A recorder trace taken at this stage shows only the $m/e = 219$ peak repeated at intervals see [Fig. (2a)]. When the sample is lowered into the heating region of the ion source, and evaporation begins, a second peak appears between the repeated $m/e = 219$ peaks. In sharp distinction from the latter, which has a constant height, this second peak ($m/e = 288$) increases in height, reaches a maximum and then decays and finally disappears. It is the envelope of these secondary peaks [see Fig. (2b)] which is a record of the rise and fall of the ion current at $m/e = 288$, and it is therefore the area under this envelope which is proportional to the integrated ion current and hence to the concentration of metal chelates.

It can now be seen that the reference compound serves a two-fold purpose, it enables the mass scale to be calibrated so that the rise and fall of the selected sample peak can be completely recorded and it provides an internal standard against which any variation of instrument sensitivity may be measured.

The alternative procedure of recording continuously the peak height at $m/e = 288$ was discarded because instrumental drift caused the peak height to vary during evaporation. The peak comparison technique, although providing an interrupted rather than a continuous trace, ensured that the full peak height was always recorded.

The ultimate sensitivity of the instrument using this technique was now investigated. The stock solution of 0·01 % nickel dimethylglyoximate in chloroform was successively diluted by factors of 10, and 1 μl of the solution was examined at each dilution. The sensitivity of the instrument itself could be varied over several orders of magnitude by adjustment of the electron multiplier gain and the electron beam current. Figure 2(b) shows the recorder trace obtained from 1 μl of the stock 0·01 % solution, corresponding to a total sample weight of 10^{-7} g. This was recorded at low sensitivity, and the sample size could be reduced to 10^{-10} g before it was necessary to increase the

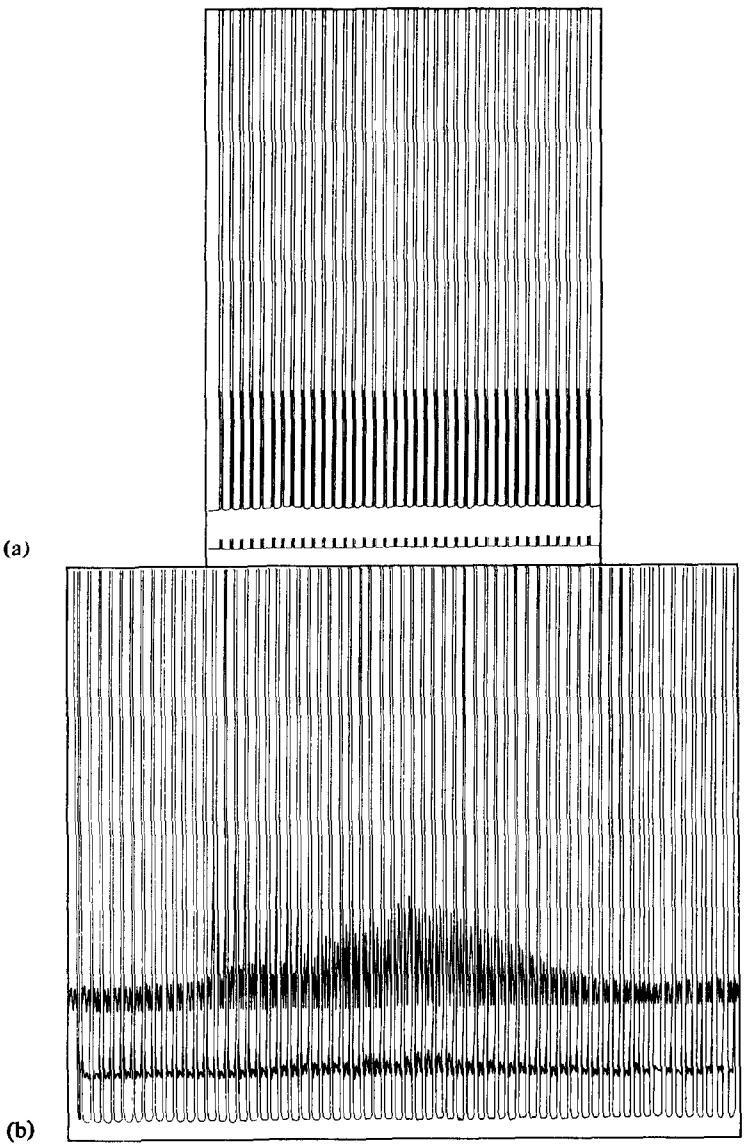

FIG. 2.—Continuous records of peaks at *m/e* 219 and 288.
(a) Before evaporation of nickel dimethylglyoximate
(b) During evaporation.

electron multiplier gain. As the gain was increased the signal-to-noise ratio was reduced, but at the highest usable gain the sample size could be reduced to 10^{-14} g (see Fig. 3).

With the electron multiplier gain constant, a series of determinations were made for different sample sizes. When the area under the envelope is plotted against sample size a straight-line relationship is obtained.

When determinations were repeated with stock solutions which had been allowed to stand for a day, it was found that the sensitivity had apparently dropped. This effect was traced to the instability of nickel dimethylglyoximate in chloroform, by the

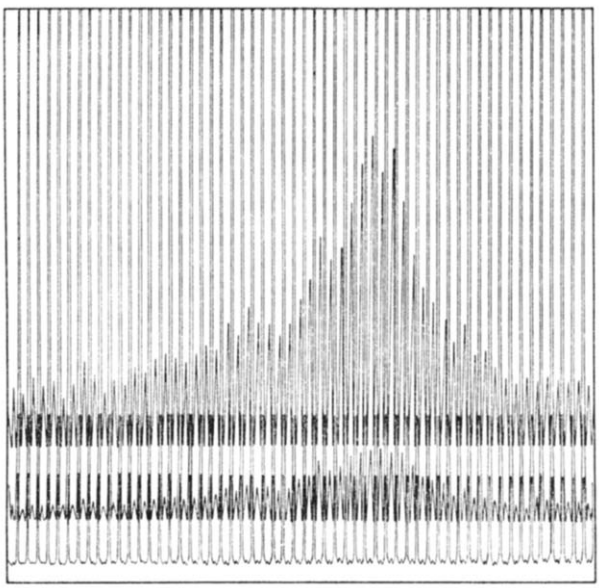

FIG. 3.—Record obtained during evaporation of 10^{-14} g of nickel dimethylglyoximate.

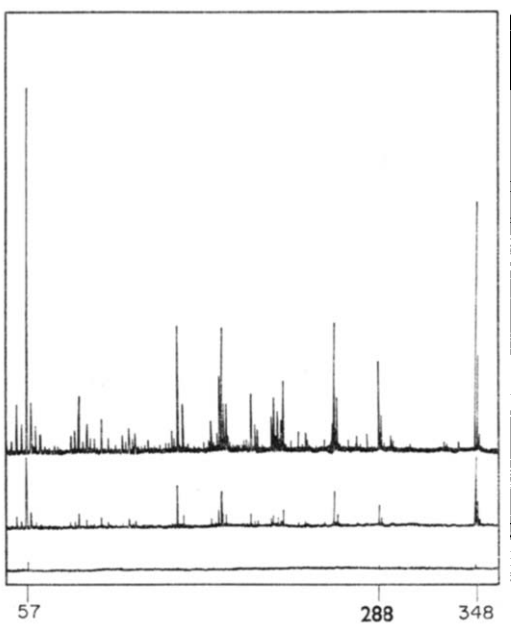

FIG. 4.—Mass spectrum of decomposition products of nickel dimethylglyoximate in chloroform.

observation of the appearance of a small subsidiary peak at $m/e = 288$, due to an ion with a mass sufficiently different from that of $C_8H_{14}N_4O_4{}^{58}Ni^+$ to be resolved by the instrument at low resolution. The determination of its precise mass revealed that it contained no nickel.

A complete mass spectrum was therefore recorded for the stock solution at various times after its preparation. This spectrum is illustrated in Fig. 4 and reveals the gradual

decay of the nickel dimethylglyoximate molecule ion peak, and the rise of peaks at m/e values above 288. Precise mass measurements of these peaks revealed that the corresponding ions contained no nickel atoms. The compounds responsible for these spectra are most probably formed by the polymerization of dimethylglyoxime molecules or their breakdown products. It can be demonstrated that several compounds are involved, by recording a mass spectrum very rapidly (8 sec) as soon as the sample is lowered into the heating region of the source, and before evaporation of the chelate has begun. Such a spectrum contains no peaks due to ions containing nickel atoms, and must be derived from a compound more volatile than the metal chelate. However, the spectrum obtained from the chloroform solution on prolonged standing does not correspond to a simple superposition of this spectrum on that of the metal chelate.

CONCLUSIONS

A method has been devised for the detection of metal chelates in quantities down to 10^{-14} g. Quantitative determination of these low concentrations is dependent on the development of an unequivocal procedure for calibrating the instrument. It has been found that because of their instability the stepwise dilution of chloroform solutions of nickel dimethylglyoximate does not provide a reliable calibration procedure unless the solutions are used immediately.

Acknowledgement—The authors wish to thank Miss M. Reade for her assistance in recording the mass spectra.

Zusammenfassung—Eine Methode zu Nachweis und Bestimmung von Metallen in Form von Chelaten in Mengen bis herunter zu 10^{-13} g wurde entwickelt. Das Chelat wird in der Ionenquelle eines Massenspektrometers verdampft und der Ionenstrom bei einer geeigneten Massenzahl registriert. Der integrierte Ionenstrom ist direkt proportional zur Chelatkonzentration.

Résumé—On a élaboré une methode pour la détection et l'estimation de métaux sous forme de chélates en quantités pouvant descendre jusqu'à 10^{-12} g. On évapore le chélate dans la source d'un spectromètre de masse et effectue un enregistrement continu du courant ionique à un nombre de masse significatif. Le courant ionique intégré est directement proportionnel à la concentration du chélate métallique

ANION-EXCHANGE SEPARATION OF COBALT FROM NICKEL

O. G. BALAKRISHNAN NAMBIAR and P. R. SUBBARAMAN
National Chemical Laboratory, Poona-8, India.

(*Received* 23 *December* 1966. *Accepted* 10 *February* 1967)

Summary—An anion-exchange method has been developed for the separation of cobalt from nickel, based on the observation that from a malonic acid solution containing sodium nitrite, cobalt is preferentially adsorbed by the exchanger but nickel passes through. The cobalt is eluted with 2*M* ammonium chloride in dilute ammonia solution. From an ammonium malonate solution containing chloride and nitrate, cobalt is quantitatively electro-deposited on a platinum cathode to give a bright, adherent deposit. Nickel is deposited from a solution of similar composition.

AMONG the available methods for the determination of cobalt, the titrimetric procedure with EDTA,[1] and the two gravimetric procedures[1] based on precipitation with 1-nitroso-2-naphthol and on electro-deposition appear to be the most popular. While the first two procedures cannot handle more than 50 mg of cobalt, the electrogravimetric procedure is more flexible, enabling much higher quantities to be determined. The 1-nitroso-2-naphthol method suffers from the fact that the oxygen–cobalt ratio in the final weighing form Co_3O_4 is not strictly stoichiometric. The more accurate electro-gravimetric procedure is also not entirely satisfactory. Salyer and Sweet[2] have critically examined the different electrolytic baths proposed and shown that slightly higher results are obtained in every case although cobalt in amounts varying from 0·05 to 4 mg remains in solution. Depending on the depolarizers added to the bath, the cobalt deposits are contaminated with carbon, sulphur or phosphorus.

When cobalt and nickel co-exist, they have to be separated from one another before the titrimetric or electrolytic methods can be employed. Most of the methods of separation of cobalt from nickel are based on[3,4,5] the selective adsorption from hydrochloric acid solution of the chloro-complex of cobalt on a strongly basic anion-exchanger. A recent report indicates that an anion-exchange separation is also possible by preferentially adsorbing cobalt from a cyanate solution.[6]

While investigating the complex formation of some transition metals with malonic acid and its derivatives, we have observed that both cobalt and nickel give bright adherent quantitative deposits on a platinum cathode from a malonic acid bath. Cobalt is also quantitatively taken up on a strongly basic anion-exchanger to the exclusion of nickel from a malonic acid solution containing nitrite. The methods developed, based on these observations, for the separation of cobalt from nickel and its electro-deposition, are reported in this communication.

EXPERIMENTAL

A conventional type of electro-analysis assembly was used. The cathode was a hollow perforated platinum cylinder (surface area about 35 cm^2) and the anode a stout platinum wire, coiled into a helix

and suspended at the centre of the cathode. A Bausch and Lomb Spectronic 20 was used for colorimetric estimation.

Beds, 15 × 2 cm, of Amberlite IRA 400, −80 + 200 BSS, 8% cross linked chloride form, were used for the anion-exchange.

Reagents

Malonic acid prepared by the Fine Chemicals Section of this laboratory was used. All other chemicals were of AnalaR grade. The eluting agent for cobalt was 2*M* ammonium chloride in dilute ammonium hydroxide.

Electro-deposition

The volume of the electrolytic bath was maintained at around 150 ml. Electrolysis was carried out at room temperature. Completeness of electro-decomposition of cobalt was tested for by treating a few drops of the electrolyte with 0·5% aqueous nitroso-R-salt solution after buffering with 50% aqueous sodium acetate and acidifying with nitric acid. Nickel was tested for with dimethylglyoxime.

After deposition the cathode was rinsed with water and ethanol, dried at 100°, cooled and weighed. The cobalt deposit was dissolved in cold concentrated nitric acid, fumed with sulphuric acid, heated to 600° in a platinum dish, cooled and weighed as cobalt sulphate.

Anion-exchange separation of cobalt from nickel

Solutions of cobalt and nickel chlorides were prepared from their pure salts and standardized. Cobalt was determined as sulphate (after 1-nitroso-2-naphthol precipitation) and nickel by precipitation with dimethylglyoxime. The anion-exchange resin was poured in the form of a slurry into a Pyrex glass column and converted into the chloride form with hydrochloric acid.

The desired volumes of standard cobalt and nickel solutions were mixed in a 250-ml beaker; 2 g of malonic acid were added and the solution was diluted to about 100 ml and warmed. Then 2 g of sodium nitrite dissolved in 15 ml of water were added slowly to the solution, which was then cooled to room temperature and passed through the anion-exchanger at the rate of 5 ml/min. The column was flushed with 60 ml of 1% ammonium chloride solution. The effluent then contained all the nickel, while the column held the cobalt in the form of an anionic-complex. The nickel in the effluent was determined either by precipitation with dimethylglyoxime or by electro-deposition from a malonic acid medium. The bromine-dimethylglyoxime colorimetric method was used for amounts of nickel below 5 mg.

The cobalt was eluted with 2*M* ammonium chloride in dilute ammonia solution at the rate of 5 ml/min, 80–100 ml of the eluent sufficing for complete elution of cobalt. Because of the intense red colour of the adsorbed cobalt band, its movement down the column was readily followed. The effluent containing the cobalt was acidified with hydrochloric acid, boiled to remove nitrous fumes, and cooled. To the cooled solution, 4 g of malonic acid, 3 g of ammonium nitrate and 30 ml of dilute ammonia solution (1 + 1) were added, the mixture was diluted to 150 ml, and the cobalt was determined by electro-deposition. Cobalt in amounts less than 2 mg was determined by the colorimetric nitroso-R-salt method.

RESULTS AND DISCUSSION

Electro-deposition of cobalt

From an ammonium malonate bath containing chloride or sulphate, cobalt was deposited on the perforated platinum cathode almost quantitatively, but the deposit was dull and non-adherent. Curiously enough, when to such a bath a little ammonium nitrate (which ordinarily inhibits[7] the deposition of cobalt) is added, the cathodic deposit is bright, adherent and quantitative. However, increasing amounts of nitrate prolong the time needed for deposition. For instance, complete deposition of 200 mg of cobalt takes over 150 min when 10 g of ammonium nitrate are added to the bath, but if the initial concentration of the nitrate is controlled, quantitative deposition is effected in a reasonable time. The deposition of nickel from such baths also proceeds satisfactorily. Table I shows typical results for the deposition of cobalt and nickel from malonate baths. Deposition of over 1 g of cobalt is complete in about 90 min at a current of 9 A/dm^2. The desirable physical characteristics of the deposit are

not impaired even at higher current densities. Less than 10 μg of cobalt were found by the nitroso-R-salt method in the electrolytic bath after deposition. The purity of the cobalt deposit was confirmed by dissolving it and weighing as cobalt sulphate (Table I). The pink colour of the malonate bath suggests that malonate stabilizes cobalt(II) even in ammoniacal solution.

Separation of cobalt from nickel

The difference in behaviour of their complexes with isonitrosomalonic acid can be used to advantage in making an ion-exchange separation of cobalt and nickel. On treatment of a solution of malonic acid with sodium nitrite, nitrous fumes are evolved, followed by the formation of isonitrosomalonic acid.[8] When the reaction is carried out in the presence of cobalt, a deep red solution results which is not affected by the addition of either dilute acid or alkali, unlike isonitrosomalonic acid which is colourless in acid solution. When such a cobalt solution is passed through an anion-exchange column (IRA-400 in the chloride form) the cobalt is quantitatively retained in the

form of an intensely red band. In contrast, when a nickel solution is similarly treated no nickel is taken up by the exchanger. The complex species of cobalt and nickel formed in a malonic acid–nitrite medium thus appear to be dissimilar. The cobalt complex is taken up by the anion-exchanger from solutions of pH between 2 and 10. It is not desirable to have the ion-exchanger initially in the hydroxide form, because of the tendency of nickel to precipitate in the column at high pH. The results obtained for the separation of synthetic mixtures of cobalt and nickel are presented in Table II.

A dilute solution of sodium hydroxide containing sodium chloride fails to elute the cobalt from the column. Presumably, ammonia reacts with the cobalt complex to give a new cobalt species not adsorbed on the anion-exchanger.

Zusammenfassung—Eine Anionenaustauschmethode zur Kobalt-Nickel-Trennung wurde entwickelt auf Grund der Beobachtung, daß aus einer Natriumnitrit enthaltenden Malonsäurelösung Kobalt vorzugsweise vom Austauscher adsorbiert wird, während Nickel durchläuft. Kobalt wird mit 2*M* Ammoniumchlorid in verdünntem Ammoniak eluiert. Aus einer chlorid- und nitrathaltigen Ammonium-malonatlösung wird Kobalt quantitativ elektrolytisch auf einer Platinkathode abgeschieden und gibt einen blanken, gut haftenden Niederschlag. Nickel wird aus einem Bad ähnlicher Zusammensetzung abgeschieden.

Résumé—On a élaboré une méthode par échange d'anions pour la séparation du cobalt du nickel, basée sur l'observation que, à partir d'une solution d'acide malonique contenant du nitrite de sodium, le cobalt est adsorbé préférentiellement par l'échangeur alors que le nickel n'est pas retenu. On élue le cobalt par du chlorure d'ammonium 2*M* en solution ammoniacale diluée. A partir d'une solution de malonate d'ammonium contenant du chlorure et du nitrate, le cobalt se dépose quantitativement par électrolyse sur une cathode de platine en donnant un dépôt brillant et adhérant. Le nickel est déposé à partir d'un bain de composition similaire.

EMISSION SPECTRA OF NITROUS OXIDE SUPPORTED ACETYLENE FLAMES AT ATMOSPHERIC PRESSURE

G. F. KIRKBRIGHT, M. K. PETERS and T. S. WEST
Chemistry Department, Imperial College, London S.W.7

(*Received* 8 *December* 1966. *Accepted* 9 *February* 1967)

Summary—The emission spectra of a premixed flame of acetylene supported by nitrous oxide have been recorded under different fuel–gas mixture conditions. The emission spectra in these flames of a series of metals, for which it is difficult to obtain a significant population of ground state atoms for atomic absorption spectroscopy in more conventional flames, have also been studied. The red secondary zone which is present in the fuel-rich flames shows emission attributable to long-lived CN and NH species which form a strongly reducing atmosphere to inhibit refractory oxide formation from elements such as molybdenum, titanium and aluminium introduced into the flame. An attempt has also been made to explain some of the reactions which may occur between the flame species above the primary reaction zone.

THE use of flames of acetylene supported by nitrous oxide has been recommended for the determination by atomic absorption spectrophotometry of elements which form refractory oxides in premixed flames of hydrocarbons with air.[1,2] The higher sensitivity which is reported for several elements (*e.g.*, aluminium, titanium, tungsten and molybdenum) when this flame is used instead of luminous air–acetylene flames, probably arises from the production of a larger population of free metal atoms in the ground state when nitrous oxide–acetylene is employed. Little evidence has been presented, however, concerning the cause of the effectiveness of this flame in the production of free metal atoms for atomic absorption spectroscopy. The maximum temperature of a nitrous oxide–acetylene flame burning at atmospheric pressure has been quoted as 2955°.[3] No data are available, however, concerning the region of the flame in which this temperature is found, or the nature of the flame to which this temperature relates (truly stoichiometric, fuel-lean, or fuel-rich). Amos and Willis[2] considered the combustion process in a stoichiometric nitrous oxide–acetylene flame as

$$5N_2O \rightarrow 5N_2 + \tfrac{5}{2}O_2 \ldots \Delta H_{298} = +101{\cdot}5 \text{ kcal}$$

$$C_2H_2 + \tfrac{5}{2}O_2 \rightarrow 2CO_2 + H_2O \ldots \Delta H_{298} = -300{\cdot}1 \text{ kcal}$$

i.e., the nitrous oxide decomposes, and the temperature of the flame is increased by absorption of the energy liberated by the decomposition. The effectiveness for refractory elements of the nitrous oxide–acetylene and oxy-acetylene flames has been ascribed to their high temperatures (2955 and 3060° respectively) compared to that of an air–acetylene flame (2300°). It is difficult to accept an explanation of this type based solely on the improved atomization of the refractory species at these higher temperatures, bearing in mind that to obtain these temperatures more free oxygen is

provided for the acetylene combustion (either directly in oxy-acetylene flames or indirectly by the decomposition of nitrous oxide) than is employed in air–acetylene flames. It might be expected that this increase in the availability of oxygen might favour the formation of refractory species and that this should outweigh the ability of the hotter flame to dissociate the refractory oxides.

It appears that a more important cause of the high population of free atoms could be the existence of sufficient free carbon species in the flame to provide reducing conditions to prolong the lifetime of the larger atomic population produced by the higher temperature. The existence of free carbon itself would aid the production of free atoms by the reaction

$$MO + C \rightleftharpoons M + CO.$$

where MO is the refractory form of metal "M".

A mechanism of this type has already been suggested by Gibson, Grossman and Cooke[4] and also by Amos and Thomas[5] to explain the success of oxy-acetylene flames in the atomic absorption spectrophotometry of elements such as aluminium. Presumably, although they do not specify this, the carbon is provided immediately above the primary reaction zone of the oxy-acetylene flame and manifests itself as the continuous yellow–white luminosity always present in fuel-rich hydrocarbon flames.

The nitrous oxide–acetylene flame, on the other hand, provides good sensitivity for refractory elements without the need for the production of a yellow luminous flame. In slightly fuel-rich flames of nitrous oxide–acetylene a characteristic "red feather" exists between the primary reaction zone and the blue outer diffusion flame. This zone is clearly a secondary reaction zone and has a well-defined "reaction-front" of its own (see Fig. 2b). It is this zone of the flame which is often the most suitable for atomic absorption measurements for many elements.

In an attempt to explain the effectiveness of the nitrous oxide–acetylene flame, in particular the red zone, for atomic absorption work, we have examined spectrographically the emission from various zones of flames of differing compositions, in the presence and absence of elements which form refractory oxides or which are difficult to determine by atomic absorption methods in flames of hydrocarbons mixed with air. Gibson *et al.*[4] have shown that the emission intensity is closely related to the ground-state concentration of the species concerned; hence these investigations are useful in the interpretation of absorption processes in the flame. We have identified the principal molecular and atomic species which exist in each region of the flame, and attempted to account for some of its analytically interesting properties.

EXPERIMENTAL

Apparatus

Nitrous oxide–acetylene burner. This burner has been described previously.[6] It consists of a brass plate, with a slit 0·015 in. wide and 2 in. long, mounted on a brass base and premixing chamber similar to that employed in the air–acetylene burner used on the Unicam SP900A flame spectrophotometer. An air–acetylene mixture was first used in the burner, and the change to nitrous oxide–acetylene effected by gradual replacement of the air by nitrous oxide *via* a T-piece and two rotameters. The sample solutions were introduced *via* a nebulizer and glass expansion chamber and aspiration was *via* the nitrous oxide supply to the flame.

Spectrographic equipment. A Hilger large quartz spectrograph was used for these studies. The burner (B) was mounted on the optical bench so that it was "end-on" *i.e.*, an image of the 0·015–in. side of the burner was presented to the spectrograph (S) and focused either at the slit or the collimating

lens by quartz lenses (L) (Fig. 1). The "end-on" position was used to give more intensity at the spectrograph than when the burner was "broadside" on, but it was realized that there might be self-absorption of radiation from flame species with the burner in this position. Exposures were made on either Kodak or Ilford N.30, B.10 or R.40 plates depending on the wavelength range to be examined and the speed required. The plates were developed in Ilford ID36 developer under standardized conditions, and intensities were measured where necessary with a Hilger photomicrodensitometer. Metals were introduced into the flames as 10^{-1} or $10^{-2}M$ solutions of their nitrates, sulphates or chlorides *via* a Hilger and Watts "Uvispek" nebulizer (A) aspirated by nitrous oxide.

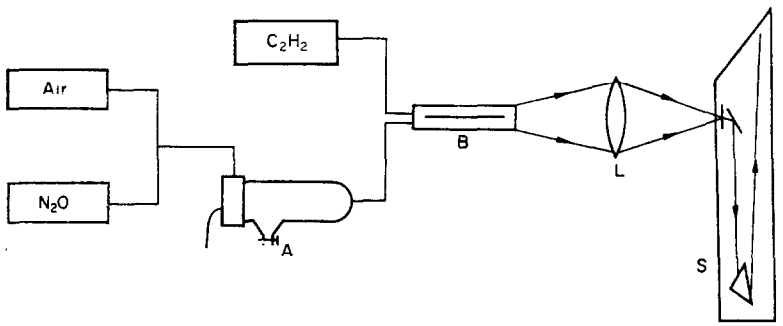

FIG. 1.—Diagrammatic arrangement of apparatus employed.

RESULTS AND DISCUSSION

Flames

Figure 2 shows the appearance of the nitrous oxide–acetylene flames examined.

Lean flames. Lean flames were obtained for nitrous oxide–acetylene with a flow-rate of 3 l/min of nitrous oxide and 1·8 l/min of acetylene. These flames appear as in Fig. 2a and exhibit only two zones, the primary reaction zone which is intensely white–blue in colour, and the outer (or diffusion) zone which is the typical blue colour of all stoichiometric or lean hydrocarbon–air flames. The emission spectra obtained over the range 2800–6700 Å are shown in Fig. 3a. The species identified in the primary reaction zone are OH, NH, CH, CN and C_2. Investigation at wavelengths less than 2800 Å also reveals emission from NO in this zone. The outer cone of these flames

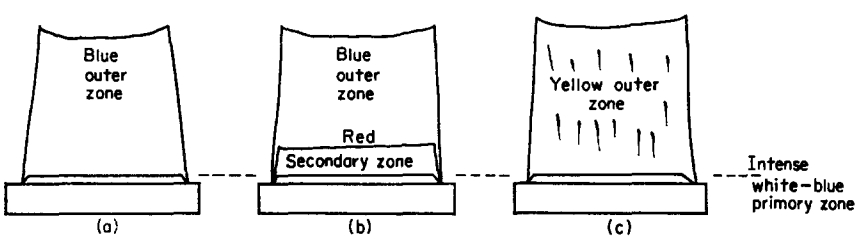

FIG. 2.—Appearance of (a) fuel-lean, (b) slightly fuel-rich, and (c) very fuel-rich nitrous oxide-acetylene flames burning at the rectangular burner (2 in. × 0·015 in. slit).

reveals intense emission only from OH bands at 2811 Å ($^2\Sigma$–$^2\Sigma$ (1, 0)) and 3064 Å ($^2\Sigma$–$^2\Pi$ (0, 0)). Also present in this zone is the continuum emission between 3000 and 5000 Å from the chemiluminescence of the reaction $CO + O \rightarrow CO_2 + h\nu$, which is responsible for the familiar blue colour of the flame. This continuum is overlaid by diffuse bands. Comparison of these lean flame emission spectra with

lean or stoichiometric hydrocarbon–air emission spectra reveals, as expected, that the species present in both zones are the same. The intensity of the band emission from these species, however, is considerably greater in nitrous oxide–acetylene flames, presumably due to the more favourable excitation conditions provided by the higher temperature.

"*Atomic absorption*" *flame.* This flame, which has already been used for the atomic-absorption spectrophotometry of several elements, was obtained with a flow-rate of 3 l/min of nitrous oxide and 2 l/min of acetylene. The flame, which is slightly fuel-rich, consists of three distinct zones as shown in Fig. 2b. These are (1) the intensely white–blue primary reaction zone, (2) the "red-feather" zone, and (3) the outer zone. A typical emission spectrum from this flame over the range 2800–6700 Å is shown in Fig. 3b. The species present in the primary reaction zone are again, as for the lean flame, the same as those present in most premixed flames of hydrocarbons burning with air. The outer diffusion zone also again exhibits emission from OH, although this is not as intense as in fuel-lean flames. The CO continuum is also weakened, as would be expected, as less oxygen is presumably available for its combustion with emission of chemiluminescence. The "red-feather" zone, which exists between the primary and outer zones, has a well-defined front of its own and appears as a separate reaction zone. With the burner used the height of this red zone could be as much as 2 cm, and was proportional to the amount of acetylene supplied to the flame. As can be seen in Fig. 3b, the species which predominate in this zone are CN and NH. The CN violet band system is clearly visible. This system is degraded towards the violet and has very well marked sequences. The (0, 0) sequence at 3883 Å is the strongest. The (0, 1) sequence of CN at 4216 Å, which is often obscured by CH unless it is very strong, is clearly visible, free from masking from the nearby CH (0, 0) system at 4315 Å which only appears at the bottom of the red zone. The intense (1, 0) sequence of CN at 3590 Å is present in this red zone and is clear from major overlapping features. This sequence often shows in hot flames containing nitrogen. Some sequences of the CN red system, which are not usually observed in flames with air, are emitted strongly in the red zone. Heads at 5730 Å (6, 1), 5858 Å (7, 2), 6191 Å (4, 0), 6332 Å (5, 1) and 6468 Å (6, 2), similar to those obtained in burning cyanogen,[7] are clearly visible. Emission assignable to CH is also present in this zone, but is restricted to the lower part of the red zone, immediately above the primary zone. The 4315 Å CH system is the strongest and is due to a $^2\Delta$–$^2\Pi$ transition. It is degraded towards shorter wavelengths, but only weakly. The 3900 Å system ($^2\Sigma$–$^2\Pi$) of CH is also visible, fairly strongly degraded towards the red so that its rotational structure appears more open than that of the 4315 Å system. The weakest sequence of CH in most flames is that at 3143 Å. This system is not easily observed in the red zone (but is clearly seen in the primary cone). This band is usually partly obscured by the strong rotational structure of the OH 3064 Å band, but can just be observed at 3143 Å at the expected intensity maximum from the Q branch. C_2 emission, like CH, is also present in the lower part of the red zone immediately above the reaction zone. The C_2 bands are degraded towards the violet and show well-marked sequences, the (1, 0), (0, 0) and (0, 1) sequences having heads at 4737, 5165 and 5635 Å. Only the strongest (0, 0) sequence of NH at 3360 Å ($^3\Pi$–$^3\Sigma$) is observed, but the intense emission from this is present throughout the whole of the red zone. Investigation of the emission from the base of the red zone

at wavelengths less than 2800 Å reveals the presence of the bands of the γ system of NO with heads at 2370 Å (0, 1), 2478 Å (0, 2) and 2595 Å (0, 3). The NO head at 2478 Å prevents the detection of the atomic carbon line reported to appear at 2478 Å in some very hot flames of carbon-rich fuels. The emission from OH at 3064 and 2811 Å in this zone is weaker than that in the primary and outer zones. It thus appears that the species responsible for the visible "red feather" is CN, which, along with NH, persists through the whole zone and is present in great abundance. At the base of the red zone, immediately above the primary reaction zone, C_2, CH and NO are also present and the OH emission is weak.

Fuel-rich flame. This flame was obtained with a flow-rate of 3 l/min of nitrous oxide and 2·3 l/min of acetylene. The flame appears as in Fig. 2c, and consists of two visible zones, the primary reaction zone and the intensely luminous outer cone. The primary combustion zone is not easily observed visually, and, although identifiable in the emission spectrum, no red emission zone can be seen. The yellow luminosity from carbon particles tends to mask the whole flame. The emission spectrum of this flame is shown in Fig. 3c. The visible region, between *ca.* 3600 and 6700 Å is overlaid by intense continuum emission from the incandescent carbon particles. Little difference is observed in the spectra of the primary and secondary zones from those of the slightly fuel-rich flames, with the exception that the γ NO system in the primary cone is weakened in this very fuel-rich flame. It is possible to distinguish the principal bands of CN and NH which presist very high in the flame. Weak C_2 emission is also present throughout the greater part of the flame length. Emission from OH and CH is very weak throughout the whole flame. The red emission of the CN bands at 5730 Å and above is obscured by the luminous carbon continuum. From these observations on the emission from the reaction zones of the different flames, it is possible to suggest an explanation of the analytically useful properties of the red zone in slightly fuel-rich flames. The CN and NH bands which persist through this zone, and the C_2 and CH bands in the lower part of the zone, occur when there is not sufficient oxidant in the mixture to convert all the carbon into carbon monoxide. Under these reducing conditions the CN and NH molecules formed in the reaction zone and above have an unusually long life-time. The OH emission in the lower part of the red zone is weakened, and the position of this weakening coincides with the disappearance of C_2 and CH species, probably by the reactions

(*a*) $$C_2 + OH \rightarrow CO + CH$$

(*b*) $$CH + OH \rightarrow CO + H_2.$$

There is strong evidence to suggest that much of the CH is produced from C_2 (as in *a* above) in hydrocarbon flames,[8] although the reaction path is not known with certainty. The red zone exhibits a clearly defined "reaction front" similar to those observed by Parker and Wolfhard[3] in other flames supported by oxides of nitrogen. The formation of more than one reaction zone is frequently linked with the fact that different reactions begin at different temperature levels in the combustion wave. Our evidence suggests that the nitrous oxide is not all decomposed to N_2 and O_2 in the primary reaction zone. It seems that appreciable quantities of NO are formed, either directly at the primary reaction front from N_2O or more probably as a product from the initial reaction of an acetylene molecule with N_2O. This latter

mechanism is suggested by the strength of the band systems of species containing nitrogen (CN, NH) in the flame which cannot be satisfactorily explained if decomposition of N_2O proceeds directly to N_2 and O_2.[8] The γ NO system is quite strong in and slightly above the primary zone. Little, if any, atomic oxygen is present in the red zone. The test for atomic oxygen in flames is to add small amounts of nitric oxide to the flame gases before combustion, and if atomic oxygen is present the continuum emission from the reaction $NO + O \rightarrow NO_2 + h\nu$ is always seen.[9] This continuum extends from *ca.* 4000 Å to the near infrared but is strongest in the yellow and green regions. Despite the significant emission from NO low in the zone, no trace of a continuum from atomic oxygen can be detected.

The red zone is not in itself a "diffusion" flame, and does not depend on the diffusion of oxygen in from the atmosphere or through the outer zone as does the burning of CO in the outer blue diffusion zone itself. This may be demonstrated by sheathing the whole flame in an atmosphere of argon, when no change in the appearance of the red zone is observed. The reaction front of the red zone thus appears similar to that of a premixed flame in nature, *i.e.*, the reactants are both present "behind" the reaction front.

The high concentration of CN and NH in the fuel-rich flames must result from the way in which the nitrous oxide reacts initially with an acetylene molecule. The long life-time of the reducing CN and NH species may then be attributed to the lack of sufficient oxidant in the form of OH or NO to consume these species rapidly. Thus reactions of the following type may account for the slow consumption of CN and NH.

$$CN + OH \rightarrow CO + N + H \quad \text{or} \quad CO + NH \tag{1}$$

$$NH + OH \rightarrow H_2 + NO \quad \text{or} \quad H_2O + N \tag{2}$$

$$CN + NO \rightarrow CO + N_2 \tag{3}$$

$$NH + NO \rightarrow OH + N_2 \tag{4}$$

The reactions (1) and (2) could explain the weakening of OH intensity in the red zone, and also account for the similar life-time of CN and NH due to reaction with the same species. Reactions (3) and (4) could also account for the slow consumption of CN and NH, and the disappearance of NO in the red zone and from the primary zone in very fuel-rich flames. These last reactions could also lead to a similar life-time of CN and NH owing to reaction with the same NO species whose production is dependent upon the decomposition of nitrous oxide in the primary zone.

It may be, however, that the combustion mechanism is better explained in the way suggested by Parker and Wolfhard[3] to account for the double reaction zones shown by hydrocarbon flames supported by nitrous oxide and nitrogen dioxide. Flames of hydrogen, for example, burning with a mixture of nitrous and nitric oxides show two reaction zones, and the second upper reaction zone is thought to coincide with the burning of hydrogen with nitric oxide which requires a higher temperature than the hydrogen–nitrous oxide reaction. The situation might be complicated by this type of effect in the nitrous oxide–acetylene flame, in which the nitric oxide produced in the primary zone does not react with degraded fuel molecules until well above this zone.

It seems certain that the effectiveness of the fuel-rich flame for atomic-absorption

spectrophotometry of refractory elements is not solely due either (*a*) to the high temperature available for refractory oxide dissociation, or (*b*) to the existence of "free" carbon for the reaction $MO + C \rightarrow M + CO$ to occur as suggested for luminous oxygen–acetylene flames by Gibson[4] and Amos and Thomas.[5] It will be seen from our results for elements such as molybdenum, that emission from the principal resonance lines occurs only in relatively fuel-rich nitrous oxide–acetylene flames and not in fuel-lean flames. For the nitrous oxide–acetylene flame, however, as for many hydrocarbon–air flames, the temperature and burning velocity are actually *lower* in fuel-rich flames than in fuel-lean flames. The red zone is virtually free from the incandescent carbon continuum. The reaction $MO + C_2 \rightarrow M + CO + C$ is possible at the base of the red zone, but C_2 emission is probably chemiluminescent and its actual concentration is low. Amos and Willis[2] made a comparison of nitrous oxide–acetylene and oxygen–nitrogen–acetylene flames for the atomic absorption spectrophotometry of many elements. They obtained similar sensitivities in the two flames for many refractory elements, and seem to ascribe this similarity to the similar high temperatures of the two flames. It appears, however, that the actual mechanisms by which the atmosphere of ground state atoms of the elements is maintained in these flames is different. It seems probable that in slightly fuel-rich luminous nitrogen–oxygen–acetylene flames the production of metal atoms from the oxide is assisted *via* the $MO + C \rightarrow CO + M$ reaction, and that in the red zone of the nitrous oxide–acetylene flame at a similar temperature the metal atom is protected by the extremely reducing atmosphere of CN and NH. When metal oxide is formed in the primary zone or above, it may also be attacked by NH or CN at this high temperature to provide free atoms by reactions of the type:

$$MO + NH \rightarrow M + NO + H \quad \text{or} \quad M + OH + N$$

$$MO + CN \rightarrow M + CO + N.$$

Emission spectra of metals in the flame

The emission spectra of the fuel-lean, slightly fuel-rich and very fuel-rich flames were recorded in the presence of a series of metals introduced into the flame as aqueous solutions of their simple salts. The metals chosen for examination were some of those elements which are difficult or impossible to determine by absorption spectrophotometry in flames burning with air owing to total or partial lack of atomization because of the formation of refractory oxides or other species. The emission spectra yield information concerning the existence and position in the flame of free excited atoms as well as molecules such as CaOH. The intensity of the emission is closely related to the ground-state concentration of the species concerned at any given temperature, and thus information on position and intensity of thermal emission is useful in the study of absorption processes.

Calcium. The emission spectra of the nitrous oxide–acetylene flame burning under the three fuel conditions in the presence of calcium are shown in Fig. 4. The calcium emission in a fuel-lean flame (Fig. 4a) resembles that in a hydrocarbon–air flame. Amos and Willis[2] have reported greater sensitivity for calcium in nitrous oxide–acetylene than in air–acetylene flames, and attributed this to more complete atomization. The presence, even in this flame, of much incompletely atomized calcium can be seen from the intense band emission at 5498 and 6097 Å attributable

to CaOH.[11] The 4226 Å line which is most commonly used for the determination of calcium by atomic absorption, is very intense throughout the whole length of the flame. The strong lines at 3933·7 and 3968·5 Å correspond to emission from singly ionized calcium atoms, Ca^+. The strength of these lines bears out the observation of Amos and Willis[2] concerning the high degree of ionization in this flame compared to air–acetylene flames. They estimate the ionization for calcium to be 43% in nitrous oxide–acetylene and 3% in air–acetylene. Figure 4d shows the emission spectrum of calcium in the corresponding air–acetylene flame, in which the ion lines are barely detectable. Figures 4e and 4f show the effect on calcium emission in slightly fuel-rich nitrous oxide–acetylene and air–acetylene flames of the addition of excess of potassium chloride. Potassium is more easily ionized than calcium, and the high concentration of electrons formed by the reaction $K \rightarrow K^+ + e$, tends to reverse the ionization $Ca \rightarrow Ca^+ + e$. The calcium lines at 3933·7 and 3968·5 Å are not visible in the nitrous oxide–acetylene flame in the presence of potassium, indicating virtually complete suppression of ionization. Ionization of calcium in its determination by atomic-absorption spectrophotometry leads to some curvature away from the concentration axis, and a linear curve may thus be obtained by adding potassium.

The calcium emission spectra from slightly fuel-rich and fuel-rich flames (Figs. 4b and 4c) are very similar. The principal difference in these spectra compared to that from a fuel-lean flame is that the CaOH band at 5498 Å is somewhat less broad, suggesting that the highly reducing nature of the flame results in more complete atomization. Some broadening of the CaOH bands on the spectrographic plate is also evident higher in the flame, possibly due to the production of more CaOH in this region by a three-body recombination reaction.

Molybdenum. The emission spectra of flames containing molybdenum are shown in Fig. 5a, b and c. In fuel-lean flames (Fig. 5a) no lines of molybdenum are observed. A diffuse continuum exists around 5600 and 6500 Å in the outer cone which is attributable to the species MoO.[12] In slightly fuel-rich flames (Fig. 5b) the molybdenum lines at 3132·6, 3158·2, 3170·3 and 3194·0 are strong and persist throughout the red zone of the flame, as do the strong lines at 3798·3, 3864·1 and 3903·0 Å. Several other lines are also weakly visible in the red zone, but no line emission occurs above this cone. In a very fuel-rich flame (Fig. 5c) the same lines are visible but persist throughout a greater length of the flame.

Aluminium. Figures 6a, b and c show the emission spectra of aluminium introduced into the nitrous oxide–acetylene flames. In the fuel-lean flame (Fig. 6a) only two strong lines are obtained, at 3944·0 and 3961·5 Å, and these are present over most of the length of the flame. The aluminium doublet at 3092·7 Å, which has been used for the determination of aluminium by atomic absorption in a nitrogen–oxygen–acetylene flame,[5] cannot be detected. The outer zone of the flame exhibits a series of moderately strong bands with heads at 4470·5, 4648·2, 4842·1 and 5079·3 Å and a weak one at 5336·9 Å. These bands have been attributed to the vibrational structure within the ground state $B^2\Sigma$–$^2\Sigma$ (ground state) electronic transition for AlO.[13] In slightly fuel-rich flames (Fig. 6b) these bands of AlO are weakened considerably and only the strongest at 4648·2, 4842·1 and 5079·3 Å are visible. The 3944·0 and 3961·5 Å lines are clearly visible, and appear more intense than in the fuel-lean flame. Although partly obscured by the OH bands at 3064 Å, the aluminium resonance

lines at 3082·2 and 3092·7 Å can be distinguished in the red zone. The fuel-rich flame spectrum (Fig. 6c) is similar, and the lines at 3082·2 and 3092·7 Å appear only slightly more intense than in the red-zone flame. The AlO bands, however, are barely visible in the fuel-rich flame.

Titanium. The titanium emission spectra in the different flames are shown in Figs. 7a, b and c. The behaviour of this element in the nitrous oxide–acetylene flame is similar to that of aluminium. Only bands due to TiO are found in fuel-lean flames. Some of the bands of the γ red system of TiO are present above 6215 Å, but most of the sequences of this strong system lie outside the upper limit of the investigation above 6800 Å. Sequences of the α blue-green system of TiO, where the electronic transition is $^3\Pi$–$^3\Pi$, ground state,[14] are present with a complex series of heads between 4462·1 and 6214·9 Å. Superimposed on these bands are those of the TiO orange system (β) with heads between 5597·8 and 5694·4 Å. No resonance lines of titanium are observed in this flame. In slightly fuel-rich flames (Fig. 7b) the TiO band systems are weakened in the outer zone, but are obscured to some extent by the C_2 and CN emission. Many resonance lines of titanium appear in the red zone, but not above, and the strongest appear at 3635·5, 3642·7 and 3653·5 Å. The appearance of this spectrum suggests that the slightly fuel-rich nitrous oxide–acetylene flame should enable titanium to be determined readily if the light path of the radiation from the source is restricted to pass within the red zone. The fuel-rich flame spectrum (Fig. 7c) is similar, with the exception that the Ti lines persist higher in the flame, and the TiO band spectrum is weakened further.

Iron. The iron flame emission spectra are shown in Figs. 8a, b and c. Very little difference is seen between fuel-lean, slightly fuel-rich and very fuel-rich flames. More of the principal resonance lines of iron are present over most of the flame length in nitrous oxide–acetylene than in the corresponding air–acetylene flames, presumably because of the higher temperature. Very little difference in the line intensities is observed in the flame under the different conditions. It is possible, therefore, that a fuel-lean flame might yield better precision (perhaps at some loss of sensitivity) for the determination of iron by atomic absorption spectroscopy in nitrous oxide–acetylene, owing to lack of background radiation from CN, CH and C_2. The continuum CO emission in the outer cone of the fuel-lean flame should not provide a source of noise as great as the other flame species containing carbon.

Chromium. The chromium emission spectra in the nitrous oxide–acetylene flame under different flame conditions are shown in Figs. 9a, b and c. As with iron, the spectra are similar. Two intense groups of three lines appear at 3578·7, 3593·5, 3605·3 and 4254·3, 4274·8, 4289·7 Å. The lines which have been used for the atomic absorption spectrophotometry of chromium in air–acetylene flames (3578·7 and 3593·5 Å) lie on the 3590 Å CN sequence in the fuel-rich nitrous oxide–acetylene flame. Our experience shows that greater sensitivity for chromium is obtained in the red zone than above it, or in fuel-lean flames. The noise levels at the 3578·7 and 3593·5 Å lines, however, even with a modulated hollow-cathode source and tuned amplifier, are too great to allow good precision. The 3605·3 Å line should provide good sensitivity with less background noise, and the 4254·3 Å line should give even less noise but probably less sensitivity.

Vanadium. The vanadium emission spectra are shown in Fig. 10a, b and c. In the fuel-lean flame no strong lines are observed above the primary reaction zone,

although the vanadium lines at 3066·4, 3183·4, 3184·0 and 3185·4 Å may show weak emission but are not distinguishable against the strong OH emission in this region. In slightly fuel-rich flames, the persistent lines at 3183·4, 3184·0 and 3185·4 Å are observed at the base of the red cone (and higher in very fuel-rich flames) against the weakened OH emission. The 3703 Å line, and the group of three lines at 4379·2, 4384·7 and 4390·0 Å, are clearly visible and persist in the reducing atmosphere. Because of the intense CN emission at the wavelengths concerned it is not possible to determine whether the vanadium lines at 3840·0 and 3855·8 Å examined by Amos and Willis[2] are present. No clearly assignable bands of the VO species can be detected. It seems that the determination of vanadium by atomic absorption spectrophotometry would be best conducted at 3184·0 Å in fuel-rich flames immediately above the reaction zone where OH noise is minimal.

Beryllium. Figures 11a, b and c show the emission spectra of beryllium introduced into the different flames. The fuel-lean flame (Fig. 11a) shows a strong band with a head at 4708 Å and a weak sequence with a head at 4427 Å attributable to the (0, 0) and (1, 0) vibrational bands within the $C^1\Sigma \rightarrow X^1\Sigma$ electronic transition of the blue-green system of BeO.[15] No beryllium resonance lines are observed. In slightly fuel-rich flames, however, the beryllium resonance line at 2348·6 Å is visible in the red zone, but this atomic emission is short-lived and does not persist to the top of the red cone. The BeO band at 4708 Å is not detectably weaker in this flame than in the fuel-lean flame. In the very fuel-rich flame (Fig. 11c) the Be line at 2348·6 Å is not easily observed, even against the weakened NO emission of the primary zone. The determination of beryllium in nitrous oxide–acetylene by atomic absorption would therefore appear most favourable at the base of the red zone in slightly fuel-rich flames.

Tin. The emission spectra of tin in the different flames are shown in Figs. 12a, b and c. In the fuel-rich flame the most prominent features are lines attributable to iron and chromium impurities. The persistent tin lines are not shown in the ultraviolet below 3300 Å above the primary zone. In the slightly fuel-rich flame (Fig. 12b), however, the atomic lines at 2354·8, 2429·5, 2546·6 and 2706·5 Å and the lines at 2840·0, 2863·3, 3175·1 and 3262·3 Å are visible in the red zone. The lines at 3009·1 and 3034·1 Å are quite strong and persist above the red zone. Any lines above 3262·3 Å are obscured by the flame emission bands. No definite band emission assignable to SnO, SnH or SnCl is observed in these flames. The fuel-rich spectrum (Fig. 12c) is similar, but the emission from the lines mentioned is stronger and longer-lived.

CONCLUSIONS

Our results suggest that the reactions which occur in the nitrous oxide–acetylene flame to provide and maintain an atomic population for refractory elements are somewhat more complex than can be explained by the reducing action of incandescent carbon particles which has been postulated to explain the action of the oxy-acetylene flame. In summary, it appears that nitrous oxide decomposes to provide oxygen at the primary reaction zone to raise the temperature and burning velocity of the flame. Some of the nitrous oxide decomposes to form nitric oxide and this, or the nitrous oxide itself, appears to react directly with fuel molecules in the primary zone to produce more CN and NH than are produced in a conventional hydrocarbon–air

flame. The life-time of these species is prolonged in regions well above the reaction zone, in the red zone, and in very fuel-rich flames, because of the lack of sufficient oxidant and owing to their slow rate of consumption by OH and possibly NO. A reducing atmosphere is thus provided to protect the metal atoms produced in the primary reaction zone by the high temperature. It is also possible that metal-oxide species produced may be reduced above the primary zone by the CN and NH species. As the flame is made very fuel-rich the reducing conditions due to CN and NH persist higher in the flame and their protective reducing action is supplemented by that of free incandescent carbon particles. It seems probable, from the results obtained on the introduction of metal ions into the flame, that very fuel-rich nitrous oxide–acetylene flames can provide good sensitivity in the atomic absorption spectrophotometry of refractory elements without the need for a limited flame area technique where radiation from the source is passed through the red zone of a slightly fuel-rich flame.

Résumé—Les spectres d'emission d'une flamme préalablement mélangée d'acétylène porté par du protoxyde d'azote ont été enregistrés dans différentes conditions de mélange avec du gaz combustible. On a aussi étudié les spectres d'émission dans ces flammes d'une série de métaux pour lesquels, dans des flammes plus usuelles, il est difficile d'obtenir une population importante d'atomes à l'état fondamental pour la spectroscopie d'absorption atomique. La zone rouge secondaire qui est présente dans les flammes riches en combustible montre une émission attribuable aux espèces CN et NH de longue vie, qui forment une atmosphère fortement réductrice inhibant la formation d'oxyde réfractaire à partir d'éléments tels que le molybdène, le titane et l'aluminium introduits dans la flamme. On a aussi tenté d'expliquer quelques-unes des réactions qui peuvent se produire entre les espèces de la flamme au-dessus de la zone de réaction primaire.

Zusammenfassung—Die Emissionsspektren einer vorgemischten Flamme aus Acetylen und Distickstoffoxid wurden bei verschiedene Mischungsverhältnissen registriert. Auch die Emissionsspektren einiger Metalle wurden in solchen Flammen untersucht, bei denen es in gebräuchlicheren Flammen schwierig ist, eine wesentliche Anzahl von Atomen im Grundzustand für die Atomabsorptions-Spektroskopie zu erhalten. Die rote Sekundärzone in acetylenreichen Flammen zeigt Emission langlebiger CN- und NH-Spezies, die eine stark reduzierende Atmosphäre bilden und damit die Bildung feuerfester Oxide zum Beispiel aus Molybdän, Titan und Aluminium verhindern. Es wurde auch versucht, einige der Reaktionen zu erklären, die sich zwischen den Flammen-spezies oberhalb der primären Reaktionszone abspielen können.

(*Received* 7 *July* 1966. *Accepted* 9 *February* 1967)

Summary—The use of alkylphosphoric acids for solvent extraction separations is described, and the use of antisynergic agents for stripping is discussed.

ALKYLPHOSPHORIC acids (APA) have found a practical application in the production technology of uranium, thorium, vanadium, scandium and indium, where they are used for the extraction, separation, and concentration of actinides and lanthanides. This class of extracting agents appears to be of much promise in the production of high-purity metals and their compounds, as well as for purely analytical use, because of the following factors: they give high distribution coefficients in extractions from solutions of different oxy-acids over a wide range of concentrations; the distribution coefficients do not decrease with a decrease in the concentration of the metal being extracted; it is possible to strip the extracts selectively with salts, acids, and mixtures of acids with antisynergic agents; they have low solubility in mineral acids.

We have studied the extraction mechanisms for gallium, indium, thallium(III), antimony(III) and (V), bismuth, and tin(II) and (IV), and the role of diluents and antisynergic agents. We have also examined the analytical possibilities of APA, using chiefly 1 *N* solutions of mono-2-ethylhexylphosphoric acid (MEHPA) and di-2-ethylhexylphosphoric acid (DEHPA) in heptane, and also a 1*N* mixture of pyro-2-ethylhexylphosphoric acids (PEHPA) in heptane. Certain problems can be solved by changing the extractant used, since in many cases the three acids behave differently.

Extraction from solutions of oxy-acids

As can be seen from Fig. 1, the extraction of gallium, indium, thallium(III), antimony(III), bismuth and tin(IV) by APA from sulphuric acid solutions is practically quantitative over a wide range of acid concentration, and (which is also of importance) over a wide range of metal concentration. This behaviour can be made use of both for the extraction separation of micro-quantities of the metal to be determined, and for removal of the matrix element. The equilibrium in the extraction of indium, gallium, thallium(III), antimony(III), bismuth and tin(II) is established in 20–30 sec, and in 60–70 min for the extraction of antimony(V) and tin(IV). Figure 2 shows that the nature of the APA is of decisive importance for the extraction of gallium, thallium and bismuth.

All the metals mentioned above can be separated by extraction from almost any quantity of the following elements, which are characterized by their low extractability into APA from acid media: alkali and alkaline earth metals, copper, zinc, iron(II),

cobalt, nickel, manganese(II) or (VII), mercury, arsenic(III) or (V), selenium, tellurium, germanium, chromium(III) or (VI), silver, gold, platinum metals,[1–3] and also lead if the latter is extracted from perchloric or nitric acid solution. This holds, with minor variations, for nitric and perchloric acid media as well as for sulphuric acid.

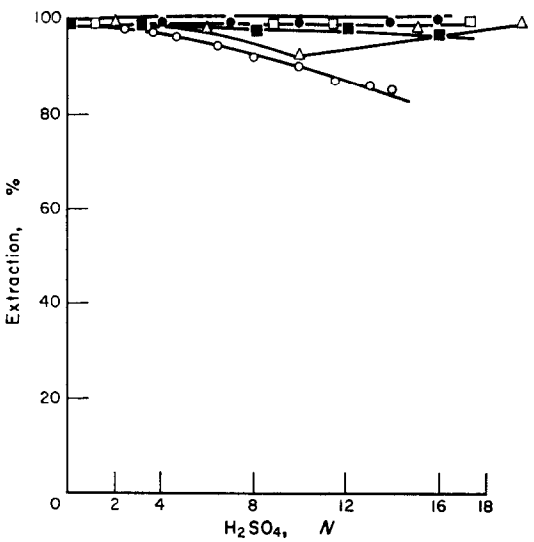

FIG. 1.—Effect of sulphuric acid concentration on extraction with PEHPA.
○—Sb(III); △—Ga; ●—Tl(III); □—In; ■—Bi.

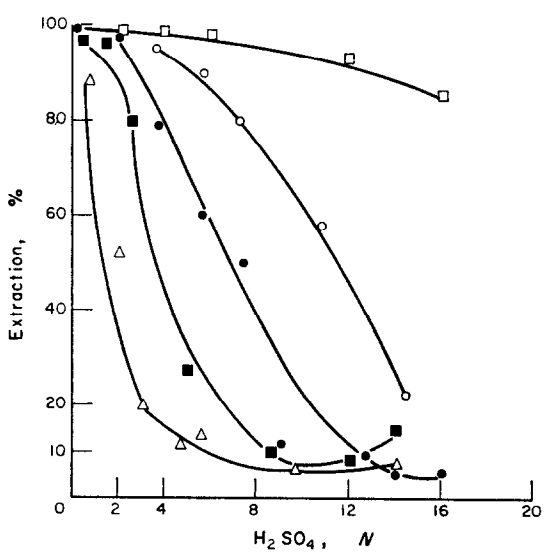

FIG. 2.—Effect of sulphuric acid concentration on extraction with DEHPA.
○—Sb(III); □—In; ●—Tl(III); △—Ga; ■—Bi.

It is difficult, however, to strip some of the metals extracted, and hydrofluoric acid is usually required as stripping agent. Such metals reduce the capacity of the extractant and are considered as "poisons" in technological processes. In analysis,

on the other hand, this creates additional possibilities for their separation. In certain cases, gallium, indium, thallium, antimony(III) and bismuth can be separated at the stripping stage from titanium, zirconium, hafnium, selenium, thorium, tin(IV) and iron(III). Oxalate does not interfere with the extraction of indium and tin(II) or (IV),[4] but prevents the extraction of antimony and bismuth;[5] it can therefore be used as stripping agent in the separation of these metals.

Extraction from hydrohalic acid media

With halide ions, the metals gallium, indium, thallium(III), antimony(III), bismuth and tin form anionic complexes which are weakly extractable into APA, and in several instances hydrohalic acids can be used as efficient stripping agents, permitting manifold concentration of these metals. The degree of concentration that can be achieved is limited by the minimum volume of stripping agent permissible analytically. Antimony(III), indium, gallium and tin(II) or (IV) are extracted quantitatively from dilute hydrochloric acid; even hydroxide and basic salt precipitates do not affect the extraction. Intensive shaking leads to a rapid shift of the equilibrium and the disappearance of the precipitate. With increase in the concentration of hydrochloric or hydrobromic acid, the extractability falls sharply. The distribution coefficients (D) sometimes decrease with change in the acid in the order HCl—HBr—HI—HF, and sometimes in the reverse order. Thus for extraction from isomolar solutions of the hydrohalic acids, the order of the D values is:

$$\text{In—HI} \gg \text{HF} > \text{HBr} > \text{HCl}$$
$$\text{Sb(III)—HCl} > \text{HBr} > \text{HI} > \text{HF}$$
$$\text{Sn(II)—HF} \gg \text{HBr} > \text{HCl}$$
$$\text{Sn(IV)—NBr} > \text{HCl} \gg \text{HF}$$
$$\text{Bi—HCl} > \text{HBr} > \text{HI}.$$

The behaviour of bismuth and thallium(III) in extractions from hydrohalic acid or halide solutions is peculiar; they are not extracted into APA even from solutions containing comparatively minor concentrations of chloride, bromide or iodide, and appear to form halide complexes of the type $MeHal_x^{(m-x)+}$ where m is the charge on the metal ion. Antimony(V) also shows unusual behaviour, being easily extracted with MEHPA or DEHPA from high or low concentrations of hydrohalic acid, but not from medium concentrations (Fig. 3). If only the right-hand branch of the extraction curve was observed, it could be interpreted as indicating the presence of strongly hydrolysed ionic or molecular species in the aqueous phase, but the existence of the left-hand branch, showing that extraction occurs even if hydroxide or basic salt precipitates are present, can only be explained by a change in the mechanism of extraction, from chelate formation to production of molecular species, as happens with tributylphosphate. The behaviour of gallium and thallium also seems anomalous but for gallium this is only so if the extractant is DEHPA (Fig. 4). The behaviour of thallium(III) is the same for all three extractants.

We have shown that in extraction of gallium and antimony(V) from weakly acidic solutions an exchange reaction is involved and that the amount of halide found in the organic phase is insignificant, whereas from strongly acidic media the organic phase extracts molecular species such as $HGaCl_4 \cdot n$DEHPA and $HSbCl_6 \cdot n$APA. Further

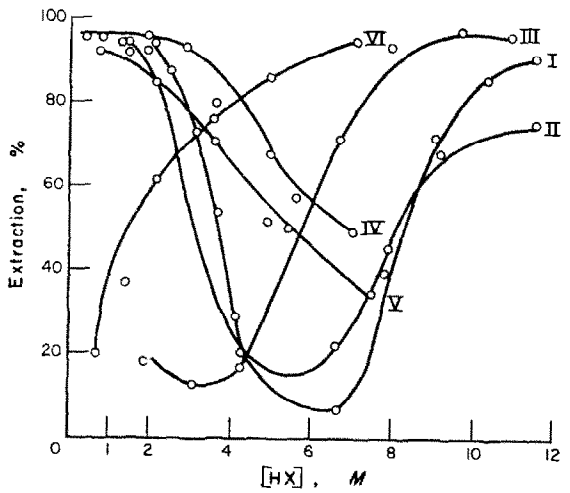

FIG. 3.—Effect of hydrohalic acid concentration on extraction of antimony(V)
PEHPA—I, HCl; IV, HBr
MEHPA—II, HCl; V, HBr
DEHPA—III, HCl; VI, HBr

work is being undertaken on the composition of these species. The change in the mechanism of extraction is also shown by the fact that in APA extractions halides can act as salting-out agents. Thus the distribution coefficient for gallium in extration from 1*M* hydrochloric acid with DEHPA can be increased from 0·07 to more than 100 by saturating the solution with calcium chloride. A further

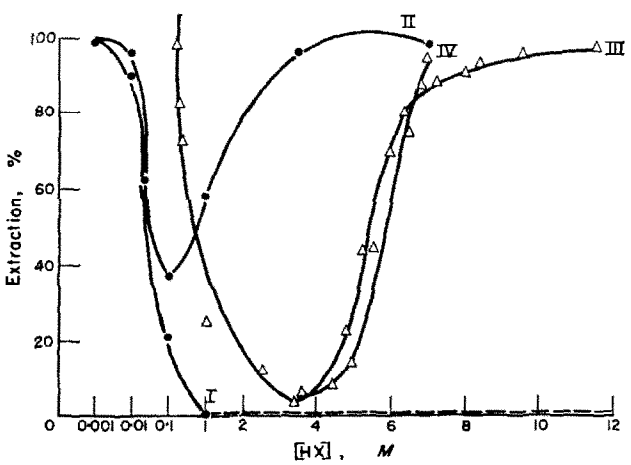

FIG. 4.—Effect of hydrohalic acid concentration on extraction of gallium and thallium with DEHPA.
I and III—HCl; II and IV—HBr
●—Tl(III); △—Ga.

indication of the change in mechanism is provided by the infrared absorption spectra. When gallium is extracted with DEHPA at pH ~ 2, the spectrum of the extract shows a considerable decrease in the intensity in the range of hydroxyl stretching modes

(2550–2700 cm^{-1}), caused by replacement of the hydrogen by metal.[6–8] When the extraction is made from concentrated hydrochloric acid solutions, the intensity of the 2550–2700 cm^{-1} band does not change but there is a sharp drop in the intensity of the band which has a maximum at 1240 cm^{-1}, corresponding to the P=O vibration. Similar changes are observed for the extraction of antimony(V) from concentrated hydrochloric acid solutions (Fig. 5). It should be noted that for extraction of gallium and antimony(V) with tributylphosphate from hydrochloric acid there is only a 70–80 cm^{-1} shift of the P=O band (Fig. 6) whereas the spectra of the DEHPA extracts show a considerable decrease in intensity as well as a shift that may be as small as 10–20 cm^{-1}.

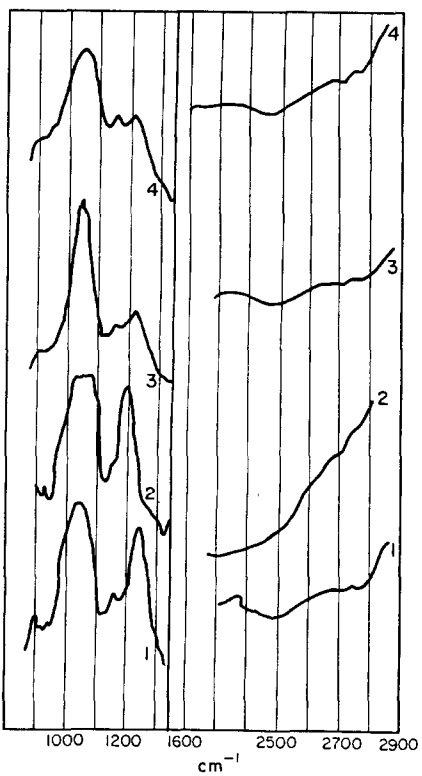

FIG. 5.—Infrared spectra of extracts *1*—DEHPA; *2*—Ga–DEHPA (from HCl, pH 2); *3*—Ga–DEHPA (from conc. HCl); *4*—Sb(V)–DEHPA (from conc. HCl).

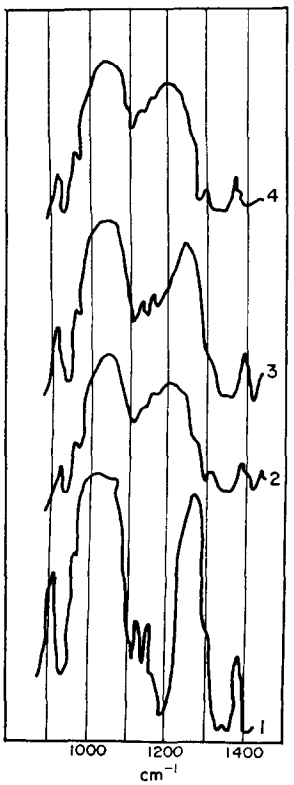

FIG. 6.—Infrared spectra of extracts *1*—TBP; *2*—HCl; *3*—Ga; *4*—Sb(V).

Antisynergic stripping

Antisynergism is manifested in APA systems by the reduction in the extracting ability of these reagents by addition of other solvents, especially alcohols, ketones and trialkylphosphates,[9–21] and is apparently caused by interaction between the components of the mixed extractant, according to the equation

$$xS + y(APA)_n \rightarrow ky(APA)_m \cdot xS$$

where S represents the second solvent and $m = n/k$. The degree of association (n)

of the APA depends on such factors as the nature of the diluent and the presence of moisture.

The utilization of antisynergism not only facilitates stripping, but also extends the range of stripping agents available, so that the most convenient one for a particular purpose can be selected. A typical example is shown in Fig. 7. Strictly speaking, all diluents can be regarded as potential antisynergic agents, but there is no universal comprehensive explanation so far of their influence on extraction with APA. To explain it entirely in terms of dielectric constants, dipole moments, polarizability, *etc.*, is to oversimplify the problem. This is clearly shown by the data summarized in Table I.

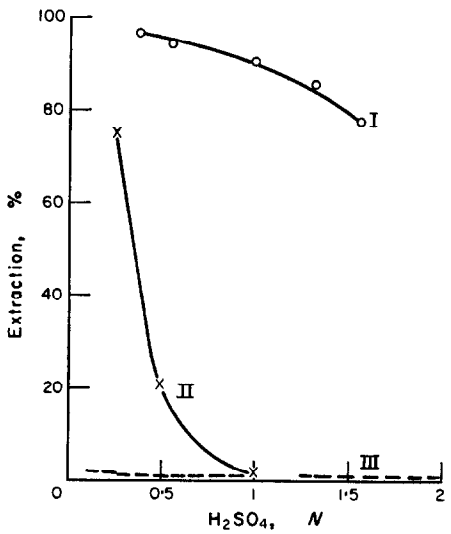

FIG. 7.—Antisynergic effect in the system MEHPA—TBP—H_2SO_4—Bi.
I—Bi—MEHPA; [Bi] 1 g/l.; [MEHPA] 0·25*N*
II—Bi-MEHPA-TBP; [MEHPA] 0·25*N*; [TBP] 1·25*N*
III—Bi-TBP; [TBP] 3·76*N*.

It seems to us that the decisive factor is hydrogen bonding between the APA and the diluent. It leads to depolymerization of the extracting agent, resulting in a greater accessibility of hydrogen ions to the cations being extracted. The influence of the nature of these cations is being studied.

SEPARATION METHODS

Indium

Indium can be extracted from 1–2*N* sulphuric, nitric or perchloric acid solution with a 1*N* solution of mono-, di- or pyro-2-ethylhexylphosphoric acid (or a similar APA) in a saturated hydrocarbon. Feebly extracted impurities such as copper, zinc and cadmium remain in the aqueous phase after scrubbing. Gallium, thallium, antimony, bismuth, tin, titanium, zirconium, hafnium, scandium, uranium, thorium, and molybdenum are extracted along with the indium. Gallium, however, is not extracted if DEHPA is used. Iron(III) must be reduced before the extraction. Antimony and bismuth are stripped with an oxalic acid solution, but if bismuth is present

in large amounts it can be stripped with potassium iodide solution. The indium is then stripped with hydrochloric or hydrobromic acid or by addition of an antisynergic agent and extraction with an oxygen acid (sulphuric is best). The other elements are either not stripped or do not interfere if the indium is then determined with Rhodamine 6 G.

TABLE I.—INFLUENCE OF DILUENTS ON THE EXTRACTION OF INDIUM WITH MEHPA AND DEHPA

DEHPA				MEHPA			
Diluent	ε	μ	D	Diluent	ε	μ	D
Iso-octane	1·94		6·6	Carbon

				TBP			0·001

ε—dielectric constant; μ—dipole moment; D—distribution coefficient; 0·01M indium, 1·5N sulphuric acid.

Antimony

Antimony(III) can be extracted from 1–4N sulphuric, nitric or perchloric acid with a 1N solution of mono-, di- or pyroalkylphosphoric acid in a saturated hydrocarbon. Feebly extracted species such as copper and zinc remain in the aqueous phase after scrubbing with 1–2N sulphuric acid. Thallium and bismuth are stripped with a halide solution and then antimony(III) is stripped with hydrochloric, hydrobromic or oxalic acid, or by adding an antisynergic agent and an oxy-acid. The choice of stripping agent is determined by the other elements present in the extract. The expediency of extracting antimony(V) from concentrated hydrochloric or hydrobromic acid is being examined.

Bismuth

Bismuth can be extracted from 1–6N sulphuric acid with a freshly diluted or stabilized[22] 1N solution of pyroalkylphosphoric acid in a saturated hydrocarbon. The organic phase is scrubbed with 1–2N sulphuric acid to free it from feebly extracted species such as zinc and cadmium *etc.* Bismuth is stripped with a hydrohalic acid, oxalic acid, halide, or ammonium oxalate solution, the best choice being potassium iodide solution, as the bismuth can then be determined colorimetrically in the aqueous phase.

Zusammenfassung—Die Verwendung von Alkylphosphorsäuren zu extraktiven Trennungen wird beschrieben und der Gebrauch antisynergischer Agentien zur Rückextraktion diskutiert.

Résumé—On décrit l'emploi d'acides alkylphosphoriques pour les séparations par extraction par solvant et discute de l'emploi d'agents antisynergiques pour les réextractions.

APDC-MIBK EXTRACTION SYSTEM FOR THE DETERMINATION OF TRACE ELEMENTS IN SALINE WATERS BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY*

ROBERT R. BROOKS®, BOB J. PRESLEY and ISAAC R. KAPLAN
Department of Geology and Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California, U.S.A.

(*Received* 8 *February* 1967. *Accepted* 8 *March* 1967)

Summary—A technique has been developed for the determination of "soluble" cobalt, copper, iron, lead, nickel and zinc in saline waters by simultaneous extraction of their complexes with ammonium pyrollidine dithiocarbamate (APDC) into methyl isobutyl ketone (MIBK) and subsequent analysis by atomic-absorption spectrophotometry. Particulate matter is analysed separately by dissolving millipore filters in an acetone–hydrochloric acid mixture. Various analytical and instrumental parameters have been evaluated. The method is self-compensating in that it makes allowance for any incomplete extraction of the complexes. The technique has been applied to the determination of these elements in sea-water and saline lakes.

IN RECENT years, the determination of trace elements in sea-water has received increasing attention and the use of modern instrumental methods is beginning to produce significant success in this field. Riley[1] has summarized available data and it would appear that neutron activation, isotope dilution and atomic-absorption spectrophotometry may offer the best hope for reliable analyses of trace constituents in sea-water.

In 1962, Fabricand *et al.*[2] used direct aspiration of raw sea-water for the determination of trace elements by the atomic-absorption technique. Their work does not appear to have been repeated by other workers for the elements studied and because of scattering effects and clogging of the burner it is difficult to understand how they could have obtained the sensitivities and reproducibilities claimed under the conditions used.

Recently, Sprague and Slavin[3] have shown that a number of elements may be separated from 25% potassium chloride solutions by extraction of their complexes with ammonium pyrollidine dithiocarbamate (APDC) into methyl isobutyl ketone (MIBK). They have suggested use of this system for the determination of trace elements in sea-water. In an earlier paper,[4] Brooks *et al.* explored the potentialities of this system for the determination of copper in sea-water and developed a self-compensating method in which incomplete extraction of the copper complex was corrected for by extracting the standards from previously-extracted sea water.

The purpose of this publication is to describe a modification of that method, in which the scope of the technique is extended to cover the determination of cobalt, iron, lead, nickel and zinc as well as copper. A number of sea-water samples have been analysed for all these elements both in the "dissolved" and particulate fractions. The method is rapid and simple, and essentially involves the use of only two reagents, both of which can be easily purified.

* Publication No. 575, Institute of Geophysics and Planetary Physics.

EXPERIMENTAL

Apparatus

Atomic-absorption measurements were carried out on a Perkin Elmer 303 Atomic Absorption Spectrophotometer equipped with a standard burner for use with air–acetylene. The output of the instrument was connected to a Sargent Model MR recorder *via* a Perkin Elmer Recorder Readout Accessory. Standard hollow cathode lamps were used for all elements except cobalt, for which a "High-Brightness" lamp was used.

Reagents

Redistilled reagent-grade hydrochloric acid, 6*N*.

Redistilled commercial-grade methyl isobutyl ketone.

A 1% aqueous solution of APDC (Eastman Chemicals). The solution, which was prepared daily, was purified by shaking with an equal volume of MIBK, separating the phases and filtering the lower aqueous phase. Since APDC is only slightly soluble in MIBK whereas metal complexes are very soluble, the reagent is easily purified in this manner.

A standard aqueous solution (pH 4) containing 40 ppm each of cobalt, copper, iron, lead, nickel and zinc.

Distribution coefficients of the metal complexes between sea-water and MIBK

The method is dependent on the use of large sea-water/solvent ratios in order to achieve a concentration effect as well as separation from bulk constituents. The degree of extraction will decrease as the volume ratio increases since the relationship between the distribution coefficient (D), the degree of extraction (E) and the volumes of the organic phase (V_o) and aqueous phase (V_a) is given by the expression:

$$E = \frac{100D}{D + V_a/V_o} \%.$$

This relationship is illustrated graphically in Fig. 1. It will be noted that it is essential to have some indication of the value of the distribution coefficient before deciding what sea-water/solvent ratio to use. For example, doubling the volume ratio from 50 to 100 will increase the concentration in the organic phase by 91% for a complex with a value of $D = 1000$, 82% for $D = 500$, 50% for $D = 100$, 33% for $D = 50$ and only 9% for $D = 10$. Little increase in sensitivity would therefore be gained for the less-strongly extracted elements by changing the phase ratio. Figure 1 has been presented so that others working with this method may choose their own volume ratios, but in the following study a ratio of 750:20 was used.

Approximate distribution coefficients for the elements were determined by analysis of successive extracts from sea-water spiked with 5 ppm quantities of the ions concerned. Provided that D is greater than 10, the ratio of the concentrations in any two successive extracts is an approximate measure of the distribution coefficient. These values obtained are shown in Table I.

Stability of the complexes

The stability of the complexes was measured by preparing APDC extracts in MIBK and comparing the absorbance of these with stable solutions in dilute acid. All complexes were stable for several hours. The minimum times for which no appreciable loss of absorbance was noted are also shown in Table I. It is clear that provided that all samples are analysed within 3 hr of extraction, no difficulty should be encountered. The extracts may be preserved for considerably longer periods by freezing in acetone–dry ice or liquid nitrogen. It is also possible to prolong storage by freezing as before, allowing the extract to warm until the MIBK has melted, and then decanting off the organic layer from the small bead of ice which forms at the bottom of the container.

The determination of "soluble" cobalt, copper, iron, lead, nickel and zinc in sea-water

The following technique was developed to fully compensate for any incomplete extraction of the elements with a sea-water/solvent ratio of 750:20 and was carried out on the "soluble" ions present in sea-water that had been filtered through a 0·45 μ millipore.

Sufficient redistilled hydrochloric acid was added to the filtered sea-water to adjust the pH to between 4 and 5. This step is only necessary if the water is to be stored for some time before use and is a precautionary measure to lessen the danger of adsorption or precipitation of colloidal material on the walls of the container. Extraction can be carried out equally well at the pH of sea-water (8) and the authors have noted experimentally that a dilute suspension of iron(III) hydroxide will gradually dissolve in APDC at this pH though equilibrium is likely to be reached faster at the lower pH. Great

Approximate limits of detection, *ppb*	0·10	0·10	0·10	0·10	0·20	0·05

care must be taken to ensure that the pH of the sea water does not fall below 3·5 as our investigations have shown that extraction of zinc decreases rapidly below this pH and ceases completely at a pH of about 2·5.

Samples of sea-water (750 ml) were placed in 1000-ml polypropylene Erlenmeyer flasks (glassware has been used successfully but polypropylene is considered more satisfactory as there is less danger from contamination or adsorption effects) and 35 ml of MIBK were added to each flask followed by 7 ml of 1% APDC solution. The samples were then equilibrated for 30 min on a mechanical shaker. The phases were separated by means of a separatory-funnel and the organic phases were stored in polypropylene bottles.

In order to prepare a working curve, a further 20 ml of MIBK were added to each sample of extracted sea-water and the phases were separated after a further 5 min equilibration. The purpose of this operation was to ensure that the sea-water was as free as possible from the trace elements under

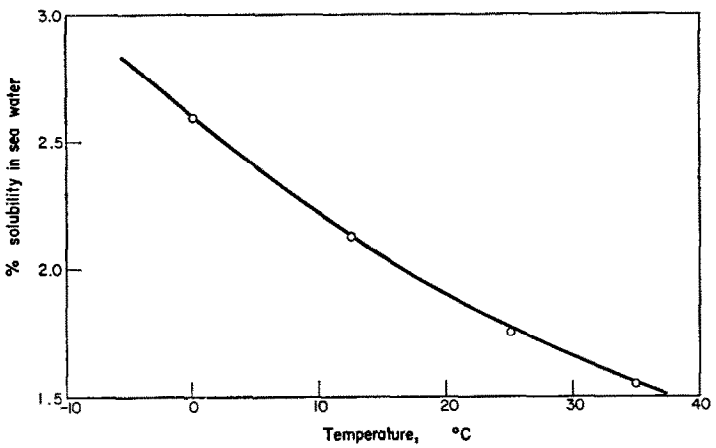

FIG. 2.—Solubility of MIBK in sea-water as a function of temperature.

investigation. The sea-water samples were then recombined to ensure homogeneity and eight 750-ml samples were replaced in the flasks. Incremental amounts of the six elements were then added to give concentrations of 0, 2, 5 and 10 ppb* in the sea-water. The temperature of the water was measured and the volume of MIBK remaining after the first equilibration (approx 20 ml) was calculated from the authors' data on the solubility of this solvent in sea-water (see Fig. 2). This volume of MIBK and 7 ml of APDC solution were then added to the contents of each flask. Shaking for 30 min and phase separations were carried out as before.

The samples were then aspirated into a fuel-lean air–acetylene flame under the working conditions shown in Table I. Typical working curves are shown in Fig. 3.

A number of sea-water samples (salinity 3·5%) were analysed by the method and the results are summarized in Table II. Results for Lake Abert, Oregon (salinity 31·6%) and interstitial water from sediment of the Dead Sea (salinity 31·0%) were also obtained.

The precision of the method

The precision of the method was tested by replicate analyses on twelve identical samples of sea-water. The coefficients of variation are shown in Table I and are applicable for concentrations of 1 ppb of cobalt, 3 ppb of copper, 12 ppb of iron, 5 ppb of lead, 2 ppb of nickel and 1 ppb of zinc.

The preparation of the blank

Since extremely small quantities of trace elements are involved in these studies, extreme care must be taken in preparing the blank. The zero of the working curve is usually sufficient for this purpose. It does not however take account of the amount of MIBK which dissolved in the sea-water or the acid which is sometimes used to reduce the pH. It was found that if the MIBK was evaporated down to the volume of it normally left after extraction with sea-water, the atomic-absorbance of this "concentrated" solvent was exactly the same as that of the original material for all six elements. It is not

* *i.e.*, 1 in 10^9.

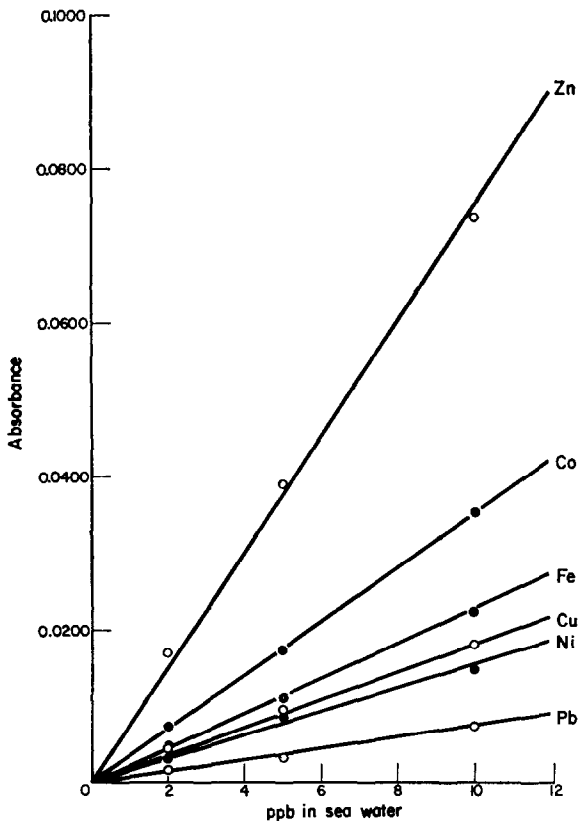

FIG. 3.—Working curves for various elements.

therefore our practice to make a blank correction for the MIBK itself having once ensured that a particular batch is free from contamination.

If a blank correction is made for the acid however, anomalous results can sometimes occur, possibly because of a compositional effect which becomes evident at high scale-expansions. The best procedure to follow in such cases is either not to use acid at all in the analytical procedure or else to check that the acid used is free from contamination, by analysing it by direct aspiration, and then not to use it in the determination of the blank correction.

The determination of particulate cobalt, copper, iron, lead, nickel and zinc

A simple technique has been developed for the simultaneous determination of these elements in the particulate matter of sea-water.

After passage of 1000 ml of sea-water through a 0·45-μ millipore filter, the filter was washed with 50 ml of distilled water and placed in a polypropylene bottle. Five ml of redistilled 6*M* hydrochloric acid were added to each sample and the bottles were sealed and maintained at 70° for 1 hr; then 15 ml of acetone were added to each sample to dissolve the millipore and to form a single phase. Addition of a threefold amount of acetone served rather to enhance absorption than to reduce it, in spite of the dilution effect. This is because of the "solvent effect" in atomic-absorption spectrophotometry[5] (which is also utilized in the MIBK extraction method to give a threefold absorption enhancement compared with aqueous solutions). The effect of adding acetone is demonstrated in Fig. 4 and is particularly important in this work as it provides a sufficient sample volume for the determination of six elements simultaneously.

The samples were analysed against standards prepared in a similar matrix and the results are shown in Table II.

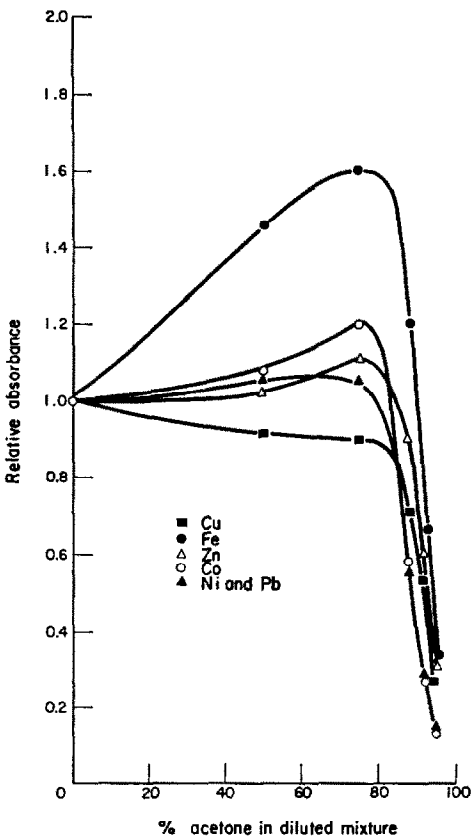

FIG. 4.—Effect of dilution with acetone on the relative absorbance of an initially aqueous solution.

RESULTS AND DISCUSSION

With the exception of lead, the "soluble" and particulate values for the various elements fall within the expected limits. The fact that particulate values are higher than the "soluble" figures for iron and lead and lower for copper and zinc, conforms to the expected pattern.

Values for "soluble" cobalt, iron, lead and nickel show a steady decrease as the sampling points move progressively further away from the coast. The values for lead are particularly striking and are probably due to excessive atmospheric pollution above the Los Angeles Basin as well as to sewage effluent.

It is concluded that the advantages of the method lie in its speed, relative freedom from contamination effects, relatively good precision, high sensitivity (limits of detection are shown in Table I) and the self-compensation for any incomplete extraction of the ions concerned. For this last reason, it has not been necessary to carry out the usual addition and recovery experiments which are conventionally applied to a new technique. The method is now being used for further analyses of sea-water and the interstitial waters of ocean sediments.

Acknowledgements—The authors gratefully acknowledge the assistance of Dr. D. Gorsline of the University of Southern California for his assistance in the collection of samples of sea-water. Partial

support for this study was supplied by Atomic Energy Commission Contract, AT(11-1)-34 P.A. 134. Support for B. J. Presley came from an NDEA fellowship supplied by the Health, Education and Welfare Department. We wish to thank both agencies for their support.

Zusammenfassung—Ein Verfahren wurde für die Bestimmung von "löslichem" Kobalt, Kupfer, Eisen, Blei, Nickel und Zink in salzhaltigen Wassern entwickelt. Es bestand aus der Extraktion des Komplexes mit Ammoniumpyrollindithiocarbamat (APDC) und Methylisobutylketon (MIBK) mit anschliessender Bestimmung mit Flammenabsorptionsspektroskopie. Unlösliche Bestandteile wurden bei direkter Lösung des Filters in einer Azeton–Salzsäuremischung bestimmt. Verschiedene analytische und instrumentalische Parameter wurden festgestellt und das Verfahren enthält Selbstkompensation fur unvollständige Extraktion. Die Methode wurde verwendet um diese Elemente in Seewasser und salzhaltigen Seen zu bestimmen.

Résumé—On a developpé une méthode pour le dosage de cobalt, cuivre, fer, plomb, nickel et zinc "solubles" en eaux salinaires. On a extrait le complexe avec du pyrollidine-dithiocarbamate (APDC) d'ammonium en solution de méthylisobutylcétone (MIBK) et effectué la détermination finale par spectrophotométrie par absorption atomique. On a dosé les constituants insolubles par dissolution du filtre dans un melange d'acétone et d'acide chlorhydrique. On a évalué plusieurs parametres analytiques et instrumentaux et la méthode possède une compensation interne pour l'extraction incomplète. On a utilisé la méthode pour le dosage de ces elements dans l'eau de mer et lacs salinaires.

RADIOCHEMISCHE TRENNUNGEN MIT HILFE DER RINGOFENMETHODE—II

DAS SYSTEM $^{99}Mo/^{99m}Tc$

D. KLOCKOW
Chemisches Laboratorium der Universität Freiburg i.Br., Analytische Abeilung, Bundesrepublik, Deutschland

(*Eingegangen am* 10 *November* 1966. *Angenommen am* 31 *Dezember* 1966)

Zusammenfassung—^{99}Mo-^{99m}Tc-Trennungen lassen sich unter Anwendung der Ringofenmethode durchführen. Am besten gelingt die Trennung auf Rundfiltern, welche mit Berliner Blau oder Mangandioxid imprägniert sind. Hierbei bleibt Molybdän im Zentrum des Rundfilters fixiert, während Technetium mit 70 bis über 90% Ausbeute im Ring konzentriert wird. Die Dekontaminationsfaktoren erreichen Werte von $\geqslant 10^3$. Ist nach einer Trennung wieder genügend ^{99m}Tc nachgebildet, so kann es erneut vom Mutternuklid "abgemolken" werden. Die Halbwertszeit des abgetrennten ^{99m}Tc wurde zu 6,06 ± 0,05 Std. ermittelt.

KÜRZLICH wurde am Beispiel des Mutter-Tochter-Paares $^{137}Cs/^{137m}Ba$ gezeigt, wie sich die Ringofenmethode nach Weisz für einfach und schnell auszuführende radiochemische Trennungen heranziehen läßt.[1] Die Trennoperationen wurden auf Rundfiltern vorgenommen, welche mit anorganischen Ionenaustauschern imprägniert waren. Hierbei blieb das ^{137}Cs in der Mitte des Rundfilters fixiert, während das ^{137m}Ba vom Mutternuklid "abgemolken" und in einer scharfen Ringzone von 22 mm Durchmesser wieder konzentriert werden konnte.

Im folgenden wird gezeigt, wie man nach dem gleichen Prinzip in 2–2½ min ^{99m}Tc von ^{99}Mo abtrennen kann. Zur Durchführung dieser Trennung war es notwendig, geeignete Sorbentien für Molybdän zu finden und die 5·5 cm-Rundfilter damit zu imprägnieren. Von allen getesteten Imprägnierungen wurden schließlich nur vier eingehender untersucht, nämlich Berliner Blau, Mangandioxid, Zirkoniumphosphat und Aluminiumoxid.

Die Verwendung von Aluminiumoxid als Säulenmaterial für ^{99m}Tc-Generatoren wurde verschiedentlich beschrieben.[2,3] Z. Kolařik und J. Krtil[4] untersuchten die Sorption einiger Spaltprodukte an Mangandioxid-Säulen. Die Ionenaustauscheigenschaften von Zirkoniumphosphat[5–11] sowie deren Ausnutzung für radiochemische Trennungen[12–16] waren Gegenstand eingehender Untersuchungen.

EXPERIMENTELLER TEIL

Filtermaterialien

Berliner Blau-Papiere. Die Imprägnierung von Rundfiltern mit Berliner Blau wurde bereits beschrieben.[1] Die Papiere wurden teilweise lufttrocken verwendet, zum Teil jedoch vor Gebrauch 10 min bei 110° im Trockenschrank getrocknet.

Mangandioxid-Papiere. Rundfilter MN 2260 von 5,5 cm Durchmesser (Hersteller: Macherey, Nagel u. Co., Düren) wurden mit einer 1,5%igen $KMnO_4$-Lösung getränkt und auf Filterpapier abgepreßt. Anschließend tauchte man jeweils 5 Papiere 15–30 sec in 100 ml einer 3%igen H_2O_2-Lösung, preßte sie wiederum ab und legte sie *ca.* 1 Std. in dest. Wasser, wobei dieses alle 10 min erneuert wurde.

Zum Schluß wurden die Rundfilter mit dest. Wasser abgespült und auf Filterpapier an der Luft getrocknet. Nach der Imprägnierung von je 5 Rundfiltern wurde die H_2O_2-Lösung erneuert.

Zirkoniumphosphat-Papiere. Rundfilter MN 2260 wurden mit einer $ZrOCl_2$-Lösung, welche 2%ig in Bezug auf Zr(IV) ist, getränkt, auf Filterpapier abgepreßt, 15–30 sec in 1%iger Phosphorsäure gebadet und wiederum abgepreßt. Anschließend wässerte und trocknete man die Papiere wie oben.

Aluminiumoxid-Papiere. Es wurden 5,5 cm-Rundfilter aus Bögen des Aluminiumoxid-Papiers Nr. 288 der Fa. Schleicher und Schüll (Dassel/Kr. Einbeck) ausgeschnitten.

Meßgeräte

Gammaspektren wurden mit einem Harshaw-NaJ (Tl)-Kristall (2 in. × 2 in.; 8 S 8/EP) sowie einem 100 Kanal-Impulshöhenanalysator der Fa. Technical Measurement Corp., North Haven, (Gammascope II/Modell 102) aufgenommen. Die zur Ermittlung der Halbwertszeit des abgetrennten ^{99m}Tc notwendigen Messungen erfolgten mit einem FH 421/Z4-NaJ(Tl)-Kristall sowie einem FH 49-Zählgerät der Fa. Frieseke u. Hoepfner, Erlangen-Bruck.

Durchführung der Versuche

Eine alkalische $Na_2{}^{99}MoO_4$-Lösung mit einer spez. Aktivität von etwa 140 μC/ml und einer Trägermenge von rund 0,2 mg Mo(VI)/ml stand zur Verfügung. Hiervon wurden 0,6 ml mit 4 Tropfen 65%iger Salpetersäure angesäuert und 5 μl der so erhaltenen Probelösung im Zentrum eines imprägnierten Rundfilters aufgetragen. (Auf dem Filter befanden sich somit *ca.* 0,5 μC ^{99}Mo mit 0,75 μg Mo(VI)-Träger). Nach dem Trocknen wurde auf dem Ringofen mit 80–120 μl 0,05n Salpetersäure oder 120–150 μl 50% äthanolischer 0,05n Salpetersäure das ^{99m}Tc aus dem zentralen Mo(VI)-Tüpfelfleck abgetrennt und im Ring konzentriert. Diese Trennung ließ sich in 2–2½ min ausführen. Anschließend wurde das Rundfilter getrocknet und aus dem Zentrum desselben ein Scheibchen von 17 mm Durchmesser (mit dem Mo(VI)-Tüpfelfleck in der Mitte) herausgeschnitten vgl. 1. Mitteilung[1]). Das Scheibchen (^{99}Mo) und das restliche Filter mit dem im Ring konzentrierten ^{99m}Tc gelangten unmittelbar danach zur Aktivitätsmessung.

Es konnte 22–24 Std. (~4 Halbwertszeiten von ^{99m}Tc) nach der ersten Trennung aus dem 17 mm-Scheibchen mit dem Mo(VI)-Tüpfelfleck erneut ^{99m}Tc "abgemolken" werden. Hierzu wurde das Filterscheibchen auf die mitte eines neuen imprägnierten Rundfilters gepreßt[1,17] und das ^{99m}Tc mit 120–150 μl wsäsriger 0,05n Salpetersäure oder rund 200 μl 50% äthanolischer 0,05n Salpetersäure in die Ringzone gewaschen. Hierbei gingen bis zu 10% des ^{99}Mo aus dem Filterscheibchen mit in das untere Rundfilter über, sodaß vor Beginn der Messungen aus dessen Zentrum ein Scheibchen von 18 mm Durchmesser (mit der störenden ^{99}Mo-Aktivität) ausgeschnitten werden mußte (vgl. 1. Mitteilung[1]).

ERGEBNISSE UND DISKUSSION

Die nach jeder Trennung aufgenommenen γ-Spektren vom 17 mm-Scheibchen und Ring dienten zur Bestimmung der ^{99m}Tc-Ausbeute und der radiochemischen Reinheit des abgetrennten Tochternuklids. Die Ausbeute wurde an Hand des 0,14 MeV-Peaks von ^{99m}Tc, der Dekontaminationsfaktor mit Hilfe des 0,74/0,78 MeV-Peaks von ^{99}Mo ermittelt. Abbildung 1 zeigt die nach einer Trennung auf Berliner Blau-Papier (mit 0,05n Salpetersäure) gemessenen γ-Spektren von Scheibchen und Ring im Bereich der 0,38 MeV- und 0,74/0,78 MeV-Peaks von ^{99}Mo.

Beim Vergleich der zwei verwendeten Waschflüssigkeiten (äthanolische bzw. wässrige 0,05n Salpetersäure) ergab sich, daß man für das abgetrennte ^{99m}Tc mit ersterer die niedrigsten, mit letzterer die höchsten Dekontaminationsfaktoren erzielt.

Hinsichtlich der Ausbeuten ließen sich nur bei Verwendung von Aluminiumoxid-Papieren merkliche Unterschiede zwischen den zwei Waschflüssigkeiten feststellen: hier lieferte wässrige 0,05n Salpetersäure die geringsten ^{99m}Tc-Ausbeuten. Trocknete man die Berliner Blau-Papiere vor Gebrauch 10 min bei 110°, so bewirkte dies eine deutliche Steigerung der ^{99m}Tc-Ausbeute. Ähnliche Veränderungen in den Ionenaustauscheigenschaften in Abhängigkeit von der Trocknungstemperatur wurden für Zirkoniumphosphat beschrieben.[16,18]

Beim Vergleich der vier untersuchten Papiersorten liess sich folgendes feststellen: beim Arbeiten mit wässriger 0,05n Salpetersäure als Waschflüssigkeit und unter Verwendung einer frisch angesäuerten $^{99}MoO_4^{2-}$-Lösung wurden auf Zirkoniumphosphat-, Berliner Blau- und Mangandioxid-Papier ^{99m}Tc-Ausbeuten von 70 bis über 90% erreicht. Lediglich das Aluminiumoxid-Papier lieferte Ausbeuten von 50–60%. Beim "Abmelken" aus den 17 mm-Scheibchen fielen diese Werte unterschiedlich ab, am wenigsten bei Trennungen auf Mangandioxid-Papieren, besonders

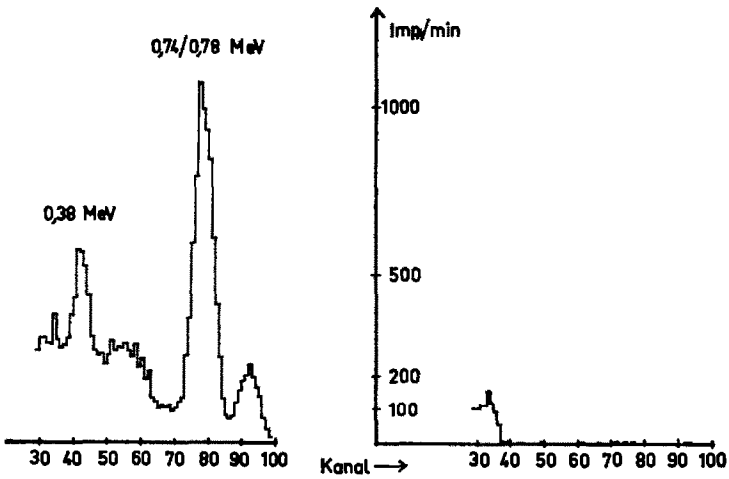

Abb. 1.—Gammaspektren von ^{99}Mo.
(*a*) Im Zentrum von 17 mmϕ.
(*b*) Im äusseren Ring.

stark bei Trennungen auf Aluminiumoxid-Papieren. Mehrere Versuchsreihen ergaben, daß man die radiochemisch reinsten ^{99m}Tc-Präparate dann erhält, wenn man Berliner Blau- oder Mangandioxid-Papiere verwendet. Mit wässriger 0,05n Salpetersäure als Waschflüssigkeit wurden hier stets Dekontaminationsfaktoren $> 10^3$ erreicht, während auf Zirkoniumphosphat- und Aluminiumoxid-Papieren häufig nur kleinere Werte erzielt werden konnten.

Zusammenfassend konnte festgestellt werden, daß hinsichtlich Ausbeuten und Dekontaminationsfaktoren optimale ^{99}Mo-^{99m}Tc-Trennungen auf Berliner Blau-Papieren (bei 110° getrocknet) sowie Mangandioxid-Papieren unter Verwendung einer salpetersauren Probelösung und von wässriger 0,05n Salpetersäure als Waschflüssigkeit auszuführen sind.

Wie bereits angedeutet, werden die obengenannten Ausbeuten nur in den ersten Stunden nach dem Ansäuern der alkalischen $^{99}MoO_4^{2-}$-Lösung mit Salpetersäure erreicht. Je länger die Zeitspanne zwischen Ansäuern und Durchführung einer Trennung ist, desto mehr gehen die ^{99m}Tc-Ausbeuten zurück, und zwar bei allen hier verwendeten Adsorbentien. Inwiefern dabei ein Wechsel der Oxydationsstufe des Technetiums eine Rolle spielt (vgl. bei R. Münze[19]), muß noch untersucht werden. In mehreren Versuchen wurde die Zerfallskurve des abgetrennten ^{99m}Tc aufgenommen. Abbildung 2 zeigt ein Beispiel hierfür. Aus vier solchen Abfällen (Dekontaminationsfaktoren $> 10^3$) wurde die Halbwertszeit von ^{99m}Tc durch Ausgleichsrechnung zu 6,06 $\pm$ 0,05 Std. berechnet.

Bemerkenswert erscheint die Tatsache, daß von allen untersuchten Hexacyanoferraten(II) (Berliner Blau, Co-Hexacyanoferrat, Cu-Hexacyanoferrat, V(IV)-Hexacyanoferrat) lediglich Berliner Blau Molybdän(VI) in solchem Ausmaße zu sorbieren vermag, daß es für eine ^{99}Mo-^{99m}Tc-Trennung nach dem geschilderten Verfahren geeignet ist. Mangandioxid wies von allen getesteten Sorbentien die

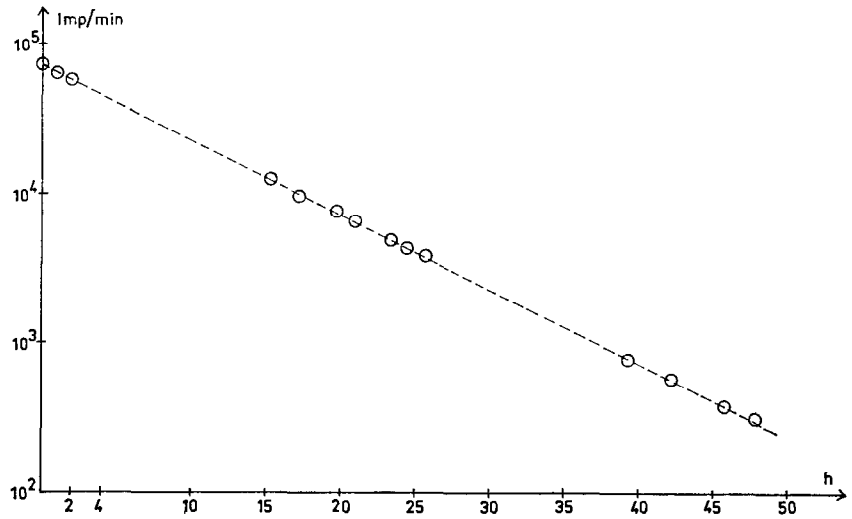

ABB. 2.—^{99m}Tc-Abfall im Ring.

geringste Stabilität gegenüber der verwendeten Waschflüssigkeit auf. Es zeigte sich eine deutliche Aufhellung im Zentrum der mit Mangandioxid imprägnierten Rundfilter nach dem Waschen mit 0,05n Salpetersäure.

Trotzdem liessen sich auf Mangandioxid-Papieren saubere Trennungen durchführen. Im Hinblick auf die Tatsache, daß ^{99m}Tc in steigendem Maße an Stelle von ^{131}J zur Markierung von Proteinen herangezogen wird,[20–22] dürften die geschilderten Eigenschaften von Berliner Blau und Mangandioxid von Interesse sein.

Herrn Prof. Dr. W. Seelmann-Eggebert, dem Direktor des Instituts für Radiochemie im Kernforschungszentrum Karlsruhe, möchte ich an dieser Stelle für die Überlassung der ^{99}Mo-Lösung herzlich danken.

Summary—The separation of ^{99}Mo and ^{99m}Tc by the ring-oven technique is described. The separation is best carried out on round papers impregnated with Prussian Blue or with manganese dioxide, when the molybdenum is fixed in the centre of the paper and the technetium is concentrated with 70–90% yield in the ring. Decontamination factors of $\geqslant 10^3$ were obtained. ^{99m}Tc formed after the separation can be further leached from the parent nuclide. The half-life of ^{99m}Tc was found to be 6·06 ± 0·05 hr.

Résumé—On décrit la séparation de ^{99}Mo et ^{99m}Tc par la technique du four annulaire. La séparation est menée au mieux sur des ronds de papier imprégnés de bleu de Prusse ou de bioxyde de manganèse, auquel cas le molybdène est fixé au centre du papier et le technécium est concentré dans l'anneau avec un rendement de 70–90%. On a obtenu des facteurs de décontamination de 10^3. Le ^{99m}Tc formé après la séparation peut être davantage lixivié du nucléide-mère. On a trouvé que la demi-vie du ^{99}Tc es de 6,06 ± 0,05 h.

DETERMINATION OF TRACES OF CALCIUM, MAGNESIUM, IRON AND NICKEL IN ALUMINIUM SALTS BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY WITH A MICROWAVE-EXCITED SOURCE AND HOLLOW-CATHODE LAMPS

G. B. MARSHALL and T. S. WEST
Chemistry Department, Imperial College, London, S.W.7

(*Received* 20 *February* 1967. *Accepted* 3 *March* 1967)

Summary—The determination of trace amounts of calcium and magnesium in solutions containing large concentrations of aluminium salts may be accomplished by co-precipitating their hydroxides on iron(III) hydroxide, dissolving the precipitate, and extracting the 8-hydroxyquinolates of calcium and magnesium into methyl isobutyl ketone at about pH 11. The extract may be sprayed into the air-propane flame of a simple unmodulated spectrophotometer and atomic-absorption measurements for calcium and magnesium made at 4227 and 2852 Å respectively. The limits of determination correspond to 10 and 1 ppm of calcium and magnesium in solid alumina. Iron and nickel may be co-precipitated on hydrated manganese(IV) oxide and their 8-hydroxyquinolates extracted at pH 4·5. Measurements of atomic absorption for these elements at 2483 and 2320 Å respectively yield limits of determination corresponding to 10 ppm in alumina. Hollow-cathode lamps may be used for calcium, magnesium and nickel, but a simple microwave-excited discharge tube gives much better sensitivity than a hollow-cathode lamp for iron.

THE determination of trace metals in nearly pure alumina presents special problems which are not easily solved by conventional analytical techniques. This communication describes attempts made to apply the sensitivity and selectivity of atomic-absorption spectroscopy to the determination of calcium, iron, magnesium and nickel in the presence of large amounts of aluminium.

The measurement for analytical purposes of absorption of radiation by free atoms demands the production of a tenuous population of these in a gas phase. At the present time this is achieved for absorption spectrophotometry almost exclusively by spraying a finely nebulized solution into a flame and measuring the attenuation in the signal from a hollow-cathode lamp emitting the necessary resonance line of the absorbing species. For many elements this procedure is entirely satisfactory, but those which form refractory oxides in flames present special difficulties because most flames are not hot enough to promote thermal dissociation of those oxides. Aluminium is one such element. Whilst many of those compounds may be sufficiently well broken down in the hot oxygen-free nitrous oxide–acetylene flame[1] to make this determination possible for trace amounts, a very considerable problem exists when these elements form the matrix in which traces of other elements have to be determined. This was confirmed in the present study when it was found that atomic absorption signals for these trace elements could not be obtained in the presence of very large amounts of aluminium.

There are several ways of overcoming this problem. One is obviously to use very hot flames such as cyanogen[2] to break down the oxide particles, but this introduces other problems which are rather difficult to solve and the depletion of ground state spectral lines and emergence of ionic lines is marked for calcium. The background emission of fuel-rich (*i.e.*, reducing) high-temperature flames is also rather high and causes excessive detector noise even in well modulated systems.

For this reason it was decided to separate (and concentrate) the desired elements from the matrix element, aluminium, by co-precipitation and solvent extraction, and to spray the extract into the flame for absorption measurements. In this way the solid matrix of alumina which might physically sequester the otherwise volatile metal atoms is eliminated, and the desired element is concentrated. At the same time the efficiency of nebulization is increased from 10–15% for aqueous solutions to 40–60% for organic solvents, thus further increasing the sensitivity of determination.

There is no need to employ specific or even selective extracting agents since inter-element interference is scarcely observed at trace levels in atomic-absorption spectroscopy.[3] For this reason an unselective and cheap extracting agent is entirely satisfactory. 8-Hydroxyquinoline is one such reagent and has been applied extensively in this laboratory to such problems.[4,5]

Calcium and magnesium are extracted only from alkaline media and in the presence of a considerable excess of 8-hydroxyquinoline. Under these conditions aluminium is much more easily extracted than either. Consequently a preliminary separation by co-precipitation on iron(III) hydroxide[6] was used to remove these elements from the aluminium in sodium hydroxide medium. Iron(III) 8-hydroxyquinolate is not easily extracted from alkaline solution by most organic solvents and the numerous lines in the iron absorption spectrum render the determination of the two other metals rather difficult. However, iron(III) 8-hydroxyquinolate can easily be extracted into ethyl acetate from an acid solution (pH $\sim$ 4·5) containing a high concentration of sodium chloride,[7] and the solution remaining can be made alkaline and the magnesium and calcium 8-hydroxyquinolates extracted into methyl isobutyl ketone and examined by atomic-absorption spectrophotometry. Sodium chloride has a marked salting-out effect on the extraction of iron(III) 8-hydroxyquinolate and to a lesser extent enhances the extraction of the magnesium and calcium complexes. Any tendency for aluminium not to be removed by this procedure would be nullified by the effect noted by Wallace.[8]

Both calcium and magnesium form 8-hydroxyquinolates with the 6-co-ordination completed by two water molecules. Consequently it is necessary to use oxygen donor solvents such as methyl isobutyl ketone to displace the co-ordinated water molecules and/or to use a large excess of 8-hydroxyquinoline for the same purpose. In this study the latter was found to be more important, and no magnesium or calcium could be detected by atomic-absorption spectroscopy of the aqueous phases after extraction of the $CaOX_2 \cdot HOX$ and $MgOX_2 \cdot HOX$ complexes[9] with 6% ethanolic 8-hydroxyquinoline solution used in conjunction with methyl isobutyl ketone as the solvent. The addition of tri-n-butylamine or butylcellosolve was not found to be beneficial.[10] The magnesium 8-hydroxyquinolate extract was found to be perfectly stable, but the corresponding calcium complex showed a tendency to separate out as a solid phase, although it remained in solution for 20 min. Consequently no difficulty is encountered if the atomic absorption of the calcium is measured within this time, preferably before that of the magnesium.

