to the sum of the zinc added and the blank.

Calculation of results. The zinc content, *X*, in the sample is given by the relation:

$$X = \frac{(a-b)}{(c-b)} \cdot \frac{4 \times 10^{-4}}{\text{Sample weight}} \%,$$

where the sample weight is expressed in g.

RESULTS AND DISCUSSION

Selectivity

Because the stripping of excess of dithizone, a step used by Margerum and Santacana,[4] was omitted, it was necessary to check the selectivity. Solutions of sodium potassium tartrate containing known amounts of zinc and other metals were titrated in the presence of diethanoldithiocarbamate as described above. The results were compared with those obtained for pure solutions of zinc. From the results shown in Table I it may be concluded that the titration of zinc by this procedure is highly selective; bismuth, copper, cobalt, nickel, cadmium, lead, iron(II), and (III), manganese, thallium and tin(II) do not interfere. Other metals such as mercury and silver which form dithizonates would not be expected to interfere.[7] Indium is not extracted to any significant extent over the pH range used.[2]

TABLE I.—SELECTIVITY OF THE TITRATION OF ZINC

Zinc present, μg	Zinc found, μg	Difference, %	Other metals present, μg
3·58	3·66	+2·2	2·57 Cu
3·58	3·64	+1·7	45 Cu
3·58	3·55	−0·8	90 Cu
3·58	3·58	0	100 Cd
3·58	3·78	+5·6	200 Ni, 200 Pb and 100 Bi
3·58	3·42	−4·5	200 Co, 200 Cd and 90 Cu
7·16	7·80	+9	200 Mn, 200 Ni
7·16	7·40	+3·4	200 Tl, 200 Bi
7·16	6·56	−8·4	200 Mn, 200 Tl and 200 Sn
7·16	6·80	−5	200 Fe(II) and 200 Ni
7·16	7·60	+6·2	90 Cu, 200 Fe(III)

The selectivity was compared with that of the single colour zinc determination by extraction with an excess of dithizone at pH 8–9. Instead of sodium sulphide, dilute aqueous ammonia was used as stripping agent. Serious interference from copper and cadmium was observed, emphasizing the advantages of the titration procedure.

* Blank value and sample content subtracted.

Recovery of standard additions

Because of the lack of germanium dioxide or germanium chloride with a known zinc content the proposed titration procedure was checked by standard additions to samples of which the zinc content was determined by this procedure. The standard additions were made to analysed samples before their dissolution. Results of these experiments given in Table II show the precision of the method.

Sensitivity

During the analyses involving standard additions, blank values were obtained. The standard deviation of the blank was found from 20 results to be 0·305 μg of zinc. Consequently, the detection limit is 0·7 μg of zinc, *i.e.*, 3×10^{-5}% of zinc for a triplicate analysis of a 2 g sample and triplicate blank determinations. This high value is probably due to all the experiments being performed in a technological laboratory under conditions where it was not possible to apply the enclosed system[8] and so keep the blank value low. It is possible to lower the detection limit by increasing the sample weight, and this is especially easy in the case of germanium chloride.

Simultaneous titration of the blank and sample

The titration described takes about 30 min (if 5 points on each branch of the titration curve are necessary to establish the end-point. Because titration of the blank takes about the same time, an attempt was made to titrate sample and blank simultaneously.

Procedure. Dissolve 2 g of the sample in 50 ml of sodium potassium tartarte solution in a 100-ml quartz beaker, add 3·00 ml of masking solution and adjust the pH of the solution to 8–9. Prepare the blank by mixing the same volumes of reagents for the same length of time. Transfer both solutions into titration cells and add to them the same volumes of carbon tetrachloride (5 to 10 ml according to the zinc content expected). Titrate with dithizone solution by adding precisely the same volumes of titrant to both cells. After each addition shake for 2 min and, when the organic phases have become clear, measure the absorbance of the sample against the blank, at 532 mμ. The absorbance does not change very much until the zinc in the blank is incompletely extracted. Then the absorbance increases, as the zinc in the sample is titrated until the end-point is reached, The titration volume is the volume between the first and the second breaks of the titration curve, typified by Fig. 2.

The simultaneous titration of sample and blank takes only 45 min, compared to 1 hr when the titrations are performed separately, and results in a lower contamination hazard and eliminates most of the error connected with changes of contamination hazard during the analysis.

There are also other advantages of the simultaneous titration technique. When germanium dioxide is to be analysed, the dissolution of the sample is performed simply by mixing the sample with sodium potassium tartrate solution at a pH previously adjusted to 8–9. During the dissolution essentially no change of pH occurs, so it is evident that the pH of the blank and sample solutions are the same, and hence there is the same distribution of free dithizone between the aqueous and organic phases in both cells. Because only the difference in absorbance is measured, the slope of the titration curve after the end-point must be zero.

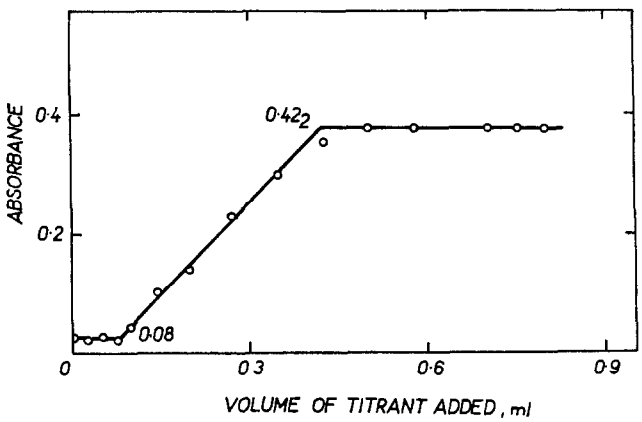

FIG. 2.—Simultaneous titration of zinc in GeO_2.

In the analysis of germanium tetrachloride, neutralization of the hydrochloric acid liberated during dissolution is necessary. Thus neither the same pH nor the same distribution of free dithizone in both cells is to be expected. When the sample and blank are titrated independently, the equation of the titration curve sufficiently far after the end point may be written as follows:

$$A = k \cdot \frac{m_{H_2Dz}}{V_{org}} \cdot \frac{1}{\left\{1 + \frac{V_{H_2O}}{V_{org}} \cdot \frac{K_{HA}}{q[H]}\right\}} + A_{Zn(HDz)_2}$$

where k is the product of the length of the light-path and the molar absorptivity of dithizone at 532 mμ, m_{H_2Dz} is the number of moles of excess of dithizone added after the end-point, V_{H_2O} and V_{org} are the volumes of the aqueous and organic phases respectively, K_{HA} (2×10^{-5}) is the acid dissociation constant of dithizone,[9] q($1{\cdot}1 \times 10^4$) is the distribution coefficient of dithizone between water and carbon tetrachloride,[9] $A_{Zn(HDz)_2}$ is the absorbance of the zinc dithizonate, and [H] is the concentration of hydrogen ions in the aqueous phase. As the pH of the solution may vary from 8 to 9 in the procedures described, the slope of the titration curve after the end-point may

vary from about 0·5 k/V_{org} for pH 8 to about 0·1 k/V_{org} for pH 9. If simultaneous titration is used, the slope of the titration curve after the end-point may vary over the range $\pm 0{\cdot}4\ k/V_{org}$, and if it is $<0{\cdot}1$ simultaneous titration gives better location of the end-point. The saving of time, however, may lead to preference of simultaneous titration even for zinc in germanium tetrachloride. Simultaneous titration may fail if the zinc content is so low that no distinct break appears on the curve after the blank has been titrated.

Acknowledgement—The author thanks Docent Dr. Ing. H. Leopold for his kind help in preparation of the manuscript.

Zusammenfassung—Ein einfaches und selektives Verfahren zur Bestimmung von Zink in Germaniumchlorid und Germaniumdioxid wird beschrieben. Die Probe wird in Natriumkalium tartratlösung gelöst und Zink spektrophotometrischen bei 532 nm mit einer Dithizonlösung in Tetrachlorkohlenstoff titriert, ohne daß die organische Phase abgetrennt wird. Störende Ionen wie Bi(III), Cu(II), Cd(II), Ni(II), Pb(II), Sn(II), Fe(II), Fe(III), Mn(II) und Tl(I) werden mit Bis(2-hydroxyäthyl)dithiocarbamat maskiert. Die Nachweisgrenze ist $3{,}23.10^{-5}$% Zink; sie kann gesenkt werden durch Verwendung einer großeren Probe und Ausführen der Analyse in einem geschlossenen System. Es wird auch ein vereinfachtes Verfahren beschrieben, das in der gleichzeitigen Titration von Probe und Blindprobe besteht.

Résumé—On décrit une méthode simple et sélective pour le dosage du zinc dans le chlorure et le bioxyde de germanium. On dissout l'échantillon dans une solution de tartrate de sodium et potassium, et titre le zinc par spectrophotométrie à 532 mμ avec une solution de dithizone dans le tétrachlorure de carbone sans séparation de la phase organique. Les ions gênants comme Bi(III), Cu(II), Cd(II), Co(II), Ni(II), Pb(II), Sn(II), Fe(II), Fe(III), Mn(II) et Tl(I) sont dissimulés par le dithiocarbamate de bis(2-hydroxyéthyle). La limite de détection est de $3{,}23 \times 10^{-5}$% de zinc et peut être abaissée en prélevant un échantillon plus important et en menant l'analyse dans un système clos. On décrit une technique simplifiée, consistant à titrer simultanément l'échantillon et le témoin.

FORMATION OF MIXED COMPLEXES IN THE EXTRACTION OF INDIUM WITH 1-(2-PYRIDYLAZO)-2-NAPHTHOL

YU. A. ZOLOTOV, I. V. SERYAKOVA and G. A. VOROBYEVA
Vernadsky Institute of Geochemistry and Analytical Chemistry, Academy of Sciences, Moscow, U.S.S.R.

(*Received* 10 *January* 1967. *Accepted* 18 *February* 1967)

Summary—A detailed study has been made of the extraction of indium into chloroform by 1-(2-pyridylazo)-2-naphthol (PAN). The rate of extraction is maximal if the PAN is added to the aqueous phase and is not added as its chloroform solution. The ratio of indium to PAN is 1:1 and the cationic complex can be extracted only if a suitable anion is present, such as acetate or chloride.

INDIUM forms a brightly coloured chelate compound with 1-(2-pyridylazo)-2-naphthol, and this compound may be extracted into chloroform and other solvents.[1,2] The conditions of formation of this compound and its spectrophotometric uses have been studied.[3–5] The compound was extracted from an acetate buffer, and an ethanolic or methanolic solution of PAN was added to the aqueous phase, the phases then being shaken for several minutes. The extraction mechanism of PAN complexes of indium and other metals has been insufficiently studied. According to the literature[3–9] indium and some other multicharged cations react with PAN in the ratio 1:2 or 1:1. Cheng and Goydish, however, assign the composition $In_2(PAN)_3$ on the basis of spectrophotometric molar ratio studies.[10] In a 1:1 or a 1:2 ratio however, PAN (a monobasic acid) would not be able to form a neutral complex with indium. In that case the complex would only be extractable into chloroform if a suitable anion formed a neutral ternary complex with it. This problem was investigated in the work described here.

EXPERIMENTAL

Reagents

Indium nitrate solutions were prepared, $2{\cdot}0 \times 10^{-3}$ and $3{\cdot}1 \times 10^{-4}M$, tagged with ^{114m}In and containing nitric acid (0·06*M*).

PAN solutions in chloroform or ethanol were accurately prepared from the solid reagent (Reanal, Hungary) the purity of which was checked by spectrophotometric titration with copper.[11]

Chloroform was purified by washing with small amounts of water, and distillation after drying over calcium chloride: 1% v/v of ethanol was added as stabilizer.

Buffer solutions included 0·2*M* sodium acetate adjusted to pH 5·9–7·0 with acetic acid or to pH < 5·3 with hydrochloric acid; hexamine at pH 6·1 (28·5 ml of 1*M* hexamine and 7·0 ml of 1*M* hydrochloric acid mixed and diluted to 100 ml); 0·2*M* potassium hydrogen phthalate and 0·05*M* citrate.[12]

Solutions of lithium chloride, sodium perchlorate and sodium nitrate were made from chemically pure reagents.

Procedure

The extractions were carried out in graduated 20-ml test-tubes with ground-in stoppers, the phases (5 ml of each) being mixed by a mechanical shaker in an air-bath thermostatically controlled at 25 ± 0·2°. Two methods were used for introducing PAN into the system. In the first, 0·5 ml of ethanolic PAN solution was added to a known volume of indium solution (up to 0·2 ml) and then diluted to 5 ml with buffer. An orange–red precipitate appeared in 30–60 sec; 10 min later, 5 ml of chloroform were added and the extraction was begun. In the other method, a known volume of

indium solution was diluted to 5 ml with buffer and 5 ml of a chloroform solution of PAN were added immediately, and the tube was shaken.

When the phases had separated, 0·1–0·2 ml of each phase was withdrawn and its indium content was determined by β-counting. The sample aliquot was evaporated to dryness on a steel planchette under an IR lamp, and the activity was measured with an end-window counter. In some cases the indium content of the organic phase was measured colorimetrically with an FEK-56 photocolorimeter (1-cm cells, No. 6 filter—maximum transmission at 540 mμ) against a reagent blank. A pH meter was used to measure the pH of the aqueous phase at equilibrium. The distribution ratio (E) or the degree of extraction (R) was calculated.