The effect of sodium chloride concentration on the extraction of 50 μg of calcium is shown in Fig. 1a, and the effect of 8-hydroxyquinoline concentration in Fig. 1b. The extraction is quantitative at pH $\geqslant$ 11. This pH is easily maintained by the addition of sodium hydroxide.

With a sample of potassium aluminium sulphate corresponding to 1 g of Al_2O_3 it was found that successful co-precipitation of magnesium and calcium hydroxides occurred when >1 mg of iron was added to a solution of the sample made alkaline with sodium hydroxide. There is no tendency for the aluminium to co-precipitate at the pH used. When amounts of iron >4 mg were used, difficulties arose in the filtra-

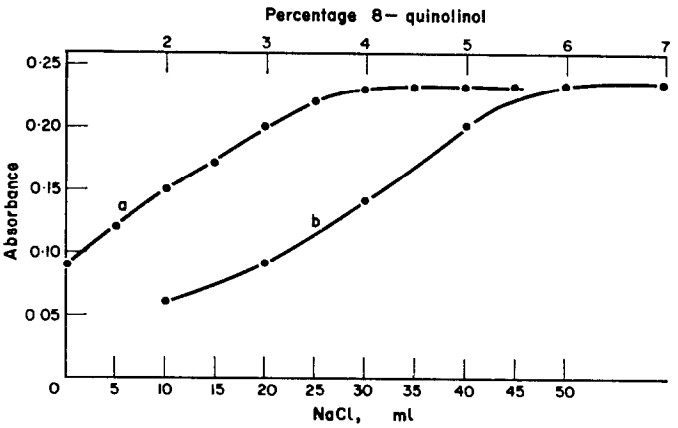

FIG. 1.—Effect of sodium chloride and 8-hydroxyquinoline concentrations on the extraction and determination of calcium.

(a) Variation of [NaCl] in solution containing 50 μg of Ca^{2+} and 2 ml of 6% 8-hydroxyquinoline solution.

(b) Variation of [8-hydroxyquinoline] in solution containing 50 μg of Ca^{2+} and 40 ml of saturated NaCl solution.

Absorbance measured in flame at 4227 Å: extraction into 10 ml of methyl isobutyl ketone.

tion and the subsequent extraction of iron, and 2 mg of iron(III) [2 ml of 0·1% solution] were therefore used as the optimal amount.

The best conditions for atomic-absorption measurements for calcium and magnesium in the air–propane flame were established in the usual way. The air–propane flame was selected because of its steady combustion and because it gave adequate sensitivity and an extremely low radiative background so that it could be used with an unmodulated instrument relying on simple defocussing of resonance emission (Ca) in the flame. Commercial hollow-cathode lamps operating at 10 mA were used. Efficient aspiration and good nebulization were obtained with an air pressure of 20 lb/in^2; the flame used sufficiently little propane to be non-luminous when methyl isobutyl ketone was sprayed. A flame profile of the magnesium atoms showed their presence to be most marked low down, immediately over the cones of the combustion zone. The 2852 Å line[11] proved to be the most suitable for magnesium; the slit-width was 0·1 mm. The flame conditions for calcium were found to be more critical in that the absorbing atomic species were situated in a much more sharply defined band at the base of the outer mantle of the flame immediately above the primary reaction zone. The 4227 Å absorption line was found to be most suitable with a slit-width of

0·3 mm. Separate experiments proved that calcium and magnesium did not mutually interfere and that there was no interference from moderate concentrations of other ions such as nickel and chromium which are likely to be present in alumina. Some results obtained for the determination of known amounts of calcium and magnesium added to a saturated alum solution are given in Table I.

TABLE I.—DETERMINATION OF KNOWN AMOUNTS OF Ca, Mg, Fe AND Ni IN PRESENCE OF POTASSIUM ALUMINIUM SULPHATE (≡1 g OF Al_2O_3)

12·16	12·05						

Because aluminium 8-hydroxyquinolate is extracted over the same pH range as the iron(III) and nickel complexes and is present in vastly greater amounts, co-precipitation with hydrated manganese(IV) oxide was used to separate and concentrate the iron and nickel. This technique has been used previously for the collection of iron(III) but there appears to be no record of its use for nickel.[12] A solution of the sample in sodium hydroxide was treated with 1–2 mg of manganese in the form of permanganate and sulphur dioxide was passed through the solution to reduce the permanganate to manganese(IV). This procedure proved to be very efficient for scavenging all traces of iron(III) and nickel from concentrated solutions of aluminium salts. No iron(III) or nickel could be detected in the filtrate by atomic-absorption measurements.

The hydrated manganese(IV) oxide may be filtered off immediately on paper pulp and is readily dissolved in a small amount of concentrated hydrochloric acid. Some hydroxylamine hydrochloride is added to ensure reduction of manganese(IV) to manganese(II), and the pH of the solution is then adjusted to 4·5 with acetate buffer for extraction of the nickel and iron(III) 8-hydroxyquinolates into methyl isobutyl ketone. Since the iron(III) and nickel contents of the potassium aluminium sulphate and the reagents used were unknown a blank experiment was performed simultaneously without the addition of trace amounts of iron(III) or nickel and this blank was deducted in drawing the calibration curves. An average blank for the potassium aluminium sulphate, obtained separately by deducting a blank for the reagents, corresponded to 0·0003% of iron and 0·00005% of nickel. Manganese(II) 8-hydroxyquinolate is not formed appreciably at pH 4·5 and therefore does not interfere with the extraction or the atomic-absorption measurements.

Some difficulties were encountered in measuring the atomic absorption due to iron in the air–propane flame at 2483 Å. The region of measurement in the flame

was not found to be critical, as it was with calcium, and the iron atoms appeared to be uniformly distributed throughout the flame above the primary reaction zone. The sensitivity of determination increased with decrease of slit-width down to a minimum of 0·2 mm and by increase of the current to the hollow-cathode lamp up to the maximum rating of 45 mA. With aqueous solutions, the calibration curves were linear over the range 10–50 ppm, but not at higher concentrations, see Fig. 2A(ii), which suggested lack of resolution of the 2483 Å line from neighbouring lines emitted by the hollow-cathode lamp. Because of lack of intensity it was not possible to close the slits to less than 0·2 mm. A similar state of affairs was found with extracts of iron(III) 8-hydroxyquinolate in methyl isobutyl ketone, Fig. 2B(ii).

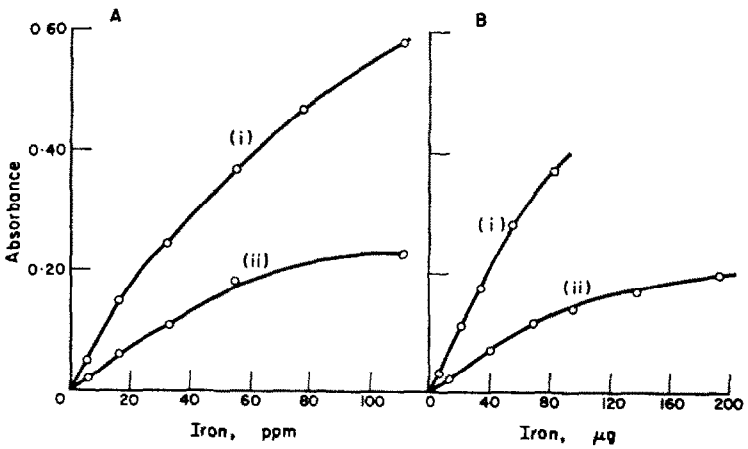

FIG. 2.—Comparison of microwave-excited source and hollow-cathode source in the determination of iron by atomic-absorption spectrophotometry.

(A) In aqueous solution
(*i*) microwave-source (*ii*) hollow-cathode
Optimized conditions for each.
(B) In methyl isobutyl ketone extract
(*i*) microwave-source (*ii*) hollow-cathode
Optimized conditions for each.

Accordingly, to obtain a much more intense source we constructed and used a microwave-excited discharge tube for iron by sealing some electrolytic iron powder and iodine in a quartz ampoule, thoroughly purged with argon and sealed off at *ca.* 1 mm Hg pressure of argon. The construction of such tubes has been described in a privious communication from this laboratory.[13] With this tube excited at 2450 Mc/s and operating at *ca.* 50 W, sufficient intensity was obtained to allow the slits to be closed to 0·05 mm, thus isolating the 2483 Å iron line from its neighbours much more effectively. Figures 2A(i) and 2B(i) show calibration curves obtained for aqueous and organic extracts of iron(III) with the microwave-excited source; it will be seen that the range of linearity is extended and the sensitivity increased considerably. This source was, therefore, used for all subsequent studies of the atomic-absorption of iron. Figure 3 shows the experimental arrangement of the atomic absorption apparatus and the microwave source and supply unit. A colour photograph of a microwave-excited thallium source has been published elsewhere by one of us.[14]

The stability of the iron discharge tube was not quite as good as that of a hollow-cathode lamp, but no special precautions were taken to stabilize it and it was found that provided frequent checks were made of the zero absorbance setting, no difficulty arose from this source. Our experience with other microwave tubes suggests that their output is as stable as that of a conventional hollow-cathode lamp. No special study was made of the best conditions for manufacture of an iron tube or of its effective life-time; it was entirely satisfactory over the period during which it was used.

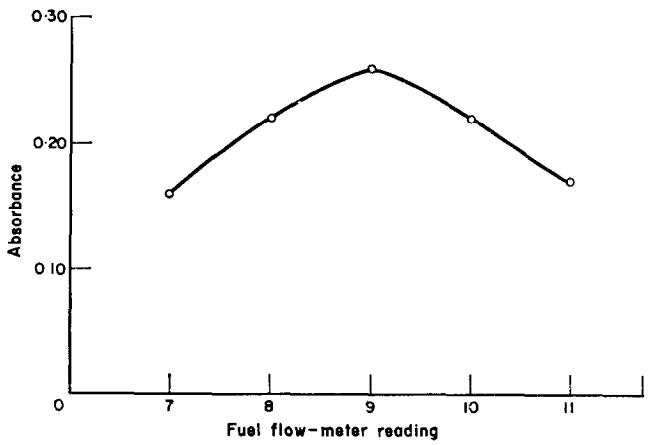

FIG. 4.—Variation of sensitivity with propane pressure for the determination of nickel at 3414 Å.

Aqueous solutions: air pressure 20 lb/in²: 59 ppm of Ni: slit-width 0·05 mm.

A conventional hollow-cathode lamp proved entirely satisfactory for the determination of nickel. The lines at 3414 and 2320 Å were examined for absorption measurements. With both lines the sensitivity increased with decrease of slit-width and reached a maximum at a particular propane pressure, see Fig. 4. The 2320 Å line was found to give a sensitivity about four times that of the 3414 Å line and yielded nearly linear calibration curves over the range 2–60 ppm with aqueous solutions. The same uniform distribution of nickel atoms was observed in the air–propane flame as was found for iron. Some results obtained for the determination of known amounts of iron and nickel added to a saturated solution of potassium alum are shown in Table I.

It is probable that the hydrated manganese(IV) oxide could also be used to co-precipitate calcium and magnesium, but iron hydroxide is more convenient because it can easily be separated from them by 8-hydroxyquinoline extraction whereas manganese can not; nor can manganese be masked against extraction along with the calcium and magnesium, even by potassium cyanide.

Further work is in progress on the evolution of similar procedures for chromium and cobalt in alumina. This communication does not describe the analysis of alumina itself, but demonstrates its feasibility. The amount of potassium aluminium sulphate solution used in these experiments corresponds to 1 g of alumina. The method is directly applicable to the analysis of soluble aluminium salts by the method of standard additions. Calibration curves are obtained by making standard additions of the metal

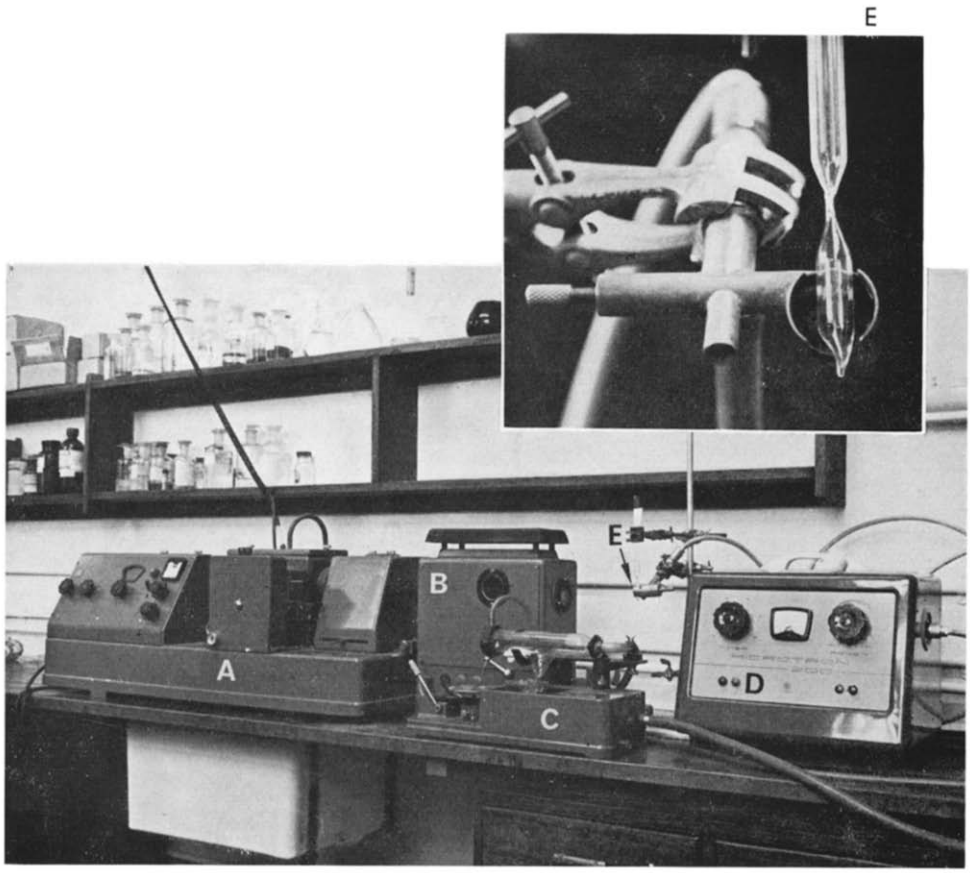

FIG. 3.—Apparatus for A.A.S. with microwave-excited source insert showing detail of microwave cavity and source-tube.

ion concerned to the aluminium salt solution and measuring against a *reagent* blank. These curves are then extrapolated, and the negative intercepts on the concentration axes represent the trace metal ion contents of the aluminium salt. In this way, the nickel content of the potassium aluminium sulphate used was found to be 5×10^{-5}%.

EXPERIMENTAL

Reagents

All reagents used were of analytical-reagent grade except where stated.

8-Hydroxyquinoline solutions, 2% and 6% in ethanol.

Iron(III) solution, 0·1%. Dissolve 8·687 g of iron(III) ammonium sulphate 12-hydrate in distilled water containing 10 ml of concentrated sulphuric acid and dilute to 1 l.

Buffer, pH 4·5. Dissolve 100 g of hydrated sodium acetate and 150 ml of glacial acetic acid in distilled water and dilute to 1 l.

Potassium aluminium sulphate solution. Dissolve 138·9 g of the 12-hydrate in distilled water and dilute to 1 l.

Standard calcium solution (5 *μg/ml*). Dilute 25 ml of 0·1*M* calcium chloride made by dissolving calcium carbonate in hydrochloric acid to 2 l. to give a stock 50 ppm solution. Dilute the stock solution tenfold just before use.

Standard magnesium solution (0·61 *μg/ml*). Dilute 25 ml of 0·1*M* magnesium sulphate (24·65 g of heptahydrate per l.) to 2 l. to give a 30·4-ppm stock solution. Just before use dilute 10 ml of stock solution to 500 ml.

Standard iron(III) solution (7 *μg/ml*). Dilute 10 ml of 0·1*M* iron(III) ammonium sulphate (48·521 g of the 12-hydrate per l.) to 1 l. with acidified distilled water stock solution. Just before use dilute 25 ml of the stock solution to 200 ml.

Standard nickel solution (3·67 *μg/ml*). Dilute 25 ml of 0·1*M* nickel sulphate (26·285 g of the hexahydrate per l.) solution to 1 l. to just before use dilute 25 ml of this solution to 1 l.

Apparatus

Hilger Uvispek (H 700) spectrophotometer with H 1100 atomic-absorption attachment. Premixed air–propane flame. Hilger aspirator-nebulizer (ca. 15% efficient for aqueous solutions). Perforated-plate burner head with *ca.* 10-cm flame. Hilger hollow-cathode lamps for calcium, magnesium and nickel.

Microwave signal generator (Microtron 200, Electromedical Supplies Ltd.) with 214 L cavity and coaxial cable.

Iron-iodine discharge tube constructed as detailed elsewhere.[13]

Methods

Calcium and magnesium

Transfer by pipette 70 ml of the potassium aluminium sulphate solution into each of a series of 400 ml beakers and add from 4 to 20 ml of standard calcium solution and from 2 to 15 ml of standard magnesium solution as required. Add 50 ml of 2*M* sodium hydroxide and 2 ml of the 0·1% iron(III) solution to each. Stir the suspensions of iron(III) hydroxide well and filter off each on a paper pulp pad. Wash the pads with water until alkali-free.

Transfer each funnel to the neck of a 250-ml separating funnel and dissolve the precipitates by slow addition of 2 ml of hydrochloric acid (1 + 1) to each. Wash the pads thoroughly with distilled water and dilute each solution to about 25 ml. To each funnel add 40 ml of saturated sodium chloride solution and 2 ml of 6% ethanolic 8-hydroxyquinoline solution. Then add 2*M* sodium hydroxide from a dropping tube till the first appearance of a black precipitate of iron(III) 8-hydroxyquinolate. Extract this complex at pH 4·5 by thorough shaking with 35 ml of ethyl acetate.

Discard the organic phase and add 2 ml of 6% ethanolic 8-hydroxyquinoline solution to each of the aqueous solutions; add enough sodium hydroxide solution to make the total 9 ml and give a pH $\geq$11·0 in each funnel. Extract the magnesium and calcium 8-hydroxyquinolate complexes by shaking vigorously for 1 min with 10 ml of methyl isobutyl ketone. Measure the atomic absorption of the calcium and magnesium by spraying the extracts into the air–propane flame, under the conditions described below, with methyl isobutyl ketone as a blank. Measure the absorption of a blank solution obtained by taking the reagents only through the procedure, and deduct it from the readings obtained. The calcium curve is linear over the range 10–100 *μg* and the magnesium curve from 1 to 10 *μg*. No effort was made to extend the curves beyond these limits.

If the same amount of potassium aluminium sulphate is added to the reagent blank solution a true calibration curve is obtained which passes through the origin. If the potassium aluminium sulphate

is excluded from the blank determination the negative intercept of the calibration curve on the concentration axis corresponds to the amount of calcium or magnesium in the potassium aluminium sulphate taken, *i.e.* the calcium and magnesium are determined by the method of standard additions.

Instrument settings

Calcium. Wavelength 4227 Å: slit-width 0·3 mm: lamp current 10 mA: burner height adjusted so that optical path is just above primary cones: air pressure 20 lb/in²: propane pressure sufficient to obtain a flame which is just non-luminous and has well defined primary cones when the organic extract is being sprayed.

Magnesium. Wavelength 285 Å: slit-width 0·1 mm: lamp current 10 mA: flame parameters as for calcium.

N.B. It is important to measure the absorption of the calcium first because of the tendency for calcium 8-hydroxyquinolate to precipitate in the extract.

Iron and nickel

Transfer by pipette 70 ml of the potassium aluminium sulphate solution into a series of 400-ml beakers and add from 1 to 10 ml of the standard iron solution and from 3 to 20 ml of the standard nickel solution. Add 50 ml of 4*M* sodium hydroxide to each and 3 ml or 0·01*M* potassium permanganate. Bubble sulphur dioxide through the solutions till all the permanganate has been converted into manganese dioxide, and filter off immediately on pulp pads. Wash the pads alkali-free with distilled water and transfer the funnels to the mouths of a series of 100-ml separating funnels. Dissolve the manganese dioxide on each pad with 4 ml of concentrated hydrochloric acid and wash the pads well with water. Dilute the solutions in each separatory funnel to 25 ml and ensure reduction to manganese(II) by adding a few crystals of hydroxylamine hydrochloride. Add 2 ml of 2% ethanolic 8-hydroxyquinoline solution and neutralize by addition of 4*M* sodium hydroxide till a *slight* turbidity appears. Then add 5 ml of the sodium acetate buffer, pH 4·5, and 10 ml of methyl isobutyl ketone. Shake thoroughly for 1 min to extract the 8-hydroxyquinolates of nickel and iron(III) and discard the aqueous layers. Spray the extracts into the air–propane flame and measure the atomic-absorbances for nickel and iron against methyl isobutyl ketone, using the instrumental settings described below. Measure the absorbance of a blank solution obtained by taking the reagents only through the procedure and deduct it from the readings. Both curves are linear from 10 to 80 μg.

The iron and nickel contents of the aluminium salt may be determined in the manner described for calcium and magnesium.

Instrument settings

Nickel. Wavelength 2320 Å: slit-width 0·1 mm: lamp current 35 mA: burner height sufficient to ensure that light path is above cones of primary zone: air pressure 20 lb/in²: propane pressure sufficient to obtain a non-luminous flame with well defined primary cones when the extracts are being sprayed.

Iron. Wavelength 2483 Å: slit-width 0·05 mm: flame conditions as for nickel.

Microwave cavity energized at 40–60 W with 2450 Mc/s radiation. Quartz tube containing Fe/I_2 slightly cooled by stream of air. Discharge initiated in tube by means of "Tesla" coil. The tube should be well run-in for 1 hr after manufacture and allowed to run for about 15 min each time before use.

Acknowledgement—We are grateful to the U.K.A.E.A. (Aldermaston) for a grant in aid of this work, and to the Science Research Council for the award of a special grant for the purchase of the atomic-absorption equipment. Our thanks are also due to the Central Electricity Generating Board (Midland Region) for granting study leave to one of us (G. B. M.) during the period in which this work was done.

Zusammenfassung—Die Bestimmung von Spuren Calcium und Magnesium in große Mengen Aluminium enthaltenden Lösungen erreicht man durch Mitfällung ihrer Hydroxide auf Eisen(III) hydroxid, Lösen des Niederschlags und Extraktion der 8-Hydroxychinolate von Calcium und Magnesium bei etwa pH 11 in Methylisobutylketon. Der Extrakt kann in die Luft-Propan-Flamme eines einfachen unmodulierten Spektrophotometers gesprüht werden; die Atomabsorptionsmessungen für Calcium und Magnesium werden bei 4227 bzw. 2852 Å gemacht. Die Nachweisgrenzen entsprechen 10 und 1 ppm Calcium bzw. Magnesium in Aluminiumoxid. Eisen und Nickel können auf Mangan(IV) oxidhydrat mitgefällt und ihre 8-Hydroxychinolate bei pH 4,5 extrahiert werden. Die Atomabsorptionsmessung dieser

Elemente bei 2483 und 2320 Å entspricht Nachweisgrenzen von 10 ppm in Aluminiumoxid. Für Calcium, Magnesium und Nickel lassen sich Hohlkathodenlampen verwenden; für Eisen gibt eine einfache mit Mikrowellen erregte Entladungsröhre viel, bessere Empfindlichkeit als eine Hohlkathodenlampe.

Résumé—On peut réaliser le dosage de traces de calcium et de magnésium dans des solutions à fortes concentrations en sels d'aluminium en coprécipitant leurs hydroxydes sur l'hydroxyde de fer(III), dissolvant le précipité et extrayant les 8-hydroxyquinoléinates de calcium et de magnésium en méthylisobutylcétone à pH voisin de 11. On peut pulvériser l'essai dans la flamme air-propane d'un spectrophotomètre simple non modulé et effectuer les mesures d'absorption atomique pour le calcium et le magnésium à 4227 et 2852 Å respectivement. Les limites de dosage correspondent à 10 et 1 p.p.m. de calcium et de magnésium dans l'alumine solide. On peut coprécipiter le fer et le nickel sur l'oxyde de manganèse(IV) hydraté et extraire leurs 8-hydroxyquinoléinates à pH 4,5. Les mesures d'absorption atomique pour ces éléments à 2483 et 2320 Å respectivement donnent des limites de détermination correspondant à 10 p.p.m. dans l'alumine. On peut utiliser des lampes à cathode creuse pour le calcium, le magnésium et le nickel, mais un tube à décharge excitée par microondes donne pour le fer une sensibilité bien meilleure qu'une lampe à cathode creuse.

COMPUTER CALCULATION OF EQUILIBRIUM CONCENTRATIONS IN MIXTURES OF METAL IONS AND COMPLEXING SPECIES

D. D. PERRIN and I. G. SAYCE
Department of Medical Chemistry, Australian National University, Canberra, Australia

(*Received* 2 *December* 1966. *Accepted* 6 *March* 1967)

Summary—A method is described for calculating equilibrium concentrations of all species in multi-metal—multi-ligand mixtures from the pH of the solution, the total concentration of each metal and each complexing agent, and the relevant equilibrium constants (pK_a values and stability constants). No restriction is imposed on types of possible complexes, which can include mixed, hydrolysed, protonated and polynuclear species. Two examples are given. One of these comprises a 10-metal–10-ligand system (195 equilibrium constants). In the second system, mixed complex formation is important. The computer program is given.

KNOWLEDGE of equilibrium concentrations in solutions of metal ions and complex-forming species is important to the analyst in many ways. Thus, he may wish to establish the most favourable conditions for a determination, to assess the extent to which other species interfere, to develop new methods of analysis, or to compare the possible accuracies of existing procedures. The law of mass action provides the necessary basis for such calculations, given the relevant stability constants. However, when more than one type of metal ion and several different ligands are present at the same time, an iterative approach must be used. Such an approach, although possible by conventional means, is extremely laborious unless a digital computer is used.

Recently,[1] a computer program* was described for calculating the equilibrium concentrations of all species in a multi-metal–multi-ligand mixture, provided that the complexes formed were of the types ML, ML_2, ML_3, . . . ML_n. The only information needed was the pH of the solution, the total concentration of each metal and complexing agent, and the relevant equilibrium constants (pK_a values and stability constants). Such systems are also important as models for biological fluids. A comparable (but not general) procedure has been published for the computation of metal binding in the 2-metal–2-chelate system K^+, Mg^{2+}, ATP, EDTA.[2]

We have now developed an entirely general treatment for calculating concentrations in the presence of all types of metal complex equilibria, including the formation of mixed species (such as ML′L″ or M′LM″), hydrolysed species [such as M(OH), $M_2(OH)_3$ or M(OH)L], protonated species [such as LM(HL) or $M(HL)_2$], and polynuclear species [such as M_2L_3 or $M_2(OH)_2L_2$].

METHOD

If M^a, M^b, M^c, . . . represent the different kinds of metal ions, and L^r, L^s, L^t, . . . are different kinds of ligands, any complex that can be formed from them can be represented by $(M^a)_\alpha(M^b)_\beta(M^c)_\gamma \ldots (L^r)_\rho(L^s)_\sigma(L^t)_\tau \ldots (OH)_\omega$, where $\alpha, \beta, \gamma \ldots \rho, \sigma, \tau \ldots$ may be positive integers or zero, and ω may be a positive integer (for hydrolysed species), zero, or a negative integer (for protonated species). The concentration of

* The spelling *program* is used instead of *programme* out of deference to workers in the U.S. who first applied the term to computers.

any one of these complexes (including protonated ligand species and hydrolysed metal ions) is then given by

$$c_j = \beta_j[M^a]^\alpha[M^b]^\beta[M^c]^\gamma \ldots [L^r]^\rho[L^s]^\sigma[L^t]^\tau \ldots [OH]^\omega,$$

where β_j is the overall formation constant, so that the total concentration of metal i is:

$$[M^i]_T = [M^i] + \sum_{j=1}^{j=n} p_{ij}c_j \qquad (1)$$

where p_{ij} is the number of metal ions of M^i in the species j. A similar set of equations can be written for total ligand concentrations.

Using the program described in the Appendix, the computer reads in from cards the relevant set of values α, β, $\gamma \ldots \omega$, for each species, and the corresponding equilibrium constant. It then calculates free metal and ligand concentrations by the following iterative method.

Beginning with the crude approximation that complex formation is negligible (so that $[M^i] = [M^i]_T$, and $[L^x]$ can be calculated from $[L^x]_T$ by using the appropriate pK_a values), the machine computes the quantity on the right-hand side of equation (1) for each kind of metal ion, and similarly for each complexing species, to give quantities that can be designated as $[M^i]_T^{calc}$ and $[L^x]_T^{calc}$, respectively. The initial estimates of $[M^i]$ and $[L^x]$ are then replaced by $[M^i]([M^i]_T/[M^i]_T^{calc})^{1/2}$ and $[L^x]([L^x]_T/[L^x]_T^{calc})^{1/2}$. With these new estimates the calculations are repeated, to obtain better values of $[M^i]$ and $[L^x]$. The process is continued until all values of $[M^i]_T^{calc}$ and of $[L^x]_T^{calc}$ differ from the corresponding values of $[M^i]_T$ and of $[L^x]_T$ by less than a specified quantity. (For the results given in Tables I and II this was chosen to be 0·001 % of $[M^i]_T$ and of $[L^x]_T$.) Within this accuracy, the final values of $[M^i]$ and $[L^x]$ satisfy all equations for metal and ligand concentrations. They are then used to compute the equilibrium concentrations of all species, and the results are finally printed out in tabular form.

DISCUSSION

The program has been tested for a system containing ten different kinds of metal ions and ten substituted iminodiacetic acids of the types R—$N(CH_2COO^-)_2$, and having a total of 195 species for which equilibrium constants are available.[3] These include pK_a values for the ligands and for hydrolysed metal ions, and constants for protonated and hydrolysed complexes. An IBM 360/50 electronic computer took 7·0 min to calculate all of the equilibrium concentrations at pH 10 for a solution in which the total concentration of each complexing species was 0·002M and the total concentration of each metal ion was 0·001M. These results are given in Table I.

They are of some interest in providing a quantitative measure of the relative metal-binding abilities of these ligands under the particular experimental conditions chosen, and also in demonstrating preferences among the different metal ions for individual ligands. Thus, magnesium, calcium and manganese form mainly their 1:1 complexes with the ligand where R is $^-OOC—CH_2—$, whereas the most stable 1:1 complexes of cobalt, nickel, copper and zinc are with the ligand where R is $NH_2—CH_2—CH_2—$. On the other hand, complex formation is only slight when R is $NC—CH_2—$ or $(CH_3)_3\overset{+}{N}—CH_2—CH_2—$. Strontium and barium show little discrimination between the four ligands for which R is $HO—CH_2—CH_2—$, $(CH_3)_3C—CH_2—CH_2—$, $^-OOC—CH_2—$ and $NH_2—CO—CH_2—$.

As a further test of the program, it has been applied to the published data[4] for mixed complex formation by nickel and zinc with pyruvate and glyoxalate ions and

At pH 10. All concentrations in μM. The total concentrations of each metal ion and complexing species were 1000 μM and 2000 μM, respectively.

Concentrations of free metal ions (rounded off to 1 μM); Mg, 121; Ca, 12; Sr, 5; Ba, 193, Mn, 1; Co, 0; Ni, 0; Cu, 0; Zn, 0; Cd, 4. An × indicates that no stability constant was available for a particular species, or that the species was not known, whereas a dash implies that the concentration was less than 0·5 μM. Constants were also included for $MnOH^+$, $CoOH^+$, $NiOH^+$, $Cu_2(OH)_2^{2+}$, $Cu_3(OH)_4^{2+}$, $ZnOH^+$ and $CdOH^+$. The ligands were all of the type $R—N(CH_2COO^-)_2$, where R is $CH_3—$, $HO—CH_2—CH_2—$, $(CH_3)_3C—CH_2—CH_2—$, $(CH_3)_3\overset{+}{N}—CH_2—CH_2—$, $CH_3S—CH_2—CH_2—$, $NH_2—CH_2—CH_2—$, $^-OOC—CH_2—$, $NH_2—CO—CH_2—$, $NC—CH_2—$, and $C_2H_5O—CO—NH—CH_2—CH_2—$, for ligands 1–10 respectively.

glycine. Equilibrium concentrations of 28 different species were calculated in 16 sec for a solution at pH 9 and 0·001M in each metal ion and complexing species. These results are summarized in Table II, rounded off to 1 μM.

An alternative program has also been developed to solve simultaneously the $(m + n)$ non-linear equations that can be written to express total concentrations in systems containing m kinds of metal ions and n kinds of complexing species. The method chosen makes use of a Newton–Raphson procedure,[5] which we have generalized to deal iteratively with $(m + n)$ unknowns. This technique had already proved useful for the simultaneous solution of two equations in the refinement program GAUSS[6] (which was developed from a similar program written by Tobias[7]) for dealing with equilibria in systems of one metal and one ligand. When the method was employed with the 10-metal–10-ligand system, convergence was not satisfactory, possibly because the available precision of the computer was insufficient for the calculations. However, for systems containing only small numbers of metals and ligands (up to about three

At pH 9. All concentrations in μM. Total concentrations of each metal ion and complexing species, 1000 μM. Free nickel ion, 341 μM; free zinc ion, 764 μM.

of each) calculations were appreciably faster than by the other program.

The two types of program are thus complementary. The simpler program deals reliably with the more complicated systems, while the Newton–Raphson approach calculates more rapidly the relevant concentrations in simpler systems.

A continuing handicap to the application of either of these programs to equilibria in metal–ligand mixtures is the small number of recorded stability constants for mixed complexes and also for protonated and hydrolysed species. Existing computer programs such as GAUSS[6] and LETAGROP[8] can be used to calculate stability constants for polynuclear, protonated or hydrolysed complexes but hitherto no general program has been available for similar computations for mixed species, notwithstanding their great importance for a quantitative understanding of metallo–enzyme–substrate interactions. For this reason we have also developed a general program for calculating the stability constant of any type of mixed complex from titration data, provided the constants for the other complexes are known. This program uses the Newton–Raphson method. Thus, in principle, it should now be possible to obtain constants for all of the types of complexes that need to be considered in multi-metal–multi-ligand systems.

These programs have further applications, particularly in the quantitative investigation of metal ion equilibria in biological systems, in metal ion toxicity studies, and in dealing with simultaneous buffering with respect to more than one metal ion.

Zusammenfassung—Eine Methode zur Berechnung der Gleichgewichtskonzentrationen aller Spezies in Mischungen mehrerer Metalle und mehrerer Liganden aus dem pH der Lösung, den Gesamtkonzentrationen jedes Metalls und jedes Komplexbildners und den einschlägigen Gleichgewichtskonstanten (pK_a-Werten und Stabilitätskonstanten) wird beschrieben. Die Typen möglicher Komplexe unterliegen keiner Beschränkung: es können gemischte, hydrolysierte, protonierte und mehrkernige Spezies vorkommen. Zwei Beispiele werden angegeben. Eines davon enthält ein System aus 10 Metallen und 10 Liganden (195 Gleichgewichtskonstanten). Im zweiten System ist die Bildung gemischter Komplexe von Bedeutung. Das Rechenprogramm wird angegeben.

Résumé—On décrit une méthode pour calculer les concentrations d'équilibre de toutes les espèces dans des mélanges multi-métaux-multi-ligands à partir du pH de la solution, de la concentration totale de chaque métal et de chaque agent de complexation et des constantes d'équilibre correspondantes (valeurs de pK_a et constantes de stabilité). Aucune restriction n'est imposée quant aux types des complexes possibles, qui peuvent inclure des espèces mixtes, hydrolysées, protonées ou polynucléaires. On donne deux exemples. L'un d'eux comprend un système 10-métaux-10-ligands (195 constantes d'équilibre). Dans le second système, la formation de complexe mixte est importante. On donne le programme de computation.

APPENDIX

The computer program described above is in two parts. The main program, which we have called COMICS (*c*oncentrations *of* *m*etal *i*ons and *c*omplexing *s*pecies), is used to read the data, to set up initial approximations for the free metal and free ligand concentrations, and later to print out the results. The iterative procedure for adjusting the free metal and free ligand concentrations is carried out in a subroutine called COGS (*c*oncentrations *of* *g*eneralised *s*pecies), which returns the computed concentrations of free metal ions, free ligands, and of all complex species to the main program for tabulation, after a satisfactory degree of convergence has been achieved.

The program, as listed below, is intended to calculate concentrations at a series of pH values. In order to speed the calculation for the second and subsequent pH values, the initial approximations for the concentrations of free metals and free ligands for the nth point are taken to be the final values of these quantities for the $(n-1)$th point. The listing of the program includes a description of the input data, and is followed by a list of the variables used, and by a simplified flow sheet showing the calculation method.

END-POINT SHARPNESS IN THERMOMETRIC TITRIMETRY

H. J. V. TYRRELL
Department of Chemistry, Chelsea College of Science and Technology, Manresa Road, London S.W.3

(*Received* 23 *January* 1967. *Accepted* 2 *March* 1967)

Summary—It is shown that the sharpness of an end-point in a thermometric titration where the simple reaction

$$A + B \rightleftharpoons AB$$

takes place, depends on Kc_A' where K is the equilibrium constant for the reaction, and c_A' is the total concentration of the titrand (A) in the reaction mixture. The end-point is sharp if, (*i*) the enthalpy change in the reaction is not negligible, and (*ii*) $Kc_A' > 10^3$. This shows that it should, for example, be possible to titrate 0·1*M* acid, $pK_A = 10$, using a thermometric end-point. Some aspects of thermometric titrimetry when $Kc_A' < 10^3$ are also considered.

IN A thermometric titration the rate of change of temperature of a reaction vessel, dT/dt, is measured as a titrant is added at a constant rate. A sudden change in dT/dt marks the end-point, and it is the sharpness of this change that determines the analytical usefulness of the technique. The shape of the experimental curve of temperature *vs.* titrant volume added (the "thermogram") depends upon:

(*i*) the heat capacity of the system, and its change during the titration,
(*ii*) the rate of heat exchange of the system with its surroundings,
(*iii*) the molar enthalpy change in the reaction, and any enthalpy of dilution,
(*iv*) the amount of product formed for a given addition of titrant.

The design of the titration assembly determines (*i*) and (*ii*), and it is always possible in principle to convert the "thermogram" into an "enthalpogram" representing the relationship between the heat evolved or absorbed in the reaction and the amount of titrant added. If the molar enthalpy change in the reaction is small, the change in slope of both the thermogram and of the derived enthalpogram at the end-point will necessarily be small, and the reaction is unsuitable for thermometric titrimetry. The change will be large, and the end-point sharp, when the molar enthalpy change is large and the reaction is complete. If, however, the reaction is not complete near the end-point, the slope of the enthalpogram will change more slowly in this region, and the end-point will be correspondingly less distinct however large the enthalpy change may be. It is known from experiment that it is possible to use the thermometric method for end-point detection in cases where the reaction is insufficiently complete for other methods to be used. For example, acids as weak as boric acid, or the ammonium ion, can be titrated successfully in this way.[1] For even weaker acids, where the end-point is not detectable with sufficient sharpness for analytical purposes, enthalpograms can be utilized to calculate the thermodynamic parameters of the proton equilibria

involved.[2] Several authors have discussed methods of doing this[2,3,4] for these and other reactions but there appears to be no published treatment which can lead at once to an appreciation of the likelihood of a given reaction yielding a thermometric end-point of sufficient sharpness for practical use. It is the purpose of this paper to remedy this lack for a simple class of reactions of considerable analytical importance.

Consider the normal type of titration procedure where a small volume of a concentrated solution of a reagent B is added, either in successive aliquots, or continuously, to a dilute solution of a reagent A, an equilibrium of the following type being established:

$$A + B \rightleftharpoons AB.$$

The concentrations of A, which is initially in excess, and of B, are c_A and c_B respectively. Only a small volume of the titrant solution B is added, but, even so, the total concentration of the species A in the reaction vessel will change slightly from its initial value to some other value c_A', after a volume V_B of titrant has been added to the original volume, V_A, of titrand. Assume that a proportion α of B is converted into AB when the total concentration of B in the reaction vessel is c_B', and define a coefficient β such that

$$\beta = c_B'/c_A' = c_B V_B/c_A V_A. \tag{1}$$

The free concentrations of the species are therefore

$$\begin{aligned} [A] &= c_A' - \alpha c_B' = c_A'(1 - \alpha\beta) \\ [B] &= c_B'(1 - \alpha) \\ [AB] &= \alpha c_B'. \end{aligned} \tag{2}$$

If concentrations are assumed to be equal to activities, the formation constant, K, for the species AB, can be written

$$K = \frac{[AB]}{[A][B]} = \frac{\alpha}{c_A'(1 - \alpha\beta)(1 - \alpha)}. \tag{3}$$

This is a quadratic equation in α which can be transformed into:

$$\alpha^2\beta - \alpha(\beta + \zeta + 1) + 1 = 0 \tag{4}$$

where $\zeta = 1/Kc_A'$. The quantity ζ is almost, though not quite, constant during the titration since V_A is always much larger than V_B in any normal type of thermometric titration and $c_A \sim c_A'$.

Equation (4) has two roots, only one of which is physically significant, namely,

$$\alpha = \frac{(\beta + \zeta + 1) - [(\beta + \zeta + 1)^2 - 4\beta]^{1/2}}{2\beta}. \tag{5}$$

The proportion α of added B that has been converted into AB is therefore a function of β, the ratio of total B to total A in the reaction vessel, and of ζ, and can be calculated for chosen values of these variables.

For simplicity, it is assumed that the experimental thermogram has been converted into an enthalpogram, and that all heat of dilution effects have been allowed for ("corrected enthalpogram"). If the molar enthalpy change in the formation of AB is ΔH_R, then the total heat, q_R, (after correction for heat of dilution effects) evolved in

the titration up to the point at which a volume V_B of the titrant has been added, is given by

$$\begin{aligned} q_R &= -[AB](V_A + V_B)\Delta H_R \\ &= -c_B V_B \alpha \Delta H_R \end{aligned} \tag{6}$$

from (2) and the definition of α. The corrected enthalpogram is a plot of q_R against volume V_B of titrant added and will be linear as long as α remains constant. If every molecule of B added reacts to form AB, then $\alpha = 1$ as long as A is in excess, *i.e.*, while $\beta < 1$. At, and after, the equivalence point ($\beta = 1$)

$$\alpha = \frac{c_A V_A}{c_B V_B}, \tag{7}$$

which with equation (6) gives

$$q_R = -c_A V_A \Delta H_R \qquad (\beta \geqslant 1) \tag{8}$$

i.e., after the equivalence point q_R is independent of V_B. The change in slope of the corrected enthalpogram at the end-point is sharp if ΔH_R is large enough, and the reaction then has an easily detectable thermometric end-point. When the reaction is incomplete, α deviates from unity before the equivalence point is reached, and the limiting form of the enthalpogram as given by equation (8) is not even approximately attained until an excess of B has been added.

Equation (5) shows that at a given value of β, α depends on ζ. The simplest case is at the equivalence point where equation (3) takes the form

$$1/\zeta = Kc_A' = \alpha/(1 - \alpha)^2.$$

For α to be 0·99 at this point, Kc_A' must be about 10^4. This value of α would correspond to a very sharp thermometric end-point. A more detailed picture of the effect of the formation constant on the sharpness of the end-point can be obtained as follows. From equations (1) and (6)

$$\frac{-q_R}{c_A V_A \Delta H_R} \equiv \xi = \alpha\beta \tag{9}$$

where ξ is a dimensionless variable, the "reduced heat output", and can be calculated for arbitrary values of β and ζ, from equations (5) and (9). When ξ is plotted against β, a set of "reduced enthalpograms", each characteristic of a particular value of ζ, is obtained. These differ from experimental corrected enthalpograms only in scale, and give an immediate impression of the expected end-point sharpness corresponding to any value of ζ, provided only that ΔH_R is large enough for the change in temperature of the system due to the heat of the reaction to be measurable experimentally. A set of such curves is shown in Fig. 1. From this it appears that a reasonably sharp end-point can be expected for a reaction with $\zeta \leqslant 10^{-3}$, *i.e.*, $Kc_A' \geqslant 10^3$. For larger values of ζ the curvature of the reduced enthalpogram near the end-point shows that a sharp thermometric end-point would not be obtained under any experimental conditions. The conditions under which a weak monobasic acid can be titrated thermometrically with a strong base follow immediately. The titrand (A) is the weak acid HX and the

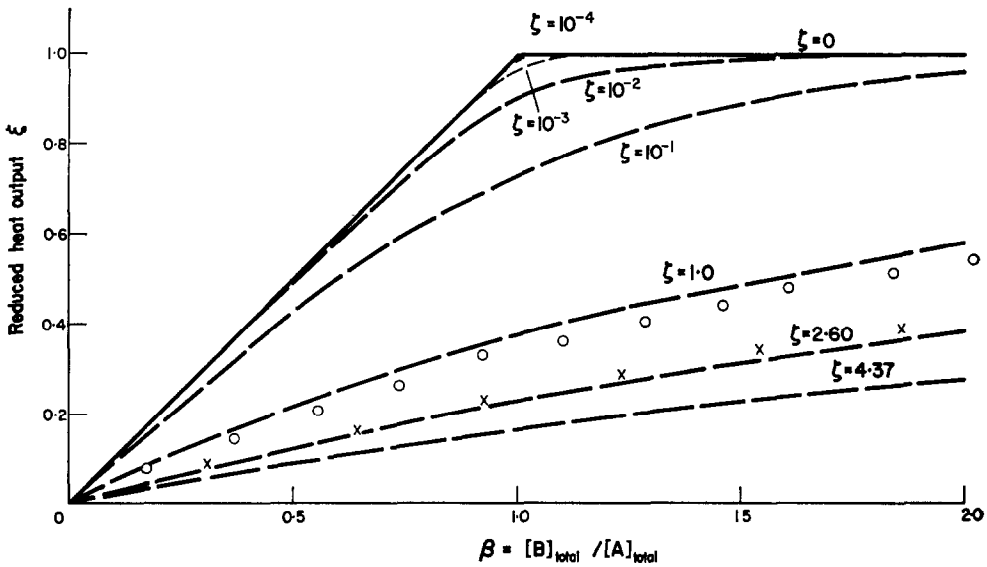

FIG. 1.—Reduced enthalpograms for varying values of ζ.
The full line refers to the limiting case of a complete reaction ($\zeta = 0$); the broken lines are calculated for the values of ζ shown. The points shown are calculated from the data[2] for the reaction $HPO_4^{2-} + OH^- \geq PO_4^{3-} + H_2O$. Those marked ○ correspond to an experiment in which the initial concentration (c_A) of Na_2HPO_4 was $0{\cdot}009464M(1/K_Tc_A = 2{\cdot}60)$, and those marked × to one where c_A was $0{\cdot}005644M(1/K_Tc_A = 4{\cdot}37)$.

titrant (B) is the hydroxyl ion. The reaction is,

$$HX + OH^- \rightleftharpoons H_2O + X^-$$

with

$$K = \frac{[X^-]}{[H^+][OH^-]} = \frac{K_a}{K_w}$$

where K_a is the normal dissociation constant of the acid, and K_w is the ionic product of the solvent water. If K_a is 10^{-9}, $K = 10^5$ at 25°, and if $c_A = 0{\cdot}1$, then $Kc_A = 10^4$, *i.e.*, a $0{\cdot}1M$ solution of an acid with $pK_a = 9$ should give a thermometric end-point almost as sharp as that of a strong acid, provided that the heat of neutralization is large enough. This is usually the case for weak protonic acids which have small heats of ionization. A usable end-point would also be expected at this concentration if $pK_a = 10$, but the end-point for still weaker acids must become indistinct in this concentration range. These conclusions have been amply confirmed by experiment on such acids as boric acid and the ammonium ion.[1]

The reduced enthalpogram for $\zeta = 1$ in Fig. 1 shows that at low values of β the limiting slope of the reduced enthalpogram does not become equal to that for the reduced enthalpogram with $\zeta = 0$ in the range $0 \leqslant \beta \leqslant 1$. The value of this limiting slope can be found by expanding (5):

$$\alpha = \frac{1}{\beta + \zeta + 1} + \frac{\beta}{(\beta + \zeta + 1)^3} + \text{higher terms.}$$

For small values of β only the first term need be considered and,

$$\lim_{\beta \to 0} (\alpha) = 1/(\zeta + 1).$$

This is the limiting slope of the reduced enthalpogram. That of the corrected experimental enthalpogram is, from this and equation (6),

$$-\frac{c_B}{(\zeta+1)}\Delta H_R .$$

Keily and Hume[5] proposed, in effect, that ΔH_R could be found from this limiting slope by equating $(\zeta + 1)$ with 1; this procedure clearly introduces an appreciable error if $\zeta \geqslant 10^{-2}$, and would not be applicable to weak complexes without modification. Dilke and Eley calculated the formation constant and enthalpy of formation for such complexes by first using the limiting slope of the enthalpogram to obtain ΔH_R, assuming $\zeta = 1$, and then combining this with calorimetric data near the equivalence point to obtain K. Such data are insensitive to ζ, and hence to K, when $\zeta < 10^{-3}$, and this method is limited to systems for which $10^{-3} < \zeta < 10^{-2}$, unless a successive approximation technique is used.

There are a number of more sophisticated methods available[4] for calculating K and ΔH_R from thermometric measurements, and Christensen, Izatt, Hansen and Partridge[2] have used such methods to analyse thermometric titration curves for the ionization of HSO_4^- and HPO_4^{2-}. To test the graphical method described here, reduced enthalpograms have been calculated from their results on HPO_4^{2-} at two concentrations; these are shown in Fig. 1. From their data they calculated a thermodynamic ionization constant, K_T, corrected to zero ionic strength, for the process

$$HPO_4^{2-} + OH^- \rightleftharpoons PO_4^{3-} + H_2O.$$

Their mean value for log K_T was $1{\cdot}61 \pm 0{\cdot}03$. Using this, and the initial titrant concentrations used[2], it is found that $\zeta = 2{\cdot}6$ and $4{\cdot}37$ respectively. Theoretical reduced enthalpograms for these ζ values are also shown in Fig. 1 and it is clear that the fit with the experimental data is not good. In fact the data which apparently correspond to $\zeta = 4{\cdot}37$ fit approximately to $\zeta = 2{\cdot}6$, and those nominally associated with $\zeta = 2{\cdot}6$ lie close to the curve for $\zeta = 1$. The discrepancies are caused by the fact that an equilibrium constant corresponding to the experimental ionic strength in the titration, rather than K_T, should have been used to calculate ζ. For the equilibrium above,

$$\log K_T = \log K + \log \frac{f_{PO_4^{3-}}}{f_{OH^-} f_{HPO_4^{2-}}}$$

If the simplest form of the Debye-Hückel equation for activity coefficients, $\log f_i = -0{\cdot}509\, z_i^2 \mu^{1/2}$, is applied to $0{\cdot}01M$ sodium dihydrogen phosphate,

$$\begin{aligned}\log K_T &= \log K - 2{\cdot}18\, \mu^{1/2} \\ &= \log K - 0{\cdot}37.\end{aligned}$$

The most concentrated solution used by Christensen *et al.* was approximately $0{\cdot}01M$, and the appropriate log K to use in calculating ζ can be obtained from the thermodynamic constant log K_T by adding $\sim 0{\cdot}37$ to it. This would reduce ζ from 2·6 to something close to 1. Quite obviously the reduced enthalpogram plot is very sensitive to ζ, and hence to K, for such weak acids.

Zusammenfassung—Es wird gezeigt, daß die Schärfe des Endpunktes einer thermometrischen Titration, in der die einfache Reaktion

$$A + B \rightleftharpoons AB$$

abläuft, von Kc_A' abhängt, wo K die Gleichgewichtskonstante der Reaktion und c_A' die Gesamtkonzentration des Titranden (A) im Reaktionsgemisch ist. Der Endpunkt ist scharf, wenn (1) die Reaktionsenthalpie nicht vernachlässigbar und (2) $Kc_A' > 10^3$ ist. Hieraus folgt, daß man beispielsweise eine 0,1 M Säure vom $pK_A = 10$ thermometrisch titrieren konnen sollte. Auch einige Aspekte der thermometrischen Titration bei $Kc_A' < 10^3$ werden erörtert.

Résumé—On montre que la netteté d'un point de fin de réaction dans un dosage thermométrique où se produit la réaction simple:

$$A + B \rightleftharpoons AB$$

dépend de Kc_A' où K est la constante d'équilibre pour la réaction et c_A' est la concentration totale de l'agent de titrage (A) dans le mélange réactionnel. Le point de fin de réaction est net si (1) la variation d'enthalpie dans la réaction n'est pas négligeable et (2) $Kc_A' > 10^3$. Ceci montre qu'il devrait, par exemple, être possible de doser un acide 0,1 M, $pK_A = 10$, en utilisant un point de fin de réaction thermométrique. On considère aussi quelques aspects de la titrimétrie thermométrique lorsque $Kc_A' < 10^3$.

OXIDIMETRIC DETERMINATION OF INDIGO WITH IRON(III) AND HEXACYANOFERRATE(III)

G. GOPALA RAO and V. RUKMINI
Andhra University, Waltair, India

(*Received* 23 *December* 1966. *Accepted* 21 *January* 1967)

Summary—The use of iron(III) in sulphuric acid medium and of potassium hexacyanoferrate(III) in hydrochloric acid medium has been investigated for the oxidimetric determination of indigo and indigo sulphonic acid. Conditions have been established for the assay of the dye with iron(III) sulphate at 100° and with potassium hexacyanoferrate-(III) at room temperature.

INDIGO has been determined by oxidation with vanadium(V),[1] cerium(IV),[2] dichromate[3] and potassium iodate[4]. It has now been observed that indigo sulphonate is quantitatively oxidized when heated with excess of iron(III) sulphate in sulphuric acid. This reaction has been studied in detail and a method developed for the assay of indigo or indigo sulphonic acid. The reaction is of interest analytically because it is one of the few instances of an organic compound being quantitatively oxidized by iron(III). It is also of considerable significance in textile dyeing and laundering. If the water used in dyeing operations with indigo (and possibly other vat dyes) contains iron salts, the dyeing may not be uniform. If the laundering water is similarly contaminated, indigo dyeings may be partially bleached.

Flatow[5] carried out the direct titration of 0·0025–0·002*M* hexacyanoferrate(III) with 0·0005–0·0002*N* indigo sulphonic acid in potassium hydroxide medium. Flatow[6] has also titrated hexacyanoferrate(III) with indigo carmine solution in a sodium carbonate medium in connection with the estimation of uric acid. According to Welcher[7] the indigo carmine is oxidized in alkaline medium by potassium hexacyanoferrate(III) to form the pale yellow disulpho-dehydro-indigo, and not to isatin. The present work is concerned with the oxidation of indigo sulphonate in acid medium with hexacyanoferrate(III). It had been observed that the rate of oxidation of indigo by potassium hexacyanoferrate(III) at room temperature increases with increase in hydrochloric acid concentration. The reaction becomes very fast in 8*M* hydrochloric acid. In 3*M* hydrochloric acid the reaction takes about 60 min for completion, whereas in 6*M* hydrochloric acid it is complete within 1 min. In this reaction indigo is oxidized almost stoichiometrically to isatin; in sulphuric acid medium the reaction is very slow at all acidities tried from 0·25 to 2*M*.

It was also found by us that the rate of oxidation of indigo sulphonate by iron(III) in sulphuric acid was appreciable only at elevated temperature (100° is suitable) and that it decreases if the sulphuric acid concentration is increased above 1*M*, and increases as the ratio of iron(III) to indigo increases, reaching a maximum when this ratio is about 8.

EXPERIMENTAL

Reagents

Indigo sulphonate solution. About 1 g of pure indigo was sulphonated by digestion with 15 ml of concentrated sulphuric acid at 90° for 45 min. The reaction mixture was then cooled, diluted to

500 ml with conductivity water, and standardized by the vanadate procedure of Sastri and Gopala Rao. (The solution was 0·00763*M*. As the solution deteriorates on keeping, it had to be restandardized every day. The solution is preferably made with deionized water.)

Iron(III) and hexacyanoferrate(III), 0·1*M*. Prepared from salts of analytical reagent quality. The iron(III) sulphate solution was prepared in 0·5*M* sulphuric acid.

All other reagents were of analytical reagent quality.

Procedure with iron(III)

Adjust the acid concentration to 1*M* and the ratio of iron(III): indigo to 8–9 and heat the reaction mixture in a flask fitted with a Bunsen valve, in a boiling water-bath for 10 min. The reaction is complete when a clear golden yellow colour appears. When the reaction is complete, cool the mixture, add 3–5 ml of syrupy phosphoric acid, and titrate with a standard solution of potassium dichromate or sodium vanadate, using barium diphenylamine sulphonate as indicator. If sodium vanadate is used as reagent, add oxalic acid to the mixture to catalyse the indicator reactions. The number of moles of iron(III) consumed per mole of indigo is 4 ± 0·1, one mole of indigo being oxidized to two moles of isatin.

Typical results are shown in Table I.

TABLE I

Indigo sulphonate taken, *μmole*	Indigo sulphonate found, *μmole*
60·02	60·15
53·76	53·55
45·15	44·94
30·66	30·66
12·60	12·52
9·76	9·75
6·13	6·08

Procedure with hexacyanoferrate(III)

Treat 5 ml of indigo sulphonate solution with 5 ml of hexacyanoferrate(III) solution and sufficient concentrated hydrochloric acid to give an overall concentration of 6*M* hydrochloric acid on dilution to 35–40 ml. Set the mixture aside for a minute or two until the reaction is complete as shown by a clear golden yellow colour. Then dilute it with enough water to make the concentration of the acid 1*M*. To determine the amount of unreacted hexacyanoferrate(III), add 10 ml of 10% potassium iodide solution and 3 ml of 30% w/v zinc sulphate solution, and titrate the liberated iodine with 0·05*N* sodium thiosulphate. Standardize the hexacyanoferrate(III) solution by the same method.

Typical results are shown in Table II.

TABLE II

Indigo taken, *μmole*	Indigo found, *μmole*
34·33	34·35
41·19	41·17
45·30	45·33
46·96	46·95
53·55	53·58
63·01	62·95

One mole of indigo requires four moles of hexacyanoferrate(III). Oxalic acid, tartaric acid, citric acid, gum acacia, glucose, starch, dextrin, *etc.*, do not interfere in this procedure.

DISCUSSION

Interferences

The titrimetric determination of indigo sulphonate with potassium permanganate or cerium(IV) sulphate gives high values in the presence of organic substances such

as oxalic acid, citric acid, tartaric acid, glucose, starch and dextrin. These substances, except oxalic acid, do not interfere in the present method provided sodium vanadate is used for the determination of the iron(II) formed in the reaction between iron(III) and indigo. Potassium dichromate is unsuitable because during the titration of iron(II) the organic substances are also oxidized by an induced reaction. The presence of oxalic acid causes high results, the extent of interference increasing with increase in the concentration of oxalic acid. Further work is in progress to ascertain the cause of this interference.

Direct titration of hexacyanoferrate(III) with indigo sulphonic acid

Although indigo sulphonic acid is rapidly oxidized by hexacyanoferrate(III) in 8*M* hydrochloric acid, a direct titration has not been found possible, because of the difficulty experienced in locating the end-point visually and because of the difficulty of attainment of steady potentials if a potentiometric method is used. In the reverse titration of hexacyanoferrate(III) with indigo sulphonic acid in 8*M* hydrochloric acid medium, the potentials are stabilized quickly but the ratio of hexacyanoferrate(III) to indigo is irregular. However, the titration is possible with a visual end-point at room temperature, the self-colour of indigo sulphonic acid itself serving to mark the end-point. After all the hexacyanoferrate(III) disappears, the addition of a fraction of a drop of indigo solution imparts a green colour to the titration mixture; in such titrations, an average of 3·76 moles of hexacyanoferrate(III) is required for the oxidation of 1 mole of indigo. Although the oxidation of indigo does not proceed to isatin stoichiometrically, this titration can still be used because of the near constancy ($\pm 1{\cdot}5\%$) of the ratio of hexacyanoferrate(III) to indigo.

This reaction is one of the few instances of hexacyanoferrate(III) being used as an oxidimetric reagent in acid medium. According to Berka, Vulterin and Zýka,[8] most oxidations with hexacyanoferrate(III) are carried out in alkaline medium.

Zusammenfassung—Die Verwendung von Eisen(III) in schwefelsaurer und von Kaliumhexacyanoferrat(III) in salzsaurer Lösung zur oxidimetrischen Bestimmung von Indigo und Indigosulfonsäure wurde untersucht. Es wurden Arbeitsbedingungen festgelegt für die Gehaltsbestimmung der Farbe mit Eisen(III) sulfat bei 100° und mit Kaliumhexacyanoferrat(III) bei Zimmertemperatur.

Résumé—On a étudié l'emploi du fer (III) en milieu acide sulfurique et du ferricyanure de potassium en milieu acide chlorhydrique pour le dosage oxydimétrique de l'indigo et de l'acide indigo sulfonique. On a établi les conditions de dosage des colorants avec le sulfate de fer (III) à 100° et avec le ferricyanure de potassium à température ordinaire.

SHORT COMMUNICATIONS

Milligram determination of aromatic amines and phenols with *N*-bromosuccinimide

(*Received* 29 *September* 1966. *Accepted* 8 *February* 1967)

THE usual bromination reactions[1-5] employed for the determination of a large number of aromatic amines and phenols have been found to be inapplicable to compounds such as *p*-aminobenzoic acid, *p*-nitroaniline and aniline at higher temperature. The reaction takes a long time in many cases and does not give accurate results.

Taking advantage of the rapid bromination reaction of *N*-bromosuccinimide with different aromatic compounds,[6] we have developed a quantitative and accurate method for the milligram determination of aromatic amines and phenols. A 2–4 mg sample is dissolved in a hydrochloric–acetic acid mixture and treated with a known excess of the *N*-bromosuccinimide solution. The reaction is allowed to proceed for about 10 min and the excess of the reagent is determined iodometrically. A blank determination is made under identical conditions and a correction for it is applied.

EXPERIMENTAL

Reagents

N-*Bromosuccinimide, ca.* 0·01*M*. Dissolve about 0·2 g of reagent in hot distilled water, cool the solution and dilute it to 100 ml with distilled water. The solution should be freshly prepared before use, and standardized iodometrically.[7]

Sample. Weigh accurately 20–40 mg of sample, dissolve it in the minimum amount of 4*M* hydrochloric acid (for amines) or water, or 4*M* sodium hydroxide (for phenols), and dilute to 50 ml with distilled water. Alternatively use 2–4 mg of sample, without dilution.

General procedure

Transfer 5 ml of the sample solution to a 100-ml iodine flask, add 5 ml of 4*M* hydrochloric acid, 5 ml of glacial acetic acid, and 10 ml of *N*-bromosuccinimide solution, stopper and shake well. After about 10 min, add about 1 g of potassium iodide and titrate against 0·025*N* sodium thiosulphate with starch (1% aqueous solution) as indicator. The same procedure is followed for a blank, and the difference in the titrations is used for the calculation:

$$\text{Amine content} = \frac{MVC}{n}\ \text{mg}$$

where M = molecular weight of sample,
V = volume (in ml) of *N*-bromosuccinimide solution used in the reaction,
C = molarity of the *N*-bromosuccinimide solution.
and n = number of moles of *N*-bromosuccinimide required per mole of the sample for complete reaction.

RESULTS AND DISCUSSION

Amines

For the quantitative determination of amines, aniline was chosen as the representative compound. At first, direct titration of the aniline sample in acidic medium against *N*-bromosuccinimide, with Methyl Red as indicator, was tried, but the end-point was not very sharp and the results obtained were about 12% low.

The indirect titrimetric method—addition of a known excess of *N*-bromosuccinimide solution and iodometric titration of the excess of reagent—was next tried. This procedure gave sharp end-points and was specially suited for the determination of coloured compounds such as nitroanilines and nitrophenols and also for compounds which require a moderate reaction time. It was therefore used in all the subsequent determinations. With some loss of accuracy, as little as 0·5 mg of aniline could be determined (Table I).

TABLE I.—DETERMINATION OF ANILINE BY INDIRECT TITRATION

Sample, *mg**	Aniline found, *mg*	Error, %
5·02	4·86, 4·85, 4·86	−3·2

* In each case, 3 aliquots taken.

In general too large an excess of the brominating agent causes low results, perhaps because loss of bromine by volatilization may be greater in the blank. The recommended procedure gives reasonably accurate results with *p*-nitroaniline, which cannot be determined by the classical bromination method. Determination of toluidines presented difficulty in judging the end-point; a continuing consumption of the reagent was noticed on allowing the reaction mixture to stand. However, *o*-toluidine could be determined with less difficulty. The abnormal behaviour of toluidines may be due to partial bromination of the methyl group along with bromination of the benzene ring. In the case of benzidine the expected derivative is a tetrabromo compound but the amount of the brominating reagent consumed varied continuously with time and no proper stoichiometry could be obtained. Similarly in mono- and dimethylanilines a constant end-point could not be obtained.

The presence of carboxylic and sulphonic acid groups in the aniline molecule retards the speed of

* In each case, 3 aliquots taken.
† *N*-Bromosuccinimide.

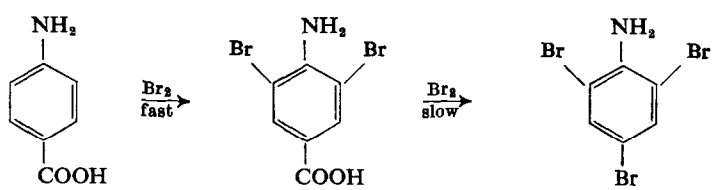
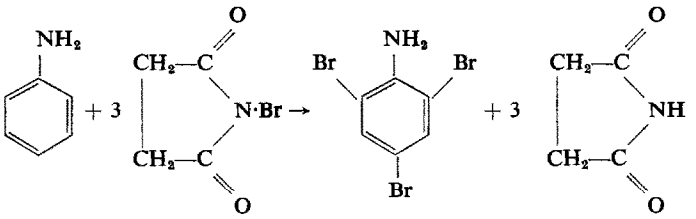
the reaction to a great extent, which may be explained by the fact that the reaction proceeds faster in the first step whereas the last step is slow.



Diphenylamine also reacts slowly. Tertiary amines such as dimethylaminobenzaldehyde and tetramethyldiaminobenzophenone give inconsistent results, probably due to the effect of the methyl groups. Results obtained with a few of the compounds are given in Table II.

The bromination reaction with *N*-bromosuccinimide is almost instantaneous with some amines and phenols, but in some cases the reaction is not so fast and the reaction takes about 10 min to reach completion. In a general procedure for the analysis of an unknown sample the reaction time allowed should be 10 min.

Taking aniline as an example, the bromination reaction may be represented by the equation



The number of bromine atoms entering the molecule may differ in different compounds but must be known for the determination; however, the bromination reactions of aromatic amines and phenols are well established by the usual bromination methods with bromate–bromide mixture as reagent.[3–5]

Phenols

In the determination of phenols, we observed that the presence of a nitro group *meta* or *para* to the phenolic group does not hinder the reaction, while a carboxyl group in the *ortho* position makes the reaction very slow, possibly because of hydrogen-bonding between the hydroxyl and carboxyl groups. In the case of dihydric phenols, the presence of hydroxyl groups *meta* to each other does not cause any trouble, but *ortho* and *para* dihydroxy groupings lead to inconsistent results. Probably the compounds undergo slow oxidation as well as or instead of bromination. Similar behaviour was noticed in the case of quinhydrone. Results obtained with some of the phenolic compounds are given in Table III.

Summary—A simple and rapid method has been developed for the determination of milligram amounts of aromatic amines and phenols. An aliquot containing 2–4 mg of sample is dissolved in a mixture of hydrochloric and acetic acids and allowed to react with *N*-bromosuccinimide, the excess of which is determined iodometrically after the reaction is over. The reaction time varies from 1–10 min and the absolute error generally is negative, ranging from −1 to −4%.

Zusammenfassung—Eine einfache und schnelle Methode zur Bestimmung von Milligrammengen aromatischer Amine und Phenole wurde entwickelt. 2–4 mg Probe werden in einer Mischung aus Salzsäure und Essigsäure gelöst und mit N-Bromsuccinimid zur Reaktion gebracht; dessen Überschuß wird nach Ablauf der Reaktion jodometrisch bestimmt. Die Reaktionszeit leigt zwischen einer und zehn Minuten und der Absolutfehler ist im allgemeinen negativ, zwischen −1 und −4%.

Résumé—On a élaboré une méthode simple et rapide pour le dosage de quantités d'amines aromatiques et de phénols de l'ordre du milligramme. On dissout un prélèvement contenant 2–4 mg d'échantillon dans un mélange d'acides chlorhydrique et acétique et le fait réagir avec le N-bromosuccinimide, dont l'excès est dosé par iodométrie après fin de réaction. Le temps de réaction varie de 1 à 10 mn et l'erreur absolue est généralement négative, allant de −1 à −4%.

Microchemical detection of isocyanides

(*Received* 2 *February* 1967. *Accepted* 13 *March* 1967)

RECENT surveys on α-addition reactions[1] and synthesis methods[2] indicate considerable interest in the use of isocyanides in organic chemistry. The characteristic and unpleasant odour of an iso-cyanide gives such a sensitive and rapid method of identification[3] it is not surprising that only one chemical detection method was found in the literature. Smith and Kalenda[3] mentioned that the colour test of Pertusi and Gastaldi[4] is useful for detecting the presence of isocyanides in reaction mixtures but gave no experimental details. This particular test is based on the oxidation of benzidine to benzidine blue by copper(II) acetate when a suitable complexing agent is present. It is well-known for its adaption to the detection of hydrogen cyanide.[5,6] We studied several aromatic amine—metal ion redox systems and report in this paper the microchemical detection of isocyanides on filter paper or in tubes of silica gel with benzidine acetate–copper(II) acetate or *p,p'*-tetramethyldiamino-diphenylmethane–copper(II) sulphate reagents.

EXPERIMENTAL

Reagents

Benzidine acetate—copper(II) acetate reagent (benzidine reagent). Mix, just before use, equal volumes of (*a*) aqueous cupric acetate solution, 2·86 g/l and (*b*) 675 ml of benzidine acetate solution (saturated at room temperature) mixed with 525 ml of water. The stock solutions are best stored separately in well stoppered, dark bottles.

Tetrabase—copper(II) sulphate reagent (tetrabase reagent). Mix equal volumes of solutions of (*a*) 100 mg of tetrabase (*p,p'*-tetramethyldiaminodiphenylmethane) and 500 mg of salicylic acid in 100 ml of acetone and (*b*) 1·5 g of copper(II) sulphate in 100 ml of water.

Apparatus

Silica gel tubes. A 2 × 9-cm test-tube with a capacity of about 12 ml was fitted, by means of a 19/38 standard taper joint, with an adapter supporting a side-arm air inlet and a length of glass tubing that extended to within 5 to 10 mm of the bottom of the test tube (Fig. 1). Silica gel tubes[7–9] were connected by a short length of rubber tubing to the upper end of the glass tubing. Vapours from the test-tube were drawn through the detector tube by compressing a rubber bulb.

Procedure with silica gel tubes

Samples of varying amounts of the pure isocyanides dissolved in methylene chloride (1–50 μl, 0·0004–0·002*M*) were measured with disposable pipettes and placed in the test apparatus described above. When an unimpregnated silica gel detector tube is used, the isocyanide vapour is collected on the silica gel, the detector tube is removed from the apparatus, and the silica gel is moistened with a drop of either reagent. The appearance of a blue colour is a positive test for isocyanide. A blue colour is produced directly when the isocyanide vapour is sampled by drawing it through a silica gel tube impregnated with tetrabase reagent. Such a detector tube is prepared from silica gel impregnated with copper(II) sulphate pentahydrate, *p,p'*tetramethyldiaminodiphenylmethane and salicyclic acid.[10] A red dye (diazotized anthranilic acid coupled with diethylaniline) is also added to mask the blue colour of the copper(II).

The n-butyl, s-butyl, and t-butyl isocyanides were synthesized by reacting tosyl chloride, quinoline and the corresponding n-alkyl formamide.[2,11]

RESULTS

Spot-tests on filter papers

The isocyanide test was initially developed as a spot-test on filter paper. Several kinds of paper were compared since the sensitivity of certain spot-tests can be increased by using the proper filter paper.[12]

Benzidine reagent. In each test, 10 μl of the benzidine reagent were placed on the filter paper, and 10 μl of methylene chloride containing 0·18 μg of n-butyl isocyanide were added. On the basis of the intensity of the blue colour produced the papers were grouped into three categories:

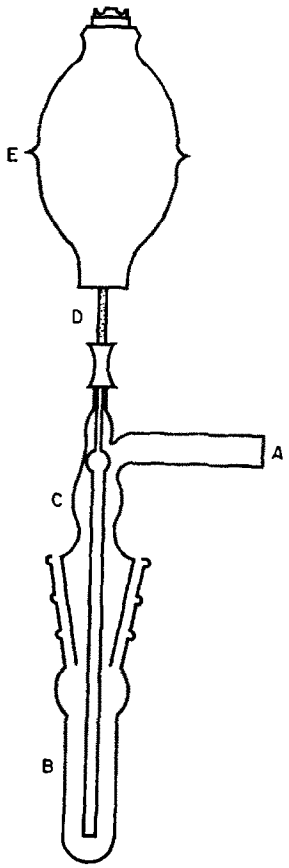

FIG. 1.—Test apparatus.
A—Air inlet; B—2 × 9-cm test-tube with 19/38 standard taper joint; C—adapter; D—silica gel tube; E—rubber aspirator bulb with one-way valve.

Most sensitive (positive test)	*Least sensitive* (negative test)
Detector paper*	Whatman 30
S&S† 589	Whatman 1
Whatman‡ 3	Whatman 4
	Whatman 40
Intermediate sensitivity (doubtful test)	Whatman 41
Whatman 120	Whatman 2
Whatman 31	S&S 576
Whatman 5	S&S 410
S&S 597	S&S 602
S&S 604	S&S 589 Blue ribbon
	S&S 589 Black ribbon

Tetrabase reagent. The tetrabase reagent (10 μl) gave a pale blue colour with 5 μg of n-butyl isocyanide on the paper tape impregnated with Parez® 607 resin (about the same intensity as that given by 0·5 μg of n-butyl isocyanide with the benzidine reagent). Similar results were found with the Whatman 120 paper. The blue colour with tetrabase reagent was stable, whereas that with benzidine faded within a few minutes.

Tests on the silica gel tubes

The sensitivity of isocyanide detection was improved by the use of silica gel detector tubes (Table I).

TABLE I.—COLORIMETRIC DETECTION OF ISOCYANIDES IN THE VAPOUR STATE WITH SILICA GEL TUBES

Technique	Amount of isocyanide tested*		
	n-Butyl	s-Butyl	t-Butyl
Sampling through silica gel tubes followed by addition of benzidine reagent	0·15 μg, definite light blue 0·06–0·12 μg, faded rapidly	0·09 μg, definite test 0·06 μg, faint test	0·12 μg, definite test 0·09 μg, faint test
Sampling through silica gel tubes impregnated with tetrabase reagent	0·12 μg, definite blue colour 0·06–0·09 μg, faint test	0·09 μg, definite test 0·06 μg, faint test	0·09 μg, definite test 0·06 μg, faint test

* It is assumed that all of the isocyanide placed in the test apparatus was sampled.

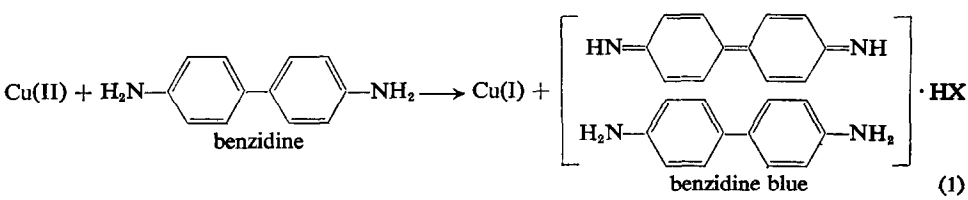
About 0·1 μg of the butyl isocyanides was easily detected. The colour formed in the benzidine test faded rapidly after 1–5 min. The blue colour formed in tetrabase impregnated tubes was stable, but after prolonged standing (about 2 hr) all the impregnated tubes, including the blank controls, turned deep blue.

Interferences

Substances that interfere in the detection of hydrogen cyanide also interfere in the detection tests for isocyanides.[5] They include volatile oxidizing or reducing agents and certain electrophiles or acids. For example, with the tetrabase reagent, we confirmed that strong acids give a yellow colour and sulphides give a brown colour.

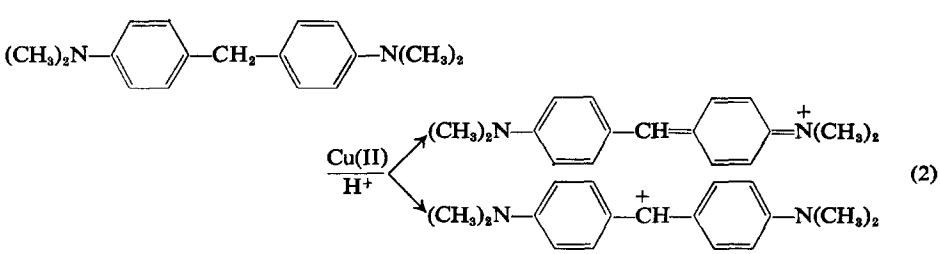
DISCUSSION

The mechanisms of the colorimetric tests for alkyl isocyanides with the benzidine or the tetrabase reagent are probably similar to those described for the well-known methods for cyanide. The benzidine test, sensitive to 0·25 μg of cyanide at a limit of dilution of 1 in 200,000,[5] is one of the easiest and most sensitive methods for detecting cyanide.[6] This reaction, equation (1), takes place because the oxidation potential of copper(II) is increased by the removal of copper(I) as an insoluble complex.



(1)

The coloured oxidation product of tetrabase contains the quinoidal or carbonium cation, equation (2). Only the salts of these cations are blue, and



(2)

when they are exposed to ammonia vapour the colourless carbinol base is formed; with the addition of acetic acid, the blue colour reappears.

The benzidine test can be modified by the use of other amines such as *o*-tolidine, *p*-diaminodiphenylamine, *p*-aminodimethylaniline, or *o*-dianisidine.

After this work had been terminated, Feigl and Anger[14] published a procedure for hydrogen cyanide and cyanogen in which the benzidine and copper(II) acetate were replaced by tetrabase and copper(II) ethyl acetoacetate. The detection limit was 1 μg of hydrogen cyanide. This reagent combination should also be effective with the alkyl isocyanides, but it was not tested.

Summary—Microgram quantities of isocyanides may be easily detected on filter paper or in tubes of silica gel by using benzidine acetate–copper(II) acetate or *p,p'*-tetramethyldiaminodiphenylmethane–copper(II) sulphate reagents. Interferences include those substances which are known to interfere in the use of the same reagents for the detection of hydrogen cyanide. The lowest amount of n-, s-, or t-butyl isocyanide detectable is approximately 0·1 μg.

Zusammenfassung—Mikrogrammengen von Isonitrilen lassen sich auf Filtrierpapier oder in Kieselgelrohrchen leicht nachweisen mit Benzidinacetat-Kupfer(II) acetat oder *p,p'*-Tetramethyldiaminodiphenylmethan-Kupfer(II) sulfat als Reagentien. Es stören die Substanzen, die auch beim Nachweis von Blausäure mit diesen Reagentien stören. Die kleinste nachweisbare Menge n-, s- oder t-Butylisonitril ist etwa 0,1 μg.

Résumé—On peut aisément détecter des quantités de carbylamines de l'ordre du microgramme sur papier filtre ou dans des tubes en gel de silice en utilisant des réactifs à l'acétate de benzidine-acétate de cuivre(II) ou au *p,p'*-tétraméthyldiaminodiphénylméthane-sulfate de cuivre(II). Les interférences comprennent les substances qui sont connues comme gênantes lors de l'emploi des mêmes réactifs pour la détection de l'acide cyanhydrique. La plus faible quantité de *n*-, *s*- ou *t* butylcarbylamine détectable est approximativement de 0,1 μg.

p-Aminoacetophenone as a reagent for the colorimetric determination of cerium(IV)

(*Received* 16 *November* 1966. *Accepted* 7 *January* 1967)

THERE exist in the literature only a few methods for the colorimetric determination of cerium(IV). Sandell[1] and Medalia and Byrne[2] utilized the yellow colour of cerium(IV) solutions. Telep and Boltz[3] used the carbonato-complex of cerium(IV) which absorbs at 304 mμ. Gordon and Feibush[4] developed an indirect colorimetric determination of cerium(IV) in which an excess of iron(II) was added to it and the excess of iron(II) was complexed with 1,10-phenanthroline. Recently Sarma and Dieter[5] determined cerium(IV) in the presence of rare earths by means of its colour reaction with sulphanilic acid, but the colour is very unstable and many oxidizing agents and coloured metal ions interfere.

p-Aminoacetophenone has been used as a reagent for the detection[6] and determination[7] of palladium. Since then no-one appears to have used this compound for analytical purposes. We have observed that cerium(IV) gives a purple colour with *p*-aminoacetophenone and that cerium(IV) can be detected with an identification limit of 1·0 μg even in the presence of rare earths and some oxidizing agents and coloured ions. The dilution limit is 1 in 50000. We have been able to use this reaction for the colorimetric estimation of cerium(IV). This method is found to be more accurate and precise and with less interferences than the existing methods.

EXPERIMENTAL

Reagents

Cerium(IV) sulphate solution. Prepared and standardized according to Willard and Young,[8] and suitably diluted with 0·5*N* sulphuric acid.

p-*Aminoacetophenone solution*, 0·5%. The compound is dissolved in hot dilute hydrochloric or sulphuric acid, cooled, and diluted with redistilled water, to yield a 0·01*N* acid solution.

Buffer solutions. Clark and Lubs buffer mixtures of potassium chloride and hydrochloric acid.

Procedure

Take a known volume of cerium(IV) solution of unknown concentration in a 25-ml volumetric flask. Add 15·0 ml of buffer solution (pH 1·6) and 2·0 ml of the reagent solution, and dilute to the mark with redistilled water. Mix thoroughly, and measure the absorbance exactly 3 min after addition of the reagent.

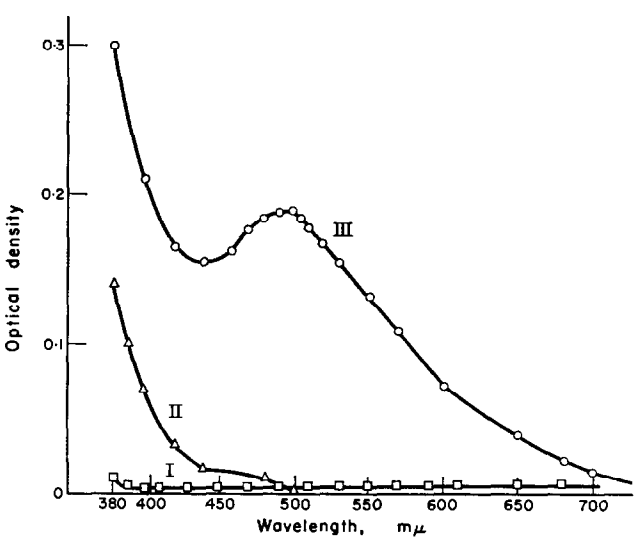

FIG. 1.—Absorption spectra of cerium(IV), *p*-aminoacetophenone, and their reaction product at pH 1·6.
I—*p*-Aminoacetophenone (0·04%); II—0·0002*M* Cerium(IV); III—reaction product.

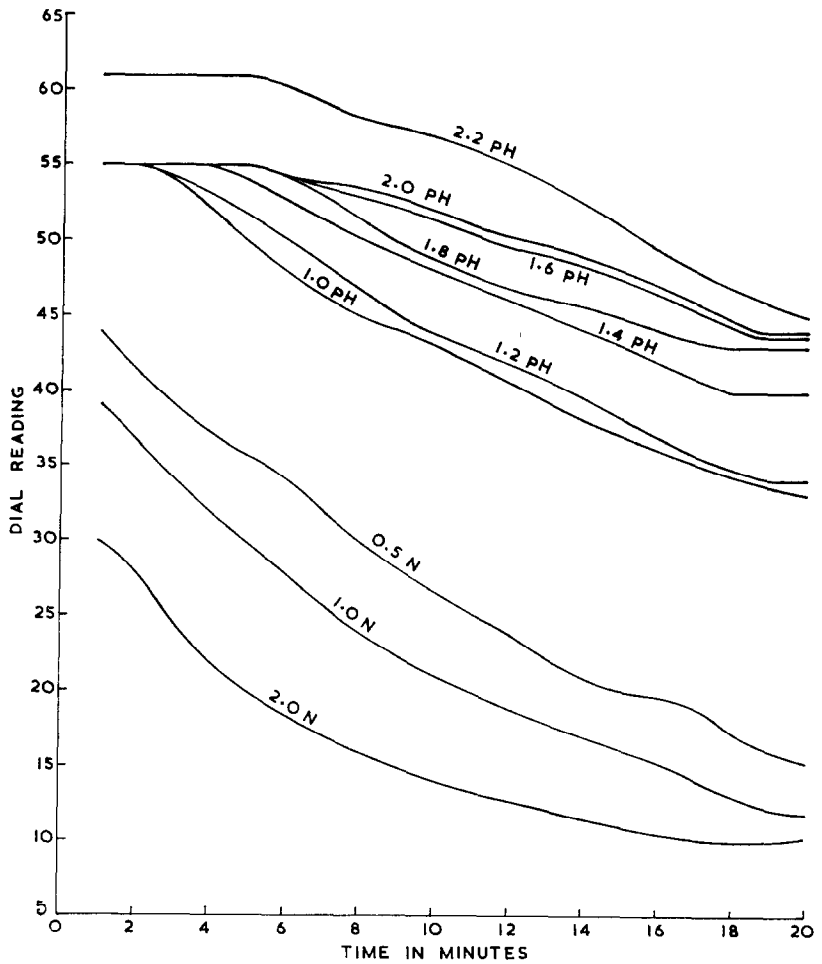

FIG. 2.—Stability of colour at various acidities.

Beer's law is obeyed over the range 14–350 μg of cerium per 25 ml of solution. A green filter (EEL 623 or 624) should be used, or a wavelength of 500 mμ. The error is about 1% over the range quoted. The absorption spectrum is shown in Fig. 1.

RESULTS AND DISCUSSION

When 1·0 ml of 0·0025*M* cerium(IV), 15 ml of buffer solution and 2·0 ml of the reagent solution were mixed and diluted to 25·0 ml, it was found that the absorbance, measured within 5 min, was independent of pH over the range 1·4–1·6, see Fig. 2. At pH > 1·8 the solution rapidly becomes turbid, probably because of hydrolysis of the cerium(IV). Even if the acidity is increased the coloured product seems to be stable for 5 min at most. Hence a pH of 1·6 was chosen as suitable and absorbances were measured 3 min after mixing the reagents.

When the ratio of the reagent and cerium(IV) concentrations was varied from 1 to 300 and the absorbances were measured, the absorbance increased slightly with increase of the ratio from 1 to 5, remained constant up to a ratio of 120 and thereafter decreased again. Hence the reagent should be present in from 10- to 100-fold excess.

The absorbance decreases as the temperature is raised and at above 50° the solution turns turbid immediately.

Interferences

Oxidizing agents such as permanganate, bismuthate and lead dioxide interfere by giving colour reactions with the reagent, though the last two could be filtered off before the reagent is added. Periodate causes turbidity in the solution. Hence these ions should be absent. Bromate does not interfere if present in amounts less than twenty times that of the cerium(IV). Vanadate and persulphate do not interfere at all. Bromate, dichromate and periodate give a brown colour with the reagent at higher temperatures.

Among the coloured ions, chromium(VI) does not interfere if its concentration is less than that of the cerium. Cobalt, nickel and copper do not interfere even if present in amounts ten times that of the cerium. Aluminium, calcium, zinc, thorium, zirconium, thallium, manganese(II), tantalum, and rare earths do not interfere. Chloride does not interfere but nitrate decreases the intensity of the colour.

Since the oxidizing agents which interfere give nearly the same colour as that obtained with cerium(IV), the coloured species produced is probably an oxidation product of the reagent. Further work is in progress on the mechanism of the oxidation of the compound.

Summary—With a solution of *p*-aminoacetophenone, cerium(IV) gives a purple colour which can be used for its detection and determination. The limits of identification and dilution are 1·0 μg and 1 in 50000 respectively. Beer's law is obeyed in the range 14–350 μg. The colour is stable for only 5 min and measurements of absorbance must be made quickly. The interferences are fewer than with existing methods.

Zusammenfassung—Mit einer Lösung von *p*-Aminoacetophenon gibt Cer(IV) eine Purpurfärbung, die zu seinem Nachweis und zu seiner Bestimmung dienen kann. Nachweis- und Verdünnungsgrenze sind 1,0 μg bzw. 1:50 000. Das Beersche Gesetz gilt bei 14–350 μg. Die Färbung ist nur 5 min stabil; die Extinktionsmessungen müssen schnell vonstatten gehen. Es gibt weniger Störungen als mit den bekannten Methoden.

Résumé—Le cérium (IV) développe avec une solution de *p*-amino-acétophénone une coloration pourpre qu'on peut utiliser pour sa détection et son dosage. Les limites d'identification et de dilution sont de 1,0 μg et 1 dans 50,000 respectivement. La loi de Beer est respectée dans le domaine 14-350 μg. La coloration est stable pendant 5 mn seulement et les mesures d'absorption doivent être effectuées rapidement. Les interférences sont moins nombreuses qu'avec les méthodes existantes.

Some solvent effects on the solvent extraction of 8-quinolinol

(*Received* 9 *February* 1967. *Accepted* 14 *March* 1967)

UNTIL recently, the study of the solvent extraction of metal ions with chelating agents has been concentrated on the chemical formation of the metal chelates rather than on their properties once they have been formed.

Some work has been reported on the role of the solvent on the chelate extraction process.[1-11] In an earlier paper[12] dealing with the determination of the distribution constants of 8-quinolinols and their copper(II) chelates, we were able to explain the solvent effects largely in terms of non-specific interactions. Correlated parameters of importance included mutual solubility of phases, dielectric constant, and solubility parameter of the solvent.

An important exception among the solvents studied was chloroform, in which distribution constants were found to be significantly higher than expected. Similar behaviour for β-diketones in chloroform–water systems had been noted earlier.[2,8] Since the hydrogen-bonding ability of chloroform might well be responsible for the high distribution constants observed it was decided to determine the distribution behaviour of 8-quinolinol between water and a series of substituted aliphatic hydrocarbon solvents having electron withdrawing groups which might impart hydrogen-bonding ability.

EXPERIMENTAL

Reagents

8-Quinolinol (Eastman Organic Chemicals) was recrystallized from boiling absolute ethanol. The melting point of the recrystallized product, after drying *in vacuo* in a desiccator, was 71·5–73·0°.

Nitro- and chloronitroalkanes (Commercial Solvents Corporation) were washed several times with deionized water and with the corresponding buffered aqueous phase used in the distribution experiments. The nitroalkanes, with densities close to that of water, were used in carbon tetrachloride (J. T. Baker, Analytical Reagent) solution. The amount of nitroalkane in the mixture after washing was calculated, taking into account its solubility in water.

1-Bromo-3-chloropropane, *1,2-dichloroethane*, *dibromomethane*, *and bromochloromethane*, were commercial-grade solvents (Dow Chemical Company); they were purified by distillation and washing with deionized water and the corresponding buffered aqueous phase used in the distribution experiments.

1-Bromobutane was practical grade from Matheson, Coleman and Bell and was purified in a similar way.

All other solvents were of analytical grade and were washed several times with water and buffer solution. Finally, after washing, all solvents were presaturated with the buffered aqueous phase.

The aqueous phase was buffered with sodium dihydrogen phosphate and sodium hydroxide and maintained at ionic strength 0·10 ± 0·02.

All other chemicals were of analytical reagent quality. All experiments were carried out at 25·0 ± 0·2° and the reported values are averages of at least three separate determinations. The experimental procedure and apparatus used in the determination of concentrations are described in a preceding paper.[12]

RESULTS AND DISCUSSION

Distribution of 8-quinolinol between some halogenated hydrocarbon–water pairs

In Table I are listed the distribution-constant values for 8-quinolinol expressed in terms of molarity ratios, K_D, and mole fraction ratios, K_D^x. From the values of K_D, the practical advantage of using an organic solvent having a high molecular weight and density can be seen. For example, the K_D in bromochloromethane is almost 20% higher than the corresponding chloroform value though the K_D^x values are almost the same. Again, despite the lower K_D^x value, the K_D in dibromomethane is slightly larger than that in chloroform.

K_D^x values provide a more rational basis for evaluation of the role of the solvent inasmuch as they provide a comparison of equal numbers of molecules. Of all the solvents studied, chloroform appears to be the best. Although not many examples are presented, there seems to be a trend towards increasing K_D^x with introduction of bromine atoms.

Bromochloromethane	$8{\cdot}0_7$	10·2	503	1874
1-Bromo-3-chloropropane	9·43	—	310	1703
n-Hexane†	1·9	7·3	21·2	153·8

* The values of solubility parameters have been taken from: (*a*) J. H. Hildebrand and R. L. Scott, *Regular Solutions*, Prentice-Hall, 1962; (*b*) *Bromine and Brominated Products Handbook*, Dow Chemical Company, Midland, Michigan, except for bromochloromethane which was calculated from its latent heat of vaporization at 25°.

† The value for n-hexane is included for comparison.

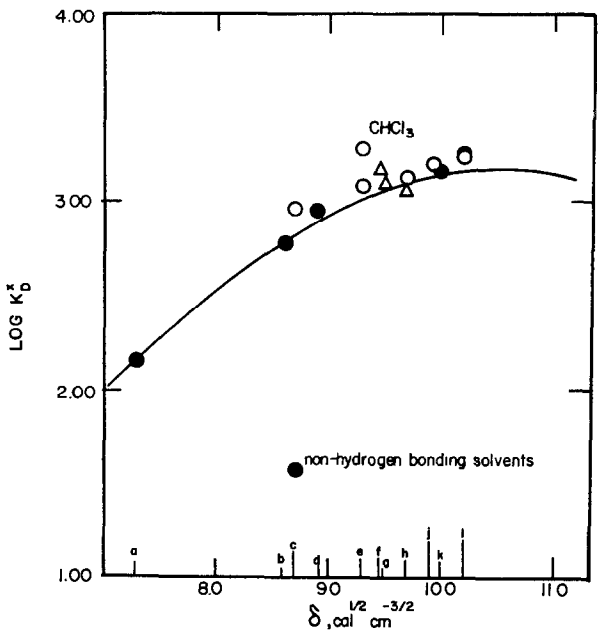

FIG. 2.—Distribution of 8-quinolinol between a series of halogenated hydrocarbon–water systems; effect of solubility parameter of pure solvent.
Values for nitroalkane-CCl_4(Δ) added for comparison (1:1 mole mixture, $10^{-1}M$ 8-quinolinol in organic phase.)

a: n-Hexane
b: Carbon tetrachloride
c: Bromobutane
d: Toluene
e: Chloroform
f: 2-Nitropropane
g: 1-Nitropropane
h: Nitroethane and dichloromethane
j: 1,2-Dichloromethane
k: Dichlorobenzene
l: Bromochloromethane and dibromomethane

Even though there exists no simple and general quantitative relation between distribution constants and properties of solvents, the empirical correlation of distribution data and the dielectric constant as well as the solubility parameter of the pure solvent show interesting trends. Figure 1 shows a plot of log K_D^x *vs.* the log of the dielectric constant of the pure solvent (ε). Confirming earlier observations,[12] the plot is somewhat parabolic in shape. The maximum appears close to the value for the dielectric constant of 8-quinolinol (4·73).[13]

Any correlation based on solubility parameter alone, as introduced by the regular solution theory, focuses attention on non-specific interactions. A plot of log K_D^x *vs.* the solubility parameter of the pure solvent is shown in Fig. 2. The solid line has been calculated with the help of the equation

$$2{\cdot}3RT \log K_D^x = V_c[(\delta_c - \delta_{aq})^2 - (\delta_c - \delta_0)^2]$$

where δ_c and V_c are the solubility parameter and molar volume respectively of the distributing species, and δ_{aq} and δ_0 the solubility parameter of the aqueous and organic phases respectively. A value of 132 cm^3/mole was chosen for V_c on the assumption that the density of liquid 8-quinolinol is 1·100 g/cm^3, slightly greater than that of quinoline (1·094 g/cm^3). The solubility parameter of the aqueous phase was taken as equal to 16·3. This value is substantially equal to the one obtained by Suzuki *et al.*[3] and gave values of K_D^x close to those obtained experimentally. It is substantially lower than the value 24·0 calculated from the heat of vaporization.[14] Since water is not a regular liquid, it cannot be expected to behave altogether normally. It can serve, however, as reference phase against which regular organic solvents may be compared.

According to the experimental results, the value of the solubility parameter of 8-quinolinol should be close to 10·5. A value of 10·6 was used to calculate the parabola represented by the solid line in Fig. 2. It will be noted that the experimental results for those solvents which should obey

the regular solution theory closely, such as n-hexane and carbon tetrachloride, lie on this line. All of the other solvents, with the exception of chloroform also lie close to the line.

The deviation observed in the case of chloroform may reflect significant solvent-solute interaction through hydrogen-bonding. The values for 1-bromobutane and bromochloromethane show some deviation. The rest of the solvents in the series studied show values close to a flat portion of the parabola covering about 2 units of solubility parameter.

Distribution of 8-quinolinol between nitroalkanes (and chloronitroalkanes) and aqueous buffer systems

In Fig. 3, the logarithm of the distribution ratios, D, of 8-quinolinol between water and mixtures of nitroalkanes and carbon tetrachloride are plotted against the logarithm of the solute concentration in the organic phase, at equilibrium. The distribution ratio between water and 1-nitroethane plus carbon tetrachloride varies markedly with solute concentration within the range explored (0·10–0·001 M). A less pronounced variation was observed with 1-nitropropane and 2-nitropropane. It was also observed that D in the 1-nitroethane–carbon tetrachloride–water system decreased when the proportion of nitroalkane increase (initial solute concentration about $10^{-2}M$). No marked dependence was observed when the proportion of nitropropanes in the mixture was changed. Figure 3 suggests the presence of a limiting value for D which seems to be reached at lower solute concentration for the nitropropanes than for nitroethane.

Although additional experimental studies are needed to postulate a quantitative explanation for the dependence, the results obtained point to a solvent-solute interaction as responsible for the

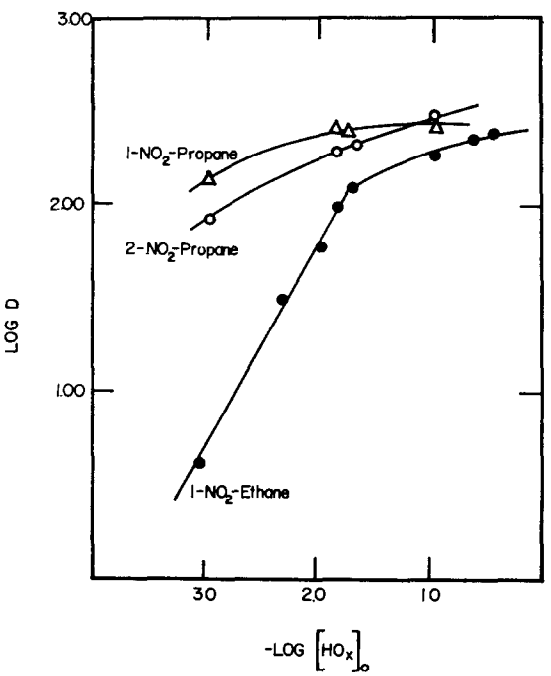

FIG. 3.—Distribution of 8-quinolinol between aqueous systems and 1:1 mole mixtures of carbon tetrachloride and some nitroalkanes at various values of $[HOx]_0$.

variation of D with solute concentration. The organic phase contains the nitroalkane and carbon tetrachloride; since carbon tetrachloride is a "non-polar" or "non-associated" liquid, it may be ruled out as interacting with the solute. The effect has to be ascribed solely to the nitroalkane.

To make a comparison between the behaviour of the nitro compound and those of the halogenated hydrocarbons, an equimolar mixture of it with carbon tetrachloride was used as the organic phase.

Its dielectric constant and solubility parameter were calculated as the sum of the contributions of each component with the help of:

$$\varepsilon_{mix} = \varepsilon_{NA} \cdot \phi_{NA} + \varepsilon_{CCl_4} \cdot \phi_{CCl_4}$$
$$\delta_{mix} = \delta_{NA} \cdot \phi_{NA} + \delta_{CCl_4} \cdot \phi_{CCl_4}$$

where ϕ is the volume fraction and the subscript NA refers to nitroalkanes.

The solubility parameter of the pure nitroalkanes was calculated from the heat of vaporization at 25°.

The values for D at an equilibrium ligand concentration in the organic phase of $10^{-2}M$ show an appreciable deviation from both plots in Figs. 1 and 2, in the case of 1-nitroethane. The values for the nitropropanes are closer to the plot but somewhat lower. 1-Nitropropane shows the higher D value. On the other hand, the values for D at an equilibrium ligand concentration in the organic phase of $10^{-1}M$ are surprisingly close to the dependence trend observed with the halogenated hydrocarbons, as can be seen in Figs. 1 and 2. On the basis of these observations 2-nitropropane gives slightly higher D values. Its deviation is in the same direction as that observed for chloroform. It may be noted that the active hydrogen is in a more symmetrical position in the case of 2-nitropropane than in either 1-nitroethane or 1-nitropropane. Also, 2-nitropropane, with a lower boiling point than 1-nitropropane, should be less associated. Moreover, the good correlation of D values with the dielectric constant and the solubility parameter, compared with the halogenated hydrocarbons, suggests that the extraction at D_{max} between water and nitroalkane–carbon tetrachloride systems would correspond to the extraction of molecular 8-quinolinol. It may be mentioned that the lower values of D for nitroethane are in qualitative agreement with its greater solubility in water. A few experiments with chloronitroalkanes were also performed. Because of their density, it was possible to use them as organic phases without dilution with carbon tetrachloride. They proved to be too reactive, however, and readily hydrolysed in contact with the aqueous phase. Nevertheless, it was possible, working quickly, to obtain distribution values with 1-chloro-1-nitropropane and 10^{-2} and $10^{-1}M$ 8-quinolinol solutions. The values of log D, 2·37 and 2·45 respectively, are surprisingly similar to the values for the simple nitroalkanes.

It must be concluded that, for 8-quinolinol and probably for its chelates as well, nitroalkanes offer no particular advantages as organic solvents over the halogenated hydrocarbons. Of this latter group, bromochloromethane seems to be about the best solvent, having a K_D value about 20% better than that of chloroform.

Summary—The distribution constants of 8-quinolinol between water and a series of substituted aliphatic hydrocarbons, at 25°, are reported. The results are discussed in terms of dielectric constant and solubility parameter of the solvents. For 8-quinolinol, and possibly for its chelates, bromochloromethane, dibromomethane and chloroform seem to be about the best solvents, in that order. Among the solvents studied, chloroform shows significantly higher values than expected; the deviation may be explained as a specific interaction of the hydrogen-bonding type.

Zusammenfassung—Die Verteilungskonstanten von 8-Hydroxychinolin zwischen Wasser und einigen substituierten aliphatischen Kohlen-Wasserstoffen bei 25° werden mitgeteilt. Die Ergebnisse werden im Hinblick auf Dielektrizitätskonstante und Löslichkeitsparameter der Lösungsmittel diskutiert. Für 8-Hydroxychinolin und vielleicht auch für seine Chelate sind anscheinend Bromchlormethan, Dibrommethan und Chloroform in dieser Reihenfolge die besten Lösungsmittel. Unter den geprüften Lösungsmitteln zeigt Chloroform erheblich hohere Werte als erwartet; die Abweichung kann durch eine spezifische Wechselwirkung vom Wasserstoffbrückentyp erklärt werden.

Résumé—On donne les coefficients de partage de la 8-hydroxyquinoléine entre l'eau et une série d'hydrocarbures aliphatiques substitués, à 25°. On discute des résultats en fonction de la constante diélectrique et du paramètre de solubilité des solvants. Pour la 8-hydroxyquinoléine, et peut-être pour ses chélates, le bromochlorométhane, le dibromométhane et le chloroforme semblent être sensiblement les meilleurs solvants, dans cet ordre. Parmi les solvants étudiés, le chloroforme montre des valeurs notablement plus élevées que celles attendues; l'écart peut être expliqué par une interaction spécifique du type liaison hydrogéne.

ANNOTATION

Explosion hazards with xenon trioxide solutions ("xenic acid")

THE strong oxidizing properties of aqueous xenon trioxide solutions ("xenic acid") have been recognized for some years.[1,2] That they are going to find wide application has become apparent with the recent publication of papers by Jaselskis and his co-workers.[3,4] These papers have stimulated interest amongst chemists who have not previously worked with xenon compounds. We have had several requests for solutions of xenon trioxide or for xenon fluorides for the preparation of such solutions, from people interested in carrying out work similar to that described in the papers cited. Generally, however, the people making the requests have been unaware of the dangers involved in the preparation and handling of such solutions, and attention should be drawn to these hazards.

Xenon trioxide solutions are prepared from either xenon tetrafluoride or xenon hexafluoride. The fluorides themselves are thermally stable, but their uncontrolled hydrolysis leads ultimately to the formation of solid, involatile xenon trioxide. This is extremely unstable and has an explosive force comparable to that of T.N.T. Few papers or reviews concerned with the preparation of xenon fluorides mention the dangers involved in their preparation and handling. A notable exception is the series of articles[5] in Inorganic Syntheses, which describes in detail some recommended methods for their preparation. Adequate detailed reference is made to precautions which should be taken when performing the syntheses.

There are warnings about the explosive nature of solid xenon trioxide in many of the papers concerned with it, (*e.g.*, references 6–9) and in recent review papers,[10–12] but only one of these[12] gives references to sources of information on hazards and safety precautions.

There are four main sources dealing with safety aspects: (1), a chapter of the book[13] edited by Hyman which followed the first Symposium on Noble Gas Chemistry in 1963; (2), an information sheet published by the Division of Operational Safety of the U.S.A.E.C.;[14] (3) a short article published in the Argonne National Laboratory Reviews;[15] and (4), two brief letters in the Journal of Chemical Education.[16] Of these (1) is readily available and is probably the most useful document on safety practices, (2) and (3) are not easily obtained (at any rate in Britain), and (4), though accessible, is not widely known amongst those concerned only with research. The best information available about the preparation of pure xenon trioxide *solutions* is in an excellent article by Appelman and Malm in Preparative Inorganic Reactions,[17] giving a recommended procedure by the hydrolysis of xenon hexafluoride. The hazards are clearly stated and points where special care is necessary are mentioned.

Because of the general lack or inaccessibility of safety information on noble gas chemistry, no excuse is made here for repeating recommendations which have been published elsewhere.

Precautions when handling fluorine

Fluorine is inherently dangerous because it is the most reactive element. It should therefore be treated with respect. Fluorine can be obtained either from electrolytic generators or from cylinders. Suppliers of fluorine publish data sheets which describe in detail precautions to be taken when handling fluorine.[18] No worker should attempt to use fluorine without first consulting these sheets. It is also desirable to consult experienced personnel.

Precautions when handling xenon compounds

All xenon compounds must be treated as potential sources of explosive solid xenon trioxide, because this is so readily formed by the hydrolysis of xenon tetrafluoride, xenon hexafluoride and xenon oxide tetrafluoride ($XeOF_4$). No exception should be made for xenon difluoride, which, although it does not form xenon trioxide on hydrolysis, is often contaminated with xenon tetrafluoride which does. Xenon fluorides and oxide fluorides, if contaminated with organic materials, should also be treated as sensitive explosives.

Safety glasses and/or a face-mask should be worn at all times when xenon compounds are being

prepared or manipulated. Leather gloves with cuffs, which give protection to the wrists, should be worn whenever xenon trioxide is handled, especially in equipment subject to fragmentation (*e.g.*, glass).

When xenon compounds are handled in vacuum systems it is inevitable that some materials will find their way into the traps protecting diffusion pumps. These materials often explode if the trap is allowed to warm up, or if moisture leaks into the system. Sometimes xenon compounds collected in glass traps react with the glass to produce explosive materials. Liquid-nitrogen dewars or traps of this kind should be surrounded with metal cylinders to direct the force of any explosion upwards. The traps should not be allowed to warm up whilst containing residues. They should be cleaned out frequently to avoid the collection of large quantities of explosive materials. The best way to clean the traps is to allow dilute alkali to be drawn into the evacuated trap at liquid-nitrogen temperature. The trap is then allowed to warm slowly to room temperature. The whole operation is particularly dangerous, there being a risk of a serious explosion at any time before thawing is complete. The preparation of xenon trioxide solutions by the addition of water to xenon tetrafluoride or hexafluoride is equally hazardous.[19] Appropriate precautions should be taken; face-masks, leather gloves and if possible protective canvas or PVC clothing should be worn. Substantial safety screens should be used.

All containers should be labelled with the nature of the contents. Where there is any chance that xenon trioxide is present the explosion hazard should be clearly indicated.

Precautions when handling xenon trioxide solutions

Xenon trioxide solutions are usually prepared from xenon hexafluoride by hydrolysis. This is a more efficient reaction than the hydrolysis of xenon tetrafluoride, but it is also more violent. Two different methods are possible. The first is the procedure recommended by Appelman and Malm.[19] This should be followed in every detail and extreme safety precautions should be taken (see previous section). The second method has been developed by Huston.[20,21] The method is probably safer than that of Appelman and Malm since, if properly executed, it avoids the sudden mixing of large quantities of xenon hexafluoride with water. The xenon hexafluoride is contained in a U-shaped Monel weighing-can fitted with two Hoke A431 valves (recently recatalogued as Hoke type 4171M2B). The contents of the can are swept through Kel-F (polytrifluorochloroethylene) tubing into water by means of a stream of dry nitrogen, (see Fig. 1). The Hoke valve is removed from one side of the U-tube, and the Kel-F tubing is connected directly to the exit of the can to minimize possible metallic contamination. The water is held in a Teflon (polytetrafluoroethylene) bottle in which the solution is afterwards stored. The hydrolysis reaction is carried out over a period of several hours.[20] It is most important that when this procedure is used a positive pressure of dry nitrogen *must* be maintained *at all times* when starting the hydrolysis.[21] If pressure is allowed to fall, back-suction of water into the weighing-can will cause explosions.

Once prepared, xenon trioxide solutions are safe provided they are not allowed to come to dryness. Containers, glass rods, pipettes *etc.*, wetted with xenon trioxide solution will deposit solid xenon trioxide if allowed to dry and explosions will result when they are handled. Ground-glass stoppered bottles should be avoided. These are not usually air-tight. Solid xenon trioxide may be formed in the

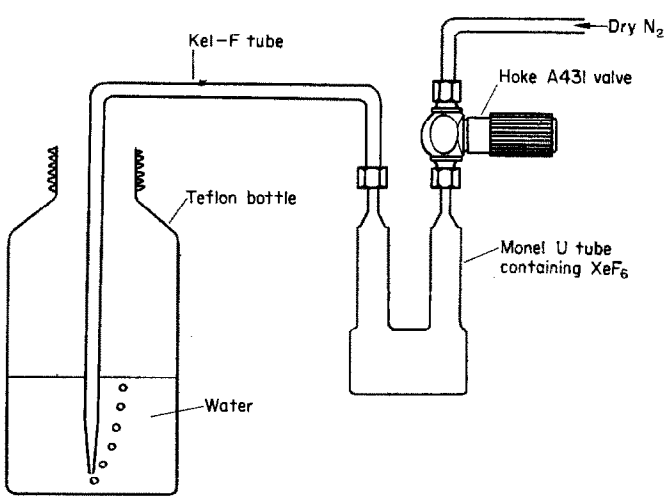

FIG. 1.—Apparatus for hydrolysis of xenon hexafluoride.[20,21]

neck of the bottle and in an extreme case the contents may evaporate slowly to dryness. Solutions are best stored in Teflon bottles with screw-tops or glass vessels with air-tight Teflon stoppers. Polythene appears to be subject to attack by xenon trioxide solutions, presumably by some kind of oxidation, and does not, therefore, make good containers.[22] Clean systematic working is essential. Scrap should not be allowed to collect.

This article is not intended to be fully comprehensive. Anyone intending to enter the field should at least consult the references cited here, many of which contain additional information. Better still, experienced personnel should be consulted.

PRELIMINARY COMMUNICATIONS

Spectrophotometric determination of chromium with Xylenol Orange and Methylthymol Blue

(*Received* 3 *February* 1967. *Accepted* 13 *March* 1967)

CHROMIUM(III) reacts with EDTA to form a purple complex. This reaction has been widely used for the photometric determination of chromium.[1-8] It has been found that other polyamino carboxylic acids also form purple complexes with chromium(III) upon heating, but these analogues do not offer any advantages over EDTA as a chromogenic reagent for chromium because of lack of sensitivity. It was thought that a phenolic dye containing an iminodiacetic acid group [—$N(CH_2COOH)_2$] or a carboxylic group might form an intensely coloured complex with chromium(III) upon heating. Xylenol Orange and Methylthymol Blue were chosen to test the speculation. The experimental results have confirmed the prediction. The chromium(III) Xylenol Orange complex is red with a maximum absorption at 530 mμ and the chromium(III) Methylthymol Blue complex is straw-yellow-red with a maximum absorption at 560 mμ. It seems that the substituted iminodiacetic acids are chromogenic reagents for chromium(III). This paper describes preliminary results for determination of chromium with Xylenol Orange and Methylthymol Blue.

EXPERIMENTAL

Reagents

Xylenol Orange solution, $1 \times 10^{-3}M$. Prepared from the sodium salt of 5,5′-bis{[bis(carboxymethyl)amino]methyl}-*o*-cresolsulphonphthalein.

Methylthymol Blue solution, $1 \times 10^{-3}M$. Prepared from the pentasodium salt of 3,3′-bis{[bis(carboxymethyl)amino]methyl}thymolsulphonphthalein. The solution was acidified with a small amount of acetic acid.

Acetate buffer solution, pH 3. Prepared by mixing $2M$ monochloroacetic acid and $1M$ sodium acetate to give a reading of pH 3 on a pH meter.

Preparation of calibration curves

Transfer 0, 1·0, 2·0, 3·0 and 4·0 ml of $2{\cdot}5 \times 10^{-4}M$ potassium chromium sulphate solution to a series of 50-ml pyrex test-tubes, add 0·5 ml of the acetate buffer solution, and dilute to approximately 8 ml. Add 4 ml of $1 \times 10^{-3}M$ Xylenol Orange solution or Methylthymol Blue solution. Place the tubes in boiling water for 20 min. Cool to room temperature, transfer to a 25-ml volumetric flask, dilute to volume, and mix. Measure the absorbance at 530 mμ for the Xylenol Orange complex, or at 560 mμ for the Methylthymol Blue complex, against a reagent blank.

DISCUSSION AND RESULTS

Chromium(VI) does not react with Xylenol Orange or Methylthymol Blue. It is easily reduced to chromium(III). The red chromium(III) Xylenol Orange complex has a maximum absorption at 530 mμ. When Methylthymol Blue is in large excess, its chromium(III) complex has a maximum absorption at 560 mμ, but when chromium is in excess, a blue or violet chromium Methylthymol Blue complex is formed.

Similarly to NTA and EDTA, Xylenol Orange and Methylthymol Blue react with chromium(III) extremely slowly at room temperature. When microgram amounts of chromium were taken, no reaction between chromium and Xylenol Orange or Methylthymol Blue could be detected at room temperature for several hours. The colour reactions were noticed when the temperature exceeded 70° and were complete at 100° in 15–20 min. Rao and coworkers[2] reported the catalytic action of bicarbonate ion on the formation of the chromium(III) EDTA complex and Irving and Tomlinson[8] described the electron exchange catalysis in the formation of chromium(III) EDTA complex by chromium(II) generated by metallic zinc. The present author found a similar catalytic action of carbon dioxide gas at pH 5 on the formation of the coloured chromium(III) EDTA complex.

However, no catalytic action of bicarbonate, carbon dioxide, or metallic zinc on the formation of chromium(III) Xylenol Orange complex or chromium(III) Methylthymol Blue complex was observed at pH 3 and room temperature.

The molar absorptivity of the chromium(III) EDTA complex has been reported as varying from 155 to 201 by different authors.[3] The molar absorptivity of the chromium(III) Xylenol Orange complex was found to be $19{\cdot}0 \times 10^3$ which is comparable with those of other Xylenol Orange complexes.[4,5] Based on Sandell's expression, the sensitivity of the Xylenol Orange method is 0·003 μg. cm^{-2} for 0·001 absorbance. Methylthymol Blue is a less sensitive reagent for chromium than Xylenol Orange. The molar absorptivity of chromium(III) Methylthymol Blue complex has a value of $11{\cdot}5 \times 10^3$ and its sensitivity is 0·005 μg. cm^2 for 0·001 absorbance. The phenolic donor group adjacent to the iminodiacetic acid donor groups is mainly responsible for the high molar absorptivity of the Xylenol Orange complexes. Obviously, the chelation resulting in the formation of multiple rings causes a bathochromic shift.

There are not many sensitive reagents for chromium. Most existing photometric methods for chromium are based on oxidation of a dye by chromate ion. The Xylenol Orange method is a rare, sensitive colour reaction occurring through complex formation with chromium(III). Like other Xylenol Orange complexes, the chromium(III) complex is stable for at least a few days. Beer's law is obeyed for the range $4\text{–}40 \times 10^{-6} M$ chromium for both the Xylenol Orange and Methylthymol Blue methods.

When we had finished the preliminary work, a brief note by Malát[6] was brought to our attention. It noted that Xylenol Orange gave a red colour with chromium(III) in a weakly acidic medium upon heating, and that the complex formed had a maximum absorption at 490 mμ and might be suitable for the colorimetric determination of chromium. No procedure was given. It is surprising to note the maximum absorption at 490 mμ reported by Malát because Xylenol Orange shows a maximum absorption at 440 mμ and most red Xylenol Orange complexes have their maximum absorptions around 535 mμ or at longer wavelengths.

Xylenol Orange is not a selective reagent, but it is possible to correct for the absorbance obtained at room temperature due to interfering metals if their amounts are smaller than the concentration of chromium to be determined. It should be noted that niobium, aluminium, palladium and chromium are the only four metals known to require a temperature of 100° to hasten their complex formation with Xylenol Orange and Methylthymol Blue.

Further investigation is being undertaken to determine many factors affecting the colour development, complex formation, and interferences when Xylenol Orange and Methylthymol Blue are used as chromogenic reagents for chromium.

K. L. CHENG

Summary—A new simple and sensitive method for determining traces of chromium is described. Xylenol Orange and chromium(III) form a red complex at pH 3 on heating in boiling water for 20 min. The molar absorptivity is $19{\cdot}0 \times 10^3$. No catalytic action of the bicarbonate ion, carbon dioxide, or chromium(II) generated by metallic zinc was observed. Methylthymol Blue is a less sensitive reagent for chromium, the molar absorptivity being $11{\cdot}5 \times 10^3$.

Zusammenfassung—Eine neue einfache und empfindliche Methode zur Bestimmung von Chromspuren wird beschrieben. Xylenolorange und Chrom(III) bilden bei pH 3 und 20-minütigem Erhitzen in siedendem Wasser einen roten Komplex. Der molare Extinktionskoeffizient ist $19{,}3 \cdot 10^3$. Eine Katalyse von Bicarbonat, Kohlendioxid oder durch metallisches Zink erzeugtem Chrom(II) wurde nicht beobachtet. Methylthymolblau ist als Reagens für Chrom weniger empfindlich, der molare Extinktionskoeffizient beträgt $11{,}5 \cdot 10^3$.

Résumé—On décrit une nouvelle méthode simple et sensible pour la détermination de traces de chrome. Le Xylénol Orangé et le chrome(III) forment un complexe rouge à pH 3 par chauffage dans l'eau bouillante pendant 20 mn. Le coefficient d'absorption moléculaire est 19,0 × 10^3. On n'a pas observé d'action catalytique de l'ion bicarbonate, du gaz carbonique ou du chrome(II) engendré par le zinc métallique. Le bleu de méthylthymol est un réactif moins sensible du chrome, le coefficient d'absorption moléculaire étant 11,5 × 10^3.

Solvent extraction of ammine complexes

THE separation of metals based on their ability to form halide and thiocyanate complexes extractable by many oxygen-containing organic solvents is widely used in analytical chemistry.[1] Extractions based on the decrease in hydration produced by the formation of simple ammine complexes [$Me(NH_3)_n^{j+}$] have not been reported. It is obvious that the differences in the stabilities of ammine complexes of metals could be used for useful extraction separations. The ammine complexes should be extractable as ion-association species[2] if a highly polar solvent and large hydrophobic organic anions are used.

The results obtained in our laboratory are in accord with these ideas. If nitrobenzene is used as the solvent, and dipicrylaminate (DPA^-) or tetraphenylborate (TPB^-) as the anion, the ammine complexes of zinc and of cobalt can be extracted effectively. Typical results are summarized in Table I, from which it can be seen that both the formation of ammine complexes and the presence of large anions are necessary for the metal extraction. Consequently, it is believed that the species $Zn(NH_3)_n^{2+}$ and DPA^- (or TPB^-) exist in the organic phase and that partial association between them may occur.[3]

The driving force behind this type of extraction is the squeezing out of large, unhydrated, low-charged ions by the hydrogen-bonded water structure.[4] The effect is to force these ions together so as to maximize the water-water interactions and minimize the disturbance caused in the water structure by the presence of these ions, and the ion-pairs formed in this way are then easily extracted. The cations accompanying the anions in the organic phase are those with the largest crystallographic radius and the smallest degree of hydration. Consequently, the sequence of increasing extractability

is $Ca^{2+} < Li^+ < Na^+ < NH_4^+ < K^+ < Rb^+ + < Cs^+ < NC_2H_5^+ < Zn(NH_3)_4^{2+}$. The possibility of a number of interesting cation separations is obvious.

A disadvantage of the extraction of ammine complexes in some cases results from the need to use a rather high pH in the aqueous phase, so causing precipitation of some metals unless they are present in tracer concentrations. This could be eliminated by suitable masking, but considerable changes in the selectivity of these extraction separations might then be produced. When ethylenediamine is used instead of ammonia, higher D_{Zn} values (distribution coefficients) are obtained. Further work is in progress.

SUBSTOICHIOMETRIC DETERMINATION OF TRACES OF GOLD BY RADIOACTIVE ISOTOPE-DILUTION ANALYSIS

D. A. BEARDSLEY, G. B. BRISCOE, J. RŮŽIČKA* and M. WILLIAMS†
Department of Chemistry, The University of Aston in Birmingham, Birmingham 4, England

(*Received* 2 *December* 1966. *Accepted* 12 *March* 1967)

Summary—A radioactive isotope-dilution method for the determination of traces of gold has been developed. It is based on the solvent extraction of gold diethyldithiocarbamate from 0·5*N* sulphuric acid containing ascorbic acid, by means of a substoichiometric amount of zinc diethyldithiocarbamate in chloroform. The separation has been applied to the analysis of gold-doped semiconductor-grade silicon and of gold-bearing ores. Amounts of gold down to 5×10^{-7} g/20 ml of test solution can be determined.

THE success of a neutron-activation method for the substoichiometric determination of traces of gold[1] suggested that an isotope-dilution method involving the same separation procedure could be developed. Isotope-dilution analysis has been applied to the determination of a number of elements,[2] but no reference could be found to its application to gold.

EXPERIMENTAL

Apparatus

Scintillation counter. The detector used was a 1·75-in. diameter × 2 in. NaI(Tl) well-type crystal (well-volume 5 ml), associated with a single channel gamma-ray spectrometer. A discriminator voltage setting corresponding to 0·07 MeV ensured a high sensitivity of counting the ^{198}Au activity.

Reagents

All reagents were prepared from analytical reagent grade chemicals unless otherwise stated. Electronic grade nitric and hydrochloric acids and micro analytical reagent grade sulphuric acid were used.

Labelled gold stock solution (1·0 *μg/ml in* 2·5*M hydrochloric acid*). About 10 mg of metallic gold (metal leaves *ca.* 0·1-*μ* thick, General Chemical Co., Division of Fisons Scientific Apparatus Ltd., Loughborough, England) were irradiated in a flux of 6×10^{11} neutrons cm^{-2} sec^{-1} for 6 hr (Universities of Manchester and Liverpool Research Reactor). The amount of ^{198}Au produced by ^{197}Au(n, γ)^{198}Au($t_{1/2}$ = 2·7 days; σ = 96 barns; β^- = 0·96 MeV; γ = 0·41 MeV)[3] was sufficient for experiments over about 17 days. After irradiation the gold was dissolved in *aqua regia*, and the solution was twice evaporated almost to dryness with hydrochloric acid to remove oxides of nitrogen. The solution was then diluted appropriately with 2·5*M* hydrochloric acid.

Non-labelled gold stock solution (1·0 *μg/ml in* 2·5*M hydrochloric acid*). Prepared from a weighed amount of non-irradiated gold as described above.

Gold solutions of lower concentrations were prepared by dilution of the stock solutions.

Zinc diethyldithiocarbamate solution (1×10^{-4}*M*). Prepared by mixing 25 ml of zinc sulphate solution (0·0285 g of the heptahydrate) with 125 ml of an aqueous solution of sodium diethyldithiocarbamate [0·0225 g, preferably freshly purified (see p. 880)] containing 5 ml of 0·2*M* sodium acetate/acetic acid buffer (pH 4·7). The precipitate formed was extracted with two 200-ml portions of chloroform, and the combined extracts diluted to 500 ml with the same solvent. The reagent was standardised by a spectrophotometric extractive titration with 10^{-4}*M* copper solution (prepared by

* On leave from Department of Nuclear Chemistry, Faculty of Technical and Nuclear Physics, Prague 1, Břehová 7, Czechoslovakia.

† Present address: Learned Journals Division, Pergamon Press Ltd., Headington Hill Hall, Oxford, England.

dilution of $10^{-2}M$ copper sulphate standardised iodometrically). The absorbance of the copper diethyldithiocarbamate was measured at 440 mμ (zinc diethyldithiocarbamate shows no absorbance at this wavelength).

Distilled water. The water used must be as pure as possible, and we have found that double distilled as obtained from a Scorah Type 4 glass distillation unit (L.V.D. Scorah, 44 Northfield Road, Birmingham 30, England) satisfactory. To check the purity a sample was extracted with dithizone ($5 \times 10^{-6}M$ in chloroform). No change in the green colour of the reagent was taken as the criterion of purity.

DEVELOPMENT OF METHOD

Preliminary experiments

Our neutron-activation studies[1] showed that 0·01–10N sulphuric or hydrochloric acid was a suitable medium from which to extract gold reproducibly with copper diethyldithiocarbamate in chloroform. Preliminary experiments showed that the following factors were of importance in the

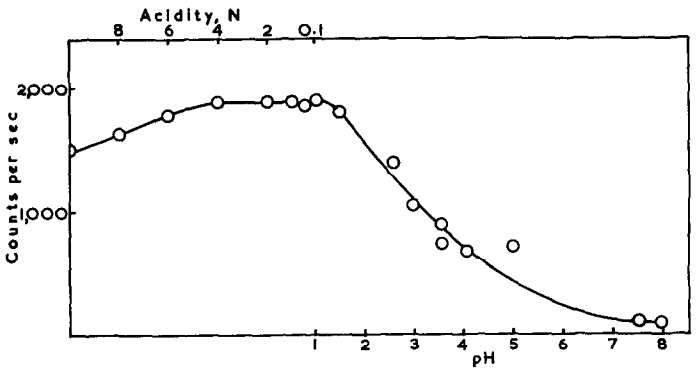

FIG. 1.—Influence of acidity on the substoichiometric extraction of gold from sulphuric acid with zinc diethyldithiocarbamate in chloroform.

extraction of gold under the conditions required for isotope-dilution analysis.

1. Sulphuric acid is a better solvent medium than hydrochloric acid—chloride competes more strongly with chelating agent for the gold in the absence of a gold-carrier.
2. Zinc diethyldithiocarbamate gives better extraction of gold than does copper diethyldithiocarbamate—the difference in extraction constants is greater for zinc and gold than for copper and gold.
3. The presence of a mild reducing agent, ascorbic acid, is particularly advantageous—reduction of gold to gold(I) seems necessary for complete complex formation.

Reproducibility

The optimum conditions for a reproducible substoichiometric extraction of gold diethyldithiocarbamate in the presence of ascorbic acid were next established.

Any sulphuric acid concentration from 0·1 to 4N was found to be suitable (Fig. 1). For all further experiments 0·5N sulphuric acid (containing 1 ml of 1% ascorbic acid solution) was used. Extraction equilibrium was reached in 1·5 min with 1·25 μg of gold and in 2 min with 0·1 μg (Fig. 2). An extraction time of 5 min was therefore used in all further experiments.

Stability of solutions. The reproducibility of the substoichiometric separation using a labelled gold solution of 1·0 μg/ml was good (Fig. 3, upper curve), but when the gold concentration was 0·1 μg/ml the reproducibility became poor. This was traced to two causes: the labelled gold solution in 1M hydrochloric acid was slowly hydrolysing, and the zinc diethyldithiocarbamate solution in chloroform ($5 \times 10^{-8}M$) was not very stable.

The maximum period during which different solutions of gold and zinc diethyldithiocarbamate were found to be stable (not more than 10% change from the initial concentration) is given in Table I. If the sodium diethyldithiocarbamate was purified to remove oxidation products,[4] the zinc diethyldithiocarbamate solution prepared from it was more stable ($2·5 \times 10^{-7}M$ solution stable for at least 3 hr).

With a freshly labelled gold solution (0·1 μg/ml) and fresh reagent solution ($5 \times 10^{-8}M$) good reproducibility of separation was now achieved (Fig. 3, lower curve), but below this concentration reproducibility was poor.

Role of chloride ions

Very dilute gold solutions are known to undergo hydrolysis especially if the temperature is increased. Chloride ions in sufficient quantity retard hydrolysis, but they can also compete with the chelating agent for the gold, thus preventing complete consumption of the substoichiometric amount of chelating agent. Therefore the concentration of chloride in the test solution is very critical, and that permissible will depend on the gold concentration; it is given in Table II. It is advisable to prepare the labelled gold solutions in 2·5*M* hydrochloric acid. If the amount of chloride ions introduced into a test solution by the addition of the labelled gold is more than can be tolerated (Table II), it is best to make a more concentrated labelled gold stock solution and to dilute it with water to the desired concentration before use.

TABLE II.—MAXIMUM CONCENTRATION OF CHLORIDE IONS THAT CAN BE TOLERATED FOR A GIVEN GOLD CONCENTRATION

Weight of gold in 20 ml of test solution, μg	Maximum concentration of chloride ions, M
1·0	0·36
0·5	0·18
0·2	0·06
0·1	0·05

Accuracy and precision

To a series of 50-ml separatory-funnels 20 ml of 0·5*N* sulphuric acid were added followed by 1·0 ml of labelled gold solution (1·06 μg/ml) and 1·0 ml of non-labelled gold solution (1·00 μg/ml). Then 1 ml of 1 % ascorbic acid solution was added followed by 5 ml of $5 \times 10^{-7}M$ zinc diethyldithiocarbamate in chloroform (substoichiometric amount). The funnels were shaken for 5 min, and 3·0 ml of the organic phase were separated for counting (activity A_2). An extraction was next made under the same conditions but with 2·0 ml of labelled gold solution and no non-labelled gold. The activity (A_1) of an equal volume of the organic phase was measured; this was sometimes referred to as the standard. The same procedure was used with labelled gold solutions of 0·1, 0·05, and 0·02 μg/ml concentration, the concentration of the chelating reagent being reduced accordingly.

The weight of non-labelled gold determined (x) can be calculated from the substoichiometric formula applied to isotope dilution[14]

$$x = y\left(\frac{A_1}{A_2} - 1\right)$$

where y = the weight of labelled gold used. A summary of our results is given in Table III.

TABLE III.—ACCURACY AND PRECISION OF SUBSTOICHIOMETRIC DETERMINATION OF GOLD BY ISOTOPE-DILUTION ANALYSIS

Weight (x) of non-labelled gold added, μg	Weight (y) of labelled gold added, μg	Weight ($\bar{x}$)* of non-labelled gold found, μg	Standard deviation, s†	Number of tests, n
1·00	1·06	1·03	0·057	15
0·10	0·11	0·10	0·016	15
0·05	0·05	0·06	0·013	10
0·01	0·02	0·01	0·003	6

* $\bar{x}$ = mean weight of non-labelled gold found.

† $s = \sqrt{\Sigma\Delta^2/n - 1}$, where Δ is the deviation from the mean.

Selectivity

The selectivity of the substoichiometric separation was investigated in the presence of a number of ions which either have extraction constants similar to that for the gold-diethyldithiocarbamate system,[5] or cause interference by some other mechanism, *e.g.*, reduction of the gold or oxidation of the diethyldithiocarbamate. The effect of reagents likely to be present after the dissolution of various test samples was also studied.

The procedure was that described under *Accuracy and precision* except that 1 ml of labelled gold solution (1·00 μg/ml in 2·5*M* hydrochloric acid) was used together with 100 or 1000 μg of the foreign ion to be examined. No non-labelled gold was added and the extraction was carried out with 4 ml of $2{\cdot}5 \times 10^{-7}M$ chelating agent, the activity of 2·5 ml of the organic phase being measured. Ideally, a result of $x = 0$ should be obtained because no non-labelled gold was present. In practice, if $-0{\cdot}1 > x > +0{\cdot}1$ μg the foreign ion was considered to interfere. The results of the selectivity studies are summarised in Table IV.

TABLE IV.—INFLUENCE OF FOREIGN IONS ON THE SUBSTOICHIOMETRIC EXTRACTION OF GOLD WITH ZINC DIETHYLDITHIOCARBAMATE

§ Interference removed by extraction with dimethylglyoxime in chloroform.

Elimination of interferences

Three methods were investigated for eliminating interferences.

Preliminary extraction of gold. Extraction of gold into diethyl ether from chloride or bromide solutions is well known.[6–8] Some authors prefer the use of isopropyl ether[7] or ethyl acetate.[8] According to Morrison and Freiser[6] gold can be quantitatively extracted as $HAuCl_4$ into diethyl ether from 1·5–3*M* hydrochloric acid.

We found that when 1·0 μg of gold in 10 ml of 2*M* hydrochloric acid was shaken with 20 ml of diethyl ether for 3 min, about 80% of it was extracted. The interferences were studied by repeating this extraction in the presence of 100 or 1000 μg of the foreign ions concerned. The ether phase was separated and washed with 5 ml of 2*M* hydrochloric acid, added to 0·5 ml of 3*M* hydrochloric acid and heated at 50° on a water-bath to remove the ether. The resulting solution was diluted to 20 ml with 0·5*N* sulphuric acid and the gold separated and determined as under *Accuracy and precision*. Our results are summarised in Table IV.

If the hydrochloric acid concentration during evaporation of the diethyl ether was less than 3*M* hydrolysis occurred and not all the gold was in a form extractable by the chelating agent. Hydrolysis also occurred if sulphuric or nitric acid was used, even if they were more concentrated than 3*N*. During evaporation of the ether, gold was lost if chloride was absent. Therefore, chloride must be present to prevent hydrolysis and the loss during evaporation. The lowest amount of gold for which 0·5 ml of 3*M* hydrochloric acid would not interfere in the final separation was 0·5 μg (Table II).

The possibility of stripping the gold from diethyl ether solutions was studied; from an ether solution (20 ml) containing 0·7–0·8 μg of gold, half the gold could be transferred with two 20-ml portions of water, each shaken for 3 min with the ether phase. Before the substoichiometric separation it was then necessary to scrub with chloroform to remove traces of diethyl ether and to make the solution 0·5*N* with respect to sulphuric acid; if the ether was not removed it diluted the chelating agent, leading to erroneous results.

This stripping method was successful for solutions initially containing 1 μg of gold in 10 ml of 2*M* hydrochloric acid, the final concentration of gold being 0·4 μg/20 ml of solution which is near the lower limit for the method (0·1 μg/20 ml). The evaporation procedure gave about 0·8 μg of gold in 20 ml of test solution and therefore was preferred.

The extraction of gold from bromide solutions was then examined. Gold was more efficiently extracted by diethyl ether (*ca.* 80%) than by isopropyl ether (*ca.* 70%) with the same volumes and extraction times. The degree of stripping by water was higher from isopropyl ether solutions (*ca.* 85%) than diethyl ether solutions (*ca.* 70%). Even so, neither the evaporation nor the stripping method was successful, because traces of bromide seriously interfered in the final substoichiometric separation.

EDTA. Prevention of the interference of copper(II), bismuth(III), and mercury(II) by addition of 1 ml of 0·1*M* EDTA to the test solution before the substoichiometric separation (20 ml of 0·5*N* sulphuric acid; no ascorbic acid present) was studied. In 0·5*N* sulphuric acid there was no effect but in 0·1*N* sulphuric acid these interferences were overcome (Table IV), which can be explained from the conditional formation constants of their EDTA complexes.[10] The sulphuric acid must not be less than 0·1*N*, the lowest value suitable for the substoichiometric separation (Fig. 1).

Dimethylglyoxime. Many authors[11–18] have separated palladium from aqueous solutions of gold by extracting its dimethylglyoximate into chloroform. When 3 ml of 1% aqueous sodium dimethylglyoximate solution were added to the test solution before the substoichiometric separation (20 ml of 0·5*N* sulphuric acid; no ascorbic acid present) and the solution was let stand for 30 min, interference from palladium was eliminated by extracting the palladium complex with three 10-ml portions of chloroform, shaking the mixture for 3 min each time (Table IV).

ANALYSIS OF TEST SAMPLES

Because the concentration of chloride ions must be kept to a minimum, attempts were made to dissolve a gold-doped semiconductor-grade silicon sample in a mixture of nitric and hydrofluoric acids. Complete dissolution was achieved but a considerable loss of gold was incurred (*ca.* 50%). It was therefore necessary to include chloride ions, and after dissolution to reduce their concentration to a tolerable level by a diethyl ether extraction as used for the elimination of interfering species.

Procedure

To the test sample in a 50-ml Teflon beaker was added a weight (y) of labelled gold approximately equal to the weight of gold expected in the sample. The test sample was then dissolved, initially at room temperature and finally with gentle heating, in a mixture of nitric acid (10 ml) and hydrochloric acid (2 ml) with gradual addition of hydrofluoric acid (10 ml). The solution was then evaporated to about 0·5 ml and the evaporation repeated twice, each time after addition of 5 ml of hydrochloric acid. The resulting solution was diluted with water and 2*M* hydrochloric acid to give finally 10 ml of 2*M* hydrochloric acid solution. The activity of this solution was measured before extraction so that the recovery after the dissolution could be checked: it was at least 95% for each sample analysed.

The test solution, prepared as described above, was transferred to a 100-ml separatory funnel and shaken with 20 ml of diethyl ether for 3 min. The ether phase was scrubbed with 5 ml of 2*M* hydrochloric acid and transferred to a 50-ml beaker; then 0·5 ml of 3*M* hydrochloric acid was added and the solution heated at 50° on a water-bath to remove the ether. The resulting solution was transferred to a 100-ml separatory funnel and diluted to 20 ml with 0·5*N* sulphuric acid. If necessary, EDTA was added and palladium removed with dimethylglyoxime at this stage. Finally, 1 ml of 1% ascorbic acid solution was added and the gold extracted by a substoichiometric amount of zinc diethyldithiocarbamate solution in chloroform (4 ml of $2{\cdot}5 \times 10^{-7}M$ for gold-bearing ores; 4 ml of $5 \times 10^{-8}M$ for gold-doped semiconductor-grade silicon). The extractions were carried out for 5 min, then an aliquot of the organic phase (3·0 ml in each case) was removed for counting (A_2).

For the standard (run simultaneously) the same weight (y) of labelled gold was taken as that added to the sample, and it was extracted under the same conditions as for the test sample, and the same volume of organic phase was separated for counting (A_1). The weight of gold in the test sample (x) was then calculated, using the substoichiometric equation given above. The results of our analyses are given in Table V.

CONCLUSION

The method is capable of determining gold down to 0·1 μg/20 ml of test solution, but the need to have chloride ions present during dissolution of samples and also to prevent hydrolysis raises the lower limit to 0·5 μg/20 ml of test solution. The smallest amount of gold we have actually determined in a test sample by isotope dilution is $1{\cdot}45 \times 10^{-7}$ g, compared with 2×10^{-10} g by our neutron-activation method.[1] The limit of detection for gold is about three orders of magnitude lower by neutron activation, which is to be expected.

† Provided by Royal School of Mines, Imperial College, London, England.

‡ By fire assay at Royal School of Mines, using a factor-weight sample of 32·67 g.

§ Provided by Mullard Southampton Works, Southampton, England.

¶ See reference 1.

Antimony(III), selenium(IV), and tellurium(IV) interfered if present in amounts 100 times that of the gold (w/w), and mercury(II) and platinum(IV) if present in amounts 1000 times that of the gold (Table IV).

The results obtained from the analysis of the gold-doped semiconductor-grade silicon sample (Table V) were in good agreement with those previously found by neutron activation.[1] Those for the gold-bearing ores compared reasonably well with the values from fire assay, considering the large difference in the weights of sample taken for the two methods. Sample RSM 25 contains *ca.* 12 ppm of silver and RSM 349 *ca.* 11 ppm of silver, interference from which is eliminated during the extraction with diethyl ether. No interfering elements were known to be present in the semiconductor silicon sample.

If amounts of gold greater than about 10^{-6} g are to be determined, the use of radioisotopes generally offers no advantages over spectrophotometric methods. Our investigations[9] into a spectrophotometric titration procedure for gold, based on solvent extraction of its diethyldithiocarbamate into chloroform, indicated it had no advantage over existing spectrophotometric methods for this element.

Work is now in progress to establish the composition of the gold complexes extracted with diethyldithiocarbamic acid and dithizone under the various conditions that have been used in development of our neutron-activation and isotope-dilution methods for gold.

Acknowledgements—The authors wish to thank the Universities of Manchester and Liverpool Research Reactor, Risley, Lancs., England, for the provision of irradiation facilities. Thanks are also due to the University of Aston in Birmingham for the provision of a visiting lectureship (J. R.) and a research assistantship (D. A. B.) which enabled the work reported to be carried out.

Zusammenfassung—Eine Methode der Verdünnung mit einem radioaktiven Isotop zur Bestimmung von Goldspuren wurde entwickelt. Es beruht auf der Extraktion von Golddiäthyldithiocarbamat aus Ascorbinsäure enthaltender 0,5 M Schwefelsäure mit einer unterstöchiometrischen Menge Zinkdiäthyldithiocarbamat in Chloroform. Die Abtrennung wurde auf die Analyse von Gold-dopiertem Halbleitersilicium und von goldführenden Erzen angewandt. Goldmengen bis herunter zu $5 \cdot 10^{-7}$ g/20 ml Probelösung können bestimmt werden.

Résumé—On a élaboré une méthode radioactive par dilution isotopique pour le dosage de traces d'or. Elle est basée sur l'extraction par solvent du diéthyldithiocarbamate d'or à partir d'acide sulfurique 0,5 *N* contenant de l'acide ascorbique, au moyen d'une quantité substoechiométrique de diéthyldithiocarbamate de zinc en chloroforme. On a appliqué la séparation à l'analyse du silicium qualité semiconducteur dopé à l'or et à celle de minerias aurifères. On peut doser des quantités d'or aussi faibles que 5×10^{-7} g/20 ml de solution essai.

(*Reçu le* 17 *Novembre* 1966. *Accepté le* 28 *Février* 1967)

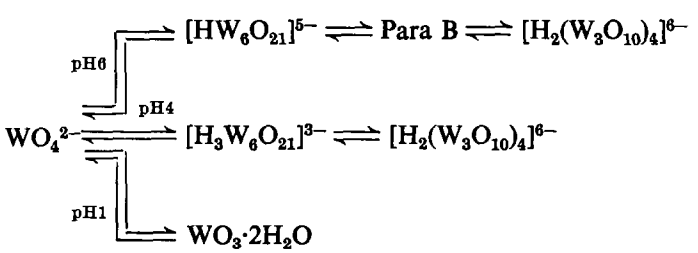
Résumé—Dans le présent travail en expose une étude physico-chimique sur les conditions de formation (pH, température, temps) et de séparation de dodécatungstates à l'aide du chlorure de tétraphénylphosphonium. Dans la série des iso- et hétéropolytungstates, seuls les anions de forme $[XW_{12}O_{40}]^{(8-n)-}$ (où n dénote l'état d'oxydation de l'atome X) précipitent avec ce réactif.

La réaction est quantitative et à l'aide de ce réactif on a réussi à séparer le dodécatungstate sous forme de précipité d'un mélange d'anions tungstiques.

En utilisant $[(C_6H_5)_4P]Cl$ comme réactif spécifique pour l'anion dodécatungstique, dans l'étude de la condensation de Na_2WO_4 sous l'action des acides forts, on a établi que cette forme 12 condensée de Na_2WO_4 commence à apparaître à pH $\sim$ 6, tandis qu'à pH $\sim$ 2 tout le tungstate présent est transformé en dodécatungstate. Les facteurs tels que la dilution, le temps et la température dans cet intervalle de pH 2–6 influencent le processus de condensation dans le sens de la formation de l'anion dodécatungstique. La réaction mentionnée est utilisée pour le dosage d'une série de 12-tungstates.

L'ÉTUDE complexe des espèces d'anions tungstiques en solution, constitue un chapitre très discuté de la littérature specialiseé. Parmi les méthodes utilisées, nous mentionnons: les méthodes conductimétriques,[1–3] potentiométriques,[4–6] de diffusion,[7,8] de dialyse,[6,8] polarographiques,[7,9–11] chromatographiques,[3,12,13] réfractométrique,[14] d'ultracentrifugation et mesures de densités,[15] radiochimiques,[16,17] de spectres Raman,[18] spectres d'absorption,[19] spectres IR,,[20] *etc.*

Nous donnons ci-dessous l'un des schémas, qui contient les espèces d'anions tungstiques probablement formés au cours de l'acidification d'une solution de Na_2WO_4 avec des acides forts.[21]



(I)

Dans le système complexe (I) il est difficile d'identifier chimiquement chaque espèce ou l'une d'entre elles par les réactifs connus et de suivre la formation du

dodécatungstate, étant donné que ces réactifs sont communs à plusieures des espèces formées.

Dans le présent travail, on apporte des nouvelles données à ce problème, par l'utilisation du chlorure de tétraphénylphosphonium comme réactif de precipitation. On a constaté que les espèces d'ions polytungstiques, tels que $[HW_6O_{21}]^{5-}$, $[NiW_6O_{21}]^{4-}$, $[CeW_8O_{28}]^{4-}$, $[ThW_8O_{28}]^{4-}$ et $[Co_2W_{12}O_{42}]^{8-}$ ne précipitent pas avec $[(C_6H_5)_4P]Cl$. Seuls ceux de forme dodécatungstique $[XW_{12}O_{40}]^{(8-n)-}$ tels que $[H_2W_{12}O_{40}]^{6-}$, $[SiW_{12}O_{40}]^{4-}$, $[PW_{12}O_{40}]^{3-}$, $[BW_{12}O_{40}]^{5-}$ et $[CoW_{12}O_{40}]^{5-}$ forment des sels de tétraphénylphosphonium, difficilement solubles dans l'eau, cristallins et stables (Tableau I).

TABLEAU I.—RÉSULTATS DES ANALYSES DE DODÉCA- ET HÉTÉRODODÉCATUNGSTATES

Combination	WO_3		C		P		H		$SiO_2 + WO_3$	
	calc. %	trouvé %	calc. %	trouvé %	calc. %	trouvé %	calc. %	trouvé %	calc. %	trouvé %
$[(C_6H_5)_4P]_6[H_2W_{12}O_{40}]$	57,0	56,6	35,4	33,8	3,8	3,1	2,6	2,5	—	—
$[(C_6H_5)_4P]_4[SiW_{12}O_{40}]$	—	—	27,2	26,5	2,9	2,5	1,9	2,0	67,3	65,9
$[(C_6H_5P]_3[PW_{12}O_{40}]$	70,1	70,8	22,0	21,9	3,1	2,9	1,8	2,0	—	—
$[(C_6H_5)_4P]_5[BW_{12}O_{40}]$	58,8	58,4	30,4	29,5	3,8	3,9	2,1	1,9	—	—

La précipitation du dodécatungstate de tétraphénylphosphonium a lieu probablement selon la réaction suivante:

$$[XW_{12}O_{40}]^{(8-n)-} + {}^{8-n}[(C_6H_5)_4P]^+ = [(C_6H_5)_4P]_{8-n}[XW_{12}O_{40}]$$

où n dénote l'état d'oxydation de l'atome X.

Nous avons suivi par potentiométrie, sous l'action d'ions H^+, la condensation de Na_2WO_4 en absence et en présence du chlorure de tetraphénylphosphonium. Les valeurs du pH obtenues dans les deux titrages potentiométriques s'inscrivent sur la même courbe (Fig. 1). Elle montre d'une part que la variation du pH n'est pas influencée par la présence du chlorure de tétraphénylphosphonium et d'autre part dans la solution qui contient le réactif on observe l'apparition d'un précipité à partir de pH $\sim$ 6. Ceci montre l'apparition d'ions dodécatungstiques, qui s'intensifie si l'on continue d'ajouter de l'acide chlorhydrique.

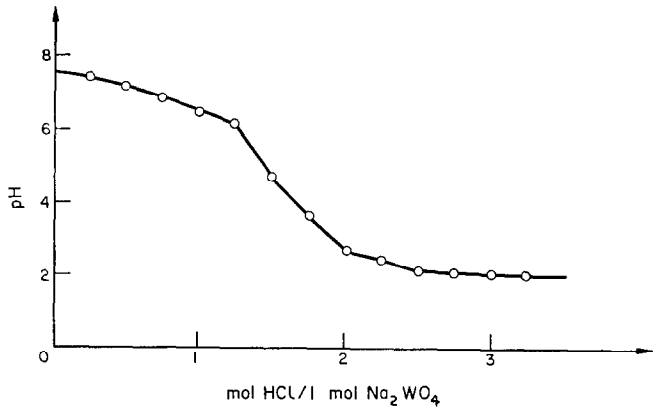


FIG. 1.—Le courbe potentiométrique des systemes (Na_2WO_4 + HCl) et (Na_2WO_4 + $[(C_6H_5)_4P]Cl$ + HCl).

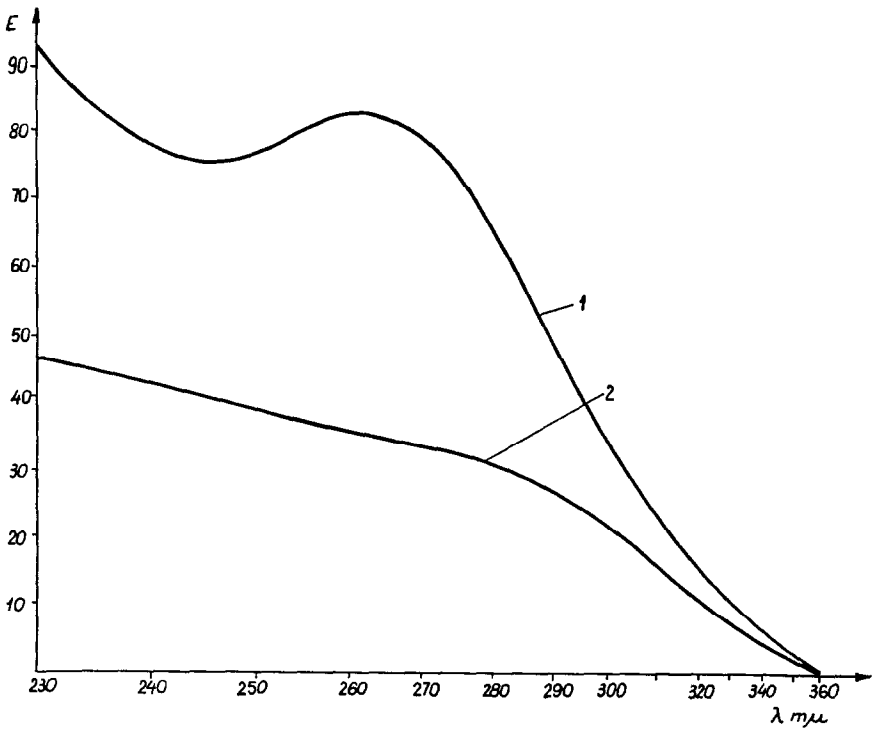

FIG. 2.—Spectre d'absorbtion de deux fractions de tungstates obtenues par la chromatographie d'une solution de Na_2WO_4 à pH = 4,5.
1. La fraction qui reste au point de dépôt.
2. La fraction qui va de front avec le solvent.

Par des séparations chromatographiques sur papier en solution saturée de NaCl et des déterminations du spectre d'absorption UV sur les solutions aqueuses de Na_2WO_4, pH 2–6, on a constaté que seule la fraction qui reste au point de dépôt et qui présente un maximum d'absorption à 257 mμ (Fig. 2) (spécifique pour l'anion métatungstique[19]) précipite avec $[(C_6H_5)_4P]Cl$.

D'autre part, l'analyse des précipités obtenus des mélanges de 0,01*N* Na_2WO_4 et $[(C_6H_5)_4]Cl$ portés à pH 6,00; 4,30; 2,80; 2,00; 1,50; conduit toujours à une seule combinaison: $[(C_6H_5)_4P]_6[H_2W_{12}O_{40}]$.

Les mêmes essais (Tableau II) montrent encore que le poids de précipité augmente à mesure que le pH décroît et que pour pH $\sim$ 2 tout le tungstène se trouve dans le précipité. À pH $\sim$ 1 le $WO_3 \cdot 2H_2O$ en solution commence a précipiter.

TABLEAU II.—LA PRÉCIPITATION DU MÉLANGE DE 0,01*M* Na_2WO_4 + $[(C_6H_5)_4P]Cl$ PORTÉ A DIVERS pH

pH	W en solution, *g*	W précipité, *g*	W précipité, %
7,00	0,09200	—	—
6,00	0,09200	0,00602	6,6
4,30	0,09200	0,04610	50,1
2,80	0,09200	0,08272	89,9
2	0,09200	0,09208	100,1
1,5	0,09200	0,09132	99,3
1	commence a précipité $WO_3 \cdot 2H_2O$		

De plus l'influence du temps et de la température sur le processus de condensation de Na_2WO_4 a été étudiée sur deux séries d'essais; l'une à pH = 5,5 et l'autre à pH = 3,5. La précipitation des deux séries de solutions avec $[(C_6H_5)_4P]Cl$ a été effectuée immédiatement, 24 h ou 48 h après l'acidification des solutions aux températures de 20° et 100°. Après filtration des précipités, le pH de chaque solution a été mesuré.

Les résultats mentionnés au Tableau III montrent que: la précipitation est plus riche dans les solutions de la série ayant un pH plus bas; le poids du précipité formé croît avec le temps; le pH des solutions, après filtration des précipités, croît avec le temps; la température accélère beaucoup le processus de condensation de Na_2WO_4 et la précipitation est plus abondante dans les solutions bouilles.

TABLEAU III.—CONDENSATION DES SOLUTIONS DE 0,01*M* Na_2WO_4 SOUS L'ACTION DE 0,1*M* HCl EN FONCTION DE pH, DU TEMPS ET DE LA TEMPÉRATURE

pH initial	5,5	5,5	5,5	3,5	3,5	3,5	5,5	3,5
Temps, *h*	0	24	48	0	24	40	1/6	1/6
Température, °*C*	20	20	20	20	20	20	100	100
W précipité, %	22,5	23,5	37,5	91,2	93,8	94,2	43,2	98,0
pH après la précipitation	5,6	5,6	5,7	3,6	4,5	4,7	5,7	5

La réaction entre $[XW_{12}O_{40}]^{(8-n)-}$ et $[(C_6H_5)_4P]^+$ étant quantitative, elle est utilisée pour le dosage des dodécatungstates. Dans la note présente on rapporte les résultats des dosages du métatungstate $[H_2W_{12}O_{40}]^{6-}$, du silicotungstate $[SiW_{12}O_{40}]^{4-}$, du phosphotungstate $[PW_{12}O_{40}]^{3-}$ et du borotungstate $[BW_{12}O_{40}]^{5-}$ (Tableau IV).

TABLEAU IV.—DOSAGE DE SOLUTIONS 0,01*M* DE DODÉCA- ET HÉTÉRODODÉCATUNGSTATES

Solution dosée	précipité obtenu	W	
		en solution, *g*	en précipité, *g*
$H_6[H_2W_{12}O_{40}]$	$[(C_6H_5)_4P]_6[H_2W_{12}O_{40}]$	0,03316	0,03308 ± 0,00008
$H_4[SiW_{12}O_{10}]$	$[(C_6H_5)_4P]_4[SiW_{12}O_{40}]$	0,04050	0,04055 ± 0,00002
$H_3[PW_{12}O_{40}]$	$[(C_6H_5)_4P]_3[PW_{12}O_{40}]$	0,03560	0,03558 ± 0,00009
$H_5[BW_{12}O_{40}]$	$[(C_6H_5)_4P]_5[BW_{12}O_{40}]$	0,04588	0,04605 ± 0,00007

Connaissant la transformation quantitative du tungstate à pH $\sim$ 2 en dodécatungstate, on a établi aussi les conditions pour le dosage des tungstates avec le chlorure de tétraphénylphosphonium.

CONDITIONS EXPÉRIMENTALES

Dosage des dodéca- et hétérododécatungstates

Le dosage de l'acide métatungstique ou de ses sels solubles s'effectue en solution 0,01–0,001*M* à chaud, 50–60°, avec une solution 0,05*M* de chlorure de tétraphénylphosphonium (la solution aqueuse du réactif a été préparée par dissolution de la substance dans l'eau: elle est stable pendant une semaine). L'exces du réactif doit être > 0,2%.

Le précipité qui se forme est filtré après refroidissement complet de la solution. Pendant ce temps le précipité amorphe se transforme en précipité cristallin. On filtre sur creuset G4 et on lave avec une solution à 0,2% de chlorure de tétraphénylphosphonium; séchage en étuve à 70–80° pendant 90–120 min.

Les dosages des hétéropolytungstates tels que $[SiW_{12}O_{40}]^{4-}$, $[PW_{12}O_{40}]^{3-}$ et $[BW_{12}O_{40}]^{5-}$ s'effectuent dans les mêmes conditions.

Dosage des tungstates

Les solutions de tungstates alcalins sont portées à pH ~ 2 (pour être transformées en dodécatungstates) en ajoutant 45–50 ml d'une solution tampon de type Clark-Lubs de pH = 2 (88,10 ml 0,2*M* KCl + 11,90 ml 0,2*M* HCl dilués à 200 ml). On fait bouillir 15–20 min; on laisse refroidir jusqu'a 50–60° et puis on continue de procéder comme pour le dodécatungstate.

Summary—A physico-chemical study of the conditions of formation (pH, time, temperature) of dodecatungstates and of their separation with tetraphenylphosphonium chloride is presented. In the iso- and heteropolytungstate series only the anions of the form $[XW_{12}O_{40}]^{(8-n)-}$ (where *n* is the oxidation number of X) are precipitated by this reagent. The reaction is quantitative and can be used to separate the dodecatungstate from a mixture of tungstate anions. By using tetraphenylphosphonium chloride as a specific reagent for dodecatungstate it has been possible to show that in the condensation of sodium tungstate in high concentrations of acid the dodecatungstate begins to appear at pH ~ 6 and all the tungstate is in this form at pH ~ 2. Factors such as dilution, time and temperature also affect the formation of dodecatungstate over this pH range. The reaction is used for the determination of a series of dodecatungstates.

Zusammenfassung—Die Bildungsbedingungen (pH, Zeit, Temperatur) von Dodekawolframaten und ihre Abtrennung mit Tetraphenylphosphoniumchlorid wurden physikalisch-chemisch untersucht. In der Iso- und Heteropolywolframat-Reihe werden nur die Anionen des Typs $[XW_{12}O_{40}]^{(8-n)-}$ (wo *n* die Oxidationszahl von X bedeutet) durch dieses Reagens gefällt. Die Reaktion ist quantitativ und kann dazu dienen, Dodekawolframat aus einem Gemisch von Wolframat-Anionen abzutrennen. Mit Tetraphenylphosphoniumchlorid als spezifischem Reagens auf Dodekawolframat ließ sich zeigen, daß bei der Kondensation von Natriumwolframat in hohen Säurekonzentrationen das Dodekawolframat bei pH ~6 auftritt und bei pH ~2 alles Wolframat in dieser Form vorliegt. Faktoren wie Verdünnung, Zeit und Temperatur sind ebenfalls von Einfluß auf die Bildung von Dodekawolframat in diesem pH-Bereich. Die Reaktion wird zur Bestimmung einer Reihe von Dodekawolframaten verwendet.

REACTIONS OF ERIOCHROME BLUE BLACK R

G. L. SILVER and R. C. BOWMAN
Monsanto Research Corporation, Mound Laboratory,* Miamisburg, Ohio, U.S.A.

(*Received* 2 *February* 1967. *Accepted* 20 *March* 1967)

Summary—The reactions of Eriochrome Blue Black R with approximately 25 metals are tabulated. Photometric titrations of molybdenum and uranium are described, and a new method of titrating thulium with EDTA is presented.

IN 1948 Schwarzenbach[1] introduced Eriochrome Blue Black R (Calcon, C.I. 15705, previously C.I. 202) and described its properties. Since that time, this dye, "Erio R", has been suggested as an indicator for various metal–EDTA titrations, such as the determination of calcium and magnesium.[2] In order to understand the reactions of this more or less typical *o,o'*-dihydroxyazo indicator and to gain some insight into the analytical potential of this type of compound, we have compiled a summary of the reactions of Erio R. This indicator has already been the subject of some investigations,[1,2,3] but the results have not yet all appeared in the literature.

EXPERIMENTAL

All chemicals were reagent grade except lanthanum, which was "C.P", and the Erio R. Crude Erio R was obtained from the G. Frederick Smith Chemical Company of Columbus, Ohio; 3 g of it were dissolved with the aid of sodium hydroxide in 500 ml of distilled water. It was precipitated by adding 150 ml of concentrated hydrochloric acid, filtered off, and washed by stirring in distilled water; then it was redissolved and reprecipitated. It was then collected on filter paper and dried in a vacuum desiccator. Thin-layer chromatography on silica gel indicated the presence of only one coloured species in the material and it was not purified further. Standard solutions of the dye were prepared by dissolving 90–100 mg of it in a litre of distilled water. They were standardised by titrating photometrically with copper (which forms a 1:1 complex with Erio R) a 50-ml aliquot in 300–400 ml of distilled water made basic with ammonia buffer. The wavelength 635 mμ was selected for monitoring.

Combining ratios were studied by means of photometric titrations of Erio R in buffered solutions of various pH values with the metals listed in Table I. Metal titrant solutions were $\sim 10^{-2}M$. A Cary Model 14 Recording Spectrophotometer and 1-cm silica cells were used in these studies. Stability constants were determined photometrically in the visible region of the spectrum by (*a*) the Bjerrum titration method, (*b*) the molar ratio method, or (*c*) abbreviated complementary tristimulus colorimetry. The use of these methods for studying stability constants has been outlined elsewhere.[2,3,5,6] Dye factors, *i.e.*, the ratio of $[H_3A]$ to total free indicator concentration, were used when necessary to correct the photometric Bjerrum method in pH ranges where more than one form of the free dye exists. In such cases the photometric absorbance data were obtained near an isosbestic point of uncomplexed Erio R. The ionization constants[3] of tribasic Erio R (H_3A) were taken as $pK_1 = 1{\cdot}0$, $pK_2 = 7{\cdot}4$, $pK_3 = 13{\cdot}5$. Buffers were generally acetate and borate solutions except where inappropriate [*e.g.*, with lead(II)]. Low concentrations of the buffer were employed to avoid side-reactions with the metal.

RESULTS AND DISCUSSION

When a metal complex of Erio R dissociates by displacement of the metal with hydrogen ions, the reaction usually involves two protons (charges on the various species are omitted for simplicity):

$$MA + 2H = M + H_2A \qquad (1)$$

* Mound Laboratory is operated by Monsanto Research Corporation for the U.S. Atomic Energy Commission under Contract No. AT-33-1-GEN-53.

The molar ratio method for ascertaining equilibrium constants, as applied here, is not capable of giving information on the number of protons involved in the dissociation reaction. Therefore this method was used only in cases where an excess of the metal caused the Erio R to precipitate and made the other methods inconvenient or impractical. In such cases, the reaction was assumed to involve two protons as

described above. With some ions [*e.g.*, aluminium, iron(II), gallium(III) and cobalt(II)] reaction (1) is slow. The pK values listed in Table I are for the reaction:

$$MA = M + A \qquad (2)$$

except as noted otherwise. These were calculated from the measured equilibrium constant of reaction (1), and the second and third ionization constants of Erio R. Table I lists the pK values for reaction (2), and the combining ratio of Erio R with the metals under various conditions of pH. A complex containing two Erio R ions per metal ion is designated 2:1. Methods (*a*), (*b*), and (*c*) are abbreviated BT, MR

and CTC. Stability constants were determined in the presence of 0·1*M* sodium chloride except as noted.

In addition to the elements listed in Table I, arsenite, potassium niobate, and rhodium(III) chloride were investigated and found to be unreactive toward Erio R. Species which react with Erio R by undergoing reduction include iron(III), diamminosilver(I), mercury(II), ruthenium(IV) chloride, platinum(IV)chloride and plutonyl(VI). There is evidence of complexing with palladium(II) chloride. The indicator is precipitated even by small amounts of hafnyl and zirconyl ions, and of dicyclopentadienyl zirconium dichloride.

Perhaps the most interesting reactions of Erio R are the reactions with molybdate and tungstate. There is no evidence of reaction between Erio R and either the molybdate or the tungstate ions in basic solution. In acidic solution, however, both combine with Erio R to form a 1:1 complex. The reaction with molybdenum was studied by complementary tristimulus colorimetry at a total molybdenum concentration of about $10^{-3}M$. The reaction at this molybdenum concentration is complete near pH 4. In the equation below, the symbols [Mo] and [MoA] represent the reacting molybdenum species and the Erio R complex formed and the constant is for the complexation reaction as written.

$$[\mathrm{Mo}] + \mathrm{H_2A} + 2\mathrm{H^+} = [\mathrm{MoA}]; \qquad \log K = 13{\cdot}8.$$

Molybdenum derived from sodium molybdate or ammonium isopolymolybdate $[(NH_4)_6Mo_7O_{24}\,.\,4H_2O]$ reacts similarly. When the latter is used, seven Erio R molecules react with one isopolymolybdate species, indicating that this complex species is cleaved in solution. Molybdenum(V), prepared by reduction of molybdenum(VI) with hydrazine sulphate,[7] does not react with Erio R.

The reaction of tungsten (from Na_2WO_4) with Erio R also occurs in acidic solution, but the reaction, studied in the same manner as the molybdenum reaction, proceeds apparently by a one-proton step. For the complexation reaction $[\mathrm{W}] + \mathrm{H_2A} + \mathrm{H^+} = [\mathrm{WA}]$ the value of log K was determined to be 5·4.

From the results listed in Table I, and the discussion above, certain uses of Erio R, and possibly other hydroxyazo dyes, are suggested. These procedures are listed principally as suggestions for new avenues of research with hydroxyazo indicators.

Determination of molybdenum

To a solution containing about 10^{-5} mole of molybdenum(VI) in 300 ml of distilled water, add sufficient acid to adjust the pH to 1·5–3·0. Acetate may be used as a buffer at pH 3. Titrate photometrically with $\sim 2 \times 10^{-3}M$ Erio R (kept at pH ~4 to inhibit decomposition). The wavelength 510 mμ is best for visible photometric titrations, although at this wavelength the extrapolated end-point is not sharp because the absorbances of the chelate and uncomplexed dye do not differ greatly. The Erio R should be previously standardised against Mo(VI). Many metal ions interfere [*e.g.*, iron(III) and lead] but cadmium and lanthanum do not. Six determinations on molybdenum solutions of varying concentration gave an average deviation of $\pm 1\%$.

Estimation of uranium, plutonyl(VI) *and thulium*

The high association constant of uranium and Erio R allows uranium to be titrated photometrically with Erio R. At pH 4 in acetate buffer many metals interfere, but lead does not. The wavelength 500 mμ may be used, but at this wavelength the extrapolated end-point is not sharp. The precision of the method was not checked.

The bivalent plutonyl(VI) ion acts as an oxidant toward Erio R, and this property may be used to estimate its concentration in solution at pH 3. The photometric titration may be carried out at 510 mμ. The method is only approximate for the 238 isotope because of extensive valence wandering.[8]

Erio R has not been suggested for the direct titration of the rare earths with EDTA. We have

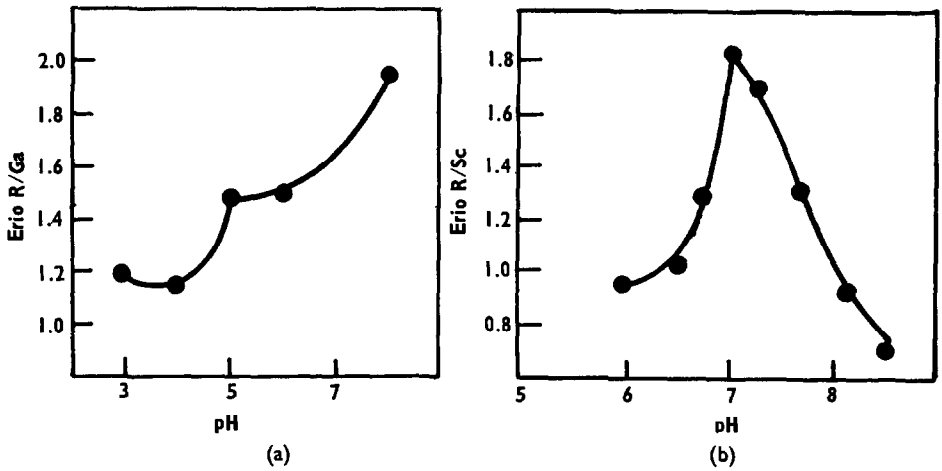

FIG. 1.—Apparent ratio of Erio R to (a) gallium and (b) scandium as a function of pH.[3]

found that 10^{-5} mole of thulium in 50 ml of solution to which has been added 10^{-3} mole of α-hydroxyisobutyric acid can be titrated visually in ammonia buffer (pH 8–9) with $10^{-2}M$ EDTA. The change at the end-point is from purple to sky-blue. Six determinations gave an average deviation of less than 2%.

Zusammenfassung—Die Reaktionen von Eriochromschwarz R mit etwa 25 Metallen werden tabelliert. Photometrische Titrationen von Molybdän und Uran sowie eine neue Methode zur Titration von Thulium mit EDTA werden beschrieben.

Résumé—On a répertoirié les réactions du Bleu Noir d'Eriochrome R avec environ 25 métaux. On décrit les dosages photométriques du molybdène et de l'uranium, et présente une nouvelle méthode de dosage du thulium avec l'EDTA.

APPLICATION DES COURBES DE VOLATILISATION-EXCITATION A LA DETERMINATION DES CONDITIONS DE L'ANALYSE SPECTROCHIMIQUE DE L'OXYDE DE TANTALE

J. BRIL* et J. VINOT
Cie Pechiney -LRM-38- Grenoble, France

(*Reçu le* 16 *Janvier* 1967. *Accepté le* 4 *Mars* 1967)

Résumé—La détermination des conditions spectrographiques optimales pour l'analyse de l'oxyde de tantale est facilitée par la considération des courbes de volatilisation des éléments recherchés. La méthode est appliquée au dosage de Cr, Fe, Hf, Ni, Nb, Ti, Y et Zr à des concentrations de l'ordre de 10 à 1000 ppm.

UN MÉCANISME des réactions chimiques survenant au niveau des électrodes de graphite utilisées en spectrographie d'arc sur oxydes a été suggéré antérieurement.[1] Les conclusions énoncées s'appuyaient sur l'examen de "courbes de volatilisation-excitation"† qui, selon l'élément considéré (ou plutôt la combinaison dans laquelle il se trouve engagé), revêtent l'une des allures, monotones et décroissantes (type A), ou présentant un minimum (type B), des courbes de la Fig. 1.

La considération de ces courbes est appliquée dans ce qui suit à la détermination des conditions opératoires optimales pour le dosage de Cr, Fe, Hf, Ni, Nb, Ti, Y et Zr dans l'oxyde de tantale, sujet qui n'a été abordé que par de rares auteurs dont particulièrement Laib.[2]

Supposons construite la courbe de volatilisation-excitation, relative à une raie d'un des éléments à doser; soit t_1 le temps de préflambage et t_2 le temps d'exposition, les autres conditions expérimentales étant supposées définies. En première approximation, et sous certaines conditions, le noircissement de la plaque sous l'effet de la radiation pourra être considéré comme proportionnel à la surface comprise entre la courbe de vaporisation-excitation, l'axe des temps et les deux droites paralleles à l'axe des ordonnées d'abscisses t_1 et t_2.

Dans la pratique, on pourra ainsi sélectionner une raie analytique, optimaliser les temps de préflambage et d'exposition, déterminer l'intensité de l'arc, en fonction de la sensibilité recherchée. De même, il devient possible, dans certains cas, de réduire l'intensité d'une raie parasite, de déterminer les conditions dans lesquelles l'application de la méthode dite "de l'étalon interne" est licite, *etc.*

PARTIE EXPERIMENTALE

Construction des courbes de volatilisation-excitation des éléments à doser

Ce travail a été fait dans les conditions générales déjà exposées et rappelées ci-dessous.
Générateur d'arcs continus.
Electrode cratère positive inférieure emplie d'un
Mélange de 1 partie d'oxyde avec 1,25 partie de graphite.
Spectrographe Optica B 5 (équipé d'un réseau de 2160 tr/mm fournissant une dispersion inverse de 3,6 Å/mm).
Plaques: Kodak B 10.

* Actuellement Cie Pechiney -CRV-38- Voreppe.

† Les courbes expriment, pour une radiation déterminée, l'énergie lumineuse reçue par la plaque en fonction de l'âge de l'arc; on peut, dans l'application courante, se contenter de porter en ordonnée la mesure de la densité optique ainsi qu'il ressort de l'exposé fait dans.[1]

Les données relatives aux 40 courbes construites figurent au Tableau I.

TABLEAU I.—CONDITIONS D'OBTENTION DES COURBES DE VOLATILISATION-EXCITATION

Elément	Taux, %	Raie spectrale, Å		Excitations, Å	Type de la courbe
Cr	0,1	4254,3	I	*10*	A
Fe	0,1	*3020,6*	I	2–4–*10*	A
		2599,4	II	14–21	
Hf	1.0	*2773,4*	II	5–*10*–14	B
		2783,7	I	10	
Nb	1,0	*3094,2*	II	2–4–*10*–14	B
		3225,5	II	5–*10*–14	
Ni	0,1	3050,8	I	*10*	A
Ta	Matrice	2594,3	II	5–*10*–14	B
Ti	1,0	*3078,6*	II	2–4–*10*–14	B
		3106,2	II	5–10–14	
Y	0,2	3195,6	II	10–21	
		4309,6	II	10–14–21	A*
		4374,9	II	10–14–21	
Zr	1,0	2799,1	II	10	B
		3306,3	II	5–10–14	

* Les courbes relatives à l'Y accusent, sous certaines conditions, une légère remontée qui les apparente à celles du type B.

N.B. Les valeurs en italique ont été retenues pour le protocole opératoire (*cf.* Tableau 3).

Chaque courbe est construite à l'aide de deux séries indépendantes de 13 points correspondant à des poses de 5 sec espacées de 5 sec, durant lesquelles la plaque est déplacée (Moving Plate Method).

Les courbes relatives à une raie de chacun des 4 éléments Hf, Nb, Ni et Ti, sont représentées Fig. 1 à titre d'exemple; elles correspondent à des arcs d'une intensité de 10 A, qui sont ceux qui ont donné les dispersions minimales.

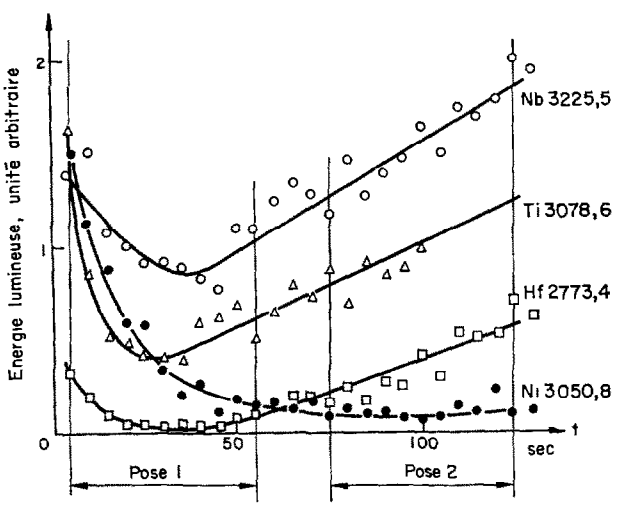

FIG. 1.—Courbes de volatilisation-excitation de Hf, Nb, Ni et Ti.

La recherche de la sensibilité a conduit à considérer successivement, comme il ressort de l'observation de ces courbes, deux temps de pose de 50 sec décalés de 20 sec l'un par rapport à l'autre: ainsi, les éléments présentant des courbes de type A, soit Cr, Fe, Ni (et Y), sont dosés à l'aide d'une première exposition après un préflambage de 5 sec. Les autres éléments, soit Hf, Nb, Ti et Zr, sont dosés à l'aide d'une seconde pose prise au cours de la même décharge, mais dont le début a lieu 75 sec après l'amorçage de l'arc.

Le Tableau II exprime, avec une unité arbitraire commune, l'intensité relative des 4 raies de la Fig. 1, d'une part pour la pose 1 ($t_1 = 5$ sec, $t_2 = 50$ sec), d'autre part pour la pose 2($t_1 = 75$ sec, $t_2 = 50$ sec).

TABLEAU II.—INTENSITES RELATIVES ESCOMPTÉES DES RAIES DE Hf, Nb, Ni, Ti

Conditions de pose (*cf.* Fig. 1)	Hf	Nb	Ni	Ti
1	2	26	14	16
2	11	40	3	21

Courbes d'étalonnage

La sensibilité souhaitée, des interférences gênantes et la recherche d'un compromis entre la grande dispersion du spectrographe et l'utilisation d'une plage restreinte de longueurs d'onde, nous ont conduits dans la pratique: à adopter les raies et les conditions opératoires du Tableau III; à disjoindre le cas de l'ytrium qui fera l'objet d'une détermination séparée (ainsi qu'il ressort du même tableau). La Fig. 2 reproduit les courbes d'étalonnage obtenues à l'aide d'étalons préparés par mélanges directs d'oxydes.

TABLEAU III.—CONDITIONS OPÉRATOIRES ET LIMITES DE DÉTECTION

Element	Raie analytique, Å	Excitation, *A*	t_1, *sec*	t_2, *sec*	Limite de dosage, *ppm*
Cr	3021,6	10	5	50	10
Fe	3020,6	10	5	50	10
Ni	3414,7	10	5	50	10
Hf	2773,4 ou 3399,8	10	75	50	700
Nb	3225,5 ou 3094,2	10	75	50	100

Zr	3392,0	10	75	50	100
Y	3242,3	14	5	90	5

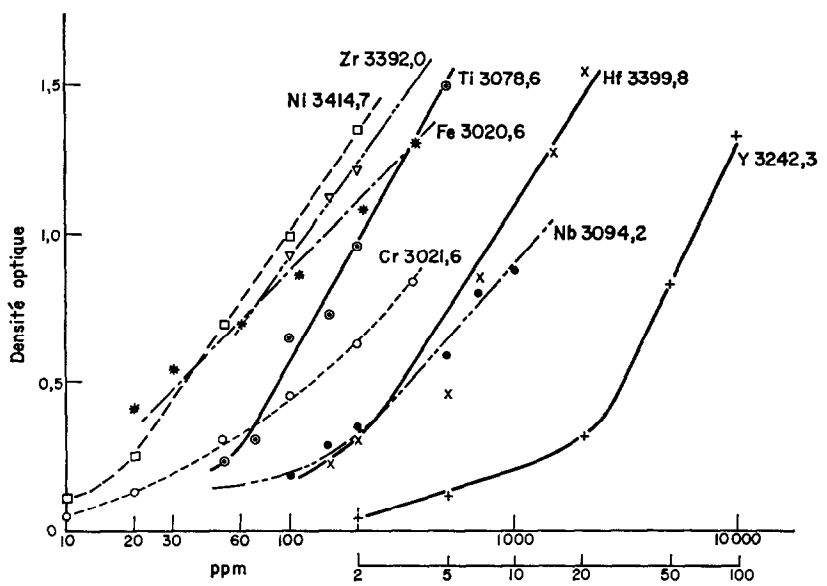

FIG. 2.—Courbes d'étalonnage.

DISCUSSION ET CONCLUSION

L'exemple précédent d'utilisation des courbes de volatilisation-excitation à des fins analytiques en montre l'intérêt. Le travail nécessité par le tracé de ces courbes, qui illustrent la cinétique du processus global (thermochimique et électronique) mis en oeuvre, peutêtre substantiellement allégé: en effet, les raies de même nature d'un atome présentent des courbes très semblables et on pourra fréquemment se dispenser de les tracer pour de nombreuses longueurs d'onde.

Cependant, la comparaison de courbes relatives à des raies d'intensité très différente ne devra se faire qu'après avoir fait correspondre aux noircissements les énergies incidentes correspondantes, ceci afin de tenir compte au plus près des phénomènes photographiques. Cette remarque prend toute sa valeur lors de l'utilisation analytique d'une raie forte dans le but d'accroître la sensibilité, alors que ce sont les courbes relatives à des raies plus faibles qui ont été tracées à l'aide de substances de concentration beaucoup plus élevées en l'élément recherché. La même remarque est à considérer lors de la recherche de l'intensité optimale d'excitation.

Summary—The determination of the optimum conditions for the spectrographic analysis of tantalum oxide is facilitated by consideration of the volatilization curves for the elements sought. The method is applied for the estimation of Cr, Fe, Hf, Ni, Nb, Ti, Y and Zr at the 10–1000 ppm level.

Zusammenfassung—Die Ermittlung der optimalen Bedingungen zur spektrographischen Analyse von Tantaloxid wird erleichtert durch Betrachtung der Verflüchtigungskurven der gesuchten Elemente. Die Methode wird angewandt auf die Bestimmung von Cr, Fe, Hf, Ni, Nb, Ti, Y und Zr bei 10–1000 ppm.

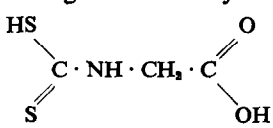
POTENTIOMETRIC STUDY OF COMPLEXES OF LEAD(II) WITH DITHIOCARBAMINOACETIC ACID

O. BUDEVSKY and E. PLATIKANOVA
Bulgarian Academy of Sciences, Institute of General and Inorganic Chemistry, Sofia 13, Bulgaria

(*Received* 25 *July* 1966. *Revised* 14 *February* 1967. *Accepted* 13 *March* 1967)

Summary—A potentiometric determination of the stability constants of lead(II)–dithiocarbaminoacetic acid complexes has been made. Potentiometric data have been used for estimating the maximum number of co-ordinated ligands. After graphical solution of the Fronaeus integral, the relationship between the concentration variables has been found, and the curve-fitting method, in which both variables are normalised, has been used for determining the stability constants. The values found are $\log \beta_1 = 7{\cdot}32 \pm 0{\cdot}12$ and $\log \beta_2 = 13{\cdot}03 \pm 0{\cdot}20$ ($\mu = 0{\cdot}1$; 25°). From these data, the relationship between the conditional stability constant $\log \beta_2'$ and pH has been calculated, thus furnishing a full description of TCA as a masking agent for lead ions.

DITHIOCARBAMINOACETIC acid (TCA) forms very stable water-soluble complexes with a number of metal ions.[1–3] Although the stability constants of the complexes have



(TCA)

not been determined, our preliminary qualitative investigations showed that they follow a sequence corresponding to the solubility of the metal sulphides. This fact was used in the application of TCA as a new masking agent in complexometry.[4]

For wider and more expedient use of TCA in analytical chemistry, the stability constants must be known. This paper describes an attempt to determine the stability constants of lead(II) TCA complexes by a potentiometric method with an amalgam electrode. The potentiometric determination of the acid dissociation constants of TCA[5] and the spectrophotometric determination of the stability constants of cobalt(II) TCA complexes[6] have previously been reported.

EXPERIMENTAL

Symbols[7]

A—total concentration of ligand A.
a—concentration of free ligand.
B—total concentration of central group B.
b—concentration of free central group.
h—concentration of free hydrogen ions.
n—number of ligands in mononuclear complex BA_n.
N—maximum value of n.
$\bar{n} = (A - a)/B$—average number of ligands A bound to one central group B.
$\alpha_c = [BA_c]/B$—fraction of B in form of BA_c.
$\beta_n = [BA_n]/ba_n$—over-all concentration stability constant.
$\beta_j^H = [H_jA]/ah^j$—over-all proton stability constant.

Apparatus

Measurements were carried out in such a manner that the concentration b of the free central group was determined as portions of ligand A were added.

The galvanic cell

$Hg\text{-}Hg_2Cl_2$	satd. KCl soln.	$0{\cdot}1M$ KNO_3	$0{\cdot}01M$ formate buffer $0{\cdot}09M$ KNO_3 $x.10^{-4}M$ $Pb(NO_3)_2$ $y.10^{-4}M$ TCA	Hg-Pb

consisted of an amalgam electrode, reversible with respect to the concentration of free metal ions, and a saturated calomel electrode (SCE) as a reference half-cell.

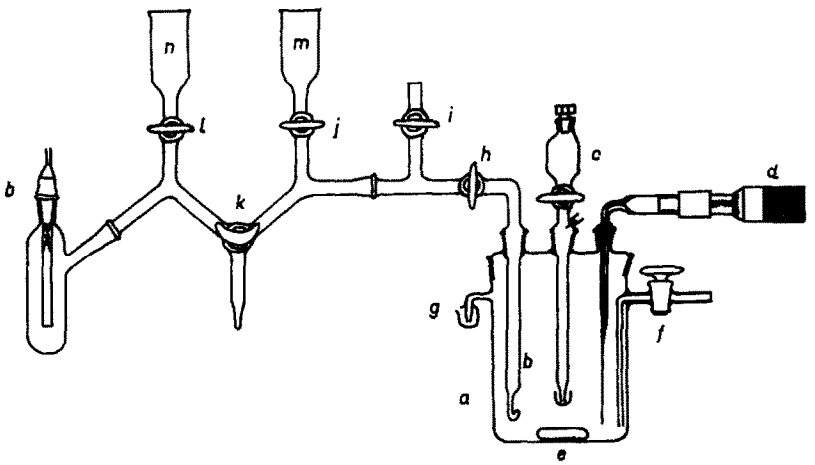


FIG. 1.—The apparatus for potentiometric titration with an amalgam electrode.

The apparatus (shown in Fig. 1) was prepared for measurements as follows: a solution of known concentration B was placed in the vessel a. The holes in the glass cover were closed with glass stoppers. Through the cock f and the water-trap g, a stream of very pure nitrogen (99·999%), saturated with water vapour, was passed through the solution. The apparatus was kept in an air-thermostat at 25 ± 0·1°. The salt-bridge was filled with potassium chloride solution (saturated at 25°) by means of the vessel n and the stop-cocks k and l; the right-hand side of the bridge was filled with $0{\cdot}1M$ potassium nitrate solution through the vessel m and the stop-cocks k, j, i and h. The amalgam in the lower part of the amalgam electrode was replaced with fresh and the electrode was put in the vessel a. The amalgam in the upper part of the electrode was kept under a layer of liquid paraffin. Just before measurements were started, the stop-cocks k and h were opened. In this way conditions for very reproducible contact between the two solutions were realized. The solution in the vessel a was stirred with a magnetic stirrer e. Portions of the $0{\cdot}1M$ solution of the ligand were added from the microburette d. The potential of the amalgam electrode was measured with a potentiometer with a precision of ±0·05 mV. The potentiometer was checked with a Weston standard cell.

Preliminary investigations

First, the dependence of the potential of the amalgam electrode on the concentrations of lead ions in the absence of complexing agents was determined. Experiments showed that in the concentration range 10^{-3}–$10^{-4}M$, the relationship E/-log $[Pb^{2+}]$ is linear and has approximately the theoretical slope of ~28 mV. Because TCA is the conjugate base of a weak acid, measurements with it were carried out in the presence of buffer. Formic acid forms very weak complexes with lead ions ($\log \beta_1 = 0{\cdot}78$, $\log \beta_2 = 1{\cdot}20$, $\log \beta_3 = 1{\cdot}43$ and $\log \beta_4 = 1{\cdot}18$),[8] so a formate buffer will not noticeably interfere. This was confirmed by our experiments, which showed that the alteration of the potential $0{\cdot}01M$ formic acid was added was negligible (about 0·5 mV). Our measurements were carried out in the presence of $0{\cdot}01M$ potassium formate–formic acid buffer solution, pH = 4 ± 0·05.

Measurements and data processing

A series of experiments was performed with the equipment described and the course of the complexation reaction was followed. Difficulties arose from appearance of a precipitate when a portion of ligand A was added, but if $10^{-4}M$ lead was used the solution remained clear throughout.

TABLE I.—DATA OF A, E, α_0, $\bar{n}$, a OBTAINED FROM ONE EXPERIMENT. CONDITIONS: $B = 1{\cdot}10^{-4}$ M $Pb(NO_3)_2$; 0·01 M FORMIATE BUFFER pH = 4·00 ± 0·05; VOLUME 25 ml; IONIC STRENGTH μ = 0·1 (KNO_3); 25 ± 0·2°C; TITRATED WITH 0·1 M TCA.

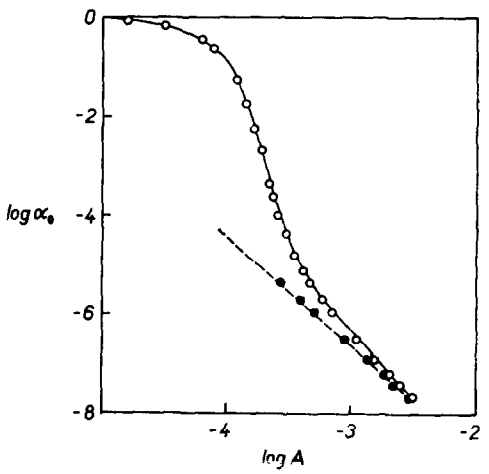

FIG. 2.—Dependence of log α_0 on the total amount of TCA added.

From the relationships[7]

$$(E)_A = E_0' - \frac{RT}{zF} \ln b \qquad \text{and} \qquad (E)_{A=0} = E_0' - \frac{RT}{zF} \ln B \tag{1}$$

we calculated

$$(\Delta E)_B = (E)_{A=0} - (E)_A = \frac{RT}{zF} \ln \frac{b}{B} = 0{\cdot}028 \log \alpha_0, \tag{2}$$

where E is the potential of the system, E_0 is the standard electrode potential and z is the number of electrons involved in the electrode reaction.

By measuring the potential of the amalgam electrode before and after the addition of the ligand, the relationship between log α_0 and log A was found (see Table I and Fig. 2). Under the chosen

conditions the value of the liquid–junction potential was negligible, but in any case it is evident from equation (2) that the liquid–junction potential is eliminated.

From the well-known relationship between the secondary concentration variables[7,9]

$$\frac{\mathrm{d}\log\alpha_0}{\mathrm{d}\log a} = -\bar{n} \tag{3}$$

the value of $\bar{n}$ can be obtained. In our case, we do not measure directly the function $\log\alpha_0/\log a$; however, when the ligand is in excess, the approximation

$$\frac{\mathrm{d}\log\alpha_0}{\mathrm{d}\log A} \approx \frac{\mathrm{d}\log\alpha_0}{\mathrm{d}\log a} = -N \tag{4}$$

can be used.

As our experiments were not carried out with an extremely large excess of the ligand, we did not obtain a precise meaning for the maximum value of N from equation (4) (the result obtained was $N' = 2{\cdot}55$, see Fig. 2—open circles). To have a more precise value for a, we used the relationship

$$a = A - N'B \tag{5}$$

from which a number of a values were calculated. Then the more precise relationship of $\log\alpha_0$ to $\log a$ was obtained, from which a better value, N, was determined. The N–a pairs were then refined by successive approximation until convergence was obtained. The number of co-ordinated ligands finally found is $N = 2$ (see Fig. 2—black circles).

For the calculation of the stability constants β_1 and β_2, knowledge of the relationship between α_0 and a was needed. It was found by solving the Fronaeus integral.[7,10]

From equation (3),

$$\log a_1 = -\int\frac{1}{\bar{n}}\,\mathrm{d}\log\alpha_0 + \log a_2 \tag{6}$$

where a_1 is the unknown value of the free ligand concentration, a_2 is the known value of free ligand concentration, calculated from (5) for the case in which the ligand is in excess ($A \gg B$). The Fronaeus integral was solved graphically by drawing the function $(1/\bar{n})$ $(-\log\alpha_0)$ and using the approximation

$$\bar{n} \approx \frac{A}{B} \tag{7}$$

in the region $A < NB$, the complexes being very stable. The approximation $\bar{n} \approx N$ was used in the region $A > NB$ (see Fig. 3). After solution of the Fronaeus integral, the rigorous values of a were used to refine the approximation (7), by means of the exact expression

$$\bar{n} = \frac{A - a}{B} \tag{8}$$

The $\bar{n}$ and a values were refined by successive approximation with equation (6) and (8) until convergence was obtained (see Fig. 3—closed circles).

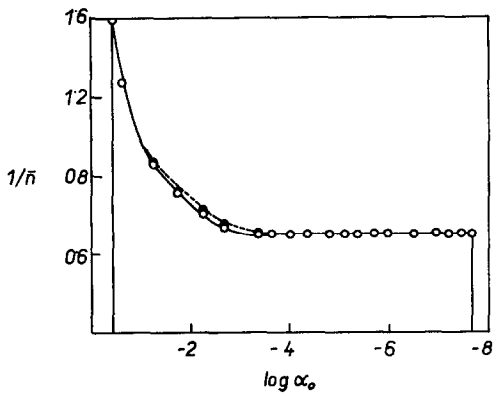

FIG. 3.—Graphical solution of the Fronaeus integral.

The stability constants were computed from α_0 and a values by Sillén's curve-fitting method, in which the two variables were normalised.[11] More details of this method can be found in Rossotti and Rossotti's excellent book on the determination of stability constants.[7] In Fig. 4, is shown a plot of log $(B - b)/ba$ *vs.* log a with data obtained from four experiments. Experiments were performed with various concentrations of the total central group B, and the results show that the complex is mononuclear.

As measurements were carried out at constant pH, the stability constants are conditional (or apparent). The concentration stability constants were found by using the α_H factor

$$\beta_1 = \beta_1'(1 + \beta_1^H h + \beta_2^H h^2) \tag{9}$$

$$\beta_2 = \beta_2'(1 + \beta_1^H h + \beta_2^H h^2)^2 \tag{10}$$

where β_1' and β_2' are the corresponding conditional constants and $\beta_1^H = 5{\cdot}6 \times 10^3$ and $\beta_2^H = 4{\cdot}7 \times 10^6$ are the proton stability constants of TCA, determined at 25° and ionic strength 0·1. The values for β_1 and β_1 found here are

$$\log \beta_1 = 7{\cdot}32 \pm 0{\cdot}12 \qquad \beta_1 = (2{\cdot}1 \pm 1{\cdot}3) \times 10^7$$

$$\log \beta_2 = 13{\cdot}03 \pm 0{\cdot}20 \qquad \beta_2 = (1{\cdot}1 \pm 1{\cdot}6) \times 10^{13}$$

where the limits of error are the permissible vertical and horizontal displacements of the origin of the normalized curve.

For a fuller description of the complexation reaction it was necessary to know the stability constants of mixed hydrogen and hydroxo complexes of type BH_jA_n and $B(OH)_jA_n$. To achieve this, we used Sillén's[7,12] method of obtaining the relationship between two of the free concentration variables

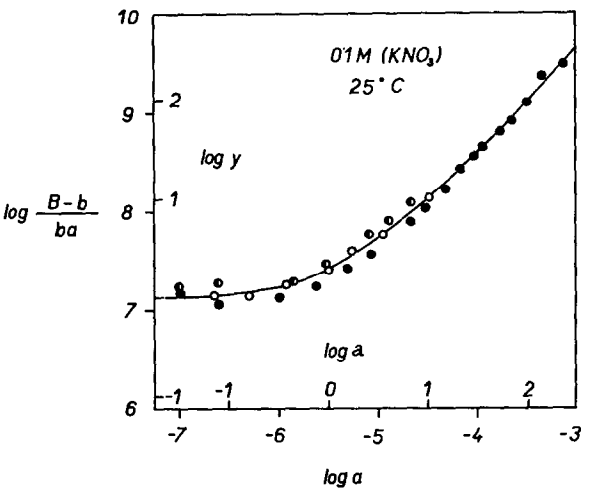

FIG. 4.—The experimental data for log $(B - b)/ba$ as a function of log a for the lead(II)–TCA system, superimposed on the normalised curve for log a as a function of log y.

for a series of constant values of the third. For a mononuclear system of complexes the total concentration of the central group is given by the expression

$$B = b + b \sum_0^j \sum_1^N \beta_{1jn} h^j a^n \tag{11}$$

and then

$$F_1 = \frac{B - b}{ba} = \sum_0^j \sum_1^N \beta_{1jn} h^j a^{n-1} = \sum_1^N \Phi_n a^{n-1} \tag{12}$$

where the function

$$\Phi_n = \sum_0^j \beta_{1jn} h^j$$

is constant at a given hydrogen ion concentration.

Thus the relationship between Φ_n and h at different pH values can be defined and the various stability constants can be found. The analysis of the function $\Phi_n(h)$ shows that Φ_1 and Φ_2 are independent of variation in h, which is a proof that in the region investigated (pH 4–9) no mixed hydrogen or hydroxo complexes are present.

DISCUSSION

Because of the stepwise complex formation, TCA can be used only for masking and not as a titration agent in spite of the high stability of its lead ion complexes. The relationship between the conditional stability constant β_2' and the pH value of the solution gives a good idea of the masking efficiency of TCA. It is the β_2' and not the β_1' constant that is the more useful, because a masking agent is added in excess and so provides conditions for the formation of the complex with the maximum co-

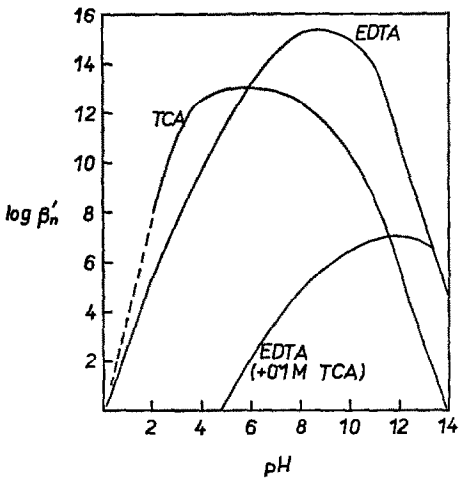

FIG. 5.—The pH-dependence of the conditional stability constant log β_2' for the Pb(TCA) complex and of log β_1' for the Pb-EDTA complex in the presence and absence of TCA.

ordination number. The relationship between log β_2' and pH was calculated according to Ringbom,[13] with data from the present paper (see Fig. 5). Depending on the acidity of the solution, TCA decomposes more or less rapidly at pH < 2, so values for this pH-region are shown by a dashed line. The β_2' values at pH > 9 are calculated without taking into consideration the possible co-existence of mixed hydroxo complexes. This factor would probably not improve the masking efficiency of TCA in the pH region mentioned. As can be seen from Fig. 5, the conditional constant β_2' reaches a maximum value between pH 4 and 8. Thus TCA can successfully be used as a masking agent for lead ions in this pH-region.

This can be illustrated in complexometry, by comparison of the conditional constant for lead–EDTA in the presence and absence of TCA, as a function of pH. The course of the two curves plotted in Fig. 5 shows that the masking efficiency of TCA will be higher at pH 3–5, where the lead–EDTA conditional constant in the presence of TCA is rather low. In basic solution TCA can be used less successfully because the conditional constant of the lead–EDTA complex even in the presence of TCA has a value 10^6–10^7. This fact is in a good agreement with former data concerning the application of TCA as a masking agent in complexometry.[4]

Acknowledgement—The authors thank Professor Anders Ringbom, Åbo Akademi, Finland for valuable help and discussions.

Zusammenfassung—Die Stabilitätskonstanten von Blei(II) dithiocarbaminoessigsäure-Komplexen wurden potentiometrisch bestimmt. Die potentiometrischen Daten wurden zur Ermittlung der maximal koordinierten Ligandenzahl verwendet. Nach graphischer Lösung des Fronaeus-Integrals wurde die Beziehung zwischen den Konzentrationsvariablen gefunden; die Stabilitätskonstanten wurden mit der Kurvenanpassungs-Methode ermittelt, bei der beide Variablen normiert sind. Gefunden wurden $\log \beta_1 = 7{,}32 \pm 0{,}12$ und $\log \beta_2 = 13{,}03 \pm 0{,}20$ ($\mu = 0{,}1$; 25°). Aus diesen Daten wurde die Beziehung zwischen der Stabilitätskonstante $\log \beta_2$ und dem pH-Wert ermittelt; damit ist TCA als Maskierungsmittel für Blei-Ionen voll charakterisiert.

Résumé—On a effectué une détermination potentiométrique des constantes de stabilité des complexes plomb (II)-acide dithiocarbaminoacétique. On a utilisé les données potentiométriques pour estimer le nombre maximal de ligands coordinnés. Après résolution graphique de l'integrale de Fronaeus, on a trouvé la relation entre les variables de concentration et utilisé la méthode d'ajustage des courbes, dans laquelle les deux variables sont normalisées, pour déterminer les constantes de stabilité. Les valeurs trovées sont $\log \beta_1 = 7{,}32 \pm 0{,}12$ et $\log \beta_2 = 13{,}03 \pm 0{,}02$ ($\mu = 0{,}1$; 25°). De ces données, on a calculé la relation entre la constante de stabilité conditionnelle $\log \beta_2$ et le pH, fournissant ainsi une description complète du TCA en tant qu'agent de dissimulation pour les ions plomb.

METAL CHELATE EXCHANGE IN THE ORGANIC PHASE—I

THEORY: APPLICATION IN SPECTROPHOTOMETRY AND COMPLEX CHEMISTRY

JAROMÍR RŮŽIČKA and JIŘÍ STARÝ
Department of Nuclear Chemistry, Faculty of Technical and Nuclear Physics
Prague 1, Břehová 7, Czechoslovakia

(*Received* 5 *January* 1967. *Accepted* 22 *February* 1967)

Summary—Metal chelates, extracted from an aqueous phase by organic solvents, can react with other chelating agents (or their metal chelates) dissolved in the same solvent. This exchange of metal chelates in the organic phase can be used for (1) investigation of the exchange equilibrium and composition of the metal chelates formed, (2) determination of the extraction constants, (3) preparation of new inner-complexes soluble in organic solvents, and (4) spectrophotometric determination of small amounts of metals. The theory and experimental verification of this phenomenon are given. The extraction constants of silver and zinc diethyldithiocarbamates in carbon tetrachloride have been determined by means of the extraction constants of the corresponding dithizonates. A mixed complex of arsenic(III) with dithizone and diethyldithiocarbamic acid has been prepared and its properties studied. A simple method for spectrophotometric determination of microgram quantities of arsenic is proposed.

EXTRACTED metal chelates can be easily transformed into other metal chelates by addition of a suitable chelating agent directly to the separated organic layer. As an example the following simple experiment can be considered. To a golden-yellow solution of silver dithizonate in carbon tetrachloride a colourless solution of diethyldithiocarbamic acid in the same solvent is added; emerald green dithizone is immediately liberated. The chemical reaction which takes place can be described by the equation

$$\underset{\text{golden-yellow}}{(AgHDz)_{CCl_4}} + \underset{\text{colourless}}{(HDDC)_{CCl_4}} = \underset{\text{colourless}}{(AgDDC)_{CCl_4}} + \underset{\text{green}}{(H_2Dz)_{CCl_4}} \quad (1)$$

Similarly, by addition of diethyldithiocarbamic acid, dithizone can be liberated from zinc dithizonate*

$$\underset{\text{red}}{Zn(HDz)_2} + \underset{\text{colourless}}{2HDDC} = \underset{\text{colourless}}{Zn(DDC)_2} + \underset{\text{green}}{2H_2Dz} \quad (2)$$

and as a result of this reaction the colour of the solution rapidly changes from red to green. The same applies for other dithizonates. The amount of dithizone liberated depends on the amount of diethyldithiocarbamic acid added and on the nature of the metal complex involved.

* In this and all further equations, subscripts CCl_4 are generally omitted for sake of simplicity.

Further, when different metal chelates are mixed, *e.g.*, zinc diethyldithiocarbamate and silver dithizonate, an exchange reaction between the metal chelates immediately takes place:

$$\underset{\text{colourless}}{Zn(DDC)_2} + 2\underset{\text{yellow-orange}}{AgHDz} = \underset{\text{red}}{Zn(HDz)_2} + 2\underset{\text{colourless}}{AgDDC}. \qquad (3)$$

Similar reactions occur not only between various dithizonates and diethyldithiocarbamates but also between thio-oxinates and dithizonates, thio-oxinates and diethyldithiocarbamates, dithizonates and cupferrates, dithizonates and oxinates, *etc.*, in carbon tetrachloride and chloroform.

The exchange of metal chelates in the organic phase could have considerable analytical value. Thus if some other suitable chelating agent (or metal chelate) dissolved in the same solvent were added to a colourless extract of a metal chelate the change of colour would enable the metal in question to be determined spectrophotometrically. However, for development of such an analytical procedure not only must the colour of metal chelates involved be known but also the chemical equilibria and species formed.

For this purpose a general theory of metal chelate exchange has been developed which enables one to choose the most suitable colour-forming reagent and to study the composition of species produced by such chemical reactions. The theory has been tested by exchange reactions between metal dithizonates and diethyldithiocarbamates.

THEORETICAL

According to equation (1) the equilibrium constant of the exchange reaction between silver dithizonate and diethyldithiocarbamic acid can be expressed as:

$$E_{AgHDz-HDDC} = \frac{[AgDDC][H_2Dz]}{[AgHDz][HDDC]} = \frac{K_{AgDDC}}{K_{AgHDz}} \qquad (4)$$

where

$$K_{AgDDC} = \frac{[AgDDC]_{org}[H^+]_{aq}}{[Ag^+]_{aq}[HDDC]_{org}}$$

and

$$K_{AgHDz} = \frac{[AgHDz]_{org}[H^+]_{aq}}{[Ag^+]_{aq}[H_2Dz]_{org}}$$

are the extraction constants of silver diethyldithiocarbamate and silver dithizonate respectively. From the above it follows that the values of the exchange constants, E, can be generally used for calculation of extraction constants and *vice versa*.

Similarly, for equation (3)

$$E_{Zn(DDC)_2-AgHDz} = \frac{[Zn(HDz)_2][AgDDC]^2}{[Zn(DDC)_2][AgHDz]^2} = \frac{K_{Zn(HDz)_2}K^2_{AgDDC}}{K_{Zn(DDC)_2}K^2_{AgHDz}}$$

$$= \frac{E^2_{AgHDz\text{-}HDDC}}{E_{zn(HDz)_2-HDDC}} \qquad (5)$$

For the general case, an exchange reaction between metal chleate, MA_n, and chelating agent, HB, can be described as

$$MA_n + nHB = MB_n + nHA \qquad (6)$$

with an exchange constant

$$E_{MA_n-HB} = \frac{[MB_n][HA]^n}{[MA_n][HB]^n} = \frac{K_{MB_n}}{K_{MA_n}} \quad (7)$$

Thus for a quantitative transformation of MA_n to MB_n (*i.e.*, $[MB_n]/[MA_n] > 100$) it is necessary that $E_{MA_n-HB}\{[HB]^n/[HA]^n\} > 100$. Therefore, when a tenfold excess of colour-forming reagent HB is applied the value of E_{MA_n-HB} for $n = 1$, 2, 3 and 4 should be greater than 10, 1, 0·1 and 0·01 respectively.

When an exchange between various metal chelates MA_n and $M'B_{n'}$ takes place:

$$n'MA_n + nM'B_{n'} = n'MB_n + nM'A_{n'} \quad (8)$$

the following equation applies:

$$E_{MA_n-M'B_{n'}} = \frac{[MB_n]^{n'}[M'A_{n'}]^n}{[MA_n]^{n'}[M'B_{n'}]^n} = \frac{K^{n'}_{MB_n}K^n_{M'A_{n'}}}{K^{n'}_{MA_n}K^n_{M'B_{n'}}} = \frac{(E_{MA_n-HB})^{n'}}{(E_{M'A_{n'}-HB})^n} \quad (9)$$

From equation (9) it is evident that for quantitative transformation of chelate MA_n into MB_n (*i.e.*, for $[MB_n]/[MA_n] > 100$) the ratio

$$\frac{E_{MA_n-HB}}{(E_{M'A_{n'}-HB})^{n/n'}}\left(\frac{[M'B_{n'}]}{[M'A_{n'}]}\right)^{n/n'}$$

must be higher than 100. From the analysis of the expressions above it can be seen that it is more favourable to use as a reagent a chelate of a univalent metal than of a bi- or tervalent metal. However, the choice of the second chelating agent, HB, is even more important as its nature has a large influence on the value of E_{MA_n-HB}.

The equilibria considered above are valid only when mixed complexes are not being formed. If they are, their composition (and the corresponding equilibrium constants) can be found from the course of the chemical reaction, which can be generally written as:

$$MA_n + mHB = MA_{n-m}B_m + mHA. \quad (10)$$

Thus the corresponding exchange constant is given by

$$E_{MA_n-HB} = \frac{[MA_{n-m}B][HA]^m}{[MA_n][HB]^m}. \quad (11)$$

In the present paper an investigation of a mixed complex of arsenic with dithizone and diethyldithiocarbamic acid is given as an example.

EXPERIMENTAL

Apparatus

Spectrophotometer. Zeiss (Jena).
Recording spectrophotometer. Unicam S.P. 800.
Scintillation counter. Well-type with NaI(Tl) crystal.
pH-Meter. Radiometer pHM-2, Copenhagen.

Reagents

Unless otherwise stated, all reagents were of analytical reagent grade.

Carbon tetrachloride. Twice distilled, and after the second distillation stored not longer than one day. The quality of the carbon tetrachloride affects considerably the stability of solutions of diethyldithiocarbamic acid.

Dithizone, (H_2Dz). Purified by solvent extraction with carbon tetrachloride in the usual way.[1,2]

The concentration of dithizone solution is adjusted to the required value before each series of experiments by dilution with freshly distilled carbon tetrachloride, and checked spectrophotometrically at 620 mμ (molar absorptivity 32,800).[1,2]

Silver dithizonate, [*AgHDz*]. An excess of 0·1*M* silver nitrate (5 ml) in 50 ml of 0·05*M* sulphuric acid is extracted with 50 ml of $10^{-4}M$ dithizone in carbon tetrachloride. The organic layer is separated, filtered, diluted to the required concentration and stored protected from light. This solution must be freshly prepared before each series of experiments and its concentration checked spectrophotometrically at 462 mμ (molar absorptivity 30,500).[1,2]

Zinc dithizonate [$Zn(HDz)_2$]. To 50 ml of $2 \times 10^{-3}M$ zinc sulphate, 10 ml of 0·1*M* ammonia–ammonium chloride buffer (pH 8–9) are added and the extraction with 50 ml of $10^{-3}M$ dithizone solution is carried out. The organic layer is separated, washed with the same buffer solution, filtered and stored in a dark bottle. The concentration of zinc dithizonate is measured spectrophotometrically at 538 mμ (molar absorptivity 96,000).[2] This solution is fairly stable.

Sodium diethyldithiocarbamate ($NaDDC.2H_2O$). Sodium diethyldithiocarbamate dihydrate (22·5 mg) is dissolved in 100 ml of doubly distilled water, to which 0·1 g of ammonium carbonate is added. The concentration of this solution is checked by precipitation with an excess of copper sulphate. The copper diethyldithiocarbamate precipitated in this way from 0·50 ml of the reagent solution is extracted with 10 ml of carbon tetrachloride and its absorbance measured at 436 mμ (molar absorptivity 13,000).[2]

Diethyldithiocarbamic acid (*HDDC*). To 50 ml of $10^{-3}M$ solution of sodium diethyldithiocarbamate, placed in a separating funnel, 50 ml of carbon tetrachloride are added. Then between shakings, 0·5*M* sulphuric acid is added dropwise until the pH is 2–3. The organic layer is separated, filtered and stored protected from light. This solution is unstable and must be freshly prepared before each experiment. The concentration of diethyldithiocarbamic acid is determined by shaking the reagent with an excess of copper sulphate solution and measuring the absorbance as described above.

Silver diethyldithiocarbamate (*AgDDC*). To 50 ml of $10^{-3}M$ solution of sodium diethyldithiocarbamate 5 ml of $10^{-1}M$ silver nitrate are added and the acidity is adjusted to pH 2–3. The white precipitate formed is extracted with 50 ml of carbon tetrachloride, filtered and stored in a dark bottle.

Zinc diethyldithiocarbamate [$Zn(DDC)_2$]. Prepared in a similar way to silver diethyldithiocarbamate. Its concentration is determined spectrophotometrically after its conversion into copper diethyldithiocarbamate.

Arsenic diethyldithiocarbamate [$As(DDC)_3$]. Prepared and standardised in the same way as zinc diethyldithiocarbamate.

Sodium arsenite, 0·05 *M*. Prepared by dissolving 2·4725 g of arsenic trioxide in 20 ml of 1*M* sodium hydroxide and adding 0·5*M* sulphuric acid until the solution is either neutral or only slightly alkaline. The solution is transferred to a standard flask and made up to 500 ml.

Radioarsenic, ^{76}As. Prepared by irradiation of 1·0 mg of arsenic trioxide in a nuclear reactor with a flux of 1×10^{12} neutrons cm^{-2} sec^{-1} for 24 hr. After dissolution in 1*M* sodium hydroxide and dilution with water it is used for tracer experiments. The specific activity of radioarsenic prepared in this way is very high. For this reason the amount of isotopic carrier in solutions of ^{76}As is always negligible compared to the amount of arsenic in a non-active solution to be labelled.

RESULTS AND DISCUSSION

Investigation of exchange reaction between AgHDz and HDDC.

The experiments were carried out as follows. To a certain amount of silver dithizonate various known amounts of diethyldithiocarbamic acid were added. The volume was made up to 10 ml with carbon tetrachloride. After mixing, dithizone and silver diethyldithiocarbamate are immediately formed according to equation (1). For calculation of the exchange constant $E_{AgHDz-HDDC}$, it is necessary to determine the equilibrium concentrations of all species involved [see equation (4)]. The equilibrium concentration of dithizone and silver dithizonate can be found by the mixed colour method when the absorbancies at 620 mμ and 426 mμ are measured. The equilibrium concentration of silver diethyldithiocarbamate can be easily found from the difference between the original and equilibrium concentrations of silver dithizonate:

$$[AgDDC] = [AgHDz]_{orig} - [AgHDz] = [H_2Dz]. \qquad (12)$$

Similarly, the equilibrium concentration of diethyldithiocarbamic acid is calculated from the equation:

$$[HDDC] = [HDDC]_{orig} - [AgDDC] = [HDDC]_{orig} - [H_2Dz]. \quad (13)$$

However, because of the large value of the equilibrium constant $E_{AgHDz-HDDC}$ practically all the diethyldithiocarbamic acid reacts with silver dithizonate forming an equivalent amount of dithizone and therefore the precision of the determination of the *remaining* diethyldithiocarbamic acid is very low. For this reason it is necessary to add to the reacting species a known amount of silver diethyldithiocarbamate, so that reaction (1) is shifted to the left and sufficient diethyldithiocarbamic acid remains in the solution to enable a more precise determination of the equilibrium constant to be made. The results obtained are summarised in Table I.

TABLE I.—DETERMINATION OF EQUILIBRIUM CONSTANT $E_{AgHDz-HDDC}$.

Log of original concentrations				Log of equilibrium concentrations				Log
[AgHDz]	[HDDC]	[AgDDC]	[H_2Dz]	[AgHDz]	[HDDC]	[AgDDC]	[H_2Dz]	$E_{AgHDz-HDDC}$
−4·41	−4·51	−3·30		−4·92	−5·37	−3·28	−4·57	2·44
−4·41	−4·69	−3·30		−4·69	−5·69	−3·29	−4·74	2·35
−4·41	−4·42	−3·87		−5·30	−5·48	−3·88	−4·45	2·45
−4·40	−4·42	−3·87		−5·35	−5·62	−3·88	−4·45	2·64
−4·40	−4·58	−3·87		−4·84	−6·40	−3·90	−4·59	2·50
		−3·30	−4·56	−5·32	−5·32	−3·31	−4·64	2·69
		−3·30	−4·68	−5·39	−5·39	−3·31	−4·78	2·69
		−3·30	−4·81	−5·48	−5·48	−3·31	−4·95	2·70
		−3·30	−4·90	−5·47	−5·47	−3·31	−5·04	2·59
		−3·30	−4·98	−5·55	−5·55	−3·31	−5·13	2·66
		−3·60	−4·81	−5·60	−5·60	−3·61	−4·87	2·72
		−3·60	−4·98	−5·60	−5·60	−3·61	−5·06	2·53
		−4·00	−4·65	−5·72	−5·72	−4·01	−4·68	2·75
		−4·30	−4·54	−5·70	−5·70	−4·32	−4·57	2·51
		−4·52	−4·54	−5·83	−5·83	−4·54	−4·57	2·55
							Average =	2·58 ± 0·03

The equilibrium constant $E_{AgHDz-HDDC}$ can also be measured by investigation of the exchange reaction of the products, *i.e.*, by mixing silver diethyldithiocarbamate and dithizone. The equilibrium concentrations of silver dithizonate and dithizone are determined by the mixed colour method, and of silver diethyldithiocarbamate and diethyldithiocarbamic acid by calculation from the relationships

$$[AgDDC] = [AgDDC]_{orig} - [AgHDz] \quad (14)$$

$$[HDDC] = [AgDDC]_{orig} - [AgDDC] = [AgHDz]. \quad (15)$$

The results obtained in this way are in good agreement with those obtained by the investigation of the reverse reaction (see Table I).

The mean value of log $E_{AgHDz-HDDC}$ is 2·58 ± 0·03. If the log of the extraction constant of silver dithizonate is taken to be 8·94,[2] the log of the extraction constant of silver diethyldithiocarbamate according to equation (4) is 8·94 + 2·58 = 11·52 (solvent carbon tetrachloride). It is interesting to note that the value of the log of this constant calculated from Still's data[3] is 12 (chloroform as solvent).

Investigation of exchange reaction between ZnHDz and HDDC

This investigation was carried out in a way similar to that described for silver. Equilibrium concentrations of zinc dithizonate and dithizone were determined by the mixed colour method from the absorbances measured at 538 mμ and 620 mμ; equilibrium concentrations of zinc diethyldithiocarbamate and diethyldithiocarbamic acid were calculated from

$$[Zn(DDC)_2] = [Zn(HDz)_2]_{orig} - [Zn(HDz)] = 0{\cdot}5[H_2Dz] \quad (16)$$

$$[HDDC] = [HDDC]_{orig} - 2[Zn(DDC)_2] = [HDDC]_{orig} - [H_2Dz]. \quad (17)$$

The reversibility of this reaction has been studied by mixing zinc diethyldithiocarbamate with dithizone. The rate of this reaction is very high; equilibrium is reached in

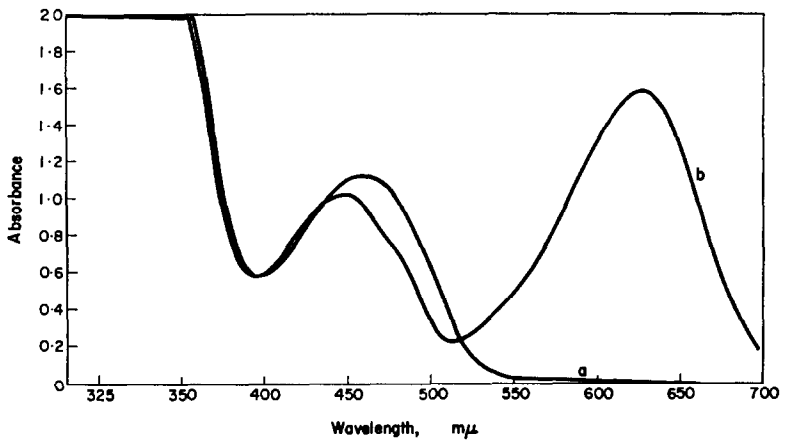

FIG. 1.—Absorption spectra of arsenic dithizonate–diethyldithiocarbamate (AsDzDDC) and of dithizone (H_2Dz) liberated from this complex.
Path-length, 1·00 cm; carbon tetrachloride used as solvent and reference sample.
Curve *a*—AsDzDDC, curve *b*—H_2Dz.

a few seconds. From the results summarised in Table II it can be seen that reaction (2) is fully reversible, for the values of the exchange constant do not depend on the way in which the equilibrium has been reached.