RESULTS AND DISCUSSION

Extraction from acetate solutions

Influence of the buffer. According to the literature[1–5] maximum formation of the PAN-indium complex occurs at pH 5·5–6·5 in acetate buffers. We studied the extraction of indium over this pH range, using acetate, biphthalate, citrate and hexamine

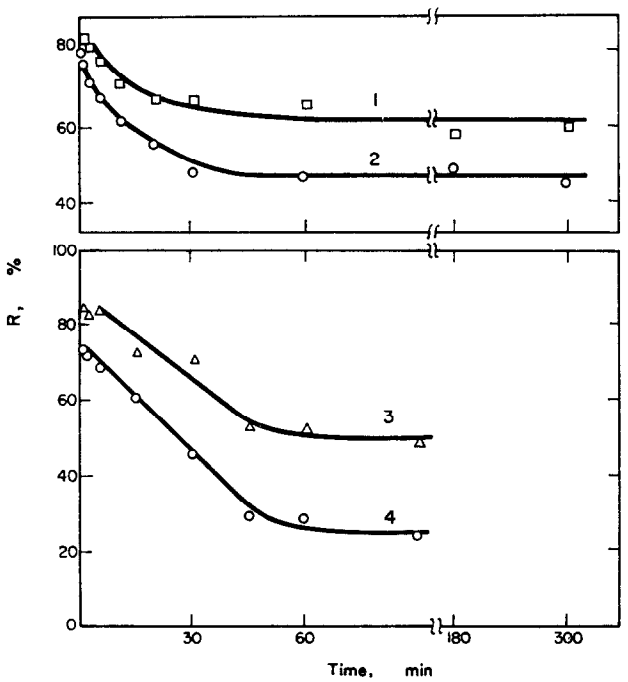

FIG. 1.—Rate of extraction of indium with PAN added in the aqueous phase.
1—$6 \times 10^{-3}M$ PAN, pH 6·0; *2*—$6 \times 10^{-3}M$ PAN, pH 5·3;
3—$1{\cdot}5 \times 10^{-3}M$ PAN, pH 6·0; *4*—$1{\cdot}5 \times 10^{-3}M$ PAN, pH 5·3.

buffers, adding ethanolic PAN solution to the indium, and extracting for 90 sec. Before extraction the concentration of indium in the aqueous phase was 2×10^{-5} M and of reagent $1{\cdot}5 \times 10^{-3}$ M. Indium was extracted best from acetate medium (90–92%), poorly from biphthalate (7–13%) and not at all from citrate media. When hexamine was used, 60% of the indium was extracted but phase separation was not very good and the radioactive measurements were unreliable; colorimetric measurements were also unsatisfactory, the absorbance of the organic phase falling rapidly with time, whereas the colour of the extract from acetate medium was stable for 1·5–2 hr. The nature of the buffer obviously influences the degree of extraction considerably, acetate being the best.

Rate of extraction. It was noticed that prolonged shaking resulted in a decrease in the degree of extraction. The kinetics of the extraction were therefore investigated with an initial indium concentration of $1{\cdot}2 \times 10^{-5}M$, PAN concentrations of $1{\cdot}5 \times 10^{-3}$, 6×10^{-3} and $3 \times 10^{-2}M$, and acetate buffers of pH 5·3, 5·9–6·0, 6·4 and 6·8. The kinetic curves obtained when PAN is added in ethanolic solution to the aqueous phase before the chloroform extraction are unusual—they pass through a maximum (Fig. 1). The precipitate initially produced is at first rapidly extracted to a high

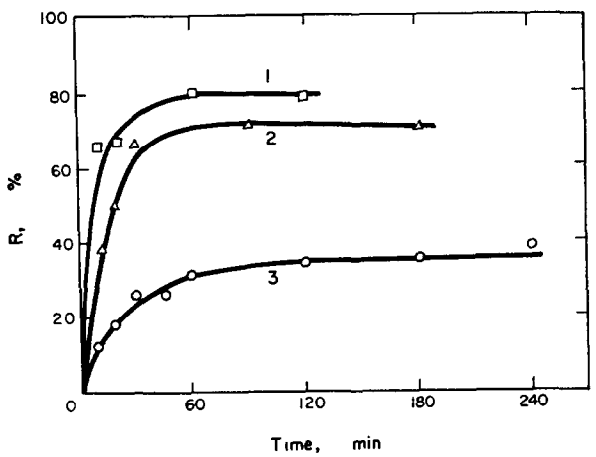

FIG. 2.—Rate of extraction of indium with various concentrations of PAN in chloroform, at pH 6·0.
1—$3 \times 10^{-2}M$; *2*—$6 \times 10^{-3}M$; 3—$1{\cdot}5 \times 10^{-3}M$.

degree by the chloroform, but after 1 or 2 min begins to return to the aqueous phase, true equilibrium being reached after about an hour. This means that in all previously published work the indium was extracted under non-equilibrium conditions and at maximum efficiency. When the PAN was added in chloroform solution, the curves were of the usual shape (Fig. 2); the rate of extraction was very slow, 1–2 hr being needed to reach equilibrium. At equilibrium, however, the degree of extraction is the same for both methods of introducing the reagent (Fig. 3). Alcohol was added to the chloroform-PAN extraction system to make conditions the same for both methods.

The higher the concentration of PAN, the faster the extraction equilibrium is established—2–3 hr for $1{\cdot}5 \times 10^{-3}M$ PAN, and less than 1 hr for 6×10^{-3} and $3 \times 10^{-2}M$ PAN. The rate of extraction seems to be independent of pH over the range 5·3–6·4 but becomes slower at higher pH values. Above pH 6·4 the radio-counting results are unreliable, especially when the equilibration times become very long.

Effect of pH and concentration of PAN. Figures 4 and 5 show the effect of pH on extraction when the PAN concentration is varied, but the acetate and indium concentrations are kept constant. The phases were shaken for 90 sec (Fig. 4) or 3 hr (Fig. 5). The results show that for short shaking-periods the degree of extraction is not much affected by the PAN concentration, and reaches a maximum at pH 6–7. For the longer shaking, the optimum pH is 6·0–6·4, and the extraction is strongly dependent on the concentration of PAN, at higher pH values the material balance is poor.

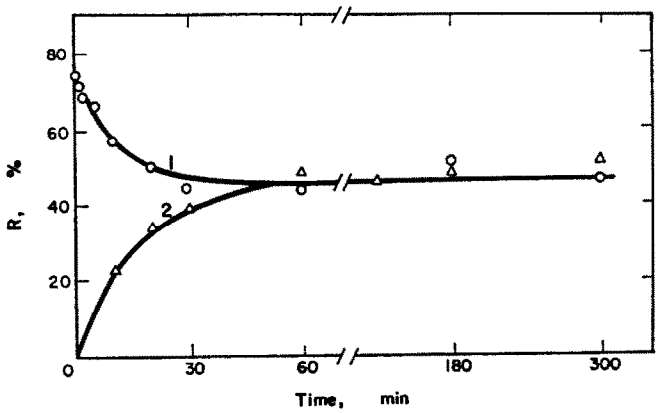

FIG. 3.—Rate of extraction with both methods of adding PAN.

Composition of the compound extracted

Because the extraction curves obtained under equilibrium conditions (shaking for 3 hr) show strong dependence of the degree of extraction on the PAN concentration, it is not possible to use continuous variation or mole-ratio methods to determine the ratio of the components in the compound extracted. Instead, a logarithmic method[13] (based on the shift of equilibrium) was used.

Figure 6 shows the log-log plot of distribution ratio *vs.* PAN concentration for

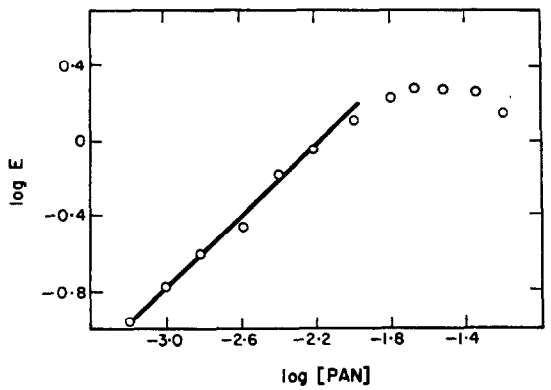

FIG. 6.—Determination of the mole ratio of indium to PAN by the equilibrium shift method.

3-hr extraction of indium ($1{\cdot}2 \times 10^{-5}M$) from acetate buffer at pH 5·5 with a chloroform solution of PAN. At this low concentration indium does not form polynuclear complexes in aqueous medium, and this was confirmed by the fact that log E was independent of the indium concentration. Because PAN was used in very large excess, its initial concentration is plotted on the graph. The ratio of indium to PAN is seen to be 1:1.

The ratio of indium to PAN in the complex extracted in non-equilibrium conditions was also studied, in this case by the methods of continuous variation and of mole ratio. An alcohol solution of PAN was added to the aqueous phase at pH 6·0 and the complex was extracted with chloroform for 90 sec. The total concentration of indium and PAN was $6 \times 10^{-4}M$ for the continuous variation method, and for the mole-ratio method the concentration of indium was $7{\cdot}4 \times 10^{-5}M$ and that of PAN was varied from $2{\cdot}4 \times 10^{-5}$ to $2{\cdot}0 \times 10^{-4}M$. The alcohol concentration was kept constant throughout. Both methods gave a 1:1 ratio for In:PAN.

Since there is only one PAN molecule associated with each indium ion, the complex must be cationic, and an anion must be involved in forming the species extracted. When the 90-sec extract was tested by the lanthanum nitrate–iodine test,[14] acetate was found in it when indium was present but not when indium was absent. Increase in the acetate concentration in the aqueous phase was found to increase strongly the degree of extraction of indium (Fig. 7) indicating indirectly that acetate is involved in the complex extracted.

Influence of anions

Various anions other than acetate were tested for their effect on the extraction of indium. In all these experiments the complex was extracted during 90 sec from a

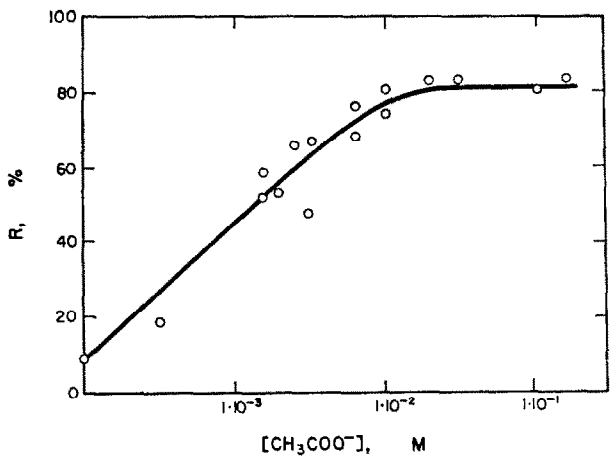

FIG. 7.—Dependence of extraction of indium with PAN on the acetate concentration. PAN added in the aqueous phase at pH 6, shaking-time 1·5 min.

solution to which PAN had been added in alcohol solution: the indium concentration was $1{\cdot}2 \times 10^{-5}M$ and the PAN was $1{\cdot}5 \times 10^{-3}M$. The anions included isobutyrate, isovalerate, caproate, chloride, perchlorate and nitrate. The organic anions were added as the free acid to an indium solution buffered with biphthalate, their concentration being $0{\cdot}14M$, and the pH was varied over the optimum range for extraction of the PAN complex. For comparison, an extraction was made with $0{\cdot}2M$ sodium acetate present in the biphthalate buffer. The inorganic anions were added as their lithium or sodium salts, extractions being made from the salt solutions with and

† No buffer present.

without biphthalate buffer. In the absence of buffer the pH was adjusted by addition of 0·4*M* sodium hydroxide.

The results in Table I show that the organic anions are even more efficient than acetate in promoting the extraction of indium. Indium is also extracted well from biphthalate buffer if relatively large amounts of lithium chloride or sodium perchlorate are added. A poor material balance was obtained when the biphthalate was omitted and 5*M* solutions of the anions were used, and these results are not reported, but a good balance was obtained when indium was extracted from 9*M* lithium chloride.

Chloride was easily detected in the extracts by mercurimetric titration, with diphenylcarbazone as indicator, of the chloride found in the aqueous phase when the extract was stripped with 0·06*M* nitric acid. A blank run was made and corrected for. Attempts to determine the ratio of indium to chloride gave results which were not constant but varied between 1:1 and 1:2. It was found that under equilibrium conditions indium is not extracted with chloride as a counter-anion. The ratio of PAN to indium remained 1:1 irrespective of the anion used.

CONCLUSION

It is evident that when indium is extracted with PAN, a mixed complex is formed with a counter-anion. Similar species appeared to be formed with other metals which react with PAN in a ratio too low to produce an uncharged complex, *e.g.*, iron(III), cobalt(III), yttrium, palladium(II), rhodium(III), iridium(III).[6–9] It is significant that the extraction of these elements was studied with acetate or chloride buffers.

Zusammenfassung—Die Extraktion von Indium in Chloroform mit 1-(2-Pyridylazo)-2-naphthol (PAN) wurde eingehend untersucht. Die Extraktionsgeschwindigkeit ist an größten, wenn PAN zur wäßrigen Phase gegeben und nicht als Chloroformlösung zugesetzt wird. Das Verhältnis Indium: PAN ist 1:1 und der kationische Komplex kann nur extrahiert werden, wenn ein geeignetes Anion wie Acetat oder Chlorid anwesend ist.

Résumé—On a effectué une étude détaillée de l'extraction de l'indium en chloroforme au moyen de 1-(2-pyridylazo)2-naphtol (PAN). La vitesse d'extraction est maximale si le PAN est ajouté à la phase aqueuse et non en solution chloroformique. Le rapport de l'indium au PAN est 1:1 et l'on ne peut extraire le complexe cationique qu'en présence d'un anion convenable, comme l'acétate ou le chlorure.

POLAROGRAPHIC STUDY OF BIS(2-PYRIDYL)DISULPHIDE DI-*N*-OXIDE AND BIS(2-QUINOLYL)DISULPHIDE DI-*N*-OXIDE IN AQUEOUS ETHANOL

I. EL-KHIAMI and R. M. JOHNSON®
Department of Chemistry, Chelsea College of Science and Technology, University of London, London S.W.3

(*Received* 11 *January* 1967. *Accepted* 7 *February* 1967)

Summary—The polarographic reduction of bis(2-pyridyl)- and of bis(2-quinolyl)disulphide di-*N*-oxide in aqueous alcohol yields aryl mercaptans. The electrode reaction is kinetically controlled by an initial one-electron transfer step, and values for the transfer coefficients and the specific heterogeneous rate constants for the forward reactions are presented. The polar *N*-oxide function in the α-position withdraws electrons from the disulphide bond, making the half-wave potential less negative than that of the diphenyl disulphide. The pK_a values of the mercapto compounds formed have been evaluated and the low values obtained for the heterocyclic *N*-oxides are further evidence for tautomerism in these compounds.