The mean value of log $E_{Zn(HDz)_2-HDDC}$ is 0·24 ± 0·03, so the log of the extraction constant of zinc diethyldithiocarbamate is 2·54 (assuming that log $K_{Zn(HDz)_2} = 2{\cdot}3$).[2] The value of log $K_{Zn(DDC)_2}$ determined by solvent extraction is 2·95.[4]

Investigation of exchange reaction between As(DDC)$_3$ and H_2Dz

The examples above deal with the investigation of metal dithizonates and diethyldithiocarbamates of which the properties are known. However, it is interesting to investigate an exchange reaction the products of which might include a complex not previously described. We have investigated a reaction between arsenic diethyldithiocarbamate and dithizone in carbon tetrachloride. It has been observed that a yellow complex is formed as a result of this reaction. The spectrum of this complex was measured after the excess of dithizone had been removed by washing with ammonia–ammonium chloride buffer, pH ~ 9·5 (Fig. 1, Curve a). It differs from the spectra

of all known dithizonates and decomposition products of dithizone. The complex is fairly stable and can be stored for several days. It was also found that Beer's law is obeyed over the range 0–5 $\times$ $10^{-5}M$ (at 460 mμ).

Further, the behaviour of this complex, when shaken with an aqueous phase, has been studied spectrophotometrically at 400 mμ (Fig. 2). At pH lower than 4·5 the complex is destroyed and the green colour of liberated dithizone appears (Fig. 1,

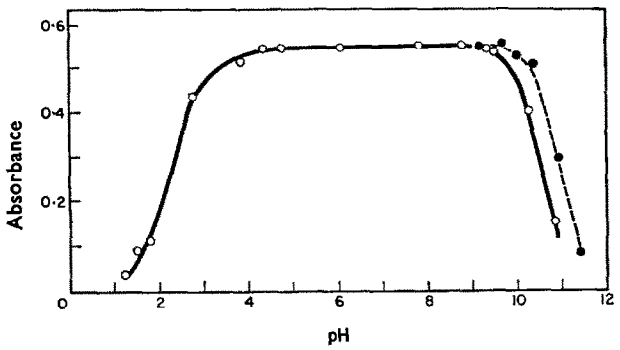

FIG. 2.—Decomposition of 2·5 $\times$ $10^{-5}M$ AsDzDDC when shaken with an aqueous solution at various pH values.
Time of shaking: 2 min (full line), 15 sec (dotted line). At pH > 7; 1 ml of 0·05M KCN present.

curve b). The complex can also be destroyed by hydrogen sulphide (yellow As_2S_3 is precipitated) or by an excess of diethyldithiocarbamic acid in carbon tetrachloride. These observations have been verified by means of radioarsenic as a tracer.

From the amount of arsenic originally present in the yellow complex (determined by measuring its radioactivity) and from the amount of dithizone liberated by shaking with 1M sulphuric acid it has been found that the ratio between arsenic and dithizone is 1:1.

From these experiments it follows that the composition of the complex formed is either As(HDz)$(DDC)_2$ or AsDzDDC. However, if a primary dithizonate [such as Ag(HDz), In$(HDz)_3$, *etc.*] is added to arsenic diethyldithiocarbamate, free dithizone is always liberated, which can only be explained by the formation of a complex AsDzDDC.

To check this statement the reaction

$$As(DDC)_3 + H_2Dz = AsDzDDC + 2HDDC \qquad (18)$$

was investigated and the value of the exchange constant

$$E_{As(DDC)_3-H_2Dz} = \frac{[AsDzDDC][HDDC]^2}{[As(DDC)_3][H_2Dz]} \qquad (19)$$

has been calculated. In this case, the equilibrium concentration of dithizone was spectrophotometrically determined at 620 mμ. Other equilibrium concentrations of species involved were determined from the original concentrations of arsenic

diethyldithiocarbamate and dithizone according to the equations

$$[\text{AsDzDDC}] = [\text{H}_2\text{Dz}]_{\text{orig}} - [\text{H}_2\text{Dz}] \tag{20}$$

$$[\text{HDDC}] = 2[\text{AsDzDDC}] \tag{21}$$

$$[\text{As(DDC)}_3] = [\text{As(DDC)}_3]_{\text{orig}} - [\text{AsDzDDC}]. \tag{22}$$

It was found that it takes 2–4 min to reach equilibrium, after mixing of arsenic diethyldithiocarbamate and dithizone.

From Table III, it can be seen that $\log E_{\text{As(DDC)}_3\text{–H}_2\text{Dz}}$ is $-7{\cdot}93 \pm 0{\cdot}06$. This value is not as precise as the values for $\log E_{\text{AgHDz–HDDC}}$ and $\log E_{\text{Zn(HDz)}_2\text{–HDDC}}$

TABLE III.—DETERMINATION OF EQUILIBRIUM CONSTANT $E_{\text{As(DDC)}_3\text{–H}_2\text{Dz}}$

Log of original concentration		Log of equilibrium concentrations				Log
[As(DDC)$_3$]	[H$_2$Dz]	[As(DDC)$_3$]	[H$_2$Dz]	[AsDzDDC]	[HDDC]	$E_{\text{As(DDC)}_3\text{–H}_2\text{Dz}}$
−4·78	−4·76	−4·81	−4·78	−6·05	−5·75	−7·96
−4·48	−4·76	−4·50	−4·79	−5·89	−5·59	−7·78
−4·18	−4·82	−4·19	−4·87	−5·85	−5·55	−7·89
−4·00	−4·82	−4·01	−4·88	−5·72	−5·42	−7·67
−4·00	−4·76	−4·01	−4·81	−5·73	−5·43	−7·77
−3·88	−4·89	−3·89	−4·96	−5·72	−5·42	−7·71
−3·78	−5·21	−3·78	−5·30	−5·93	−5·63	−8·11
−3·78	−4·89	−3·79	−4·94	−5·82	−5·52	−8·13
−3·78	−4·77	−3·78	−4·81	−5·80	−5·50	−8·21
−3·78	−4·67	−3·78	−4·81	−5·74	−5·44	−8·03
					Average =	$-7{\cdot}93 \pm 0{\cdot}06$

because during the time of equilibration some diethyldithiocarbamic acid may be decomposed. To confirm the value of this constant, the exchange reaction

$$\text{As(DDC)}_3 + 2\text{AgHDz} = \text{AsDzDDC} + 2\text{AgDDC} + \text{H}_2\text{Dz} \tag{23}$$

was studied to determine the value of

$$E_{\text{As(DDC)}_3\text{–AgHDz}} = \frac{[\text{AsDzDDC}][\text{AgDDC}]^2[\text{H}_2\text{Dz}]}{[\text{As(DDC)}_3][\text{AgHDz}]^2}. \tag{24}$$

This equilibrium is also reached in 2–4 min from mixing of the reactants. From the concentration of dithizone liberated the equilibrium concentrations of other species involved can be calculated as follows:

$$[\text{AsDzDDC}] = [\text{H}_2\text{Dz}] \tag{25}$$

$$[\text{AgDDC}] = 2[\text{H}_2\text{Dz}] \tag{26}$$

$$[\text{As(DDC)}_3] = [\text{As(DDC)}_3]_{\text{orig}} - [\text{AsDzDDC}] \tag{27}$$

$$[\text{AgHDz}] = [\text{AgHDz}]_{\text{orig}} - [\text{AgDDC}]. \tag{28}$$

The mean value of $\log E_{As(DDC)_3-AgHDz}$ is $-2{\cdot}97 \pm 0{\cdot}03$ (see Table IV). From equations (4), (19) and (24) it can be seen that

$$\log E_{As(DDC)_3-AgHDz} = 2 \log E_{AgHDz-HDDC} + \log E_{As(DDC)_3-H_2Dz}$$

$$= 5{\cdot}16 - 7{\cdot}93 = -2{\cdot}77$$

which is in very good agreement with the value $-2{\cdot}97$ found from the reaction of arsenic diethyldithiocarbamate and dithizone.

Spectrophotometric determination of small amounts of arsenic

These experiments suggest a method for the spectrophotometric determination of arsenic. The value of $E_{As(DDC)_3-AgHDz}$ is such that arsenic diethyldithiocarbamate is quantitatively transformed into the complex AsDzDDC even when only a tenfold excess of silver dithizonate is used. Obviously two possibilities exist for the determination of arsenic in this way [equation (23)]: (1) measurement of the absorbance of the complex AsDzDDC at 450 mμ, (2) measurement of the absorbance of dithizone liberated at 620 mμ. When the absorbance of AsDzDDC is measured the excess of silver dithizonate as well as the dithizone liberated must be removed. For this reason the second approach was chosen. The principle is very simple: arsenic(III) is quantitatively extracted as diethyldithiocarbamate at a pH lower than 5,[5] and then allowed to react with silver dithizonate with the quantitative release of dithizone [equations (1) and (23)]. At pH lower than 2–3, diethyldithiocarbamic acid in the aqueous phase, which would also displace dithizon, is immediately destroyed, whilst arsenic diethyldithiocarbamate is unaffected. To increase the selectivity, metals forming extractable diethyldithiocarbamates or dithizonates could be removed by a preliminary extraction at pH > 8, at which arsenic(III) is not extracted.

Procedure

Place a neutral or slightly acid solution (volume 10–20 ml), containing the arsenic(III) to be determined (0–40 μg As) in a 50 ml separating funnel. Add 1 ml of 0·1*M* ammonium acetate followed by 1 ml of $4 \times 10^{-3}M$ sodium diethyldithiocarbamate solution. Shake for a few sec, then add 5 ml of 0·1*N* sulphuric acid and shake again. Allow to stand for 60 sec (to destroy excess of diethyldithiocarbamic acid) then add 10·0 ml of carbon tetrachloride and extract for 3 min. To a suitable aliquot of extract (6·00 ml) add 4·00 ml of freshly prepared silver dithizonate ($2 \times 10^{-4}M$) in carbon tetrachloride. Measure the amount of dithizone liberated, at 620 mμ. The colour is developed after 3 min and is stable for at least 10 min.

Theoretically 1 μg of arsenic liberates $1{\cdot}4 \times 10^{-6}$ mole of dithizone the absorbance of which in a 1·00 cm cell is 0·460 (volume 1 ml). However, in practice a suitable aliquot of organic layer must be taken and further diluted with colour forming reagent (silver dithizonate), and it is preferable to use a calibration curve

CONCLUSION

A study of exchange equilibria between metal dithizonates and diethyldithiocarbamates has been made to show that such exchanges take place and that they can be explained. Generally the rates of reaching equilibrium are very high, probably because of the lack of solvolysis and solvation in the non-polar organic solvents used. Very good experimental reproducibility has been observed in all cases.

These properties are valuable analytically and an attempt has been made to show the potentialities of the method; a procedure for the spectrophotometric determination of small amounts of arsenic has been proposed. Its sensitivity is high, and to judge from the known properties of metal dithizonates and diethyldithiocarbamates[2] it is likely to be highly selective. Investigations to assess its practical worth are under way.

In the present study an exchange between metal chelates with the same functional groups (—SH) is described, but exchange between chelates containing different functional groups (*e.g.*, dithizonates—cupferrates) will be probably more valuable analytically, and will also be investigated in our laboratory. It is hoped that exchange of chelates in the organic phase will contribute not only to the study of solvent extraction and composition of metal chelates but also to development of selective spectrophotometric and titrimetric procedures.

Zusammenfassung—Durch organische Lösungsmittel aus wäßriger Phase extrahierte Metallchelate können mit in dem selben Lösungsmittel gelösten anderen Chelatbildnern (oder deren Metallchelaten) reagieren. Dieser Austausch von Metallchelaten in organischer Phase kann verwendet werden (1) zur Ermittlung der Lage des Austauschgleichgewichts und der Zusammensetzung der geblideten Metallchelate; (2) zur Bestimmung von Extraktionskonstanten; (3) zur Darstellung neuer in organischen Lösungsmitteln löslicher Inner-Komplexe; (4) zur spektrophotometrischen Bestimmung kleiner Metallmengen. Theorie und experimentelle Realisierung des Phänomens werden mitgeteilt. Die Extraktionskonstanten der Diäthyldithiocarbamate von Silber und Zink in Tetrachlorkohlenstoff wurden über die Extraktionskonstanten der Dithizonate bestimmt. Ein gemischter Komplex von Arsen(III) mit Dithizon und Diäthyldithiocarbaminsäure wurde dargestellt und seine Eigenschaften untersucht. Eine einfache Methode zur spektrophotometrischen Bestimmung von Mikrogrammengen Arsen wird vorgeschlagen.

Résumé—Des chélates métalliques, extraits d'une phase aqueuse par des solvants organiques, peuvent réagir avec d'autres agents chélatants (ou leurs chélates métalliques) dissous dans le même solvant. Cet échange de chélates métalliques dans la phase organique peut être utilisé pour (1) l'étude de l'équilibre d'échange et de la composition des

chélates métalliques formés, (2) la détermination des constantes d'extraction, (3) la préparation de nouveaux complexes internes solubles en solvants organiques et (4) le dosage spectrophotométrique de petites quantités de métaux. On donne la théorie et la vérification expérimentale de ce phénomène. On a déterminé les constantes d'extraction des diéthyldithiocarbamates d'argent et de zinc en tétrachlorure de carbone au moyen des constantes d'extraction des dithizonates correspondants. On a préparé un complexe mixte d'arsenic(III) avec la dithizone et l'acide diéthyldithiocarbamique et étudié ses propriétes. On propose une méthode simple pour le dosage spectrophotométrique de quantités d'arsenic de l'ordre du microgramme.

SPECTROPHOTOMETRIC DETERMINATION OF HEXAFLUOROARSENATE WITH FERROIN

VERNON S. ARCHER and FRANKLIN G. DOOLITTLE
Department of Chemistry, University of Wyoming, Laramie, Wyoming, U.S.A.

(*Received* 8 *March* 1967. *Accepted* 2 *April* 1967)

Summary—A spectrophotometric method for the hexafluoroarsenate anion is described. The determination involves selective extraction of the tris(1,10-phenanthroline)iron(II) salt of the anion into n-butyronitrile, followed by measurement of the absorbance of the organic layer. The extracts give good Beer's law plots over a wide range of concentrations and more than 98% of the hexafluoroarsenate is removed in a single extraction. Interference studies were made on a number of anions.

HEXAFLUOROARSENATE is one anion for which very few analytical methods have been developed. Lange and Müller[1] erroneously thought they had synthesized this anion and indicated that it could be precipitated as nitron (4,5-dihydro-1,4-diphenyl-3,5-phenylimino-1,2,4-triazole) hexafluoroarsenate monohydrate. In the process of a study of complex fluoroarsenates, Dess and Parry[2] showed that the actual anionic species produced by Lange and Müller was the $[AsF_5OH^-]$ ion and that nitron precipitated this anion as the unhydrated salt. These investigators also produced the hexafluoroarsenate ion and found that it was quite hydrolytically stable, in contrast to the $[AsF_5OH^-]$ anion. Dess[3] established that the hexafluoroarsenate ion was precipitated by nitron or tetraphenylarsonium chloride and that the corresponding salts were both useful for gravimetric determinations. He found, however, that the physical properties of the tetraphenylarsonium salt were more suitable for analytical application, and developed a gravimetric method for hexafluoroarsenate, utilizing tetraphenylarsonium chloride. This method appeared to give good results and is so far the only fully developed analytical method for this anion.

Ferroin [tris(1,10-phenanthroline)iron(II)sulphate] has been used previously as a spectrophotometric reagent for the determination of perchlorate[4] and hexafluorophosphate.[5] The present spectrophotometric method for hexafluoroarsenate is similar to the method for hexafluorophosphate. It entails the extraction of tris(1,10-phenanthroline)iron(II) hexafluoroarsenate with n-butyronitrile followed by measurement of the absorbance of the organic layer as a function of the amount of hexafluoroarsenate present in the aqueous layer.

EXPERIMENTAL

Reagents

A 0·01*M* solution of ferroin was prepared from iron(II) sulphate and 1,10-phenanthroline. A standard solution of $2{\cdot}784 \times 10^{-3}M$ potassium hexafluoroarsenate was prepared from $KAsF_6$ previously analysed by precipitation with tetraphenylarsonium chloride according to a procedure developed in this laboratory. Tetraphenylarsonium chloride was obtained from the G. F. Smith Chemical Co. of Columbus, Ohio. n-Butyronitrile was obtained from Eastman Organic Chemicals and was used without purification.

Procedure for calibration curve

Portions of 0·200–2·000 ml of the hexafluoroarsenate solution were added to 15-ml glass-stoppered centrifuge tubes and diluted with water to 2·000 ml. Then 1 ml of ferroin solution and 5·000 ml of n-butyronitrile were added to each, and the mixtures were shaken vigorously for 2 min and then centrifuged for 2 min to separate the layers. A 1-ml aliquot of each upper (organic) layer was taken and diluted to volume with n-butyronitrile in a 5-ml volumetric flask. The transmittance of this solution was measured immediately in a 1-cm cell against pure n-butyronitrile at 505 mμ on a Beckman DU spectrophotometer with a 0·1-mm slit-width. The transmittances were converted into absorbances which were tabulated and plotted *vs.* mmoles of potassium hexafluoroarsenate present. Unknowns may be determined by applying a similar procedure and reading off the concentration from the calibration curve. In the presence of mild interferences, the standard plot should be run with amounts of the interfering ions equal to those present in the unknown solution, or the method of standard additions could be used.

Development of method

Standardisation of the potassium hexafluoroarsenate. Take 10 ml of a solution containing from 0·04 to 0·06 g of the salt, add 10 ml of water and 1 ml of 5*M* ammonium chloride. Slowly add, with stirring, 5 ml of 0·09*M* tetraphenylarsonium chloride. Heat on a hot-plate until the precipitate flocculates. Cool to room temperature, filter off on a sintered glass crucible, and wash with 40–50 ml of 0·001*M* hydrochloric acid. Dry to constant weight at 105° and weigh as $(C_6H_5)_4As_3F_6$.

Effect of pH. The effect of pH on the extraction was determined by performing the extraction of the hexafluoroarsenate anion from a series of aqueous solutions buffered in the range pH 2·2–10·6.

Anion interference studies. A series of anions was tested for possible interference with the experimental method by adding 1 ml of 0·20*M* solution of a sodium, potassium or ammonium salt of the anion to 1 ml of $2·784 \times 10^{-3}$*M* hexafluoroarsenate and applying the extraction procedure. Fluoride, which did not interfere when present in the amount stated, was tested for interference at higher concentrations.

Stability studies on the extracts. Extractions were made on a series of hexafluoroarsenate solutions in the usual way, after which the absorbances were measured as a function of time over a 24-hr period.

Exhaustive extractions. Two ml of hexafluoroarsenate solution mixed with 1 ml of ferroin were extracted with four successive 5·00-ml portions of n-butyronitrile. The organic extracts were combined and diluted to volume with n-butyronitrile in a 25-ml volumetric flask, and the absorbance of this solution was measured.

RESULTS AND DISCUSSION

Data from the gravimetric standardisation of the hexafluoroarsenate with tetraphenylarsonium chloride are given in Table I. The relative precision of the method is shown because this information has not previously appeared in the literature.

TABLE I.—GRAVIMETRIC STANDARDISATION OF THE $KAsF_6$ SAMPLE WITH TETRAPHENYLARSONIUM CHLORIDE

$KAsF_6$ taken, *g*	No. of determinations	Mean $(C_6H_5)_4AsAsF_6$, *g*	Mean AsF_6^-, %	Relative standard deviation, %
0·04604	3	0·1157	$82·9_0$	$0·5_2$
0·04656	3	0·1168	$82·8_1$	$0·3_4$
0·04270	3	0·1074	$83·0_3$	$0·3_7$
0·03917	3	0·0983	$82·8_5$	$0·2_0$
0·05218	3	0·1311	$82·9_4$	$0·0_8$
0·04158	3	0·1045	$82·9_7$	$0·1_9$

Overall mean AsF_6^- = 82·93%; theoretical AsF_6^- in $KAsF_6$ = 82·85%.

It was found that the spectrophotometric method gives good Beer's law plots over the range of hexafluoroarsenate concentrations used. Based on a least-squares analysis of the data, the slope of the calibration line was found to be 229 $mmole^{-1}.\ cm^{-1}$ with a standard deviation of 1·44 $mmole^{-1}.cm^{-1}$. It was found from the exhaustive extractions (see Table II) that a single extraction removes approximately 98% of the hexafluoroarsenate from the aqueous layer. The rate of fading of the colour is also shown

TABLE II.—ABSORBANCES OBTAINED FOR SINGLE EXTRACTION, EXHAUSTIVE EXTRACTION, AND STABILITY STUDY ON EXTRACTS

$KAsF_6$ μmole	Absorbances					
	Single extraction*	Exhaustive extraction*	Measured after			
			2 hr	5 hr	10 hr	24 hr
0·5568	—	0·138	—	—	—	—
1·392	0·315	0·335	0·285	0·267	0·249	0·245

5·568	1·28	1·30	1·25	1·23	1·22	1·21

* The dilution factors are the same, so the absorbances are directly comparable.

TABLE III.—ANION INTERFERENCES

Compound used	Effect
Ammonium acetate	negative
Sodium carbonate	negative
Ammonium chloride	negative
Potassium chromate	negative
Sodium dihydrogen phosphate	lowered absorbance slightly
Potassium ferricyanide	lowered absorbance slightly
Potassium fluoride	negative
Sodium hydrogen phosphate	negative
Potassium iodate	negative
Sodium monofluorophosphate	negative
Sodium phosphate	very slight extraction
Sodium sulphate	negative
Sodium sulphite	negative
Sodium potassium tartrate	negative
Sodium oxalate	negative

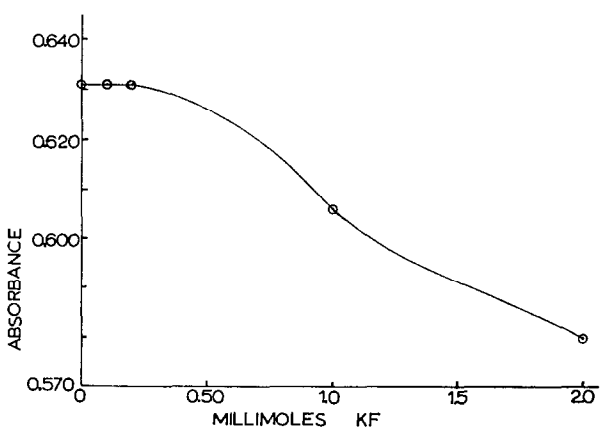

FIG. 1.—Effect of KF on the spectrophotometric method.

in Table II. From these results it would seem imperative that the extractions and measurements be made over a short period of time. It was found that pH variations between 2·2 and 10·6 had essentially no effect on the results. Data from the anion interference study are shown in Table III. As can be seen from Fig. 1, fluoride does not interfere until present in amounts greater than 0·20 mmoles.

This amount compares favourably with other spectrophotometric methods in terms of sensitivity, reproducibility and adherence to Beer's law. This method using potassium hexafluoroarsenate, standardised by the given gravimetric method, as a secondary standard, should prove to be a very reliable and fast method for routine analyses of hexafluoroarsenate.

Acknowledgement—The potassium hexafluoroarsenate used in this work was donated by the Ozark-Mahoning Co., Tulsa, Oklahoma, U.S.A.

Zusammenfassung—Eine spektrophotometrische Methode zur Bestimmung des Hexafluoroarsenat-Anions wird beschrieben. Bei dem Verfahren wird das Tris(1,10-phenanthrolin)eisen(II)- Salz des Anions in *n*-Butyronitril extrahiert und die Extinktion der organischen Schicht gemessen. Die Extrakte geben gut lineare Extinktions-Konzentrations-diagramme in einem weiten Konzentrationsbereich und mehr als 98% des Hexafluoroarsenats werden bei einer Extraktion erfaßt. Störuntersuchungen wurden en einer Anzahl von Anionen gemacht.

Résumé—On décrit une méthode spectrophotométrique pour l'anion hexafluoroarséniate. Le dosage comprend une extraction sélective du sel tris(1,10-phénanthroline) fer(II) de l'anion en *n*-butyronitrile, suivie de la mesure de l'absorption de la couche organique. Les extraits donnent des tracés suivant bien la loi de Beer dans un large domaine de concentrations, et l'on extrait plus de 98% de l'hexafluoroarséniate en une seule extraction. Des études d'interférence ont été effectuées pour un certain nombre d'anions.

POLAROGRAPHIC STUDY OF INHIBITORS AND CATALYSTS FOR THE REACTION OF DISSOLVED OXYGEN WITH SULPHITE ION

YECHESKEL ISRAEL, AVRAHAM VROMEN and BRUNO PASCHKES
Israel Mining Industries, Institute for Research and Development P.O. Box 313, Haifa, Israel

(*Received* 13 *February* 1967. *Accepted* 21 *March* 1967)

Summary—Oxygen reduction waves are utilized to determine the inhibition effect of some reagents commonly added in polarographic work, on the reaction of dissolved oxygen with sodium sulphite in neutral and alkaline supporting electrolytes. Alkali metal hydroxides, EDTA, TEA, ethanol and methyl cellosolve inhibited the reaction to various extents. In this work, it appeared that some metallic ions, such as cobalt(II) and manganese(II) can catalyse the oxygen–sulphite reaction, enabling wider application to be made of sodium sulphite for de-oxygenation of neutral and alkaline supporting electrolytes containing inhibitors.

DISSOLVED oxygen gives two reduction waves at the dropping mercury electrode. The first corresponds to the reduction of oxygen to hydrogen peroxide and the second to its reduction to water or hydroxyl ion. Inert gas, *i.e.*, nitrogen, hydrogen or helium, is bubbled into solutions to displace dissolved oxygen and eliminate its interference in polarographic determinations. Sodium sulphite has found use in routine polarographic determinations, by virtue of its ability to remove dissolved oxygen from neutral and alkaline supporting electrolytes. When theoretical studies are involved, the use of sodium sulphite is undesirable, mainly because of its formation of metallic complexes and its reactivity towards some organic compounds. Its limited use in routine analysis stems, however, from the slow rate of absorption of oxygen under the influence of inhibitors.

Lingane[1] has reported that the oxygen–sulphite reaction is so slow in sodium hydroxide solutions containing plumbite ion, that sulphite ion cannot be used to remove dissolved oxygen. Israel and Vromen[2] observed in the course of determination of silver(I) that potassium cyanide in copper-free ammoniacal solution depolarized the dropping mercury electrode in the presence of sodium sulphite. They recommended the addition of 0·1 g of copper ion to each l. of solution, while keeping cyanide present in excess, to obviate this interference. Meites[3] and Stackelberg[4] emphasized the catalytic effect of copper ion on the oxygen–sulphite reaction. Zuman[5] did not recommend the use of sodium sulphite for de-aeration of solutions in organic polarographic determinations since sulphite is reactive towards many organic compounds and may interfere in their determination. Stackelberg[4] mentioned that organic compounds often slow down the rate of the oxygen–sulphite reaction. In organic determinations such as of azobenzene and dipicrylamine[6], sodium sulphite was not suitable because it tended to react slowly with dissolved oxygen in the presence of organic constituents. This became evident when catalysts were introduced.

The present work demonstrates the use of oxygen reduction waves at the dropping mercury electrode for the rapid study of the effect of various inhibitors and catalysts on the oxygen–sulphite reaction. The inhibitors chosen were those commonly used in polarographic determinations, such as triethanolamine (TEA), EDTA, ethanol and alkali hydroxides. The catalysts were ions that interfere the least in polarographic determinations, such as cobalt(II) and manganese(II). For this reason other known metallic oxygen-carriers, such as iron(II) and copper(II), were not included in this work in spite of their evident effectiveness in catalysing the oxygen–sulphite reaction. Although the knowledge obtained in this study, and in the chronoamperometric study that follows,[7] is particularly applicable to polarography, it may be used for the broader aspects of this reaction in commercial processes, where either inhibition or catalysis of reactions may be desirable.[8]

EXPERIMENTAL

Apparatus

A Radiometer type PO4 recording polarograph was used, with the cell supplied. A separate saturated calomel electrode was connected to the main cell compartment by an agar-saturated potassium chloride bridge. When necessary, deoxygenation was effected by bubbling nitrogen into the solution through a capillary which could be raised during measurements. For more efficient de-oxygenation with nitrogen, a modified H-cell with fritted glass cylinder[9] was employed.

Reagents

Analytical grade reagents were used. High purity nitrogen was freed from traces of oxygen by passage through a solution of chromium(II) in dilute sulphuric acid containing an excess of amalgamated zinc. Mercury was cleaned by "pin-holing" (passing it through a pin-hole in a filter paper) and by bubbling air through it for a few days after covering it with 10% nitric acid, followed by washing, degreasing, pin-holing and drying.[10]

The following reagent solutions were prepared: (1) cobalt(II) nitrate solution: 5·0 g/l; (2) manganese(II) sulphate: 5·2 g/l; (3) sodium sulphite: 250 g/l, freshly prepared every week; (4) sodium hydroxide: 2*F*; (5) ammonium hydroxide–ammonium chloride: 2*F* in each; (6) potassium chloride: 2*F*. Triethanolamine (TEA) and the disodium salt of ethylenediaminetetra-acetic acid (EDTA), were added by weighing the required amounts.

RESULTS AND CONCLUSIONS

Polarograms of 1*F* ammonia–ammonium chloride supporting electrolyte, obtained after de-oxygenation with sodium sulphite or by bubbling purified nitrogen, indicated that sodium sulphite was efficient in eliminating dissolved oxygen. Current measurements, at the plateau of the first oxygen reduction wave, −0·3 V *vs.* S.C.E., were lowest, *ca.* 0·032 μA (anodic), when solutions containing 26 g of sodium sulphite per l. were examined. After prolonged bubbling of purified nitrogen through the supporting electrolyte in the modified H-cell with a fritted glass cylinder, the anodic current obtained was *ca.* 0·011 μA. Less efficient de-oxygenation was obtained when a capillary was used for bubbling nitrogen.

Polarogram *a* in Fig. 1, depicts oxygen reduction waves in 1*F* sodium hydroxide supporting electrolyte. The addition of 25 g of sodium sulphite per l. to the same supporting electrolyte did not eliminate the reaction waves of dissolved oxygen (polarogram *b* Fig. 1). The first reduction wave decreased, which is an indication of partial de-oxygenation. The dip that occurs at *ca.* −1·0 V *vs.* S.C.E., is a familiar phenomenon,[11] resulting from partial blocking of the surface of the electrode by adsorptive constituents and, depending on the extent of coverage, renders the electrode surface unavailable for the reduction of active depolarizers (oxygen in this instance).

At a more negative potential, desorption follows, the dip disappears and the whole surface becomes available for reduction, and therefore the plateau of the second wave of polarogram *b* represents the normal sum of the two reduction waves of dissolved oxygen. Polarogram *c* depicts the behaviour of the solution of polarogram *b* to which an amount of cobalt(II) corresponding to 0·05 g/l was added. Cobalt(II) obviates the inhibition effect of sodium hydroxide medium on the oxygen–sulphite reaction,

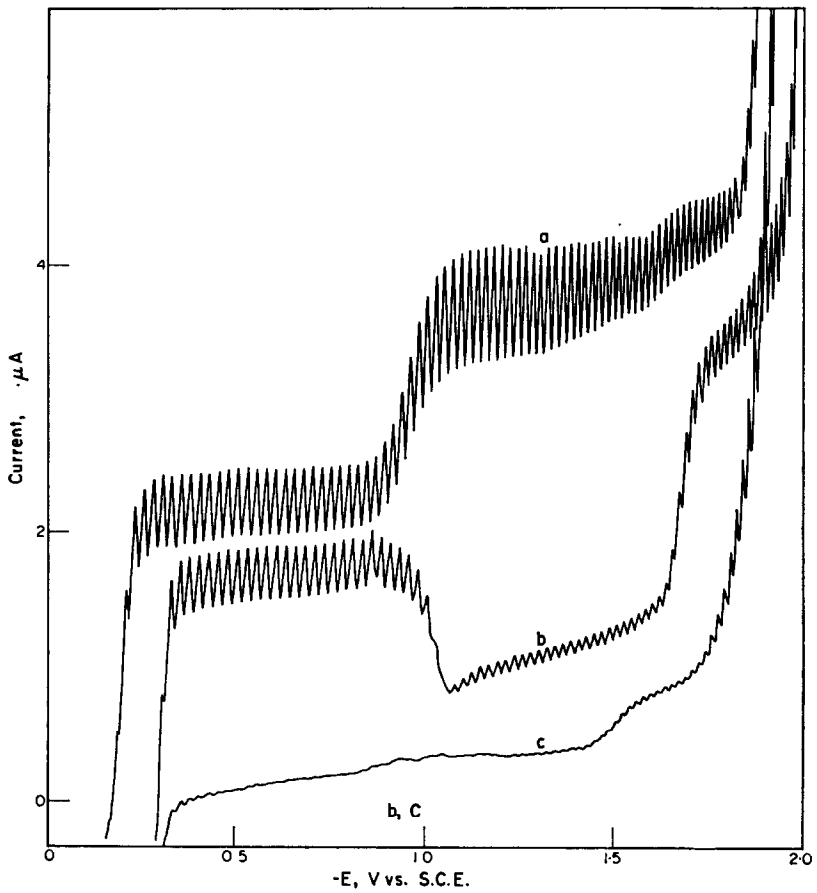

FIG. 1.—Polarograms of 1*F* NaOH and 0·005% gelatin supporting electrolyte, containing: (a) no addition; (b) 25 g/l Na_2SO_3; (c) 25 g/l Na_2SO_3 and 0·05 g/l Co(II).

irrespective of the tendency of cobalt to precipitate in this medium. Other alkali hydroxides, such as lithium or potassium hydroxides, display essentially the same behaviour as sodium hydroxide.

Some common solvents, such as ethanol and methyl cellosolve, inhibit the oxygen–sulphite reaction to some extent. Figure 2 depicts the behaviour of 1*F* potassium chloride in 30% v/v ethanol. The total diffusion current of both oxygen reduction waves displays an increase of 50% over that in polarogram *a* in Fig. 1. This is a reflection of increased oxygen solubility in aqueous ethanol medium and also of the increase of the rate of diffusion due to the low viscosity of potassium chloride in

aqueous ethanol, as compared to aqueous sodium hydroxide solution. When the solution also contained 25 g of sodium sulphite per l., substantial but incomplete de-oxygenation occurred (polarogram *b*). Further de-oxygenation was observed in polarogram *c* upon addition of 0·05 g of cobalt(II) per l., and bubbling nitrogen into the solution did not alter the shape of polarogram *c*. The appearance of a reduction

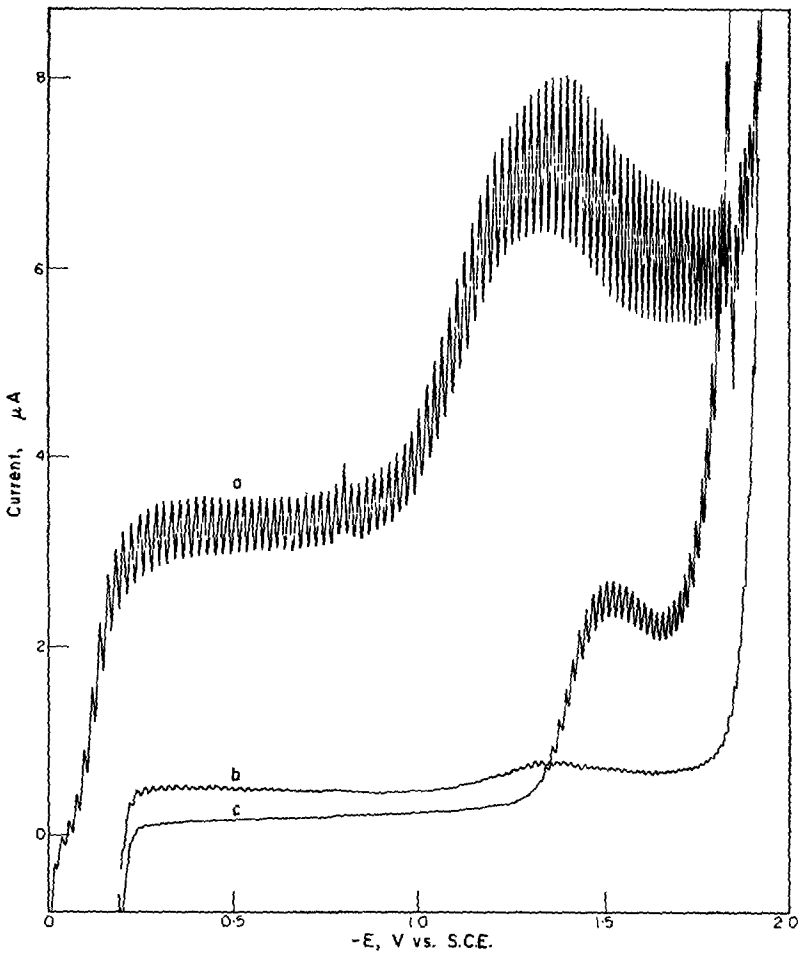

FIG. 2.—Polarograms of 1*F* KCl in 30% v/v ethanol–water supporting electrolyte, containing: (a) no addition; (b) 25 g/l Na_2SO_3; (c) 25 g/l Na_2SO_3 and 0·05 g/l Co(II).

wave at −1·4 V *vs.* S.C.E. was due to the reduction of cobalt(II). No inhibition of the oxygen–sulphite reaction was observed when 1*F* potassium chloride in aqueous solution or in 30% v/v acetone was employed.

The inhibition effect of EDTA is exhibited in Fig. 3. Polarogram *a*, obtained in 1*F* ammonia–ammonium chloride supporting electrolyte containing 0·01*F* EDTA, displays two oxygen reduction waves. Polarogram *b* was obtained after the inclusion of 25 g of sodium sulphite per l. Partial de-oxygenation of the solution occurred, but the distinct difference in magnitude of current of the two reduction waves demands

further elucidation. The oxidation of inhibitors in the presence of sodium sulphite has been reported in the literature,[8,12] and may lead to the formation of free hydrogen peroxide, thus increasing the second reduction wave of oxygen. A less probable explanation could be the formation of a reducible product of the inhibitor contributing to the second wave alone. When 0·05 g of cobalt(II) per l. was also included, complete de-oxygenation resulted (polarogram *c*).

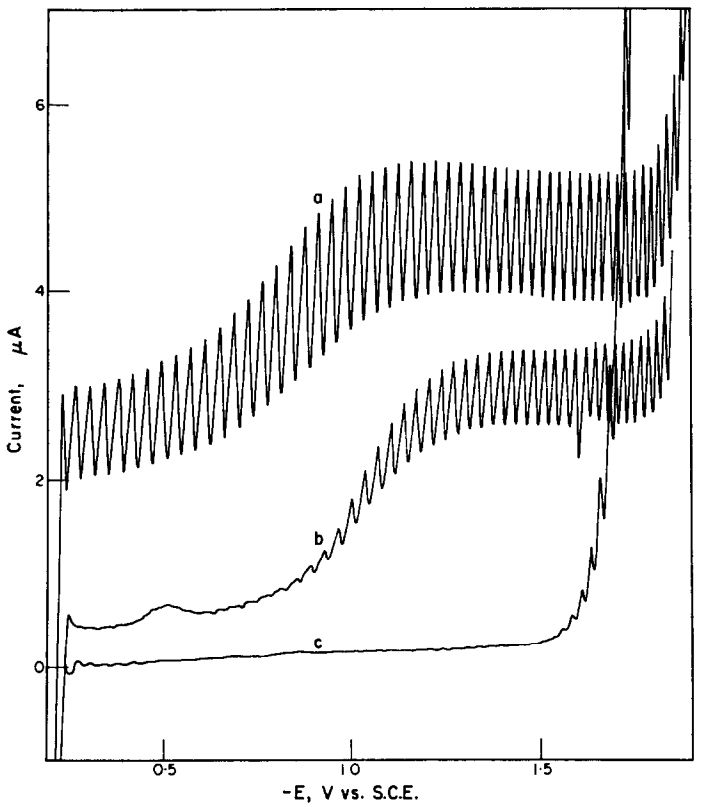

FIG. 3.—Polarograms of 1*F* NH_4OH, 1*F* NH_4Cl and 0·01*F* EDTA supporting electrolyte, containing: (a) no addition; (b) 25 g/l Na_2SO_3; (c) 25 g/l Na_2SO_3 and 0·05 g/l Co(II).

The addition of TEA to potassium chloride, or ammonia–ammonium chloride supporting electrolytes, strongly inhibits the oxygen–sulphite reaction (Fig. 4). Polarogram *a* was obtained with a solution consisting of 1*F* potassium chloride, 0·1*F* TEA and 25 g of sodium sulphite per l., whereon only partial de-oxygenation resulted. Complete de-oxygenation was obtained by the addition of 0·052 g of manganese(II) per l. to the solution (polarogram *c*). In the absence of sodium sulphite, manganese(II) (0·052 g/l.) eliminated only part of the dissolved oxygen present (polarogram *b*). The magnitude of the first reduction wave is higher than the second, since the product of oxidation of manganese(II), presumably manganese(IV), is reducible at positive potentials, contributing to the first oxygen wave. This is easily verified by de-oxygenation of the solution, by bubbling nitrogen through it, whereon

a single and smaller wave is obtained at the beginning of the polarogram. In the presence of sodium sulphite, however, no oxidation product of manganese(II) was observed in polarogram *c*.

It is to be noted that the addition of cobalt(II) or manganese(II) causes early depolarization of the dropping mercury electrode, possibly decreasing the hydrogen over-voltage, whereas the addition of sodium sulphite or EDTA causes anodic depolarization of mercury at a more negative potential (see corresponding polarograms

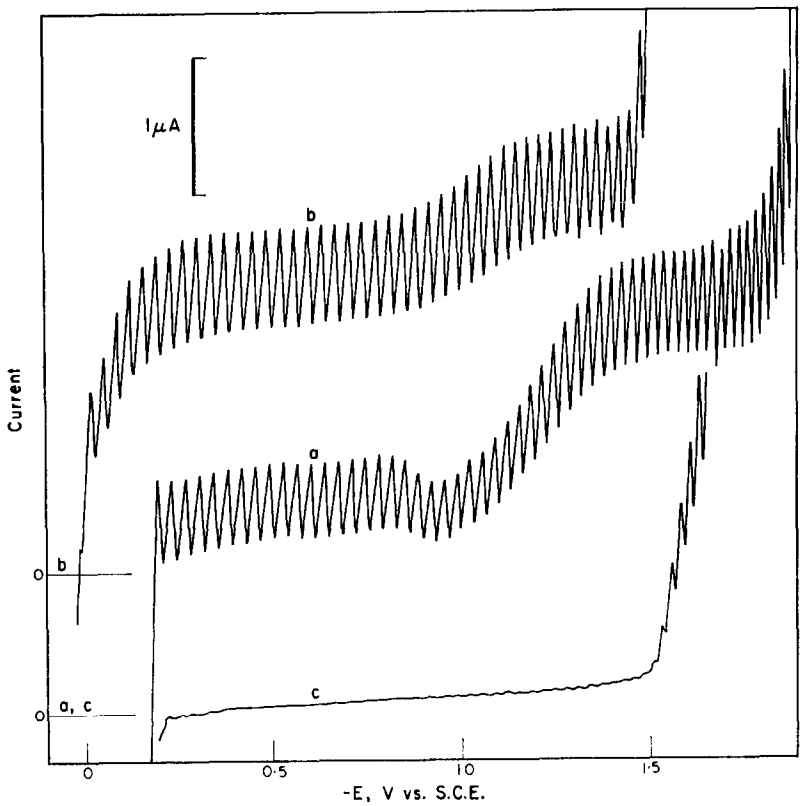

FIG. 4.—Polarogram of 1*F* KCl and 0·1*F* TEA supporting electrolyte, containing: (a) 25 g/l Na_2SO_3; (b) 0·052 g/l Mn(II); (c) 25 g/l Na_2SO_3 and 0·052 g/l Mn(II).

in all Figs.). In both cases, the useful range of potential span available for polarographic determination of active constituents is more limited. Even so, sodium sulphite can be utilized for de-oxygenation of the neutral and alkaline supporting electrolytes described when a large number of active constituents are determinable.

The polarograms, depicted in the presence of inhibitors and catalysts in this investigation, are time dependent. However, chronoamperometric study with the dropping mercury electrode at constant potential[7] makes it possible to follow the rate of disappearance of dissolved oxygen under various conditions. It can be shown that the rate of removal of oxygen increases with the increase in concentration of sodium sulphite and/or catalyst, and decreases with the increase in concentration of inhibitors.

Acknowledgement—The permission of the Israel Mining Industries to publish this paper is gratefully acknowledged.

Zusammenfassung—Die Sauerstoff-Reduktionswellen werden zur Bestimmung des Inhibitionseffektes verwendet, den einige bei der Polarographie häufig zugesetzte Reagentien auf die Reaktion von gelöstem Sauerstoff mit Natriumsulfit in neutralen und alkalischen Trägerelektrolyten ausüben. Alkalimetallhydroxide, EDTA, TEA, Äthanol und Methylcellosolve hemmten die Reaktion in verschiedenem Ausmaß. In dieser Arbeit schien es, als könnten einige Metallionen wie Kobalt(II) und Mangan(II) die Sauerstoff-Sulfit-Reaktion katalysieren, was die Anwendbarkeit von Natriumsulfit zur Entfernung von Sauerstoff aus inhibitorhaltigen neutralen und alkalischen Trägerelektrolyten erweitern würde.

Résumé—On utilise les vagues de réduction de l'oxygène pour déterminer l'effet d'inhibition de quelques réactifs, communément ajoutés lors du travail polarographique, sur la réaction de l'oxygène dissous avec le sulfite de sodium dans des électrolytes-supports neutres et alcalins. Les hydroxydes de métaux alcalins, l'EDTA, la TEA, l'éthanol et le méthylcellosolve inhibent la réaction à des degrés divers. Dans ce travail, il est apparu que quelques ions métalliques, comme le cobalt (II) et le manganèse (II) peuvent catalyser la réaction oxygène-sulfite, permettant une application plus large du sulfite de sodium pour la désoxygénation d'électrolytes-supports neutres et alcalins contenant des inhibiteurs.

DETERMINATIONS OF TRACES OF CALCIUM IN PHOSPHORIC ACID AND ITS SALTS BY ATOMIC-ABSORPTION SPECTROMETRY

MASAAKI YANAGISAWA, MASAMI SUZUKI and TSUGIO TAKEUCHI
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

(*Received* 13 *December* 1966. *Accepted* 29 *March* 1967)

Summary—A method for the determination of traces of calcium by atomic-absorption spectrometry after extraction into an organic solvent, has been investigated for the determination of traces of calcium in phosphoric acid and its salts. Calcium is extracted as the hydroxyquinolate complex, the extract is introduced into the flame, and the calcium atomic-absorption is measured. The effects of pH, concentration of reagent, and diverse ions on the calcium extraction were investigated.

ATOMIC-ABSORPTION spectrometry has been applied to the determination of calcium in various kinds of sample. However, difficulty may be encountered in the determination of traces of calcium in phosphoric acid and its salts because of the effect of phosphate on the calcium absorption. For this kind of sample, it was considered preferable to combine the techniques of solvent extraction and atomic absorption, as had been done previously for magnesium[1], and this paper describes the results.

EXPERIMENTAL

Apparatus

A Hitachi photoelectric spectrophotometer EPU-2A was used with the atomic-absorption attachment RA-1. An air–acetylene flame was used with a 9-cm fishtail burner. Hitachi and Westinghouse hollow cathode lamps were used as light sources. The operating parameters were:

Air pressure	1·5 kg/cm²
Acetylene pressure	0·04 kg/cm²
Wavelength	4227 Å
Slit-width	0·03 mm
Lamp current	40 mA (Hitachi), 10 mA (Westinghouse).

Reagents

Calcium solution. Dissolve 0·250 g of calcium carbonate in a minimum excess of hydrochloric acid, and dilute to 100 ml with water.

8-*Hydroxyquinoline solution.* Dissolve 5 g of 8-hydroxyquinoline in 100 ml of ethanol.

Sodium tartrate solution, 10% w/v.

Saturated sodium chloride solution.

Buffer solution. Mix 1*M* potassium chloride solution and 1*M* sodium hydroxide solution to give a buffer of pH 13.

Reagents were of analytical grade unless otherwise stated.

Procedure

To 9·80 g of phosphoric acid in a polyethylene beaker, add 1 ml of 6*M* hydrochloric acid and 20 ml of sodium tartrate solution. Neutralize the solution by slowly adding 6*M* sodium hydroxide and dilute to 100 ml with water in a standard flask. Place 10 ml of this sample solution in a 50-ml separatory funnel, and add 10 ml of sodium chloride solution. Mix well, and then add 2 ml of butyl cellosolve, 3 ml of 8-hydroxyquinoline solution, and 5 ml of buffer solution. Adjust the volume to 40 ml, add exactly 5 ml of 3-methyl-1-butanol and shake vigorously for 1 min. Drain off and discard the aqueous phase. Spray the organic phase into the flame and measure the calcium absorption.

For phosphate samples, dissolve a suitable weight (3 g for diammonium hydrogen phosphate and 8·9 g for sodium pyrophosphate) in 2 ml of 1*M* hydrochloric acid and 20 ml of sodium tartrate solution, and dilute to 100 ml with water. Place 10 ml of the sample solution in a separatory funnel and proceed as above. If the pH of the solution is lower than 13, adjust it with sodium hydroxide before extraction.

Prepare a calibration curve by taking appropriate volumes of standard calcium solution in 50-ml separatory funnels, adding 10 ml of sodium chloride solution and 2 ml of sodium tartrate solution to each, mix, and apply the procedure.

RESULTS AND DISCUSSION

Atomic-absorption of calcium

The air–fuel ratio had a significant effect on the calcium absorption. The air pressure was set at a constant value (1·5 kg/cm^2), and the acetylene pressure was varied. The results are shown in Fig. 1. Although the acetylene pressure which gives maximum

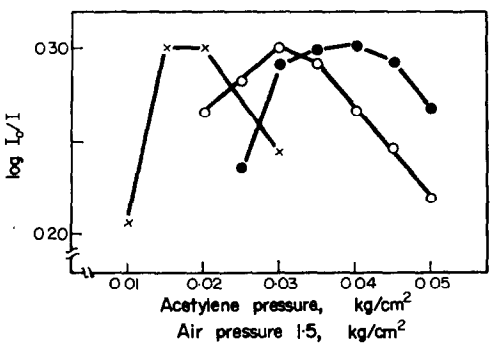

FIG. 1.—Effect of acetylene pressure on calcium absorption
Beam height above burner top: ×—2·0 mm; ○—3·0 mm; ●—4·5 mm.

absorption depends on the beam height above the burner-top, the maximum absorption was constant irrespective of the beam height.

Extraction of calcium

Extraction of calcium hydroxyquinolate has been used for spectrophotometric determinations,[2–4] and we investigated the use of various solvents such as 3-methyl-1-butanol, 4-methyl-2-pentanone, butyl acetate, 1-butanol and chloroform. Of all the solvents tested 3-methyl-1-butanol was found to be best for extraction because it gave a higher sensitivity of measurement. The extraction efficiency was estimated by extracting with successive 5-ml portions of 3-methyl-1-butanol. It was found that 89% of the calcium was extracted in a single pass, over the range of calcium concentration studied. In the present work, a single extraction was used because it was highly reproducible. Shaking vigorously for longer than a minute did not improve the extraction. Although calcium hydroxyquinolate could be extracted into 3-methyl-1-butanol, the addition of butyl cellosolve resulted in better extraction and repeatability for increasing amounts of calcium. Some workers[2,4] have successfully extracted calcium hydroxyquinolate complex with chloroform by using butyl cellosolve as a supplementary solvent. However, chloroform gives an unstable flame and noxious gases during the combustion. Solvents other than esters, ketones and alcohols were not suitable for atomic-absorption measurements because of incomplete combustion and self-absorption of radiation.

The extraction of calcium hydroxyquinolate was examined over a pH range of 10·0–13·6. The degree of extraction was constant when the pH was greater than 12·5. The effect of reagent concentration on the degree of extraction was also investigated. The degree of extraction was constant if more than 100 mg of 8-hydroxyquinoline were added.

Sodium chloride was useful for salting-out and preventing emulsification, the minimum necessary for reproducible results being 5 ml of saturated sodium chloride solution in 40 ml of aqueous phase. Tartrate, which served to prevent the formation of calcium phosphate at higher pH, had no effect on the extraction of calcium when present in concentrations of 0·01–0·05*M*.

The calibration curves are almost linear and were corrected for a very small blank value which we attributed to absorption caused by 8-hydroxyquinoline.

Various metals form hydroxyquinolate complexes at pH 13, some of which are extractable into 3-methyl-1-butanol. To ascertain the influence of diverse ions on extraction and on the calcium atomic-absorption in the flame, calcium was extracted with 8-hydroxyquinoline from solutions containing diverse ions; Al (489 μg), Ba (1063 μg), Cr (456 μg), Cu (532 μg), Fe (989 μg), Mg (1004 μg), Mn (511 μg), Mo (320 μg), Ni (964 μg), Pb (801 μg), Si (1554 μg), Sn (654 μg), Sr (1440 μg), Ti (497 μg), W (1000 μg) and Zn (1266 μg) did not interfere in the determination of 40 μg of calcium. Aluminium and titanium depressed the calcium absorption when an aqueous solution was sprayed into the flame, but no interference was observed in the present method, even though both metals were extracted into the organic phase as hydroxyquinolates. It may be considered that 8-hydroxyquinoline in the extracts counteracts the depressive effect of aluminium and titanium on the calcium absorption. Larger amount of these metals did cause depression of the calcium absorption. Large amounts of chromium and molybdenum also affected the calcium absorption, but this effect could be controlled by changing the air–fuel ratio, a fuel-rich flame being recommended. The copper complex remained in the aqueous phase as a precipitate and did not dissolve in 3-methyl-1-butanol, but resulted in a lower result for the calcium. A complexing agent such as cyanide was necessary to keep copper in solution. Traces of calcium could be extracted from solutions containing large amounts of phosphate (100 mg of P) without loss.

Attempts to use 8-hydroxyquinaldine as complexing agent were unsuccessful. The atomic-absorption of the calcium in the flame was very low, and it was concluded that the calcium was very incompletely extracted into the solvents tried (3-methyl-1-butanol, 4-methyl-2-pentanone, butyl acetate, amyl acetate and 1-butanol).

Determination of traces of calcium in phosphoric acid and its salts

Table I shows the results for some samples of phosphoric acid and phosphates. One sample was analysed five times to evaluate the reproducibility of the method. The mean value was found to be 13·5 ppm and the coefficient of variation was 3·7%. Recovery of added calcium was excellent. Earlier workers[5,6] have described the determination of calcium in phosphoric acid, but the present method appeared to be very convenient for traces of calcium in phosphoric acid and its salts.

Application of the method to polypropylene polymers

Polypropylene polymers contain titanium, aluminium and phosphorus together with calcium derived from additives or the polymerization catalyst. The present

TABLE I.—DETERMINATION OF TRACES OF CALCIUM IN PHOSPHORIC ACID AND ITS SALTS

Sample	Calcium, *ppm*	
	Added	Found
Phosphoric acid A	—	13·2, 13·3
	20·0	32·9
Phosphoric acid B	—	1·6, 1·6
	20·0	21·5
Diammonium hydrogen phosphate	—	15·4, 15·4
	133·5	149
Sodium pyrophosphate	—	3·2, 3·2
	22·4	25·6

extraction method was applied to the determination of calcium in such samples. For estimation 1 g of sample was ashed in a platinum crucible with 0·3 g of sodium carbonate. After addition of 6M hydrochloric acid to acidify the residue, the contents of the crucible were heated with 20 ml of sodium tartrate solution to give a clear solution which was then diluted to 100 ml, and 10 ml of this solution were used for analysis.

TABLE II.—DETERMINATION OF CALCIUM IN POLYPROPYLENE POLYMERS

Polypropylene	Calcium, *ppm*	
	Added	Found
A	—	45, 45
	100·0	146
B	—	120, 120
	200·0	324
C	—	267, 267
	200·0	460

The results obtained for some polymers are shown in Table II. Calcium in polymers can be determined only with difficulty by the usual method because of the low content of calcium and the presence of titanium, aluminium and phosphorus. The present method is convenient for measuring the calcium.

Résumé—On a étudié une méthode de dosage de traces de calcium par spectrométrie d'absorption atomique après extraction en solvant organique pour doser des traces de calcium dans l'acide phosphorique et ses sels. On extrait le calcium à l'état de complexe hydroxyquinoléinique, introduit l'extrait dans la flamme et mesure l'absorption atomique du calcium. On a étudié les influences du pH, de la concentration du réactif et de divers ions sur l'extraction du calcium.

Zusammenfassung—Ein Verfahren zur Bestimmung von Calciumspuren durch Atomabsorptionsspektrometrie nach Extraktion in ein organisches Lösungsmittel wurde zur Bestimmung von Calciumspuren in Phosphorsäure und ihren Salzen geprüft. Calcium wird als Hydroxychinolatkomplex extrahiert, der Extrakt in die Flamme gebracht und die Atomabsorption von Calcium gemessen. Der Einfluß von pH, Reagenskonzentration und verschiedenen Ionen auf die Extraktion von Calcium wurden untersucht.

HOMOGENEOUS NUCLEATION OF MAGNESIUM HYDROXIDE†

DAVID H. KLEIN, MELVIN D. SMITH and JAMES A. DRIY
Department of Chemistry, Hope College, Holland, Michigan, U.S.A.

(*Received* 1 *March* 1967. *Accepted* 2 *April* 1967)

Summary—The rate of homogeneous nucleation of magnesium hydroxide has been determined as a function of solution concentration, using a quasi-homogeneous precipitation technique and electronic particle counting. The nucleation rate becomes measurable at supersaturations of about 4, and is dependent on the 33rd power of the product $a_{Mg}a_{OH}^2$. The experimental results are consistent with nucleation theory. The nucleus–solution interfacial energy is calculated to be 115 erg/cm^2.

THE rate of homogeneous nucleation of magnesium hydroxide precipitating from solution may be written[1]

$$dN/dt = k(IP)^n$$

where N = number of nuclei formed, t = time, (IP) = ion product = $a_{Mg}a_{OH}^2$, and n = number of $Mg(OH)_2$ units in the nucleus. Determination of the rate of nucleation as a function of the ion product thus provides a conceptually simple means for determining the size of the precipitation nucleus. Because nucleation is a very high order rate process, this approach is useful only if the ion product can be varied within quite narrow limits. The approach has been successfully applied to a study of strontium sulphate nucleation,[1] the results of which gave strong support to current nucleation theory, as developed by Nielsen.[2] The approach and techniques of the strontium sulphate study have been modified and applied to the magnesium hydroxide system, a system of some commercial importance because of the occurrence of this material in scale deposits.

EXPERIMENTAL

Magnesium ion and hydroxide ion were generated simultaneously, in stoichiometric amounts, by electrolysis of a 0·10*M* solution of sodium nitrate with a magnesium anode and a platinum cathode. The electrolysis current was 1 mA and the solution volume was about 200 ml, so the concentration of magnesium hydroxide was increasing at the rate of $2{\cdot}6 \times 10^{-8}$ mole l^{-1} sec^{-1}. The electrolysis cell was a jacketed beaker thermostatically kept at 25·0°.

Precautions were taken to keep carbon dioxide out of the system, and to remove most (if not all) of the foreign particles from the solution. The latter was accomplished by continuously pumping the solution from the cell through a fibreglass filter mat and back into the cell. After a few hours of filtration the number of foreign particles dropped to a few thousand per cm^3, as determined with the Coulter particle counter, the filtering system was closed off from the cell, and electrolysis was begun.

The solution concentration was monitored by pH measurement. A Sargent glass–calomel combination electrode was placed in the solution as far as possible from the electrolysis electrodes, and was also surrounded by a grounded platinum screen. With these precautions the electrolysis current did not affect the pH reading. The pH was recorded with scale expansion of such sensitivity that pH changes of 0·001 pH could be measured.

At intervals during the electrolysis a 3-ml portion was removed, and the number of particles present in it was counted, using a Coulter electronic particle counter with a 30-μ orifice.

† This study was aided by a grant from the Office of Saline Water, U.S. Department of the Interior.

RESULTS AND DISCUSSION

The pH measurements indicated that the precipitation of magnesium hydroxide in these experiments followed the typical pattern for precipitations from homogeneous solution[3,4]—an increase in concentration to beyond the saturation concentration, and then a decrease as nucleation began to occur at a rate sufficient to cause rapid precipitation. The maximum pH obtained was 11·186 and represents the pH at which the rate of removal of magnesium hydroxide by crystal growth was equal to the rate of electrolytic generation of magnesium hydroxide.

Each experiment yielded two plots, one of pH as a function of time and one of number of particles as a function of time. The maximum rate of formation of particles occurs at the maximum pH, but because of the nature of the counting instrument, particles are not detected until some time after they are formed, and so the maximum in the rate of production of particles does not appear to the detector until well after the pH has reached its maximum value. Nuclei are only a few Å in diameter, but particles cannot be counted until they are a few hundred mμ in diameter, and so the number–time plot will lag behind the pH–time plot by the amount of time necessary for the nuclei to grow to detectable size. In the present experiments the apparent maximum rate of production of particles was observed by the detector about 30 min after the solution had reached its maximum pH. The number–time curves were then reconciled with the pH–time curves by shifting the time axes so that the maximum rate of production of particles occurred at the maximum pH. This assumes that the rate of production of particles is the same as the rate of nucleation, or that each nucleus, whenever it was formed, requires the same amount of time to grow to observable size, regardless of the solution concentration. This assumption is clearly wrong, because the nuclei formed earlier grow in a more concentrated solution than those formed later, and so will reach observable size more quickly. However, the pH change during the period under consideration is only about 0·06 and this small change in the hydroxyl ion concentration, coupled with the fact that crystal growth is a much lower order rate process than nucleation, makes the uncertainty from this approximation rather small.

Figure 1 shows the results of a typical experiment; the time axis of the number–time plot has been shifted as described above. Nucleation occurred at conveniently measurable rates only at pH values above 11·170. The ion product, $a_{M_g}a_{OH}^2$ was calculated from the pH, the sequence of calculations being as follows: (1) the activity of the hydroxyl ion, a_{OH}, was calculated from the pH, (2) the ratio a_{M_gOH}/a_{M_g} was calculated from a_{OH}, using 4×10^2 as the formation constant for the complex MgOH,[5] (3) the ratio [MgOH]/[Mg] was calculated from a_{M_gOH}/a_{M_g}, using 0·80 and 0·45 as estimates of the activity coefficients of MgOH and Mg, respectively, (4) [OH] was calculated from a_{OH}, using 0·76 as the activity coefficient for OH, (5) [Mg] was calculated from [OH] and [MgOH]/Mg], by means of the equation

$$2([Mg] + [MgOH]) = [OH] + [MgOH],$$

which results from the generation of Mg and OH in equivalent amounts, (6) a_{M_g} was calculated from [Mg], (7) (*IP*), the ion product was calculated as $a_{M_g}a_{OH}^2$. The results of four experiments are presented in Fig. 2, a plot of log dN/dt against log (*IP*). Values of (*IP*) were calculated as indicated above, and dN/dt values were obtained by taking the slopes of the number–time plots at various pH values. The

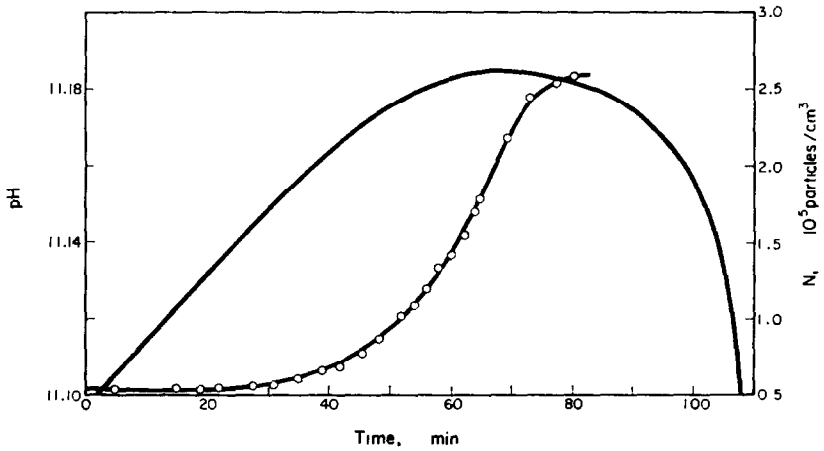

FIG. 1.—Variation with time, of pH [upper curve] and of number of particles, during an experiment.

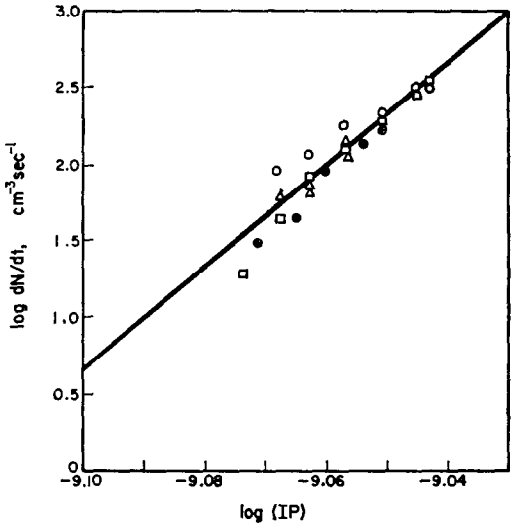

FIG. 2.—Dependence of rate of nucleation [particles/cm^{3}sec] on solution concentration expressed as $(IP)[a_{Mg}a_{OH}{}^2]$.

least-squares slope for the points of Fig. 2 is 33 $\pm$ 4 (90% confidence limits) and so the best value for the number of $Mg(OH)_2$ units in the nucleus is 33.

To confirm that the process observed was homogeneous nucleation, a comparison between experiment and theory was made. From Fig. 2, $\log dN/dt = 2{\cdot}98$ at $\log(IP) = -9{\cdot}030$. The theoretical expression for the rate of homogeneous nucleation may be expressed as:[2]

$$dN/dt = (D/d^2 v_0)(2\phi/3\pi kTn^*)^{1/2} \exp(-\Delta G^*/kT),$$

where dN/dt = rate of nucleation = 10^8 ml^{-1} sec^{-1}

D = diffusion coefficient of $Mg(OH)_2 = 2 \times 10^{-5}$ (estimated from values for $Ca(OH)_2$ and $Ba(OH)_2$]

d = mean diameter of one Mg and two OH ions = 5×10^{-8} cm (estimated from Debye-Hückel hydrated ion diameters)

v_0 = molecular volume of solvent = 3×10^{-23} cm^3

$\phi = kT \ln S = kT \ln [(IP)/K_{sp}]^{1/3}$; $\log K_{sp} = -10{\cdot}90^5$ and $\log (IP) = -9{\cdot}030$, so $\phi = 1{\cdot}43\ kT$

n^* = number of ions in the nucleus = 3×33

ΔG^* = free energy of nucleation.

This kinetic method yields $\Delta G^* = 64{\cdot}6\ kT$. A thermodynamic value for ΔG^* may be calculated from Gibb's equation

$$\Delta G^* = \phi n^*/2 = 70{\cdot}7\ kT$$

The thermodynamic and kinetic values for ΔG^* differ by less than 10%, an agreement which is satisfactory but not overwhelming. Exact agreement between the two values would be obtained for a nucleus of 30 $Mg(OH)_2$ units, well within the experimental error of the 33 found in this study.

ΔG^* may also be related to the nucleus–solution interfacial tension through the equation[2]

$$\Delta G^* = \phi n + \sigma A,$$

where σ = interfacial tension, and A = surface area of the nucleus.

The volume of 33 $Mg(OH)_2$ units in the crystal is $1{\cdot}3 \times 10^{-21}$ cm^3; this volume could be occupied by a sphere with $A = 6 \times 10^{-14}$ cm^2, a cube with $A = 7{\cdot}2 \times 10^{-14}$ cm^2, or a rectangular parallelepiped with edge lengths proportional to unit cell dimensions, with $A = 7{\cdot}7\ 10^{-14}$ cm^2. Assuming, with no experimental basis, that the parallelepiped is correct, σ is calculated to be 115 erg/cm^2.

In 1942, Gjaldback[6] determined the K_{sp} of $Mg(OH)_2$, using a precipitation method. He reported an "active" phase of $Mg(OH)_2$ with $\log K_{sp} = -9{\cdot}2$. The present study indicates that a concentration corresponding to this K_{sp} is required to initiate homogeneous nucleation, and it may therefore be concluded that the "active" phase is the $Mg(OH)_2$ homogeneous nucleus.

Zusammenfassung—Die Geschwindigkeit der homogenen Keimbildung von Magnesiumhydroxid wurde in Abhängigkeit von der Lösungskonzentration mit Hilfe eines quasihomogenen Fällungsverfahrens und elektronischer Teilchenzählung bestimmt. Die Keimbildungsgeschwindigkeit wird bei Übersättigungen von etwa 4 meßbar und hängt von der 33. Potenz des Produkts $a_{Mg}a_{OH}{}^2$ ab. Die experimentellen Ergebnisse sind in Einklang mit der Keimbildungstheorie. Die Grenzflächenenergie Keim-Lösung wird zu 115 erg/cm^2 berechnet.

Résumé—On a déterminé la vitesse d'amorçage homogène de l'hydroxyde de magnésium en fonction de la concentration de la solution, en utilisant une technique de précipitation quasi homogène et un comptage de particule électronique. La vitesse d'amorçage devient mesurable à des sursaturations d'environ 4, et dépend de la 33^e puissance du produit $a_{Mg}a_{OH}{}^2$. Les résultats expérimentaux sont conformes à la théorie de l'amorçage. On a calculé que l'énergie interfaciale amorce-solution est de 115 erg/cm^2.

SPECTROPHOTOMETRIC DETERMINATION OF NITRATE WITH *p*-DIAMINODIPHENYLSULPHONE AND DIPHENYLAMINE–*p*-DIAMINODIPHENYLSULPHONE

E. SZEKELY
The Negev Institute for Arid Zone Research, Beer Sheva, Israel

(*Received* 21 *October* 1966. *Accepted* 5 *March* 1967)

Summary—*p*-Diaminodiphenylsulphone is used in a new spectrophotometric method for the determination of nitrate. Factors affecting the colour development are given. The useful range for a 1-cm cell is 30–300 mg/l. In this range the coloured solutions are stable and obey Beer's law. The method is rapid and precise and is applicable to routine analysis of samples containing macro amounts of nitrates. For determination of micro amounts of nitrate the reagent is modified by addition of diphenylamine. The limit of determination is then 0·25 mg/l at 15°. This method can be considered specific for nitrate and is applicable in the presence of nitrite.

ALTHOUGH many methods for nitrate determination are known and used,[1–6] most of them are either subject to numerous interferences or are difficult to use. There is a need for a new method which is accurate and rapid.

EXPERIMENTAL

Reagents

p-*Diaminodiphenylsulphone solution.* Dissolve 2 g of pure 4,4′-diaminodiphenylsulphone(DDS) in 1000 ml of reagent-grade concentrated sulphuric acid. The reagent is colourless and stable for several months.

Standard nitrate stock solution (1000 *ppm* NO_3^-). Dissolve in water 1·630 g of dried potassium nitrate (reagent-grade) and dilute to 1000 ml. Prepare working standard nitrate solutions by suitably diluting the stock standard solution.

Procedure

By pipette transfer to a test-tube 1 ml of halide-free sample solution, containing 30–300 ppm of nitrate, and add dropwise with continuous stirring 4 ml of DDS reagent and continue stirring for several seconds to ensure intimate mixing. Put the tube in a water-bath, heat to boiling, and let stand for 2 min. Cool the tube to room temperature, dilute the solution accurately to 25 ml, mix, and read the absorbance at 410 mμ in a 1-cm cell. As a blank use either 4 ml of reagent diluted to 25 ml or approximately 3*M* sulphuric acid. Determine the nitrate content of the sample from a calibration curve covering the range 30–300 μg of nitrate per ml of sample. Beer's law is obeyed over this range, and the colour is stable. The molar absorptivity is 2400.

The absorption spectrum is shown in Fig. 1.

RESULTS AND DISCUSSION

When DDS reagent is added to nitrate 3,3′-dinitro-4,4′-diaminodiphenylsulphone is formed; this is a yellow dye, stable in acid. The procedure is simple and accurate. It is not necessary to dry the samples or to add a base for the colour development. The interference of halides must be removed by adding solid silver sulphate and then filtering. Table I shows the average, range and maximal deviation for a series of five consecutive nitrate determinations, for each concentration shown.

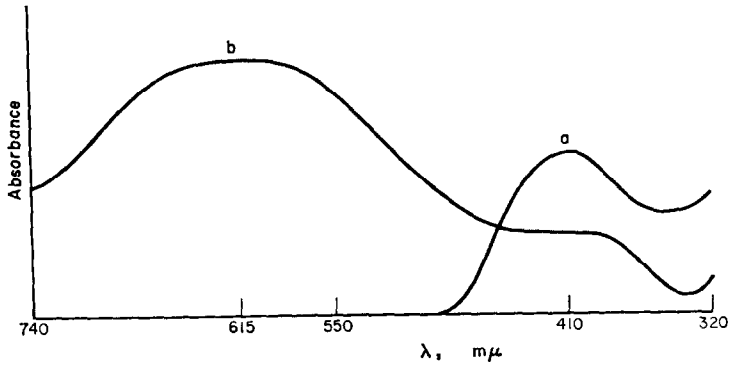

FIG. 1.—Absorption spectra of the reaction products.
a—*p*-diaminodiphenylsulphone reagent; *b*—diphenylamine–*p*-diaminodiphenylsulphone reagent.

TABLE I

Nitrate taken, *ppm*	Nitrate found, *ppm*					Average, *ppm*	Max. deviation, *ppm*
30	30	29	28	32	29	30	2
60	61	58	59	60	61	60	2
100	99	102	99	100	101	100	2
200	200	202	199	201	200	200	2
300	299	297	296	298	298	298	4

Effect of time and temperature

The reagent was added dropwise from a burette to 1 ml of 100 ppm nitrate solution with continuous stirring to avoid local over-heating. The temperature of the mixture rose to 60–70° and some colour developed.

When the solutions were allowed to stand at room temperature for 15, 30, 60 and 120 min and were then diluted and measured, the results in Table II were obtained.

TABLE II

Time, *min*	Absorbance	Colour development, %
15	0·235	76
30	0·290	94
60	0·310	100
120	0·310	100

When the solutions were placed in a cold water-bath, heated to boiling, cooled, diluted and measured, the results shown in Table III were obtained.

TABLE III

Time from start of boiling, *min*	Absorbance	Colour development, %
0	0·300	96
2	0·310	100
5	0·310	100
10	0·310	100

If the test-tubes were cooled in tap water while the reagent was added, no colour development had occurred at the end of mixing but after heating *etc.* the same colour intensity was obtained as before.

Interferences

Table IV shows the effect of other species. The nitrate concentration of the test solutions was 100 ppm after addition of the interfering substances.

Substances which cause a decrease in colour intensity are listed as negatively interfering, and those which cause an increase (mostly due to incompatibility with the concentrated sulphuric acid) are listed as positively interfering.

TABLE IV

Substance	Concentration, *ppm*	Effect

Halides are removed as the silver salts. Chlorine, bromine, bromate and iodate must be reduced with bisulphite and the reduction product removed with solid silver sulphate. Iron(II) is oxidized with ammonium persulphate. Nitrite is removed with a small excess of urea, but not with sulphamic acid, which itself interferes.

Conclusion

The low sensitivity of the method makes it possible to determine relatively large amounts of nitrate, with relatively few interferences. The existing volumetric and

gravimetric methods are subject to numerous interferences. The chief advantages of this method are its accuracy and rapidity. The whole determination takes less than half an hour even when halides *etc.* must be removed.

For microdeterminations the reagent must be modified by addition of diphenylamine, as described below.

DIPHENYLAMINE–*p*-DIAMINODIPHENYLSULPHONE METHOD

EXPERIMENTAL

Reagent

*Diphenylamine–*p*-diaminodiphenylsulphone solution.* Take 225 ml of water in a 1-l. beaker, add 50 mg of diphenylamine (reagent-grade) and 2 g of *p*-diaminodiphenylsulphone (pure), and mix well; add slowly, while continuously stirring, 600 ml of nitrate-free, colourless concentrated sulphuric acid. Allow to cool, add 100 ml of concentrated phosphoric acid (reagent-grade), transfer to a 1-l. volumetric flask, and make up to the mark with concentrated sulphuric acid. The solution is colourless and stable for several months.

Sodium chloride solution (approximately 20,000 ppm Cl^-). Dissolve 3·3 g of sodium chloride (reagent-grade) in 100 ml of water.

Procedure

By pipette transfer 1 ml of sample containing 0·25–2, 0·3–2·5 or 0·4–3 μg of nitrate ion (depending on the working temperature) and 0·5–5 mg of chloride ion into a 25-ml Erlenmeyer flask cooled in ice-water; add very slowly, by burette or pipette, 10 ml of reagent, while continuously stirring, and continue stirring for several seconds to ensure intimate mixing. Allow the flask to stand in ice-water during the reagent addition and for 30 min more, and afterwards keep it at room temperature or in a thermostat. Read the intensity of the blue colour at 600 mμ in a 1-cm cell. Use as blank a mixture of 1 ml of sodium chloride solution (containing 500–5000 ppm of chloride) and 10 ml of reagent.

Determine the nitrate content of the sample from a calibration curve when working at constant temperature (thermostat) or by comparison with a standard solution (preferably 1·5 ppm of nitrate) when working at room temperature.

Calibration curve

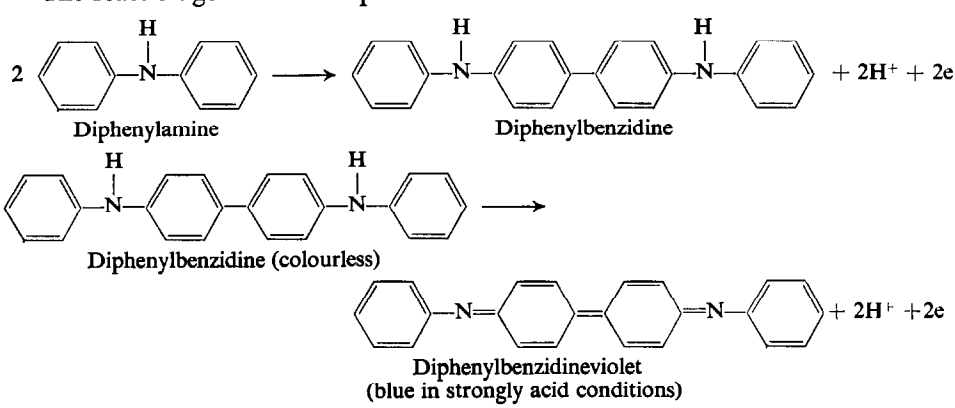
Standards are prepared covering the range 0·25–3 μg of nitrate per ml of solution by suitable double dilution of the 1000-ppm nitrate standard, and are treated as described above. Colour stability is obtained in 1½–2½ hr (depending on the temperature); the intensity of the colour remains constant for at least as long as the time of development and the system obeys Beer's law, over the ranges 0·25–1·7 ppm at 15°, 0·30–2·2 ppm at 20° and 0·40–2·7 ppm at 25–30°.

The molar absorptivity is 300×10^3 at 15° and 170×10^3 at 25–30°C. The absorption spectrum gives a plateau maximum from 590 to 615 mμ (Fig. 1).

RESULTS AND DISCUSSION

When the reagent is added to nitrate the oxidation product of the diphenylamine is developed and a blue coloration results.

The reaction goes in two steps:[7]



In the various methods in which diphenylamine is used for colorimetric estimation of the nitrate ion, it is nearly impossible to obtain stability in colour development. There is a rapid initial increase of intensity followed by a decrease and a colour change to (green absorption peak at 450 mμ). Beer's law is not followed. The *p*-diaminodiphenylsulphone in the mixed reagent stabilizes the colour for at least 1½–2½ hr and accurate readings can be taken, see Fig. 2.

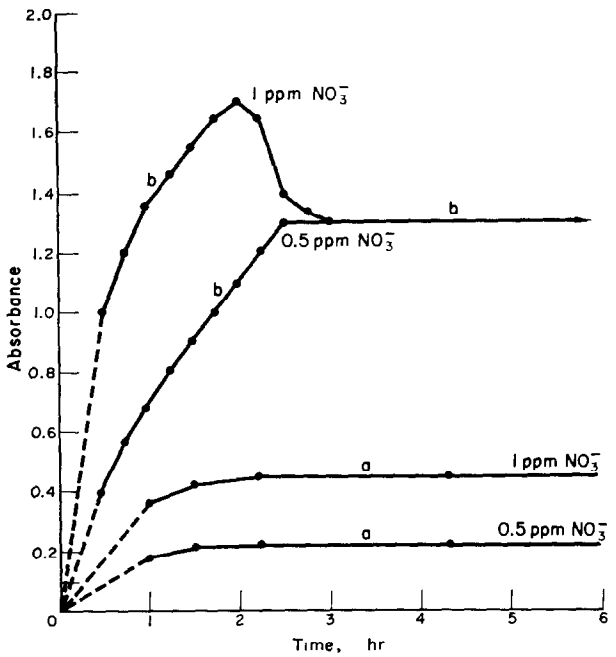


FIG. 2.—Stabilization of colour by use of mixed reagent.
a—Diphenylamine-*p*-diaminodiphenylsulphone reagent;
b—Diphenylamine reagent.

The dependence of the colour development on time, temperature, and the presence of chloride, is shown in Tables V and VI and Fig. 3.

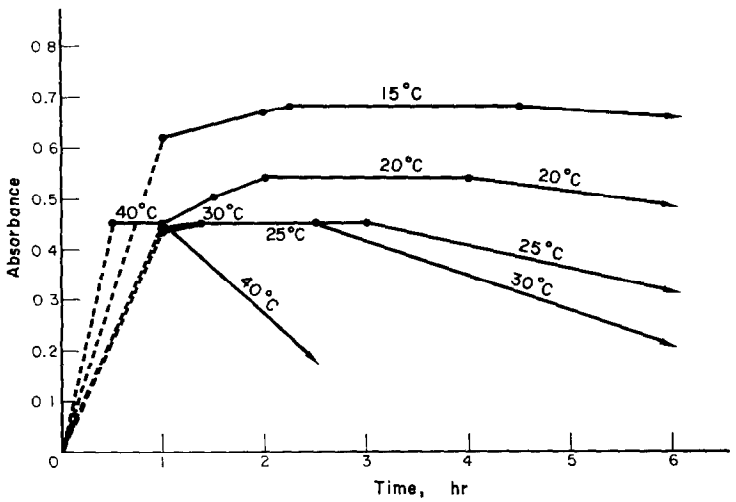

FIG. 3.—Influence of time and temperature on absorbance resulting from 1·5 ppm of nitrate.

Interferences

Only a few substances affect the colour development. If possible, coloured solutions should be decolorized and filtered; otherwise a mixture of 1 ml of sample and 10 ml of approximately 80% sulphuric acid is used as a comparison blank. Though diphenylamine is an intense and sensitive redox indicator, oxidizing agents have a relatively slight effect on the colour development with this reagent. Results obtained with various oxidants are shown in Table VII.

TABLE VII.—INFLUENCE OF OXIDANTS ON DETERMINATION OF 1 ppm OF NITRATE AT 15°C

H_2O_2	10	1·28	1·73	1·73

Readings were taken after 1 hr (A), 2½ hr (B) and 3½ hr (C); the results are the averages of 3 determinations.

Though small amounts of strong oxidizing agents other than peroxides have little effect, for precise work it is best to remove them. This can be done by taking an aliquot (10–50 ml) of sample, acidifying it with dilute sulphuric acid, adding potassium iodide and starch solution and titrating with 0·05*N* sulphite until colourless; then to another aliquot of sample the same volume of sulphite solution is added and this solution is then used for the nitrate determination. A small excess (10–20 ppm) of sulphite does not interfere.

Any iron(III) present is also reduced to iron(II) and interferes by reducing nitrate in acid conditions. The iron(III) can be removed by ion-exchange or the iron(II) reoxidized with a small excess of sodium persulphate or potassium permanganate.

Permanganate can be used to destroy peroxides, the excess of it being removed with oxalate. Any nitrite present then interferes because of its oxidation to nitrate, and a correction must be applied for the amount of the nitrate found by a suitable nitrite determination. Nitrite ion generally interferes more or less in all colorimetric nitrate determination methods except this one, where it reacts quantitatively with the *p*-diaminodiphenylsulphone (diazotization).[8] Samples containing 0·1–1 ppm of nitrite remain colourless on reagent addition; samples containing 10 ppm give an initial violet colour which vanishes on further addition of reagent; a blue colour develops only if the sample also contains nitrate. The effect of nitrite is shown in Table VIII.

Most of the inorganic acids, and organic acids such as formic, oxalic, acetic, tartaric and citric, have no influence on the colour development. Bromide and iodide interfere and must be removed with excess of silver sulphate. As the chloride necessary for colour development is unavoidably removed in the same operation, an excess of sodium chloride must be added after the silver sulphate to give a final chloride concentration of 500–5000 ppm.

Few cations interfere; barium and lead precipitate as the sulphates on reagent addition, and must be removed previously with dilute sulphuric acid. Large amounts (10–20% in the sample) of organic solvents such as methanol, ethanol and ethyl acetate have no influence on the colour development. Chloroform does not interfere but acetone decreases the colour. Isopropanol and isobutanol inhibit the reaction

TABLE VIII.—EFFECT OF NITRITE ON NITRATE DETERMINATION AT 15°C

Taken, *ppm*		Nitrate found,	Error,
NO_3^-	NO_2^-	*ppm*	%
1	—	0·994	−0·6
1	0·1	1·003	+0·3
1	1·0	1·007	+0·7
1	10·0	1·015	+1·5

completely. No interference is caused by aliphatic amines (diethylamine), amino-alcohols (triethanolamine), amino-acids (glycine), and chelating agents (EDTA).

For drinking water, river and saline water samples, there is generally no need for preliminary preparative procedures. For sewage, polluted waters, plant tissue and soil extract, *etc.*, in which a wide variety of impurities can be present, the following procedure is recommended.

Acidify the sample with dilute sulphuric acid and add excess of permanganate. Remove the excess with oxalic acid. Note that nitrites are also oxidized in this procedure. If appreciable amounts of oxidizing agents are present, reduce them with a small excess of sulphite. Replace the cations with sodium on a suitable cation-exchange resin.

This method is useful for the determination of traces of nitrate in concentrated sulphuric acid. The following procedure is recommended.

Add to 2·5 ml of water the necessary amount of concentrated sulphuric acid to obtain a total volume of 10 ml; 1 ml of this diluted acid contains 1·5 g of sulphuric acid. Take 1 ml of 0·3% sodium chloride solution in an Erlenmeyer flask cooled in ice-water; add slowly, while stirring, the following volumes of the diluted sulphuric acid sample: 0·2 ml for "pure" (maximum nitrate admissible 0·0005%); 1 ml for "reagent" grade (0·00005%); 2 ml for "Analar" grade (0·00002%) and continue as described in the procedure, subtracting the volume of the acid sample from the reagent volume.

This simple method can be successfully used in place of the present "Standard" methods, which are less sensitive and precise. These are the diphenylamine method,[9] the indigocarmine method,[10] the ferrous sulphate methods[11,12] in which selenium interferes, and the complicated 2,4-xylenol method.[11] Selenium (50 ppm) does not affect the method described here.

Table IX shows that the method described is the most sensitive of the standard or commonly used colorimetric methods for nitrate determination. The reagent is simple to prepare and use, and the few interfering substances are easily removed.

The test can be made more rapid by keeping the reaction mixture in ice-water for only 15 min, then keeping it at 40 ± 2° for 15–20 min and reading the absorbance. A standard solution is run simultaneously.

The approximate nitrate content of a sample can easily be estimated visually. Make two comparison solutions by adding 1 and 2 drops of 0·1% alcoholic thymolphthalein solution to 10 ml of 1*M* sodium hydroxide. Working at room temperature, add sufficient chloride to the sample solution and add 1 and 2 drops of it to two 2-ml portions of reagent, and mix. Compare the sample colours with those of 2 ml of the comparison solutions. A match of the 1-drop colours after 5 min indicates about 10 ppm of nitrate, and after 15 min about 5 ppm. A match of the 1-drop sample with the 2-drop comparison solution after 5 min indicates about 20 ppm, and match of the 2-drop sample with the 1-drop comparison solution after 15 min indicates about 2 ppm. If colour development is too rapid the sample can be diluted.

TABLE IX.—COMPARISON OF METHODS

Résumé—On utilise la *p*-diaminodiphénylsulfone dans une nouvelle méthode spectrophotométrique de dosage du nitrate. On donne les facteurs affectant le développement de la coloration. Le domaine utile pour une cellule de 1 cm est de 30–300 mg/1. Dans ce domaine, les solutions colorées sont stables et suivent la loi de Beer. La méthode est rapide et précise et elle est applicable à l'analyse de routine d'échantillons contenant des macroquantités de nitrates. Pour le dosage de microquantités de nitrate on modifie le réactif par addition de diphénylamine. La limite de dosage est alors de 0,25 mg/1 à 15°. On peut considérer cette méthode comme spécifique pour le nitrate et elle est applicable en présence de nitrite.

Zusammenfassung—p-Diaminodiphenylsulfon wird in einer neuen spektrophotometrischen Methode zur Nitratbestimmung verwendet. Die die Farbentwicklung beeinflussenden Faktoren werden angegeben. Der nutzbare Bereich für 1-cm-Küvetten liegt bei 30–300 mg/l. In diesem Bereich sind die farbigen Lösungen stabil und folgen dem Beerschen Gesetz. Die Methode ist schnell und genau und läßt sich auf die Routineanalyse von Proben anwenden, die Makromengen Nitrate enthalten. Zur Bestimmung von Mikromengen Nitrat wird das Reagens durch Zusatz von Diphenylamin modifiziert. Die Nachweisgrenze ist dann 0,25 mg/l bei 15°. Die Methode kann als spezifisch für Nitrat angesehen und in Gegenwart von Nitrit angewandt werden.

RADIOCHEMICAL SEPARATION OF STRONTIUM BY ISOTOPIC EXCHANGE

I. H. QURESHI, M. S. SHAHID and S. M. HASANY
Atomic Energy Centre, Ferozepur Road, Lahore, Pakistan

(*Received* 27 *February* 1967. *Accepted* 29 *March* 1967)

Summary—Isotopic exchange has been used for the rapid separation of minute quantities of radio-strontium. A number of variables such as agitation time, concentration of strontium in both phases, mode of preparation and aging of the precipitates, were studied and optimized. With an optimized procedure, exchange yields of 96% and 94% respectively were obtained when strontium sulphate and strontium oxalate precipitates were used for the exchange. Decontamination studies made with radioactive tracers of 15 elements showed that the sulphate precipitate is more selective than the oxalate, most of the elements showing <1% contamination except ^{140}Ba–^{140}La and ^{110}Ag which show high contamination. This simple procedure has also been applied for the determination of radioactive strontium in rain-water samples.

FOR many years the principle of isotopic exchange has been used in the preparation of radioactively labelled compounds and in studies on the aging of precipitates. It can also be used for devising new rapid radiochemical separation procedures, especially by isotopic exchange between an insoluble compound of an element and its ions in aqueous solution.[1–5] In the present study this technique has been applied to the separation of minute quantities of radioactive strontium from aqueous solutions.

When freshly prepared strontium sulphate and strontium oxalate precipitates are agitated in solutions containing radioactive strontium ions, a rapid isotopic exchange of strontium takes place, and in a short time most of the radioactivity is incorporated into the precipitate. A high exchange is possible only when the concentration of inactive strontium is much greater in the precipitate than in the solution, and the precipitate has low solubility. Under such conditions the very favourable equilibrium exchange ratio forms the basis of a single-step procedure for the separation of small amounts of radioactive strontium.

EXPERIMENTAL

Apparatus

Flint glass, 1-oz, square-bottomed narrow-mouth bottles with polyethylene screw caps were used in a thermostatically controlled tank to agitate the precipitate during separation. They were clamped in a mechanical shaker (Wrist-Action Shaker, Burrell Corp; Pittsburg, Pa., U.S.A.) to which a 9-in. extension arm was connected to give additional radial action.

Gamma-ray measurements were made with a Baird Atomic Model-810 Scintillation Well-Counter, and beta-activity was measured with a Tracerlab Geiger tube TGC-1. Low-level beta-measurements were made in a Nuclear-Chicago Spectroshield low background counting system with a "micromil window" and having a 40% counting efficiency for ^{90}Sr. In this system an anti-coincidence circuit was used.

Reagents

All non-radioactive chemicals used were of C.P. or analysed grade. All radioisotopes used as tracers were obtained from the Radiochemical Centre, Amersham, England, and from the Union Carbide Nuclear Company, Oak Ridge, Tenn; U.S.A. Strontium-90 free from yttrium-90 was prepared[6] by extracting ^{90}Y into 2 ml of 0·1*M* dibutylphosphate solution in chloroform from 2 ml of

equilibrium solution of ^{90}Sr–^{90}Y in 0·1*M* nitric acid. Pure carrier-free ^{90}Sr tracer remains in the aqueous layer.

Preparation of strontium sulphate and strontium oxalate

Acidify 150 ml of 3% strontium chloride solution with 2 ml of 0·5*M* hydrochloric acid and add 200 ml of 0·1*M* sulphuric acid in small portions with stirring. Allow the precipitate to stand in the mother liquor for 30 min. Separate the precipitate and wash it thoroughly by decantation with deionized water, filter it off and then dry it in an oven at 60° for 30 min. Prepare strontium oxalate similarly with 100 ml of 5% strontium chloride solution and 200 ml of 0·5*M* oxalic acid.

Isotopic exchange procedure

Take 5 ml of 0·5*M* sulphuric acid in a bottle and add strontium-85 tracer (10^4–10^5 cpm) for yield and interference studies. For contamination studies add radioactive tracers (10^5–10^6 cpm) of the contaminating ions and 1 μg of inactive strontium. Shake well to ensure thorough mixing and take out 500 μl for counting. Add 300 mg of freshly prepared strontium sulphate and shake mechanically for 10 min. Transfer the precipitate to a centrifuge cone and centrifuge at top speed for 30–60 sec. Remove the supernatant liquid, transfer the precipitate to another cone, wash it twice with water and then count it in a scintillation well-counter.

In experiments with strontium oxalate use 300 mg of the precipitate and 0·5*M* oxalic acid as exchange medium.

For the determination of radio-strontium in rain-water, evaporate 500 ml of the sample to dryness in a beaker. Wash the sides of the beaker with deionized water and evaporate to dryness again. Take up the residue in 6 ml of 0·5*M* sulphuric acid and transfer it to a bottle. Rinse the beaker twice with 3-ml portions of 0·5*M* sulphuric acid and add the rinsings to the sample bottle. Perform the exchange as above. Centrifuge and wash the precipitate, transfer it to a filter paper, and count it in a low-level beta-counter.

DISCUSSION AND RESULTS

In preliminary experiments strontium sulphate and oxalate were agitated separately for 10 min in various exchange media containing radioactive strontium tracer. The results are shown in Table I. Exchange was best with media containing the anions of the precipitate, and increased with increasing concentration of the exchange medium,

* Average of triplicate runs. The standard deviation ranges from 1·8 to 2·9.

probably because of reduction in solubility by the common ion effect, and best yields were obtained with 0·5*M* solutions, which were therefore used for further studies.

The isotopic exchange reaction follows an exponential law and the progress of the reaction may be followed with the help of McKay's equation[7]

$$K = \frac{ab \ln(1 - F)}{(a + b)t}$$

where K is the rate constant in mole/sec, a and b are the concentrations of the reactants in each of the two phases (in mole/l) and F is the ratio of the quantity exchanged at time t to that exchanged at equilibrium. Since the rate of the exchange reaction is dependent on the time of contact and the concentrations of strontium in the two phases, it is necessary to study these parameters in order to develop an optimum separation procedure.

The exchange yield increases exponentially with the contact time. In the sulphate system, it increases gradually from 52% in 1 min to 96% in 10 min and then begins to level off, whereas in the oxalate system it increases rapidly from 14% in 1 min to 95% in 12 min and then levels off. In both systems equilibrium is reached after 25 min, giving a maximum exchange yield of 99%. In the optimum procedure agitation times of 10 and 12 min respectively were used for the sulphate and oxalate systems.

The recovery of strontium tracer was studied with different amounts of precipitate. With 50, 100, 200, 300 and 400 mg of precipitate, a fixed aqueous concentration of strontium, and 10 min of agitation, corresponding exchange yields of 73, 89, 95, 96 and 96% were obtained in the sulphate system, and 61, 74, 93, 94 and 94% for the oxalate system. Therefore 300 mg of precipitate was chosen as the optimum quantity for both systems.

When 300 mg of strontium sulphate was shaken with various aqueous concentrations of strontium it was found that with an aqueous concentration of strontium >40 μg/ml the exchange yield decreased slightly, and with >80 μg/ml the solution became slightly turbid with strontium sulphate. To get the best yield the solution should contain less than 40 μg of strontium per ml.

The exchange yield is also dependent on the volume of solution. It decreases as the volume increases above 10 ml, falling by 17% when the aqueous volume is 25 ml, but this decrease can be compensated by increasing the amount of precipitate to 1 g.

Adsorption plays an important role in this type of heterogeneous isotopic exchange reaction. Therefore, the mode of preparation and the aging of the precipitate may affect the exchange if they produce changes in the surface area of the precipitate. Strontium sulphate prepared from 0·005–0·01*M* solutions gave ~10% lower exchange yield than that prepared from 0·1–0·5*M* solutions, possibly because the crystals obtained from the more dilute solutions may have been more uniform and regular in shape, with a smaller total surface area available for exchange.

Aging of the precipitate in the mother liquor also decreases the exchange yield. Aging for 5 hr gave a 15% decrease in exchange yield, and washing the precipitate with ethyl alcohol decreased the exchange yield by 17%. Thermal aging of the precipitate at 300° for 1 hr decreased the yield by 25%, probably by growth of particle size. Aging for 4 hr gave no further decrease in the yield, but raising the aging temperature to 500° further decreased the yield.

Interferences

Hydrochloric, hydrobromic and nitric acids below 1*M* concentration do not affect the yield in the sulphate system. Oxalic, tartaric and citric acids below 0·1*M* concentration have no effect on the yield either but increasing the concentration of these acids decreases the yield rapidly. Sulphites, phosphates and phosphoric acid also decrease the yield when present in concentrations above 0·05*M*.

Since mineral acids attack strontium oxalate, they decrease the yield considerably in the oxalate system, even at concentrations of 0·1*M*, and must be neutralized before the exchange step for the best yield to be obtained. Elements which would precipitate during neutralization must be removed first. Sulphites, phosphates, tartaric acid and citric acid in concentration above 0·05*M* also decrease the yield.

Decontamination

Decontamination studies were made for both systems to check the selectivity of the procedure. Radioactive tracers (with their daughters) of 15 elements, representative of various parts of the Periodic Table, were used. The results are summarized in Table II. In most cases the contamination was less than 1%. Silver and Ba–La

showed high contamination. Contamination by silver is probably due to adsorption of its ions on the precipitate, which can be reduced considerably by adding 1 mg of silver carrier. Since barium behaves similarly to strontium but forms a less soluble sulphate and oxalate, it exchanges with strontium in the precipitates, and shows very high contamination. Therefore, the method is not useful when

the sample contains radioactive barium and calcium. From the decontamination data, it can be seen that the sulphate system is the more selective.

The simple isotopic exchange procedure was applied for the separation of radio strontium from fall-out rain-water samples. Chemical recovery of strontium was determined to be 94 ± 2% by adding a known amount of strontium tracer to 590-ml samples of deionized water and carrying out the separation as described for rain-water samples. Rain-water samples, collected during the months of March, July and September, 1966 by the Health Physics Division of the Atomic Energy Centre, Lahore, were analysed for radio-strontium by this procedure. The measurement of beta-emitting ^{90}Sr is considerably affected by self-absorption in the precipitate (which weighs ~78 mg/cm²) and corrections must be applied to the observed count. Gross beta-activity of the samples was also determined by evaporating a total of 25 ml in 1-ml portions on a planchet. The results are summarized in Table III.

All samples were counted for 80 min each. Background of the counter was 1·1 cpm. The error quoted is the error due to the counting statistics.

The isotopic exchange technique for the separation of trace amounts of radioactive strontium is rapid and fairly selective. The simple procedure gives a high chemical yield and does not require special equipment. The technique can be easily applied to samples such as rain-water.

Acknowledgements—This work was supported in part by the U.S. National Bureau of Standards, Washington, D.C., under the International Research Grant Program, Contract No. NBS(G)-46. The assistance of Mr. Umar H. Khan of the Health Physics Division of this Centre, in furnishing the rain-water samples, is gratefully acknowledged.

Zusammenfassung—Zur schnellen Abtrennung kleiner Mengen Radiostrontium wurde der Isotopenaustausch verwendet. Eine Anzahl von Variablen wie Schüttelzeit, Konzentration von Strontium in beiden Phasen sowie Art der Herstellung und Alterung der Niederschlage wurden untersucht und optimiert. Mit einer optimierten Vorschrift wurden Austausch-Ausbeuten von 96 und 94% mit Strontiumsulfat bzw. Strontiumoxalatniederschlägen beim Austausch erhalten. Dekontaminationsuntersuchungen mit radioaktiven Tracern von 15 Elementen zeigten, daß der Sulfatniederschlag selektiver ist als das Oxalat, wobei die meisten Elemente unter 1% Kontamination zeigen, außer ^{140}Ba, ^{140}La und ^{110}Ag, die hohe Kontamination zeigen. Dieses einfache Verfahren wurde auch auf die Bestimmung von Radiostrontium in Regenwasserproben angewandt.

Résumé—On a utilisé l'échange isotopique pour la séparation rapide de faibles quantités de radio-strontium. On a étudié et rendu optimales un certain nombre de variables comme le temps d'agitation, la concentration du strontium dans les deux phases, le mode de préparation et de vieillissement des précipités. Avec la technique rendue optimale, on a obtenu des rendements d'échange de 96% et 94% respectivement quand les précipités de sulfate de strontium et d'oxalate de strontium ont été utilisés pour l'échange. Des études de décontamination effectuées avec les traceurs radioactifs de 15 éléments ont montré que le précipité de sulfate est plus sélectif que celui d'oxalate, la majeure partie des éléments montrant une contamination <1% à l'exception de ^{140}Ba, ^{140}La et ^{110}Ag qui montrent une contamination élevée. On a aussi appliqué cette technique simple au dosage du strontium radioactif dans des échantillons d'eau de pluie.

DETERMINATION OF SELENIUM AND TELLURIUM IN SILVER CHLORIDE AND URANIUM OXIDE

B. G. RUSSELL®, W. V. LUBBE, ANITA WILSON, ELAINE JONES, J. D. TAYLOR and T. W. STEELE
National Institute for Metallurgy, Yale Road, Milner Park, Johannesburg, South Africa

(*Received* 20 *December* 1966. *Accepted* 23 *March* 1967)

Summary—Methods are described for the determination of selenium and tellurium in crude silver chloride produced as a by-product of the refining of gold, and in high-purity uranium oxide. Selenium and tellurium are separated from one another as well as from the numerous other substances in the sample before they are extracted into organic solvents and determined spectrophotometrically. For the determination of selenium 3,3′-diaminobenzidine is used and for tellurium, *sym*-diphenylthiourea. A minimum of 2 ppm of each element may be determined in silver chloride and 0·3 ppm in uranium oxide. Statistical data are given to show the precision and accuracy of the methods.

SILVER compounds of high purity are often specified for photographic and other industrial purposes, and it is proposed to prepare them from the crude silver chloride produced as a by-product of South African gold. At the outset it is necessary to be able to analyse the crude material as well as the refined products. Selenium and tellurium are two particularly undesirable elements in silver compounds, and the uranium oxide used for making nuclear fuels must also be of high purity and containing as little as possible of these two elements. The work covered in this paper was prompted by the lack of published analytical procedures for small amounts of the elements in these types of material.

The selenium and tellurium are assumed to occur as minute inclusions of selenide and telluride. Many elements interfere in the methods that have been proposed for the determination of selenium and tellurium, so that a fairly complete separation of the two elements from the impurities and from each other is necessary. Schoeller and Powell[1] suggest roasting in a stream of dry chlorine gas as a means of separating selenium and tellurium from silver, but the present investigators were unsuccessful in applying this technique. Spectrographic methods lack the necessary sensitivity, especially for selenium; polarographic methods require the isolation of the two elements. Spectrophotometric methods appear to be the most applicable.

The best spectrophotometric procedures for the determination of selenium depend upon the formation of the compound piazselenol, which has an intense yellow colour and is extractable into organic solvents. The most frequently used reagents for the formation of piazselenol are 2,3′-diaminonaphthalene and 3,3′-diaminobenzidine. The former reagent was investigated by Lott[2] but the method lacks reproducibility. Hoste,[3] and Hoste and Gillis[4] originally applied 3,3′-diaminobenzidine to selenium determinations, and showed it to be a selective and moderately sensitive reagent. Cheng[5] investigated the reagent in detail and proposed a modified procedure in which small amounts of most of the elements do not interfere.

The only reagents for tellurium that appear to possess the necessary sensitivity are bismuthiol(II) and *sym*-diphenylthiourea. The former was investigated by Jankowsky and Ksir,[6] but we were unable to obtain reproducible results with their method. The results obtained with *sym*-diphenylthiourea, as proposed by Yoshidu and Hikime,[7] are reproducible and relatively sensitive, though many substances interfere and necessitate the separation of the tellurium.

EXPERIMENTAL

Reagents

All reagents should be of the highest purity obtainable.

Sodium peroxide, +20 mesh.

Sodium nitrate wash solution. Dissolve 20 g of sodium nitrate in water and dilute to 1 l. Adjust the pH value to 8·5 by means of 5% sodium hydroxide solution.

Nitric acid, 50% v/v, and 1% v/v.

Aluminium nitrate solution. Dissolve 69·53 g of $Al(NO_3)_3.9H_2O$ in water containing 5 ml of nitric acid, and dilute to 100 ml; 1 ml ≡ 50 mg of aluminium.

Methyl Red, aqueous solution, 0·2% *w/v.*

Ammonium chloride, solution, 1% *w/v.*

Sodium carbonate–bicarbonate solution. Dissolve 50 g of sodium carbonate and 50 g of sodium bicarbonate in water and dilute to 500 ml.

Formic acid, 2·5M solution. Dilute 11·5 ml of formic acid to 100 ml with water.

3,3′-Diaminobenzidine solution, 0·5% *w/v.* Dissolve 0·125 g of 3,3′-diaminobenzidine tetrahydrochloride in water and dilute to 25 ml. Prepare just before use.

Sodium hydroxide, 2M.

Standard selenium solution. Transfer 0·2000 g of selenium powder to a 125-ml Phillips beaker. Add 15 ml of nitric acid and heat until dissolved. Dilute to 1 l. in a volumetric flask. The selenium is in the quadrivalent state. For use dilute 10 ml to 200 ml; prepare fresh weekly.

Iron(III) nitrate solution. Dissolve 73·5 g of $Fe(NO_3)_3.9H_2O$ in water containing 5 ml of nitric acid and dilute to 100 ml; 1 ml ≡ 100 mg of iron.

Ammonium nitrate wash solution. Neutralize 100 ml of nitric acid with aqueous ammonia and dilute to 1500 ml with water. Adjust the pH value to approximately 8.

Cation-exchange resin. Dowex 50W–8X (50–100 mesh).

Sym-*Diphenylthiourea solution,* 1% *w/v.* Dissolve 2 g of *sym*-diphenylthiourea in approximately 100 ml of chloroform and dilute to 200 ml with chloroform. Prepare fresh monthly.

Standard tellurium solution. Dissolve 0·8999 g of telluric acid ($H_2TeO_4.2H_2O$) in 100 ml of water, add 10 ml of hydrochloric acid and dilute to 500 ml. The tellurium is in the sexivalent state; 1 ml ≡ 1 mg of tellurium. For use dilute 5 ml to 1 l.; prepare fresh daily.

Procedure

Dissolution of uranium oxide sample. Dissolve 5 g of the sample in a mixture of 9 ml of nitric acid and 1 ml of hydrochloric acid, and evaporate to a moist state. Add 1 ml of iron(III) nitrate solution and about 200 ml of water. Heat to about 60°, and add hot sodium carbonate–bicarbonate solution until the uranium is all complexed and the iron precipitated, then add 10 ml in excess. Filter off the precipitate on a Whatman No. 541 filter paper and wash once with hot 2% sodium bicarbonate solution. Dissolve the precipitate in a minimum of hot 50% nitric acid and repeat the precipitation with the sodium carbonate–bicarbonate solution. Dissolve the precipitate in 20 ml of hot 50% nitric acid. Add 0·6 g of silver nitrate, dilute to 250 ml, and add 8 g of sodium peroxide. Continue as described for silver chloride after the leaching of the fusion.

Dissolution of silver chloride sample. Transfer the sample (not exceeding 1 g) to a nickel crucible of suitable capacity. Add 5 g of sodium peroxide, mix, and fuse over a low flame until all the sample is decomposed. Cool the fusion, leach it in 250 ml of water, and adjust the pH value to 8·5 with dilute nitric acid (Note 1). Boil for 20 min to decompose the peroxides. Dilute with boiling water to approximately 350 ml, add 1 g of paper pulp and stir. Allow the precipitate to settle for 1 or 2 min, and filter it off on a Whatman No. 541 filter paper, decanting off the supernatant liquid before transferring the precipitate. Wash with hot sodium nitrate wash solution until the precipitate is free from chloride. Ten washes are normally sufficient.

Selenium is determined in the filtrate and tellurium in the precipitate.

Determination of selenium. Evaporate the filtrate to approximately 20 ml, neutralize it with hydrochloric acid, and add 30 ml in excess. Adjust the volume to 70 ml and boil gently for 2 min. Dilute

to 250 ml and add 1·5 ml of aluminium nitrate solution. Heat to approximately 80°, and add 2 drops of Methyl Red solution and aqueous ammonia until the indicator colour just changes to yellow. Boil for 2 min, and immediately filter off the precipitate on a 12·5-cm Whatman No. 541 filter paper, and wash it four times with hot ammonium chloride wash solution. Sluice the precipitate back into the original beaker, and dissolve the remaining traces off the paper with hot 50% nitric acid. Add 1 ml of 2*M* sodium hydroxide, and evaporate the solution to a moist state (Note 2).

Add 3·5 g of tartaric acid and 10 ml of water. Rotate the beaker until the salts are dissolved, and transfer the solution to a 150-ml beaker that has been marked at the 40-ml level. The volume must not exceed 30 ml at this stage. Add 2 ml of 2·5*M* formic acid, and, with aqueous ammonia checking it with a pH-meter, adjust the pH value to between 2 and 2·5. Adjust the volume to 40 ml. Add 2 ml of 3,3′-diaminobenzidine solution, mix, and allow to stand for 45 min.

Adjust the pH value to 6·5 with ammonia (check with a pH-meter). Transfer the solution to a 125-ml separating funnel that has been previously marked at the 50-ml level, and adjust the volume to 50 ml. Add 10 (±0·01) ml of toluene and shake for 2 min. Allow 5 min for the phases to separate, and discard the aqueous solution. Filter the organic phase through dry, double, 7-cm Whatman No. 541 filter paper into a 50-ml beaker. Cover it with aluminium foil to prevent evaporation. Within 1 hr read the transmittance at 420 mμ on a spectrophotometer against a reference blank treated in the same way as the sample.

Prepare a calibration curve by adding portions of the diluted standard selenium solution containing 5, 10, 15, and 20 μg of selenium to 0·5 g portions of selenium-free silver chloride in nickel crucibles. Add a pellet of sodium hydroxide, and evaporate to dryness in an oven at 110°. Continue as described in the procedure (Note 3).

Determination of tellurium. The tellurium is quantitatively held in the precipitate obtained as described under "Dissolution of sample". Dissolve the precipitate through the paper, using a jet of hot 50% nitric acid from a wash bottle. Wash the paper with hot 1% nitric acid to give a total volume of 200 ml. Add 1 ml of iron(III) nitrate solution and heat the solution to approximately 85°. Precipitate the iron with aqueous ammonia, and adjust the pH to approximately 8. Filter off hot on a Whatman No. 541 filter paper without washing. Sluice the precipitate back into the original beaker, and wash the paper with 20 ml of hot 50% nitric acid and then hot water to give a total volume of 150 ml. Repeat the precipitation as described above but wash with five 20-ml portions of hot ammonium nitrate was solution (Note 4). Sluice the precipitate back into the original beaker with a minimum of water, and dissolve the last traces from the paper with hot 50% nitric acid. Evaporate the solution to 2 ml, and then dilute to 100 ml. Wear goggles when using hot nitric acid.

Place a small wad of glass wool at the base of a 50-ml burette, wash in 15-ml of resin, and condition the resin with 50 ml of 50% nitric acid at a flow-rate of 1 drop/sec. Wash the column free from acid. Pass the sample through the column at a rate of 1 drop/sec, and wash the column 5 times with 15-ml portions of water. To the eluate, add 5·5 ml of perchloric acid and 5 ml of hydrochloric acid, and evaporate to fumes. Transfer the material so obtained to a 125-ml Phillip's beaker, using a minimum amount of water. Add 2 ml of hydrochloric acid, evaporate to fumes, and fume for 1 min (Note 5). Transfer to a 50-ml separating funnel previously marked at the 10·5-ml level, and dilute to 10·5 ml. Add 10 (±0·01) ml of *sym*-diphenylthiourea solution, and shake for 1 min. Allow 10 min for the solutions to separate, and collect the organic phase in a 50-ml beaker containing 0·5 g of anhydrous sodium sulphate. Cover it with aluminium foil. Read the transmittance at 380 mμ on a spectrophotometer against a reference blank prepared by adding 5·5 ml of perchloric acid and 2 ml of hydrochloric acid to a 125-ml Phillip's beaker, fuming, and extracting as described above.

Prepare a calibration curve by adding portions of tellurium solution containing 5, 10, 15, 20, and 25 μg of the element to 0·5 g portions of tellurium-free silver chloride in nickel crucibles, and add a pellet of sodium hydroxide. Evaporate to dryness in an oven at 110° and follow the procedure described. Plot a calibration graph.

Notes

1. This step should be carried out as quickly as possible because the highly alkaline solution dissolves silica from the beaker and makes subsequent filtration difficult.

2. The addition of a sodium salt prevents the volatilization of selenium that otherwise occurs when hydrochloric acid solutions are evaporated. To prevent a loss of selenium, the residue must not be allowed to become dry.

3. Because small losses of selenium occur in the procedure, it is necessary to prepare the calibration graph by carrying standard samples through the entire procedure.

4. To prevent tellurium from passing into the filtrate, it is essential to wash with a solution that approximates as closely as possible to the sample solution.

5. The hydrochloric acid reduces tellurium to the quadrivalent state, but prolonged fuming with perchloric acid causes re-oxidation.

DISCUSSION

Dissolution of the sample

Samples of uranium oxide were dissolved in nitric acid and a little hydrochloric acid was added to reduce the selenium and tellurium to the quadrivalent state for precipitation with sodium carbonate; iron was added as a carrier. The addition of sodium peroxide to the redissolved precipitate is necessary to oxidize the selenium and tellurium to the sexivalent state for the separation of the two elements; the presence of silver and iron is necessary for a complete separation.

Because silver chloride is insoluble in acidic solutions, any operations in an acid medium required the previous complete separation of the silver from the chloride. Also, because selenium interferes in the spectrophotometric methods for tellurium, the separation of the two elements is of the utmost importance.

Fusions with sodium carbonate, sodium hydroxide, and sodium peroxide were investigated, the last-named proving to be by far the most satisfactory. One g of the sample was dissolved in 5 g of sodium peroxide in a nickel crucible. After a water leach, the precipitate of silver and nickel occluded the tellurium, whereas the selenium passed into the filtrate. Hydrogen peroxide was decomposed by boiling, though it was necessary to partially neutralize the solution first. At the reduced alkalinity, the precipitate settled more rapidly, and the dissolution of silica from the beaker, which rendered subsequent filtration difficult, was prevented. Most of the metallic impurities, including the silver, accompanied the tellurium, whereas the chloride remained in solution with the selenium. When the sample was dissolved by sintering with sodium peroxide in a platinum crucible and leaching with water, not all of the tellurium was collected in the precipitate. This indicates that silver alone is not an effective collector for tellurium. When a nickel crucible was used, a complete separation of selenium and tellurium was obtained, and the nickel was easily separated in subsequent operations. Selenium recoveries were checked by the addition of the radioactive isotope (^{75}Se) to the fusion mixture and measurement of the activity of the filtrate, which was found to contain virtually all the selenium. No suitable tellurium isotope was available, so the tellurium recovery was assessed on the results obtained with the whole procedure and by the absence of tellurium in the filtrate.

Determination of selenium

Reduction of sexivalent selenium. Selenium is precipitated by ammonia in the presence of aluminium only if it is in the quadrivalent state; it must also be in the quadrivalent state before it will react with 3,3′-diaminobenzidine. The element is present in the oxidized state after fusion with sodium peroxide, and it was therefore necessary to find a suitable reducing agent. Formaldehyde, iron(II) ammonium sulphate, hydrazine, sulphur dioxide, and ascorbic acid were tried, but they either interfered in the later stages of the method or reduced the selenium to the element. Boiling the sample for 2 min in 4*M* hydrochloric acid was found to effectively reduce the selenium without loss, though conflicting reports appear in the literature on the volatility of selenium in boiling hydrochloric acid solutions. This point was settled by the use of seven 50-μg portions of selenium; the mean recovery was 49·7($\pm$0·5) μg.

Precipitation of selenium with aluminium hydroxide. The large amount of sodium salts present in the solution prevents evaporation to the low volume necessary for the

colour development stage of the method and thus requires separation. Iron(III) hydroxide has been used as a carrier for both selenium and tellurium,[8,9] but the precipitation of selenium was found to be incomplete in both the (IV) and (VI) oxidation states; also, iron is an undesirable element in the colour development stage of the method. The precipitation of quadrivalent selenium with ammonia in the presence of aluminium was found to be quantitative, and the precipitate can be washed at pH 5 with ammonium nitrate solution without loss of selenium. This was tested by precipitating six 20-μg portions of selenium on aluminium hydroxide as described. The recovery was 19·8($\pm$0·2) μg, whether the precipitate was washed or not.

TABLE I.—EFFECT OF TARTARIC ACID ON THE FORMATION OF PIAZSELENOL IN THE PRESENCE OF ALUMINIUM

Tartaric acid added, *g*	Selenium recovered, μg
1·0	42·4
1·5	44·8
2·0	45·8
3·0	49·4
3·5	50·6
4·0	50·8

The solution contained 50 μg of selenium and 75 mg of aluminium.

Dissolution of aluminium hydroxide precipitate. After the precipitation of the selenide on aluminium hydroxide, a considerable excess of acid was required to redissolve the precipitate. Neutralization of this acid was necessary to obtain the correct pH value for colour development, and the ammonium salts of nitric, sulphuric, and hydrochloric acids interfere. The difficulty was overcome by dissolving the aluminium hydroxide precipitate in nitric acid and evaporating off most of the excess of acid. Selenium was not lost during this evaporation, as has been established by other investigators.[9]

Colour development and measurement. For the spectrophotometric determination of the selenium, 3,3′-diaminobenzidine was used. The reaction depends upon the formation of the intensely yellow compound, piazselenol, formed at pH values below 4 and extracted into organic solvents above pH 5. The formation is complete in 30 min in the presence of formic acid, and may be hastened by heating, though this is not recommended because the period of heating is critical. Piazselenol has absorption maxima at wavelengths of 340 and 420 mμ, but the former is not recommended because the 3,3′-diaminobenzidine absorbs strongly at this wavelength. The experimental conditions established by Cheng[5] were adopted for the formation, extraction, and measurement of the piazselenol. As observed by other investigators,[10] variations in the colour of the extracted piazselenol are significant and account for the major portion of the standard deviation in Table IV.

Effect of tartaric acid. Aluminium, added as a co-precipitant for selenium, interfered in the formation and extraction of the piazselenol by causing emulsions to form with the extracting solvent. As reported by Cheng,[5] tartaric acid could be used to form complexes with the aluminium, but a considerable excess was necessary for a complete recovery of the selenium. This effect is illustrated in Table I.

The results were obtained by comparing the measurements with a calibration graph drawn from standards containing no aluminium or tartaric acid.

Effect of ammonium salts. The effect of ammonium salts was studied in the absence of tartaric acid by adding varying amounts of the corresponding concentrated acid to standard selenium solutions, neutralizing with ammonia, and extracting the piazselenol as described in the method. Additions of 0·5 ml of concentrated nitric, sulphuric, or hydrochloric acid resulted in a reduced extraction of selenium. Tartaric acid greatly diminished the effect of ammonium nitrate and, in the presence of 3 g or more of tartaric acid, 2 ml of nitric acid could be tolerated, as shown in Table II.

TABLE II.—EFFECT OF AMMONIUM NITRATE ON THE RECOVERY OF SELENIUM

Nitric acid (sp.gr. 1·39) added and neutralized, *ml*	Selenium recovered, *μg*	
	In the presence of tartaric acid, *μg*	In the absence of tartaric acid,
1	50·8	46·8
2	49·9	43·5
3	48·5	35·6
4	47·1	33·8
5	46·0	33·8

The solutions contained 50 μg of selenium and 75 mg of aluminium.

The experimental conditions for the selenium determination were thus established; the 75 mg of aluminium used for precipitation required 3·5 g of tartaric acid, which in turn allowed up to 2 ml of nitric acid to be present before neutralization.

Interference of cations. Cheng[5] found that in the presence of EDTA and tartaric acid 1 mg of tellurium(IV) and up to 5 mg each of chromium(III), molybdenum(VI), nickel(II), copper(II), and iron(III) did not interfere with 10 μg of selenium. If these elements are present, 10 ml of 0·1*M* EDTA may be added without altering the sensitivity of the method. Vanadium(V) (0·2 mg) also interferes, as do oxidizing agents which oxidize the 3,3′-diaminobenzidine.

Determination of tellurium

The precipitate obtained after dissolution and filtration of the fused sample contains the tellurium, the silver, and most other metallic elements present in the sample. It must be washed until free of chloride since as little as 6 mg of silver chloride co-precipitates 40% of the tellurium at the 25-μg level. Thus when the precipitate is dissolved in nitric acid, the solution must be clear.

Co-precipitation of tellurium with iron(III). As the interferences in the spectrophotometric determination of tellurium by *sym*-diphenylthiourea are numerous, it is necessary to separate the tellurium from most elements. Several investigators have reported that sexivalent tellurium is quantitatively precipitated with ammonia in the presence of iron,[11] but it is generally agreed that tellurium is lost if the precipitate is washed. The present investigators have established that if the wash solution corresponds closely to the supernatant solution after the iron has been precipitated with aqueous ammonia no losses of tellurium are incurred on washing. The precipitation of the tellurium was found to be quantitative for both the quadrivalent and sexivalent states. Analysis of solutions containing 25 μg of tellurium(IV) yielded 24·8(±0·2) μg of tellurium after precipitation as described and analysis of the precipitate; solutions of tellurium(VI) yielded 25·1(±0·4) μg of tellurium.

Two iron(III) hydroxide precipitations were carried out, but only the precipitate from the second precipitation was washed, since it was not possible to ascertain the salt concentration in the first solution closely enough to prepare an efficient wash solution at the time of the first precipitation.

Ion-exchange separation of the iron and other impurities. The amount of iron required as a "collector" for the precipitation of the tellurium with ammonia was more than could be tolerated in the colour development stage. Also other cations present in the original sample required separation. The cation-exchange resin, Dowex 5W–8X, effectively absorbed the remaining interfering cations while tellurium(VI) passed quantitatively through the column. Tellurium(IV) was sorbed on the column.

Reduction of the tellurium. All the operations carried out so far require the tellurium to be in the sexivalent state. As the reaction with *sym*-diphenylthiourea takes place only with tellurium(IV), reduction is necessary. Reducing agents such as sodium dithionite, sulphur dioxide, ascorbic acid, hydroxylamine hydrochloride, and hydrazine sulphate were unsuccessful. The addition of hydrochloric acid and evaporation to fumes with perchloric acid was found to reduce all the tellurium. It is necessary to remove all but traces of the hydrochloric acid, but prolonged fuming is undesirable because it causes re-oxidation of the tellurium. The reduction reaction is

$$H_2TeO_4 + 2HCl \rightarrow H_2TeO_3 + Cl_2 + H_2O.$$

The completeness of reduction was checked by preparation of standard solutions of tellurium(IV) and tellurium(VI). Calibration graphs for the two solutions coincided after the tellurium(VI) had been reduced with hydrochloric acid. The length of time for which the solutions could be fumed strongly before re-oxidation took place was also ascertained, as shown in Table III. One minute of strong fuming was adopted for the procedure.

TABLE III.—OXIDATION OF TELLURIUM BY FUMING PERCHLORIC ACID

Tellurium(IV) (μg) recovered after fuming strongly for					
0·5 min	1 min	3 min	5 min	10 min	30 min
29·7	29·9	28·5	27·5	22·5	3·1
29·9	30·6	29·1	26·5	20·1	9·6

The solution contained 30 μg of tellurium.

Portions of the standard tellurium(VI) solution were determined spectrophotometrically without going through the preliminary separation steps of procedure, and the results were accumulated. These results were obtained over a period of several months. A statistical analysis of these values indicates the reproducibility of this part of the method.

Number of determinations	18
Tellurium added	25·0 μg
Mean tellurium recovered	24·77 μg
Standard deviation	1·02 μg.

Extraction and spectrophotometric measurement. *sym*-Diphenylthiourea[7] is used for the spectrophotometric determination of the tellurium. Many substances interfere, but these are eliminated in the preceding separations.

Iron, bismuth, lead, and selenium are perhaps the most serious interferences and must be absent. The tellurium complex may be extracted from either hydrochloric

or perchloric acid, but the latter was chosen because it permitted the nitric acid in the sample solution to be eliminated by fuming. Maximum sensitivity is attained by measuring the complex at 380 mμ.

RESULTS

Results obtained on the crude silver chloride sample were analysed statistically for both selenium and tellurium as shown in Tables IV and V. The sample was also "spiked" with known amounts of selenium and tellurium and analysed to determine the completeness of recovery.

TABLE IV.—SELENIUM RESULTS OBTAINED ON THE SAMPLE OF CRUDE SILVER CHLORIDE

Se added, μg	Total Se recovered, μg	Nett Se recovered, μg	Mean value, μg	No. of determinations	Standard deviation, μg
0	14·6	14·6			
5	19·9	14·9	14·23	23	1·28
10	23·2	13·2			

One gram of sample was used for each determination.

TABLE V.—TELLURIUM RESULTS OBTAINED ON THE SAMPLE OF CRUDE SILVER CHLORIDE

Te added, μg	Total Te recovered, μg	Nett Te recovered, μg	No. of determinations	Standard derivation, μg
0	3·4	—	8	
5	7·8	4·5	3	
10	12·6	9·3	10	0·31
15	17·7	14·3	12	0·70
25	27·3	23·9	2	
30	34·5	31·1	2	
40	45·5	42·1	2	
50	53·4	50·0	2	

One gram of sample was used for each determination.

A sample of triuranium octaoxide was analysed for selenium and tellurium giving the results shown in Table VI. The sample was also "spiked", and a portion of the pure oxide was run concurrently as a blank. The results indicate that the selenium and tellurium content was under 0·5 ppm, and, at this low level, the "spike" recoveries were considered satisfactory.

Discussion of results

The amounts of selenium and tellurium recovered, when known amounts of these elements were added to pure silver chloride and analysed as described in the complete procedure, were low when compared with standard solutions analysed by the colour

TABLE VI.—SELENIUM AND TELLURIUM RESULTS ON A SAMPLE OF U_3O_8

development and solvent extraction part of the procedure, *i.e.*, standards not taken through the separation procedures described in the method. When these results were plotted, the curves in Figs. 1 and 2 were obtained, indicating that losses of selenium and tellurium were incurred during the procedure and these losses increased with increasing amounts of selenium and tellurium. The authors can offer no explanation for the latter phenomenon, but the former possibly results from consistent losses, at various stages in the procedure, that were too small to be detected by the spectrophotometric procedure. The cumulative effect of these small losses may account for the low results obtained on the pure silver chloride. As the calibration graph obtained by the complete procedure was reproducible and enabled reasonably accurate results to be obtained, it was decided not to investigate these losses any further. The curved graphs could be closely reproduced by three independent operators, and the results reported for the samples were calculated by use of these calibration graphs.

With modification to the dissolution technique, the procedure is adaptable to the determination of selenium and tellurium in other silver and uranium compounds, as well as in the metals.

Zusammenfassung—Methoden zur Bestimmung von Selen und Tellur in als Nebenprodukt der Goldraffination anfallendem rohem Silberchlorid und in hochreinem Uranoxid werden beschrieben. Selen und Tellur werden voneinander und von den zahlreichen anderen Stoffen in der Probe getrennt, ehe sie in organische Lösungsmittel extrahiert und spektrophotometrisch bestimmt werden. Zur Bestimmung von Selen wird 3,3′-Diaminobenzidin verwendet, für Tellur sym-Diphenylthioharnstoff. Als Minimum konnen 2 ppm von beiden Elementen in Silberchlorid und 0,3 ppm in Uranoxid bestimmt werden. Zum Nachweis von Genauigkeit und Richtigkeit der Methode werden statistische Daten angegeben.

Résumé—On décrit des méthodes de dosage du sélénium et du tellurium dans le chlorure d'argent brut obtenu comme sous-produit du raffinage de l'or et dans l'oxyde d'uranium de haute pureté. On sépare le sélénium et le tellurium l'un de l'autre ainsi que de nombreuses autres substances dans l'échantillon avant de les extraire en solvants organiques et de les doser spectrophotométriquement. Pour le dosage du sélénium, on utilise la 3,3′-diaminobenzidine et pour le tellurium la diphénylthiourée symétrique. On peut doser un minimum de 2 p.p.m. de chaque élément dans le chlorure d'argent et 0,3 p.p.m. dans l'oxyde d'uranium. On fournit des données statistiques pour montrer la précision et l'exactitude des méthodes.

SPEKTROPHOTOMETRISCHE BESTIMMUNG VON WOLFRAM IN MOLYBDÄN

B. NEEF und H.-G. DÖGE
Institut für Metallphysik und Reinstmetalle der Deutschen Akademie der Wissenschaften zu Berlin, Dresden

(*Eingegangen* 7 *Februar* 1967. *Angenommen* 21 *März* 1967)

Zusammenfassung—Ein Verfahren zur spektrophotometrischen Bestimmung von Wolframspuren in Molybdän wird beschrieben. Die Trennung beruht auf dem verschiedenen Verhalten beider Elemente gegenüber Reduktionsmittel. Zuerst wird das Molybdän mit Thioglykolsäure reduziert und als Molybdän(V)-thiocyanatokomplex extrahiert. Nach Reduktion mit Titan(III)-chlorid wird Wolfram als Wolfram(V)-thiocyanatokomplex extrahiert und spektrophotometrisch bestimmt. 0,5 μg Wolfram können in 0,1–0,5 g Molybdän erfaßt werden.

DIE BESTIMMUNG kleiner Wolframgehalte in Molybdän ist mit Ausnahme eines spektrophotometrischen Verfahrens,[1] mit dem noch 10 ppm Wolfram erfaßt werden können, bisher nur spektralanalytisch ohne Trennung der beiden Elemente ausgeführt worden. Um das Nachweisvermögen der verschiedenen Bestimmungsmethoden für Wolframspuren voll ausnutzen zu können, ist eine Abtrennung des Wolframs vom Grundmaterial notwendig. Bei dem erwähnten spektrophotometrischen Verfahren erfolgt diese Trennung durch Extraktion des Wolfram(VI) als 8-Hydroxychinolinkomplex, während das mit Hydrazinhydrochlorid reduzierte Molybdän als nichtextrahierbarer Molybdän(V)-Äthylendiamintetraessigsäurekomplex in der wäßrigen Phase zurückbleibt.

Aus der Literatur ist die Extrahierbarkeit der Molybdän(V)- bzw. Wolfram(V)-thiocyanatokomplexe bekannt. So wurde Molybdän nach Reduktion mit Thioglykolsäure[2,3] und Wolfram nach Reduktion mit Zinn(II)-chlorid[4] extrahiert. Außerdem ist ein Verfahren zur Abtrennung von Molybdänspuren von einer Makromenge Wolfram aus thiocyanathaltiger Lösung bekannt.[5]

Es sollte deshalb untersucht werden, ob die Extraktion aus thiocyanathaltiger Lösung auch für die Abtrennung von Wolframspuren aus einer Makromenge Molybdän anwendbar ist. Da Molybdationen leichter als Wolframationen reduziert werden, ist es notwendig, zunächst das Molybdän aus der Lösung zu entfernen, wobei Wolfram aber möglichst vollständig in der wäßrigen Phase verbleiben muß. Anschließend kann dann Wolfram extrahiert und photometrisch bestimmt werden.

MOLYBDÄN-WOLFRAM-TRENNUNG

Abbildung 1 zeigt das Verteilungsverhalten des Molybdän(V)-thiocyanatokomplexes in Abhängigkeit von der Säurekonzentration. Die Probelösung, insgesamt 15 ml, enthält 100 mg Molybdän als Natriummolybdat, 2 ml 60%ige Citronensäurelösung, 2 ml 5 m Ammoniumthiocyanatlösung, 10 Tropfen Thioglykolsäure und der angegebenen Konzentration entsprechende Mengen an Schwefel- bzw. Salzsäure. Nach Zugabe der Thioglykolsäure muß bis zur Extraktion, die mit 15 ml Butylacetat erfolgt, 15 min gewartet werden, damit sich die Reduktion des Molybdän(VI) zu Molybdän(V) vervollständigen kann. Extrahiert man vor Ablauf dieser Zeit, so erhält man kleinere und schwankende Verteilungsverhältnisse.

Zur Ermittlung der Verteilungsverhältnisse wurde der Molybdängehalt der wäßrigen Phase nach Zerstörung der organischen Substanzen durch Abrauchen mit konzentrierter Schwefelsäure spektrophotometrisch mit Phenylhydrazin bestimmt.[6]

Abbildung 2 zeigt die unter gleichen Bedingungen ermittelten Verteilungsverhältnisse für jeweils 200 μg Wolfram in Gegenwart von 100 mg Molybdän. Sie wurden durch Messung der Wolfram-187-Aktivitäten in beiden Phasen erhalten. Die Zugabe

II—Schwefelsäure.

der Citronensäure verhindert infolge Bildung nichtextrahierbarer Citratkomplexe die Extraktion des Wolfram(VI).[7]

Zur Ermittlung der für die Trennung optimalen Extraktionsbedingungen sind in Tab. I die Verteilungsverhältnisse für Molybdän und Wolfram und die daraus erhaltenen Trennfaktoren in salz- bzw. schwefelsauren Lösungen zusammengestellt. Unter Berücksichtigung dieser Werte wurde in der Arbeitsvorschrift die Extraktion aus 4 n schwefelsaurer Lösung festgelegt. Diese Bedingungen entsprechen nicht der Regel, nach der optimale Trennwirkung dann erzielt wird, wenn das Produkt der Verteilungskoeffizienten der zu trennenden Elemente 1 ist.[8] Durch die Steigerung der Schwefelsäurekonzentration von 2,5 auf 4 n erhält man aber eine bessere Molybdänabreicherung, so daß schon zwei Extraktionen zur vollständigen Abtrennung ausreichen. Der dabei auftretende Wolframverlust von etwa 5% wird bei der Eichung berücksichtigt.

WOLFRAMBESTIMMUNG

Nach Entfernung des Molybdäns befindet sich das Wolfram gemeinsam mit den unter diesen Bedingungen nicht extrahierbaren Verunreinigungen in der wäßrigen Phase. Zur extraktionsphotometrischen Bestimmung wird es nach Reduktion mit Titan(III)-chlorid als Wolfram(V)-thiocyanatokomplex extrahiert. Abbildung 3, die das Verteilungsverhalten des Wolfram(V)-thiocyanatokomplexes in Abhängigkeit von

der Schwefelsäure- und Ammoniumthiocyanatkonzentration zeigt, ist zu entnehmen, daß die Extrahierbarkeit des Wolframs mit steigender Säure- und Thiocyanatkonzentration zunimmt.

Zweckmäßigerweise extrahiert man aber bei einer nicht zu hohen Thiocyanationenkonzentration, weil die Thiocyanwasserstoffsäure, die ebenfalls gut extrahiert wird, sich in der organischen Phase oberhalb einer bestimmten Konzentration unter Bildung der gelbgrünen Isoperthiocyansäure zersetzt, die die photometrische Be-

II—0,66 m Ammoniumthiocyanat;
III—1,0 m Ammoniumthiocyanat.

stimmung stört. Als ausreichend hat sich die Extraktion aus 0,66 n Ammoniumthiocyanatlösung erwiesen, wobei 97–98% des Wolframs erfaßt werden. Es zeigte sich jedoch, daß bei dieser Konzentration schon Isoperthiocyansäure gebildet wird, die sich aber zusammen mit der Thiocyanwasserstoffsäure ohne nennenswerte Wolframverluste aus der organischen Phase mit verdünnter Salzsäure auswaschen läßt. Tabelle II zeigt das Verteilungsverhalten des Wolfram(V) thiocyanatokomplexes zwischen Butylacetat und Salzsäure verschiedener Konzentration.

Untersuchungen über den Einfluß von Molybdän auf die Wolframbestimmung ergaben, daß die bei einem Trennfaktor von etwa $5 \cdot 10^5$ in der wäßrigen Phase verbleibenden Matrixspuren die Wolframbestimmung nicht stören.

Die Extinktionskurve des in Butylacetat extrahierten Wolfram(V)-thiocyanatokomplexes entspricht in ihrem Verlauf der Kurve der wäßrigen Komplexlösung.[9] Das Extinktionsmaximum liegt bei 400 mμ, der molare Extinktionskoeffizient beträgt dort $1{,}7 \cdot 10^4$.

ARBEITSVORSCHRIFT

(a) Wolframgehalte von 50 bis 200 ppm

In einem Gemisch von 2 ml Wasser, 2 ml konzentrierter Flußsäure und 1,5 ml konzentrierter Salpetersäure werden 100 mg Molybdän gelöst. Die Lösung wird zur Trockne eingedampft und der Rückstand in 1 ml 8 n Natronlauge aufgenommen. Man neutralisiert die Probelösung und überführt sie mit wenig Wasser in einen Schütteltrichter. Zu dieser Lösung, die etwa 5 ml betragen soll, werden 2 ml 60% ige Citronensäurelösung, 2 ml 5 m Ammoniumthiocyanatlösung, 6 ml 10 n Schwefelsäure und 10 Tropfen Thioglykolsäure gegeben. Nach einer Wartezeit von 15 min schüttelt man 90 sec mit 15 ml Butylacetat. Auf eine vollständige Trennung der Phasen ist zu achten. Die wäßrige Phase wird in einen zweiten Schütteltrichter überführt und die organische Phase verworfen.

Anschließend wird die wäßrige Phase mit 1 ml 5 m Ammoniumthiocyanatlösung und 2 Tropfen Thioglykolsäure versetzt. Nach 5 min schüttelt man 60 sec mit 10 ml Butylacetat und überführt die wäßrige Phase zur Wolframextraktion in einen weiteren Schütteltrichter.

Zu dieser Lösung gibt man 2 ml 5 m Ammoniumthiocyanatlösung, 2 ml 10 n Schwefelsäure und 3 ml 0,1 m Titan(III)-chloridlösung in 4 n Schwefelsäure. Nach 15 min extrahiert man mit genau 10 ml Butylacetat. Danach wird die organische, wolframhaltige Phase dreimal mit 10 ml 1 n Salzsäure 60 sec gewaschen und anschließend zentrifugiert. Die Extinktion der Lösung wird in einer 3-cm Küvette bei 400 mμ gemessen.

(b) Wolframgehalte von 1 bis 50 ppm

Zu der 0,5 g Molybdän enthaltenden Probelösung (7 ml) werden 6 ml 60%iger Citronensäurelösung, 10 ml 5 m Ammoniumthiocyanatlösung, 6 ml 20 n Schwefelsäure und 1 ml Thioglykolsäure gegeben. Nach einer Wartezeit von 15 min wird der Molybdän(V)-thiocyanatokomplex zunächst mit 30 ml Butylacetat und anschließend mit 15 ml Butylacetat 90 sec extrahiert. Die Extraktion des restlichen Molybdäns erfolgt nach Zugabe von 2 ml 5 m Ammoniumthiocyanatlösung und 6 Tropfen Thioglykolsäure mit 15 ml Butylacetat.

Zur wäßrigen Phase gibt man 4 ml 5 m Ammoniumthiocyanatlösung, 2 ml 20 n Schwefelsäure und 3 ml 0,1 m Titan(III)-chloridlösung in 4 n Schwefelsäure. Die weitere Ausführung der Analyse erfolgt wie unter (*a*) beschrieben.

BEWERTUNG DES VERFAHRENS

In Tab. III sind die spektrophotometrisch bestimmten Wolframgehalte einiger Molybdänproben den Resultaten aktivierungsanalytischer Vergleichsanalysen gegenübergestellt.

TABELLE III.—ERGEBNISSE VON WOLFRAMBESTIMMUNGEN IN MOLYBDÄN

4	0,5	26	2,7	9
5	0,5	2	20	4

Standardabweichung der Blindwerte ist nach dem 3-σ-Kriterium die Nachweisgrenze des Verfahrens ermittelt worden. Sie beträgt bei einer Einwaage von 0,1 g Molybdän 5 ppm und bei einer Einwaage von 0,5 g Molybdän 1 ppm Wolfram. Die Blindwerte sind in Gegenwart der genannten Molybdänmengen bestimmt worden.

Zur Durchführung von zwei Analysen benötigt man etwa zwei Stunden.

Summary—A procedure is described for the spectrophotometric determination of traces of tungsten in molybdenum. The separation is based on the different behaviour of both elements towards reduction reagents. First the molybdenum is reduced with thioglycollic acid and extracted as molybdenum(V) thiocyanate complex. After reduction with titanium(III) chloride, tungsten is extracted as tungsten(V) thiocyanate complex, which is determined spectrophotometrically. Amounts of 0·5 μg of tungsten can be determined in 0·1–0·5 g of molybdenum.

Résumé—On décrit une technique de dosage spectrophotométrique de traces de tungstène dans le molybdène. La séparation est basée sur le comportement différent des deux éléments vis-à-vis des réactifs de réduction. Le molybdène est d'abord réduit par l'acide thioglycolique et extrait à l'état de complexe thiocyanate-molybdène (V). Après réduction par le chlorure de titane (III), on extrait le tungstène à l'état de complexe thiocyanate-tungstène (V), que l'on dose spectrophotométriquement. On peut doser des quantités de 0,5 μg de tungstène dans 0,1–0,5 g de molybdène.

SHORT COMMUNICATIONS

Reduction of iridium after oxidation in fuming perchloric acid

(*Received* 23 *December* 1966. *Accepted* 2 *April* 1967)

RECENT papers[1–3] on the electrolytic reduction of iridium in perchloric acid media have contained no reference to the work carried out by Pshenitsyn *et al.*[4] These authors have suggested that the high results obtained in reduction titrations of iridium solutions which have been fumed with perchloric acid are due to reduction products of the acid remaining in combination with the iridium(IV), rather than to the existence of a higher oxidation state of iridium. They attributed the two-stage potentiometric titration curve to the reduction of one of these products followed by titration of the other simultaneously with iridium. McBryde and Cluett[5] also suggested that varying amounts of oxides of chlorine remained in solution in analogous systems. The behaviour of perchlorate solutions of the platinum metals is relevant to our present study of various oxidation states of these metals in which the reduction of iridium has received particular attention.

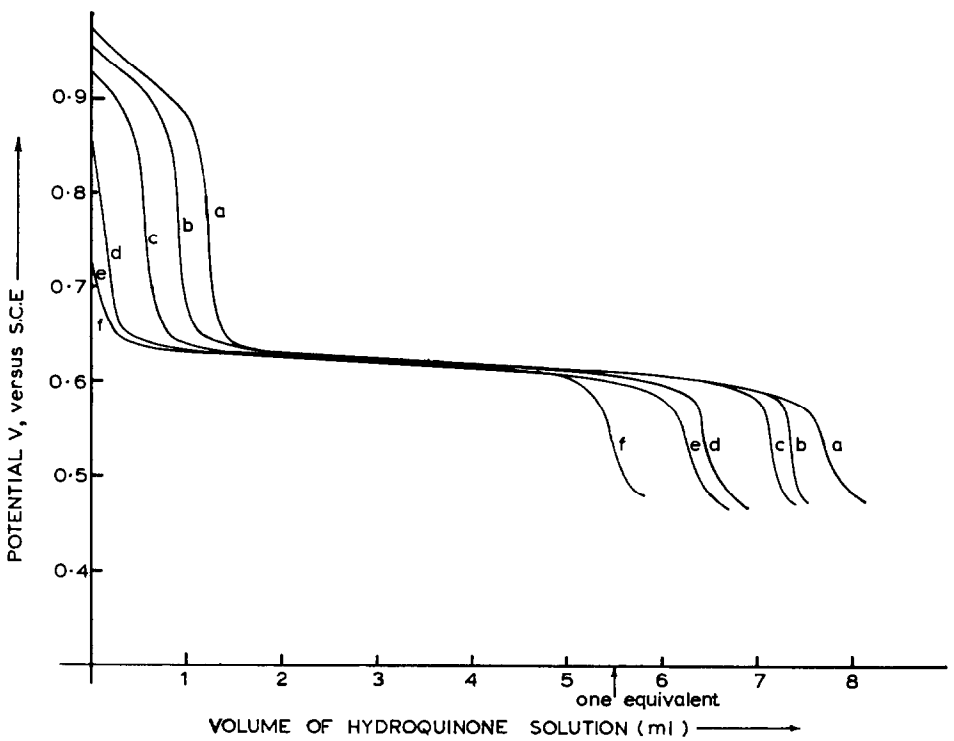

FIG. 1.—Effect of increasing nitrogen flushing time on the reduction titration of iridium after oxidation in fuming perchloric acid.

(*a*) No nitrogen; (*b*) 0·5 hr; (*c*) 1 hr; (*d*) 2 hr; (*e*) 3 hr; (*f*) 8 hr.

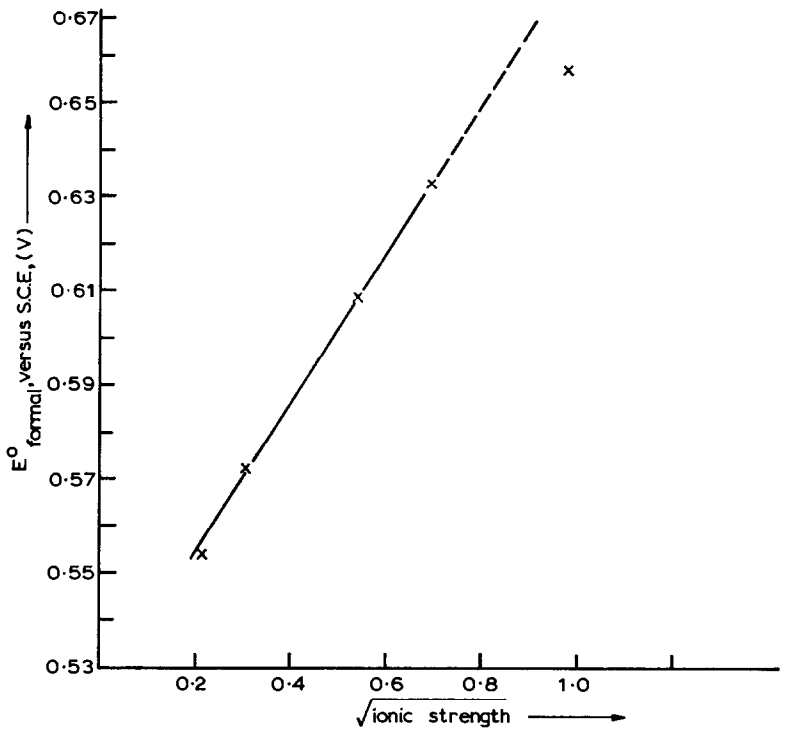

FIG. 2.—Effect of ionic strength on the formal redox potential of the Ir(IV)–Ir(III) system in perchlorate solution.

Despite the inability of Pshenitsyn *et al.* to remove the volatile products by prolonged heating of the solutions, it seemed reasonable to suppose that, if they existed, flushing of the solution with an inert gas for an extended period might accomplish this removal.

EXPERIMENTAL

A stock solution of chloroiridite was prepared from ammonium chloroiridate by reduction with the theoretical quantity of hydrazine hydrochloride. After boiling, the solution was diluted appropriately. The solution was standardised by the gravimetric modification of Pollard's thiourea method[6,7] and was found to contain 1·10 mg of Ir/ml.

Five-ml portions of this solution were evaporated to strong fumes with 1 ml of 60% perchloric acid. After dilution with 10 ml of water each solution was boiled, cooled, diluted to 100 ml, deaerated with nitrogen and titrated potentiometrically with a standard hydroquinone (0·2848 g/l) or iron(II) perchlorate solution. A platinum indicating electrode was used in conjunction with a saturated calomel electrode equipped with a lithium acetate bridge: the cell's potential was measured with a valve voltmeter. Figure 1a is a typical curve and is similar to those obtained by Pshenitsyn *et al.*

Further 5-ml portions of the chloroiridite solution were evaporated to strong fumes with perchloric acid. After dilution, each solution was transferred to a flask and a stream of nitrogen or carbon dioxide was passed through it at a flow rate of 10 l/hr, with the temperature of the solution maintained almost at boiling point. Great care was taken to avoid extraneous reduction and evaporation: an all-glass assembly was used, and the nitrogen was passed through a series of flasks containing acidified permanganate and finally a flask of water before it entered the test solution. After an appropriate time each iridium solution was titrated. Curves b–f in Fig. 1 are those obtained with increasing flushing time. When no gas was admitted the titration curve remained substantially as Fig. 1a even after more than 8 hr.

The two gas streams were equally effective, but use of carbon dioxide generated *in situ*, although showing some reduction in the titration volume, was impracticable since large quantities of carbonates had to be added for a correspondingly small reduction in the volume of titrant needed. In an analogous

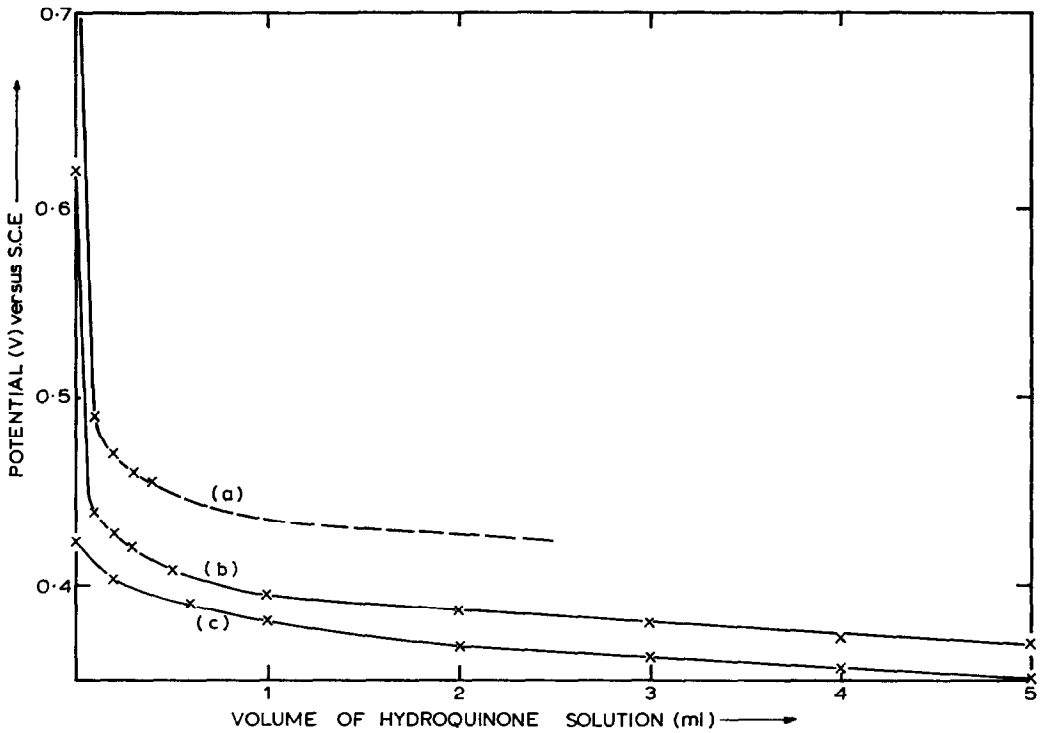

FIG. 3.—Reduction titrations of distillates and fumed perchloric acid.

(*a*) Distillate trap solution;
(*b*) Pure perchloric acid strongly fumed and diluted only;
(*c*) Pure perchloric acid strongly fumed and degassed.

case of chromium oxidized with fuming perchloric acid, *in situ* generation of carbon dioxide proved successful.[8]

RESULTS AND DISCUSSION

A titration, stoichiometric for a one-electron reduction, was obtained after 8 hr or more of nitrogen or carbon dioxide treatment; further extension reduced the volume of titrant needed no further and in all cases the solution at the final inflexion had all the properties of that of iridium(III) alone. No further inflexions could be detected even with large excesses of reducing agent. The titration curve remained very flat compared with that for chloroiridate reduction, which gives a normal curve for a one-electron change, and the slope of a plot of potential *vs.* log [Ir(IV)]/[Ir(III)] gave an apparent electron change of ~4. A further anomaly was found to be the positive shift in the $E^{\circ}_{\text{formal}}$ value with increasing ionic strength of the solution (Fig. 2), similar effects being obtained with perchloric acid and with magnesium perchlorate as added electrolyte. This is the behaviour expected of an anionic system,[9] whereas ion-exchange tests firmly indicated that the iridium is in the cationic form. In view of the findings of Dwyer *et al.*[9] that potentials determined from titration curves of chloroiridate were appreciably lower than those obtained from direct potential measurements of $IrCl_6^{2-}$–$IrCl_6^{3-}$ mixtures, such errors might exist also in the case of the present system, but this should not account for the direction of change of $E^{\circ}_{\text{formal}}$ with ionic strength.

Attempts to collect and identify chemically any volatile products proved unsuccessful even with amounts of iridium up to 50 mg. Since these products would be evolved over the 8-hr period in a volume of some 80 l. of gas their detection would be difficult. However, the distillate-trap solutions had a highly positive potential which decreased on addition of standard hydroquinone solution. Comparison was made with potentiometric titrations of strongly fumed and diluted pure perchloric acid, with and without degassing (Fig. 3) and this suggests the presence of highly oxidizing species both in the strongly fumed perchloric acid and in the distillate-trap solution. No further oxidizing species were detected in the trap after the 8-hr flushing period.

Figure 1 shows that the nitrogen treatment eliminates the first inflexion point relatively rapidly, while the position of the second remains substantially constant. Only when the first inflexion disappears does the position of the second begin slowly to decrease to give ultimately a stoichiometric one-electron reduction titre. This could suggest, if distortion is not excessive, the existence of two distinct oxidizing species, the first of which may be "free" and is removed relatively easily, while the second appears to be more firmly "bound" and is removed with greater difficulty and is characteristic of the presence of iridium in the solution. In general, this work supports the view of Pshenitsyn[4] that strongly-oxidizing volatile species, possibly Cl_2O and Cl_2 originating from the perchloric acid, reach high proportions by some form of association when iridium is present: one of the products gives a separate inflexion in the potential curve, the other is titrated along with the iridium(IV) to give an apparently single step.

This work also indicates that a higher oxidation state of iridium is not likely to be present. Removal of the products by lengthy displacement with an inert gas is similar to what happens in the case of chromium, which is known[8] not to be in a higher oxidation state. Nevertheless, the removal is remarkably slow, which indicates either that the oxidizing products are rather involatile (which should have made them easier to detect in the exhaust gases) or, more likely, that they are at least weakly associated with the iridium or perhaps the perchloric acid in solution. The anomalous shift in the formal electrode potential is receiving further attention in this connection.

Summary—Evidence is given in support of the theory that high results obtained for reduction titrations of iridium solutions which have been fumed with perchloric acid are due to retention in solution of volatile reduction products of the acid.

Zusammenfassung—Zu hohe Ergebnisse bei Reduktionstitrationen von mit Überchlorsäure abgerauchten Iridiumlösungen könnten vom Verbleiben flüchtiger Reduktionsprodukte der Säure in der Lösung herrühren. Hinweise auf die Richtigkeit dieser Theorie werden angegeben.

Résumé—On donne des arguments à l'appui de la théorie suivant laquelle les résultats élevés obtenus dans les dosages par réduction des solutions d'iridium qui ont été chauffées avec de l'acide perchlorique sont dûs à la rétention en solution de produits de réduction volatils de l'acide.

Spectrophotometric determination of cobalt with phenanthrenequinone monoxime

(*Received* 6 *December* 1966. *Accepted* 13 *March* 1967)

Of the organic reagents employed for the spectrophotometric determination of cobalt[1-8] those with the grouping —CO—C(=NOH)—, present in the monoxime of diketones, give a selective reaction. Nitroso-R-salt continues to be favoured by analysts. Phenanthrenequinone monoxime (PQM),[4-7] a reagent of this class, forms insoluble coloured chelates with a number of metals, particularly cobalt, iron(II), copper and nickel.

The present communication deals with the spectrophotometric study of the reaction of cobalt with PQM and the determination of cobalt. The reagent reacts with cobalt(III) in an aqueous ethanolic medium to give a yellow–orange chelate, extractable into organic solvents, such as benzene, chloroform and carbon tetrachloride. The rate of reaction is slow at room temperature, but can be hastened by heating. The complex is stable towards strong acids.

The reagent compares favourably with Nitroso-R salt in sensitivity and freedom from interferences. Unlike Nitroso-R salt, in solution it is stable to heat and light, and can be stored for long periods without deterioration.

EXPERIMENTAL

Reagents

PQM solution, 0·1% w/v in ethanol. The reagent was synthesized by Goldschmidt's procedure.[8]

Cobalt solution. A stock solution of reagent-grade cobalt(II) sulphate heptahydrate, prepared in doubly distilled water, was standardised gravimetrically as the anthranilate.[9] It contained 2·54 mg of cobalt per ml.

Reagent grade chemicals were used in the study of interferences.

Procedure for spectrophotometric determination

Take a suitable aliquot containing up to 3·0 ppm of cobalt and adjust its pH to 5·0 with 10 ml of acetate buffer. Dilute to 20 ml, and add 2 ml of 0·1% reagent solution.

Allow to stand for at least 1 hr, the minimum time for complete complex formation, or heat on a boiling water-bath for 3 min. Add 20 ml of chloroform and extract the orange complex. Centrifuge the organic phase and measure its absorbance at 470 mμ against a reagent blank, prepared under identical conditions. For larger amounts of cobalt, use larger volumes of chloroform. The absorbance remains constant for at least 48 hr.

RESULTS AND DISCUSSION

Spectrophotometric studies

The cobalt complex of PQM has an absorption maximum at 410 mμ and exhibits a broad shoulder between 450 and 470 mμ (Fig. 1). The reagent also absorbs strongly at 410 mμ, but not at 470 mμ, so the latter wavelength has been used for these studies.

A study of solutions in which the mole ratio of cobalt to reagent was varied from 2:1 to 1:10 revealed that a five-fold excess of the reagent is required for full coloration. However, a ten-fold excess was maintained in subsequent studies.

The effect of pH on stability of the complex was determined by preparing a series of solutions varying in pH from 3·72 to 9·0. The absorption maximum (and the wavelength at which it occurs) remain unchanged between pH 4·45 and 8·0. Thus rigid control of pH is not necessary, and sodium acetate-acetic acid buffer of pH 5·0 was employed in the determinations.

Validity of Beer's law and sensitivity of the reaction

The complex was found to obey the Lambert-Beer law over the concentration range 0–3·0 ppm of cobalt at 470 mμ. The optimum range, evaluated by a Ringbom[10] plot, is 0·60–2·4 ppm. The sensitivity of the colour reaction according to Sandell's definition is 0·00336 μg of Co/cm² at 470 mμ for 0·001 absorbance. The molar absorptivity is $17{\cdot}5 \times 10^3$.

Composition and apparent instability constant

For evaluating the composition of the cobalt-PQM complex, equimolar solutions ($1 \times 10^{-4}M$) of cobalt and reagent were employed. Job's method of continuous variations,[11] extended to a two-phase system by Irving and Pierce[12] (Fig. 2) and the mole-ratio method[13] (Fig. 3) indicate the formation of a complex of definite composition between cobalt and the reagent in the mole ratio of 1:3. This was further confirmed by analysis of the extracted chelate and is in conformity with the composition reported previously.[5–7] The 1:3 complex seems to contain tervalent cobalt as do the cobalt chelates with nitroso-naphthols.[14]

The apparent instability constant K, calculated from the equation

$$K = \frac{(\alpha C)(n\alpha C)^n}{C(1-\alpha)}$$

is $2{\cdot}34 \times 10^{-15}$ (where C is the concentration of the complex in mole l^{-1} and n is 3).

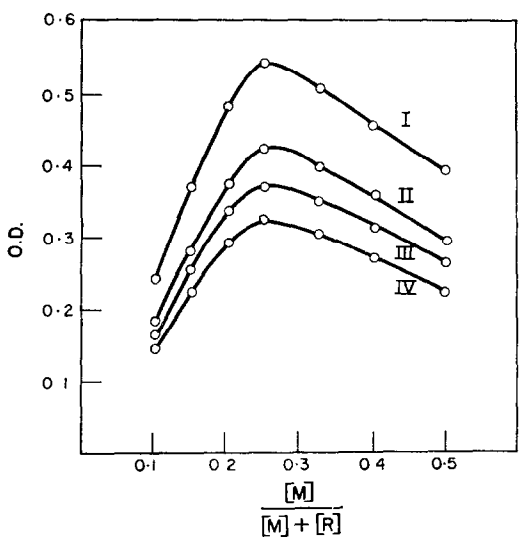

FIG. 2.—Composition of cobalt–PQM complex by Job's method, at pH 5·0. Total molarity: $1 \times 10^{-4}M$. I—400 mμ; II—440 mμ; III—470 mμ; (IV)—500 mμ.

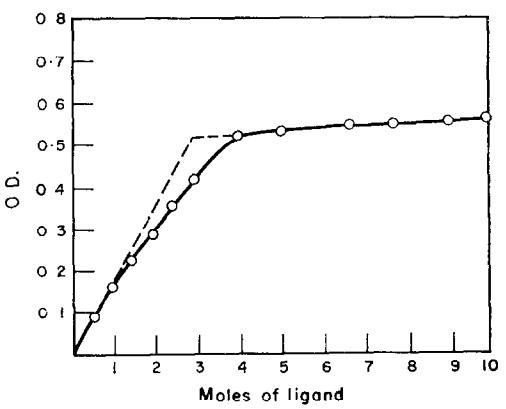

FIG. 3.—Mole-ratio method pH 5·0, 470 mμ; concentration of cobalt = $3 \times 10^{-5}M$

The degree of dissociation α is calculated from the relationship[15]

$$\alpha = \frac{E_m - E_s}{E_m}$$

where E_s is the absorbance at the mole ratio 1:3 and E_m is the absorbance that would have been observed at the point in the absence of dissociation. The E_m and E_s values are 0·55 and 0·42 at a cobalt concentration of $3 \times 10^{-5}M$ and α is thus 0·236.

Effect of diverse ions

Synthetic solutions, containing known quantities of cobalt and varying amounts of diverse ions were prepared and the cobalt was determined. Calcium, barium, strontium, magnesium, vanadium, aluminium, beryllium, bismuth, chloride, tartrate, citrate, nitrate, sulphate, iodate, sulphite, thiocyanate, malonate, phthalate, chlorate, perchlorate and chromate ions do not interfere with the determination even when present in a thousand times the cobalt concentration. EDTA and NTA interfere even in traces.

Copper, nickel, iron, mercury, silver and palladium also form extractable complexes with the reagent. Arsenic, antimony, platinum, gold and tin, though themselves not extracted, affect the recovery of cobalt.

Palladium is removed by precipitating it from highly acidic solutions (0·1*M* hydrochloric acid) with PQM as reagent,[16] centrifuging and analysing the supernatant layer for cobalt or by precipitating the palladium at pH 1·00 and extracting it into chloroform. Iron(II) forms a green complex. Interference from it is eliminated by oxidation with hydrogen peroxide in the presence of sodium citrate in the cold. Silver and mercury are removed by precipitation as chloride and iodide respectively. It is possible to extract cobalt in the presence of copper by adding excess of iodide or thiosulphate. The iodine liberated must be reduced with sodium sulphite. Thiourea can also be used to mask copper. Nickel–cobalt mixtures can be dealt with by precipitating both metals and adding

TABLE 1.—EFFECT OF FOREIGN IONS ON THE DETERMINATION OF 1·2 ppm OF COBALT

Summary—Phenanthrenequinone monoxime reacts with cobalt to form a yellow–orange insoluble 1:3 (cobalt:ligand) complex which is extractable into chloroform in the pH range 4·45–8·0. The determination of cobalt is carried out at 470 mμ. Beer's law is obeyed over the concentration range 0–3·0 ppm of cobalt. The sensitivity is 0·00336 μg of Co/cm^2 for 0·001 absorbance. The effect of a number of foreign ions has been studied.

Zusammenfassung—Phenanthrenchinonmonoxim reagiert mit Kobalt zu einem gelborangen unlöslichen 1:3-(Kobalt:Ligand)-Komplex, der sich bei pH 4,45–8,0 in Chloroform extrahieren läßt. Kobalt wird bei 470 nm bestimmt. Das Beersche Gesetz gilt bei 0–3,0 ppm Kobalt. Die Empfindlichkeit beträgt 0,00336 μg Kobalt/cm^2 bei der Extinktion 0,001. Der Einfluß einer Anzahl von Fremdionen wurde untersucht.

Résumé—La monoxime de la phénanthrènequinone réagit avec le cobalt pour former un complexe jaune orangé insoluble 1:3 (cobalt: ligand) qui est extractible en chloroforme entre pH 4,45 et 8,0. Le dosage du cobalt est mené à 470 mμ. La loi de Beer est observée pour les concentrations en cobalt allant de 0 à 3,0 ppm. La sensibilité est de 0,00336 μg de Co/cm^2 pour une absorbance de 0,001. On a étudié les effets d'un certain nombre d'ions étrangers.

Determination of sorbic acid with sodium chlorite

(*Received* 8 *December* 1966. *Accepted* 14 *March* 1967)

THE diene structure of sorbic acid suggests the possibility of its determination by a method similar to that used to measure the degree of unsaturation of fats and fatty acids. Such attempts included those by Maurel and Touyé,[1] who tried to use iodine monobromide (Hanus method) or iodine trichloride (Wijs method) in a way resembling the determination of iodine number in fats, but were not satisfied with the results obtained. Spanyár and Sándor,[2] using a bromate–bromide mixture, obtained a good quantitiative bromination in useful analytical conditions, and proposed a method applicable to complex foods, with a maximum error of ±5%.

Using a similar procedure but another halogenation mixture, we have developed a new method for the determination of aldrin (1,2,3,4,10,10-hexachloro-1,4,4*a*,5,8,8*a*-hexahydro-1,4,5,8-dimethanonaphthalene), the halogen being added to the "reactive" double bond in the unchlorinated ring and the excess being determined iodimetrically or potentiometrically.[3,4]

Starting from these and other results we have tried to use sodium chlorite in hydrochloric acid medium for the determination of sorbic acid (hexa-2,4-dienoic acid).

EXPERIMENTAL

Reagents

Sodium chlorite, 0·1*N*. Dissolve 2·25 g of anhydrous sodium chlorite (*p.a.*) in doubly distilled water and make just alkaline with sodium hydroxide. The solution is stable for several months if kept in the dark and at low temperature (refrigerator). The solution is standardised with 0·1*N* thiosulphate, in sulphuric acid medium in the presence of potassium iodide, starch being used as indicator. The solution can be diluted if required.

Procedure

Take a 5- or 10-ml aliquot, containing 2–25 mg of sorbic acid, in an iodine flask or a well-stoppered conical flask. From a burette add 10 ml of sodium chlorite solution and then rapidly add 6 ml of 8*M* hydrochloric acid from a graduated cylinder. Swirl the flask and close it with a ground-glass stopper.

The solution gradually becomes yellow–green, reaching an apparently constant colour in a few seconds. After 30–90 sec add 5 ml of 10% potassium iodide solution rapidly but carefully down the flask walls. To prevent loss of iodine agitate the closed flask gently until the solution becomes homogeneous. Then mix the solution well, wash down the walls with distilled water and immediately titrate to pale-yellow, add 1–2 ml of starch solution and continue the titration until the solution becomes colourless.

The quantity of sorbic acid in the aliquot titrated is $56{\cdot}1\,f(V_1 - V_2)$ mg where V_1 and V_2 are the volumes of f *N* thiosulphate consumed by a blank and the sample respectively. More dilute thiosulphate (0·01 or 0·05*N*) may be used if desired.

RESULTS AND DISCUSSION

The reaction on which the determination is based appears to be chlorination at the 2 and 5 positions leading to a double bond at the 3,4 position:

$$HClO_2 + 3HCl = 2H_2O + 2Cl_2$$

$$CH_3{-}CH{=}CH{-}CH{=}CH{-}COOH + Cl_2 \rightarrow CH_3{-}CHCl{-}CH{=}CH{-}CHCl{-}COOH$$

A similar reaction forms the basis of the Spanyár and Sándor method,[2] though in the original work its mechanism is not discussed by the authors. Maurel and Touyé,[1] in trying to apply this method to the determination of pure sorbic acid obtained recoveries of about 50%. In contrast, we obtained a good recovery. The explanation of this contradiction most probably lies in the fact that the earlier authors considered that addition took place at both double bonds. Some results for pure sorbic acid solutions are shown in Table I.

TABLE I.—DETERMINATION OF SORBIC ACID

Sorbic acid		Difference, *mg*
Taken, *mg*	Found, *mg*	
2·50	2·47	−0·03
2·50	2·57	+0·07
2·50	2·52	+0·02
5·00	4·94	−0·06
5·00	5·16	+0·16
6·00	6·08	+0·08
7·50	7·39	−0·11
7·50	7·50	nil
10·00	10·28	+0·28
12·50	12·45	−0·05
12·50	12·70	−0·20
15·00	15·03	+0·03
15·00	14·83	−0·17
17·50	17·62	+0·12
17·50	17·48	−0·02
20·00	20·21	+0·21
25.00	25·31	+0·31
25·00	25·00	+0·00

The precision and reproducibility are influenced by the conditions of halogenation. To ensure quantitative addition an excess of reagent is necessary. In the conditions specified, reaction is complete in 30–90 sec. The rate of the reactions is determined by the excess of sodium chlorite added. The end of the reaction is indicated by cessation of the colour change to yellow–green. Prolongation of the reaction beyond this time is neither necessary nor useful, because it allows loss of chlorine. Premature addition of iodide, before the yellow–green colour is obtained, gives low results, and so may too small an excess of chlorite reagent. If a large excess of chlorite is used, the reaction is rapid, the yellow colour appears in 4–6 sec and iodide must be added immediately to prevent loss of chlorine. The speed of addition is greater than that of bromine or iodine.

Interferences

A few substances which are used for food conservation and can exist together with sorbic acid in foods have been tested for possible interference. Benzoic, citric and formic acids do not affect the determination; salicylic acid consumes a small quantity of reagent, and sulphite interferes. The effects of maleic and fumaric acids were not investigated.

TABLE II.—DETERMINATION OF SORBIC ACID IN VEGETABLE PRODUCTS*

Extraction method	Sorbic acid added,† *mg*	Sorbic acid found, *mg*	Difference, *mg*	Recovery, %

* Tomato juice, wine and fruit pulps.
† Added before extraction.

Determination of sorbic acid in food

The sorbic acid must first be extracted from the food sample with solvents or steam to give a solution of the required concentration. We tried three schemes for extraction. The first was the ether extraction at pH 1–2 used by Spanyár and Sándor,[2] followed by stripping of the sorbic acid with an alkaline aqueous phase. We also tried evaporating the ether extract at room temperature and redissolving the residue in 5 ml of 0·5% sodium hydroxide solution. The same procedure was used with a chloroform extraction[5] but persistent emulsions appeared, especially when alkaline solutions were used.

We also used the Sudario[6] and the Schmidt[7] methods based on steam-distillation of sorbic acid. The principal disadvantage was the need to collect a large quantity of distillate to ensure the quantitative removal of the sorbic acid, and the final solution was too dilute to be used directly and had to be concentrated either by evaporation (after it had been made alkaline) or by extraction.

The results obtained were influenced by the extraction method used and the relative error was never less than 6%. However, the procedure can be successfully used for the determination of sorbic acid in various samples and has the advantage of considerable rapidity.

Summary—A new method for the determination of sorbic acid is proposed, using sodium chlorite in hydrochloric acid medium as reagent. In these conditions the hydrochloric acid is oxidized to chlorine which adds on to the double bonds of the sorbic acid. The addition is rapid (30–90 sec) and for this reason the determination is more rapid then others similar to it. Sorbic acid has been determined in foods by this method, after a preliminary solvent extraction or steam-distillation.

Zusammenfassung—Eine neue Methode zur Bestimmung von Sorbinsäure mit Natriumchlorit in Salzsäure als Reagens wird vorgeschlagen. Unter diesen Bedingungen wird Salzsäure zu Chlor oxidiert, das sich an die Doppelbindungen der Sorbinsäure addiert. Die Addition geht schnell (30–90 sec); aus diesem Grund geht die Bestimmung schneller als andere, ähnliche Methoden. Auf diese Weise wurde Sorbinsäure in Lebensmitteln nach vorausgehender Extraktion oder Wasserdampfdestillation bestimmt.

Résumé—On propose une nouvelle méthode de dosage de l'acide sorbique, en utilisant comme réactif le chlorite de sodium en milieu acide chlorhydrique. Dans ces conditions, l'acide chlorhydrique est oxydé en chlore qui s'additionne sur les doubles liaisons de l'acide sorbique. L'addition est rapide (30–90 sec) et, pour cette raison, le dosage est plus rapide que les autres qui lui sont similaires. On a dosé l'acide sorbique par cette méthode dans des aliments, après extraction par solvant ou entraînement à la vapeur préliminaires.

Decomposition of thiosulphate in acidified oxidants

(*Received* 4 *February* 1967. *Accepted* 22 *March* 1967)

THE reaction of thiosulphate with iodine is not immeasurably fast, but proceeds *via* the following reactions:[1,2]

$$S_2O_3^{2-} + I_3^- \longrightarrow S_2O_3I^- + 2I^-$$

$$S_2O_3I^- + S_2O_3^{2-} \xrightarrow{\text{slow}} S_4O_6^{2-} + I^-.$$

Experiments have shown that both chloride and nitrite can compete successfully with the iodine in the oxidation, altering the stoichiometry (in the latter case forming a mixture of thiosulphate and sulphate and ultimately regenerating the nitrite).[2] Apparently, no comparable study has been made of the combined effects of acid and oxidant on thiosulphate although extensive literature exists on the acid decomposition of thiosulphate[3,4] as well as on its behaviour with selected oxidants in limited pH ranges.[5] This paper summarizes some of the results of such an investigation.

EXPERIMENTAL

Reagents and solutions

Reagent-grade chemicals and distilled water were used in all of the studies. The oxidants and thiosulphate were prepared and standardized in conventional ways. The acids were standardized against sodium carbonate, Methyl Orange being used as indicator and the end-point being compared with a reference solution.

Procedure

The tetrathionate produced when thiosulphate was added directly to a solution containing a known, but excessive, amount of oxidant and a known amount of strong acid was determined as follows: the unreacted oxidant was reduced by addition of sulphite, excess of sulphite was added, and the pH of the solution was adjusted to 10 (at this pH $S_4O_6^{2-}$ reacts with SO_3^{2-} to regenerate $S_2O_3^{2-}$), formaldehyde was added (to complex any unreacted sulphite) and the regenerated thiosulphate was titrated iodimetrically. This procedure, known as the Wollack titration, has been described previously.[6]

In those cases in which the end-point in the iodimetric finish faded, the pH was carefully adjusted to between 4·5 and 4·8 before the titration was completed. When either chloramine-T or iodate was used as oxidant, the destruction of the unreacted oxidant could not be observed visually; in these experiments 5 ml of 30% sulphite solution, empirically determined to be a slight excess, were added; the procedure described above was then followed.

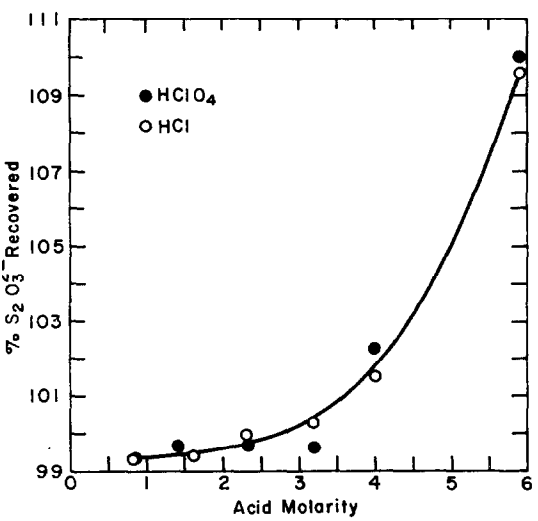

FIG. 1.—The effect of acid on the iodine oxidation of $S_2O_3^{2-}$.

TABLE I.—EFFECT OF TIME OF STANDING OF THE ACIDIFIED THIOSULPHATE IODINE REACTION MIXTURES ON THIOSULPHATE RECOVERIES

Time of standing, *min*	[Acid], *M*	% Thiosulphate found	
		HCl	$HClO_4$
5	2·4	100·0	99·7
	3·2	100·3	100·0
	4·0	101·5	102·3
	5·9	109·6	110·0
60	2·4	100·5	100·0
	3·2	101·3	101·9
	4·0	101·5	102·3
	5·9	118·5	126·3

RESULTS

The results shown in the figures and tables can be summarised as follows.

(*a*) When acidified iodine is used as oxidant, recoveries of thiosulphate increase with increasing acidities (Fig. 1); when no acid is present, low values are obtained because in neutral solution partial oxidation to sulphate occurs. The recoveries from solutions containing $<4{\cdot}0M$ acid remain about the same with increasing time (Table I) which reflects the relatively slow rate at which tetrathionate is decomposed either by iodine[1] or acid.[8] Similar recoveries from perchloric acid and hydrochloric acid media argue that it is the hydrogen ion which affects the reaction and not the anion of the acid. (Conversion of thiosulphate exclusively into tetrathionate would, of course, simply give 100% recovery of thiosulphate. As will be shown later, the high values are believed to arise because the thiosulphate is converted into higher polythionates.)

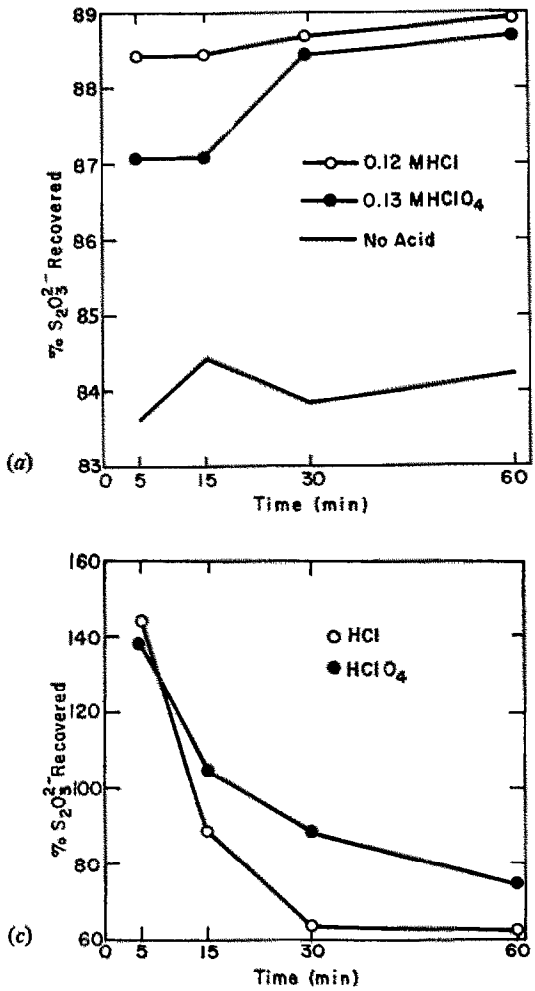
(*b*) When acidified permanganate is the oxidant, thiosulphate recoveries are low (Fig. 2). Increasing the acidity (the range over which this can be done is limited by side-reactions) increases the recovery by about 4%. The recoveries do not vary widely with time. Dithionic acid is known to be a product of acidified permanganate oxidations of thiosulphate; it is reasonably stable towards strong oxidants and would not be expected to react with sulphite. Recoveries of thiosulphate would be expected to be low if dithionic acid were a reaction product; however, consistent recoveries of thiosulphate imply that, under the conditions used, the majority of the thiosulphate is converted into polythionate.

(*c*) The recovery of thiosulphate in acidified iodate solutions depends on the acid used, its concentration and the reaction time (Fig. 2b and Table II). Iodine chloride is, no doubt, an intermediate when oxidation takes place in $6M$ hydrochloric acid. Carrier and Delpla[10] also found that the concentration of hydrochloric acid had a very significant effect on the oxidation; their results indicated that in $<0{\cdot}2M$ hydrochloric acid increasing the acidity increased the amount of sulphate produced, whereas ours suggest that polythionate formation is favoured. The difference may arise because of the large difference in acidities and in experimental procedures, or both suggestions may be true, *i.e.*, both the production of sulphate and of polythionate are functions of increasing acidity.

(*d*) When chloramine-T is used, recoveries of thiosulphate are >100% in weakly acid solution and increase with increasing acid concentration (Table II). In a given acid, the recoveries decrease with time (Fig. 2c). No thiosulphate should have been found if quantitative oxidation to sulphate had taken place as suggested by Murthy.[11]

TABLE II.—THE EFFECT OF ACID AND OXIDANT ON THE RECOVERY OF THIOSULPHATE

Oxidant	% Thiosulphate recovered		
	$10^{-3}M$ H^+	$6M$ HCl	$6M$ $HClO_4$
Iodate	96·3	123·3	50·8
Chloramine-T	104·4	137·2	132·3
Iodine	100·0	109·6	110·0



DISCUSSION

The decomposition of thiosulphate yields a variety of products depending upon the experimental conditions *e.g.*, sulphur dioxide, hydrogen sulphide, and polythionates result from acid decomposition, whereas sulphite, sulphate and dithionates are oxidation products. Because only those compounds containing bivalent sulphur undergo S_N2 reactions with sulphite to regenerate thiosulphate, the Wollack procedure can be used to measure directly the amount of polythionates present in solution.

Quantitative recovery of the thiosulphate would imply reaction to form thiosulphate exclusively. Low thiosulphate values mean that some, if not all, of the reaction products, *e.g.*, sulphate, dithionate, hydrogen sulphide or sulphur dioxide, are not reconvertible into thiosulphate on treatment with sulphite. Acid permanganate and perchloric acid–iodate oxidations illustrate this trend.

Two possibilities exist which would explain the high recoveries of thiosulphate.

1. Tetrathionate produced by normal oxidation of thiosulphate could react as follows:[5]

$$4S_4O_6^{2-} + 6OH^- \longrightarrow 5S_2O_3^{2-} + 2S_3O_6^{2-} + 3H_2O \qquad (1)$$

The overall stoichiometry for the reaction would then be 5 moles of thiosulphate recovered for every 8 added rather than the 1:2 predicted if the reactions were with sulphite. Reaction (1), however, can only take place in very strong base (pH > 14).[5] Since the highest pH value reached during the entire procedure is when the tetrathionate is reconverted into thiosulphate with sulphite at a pH of 10, and because recoveries from iodine oxidations in weakly acidic media show that at pH 10 the preferential reaction is with sulphite, this cannot be a plausible explanation.

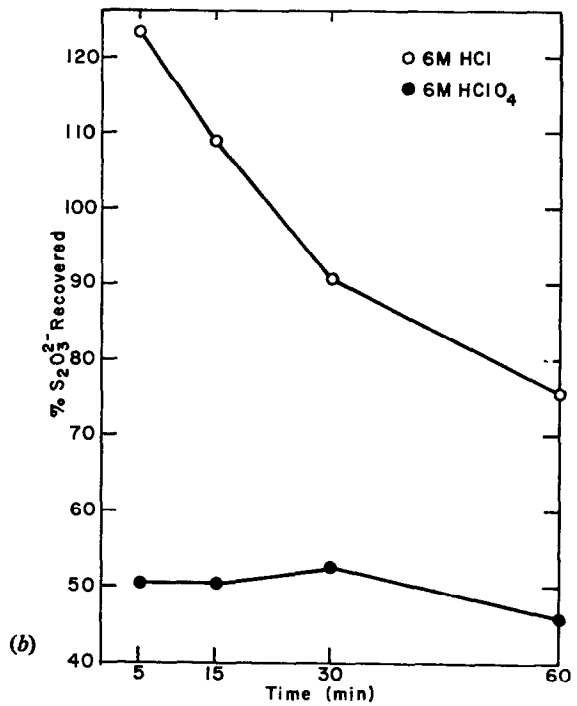


FIG. 2.—The effect of time on the oxidation of $S_2O_3^{2-}$.
(*a*) $KMnO_4$ as oxidant;
(*b*) Iodate as oxidant;
(*c*) Chloramine-T as oxidant.

2. If, however, acid decomposition of the thiosulphate occurs competitively with or to the exclusion of oxidation, polythionates are formed. The polythionates could then react with sulphite in a variety of ways.

$$(1)\quad 3S_2O_3^{2-} + 4H^+ \longrightarrow S_5O_6^{2-} + S(OH)_2 + H_2O$$

$$S_5O_6^{2-} + 2SO_3^{2-} \xrightarrow[pH\ 10]{\text{excess of } SO_3^{2-}} S_3O_6^{2-} + 2S_2O_3^{2-}$$

$$(2)\quad 6H^+ + 5S_2O_3^{2-} \longrightarrow 2S_5O_6^{2-} + 3H_2O$$

$$2S_5O_6^{2-} + 4SO_3^{2-} \xrightarrow[pH\ 10]{\text{excess of } SO_3^{2-}} 2S_3O_6^{2-} + 4S_2O_3^{2-}$$

In the former case the stoichiometry would be 2 moles of thiosulphate recovered for every 3 added while in the latter the ratio would be 5:4; in both cases higher than the 1:2 computed for the Wollack titration itself.

On the basis of these suggestions, the data obtained for all oxidants studied argue that acid decomposition of thiosulphate to produce higher polythionates is occurring competitively with oxidation.

ELAINE I. STETCKO,

Summary—The Wollack procedure has been used to study the competition between oxidant and acid for the thiosulphate ion. In concentrated hydrochloric acid solutions of iodine, iodate and chloramine-T, polythionates are the chief products, whereas in acid permanganate substantial amounts of other products occur. Both the concentration of the acid and the acid anion affect the course of the reaction in these solutions. Production of polythionate, an acid-decomposition product, suggests that acid decomposition successfully competes with oxidation.

Zusammenfassung—Das Wollack-Verfahren wurde zur Untersuchung der Konkurrenz zwischen Oxidationsmittel und Säure um das Thiosulfation verwendet. In konzentriert salzsauren Lösungen von Jod, Jodat und Chloramin-T sind Polythionate die Hauptprodukte, wogegen in saurem Permanganat erhabliche Mengen anderer Produkte auftreten. Säurekonzentration und -anion beeinflussen den Reaktionsverlauf in diesen Lösungen. Die Bildung von Polythionat, einem Produkt der Säurezersetzung, deutet darauf hin, daß die saure Zersetzung erfolgreich mit der Oxidation konkurriert.

Résumé—On a utilisé la technique de Wollack pour étudier la concurrence entre l'oxydant et l'acide pour l'ion thiosulfate. Dans des solutions en acide chlorhydrique concentré d'iode, d'iodate et de chloramine-T, les polythionates sont les produits majeurs, tandis qu'en permanganate acide il apparaît des quantités substantielles d'autres produits. Les concentrations tant de l'acide que de l'anion acide affectent la marche de la réaction dans ces solutions. La production de polythionate, un produit de décomposition acide, suggère que la décomposition acide entre avec succès en compétition avec l'oxydation.

Interfacial free energies of ionic crystals

(*Received* 6 *March* 1967. *Accepted* 18 *April* 1967)

THE interfacial free energy between an ionic crystal and its supersaturated aqueous solution is of some importance in classical nucleation theory.[1] In this work, data on the maximum supercoolings attainable with small droplets of aqueous solutions of inorganic salts have been used in conjunction with the Volmer theory of homogeneous nucleation[1] to obtain minimum values of the liquid–crystal interfacial free energy.

The maximum supercoolings observed in droplet experiments by Melia and Moffitt,[2] and Turnbull and Newkirk[3] are shown in Table I. These values are much greater than those previously reported

TABLE I.—CRYSTALLISATION DATA FOR DROPLETS OF AQUEOUS SOLUTIONS OF INORGANIC SALTS (DIAMETER OF DROPLETS APPROXIMATELY 1·0 mm)

Solute	Saturation temperature, °C	S	% Crystallised at 0°C	Reference
NH_4Cl	70	1·5	80	2
NH_4I	35	1·2	100% at 1°C	3
KNO_3	30	3·4	100% at 4°C	2
$KClO_3$	30	3·2	100% at 10°C	2
$K_2Cr_2O_7$	70	12·0	12	2

by other workers[4–7] for bulk samples. This is attributed (*cf.* Vonnegut[8]) to the sequestration of the more active, adventitious, nucleation catalysts which are present in bulk samples as a result of atmospheric (or other) contamination, in a small fraction of the droplets. The remainder may thus be supercooled to a lower temperature. This temperature approaches more closely that temperature associated with true homogeneous nucleation than those reported previously for these solutes.

The Volmer expression[1] for the rate of homogeneous nucleation is

$$\log_{10} J = \log_{10} A - \frac{16\pi\sigma^3 V^2 N}{3(2{\cdot}303RT)^3(\log_{10} S^n)^2} \qquad (1)$$

where J is the nucleation rate, A is the kinetic constant, σ is the interfacial free energy, V is the molar volume of the solid solute, N is the Avogadro number, R is the gas constant, T is the temperature of maximum supercooling in °K, S is the supersaturation ratio $= (m\gamma/m_0\gamma_0)^n$ where m and m_0 and γ and γ_0 represent the molalities and mean ionic activity coefficients of the solute in the supersaturated and saturated solutions respectively at the temperature T, and n is the number of ions produced by one molecule of the solute. Unfortunately, data relating to the molality over the concentration and temperature ranges used in the experiments under consideration are not available. However, data for comparable electrolytes indicate that γ is not strongly dependent on m at the molalities used. Consequently, we shall assume that $\gamma/\gamma_0 = 1$. Assuming also a sensible rate of nucleation $J = 1$ cm^{-3} sec^{-1} and putting $A = 10^{30}$ cm^{-3} sec^{-1}, we calculate from equation (1) the σ_{min} values given in Table II.

TABLE II.—MINIMUM INTERFACIAL FREE ENERGIES OF VARIOUS IONIC CRYSTALS

Solute	σ_{min}, *erg cm*$^{-2}$
NH_4Cl	35
NH_4I	15
KNO_3	57
$KClO_3$	56
$K_2Cr_2O_7$	72

The values of the interfacial free energies obtained in this work are 20 to 30 times those obtained by Chatterji and Singh[9] from their measurements on bulk samples, and approach the values expected[9] for the homogeneous nucleation of ionic crystals from aqueous solution. It follows that the maximum supercoolings observed in the droplet experiments[2,3] closely approach the maximum attainable supercooling of these solutes in aqueous solution.

TALANTA REVIEW*

A CRITICAL REVIEW OF METHODS OF ISOLATING AND SEPARATING THE NOBLE METALS—II†

ION-EXCHANGE AND SOLVENT EXTRACTION

F. E. BEAMISH
Department of Chemistry, University of Toronto, Toronto 5, Ontario, Canada

(*Received* 23 *February* 1967. *Accepted* 2 *May* 1967)

Summary—This review deals with ion-exchange and solvent extraction methods of separating the seven noble metals, published subsequent to the previous reviews and prior to January 1966. The noble metal species present in solution are discussed in so far as they relate to separation and determination.

THE past decade has witnessed some extension of classical methods of separation as well as new approaches to separational techniques. However, the development in separational methods which in general, constitute the more far-reaching aspects of analytical chemistry, has not been matched by the interest in determinative methods. The recorded determinative methods for the noble metals have been reviewed by the author.[1,2]

One may expect a considerable impetus in separational research from the continually increasing literature dealing with the solution composition of useful analytical systems and from the increasing emphasis on the determination of stability constants and rates of reaction. Given more precise data on the effect of acidity and salt content on the noble metal species existing in solution, the analytical researcher will approach more intelligently the problems of separation by ion-exchange, solvent extraction and chromatography. A case in point concerns an explanation for the failure to separate large amounts of iron from traces of gold by cation-exchange. Although gold in pure solution may not be retained by the resin, the presence of certain base metals produces low gold values. Attempts to solve the problem have indicated changes in the chemical species present in the gold–iron solution. There is also a need for a convincing explanation for the ability of certain cation-exchangers to remove gold from solution; this problem requires more detailed information on the mechanism of adsorption by certain common exchangers. The effect of aging on such methods of separation as ion-exchange or chromatography also needs explanation; some of the more practical instances of this phenomenon have been discussed in previous reviews and examples are also recorded below. Fundamental inorganic researches could provide useful reducing reagents to produce metallic iridium; this reduction is not

† Part I—*Talanta*, 1960, **5**, 1.

accomplished quantitatively by even such theoretically favourable reagents as copper, and precipitation by sulphide is also incomplete. The deleterious effect of fuming with sulphuric acid on the precipitation of rhodium sulphide and on the separation of platinum from the remaining group by oxidation and hydrolysis to hydrated oxides also needs further examination.

Some effort has been made to include in this review the available data dealing with the noble metal species present in solution, particularly in those instances where their character may influence the degree of separation by ion-exchange or chromatography. Unfortunately, this phase of the review is somewhat incomplete. In some instances, especially in the case of Russian literature, the author failed to secure copies of original publications. One may hope that a more complete selection of published literature, with or without translations, will ultimately be made generally available.

The present review deals with literature pertinent to the separation of noble metals and recorded in abstracts from 1 January 1960 to 31 December 1965. An earlier review[3] dealt with publications earlier than this. The separational methods are discussed under the headings ion-exchange, solvent extraction, chromatography, precipitation, and fire assay. It should be noted that some are integral parts of determinative procedures, particularly in the case of solvent extraction integrated with colorimetric techniques. Thus an earlier review[4] included references to solvent extraction methods used before application of colorimetric methods. In such cases the references to restricted solvent extraction are, in general, omitted from the present review. In one or two instances where the author had previously failed to record a spectrophotometric method involving solvent extraction the reference is included here.

An effort was made to avoid repetitive discussion of extractive methods, some of which were developed to apply specifically to spectrophotometric methods for relatively simple systems. More detailed discussions of these will be found in the author's reviews of colorimetric methods. However, emphasis is given here to extraction methods for such restricted mixtures as rhodium and iridium, because of the relative analytical difficulty of their separation, and all extraction methods recorded subsequent to the period covered for the colorimetric review and up to December 1965 are also included.

ION-EXCHANGE

Gold

A new principle was proposed by Kraus *et al.*,[5] who recognized that factors other than ion-exchange play some part in the mechanism of separation by exchangers; in particular they considered the fact that adsorbability of some negatively charged complexes by anion-exchangers was abnormally high, and that a possible explanation involved reactions between the anionic complexes and the organic network. On this basis it was possible that cation-exchangers might adsorb appropriate anions selectively. The cation-exchanger Dowex-50, which contains the same polystyrene–divinylbenzene network as the anion-exchanger Dowex-1, was applied successfully to the isolation of the anion $AuCl_4^-$ or such partially hydrolysed species as $AuCl_3OH^-$ contained in chlorinated solutions of lithium, sodium, potassium and calcium chlorides that were about 0·1*M* in hydrochloric acid. The authors noted the relatively high distribution coefficients for lithium chloride solutions compared with those for hydrochloric acid solutions and the fact that with the anion-exchanger Dowex-1 × 10, while the same divergence occurred in the two media, the coefficients in both cases were of a higher order of magnitude for the salt solution.

This important approach[5] was investigated further by Wang *et al.*[6] who applied the technique to the separation by Dowex-50 × 8 of gold-199 from activated platinum. The authors believed that the mechanism of the anion adsorption by the sulphonated cationites from acid and salt solutions involved basic properties of the oxygen atoms of the neutral sulpho group and that "by the addition of a proton or metal ions, the functional groups of the resins acquire a positive charge." The exchangers used were the cationites Dowex-50 and KU-2, both of which have the functional group

HSO_3^-. Each resin was pretreated with 6–8*M* hydrochloric acid and with chlorine to avoid the reduction of gold. To prepare carrier-free gold-199 from platinum irradiated with thermal neutrons, 1 g of platinum was dissolved in *aqua regia* and the solution was evaporated to 1 ml, diluted with 7–8*M* hydrochloric acid saturated with chlorine, and filtered through 200 mg of Dowex-50 × 8 (200–400 mesh) contained in a 2-mm diameter tube, at a rate of 0·1 ml/min. Platinum was washed from the column with 8*M* hydrochloric acid and gold was eluted with chlorine water; if neutral solutions of gold-199 were required, the platinum was washed out with a hydrochloric acid solution of sodium chloride followed by water to remove the gold. The authors found that the distribution coefficient of gold between resin and solution was directly proportional to the concentration of acid or salt, thus supporting the assumption that the mechanism involved positively charged sulpho groups. The coefficients for salt solutions increased from 9·2 for lithium chloride to 33·5 for caesium chloride. Explanations for these findings were discussed as well as the influence of cross-linkage of the resin on the distribution coefficient.

Beyond question, this technique of separation is worthy of continued examination and it is disappointing that no quantatitive data were provided to indicate the precision and accuracy of the separation, even though the authors did not propose the method as an analytical procedure.

Kraus and Nelson[7] used the tracer ^{198}Au to study the mechanism of adsorption of $AuCl_4^-$ in 0·12–12*M* hydrochloric acid on the basic anion-exchanger Dowex-1. Gold (III) was found to be strongly adsorbed over the whole acid range and the distribution coefficient decreased with increasing acidity.

One of the earliest applications of anion-exchangers to the separation of gold and platinum metals was described by Sussman *et al.*[8] This industrial recovery method involved separation of gold, platinum and palladium as well as chromium, molybdenum, vanadium, *etc.* The recovery of gold, platinum and palladium was more effective by anion-exchange than by adsorption on carbon, and the efficiencies of recovery were Pt > Au > Pd. The authors state that "the method offers interesting possibilities for relatively low cost metal recovery from waste effluents."

A new approach to the separation of gold from large proportions of associated base metals was developed by Ziegler and Matschke.[9] Nitric acid solutions free from hydrochloric acid and containing from 140 to 700 μg of gold with decagram amounts of iron, cobalt, nickel, manganese, copper and lead were adjusted to pH 1–1·5 and passed through filter pulp impregnated with silver sulphide. The pulp or the stained part of it containing the gold (III) sulphide was removed, ignited, treated with *aqua regia*, and evaporated in the presence of hydrochloric acid. The gold was extracted at pH 1–4 with methylene chloride and the absorbance of the organic phase was determined at 394 mμ. This procedure may provide a variety of useful adaptations for the determination of gold in such natural products as ores, concentrates, *etc.* It is noted particularly that 140 μg of gold may be thus separated and determined accurately in solutions containing as much as 284 g of copper or 28 g of iron or lead. One hopes that the recovery will be compared with that attainable by fire assay and the the method can be extended to cover trace amounts of gold.

Anion-exchange resins were used by Darbinyan and Karapetyan[10] to separate gold (3 troy oz/ton) from selenium (0·03 oz/ton) and tellurium (1·3 oz/ton) in ores. Samples were treated with *aqua regia* and then fumed with sulphuric acid. Tin(II) chloride was used to precipitate the three elements, which were then redissolved in *aqua regia*. Gold and selenium were selectively adsorbed from hydrochloric acid at pH 2 by the exchangers ON and AN-F2, and selenium was selectively eluted by 1*M* hydrochloric acid. Gold and tellurium were adsorbed selectively from 6*M* hydrochloric acid by the resins AV-17 and AV-27, and tellurium was eluted by 1*M* hydrochloric acid. The resins were burned and the gold was determined colorimetrically.

Davankov and Laufer[11] collected the chloraurate ion on the chloride form of the resins N–O (59% moisture) and TN (32% moisture). Attempted elution with acids, solutions of thiourea, and dilute solutions of hydrochloric acid in acetone or ethanol were unsuccessful. Gold was recovered by ignition of the resin.

Burstall *et al.*[12] examined the concentration of gold from ores by adsorption of cyanide complexes on anion-exchangers, particularly IRA-400. Gold, copper, nickel, iron, cobalt, zinc and silver were completely adsorbed. Consecutive elutions with 0.2*M* hydrochloric acid, 2*M* sodium cyanide, acetone containing 5% of hydrochloric acid, and 2*M* potassium thiocyanate removed nickel and zinc, copper and iron, silver and gold, and cobalt respectively. By multicycle treatments of effluent and eluate the authors effectively concentrated copper, nickel, iron and gold.

Anion-exchangers were used by Ezerskaya and Markova[13] for the extraction of gold from mill-cyanide, hydrochloric acid, and iodide solutions. The weakly basic resins AN-2F, EDE-10, and Aspatite TM were used batchwise, 200 ml of gold solution being shaken for 1–1·5 hr with a few grams of resin. The amounts of gold ranged from 1·5 g to 15 μg in the case of chloride and cyanide solutions and as little as 1 μg for the iodide solutions. Sulphite was added to the iodide solution to avoid adsorption of iodine by the resin. The copper, zinc and iron complex cyanides were adsorbed with the gold, and the copper interfered with the determination. To avoid this the ignited resin was

selectively extracted with nitric acid. The gold was recovered by ignition and determined polarographically, volumetrically or colorimetrically.

For gold in cyanide solutions, Fridman and Popova[14] used the anion-exchanger AN-2F, 5 g of which adsorbed 23 μg of gold in 30 min; 10 g could adsorb 230 μg from 3 l. of solution. The adsorption of gold was reduced in the presence of iron. Copper and zinc showed relatively little interference.

For the determination of 0·01–100 ppm of gold in copper, Mizuike *et al.*[15] used the chloride form of the anion-exchanger Amberlite IRA-400. After column and batch separations the gold was determined spectrophotometrically and by neutron activation. The results were compared with those obtained by dry assay, solvent extraction–photometric[16] and amalgamation–photometric methods.[17] For the separation by batch process the sample (1–5 g) was dissolved in nitric and hydrochloric acids and diluted to 15 ml per g of copper. Silver chloride was removed and 200 mg of resin were mixed with the solution for 40 min. The resin was filtered off and washed with dilute hydrochloric acid. For the column method the sample was dissolved and diluted to about 12 ml per g of copper. The column, 4 mm in diameter and 20 mm long, contained 0·1 g of dry resin. The dissolved sample was passed through the column at a flow-rate of 1–1·5 ml/min and followed by an acid wash to remove copper. Efforts to elute the adsorbed gold with mixed mineral acids and organic solvents failed and the authors ignited the resin at a temperature below 600° in an alumina crucible. The used of glazed crucibles resulted in low values and wet ashing was incomplete. The ashed residue was dissolved in *aqua regia* and finally the gold was determined spectrophotometrically from an aliquot of the chloride solution.

Alternatively the resin was neutron-activated, and standards were fused as usual, salted with gold, and the gold was gamma-counted. The results for synthetic samples indicated an error of 5–10% over the range 0·4–110 ppm. For crude copper the gold values agreed closely with those obtained by other methods.

Hirano, Mizuike and Iida[18] used the anion-exchanger Amberlite IRA-400, chloride form, to separate gold from copper alloys. The alloy was dissolved in nitric and hydrochloric acids, the solution was passed through the column and the resin was ashed in an alundum crucible. From 0·5 to 100 ppm of gold-198 were determined in the residue with *p*-dimethylaminobenzylidinerhodanine, with an error of 5–10%. Silver was separated as the chloride and palladium was masked by dimethylglyoxime or extracted by ethyl acetate.

For the separation of gold from copper Steele and Hyde[19] used ion-exchange and solvent extraction methods. In the latter case, the solvent was tributyl phosphate mixed with carbon tetrachloride (1 + 2). More than 99·3% of 0·5 g of gold in 20 ml of hydrochloric acid could be extracted by shaking for 1 min if the acidity was >4*M*. Nitric acid depressed the extraction. For ion-exchange Deacidite FF (−50 + 100 mesh) was used in the chloride form. The gold solution was passed through the resin at a rate of 2 ml/min and washed with 2·5% hydrochloric acid. The two separations were of comparable efficiency, and took about a day to complete.

The relative efficiencies of adsorption of tetrachloroaurate(III) anion on cellulose and on the exchanger Dowex-50 were discussed by Beckmann and Lederer.[20] The adsorption coefficient from 6*M* hydrochloric acid was 1·5 for cellulose and 100 for the resin. The authors found that the chromatographic separation was faster than solvent extraction.

Anion-exchange resin was used by Brooks[21] for the determination of gold and other constituents in sea-water. Enrichment factors of up to 2×10^7 were achieved. Columns 0·5 $cm^2 \times 13{\cdot}2$ cm were used to adsorb from 250 l. of sea-water the elements such as gold, thallium and bismuth which had distribution coefficients >38000. The flow-rate was 120 ml/hr applied over about 100 days. After adsorption the column was washed with 2*M* hydrochloric acid and then eluted with 1 l. of 0·25*M* nitric acid. The resin containing the adsorbed gold was ignited and the ash examined spectrochemically at 2676 Å for gold. A single determination indicated a gold content of 0·009 mg/ton of sea water.

Platinum and gold

Sherma and Cline[22] examined the migration of 26 ions on anion-exchange paper with five complexing solvents. The results were reported as a function of the sign of the charge on each ion, determined electrochromatographically. The authors concluded that predicting the results of separations to be attempted by ion-exchange paper chromatography was virtually impossible. In the case of gold and platinum in the tartrate form, on anion-exchange paper SB-2 developed with 0·05*M* tartaric acid at pH 2·2, the anions of both metals showed R_f values of 0. With gold and SB-2 paper in the fluoride form with ammonium fluoride at pH 6·5 as the developing reagent, gold appeared as a cation and platinum as an anion, both with R_f values of 0.

With the paper in the malonate form developed with malonic acid pH 2·2, both gold and platinum appeared as cations with an R_f value of 0. With SB-2 paper in the chloride form developed with diethylenetriamine at pH 11, gold appeared as an anion with an R_f value of 0·20 with streaking back to the origin, and platinum as an anion with an R_f value of 0. With the paper in the chloride form

developed with diethylenetriamine in 0·080*M* hydrochloric acid both gold and platinum appeared as anions with R_f values of 0. In general, these results might encourage development of methods of separation from associated base metals.

For the determination of 0·01–0·4 ppm of platinum in sodium chlorate electrolytic solutions, Iida and Mizuike[23] used Amberlite IRA-400 following reduction of the chlorate and dichromate by heating with hydrochloric acid.

Ruthenium and osmium

In a previous review[3] the present author stated that "no successful application of either cation or anion-exchange separation of osmium and ruthenium has been reported. One would guess that the ease of reduction of osmium salts by organic reagents would preclude such separations. The few reports which include ruthenium *etc.* indicate that reduction or partial hydrolysis or both have prevented quantitative separation." At about that time Hayashi *et al.*[24] used the cation-exchanger IR-120, to separate ruthenium from natural waters. The columns were eluted with 4*M* hydrochloric acid and for mixtures of ruthenium(III) and (IV) the amount of ruthenium bound on the resin was found by using ruthenium-106. The authors state that a considerable amount of ruthenium was adsorbed when the acid concentration of the sample was <0·2*N*.

Contrary to these findings and in part to the present author's predictions, both ruthenium and osmium can be separated by cation-exchange from associated base metals even when <0·1 ppm is present. Zachariasen and Beamish[25] found that when chlororuthenate solution was passed through Dowex-50, at pH 1·5 only 80–90% of the ruthenium was recovered in the effluent. The rest was found on the resin. Treatment of the ruthenium solution with various amounts of sodium chloride increased the recovery, but recovery of ruthenium in the effluent was not quantitative until the ruthenium solution was evaporated to near dryness in the presence of hydrochloric acid and sodium chloride, then diluted with water and adjusted to pH 1·0 before passage through the column. About 25 μg of ruthenium from 5 mg were retained by the column. Application of the method to 20 g of iron-copper-nickel alloys showed negligible losses of ruthenium to the resin. The cause of the losses was discussed by the authors with the guess that low recoveries were associated with aging solutions and presumably caused by the slow production of dissolved cationic species and/or by hydrolysis to hydrated oxides. Spectrophotometric data have been recorded showing a change in solution composition of weakly acidic ruthenium solutions during various aging periods.[26] Zachariasen and Beamish[27] applied their method to the isolation of platinum metals from partially refined concentrates and separated base metals from solutions of the hydrated oxides of palladium, rhodium and iridium.

Several researches have been concerned with the identification of the ruthenium species in aqueous acid and salt solutions. Information of this type can be useful to the analytical chemist who seeks to provide methods of separation, particularly by such techniques as ion-exchange, chromatography, solvent extraction, *etc.* Investigations of ruthenium species present in nitric, perchloric or hydrochloric acids with or without alkali metal salts are of special interest to the analytical chemist. Atwood and De Vries[28] found that in contact with Dowex 50W-×2 polymeric ruthenium(IV) was converted into the monomeric form. In an ion-exchange study of the complexes formed by ruthenium(IV) in hydrochloric and perchloric acids, Paramanova and Latyshev[29] found that micro quantities of ^{106}Ru(IV) in a 1*M* salt solution were hydrolysed after stirring for several days if the acidity was <0·05*M*. The complexes formed in hydrochloric acid <0·07*M* were $Ru(OH)_2^{2+}$, $Ru(OH)_2Cl_2$ (except when 1*M* perchloric acid was present) and $Ru(OH_2)Cl_4^{2-}$. In 0·15*M* and 0·6*M* hydrochloric acid six chloride ions were added to the inner sphere. Presumably $[RuCl_6]^{2-}$ was present. Researches on the species present in aqueous ruthenium(III) solutions have indicated the existence of the cations Ru^{3+} and $RuCl^{2+}$; Connick and Fine[30] have now isolated the *cis* and *trans* isomers of $RuCl_2^+$ and $[Ru(H_2O)_4Cl_2]^+$, which are partially separable by elution from the cation-exchanger Dowex-50.

Van Loon and Beamish[31] applied ion-exchange successfully to the separation of traces of osmium from solutions containing large amounts of base metals. As in the case of ruthenium the separation depends on maintaining osmium in anionic or neutral species over the narrow range of acidity required for the retention of the base metals. Partial hydrolysis of iron, copper and nickel salts in solution was indicated above pH 1·5. Below pH 0·8 incomplete retention of the base metals occurred. The difficulties with ruthenium that were caused by partial hydrolysis were absent in the case of osmium. On aging, osmium solutions at pH 1–11 and in the presence of sodium chloride showed no significant variation in absorption maxima in the range 200–700 mμ. The recommended procedure applied to base-metal alloys involved, as it did in the case of ruthenium, dissolution with hydrochloric acid and small amounts of nitric acid. The large volume of eluate from the cation-exchange separation required evaporation to a volume appropriate for distillation. Small losses of osmium during this evaporation were caused by the presence of small amounts of the three base metals in the first effluent, particularly of copper, and these were avoided by having sulphur dioxide present during the evaporation.[32]

Rhodium and iridium

Karttunen and Evans[33] have applied ion-exchange methods for the isolation of rhodium from solutions of uranium-based fissium alloys. In addition to uranium these solutions contained metals with atomic numbers 40–46. Before passage through the Dowex-50W-$\times$8 exchanger the alloy was dissolved in *aqua regia* containing hydrofluoric acid, and a suitable aliquot of the solution was fumed with perchloric acid to remove fluoride, chloride and ruthenium. Nitric acid was then added followed by tributyl phsophate in carbon tetrachloride to remove uranium. The aqueous phase was then fumed with perchloric acid to remove the remaining traces of chloride, fluoride, ruthenium and nitrate. This fuming process was critical and the permitted volume of 0·5–0·7 ml was cooled and adjusted to within these limits with perchloric acid. The solution was transferred to the resin column which was drained and washed at the rate of 3 ml/min. Palladium was removed with 0·3*M* hydrochloric acid, and then rhodium with 6*M* acid. The rhodium eluate was treated with nitric, perchloric and sulphuric acids to remove organic matter. After fuming, the sulphate solution was treated to yield rhodium chloride which was determined by measuring the absorbance at 475 mμ of its tin(II) chloride complex. Presumably, rhodium in a sulphuric acid solution that has been fumed interferes with the cation-exchange separation.

In a later paper Evans *et al.*[34] recorded an anion-exchange method of isolating rhodium from solutions of plutonium-uranium-fissium alloys. This method, preferred to the earlier procedure which was sensitive to the acidity of the feed solution, required prior separation of uranium as well as multiple fumings of the treated rhodium eluate. The sample was dissolved in hydrochloric and perchloric acids in a sealed tube, and then adjusted to be 8*M* in hydrochloric acid. A suitable aliquot was adjusted in acidity to 8*M*, heated in the presence of nitric acid, allowed to stand for 2½ hr, and passed through Bio-Rad anion-exchanger AG 1 $\times$ 10, 200–400 mesh, at the rate of 35 $\pm$ 5 drops/min with gentle suction applied, and then washed with 8*M* hydrochloric acid. Plutonium was eluted with 0·30*M* hydrochloric acid. The rhodium eluate was first treated to remove organic matter, ruthenium and nitrate by a series of fumings with sulphuric acid, followed by a series of perchloric and sulphuric acid fumings. Rhodium sulphate was converted into the chloride and the absorbance of the tin(II) chloride complex was measured at 470 mμ. The method allowed an efficient adsorption of plutonium, uranium and molybdenum. Plutonium(III), which was not adsorbed, was oxidized by nitric acid to the required oxidation states. The unavoidable leakage of palladium, less than 12 μg, could be tolerated by the tin(II) chloride method.

In several publications the present author has emphasized the varied influence of methods of dissolution of noble metals on methods of separation, or determination, and on the character of interference by associated base metals. Fortunately, precise data are now being recorded for many of the common dissolution reactions of the noble metals. In this connection, there is analytical significance in the report by Kristjanson and Lederer[35] who have described the solution chemistry of rhodium. Unfortunately, the authors confined their study to 6*M* hydrochloric acid solutions on the basis that "this seemed the only concentration for HCl in which analytical ion-exchange separations would be possible." On the contrary, many separations of rhodium have been effected by cation-exchange at pH ~1, *etc.*, conditions under which the identities of the constituents can at present only be guessed. The authors found that dissolution of rhodium hydroxide in 6*M* hydrochloric acid and refluxing at 110° for 1 hr resulted in a 70% conversion into hexachlororhodate(III) and a constituent which formed a strongly adsorbed red-brown band on a Dowex-2 resin column. The same effect was found on dissolving a sample of commercial rhodium chloride in 6*M* acid and aging it for 2 days; with a solution obtained by dissolving in 6*M* hydorchloric acid the residue from evaporation to dryness of rhodium chloride dissolved in 6*M* hydrochloric acid; and with a 6*M* hydrochloric acid solution of rhodium refluxed for 1 hr at 110°. In the case of the dissolution of rhodium hydroxide the evidence obtained by adsorption on the Dowex-2 column and by absorption spectra indicated the following series of reactions with 6*M* hydrochloric acid: cationic and neutral complexes $\rightarrow$ diaquotetrachlororhodate(III) $\rightarrow$ aquopentachlororhodate(III) $\rightarrow$ hexachlororhodate(III). With hexachlororhodate(III) solutions in 6*M* hydrochloric acid there was no detectable shift in absorption maximum on heating, but there was an increase in absorption at the two characteristic maxima. This was interpreted as indicating the presence of a small amount of polynuclear rhodium complexes. In the case of a sample of "ammonium chlororhodite" the change in solution composition on refluxing in 6*M* acid was much the same as with the sodium salt, but the form isolated on the Dowex-2 column suggested the constituent $[Rh(NH_3)Cl_5]^{2-}$.

The authors state that in general refluxing rhodium chloride or hydroxide can accomplish a 95% conversion into the hexachlororhodate. They were thus able to separate rhodium on Dowex-2 from cobalt, copper and ruthenium. It is suggested, however, that any significant amount of the polynuclear complexes would interfere with the separation.

A variety of ion-exchange separations of rhodium from iridium have been proposed. Pshenitsyn *et al.*[36] approached the problem with the guess that complex ions of rhodium and iridium of opposite charges could be obtained through a difference in rates of formation of amine complexes. Although

both rhodium and tervalent iridium reacted with pyridine to form $[M(C_5H_5N)_4Cl_2]Cl$ the former reacted 6·5 times as fast as the latter, the iridium constituent remaining largely as the anion.

Separations by the cation-exchanger KU-2 in the H^+ form were approximately quantitative for rhodium to iridium ratios of 10, 5 and 2 1. With both metals there was a small adsorption of the aquo complexes. In a later paper[37] the authors described a second method of separation which also involved the formation of pyridine complexes. In this case the tervalent indium complex $[Ir(C_5H_5N)_2Cl_4]^-$ was oxidized with chlorine to form the neutral complex $[Ir(C_5H_5N)_2Cl_4]$. Because of the relative insolubility of the latter and the probable adsorption of iridium as a cation the authors preferred to reduce this complex with ascorbic acid back again to $[Ir(C_5H_5N)_2Cl_4]^-$, which was adsorbed quantitatively by the anion-exchanger while rhodium passed through as a cation complex.

The error in iridium determinations was ±3% and for rhodium +4 to −7%. In contrast to the first method, high ratios of iridium to rhodium could be used, ranging from 22 to 98. The amounts of each element were 0·1–10 mg. The order of addition of reagents proved critical. The best results were obtained by chlorine oxidation both before and after the addition of pyridine. Presumably, the authors were not entirely satisfied with the method because further work was being done to find improved conditions for "a more satisfactory separation of rhodium from iridium."

Anion-exchangers have been used to separate rhodium from platinum. Coufalik and Svach[38] applied the method to the determination of rhodium in platinum catalysts. The acid solution of the alloy was treated with sodium hydroxide to precipitate the hydrated rhodium(III) oxide and after a short interval the mixture was adjusted to pH 3·5 with dilute hydrochloric acid. The solution was then passed through anion-exchanger OAL (chloride form) at the rate of 2 ml/min. The rhodium was eluted with 0·2*M* hydrochloric acid and determined colorimetrically with tin(II) chloride. The average recovery was about 96·5% which was acceptable for the required purpose. Platinum was retained on the exchanger and could be eluted only with difficulty by 2*M* ammonia.

Multicomponent metal systems

Polyamidoximes have been used for column or batch adsorption of gold, platinum, palladium, ruthenium and rhodium along with copper, nickel, cobalt, chromium, plutonium, uranium, *etc.*[39] Copper, nickel, cobalt and chromium were complexed at pH 3·4–4·0 while the remaining metals required a pH of 1·0. The amidoximes were made by the reaction of ammonium hydroxide with cyanoethylated cotton, rayon; polyvinyl alcohol fibres containing acrylonitrile, and copolymers of the acrylonitrile with vinyl chloride or vinyl acetate were also used.

For the separation of 0·1–1 mg of rhodium, iridium, platinum and palladium by partition chromatography on ion-exchange resins Moskvin and Preobrazhenskii[40] used a variation of the principle first proposed by Kraus *et al.*[5] and applied by Wang.[6] Sulphostyrene cation-exchange resins KU-2 × 4 and KU-2 × 10 were used. Solutions of the four noble metals with lithium chloride added were evaporated to dryness successively with perchloric acid and water, and several times with hydrochloric acid. Finally the moist residue was treated with hydrochloric acid saturated with chlorine. The precipitate was dissolved in acetylacetone and the solution was added to the exchanger, which was then washed successively with 0·1*M* hydrochloric acid saturated with chlorine, 0·1*M* hydrochloric acid, and acetylacetone saturated with 0·1*M* hydrochloric acid, thus removing the palladium. Then platinum was removed by adding to the resin column a mixture of equal volumes of dibutyl ether saturated with gaseous hydrogen chloride and sulphur dioxide, the latter to reduce the iridium to the tervalent state, and eluting with a 50% solution of n-hexanol or tributyl phosphate in dibutyl ether pretreated with hydrochloric acid and sulphur dioxide. The column was then washed first with carbon tetrachloride and then with the tetrachloride saturated with chlorine to produce iridium(IV) which was then eluted with tributyl phosphate in carbon tetrachloride pretreated with hydrochloric acid and chlorine. Rhodium was then eluted with 4*M* hydrochloric acid. Several procedures for the separation of various combinations of the platinum metals (Rh–Ir, Pd–Rh, Pd–Pt, Ir–Pt) were included in the report, each involving an appropriate selection of eluents.