IN aqueous alcohol, aromatic disulphides are polarographically reduced to aryl mercaptans.[1] The overall reaction may be written

$$\mathrm{ArSSAr} + 2\mathrm{H}^+ + 2\mathrm{e} \rightarrow 2\mathrm{ArSH}.$$

In a buffered solution, a polarographically reversible reaction of this type will give a wave in accordance with the equation

$$E = E^\circ + \frac{RT}{2F} \cdot \ln\left(\frac{i_d - i}{i^2}\right) - 0{\cdot}0591\ \mathrm{pH} + \frac{0{\cdot}0591}{2} \log\left(\frac{k_2^2}{k_1^2}\right) \qquad (1)$$

at 25°, where k_1 is the Ilkovič constant for the reactant, and k_2 for the product (ArSH), and the other symbols have their usual significance. This equation (ignoring activity coefficients) predicts that a plot of E against $\ln [(i_d - i)/i^2]$ will be linear, with slope $RT/2F$ for a reversible reaction. Furthermore, the half-wave potential will depend upon the diffusion current i_d and hence upon the disulphide concentration.

$$E_{1/2} = E^\circ + \frac{RT}{2F} \cdot \ln\left(\frac{2}{i_d}\right) - 0{\cdot}0591\ \mathrm{pH} + \frac{0{\cdot}0591}{2} \log\left(\frac{k_2^2}{k_1^2}\right). \qquad (2)$$

It has already been shown[1] that for diphenyl disulphide a plot of E against $\ln [(i_d - i)/i^2]$ is curved, whereas a plot of E against $\ln [(i_d - i)/i]$ is a straight line. Furthermore, equation (2) predicts that $E_{1/2}$ will vary with pH at all values, whereas in alkaline solutions the $E_{1/2}$ values for diphenyl disulphide are independent of the hydrogen ion concentration. The waves obtained for diphenyl disulphide are consistent with a slow rate-determining step involving the transfer of one electron to the aromatic disulphide:

$$\mathrm{ArSSAr} + \mathrm{e}^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} (\mathrm{ArSSAr})^-. \qquad (3)$$

Here, k_f and k_b refer to the heterogeneous rate constants for the forward and back reactions, respectively. If we assume that a second electron is added rapidly to the anion produced, there is still an overall two-electron transfer.

$$(ArSSAr)^- + e^- \rightarrow 2ArS^- \tag{4}$$

$$2ArS^- + 2H^+ \rightleftharpoons 2ArSH. \tag{5}$$

Once again ignoring activity coefficients we may write an equilibrium constant (K_a) for equation (5) and derive a new equation for the polarographic wave (6):

$$E = E_{1/2} - \frac{RT}{\alpha n_a F} \cdot \ln\left(\frac{i}{i_d - i}\right). \tag{6}$$

In this equation α is the transfer coefficient and n_a, the number of electrons transferred in the rate-determining step, is unity. The half-wave potential in a buffered solution is given by equation (7), but E° is not strictly the standard potential, and the terms k_1' and k_2' include kinetic factors.

$$E_{1/2} = E^\circ - \frac{RT}{\alpha F} \cdot \ln\left(\frac{k_2'}{k_1'}\right) - \frac{RT}{F} \cdot \ln\left(\frac{K_a}{K_a + C_{H^+}}\right) \tag{7}$$

Thus in buffered acid solution where $C_{H^+} \gg K_a$, the half-wave potential varies with pH, but in alkaline solution, where $C_{H^+} \ll K_a$, the half-wave potential is independent of the hydrogen ion concentration.

Kapoor and his coworkers[1] assumed this reaction sequence, but the possibility cannot be ignored that the anion might dissociate before the second electron is added. In this case, the second electron would be added to the radical formed when the disulphide ion dissociates. Unfortunately, the polarographic data do not indicate which mechanism is correct.

$$(ArSSAr)^- \rightarrow ArS^- + ArS. \tag{8}$$

$$ArS^\cdot + e \rightarrow ArS^- \tag{9}$$

EXPERIMENTAL

Apparatus

Polarograms were recorded with an Atlas Tast-Polarograph Selector D. All potentials were measured against a saturated calomel electrode at 21°. Corrections for cell resistance were very small. Pure nitrogen gas was bubbled first through the appropriate solvent to saturate the gas and then through each solution, for 30 min before the polarograms were recorded and was passed over the surface during the voltage scans.

The capillary characteristics were:

$$m = 2{\cdot}723 \text{ mg.sec}^{-1}$$

$$t = 3{\cdot}24 \text{ sec}$$

$$m^{2/3}t^{1/6} = 2{\cdot}37 \text{ mg}^{2/3}\text{.sec}^{-1/2}$$

$$h = 60{\cdot}0 \text{ cm}.$$

The pH measurements were made with a pH meter Model 23A (Electronic Instruments Ltd.), using prepared glass and calomel electrodes. In view of the solvent mixture used, these pH values must be regarded as "apparent pH."

Materials

Bis(2-pyridyl)disulphide di-N-oxide. A mixture of 2-mercaptopyridine-1-oxide (8·0 g), chloroform (50 ml) and water (50 ml), was titrated with 0·1*N* iodine in aqueous potassium iodide, with shaking

between each addition, until a red colour appeared in the chloroform layer. A few drops of 0·03*N* sodium thiosulphate were then added and the mixture was shaken. The clear chloroform layer was removed and the aqueous layer extracted with two further 100-ml portions of chloroform. The combined chloroform extracts were concentrated by evaporation, and the addition of diethyl ether gave crystals of bis(2-pyridyl)disulphide di-*N*-oxide (6·5 g, 81·4%) m.p. 200–202° (lit.[2] 200–201°), (found: C, 47·6; H, 3·1; N, 11·7%; calc. for $C_{10}H_8N_2O_2S_2$: C, 47·6; H, 3·2; N, 11·1%).

Bis(2-quinolyl)disulphide di-N-oxide. 2-Mercaptoquinoline-1-oxide (0·2 g) was oxidized with iodine solution as described above to give crystals of the bis(2-quinolyl)disulphide di-*N*-oxide (0·15 g, 75·0%) m.p. 192–194° (found: C, 61·1; H, 3·7; N, 8·0%; calc. for $C_{18}H_{12}N_2O_2S_2$: C, 61·4; H, 3·4; N, 7·9%).

Procedure

Solutions of bis(2-pyridyl)disulphide di-*N*-oxide ($6{\cdot}00 \times 10^{-4}$ *M*) or bis(2-quinolyl)disulphide di-*N*-oxide ($8{\cdot}00 \times 10^{-4}$ *M*) in 50% aqueous ethanol at different pH values (Britton-Robinson buffers) were used for polarographic measurements. In certain experiments the concentrations of disulphide were varied and in others the height of the mercury column was altered, but these are referred to specifically in the discussion.

RESULTS AND DISCUSSION

Well-defined polarographic waves were obtained for both disulphides over a wide pH range (Fig. 1), but the more alkaline solutions were unstable, rapidly becoming yellow. The polarograms were analysed by plotting log $[i/(i_d - i)]$ against potential, and half-wave potentials were evaluated from the linear plots obtained. Some waves were analysed by plotting log $[i^2/(i_d - i)]$ against potential and the curvature of these plots confirms the irreversible nature of the electrode reactions (*e.g.*, Fig. 2). The wave height was proportional to concentration, and the half-wave potential was independent of the concentration for each compound in the range studied (Table I).

For each disulphide, a plot of the half-wave potential against pH gave two

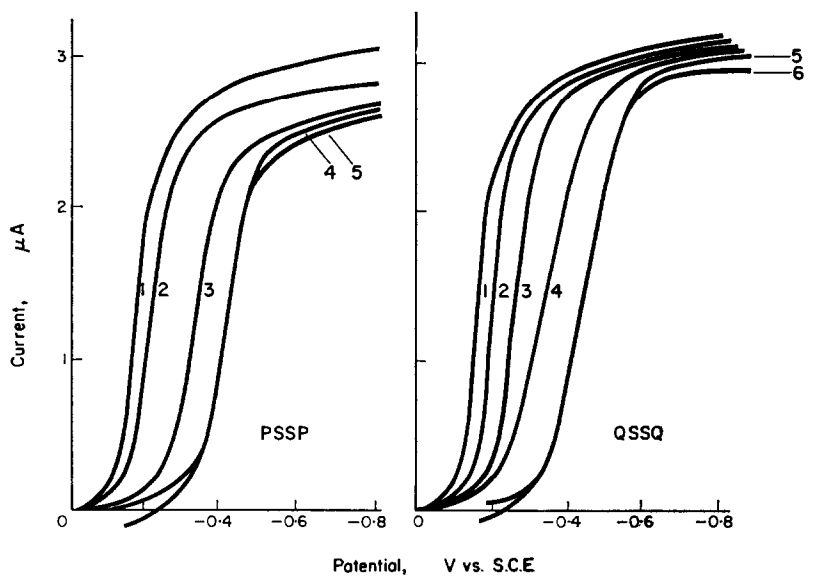

FIG. 1.—Polarographic waves for bis(2-pyridyl)- and bis(2-quinolyl)disulphide di-*N*-oxide (PSSP and QSSQ) at various pH values.

straight lines (Fig. 3). In acid medium the slope of the line was consistent with n_a equal to unity, and in alkaline media the half-wave potential was independent of pH, [equation (7)]; thus the intersection gives pK_a for the product, *i.e.*, 6·21 for 2-mercaptopyridine-1-oxide and 6·82 for 2-mercaptoquinoline-1-oxide, in 50% aqueous ethanol.

If equation (3) is the slow rate-determining step, it is possible, by neglecting the back-reaction, to calculate the heterogeneous rate constant for the forward reaction from the relationship given by Koutecký,[3]

$$k_f = \frac{\lambda D^{1/2}}{t^{1/2}} \tag{10}$$

The values of λ for various values of the ratio i/i_d are given in Koutecký's table.[3]

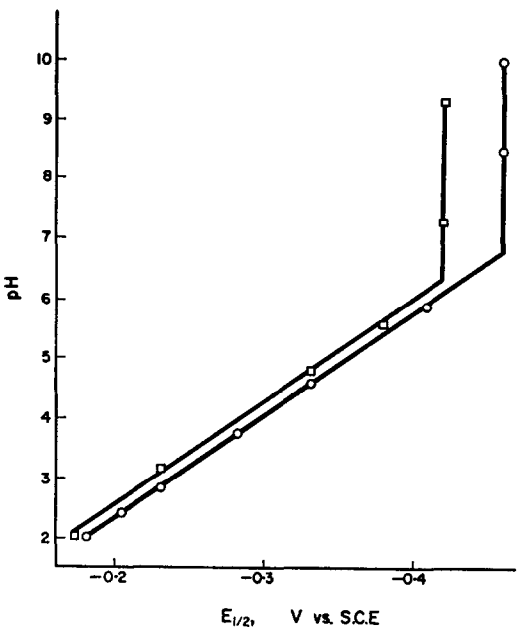

FIG. 3.—Variation of half-wave potential with hydrogen ion concentration.
□—PSSP; ○—QSSQ.

The value of D may be calculated from the Ilkovič equation assuming that n is two for the overall reaction. Here t is the drop-time. By plotting log k_f against potential for each wave (Fig. 4) we obtain log $k_f°$ (where the electrode potential is equal to that of the normal hydrogen electrode). The slope of this curve gives the value of α, the transfer coefficient (since n_a is unity).

$$\ln k_f = \ln k_f° - \alpha n_a FE/RT \tag{11}$$

The same values for the transfer coefficients are obtained by the use of equation (7) and the slope $RT/\alpha n_a F$ of the plot of E against ln $[i/(i_d - i)]$.

Rearranging equation (11) for the half-wave potential, we obtain equation (12), where $\lambda_{1/2}$ is the value of λ when i/i_d is 0·5.

$$E_{1/2} = \frac{RT}{\alpha n_a F} . \ln \frac{k_f°}{\lambda_{1/2} D^2} - \frac{RT}{\alpha n_a F} . \ln t \tag{12}$$

The variation of half-wave potential with drop-time predicted by this equation has been verified experimentally (Fig. 5) for both compounds. In one series of experiments the height of the mercury column was varied from 25 to 60 cm and the $E_{1/2}$ values were evaluated. From equation (13), where $\Delta E_{1/2}$ is the difference in half-wave potential

$$\Delta E_{1/2} = \frac{RT}{2 \times 2{\cdot}303 \alpha n_a F} . \log \frac{t_1}{t_2} \tag{13}$$

observed for drop-times t_1 and t_2 seconds, the value of $\Delta E_{1/2}$ for mercury columns 60 and 25 cm high was 20 mV and the values obtained experimentally were 20·2

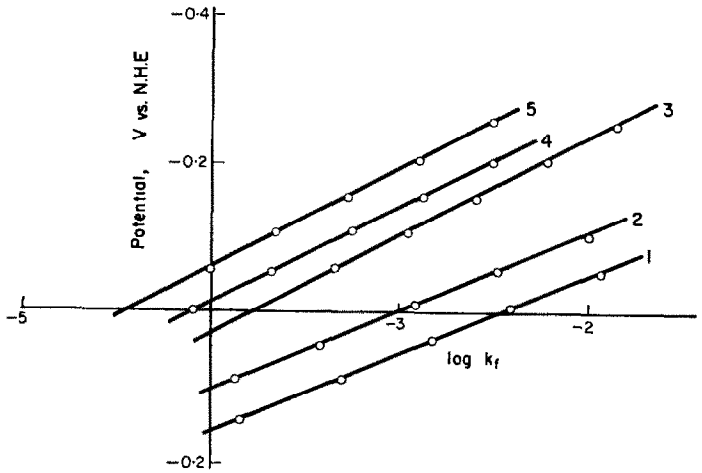

FIG. 4.—Variation of log k_f with applied potential for bis(2-pyridyl)disulphide di-*N*-oxide at different pH values.
pH: *1*—2·0; *2*—3·3; *3*—4·8; *4*—5·5; *5*—7·0.

and 21·3 mV for bis(2-pyridyl)- and bis(2-quinolyl)disulphide di-*N*-oxide, respectively. These results confirm that α and k_f° do not change with drop-time.

For the purposes of discussion it is useful to compare the results of the present work (Table II) with the results of Kapoor *et al.*[1] on diphenyl disulphide (Table III). The half-wave potentials and $-\log k_f^\circ$ values are quoted for the alkaline solutions where the product is fully dissociated. The low half-wave potentials for the *N*-oxides are attributed to the electron-withdrawing effect of the *N*-oxide function which is particularly marked in the α-position, reducing the electron density on the S—S bond. In the case of the bis(2-quinolyl)disulphide di-*N*-oxide, this effect is counteracted to a small extent by the annulated benzene ring.

The pK_a values found for these mercapto *N*-oxides are very low compared to that for thiophenol. The interaction of the *N*-oxide function with the heteroaromatic ring (resulting in a positive charge in the α- and γ-positions) is well known,[4] and

(III)

Similarly, the anion formed when 2-mercaptopyridine-1-oxide dissociates will be stabilized by charge dispersal (III). The resulting low pK_a value for 2-mercaptopyridine-1-oxide (and for 2-mercaptoquinoline-1-oxide) favours the formation of stable metal mercaptide complexes in more highly acidic solutions than for thiophenol. The results quoted for diphenyl disulphide refer to solutions in 60% v/v ethanol in water. The analytical applications of 2-mercaptopyridine-1-oxide have already been reported[6] and 2-mercaptoquinoline-1-oxide has been investigated.[7]

Acknowledgement—We wish to thank Dr. J. A. W. Dalziel for helpful and stimulating discussions, and I. E. K. thanks the University of Damascus for financial assistance during the course of this work.

Zusammenfassung—Die polarographische Reduktion von Bis(2-pyridyl)- und Bis(2-chinolyl)disulfid-di-*N*-oxid in wäßrigem Alkohol gibt Arylmercaptane. Die Elektrodenreaktion ist kinetisch kontrolliert durch eine anfängliche Einelektronenübergangsstufe; Werte der Durchtrittsfaktoren und der spezifischen heterogenen Geschwindigkeitskonstanten der Hinreaktionen werden angegeben. Die polare *N*-Oxidgruppe in Alpha-Stellung entzieht der Disulfidbindung Elektronen; dadurch wird das Halbstufenpotential weniger negativ als das von Diphenyldisulfid. Die pK_a-Werte der gebildeten Mercaptoverbindungen wurden berechnet; die bei den heterocyclischen *N*-Oxiden gefundenen niedrigen Werte geben einen weiteren Hinweis auf die Tautomerie dieser Verbindungen.

Résumé—La réduction polarographique des di N-oxydes des bis(2-pyridyl) et bis(2-quinoleyl) disulfures en alcool aqueux donne des arylmercaptans. La réaction à l'électrode est contrôlée cinétiquement par un stade initial de transfert à un électron et l'on donne des valeurs pour les coefficients de transfert et les constantes spécifiques de vitesse hétérogène pour les réactions directes. La fonction polaire N-oxyde en position α enlève des électrons de la bande disulfure, rendant le potentiel de demi-vague moins négatif que celui du disulfure de diphényle. On a estimé les valeurs de pK_a des composés mercapto formés et les faibles valeurs obtenues pour les N-oxydes hétérocycliques sont un nouvel argument en faveur du tautomérisme de ces composés.

INSTRUMENTAL ACTIVATION ANALYSIS OF VEGETABLE TISSUE

E. STEINNES
Isotope Laboratory, Institutt for Atomenergi, Kjeller, Norway

(*Received* 23 *November* 1966. *Accepted* 14 *February* 1967)

Summary—A non-destructive method for the determination of bromine, manganese, phosphorus, potassium, sodium and zinc in plant tissue by neutron activation and gamma-ray spectrometry is described. Phosphorus and potassium have been determined also by beta-counting. The method should be especially attractive for analysis of manganese and zinc.

ACTIVATION analysis, besides being a very sensitive method for the determination of trace elements, has also proved its usefulness as a rapid non-destructive technique. The combination of neutron activation and gamma spectrometry without any intermediate chemical separation step has found applications in numerous cases. The use of beta-counting in non-destructive analysis has also been successfully demonstrated.[1,2] In the present work applications of the purely instrumental neutron activation analysis to vegetable tissue are shown. The material selected for this investigation was leaves of Norway Spruce (*Picea abies*), which is an important raw material in paper manufacturing. The experience gained in this work can, however, undoubtedly be applied to a great variety of plant material samples.

EXPERIMENTAL

Counting equipment

A 400-channel gamma-spectrometer with a well-type 3 in. × 3 in. NaI(Tl) detector was used in the gamma measurements. For the beta measurements a Geiger–Mueller counter with conventional shelf arrangement was used. The window thickness of the tube was 10 mg/cm^2, and the effective diameter was 28 mm.

Irradiation

Samples of about 100 mg, dried at 50° for 24 hr, were weighed into polyethylene ampoules and irradiated for 2 days in the reactor JEEP I (Kjeller, Norway) at a thermal neutron flux of about 2×10^{12} n.cm^{-2}.sec^{-1}. After the irradiation the samples were mounted on cardboard sample holders for activity measurements. Together with the samples silica ampoules were activated, each containing 1 ml of a standard solution of an element to be determined. From each silica ampoule two 0·100-ml aliquots of the standard solution were adsorbed on diameter 20-mm filterpapers, dried carefully under a heating lamp and mounted for counting in the same way as the samples.

The standard solutions were prepared by dissolving accurately known amounts of *pro analysi* chemicals in water or dilute hydrochloric acid. The chemicals used and the approximate concentration of each standard solution are listed in Table I.

Activity measurements

The gamma-spectra of the samples were recorded at intervals after the end of the irradiation, as indicated in Fig. 1. The half-life of the different radionuclides were checked by repeated measurements.

The areas under the photopeaks were evaluated according to the method of Covell.[3] Data giving a more detailed description of the determination of each element are listed in Table 1.

As the measurement of the 1·52 MeV photopeak of ^{42}K is somewhat disturbed by the 1·37 MeV peak of ^{24}Na, the contribution of the latter nuclide was removed by "stripping" of the 2·75 MeV peak with a pure ^{24}Na source, before the amount of potassium was calculated.

The gamma-spectrometric measurement of ^{32}P was made possible by detection of the bremsstrahlung produced by the high energy beta-particles, and was based on the sum of counts accumulated in 5 channels (10 keV/channel) of the corresponding region in the gamma-spectrum. The observed count rates proved to decrease according to a pure ^{32}P decay for a period of at least 30 days. To detect possible variation in count rate due to channel drift, the phosphorus standard was counted at

TABLE I.—DATA FOR THE DETERMINATION OF EACH ELEMENT

	Br	K	Mn	Na	P	Zn
Radioisotope used	^{82}Br	^{42}K	^{56}Mn	^{24}Na	^{32}P	^{65}Zn
Half-life	35·9 hr	12·5 hr	2·58 hr	15·0 hr	14·3 d	245d
Type of measurement	γ	β,γ	γ	γ	β,γ	γ
Gamma-energy measured (MeV)	0·78	1·52	0·84	2·75	Brems-strahlung	1·11
Maximum beta-energy (MeV)	0·465	3·58	2·81	1·39	1·71	—
Time elapsed between end of irradiation and start of measurements	5–6 d	24–30 hr*	2–5 hr	24–30 hr	14 d	14 d
Substance used for the preparation of standard solution	KBr	K_2CO_3	Mn	Na_2CO_3	H_3PO_4	Zn
Approximate concentration of standard solution (mg/ml)	0·1	5	0·2	0·1	5	1

* The beta-counting of ^{42}K was postponed until 50 hr after the end of the irradiation, to avoid any contribution from ^{56}Mn.

intervals during the measurement of each series of samples. When gamma-measurements of ^{32}P and ^{65}Zn were to be performed, the samples and standards had to be transferred from the cardboard sample holders into glass vials and counted in the well of the NaI crystal in order to yield a sufficiently high sensitivity for the zinc determinations, and to give a higher and more reproducible ^{32}P bremsstrahlung production.

In the beta-measurements aluminium absorbers were used to take advantage of the high energy beta-rays of ^{42}K and ^{32}P compared to other induced activities with similar half-lives. In the ^{42}K measurements each sample was counted with two absorbers of thickness respectively 700 and 1700 mg/cm^2, the first one to discriminate beta-particles mainly due to ^{24}Na and ^{32}P, the second one to correct for counts due to gamma-rays. The difference between the two count rates was used to determine the amount of potassium present. In the ^{32}P measurements an absorber of 100 mg/cm^2 was used to discriminate possible contribution from low energy beta-emitters such as ^{35}S. The count rate due to gamma-rays was found to be negligible in this case. The results for both potassium and phosphorus were confirmed by repeated beta-measurements.

The measurement of ^{42}K by beta-counting could not be started until the activity of ^{56}Mn had decayed to a negligible level. In the same way the measurement of ^{32}P was dependent on the decay of ^{42}K.

RESULTS AND DISCUSSION

The present investigation includes analyses of 20 different samples. Each sample was divided into two aliquots which were activated and analysed separately. A summary of the results is given in Table II. The concentration range found for each element is given, and the relative standard deviation in the determination of the various elements calculated from the duplicate analyses are presented as a measure of the reproducibility of the method.

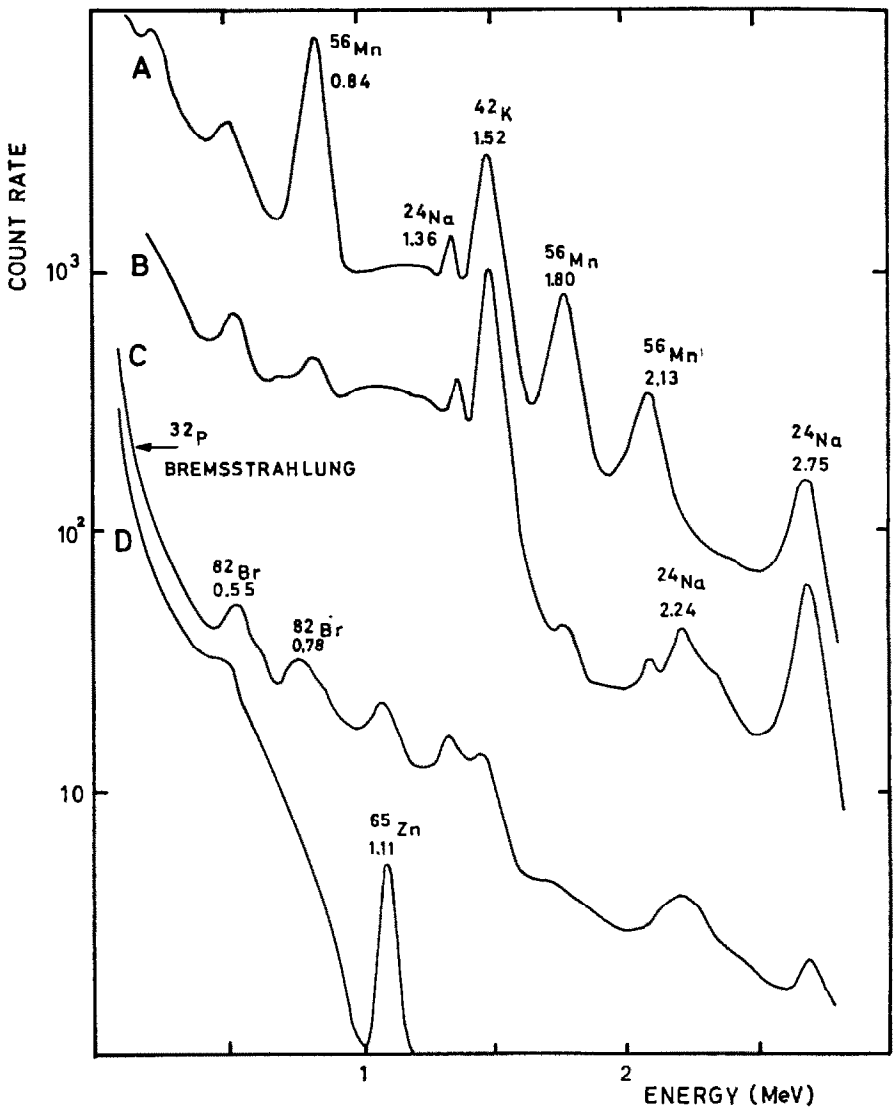

FIG. 1.—Gamma spectra of irradiated sample recorded at intervals after the end of the irradiation
A—10 hr; B—27 hr; C—6 days; D—14 days.

TABLE II.—RESULTS FOR DUPLICATE ANALYSIS OF 20 SAMPLES, BASED ON GAMMA-SPECTROMETRY

Element	Concentration range	Relative standard deviation
Br	1·0–5·2 ppm	9·3%
K	0·37–0·69%	2·7%
Mn	182–812 ppm	2·0%
Na	4–20 ppm	—
P	0·26–0·45%	2·4%
Zn	30–180 ppm	4·7%

Duplicate determinations of sodium showed a fairly wide spread, although determinations of this element by the present method are usually precise to ±5%. This is probably due to external contamination from the pre-irradiation treatment of the samples.