Blasius *et al.* have extended their earlier contributions dealing with ion-exchange and chromatographic separations of platinum metals. Blasius and Renin[41] approached the problem from the point of view that ion-exchange separations occur not only by a purely electrostatic exchange between anion and anchor groups, but also by a so-called general adsorption at the network including the active groups. On this basis they considered methods which involved precipitation and conversions from anionic to neutral and cationic complexes directly on the exchangers and applied the various conditions which control these reactions in classical systems. Thus with rhodium selective, separation occurred simultaneously with formation of the hydrated oxide. In the case of palladium a pre-wash of a suitable exchanger with a chelating reagent allowed retention on the column and thus a separation from platinum, iridium or rhodium. The exchangers used were Amberlite IRC-50, Permutit RS, Amberlite IR-4B, Permutit ES and Dowex 1. The work was confined to rhodium, iridium, palladium and platinum, in 10–20 mg amounts. The hydroxychloro complexes were prepared in 0·1*M* sodium hydroxide, and nitrite complexes were made by heating with sodium nitrite. Although quantitative

data were not included, the authors stated that quantitative determinations for rhodium, palladium and platinum were made by reduction with hydrazine sulphate in alkaline media and for iridium by precipitation as sulphide. None of these methods is recommended by the present author as particularly accurate.

The authors discussed the effects of the resin groups, cross-linking and dissolution conditions. Difficulties of elution were noted in the cases of the chlorocomplexes and the weakly basic anion-exchanger IR-4B, and with the strongly basic anion-exchangers Permutit ES and Dowex 1. In the case of the oxyhydrate solutions the cation-exchangers Amberlite IRC-50 and Permutit RS allowed the quantitative passage of iridium and platinum. These exchangers in the sodium or ammonium form will retain most of the rhodium and all of the palladium hydrated oxides, both of which can be eluted with 1*M* hydrochloric acid. It is noted, however, that freshly prepared rhodium solution, like iridium and platinum, is not retained by the exchanger. In the case of the nitrito complexes palladium alone is retained by the ammonium form of the cation-exchanger IRC-50. Rhodium, iridium and platinum pass through the exchanger as neutral complexes.

The authors recorded procedures for a variety of separations of groups of two and three metals, but their general applicability was reduced by some incomplete separations though they do suggest new approaches to some separations.

The two-component separations were: palladium from iridium as chlorocomplexes by IR-4B, with elution of iridium by 1*M* sodium hydroxide and palladium by diacetyldioxime and ammonia solution; platinum from iridium, rhodium or palladium as chlorocomplexes by Permutit ES (chloride form) iridium being eluted by 7*M* hydrochloric acid after reduction with iron(II) sulphate, and platinum eluted with the same acid after treatment of the column with sodium sulphite. The iridium eluate contained traces of platinum and the elution of platinum was not complete. Rhodium was separated from platinum by the same method, with some contamination of the rhodium eluate. A procedure was included for the simultaneous separation of rhodium, palladium and iridium from platinum by combination of these methods. Rhodium was separated from palladium or iridium by column precipitation as hydrated rhodium oxide on Amberlite IR-4B. IRC-50, sodium or ammonium form, was also used to separate palladium from rhodium, iridium or platinum by the hydrolytic method. Palladium was first selectively precipitated on the column. In the case of an aged rhodium solution part of the metal was coprecipitated with the palladium. The cation-exchanger IRC-50 was also used to separate palladium selectively from rhodium, iridium or platinum. In this case the chloride complexes were heated with a nitrite solution and palladium alone was bound to the exchanger. On the other hand, these three metals as nitrite complexes were quantitatively adsorbed on the hydroxide form of the anion-exchanger Permutit ES; palladium could then be selectively eluted by ammonia solution, with rhodium or iridium being eluted by 1*M* nitric acid. If platinum were present, it would partly be eluted with palladium. On the other hand, palladium could be selectively isolated from solutions of the four metals by a pretreatment of the cation-exchanger with salicylaldoxime. Palladium was retained as the oxime complex and eluted by 7*M* hydrochloric acid, but traces of palladium were found with each of the other metals.

The authors applied these principles to the separation of rhodium and palladium with either iridium or platinum; and palladium, iridium and platinum. They concluded that the separation of all four elements by using exchangers would be of no advantage compared to classical methods. In the present author's opinion, this situation remains true; for large amounts of metals the wet separations are more accurate and for trace amounts there are chromatographic procedures which provide cleaner separations. However, one may hope that the efforts to improve exchange techniques for the seven noble metals will continue.

A cresolic resin chlorinated to a gain of 20% and then refluxed with *p*-dimethylaminobenzilidene n acetone and concentrated sulphuric acid, isolated, washed and designated as Sel-K_3, was used by Lewandowski and Szczepaniak[42] to separate silver, copper(I), mercury(II), palladium(II), gold(III), platinum(IV) and osmium tetroxide from a solution of some 30 elements including nickel, cobalt, manganese, iron, tin and lead. Osmium tetraoxide was eluted by 1·5*M* hydrochloric acid and the remaining platinum metals by 3*M* hydrochloridic acid. No data were supplied for the noble metals and one may hope that quantitative data will be forthcoming.

Cation-exchange separations of platinum, palladium, rhodium and iridium from assay alloys of iron, copper and nickel have been reported. Dowex 50 × 8 (20–50 mesh) resin was used by Plummer *et al.*[43] to isolate platinum and palladium. The alloy was dissolved in hydrochloric acid, the solution was evaporated to low volume then a little nitric acid was added. After removal of the nitric acid the solution was filtered, and the filtrate was adjusted to pH 1·5, passed through the exchanger, which was then washed with water. The effluent was treated to remove carbon, boron and selenium and then passed through a small column of the same exchange resin. The effluent was practically free from base metals and platinum and palladium could be determined by any convenient method. By a similar procedure Tertipis and Beamish[44] separated iridium from iron–copper–nickel alloys, and Sant and Beamish[45] separated rhodium from these alloys. Sen Gupta and Beamish[46] used the exchange

separation for the recovery and determination of platinum, palladium, rhodium and iridium from the perchloric acid solutions used to eliminate osmium and ruthenium. The Dowex 50W-×8 cation-exchanger has also been used for the separation of platinum and palladium,[47] iridium,[48] and rhodium,[49] from large amounts of copper.

The cation-exchanger KU-2 adsorbs tellurium selectively from 0·01–0·1*M* hydrochloric acid solutions of tellurium, selenium, platinum metals and associated base metals. Solutions of selenium, tellurium, platinum, palladium, copper and nickel were made ammoniacal and passed through the cationite.[50] Selenium and tellurium passed into the filtrate. Copper, nickel and palladium were extracted by cold hydrochloric acid (1 + 1) and platinum by hot acid. At acidities above 0·1*M* part of the tellurium was adsorbed and could be extracted by ammonia. With 0·01–0·1*M* hydrochloric acid and KU-2, tellurium was selectively adsorbed, the platinum metals passing into the filtrate. The accuracy and precision of recoveries of platinum, palladium, rhodium and iridium in amounts of 0·1–5 mg in the presence of 100–200 mg of tellurium were somewhat indifferent. With the ammoniacal solution of platinum and palladium in the presence of copper and nickel the accuracy and precision were of a similar order.

The application of ion-exchangers to the determination of iridium, platinum, palladium and rhodium in solutions from the anodic dissolution of copper-nickel sulphide ores was described by Nadezhina *et al.*[51] These noble metals were quantitatively deposited on the anion-exchanger AV-17 from solutions at pH 2 and containing iron, nickel, cobalt and copper. Only 70% of the ruthenium was deposited although citric acid added to the eluate allowed the adsorption of the remaining ruthenium on a fresh batch of AV-17. This exchanger is similar to Dowex 1 and 2, and Amberlite IR-100. Variations in pH from 2 to 4, and the presence of sulphate, chloride, sodium and potassium were without effect. To determine the platinum metals the resin was burned in the presence of silica and the ash injected into an electric arc run at 12 amp. In an earlier report Nadezhina[52] examined the conditions for rhodium precipitation on two exchange resins. Rhodium was quantitatively adsorbed by EDE-10-p and AV-18 from 1·3*M* hydrochloric acid solutions. These anion-exchangers contain quaternary amino groups and thus have complex forming ability. However, the anion-exchanger AN-2F, which has a complex forming potential but not quaternary amino groups, adsorbed rhodium to a lesser degree. Rhodium was adsorbed most strongly by AV-18 and AV-27. The author also used the anion-exchangers AN-9, AN-1, AV-17 and the cation-exchanger KU-2. At low acidities all of the anion-exchangers adsorb >95% of the rhodium. Under these conditions, the retaining power of the anion-exchangers is equal. It is noted that the author used only rhodium chloride solutions freshly prepared from the metal.

For the separation of platinum metals from associated base metals Anisimov *et al.*[53] used the cation-exchanger KU-2 with 0·3*M* hydrochloric acid solutions. Two g of the resin were used in a column 1·5 cm in diameter and 20 cm long. The results compared favourably with those obtained by the classical hydrolysis in the presence of nitrites.

For the separation and determination of platinum metals in concentrates, Payne[54] integrated classical, ion-exchange and chromatographic methods for use with samples of up to 250 mg of platinum metals. The sample of concentrate was treated in a nickel crucible with hydrofluoric acid to remove silica and then fused with sodium peroxide, and the hydrochloric acid solution of the fused mixture was heated in a distillation flask with sodium chloride and bromate, ruthenium and osmium being collected in a train of receivers containing dilute hydrochloric acid and an end receiver containing ethanolic sodium hydroxide. Osmium was separated from ruthenium by heating the acid receiving solution and collecting in the end receiver. Osmium could then be determined gravimetrically as the hydrated oxide or absorbtiometrically as the thiourea complex. Ruthenium was determined as the metal by evaporation and reduction in hydrogen or spectrophotometically as the thiourea complex.

The pot liquid residue from the distillation was evaporated almost to dryness and the aqueous solution was treated at pH 7 with nitrite to precipitate the base metals selectively. The latter were separated and re-precipitated and, by a system of aliquots, essentially one half of the noble metal content of the pot liquid was treated with hydrochloric acid to remove nitrous fumes and the pH was adjusted to 3 with sodium hydroxide. The remaining base metals were then separated by passage through the cation-exchanger, Zeo-Karb 225. The effluent, containing the nitrited platinum metals, was evaporated in the presence of lithium chloride and fumed in the presence of perchloric acid. The latter was removed by evaporation, hydrochloric acid was added and the solution was evaporated to dryness, this treatment being repeated six to ten times; concentrated hydrochloric acid was added and the volume reduced to 2 ml by evaporation. Solid hydroquinone and hydroquinone dissolved in an isobutyl methyl ketone–hydrochloric acid mixture were added to reduce the iridium, and the organic phase was added to a 35-cm cellulose column prepared from powder slurried with isobutyl methyl ketone and hydrochloric acid. Elution with the reducing solvent was continued with each extract added to the column. Platinum was eluted first, followed by the palladium. The aqueous phases contained the rhodium and iridium. Iridium was selectively extracted by an oxidizing solvent

prepared from hydrochloric acid, sodium chlorate and the acid solvent containing hydrochloric acid and isobutyl methyl ketone. The extract, added to the column, produced a dark-brown band preceding the pink band of rhodium which appeared when the aqueous rhodium phase was subsequently added to the column. The isolated effluents, each containing one of the four metals, were treated by modified conventional methods of determination. The time required for a complete analysis was about one week and the accuracy for mg amounts of metals was about that normally expected from classical methods. Presumably, the methods of separation were not applied to microgram amounts of the metals and with these one might expect high errors from the nitrite separation of base metals contained in the pot liquid. In a footnote the author suggests a modification (addition of tributyl phosphate to the ketone) which decreases the period required for a chromatographic separation. However, platinum and palladium then have similar R_f values.

An ion-exchange separation of gold and noble metals was used by Brooks and Ahrens[55] as a method of concentration prior to spectrochemical determination. In the present author's opinion the course of their investigation would have been modified considerably had the authors been acquainted with the rather extensive analytical literature dealing with their problem. The samples examined were hortonolite dunite, platinum-bearing rock from the Merensky Reef and samples of "Cape granite." Enrichment factors of up to 2000 were obtained from samples of 159–200 g each of which was treated with hydrochloric and hydrofluoric acids, *aqua regia*, sulphuric acid and bromine. Finally a 2*M* hydrochloric acid solution was added to the basic anion-exchanger, Amberlite IR-400, then the eluates obtained first with 0·25*M* nitric acid and then with 1*M* ammonia solution were evaporated to dryness. To remove large excesses of iron the nitrate residue was redissolved in nitric acid and passed thorough a second smaller column; the nitric acid eluate was divided into one fraction containing most of the iron and another containing most of the noble metals. A spectrographic examination was then made of the ignited resin, reagent blank, ammonia fraction and the two acid fractions. No analytical data were provided to indicate the success of the procedure, and to substantiate the authors' prediction of its general applicability.

SOLVENT EXTRACTION

Gold

New and useful extractive methods for gold are being recorded. Trioctylphosphine oxide was used by Holbrook and Rein[66] to produce a gold-bromoaurate complex extractable by chloroform. The recommended range of gold was 20–100 μg. The method was preferred to existing extractions because the absorbance (at 395 mμ) was measured directly on the chloroform extract and there was no appreciable interference from associated base and noble metals. Phosphoric acid was used to complex any iron. Disadvantages are the need for a carefully controlled bromine content in the hydrobromic acid, the fractionating of the chloroform to remove ethanol, and the instability of the gold complex in chloroform solution. It is noted that measurements of the effects of diverse constituents were made without incorporating the dissolution procedure for the gold sample. It should also be recognized that non-interference by individual constitutents added singly provides no assurance of non-interference when they are present simultaneously. Furthermore, the authors' claim for a time advantage over the acetate extraction, considered on the basis of either a few or of many determinations, is invalid. However, the proposed procedure will prove useful as an alternative method or for specific applications. The authors suggested that the method could be used for sulphide ores containing 0·01% of gold but verification for this claim is necessary.

A useful solvent extraction of gold in the presence of very large proportions of platinum, palladium, rhodium, iron, cobalt, nickel and manganese was described by Ziegler.[57] Solutions of the metals containing at least 12% of hydrochloric acid and limited amounts of nitric acid were extracted three times with polyethyleneglycol 400 and the absorbance was measured at 320 mμ. Excellent recoveries were obtained for 60–170 μg of gold. A similar extraction of gold bromide was also described.[58] The method is applicable over the pH range 1–4. The aqueous layer was buffered with disodium hydrogen phosphate and phosphoric acid at pH 0·9–1·4, iron thus being complexed. The gold solution in a little nitric acid was treated with the buffer, potassium bromide was added, then the polyethyleneglycol and 2–3 extractions were made with methylene chloride. Absorbance was measured at 394 mμ. Large proportions of iron, cobalt, nickel, manganese, copper and lead and smaller proportions of bismuth are tolerated. There was interference from palladium and platinum.

In a third application[59] of this approach to the selective extraction of gold the nitric acid solution was treated with sodium saccharinate, phosphate buffer and polyethyleneglycol-400 and extracted three times with the methylene chloride. The absorbance was measured at 315 mμ. There was no interference from large proportions of lead, copper, cobalt, nickel, iron, bismuth and smaller proportions of palladium.

Blyum and Ul'yanova[60] decomposed about one third of an assay ton of ore with *aqua regia*, evaporated to remove nitric acid and dissolved the residue in hydrochloric acid. Tellurium, hydrazine,

filter paper pulp and tin(II) chloride were added to the boiling mixture. The colloidal mass was filtered off, washed and dissolved in *aqua regia*; the liquid was evaporated and then treated with a few drops of hydrochloric acid, a solution of iron(III) chloride and 30% hydrogen peroxide. Finally gold was extracted after addition of a solution of Crystal Violet and toluene, and determined photometrically. Theoretically, procedures such as these ought to produce accurate recoveries of gold in ores but in practice the techniques encourage losses by adsorption and sometimes in the multiple evaporations. In any case, these methods ought to be standardized by procedures which involve an ore of similar composition but free from platinum metals.

Ethyl Violet has also been used in an extractive photometric determination of gold. Lin and Yu[61] applied a procedure similar to that used by Blyum.[60] Sodium tellurite and tin(II) chloride were added to the hydrochloric acid solution of gold; the coagulated precipitate was re-dissolved, nitric acid was removed, and gold determined at the absorption peaks at 551 or 606 mμ. The sensitivity was 2 and 4 times as great as for the Crystal Violet and Methyl Violet methods respectively.

To determine gold in copper, Hirano *et al.*[16] dissolved the metal in a mixture of nitric and hydrochloric acids, evaporated to obtain the chlorides and extracted with ethyl acetate. The method was useful for 2–500 ppm of gold in copper. The authors obtained an error of 10% which they claimed was equal to that of a fire assay, a claim which requires reservations.

Ruthenium and osmium

Chromatographic and solvent extraction methods for the separation of ruthenium from fission products were described by Kiba *et al.*[62] Preliminary chromatographic experiments with nitrosylruthenium-106 trinitrate indicated that there should be oxidation either with bromine to produce ruthenate ions or with hypochlorite to produce perruthenate ions. Furthermore, these experiments indicated that the multicomponent ruthenium species in solution were converted by the bromine or hypochlorite into the simple ruthenium or perruthenate species. Tests with ethanol–butanol–ammonium thiocyanate (50:50:50), glacial acetic acid–water (9:1), pyridine–water (3:2) and isopropyl methyl ketone as solvents indicated superiority of the pyridine solvent. Before use the pyridine was equilibrated with 4*M* sodium hydroxide. The effect of the concentration of the oxidant and of the sodium hydroxide was determined. With the most favourable concentrations extraction was complete only after the solution has stood for 24 hr subsequent to the oxidation. "Antiformin," a solution of active chlorine, sodium hydroxide and sodium carbonate, could be used as the oxidant. The efficiency of the extraction was determined by a measurement of the beta activity of ruthenium-106. The method could be applied successfully to fission product nuclides which accounted for more than 1% of the total activity after the products had been aged for one year.

Kato,[63] in an investigation on the formation and extraction of ruthenium-8-hydroxyquinolinate, obtained findings similar to those of Jasim *et al.*[64] reported several years earlier. Kato applied the tracer ruthenium-106 and provided data on the effects of a variety of extractants, acidity, temperature, time of shaking, buffers, stripping reagents, *etc.* The recommended procedure was closely similar to Jasim's.[64] Essentially complete recoveries were accomplished after heating at 60° for 1 hr at pH 6 and extracting with chloroform or n-butanol. The author's assumption that ruthenium(IV) is the essential oxidation state was based on the use of ruthenium(IV) nitrate and the conversion of ruthenium(III) chloride by air into $Ru(OH)_2Cl_4^-$ and on the incomplete recovery in the presence of hydroxylamine hydrochloride. Aqueous stripping of the quinolinate was accomplished only with concentrated hydrochloric or sulphuric acid. Confidence in the author's data is not encouraged by the method of standardizing. The reliability of the sodium sulphide method[65] was discussed[66] in a report which indicated errors of about 50% for ruthenium.

Kato applied the extraction to the isolation of ruthenium from solutions of fission products. The single interference from zirconium–niobium-95 was eliminated by a nitric acid wash. It was claimed that "Ruthenium-103, -106 of a high radiochemical purity could be obtained from the mixed fission products" by the author's extraction method. In a later paper, Kato[67] used potassium peroxysulphate in a fission product solution made alkaline with sodium hydroxide. Hydrochloric acid and hydrogen peroxide were added, then oxine in acetic acid, and a solution of sodium acetate. After heating at 60° and pH 4 for 1 hr, ruthenium-103, -106 were extracted into benzene. A back-wash with oxalic acid removed ^{95}Zr–^{95}Nb contamination and dilute acid removed the oxine. Ruthenium-103, -106 were stripped with hydrochloric acid. Recovery was 92% in the organic phase and about 70% in the final solution. For the separation of ruthenium(IV) nitrates, nitrosylruthenium(III), and nitritonitrosylruthenium compounds, Bezděk and Menel[68] oxidized with cerium(IV) and periodate in a nitric or perchloric acid medium and extracted the octavalent oxide with tetrachloromethane. The distribution was measured through the activity of ruthenium-106. The period of oxidation, the molar ratio of oxidant, and the acidity and ion concentration of the extracting media were examined for their effect on the extraction. The ruthenium concentrations were about 1–10 μg of metal per ml and the extractions were made at room temperature.

For the extraction of ruthenium nitrosonitrate from nitric acid Nikolaev and Sinitsyn[69] used esters of butylphosphonic acid. There was some evidence that Me_3C groups should provide the highest extraction efficiency.

Aliphatic amines with benzene or hexane were used by Sinitsyn *et al.*[70] for the extraction of ruthenium nitroso pentahalides. Efficiency of extraction increased with increasing amine concentration, with increasing substitution on nitrogen, and with the halogen in the order I, Br, Cl.

For the separation of micro amounts of ruthenium in the presence of iron(III) by extraction of nitrosyl ruthenium complexes with molten naphthols, Konečný[71] investigated the effects of the iron(III) and nitric acid concentrations, and of the amount of naphthol. For the separation of ruthenium he used either a volatilization of the tetraoxide from a permanganate–sulphuric acid solution of the ignited dioxide or an extraction from oxalic acid and hydrochloric acid.

Busev and co-workers have recorded a series of extractive methods for noble metal separation, the integration of which may well introduce new concepts and approaches to both analytical and refining procedures. In a recent series of papers[72–75] pyrazolone derivatives have been proposed as collective and selective extractants. Diantipyrylpropyl-, and diantipyrylphenylmethane complexes of hexachloro-osmates and hexabromo-osmates were extracted by dichloroethane from aqueous media 1–5*M* in hydrochloric acid. Absorbance could be measured at 346 and 378 mμ, the permitted concentration range being 2–23 μg of Os/ml, and the error achieved for 2 μg/ml was $\pm 10\%$. The method allowed separation of osmium from ruthenium, based on the presence of osmium as $[OsCl_6]^{2-}$ and the conversion of $[RuOHCl_5]^{2-}$, the diantipyrylpropylmethane complexes of which are coextracted by dichloroethane, into the tervalent salt by hydrazine hydrochloride.

Coextraction of tervalent ruthenium increased with the concentration of hydrochloric acid, and with increasing concentration of ruthenium and complexing reagent. The authors avoided significant coextraction of ruthenium with osmium by "using the small excess of reagent which is necessary for ensuring almost complete extraction of $[OsCl_6]^{2-}$", the amount of ruthenium passing into the organic phase causing no significant interference with the absorbance of the osmium species. From hydrobromic acid solutions both quadrivalent and tervalent ruthenium are extracted completely. The authors commendably applied the method to distillates of osmium tetroxide from a sulphuric–chromic acid solution, collecting them in 6*M* hydrochloric acid. Hydrazine hydrochloride or sulphate was added to the distillate and the solution was heated to reduce osmium to the quadrivalent state. Presumably, the authors did not co-distil ruthenium, and thus determine osmium in its presence; solvent extraction methods for separations and determinations of this type would add very appreciably to the usefulness of the procedure. Data were included to indicate the absence of interference from iridium and rhodium. Platinum and palladium interfered.

Rhodium and iridium

For the separation of rhodium from iridium Wilson and Jacobs[76] used tributyl phosphate. The method involves conditions which significantly restrict its general usefulness. Aside from failure to provide for the determination of iridium there are inconvenient limitations on the concentrations of both rhodium and iridium. To circumvent this difficulty the authors recommend two procedures, one of which is used for 60–200 μg of rhodium, and the other for 20 μg or less. The permissible limit of iridium for both procedures was 1 mg. The procedures require adjustment to 6–7*M* in hydrochloric acid, treatment of the sample with hydrogen peroxide to oxidize to iridium(IV) and addition of tributyl phosphate, previously equilibrated with hydrochloric acid. Two extractions were recommended. The colour reagents were *N*,*N*′-bis(3-dimethylaminopropyl)-dithio-oxamide and *p*-nitrosodimethylaniline, the former for the 60–200 μg range and the latter for 1·5–25 μg.

A simple and rapid extraction method for the separation of 10–100 μg of rhodium and 7·5–73·8 μg of iridium involves the formation of the tin(II) bromide complex in a perchloric–hydrobromic acid medium and extraction with isopentyl alcohol.[77] Single extractions were sufficient except for larger amounts of rhodium. The use of 200 μg of rhodium resulted in 5 μg or more remaining in the aqueous phase, in which case a second extraction was necessary. The aqueous phase containing the iridium was heated to 99° and the absorbance of the tin(II) bromide complex was measured at 403 mμ. The absorbance of the rhodium complex in the organic phase was measured directly. Large amounts of sodium chloride could be tolerated. For the amounts of rhodium and iridium recommended, absorbance measurements were made between 80 and 140 min after mixing the reagents. Over this period the yellow rhodium complex was stable. The authors believed that the proposed method was faster and simpler than others.

For the isolation of 0·1 mg or rhodium in the presence of up to 100 mg of iridium, Fedorenko and Filimonova[78] used piperidinedithiocarbamate to precipitate rhodium selectively from nitrite solutions of rhodium and iridium. The yellow flakes were then extracted repeatedly with dichloroethene. A 15–60-fold excess of the carbamate, based on the rhodium content, increased the coextraction of iridium from 0·02 to 0·10 mg. The extract was evaporated, and the residue was treated with a solution of hydrogen peroxide and nitric acid to decompose organic matter. Rhodium was then converted into

the chloride. The proposed procedure can be considered a method of separation only insofar as the final determination of rhodium is not affected adversely by the presence of small amounts of iridium. The authors used the tin(II) chloride and polarographic methods for determination.

For the separation of microgram amounts of iridium from milligram amounts of rhodium in 0·1*M* hydrochloric acid solutions Fok[79] extracted tetraphenylarsonium chloroiridate with chloroform containing 1%w/v of tetraphenylarsonium chloride. Iridium in the organic phase was determined spectrophotometrically. Small amounts of platinum, osmium, and palladium could be tolerated. The dissociation constant and solubility product of R_2IrCl_6 in 0·10*M* hydrochloric acid were determined.

For the separation of rhodium from chloride solutions of platinum, palladium and iridium in milligram amounts Busev *et al.*[72,75] used diantipyrylpropylmethane in dichloroethane, extracting from 1*M* hydrochloric acid solution. The technique involved evaporation of the solution of metal chlorides in the presence of sodium chloride, dissolution in concentrated hydrochloric acid and a second evaporation in the presence of hydrogen peroxide, repeated three times. The final residue was dissolved in 1*M* hydrochloric acid and 20 ml of the aqueous phase were extracted with 10 ml of the organic extractant. Stripping from the organic phase was carried out thrice, this operation being repeated before each successive extraction. After separation, the rhodium was found to be spectrographically pure; with the remaining metals a large number of extractions were required to remove spectrographic traces of rhodium. The amounts of metals used by the authors are within the range of gravimetric methods and beyond the recommended range for most extractive spectrophotometric methods for the noble metals. A comparison of the time required for single and for multiple determinations, including the actual working time and the standing time, would be of some interest.

Busev and Akimov[72,75] also used diantipyrylpropylmethane for the separation of platinum, palladium, and rhodium from iridium and the spectrophotometric determination of iridium. As recorded above,[74] osmium(IV) and ruthenium(IV) are similarly isolated by the dichloroethane extractant. Busev[72] stated that 5–6% of the rhodium present is simultaneously extracted. However, "rhodium is not extracted from solutions which have been boiled or allowed to stand", and furthermore, the degree of separation from rhodium increases with increasing hydrochloric acid concentration. However, the procedure given for the separation of iridium from rhodium fails to incorporate these favourable factors. It is stated that under certain conditions of acidity and rhodium and reagent content, the absorbance of the coextracted rhodium complex is negligible at the wavelength of 498 mμ used for iridium determination. The method is applicable over ranges of 40–350 μg of iridium and 1–4 mg of rhodium. The preparation of the chloride solution for extraction required evaporation in the presence of sodium chloride, addition of hydrogen peroxide, and complete conversion into $[IrCl_6]^{2-}$. Data were recorded for iridium to rhodium ratios from 1:3 to 1:108.

For the separation of rhodium from platinum, palladium and iridium, Borbat *et al.*[80] treated the chloride solutions of the metals with tri-isobutylamine hydrochloride and extracted with chloroform. Three extractions were made from 0·3*M* hydrochloric acid. Presumably, the reaction follows an ion-exchange mechanism. Copper and iron could be removed from the organic layer containing the platinum, palladium and iridium, by washing with 0·1*M* hydrochloric acid.

Palladium and platinum

Solvent extraction studies of addition compounds of palladium halides with triphenylphosphine, -arsine and -stibine have been made.[81,82] Triphenylarsine in cyclohexane extracts palladium from weakly acidic media containing excess of iodide and sulphite. The latter prevents interference from platinum, which in excess adversely affects the separation of palladium. However, an increase in acidity encouraged the formation of sulphur dioxide with resulting mechanical losses; excesses of iodide or reagent accelerated the simultaneous extraction of platinum.

Tri-n-octylamine reacts with palladium tetrachloropalladate to form an exchange complex extractable with toluene. Mazuyova and Gindin[83] determined the effect of varying concentrations of hydrochloric acid, lithium chloride, amine reagent and palladium salt on the separation.

Isobutyl methyl ketone was used to extract the palladium iodide complex from sulphuric acid solutions of niobium and zirconium.[84] A 10% excess of potassium iodide and 20% v/v sulphuric acid were used for amounts of palladium of up to 1 mg/ml. The presence of chloride encouraged the coextraction of niobium and zirconium.

Thiocyanate and halide complexes have been used for the extraction of palladium and its separation from silver. Golub *et al.*[85] determined the distribution coefficients in various concentrations of alcohols and cyclohexanone in benzene. Palladium could be separated from silver by dissolution with nitric acid and extraction with amyl alcohol. Methods such as these could probably be applied effectively to determine palladium in silver assay beads and other silver–palladium alloys.

For the extraction of microgram amounts of palladium in the presence of large proportions of rhodium, nickel, cobalt and manganese, Ziegler and Pape[86] used methylene to extract the complex of dimethyl ether with tetraiodopalladate(II), the absorbance of which was measured at 340 mμ.

Undue exposure to daylight reduced the absorbance rapidly. Interference from platinum, iridium, copper and iron required a separation, and the previously recorded silver sulphite–cellulose method was recommended.

A more generally useful method for the separation of palladium was also described by Ziegler *et al.*[87] and allows a separation from 1000-fold quantities of platinum and large excesses of iron, cobalt, nickel, copper and chromium. In the presence of gold in ratios from 1:10 to 1:40 there are positive errors increasing from 0·9 to 2·0%. Phenylacetylene or isopropenylacetylene forms palladium complexes, extractable by methylene chloride to give solutions with an absorption maximum at 317 mμ. The procedure involved an adjustment to pH 1–4 and addition of a 10% solution of phenylacetylene in methylene chloride or a similar solution of the isopropenylacetylene. The turbidity which appears after 10–15 min standing clears after a further addition of solvent.

Solvent extraction was used by Eshelman *et al.*[88] for the separation of 5–100 μg of palladium and rhodium chlorides which were then determined flame photometrically. Palladium was first removed by extraction with salicylaldoxime in 4-methyl-2-pentanone, the pH of the aqueous phase being adjusted to 3·2 ± 0·2 with ammonia. Standing for 1 hr with occasional shaking was required. To isolate rhodium the aqueous phase was treated with a 4-methyl-2-pentanone solution of diethyldithiocarbamate. The mixture was shaken and buffered with ammonium acetate to pH 8. Standing for 2 hr and occasional shaking were required.

Useful modifications of the tin(II) chloride determination and extraction of platinum have been recorded. Khattak and Magee[89] investigated the application of high molecular weight amines for the extraction of platinum in the presence of associated base and noble metals. Two procedures were included; one for the separation of platinum from palladium, and the second for the separation from rhodium. The amines recommended were tri-n-hexylamine, tri-n-octylamine and primene, dissolved in chloroform or benzene. The separation from palladium involved the careful addition of ammonia, then concentrated hydrochloric acid and tin(II) chloride solution without delay, extraction, filtration and dilution to volume with pure solvent. Absorbance was measured at 400 mμ.

For separation from rhodium, the chloride solution was treated with the amine, the aqueous layer with the dissolved rhodium was discarded, and platinum in the organic phase was treated with tin(II) chloride.

The sensitivity was five times that of the usual tin(II) method. The high extraction efficiency was indicated by the need for only a single extraction. The complex was stable in chloroform for 2 hr and in benzene for many hr. The molar absorptivity was greater in benzene than in chloroform. The concentration of hydrochloric acid was not criticial, the most suitable range being 1·3–1·5*M*. There was no interference from osmium(IV), ruthenium(IV), iridium(IV), nickel or iron added directly to platinum solutions. The non-interference from palladium is rather surprising. The efficiency of separation depended on the basicity of the solution. One would expect that at a pH as great as 9, with subsequent acidification, the development of the palladium tin(II) chloride complex would be delayed sufficiently for platinum to be separable but one would also expect that there would be a rapid development of the platinum ammonia complex which on acidification would resist conversion into the tin(II) complex. The authors emphasize the need for the careful timing of 0·5–1 min between the addition of ammonia and the acidification. The data obtained indicated that for a 5-min delay the error was 37·5 μg in 100 μg of platinum. In the present author's opinion, complexing of the platinum by ammonia is initiated immediately on addition of ammonia and this possibility would undoubtedly limit the general usefulness of the separation, particularly with small concentrations of the metals. Coincident with this effect one may expect high results with relatively high proportions of palladium to platinum, and this effect is made clear by the authors' statements and data. One notes also that the method of separation does not include a subsequent determination of palladium and here again it would seem that the associated species do not lend themselves to a direct colorimetric determination of palladium.

Hydrochloric acid solutions (0·1*M*) containing sodium thiocyanate and platinum, irradiated for 15 min with a 500-W incandescent bulb, react with triphenylisopropylphosphonium chloride to produce a yellow complex which can be extracted with a variety of solvents. Senise and Pitombo[90] developed this method for separation of platinum from other noble metals. Separation from palladium involved irradiation of the metal solution containing excess of thiocyanate, addition of the triphenylisopropylphosphonium chloride to form the platinum complex and to precipitate the palladium complex, and extraction of the former with ethyl acetate. The precipitated palladium complex in the aqueous phase was then extracted with cyclohexanone. With large proportions of palladium and 100–500 μg or less of platinum per ml, palladium was precipitated prior to irradiation because the intense colour of its complex interfered with the irradiation required for the platinum thiocyanate reaction. The authors preferred the use of light to catalyse the reaction rather than heat which is normally used to hasten the thiocyanate reaction. With heating the authors experienced greater difficulty in achieving acceptable accuracy and precision. Irradiation for 15 min with a 500-W incandescent bulb (distilled water being used as light-filter) was found satisfactory. Bright

sunlight or ultraviolet radiation could also be applied. For 50–500 μg of platinum an exposure of 5 min was sufficient but for smaller amounts of platinum, and in the presence of foreign constituents, longer exposures were required. Isobutyl methyl ketone or tri-n-butyl phosphate could be used as solvents by coextracted small amounts of palladium. Surprisingly, the ethyl acetate extractions must be made in diffuse light, because although light was required to catalyse the formation of the platinum thiocyanate complex, the colour faded during the extraction. Absorbance was measured at 365 mμ and the optimum range was 5–20 ppm. The compositions of the two complexes were $[(C_6H_5)_3C_5H_7P]_2$-[Pt or $Pd(SCN)_6$]. Palladium was determined by measuring the absorbance of the cyclohexanone phase at 345 mμ for 10 ppm and at 410 mμ for higher concentrations. Despite the authors' conclusion that the palladium cyclohexanone solution was "not very favourable for precise determination" the data provided indicated results in which the precision and accuracy were about those obtained for platinum. It would seem that this aspect of the separation requires further exploration. Separations of platinum were successful for solutions containing rhodium and iridium, the latter requiring reduction by ascorbic acid: there was some interference from ruthenium in amounts greater than 200 μg. Gold could be removed by prior precipitation and removal with benzene. Silver did not interfere.

Derivatives of dithiocarbamic acid as separatory reagents for platinum and palladium were investigated by Pyle and Jacobs.[91] The dibenzyl derivative in chloroform solution was preferred. The procedure required the addition first of sulphur dioxide, then hydrochloric acid if platinum was present, followed by two extractions with chloroform. The organic extract was ashed prior to determination of platinum and palladium. Rhodium interfered seriously with the simultaneous determination of these two metals. For amounts of about 25 mg of the two metals there was little interference from 0·5 mg of iron and nickel. Relatively, the method has little to recommend it; the ashing technique is laborious, and in any case, further researches ought to be completed before the value of the method can be properly assessed. The authors' statement that the "reagents were used without further purification" suggests that some effort was made to ensure the purity of the reagents although no confirmatory data were included. One would hope that such investigations would include a directed effort to ensure purity of reagents.

To determine platinum metals in silicate rocks by a spectrochemical method Hahn-Weinheimer[93] decomposed a few g of sample by an alkaline fusion. An aliquot of the solution of the fused sample was treated with hydroxylamine hydrochloride at pH 3·5 while nitrogen was passed through it. Following the addition of hydrochloric acid the 2-quinolineselenol reagent was added and repeated extractions were made with chloroform. The latter was volatilized and the residue was wet-ashed at 500° with the addition of magnesium nitrate and nitric acid. The claim that losses of osmium were thus avoided most certainly requires confirmation. The resulting residue was then added to a carbon electrode and spectrochemical determinations were made by standard techniques. The detection limits in ppm for each metal were for osmium 2, iridium 0·05, ruthenium 0·05, rhodium 0·05, platinum 0·01 and palladium 0·01. The technique was insufficiently supported by experimental evidence.

For the study of the complex equilibria involved in the hydrolysis of haloplatinates Davidson and Jameson[92a] used the complexes formed with liquid anion-exchangers *e.g.*, Amberlite A-2, extracted by organic solvents. The results of extractions from hydrolysed haloplatinates indicated that the only platinum species extractable into LA-2/cyclohexane was the hexahaloplatinate ion, extraction of hydrolysis products being poor. The extraction behaviour was interpreted as a simple ion-exchange only for fresh haloplatinate solutions in the presence of the corresponding halide.

Multicomponent systems of noble metals

Various extractive and determinative procedures for platinum, palladium, rhodium and iridium were modified and integrated by Faye and Inman[89] to provide general methods for the determination of microgram amounts of these metals. The platinum and palladium iodide complexes were isolated simultaneously and selectively removed by two extractions with tributyl phosphate (TBP) in hexane followed by three aqueous extractions with concentrated nitric acid. For the separation of 50 μg or more of palladium, aliquots of the nitric acid extract were used and platinum and palladium were separated and determined with *p*-nitrosodimethylaniline by a procedure based largely on the early work of Yoe and Kirkland.[94] The aqueous extract from the tributyl phsophate separation contained the rhodium and iridium, which were then converted into the chloro salts; rhodium was separated as described by Wilson and Jacobs[76] and determined spectrophotometrically by the tin(II) bromide method of Berman and Ironside.[95]

Faye and Inman[89] extended the Wilson and Jacob separation by extracting iridium from the TBP-hexane phase with hydrobromic acid and determining it with tin(II) bromide as described by Bermah and McBryde[96] except that phosphoric acid was added to improve the precision. Extractions from the iridium-TBP-hexane phase could also be accomplished by hydrochloric or perchloric acids.

Initially, samples of the four metals were prepared for separation by evaporation in the presence of sodium chloride and treatments with 12*M* hydrochloric acid and 30% hydrogen peroxide followed by evaporations. The data indicated acceptable recoveries over a range of concentrations and ratios of one metal to another.

A theoretical and useful approach to the solvent extraction and determination of platinum metals was introduced by Forsythe, Magee and Wilson.[97] These authors prepared extractable pyridine-thiocyanate complexes of palladium and ruthenium; the composition of the former was $PdPy_2(SCN)_2$, and ruthenium probably formed anionic complexes with ratios of thiocyanate to ruthenium determined by the relative concentration of thiocyanate. The dissolved constituent $[Ru(H_2O)Cl_5]^{2-}$ in acid solution presumably formed crimson $Ru(SCN)_4^-$ or $Ru(SCN)_5^{2-}$. The latter on being heated sufficiently, and particularly at high pH, formed a blue constituent, $Ru(SCN)_4^{2-}$ or $Ru(SCN)_3^-$ as a result of reduction to bivalent ruthenium by the thiocyanate ion, catalysed by the metal. Hexone was used to extract the yellow palladium complex at pH 11–12. Two extractions were sufficient and the absorbance was measured at 345 mμ. The basic aqueous solution from the palladium–hexone extraction was acidified with concentrated hydrochloric acid and the blue ruthenium complex was extracted with hexone and its absorbance measured at 570 mμ. The minimum amounts of metals were 25 μg. The upper limit was not stated.

Perhaps the most surprising aspect of this procedure is the success achieved in making the acidic palladium solution strongly alkaline and in acidifying the strongly basic ruthenium solution without significant formation of hydrated oxides, which, particularly in the case of ruthenium, are not always readily redissolved in excess of acid or base. Presumably, the authors encountered some difficulty as indicated by their stressing the necessity of a rapid addition of acid or base.

In an associated publication[98] dealing with the separation of rhodium, palladium and platinum, pyridine was used instead of the concentrated sodium hydroxide solution, to adjust the pH to 6·0–6·5, forming the complex $PdPy_2(SCN)_2$. Hexone was again used as extractant followed by adjustment of the aqueous phase to pH 2·0–2·5 with hydrochloric acid, heating to 90° for a period of 4 min and subsequent extraction with hexone. Absorbance was measured at 385 mμ. The yellow aqueous phase from the platinum extraction was adjusted to 3–4*M* in hydrochloric acid. Hexone was used again to extract the rhodium, the absorbance of which was measured at 380 mμ. The lower limits of concentration were 25 μg of palladium and 50 μg each of platinum and rhodium. The results indicated an upper concentration of about 250 μg/20 ml.

An interesting sequential series of extractions of constituents of noble and base metal alloys was described by Senise and Pitombo.[99] The method is based on the application of a variety of solvents for the selective removal of metal complexes formed with triphenylisopropylphosphonium salts and excess of thiocyanate. Thus chloride solutions containing large proportions of gold together with iron(III), silver, copper(II), platinum(IV) and palladium(II) were treated with toluene or benzene as extractants to produce the following solutions: gold (orange), iron with tri-n-butylphosphate (red), silver with 2-methylcyclohexanol (colourless), platinum with tri-n-butylphosphate at 65–70° (yellow), copper with isobutyl methyl ketone (wine-red), and palladium with cyclohexanone (yellow). The order of extraction must be as indicated. The same principle was applied to gold alloys which were dissolved in *aqua regia* containing sufficient hydrochloric acid to dissolve silver. Because the extractions were essentially quantitative one would hope that some effort will be made to apply the approach to silver alloy beads obtained from fire assay treatement. Methods such as these could be of considerable value when modified to provide field tests or even quantitative procedures.

An interesting approach to the selection of separatory reactions for the noble metals was discussed by Gindin *et al.*[100] It was assumed that because quaternary ammonium bases were relatively basic compared with the amines previously used by these authors, there would be a lesser tendency to form co-ordination complexes with the noble metals, thus encouraging more effective extraction. The salts of alkylbenzyldimethylammonium chloride and dialkyldimethylammonium chloride proved to be promising reagents when used with 1,2-dichloroethane (containing a little aliphatic alcohol) as solvent. The order of ease of extraction from low hydrochloric acid concentration was Pt(IV) > Pd(II) > Ru(III) > Ir(IV) > Rh(III) > Ir(III). As would be expected, the complex salts formed with the organic bases produced relatively insoluble salts with platinum and iridium. The authors stated that "the solubility of the platinum-metal complexes is much higher when the nitrogen atom is at the centre, and not at the end, of the hydrocarbon chain." It was noted also that an increase in the number of carbon atoms in the quaternary compounds sharply increased the distribution coefficients of these compounds. The authors' comments and data were of a general nature and experimental analytical data would be a welcome addition.

A fundamental study of the benzene extraction of the dithizonates of gold, platinum, palladium, silver, *etc.* was made by Kawahata *et al.*[101] The ranges of pH and sulphuric acid concentrations required to achieve 100% recovery were determined. Excesses of dithizone were removed by washing with dilute alkali solutions. The molar absorptivities on the complexes in benzene solution were determined. As a solvent benzene was superior to chloroform or carbon tetrachloride. The acidities

required for maximum extraction were <15*N* and <pH 5 for palladium; 1·0–10·5*N* for platinum(II); >7*N* for gold.

Berg and Lau[102] used a countercurrent technique to separate some of the platinum metals. Berg's earlier work[103] dealt with the feasibility of extracting the chloro-complexes of platinum and palladium, platinum and rhodium, rhodium and iridium. This new work[102] involved extractions with tributyl phosphate of thiocyanate complexes of the platinum metals. Recoveries of platinum, palladium, rhodium and iridium were 93–97%. The method of separation involved evaporation and dissolution in a hydrochloric acid and potassium chloride buffer at pH 1. Solid potassium thiocyanate was added to provide a 10:1 mole ratio of thiocyanate to metal. The sample was heated, cooled, and transferred to the first tube of a Craig extractor. The distribution coefficients for palladium, platinum, rhodium and iridium were 139, 62·3, 0·19 and 0·09 respectively. The procedure provided a separation of platinum and rhodium, platinum and iridium, palladium and rhodium, and palladium and iridium in less than 10 stages.

Jasim *et al.*[64,104] used solvent extractions to separate and determine the six platinum metals. The first procedure was developed to separate ruthenium, rhodium and palladium from solutions containing only these metals. In each case chloroform was used as the solvent and the determination required a measurement of the absorbance of the 8-hydroxyquinoline complex; ruthenium at 410 mμ, rhodium at 425 mμ and palladium at 450 mμ.

From the recovery data the concentrations were about 5–100 μg/ml for palladium, and 10–100 μg/ml for ruthenium and rhodium. The procedure[64] involved adjustment to 0·1*M* in hydrochloric acid, addition of triphenylmethylarsonium iodide and sodium chloride solution and a chloroform extraction. The organic extract was then treated with oxine and chloroform to form the palladium oxinate. The aqueous phase from the palladium triphenylmethylarsonium extraction was treated with oxine in chloroform, the pH adjusted to 6·4 with sodium acetate, and ruthenium in the organic layer was combined with the residual ruthenium from the rhodium solution, and its absorbance measured. The aqueous extract from the ruthenium separation contained the rhodium, and was treated with butylcellosolve to remove the residual ruthenium; the butylcellosolve was then treated with a chloroform solution of oxine which was then combined with the main ruthenium fraction. The aqueous layer containing the rhodium was heated with oxine in acetic acid, the pH being adjusted to 6·0–8·0 with ammonium acetate, and was then heated and cooled, and the rhodium was extracted by a chloroform–oxine solution. Possible interferences from osmium, iridium and platinum were not discussed except that they did not interfere with the determination of ruthenium; this characteristic could find application in the separation of osmium from ruthenium.

Separation of the metals of the second triad were discussed in the second paper.[104] Osmium was first isolated by a chloroform extraction following colour development with pyrocatechol at pH 3 and subsequent heating. The blue chloroform layer was used for absorbance measurements at 595 mμ. Platinum in the aqueous layer was extracted with isobutyl methyl ketone which was then evaporated, and the residue was treated with nitric, sulphuric and perchloric acids. Thiosemicarbazide was added followed by sodium carbonate, and amyl acetate as the extractant. The resulting blue layer was treated to allow the determination of platinum with tin(II) chloride. The aqueous layer from the platinum extraction was treated to determine iridium volumetrically by hydroquinone in the presence of 3,3′-dichlorobenzidine as indicator. The method was used for osmium over the range of 6–100 μg/ml, for iridium 12–100 μg/ml and for platinum 7–100 μg/ml.

The application of isoamyl alcohol as an extractant for the tin(II) bromide complexes of platinum, rhodium, palladium, iridium and gold in microgram amounts was described by Pantani and Piccardi.[105] In the case of gold a precipitate was formed which required the addition of gelatin to encourage homogeneity but the gold complex was not extractable with the alcohol. In any case, a separation of gold from platinum could be accomplished by extraction of a complex aurate with ethyl ether or isoamyl alcohol, and followed by an extraction of the platinum–metal tin bromide complexes. Because the iridium–tin bromide complex does not form at room temperature its separation from the complexes of platinum, rhodium, and palladium could be thus affected. In this case the isoamyl alcohol was used with the metal solutions in perchloric and hydrobromic acids containing tin(II) bromide. For the separation of platinum from rhodium and palladium the latter is first removed selectively by extraction of the α-nitroso-β-naphthol complex into amyl alcohol. However, the results were 5–7% low. A spectrophotometric method for the simultaneous determination of rhodium and platinum was described.

Zusammenfassung—Diese Übersicht handelt von den Trennungen der sieben Edelmetalle durch Ionenaustausch und flüssig-flüssig-Extraktion, die zwischen den früheren Übersichten und Januar 1966 publiziert wurden. Die in Lösung vorliegenden Edelmetallspezies werden diskutiert, sofern sie zur Trennung und Bestimmung in Beziehung stehen.

Résumé—Cette revue traite des méthodes d'échange d'ions et d'extraction par solvant pour séparer les sept métaux nobles, publiées ultérieurement aux précédentes revues et antérieurement à janvier 1966. On discute des espèces chimiques sous lesquelles les métaux nobles sont présents en solution dans la mesure où elles sont reliées à la séparation et au dosage.

SPECTROSCOPY IN SEPARATED FLAMES—I

THE USE OF THE SEPARATED AIR–ACETYLENE FLAME IN THERMAL EMISSION SPECTROSCOPY

G. F. KIRKBRIGHT, A. SEMB* and T. S. WEST
Chemistry Department, Imperial College, London, S.W.7

(*Received* 15 *March* 1967. *Accepted* 24 *April* 1967)

Summary—The separation of a premixed air–acetylene flame is described. The interconal zone of this flame exhibits very low radiative background, and is only slightly cooler than that of a normal air–acetylene flame. The use of the separated flame in flame photometry, for which it has several pronounced advantages, has been investigated.

IT is well known that premixed hydrocarbon–air flames consist of two separate reaction zones, *i.e.*, the primary reaction zone where the combustible gas mixture burns principally to carbon monoxide, hydrogen and water, and an "outer mantle" or secondary diffusion flame where the hot gases burn with atmospheric oxygen to carbon dioxide and water. The hottest part of flames of this type is normally in the centre of the flame immediately above the primary zone. The existence of the two reaction zones may be demonstrated by using the flame "separator" introduced independently about 1891 by Teclu[1] and by Smithells and Ingle.[2] In this device the combustible gas–air mixture is made to burn on the top of a circular port fitted inside a wider glass tube which forms an extension above the inner burner port. The lower end of this tube is given an air-tight fitting around the burner stem. The primary combustion can then be made to occur on the inner burner port, while the pale bluish-violet secondary "diffusion" flame is maintained at the top of the outer glass tube. The space between the reaction zones, the interconal zone, is thus extended in length. This dark zone also contains the hottest part of the flame, and can be viewed without interference from radiation produced in the secondary reaction zone which normally surrounds it in unseparated flames. It is the interconal zone of premixed laminar flames which is usually employed in analytical flame spectrophotometry, and it is in this hot region that the atoms of most elements exhibit the strongest emission when introduced into the flame by nebulization of solutions of their salts. To the best of our knowledge the possibility that separated flames might have analytically useful properties has not been investigated. Separated flames might provide "atom reservoirs" with very low radiative background for analytical purposes, and their use could prove advantageous in emission flame photometry as well as in atomic absorption and atomic fluorescence spectrophotometry.

Smithells and Ingle[2] reported the separation of low burning-velocity air-supported flames of coal-gas, ethylene, methane, pentane, heptane, and benzene burning at an open Bunsen-type burner port. We achieved separation of flames of coal-gas or ethylene with air at a burner port of this type, but decided that a flame of higher temperature was required for flame photometry. This requirement is filled by the air–acetylene flame, but because of its high burning-velocity it is difficult to maintain

* On study leave from the University of Oslo, Norway.

at an open circular burner port*. This paper reports the separation of a premixed air–acetylene flame at a commercially available Meker-type flame photometer burner head and gives a preliminary report of its utility in emission flame photometry.

EXPERIMENTAL

Apparatus

A Hilger large quartz spectrograph was used to make qualitative identification of the radiating species in the flames. Quantitative measurements of the intensity of the radiation from the flames were made with a Unicam SP 900A flame spectrophotometer fitted with a Sargent recorder. An SP 900A stainless steel burner stem, acetylene emission head and acetylene jet were employed.

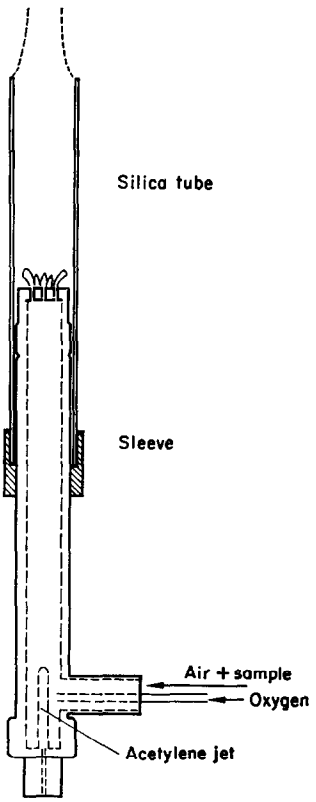

FIG. 1.—Diagram of burner arrangement employed.

Provision was made for the enrichment with oxygen of the air used for aspiration at the junction of the air inlet with the burner base (see Fig. 1). Samples of aqueous solutions were introduced into the flame *via* the Unicam indirect nebulizer and cyclone expansion chamber.

Flame separator

This study was made with a premixed air–acetylene flame which was "separated" by fitting a "Vitreosil" transparent fused silica tube, 20 mm internal bore and 12 cm long, on to the Unicam Meker type burner *via* an air-tight sleeve, enabling the silica tube to be adjusted vertically to provide variable "separating" distances. Between 6 and 8 cm was found to be a convenient distance between the top of the stainless steel burner head and the upper edge of the silica tube. The Unicam burner head has thirteen orifices of *ca.* 1·2 mm diameter arranged in a square of side 9 mm. With this arrangement as shown in Fig. 1, the flame is easily separated into a stable primary zone consisting of 13 separate

* Mavrodineanu[4] reports the separation of an air–acetylene flame at a Lundegårdh-type burner, and its use to illustrate excitation mechanisms.

cones on the burner head inside the silica tube, and a secondary diffusion flame burning at the top of the silica tube. Stable separated flames are obtained over a fairly wide range of fuel–air mixture strengths, as shown in Fig. 2. The flame tends to become turbulent and noisy with very lean mixtures, and the use of very rich (luminous) mixtures leads to the deposition of carbon on the inside walls of the silica tube. Turbulent noise also occurs when a silica tube of very wide diameter is used, or when the distance between the burner head and the upper edge of the silica tube is increased to more than 8–10 cm. This separator arrangement was employed with both air–acetylene flames and oxygen-enriched air–acetylene flames. Without alteration of the arrangement for air–acetylene, the air used

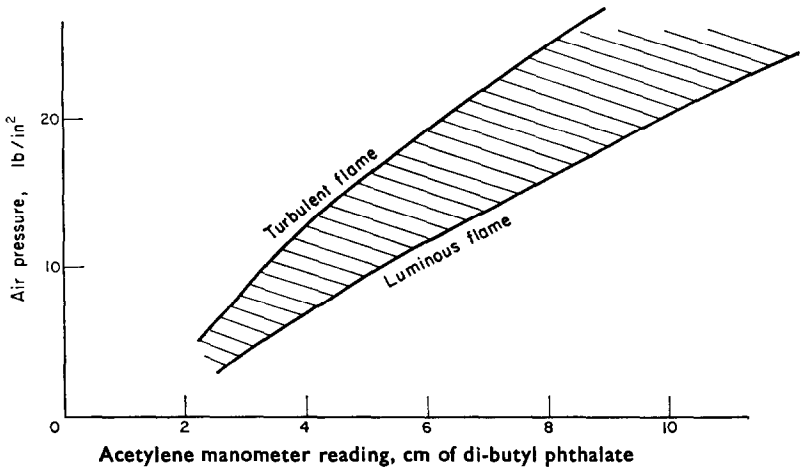

FIG. 2.—Effect of air pressure and acetylene flow-rate on stability of the separated flame.

for nebulization may be enriched by the addition at the burner base of as much as 15 volumes of oxygen to every 100 volumes of air. The acetylene flow-rate must, however, be increased to obtain a stable flame when oxygen enrichment is used. Attempts to use air enriched with more than *ca.* 15% of oxygen with this burner arrangement lead to turbulence and possible blowing back of the flame owing to the greatly increased burning-velocity of the enriched gas mixtures.

RESULTS

Flame emission characteristics

The primary zone of premixed air–acetylene flames radiates strongly over much of the visible and near ultraviolet region of the spectrum, exhibiting the molecular band spectra of C_2, CH, and OH as well as the strong CO continuum. Because of this intense background radiation the primary zone is seldom used in analytical flame photometry. The radiation from the secondary diffusion zone constitutes the main flame background in the premixed flames commonly employed in flame photometry. The emission spectrum from this zone in the air–acetylene flame burning as a diffusion flame at the top of the separator shows only the CO continuum due to the reaction $CO + O \rightarrow CO_2 + h\nu$ which persists over much of the visible region, and the strong OH band systems in the near ultraviolet with heads at 2811 Å and 3064 Å. Figure 3 shows a comparison, at the same air and acetylene flow-rates, of the background emission spectrum from the interconal zone of the separated flame with the spectrum of an unseparated air–acetylene flame. When the separator is used, the background radiation from OH and CO in the interconal zone is at least two orders of magnitude lower than in the unseparated flame. The very weak band emission which appears in the visible region (Fig. 3) is probably due to imperfect shielding of the primary cones

from the slit of the spectrophotometer. Figure 3 also shows how the intensity of this band emission depends on the fuel:oxidant ratio.

Emission from elements in separated flame

When nebulized solutions of metal salts are introduced into the separated flame, most of the atomic line emission takes place in the interconal zone. The emission intensity is greatest in the hottest part of the flame just above the tips of the primary

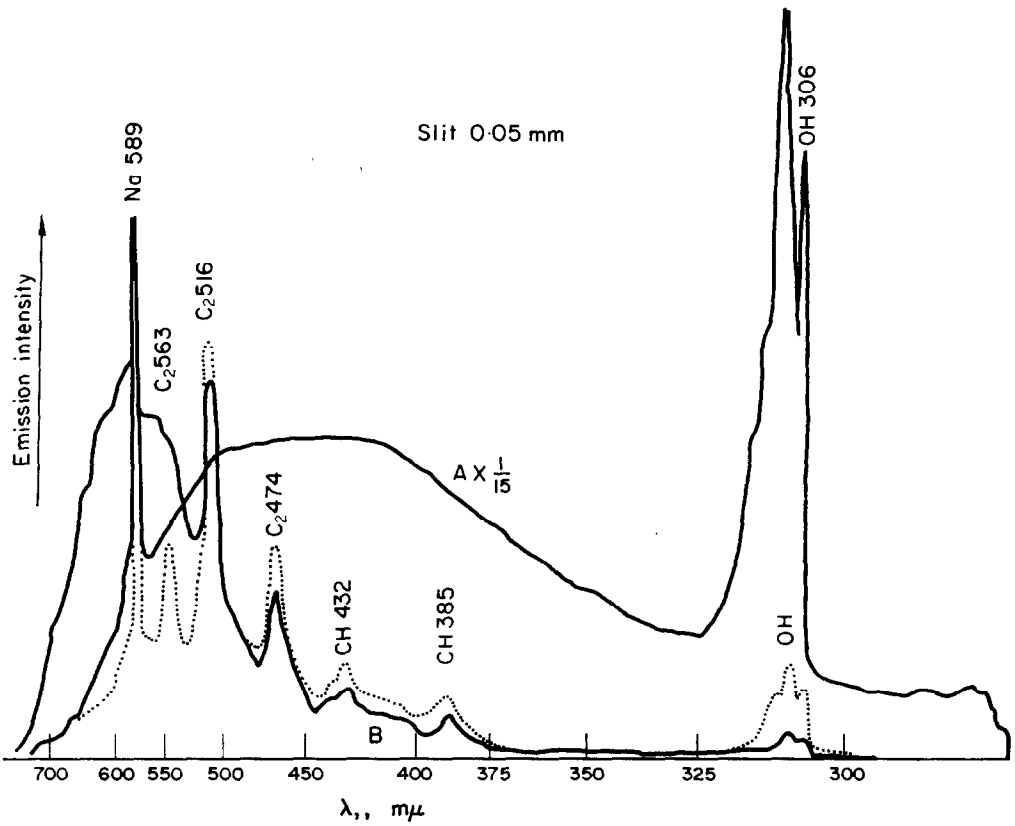

FIG. 3.—Background emission from unseparated (*A*) and separated (*B*) flame. The ordinate of A should be multiplied by 15 to compare absolute intensities. Dotted line shows effect of decreased fuel flow-rate on emission spectrum from separated flame.

cones. For the elements investigated, however, we have found that the intensity of emission from the separated flame is weaker than from a similar unseparated flame. The intensities of the thermal emissions for the elements investigated in the separated flame relative to their emission in the unseparated flame are shown in Fig. 4. Even though the observed intensities are lower, the analytical signal to background ratio is very considerably increased. There is no doubt that some loss of intensity is caused by absorption and reflection losses at the silica walls of the tube. The principal reason for the decreased emission observed, however, is that the interconal zone of the separated flame is slightly cooler than in an unseparated flame. This is caused by

the absence of the surrounding diffusion flame which normally provides heat by the reaction

$$CO + O \rightarrow CO_2 + 67{\cdot}6 \text{ kcal.}$$

The curves shown in Fig. 4 show the relative emission one would expect for a flame 20°, 30° and 40° cooler than the stoichiometric air–acetylene flame ($T = 2325°$) assuming that the emission is wholly thermal (*i.e.*, proportional to $e^{-E/kT}$), and the concentration of neutral atoms is unaffected by this slight temperature drop. The assumption of a constant ground-state atom concentration is known not to be strictly

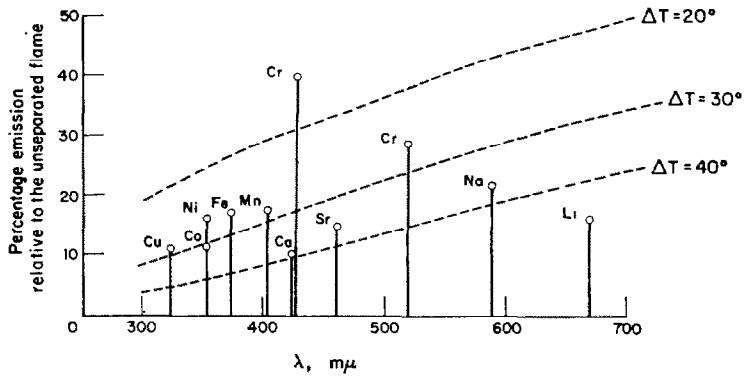

FIG. 4.—Emission intensities for elements in the separated flame compared with their emission in the unseparated air–acetylene flame at the same fuel and air flow-rates.

valid for elements forming stable hydroxides such as calcium and lithium, but suffices to a first approximation. The loss of intensity can then be explained if the separated flame is effectively only about 30° cooler than the ordinary flame immediately above the primary cones. We have observed also that the emission from the flame relative to that of an unseparated flame also depends on the spraying rate of the sample, and is favoured by decreasing the spraying rate. This suggests that the heating capacity of the separated flame may be less than that of the ordinary flame, and this may be an important factor contributory to the decreased emission intensity. The relative emission from the chromium triplet at 4254 Å is very much greater than expected from the general pattern of results shown in Fig. 4, whereas the emission from the chromium triplet at 5206 Å agrees with the results for the other transition elements. It is possible that the chromium emission at 4254 Å is partly supra-thermal in origin. This supra-thermal emission may result from a direct energy transfer reaction involving excited CH molecules and chromium atoms. Two of the three lines in the blue chromium triplet can be shown spectrographically to be virtually coincident with rotational lines within the CH band at 4315 Å [$^2\Delta - {}^2\pi(0, 0)$].

The variation of intensity of emission with the height of observation has been studied for several elements in the separated flame. This was achieved by placing a horizontal slit in front of the spectrophotometer entrance slit and adjusting the burner assembly vertically in front of the horizontal slit. Figure 5 shows the dependence of the emission intensity on the height of observation for calcium, sodium, lithium and chromium at 4227, 5890, 6708 and 4254 Å respectively. The emission profile for calcium at 4227 Å in an unseparated flame under similar mixture conditions is also shown. Other elements exhibit similar emission profiles after allowance is made for

differences in excitation energies and chemical behaviour. Owing to the absence of the surrounding diffusion zone, the emission intensities decrease much more rapidly with height in the separated flame than in a normal flame. The hottest part of the separated flame, where maximum emission is observed, is also relatively independent of the mixture strength, and is invariably immediately above the reaction zone. This may be contrasted with the unseparated flame where the height of maximum emission varies markedly with the fuel–air conditions employed. There is thus no

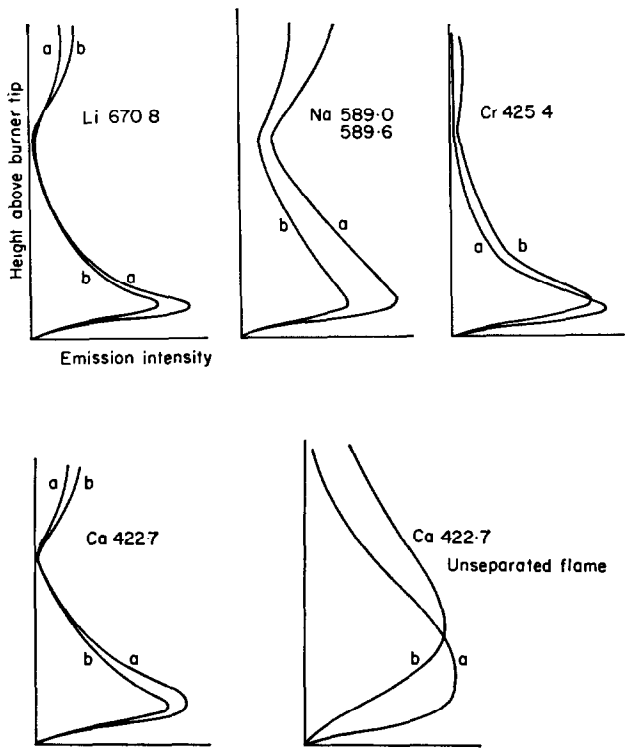

FIG. 5.—Variation of emission intensity for some elements with height of observation; (*a*) fuel-lean and (*b*) fuel-rich flames. The corresponding height profiles for calcium in the unseparated flame is also shown.

need with the separated flame to vary the height of observation according to the mixture used. The emission profiles (as a function of height) of fuel–rich separated flames are observed to be slightly steeper than those of lean flames, and the lean flame is slightly hotter immediately above the reaction zone, and gives more intense emission for several elements than the fuel–rich flame in this region.

Methods of improving sensitivity

The fact that the interconal zone of the separated flame is slightly cooler than that of an unseparated flame represents a disadvantage in its use in flame emission spectrophotometry. The small drop in temperature, while relatively unimportant in atomic absorption or atomic fluorescence spectroscopy, results in a depression of the intensity of thermal emission of elements introduced into the flame. The lowering in emissivity

is not a very great disadvantage, however, since it is never greater than one order of magnitude, but nevertheless we have investigated several methods of restoring the emission intensities to their values in unseparated flames.

The silica tube may be coated externally with magnesium oxide, which acts as a diffuse reflector, and a slot can be made in the coating facing the spectrophotometer entrance slit. With this device it is possible to double the sensitivity for calcium and other elements, and thus to restore much of the lost sensitivity.

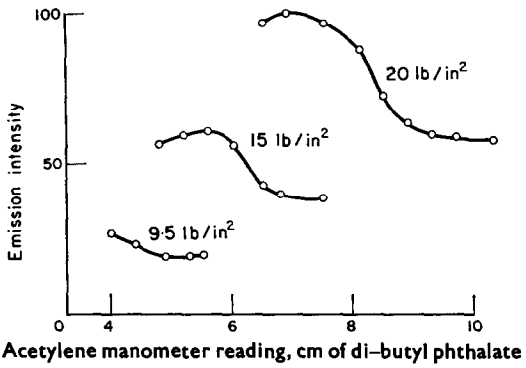

FIG. 6.—Variation of emission intensity for calcium at 4227 Å with air (nebulization) pressure and acetylene flow-rate.

A more useful method of increasing the sensitivity is to increase the flame temperature by enrichment of the air–acetylene mixture with oxygen. The oxygen may be introduced at the burner base where it is bled into the air used for sample nebulization. This oxygen-enriched air then mixes with the acetylene in the burner stem. The addition of only 15% of oxygen (by volume) to the air from the nebulizer results in a sufficient rise of flame temperature to increase the calcium emission at 4227 Å twenty-fold. This represents a considerable improvement in sensitivity for calcium over the original unseparated flame sensitivity, and although the radiative background is slightly greater, the higher emission to background ratio for the line is still retained. This thus constitutes an advantage over an unseparated flame similarly enriched with oxygen.

The utility of the oxygen-enriched separated air–acetylene flame can be demonstrated from a study of the emission of magnesium at 2852 Å and bismuth at 3068 Å In the unseparated flame it is difficult to identify the magnesium 2852 Å resonance line in emission for low concentrations of magnesium (below 100 ppm) because this line is obscured by the emission from the OH system with a head at 2811 Å. In the separated flame, as shown in Fig. 7a, this line is observed very readily for 50 ppm solutions of magnesium against the very low OH background. In a normal air–acetylene or oxy-acetylene flame bismuth cannot be determined even in concentrated solutions by its emission at 3068 Å, and is only detectable at concentrations of *ca.* 1000 ppm, owing to interference from the OH band system which has a head at 3064 Å. Figure 7b shows the emission spectrum obtained for an 800 ppm solution of bismuth in the enriched separated air–acetylene flame. It is evident from this spectrum that bismuth may be determined with good precision in the range 100–1000 ppm and detected above the low background at concentrations as low as 40 ppm.

DISCUSSION

The flame separator provides a simple "closed" burner system, which is advantageous in shielding the flame from contamination by atmospheric dust, draughts and pressure variations. Separation of the air–acetylene flame practically eliminates the flame radiative background, and although the atomic line emission of elements introduced into the flame is also decreased slightly, the ratio of the intensity of the analytical emission signal to that of the flame background radiation is greatly increased for a given slit width. On the basis on which it is normally assessed this does not, however, give great advantage in the limit of detection for the elements investigated.

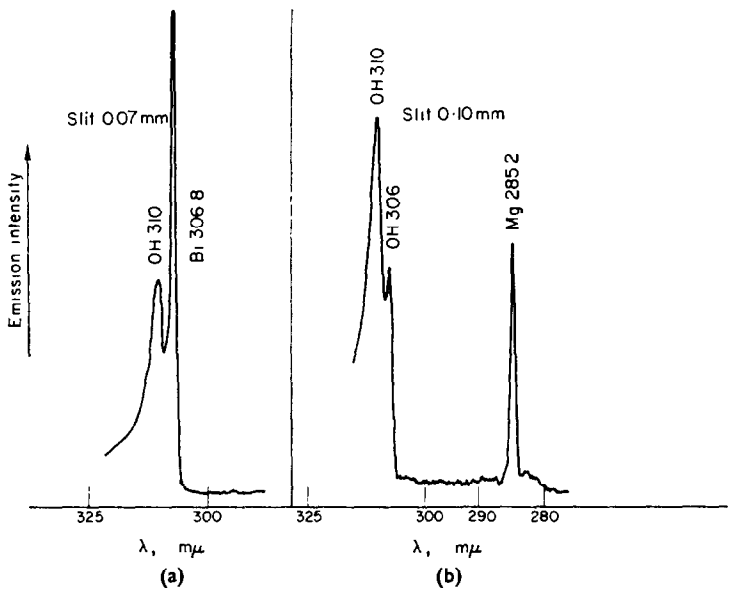

FIG. 7.—Part of the emission spectrum for (*a*) bismuth, 800 ppm, and (*b*) magnesium, 50 ppm, in the separated flame.

The reason for this is that normally in flame emission the limit of detection is defined as by the signal:background ratio. With the separated flame, however, where the radiative background has been very considerably reduced, the detection limit depends more on the signal:electrical noise ratio, as pointed out by Alkemade.[3] Consequently further improvement in limits of detection should be obtainable only by refinement of the detection and amplification system.

Oxygen enrichment of the air used for aspiration provides a separated air–acetylene flame of great utility, particularly for the emission photometry of elements which are difficult to excite. It is normally very difficult in unseparated flames to identify with certainty elements present at low concentrations in a sample simply by recording the emission spectrum of the flame and sample. It is usual under such circumstances to record the emission spectrum from the sample to which a high concentration of the suspected elements has been added. Positive identification of the elements in the original sample is then made from the small differences in the background spectrum with and without the sample at the wavelengths at which high concentrations were identified. The low emission background from the oxygen-enriched separated air–acetylene flame makes it possible to make qualitative assignments for elements

directly from flame emission spectra even for solutions of low concentration. The identification of Bi at 3068 Å and Mg at 2852 Å in this flame demonstrates this advantage.

The almost complete suppression of the OH emission band is a characteristic of the separated flame which cannot be fully taken advantage of in thermal emission flame photometry of the elements, owing to the high excitation energy requirements and consequent poor sensitivity of thermal emission methods in the OH band region between *ca.* 2800 and 3150 Å. Considerations of the background emission and excitation energy requirements lead us to believe that separated flames might prove more useful in atomic absorption and atomic fluorescence spectroscopy than in thermal emission spectroscopy. Our preliminary results for the use of separated flames in these techniques are very promising, and will form the subject of a later publication.

Acknowledgements—One of us (A.S.) is grateful to the University of Oslo, Norway for granting study leave. We also wish to thank Unicam Instruments Ltd. for the loan of the SP 900A flame spectrophotometer with which this work was carried out, and Murex Ltd. for the loan of the Sargent recorder.

Zusammenfassung—Die Auftrennung einer vorgemischten Luft-Acetylen-Flamme wird beschrieben. Die Zone zwischen den Kegeln dieser Flamme zeigt sehr geringen Strahlungsuntergrund und ist nur wenig kälter als die einer normalen Luft-Acetylen-Flamme. Der Gebrauch der aufgetrennten Flamme bei der Flammenphotometrie wurde untersucht; sie zeigt dabei mehrere deutliche Vorteile.

Résumé—On décrit la séparation d'une flamme air-acétylène préalablement mélangés. La zone inter-conique de cette flamme montre un très faible fond radiatif, et n'est que légèrement plus froide que celle d'une flamme air-acétylène normale. On a étudié l'emploi de la flamme séparée en photométrie de flamme, où elle offre plusieurs avantages prononcés.

PRECIPITATION OF NICKEL DIMETHYLGLYOXIMATE

S. J. LYLE and R. MAGHZIAN
The Chemical Laboratory, The University of Kent at Canterbury, Canterbury, Kent, U.K.

(*Received* 27 *January* 1967. *Accepted* 20 *April* 1967)

Summary—The homogeneous precipitation method of Salesin and Gordon and the aqueous acetone precipitation described by Jones and Howick are examined for the determination of nickel as the dimethylglyoximate and where applicable comparisons are made with a direct (conventional) precipitation of this substance. The co-precipitation of iron and cobalt was studied radiometrically under various experimental conditions. Relevant solubility data are also presented. Application of the methods to the determination of nickel in alloy steels showed that in the absence of cobalt there is little to choose between them. For cobalt steels the method of Jones and Howick is more convenient than that of Salesin and Gordon and more satisfactory than a conventional precipitation and gravimetric finish.

SINCE the discovery[1] that dimethylglyoxime reacted with nickel(II) to give a highly coloured insoluble substance afterwards shown[2] to be suitable for the gravimetric determination of nickel, several refinements of the method and information on the structure of the substance have been reported.[3–7] The introduction of a method of homogeneous precipitation by Salesin and Gordon[8] (S & G) and the mixed solvent method of Jones and Howick[9] (J & H) are representative of more recent attempts to improve the selectivity of the method.

In the work described here these new quantitative methods are compared with a "conventional" precipitation method. Their application to the determination of nickel in some alloys has been examined and aspects of the coprecipitation of cobalt and iron studied by using radioactive tracers. As part of this study the solubility of nickel dimethylglyoximate in various solvent media has been determined radiometrically.

EXPERIMENTAL

Reagents and apparatus

Reagent-grade chemicals were used unless otherwise stated.

Nickel. An aqueous solution containing about 3 mg of nickel per ml was prepared from nickel sulphate heptahydrate. The nickel content was determined by dimethylglyoxime precipitation.[10]

Cobalt and iron. Aqueous solutions, each containing about 2 mg of metal ion per ml, were prepared from hydrated cobalt(II) and iron(III) chlorides and standardized by EDTA titration.[11,12]

Radioactive tracer solutions. The radioactive isotopes cobalt-60, nickel-63 and iron-59 were obtained from the Radiochemical Centre, Amersham, England. Each contained some carrier. The stock solutions were diluted to the required activity levels with 1*M* hydrochloric acid.

Biacetyl. Laboratory reagent grade biacetyl (B.D.H., Poole, England) was redistilled before use as recommended by Salesin and Gordon.[8] The refractive index (1·394) measured by means of an Abbé refractometer, was used as a measure of purity.

Dimethylglyoxime. A 1% w/v solution was prepared in ethanol.

Sodium diethyldithiocarbamate. A 2% w/v aqueous solution was freshly prepared each day.

Scintillator. The initial experiments were carried out with a solution containing 0·5 g of 2,5-diphenyloxazole (PPO) and 0·05 g of 1,4-bis[2-(5-phenyloxazolyl)]benzene (POPOP) dissolved in 1 l. of toluene. Later, it was found that the commercially available scintillator NE 214 [Nuclear Enterprises (G.B.) Ltd., Edinburgh, Scotland] was more satisfactory and it was used in the work reported here.

Buffer, pH 6·4. An ammonium acetate–acetic acid solution, 5*M* in acetate, was used.

Hydroxylamine hydrochloride. A 1·8% w/v aqueous solution was used.

Alloys. The analysed alloy samples were British Chemical Standards (B.C.S.) supplied by the Bureau of Analysed Samples Ltd., Middlesbrough, England.

Radioactive counting

The cobalt-60 and iron-59 were counted in a well-type γ-scintillation counter [Na(Tl)I crystal] by using the photopeaks produced by the 1·17 and 1·33 MeV γ-rays from the cobalt and the 1·29 MeV ray from the iron.

Nickel-63 was determined by a liquid scintillation counting method. The apparatus consisted of a single photomultiplier tube (EMI 6097S type) having a satisfactory signal/noise response, used in conjunction with pre- and main amplifiers (NE 5202) and suitable discriminating equipment (single channel pulse height selector NE 5102) all supplied by Nuclear Enterprises (G.B.) Ltd.

Precipitation of nickel

Portions (10 ml) of the standard nickel solution were measured out by pipette and the procedures set out by Gordon *et al.*,[8,13,14] Jones and Howick[9] and, for example, Vogel[10] for the direct precipitation method, were followed.

Coprecipitation of cobalt and iron

The method used was similar to that described previously[15] for a study of the coprecipitation of various metal ions with aluminium tris-8-hydroxyquinolinate. The final volume of solution from which precipitation occurred was, however, 200 ml, and the weighed portion of precipitate was dissolved in a mixture of 10 ml of 1*M* sulphuric acid and enough acetone to make the final volume 25 ml. Portions (5 ml) of this solution were counted.

The measure of the total tracer activity present was obtained by diluting 2 ml of the tracer and 10 ml of the carrier nickel solutions to 100 ml with sulphuric acid and acetone in the proportions used for dissolving the precipitate, and counting 5 ml of the solution. Varying amounts of inactive nickel or dimethylglyoxime within the required range did not influence the counting efficiency for the two isotopes used.

The proportion of tracer, W%, coprecipitated with the nickel was calculated from the relation

$$W = \frac{x}{4yz} \times 100$$

where y is the initial and x the final counting rate; z is the fraction (by weight) of the precipitate dissolved in the step leading to x.

Solubility of nickel dimethylglyoximate

Samples of nickel dimethylglyoximate containing nickel-63 were carefully prepared by precipitation from dilute nickel solutions. Excess of the dried substance was shaken mechanically for 24 hr with the chosen solvent at room temperature (23°). The equilibrated mixtures were filtered through a sintered glass crucible (porosity No. 4) or through a Whatman No. 41 filter paper. Then 100 ml of the filtrate were pipetted into a 400-ml tall-form beaker and the contents carefully evaporated to near dryness after the addition of 1 ml of concentrated hydrochloric acid. The nickel was transferred to a separating funnel by rinsing the beaker with successive 2–3 ml portions of water each containing a drop of concentrated hydrochloric acid. Ten ml of buffer at pH 6·4 and 10 drops of diethyldithiocarbamate solution were added and the nickel was extracted into 10 ml of toluene. Two ml of the toluene phase were mixed with 5 ml of scintillator solution and counted. Colour quenching of the scintillator was found to be negligible if less than about 6 μg of nickel were present during counting of the sample; for larger amounts of nickel counted a correction was applied by using a calibration curve. The specific activity of the nickel dimethylglyoximate was determined by dissolving a weighed portion in 3 or 4 drops of hydrochloric acid, adding 10 ml of buffer at pH 6·4 and extracting the nickel into toluene as just described. Experiments showed that for the amounts of nickel involved, the single extraction of the carbamate proved adequate. The extractions from tartrate media were carried out directly on the equilibrated solutions without evaporation.

Nickel in alloy steels

Sufficient of the sample was weighed to contain 25–35 mg of nickel. It was dissolved in 15 ml of 8*M* nitric acid and 5 ml of concentrated hydrochloric acid and oxides of nitrogen were expelled. The solution was diluted to about 180 ml and an amount of tartaric acid equal to 8 times the sample

weight was added; any solid remaining was filtered off and the pH of the solution adjusted with concentrated aqueous ammonia to 7·5 for precipitation by the S & G method or 8 to 8·5 for the J & H method. In the latter method, 75 ml of acetone were added followed by the dimethylglyoxime. For a 1-g alloy sample, the acetone/water ratio should not exceed 1/3 v/v. The determinations in both cases were completed according to the instructions of the respective authors.[8,9]

For alloys containing appreciable amounts of cobalt, 1 g of sodium sulphite was added in the S & G method to ensure that cobalt(II) only was present during the precipitation. In order to obtain complete precipitation in cobalt alloys it was necessary, as pointed out in the original paper,[8] to set the solution aside for at least 24 hr before heating or to add some dimethylglyoxime at the end to ensure complete precipitation of nickel.[8] In the J & H method, the dimethylglyoxime should be added slowly to the hot solution (60–70°) when cobalt is present.

Precipitates are collected from cooled solutions to reduce the solubility of the nickel dimethylglyoximate.[4]

RESULTS AND DISCUSSION

Batches of 10 determinations were carried out for each of the three methods of analysis, on portions of the same nickel solution. The mean precipitate weights obtained are presented along with calculated standard deviations in Table I. It was found that unless the biacetyl was sufficiently pure, high results were obtained by the

TABLE I.—SUMMARY OF RESULTS ON THE PRECIPITATION OF NICKEL

Method	Salesin & Gordon	Jones & Howick	"Conventional"
Precipitate weights, *g*	0·1488	0·1489	0·1492
Standard deviations, *g*	0·0001	0·0001	0·0003

S & G method. For example, biacetyl used directly from the bottle and having a refractive index of 1·4220 gave 0·1504 ± 0·0001 g (10 measurements) for the same quantity of nickel as that used to obtain values recorded in Table I. Additional experimentation with nickel-63 tracer showed that the difference in weight was not due to a more efficient precipitation of the nickel. It was also found that the impurity could not be removed by prolonged drying of the precipitate at 140°.

Some coprecipitation studies were carried out to examine the efficiency with which the S & G and J & H methods prevent entrainment of cobalt and iron. The J & H method gives rapid precipitation following addition of the dimethylglyoxime; a study of coprecipitation with fractional precipitation of the carrier was not possible and measurements are therefore limited to conditions giving complete precipitation of the nickel. A more extensive study proved possible with the S & G method and the results are reported in Figs. 1 and 2. Tables II and III give coprecipitation data for both methods when precipitation of the carrier is 100%.

The results in Fig. 1 show that for tracer and mg quantities of cobalt(II) coprecipitation is quite low, increasing linearly with increase in the fraction of carrier precipitated. For tracer and 1 mg quantities of cobalt(II) the fraction entrained in the precipitate is higher than for larger concentrations, for which coprecipitation increases roughly proportionally to the amount (and hence concentration) present initially. Extrapolation backwards would suggest that the curves (Fig. 1) pass through or close to the origin, indicating that cobalt does not give rise to centres (nuclei) from which crystals grow. The presence of small amounts of silica does not have any effect on the coprecipitation of tracer amounts of cobalt(II) (Fig. 2) thus supporting this conclusion. Coprecipitation appears to be a little higher when the precipitation of

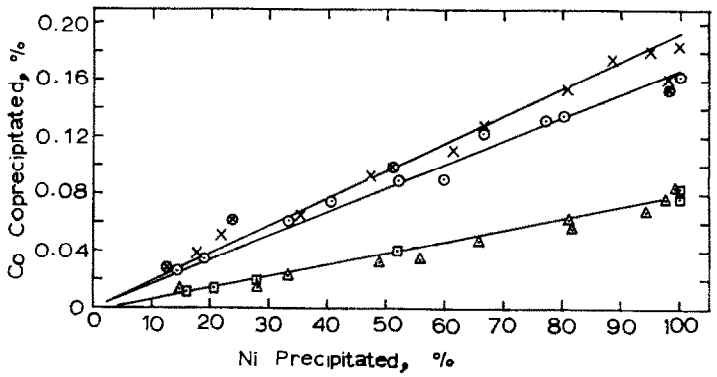

FIG. 1.—The coprecipitation of cobalt(II) with nickel dimethylglyoximate precipitated at 50°C.
×—6×10^{-5} mg of Co; ○—1·05 mg of Co; △—10·5 mg of Co; ⊡—31·5 mg of Co present; all data refer to unstirred solutions: ⊗—6×10^{-5} mg Co in a continuously stirred system.

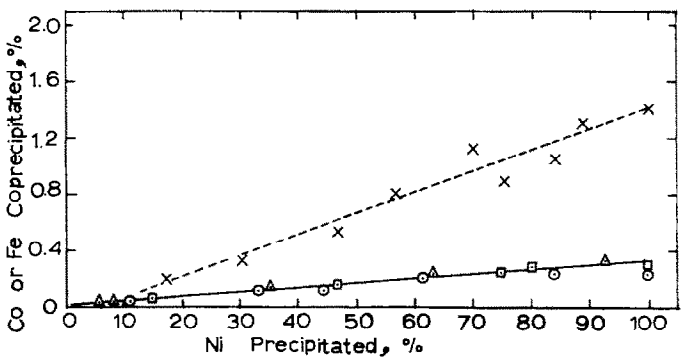

FIG. 2.—The coprecipitation of cobalt(II) and iron with nickel dimethylglyoximate at 23°.
×—4×10^{-5} mg of Fe; △—6×10^{-5} mg of Co; pH 6·8–7·0; ⊡—6×10^{-5} mg Co + silica gel (2·5 mg); ⊙—6×10^{-5} mg Co present: all data refer to unstirred solutions.

nickel is carried out at room temperature (Fig. 2) rather than at 50° (Fig. 1). The rate of precipitation is higher at the higher temperature; qualitatively the observed trend is therefore in agreement with that found by Schweitzer and McDowell[16] when studying the coprecipitation of cobalt with nickel precipitated conventionally. The results presented in Figs. 1 and 2 were mainly obtained with unstirred solutions; continuous stirring produced precipitates having an almost gelatinous character, but when tracer cobalt was present, coprecipitation did not show a significant change (Fig. 1).

Where comparison is possible between the coprecipitation data of Schweitzer and McDowell and that of Table II, cobalt entrainment is appreciably less by the homogeneous precipitation method. Increase in digestion time increased coprecipitation in the earlier, but not in the present work.

Results are given in Fig. 2 for the coprecipitation of tracer iron with fractional precipitation of nickel at room temperature by the S & G method. For complete

TABLE II.—COPRECIPITATION OF COBALT FOR COMPLETE PRECIPITATION OF NICKEL

Exp.	Method	Total cobalt present, *mg*	Temp. of precipitation, °C	Cobalt coprecipitated as % of total Co
1	S & G	T	50	0·17
2	S & G	T	23	0·24
3	S & G	1·05	50	0·16
4	S & G	10·5	50	0·85
5	S & G	31·5	50	2·48
6	S & G	1·05	50	0·17
7	S & G	1·05	23	0·50
8	S & G	T	23	0·08
9	S & G	1·05	23	0·10
10	J & H	T	70	$<2 \times 10^{-3}$
11	J & H	10·5	70	$<2 \times 10^{-3}$

In experiments 6 and 7 the solution contained 60·52 mg of Ni, in the others 30·26 mg. An addition of 1 g of tartaric acid +1 g of sodium sulphite was made before precipitation in 8 and 9. T means that only tracers of cobalt (approx 6×10^{-5} mg) were added. The values in column 5 are means of duplicate determinations.

TABLE III.—COPRECIPITATION OF IRON FOR COMPLETE PRECIPITATION OF NICKEL

Method	Iron present, *mg*	Temp. of precipitation, °C	Iron coprecipitated as % of total Fe	Additions
S & G	T	23	0·15	—
S & G	T	23	0·17	+1 g Na_2SO_3
S & G	T	23	<0·005	+1 g tartaric acid
S & G	25	23	<0·005	+1 g tartaric acid
S & G	25	23	<0·005	1g Na_2SO_3 + 1g tartaric acid
J & H	T	70	<0·005	—
J & H	30	70	<0·005	—
J & H	60	70	<0·005	—

In each experiment 30·26 mg of nickel were precipitated. T indicates that only traces of iron (approx 4×10^{-5} mg) were added. Column 5 gives additions over and above those mentioned in the basic procedure. Measurements were performed in duplicate.

precipitation of nickel the extent of iron coprecipitation is summarized in Table III under various reaction conditions. Thus, in the presence of tartaric acid, iron in moderate amounts should not present a problem through coprecipitation in either method (see also Table VII). The presence of sodium sulphite does not have a significant effect on iron entrainment.

Solubility studies

The results of measurements of the solubility of nickel dimethylglyoximate in various fluid media are given in Table IV. Good agreement is found where comparison with published data is possible. The solubility is lowest in water. The substance is less soluble in ethanol or ethanol/water than in acetone or acetone/water. Moderate

TABLE IV.—SOLUBILITY DATA AT 23° FOR NICKEL DIMETHYLGLYOXIMATE

Solvent	No. of measurements	Mean solubility (g $NiDMG_2$/100 ml)
Water (pH 6·9–7·0)	3	$(3{\cdot}4 \pm 0{\cdot}3) \times 10^{-5}$
2% w/v Ammonium acetate	3	$(1{\cdot}3 \pm 0{\cdot}1) \times 10^{-4}$

Ethanol	4	$(1{\cdot}4 \pm 0{\cdot}1) \times 10^{-4}$
1·5% w/v Ammonium tartrate pH 7·5	2	$1{\cdot}4 \times 10^{-4}$
4% w/v Ammonium tartarate pH 7·5	2	2×10^{-4}

Published data: in water at 25°, $3{\cdot}6 \times 10^{-5}$ g $NiDMG_2$/100 ml:[17] in 1:1 ethanol/water at 25°, $2{\cdot}4 \times 10^{-4}$ g Ni DMG_2/100 ml.[4]

concentrations of ammonium acetate or tartrate appear only to have a small effect. It is therefore to be expected that the loss of nickel in terms of the weight of dimethylglyoximate (0·1 or 0·2 mg) may be just measurable in the usual gravimetric determination. This conclusion finds support from results obtained for some experiments in which nickel labelled with nickel-63 was precipitated by the two methods under consideration (see Table V). The amount of nickel left in solution (Table V) is in

TABLE V.—LOSSES IN THE PRECIPITATION OF NICKEL

Method	Ni taken, *mg*	Vol. of soln, *ml*	Ni left in soln, *mg*/100 *ml*
S & G	30·26	200	0·020
			0·016
J & H	30·26	160	0·024
			0·035

reasonable agreement with that found by Salesin and Gordon[8] who also included precipitate washings (not so here) in their measurement. The loss per unit volume by the J & H method is somewhat greater possibly due to residual acetone and ammonia at the higher pH used. Results in Table IV suggest that the frequent text-book statement on the need to keep the ethanolic content of the mother liquor minimal is not explained (if justified) in terms of solubility of the precipitate.

Small concentrations of ammonium acetate should not contribute greatly to loss of nickel in a precipitation. On the other hand, free ammonia is probably best kept at a minimum. Experiments showed that the red nickel precipitate dissolves appreciably. For example, 100 ml of ammonia solution (1 + 1) take up about 37 mg of the red solid to give a clear solution. When the ammonia was expelled by boiling the original amount of red precipitate reappeared. It is therefore unlikely that appreciable nickel is converted by aerial oxidation into nickel(IV) under strongly ammoniacal conditions as has been suggested by Claassen and Bastings.[5]

Alloys

Table VI gives results for the analysis of various alloy steels. The agreement between the values given by the S & G and J & H methods and the mean values obtained from the control laboratories is good. Table VII summarizes data from experiments carried out to check that the results in Table VI were not due to compensatory effects. They were obtained by adding iron-59 or cobalt-60 to the alloy sample at

its dissolution. For alloys in which cobalt is absent the conventional method of direct precipitation also gave good results; in the presence of cobalt, the method without modification is unsatisfactory.[5] In the absence of cobalt the S & G, the J & H and the conventional methods take about 6, 5 and 4 hr respectively for a single determination. There is thus little advantage in using the longer methods other than the possible one that either of them could be used more reliably by less experienced operators than the direct precipitation method.

TABLE VII.—CONTAMINATION OF THE NICKEL DIMETHYLGLYOXIMATE FROM ALLOY STEELS

Alloy	Approx weight of alloy, *g*	Method of separation	Contamination *mg*	
			Iron	Cobalt
BCS254/1	1	S & G	<0·02	—
		J & H	<0·02	—
BCS261	0·2	S & G	<0·005	—
		J & H	<0·005	—
BCS233	0·2	S & G	0·12	0·006
		J & H	<0·01	<0·0005
BCS312	0·2	S & G	0·09	0·006
		J & H	<0·01	<0·0005

In the presence of cobalt the J & H method appears to be decidedly advantageous in that cobalt contamination of the nickel dimethylglyoximate is not significant and the analysis only takes about 5 hr compared to 24 by the S & G method. Collection of the precipitate is facilitated by the absence of "creeping" and adsorption on the beaker walls.

Zusammenfassung—Die homogene Fällungsmethode von Salesin und Gordon und die von Jones und Howick beschriebene Fällung aus wäßrigem Aceton werden zur Bestimmung von Nickel als Dimethylglyoximat überprüft und nach Moglichkeit mit einer direkten (herkömmlichen) Fällung dieser Substanz verglichen. Die Mitfällung von Eisen und Kobalt wurde radiometrisch unter verschiedenen experimentellen Bedingungen untersucht. Wesentliche Löslichkeitsdaten werden ebenfalls mitgeteilt. Die Anwendung der Methoden auf die Bestimmung von Nickel in legierten Stählen zeigte, daß sie in Abwesenheit von Kobalt praktisch gleichwertig sind. Bei Kobaltstählen ist die Vorschrift von Jones und Howick bequemer als die von Salesin und Gordon und besser als eine herkommliche Vorschrift mit gravimetrischem Abschluß.

Résumé—La méthode de précipitation homogène de Salesin et Gordon et la précipitation à l'acétone aqueuse décrite par Jones et Howick sont examinées pour le dosage du nickel à l'état de diméthylglyoximate et, là où la chose est applicable, on effectue des comparaisons avec une précipitation directe (ordinaire) de cette substance. On a étudié la coprécipitation du fer et du cobalt par radiométrie sous diverses conditions expérimentales. On présente aussi des données de solubilité s'y rapportant. L'application des méthodes au dosage du nickel dans les alliages d'acier a montré qu'en l'absence de cobalt il y a peu de choses permettant de choisir entre elles. Pour les aciers au cobalt, la méthode de Jones et Howick est plus commode que celle de Salesin et Gordon et plus satisfaisante qu'une précipitation ordinaire et une fin gravimétrique.

A HIGH SPEED MICRO VACUUM-FUSION APPARATUS

M. T. LILBURNE
National Physical Laboratory, Teddington, Middlesex, England

(*Received* 23 *January* 1967. *Accepted* 25 *April* 1967)

Summary—A micro vacuum-fusion apparatus capable of extracting, collecting and examining volumes of gas of no more than 2×10^{-3} cm³ at N.T.P. from metal samples is described. The resulting gas mixture is analysed by gas chromatography with helium as the carrier gas and with a highly sensitive ionization detector.

THE importance of trace impurities in metals, alloys and semiconductors needs no emphasis. Among the most difficult elements to remove from these materials are the permanent gases, since they are present in measurable quantities even in moderately good vacuum systems. Analysis for the permanent gases is therefore of considerable importance. Gas analysis has been applied to progressively smaller samples with a decreasing gas content (<10 ppm) and to a wider range of materials, with only partial success. For example, the determination of nitrogen in the refractory metals is not certain.[1] Thermodynamic data available lead one to the conclusion that nitrogen should be completely extracted from these metals when they are melted in an iron or platinum bath during a vacuum fusion experiment. There is, however, some factor as yet not determined which prevents the rapid removal of nitrogen. Furthermore, with smaller total amounts of gas to be extracted, the apparatus blank and its composition become of extreme importance. Almost certainly a compromise has to be made between the time taken for gas extraction and the fraction of the gas collected that is due to the apparatus blank. A further compromise has to be made between the temperature at which extraction takes place and the amount of material that can be evaporated from the bath. Such material, particularly the refractory metals and manganese, can act as "getters" and thus may remove the extracted gases from the system before they can be collected. Ideally, therefore, gas extraction should be carried out as rapidly as possible at a temperature just high enough for the gases to be extracted quickly. If, in addition, one of the constituents of the bath is volatile then it should be present as only a small fraction of the bath material so as to reduce its vapour pressure.

The purpose of this paper is to describe a micro vacuum-fusion apparatus to which has been coupled a recently developed gas chromatographic analytical system. Emphasis has beeen laid on simplicity of apparatus, speed of extraction and low blank together with good gas extraction and collection conditions.

EXPERIMENTAL

Apparatus

Furnace. The furnace-head is made of silica and is cooled by a jet of air (Fig. 1). A 2-mm diameter tungsten rod supports the graphite crucible assembly. The graphite that has been used is type EY9A, manufactured by the Morgan Crucible Co. Ltd. The crucible is supported in an outer graphite thimble, wall thickness 2 mm, by a layer of loosely packed 300-mesh graphite powder about 3 mm thick. The powder serves to curtail excessive radiation from the crucible when it is at its working

or outgassing temperature, and to insulate the crucible electrically from the thimble. A medium frequency (5000 c/s) generator supplies the power to the heating coil. The inner crucible is preferentially heated because of the wall thicknesses chosen. The central cavity in the crucible is 1 cm in diameter and 4 cm long, so giving a working volume of 3 cm^3, and the wall thickness is greater than 1 cm. A graphite ball is used as a lid to the crucible.

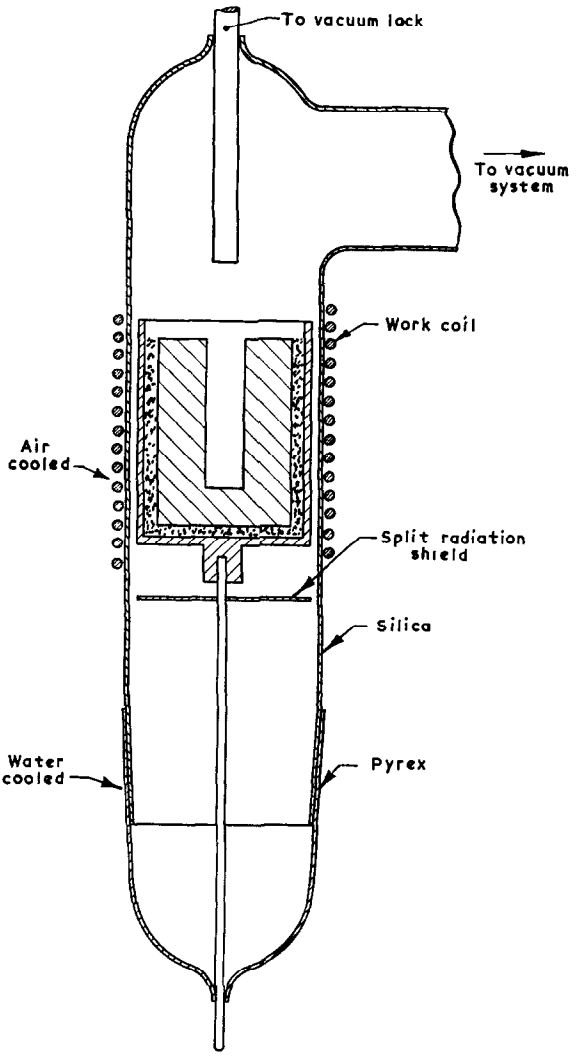

FIG. 1.—The graphite crucible assembly.

In addition to heating the crucible the use of a low frequency power supply results in efficient stirring of the melt. This method ensures that a large effective surface area is presented to the vacuum as compared with the languid conditions in a melt stirred only by convection currents, which is the case when radio-frequency (*e.g.*, 400 kc/s) heating is used. This is considered by Sloman[2] to be a major factor leading to the rapid and complete extraction of gases from such melts. Theoretically it is only necessary for the partial pressure of a gas in the melt to be greater than that in the space above, and if this condition is fulfilled the extraction rate depends on the time of exposure of the gas at the melt surface to the pumped void. Thus with other things being equal, the gas will be extracted at a rate proportional to the surface area.

Vacuum system. The furnace is pumped out by a conventional vacuum system using two high-speed mercury diffusion pumps in series. The gas evolved from the specimens is trapped in the pumping line between these pumps by closing tap T_1 shown in Fig. 2. Mercury diffusion pumps have been chosen for two reasons. First, the pumping "head" of these pumps is such that a large quantity of gas can be collected in the manner described without the pumping action being stopped. Secondly, as the pumps are used without traps in order to simplify the apparatus and to maintain high pumping speeds, some back-streaming of the pumping fluid must occur but it is not important in the case of mercury.

Samples to be analysed are held in a tube above the furnace ready to be dropped vertically through a high-vacuum stop-cock into the crucible. This tube, closed to the atmosphere by a stainless steel cap, constitutes with the stop-cock a simple vacuum lock. A guide is placed so as to keep the samples to the middle of the tube during the drop, to prevent contamination from the grease of the stop-cock.

Gas analysis. The extracted gas is analysed by the chromatographic method described previously;[8] briefly, this consists of an analytical column packed with molecular sieve powder. A Lovelock

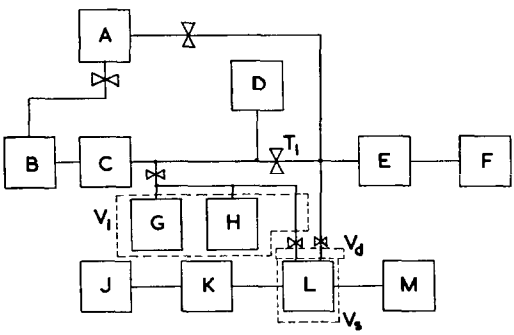

FIG. 2.—Schematic diagram of the vacuum system and gas chromatograph.

V_1, V_d and V_s are referred to in the text.

ionization detector is used which requires helium carrier gas. The analytical column, 120 cm long and 0·5 cm in diameter, is packed with Linde 5A molecular sieve powder, 36–60 mesh. The fines are removed by washing the powder in a tall beaker with a jet of water at such a flow-rate that the fine particles are washed out of the beaker while the coarser ones sink back towards the jet. It has been found that packing material treated in this manner gives sharp elution peaks. Retention times for various gases are given in Table I. The column is heated to 125° in order to elute carbon monoxide

TABLE I.—RETENTION TIME FOR VARIOUS GASES

Gas	Retention time, *sec*
Hydrogen	32
Oxygen	50
Argon	49
Nitrogen	64
Methane	90
Krypton	105
Carbon monoxide	150

reasonably quickly. At this temperature the nitrogen and oxygen peaks are well resolved. If determination of oxygen in the gas mixture is not required the analytical column can be run at a temperature high enough just to resolve the hydrogen and nitrogen peaks. The retention time of carbon monoxide will then be less and the analysis time shorter.

A "Loenco" 6-way valve, supplied in Britian by D. Pitman and Co., Weybridge, Surrey, is used to inject a sample of the gas mixture into the carrier stream. The sampling loop of the valve has a volume of 1 cm^3 and the sample gas pressure used had a maximum of 1 torr, *i.e.*, a maximum quantity of gas mixture of about $1{\cdot}3 \times 10^{-3}$ cm^3 at N.T.P. could be injected. With a carrier gas flow-rate of 90 cm^3/min and a detector voltage of 220 V this quantity of pure gas gives a peak current of 10^{-8} A, corresponding to near minimum amplifier sensitivity settings.

Gas handling apparatus. The extracted gases trapped in the pumping line to the diffusion pump occupy a large volume at low pressure. To obtain good injection conditions for the gas chromatograph this gas has first to be compressed into a small volume at a relatively high pressure. This is accomplished by pumping the trapped gas on to Linde 5A molecular sieve pellets held in a volume of 2 cm^3 and chilled by liquid nitrogen. After this pumping is complete and the 2-cm^3 volume isolated, the gases are quantitatively released by heating the trap to 200° for 3 min. The times taken to absorb (at −196°) and release the gases (at 200°) are given in Table II. The gas mixture is then expanded into the evacuated sample loop of the sampling valve. The volume of the associated dead space is 1 cm^3.

TABLE II.—TIME OF ABSORPTION AND DESORPTION FOR VARIOUS GASES

Gas	Time, *sec*	
	Absorption	Desorption
Hydrogen	180	5
Nitrogen	30	40
Methane	40	60
Carbon monoxide	5	150

The gas chromatograph can accept a pressure in the sample loop in the range 0·05–2·0 torr, depending on the composition of the mixture, without overloading the detector. Provision is therefore made to keep the pressure within this range by having a calibrated tube, which can be filled with mercury, on a side-arm to the trapping volume. By adjustment of the mercury level in this tube any known volume up to 12 cm^3 can be added when necessary. This facility is also necessary to enable the trapping volume, V_1, the dead space, V_d, and the volume of the sample loop, V_s, to be found quite easily by a gas expansion method (see Fig. 2). A mercury manometer is added to the trapping volume for this purpose.

RESULTS

To reach the outgassing temperature of 2400° an indicated power of 12 kW is required but 7 kW will enable 1600° to be reached. With the inner crucible at 2400° the outer thimble attains a temperature of 1000°. With new graphite in the crucible assembly an outgassing time of 6 hr is necessary but once the graphite has been outgassed, subsequent outgassing procedures require only 1½–2 hr. The blank rate desired is such that the contribution of the blank to the total volume of gas collected is less than 10%, *i.e.*, about 1×10^{-3} cm^3/hr at N.T.P. Generally, the blank rate rises to this value after the bath material is added to the crucible. A typical blank analysis before the bath material is added is 83% H_2, 4% CH_4 and 13% CO. After the bath material has been added the figure for hydrogen increases slighly. There is never more than a trace of nitrogen unless there is a vacuum leak. It is interesting that, although the analytical system has sufficient sensitivity, oxygen is not always found when there is a leak, probably because of a reaction between oxygen and the hot graphite of the furnace.

Gas extraction from pure iron and chromium specimens appears to be complete after 3 min. None of these specimens contained more than a total of 20 ppm of gaseous impurities. The gas extraction process is monitored by the Pirani gauge (Fig. 2). Pressure changes rather than absolute readings are noted since the sensitivity of the gauge varies with gas composition. Use is made of the maximum reading to calculate

any volume adjustment required to the molecular-sieve trap as described in the previous section. When once this volume has been fixed for a particular sample the gases are pumped into the molecular-sieve trap during extraction to minimize the effect of the apparatus blank. It is possible to complete the extraction and analyse the resultant mixture in 8 min.

Figure 3 shows the concentrations of oxygen, nitrogen and hydrogen found at different points along a 2·5 mm diameter iron rod which had been subjected to floating-zone levelling and should have been of constant composition throughout. The specimens, numbered in order from 1 to 9 along the rod were analysed in the sequence 1, 6, 2, 7, 3, 8, 4, 9, 5. Apart from specimens 5, 6 and 7 the values found were oxygen 7 ppm, nitrogen 0·5 ppm and hydrogen 1·7 ppm. Thus with a sample expected to be uniform, reasonably constant results were obtained. The reason for the high values obtained for specimens 5, 6 and 7 is not known but it is not a function of the apparatus nor of the extraction procedure. Possibly a region containing a substantial amount of oxygen and other foreign matter in the original material has not been degassed by the zone-levelling process but has been merely spread out. As is usual, the scatter among the oxygen results is larger than that for the other gases.

An analysis was made of electrolytically prepared chromium flake which had been heated in hydrogen at 1350° for 2 hr. Typical flakes were about 1 mm thick and weighed 0·5 g, and, for the purpose of analysis, were carefully broken into four equal portions. For any one flake the analysis was reasonably constant but from flake to flake the results varied markedly, particularly for oxygen. For example, the analysis of one flake was: hydrogen, 4,3, 3·5, 3·5 ppm, nitrogen, 7, 8, 8, 9 ppm and oxygen, 18, 15, 17, 17 ppm, and for another, 4, 3·5, 3·5, 3 ppm, 7, 8·5, 8, 8 ppm and 11, 10, 10, 10 ppm respectively. For comparison, specimens (up to 10g) of a representative portion of the sample were analysed by a larger apparatus and found to contain 5 ppm of hydrogen, 8 ppm of nitrogen and 22 ppm of oxygen. These results show the reproducibility of the apparatus and procedure when it can be expected that the gas content of the specimens is constant. Variation from flake to flake is therefore a gross segregation phenomenon.

Segregation can be clearly seen in Fig. 4, which gives the analysis for oxygen along a pure iron bar that had been rolled from a 25-kg ingot to 1 cm diameter and then swaged to 2·5 mm diameter. This was the starting material for the zone-levelling purification treatment mentioned previously. The weight of the specimens used for this experiment ranged from 0·05–0·15 g. The result found for an 18-g specimen of the same sample in a larger apparatus was 28 ppm compared with an average value of 32 ppm for the small samples, for which the standard deviation was 13 ppm.

CONCLUSIONS

The sensitive apparatus described in this paper has been used for the gas analysis of pure iron and chromium flake. The results have shown that gas segregation is present in all materials so far examined unless special treatments such as zone-levelling or vacuum annealing were used. Once the apparatus had been outgassed one specimen could be handled every 10 min. The vacuum lock enabled specimens to be analysed in any order, and because the lock is evacuated by a by-pass pumping line it should be possible to carry out special surface cleaning treatments, such as argon ion-bombardment, before analysis. Owing to the simplicity of the apparatus high pumping speeds

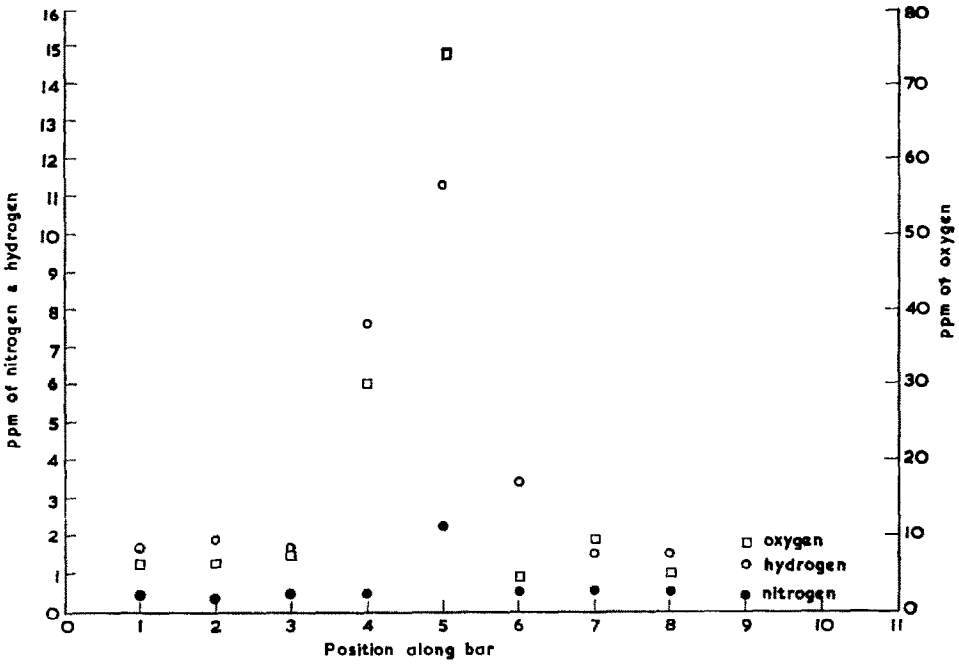

FIG. 3.—Distribution of oxygen, hydrogen and nitrogen along a zone-levelled iron bar.

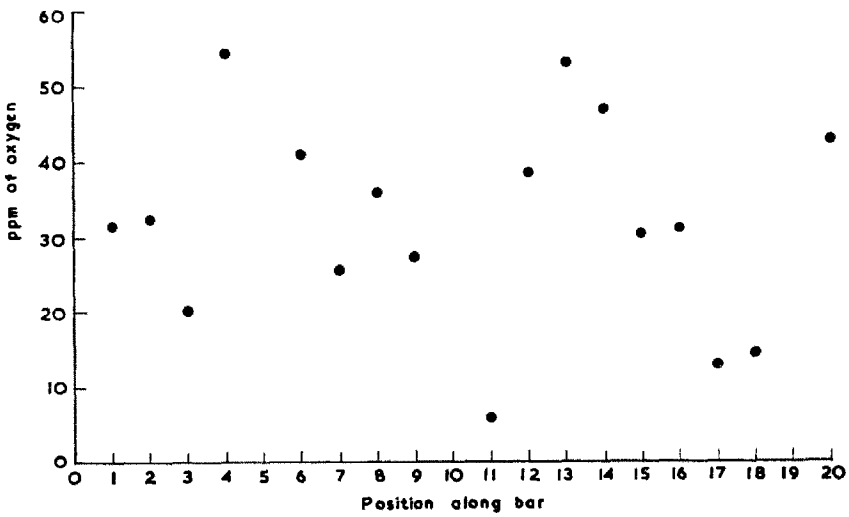

FIG. 4.—Distribution of oxygen along a swaged iron bar.

could be maintained and the extracted gas easily collected. The apparatus is of most use for samples having a very low gas content or for the study of gas segregation.

Acknowledgements—The author would like to thank Mr. I. M. Andrews who zone-levelled the pure iron used in some of the experiments and Mr. D. G. Gladman who helped in the construction of this apparatus.

Zusammenfassung—Eine Mikro-Vakuumschmelzapparatur wird beschrieben, mit der Gasvolumina von nicht mehr als $2 \cdot 10^{-3}$ cm³ bei Normalbedingungen aus Metallproben extrahiert, gesammelt und untersucht werden konnen. Das gewonnene Gasgemisch wird gaschromatographisch mit Helium als Trägergas und einem hochempfindlichen Ionisationsdetektor analysiert.

Résumé—On décrit un appareil de microfusion sous vide capable d'extraire, de recueillir et d'examiner des volumes de gaz n'excédant pas 2×10^{-3} cm³ à température et pression normales à partir d'échantillons de métaux. Le mélange gazeux résultant est analysé par chromatographie en phase vapeur avec l'hélium comme gaz porteur et avec un détecteur à ionisation hautement sensible.

MASS SPECTROMETRIC ANALYSIS OF HIGH-PURITY HELIUM AND HYDROGEN, USING A DYNAMIC SAMPLING AND CALIBRATION SYSTEM

R. T. PARKINSON
Master General of Ordnance Inspectorates, Chemical Inspectorate,
Royal Arsenal, Woolwich, London S.E. 18, U.K.

(*Received* 30 *March* 1967. *Accepted* 18 *April* 1967)

Summary—A dynamic gas sampling system has been designed for use with a mass spectrometer (A.E.I. Model MS2G). It is capable of sampling directly from gas streams at pressures in the region of 800 torr and has been satisfactorily used for the analysis of high-purity helium and hydrogen containing less than 50 vpm total impurity. The overall sensitivity is 1 vpm or better. The design permits the mass spectrometer to be used with its normal gas sampling system when required. A dynamic gas blending rig, incorporating a recirculation and purification system, has been developed for the calibration of the mass spectrometer over the range 5–100 vpm of impurity content.

IN recent years a demand for high-purity gases such as helium has arisen, and in order to ensure that these gases comply with the relevant specifications analytical techniques of high sensitivity are required.

MS2G mass spectrometers (A.E.I. Ltd) are used for certain gas analyses in this Inspectorate, but in their normal configuration they are relatively insensitive *e.g.*, if the instrument is used normally, the limit of detection of an impurity in a gas is in the region of 50 vpm,* the actual limit depending on the relative ionization efficiencies of the impurity and base gas. One method of improving the instrument sensitivity sufficiently to enable high-purity gases to be analysed with confidence is to operate the analyser tube at pressures of over 100 times the normally accepted working pressure of 10^{-7} torr.[1,2]

To take full advantage of this increase in sensitivity it becomes necessary to sample dynamically in order to minimize desorption errors associated with the normal gas sampling system. A system is therefore required which will sample from a gas stream, at a pressure above atmospheric, directly into the analyser tube which operates at a pressure of between 10^{-5} and 10^{-4} torr. In order to calibrate the mass spectrometer when such a sampling system is used, it is necessary to have a continuous supply of gas mixture of known composition.

Standard gas blends of nitrogen and argon,[1] containing trace amounts of helium and hydrogen respectively, have been successfully prepared by introducing small amounts of impurity into an evacuated gas cylinder, and topping up with base gas free from the impurity to be blended. This technique, however, can only be used on a limited scale, because the preparation of different blends over wide impurity ranges involves the use of far too many gas cylinders and prohibitive amounts of gases. A major disadvantage of this technique manifests itself when the base gas contains any of the impurities with which it is to be blended, thereby necessitating a high pressure purification system.

* *i.e.*, Parts per million, v/v.

Consideration was given to electrolytic methods of generating impurities in a pure gas stream, but although this is possible for generating oxygen and hydrogen for example, it obviously cannot be used for generating the inert gases. It was decided therefore to investigate the possibility of introducing, continuously, accurately known amounts of impurities into a pure gas stream by using controlled capillary leaks. This report is concerned with the design, construction and performance of a dynamic sampling and calibration system for use with a mass spectrometer, with particular reference to the analysis of high-purity helium and hydrogen.

EXPERIMENTAL

The Dynamic Sampling and Inlet System

Before any modifications to the inlet system of the mass spectrometer were carried out, the instrument performance was checked, using high analyser tube pressures in order to determine whether sufficient sensitivity could be obtained to enable the analysis of high-purity helium and hydrogen to be carried out directly (*i.e.*, without the use of impurity concentration techniques). It was found that an expansion reservoir pressure of up to 300 torr for helium and 100 torr for hydrogen could be used before any loss of ionization efficiency occurred in the analyser tube, resulting in the lowering of the intensity of impurity ion beams.* An expansion reservoir pressure of 70 torr was selected as optimum for both helium and hydrogen, since at this pressure neither gas had reached the point where the ionization efficiency was reduced by increasing the sampling pressure, and yet considerable improvement in sensitivity was afforded over the normal reservoir sampling pressure of 0·4 torr.†

Modified inlet leak and gas sampling system

The nominal value of the analyser tube inlet leak used in the MS2G sampling system is 35 lusec.‡ It is constructed of sintered silicon carbide and is supported in a short stainless steel tube. Since a pressure of 70 torr on the high pressure side of this leak gives the required analyser tube pressure, a leak some ten times smaller is necessary in order that a sampling pressure greater than atmospheric can be used. It was considered that this required leak could be most easily fabricated by partly blocking an existing one. Attempts to modify an existing leak by vacuum deposition of aluminium on to the leak face were unsuccessful and this technique was abandoned.

The method which proved successful consisted of completely covering the face of an existing leak with soft solder, removing the excess and piercing the solder with a sharp needle. With the modified leak it was found possible to sample high-purity helium and hydrogen directly from a gas stream at a pressure of approximately 800 torr, using a gas sampling system which eliminated the 2-l. glass expansion reservoir. This type of leak has been in continuous use for over two years and calibration checks over this period have shown that the instrument sensitivity remains constant to within $\pm 16\%$. The gas sampling system used in conjunction with the modified leak is shown in Figs. 1 and 2.

* The amplifier on the mass spectrometer has ten sensitivity ranges and all ion beam measurements are finally converted into range-seven readings for calculation of results. The conventional method of measuring ion beams is to denote a full scale deflection of ten divisions on the meter, when on range seven, as ten "inches". It is possible to measure an ion beam of 3000 inches by using the backing-off controls on the instrument but no provision is made for measuring beams in excess of 3000 inches.

When high analyser tube pressures are used for hydrogen, the $m/e = 1$ (H^+) ion beam is measured and the $m/e = 2$ (H_2^+) beam is calculated from it by using a previously determined ratio for $[m/e = 2]/[m/e = 1]$.

In the case of helium, no adequate reference beams exist, and so the analyser tube pressure is referred to the analyser tube ion gauge pressure as follows.

(*i*) Using the normal sampling system, measure the pressure P of helium in the sample reservoir (with a mercury manometer) which gives rise to a helium beam of 3000 inches.

(*ii*) Obtain the ion gauge pressure reading for the selected analyser tube pressure P_g.

(*iii*) The helium beam is given by $3000 \times P_g/P$ inches (assuming a linear relationship between sample reservoir pressure and helium ion beam height).

† The doser volume on the normal sampling system is approximately 1 ml and when this volume is expanded into the 2-l. reservoir the resulting pressure is about 0·4 torr.

‡ The unit "lusec" is used to describe leak-rate and 1 lusec is the rate required to raise the pressure of a 1-l. volume at the rate of 1 micron (10^{-3} torr) per sec.

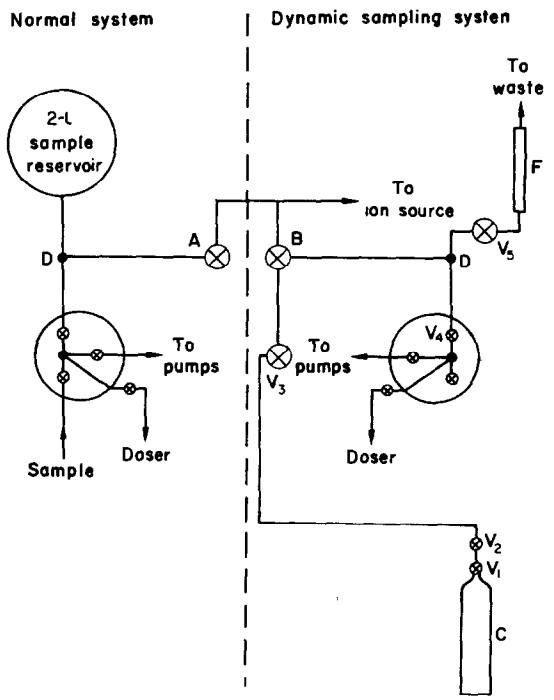

FIG. 1.—Sampling systems.

V_1—Cylinder spindle valve; V_2—gas regulator; V_3 and V_5—Edwards 1/16-in. needle valves; V_4—polythene diaphragm valve: *A*—inlet leak valve; *B*—modified inlet leak valve; *C*—test cylinder; *D*—metal flange joints; *F*—Rotameter (1–10 l/min).

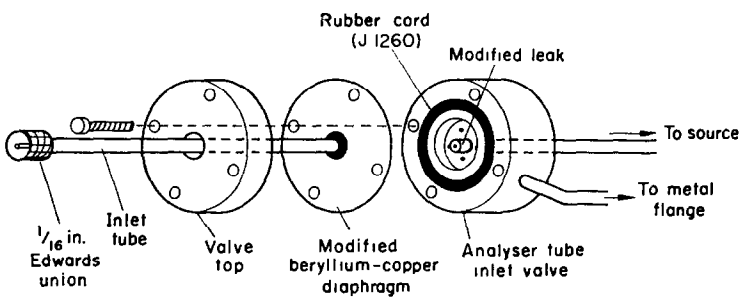

FIG. 2.—Modified analyser tube inlet leak valve.

The gas passes from the test cylinder through a gas regulator, a connecting tube and a needle valve, and then impinges directly on to the face of the inlet leak, after which it is exhausted to atmosphere *via* a second needle valve.

Cylinder helium was tested, using this dynamic sampling system with different sample flow rates, the analyser tube pressure being kept constant at $0{\cdot}5 \times 10^{-5}$ torr (as indicated by the ion gauge) by means of the two needle valves V_3 and V_5 (Fig. 1). It will be seen from the results (Fig. 3) that increasing the flow rate decreases the $m/e = 28$ ($N_2^+ + CO^+$) and $m/e = 32$ (O_2^+) readings but does not affect the $m/e = 20$ (Ne^+) reading.

The results (1, 2 and 4, Fig. 3) indicate that air is being desorbed from the rubber diaphragm in the gas regulator, and from other contaminated surfaces. To investigate this effect further, the B.O.C. gas regulator was exchanged for a Matheson type regulator employing a metal diaphragm. It will

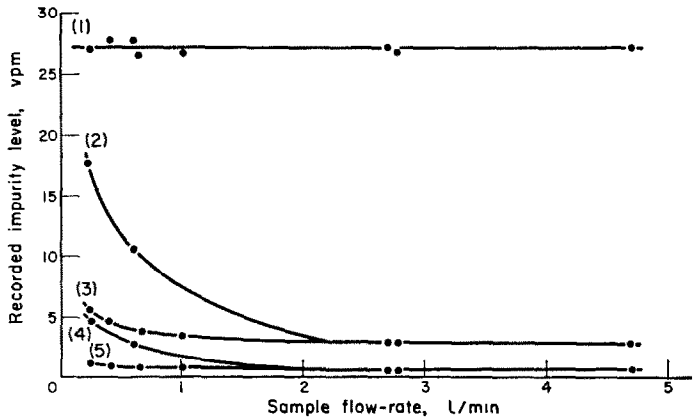

FIG. 3.—Effect of sample flow-rate on recorded impurity level.
1—m/e = 20 (Ne^+), B.O.C. and Matheson gas regulators;
2—m/e = 28 ($N_2^+ + CO^+$), B.O.C. regulator;
3—m/e = 28 ($N_2^+ + CO^+$), Matheson regulator;
4—m/e = 32 (O_2^+), B.O.C. regulator;
5—m/e = 32 (O_2^+), Matheson regulator.

be seen from the results (3 and 5, Fig. 3) that there appears to be less desorption from the metal diaphragm. At flow-rates in the region of 2–4 l/min the impurity level is independent of the type of gas regulator used.

Instrument calibration and performance at high analyser tube pressures

Known amounts of impurities (H_2, N_2, O_2, Ar and CO_2) were introduced into purified helium and hydrogen gas streams by means of a dynamic gas blending rig. With the mass spectrometer analyser tube pressure maintained at the predetermined working level, the gas blends were analysed and the impurity ion beams plotted against actual impurity content. Calibration curves for H_2, N_2, O_2, Ar and CO_2 impurities in helium and for N_2, Ar and CO_2 impurities in hydrogen were linear over the range 0–100 vpm. With oxygen in hydrogen however, the calibration deviated from a straight line and indicated an increase in sensitivity with increasing oxygen concentration. The sensitivities for these impurities are shown in Table I.

TABLE I.—INSTRUMENT SENSITIVITIES FOR IMPURITIES IN HELIUM AND HYDROGEN OVER THE RANGE 0–100 VPM

	Impurity				
	H_2	N_2	O_2	Ar	CO
Sensitivity in helium, (*in/vpm*)	0·10	0·60	0·35	0·95	0·68
Sensitivity in hydrogen, (*in/vpm*)	—	0·57	0·04–0·10	1·00	0·95

The overall precision of the new system was checked by using impure samples of helium and hydrogen contained in gas cylinders at pressures of 1500 psig and 1000 psig respectively. These samples were analysed, using the dynamic sampling system (Table II), with a flow-rate of 4 l/min and both B.O.C. and Matheson type gas regulators. The effect of using different gas regulators was shown to be negligible under the sampling conditions used.

The response time of the instrument to changes in impurity concentration, when the dynamic sampling system was used, was investigated by sampling purified helium and hydrogen *via* the dynamic gas blending rig, and suddenly introducing impurities into the gas stream by means of the rig. For impurities in helium, at the 100 vpm level, the instrument gave constant ion beam readings within 3 min. For impurities in hydrogen, the response was as good as with helium except when oxygen was the impurity. In this case the time taken to attain a constant reading was dependent on the level of impurity and could take up to 20 min (for levels greater than 100 vpm). The m/e = 18 (H_2O^+) reading also increased with increasing oxygen content, indicating that a combination reaction was

* The result for oxygen, determined by using a Hersch Oxygen Meter, was 15 vpm.

taking place, probably on the tungsten filament in the ion source. The response was poor and it could take up to 45 min for the $m/e = 18$ beam to achieve a steady value. As the impurity level was lowered (by increasing the pure gas flow through the blending rig) the response time decreased. At the 5 vpm level, the response time was less than 5 sec (except for oxygen in hydrogen), and almost all of this time could be accounted for in terms of the volume of the gas blending rig and connecting pipework to the mass spectrometer.

To determine the extent of any possible combination reaction between trace amounts of hydrogen and oxygen in helium, a blend of hydrogen in helium was prepared, and analysed in the presence of varying amounts of oxygen. The results indicated that in helium containing 25 vpm of hydrogen no detectable reaction took place up to a concentration of 50 vpm of oxygen.

It was observed during routine analysis of high purity hydrogen that the $[m/e = 29]/[m/e = 28]$ ratio, *i.e.*, $^{14}N^{15}N^+/^{14}N^{14}N^+$, was approximately 0·12 which is much higher than can be expected for the natural abundance of the ^{15}N isotope. This observation can be explained if the N_2H^+ ion is produced in the ion source of the mass spectrometer when high analyser tube pressures are used. Cylinder nitrogen was introduced into a stream of purified hydrogen, and again the observed 29/28 ratio was 0·12. In an attempt to verify whether in fact the N_2H^+ ion is formed, these experiments were repeated with deuterium instead of hydrogen. In this case an ion beam at $m/e = 30$ was found, indicating the formation of the N_2D^+ ion, the $[m/e = 30]/[m/e = 28]$ ratio being approximately 0·07. Further tests were carried out with other impurities, and, although some indication of the formation of other spurious peaks were found, none of these peaks was as obvious as the $m/e = 29$ peak in hydrogen, nor did they appear at any m/e value likely to cause interference in the determination of N_2, O_2, Ar and CO_2 in hydrogen. No spurious peaks have been observed with helium at the impurity levels normally found in the high purity gas.

Application of the method to the analysis of high purity helium and hydrogen

The modified mass spectrometer, after calibration with the dynamic gas blending rig, has been used continuously for several months. Recalibration has not been found necessary except after an ion-source change, and since recalibration is normal under these conditions it is obvious that no change in procedure is involved. The life of a source filament, working under high analyser tube pressures, appears to be between six and eight months.

Because the sensitivity of the instrument is high when high tube pressures are used, variations in the analyser tube background become less important than when normal operating pressures are used (Table III). It is therefore unnecessary to measure the background before carrying out an analysis and consequently the sample throughput can be increased considerably.

Typical analyses of high purity helium and hydrogen are shown in Table IV, together with oxygen figures obtained by using a Hersch Oxygen Meter.

TABLE III.—TYPICAL ANALYSER TUBE BACKGROUND

m/e	Ion beam height, *in.*	Equivalent *vpm* (normal tube pressure)	Equivalent *vpm* (high tube pressure)
2	0·10	100	1·0

The Dynamic Gas Blending Rig

Gas purification

Before work was started on a blending rig, it was considered necessary to have a gas purification unit capable of providing a supply of both pure helium and pure hydrogen, because the analysis of these gases was of prime importance. Several systems were considered, and the one finally adopted as being the simplest with the necessary efficiency consisted of a glass U-tube, packed with 35 g of active carbon (type C, Sutcliffe, Speakman and Co. Ltd., Leigh, Lancs., U.K.), cooled in liquid nitrogen. This purification unit was found to remove H_2, N_2, O_2, Ar and CO_2 from helium, and N_2, O_2, Ar and CO_2 from hydrogen, at flow-rates of up to 3 l/min. The capacity of the purifier for hydrogen was 10·6 ml (at S.T.P) per g of charcoal. After purification, the sum total of these impurities, in both helium and hydrogen, was approximately 1 vpm. The carbon can be regenerated *in situ* by evacuation for several hours at room temperature or for about 1 hr at 100°C.

Mass spectra of purified helium and hydrogen, together with their respective backgrounds, are

shown in Fig. 4. It will be observed that in the case of hydrogen a group of peaks appear in the m/e = 28 and m/e = 44 regions. These peaks may be due to the formation of hydrocarbons by reaction of hydrogen with carbon from the tungsten filament in the ion source. Prolonged conditioning of the filament (several days) reduced these spurious peaks to below 0·5 in. although it should be noted that, at the high analyser tube pressures used, these peaks represent less than 1 vpm of impurity.

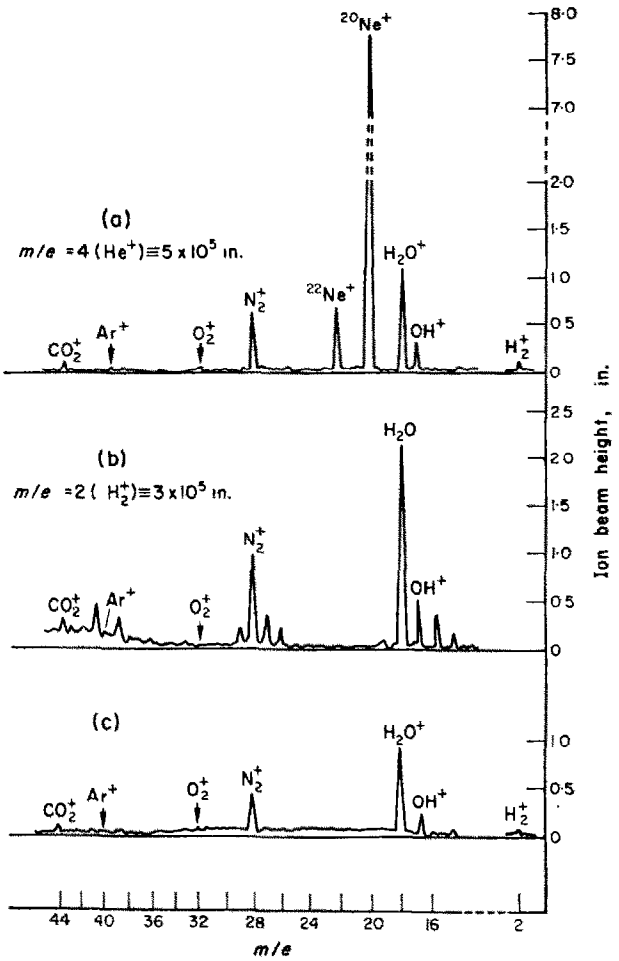

FIG. 4.—Mass spectra of purified (*a*) helium, (*b*) hydrogen, and (*c*) tube background.

Introduction of impurities into a gas stream by the use of fine bore capillary leaks

Preliminary work in which an impurity gas, under pressure, was allowed to enter a pure gas stream *via* a fine bore capillary leak (internal diameter 0·04 mm; length 30 cm) indicated that an impurity gas flow-rate of between 0·08 and 0·20 μl/min/torrΔP* could be realized, depending on the nature of the impurity. Hence, by maintaining a differential pressure of say 50 torr across the leak, and a pure gas flow-rate of 3 l/min, blends containing between 1·3 and 3·3 vpm of an impurity could be prepared.

Experiments were carried out to determine the short and long term stability of the capillary leak.

Short term stability. A stream of argon-free hydrogen was passed through a mixing chamber containing the capillary leak. Argon was passed through this leak under a constant differential pressure

* When the absolute pressure on the impurity side of the leak is greater than the absolute pressure in the pure gas stream, there is considered to be a positive differential pressure (ΔP) across the leak.

(ΔP) of 60 torr and entered the hydrogen stream. The resulting gas mixture, containing approximately 13 vpm of argon, was monitored continuously for argon content with a mass spectrometer fitted with the direct inlet leak previously described. The results showing variation of recorded impurity level with time are shown in Fig. 5. It will be seen that the blend remained constant within $\pm 4\%$ over a period of approximately 7 hr. It should be noted that this test indicates not only the stability of the capillary leak used for blending, but also of the modified mass spectrometer leak, and any other variable in the system.

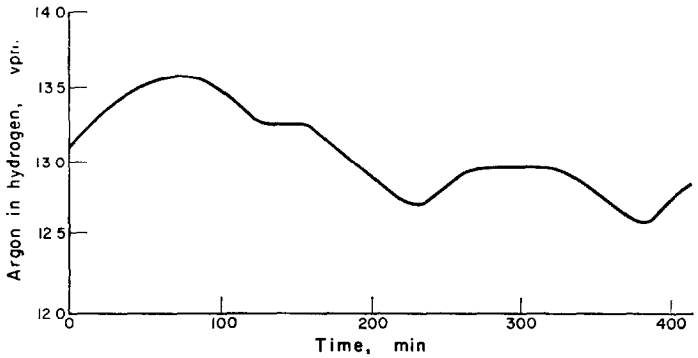

FIG. 5.—Variation of recorded impurity level with time.

Long term stability. The long term stability of the leak was checked by noting, a number of times over a period of several weeks, the time taken for the differential pressure in a reservoir (approximately 7 ml in volume) supplying the leak, to fall from 400 torr ΔP to 200 torr ΔP. Hydrogen was used as the test gas in these experiments. The results in Table V show the long term stability to be better than $\pm 4\%$ over a period of 50 days.

TABLE V.—LONG TERM STABILITY OF THE CAPILLARY LEAK

Time interval between tests, *days*	Temperature, °C	Time taken for ΔP to fall from 400 torr to 200 torr, *min*
0	25	32·4
1	28	33·8
23	25	32·0
29	26	31·4
36	26	32·5
42	25	32·2
50	25	31·5
	Mean	32·3
	Std. devn.	0·8

On the basis of these results it was decided to build a practical blending rig (Fig. 6) incorporating the following necessary requirements.

(*i*) Simple and rapid interchange of leaks, when necessary.

(*ii*) Ease of measurement of the absolute pressure (P) in the pure gas stream at the point where the impurity is introduced.

(*iii*) A means of determining and controlling the differential pressure (ΔP) across the leak, (*i.e.*, the pressure difference between the impurity reservoir and the pure gas stream).

(*iv*) Control and measurement of the pure gas flow-rate (F).

For maximum accuracy a thermostat should also be incorporated in the apparatus. However, in the author's laboratory, errors due to temperature variations were considered to be sufficiently small to render such a refinement unnecessary.

The gas mixing chamber and leak assembly. The gas mixing chamber is shown in detail in Fig. 7. and is fabricated from copper tubing and Edwards hand-tight unions. Provision is made for the inlet and outlet of pure gas, measurement of the gas stream pressure, and attachment of the capillary leak assembly. The leak assembly is shown in detail in Fig. 8. It is designed so that the capillary can be firmly held in position during assembly and use, and easily dismantled for leak changes.

Edwards Saunders valves.

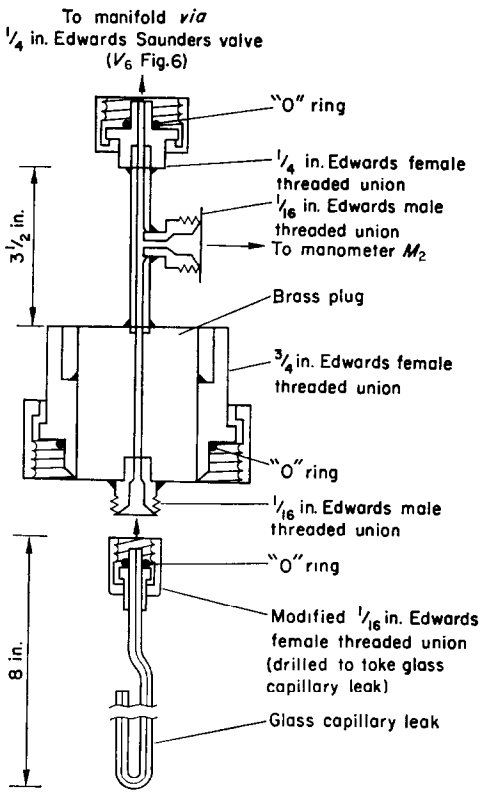

FIG. 8.—Section through the leak assembly.

Measurement of absolute pressure of the pure gas stream in the mixing chamber and differential pressure across the leak. Both these measurements were accomplished by using the manometers M_1 and M_2 shown in Fig. 6. The absolute pressure in the mixing chamber is given by the reading on M_1 plus the atmospheric pressure. The differential pressure is given by the reading on M_2 minus the reading on M_1. It was decided to operate the gas blending rig with an absolute pressure of 1000 torr in the mixing chamber, so as to ensure that an adequate pressure was available for the mass spectrometer dynamic sampling system, or any other detector which was to be calibrated.

Flow and pressure control of the pure gas stream. Control of the pure gas flow-rate (F) and pressure (P) was accomplished by manipulation of the two needle values V_4 and V_5 and the vacuum pressure controller V_3, Fig. 6. The pure gas flow-rate was measured with a Rotameter, 0·1–1 l/min, which was calibrated for each gas used by operating the blending rig at the selected mixing chamber pressure of 1000 torr and measuring the flow of gas at atmospheric pressure by a soap-bubble flowmeter, and converting this flow-rate into a flow-rate at 1000 torr.

The Rotameter was inserted in the apparatus at a point before the mixing chamber so that variations in atmospheric pressure did not have to be taken into account, since the absolute pressure in the mixing chamber is constant, and controlled at 1000 torr.

The complete apparatus was assembled in a perspex box filled with a colourless mineral oil which completely covered the mixing chamber, ballast chamber, and almost all of the impurity reservoir.

Calibration and operation of the dynamic gas blending rig

The volume* contained between V_6 (Fig. 6), the manometer M_2 and the leak assembly was raised in pressure to 1600 torr absolute, with the test gas *via* V_6. With V_6 closed, and the mixing chamber

* This volume (approximately 7 ml) is kept as small as is practically possible, so as to speed up the calibration procedure. It must be measured accurately, and corrections should be made for the change in volume which occurs due to the mercury rising in the arm of M_2 as the pressure falls during calibration.

pressure maintained at 1000 torr, the differential pressure (ΔP) across the leak was noted at time intervals of 5–10 min, down to a ΔP of 50 torr.

A plot of $d(\Delta PV)/1000\,dt$ against ΔP, where t is the time, will then show the variation of flow-rate (at 1000 torr) through the leak as ΔP is varied. Hence by noting ΔP across the leak, and the pure gas flow-rate through the mixing chamber, the compositions of the blend can be readily calculated.

The term $d(\Delta PV)/dt$ can be obtained from a plot of ΔPV against t by determining the gradient at different values of ΔP, or by calculating it as follows:

If ΔP_1V_1 = the product of differential pressure and volume at time t_1

and ΔP_2V_2 = the product of differential pressure and volume at time t_2

Then $\dfrac{d(\Delta PV)}{dt}$ at pressure ΔP is given by $\dfrac{(\Delta P_1V_1) - (\Delta P_2V_2)}{(t_1 - t_2)}$

where $\Delta P = \dfrac{\Delta P_1 + \Delta P_2}{2}$.

The latter method is recommended since it eliminates any personal error associated with choosing a gradient at a point, and is reasonably accurate providing the time intervals are relatively small, and the differential pressures are carefully measured. This procedure is repeated for each impurity gas which is required for blending purposes.

When the gas blending rig is in use, V_6 and V_8 (Fig. 6) are opened so that the reservoir R supplies the leak, hence maintaining an essentially constant ΔP across the leak and therefore a constant blend. This is required, of course, when calibrating the mass spectrometer or any other detector.

Performance of the gas blending rig

The precision attainable with the gas blending rig was determined by preparing blends of argon in hydrogen at the 13 vpm level. The blends were prepared with a wide range of differential pressures and pure gas flow-rates, adjusted so that the argon ion beam recorded by the mass spectrometer was kept constant. The blends were then calculated, and the results are shown in Table VI.

TABLE VI.—PRECISION OF THE GAS BLENDING RIG

Indicated flow-rate of hydrogen, *l/min*	Actual flow-rate of hydrogen, *l/min*	ΔP, *torr*	Argon flow-rate, *μl/min*	Argon, *vpm*

			Mean	13·2
			Std. deviation	0·27

To investigate the accuracy of the analysis system (*i.e.*, the dynamic gas blending rig and the mass spectrometer), two high pressure gas blends of impurities in helium (X and Y) were prepared and stored in cylinders at approximately 1000 psig. Both blends were analysed with a mass spectrometer which had previously been calibrated with the dynamic gas blending rig. These results are shown in Table VII.

Blend Y was also analysed at the Research Laboratories of the British Oxygen Company. Table VIII shows the comparison between their results and ours, together with the methods that were used for each determination.

The instruments (B.O.C.) were calibrated with Wosthoff metering pumps except for the Elcoflux oxygen analyser which has a built-in electrolytic calibration unit.

Gas recirculation system

In order to conserve supplies of helium when calibrating the mass spectrometer, a recirculating system (Fig. 9) was used. The purified gas was passed through the blending rig where it picked up a known amount of impurity. This blend was analysed by the mass spectrometer and was then returned

TABLE VII.—COMPARISON OF CYLINDER BLENDS WITH MASS SPECTROMETRIC ANALYSES

Blend	Impurity	Calculated composition of blend, *vpm*	Mass spectrometric results, *vpm*
X	H_2	24·3	27·5
	$N_2 + CO$	138	138
	O_2*	12·5	13·6
	Ar	25·0	24·4
	$CO_2 + N_2O$	13·0	13·8
Y	H_2	12·4	11·7
	$N_2 + CO$	22·6	23·0
	O_2*	5·7	5·4
	Ar	—	0·2
	CO_2	8·2	9·3

* The oxygen contents of the two blends, determined with a Hersch Oxygen Meter, were *X*, 14·4 vpm; *Y*, 5·9 vpm.

to the purification unit *via* a recirculating pump. An Edwards oil-filled rotary pump (Type 1SC 50.B) and a Genevac vacuum-compressor pump (Type RPC.2) were both used successfully as recirculating pumps, the latter being more satisfactory because of its small size.

Applications of the Dynamic Sampling System, Dynamic Gas Blending Rig, and Gas Recirculation System

Apart from the analysis of high-purity helium and hydrogen already described, the mass spectrometer, fitted with the dynamic sampling system, has been used as a detector for a gas chromatograph. For example, by using a column packed with Linde molecular sieve type 5A at approx 50°C and feeding the helium carrier gas to the mass spectrometer (tuned at maximum sensitivity on the $m/e = 28$ ion beam), it was possible to detect 0·5 vpm of CO in a 10-ml sample of hydrogen, and to determine CO in hydrogen at the 5 vpm level with a standard deviation of 0·2 vpm. It has also been used for investigations into the determination of hydrocarbons in helium at the 5 vpm level by oxidation to CO_2, where continuous monitoring of reaction products was necessary.

The dynamic gas blending rig has been used for the calibration of mass spectrometers, catharometer detectors and gas chromatographs, and also for studying the characteristics of a helium ionization detector.[3] It has also been used successfully for the preparation of certain gas mixtures at the 0·1 vpm level, by diluting the required impurity with another gas of approximately the same molecular weight and viscosity (hence minimizing any fractionation effects) and feeding this binary mixture through the calibrated leak. Examples are N_2O and CO_2 mixtures for preparing blends of N_2O in hydrogen, and CO and N_2 mixtures for preparing blends of CO in helium and hydrogen.

Gas recirculation systems have been used to conserve supplies of purified helium on gas chromatographs, the carrier being exhausted to atmosphere only when samples were being analysed. This has resulted in the use of about 1/7 of the amount of high-purity helium that would have been needed for a system permanently exhausted to atmosphere.

Acknowledgement—I would like to acknowledge the co-operation of Mr. J. H. Scawin (Operational Services Dept.,) and Mr. J. Pennington (Rare Gas Dept.,) both of the British Oxygen Company Ltd., who agreed to carry out the analysis of one of the cylinder blends, and who also gave permission for the results to be included in this report.

Zusammenfassung—Ein dynamisches Gaseinlaßsystem für ein Massenspektrometer (A.E.I. Modell MS2G) wurde entworfen. Es kann Proben direkt aus Gasströmen bei Drucken um 800 Torr entnehmen und wurde mit Erfolg bei der Analyse von hochreinem Helium und Wasserstoff mit weniger als 50 vpm (1 vpm = Volumenanteil 10^{-6}) gesamter Verunreinigung benutzt. Die Empfindlichkeit ist 1 vpm oder besser. Das System ist so augselegt, daß das Massenspektrometer bei Bedarf mit seinem normalen Gaseinlaßsystem benutzt werden kann. Zur Eichung des Massenspektrometers im Bereich 5–100 vpm Verunreinigung wirde eine dynamsiche Gasmischbatterie entwickelt, die ein Umlauf- und Reinigungssystem enthält.

Résumé—On a conçu un système d'échantillonnage de gaz dynamiques pour utilisation avec un spectromètre de masse (A.E.I. Modèle MS2G). Il est capable d'échantillonner directement à partir de courants gazeux à des pressions situées dans la zone de 800 torr et a été utilisé de façon satisfaisante pour l'analyse d'hélium de haute pureté et d'hydrogène

contenant moins de 50 p.p.m. (v/v) d'impuretés totales. La sensibilité globale est égale à 1 p.p.m. (v/v) ou meilleure. Cet appareillage permet l'emploi du spectromètre de masse avec son système d'échantillonnage de gaz normal si nécessaire. Une installation de mélange de gaz dynamiques, comprenant un système de recirculation et de purification, a été élaborée pour l'étalonnage du spectromètre de masse dans le domaine de 5–100 p.p.m. (v/v) de teneur en impuretés.

RADIOACTIVE SUBSTOICHIOMETRIC ISOTOPE-DILUTION PROCEDURE FOR THE DETERMINATION OF RARE EARTH METALS

G. B. BRISCOE and A. DODSON
Department of Chemistry, The University of Aston in Birmingham, Birmingham 4, England

(*Received* 1 *March* 1967. *Accepted* 5 *May* 1967)

Summary—A theory is developed which describes the equilibrium conditions when solutions containing trace metals and substoichiometric amounts of EDTA are extracted with thenoyltrifluoroacetone. Experimental evidence is given to support the theory. A method for the determination of microgram quantities of rare earth metal is outlined as an application.

ANALYSIS for trace quantities of metals, by activation analysis or radioactive isotope-dilution analysis, can be simplified by using the technique of substoichiometry. Equal quantities of metal are removed from the active standard and treated sample solutions by a known amount of complexing agent which is insufficient to react with all the metal present. The separated fractions are then compared. In this way, the need for chemical yield determination is avoided, and selectivity improved.[1]

Most substoichiometry has been performed by solvent extraction with strong chelating agents. Extraction of ion-association complexes has been used[2,3] and also the reaction with EDTA, followed by removal of excess of metal by ion-exchange.[4,5,6]

Of these methods, the first is the most straightforward. The last, EDTA reaction, can become very involved when applied to the general case. Unlike the solvent extraction method, optimum conditions have to be calculated for two reactions, the complexation and the exchange of excess of metal with the resin. In the first case, all the EDTA present must react, and in the second, no EDTA complex must be involved in the exchange. The choice of pH, and the nature and strength of the buffer for the first reaction, all have a marked effect on the ion-exchange. For example, acetate buffers, commonly used for EDTA reactions, themselves complex many metals sufficiently to prevent efficient exchange, unless they are very dilute. At large dilutions the ionic strength of the solution is a critical factor.

In this paper, the simpler case is dealt with, in which the excess of metal is removed by solvent extraction, using a weaker complexing agent than EDTA.

The system containing rare earth, EDTA, and thenoyltrifluoroacetone was studied. A possible method for the determination of microgram quantities of rare earth after separation by ion-exchange was developed.

THEORY

There are two reactions to consider.

1. Rare earth (M) plus thenoyltrifluoroacetone (HA).
2. Rare earth (M) plus EDTA (Y).

$$M + 3HA_{org} \rightarrow (MA_3)_{org} + 3H \quad (1)$$

$$M + Y \rightarrow MY \quad (2)$$

The subscript "org" indicates solution in an organic solvent immiscible with water. Electrical charges are omitted for simplicity.

The following theory makes use of the idea of conditional equilibrium constants, in a similar way to the work of Schwarzenbach and Ringbom.[7] This means that the equilibrium concentration [X] of any species, is replaced by the total amount present in any form [X']. The equation must be modified by a so-called α coefficient given by

$$\alpha = \frac{[X']}{[X]}. \tag{3}$$

Equilibrium constants calculated in this way are not really constant, but depend on the conditions used: hence the name conditional constant.

The extraction constant from equation (1) is

$$K_1 = \frac{[MA_3]_{org}[H]^3}{[M][HA]^3_{org}}. \tag{4}$$

The stability constant from equation (2) is

$$K_2 = \frac{[MY]}{[M][Y]}. \tag{5}$$

Instead of K_2 we use K_3, the conditional constant:

$$K_3 = \frac{[MY]}{[M][Y']} \tag{6}$$

where [Y'] is the total equilibrium concentration of EDTA in all its forms, *i.e.*, $[Y'] = [H_4Y] + [H_3Y] + [H_2Y] + [HY] + [Y]$ (again with charges omitted).

Then

$$\frac{[Y']}{[Y]} = \alpha_Y$$

and

$$K_2 = \frac{[MY]\alpha_Y}{[M][Y']}. \tag{7}$$

By combining equations (4) and (7):

$$K_4 = \frac{K_1}{K_2} = \frac{[MA_3]_{org}[H]^3[Y']}{[MY][HA]^3_{org}\alpha_Y}. \tag{8}$$

Assuming that a reaction equilibrium is reached, let us take the case where half of the metal present is complexed to form MY, *i.e.*, 50% stoichiometry; HA removes the remainder, which becomes transferred to the organic phase. It must be remembered that this paper follows the terminology of previous authors, *i.e.*, x% stoichiometry or substoichiometry refers to the relative amounts of the reacting species, that is the degree to which one is equivalent to the other. The actual reaction is assumed to be stoichiometric.

Under these conditions, and when the volumes of both phases are equal,

$$[MY] = [MA_3]_{org}$$

and equation (8) simplifies to:

$$K_4 = \frac{[H]^3[Y']}{[HA]_{org}^3 \alpha_Y}. \tag{9}$$

$[HA]_{org}$ is not a simple term, for two reasons. First HA dissociates, $HA \rightleftharpoons H + A$, the constant for the reaction being

$$K_{diss} = \frac{[H][A]}{[HA]}, \tag{10}$$

and secondly, HA is not entirely in the organic phase. The partition is described by:

$$P_{HA} = \frac{[HA]_{org}}{[HA]}. \tag{11}$$

Dividing equation (10) by equation (11):

$$\frac{K_{diss}}{P_{HA}} = \frac{[H][A]}{[HA]_{org}}. \tag{12}$$

Let us call the sum of the concentrations of all the forms of HA present, [HA']. In the case already mentioned, where the phases have equal volumes, [HA'] is in fact the concentration added in the organic phase at the start of the reaction, providing there is no association or polymerization in either phase.

Then

$$[HA'] = [HA]_{org} + [HA] + [A]$$

or

$$\frac{[HA']}{[HA]_{org}} = 1 + \frac{[HA]}{[HA]_{org}} + \frac{[A]}{[HA]_{org}} \tag{13}$$

and we can call this α_A:

$$\alpha_A = 1 + \frac{1}{P_{HA}} + \frac{K_{diss}}{P_{HA}[H]}. \tag{14}$$

From a knowledge of the partition coefficient and the dissociation constants, α_A can be calculated. The result is conveniently shown in graphical form in Fig. 1.

Equation 9 becomes

$$K_4 = \frac{[H]^3[Y']\alpha_A{}^3}{[HA']^3\alpha_Y}. \tag{15}$$

An essential condition of substoichiometry is that all the reagent must be consumed by the metal. As a practical condition, this is taken to be true if $[Y'] < 0{\cdot}001\ C_{HY}$, where C_{HY} is the concentration of EDTA that would be present if no reaction had taken place.

Thus

$$K_4 = \frac{[H]^3 \,.\, 10^{-3} C_{HY} \alpha_A{}^3}{[HA']^3 \alpha_Y}. \tag{16}$$

From this equation can be calculated a value of [HA'] for a particular EDTA reaction. It represents the maximum concentration of HA which may be used to remove free metal from a solution in which a substoichiometric reaction with EDTA

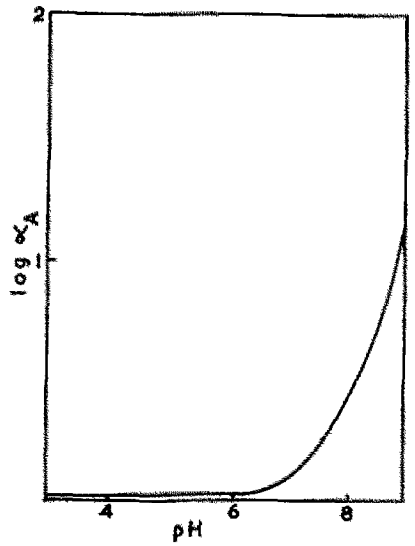

Fig. 1.—Variation of the conditional constant for thenoyltrifluoroacetone with pH.

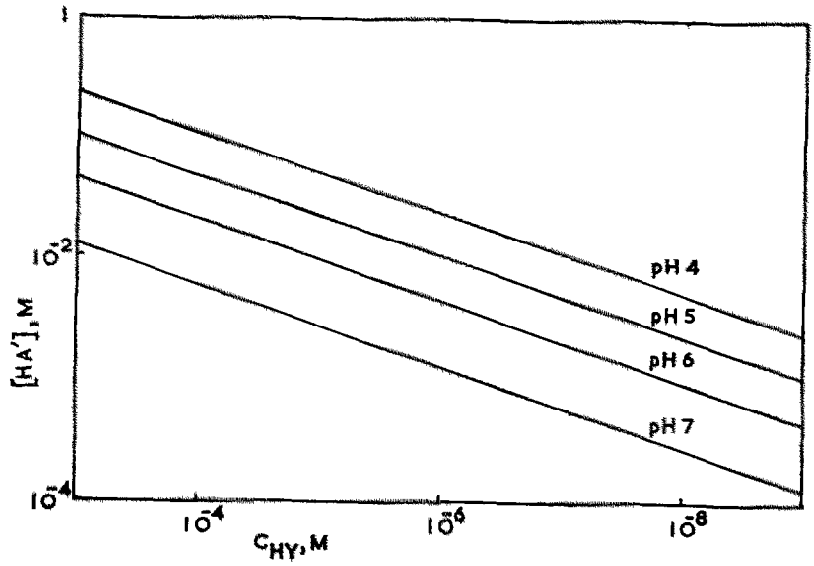

Fig. 2.—Influence of hydrogen-ion concentration on the maximum concentration of thenoyltrifluoroacetone which may be used to remove free metal from a metal–EDTA complex. Calculated for terbium.

is taking place, without breaking down more than 0·1% of the EDTA complex. A further condition is that $[HA'] \gg [MA_3]$ so that the change of concentration on reaction is negligible. This will be true for a weak complexing agent. Figure 2 shows how this value of [HA'] varies with pH for fixed concentrations of C_{HY}. The values given are calculated for terbium. Figure 3 shows how this graph is affected, at any one EDTA concentration, by the choice of metal. Like many other rare earth properties, the equilibrium constants for both these reactions, *i.e.*, K_1 and K_2, vary as the atomic

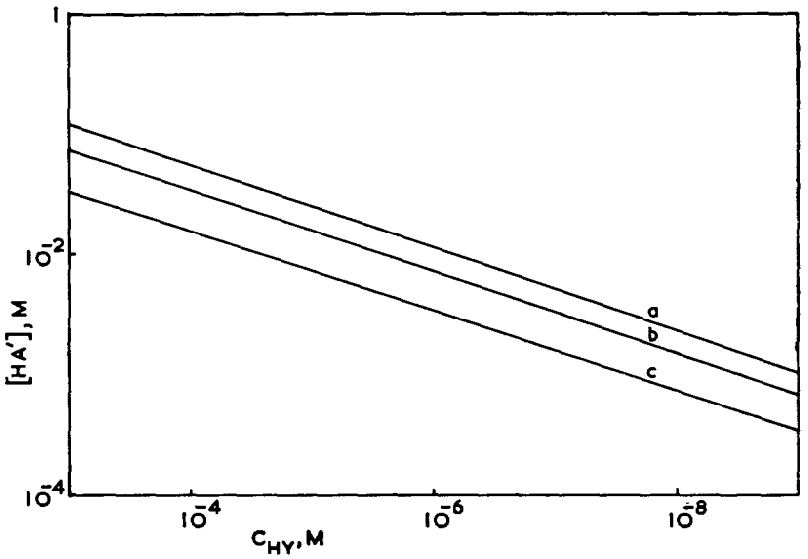

FIG. 3.—Influence of rare earth metal at a fixed pH on the maximum concentration of thenoyltrifluoroacetone which may be used to remove free metal from a metal-EDTA complex. *a*. Calculated for lutetium at pH 6. *b*. Calculated for lanthanum at pH 6. *c*. Calculated for gadolinium at pH 6.

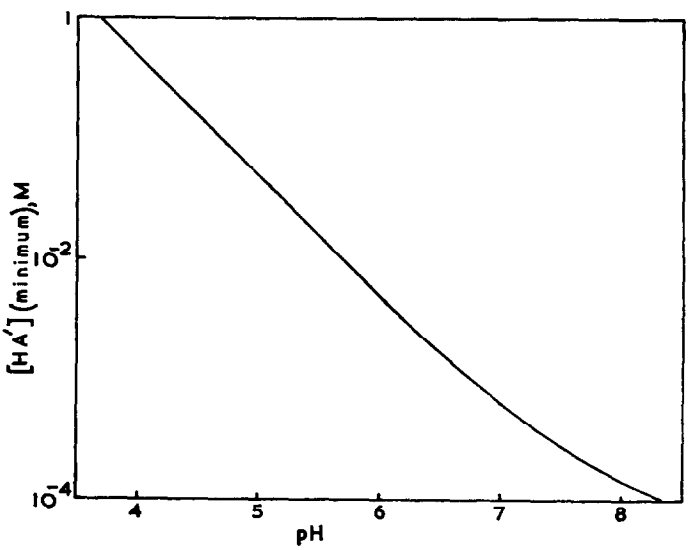

FIG. 4.—The minimum excess of thenoyltrifluoroacetone required for the extraction of rare earth metal at various pH values. Calculated for terbium.

number increases. The trends are different in each case, resulting in a maximum value of K_4 at gadolinium, in the middle of the series.

The minimum excess of HA required can be determined from equation (4), and the case of terbium is again illustrated in Fig. 4. Extraction is assumed to be complete when $[MA]_3/[M] = 1000$.

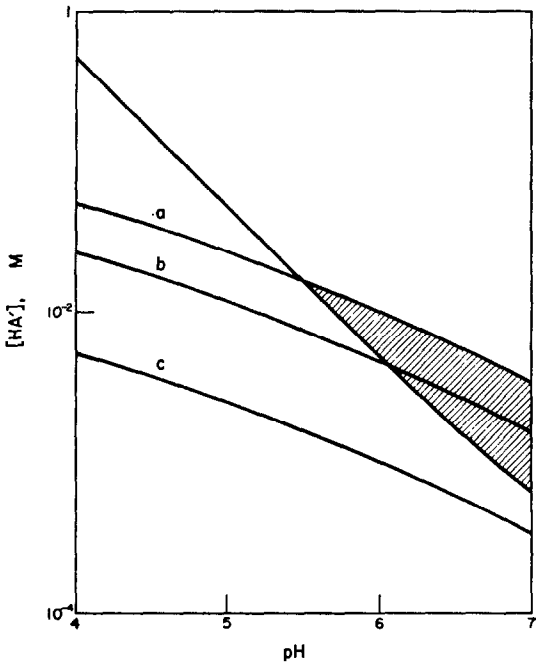

FIG. 5.—The working range of thenoyltrifluoroacetone concentration for removal of excess metal from metal–EDTA complex. *a*. $C_{HY} = 10^{-5}M$ *b*. $C_{HY} = 10^{-6}M$ *c*. $C_{HY} = 10^{-8}M$. All calculated for terbium. The working range is shaded.

If the information contained in Fig. 2 is superimposed on Fig. 4 the result is a graph which gives the working range of HA concentration, for any pH, which can be used to remove excess of metal from a solution in which substoichiometry has been performed with EDTA, without affecting the EDTA complex (Fig. 5).

Two very important assumptions have been made and require investigation. At high dilutions the metal being determined must react with HA according to equation (4). Equation (8), being the basis of further calculations, must be verified.

These experiments present no difficulty. If a dilute solution of rare earth metal is extracted with a solution of thenoyltrifluoroacetone, stoichiometrically in large excess, but still too dilute to extract all the metal, the logarithmic plot of q = [metal in org. phase]/[metal in aqueous phase] *vs.* [HA'] should be linear and have a slope of +3. This was found to be the case. The correct value of K_1 at this dilution is also determinable from the intercept.

Verification of equation (8) can be achieved in a similar way. Consider the case where all the EDTA present is just sufficient to complex all the metal, but the HA present in the organic phase is strong enough to partly decompose the EDTA complex.

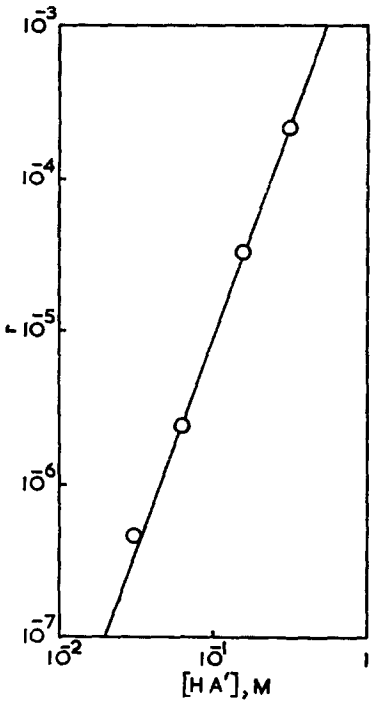

FIG. 6.—Experimental verification of equation (8).

$$r = \frac{[\text{metal in organic phase}]^3}{[\text{metal in aqueous phase}]}.$$

Any MA_3 (or free EDTA) present can be assumed to come from the decomposition of MY. Hence $[MA_3] = [Y']$.

Thus, introducing the α_A term into equation (8) and rearranging

$$\frac{K_4\alpha_Y}{[H]^3\alpha_A{}^3} = \frac{[MA_3]^2_{org}}{[MY][HA']^3}. \tag{17}$$

That is, a logarithmic plot of $r = [\text{metal in org. phase}]^2/[\text{metal in aqueous phase}]$ *vs.* [HA'] should be linear and of slope +3, having an intercept of $K_4\alpha_Y/[H]^3\alpha_A$. This was also found to be true (Fig. 6).

It was also observed that the reaction between HA and free metal came to equilibrium many times faster than the decomposition of metal–EDTA complex by HA. This is itself an important factor when considering the development of an analytical method.

EXPERIMENTAL

Reagents

Buffer solution. The choice of buffer, which must be suitable for both the EDTA reaction and the extraction, was a little difficult. The one finally used was 1*M* hexamine, adjusted to the required pH with nitric acid. Only laboratory-reagent grade hexamine was available and it was thought that further trouble might arise from metallic impurities in it. In the simplest case these would give rise to a large reagent blank, although much more complicated interferences can be envisaged. These interferences did not occur, at least not at the concentrations used in the experiments. At very large dilutions there are several other factors which may cause difficulty. These are outlined below.

All other reagents were of analytical-reagent grade purity.

Rare earth solutions were prepared by dissolving the oxide or the nitrate in nitric acid or water respectively. Whenever possible, relatively concentrated solutions were made and standardized against EDTA, before being diluted to the required trace concentration.

Water was twice distilled from glass. Tracer and isotope-dilution experiments were carried out with ^{141}Ce, ^{160}Tb and ^{170}Tm.

Apparatus

The detector used was a 1·75 in. × 2 in. NaI(Tl) well-type crystal: well-volume 5 ml. This was associated with a single channel gamma-ray spectrometer. Discriminator settings were used to give the highest possible counting efficiencies.

Verification of equations (4) *and* (8)

Equation (4). A series of labelled terbium test solutions was prepared by diluting 1 ml of a $10^{-5}M$ stock solution with 9 ml of hexamine buffer at pH 6. Each test solution was extracted with 10 ml of a xylene solution of thenoyltrifluoroacetone of concentrations varying from $10^{-4}M$ to $10^{-3}M$, until equilibrium was reached. The activity of 5 ml of both aqueous and organic phases was measured and the final pH noted. The results gave a slope of 2·9. This corresponds to a value of K_1 of $10^{-8.25}$. An assumed slope of 3·0 gives a K_1 value of $10^{-8.1}$ for all but very low q values.

Equation (8). A stock solution of rare earth plus EDTA was prepared by mixing 25 ml of a $10^{-3}M$ labelled terbium solution with an equivalent amount of EDTA solution, neutralizing to pH 4·5 and making up to 50 ml. For the purpose of this experiment it was assumed that this solution was a pure solution of terbium–EDTA complex. A number of test samples were prepared by diluting 5 ml of this stock solution with 5 ml of hexamine buffer at pH 6. Each test sample was extracted with 10 ml of a xylene solution of thenoyltrifluoroacetone of concentrations varying from $3 \times 10^{-2}M$ to $3 \times 10^{-1}M$, until equilibrium was reached. The activity of 5 ml of both aqueous and organic phases was measured and compared with the activity of 5 ml of the stock solution. Hence the exact amount of metal in both aqueous and organic phases was determined. The results, plotted in Fig. 6, show a slope of 2·8. This corresponds to a value of K_4 of 10^{-25}. This is in good agreement with a value of $10^{-24.8}$ calculated from available literature values of $K_1 = 10^{-6.9}$ at $2 \times 10^{-1}M$ thenyoltrifluoroacetone concentration,[8] and $K_2 = 10^{17.9}$ for the terbium–EDTA complex.[7]

Time to reach extraction equilibrium

As has been reported,[8] the rare earth metal was found to be extracted by the thenoyltrifluoroacetone very quickly. It was completely removed from the hexamine buffer at pH 6 in less than 30 sec. Similarly, after addition of a substoichiometric amount of EDTA to a rare earth metal solution the excess of metal was removed in just over 60 sec. The destruction of the metal-EDTA complex by the thenoyltrifluoroacetone took much longer to complete although equilibrium was virtually reached in a little over 60 min. For the verification experiments an extraction time of 2 hr was used.

Reproducibility

A series of test solutions was prepared by diluting 0·5–5 ml portions of a $10^{-4}M$ labelled terbium solution to 10 ml with hexamine buffer at pH 6. To each was added 1 ml of $10^{-4}M$ EDTA, this being insufficient to react with all of the metal in the more concentrated solutions. The excess of metal was extracted by adding 10 ml of $10^{-2}M$ thenyoltrifluoroacetone in xylene and shaking for 5 min. The resulting aqueous phase was filtered and a 5 ml aliquot counted. A typical plot of activity against concentration of terbium solution is shown in Fig. 7.

The sloping section of this curve indicates that the EDTA is successfully retaining the metal. Further, no metal–EDTA complex is being broken down, for if this were the case the extrapolation of this part of the curve would not rise to the equivalence point X. The flat plateau shows that when the metal is in excess a constant amount is retained in the aqueous phase. A good reproducibility curve, determined at similar concentrations to a solution to be analysed by a method based upon it, means that the analysis must be successful and give an answer correct within experimental error.

Non-reproducible conditions (*Fig.* 7). Some attempts to produce reproducibility curves show divergences from the type of curve illustrated and can be the result of one or all of three conditions:

(*i*) As the concentration of metal in the test solution decreases to the order of $10^{-6}M$ the working range of extractant concentrations becomes very small at practical pH values. The required equilibrium condition becomes increasingly difficult and finally impossible to achieve. For work at this level the K_4 values should be accurately determined under the test conditions before the range of extractant concentrations is calculated. In the rare earth series, the end members have the lowest K_4 values, and therefore the central members, are most affected.

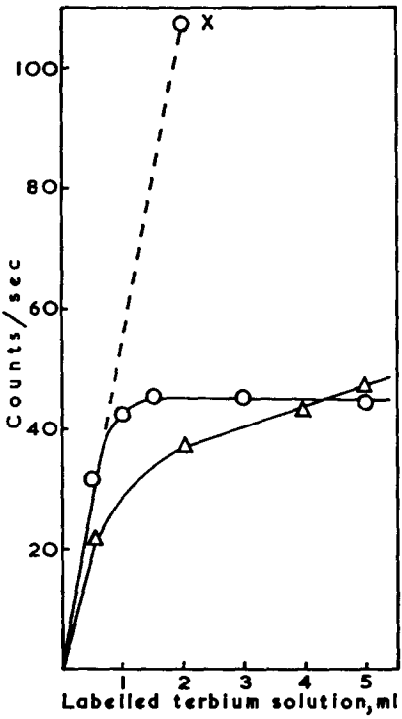

FIG. 7.—Reproducibility of extraction.
○—Reproducibility of the substoichiometric extraction of terbium in presence of EDTA.
△—Non-reproducible substoichiometric extraction of terbium in presence of EDTA.

(*ii*) The EDTA is not at all selective and foreign metal ions present in concentrations of say $10^{-7}M$ might interfere by upsetting the equilibrium. To overcome this a preliminary extraction could be used.[6]

(*iii*) The EDTA reaction may fail to reach equilibrium. We feel, however, that it is inadvisable to heat the reagents to bring the reaction to equilibrium as loss by adsorption and/or hydrolysis would give rise to even further complications. The difficulties can be partly resolved by careful choice of the degree of substoichiometry, since the value of C_{HY} [concentration of EDTA, equation (16)] rather than metal ion concentration affects the working range.

Analysis of test samples

As examples of how the technique can be used as an analytical method, a number of rare earth solutions of known concentration were analyzed by isotope dilution.

The solutions used were terbium solution labelled with ^{160}Tb, and ytterbium solution labelled with ^{170}Tm. The latter solution was readily available in our laboratory whereas radioactive isotopes of ytterbium or pure inactive thulium was not. For thulium and ytterbium the ratio of K_1/K_2 is very similar ($10^{25\cdot6}$).

To each of a number of separating funnels were added 5 ml portions of $1M$ hexamine/hexamine nitrate buffer (pH 6·0). To each were added 2 ml of a standard labelled solution, comparable in concentration to the sample. Then 2 ml of sample were transferred by pipette into some of the funnels (samples), and 2 ml of water into the rest (standards). A substoichiometric amount of EDTA (2 ml of $10^{-4}M$ EDTA for ytterbium and 1 ml of $10^{-4}M$ EDTA for terbium) was added to all the funnels, and unreacted metal was removed by shaking for 5 min with a suitable concentration of thenoyltrifluoroacetone in xylene. (The concentration is indicated by the theory and in these experiments was $10^{-2}M$.) The aqueous phases were separated and filtered, and the activity of an aliquot was measured. The amount of metal in the samples was calculated by using the substoichiometric formula

applied to isotope dilution:[1]

$$x_{\text{sample}} = x_{\text{standard}} \left(\frac{\text{activity of standard}}{\text{activity of sample}} - 1 \right)$$

where x = weight of metal. The results are shown in Table I.

TABLE I

Ytterbium			Terbium		
Taken, $\mu g/ml$	Found, $\mu g/ml$	Standard deviation, $\mu g/ml$	Taken, $\mu g/ml$	Found, $\mu g/ml$	Standard deviation, $\mu g/ml$
38·14	37·85	0·51	17·10	16·82	0·55
	38·77			17·75	
	38·46			17·42	
	38·81			17·52	
	37·85			16·87	
	38·46			16·26	
	37·33				
	37·96				
	38·66				

It must be remembered that the accuracy of the method depends on the precision of the sub-stoichiometric extraction procedure for both standard and sample. Thus the standard activity must be accurately known and should be determined as many times as possible in each set of analyses.

Acknowledgements—The authors wish to thank Mr. B. G. Cooksey for helpful discussions and the Science Research Council for provision of a research studentship (A. D.) which enabled the work reported to be carried out.

Zusammenfassung—Es wird eine Theorie entwickelt, die die Gleichgewichtsbedingungen beschreibt, wenn Lösungen, die Spurenmetalle und unterstöchiometrische Mengen EDTA enthalten, mit Thenoyltrifluoraceton extrahiert werden. Zur Stützung der Theorie werden experimentelle Ergebnisse mitgeteilt. Als Anwendung wird eine Methode zur Bestimmung von Mikrogrammengen seltener Erdmetalle skizziert.

Résumé—On développe une théorie qui décrit les conditions d'équilibre lorsqu'on extrait des solutions contenant des traces de métaux et des quantités substoechiométriques d'EDTA au moyen de thénoyltrifluoracétone. On donne des preuves expérimentales à l'appui de la théorie. A titre d'application, on donne un aperçu d'une méthode pour le dosage de métaux des terres rares en quantités de l'ordre du microgramme.

PURITY CONTROL OF URANIUM BY NEUTRON ACTIVATION ASSAY—II*

DETERMINATION OF MANGANESE, NICKEL AND COPPER

A. A. ABDEL-RASSOUL and S. S. WAHBA
Nuclear Chemistry Department, Atomic Energy Establishment, Cairo, U.A.R.

(*Received* 18 *October* 1966. *Accepted* 28 *February* 1967)

Summary—Activation analysis is applied for the simultaneous determination of manganese, nickel and copper in different uranium samples, including metallic uranium, uranium concentrates, oxide, acetate, nitrate and sodium uranate. The analytical scheme developed is based on separation of the uranium by paper chromatography and subsequent determination of these elements in the pile-irradiated residues by simple radiochemical operations. The reliability of the scheme proposed is tested, and the limits of sensitivity of the methods worked out are ascertained. Accordingly, microgram concentrations of the elements studied could be assayed in limited quantities of the samples analysed with a precision of ±15%. Reagent-blank determinations are also considered.

NEUTRON-ACTIVATION analysis has been recently used to assay a number of trace impurities in uranium metal, concentrates and other uranium compounds of different purity grades.[1–4] This technique, however, has not commonly been used for uranium analysis, owing to the high level of radioactivity caused by fission-product radionuclides and ^{239}Np formed in irradiated samples, compared to that induced from the impurities.

The possible methods for determination of foreign elements in uranium by nuclear activation are: (*i*) activation of uranium followed by efficient decontamination and identification of the radionuclides formed,[1,2] (*ii*) the separation of the impurities from uranium and their subsequent determination by classical radiochemical methods,[3] (*iii*) the separation of uranium from its impurities and their subsequent determination radiochemically without the use of several successive decontamination cycles.[4] Each method has its limitations.

In a previous paper, it was initially planned to assay the elements of atomic number 24–30 in different uranium-containing samples.[1] A scheme was developed for simultaneous determination of chromium, iron, cobalt and zinc, based on activation of uranium and radiometric assay of ^{51}Cr, ^{59}Fe, ^{60}Co and ^{65}Zn by γ-scintillation spectrometry. However, because of the comparatively short half-lives of the radioisotopes ^{56}Mn, ^{65}Ni and ^{64}Cu, the determination of manganese, nickel and copper could not be achieved by the same scheme (*cf.* Table 1). In the present paper, analytical methods are worked out for the determination of these elements simultaneously after the separation of uranium before activation.

EXPERIMENTAL

Chemicals and samples analysed

The uranium samples analysed include: (*i*) two uranium concentrates, SP-1 and SP-2, each containing about 75% of triuranium octaoxide, both provided by "Junta de Energia Nuclear, Spain"; (*ii*) a uranium trioxide sample, H-632 from "Akteibolaget Atomenergie, Sweden"; (*iii*) a sample of metallic uranium foil, 0·16 mm thick, from USSR; (*iv*) a uranyl acetate sample from Fisher Scientific

* Part I—*Talanta*, 1966, **13**, 381.

Company, New York, with certified analysis for laboratory use; (*v*) a uranyl nitrate sample of not less than 99% purity, from May & Baker Ltd., England, and (*vi*) a sample of sodium uranate of technical purity grade, from Carlo and Erba Company, Italy.

Standards, carriers, hold-back carriers, scavengers and all other chemicals used are of analytical reagent grade.

Preparation of samples and standards

Uranium is first separated by paper chromatography.[5] Suitable weights of the samples to be analysed (250 mg) are dissolved in 5 ml of nitric acid solution (1 + 1) and the excess of acid is carefully evaporated. The residual concentrate is brought to a known volume and aliquots (200–500 μl containing about 50 mg of the sample concerned) are spotted on a strip of chromatographic paper (5 × 30 cm) and dried.

For separation of uranium, the chromatograms are developed with an acid mixture of diethyl ether and concentrated nitric acid (95:5) in an atmosphere previously equilibrated with the vapours of this mixture.[5] Uranium is completely separated in 5–7 hr, leaving the manganese, nickel and copper at the starting position. Each chromatogram is then dried and a 3-cm square with the start line in the middle is cut out and separately wrapped in thin aluminium foil and made ready for the pile irradiation.

Monitoring standards are made from suitable aliquots of standard solutions of manganese, nickel and copper in dilute nitric acid, by similar treatment. Blank chromatograms are run simultaneously under the same conditions.

Pile irradiations

Duplicate samples and standards and triplicate blanks are packed in a single irradiation can of standard type, and irradiated for 10–15 min with a mean flux 5×10^{11} n/cm^2/sec.

Processing of irradiated samples

For convenience, the shorter-lived manganese (^{56}Mn, $t_{1/2}$ 2·6 hr) and nickel (^{65}Ni, $t_{1/2}$ 2·6 hr) are separated and decontaminated before the copper (^{64}Cu, $t_{1/2}$ 12·8 hr). The squares of paper are removed from the aluminium foils and separately digested with concentrated nitric acid (5 ml) added in portions, and the solutions are carefully boiled to expel any volatile radioactive substances present. Carriers of manganese, nickel and copper (20 mg each) and hold-back carriers of iron, cobalt and zinc (5 mg each) are added to the clear solution. Nitrates are then destroyed by gradual addition of concentrated hydrochloric acid and boiling. The concentrated chloride solutions are made 1*M* in hydrochloric acid and the warm solution is treated with purified hydrogen sulphide, whereby copper sulphide is separated, and reserved for the determination of copper. The filtrate is freed from excess of hydrogen sulphide and made alkaline with filtered ammonia solution (1 + 1) and the precipitate is discarded.

The solution containing nickel, manganese and the other hold-back carriers is treated with ammonium sulphide solution and the sulphides separated are washed with warm dilute hydrochloric acid and are reserved for the nickel determination; manganese is determined in the solution.

Manganese

The solution containing manganese is made acidic with hydrochloric acid, iron carrier is added (5 mg of Fe) and the solution is made ammoniacal. The precipitate is discarded and the filtrate is acidified with concentrated nitric acid, treated with excess of fuming nitric acid (s.g. 1·42) together with a few crystals of potassium chlorate, and boiled. The hydrated manganese dioxide that separates is washed and then dissolved with a few drops of concentrated nitric acid and 30% hydrogen peroxide. Iron carrier is added to the clear solution and manganese is reprecipitated after removal of iron(III) hydroxide and made ready for activity measurement and chemical yield determination.

Nickel

The nickel and cobalt sulphides precipitated are dissolved in *aqua regia* (1 ml), and iron carrier is added (5 mg of Fe) and then precipitated as hydroxide with ammonia solution added in slight excess. The solution containing the nickel and cobalt is slightly acidified with acetic acid and then 2 ml of 1% alcoholic dimethylglyoxime solution are added. The nickel dimethylglyoximate is washed and then dissolved in concentrated hydrochloric acid and the solution is boiled. Iron carrier is added to the solution and the decontamination steps are repeated before final separation of nickel as the dimethylglyoximate.

Copper

The copper sulphide is dissolved in a minimum of boiling concentrated nitric acid. Iron carrier is added (5 mg), and the solution is made alkaline with excess of ammonia solution (1 + 1). The

precipitate is discarded and the filtrate is acidified with dilute hydrochloric acid and reduced with 10% sodium sulphite solution and the copper is then precipitated as copper(I) thiocyanate with 10% potassium thiocyanate solution. The precipitate is dissolved in concentrated nitric acid, and the copper thiocyanate is reprecipitated to free it from other activities, washed, dried, weighed and the ^{64}Cu activity is measured.

The blanks and standards treated in the same way as the samples.

Calibration

For testing the reliability of the successive operations aliquots from standard solutions of manganese, nickel and copper are spotted on paper chromatograms previously loaded with 20-mg portions of triuranium octaoxide (Johnson and Matthey "specpure") in dilute nitric acid solution. Uranium is of triuranium octaoxide (Johnson and Matthey specpure) in dilute nitric acid solution. Uranium is then separated as previously outlined and each of the elements added is assayed by the methods described. Reference standards and blanks are given the same activation as the test samples and are subsequently treated similarly. The chemical yield was never less than 50%.

Radiation measurements

In all cases, the sources separated from samples, standards and blanks are in the same chemical form. Activity measurements are generally carried out with a GM-counter (2–4 mg/cm^2 window thickness). Scintillation spectrometric measurements were also made with a 1·5 × 1 in. NaI(Tl) crystal photomultiplier assembly connected to a multi-channel pulse-height analyser.

RESULTS AND DISCUSSION

The nuclear characteristics of manganese, nickel and copper (*cf.* Table I) make their determination in uranium by classical radioactivation techniques impossible.

TABLE I.—NUCLEAR DATA

Atomic No.	Element	Abundance,* %	Cross-section, *barn*	Isotope formed	Half-life, *hr*	Principal radiations, *MeV*
25	Manganese	100	13·30	^{56}Mn	2·58	β^- 2·86, 1·05, 0.75 γ 0·85, 1·81

* The values tabulated are for the stable nuclides producing the corresponding radioisotopes by (n, γ) reactions.

Other methods based on separation of uranium have been applied recently.[3,4] Systems have been developed for removal of uranium on ion-exchangers and the assessment of impurities in the eluates.[3] The expected sources of error are contamination from reagents and ion-exchangers, incomplete recovery of the impurities in the eluates, and losses due to successive handling operations before activation. Uranium has been separated on cellulose, from a number of elements with an ethereal solution containing 5% v/v of nitric acid.[5] The alkali and alkaline earth metals, rare earths, Cu, Ag, Zn, Cd, Al, In, Tl, Ti, Hf, Ge, Sn, Y, Pb, Nb, Ta, Cr, W, Te, Mn, Fe, Co and Ni remain in the start position, or move only slightly. Mercury(II), selenium, arsenic, antimony and bismuth move, but less rapidly than uranium. Separation of uranium by paper chromatography was first used by Ördögh, Szabó and Hegedüs for the determination of metallic impurities in uranium.[4] Under our experimental conditions, a simple analytical scheme is developed for the simultaneous neutron-activation determination of manganese, nickel and copper after the uranium has been separated by paper chromatography. Preliminary tests proved that diethyl ether containing 5% of nitric acid is suitable for the complete removal of uranium unaccompanied by any of the elements studied.[4,5]

The radiochemical methods described for processing irradiated samples show that possible interference due to foreign radionuclides produced from traces of uranium retained by ion-exchange on the paper, is not important. In all cases, the radiochemical purity of the radioisotopes ^{56}Mn, ^{65}Ni and ^{64}Cu was checked by following their decay (*cf.* Figs. 2, 3 and 4) and by scintillation γ-ray spectrometry.

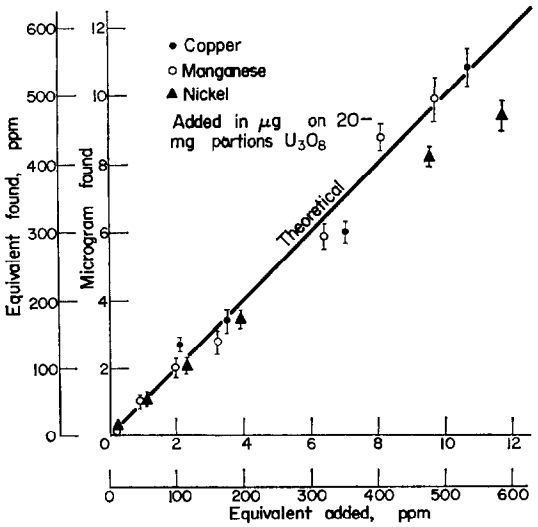

FIG. 1.—Reproducibility of neutron-activation assay.

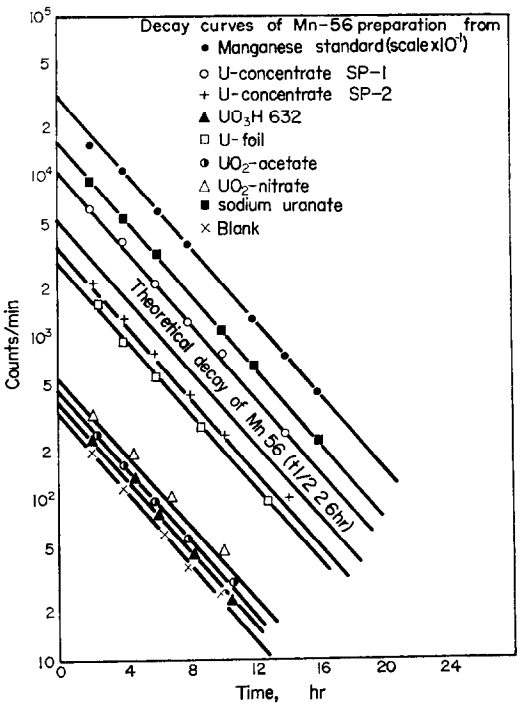

FIG. 2.—Decay curves of Mn-56.

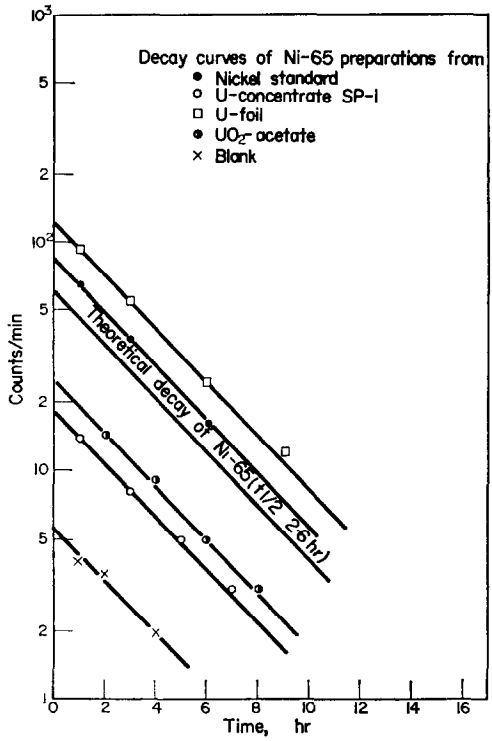

FIG. 3.—Decay curves of Ni-65.

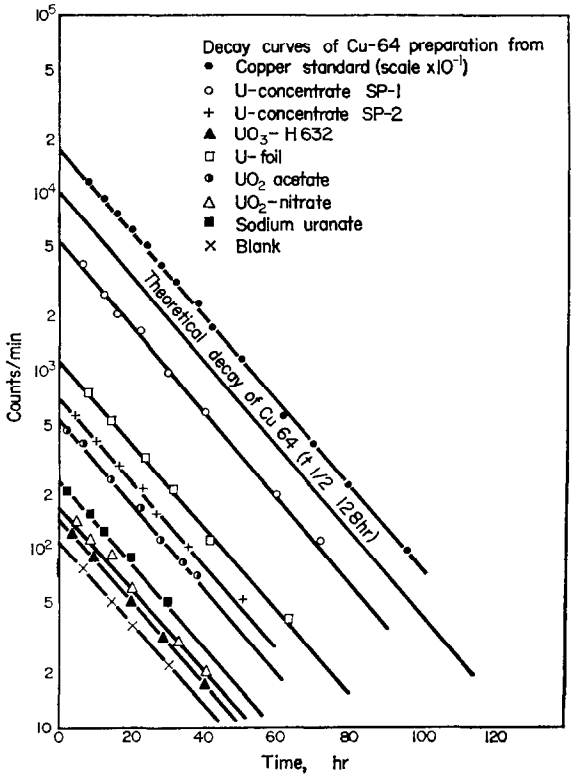

FIG. 4.—Decay curves of Cu-64.

The results of the determinations carried out are summarized in Table II. From the data reported in Table III (*cf.* Fig. 1), and from the irradiation conditions used it appears that microgram quantities of these elements can be assayed with a precision of $\pm 15\%$. The order of sensitivity attainable is that expected,[7] but it could be increased by longer irradiation at a slightly higher neutron flux.

† The first two results are excluded.

Interference due to nuclear reactions involving certain elements with atomic numbers close to those of manganese, nickel and copper was also studied, especially the formation of ^{56}Mn, ^{65}Ni and ^{64}Cu by (n, p) and/or (n, α) reactions on iron, cobalt, copper and zinc. However, nuclear data[8] for the effective cross-sections and threshold energies for these reactions show that under the irradiation conditions used possible interference should be negligible.

Zusammenfassung—Mangan, Nickel und Kupfer werden in verschiedenen Uranproben, metallischem Uran, Urankonzentraten, Oxid, Acetat, Nitrat und Natriumuranat gleichzeitig aktivierungsanalytisch bestimmt. Der analytische Vorgang beruht auf papierchromatographischer Abtrennung des Urans und nachfolgender Bestimmung der genannten Elemente in den im Reaktor bestrahlten Rückständen mit einfachen radiochemischen Operationen. Die Verläßlichkeit des vorgeschlagenen Verfahrens wird geprüft und die Empfindlichkeitsgrenzen der ausgearbeiteten Vorschriften festgestellt. Demnach ließen sich Mikrogrammengen der untersuchten Elemente in begrenzten Probemengen mit einer Genauigkeit von $\pm 15\%$ bestimmen. Auch Blindbestimmungen werden besprochen.

Résumé—On applique l'analyse par activation au dosage simultané du manganèse, du nickel et du cuivre dans différents échantillons d'uranium, y compris l'uranium métallique, les concentrés d'uranium, l'oxyde, l'acétate, le nitrate et l'uranate de sodium. Le schéma analytique est basé sur la séparation de l'uranium par chromatographie sur papier et dosage subséquent de ces éléments dans les résidus irradiés à la pile par de simples opérations radiochimiques. On a essayé l'exactitude de schéma proposé, et fixe les limites de sensibilité des méthodes élaborées. En conséquence, des concentrations à l'échelle du microgramme des éléments étudiés ont pu être déterminées dans des quantités limitées des échantillons analysés avec une précision de $\pm 15\%$. On considére aussi les déterminations du témoin des réactifs.

CATION-EXCHANGE BEHAVIOUR OF SEVERAL ELEMENTS IN NITRIC ACID–ORGANIC SOLVENT MEDIA

J. KORKISCH*, F. FEIK and S. S. AHLUWALIA
Analytical Institute, University of Vienna IX, Währingerstrasse 38, Austria

(*Received* 27 *February* 1967. *Accepted* 24 *April* 1967)

Summary—The cation-exchange behaviour of 19 elements towards the strongly acidic cation-exchange resin Dowex 50-X8 in media containing varying concentrations of organic solvents and aqueous nitric acid is reported. Based on the determination of the distribution coefficients of these elements in the organic solvents methanol, ethanol, n-propanol, isopropanol, methyl glycol, acetone, tetrahydrofuran and acetic acid, the conditions most suitable for their quantitative separation are indicated and discussed.

IN a previous paper[1] the cation-exchange characteristics of 20 elements in mixed aqueous–organic solvent media containing hydrochloric acid, with Dowex 50-X8 as the exchange resin have been described. The present investigations have been carried out by employing the same resin and the same organic solvents but in media containing nitric acid. Consequently the data which are presented in these two papers can readily be compared and evaluated.

While several investigations concerning the cation-exchange behaviour of numerous metal ions in pure aqueous nitric acid solutions have been carried out[2,3] no attempt has so far been made to investigate systematically the broad field of mixed aqueous–organic solvent media containing nitric acid.

The exchange behaviour of uranium and thorium on Dowex 50-X8 from mixtures consisting of aliphatic alcohols and dilute nitric acid has been investigated[4] and on the same resin uranium has been separated from many accompanying elements with a mixture of tetrahydrofuran and nitric acid, by use of the CIESE principle.[5–7]

Apart from these investigations, cation-exchange in nitric acid–organic solvent media has received no attention. In order to obtain a much more complete picture of the adsorption characteristics and separation possibilities of elements in organic solvent media, the research work presented in this paper was performed, the most frequently employed cation-exchange resin, Dowex 50, being used in mixtures of 8 organic solvents with nitric acid. For this purpose the effect of increasing the concentration of the organic solvent from 0 to 90% in solutions with a constant overall acidity of 0·6*M* nitric acid, and the effect of changing the acidity from 0·15 to 1·2*M* while keeping the concentration of organic solvent constant at 90%, were investigated by measuring the distribution coefficients in these media. From the distribution coefficients thus obtained, the possibilities of separating the elements investigated from one another are indicated and discussed.

EXPERIMENTAL

Reagents

Ion-exchange resin. The air-dried strongly acidic cation-exchanger Dowex 50-X8 (100–200 mesh, hydrogen form) was used for the batch and column experiments.

* Present address: Argonne National Laboratory, Chemistry Division, 9700 South Cass Avenue, Argonne, Illinois 60440, U.S.A.

Standard solutions. Exactly weighed amounts of Mg, Ca, Sr, U(VI), Mn(II), Co, Ni, Cu(II), Zn, Cd, Pb, Fe(III), Al, In, Bi, Th, Ce(III), V(V) and Mo(VI) as nitrates were dissolved in 6*M* or 12*M* nitric acid to give solutions containing 10 mg of the element per ml.

Solvents. The reagent-grade pure organic solvents used were methanol, ethanol, n-propanol, isopropanol, methyl glycol, acetic acid, tetrahydrofuran and acetone.

Determination of the various elements

Most of the elements investigated (in amounts exceeding *ca.* 100 μg) were determined titrimetrically with EDTA. Microgram quantities of the metal ions were determined spectrophotometrically[8] except for uranium which was determined fluorometrically.[9]

Determination of distribution coefficients

The weight distribution coefficients of most elements, defined by the well known equation

$$K_d = \frac{\mu g \text{ of element/g of resin}}{\mu g \text{ of element/ml of solution}}$$

(see previous paper[1]), were determined by using the batch equilibrium method. Each equilibrium experiment was performed with 20 ml of a mixture consisting of 0–90% of the organic solvent, 10% of nitric acid, and water up to 100%, and containing 10 mg of the element in question. To this mixture 1 g of the resin was added and the solution was agitated on a shaking machine for 12 hr, then the resin was filtered off and the element determined in the filtrate. The experimental errors of the measurements of the distribution coefficients were virtually the same as those earlier observed in hydrochloric acid media of comparable composition.[1]

Distribution coefficients considerably smaller than 100 were determined by the column method.[10] In this case the distribution coefficient K_d was calculated from the relationship developed by Mayer and Tompkins,[11]

$$\bar{V} = K_d m$$

where m = mass of dry resin in the column and $\bar{V}$ = volume of eluent which has passed through the column to elute the maximum of the elution peak.

RESULTS AND DISCUSSION

In Tables I–XVII the metal ions are arranged in the same order. A general feature of the distribution data presented in these Tables is that in most cases the adsorption of a given element increases rather regularly with an increase in the percentage of the non-aqueous component of the mixtures and with a decrease of the nitric acid concentration.

Aliphatic Alcohol Media

In Tables I–IV, IX–XII, the distribution coefficients measured in nitric acid–aliphatic alcohol mixtures (methanol, ethanol, n-propanol and isopropanol) are shown.

Uranium(VI), thorium(IV) and cerium(III)

It is seen that in all cases the adsorption of uranium is less than that of thorium. With increasing concentration of the aliphatic alcohol the uranium adsorption increases while that of thorium remains virtually constant so that a separation of uranium from thorium would only be feasible at low alcohol concentrations. Cerium shows a behaviour similar to thorium. Thus cerium can be separated from uranium but not from thorium, It is to be expected that other lanthanide ions will behave very similarly to cerium.

When the concentration of nitric acid is increased, the adsorption of uranium decreases markedly while the adsorption of thorium and cerium is only slightly affected by a change in the acidity of the nitric acid–aliphatic alcohol mixtures. Nevertheless no ready separation of uranium from these two elements is possible at 0·6*M* or higher overall acidities of the mixtures because even under these conditions the distribution coefficients of uranium are relatively high.

TABLE I.—DISTRIBUTION COEFFICIENTS IN AQUEOUS METHANOLIC 0·6*M* NITRIC ACID

Molybdenum(VI) and vanadium(V)

These show a very similar behaviour in all four alcohols so that they cannot readily be separated from each other. On the other hand it should be possible to separate molybdenum and vanadium from practically all other elements listed in the Tables. Such separations are however not readily performed because in these media molybdenum and vanadium are partly reduced to lower oxidation states which show distribution values which are higher by about one to two orders of magnitude than these of the sexi- and pentavalent oxidation states respectively.

Iron(III), aluminium(III), indium(III) and bismuth(III)

In all media the K_d-value of iron(III) increases with an increase in the concentration of the organic component of the mixtures. The reverse is true for media which contain hydrochloric acid in place of nitric acid.[1] Consequently one can assume that iron does not form anionic complexes in nitric acid media.

A behaviour similar to iron is shown by aluminium and indium, *i.e.*, their K_d-values increase regularly with increasing alcohol concentration.

An exceptional behaviour in all aliphatic alcohol media is shown by bismuth which shows adsorption maxima at alcohol concentrations of 60 or 80%, whereafter

Pb(II)	105	800	900	$>10^3$	$>10^3$	$>10^3$
Zn(II)	46	60	139	608	$>10^3$	$>10^4$
Cd(II)	46	65	140	402	$>10^3$	$>10^3$
Cu(II)	27	112	175	200	620	$>10^3$
Mn(II)	40	52	92	350	$>10^3$	$>10^3$
Co(II)	32	47	81	322	$>10^3$	$>10^3$
Ni(II)	30	47	90	270	$>10^3$	$>10^4$

the distribution coefficient decreases with an increase of the amount of alcohol. This suggests anionic complex formation by bismuth at alcohol concentrations exceeding 60 or 80%. This decrease in bismuth adsorption is even more pronounced when the acidity is raised at constant concentrations of aliphatic alcohols (see Tables IX–XII). Under these conditions the distribution coefficients of iron, aluminium and indium show a rather regular decrease without reaching very low values while that of bismuth decreases considerably in the acidity region from 0·6 to 1·2*M* final nitric acid concentration. Consequently separations of bismuth from these tervalent metal ions are possible at higher acidities.

Magnesium(II), calcium(II), strontium(II) and lead(II)

When the alcohol concentration is increased the adsorption of these ions shows a marked increase. A simple separation of magnesium from calcium or of calcium from strontium is impossible because of the similarity of their distribution coefficients. Thus a fractionation of these metal ions would only be possible by means of elution chromatography. A similar adsorption behaviour is observed in the case of lead.

Zinc(II) and cadmium(II)

The adsorption behaviour of these two elements is similar to that observed in the case of calcium. Because of the small differences in the K_d-values of zinc and cadmium separations of these two metal ions cannot be affected.

Copper(II) and manganese(II)

The adsorption of copper and manganese increases as the concentration of aliphatic alcohol increases to 90%. This increase is highest in propanol and lowest in methanol media, *i.e.*, the values of the distribution coefficients increase with increasing chain length of the alcohols employed.

When the concentration of nitric acid increases (see Tables IX–XII) the adsorption of copper decreases much more strongly while that of manganese does not show such pronounced variations. A separation of copper from manganese is possible in media of higher nitric acid concentrations containing methanol or ethanol.

Cobalt(II) and nickel(II)

In virtually all cases cobalt and nickel show the same adsorption behaviour and their K_d-values increase with increasing concentration and chain length of the aliphatic alcohols. Consequently no separations of these two elements from one another can be effected in any of these alcoholic media. Similar unfavourable conditions exist when the acidity is varied (see Tables IX–XII).

Methyl Glycol Media

The results of measurements of the distribution coefficients of the various elements in nitric acid–methyl glycol media are shown in Tables V and XIII.

Uranium(VI), thorium(IV) and cerium(III)

The behaviour of these elements with increasing methyl glycol concentration is virtually the same as that observed in the nitric acid–aliphatic alcohol mixtures except for a maximum of uranium adsorption at 80% of methyl glycol. This exceptional behaviour of uranium has also been observed in methyl glycol media containing

TABLE V.—DISTRIBUTION COEFFICIENTS IN 0·6*M* NITRIC ACID IN AQUEOUS METHYL GLYCOL SOLUTION

Ion	Methyl glycol concentration, %					
	0	20	40	60	80	90
UO_2(II)	40	54	110	207	434	314
Th(IV)	$>10^4$	$>10^4$	$>10^4$	$>10^4$	$>10^4$	$>10^3$
Ce(III)	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$
Mo(VI)	7	6	6	7	5	4
V(V)	7	5	6	7	6	4
Fe(III)	171	175	184	323	991	$>10^4$
Al(III)	132	151	169	193	203	$>10^3$
In(III)	173	540	10^3	$>10^3$	$>10^3$	$>10^3$
Bi(III)	135	358	540	952	358	258
Mg(II)	18	23	48	60	212	$>10^3$
Ca(II)	38	52	96	160	620	$>10^3$
Sr(II)	68	166	290	832	$>10^3$	$>10^3$
Pb(II)	105	630	800	$>10^3$	$>10^3$	$>10^3$
Zn(II)	46	60	88	245	860	$>10^3$
Cd(II)	46	58	112	247	505	884
Cu(II)	27	39	66	128	271	620
Mn(II)	40	53	94	224	817	$>10^3$
Co(II)	32	52	71	171	430	$>10^3$
Ni(II)	30	50	86	211	476	$>10^3$

hydrochloric acid.[1] With an increase of the acidity to 1·2*M* (see Table XIII) the distribution coefficient of uranium is considerably reduced so that this element can be separated from thorium, cerium and many other elements (the conditions of separation are, however, less suitable in this medium than in mixtures containing tetrahydrofuran or acetone (see Tables XV and XVI)).

Molybdenum(VI) and vanadium(V)

These two elements show an adsorption behaviour similar to that observed in aliphatic alcohol media and a separation of molybdenum from vanadium is impossible.

Iron(III), aluminium(III), indium(III) and bismuth(III)

As in the aliphatic alcohol media the adsorption of iron, aluminium and indium increases considerably at high methyl glycol concentrations, while that of bismuth shows a maximum at 60% of methyl glycol whereafter the distribution coefficient decreases with an increase in the concentration of this organic solvent. While the adsorption of iron, aluminium and indium is practically unaffected by variations of the nitric acid concentration, the distribution coefficient of bismuth decreases strongly with an increase in acidity. Consequently bismuth can be separated from these elements at high acidities (see Table XIII).

Magnesium(II), calcium(II), strontium(II), lead(II), zinc(II), cadmium(II), copper(II) and manganese(II)

These elements show in nitric acid–methyl glycol media a behaviour which is similar to that observed in the aliphatic alcohols. A separation of copper from the other bivalent ions would be possible at a final nitric acid concentration of 1·2*M* (see Table XIII).

media containing nitric acid. The elements show a similar behaviour in both organic solvents especially at high nitric acid concentrations.

Uranium(VI), thorium(IV) and cerium(III)

Thorium and cerium show the same behaviour as in the organic solvent media discussed before. An exceptional behaviour is shown by uranium. Its adsorption reaches a maximum at 60% of organic solvent in both tetrahydrofuran and acetone,

whereafter the K_d-value decreases considerably. This decrease is much more pronounced in the tetrahydrofuran media (see Table VII). As a consequence uranium can be separated from virtually all elements listed in Table VII, *e.g.*, by using a medium consisting of 90% tetrahydrofuran and 10% 6*M* nitric acid. This fact has earlier been utilized for the selective analytical separation of uranium.[5] For the theoretical interpretation of this strong decrease of uranium adsorption which is even more

* Not determined because practically complete reduction to lower valency states occurs in these media.

60% and in both organic solvents the adsorption decreases markedly with an increase in nitric acid concentration. For the purpose of separating molybdenum and vanadium from other elements the tetrahydrofuran mixtures are more suitable than the acetone media because in the former no reduction of these two metal ions occurs.

Acetic Acid Media

The results of measurements of distribution coefficients of the elements in acetic acid media containing nitric acid are shown in Tables VI and XIV. A comparison of these with those representing the systems discussed before shows that the behaviour of the elements in acetic acid is very similar to that in the aliphatic alcohols of longer chain length so that no detailed discussion need be presented.

TABLE XVII.—DISTRIBUTION COEFFICIENTS IN NITRIC ACID OF VARIED MOLARITY

Water Media

In Table XVII the behaviour of the elements in pure aqueous solutions containing varying concentrations of nitric acid is shown. In these systems no ready separation of uranium from most elements can be effected. Also the separation of other elements would in most cases only be possible by ion-exchange chromatography.

Acknowledgement—Acknowledgement is made to the donors of the Petroleum Research Fund administered by the American Chemical Society, for support of this research (PRF-grant No. 1587-A3).

Zusammenfassung—Es wird über das Kationenaustauschverhalten von 19 Elementen gegen das stark saure Kationenaustauschharz Dowex 50-X8 in Medien berichtet, die wechselnde Mengen organischer Lösungsmittel und wäßrige Salpetersäure enthalten. Auf Grund der Bestimmung der Verteilungskoeffizienten dieser Elemente in den organischen Lösungsmitteln Methanol, Äthanol, n-Propanol, Isopropanol, Methylglycol, Aceton, Tetrahydrofuran und Essigsäure werden die geeignetsten Bedingungen für die quantitative Trennung der betreffenden Elemente angegeben und diskutiert.

Résumé—On décrit le comportement échangeur de cations de 19 éléments vis-à-vis de la résine échangeuse de cations fortement acide Dowex 50-X8 dans des milieux contenant des concentrations variables de solvants organiques et d'acide nitrique aqueux. En se basant sur la détermination des coefficients de partage de ces élements dans les solvants organiques méthanol, éthanol, *n*-propanol, isopropanol, méthylglycol, acétone, tétrahydrofuran et acide acétique, on indique les conditions les plus convenables à leur séparation quantitative et en discute.

TITRIMETRIC, COULOMETRIC AND SPECTROPHOTOMETRIC DETERMINATION OF MANGANESE FOLLOWING PERCHLORIC ACID OXIDATION IN THE PRESENCE OF PYROPHOSPHATE

JOHN KNOECK and HARVEY DIEHL
Department of Chemistry, Iowa State University, Ames, Iowa, U.S.A.

(*Received* 9 *February* 1967. *Accepted* 25 *April* 1967)

Summary—Manganese is oxidized quantitatively to a violet, tervalent pyrophosphate in a boiling mixture of equal parts of perchloric acid and phosphoric acid. This Mn(III) can be titrated potentiometrically or coulometrically with iron(II); it can also be measured spectrophotometrically. If the titrimetric method is carried out with titanium (III) or chromium(II), iron can also be titrated immediately after the manganese. The methods were applied to a new reference sample, ISU 600 Manganiferous Iron Ore, and to manganese ore, spiegeleisen, ferromanganese, and rail steel. Manganese(II) oxalate dihydrate has been reinvestigated as a primary standard and is highly recommended.

IN VIEW of the great number of methods proposed for manganese, chemists advance another method only with temerity. Perhaps, though, the very number of methods described indicates that all is not well with them, and this is borne out by an unpublished report[1] of the results of the analysis of three manganese ores by fifteen participating analysts; spreads of 0·97, 1·20 and 1·30% were found for the three ores, with about equal variations between the methods employed [persulphate, bismuthate, permanganate titration to manganese dioxide (modified Volhard), permanganate titration to manganese(III) pyrophosphate (Lingane and Karplus)] and between analysts using the same method. Whether these variations arose from deficiencies in the methods, from inhomogeneity in the samples, or from defects in the primary standards used is unsettled and we have addressed our attention to all three problems. We have developed a titrimetric and a spectrophotometric method based on the oxidation of the manganese to manganese(III) by a boiling mixture of perchloric and phosphoric acids, which in our hands has given consistent and apparently true results. We have blended a manganiferous iron ore and tested the lot for homogeneity; this material, designated ISU 600, Manganiferous Iron Ore, was prepared in sufficient amount to enable us to invite requests from others interested in a reference sample. We have re-examined the earlier primary standard, manganese(II) oxalate dihydrate,[2,3] and have found it good.

Our attention was first directed to the oxidation of manganese to manganese(III) during the development of a method of dissolving iron ore with a boiling mixture of perchloric and phosphoric acids,[4] a method which has proven highly useful for the determination of iron.[5] We have now shown that in this boiling mixture, manganese is oxidized quantitatively to manganese(III), presumably stabilized by formation of a non-dissociated pyrophosphate compound. This may then be titrated with reducing

agents or measured spectrophotometrically. The titration can be made conveniently with iron(II) sulphate or coulometrically with iron(II) ions. It may be carried out with titanium(III) sulphate or chromium(II) sulphate, with either of which iron may also be determined on the same sample by continuing the titration beyond the manganese end-point. For low manganese contents, as in steel, the spectrophotometric method offers advantages.

Titration of manganese(III) pyrophosphate is not new: Ingamells[6] titrated it with iron(II) sulphate, and used nitric acid for the oxidation; Kolthoff and Watters[7] effected the oxidation with lead dioxide and titrated with iron(II) sulphate; Heczo[8] oxidized with freshly prepared perphosphoric acid and concluded the determination iodometrically. The present method has the advantage that the oxidizing agent and the solvent acid are one, and that the excess of oxidizing agent is removed by simple dilution. Manganese ores in higher oxidation states must be given a preliminary reduction by heating with hydrochloric acid.

The colorimetric determination of manganese(III) pyrophosphate is also not new. It was first suggested by Tomula and Aho;[9] bromate was used as the oxidant in a sulphuric acid–pyrophosphoric acid solution. The results were erratic with relative errors as high as 25%. The system was investigated further by Purdy and Hume[10] who were unable to reproduce Tomula and Aho's spectra and finally abandoned orthophosphate, pyrophosphate and tripolyphosphate ligands in favour of a simple sulphate solution. Our own success with the method is based on maintaining a perchloric acid–phosphoric acid solution throughout the entire analysis. Reproducibility, stability and conformity to Beer's law are thus obtained. However, the intensity of the violet colour is low, the molar absorptivity being 75 (permanganate 2200), and interference from nickel, chromium and other coloured materials is serious and although we have applied the colorimetric method successfully to manganese rail steel we are less than enthusiastic about it.

EXPERIMENTAL

Apparatus and Reagents

Potentiometric titrations with titanium(III) sulphate, vanadium(II) sulphate and chromium(II) sulphate were carried out in a 250-ml beaker covered with a rubber stopper through which the electrodes and a nitrogen inlet tube were fitted. Potential measurements were made with a Model G Beckman pH meter and a platinum wire–saturated calomel electrode pair.

Solutions of titanium(III) sulphate, chromium(II) sulphate, and vanadium(II) sulphate were stored under nitrogen and over amalgamated zinc. These solutions were fed to a self-filling burette, all connections being made through glass tubing with Teflon stop-cocks.

A solution of titanium(III) sulphate was prepared by dissolving the appropriate amount of solid titanium(III) sulphate in 3–4*N* sulphuric acid, filtering through fritted glass, and reducing with and storing over amalgamated zinc.

A solution of vanadium(II) sulphate was prepared by dissolving the appropriate amount of reagent grade vanadium(IV) sulphate in 4*N* sulphuric acid and reducing with and storing over amalgamated zinc.

A solution of chromium(II) sulphate was prepared from reagent grade sodium dichromate by reduction with hydrogen peroxide in acid solution followed by further reduction with and storage over amalgamated zinc.

Electrolytic iron ignited in moist hydrogen was obtained from the G. Frederick Smith Chemical Company, Columbus, Ohio. Potassium manganicyanide, $K_3Mn(CN)_6$, was prepared as described by Ford-Smith.[14] Oxygen was removed from cylinder nitrogen by passage through vanadium(II) sulphate.[15]

Coulometric titrations were performed with a Sargent Model IV Coulometric Current Source. Platinum wire anodes and cathodes were used. End-points were detected by using a platinum wire–S.C.E. pair and a potentiometer with a lamp and scale galvanometer.

The coulometric cell consisted of a 200-ml cathode compartment separated from a 100-ml anode compartment by first an ultrafine and then a fine glass frit. The anode compartment contained a solution 1*M* in sodium sulphate and 0·01*M* in sulphuric acid. A similar solution was fed from a reservoir to the space between the frits, thus minimizing the migration of ions from the cathode and anode compartments and helping to ensure 100% current efficiency.

Spectrophotometric measurements were made with a Beckman D.U. spectrophotometer.

Reference sample, ISU 600, Manganiferous Iron Ore

Fifteen lb of a high manganese iron ore, obtained on the Cuyuna Range, Minnesota, was ground in a Micropulverizer to pass a 200-mesh sieve. The ground material was dried at 100° for several days and then mixed in a conical stainless-steel blender for 24 hr. Six specimens were taken from different parts of the batch at the time the blender was emptied. The manganese in each specimen was determined by the titrimetric method. The results, given below under *Results and Discussion* and in Table II, indicate that the inhomogeneity of the material is smaller than the error in the method of analysis.

ISU 600 is decidedly hygroscopic and should be dried before analysis.

An X-Ray powder photograph of ISU 600 by Dr. Donald L. Biggs, Department of Geology, Iowa State University, indicated the presence of quartz, hematite and manganite and the absence of pyrolucite and psilomelane. Manganite is the hydrated oxide of manganese(III), and a preliminary reduction with hydrochloric acid is necessary if the sample is analysed by the method described in this paper.

Manganese(II) oxalate dihydrate primary standard

Manganese(II) oxalate dihydrate was first proposed as a primary standard for manganese by Coltman[3] in 1924. It was further thoroughly studied by Werm.[8] We have confirmed the character and value of manganese(II) oxalate dihydrate and find it rather astonishing that it has not found universal adoption in the years since the Coltman and Werm work. It is particularly good as a primary standard for the method for manganese proposed here, for its use eliminates any standardization against a non-manganese-bearing standard and in particular circumvents the uncertainties of the permanganate-oxalate reaction.

After trying several methods of preparing manganese(II) oxalate dihydrate, Werm concluded that the preparation from potassium permanganate and oxalic acid led to the best product. His preparation was followed, although we have found that when starting with the reagent grade materials now available it is immaterial whether the materials be recrystallized.

Solid potassium permanganate was added slowly to a hot, concentrated solution of oxalic acid with stirring. The precipitated manganese(II) oxalate dihydrate was filtered off from the hot solution, washed well with water, dried for 24 hr at 55–60°, and stored in a vacuum over anhydrous magnesium perchlorate.

Manganese(II) oxalate dihydrate is unusual as a primary standard in that all three components of of the compound can be determined easily with precision and the composition of the material thus established. Werm made a study of the permanganate titration of oxalic acid and like others before him, notably McBride,[12] found that any delay in the titration, manganese(II) ion being present, caused some oxidation by air and high values for the titre of the permanganate. By carrying out the titration with dispatch and under identical conditions (dissolution in sulphuric acid, titration at 90°, delivery rate 25 ml/min), Werm obtained identical results in the standardization of permanganate with sodium oxalate and manganese(II) oxalate dihydrate. This work, of course, predates the detailed study of the permanganate-sodium oxalate standardization by Fowler and Bright.[13]

Our determination of the oxalate content of manganese(II) oxalate dihydrate was made by permanganate titration by the Fowler and Bright procedure (90% titration at 30°, remainder at 60°). The permanganate solution was also standardized at the same time against sodium oxalate and against electrolytic iron ignited in moist hydrogen. The results are shown in Table I. Assuming the sodium oxalate (NBS 40 g) to be 99·95% pure, these figures give for the oxalate content of manganese(II) oxalate dihydrate 49·16%, the theoretical value being 49·176%.

Determinations of the manganese content of manganese oxalate dihydrate by the new method gave values similarly close to the theoretical content; (*Results and Discussion* and Table II).