An investigation of the accuracy of the method was rendered possible by analysing solutions containing the elements of interest in known concentrations, in a similar way to the vegetable samples. Two different solutions with similar composition to

TABLE III.—ANALYSIS OF SOLUTIONS OF KNOWN COMPOSITION

	Element	Amount added, μg	Amount recovered, μg							
			γ-counting				β-counting			
Solution I	K	500	492	504	502	489	500	512	515	505
	Mn	50·0	50·8	50·2	48·3	50·0				
	Na	4·6	7·0	7·1	6·9	7·1				
	P	500	489	486	488	493	500	508	507	503
	Zn	20·0	20·7	20·7	20·3	21·2				
Solution II	K	400	395	403	398	406	409	396	392	389
	Mn	25·0	24·8	25·3	25·1	25·2				
	Na	9·2	12·1	11·8	11·9	12·2				
	P	250	237	246	243	244	247	258	263	260
	Zn	10·0	10·3	10·6	10·3	10·1				

the spruce samples were prepared, and four aliquots of each solution were analysed separately. The results are listed in Table III. Except in the case of sodium the agreement between the amounts added and found is very satisfactory. The reason for the high sodium values found is evidently that additional amounts of Na have been introduced during addition of the other elements.

TABLE IV.—COMPARISON OF POTASSIUM AND PHOSPHORUS CONTENTS DETERMINED BY BETA-COUNTING AND GAMMA-SPECTROMETRY

20	0·556	0·599	0·406	0·422

In Table IV is shown a comparison of results for potassium and phosphorus obtained by beta- and gamma-measurements of the same samples. In both cases the results based on measurements of gamma-rays are about 3% higher on average. The reason for this discrepancy is not obvious. One possible source of error yielding low results might be self-scattering and self-absorption of beta-particles in the irradiated needles. The results from the gamma-activity measurements of ^{32}P are probably high owing to gamma-rays or bremsstrahlung from other long-lived nuclides present in small amounts.

Systematic errors are not expected to influence the present results seriously. Neutron shielding effects are negligible since neither samples nor standards contain significant amounts of strong neutron-absorbing elements. Errors due to different counting geometry of samples and standards are assumed to be 1% or less. Interference from competing nuclear reactions is insignificant, except in the case of phosphorus, as ^{32}P is also being produced from sulphur and chlorine by (n, p) and (n, α) reactions respectively. The fast neutron flux in the irradiation position was, however, low compared to the thermal flux. The ^{32}P activity produced by irradiation of 1 mg of phosphorus was 55 times as great as the activity of 1 mg of sulphur irradiated simultaneously, and the corresponding figure for chlorine was 250. As no values for the normal content of sulphur and chlorine in Norway Spruce seem to be available, it is difficult to establish the corrections necessary in this work. However, if sulphur and chlorine are assumed to be present in concentrations of the same order of magnitude as phosphorus, the interference is relatively small.

From the observed results and the preceding discussion the accuracy of the determination of manganese by the present method is likely to be about $\pm 3\%$. The determination of zinc is most probably accurate to $\pm 10\%$ or even $\pm 5\%$ if the activation period is increased to 4–5 days. The present method should hence be very well suited for the determination of manganese and zinc in vegetable material.

The determination of potassium is probably accurate to $\pm 5\%$ for both beta- and gamma-measurements. The same should be the case for phosphorus if a well thermalized neutron flux is employed and the contents of sulphur and chlorine are low and approximately known. The precision obtained in the determinations of phosphorus and potassium is perhaps not especially remarkable compared to conventional methods. It should be noted, however, that a large number of samples can be analysed within a short time, especially if computer technique is used for the resolution and evaluation of the gamma-spectra. The simplicity of the beta-measurements should also make this particular technique attractive for further application. The determination of manganese is also readily done by gross beta-counting through an aluminium absorber if a correction for the ^{42}K activity is introduced, or even by integral gamma-counting.

On the basis of the present work it seems unquestionable that instrumental neutron activation analysis in many cases will be a valuable supplement to methods more commonly used in chemical analysis of vegetable tissue.

Zusammenfassung—Eine zerstörungsfreie Methode zur Bestimmung von Brom, Mangan, Phosphor, Kalium, Natrium und Zink in Pflanzengewebe durch Neutronenaktivierung und Gamma-Spektrometrie wird beschrieben. Phosphor und Kalium wurden auch durch Beta-Zählung bestimmt. Die Methode sollte besonders zur Mangan- und Zink-Bestimmung von Vorteil sein.

Résumé—On décrit une méthode non-destructive de dosage du brome, du manganèse, du phosphore, du potassium, du sodium et du zinc dans le tissu végétal par activation de neutrons et spectrométrie aux rayons gamma. On a également dosé le phosphore et le potassium par comptage beta. La méthode devrait être spécialement intéressante pour l'analyse du manganèse et du zinc.

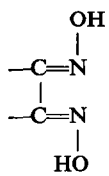
SOME ASPECTS OF THE REACTIONS BETWEEN SELENIUM-CONTAINING LIGANDS AND PLATINUM GROUP METALS

L. S. BARK* and D. BRANDON†
Department of Chemistry and Applied Chemistry, University of Salford, Salford 5, U.K.

(*Received* 6 *December* 1966. *Accepted* 16 *February* 1967)

Summary—2-(2-Pyridyl)benzo[*b*]selenophene has been investigated as a possible reagent for palladium. From a consideration of its reactions with diverse metal ions, and the probable structure of the complex formed between the compound and palladium(II) it is postulated that the group —Se⋯C⋯C⋯N— may be highly selective for palladium. From the experimental evidence it is suggested that the delocalization of the metal electron density by π-bond formation between the palladium and selenium atoms is a major factor in determining the stability of the chelated complex.

THE problem of designing a reagent which is either specific for one metal or is selective for a very small number of metals, is one which has beset analytical chemists for some time. In general there are a few atomic groupings which are relatively selective; such a group is the vicinal dioxime group



which is selective for nickel and palladium. This group can be made more selective[1,2] by alteration of the N—C—C angles so that the distance between the terminal ligand nitrogen atoms is more suited for the accommodation of palladium than for nickel. Not only these angles but also the nature of the terminal atoms is important. The grouping ⋯N⋯C⋯C⋯N⋯ arranged in a definite pattern as in 1,10-phenanthroline is reasonably selective for a few metals. However, if the ligand atoms are altered as in —N—C—C—O— (in 8-hydroxyquinoline) or —N—C—C—S— (in 8-thiolquinoline) then the metals which may be chelated vary from compound to compound.

It was decided to investigate the replacement of one of the nitrogen ligand atoms with selenium and simultaneous fixing of the —N—C—C—Se angles so that only ions of a certain radius could form a chelate without undue deformation and deviation from the usual interatomic spacings. From a consideration of the compounds containing this grouping, we decided to investigate those containing selenium as a heteroatom in an organic molecule.

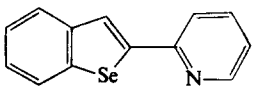
Only a few organic molecules containing selenium have been reported as forming compounds with metals, and these have been reviewed by Livingstone.[1] Some, such

* All communications to L. S. Bark.
† Present address: Department of Chemistry, Flintshire College of Technology, Connah's Quay, North Wales.

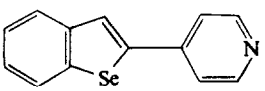
as *N'*-benzoyl-*N*-phenylseleno-urea,[2] *N'*-benzoyl-*N*-*N*,diethylseleno-urea,[2] 3,4-benzo-1',2',5'selenodiazole,[3] phenoselenazine,[4] 2-selenophene-*trans*-aldoxime,[5] and tetrahydroselenophene,[6] form addition compounds not necessarily involving a selenium-metal bond; 2,5-dibenzoyl-3,4-dihydroxyselenophene[7] forms chelates not involving selenium–metal bonds; a dialkylselenide had been reported as forming a Pt–Se bond.[8] Only a few compounds (quinoline-8-selenol)[9] and dialkyldiselenocarbamates[10] have so far been reported to form chelate compounds involving a selenium–metal bond.

We have examined a series of compounds containing the atomic grouping ··N··C··C··Se·· in an attempt to evaluate the potential of this type of compound as an analytical reagent and to elucidate the structure of the metal–organic complex formed.

The parent compound (2-selenophene-*trans*-aldoxime) containing the grouping, gives an addition compound with palladium which does not contain a Pd–Se bond.[5] However, consideration of orbital distributions and steric models indicated that a Pd–Se bond and chelate formation were probable if a reaction occurred between palladium or platinum and 2-(2-pyridyl)benzo[*b*]selenophene (I).



(I)



(II)

For comparison purposes, this compound and its isomer 2-(4-pyridyl)benzo[*b*]-selenophene (II) were prepared and investigated. The '4' isomer (II), is not capable of forming a chelate with platinum or palladium, and hence a critical comparison of any complexes of platinum or palladium formed by (I) and (II) should be possible.

EXPERIMENTAL

Preparation of the organic reagents

The organic reagents were prepared by a slight modification of the method of Buehler *et al.*,[11] using 2-stilbazole and 4-stilbazole as the starting compounds for (I) and (II) respectively. The purity and composition were determined by standard analytical procedures. The reagents were used as a 0·5% w/v ethanolic solution.

Reactions of (I) and (II) with diverse ions

The reactions of the reagents (I) and (II) with solutions of 35 metal ion species were investigated at pH 2–2·5. Higher pH values were not investigated owing to the very low solubility of reagent (I) at pH >2·5.

To 1·5-ml portions of the metal ion solutions (containing 5 mg of the ion per ml) were added 1-ml portions of the reagent solution. The mixtures were agitated at room temperature (*ca.* 23°) for 15 min and then heated at 80° for a further 15 min. The ions investigated were Al, Be, Ce(III), Cu(II), Fe(II), Pb(II)*, Hg(II), Pd(II), Rh(II), Tl(I)*, Sn(IV), V(V), As(III), Bi, Cr(III), Ir(III), Fe(III), Mn(II), Ni, Pt(II), Ru(IV), Th, Ti(IV), Zn, Ba, Cd, Co(II), Ir(IV), La, Hg(I)*, Os(IV), Pb(IV), Ag*, Sn(II) and U(IV). Hydrochloric acid was used to adjust the pH of the solutions, except in the cases marked *, where nitric acid was used.

Only palladium(II), platinum(II) and platinum(IV) and osmium(IV) gave observable reactions.

Complexes with compound(I)

Palladium(II). A primrose yellow precipitate was obtained from a cold solution, and when hot solutions were mixed. The precipitate formed within a few seconds of the mixing of the reactants.

Platinum(II). A yellow precipitate was formed in both hot and cold solutions. Platinum(II) produced *in situ* by the reaction of platinum(IV) and hydroxylamine reacted similarly.

Platinum(IV). Heating for 15 min produced a brown complex similar in appearance to the Pt(II) complex.

Osmium(IV). A dark red crystalline compound formed slowly from cold solutions. On heating, the precipitate dissolved. It recrystallized on cooling

Complexes formed with compound(II)

Yellow crystalline precipitates were obtained with Pd(II), Os(IV) and Pt(II). The precipitates formed slowly in cold solutions, but not at all in hot solutions. The precipitates dissolved on boiling and recrystallized on cooling.

The nature and composition of the complexes

Palladium(II) complex of compound(I). The reactions of the compound and its behaviour under electrophoresis at 400 V at room temperature, indicate that the compound is non-ionic. The chlorine is probably covalently bound to the palladium. It is not readily replaceable by other atoms. Silver ions do not precipitate the chloride, except on prolonged boiling. A sample of the compound was analysed for palladium (after wet oxidation) gravimetrically, with indane-1-one-2-oxime.[12] The carbon, hydrogen and nitrogen were determined by normal combustion methods. The selenium was determined iodimetrically after combustion of the compound by an oxygen-flask method, and was also calculated from the carbon content, since these two elements must be present in the same ratio as in the pure reagent. Se = 17·95% by titrimetry; Se = 18·15% by calc. The chloride content was determined coulometrically after removal of the selenium as the element. The results were C 35·9%, H 2·1%, N 3·3%, Se 18·0%, Cl 16·0%, Pd 24·5%, and indicate that the compound has an empirical formula $C_{13}H_9NSePdCl_2$. Attempts to obtain a molecular weight by cryoscopic and ebullioscopic methods were not successful.

Platinum(II) complex. Preliminary results on this compound indicate that it is similar to the palladium compound.

Osmium complex. A sample of the red "complex" heated at 110° for 1 hr became yellow. On exposure to the atmosphere for a short time it gradually regained its red colour and its original composition. Analysis showed the red material to be a hydrate of empirical formula $(C_{13}H_{10}NSe)_2OsCl_6 \cdot 2H_2O$. The loss in weight at 110° corresponds to the loss of the two water molecules. The reactions of the compound and its behaviour under electrophoresis indicate that it is an ionic salt of the type $[(RH)_2]^{2+}[MX_6]^{2-}$ (where R is a monoacidic base). Silver ions precipitate the chloride from a hot solution.

Palladium(II) complex of reagent(II)

The complex was decomposed by boiling with 0·1*M* EDTA to complex the palladium. Addition of sufficient 2*M* nitric acid to dissolve the precipitated reagent and a slight excess of silver nitrate allowed the chloride to be determined gravimetrically.

Carbon, hydrogen and nitrogen were determined by suitable combustion methods. The selenium content was calculated from the carbon content. The palladium was determined gravimetrically on a separate sample, after wet oxidation. The results, C 44·9%, H 2·7%, N 4·0%, Pd 15·3%, Cl 10·1%, Se 22·7%, give an empirical formula $PdC_{26}H_{18}N_2Se_2Cl_2$, which corresponds to Pd R_2Cl_2 where R is 2-(4-pyridyl)benzo[*b*]selenophene.

Investigation of the possible use of (I) for determination of palladium(II)

General procedure. An aliquot of the palladium(II) solution (25 ml containing 5 mg of palladium and standardized[12,18]) was diluted to 100 ml with distilled water. After adjustment of the pH to the required value by the addition of hydrochloric acid or sodium acetate and acetic acid, the samples were heated to 80 ± 1° in a water-bath. The reagent was then added dropwise with stirring. After digestion the precipitate was collected on a porosity-4 sintered glass crucible, and washed first with 0·1*M* hydrochloric acid and then with water until the washings were free from chloride. Thermogravimetric analysis and differential thermal analysis showed that 110° was a suitable temperature for drying the complex.

Variation of the pH of precipitation, A 10% excess of reagent was used, and the precipitate was digested at 80° for 30 min. Above pH 3·0 the precipitate would not coagulate unless chloride ions (from sodium chloride) were added to the reaction mixture. The effect of the addition of sodium chloride was investigated separately. The results (Table I) indicate that in the absence of sodium chloride precipitation is not quantitative at any pH. The maximum recovery occurred at pH 1·4.

TABLE I.—THE EFFECT OF VARIATION OF pH

pH	0·5	0·7	0·9	1·0	1·4	1·8	2·2	2·6	3·0
Recovery, %	42·0	73·2	89·8	91·8	92·8	92·5	90·8	89·4	87·1

The residual palladium in the filtrate was determined gravimetrically with indane-1-one-2-oxime[1] or 3,3-diphenylindane-1,2-dioxime.[13] It was found that the palladium recovered from the filtrate, when added to the original palladium recovery, gave a total of 100 ± 0·2%.

Variation in the amount of reagent. Precipitation was done at pH 1·4 with digestion for 30 min at 80 ± 1°. The palladium recovery increased as the amount of reagent was increased (Table II). Simultaneously, it became more difficult to wash the precipitate free from coprecipitated reagent.

TABLE II.—EFFECT OF VARIATION IN THE AMOUNT OF PRECIPITANT

Reagent excess, %	10	30	50	100
Palladium recovered, % (average of 3 determinations)	92·8	94·3	95·7	97·7

Variation in the time of digestion. Precipitation was achieved with 10% excess of reagent at 80° and pH 1·4. The results shown in Table III indicate that the palladium recovery increases with the time of digestion up to 30 min.

TABLE III.—EFFECT OF ALTERING THE DIGESTION TIME

Time of digestion,	0·25	0·5	0·75	1·0	24
Palladium recovered, %	84·5	92·8	92·8	92·8	93·8

The effect of addition of chloride. Precipitation was done with 10% excess of reagent with digestion for 30 min at 80° ± 1°. The pH range investigated was from 2·2 to 5·0. At the higher pH values the reagent precipitated as a white emulsion, but on digestion at 80° the yellow complex was gradually formed, but prolonged washing with 0·1*M* hydrochloric acid was necessary to remove excess of reagent. The results shown in Table IV indicate that quantitative recoveries of palladium(II) are obtained at pH 4·0–5·0 when large amounts of chloride ion are added to the reaction mixture.

TABLE IV.—DEPENDENCE OF PALLADIUM RECOVERY ON pH AND THE AMOUNT OF SODIUM CHLORIDE ADDED

pH	Palladium recovered, %			
NaCl added, *g*/5 *mg* Pd	0	1	2	5
2·2	90·8	92·3	95·5	96·6
4·0	—	100·6	100·0	100·4
5·0	—	100·5	101·2	100·8

Effect of the addition of sequestering agents. It was found that in the pH range 0·5–5·0 hydroxylamine, ammonia and EDTA completely inhibit precipitation of the complex.

The reaction of 2-(2-*pyridyl*)*benzo*[b]*selenophene with platinum(II)*

Preliminary investigations have shown that the complex formed with platinum(II) is considerably more stable than the corresponding palladium(II) complex. The platinum(II) complex is precipitated in the presence of the sequestering agents mentioned above. It has been possible to precipitate the

platinum(II) complex from homogeneous solution by *in situ* formation of Pt(II) by reduction of platinum(IV).

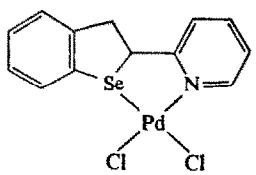
These reactions with platinum are under investigation and will be reported in a later communication

DISCUSSION

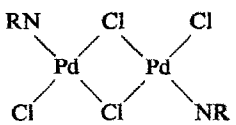
The work done shows that 2-(2-pyridyl)benzo[*b*]selenophene is of limited value as an analytical reagent for palladium. It is nevertheless of use in the general study of ligands containing selenium donor atoms, and in elucidation of their analytical chemistry.

Structure of the palladium complex of 2-(2-*pyridyl*)*benzo*[b]*selenophene*

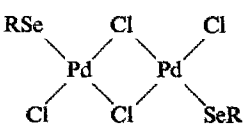
The complex of empirical formula $C_{13}H_9NSePdCl_2$ can be represented by one of the following structures:



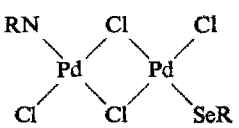
(III)



(IV)



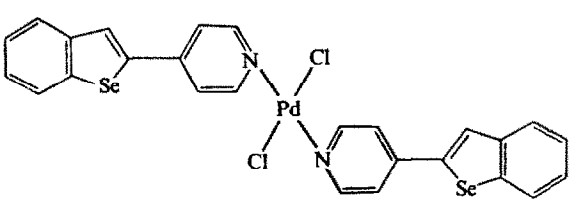
(V)



(VI)

If the reagent acts as a monodentate ligand it is probable that Pd—N bonds will be formed. If this were the case, then it would be expected that the complex would have same empirical formula as the Pd(II) complex of 2-(4-pyridyl)benzo[*b*]selenophene.

The empirical formula of the latter complex is $PdC_{26}H_{18}N_2Se_2Cl_2$ and by analogy with known palladium(II) complexes with nitrogen-containing heterocyclic monodentate ligands such as pyridine, its structure is probably



(VII)

Thus we conclude that the compound 2-(2-pyridyl)benzo[*b*]selenophene is probably not acting as a monodentate ligand, but as a bidentate one [structure (III)].

The ultraviolet, infrared and nuclear magnetic resonance spectra of the reagent and the complex were investigated (in ethanol for u.v., in deuterochloroform for NMR).

The infrared spectra give no useful information, but the ultraviolet spectra of $10^{-4}M$ ethanol solutions of the reagent and the palladium(II) complex indicate that there is a great deal of similarity between the two. The main difference is an absorption peak at about 400 mμ which is attributed to Pd bonding (Fig. 1).

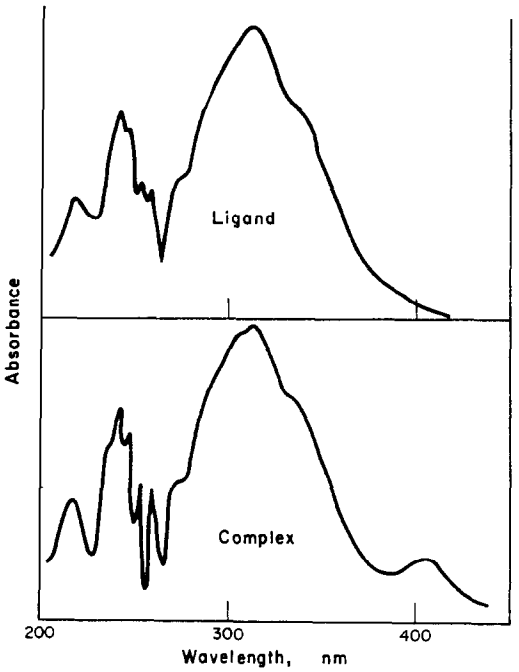


FIG. 1.—Ultraviolet absorption spectra of 2-(-2pyridyl)benzo[*b*]selenophene and its palladium(II) complex.

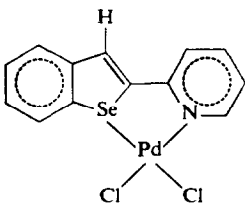
There is virtually no loss of resonance in the complex, which must, therefore have a planar configuration similar to that of the reagent. Consideration of the possible electronic structures of the complex indicates that a planar complex is possible.

The aromaticity of thiophene has been explained by Longuet-Higgins[14] who suggested that in bonding to carbon the sulphur atom uses two sp^2 hybrid orbitals to form sigma-bonds and two pd^2 hybrid orbitals to form pi-bonds. Thus the sulphur atom is left with an sp^2 "lone-pair" of electrons and an empty pd^2 hybrid orbital, both of which are oriented away from the aromatic ring, the lone-pair being in the plane of the ring, *i.e.*, in a direction suitable for σ-bond formation with a metal atom, and the pd^2 hybrid orbital normal to the plane of the ring, thus being oriented for π-bond formation.

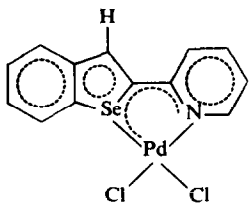
Since thiophene and selenophene are very similar in their chemical properties, and the only major constitutional difference between them is their hetero-atoms, which are of equivalent electronic structure, it may be assumed that they are of equivalent electronic structure. We therefore suggest that in the palladium(II) complex, the bond between the selenium and the palladium is formed by the selenium atom forming a σ-bond with the palladium by means of its $4s4p^2$ lone-pair electrons, accompanied by the formation of a π-bond by "back-donation" of electrons from the $4d_{(x^2-y^2)}$ orbital of palladium into the vacant $4p4d^2$ hybrid orbital of the "aromatic" selenium. In a review[15] of the criteria for π-bond formation by back-donation from the metal atom of the ligand atom, it is suggested that the availability of orbitals of similar energy is essential for the formation of such bonds; one of the main disadvantages of the theory is that to obtain this similarity of energy with nitrogen or phosphorus

which do not have 4*d* orbitals, it is often necessary to postulate a raising of the energy of the available orbitals by the difference in the electronegativities of the two atoms. In the case of selenium and palladium it is not necessary to make this qualifying assumption. The probability of bond formation is also increased if there is maximum overlap of the orbitals concerned in the bonding. Coates[16] has suggested that π-bond formation occurs *via* a vacant *d* orbital of sulphur or selenium in aliphatic molecules, and that the overlap is sufficient to give stability to the bond. In the case of thiophene, selenophene and related compounds, we suggest that since the π-bond is formed by using a pd^2 hybrid orbital which is more localized in the required region of space than is a *d* orbital, then greater orbital overlap should be obtained, resulting in a stronger bond. One of the main reasons for postulating π-bond formation in metal complexes is the need to suggest delocalization of the electron density around the central metal atom. In the case of complexes of aromatic selenium compounds in general and this particular compound in particular, if π-bonding does occur, delocalization can occur throughout the coplanar molecule as indicated in structure (IX).

It can be seen that if the molecule is not planar, then the delocalization or resonance found in the reagent would disappear and hence the spectra of the reagent and the complex would be vastly different. It was hoped that NMR studies of the nature of the 3-H atom of the selenonaphthene unit would give further evidence for the existence of the Se–Pd bond since it was thought that in the structure (VIII) the 3-H atom is likely to be more aliphatic—or less aromatic—than in structure (IX), if π bonding does not occur.



(VIII)



(IX)

The NMR studies with an HR 100 Varian Spectrometer were somewhat hindered by the insolubility of the metal complex in the normal solvents. Solvents which dissolve the complex often do so by exchange of ligand and are thus not considered suitable. A spectrum obtained by summing 200 runs for a saturated solution in deuterochloroform did not indicate any significant change in the nature of the hydrogen atom in question. It is thus concluded that an overall aromaticity, and hence structure (IX), is possible.

A consideration of the various bond angles probable in the chelate ring indicates that there will be some deviation from the normal values. This deviation may tend to decrease the stability of any metal complex of the compound relative to what it would be theoretically if the chelate ring were not strained. The size of the metal atom will thus be of great importance for determining not only the amount of overlap between itself and the selenium orbitals, but also between itself and the nitrogen of the pyridyl ring. These two bond strengths will mainly determine the stability of the ring. In the case of Os(IV) the small ionic size (0·67 Å compared to 1·32 Å for Pd^{2+}) probably mitigates against the formation of a ring system.

On the basis of the stabilities of the (dialkyl-M_2)$PtCl_4$ complexes (where M = S, Se, Te) Chatt[8] suggested that the relative co-ordinating affinities of these Group VI atoms for Pt(II) were O < S ⩾ Se < Te. (He was unable to prepare the Se complex in a state pure enough to be used in quantitative studies.) He thus suggests that there will be very little π-bonding between Pt and Se. Pluščec and Westland[17] agree that the π-bond contribution to the platinum–selenium bond is abnormally slight, but state that in the case of L_4PdCl_2 (where L is a monodentate ligand) selenium forms a strong π-bond. They suggest that the order of ligand affinity suggested by Chatt is due to the abnormally weak platinum–selenium bond. From our considerations we suggest that the order for palladium in chelate complexes may well be O < S ⩾ Se > Te.

The contribution by the donor Group VI atom to π-bonding will be governed by the two effects of increase in the size and decrease in the electronegativity of the donor atom. These will be mutually opposed as the atomic number of the atom increases. In the addition compound with 2-(4-pyridyl)benzo[*b*]selenophene, we suggest that these two effects are almost balanced and that a strong Se–Pd π-bond is not possible. Thus the palladium will bond with the other competing ligand atom, (the nitrogen of the pyridyl unit) to give a compound of the structure stated.

In the case of the 2-(2-pyridyl)benzo[*b*]selenophene palladium complex, the delocalization of the electron density around the selenium donor atom by the formation of a π-bond in the then completely conjugated system, increases the apparent electronegativity of the selenium to such an extent that the π-bond is stable.

It is known[18] that in thiophene the screening effect of the 3*d* electrons of the hetero S atom is small, and hence the effective electronegativity of sulphur in thiophene is greater than in the analogous non-aromatic system. By analogy, since the screening effect of the 4*d* electrons of the selenium in 2-(2-pyridyl)benzo[*b*]selenophene is even less than the screening in thiophene, the apparent electronegativity of the selenium will be high. This delocalization will be carried over the ··Se··C··C··N·· system, and hence increase the apparent electronegativity of the selenium. (A similar effect has been used to explain the increased quadrupole resonance frequency of the chlorine in 2-chlorothiophene, due to the decreased σ-bond polarity of the carbon–chlorine bond.[19])

Thus in the conjugated system considered, the probability of π-bonding between the palladium and selenium is high. Further experimental evidence of this π-bonding is obtained by considering the lability of the chlorine atoms in the two complexes, the palladium 2-(2-pyridyl)benzo[*b*]selenophene complex and the 4-pyridyl analogue. In the first, the delocalization of the electron density around the palladium atom should increase the polarity of the palladium–chlorine bond, and hence its strength. This we regard as the reason why the chlorine atoms in this complex may be removed by precipitation with silver only on prolonged boiling, whereas treatment of a warm suspension of the second with silver nitrate results in an immediate precipitate of silver chloride.

We thus conclude that the experimental evidence indicates that, in a suitably arranged chelate system, the grouping ··Se··C··C··N·· is highly selective for palladium, and that delocalization of the electron density by π-bond formation between the palladium and the selenium is a major factor in determining the stability of the chelated complex.

The selectivity of the reagent towards palladium(II) and platinum(II) is determined by two conditions.

(*i*) Only metal ions which have, in the square planar configuration, orbitals available for overlap with the hybrid $4p4d^2$ orbitals of the "aromatic" selenium will be capable of π-bond formation and hence delocalization of the electron density around the central metal atom.

(*ii*) Only such ions that fulfil condition (*i*) and have a size such that there is the minimum deviation from "normal" bond angles when the 5-membered chelate ring containing 4 dissimilar atoms is formed, may form a stable complex.

Of the metals ion species considered, only palladium(II) satisfies both conditions. It is possible that the introduction of groups into the pyridyl system, in such positions as to increase the electron density at the hetero atom will cause greater electron delocalization along the metal to selenium bond and hence give greater stability to the system. If such groups are hydrophobic then it is probable that the solubility of the palladium complex will be sufficiently low to enable the compound to be used as a selective reagent for palladium determinations.

Zusammenfassung—2-(2-Pyridyl)benzo[*b*]selenophen wurde als mögliches Reagens auf Palladium untersucht. Aus einer Betrachtung seiner Reaktionen mit mehreren Metallionen und der wahrscheinlichen Struktur des Komplexes aus der Verbindung und Palladium wird geschlossen, daß die Gruppe —Se⋯C⋯C⋯N— hochselektiv für Palladium sein kann. Nach den experimentellen Ergebnissen wird vermutet, daß die Delokalisierung der Elektronendichte an den Metallatomen durch Bildung von π-Bindungen zwischen Palladium- und Selenatom ein wesentlicher Faktor bei der Stabilisierung des Chelates ist.

Résumé—On a étudié la 2-(2-pyridyl) benzo [*b*] sélénophénone en tant que réactif possible du palladium. En considérent ses réctions avec divers ions métalliques et la structure probable du complexe formé entre le composé et le palladium(II), on admet que le groupe —Se⋯C⋯C⋯N— peut être hautement sélectif du palladium. En se basant sur l'expérience, on suggère que la délocalisation de la densité électronique du métal par formation de liaison π entre les atomes de palladium et de sélénium est un facteur essentiel dans la détermination de 'a stabilité du complex chélaté.

KINETICS OF THE PRECIPITATION OF PALLADIUM DIMETHYLGLYOXIMATE FROM HOMOGENEOUS SOLUTION

PAUL R. ELLEFSEN* and LOUIS GORDON†
Department of Chemistry, Case Institute of Technology, Cleveland, Ohio, U.S.A.

(*Received* 1 *December* 1966. *Accepted* 20 *January* 1967)

Summary—The kinetics of formation of palladium dimethylglyoximate in the post-nucleation and pre-nucleation stages, and the effect of palladium on the reaction of biacetyl and hydroxylamine, have been studied.

PALLADIUM[1] and nickel[2] have been precipitated with dimethylglyoxime from homogeneous solution by the reaction of biacetyl and hydroxylamine. The kinetics and mechanism of the precipitation of nickel have been investigated by Hileman and Gordon.[3] A preliminary study of the kinetics and mechanism of the reaction of biacetyl and hydroxylamine in the absence of palladium has been carried out by Ellefsen and Gordon.[4] A study of the effect of palladium on this reaction sequence and a study of the kinetics of formation of palladium dimethylglyoximate in the pre-nucleation and post-nucleation stages are presented in this paper.

EXPERIMENTAL

Apparatus

All spectrophotometric measurements were carried out on a Cary Model 14 spectrophotometer equipped with a cell compartment thermostatically controlled to 0·05°.

Reagents

Hydroxylamine hydrochloride, biacetyl monoxime, biacetyl and dimethylglyoxime were prepared as described previously.[3]

Palladium chloride (J. T. Baker) was dissolved in very dilute hydrochloric acid and its concentration was determined by precipitation with dimethylglyoxime.

Procedures

In the pre-nucleation experiments, a spectrophotometric cell containing known concentrations of hydrochloric acid, hydroxylamine hydrochloride and palladium was brought to constant temperature. A known amount of biacetyl monoxime in solution was then added by means of a Hamilton microlitre syringe (0·0500-ml capacity) fitted with a Chaney adaptor. The absorbance was measured as a function of time, at 3800 Å where a minimum occurs in the spectrum of the palladium chloride complex (*cf.* Fig. 1).

In the post-nucleation experiments, gravimetric analysis was used. Several identical solutions containing hydroxylamine hydrochloride, hydrochloric acid and palladium were brought to constant temperature and a solution of biacetyl monoxime was added to each by pipette. At various times after the formation of palladium dimethylglyoximate, the solid phase was removed, dried and weighed.

RESULTS AND DISCUSSION

Reactions of the palladium chloride complex

The visible spectra of biacetyl, the palladium chloride complex and palladium dimethylglyoximate are shown in Fig. 1. Dimethylglyoxime and biacetyl monoxime do not absorb in the visible region. The spectrum of palladium dimethylglyoximate is less exact than the other two spectra owing to the larger errors involved in measuring the absorbance of the very sparingly soluble chelate. The absorbance of a nearly saturated solution of palladium dimethylglyoximate was measured in a 10-cm cell used in conjunction with a slide wire giving full-scale expansion for the range 0·0–0·1.

Biacetyl monoxime reacted rapidly with the palladium chloride complex in neutral solution producing a yellow complex with the spectrum shown in Fig. 2. The complex slowly underwent some further unknown reaction; the absorbance in the visible region gradually decreased with no new peaks appearing.

A very slow reaction occurs in a solution (at 25°) in which [HM] = $4{\cdot}64 \times 10^{-3}M$, [B]* = $0{\cdot}115M$, $[PdCl_4^{2-}] = 9{\cdot}39 \times 10^{-4}M$ and [HCl] = $0{\cdot}406M$. The absorbance at 4800 Å (*cf.* the maximum in the spectrum of the palladium chloride complex in

* Biacetyl monoxime decomposes in acid solution. With biacetyl present virtually none of the monoxime decomposes.[4]

Fig. 1) decreased by about 5% in 7 hr. If the reaction mixture is also made 2·00*M* in potassium chloride, the absorbance remains virtually constant for 19 hr. Obviously, neither biacetyl nor biacetyl monoxime forms complexes with palladium to a detectable extent under these conditions. The lack of reaction can be attributed to both hydrogen and chloride ions, *i.e.*, biacetyl monoxime is converted into its unreactive un-ionized species and at the same time the dissociation of the palladium chloride complex is

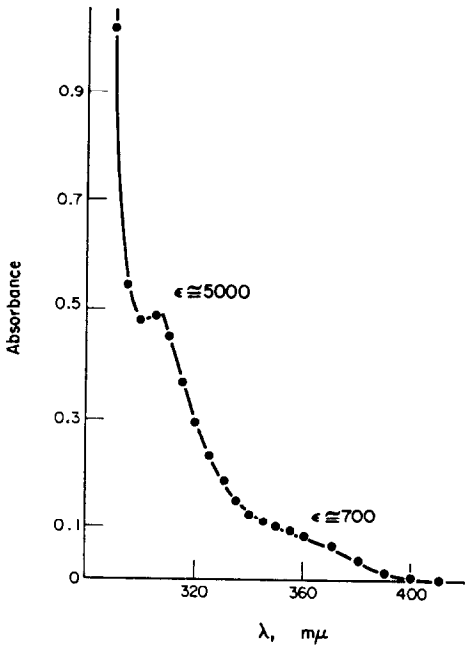

FIG. 2.—Spectrum of the biacetyl monoxime–palladium complex.

suppressed. In a similar manner, it was found that palladium would not react with hydroxylamine under these conditions, this being attributable to the formation of unreactive protonated hydroxylamine[5] and to the stability of the palladium chloride complex.

All subsequent reactions were carried out at 25° in 2·00*M* potassium chloride and 0·406 or 0·203*M* hydrochloric acid. This was done because it was found that the generation of dimethylglyoxime from biacetyl (or biacetyl monoxime) and hydroxylamine is essentially unaffected by the presence of palladium, greatly simplifying the kinetics. Biacetyl monoxime is stable in acid solution in the presence of excess of hydroxylamine hydrochloride[4] and initiation of the reaction sequence with biacetyl monoxime instead of biacetyl introduced an additional simplification.

Pre-nucleation kinetics

The mechanism for the formation of palladium dimethyglyoximate in the pre-nucleation stage has been found to be the following:

$$HM + Hx \xrightarrow{k_2'} HD + H_2O \quad (1)$$

$$HD + PdCl_4^{2-} \xrightarrow{k_3} PdDCl_2^- + 2Cl^- + H^+ \quad (2)$$

$$HD + PdDCl_2^- \xrightarrow{k_4} PdD_2 + 2Cl^- + H^+. \quad (3)$$

The formation of dimethylglyoxime is shown in equation (1) by a simplified mechanism.[4] As shown by equation (2), some intermediate such as $PdDCl_2^-$ is formed, but its exact nature has not been determined.

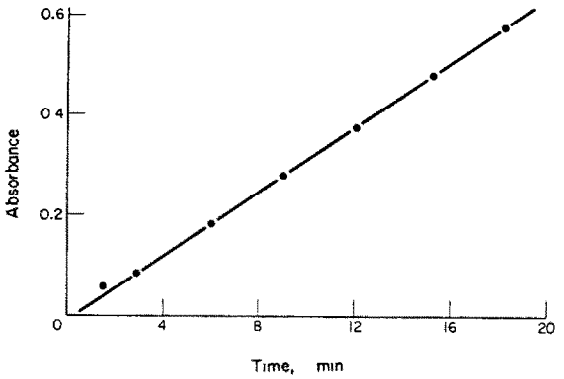

FIG. 3.—Rate of formation of PdD_2 at 25·0°C, from absorbance measurements at 3800 Å.
[KCl] 2·00M; [HCl] 0·406M; $[Hx]_i$ 3·714 × $10^{-2}M$; $[HM]_i$ 2·092 × $10^{-3}M$; $[Pd]_i$ 2·359 × $10^{-3}M$.

The reaction of high concentrations of biacetyl monoxime and hydroxylamine in the presence of palladium resulted in a linear increase in absorbance at 3800 Å over a period of 20 min (Fig. 3). A decrease in the concentration of biacetyl monoxime

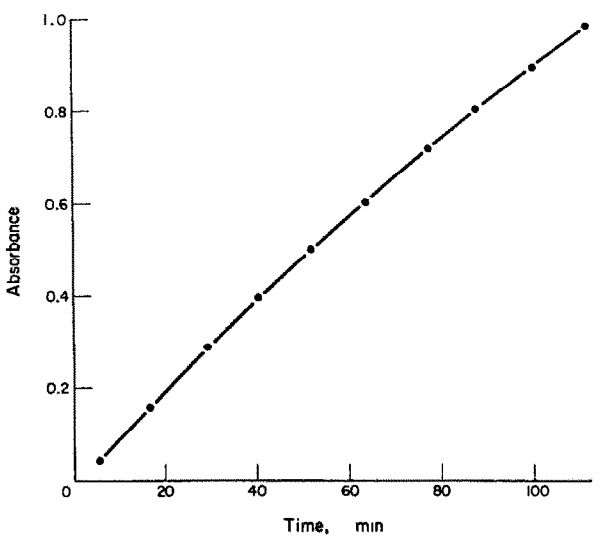

FIG. 4.—Rate of formation of PdD_2 at 25·0°C, from absorbance measurements at 3800 Å.
$[HM]_i$ 6·973 × $10^{-4}M$; other conditions as for Fig. 3.

resulted in the curved line shown in Fig. 4. A precipitate was not obtained in either of these experiments despite the very high supersaturations of palladium dimethylglyoximate existing towards the end of the reaction periods.

Preliminary investigations showed it could be assumed that (*a*) the increase in

absorbance is due to the formation of palladium dimethylglyoximate, (*b*) the concentration of the intermediate species $PdDCl_2^-$ is negligibly small ($k_4 \gg k_3$), (*c*) the formation of dimethylglyoxime by equation (1) is the rate determining step, (*d*) the presence of palladium has no significant effect on the generation of dimethylglyoxime, and (*e*) all the reactions are essentially irreversible. Then the rate constant k_2' and the molar absorptivity of palladium dimethylglyoximate at 3800 Å can be determined as shown in the following discussion.

The concentrations of HM and Hx given in Fig. 3 are high enough for the reaction to be pseudo zero-order. Thus,

$$\frac{d[PdD_2]}{dt} = \frac{k_2'[HM][Hx]}{2} = k_2'' \tag{4}$$

$$[PdD_2] = k_2'' t \tag{5}$$

$$A_{PdD_2} = k_2'' \epsilon_{PdD_2} t. \tag{6}$$

The value of $k_2''\epsilon_{PdD_2}$ and hence of $k_2'\epsilon_{PdD_2}$ can be obtained from the slope of the line in Fig. 3.

The concentration of HM given in Fig. 4 is smaller and the reaction is pseudo first-order. Hence

$$\ln\left\{\frac{[HM]_1}{[HM]_1 - 2A_{PdD_2}/\epsilon_{PdD_2}}\right\} = k_2'[Hx]t. \tag{7}$$

Because the value of $k_2'\epsilon_{PdD_2}$ is known, equation (7) can be solved for k_2' and ϵ_{PdD_2}.

By this method, the values obtained are $k_2' = 0{\cdot}115$ l.mole^{-1}.min^{-1} and $\epsilon_{PdD_2} = 770$; the value of ϵ_{PdD_2} has been corrected for the slight decrease in absorbance resulting from the disappearance of the palladium chloride complex.

The value of k_2' agrees quite well with the value of 0·0954 l.mole^{-1}.min^{-1} obtained by Ellefsen and Gordon[4] under essentially the same conditions except for the absence of palladium and with a somewhat higher concentration of hydroxylamine hydrochloride.

The value of ϵ_{PdD_2} obtained by the kinetic method agrees favourably with an approximate value obtained from the absorbance of a nearly saturated solution of palladium dimethylglyoximate of known concentration. At 3800 Å, the value of ϵ_{PdD_2} obtained was 816 ± 50. The results indicate that the assumptions made are justifiable.

In Fig. 5, the results are shown for the reaction of a large concentration of biacetyl monoxime and hydroxylamine in the presence of a variable amount of palladium. The generation of dimethylglyoxime is a pseudo zero-order reaction, and in each case the concentration of palladium is sufficiently high to be considered constant over the time-span used. As the concentration of palladium is decreased, an increasing period of time elapses before the increase in absorbance with time becomes linear (and the same in all cases). This is attributed to the time required for the build-up of a steady-state concentration of dimethylglyoxime and $PdDCl_2^-$. Some intermediate such as $PdDCl_2^-$ must be present because it is unlikely that PdD_2 would be formed by a three-body collision.

The concentrations of palladium in all experiments were high enough for reaction

(2) to be considered pseudo first-order. At higher concentrations of palladium such as in Figs. 3 and 4, the steady-state concentration of dimethylglyoxime is lower than that at the lower concentrations of palladium shown in Fig. 5. The concentration of $PdDCl_2^-$ is low in all cases. Therefore, the time required for generation of the steady-state concentrations of these species is less at higher concentrations of palladium than at lower. The curves shown in Figs. 3 and 4 can almost be extrapolated back to zero in contrast to the curves at the lower concentrations of palladium in Fig. 5.

Post-nucleation kinetics

The rate constant k_2' was determined in the post-nucleation stage from the amount of palladium dimethylglyoximate precipitated. The amounts of biacetyl monoxime and hydroxylamine consumed by the reaction were calculated from the quantity of dimethylglyoxime in the precipitate. This determination of the rate constant makes use of the assumptions mentioned in the section on pre-nucleation kinetics; the further assumption is made that all the dimethylglyoxime formed is present as palladium dimethylglyoximate. Other experiments in which palladium was precipitated from $2{\cdot}00M$ potassium chloride solution indicated no detectable increase in its solubility in this medium. The results obtained in the determination of k_2' are shown in Table I.

It can be seen that the observed rate constant increases with time, eventually reaching a limiting value. The low values obtained during the initial stages of the reaction indicate that supersaturation has not yet been relieved. The crystal growth step is not fast compared to reaction (1) until the rate of generation of palladium dimethylglyoximate decreases appreciably and until larger quantities of palladium dimethylglyoximate are present to offer many growth sites. At this stage, supersaturation approaches zero and the rate of formation of the solid phase is no longer a surface controlled reaction.

The limiting value of k_2' obtained in $0{\cdot}406M$ hydrochloric acid is about 0·127 $l.mole^{-1}.min^{-1}$. This is slightly higher than the value of 0·115 $l.mole^{-1}.min^{-1}$ obtained in the pre-nucleation stage. In $0{\cdot}203M$ acid, the limiting value of k_2' obtained is about 0·138 $l.mole^{-1}.min^{-1}$.

It is to be noted here that in both the post-nucleation, and pre-nucleation stages the rate constant is not a function of the initial concentrations of biacetyl monoxime, hydroxylamine or palladium.

MASS SPECTROMETRY OF METAL CHELATES—I

DETECTION ON THE PICOGRAM SCALE

Summary—A method has been developed for the detection and estimation of metals in the form of chelates in amounts down to 10^{-12} g. The chelate is evaporated into the source of a mass spectrometer and a continuous record of the ion current at a significant mass number is made. The integrated ion current is directly proportional to the concentration of metal chelate.

VERY small quantities of impurities in metals are commonly estimated with the aid of a spark source mass spectrometer. With this instrument a sample of the metal is vaporized before ionization and the ion currents corresponding to the components of the metal mixture are recorded on a photographic plate. The limit of detection of impurities in a sample is set at one part in 10^9. The chelates of many metals vaporize at temperatures considerably lower than those at which the parent metals have a detectable vapour pressure. As a result, it is possible to detect such metals as their chelates in the source of a conventional mass spectrometer such as the A.E.I. M.S.9 at temperatures between about 200° and 500°. It is the purpose of the present paper to describe a method in which the integrated ion current at a particular *m/e* value may be related to the concentration of a metal chelate and hence of the metal.

EXPERIMENTAL

Apparatus

All measurements were made with an A.E.I. M.S.9 mass spectrometer fitted with an insertion lock and a direct evaporation probe. Samples were admitted in pyrex glass tubes 27 mm long and 1 mm internal diameter which were fitted to the end of the probe and thrown away after use. The tubes were filled with up to 5 μl of the metal chelate solution by means of a Hamilton syringe (701-NW/G).

Reagents

Nickel dimethylglyoximate was supplied by Dr. W. I. Stephen. The sample was recrystallized from dimethylsulphoxide.

Nickel benzildioximate was obtained from the same source.

Heptacosafluoro-tri-n-butylamine was supplied by Koch–Light Laboratories Ltd.

A stock solution of nickel dimethylglyoximate was made by dissolving 1·00 mg in 10 ml of chloroform. It was stored cold.

Procedure

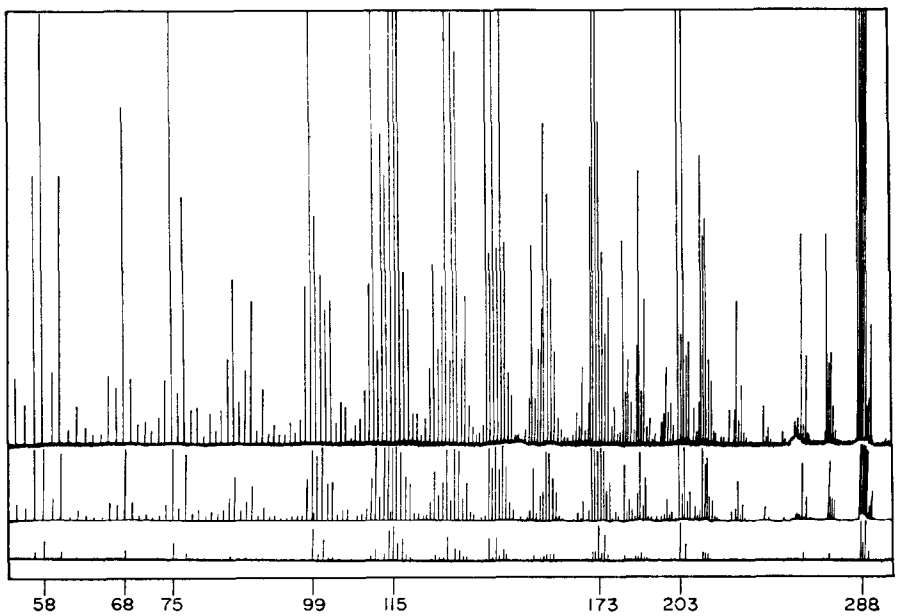
A measured volume (1–5 μl) of a solution of nickel dimethylglyoximate in chloroform was injected into the sample tube, which was then transferred to the vacuum system of the mass spectrometer through the insertion lock, and held in the cool part of the system. A measured pressure of heptacosafluoro-tri-n-butylamine was admitted to the gas-inlet system. The peak at *m/e* = 219 ($C_4F_9^+$) was selected and displayed on the oscilloscope. The decadic resistance was then set to a value of 1·315351 (the mass ratio for $C_8H_{14}N_4O_4Ni^+/C_4F_9^+$) and the peak switching system so adjusted that the oscilloscope gave an alternate display of the mass peaks at 219 and 288 ($C_8H_{14}N_4O_4Ni^+$). At this stage, the peak at *m/e* = 288 should not appear. The galvanometer recorder was then set in operation,

so as to record only the peak pair displayed on the oscilloscope. The sample tube was then lowered into the heated region of the source (*ca.* 250°) to allow evaporation of the metal chelate. When evaporation begins the peak at $m/e = 288$ appears on the oscilloscope and is recorded. Evaporation is complete in 10–20 sec depending on sample size, and the peak at $m/e = 288$ then disappears from the oscilloscope and the recorder trace. The amount of metal chelate evaporated is proportional to the integrated ion current at $m/e = 288$, and therefore to the area under the envelope of the $m/e = 288$ peaks on the recorder trace.

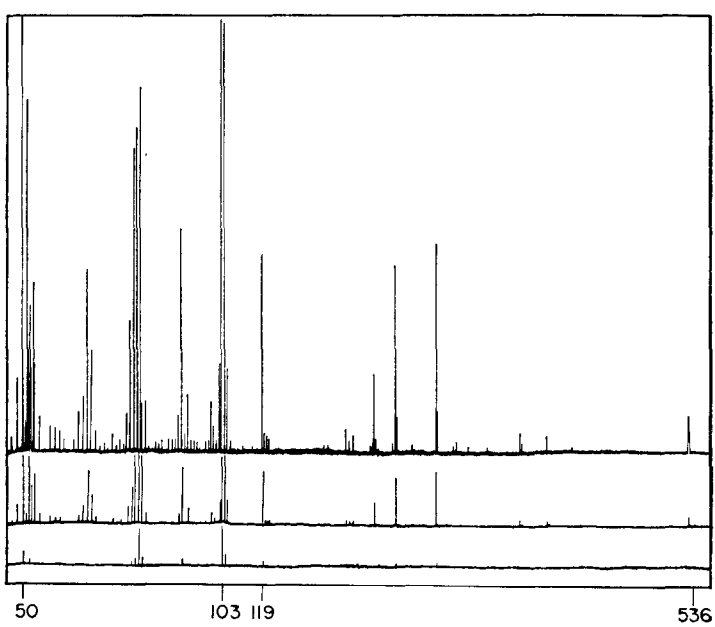
RESULTS AND DISCUSSION

It has been common practice, when carrying out quantitative analysis with a mass spectrometer, to provide a reservoir of sample vapour, the pressure of which remains substantially constant while a mass spectrum is recorded. The partial pressure of a component in the sample is then proportional to the height of mass peaks on the recorder trace which are due to that component only. The proportionality constant or sensitivity for each peak is determined by recording separately the mass spectrum of the pure component at a known pressure. The low volatility of metal chelates and the need to estimate minute quantities militates against the use of this procedure. Indeed, the only satisfactory method of recording the mass spectra of metal chelates is by their direct evaporation into the ion source from a probe which can be inserted into the vacuum system of the mass spectrometer. When such a device is used, however, two problems arise. The partial pressure of the metal chelate changes during the time required to record a mass spectrum, so that it is no longer possible to apply previously determined sensitivities, and in addition, at very low concentrations of the metal chelates, evaporation may be complete before the mass spectrum has been recorded. There is a further instrumental complication, in that the sensitivity of the instrument itself may change owing to deliberate or unintentional variations in the gain of the electron multiplier. It is therefore necessary to provide an internal standard of which the partial pressure is known and remains constant, and of which the mass spectrum may be recorded at the same time as that of the metal chelate. This may be most simply achieved by providing a reservoir of the vapour of heptacosa-fluoro-tri-n-butylamine (a compound commonly used as a mass marker in mass spectrometry) at a known pressure and allowing this to leak into the ion source at a constant rate at the same time as the metal chelate is evaporating.

As the complete mass spectrum of the metal chelate at low concentration cannot be recorded in the evaporation time, and because even if this were possible the mass peak sensitivities would not remain constant, it was decided to use a single mass peak characteristic of the metal chelate and to record the rise and fall of the ion current at this particular mass value during the course of the evaporation. The integrated ion current would then be directly proportional to the amount of metal chelate evaporated, and hence to the concentration of metal in the original sample, provided that no irreproducible thermal breakdown occurs during evaporation. The most suitable ion for this purpose would be that most characteristic of the metal chelate, and hence the molecule ion itself would be most desirable. Not all molecules exhibit a mass spectrum in which the molecule ion is represented by a mass peak, because some molecule ions are unstable. For this reason, two simple, moderately volatile, easily available chelates of nickel, the dimethylglyoximate and benzildioximate compounds, were obtained and their mass spectra recorded. In these preliminary experiments, solid samples were used in order to maintain an approximately constant rate of evaporation. The results shown in Fig. 1(a) and (b) reveal that the molecule ions of the two chelates were



(a) Nickel dimethylglyoximate



(b) Nickel benzildioximate

FIG. 1.—Mass spectra of nickel chelates

sufficiently stable to provide large mass peaks in the spectrum. The peak at $m/e = 288$ corresponding to the ion $C_8H_{14}N_4O_4{}^{58}Ni^+$ was selected from the spectrum of nickel dimethylglyoximate as suitable for quantitative studies, the rise and fall of this peak and the integrated ion current being recorded. There is an instrumental difficulty associated with such a recording in that no mass spectrometer can provide a means of tuning in the ion current at a selected m/e value before the ion current itself has been established. Thus, a method had to be found in which the instrument could record the ion current at $m/e = 288$ before, during and after evaporation. The method employed was to use a second substance, in this case heptacosafluoro-tri-n-butylamine, which did not exhibit a spectrum containing a peak at $m/e = 288$. A constant partial pressure of this substance is maintained within the ion source, using the conventional gas handling facilities of the instrument. It is then possible to select a peak from the mass spectrum of this compound which is close to $m/e = 288$. The peak selected is then displayed on the oscilloscope facilities of the instrument by the normal tuning in procedure. Using the peak comparison technique, it is now possible to display on the oscilloscope alternately the reference peak, which in this case is $m/e = 219$ ($C_4F_9^+$), and that at $m/e = 288$. This is achieved on the model M.S.9 by adjusting the decadic resistance to a value given by the ratio of the precise masses of the ions responsible for the peaks at m/e 219 and 288.

$$\frac{288{\cdot}055269}{218{\cdot}985620} = 1{\cdot}315407$$