Recommended procedure

Of the three procedures given here, use the titrimetric or coulometric procedures for materials high in manganese such as pyrolucite, manganiferous iron ores, ferromanganese, and high manganese steels. In the titrimetric procedure titrate with iron(II) sulphate if only manganese is to be determined but with titanium(III) or chromium(II) sulphate if manganese and iron are to be titrated successively. Use the coulometric method if higher precision is desired, the necessary apparatus is available, and the

TABLE I.—COMPARATIVE STANDARDIZATION OF A PERMANGANATE SOLUTION AGAINST ELECTROLYTIC IRON, NBS SODIUM OXALATE, AND MANGANESE(II) OXALATE DIHYDRATE

Primary standard	Mean normality found*,	No. of variates	Relative standard deviation, *parts per 1000*
Electrolytic iron†	0·1200	6	2·0
Sodium oxalate,‡ NBS 40 g	0·1200	6	1·0
Manganese(II) oxalate dihydrate§	0·1202	6	1·2

* All analyses on same day.

§ Dried at 60°C.

extra time required is warranted. Use the spectrophotometric method for the determination of manganese in steel or ores containing a few per cent of manganese, as an alternative to the periodate–permanganate spectrophotometric method when very small samples or excessive dilutions would be required.

Preparation of sample and oxidation of manganese. Place a sample containing about 220 mg (titrimetric method) or 40 mg (spectrophotometric method) of manganese in a 500-ml conical flask. If the sample contains oxides of manganese, pretreat the sample to reduce any higher oxidation states to manganese(II) by adding 15 ml of concentrated hydrochloric acid, heating, and evaporating to near dryness on a hot-plate. To this mixture and to materials bearing only manganese(II), add 30 ml of a mixture of 72% perchloric acid and 85% phosphoric acid (1 + 1). Heat the mixture on a hot-plate to a gentle boil so that the acid refluxes smoothly on the walls of the flask but no vapours of perchloric acid are expelled from the flask. Continue this boiling for 30 min after the first appearance of the violet colour of manganese(III). Cool, and determine the manganese by one of the following methods.

Titrimetric determination of manganese. If iron(II) sulphate is used as the titrant, carry out the titration in the flask used for the dissolution and oxidation. Dilute the mixture with about 5 ml of water and within 30 min titrate with 0·1*N* iron(II) sulphate. Determine the end-point potentiometrically or by the disappearance of the violet colour of the manganese(III) or with diphenylamine-sulphonic acid, adding the indicator just before the end-point.

For titration with titanium(III) or chromium(II) sulphate, transfer the solution of manganese(II) to a closed titration vessel, rinsing and washing the flask with concentrated phosphoric acid and then with water. Bubble a stream of oxygen-free nitrogen through the vessel to displace the air, and then titrate with 0·1*N* titrant, determining the end-point potentiometrically. The end-point occurs at a potential of about 0·57 V *vs.* S.C.E.

If iron is also to be determined add 10–15 g of sodium acetate [necessary if titanium(III) is used as titrant, but not necessary with chromium(II)] and continue the titration. The end-point occurs when the platinum electrode has a potential of about 0·1 V or less *vs.* S.C.E.

Coulometric determination of manganese. Place about 75 ml of 1*M* iron(III) sulphate in the cathode compartment of the coulometric titration cell. Add a few drops of a solution containing some manganese(III) pyrosphosphate. Titrate with iron(II) ion generated at a platinum cathode, following the titration with a platinum–S.C.E. pair to the end-point, in the neighbourhood of 0·75 V (platinum *vs.* S.C.E.). Set the potentiometer so that a small deflection of the galvanometer occurs, that is, so that the potential of the cell is not quite balanced, and keep the potentiometer at this setting throughout the subsequent titration. Transfer to the cell the solution obtained as described above (*Preparation of sample and oxidation of manganese*) and titrate until the galvanometer deflection is just that obtained in the pretitration. During the titration the potentiometer circuit should be closed only momentarily until close to the end-point, to avoid effecting any electrolysis by the indicator electrode. (The advantages of this method of end-point detection have been described by Cooke, Reilley and Furman.[11])

A second sample may now be added to the same solution and titrated.

Spectrophotometric determination of manganese. Transfer to a volumetric flask the oxidized sample solution (see *Preparation of sample and oxidation of manganese*) while it is still warm, the lower viscosity at the higher temperature making the transfer easier. Use a mixture of perchloric acid and phosphoric acid (1 + 1) for all rinsings and the final dilution. Measure the absorbance at 515 mμ against a perchloric acid and phosphoric acid mixture as a blank.

*** Blank used in reference cell; see text.

In similar fashion prepare a calibration curve. Weight accurately about 1·79 g of manganese(II) oxalate dihydrate primary standard. Dissolve and oxidize this material with the perchloric acid–phosphoric acid mixture as described above, and make the final dilution in a 100-ml volumetric flask, thus giving a solution about 0·1*M* in manganese. Transfer by pipette 10, 8, 6, 4, 2, and 1-ml portions of this solution into 100 ml volumetric flasks and dilute to volume with the perchloric acid–phosphoric acid mixture. Measure the absorbance at 515 mμ.

RESULTS AND DISCUSSION

Results of exploratory work which led to the final procedures are reported below; these furnish useful notes on the operation. The procedures finally recommended were applied to various reference samples; the results are given in Table II.

Oxidation of manganese

Manganese is oxidized rapidly and quantitatively in the boiling perchloric acid–phosphoric acid solution. The manganese(III) is stabilized by the formation of a non-dissociated pyrophosphate; for this compound Kolthoff and Watters[7] believe the formula to be $Mn(H_2P_2O_7)_3^{3-}$. Pyrophosphate is formed quickly in the boiling perchloric acid–phosphoric acid mixture and the addition of sodium pyrophosphate was found unnecessary, for it neither increased the stability of the manganese(III) nor speeded up the oxidation. Experiments indicated that the oxidation was complete but that on dilution with water, high concentrations of manganese(III) compound undergo slow decomposition with the formation of a brown precipitate. It is therefore necessary that the titration of large amounts of manganese be made without undue delay; within 30 min after transfer or dilution.

Some decomposition of perchloric acid occurs when it is boiled at atmospheric pressure, chlorine and oxygen being produced (Willard[16]). It was shown by Moore and Diehl[17] that on dilution this chlorine reacts with water to produce hypochlorous acid and that the hypochlorous acid has a deleterious effect if perchloric acid is being used for the destruction of organic matter prior to the determination of amino nitrogen (Kjeldahl method). In the present work a reducing action of hypochlorous acid on the manganese(III) was expected but none was found, possibly because the perchloric–phosphoric acid mixtures were always allowed to cool before any dilutions were made, permitting any chlorine to escape.

On being refluxed in a perchloric acid–phosphoric acid mixture, manganese(II) oxalate is decomposed, the oxalate being oxidized to carbon dioxide by the perchloric acid. All of the oxalate must be decomposed before manganese(III) is permanently formed. No difficulties were experienced with this procedure for dissolving and oxidizing manganese and oxalate.

Titrimetric determination

The manganese(III) pyrophosphate is a powerful oxidizing agent, $E^\circ \sim +1{\cdot}5$ V, and titration with iron(II) gives an excellent potential break at the end-point. The disappearance of the violet colour of the tervalent manganese compound serves for visual location of the end-point and occurs exactly at the potentiometric end-point. Diphenylaminesulphonic acid also serves well as an indicator and is best added just before the end-point.

The convenience of determining both manganese and iron on the same sample is

fair justification for the extra labour of preparing and storing titanium(III) or chromium(II) sulphate, assembling an anaerobic titration vessel, and carrying out the titration potentiometrically. The potential of the titanium(IV)–titanium(III) couple is highly pH-dependent and the titanium(III) titration of iron is only successful in a weakly acidic solution, most easily obtained in this titration by the addition of 10–15 g solid sodium acetate to the solution after the titration of the manganese(III). The titration curve is shown in Fig. 1. If chromium(II) sulphate is used as the titrant no sodium acetate is required and a greater potential break is observed at the iron end-point [450 mV as compared to 300 mV with titanium(III)].

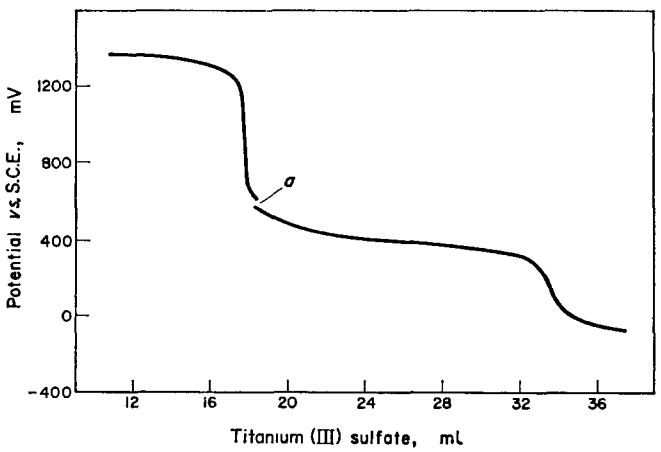

FIG. 1.—Successive potentiometric titration of Mn(III) and Fe(III) with 0·124*N* titanium(III) sulphate.
Sodium acetate, 15 g, added at point *a*.

Vanadium(II) sulphate is satisfactory as a titrant for manganese(III) but not for the subsequent titration of the iron(III). Potentials during the titration of the iron were found to be very unstable and equilibrium was not reached for several hours. Vanadium(II) is oxidized cleanly to vanadium(V) by manganese(III) and to vanadium (IV) by iron(III); the instability observed is probably caused by reaction of the vanadium(V) and iron(II) produced.

Those materials which form strong oxidizing agents when heated with boiling perchloric acid interfere in the titrimetric method, notably vanadium and chromium. This interference and a method for correcting it are discussed in a separate section below.

Coulometric titration

Its high potential makes the pyrophosphate manganese(III)–manganese(II) couple ideal for coulometric titration, and particularly convenient because the iron(III)–iron(II) couple can be used to guarantee 100% current efficiency. The potentiometric method with a platinum–S.C.E. pair proved convenient for following the reduction (Fig. 2).

Those materials which interfere in the titrimetric method interfere, of course, in the

coulometric method (see following section). In addition copper is plated on the cathode and thus also interferes, counting as manganese.

Interference of chromium and vanadium in the titrimetric and coulometric methods

Chromium and vanadium are oxidized by boiling perchloric acid to their highest oxidation states, which can then be titrated with the standard reducing agents. These oxidations are apparently complete also in the boiling mixture of perchloric and phosphoric acids, so that the proposed method for manganese gives the sum of all three metals. Correction for chromium plus vanadium can be made by a similar

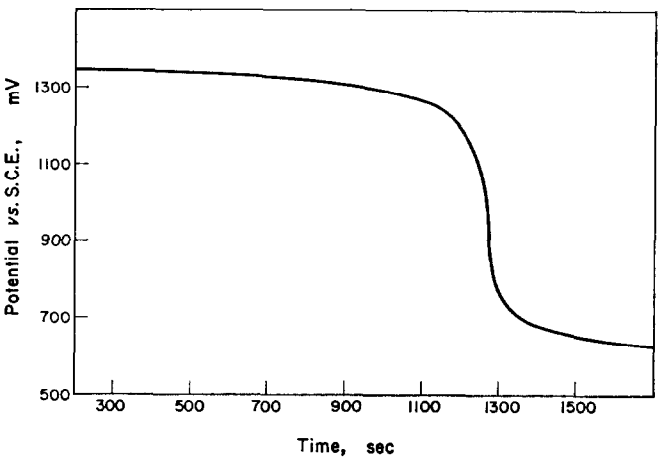

FIG. 2.—Coulometric titration of Mn(III) with electrolytically generated Fe(II). Current: 9·650 mA; 0·100 × 10^{-6} equiv/sec. Sargent Model IV coulometric current source.

determination on a separate sample with the phosphoric acid omitted. As the chromium and vanadium are low in most manganese samples, the titration should be made with 0·025*N* iron(II) sulphate, the end-point being detected conveniently with diphenylaminesulphonic acid.

The higher accuracy of the coulometric method unveiled a further source of error in the correction of the manganese determination for chromium plus vanadium just described. Any phosphorus present in the sample is converted into pyrophosphate by the boiling perchloric acid and causes corresponding small amounts of manganese to be oxidized to the manganese(III) pyrophosphate compound. Higher oxidation states of manganese, of course, are not formed in boiling perchloric acid in the absence of ligands forming non-dissociated ions. Removal of excess of permanganate in the course of a determination of chromium plus vanadium is a problem faced by earlier workers, notably Willard and co-workers, who utilized azide and also hydrochloric acid for this purpose (see Willard and Diehl[18]). Because the reduction potentials of the permanganate–manganese(II) and pyrophosphate manganese(III)–manganese(II) couples are about the same, ~ 1·5 V, it was expected that boiling with hydrochloric acid would reduce manganese(III) without reducing the chromate or vanadate, and this proved to be true.

Spectrophotometric determination

The visible spectrum of the manganese(III) pyrophosphate obtained in this work is shown in Fig. 3, and is essentially the same as that obtained by Tomula and Aho.[9] Indentical spectra were obtained by refluxing electrolytic manganese metal or manganese(II) oxalate dihydrate in the perchloric acid–phosphoric acid mixture, and by dissolving potassium manganicyanide in perchloric acid saturated with sodium pyrophosphate and warming for a few minutes. The solutions were stable for at least several weeks. The system conforms to Beer's law over the range 0·05–1 mg of manganese per ml. The molar absorptivity is low, $\varepsilon = 75.1$ cm^{-1} mole^{-1} at the wavelength of maximum absorbance, 515 mμ, and the method is therefore applicable

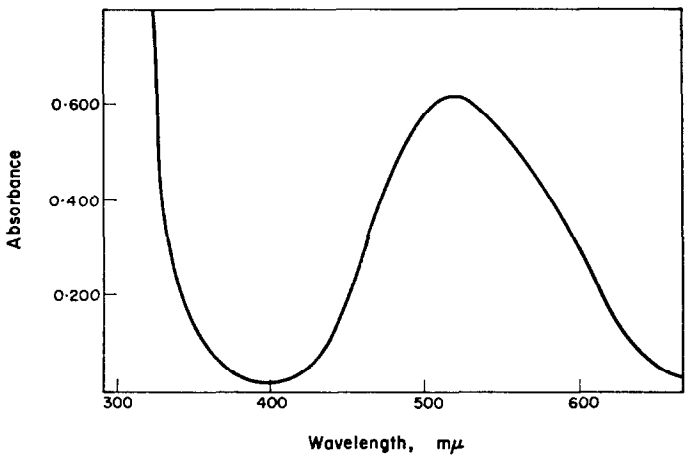

FIG. 3.—Absorption spectrum of manganese(III) in perchloric acid–phosphoric acid (1 + 1).
Manganese $8.41 \times 10^{-3}M$; 1-cm cell; absorption maximum 515 mμ; molar absorptivity 75.1 cm^{-1} mole^{-1}.

to samples of fairly high manganese content. The colours of copper, nickel, vanadium, and cobalt, which are not sufficiently intense to interfere with the permanganate colorimetric method, cause errors in the manganese(III) pyrophosphate method. Dichromate is an especially serious interference (see following section).

Interferences in the spectrophotometric method

An error of 2% in the absorbance of a sample containing 10 mg of manganese is caused by 95 mg of copper, 70 mg of nickel, or 40 mg of vanadium. Only 0·6 mg of cobalt or 0·4 mg of chromium are needed to cause the same error. These errors can be compensated by preparing a separate sample of the same material and omitting phosphoric acid during the dissolution and oxidation step, diluting to volume with a mixture of perchloric acid and phosphoric acid (1 + 1), and using this solution as the blank.

With high carbon steels, best results were obtained by dissolving the samples in 70% perchloric acid, refluxing to destroy the carbon, adding an equal volume of phosphoric acid, and continuing the refluxing to oxidize the manganese.

Results for reference samples

The accuracy and precision of the proposed methods were checked by the analysis of various reference materials; the results are summarized in Table II. These results,

of course, reflect both the precision of the method and the homogeneity of the sample. The greatest precision was obtained in the coulometric determination of the manganese in primary standard manganese(II) oxalate dihydrate, the relative standard deviation on six analyses being 0·349 parts per 1000; as the homogeneity problem is minimal with a pure material, we take this as the precision of the coulometric method. The next best precision was obtained in the titrimetric determination of manganese in ISU 600, relative standard deviation 0·62 parts per 1000. Lacking other evidence we assume this to be both the precision of the titrimetric method and evidence that the sample is blended to at least this degree of homogeneity. Poorer precision in the results for other materials may be interpreted as inhomogeneity in the sample; this was particularly noticeable in NBS 68 Ferromanganese, unless very large samples were used.

The sum of chromium and vanadium was determined in all of the reference materials analysed for manganese. This correction was made for the materials analysed by the titrimetric method by using the same procedure as for manganese but omitting the phosphoric acid. In all cases the first drop of 0·025*N* iron(II) sulphate was sufficient to bring the solution to the diphenylaminesulphonic acid end-point and the correction was thus zero. The correction became appreciable in those samples analysed by the coulometric method, owing to the increased precision and accuracy.

The analysis of the various reference materials is, of course, only as accurate as the standardizations. The standardizations of titrants used in the various analyses are listed in Table III, and in all cases show a relative standard deviation of less than 3 parts per 1000. In all cases where manganese(II) oxalate dihydrate was used as a standard an additional reference material was used to check the results, and hence the agreement of results obtained with manganese(II) oxalate dihydrate, ammonium hexanitratocerate, potassium dichromate and electrolytic iron constitutes further support for the use of manganese(II) oxalate dihydrate as a primary standard.

ISU 600 Manganiferous Iron Ore. Correction for chromium plus vanadium was negligible (titrimetric method) and we propose 19·60% manganese as a provisional value for this sample until results by others accumulate.

NBS 25b Manganese Ore. Results by the titrimetric method are in agreement with the NBS value. Correction for chromium plus vanadium was negligible although NBS reports 0·05% Cr_2O_3 (equivalent to 0·1% manganese) and 0·02% V_2O_5 (equivalent to 0·007% manganese).

NBS 66 Spiegeleisen. This material was analysed for both manganese and iron by successive titration with titanium(III) sulphate. The value obtained for manganese agrees fairly well with the NBS value but that for iron is higher than the NBS value by 0·11%. The precision for both manganese and iron was poor, far below that inherent in the method as indicated by the analysis of other materials. The results reported by the NBS collaborators range from 19·84 to 20·05% manganese. The lower precision may result from inhomogeneity in the sample or from the size of the sample, which was chosen so that both manganese and iron were determined with one loading of a 50-ml burette; the relative error in the volumes measured was thus not minimized as is possible by adjustment of the size of the sample when a single component is determined.

The correction found for chromium plus vanadium was negligible; NBS reports

TABLE III.—STANDARDIZATION OF TITRANTS USED IN ANALYSIS OF REFERENCE MATERIALS

Titrant	Primary standard	Mean normality found	No. of variates	Relative standard derivation, *parts per 1000*

Iron(II) sulphate (used in analysis of manganese(II) oxalate dihydrate)	Potassium dichromate	0·02632	6	1·2
Titanium(III) sulphate (used in analysis of NBS 66 and ISU 600)	Electrolytic iron*	0·1238	6	2·8
	Manganese(II) oxalate dihydrate	0·1236	6	2·0

* G. Frederick Smith Chemical Company; ignited in moist hydrogen.

0·009% chromium and 0·012% vanadium (equivalent together to 0·04% manganese).

NBS 68 *Ferromanganese.* Results on 0·1-g samples of this material were erratic, indicating serious segregation in the sample, not at all surprising in a ferroalloy. Satisfactory results were obtained by taking suitable aliquots after dissolution of a 1-g sample and dilution to 100 ml. The determination was concluded coulometrically; the correction for chromium plus vanadium amounted to 0·15% as manganese (NBS reports 0·025% chromium, equivalent to 0·075% manganese, and 0·075% vanadium, equivalent to 0·075% manganese, total 0·150% manganese). Preliminary determinations of the correction gave values appreciably greater than expected; this was traced to the presence of phosphorus in the sample (NBS reports 0·3% phosphorus) and the formation of manganese(III) pyrophosphate. This manganese(III) was reduced by boiling with hydrochloric acid (see above under *Interference of chromium and vanadium*) in determining the correction reported in Table II.

Manganese(II) oxalate dihydrate ($MnC_2O_4.2H_2O$, *m.w.* 178·99). The manganese in the primary standard material was determined by both the titrimetric and the coulometric methods, the increased accuracy and precision obtainable by the latter being clearly evident in the results.

NBS 100 *Manganese Rail Steel.* The manganese in this sample was determined spectrophotometrically, the blank (solution in the reference cell) being a sample of NBS 100 of identical size, carried through the dissolution and oxidation operations and then manganese(III) reduced with hydrochloric acid to manganese(II) as described above. NBS reports 0·180% chromium and 0·011% vanadium in this sample.

Zusammenfassung—Mangan wird in einem siedenden Gemisch gleicher Teile Überchlorsäure und Phosphorsäure quantitativ zu einem violetten dreiwertigen Pyrophosphat oxidiert. Dieses Mangan(III) kann potentiometrisch oder coulometrisch mit Eisen(II) titriert oder spektrophotometrisch gemessen werden. Wird die Titration mit Titan(III) oder Chrom(II) ausgeführt, so kann Eisen direkt nach dem Mangan titriert werden. Die Methoden wurden auf eine neue Referenzprobe, das manganführende Eisenerz ISU 600, auf Manganerz, Spiegeleisen, Ferromangan und Schienenstahl angewandt. Mangan(II)oxalat-Dihydrat wurde als primärer Standard nachgeprüft und wird sehr empfohlen.

Résumé—On oxyde quantitativement le manganèse en un pyrophosphate trivalent violet dans un mélange bouillant d'acide perchlorique et d'acide phosphorique en parties égales. On peut titrer ce manganèse(III) par potentiométrie ou coulométrie avec le fer(II); on peut aussi le doser par spectrophotométrie. Si la méthode titrimétrique est menée avec le titane(III) ou le chrome(II), on peut aussi titrer le fer immédiatement après le manganèse. On a appliqué ces méthodes à un nouvel échantillon de référence, le minerai de fer ISU 600 manganiferreux, et au minerai de manganèse, au spiegeleisen, au ferromanganèse et à l'acier pour rail. On a réétudié l'oxalate de manganèse(II) dihydraté en tant qu'étalon primaire et le recommande fortement.

ELEMENTS DE FLUORIMETRIE ORGANIQUE FONCTIONNELLE

M. PESEZ et J. BARTOS
Centre de Recherches Roussel-Uclaf, 93-Romainville, France

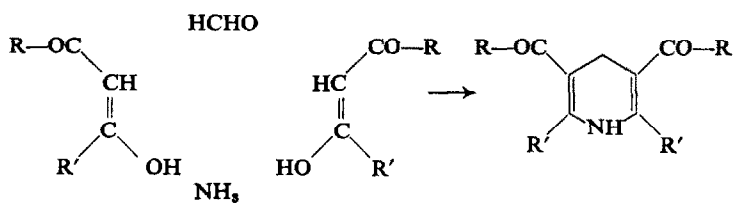
(*Reçu le* 3 *Mars* 1967. *Accepté le* 14 *Avril* 1967)

Résumé—Par des traitements chimiques convenables les 1,2-diols, hexitols, alcools primaires α-aminés, dérivés 2-nitroaliphatiques 1-hydroxylés, dérivés éthyléniques en R—CH=CH_2 et 17-cétolstéroïdes libèrent du formaldéhyde qu'on condense en un dérivé de la dihydrolutidine dosable par fluorimétrie. La formation de dérivés de la dihydropyridine autorise également la fluorimétrie des alcoylamines primaires, des nitriles et des aldéhydes aliphatiques. Les aldéhydes α-méthyléniques et les 2-désoxy oses sont dosables par cyclisation en quinaldines. Le composé fluorescent que donne l'acide glyoxylique avec le résorcinol permet d'accéder au dosage des acides α,β-dihydroxylés et hexuroniques après leur oxydation periodique. La fluorimétrie des phénols est réalisée par conversion en coumarines.

ON SAIT que l'étude spectrale des lumières incidente et émise a permis le développement de la spectrofluorimétrie au cours de ces dix dernières années. Les recherches dans ce domaine ont été nombreuses, aussi bien sur les composés à fluorescence native que sur ceux pouvant l'acquérir à l'aide d'une réaction chimique convenable. Les applications sont toutefois restées limitées, dans ce dernier cas, à des composés particuliers sans évoquer pratiquement l'extension à l'analyse fonctionnelle.

La connaissance des schémas réactionnels apparaît cependant aussi fructueuse en fluorimétrie qu'en colorimétrie. Selon nos essais, une étude théorique préalable peut permettre, en effet, par une réaction chimique portant sur la fonction à doser, d'accéder à une structure fluorescente. Par ailleurs, la fluorimétrie de composés simples, tels que le formaldéhyde ou l'acide glyoxylique, peut être étendue à des groupes fonctionnels susceptibles de les former intermédiairement. Ainsi, le choix, dans l'ensemble des possibilités réactionnelles déjà connues, apporte les différentes sélectivités dont nous faisons état dans ce premier mémoire.

La réaction de Hantzsch, par condensation du formaldéhyde sur une β-dicétone ou un ester β-cétonique en présence d'ammoniac, conduit aux dérivés substitués de la



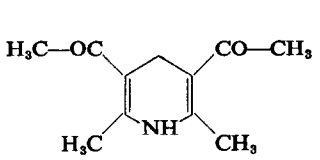
dihydropyridine. D'abord utilisée par Nash[1] et Belman[2] pour le dosage du formaldéhyde à l'aide d'acétylacétone et d'ammoniac, la cyclisation a été inversement appliquée à la colorimétrie des amines primaires aliphatiques[3] qui apportent l'azote hétérocyclique.

En fluorimétrie fonctionnelle, on peut retenir sur ce principe trois réactifs:

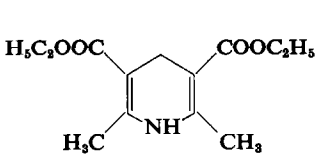
(*a*) l'acétylacétone qui, avec le formaldéhyde et l'ammoniac, forme la diacétyl-3,5 dihydro-1,4 lutidine (I), dont les solutions colorées en jaune montrent une fluorescence jaune-vert;

(*b*) l'acétylacétate d'éthyle, dont la condensation dans les mêmes conditions conduit à la dicarbéthoxy-3,5 dihydro-1,4 lutidine (II), substance aux solutions incolores mais fluorescentes en bleu:

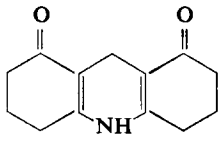
(*c*) la cyclohexane dione-1,3, qui autorise l'accès à la dioxo-1,8 décahydroacridine (III) fluorescente en bleu en milieu acide, en jaune-vert en milieu alcalin.



(I)

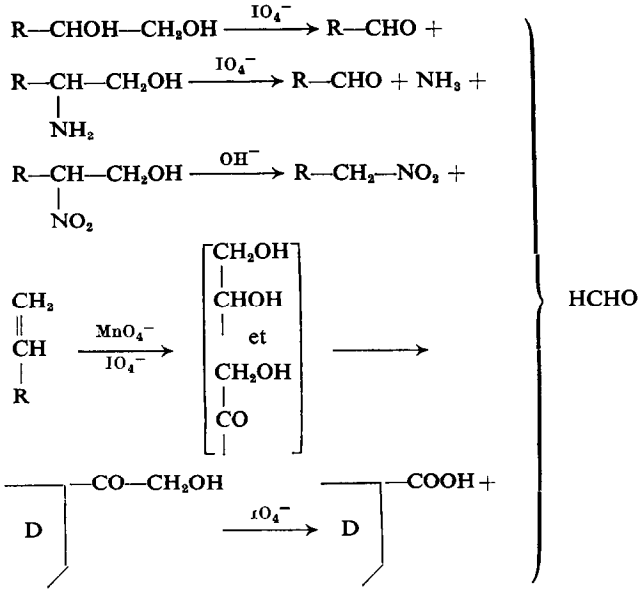


(II)



(III)

Plusieurs groupes fonctionnels sont susceptibles de donner naissance à du formaldéhyde par traitement convenable. Tel est le cas de l'oxydation periodique des diols-1,2, des hexitols et des alcools primaires α-aminés, de la décomposition alcaline des dérivés nitro-2 aliphatiques hydroxylés-1, de l'hydroxylation, puis de l'oxydation du glycol ou du cétol formé par action d'un réactif periodate-permanganate sur les dérivés éthyléniques en R—CH=CH_2, enfin de l'oxydation des cétol-17 stéroïdes (libres) par l'ion periodate.

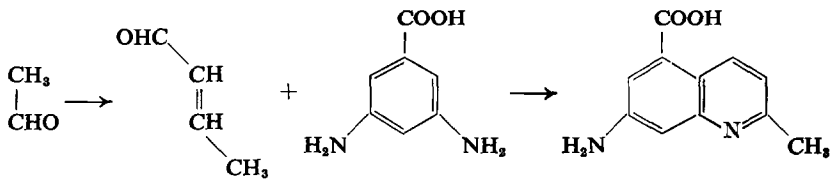


Dans ces différents cas, c'est l'acétylacétate d'éthyle que nous avons choisi comme réactif, et c'est donc la formation de la lutidine (II) qui a été mesurée.

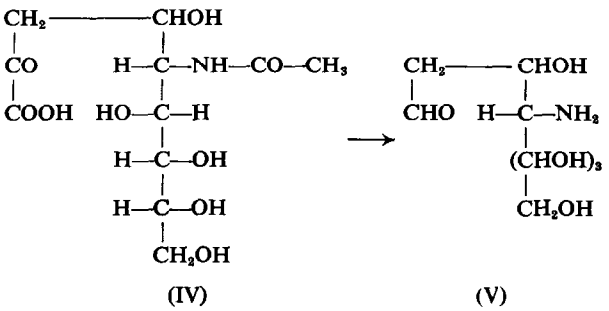
La réaction est inversement applicable à la fluorimétrie des alcoylamines primaires, avec formation de dihydrolutidines N-substituées. L'étalon alors utilisé est la lutidine (I), obtenue à partir de l'acétylacétone.

Les nitriles, qui sont aisément réduits par les hydroborures alcalins et le palladium en amines primaires,[4] bénéficient de la fluorimétrie précédente.

En remplaçant le formaldéhyde dans la réaction de Hantzsch, les aldéhydes aliphatiques peuvent aussi former des hétérocycles azotés. Le réactif de choix est dans ce cas la cyclohexane dione-1,3, et les composés fluorescents obtenus sont les alcoyl-9 dioxo-1,8 décahydroacridines. Nous rappelons ici que, par action de l'acétaldéhyde sur l'acide diamino-3,5 benzoïque, une quinaldine, la méthyl-2 carboxy-5 amino-7 quinoléine, a été isolée. Sa structure, que nous avons précisée en 1948, fait apparaître l'intervention du méthylène voisin du carbonyle, suivant le schéma de Doebner–Miller.[5]



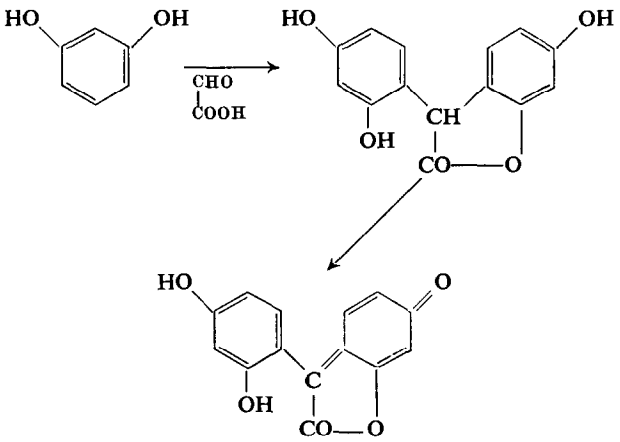
De ce fait, seuls les aldéhydes en R—CH_2—CHO sont capables de développer la fluorescence jaune-vert des amino-7 quinaldines.[6] La réaction a été appliquée au dosage du semi-aldéhyde succinique[7] ainsi qu'à celui des desoxy sucres, en particulier du désoxy-2 D-glucose[8,9] du désoxy-2D-ribose et, partant, de l'acide désoxyribonucléique.[10,11] L'acide sialique ou N-acétylneuraminique (IV) est un acide α-cétonique que l'on décarboxyle et désacétyle aisément à chaud en milieu acide en désoxy-2 amino-4 octose (V), aldéhyde en R—CH_2—CHO qui fournit alors la réaction diaminobenzoïque.[12]



(IV) (V)

Une réaction que nous avons obtenue avec le résorcinol est caractéristique de l'acide glyoxylique. Le produit de condensation s'est révélé être la lactone de l'acide tétrahydroxy-2,2',4,4' diphénylacétique, dont l'oxydation en milieu alcalin conduit à une structure quinonique fluorescente en jaune-vert. L'identification de la lactone montre que le schéma réactionnel ne peut s'appliquer qu'à l'acide aldéhydique le plus simple, l'acide glyoxylique, expliquant de ce fait la spécificité de la réaction.[13,14]

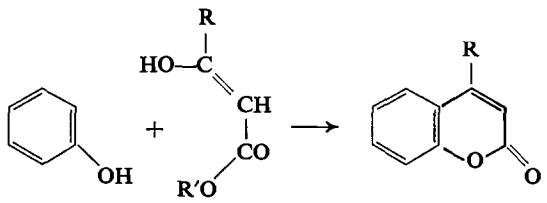
Plusieurs composés fournissent l'acide glyoxylique par une réaction chimique préalable. C'est ainsi que cet acide aldéhydique est aisément et sélectivement obtenu par réduction de l'acide oxalique à l'aide de l'amalgame d'aluminium ou du couple zinc-cuivre,[13] par deshalogénation de l'acide dichloracétique par l'hydrazine,[15] ou encore par oxydation de l'acide acétique par l'ion periodate et l'eau oxygénée.[16]



En analyse fonctionnelle, les acides α,β-dihydroxylés et en particulier les acides hexuroniques formant de l'acide glyoxylique par oxydation periodique sont aisément dosés par fluorimétrie:

$$R—CHOH—CHOH—COOH \rightarrow R—CHO + CHO—COOH.$$

Suivant le schéma de Von Pechmann-Duisberg, les esters β-cétoniques se condensent sur les phénols, en présence d'acide sulfurique, avec formation de coumarines.



La réaction est déjà classique pour le dosage de l'acétylacétate d'éthyle à l'aide du résorcinol avec formation de méthylombelliférone. Mais elle donne également accès à une fluorimétrie de l'hydroxyle phénolique, les coumarines formées étant révélées par leur fluorescence bleue.

PARTIE EXPÉRIMENTALE*

Expression de la sensibilité en fluorimétrie

Alors qu'en colorimétrie la sensibilité d'une réaction peut être définie par la quantité de substance nécessaire pour obtenir, en cuve de 1 cm d'épaisseur par exemple, une densité optique de 0,3 (50% de transmission), la réponse des fluorimètres ne conduit pas à une expression en valeur absolue. On ne peut accéder à celle-ci qu'au moyen de mesures complémentaires suivies de calculs.[17]

Pour l'analyste désirant simplement effectuer un dosage, il apparaît plus significatif de mentionner, d'une part, les limites des prises d'essai pour lesquelles l'intensité de fluorescence est linéairement proportionnelle à la concentration et, d'autre part, les prises d'essai de substance étudiée (en μg) et d'étalon (en μg/ml) pour obtenir la même réponse de l'appareil. Nous avons choisi arbitrairement les concentrations qui, dans nos conditions opératoires, correspondent à 50% de l'échelle d'étalonnage de l'appareil de mesure.

* Avec Mme C. Colombat, Mme P. Balleydier et Melle M. Pépin.

Ces données permettent le réglage, à l'aide de l'étalon d'autres fluorimètres pour obtenir, avec les prises d'essai indiquées, des mesures aisément comparables aux nôtres.

Nos lectures ont été effectuées avec le fluorimètre Electro Synthèse (France) muni de filtres interférentiels pour l'excitation et d'un monochromateur interférentiel pour l'émission. Les longueurs d'onde de la lumière excitatrice se situent ainsi à 366, 405, 436 et 546 mμ, et sont accessibles aussi bien avec les lampes à mercure qu'avec l'arc au xénon.

Il est toujours préférable d'utiliser comme étalon la substance fluorescente obtenue dans la réaction, ou tout au moins une substance dont la longueur d'onde d'émission maximale est très proche de celle de l'essai. En principe, l'excitation à longueur d'onde maximale serait souhaitable. Toutefois, pour les fluorimétries fonctionnelles, les composés formés peuvent avoir des spectres d'excitation différents. C'est en particulier le cas des condensats que donnent les aldéhydes aliphatiques avec la cyclohexane 1,3-dione. Il est dès lors préférable d'adopter pour l'excitation la longueur d'onde la plus proche du maximum du spectre de l'étalon.*

Comparée aux colorimétries usuelles,[18] la sensibilité des méthodes que nous décrivons ici apparaît 10 à 100 fois plus grande.

Préparation des étalons

Diacétyl-3,5 *dihydro*-1,4 *lutidine(I)*, *dicarbéthoxy*-3,5 *dihydro*-1,4 *lutidine(II)*, *dioxo*-1,8 *décahydroacridine(III)*. Ces composés ont été précédemment décrits.[19–21] Un mode opératoire commun a été retenu.

On dissout 3 g d'acétate d'ammonium et 1 ml de solution aqueuse à 30% de formaldéhyde dans 50 ml d'eau et ajoute 0,02 mole de β-dicétone ou d'ester β-cétonique. Après chauffage à reflux, 10 mn avec l'acétylacétone et l'acétylacétate d'éthyle, 30 mn avec la cyclohexane dione-1,3, on refroidit à 0° pendant 2 h, essore et sèche sous vide sulfurique. Les rendements sont respectivement de 62, 45 et 30%.

Les composés (I) et (II) sont recristallisés dans 20 ou 14 volumes d'éthanol avec traitement au noir. Rendements: 62 et 59%.

Le composé (III) est mis en suspension dans 12 volumes d'éthanol puis on ajoute 26 volumes de solution éthanolique *N* de potasse, traite au noir et acidifie par l'acide acétique jusqu'à virage au jaune clair de la solution orangée (environ 3 ml). Après 2 h de repos à 0°, on essore, lave avec le minimum d'éthanol et sèche sous vide sulfurique. Rendement: 64%.

On peut également recristalliser en présence de noir dans 370 volumes d'éthanol. Rendement: 61%.

Composé (I), F = 230°; composé (II), F = 192–193°; composé (III), ne fond pas à 300°.

Comparaison avec lesé talons fluorimétriques classiques: sulfate de quinine à $2H_2O$ et fluorescéine sodique:

(*a*) Diacétyl-3,5 dihydro-1,4 lutidine (I). Solution dans l'alcool aqueux à 50%. Excitation (Ex) = 436 mμ; maximum du spectre d'émission (Fl) = 510 mμ. La solution à 1 μg/ml fournit la même réponse que la solution aqueuse à 0,054 μg/ml de fluorescéine sodique.

(*b*) Dicarbéthoxy-3,5 dihydro-1,4 lutidine (II). Solution aqueuse à 1,2 ou 3% d'éthanol; Ex = 366 mμ; Fl = 470 mμ; 2 μg/ml = 0,3 μg/ml de solution de sulfate de quinine dans l'acide sulfurique 0,1*N*.

(*c*) Dioxo-1,8 décahydroacridine (III). Fluorescence bleue: solution dans l'eau contenant 2% d'éthanol; Ex = 366 mμ; Fl = 470 mμ; 0,5μg/ml $\equiv$ 1,87 μg/ml de solution de sulfate de quinine dans l'acide sulfurique 0,1*N*. Fluorescence jaune-vert: solution dans le mélange éthanol 2 ml, lessive de soude 20 ml, eau pour 100 ml; Ex = 436 mμ; Fl = 520 mμ; 1 μg/ml = 0,57 μg/ml de solution aqueuse de fluorescéine sodique.

Méthyl-2 *carboxy*-5 *amino*-7 *quinoléine*. Préparée selon Velluz *et al.*[23] Solution dans l'eau contenant 10% v/v d'acide acétique; Ex = 405 mμ; Fl = 495 mμ; 0,3 μg/ml = 3,6 μg/ml de fluorescéine sodique en solution aqueuse.

Techniques fluorimétriques

Diols-1,2 *et hexitols, alcools primaires* α-*aminés*

Principe. Oxydation periodique, puis fluorimétrie du formaldéhyde obtenu par condensation sur l'acétylacétate d'éthyle et l'ammoniac: fluorescence bleue.

Réactifs. (*a*) Solution aqueuse 0,05*N* de métaperiodate de sodium. (*b*) Solution de 2,35 g de chlorure stanneux (Cl_2Sn, $2H_2O$) dans 5 ml d'acide chlorhydrique concentré que l'on dilue à 100 ml avec de l'eau. (*c*) Solution à 4% v/v d'acétylacétate d'éthyle dans une solution aqueuse à 20 g pour 100 ml d'acétate d'ammonium.

* Déterminations effectuées avec le spectrofluorimètre Aminco-Bowman (American Instrument Co).

Mode opératoire. A 1 ml de solution aqueuse d'un dialcool, on ajoute 0,5 ml de réactif *a* et, après 30 mn de repos à température ordinaire, 0,5 ml de réactif *b* puis 2 ml d'eau et 1 ml de réactif *c*, en agitant après chaque addition. On chauffe pendant 20 mn à 60°, laisse refroidir et filtre. Lecture à l'excitation 366 mμ, émission 470 mμ.

Etalon: solution de dicarbéthoxy-3,5 dihydro-1,4 lutidine dans l'eau à 2% d'éthanol.

Applications

Voir Tableau I

Dérivés nitro-2 aliphatiques hydroxylés-1

Principe. Décomposition en milieu alcalin en nitroalcane et formaldéhyde que l'on condense sur l'acétylacétate d'éthyle en présence d'ammoniac: fluorescence bleue.

Réactif. Solution à 2% v/v d'acétylacétate d'éthyle dans une solution aqueuse à 20 g pour 100 ml d'acétate d'ammonium.

Mode opératoire. A 1 ml de solution aqueuse de dérivé nitro-hydroxylé, on ajoute 1 ml de solution de soude 0,5*N* puis, après 5 mn de repos à température ordinaire, 1 ml d'acide chlorhydrique *N* et 1 ml de réactif. On chauffe à 60° pendant 20 mn et refroidit à température ordinaire dans un bain d'eau-glace. Lecture à l'excitation 366 mμ, émission 470 mμ.

Etalon: solution de dicarbéthoxy-3,5 dihydro-1,4 lutidine dans l'eau à 1% d'éthanol.

Applications

Dérivés éthyléniques en R—CH=CH_2

Principe. Par action d'un réactif periodate-permanganate, hydroxylation puis oxydation en formaldéhyde dosé comme précédemment: fluorescence bleue.

Réactifs. (*a*) Solution aqueuse 0,05*N* de métaperiodate de sodium. (*b*) Solution aqueuse 0,005*N* de permanganate de potassium. (*c*) Solution 0,1*N* d'arsénite de potassium (anhydride arsénieux, 4,945 g; solution *N* de potasse, 75 ml; bicarbonate de potassium, 40 g; eau, q.s.p. 1000 ml). (*d*) Solution à 2% v/v d'acétylacétate d'éthyle dans une solution aqueuse à 20 g pour 100 ml d'acétate d'ammonium.

Mode opératoire. A 1 ml de solution pyridinique de dérivé éthylénique, on ajoute 4 ml d'eau, 1 ml de réactif *a* et 1 ml de réactif *b*. Après 30 mn de repos à température ordinaire, on introduit 2 ml de réactif *c*, mélange et ajoute 2 ml de réactif *d*. On chauffe pendant 20 mn à 60° puis refroidit à température ordinaire dans un bain d'eau-glace. Lecture à l'excitation 366 mμ, émission 470 mμ.

Etalon: solution de dicarbéthoxy-3,5 dihydro-1,4 lutidine dans l'eau à 3% v/v d'éthanol.

Cétol-17 stérotdes

Principe. Oxydation periodique du cétol; le formaldéhyde est ici encore révélé par l'acétylacétate d'éthyle en présence d'ammoniac: fluorescence bleue.

Réactifs. (*a*) Solution aqueuse 0,01*M* de métaperiodate de sodium. (*b*) Solution de 0,25 g de chlorure stanneux ($Cl_2Sn, 2H_2O$) dans 100 ml d'acide chlorhydrique *N*, préparée extemporanément. (*c*) Solution à 4% v/v d'acétylacétate d'éthyle dans une solution aqueuse à 20 g pour 100 ml d'acétate d'ammonium.

Mode opératoire. A 1 ml de solution d'un cétol dans l'eau à 2% d'éthanol, on ajoute 0,2 ml de réactif *a* puis, après 20 mn de repos à température ordinaire, 0,8 ml de réactif *b*, 0,8 ml de soude *N* et 1,2 ml d'eau dans l'ordre indiqué. Après addition de 1 ml de réactif *c*, on chauffe pendant 20 mn à 60°, laisse refroidir et filtre. Lecture à l'excitation 366 mμ, émission 470 mμ.

Etalon: solution de dicarbéthoxy-3,5 dihydro-1,4 lutidine dans l'eau à 2% d'éthanol.

Applications

Voir Tableau IV.

TABLEAU IV

Désoxycorticostérone	6–30	12,0	1,75
Cortisone	6–30	12,0	1,85
Prednisone	6–30	12,0	1,85
Prednisolone	8–40	17,0	2,05

Alcoylamines primaires

Principe. Formation de dihydrolutidines N-substituées par condensation sur l'acétylacétone et le formaldéhyde: fluorescence jaune-vert.

Réactif. A 10 ml de solution aqueuse *M* d'acétate de sodium, on ajoute extemporanément 0,8 ml d'acétylacétone et 2 ml de solution aqueuse à 30% de formaldéhyde. On dilue à 30 ml par l'eau.

Mode opératoire. A 2 ml de solution aqueuse sensiblement neutre d'amine, on ajoute 2 ml de réactif, bouche les tubes par un tampon de coton, chauffe pendant 10 mn au bain-marie bouillant à l'abri de la lumière vive et laisse refroidir à température ordinaire. Lecture à l'excitation 436 mμ émission 510 mμ.

Etalon: solution de diacétyl-3,5 dihydro-1,4 lutidine dans l'alcool à 50% v/v.

Applications

Voir Tableau V.

TABLEAU V

	Limites du dosage, μg	Lecture 50 Essai, μg	Lecture 50 Etalon, $\mu g/ml$

n-Butylamine	1–5	1,9	1,0
Benzylamine	1–5	2,2	1,65

Nitriles

Principe. Réduction par l'hydroborure de potassium, en milieu alcalin en présence d'un sel de palladium, avec formation d'amine primaire. Condensation comme ci-dessus.

Réactifs. (*a*) Solution à 0,2% d'hydroborure de potassium dans la soude *N*. (*b*) A 10 ml de solution aqueuse *M* d'acétate de sodium, on ajoute extemporanément 0,8 ml d'acétylacétone et 2 ml de solution aqueuse à 30% de formaldéhyde. On dilue à 30 ml par la solution aqueuse *M* d'acétate de sodium.

Mode opératoire. Dans 1 ml de solution hydroalcoolique de nitrile, on introduit 1 ml de réactif *a* et 0,05 ml de solution aqueuse à 0,5% de chlorure de palladium. Après 10 mn de repos à température ordinaire, acidification par 1 ml d'acide chlorhydrique 2*N* et agitation, cessation de dégagement gazeux, on ajoute 2 ml de solution aqueuse *M* d'acétate de sodium et 2 ml de réactif *b*. On chauffe pendant 10 mn au bain-marie bouillant, laisse refroidir et filtre. Lecture à l'excitation 405 mμ, émission 490 mμ.

Etalon: solution alcoolique de diacétyl-3,5 dihydro-1,4 lutidine.

Applications

Voir Tableau VI

TABLEAU VI

	Limites du dosage, μg	Lecture 50 Essai, μg	Lecture 50 Etalon, $\mu g/ml$
Benzonitrile	2–10	4,0	3,12
Cyanure de benzyle	3–15	6,0	3,03

La technique ne donne pas de bons résultats avec les nitriles qui, par réduction, conduisent à des amines relativement volatiles, comme par exemple l'acétonitrile.

Aldéhydes aliphatiques

Principe. Par action de la cyclohexane dione-1,3 en présence d'ammoniac, formation d'alcoyl-9 dioxo-1,8 décahydroacridines fluorescentes en bleu en milieu acide, en jaune-vert en milieu alcalin.

Réactif. On dissout 0,25 g de cyclohexane dione-1,3, 10 g d'acétate d'ammonium et 5 ml d'acide acétique dans 80 ml d'eau et complète à 100 ml par l'eau.

Mode opératoire. A 3 ml de solution aqueuse d'aldéhyde, on ajoute 1 ml de réactif, chauffe pendant 1 h à 60°, refroidit pendant 2 mn dans un bain d'eau-glace et ajoute, soit 1 ml d'eau (fluorescence bleue), soit 1 ml de lessive de soude 36° Bé (fluorescence jaune-vert).

Lecture à l'excitation 366 mμ, émission 470 mμ en milieu acide, excitation 436 mμ et émission 520 mμ en milieu alcalin.

Etalons: pour la fluorescence bleue, solution de dioxo-1,8 décahydroacridine dans l'eau à 2% d'éthanol; pour la fluorescence jaune-vert, solution de dioxo-1,8 décahydroacridine dans le mélange: éthanol 2 ml, lessive de soude 20 ml, eau q.s.p. 100 ml.

Applications

Voir Tableau VII.

TABLEAU VII

	Limites du dosage, µg	Lecture 50 Essai, µg	Lecture 50 Etalon, µg/ml
Lecture en milieu acide			
Formaldéhyde	0,5–2,5	1,0	0,51
Acétaldéhyde	0,2–1,0	0,45	0,56
Propionaldéhyde	0,3–1,5	0,62	0,44
Butyraldéhyde	0,6–3,0	1,20	0,47
Lecture en milieu alcalin			
Formaldéhyde	0,5–2,5	1,05	0,64
Acétaldéhyde	0,2–1,0	0,45	0,80
Propionaldéhyde	0,2–1,0	0,38	0,51
Butyraldéhyde	0,5–2,5	1,0	0,60

Remarque. L'isobutyraldéhyde, le citral, le glyoxal et l'acide glyoxylique réagissent beaucoup plus faiblement. Le benzaldéhyde peut être dosé entre 2 et 10 µg, avec émission à 455 mµ en milieu acide, lecture 50 pour 4 µg.

Aldéhydes en R—CH_2—CHO

Principe. Formation d'une dialcoyl-2,3 carboxy-5 amino-7 quinoléine, par action de l'acide diamino-3,5 benzoïque en milieu phosphorique; fluorescence jaune-vert.

Réactif. A 2 g de dichlorhydrate d'acide diamino-3,5 benzoïque, on ajoute 10 ml d'acide phosphorique (d = 1,62) et dilue à 20 ml par l'eau.

Mode opératoire. A 2 ml de solution aqueuse d'aldéhyde, on ajoute 2 ml de réactif. On chauffe pendant 30 mn à 50° à l'abri de la lumière vive, laisse refroidir à température ordinaire et ajoute 2 ml d'eau. Lecture à l'excitation 405 mµ, émission 495 mµ.

Etalon: solution de méthyl-2 carboxy-5 amino-7 quinoléine dans l'acide acétique dilué à 10% v/v par l'eau.

Applications

Acides α,β-dihydroxylés

Principe. Par oxydation periodique, formation d'acide glyoxylique révélé par condensation sur le résorcinol. La lactone formée s'oxyde à l'air en milieu alcalin: fluorescence jaune-vert.

Réactifs. (*a*) Solution aqueuse 0,05*M* de métaperiodate de sodium, ajustée à pH 10 par la soude *N*. (*b*) Solution 0,1*N* d'arsénite de potassium (anhydride arsénieux, 4,945 g; solution *N* de potasse, 75 ml; bicarbonate de potassium, 40 g; eau, q.s.p. 1000 ml). (*c*) A 50 ml de solution 0,1*N* de nitrate d'argent, on ajoute 5 ml de soude *N*. On lave le précipité par décantation, puis dissout et complète à 150 ml avec de la solution *N* d'acide sulfurique. (*d*) Solution aqueuse à 2% de résorcinol. (*e*) Solution aqueuse saturée de bicarbonate de potassium.

Mode opératoire. A 1 ml de solution aqueuse neutralisée d'acide α,β-dihydroxylé, on ajoute 0,2 ml de réactif *a* et, après 15 mn de repos à température ordinaire, 0,5 ml de réactif *b*. Après 20 mn de repos à température ordinaire, on ajoute 0,3 ml de réactif *c*, agite, dilue par 1 ml d'eau et filtre. A 1 ml du filtrat, on ajoute 1 ml d'acide chlorhydrique concentré (d = 1,19) puis 0,5 ml de réactif *d*. On chauffe pendant 20 mn à 60°, laisse refroidir dans un bain d'eau à température ordinaire, ajoute lentement en agitant 5 ml de réactif *e* et chauffe à 60° pendant 15 mn. On laisse refroidir à température ordinaire. Lecture à l'excitation 436 mμ émission 530 mμ.

Etalon: solution aqueuse de fluorescéine sodique.

Summary—By means of suitable chemical reactions, formaldehyde is obtained from 1,2-diols, hexitols, primary α-amino alcohols, 2-nitro-1-hydroxy aliphatic compounds, the methylene group in R—CH=CH_2 and 17-ketolsteroids, and converted into a dihydrolutidine derivative which is then determined by fluorimetry. The formation of dihydropyridine derivatives also allows the fluorimetric determination of primary alkylamines, nitriles and aliphatic aldehydes. Aldehydes with an α-methylene group and 2-deoxysugars can be determined by forming fluorescent quinaldines. The fluorescent compound obtained by condensing glyoxylic acid with resorcinol allows the determination of α,β-dihydroxy and hexuronic acids after a periodate oxidation. The fluorimetric determination of phenols is achieved by converting them into coumarins.

Zusammenfassung—Durch geeignete chemische Reaktionen erhält man Formaldehyd aus 1,2-Diolen, Hexiten, primären α-Aminoalkoholen, 2-Nitro-1-hydroxy-aliphaten, der Methylengruppe in R—CH=CH_2 und 17-Ketolsteroiden; der Formaldehyd wird in ein Dihydrolutidinderivat überführt, das dann fluorimetrisch bestimmt wird. Die Bildung von Dihydropyridinderivaten erlaubt auch die fluorimetrische Bestimmung von primären Alkylaminen, Nitrilen und aliphatischen Aldehyden. Aldehyde mit α-Methylengruppe und 2-Desoxyzucker können durch Bildung fluoreszierender Chinaldine bestimmt werden. Das fluoreszierende Produkt der Kondensation von Glyoxylsäure mit Resorcin erlaubt die Bestimmung von α,β-Dihydroxy- und Hexuronsäuren nach Perjodatoxidation. Phenole werden fluorimetrisch bestimmt durch Umwandlung in Cumarine.

NEUTRON ACTIVATION ANALYSIS BY STANDARD ADDITION AND SOLVENT EXTRACTION

DETERMINATION OF IMPURITIES IN ALUMINIUM

A. ALIAN and A. HAGGAG
Nuclear Chemistry Department, Atomic Energy Establishment, Inshas, U.A.R.

(*Received* 14 *August* 1966. *Revised* 7 *February* 1967. *Accepted* 9 *March* 1967)

Summary—A separation scheme based on selective extraction in conjunction with the standard addition technique has been developed for the determination of impurities in aluminium by neutron activation. Preliminary investigations have been carried out on the extractability of Sc, Co, Hf, Fe, Sn, Cd, Zn, Ag, Cr, Ce, Cs and Rb by TDA and TBP from acidic media. The best conditions are predicted for the separation of these elements into fractions suitable for analysis by gamma-ray spectrometry. Recovery values of ~90% were obtained for all the elements.

IN activation analysis, special techniques other than those involving the addition of inactive carriers have been used for yield determination. One such technique is the addition of a known amount of a carrier-free radioactive tracer to the sample after the irradiation.[1] When chemical yield corrections cannot be made owing to a lack of suitable carriers or tracers, the yields from standards and samples must be quantitative or equal. Selective and quantitative procedures have been proposed for the analysis of many elements.[2–4] In order to ensure equal yields from standards and samples a new method was developed previously.[5] The principle of the new approach and data on its application to the determination of uranium in aluminium and rocks were also reported.[6] In the present paper a general scheme has been developed for the radiochemical separation and analysis of the induced radionuclides in aluminium.

Many separation schemes, based on sequential ion-exchange fractionation, have been proposed for the activation analysis of impurities in aluminium.[2,7–9] The procedures involved however, are lengthy, even when automated. In the present study work has been carried out on elements giving rise to long-lived radioactive isotopes. Details of the elements are presented in Table I.

TABLE I

Element	Radioisotope determined	Half-life	Gamma energy, *MeV*
Scandium	^{46}Sc	85 d	0·89, 1·12
Cobalt	^{60}Co	5·3 y	1·17, 1·33
Hafnium	^{181}Hf	46 d	0·13, 0·34, 0·48
Iron	^{59}Fe	45·1 d	1·10, 1·29
Tin	^{113}Sn	112 d	0·39
Zinc	^{65}Zn	245 d	0·51, 1·12
Mercury	^{203}Hg	47 d	0·279
Silver	^{110}Ag	270 d	0·45, 0·68, 0·88, 1·39, 1·52
Chromium	^{51}Cr	27·8 d	0·32
Caesium	^{134}Cs	2·3 y	0·60, 0·79
Rubidium	^{86}Rb	18·6 d	1·08

Other elements that also give long-lived radionuclides are not included in the scheme because they are present at concentrations beyond determination. The extractability of some has, however, been studied.

EXPERIMENTAL

Irradiation

Aluminium samples (taken from the cans used for pile irradiation) were washed with dilute nitric acid, water and acetone and then dried. The chemicals used as standards were of high analytical purity including scandium oxide, cobalt nitrate, iron oxide, cadmium oxide, tin and zinc metals, silver nitrate, mercuric oxide, cerium oxide, chromic oxide, caesium and rubidium chlorides. Aluminium samples were carefully enclosed in thin aluminium foil. Suitable amounts of the standards in the solid form were weighed on ashless filter paper discs (about 2 cm diameter); the discs were carefully folded and enclosed in thin aluminium foil. Samples and standards were subsequently placed together in an aluminium can and irradiated in the UA-RR-1, 2MW Research Reactor at Inshas for 48 hr. The thermal flux is approximately $1{\cdot}3 \times 10^{13}$ neutrons/cm^2/sec. Samples were left to cool for about 10 days after irradiation to allow for decay of the induced short-lived activities.

Reagents

Tributylphosphate (TBP) was purified by washing with 5% sodium carbonate solution and water. Tri-n-dodecylamine (TDA), a high-purity product of Rhône-Poulenc, France, was used without further purification. TBP and TDA were used in the form of 50% and 20% solutions respectively, in xylene.

Apparatus

An ECKO scintillation counter with a $1{\cdot}75 \times 2$ in. sodium iodide (thallium) crystal (well-type) was used for determining the gross activity of the organic and aqueous phases and studying the extractability of the different components under various conditions.

A nuclear Chicago Single-Channel Model 132B analyser, with a 3×3 in. sodium iodide (thallium) crystal was used for measuring the photo-peak activities and the gamma-spectra.

Extraction experiments

The extractability of the various metals in the different extraction systems was studied by mixing the aqueous solutions of the given tracers with equal volumes (usually 5 ml) of the organic solvents till equilibrium was reached (about 30 min). Separation of the phases was enhanced by contrifugation. The degree of extraction was calculated by measuring the radioactivity of the tracer in both phases.

Extraction separations were carried out in pear-shaped separating funnels by shaking a known volume (usually 10 ml) of the sample solution or the subsequently separated fraction with the solvent or the stripping solution until equilibrium was attained ($\sim$1 min).

Processing of samples and standards

Solutions of irradiated aluminium samples (50 ml) were prepared by dissolving known amounts in concentrated hydrochloric acid to which had been added a few drops of concentrated nitric acid, heating to near dryness and then making about $1{\cdot}5M$ in hydrochloric acid and about $2{\cdot}5M$ in aluminium chloride. If a residue appeared the solution was filtered, and the residue was washed with a little acid until it was free from activity. Standards in the filter paper discs were carefully removed from the aluminium foil, transferred to 100-ml beakers and dissolved (see Table II). Each standard solution was filtered through a small sintered-glass filter, and the residue (filter paper disc) was washed several times with the solvent till free from activity. The filtrate and washings were then transferred back to the beaker, evaporated to near dryness, treated with about 10 ml of hydrochloric acid (1 + 1) (1N nitric acid in the case of Ag and Hg) and finally transferred to 50-ml graduated flasks. The beaker was washed several times (till free from activity) with the appropriate acid and the washings were transferred to the flask; the solution was then made up to the mark with the appropriate acid.

Procedures for dissolving the irradiated elements or compounds used in the preparation of standard solutions and tracers are presented in Table II.

Mechanism and conditions of extraction

In the method proposed by Růžička, Starý *et al.*,[10,11] designated substoichiometry, the induced radionuclide is selectively isolated from the sample solution and the standard by using a controlled amount of reagent in quantity less than that stoichiometrically corresponding to the amount of the

TABLE II.—PROCEDURES FOR PREPARING STANDARDS

‡ The amounts taken are not known.

element to be separated. Extraction with TDA and TBP is governed by a mechanism different from that governing extraction with chelating agents, since in the latter case extraction is mainly dependent on the hydrogen ion concentration and there is a threshold pH-value at which the best extraction is obtained.[12] Extraction with TDA and TBP, on the other hand, varies with change in the concentrations of acid, salting-out agents, and different anions and cations.[13–19] The application of such solvents therefore necessitates the extraction of the element under study from the sample solution and from the standard under the same conditions, and this can be achieved by the standard addition technique. Preliminary studies have shown that keeping a constant aqueous phase composition ensures that the same amount of the metal is always separated into the organic phase, with high precision. Data in Table III verify this for scandium extraction. Analogous results were obtained for the other radioisotopes.

TABLE III.—EXTRACTION OF ^{46}Sc

Original Sc activity, *cpm/ml*	Activity extracted, *cpm/ml*	Extraction, %
3244 ± 46	2704 ± 41	83·8
6080 ± 91	5055 ± 70	83·0
1698 ± 22	1411 ± 21	83·0
860 ± 14	712 ± 12	82·5

Moreover both accuracy and reproducibility are maintained for micro as well as macro concentrations. Because activation analysis deals basically with the determination of minute quantities of elements the change in the element concentration at such levels does not affect the degree of extraction. The extractability of a given element must also not be affected by the addition of minute amounts (of the order of the concentration of the standard) of other extractable elements. The solvent concentration is therefore selected so that at equilibrium the free solvent molarity is the same for extraction from a sample solution and that to which the standards have been added. This condition can be fulfilled by using higher solvent molarities. Preliminary studies have shown that the use of 20% TDA and 50% TBP satisfies this requirement. In Table IV are presented data on the extractability of the isotopes studied from a chloride medium with 20% TDA before and after spiking the solution (10 ml) with 1 ml of hydrochloric acid (1 + 1) containing 1, 5, 50, 8, 50, 1, 5, 2, 8, 1 and 1 μg/ml of Sc, Co, Fe, Sn, Cd, Zn, Hg, Ag, Ce, Cr, Cs and Rb, respectively.

* The aqueous phase was spiked with 1 ml of HCl(1 + 1) containing no additives.

Extractability and separation

Extraction of metals from various acidic media by TDA and TBP has already been investigated.[12,20] In the present paper data were obtained on the extractability of the given metals by TDA and TBP from different aqueous media in order to choose the best conditions of separation. The results presented in Tables V and VI show the degree of extraction from the aqueous solutions finally selected for the separation scheme.

From these results it is clear that with the exception of scandium, cerium (which was taken as representative of the other rare earths) chromium and the alkali metals, the elements are extracted almost quantitatively with TDA from 2·5*M* aluminium chloride–1·5*M* hydrochloric acid. Among

the elements that are extracted from this medium only hafnium and cobalt are not extracted by TDA from 2*M* hydrochloric acid; among the rest only iron and tin are not extracted from 3*M* hydrofluoric acid–0·5*M* hydrochloric acid and finally zinc is not extracted from 1*M* nitric acid.

Mercury and silver are almost quantitatively extracted from all media. Cadmium is partially extracted with TDA from 3*M* hydrofluoric acid–0·5*M* hydrochloric acid and from 1*M* nitric acid. From the elements that are not extracted with TDA from aluminium chloride–hydrochloric acid medium only scandium is extracted with TBP and can be selectively isolated with the latter.

Preliminary studies were also performed on the extraction of the induced isotopes from 10 ml of the irradiated aluminium sample solution in 2·5*M* aluminium chloride–1·5*M* hydrochloric acid. About 50% of the total gross activity is extracted by two 5 ml portions of TDA, 44% is subsequently extracted by two 5 ml portions of TBP and only ~6% of the total activity remains finally in the aqueous phase. This residual activity is from the isotopes induced from chromium, the rare earths and the alkali metals.

Procedure

The steps of the separation scheme are outlined in Fig. 1 and are described in more detail below.

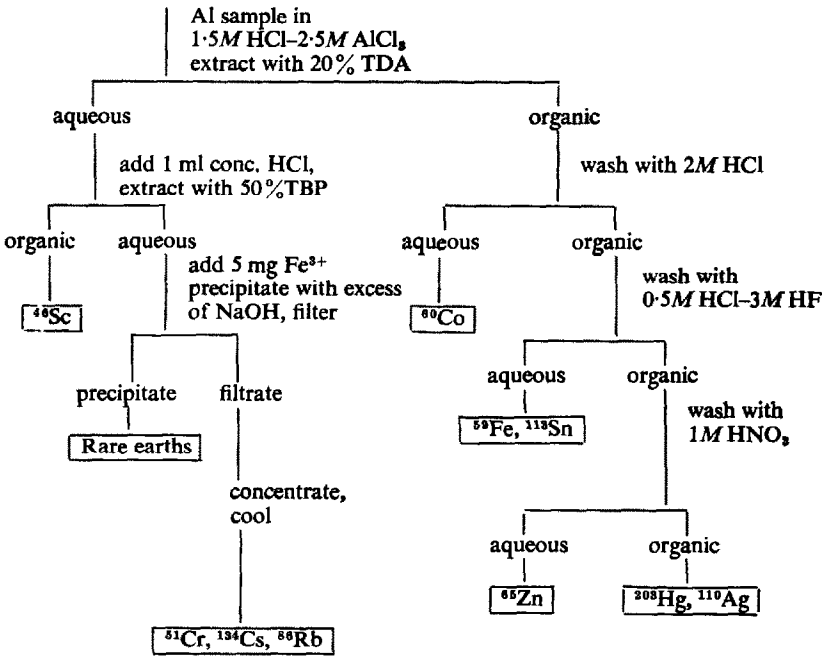

FIG. 1.—Separation scheme.

Take two equal aliquots (usually 10 ml) of the sample solution in two separating funnels (labelled 1 and 1′); add carefully to the first (solution A) 500 μl of hydrochloric acid (1 + 1) and 100 μl of 1*N* nitric acid and to the second (solution B) 50 μl of each standard solution. The acid content of the two solutions is thus equal. The amount of the standard may be varied according to the expected content in the sample. Transfer 5 ml of 20% TDA solution to each of the funnels, stopper then, shake them vigorously for 1 min and allow to stand until separation of the phases is complete (usually 3–5 min). Withdraw the aqueous phases into two other separating funnels (labelled 2 and 2′). Repeat the extraction with 5 ml of 20% TDA, allow to stand and separate the phases. Transfer the aqueous phases to two other separating funnels (labelled 3 and 3′), and add the organic phases to the first extracts in funnels 1 and 1′. According to the data in Table V the collected extracts contain almost all the induced Hf, Co, Fe, Sn, Cd, Zn, Hg and Ag activities.

Add 1 ml of concentrated hydrochloric acid and 5 ml of 50% TBP to each aqueous phase in funnels 3 and 3′, shake vigorously for about 1 min and allow the phases to separate; transfer the aqueous phases to funnels 2 and 2′ and the organic phases to two counting vials. Add 1 ml of concentrated hydrochloric acid to each aqueous phase, repeat the extraction with 5 ml of 50% TBP

and separate the phases. Transfer the aqueous phases to funnels 3 and 3′ for a third extraction with TBP in the case of higher scandium content or otherwise to two 100 ml beakers. Add the organic phases to the first TBP extracts in the counting vials (scandium).

Add 10 ml of 2*M* hydrochloric acid to the combined extracts from the first extraction in funnels 1 and 1′, shake for 1 min and allow the phases to separate. Withdraw the aqueous phases into two counting vials. According to the data in Table V the collected aqueous solutions should contain ~99% of the hafnium and cobalt present in the sample together with negligible proportions of iron and silver.

Add 10 ml of 3*M* hydrofluoric acid–0·5*M* hydrochloric acid to each of the organic phases from the previous extraction. Shake the funnels for 1 min, allow the phases to separate and withdraw the aqueous phases into counting vials (iron and tin). About 72% of cadmium, if present, will be recovered in this fraction.

Add 10 ml of 1*N* nitric acid to the organic phases in the funnel from the previous extraction, shake for 1 min, separate the phases and withdraw the aqueous solutions into counting vials (zinc).

Collect the organic phases from the previous extraction into two counting vials (silver and mercury).

Chromium, rare earths and the alkali metals are present in the aqueous phase from the second extraction. Check that no significant amount of scandium is left. This fraction may be analysed as recommended by Girardi and Pietra.[2]

Quantitative analysis

The quantitative determination of the elements by this method has been carried out by measuring the respective photo-peak activities in the fractions obtained. For this purpose identical vials were used and counting was done under the same geometrical conditions. The amount of metal (x) to be determined is calculated from:

$$x = \frac{x_s A}{(A_m - A)} \tag{1}$$

where x_s = the amount of metal in the added standard solution, A and A_m are the photo-peak activities in two fractions isolated from the sample (solution A) and from the sample to which is added the irradiated standard (solution B), respectively.

The validity of the method has been assessed by varying the value of x_s, *i.e.*, the amount of standard added, and then calculating the value of x. A calculated amount of acid was always added to solution A so as to make its composition the same as solution B. In the case of the presence of significant weighable) amounts of the elements to be determined and consequently the necessity of adding comparable amounts of standards, it is recommended to spike solution A with the calculated quantities of acid containing the same concentrations of unirradiated standards; this ensures equal yields from solutions A and B.

RESULTS AND DISCUSSION

The gamma-spectrum of an irradiated aluminium sample (Fig. 2) exhibited prominent peaks at 0·88 and 1·1 MeV. The gamma spectra of the isolated fractions show the photopeaks of the respective radionuclides. The spectra presented correspond to fractions isolated about two months after irradiation. It was found, however, that analysis can be performed 10–15 days after irradiation without any significant differences in the results, and better sensitivity is obtained. Curves 1 and 2 in Figs. 3–8 represent the gamma-spectra of the fractions obtained from two equal sample aliquots (12 ml containing 0·94 g of Al), one of which was spiked with 50, 150, 1500, 250, 150, 50, 200 and 100 μl of Sc, Co, Fe, (Sn), Zn, Ag, (Hg) and Cr irradiated standard solutions respectively, (curves 2); the equivalent amount of acid (2250 μl of hydrochloric acid (1 + 1) and 250 μl of 1*M* nitric acid) was added to the other solution (curves 1). separation was then completed as described. Tin-113 and mercury-203 isotopes were added in order to verify their separation by the given scheme. Results obtained on the quantitative analysis of trace elements in aluminium by standard addition and solvent extraction are presented in Table VII.

The rubidium concentration was evaluated from the relative activities of ^{51}Cr and ^{86}Rb as follows. The saturation activity of ^{51}Cr and ^{86}Rb (in disintegrations/min) obtained by the irradiation of 1 μg of the element in a flux of 10^{12} n cm^{-2} sec^{-1} is

(1) Sample, (2) Sample + standards.

$4{\cdot}1 \times 10^5$ and $2{\cdot}4 \times 10^5$, respectively. The corresponding activity for the photo-peaks at 0·325 and 1·08 MeV is $1{\cdot}4 \times 10^4$ and $2{\cdot}6 \times 10^3$ respectively.[2] The ratio of the two photo-peak activities is then equal to 5·4. This ratio is not changed by changing the neutron flux. For 48-hr irradiation, where the growth factors (A_t/A_∞) for ^{51}Cr and ^{86}Rb are 0·05 and 0·07, respectively, this ratio will be 3·86. After two months' decay the ratio becomes approximately 8. The ratio of the photo-peak activities of the isolated ^{51}Cr and ^{86}Rb is seen from Fig. 8 to be about 90; then the Rb concentration can be evaluated as about 0·5 ppm.

(1) Sample, (2) Sample + standards.

The tin and mercury concentrations may be similarly calculated on the basis of the iron and silver concentrations determined, but only after correcting for the activity resulting from the higher-energy components ^{59}Fe and ^{110}Ag (Figs. 5 and 7).

Although a check on the half-lives has been made by measuring the photo-peak activities for some of the nuclides (^{86}Rb, ^{51}Cr, ^{59}Fe) at varying intervals of time within 2–5 months, the identities of the product nuclides have been confirmed by comparing the shapes of the photo-peaks with those of irradiated reference standards.

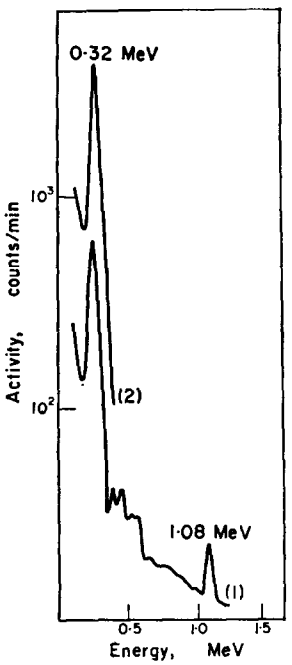

FIG. 8.—Gamma-ray spectrum of the aqueous phase (^{51}Cr, ^{86}Rb).
(1) Sample, (2) Sample + standards.

As expected from the data in Tables V and VI difficulties due to cross-contamination are not serious in the given concentration range. Although interference from other long-lived nuclides, not included in the scheme, has not been considered, they are expected (from available extraction data) to contaminate only some of the fractions and to be subsequently separable. Thus the gamma spectrum presented in Fig. 4 shows beside the photo-peaks of ^{60}Co another low-energy component (at 0·31 MeV), which is most probably ^{233}Pa produced from thorium. It follows from the other gamma spectra that aluminium does not contain other interfering elements. In the application of the scheme for the determination of these elements in more complex materials such as rocks and soils, further studies will be required in order to take care of other interferences. Additional extraction or elution steps will be also required in the case of higher content of one of the elements in order to minimize contamination of the subsequent fractions.

The results obtained by the method standard addition and solvent extraction agree well with those obtained by the conventional method.

The results obtained on the determination of scandium and zinc in aluminium by the

standard addition technique are presented in Tables VIII and IX. These results show that the method gives satsifactory precision.

The method reported can also be used for the rapid determination of individual elements and in that respect it is also more simple and selective than the other methods. Thus for the determination of scandium, for example, samples are irradiated together with a scandium standard and the chemical procedure consists of: (1) processing of samples and the standard as described before, (2) preliminary separation of hafnium, cobalt, iron, tin, zinc, cadmium, silver and mercury by extraction with TDA and (3) selective extraction of scandium with TBP.

From the relative activities isolated (see the photo-peaks in Figs. 3–8) it is to be noted that most of the induced activity in aluminium is due to the presence of scandium, zinc, chromium, iron, cobalt and silver. Moreover the activity produced decreases in the order given. Fortunately the elements mentioned are isolated by the method given with a very high selectivity and they could be determined with a high precision (see Tables VIII and IX). The remaining elements are determined with lower

precision; these elements are of less importance, however, since they make only a small contribution to the induced activity in aluminium. The sensitivity of this method is very high for most of the elements given and can be further increased by carrying out the analysis immediately after the decay of the short-lived activities.

Zusammenfassung—Ein Trennungsgang zur Bestimmung der Verunreinigungen in Aluminium durch Neutronenaktivierung wurde entwickelt. Er beruht auf selektiver Extraktion und dem Zustatz eines Standards. Es wurden Voruntersuchungen über die Extrahierbarkeit von Sc, Co, Hf, Fe, Sn, Cd, Zn, Ag, Cr, Ce, Cs und Rb mit TDA und TBP aus sauren Medien ausgeführt. Die optimalen Bedingungen zur Trennung dieser Elemente in zur Analyse durch Gamma-Spektrometrie geeignete Fraktionen werden vorhergesagt. Für alle Elemente wurden Ausbauten über 90% erzielt.

Résumé—On a élaboré un schéma de séparation basé sur l'extraction sélective en liaison avec la technique d'addition d'étalon pour le dosage des impuretés dans l'aluminium par activation de neutrons. Des essais préliminaires ont été menés sur l'extractibilité de Sc, Co, Hf, Fe, Sn, Cd, Zn, Ag, Cr, Ce, Cs et Rb par le TDA et le TEP à partir de milieux acides. On laisse prévoir les meilleures conditions pour la séparation de ces éléments en fractions convenant à l'analyse par spectrométrie de rayons gamma. On a obtenu des valeurs de récupération ~90% pour tous les éléments.

SHORT COMMUNICATIONS

Photometrische Bestimmung von Kupfer mit Polyäthylenimin

(*Eingegangen* 6 *März* 1967. *Angenommen* 18 *April* 1967)

PHOTOMETRISCHE Bestimmungen von Kupfer(II)-Koordinationsverbindungen erfordern unbequeme Abtrennungen von den Ionen Al(III), Fe(III), Cr(III), sowie auch von Ni(II), Co(II), Mn(II), sofern mit Ammoniak oder auch Aminen, wie Tetraäthylenpentamin,[1] gearbeitet wird.

Polyäthylenimine (PEI) bilden nach Thiele und Gronau[2] mit Cu(II) Komplexe, in denen der Stickstoff des PEI als Donator fungiert. Die Untersuchung der Reaktion von PEI mit anderen Übergangsmetallionen zeigte nunmehr, dass eingangs genannte Ionen und auch Mg(II), Hg(II), Pd(II) *etc.* insbesondere bei Reagensüberschuss auch bei pH 7 keine schwerlöslichen Produkte liefern.

PEI zeigt allgemein die Reaktionen sekundärer Amine. Es liefert mit Schwefelkohlenstoff in Wasser schwerer lösliche Carbate,* die mit Natriumcarbonat oder verd. Alkalilaugen aber leicht in Lösung gebracht werden können. Salpetrige Säure reagiert mit PEI unter Nitrosamin-Bildung und Abscheidung gelblicher Produkte.* Quecksilberjodid und Arsen(III)sulfid werden ebenso gelöst, wie dies auch durch andere sekundäre Amine, z.B. Dibutylamin, erfolgt.

Die Farbreaktion mit Cu(II) (λ_{max} 645 mμ) zeigt Konstanz im pH-Bereich 2,5–7,0. Die Gegenwart von 2% Natriumchlorid in Probelösungen erhöht den Extinktionskoeffizienten ($\varepsilon = 230$) im pH-Gebiet 3–5, und dieser zeigt dann in Lösungen bis zu 10%ig an Natriumchlorid keine Veränderung mehr. Der Erhöhung des Extinktions-koeffizienten ist auf den Abbau der Wasser-Koordination zurückzuführen. Abhängigkeiten der Lage λ_{max} vom Reagensüberschuss, wie diese für die Reaktionen von Cu(II) mit Ammoniak bzw. Äthylendiamin zu beobachten sind, treten bei der Benutzung von PEI nicht auf. Der Extinktions-koeffizient übertrifft die der Kupfer-Ammin-Reaktion um das Fünffache. Die Farb-Konstanz beträgt innerhalb der Grenze von 1% etwa 48 Stunden. Im Bereich 0,4–4 mg Cu/100 ml folgt die Lichtabsorption streng dem Lambert-Beerschen Gesetz.

EXPERIMENTELLER TEIL

Reagentien

Reagens-Lösung. Polyäthylenimin (200 g 50%ig Wässrige Lösung) werden unter stärkerem Rühren mit Wasser auf 1 l. verdünnt. Von der erhaltenen opaleszierenden Lösung werden 100 ml mit 80–90 ml 2n Salzsäure auf den pH-wert 1–2 eingestellt. Diese Lösung ist mehrere Wochen haltbar. Eine langsam auftretende geringe Trübung kann vor Gebrauch mit einem Faltenfilter abgetrennt werden.

Pufferlösung. Natriumchlorid *p.a.* (200 g), Natriumacetat *p.a.* (50 g) und Eisessig *p.a.* (160 ml) werden in Wasser zu 1 l. gelöst.

Arbeitsvorschrift

Die durch Abdampfen oder Neutralisieren mit Natriumhydroxid von grossen Überschüssen an Mineralsäuren befreite salz- oder salpetersaure Probelösung, welche etwa 0,1–1 mg Kupfer in 10 ml enthält, wird im Messkolben von 25 ml Inhalt mit 5 ml Reagenslösung vermischt, und sofern noch keine intensivere Blaufärbung aufgetreten ist, mit kleinen Anteilen gesättigter Natriumacetat-Lösung versetzt. Es soll ein pH-Wert im Bereich 3–6 vorhanden sein. Man fügt dann 5 ml Pufferlösung hinzu, füllt bis zur Marke auf, und photometriert bei 645 mμ in Glasküvetten von 5 cm Schichtlänge mit einem Spektral-, oder auch Filter-Photometer gegen einen Blindansatz der Reagentien.

* Über die Reaktionen der PEI-Carbate und PEI-Nitrosamine, desgleichen über die von PEI-Cellulose und von Cellulose-PEI-Carbat wird berichtet werden.

Spezifität der Farbreaktion

Die Ionen Ni(II), Co(II) und Fe(II) liefern mit PEI schwächere Farbreaktionen bei anderen Lagen für λ_{max}. In der Arbeitsweise gemäss vorstehender Vorschrift werden bei der Bestimmung von 500 μg Cu(II) folgende Spezifitäten erreicht:

Cu(II)	Ca(II)	Mg(II)	Fe(II)	Al(III)	Fe(III)	Co(II)	Ni(II)	Zn(II)	Mn(II)
1	800	5000	15	100	2	10	3	50	1000

Anwendbarkeit des Verfahrens

In in Königwasser gelösten Legierungen kann nach Abfiltrieren der Kieselsäure und Puffern auf pH 3–5 der Kupfer-Gehalt unmittelbar bestimmt werden, wie die Untersuchung folgender Legierungen zeigt:

	Si %	Mg %	Fe %	Ni %	Mn %	Ti %	Zn %	Cr %	Haupt Bestandteil	Cu gegeben %	Cu gefunden %
Gegeben	0,28	1,57	0,4	2,0	—	0,013	—	—	Al	4,16	4,15
Gegeben	0,23	2,6	0,28	—	0,2	—	5,1	0,17	Al	1,25	1,27

Synthesis and analytical applications of 2,4-dinitro-6-chlorophenylazothymol

(*Received* 12 *July* 1966. *Accepted* 18 *December* 1966)

VARIOUS azo-dyes,[1-5] anthraquinone dyes,[6-8] and Thiazole Yellow,[9] have been used as sensitive reagents for the spot detection of magnesium, but certain cations interfere in these tests. The compound 2,4-dinitro-6-chlorophenylazothymol (MS) has been found to be not only a suitable spot-test reagent for magnesium but also a useful acid–base indicator.

EXPERIMENTAL

Synthesis of MS

To a solution of 2,4-dinitro-6-chlorophenylhydrazine[10] (2·3 g) in alcohol (*ca.* 10 ml) add a solution of thymoquinone[11] (1·6 g) in alcohol (8 ml). Heat the mixture under reflux on a boiling water-bath for 30 min. Cool the mixture and add 30 ml of distilled water. Scrape the sides of the reaction vessel to produce a red amorphous compound (yield 3 g), filter it off, wash it with water, and dry it. The compound does not appear to be amenable to crystallization, but the analytical results for it are satisfactory. (Found: C 50·5%; H 3·8%; Cl 9·3%; N 14·6: $C_{16}H_{15}ClN_4O_8$ requires C 50·72%; H 3·96%; Cl 9·37%; N 14·79%: m.p. 183°.)

Spot-test for magnesium

On a spot-plate. Mix one drop (0·05 ml) of the magnesium test solution on a porcelain spot-plate with one drop of 0·01 *M* sodium hydroxide, and one drop of $10^{-3}M$ alcoholic solution of MS. A blue precipitate indicates a positive test. The limit of identification is 0·14 μg of magnesium in 0·05 ml, and the dilution limit is 1:350,000.

On a test-paper. Dip filter paper (Whatman No. 1) into 0·01*M* sodium hydroxide and then into $10^{-3}M$ alcoholic solution of MS, and dry it. The dry paper is pale blue. Add a drop of the test solution to the paper. Magnesium reacts immediately to give a blue spot. The sensitivity is 0·12 μg of magnesium.

Interferences

Oxalate, tartrate, acetate, borate, phosphate, chloride and bromide did not interfere in the test. Several cations were tested for interference and the maximum amounts of them that could be tolerated in 1 drop of test solution are shown in Table I. Silver gave a buff colour and manganese(II) gave a

* Absorbance when the compound was in completely molecular form.
† Absorbance when the compound was in completely dissociated form.

Choice of reaction conditions

An alcoholic solution of the dye was deep red; in alkaline medium it was blue-violet. The sharpest development of the deep blue colour formed between magnesium hydroxide and the dye occurred in the pH range 10·5–11·6. At a pH lower than 10·5 no colour change appeared.

When the amount of magnesium was varied from 1·2 down to 0·11 μg, it was found that with less than 0·14 μg of magnesium the precipitate developed a green colour instead of blue. When the amount of magnesium was kept constant at 0·14 μg and that of the dye was varied, it was found that the best colour adsorption on the precipitate could be achieved when 0·05 ml of $10^{-3}M$ alcoholic solution of the dye was used.

Spectrophotometric determination of the acid dissociation constant of the dyestuff

The pK_a value was determined by Robinson's method.[12] The concentration of the dye was kept at 0·01M throughout, and precipitation of the dye during dilution with water was prevented by addition of alcohol. The results are given in Table II. The compound is yellow in acidic and sky-blue

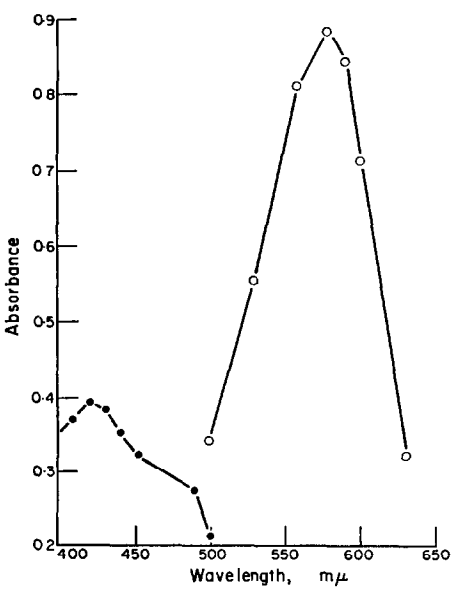

FIG. 1.—Absorption spectra of MS.
●—Acidic medium; ○—alkaline medium.

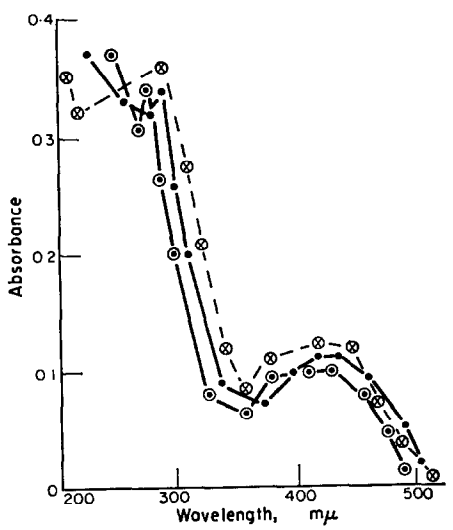

FIG. 2.—Absorption spectra of MS in various solvents (2 ppm solution).
●—Alcohol; ⊙—benzene; ⊕—hexane.

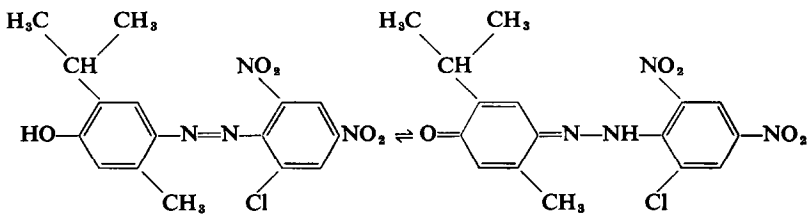
in alkaline media, and exhibits halochroism when dissolved in conc. sulphuric acid. The absorption spectra of the two forms are shown in Fig. 1. Its transition interval is from pH 7 to pH 9.

Use of the dye as an indicator

The reagent was tested as an indicator for the titration of 1, 0·02, and 0·001 *M* solutions of hydrochloric, nitric, and acetic acids with alkali of corresponding concentration. The relative standard deviation for a 50-ml titration ranged from 0·04 to 0·20% for hydrochloric and acetic acids, depending on their concentration, but was higher (0·2–0·3%) for all concentrations of nitric acid. The compound is not very suitable as an indicator for titrations of acids or bases more dilute than $10^{-3}M$, as the indicator then loses its colour near the equivalence point, though the colour is restored on further addition of acid or alkali.

DISCUSSION

The condensation product gave similar absorption spectra irrespective of the solvent (Fig. 2). Although it behaves predominantly as an azophenol it exhibits tautomeric behaviour as a mono-phenylhydrazone of thymoquinone.



Thus it not only forms a sodium salt and an acetyl derivative (like phenolic compounds) but also a dihydrazone with phenylhydrazine (like quinonoid compounds).

MS obtained by the condensation of thymoquinone and the substituted hydrazine was found (by means of a mixed m.p. determination and from the absorption spectra) to be identical with the compound formed by coupling the diazonium salt of 2,4-dinitro-6-chloroaniline with thymol, indicating that its structure is 2,4-dinitro-6-chlorophenylazothymol.

The production of the blue lake probably involved chemi-adsorption of the dyestuff on magnesium hydroxide, since no simple stoichiometry was found for the reaction. The dye anion may be bound on the surface of magnesium hydroxide gel particles, the magnesium ions in the surface of the gel binding the azothymol:

$$[Mg(OH)_2]_x + H\cdot Az\cdot Th \rightarrow [Mg(OH)_2]_{(x-1)}\cdot Mg\begin{matrix}Az\cdot Th\\ \diagup\\ \diagdown\\ OH\end{matrix} + H_2O$$

$$[Mg(OH)_2]_x + Az\cdot Th^- \rightarrow [Mg(OH)_2]_{(x-1)}\cdot Mg\begin{matrix}Az\cdot Th\\ \diagup\\ \diagdown\\ OH\end{matrix} + OH^-$$

That a bluish violet alkaline solution of the dyestuff was taken up by pure filter paper free from magnesium to give a sky-blue colour also supported the fact that the colour change was due to adsorption and not to compound formation.

Summary—The newly synthesized 2,4-dinitro-6-chlorophenylazothymol, a weak acid with pK_a 8·33 ± 0·04 at 27°, is proposed as a sensitive spot reagent for magnesium, with an identification limit of 0·14 μg at pH 10·5–11·6. Silver and manganese(II) interfere but can be masked by means of cyanide and periodate respectively. There is little interference by anions. The reagent also serves as an acid–base indicator with a transition interval of pH 7–9, giving a sharp colour change at the equivalence point.

Zusammenfassung—Das neu dargestellte 2,4-Dinitro-6-chlorphenylazothymol, eine schwache Säure mit pK_a = 8,33 ± 0,04 bei 27°, wird als empfindliches Tüpfelreagens auf Magnesium vorgeschlagen; die Nachweisgrenze ist 0,14 μg bei pH 10,5–11,6. Silber und Mangan(II) stören, können jedoch mit Cyanid bzw. Perjodat maskiert werden. Anionen stören wenig. Das Reagens dient auch als Säure–Basen-Indikator mit Umschlagsbereich bei pH 7–9; der Farbumschlag am Äquivalenzpunkt ist scharf.

Résumé—On propose le 2,4-dinitro 6-chlorophénylazothymol nouvellement synthétisé, qui est un acide faible avec pK_a = 8,33 ± 0,04 à 27°, comme réactif à la touche sensible du magnésium, avec une limite d'identification de 0,14 μg à pH 10,5–11,6. L'argent et le manganèse-(II) interfèrent mais peuvent être dissimulés au moyen de cyanure et de periodate respectivement. Il y a peu d'interférences du fait des anions. Le réactif sert aussi comme indicateur acide–base avec un intervalle de transition de pH 7 à 9, offrant un changement de coloration net au point d'élquivalence.

Studies on metallochromic indicators—I

Pyrocatecholphthalein as metallochromic indicator

(*Received* 21 *June* 1966. *Revised* 7 *February* 1967. *Accepted* 4 *April* 1967)

ALTHOUGH a number of phthalein[1] and sulphonphthalein[2,3] dyes have been used as metallochromic indicators, the metallochromic behaviour of pyrocatecholphthalein (PCP) has not been reported. Patrovský[4] used it for the photometric determination of boron, and mentioned the possibility of its being used as an indicator for metals. In the present studies, the indicator properties of PCP have been investigated, and the dye has been found useful in titrations of a number of metals with EDTA, both in alkaline and in slightly acidic medium. Thorium and bismuth(III) may be titrated in the pH ranges 2·5–3·5 and 2–3 respectively, the buffer used being a mixture of sodium acetate and nitric acid. In alkaline medium, copper(II), nickel, cobalt(II), manganese(II) and lead(II) may be titrated at pH 9–9·5, magnesium, cadmium and zinc at pH 10–10·5 in ammonia–ammonium chloride buffer, and calcium at pH 12 in the presence of sodium hydroxide. Further, calcium, strontium and barium can be titrated in an ammoniacal buffer at pH 10 with added magnesium–EDTA complex, using this indicator. It has been found that in alkaline medium, sharper end-points are obtained with this indicator than with Pyrocatechol Violet (PCV).

EXPERIMENTAL

Synthesis of pyrocatecholphthalein

Patrovský's method was used[4] and also the following method, which gave better yields. Pyrocatechol (22 g), phthalic anhydride (15 g), and concentrated sulphuric acid (2 ml) were heated on an oil-bath at 120–130° until the melt became viscous (about 30–35 min). The melt was dropped into 250 ml of water which was then boiled, cooled and filtered. Upon further cooling with ice, a viscous black product precipitated. This was separated and dissolved in dilute sodium hydroxide solution; on addition of dilute hydrochloric acid a greenish black precipitate was obtained and filtered off. It was dried in air and recrystallized from ethanol; yield 19·5 g.

Reagents

EDTA solutions were prepared from the disodium salt, analytical reagent grade (B.D.H.).[6]

Metal ion solutions were prepared from analytical reagent grade salts.

Buffer solutions of the required pH values were prepared[6] and their pH was checked with a Cambridge pH meter.

Spectral characteristics

The absorption spectra of PCP at various pH values were determined with the Beckman model DU spectrophotometer, and are shown in Fig. 1. The absorption maximum at high pH occurs at 595 mμ.

Direct titrations in acidic medium

Solutions containing not more than 1·0 mg of thorium or 0·5 mg of bismuth per ml were mixed with equal volumes of the acetate buffer solution at pH 2·5–3·5 or 2–3 respectively. Two drops of 0·2% ethanolic solution of the indicator were added for each 10 ml of solution, giving a green colour. The solution was titrated with standard EDTA solution till the colour changed abruptly to pale yellow.

Direct titrations in alkaline medium

Solutions of the appropriate metal ion (0·05, 0·01 or 0·001 *M*) were mixed with equal volumes of ammoniacal buffer solution, and two drops of a 0·1% indicator solution were added. The greenish blue solution was titrated with EDTA solution till the colour changed to reddish violet. For the titration of calcium, strontium or barium, 1 ml of 0·01 *M* solution of the magnesium–EDTA complex was added before titrating. Calcium was also titrated in the presence of 0·01 *M* sodium hydroxide.

RESULTS AND DISCUSSION

Pyrocatecholphthalein in aqueous solution is yellow below pH 5, reddish violet above pH 8, and

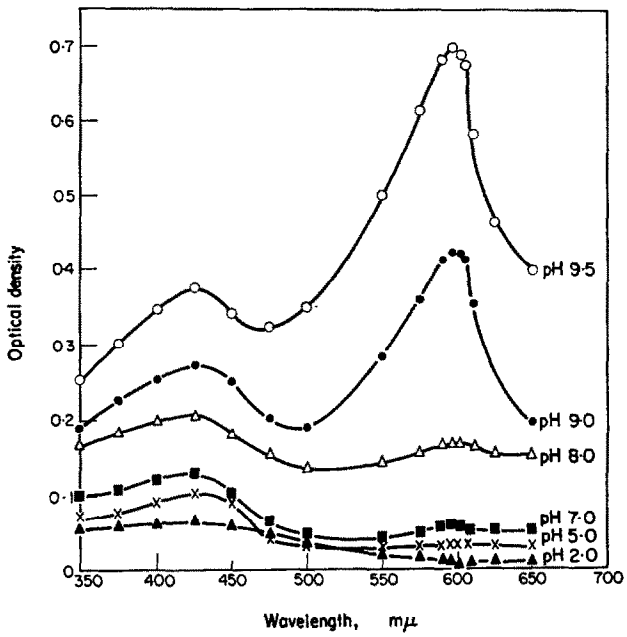

FIG. 1.—Absorption spectra of pyrocatecholphthalein at varied pH.

green between pH 5 and 8. Above pH 8 it forms greenish blue complexes with various bivalent metal ions *e.g.*, magnesium, zinc, manganese, lead, cobalt, nickel, copper, and cadmium. The colour change at the end-point in EDTA titrations is from greenish blue to reddish violet, and is very sharp and reversible. Calcium, strontium and barium do not form green complexes with the dye in ammoniacal medium, but can be titrated in the presence of the magnesium–EDTA complex, in which case the end-point is indicated by the change of the colour of the magnesium–dye complex to that of the free dye. In the absence of the ammoniacal medium, but in dilute sodium hydroxide solution, calcium gives a green colour with the dye, and may be titrated directly with EDTA. Barium and strontium do not show this behaviour and cannot be titrated.

At lower pH values (2–4) the dye forms green complexes with thorium, bismuth, iron(III), zirconium, gallium, indium and aluminium, the free indicator being yellow. However, only thorium and bismuth can be titrated with EDTA with this indicator (colour change from green to pale yellow) as the other metal ions give a slow, gradual colour change at the end-point.

TABLE I.—TITRATIONS WITH EDTA AND PCV OR PCP AS INDICATOR

Metal ion	Concentration, *M*	Volume of EDTA,* *ml*	
		PCV	PCP
Zn^{2+} Mg^{2+} Cu^{2+}	0·05	9·99–10·01	9·99–10·01
Ni^{2+} or Cd^{2+}	0·01	9·98–10·03	9·99–10·02
Zn^{2+}	0·001	9·91–10·12	9·95–10·06
Mg^{2+}	0·001	9·90–10·12	9·95–10·07
Cu^{2+}	0·001	9·92–10·10	9·96–10·04
Ni^{2+}	0·001	9·98–10·14	9·94–10·06
Cd^{2+}	0·001	9·91–10·13	9·96–10·05

* The EDTA solutions were of the same molarity as the metal to be determined. The spread of results was that obtained from six titrations for each metal.

A comparison of the indicator properties in alkaline medium shows the superiority of PCP over PCV. The colour change with the former is from greenish blue to reddish violet which is more easily observed than the blue to violet one in the case of PCV.[5] Not only does PCP give a better colour change than PCV, because of the greater spectral shift, but it is slightly more stable in alkaline solution. Moreover, this indicator is found suitable in the titration of lead in ammoniacal buffer, using tartrate as auxiliary complexing agent, under which conditions PCV gives an indistinct colour change at the end-point. However, at lower pH values, PCV is a superior indicator. The sulphonic acid group on PCV is a stronger acid than the carboxylic acid group on PCP. In Table I are summarized the results of titrations done with the two indicators, showing the spread of results at different concentrations of the metal ions. From these data it is evident that PCP is superior in alkaline solution.

Pyrocatecholphthalein is a better indicator than pyrocatecholviolet for EDTA titrations of several metal ions in alkaline medium, because of its sharper colour change at the end-point. It is also cheap and easy to synthesize.

Summary—Pyrocatecholphthalein has been used as a metallochromic indicator for the direct complexometric titrations of a number of metal ions with EDTA, both in acidic and in alkaline medium. Th, Bi(III), Ba, Sr, Ca, Mg, Mn(II), Pb(II), Cu(II), Cd, Ni, Co(II) and Zn have been successfully titrated. In comparison with Pyrocatechol Violet, this dyestuff gives sharper end-points when the titrations are done at high pH.

Zusammenfassung—Brenzcatechinphthalein wirde als Metallfarbindikator zu direkten komplexometrischen Titrationen einer Anzahl von Metallionen mit EDTA in saurem und alkalischem Medium verwendet. Th, Bi(III), Ba, Sr, Ca, Mg, Mn(II), Pb(II), Cu(II), Cd, Ni, Co(II) und Zn wurden mit Erfolg titriert. Verglichen mit Brenzcatechinviolett gibt dieser Farbstoff schärfere Endpunkte, wenn die Titrationen bei hohem pH ausgeführt werden.

Résumé—On a utilisé la pyrocatécholphtaléine comme indicateur métallochrome pour les dosages complexométriques directs d'un certain nombre d'ions métalliques au moyen d'EDTA en milieu tant acide qu'alcalin. Th, Bi(III), Ba, Sr, Ca, Mg, Mn(II), Pb(II), Cu(II), Cd, Ni, Co(II) et Zn ont été dosés avec succès. Par comparaison au violet de pyrocatéchol, ce colorant donne des points de fin de dosage plus nets lorsque les dosages sont menés à pH élevé.

Interference of the ammonium ion in Mohr's method for the determination of chloride

(*Received* 20 *February* 1967. *Accepted* 26 *April* 1967)

THE ammonium ion has never been regarded as interfering in the Mohr method for chloride as long as an appropriate pH is maintained. Kolthoff and Stenger[1] state "In the presence of ammonium salts a pH between 6·5 and 7·2 should be maintained". Belcher, Macdonald and Parry[2] concur: "It is well-known that when ammonium salts are present the pH should not exceed 7·2, otherwise the end-point comes too late . . . " A standard text[3] even recommends the use of ammonia solution and ammonium acetate for the neutralization of mineral acids prior to the titration.

We used ammonia solution for pH adjustment of acidic chloride solutions and obtained high results. We decided to investigate this by titrating standard sodium chloride solutions in the presence of weighed quantities of ammonium nitrate and ammonium sulphate.

EXPERIMENTAL

Reagents

Analytical reagent-grade chemicals were used throughout.

A stock sodium chloride solution was prepared by dissolving 5·0021 g of sodium chloride in distilled water, and diluting to the mark in a 1-litre volumetric flask.

A 0·1*M* silver nitrate solution was prepared and standardized against aliquots of the sodium chloride solution.

The mixed chromate-dichromate indicator recommended by Belcher *et al.*[2] was used.

A 0·02*M* sodium hydroxide solution was used for pH adjustment.

A Beckman Zeromatic II pH meter was used for pH measurement.

Procedure

Aliquots (10 ml) of the stock chloride solution were taken for analysis and diluted to 60 ml with distilled water. A weighed amount of ammonium nitrate was added and the pH was adjusted with sodium hydroxide solution. Then 20 drops of the mixed indicator were added, and the sample was titrated with the standard silver nitrate solution.

RESULTS AND DISCUSSION

The results are summarized in the Table I.

TABLE I.—TITRATION OF CHLORIDE IN THE PRESENCE OF THE AMMONIUM ION

NH_4^+ salt added, *g*		Final pH	Cl^- taken, *mg*	Cl^- found, *mg*	Error, %
NH_4NO_3	0·10	6·75	30·4	30·4	0·0
NH_4NO_3	0·30	6·79	30·4	30·5	+0·3
NH_4NO_3	0·60	6·72	30·4	30·7	+1·0
NH_4NO_3	1·00	6·61	30·4	30·9	+1·7
NH_4NO_3	1·50	6·61	30·4	31·3	+3·0
NH_4NO_3	2·00	6·60	30·4	31·4	+3·3
$(NH_4)_2SO_4$	1·65	6·62	30·4	31·4	+3·3

From these results, we feel that the presence of more than 100 mg of ammonium ion cannot be tolerated for quantitative work. If the ammonium ion is present, we recommend it be removed by the addition of sodium hydroxide and boiling and that the pH subsequently be readjusted.

We believe that the probable cause of the interference is the removal of free silver ion from the

solution through the formation of stable silver-ammonia complexes. The removal of free chromate from solution by the equilibrium reaction

$$NH_4^+ + CrO_4^{-2} = NH_3 + HCrO_4^-$$

is also possible.

LETTER TO THE EDITOR

Thorium-free ammonium hexanitratocerate

SIR,

There is considerable interest in the provision of pure chemicals and in the assessment of the impurities present in them. We have recently modified the Smith, Sullivan and Frank preparation and purification of ammonium hexanitratocerate,[1] and have assessed different methods of determining the thorium content of the product. It is difficult to remove the thorium because of isomorphism, and multiple recrystallization is required to remove it completely.

Bastnaesite, a thorium-free cerium fluocarbonate, $CeFCO_3$, from deposits at Mountain Pass, California (Molybdenum Corporation of America) is commercially available. Its conversion into ammonium hexanitratocerate seems rather complicated. Hydrated cerium dioxide, low in thorium content, obtained from monazite sand after separation of the thorium, is also commercially available. The preparation of ammonium hexanitratocerate from this raw material has been described by Smith, Sullivan and Frank,[1] and by Smith and Fly,[2] and the product is now commercially available[3] in reference-purity quality.

solution through the formation of stable silver-ammonia complexes. The removal of free chromate from solution by the equilibrium reaction

$$NH_4^+ + CrO_4^{-2} = NH_3 + HCrO_4^-$$

LETTER TO THE EDITOR

Thorium-free ammonium hexanitratocerate

SIR,

There is considerable interest in the provision of pure chemicals and in the assessment of the impurities present in them. We have recently modified the Smith, Sullivan and Frank preparation and purification of ammonium hexanitratocerate,[1] and have assessed different methods of determining the thorium content of the product. It is difficult to remove the thorium because of isomorphism, and multiple recrystallization is required to remove it completely.

Bastnaesite, a thorium-free cerium fluocarbonate, $CeFCO_3$, from deposits at Mountain Pass, California (Molybdenum Corporation of America) is commercially available. Its conversion into ammonium hexanitratocerate seems rather complicated. Hydrated cerium dioxide, low in thorium content, obtained from monazite sand after separation of the thorium, is also commercially available. The preparation of ammonium hexanitratocerate from this raw material has been described by Smith, Sullivan and Frank,[1] and by Smith and Fly,[2] and the product is now commercially available[3] in reference-purity quality.

Spectroscopic analysis indicated that the starting supply of commercially available nitratocerate[3] contained not more than 50 ppm of thorium, whereas chemical analysis showed the presence of only 5 ppm of thorium.

The ammonium hexanitratocerate (200 g) was dissolved in 150 ml of hot water. Enough hydrated thorium nitrate was then added to give a Th to Ce ratio of 1:60. The temperature was raised to 100° and 200 ml of 67% nitric acid were added at the rate of 15–20 ml/min with constant heating and stirring. The heating was stopped and stirring continued until the mixture had reached room temperature.

The nitratocerate thus recrystallized was filtered off with the equipment previously described[4] and centrifuged at 2000 rpm for 10 min at an average distance of 17·5 cm from the centre of rotation: yield 70–75%. The product obtained was drenched by addition of 25 ml of reagent-grade nitric acid and centrifuged for 10 min: this treatment was then repeated and the product was called the first crop. It was dried at 85° and part of it was set aside for analytical determination of its thorium content.

This recrystallization process was repeated, with proportionate diminution of the volumes of solution and nitric acid, to obtain the second, third and fourth crops of crystals, which were then evaluated for their co-precipitated thorium content by spectroscopic, neutron-activation, and chemical procedures. Recognized experts in their various fields of specialization were commissioned to carry out referee analyses. The results are shown in Table 1.

TABLE 1

	Thorium, *ppm*			
	Analyst 1*	Analyst 2*	Analyst 3†	Analyst 4‡
Starting material	50	50	125	5
1st Crop	1240	1250	1490	—
2nd Crop	415	460	506	—
3rd Crop	110	140	226	—
4th Crop	40	50	129	87

* Analysis by emission spectroscopy.
† Analysis by activation analysis.
‡ Analysis by extraction and spectrophotometry.

It is noteworthy that the independent spectroscopic analyses agreed better with each other than with the other analyses, and it is evident that considerable research remains to be done on comparison of methods of trace analysis and selection of referee methods.

As expected, the amount of thorium left in ammonium hexanitratocerate on recrystallization is governed by the original thorium content. The best method of obtaining thorium-free hexanitratocerate appears to be to start with hydrated cerium dioxide, dissolve it in nitric acid, and precipitate the desired product by adding ammonium nitrate. By this means lower yields are obtained, but the product is certainly less contaminated by thorium from the raw material. Hydrated cerium dioxide, sufficiently low in thorium content for the hexanitratocerate obtained from it to need no recrystallization to be equal in quality to the fourth crop quoted above, is commercially available in quantity, and therefore so is ammonium hexanitratocerate of the quality needed for radiochemically pure cerium.[5] The results reported here confirm those previously reported,[5] and show that this is probably the best method of preparing a cerium(IV) salt with minimal thorium content.

TALANTA REVIEW*

A CRITICAL REVIEW OF METHODS OF ISOLATING AND SEPARATING THE NOBLE METALS—III†

CHROMATOGRAPHY, PRECIPITATION AND FIRE ASSAY

F. E. BEAMISH
Department of Chemistry, University of Toronto, Toronto 5, Ontario, Canada

(*Received* 23 *February* 1967. *Accepted* 2 *May* 1967)

Summary—This review deals with the chromatographic, precipitation and fire-assay methods of separating the seven noble metals, published subsequent to the previous reviews and prior to January 1966. The noble metal species present in solution are discussed in so far as they relate to separation and determination.

THIS paper continues the review of recent methods of separating and isolating the noble metals, and the prologue to Part II† applies equally to Part III.

PAPER CHROMATOGRAPHY

The platinum metal complexes with tin(II) chloride and bromide were used by Lederer and Shukla[1] for a number of separations by paper chromatography: 1 ml of aqueous solution containing 1 mg of each of the six metals was mixed with 1 ml of 1*M* tin(II) chloride in hydrochloric acid. Ascending development was used with the metal solution applied as a thin band. The solvent was 1*M* tin(II) chloride in 6*M* hydrochloric acid. Investigation was made of the effects on the R_f values when the hydrochloric acid and tin(II) chloride concentrations in the solvent were varied. The separation of platinum and palladium was better than that achieved by partition chromatography of the chloro-complexes. The spots were well defined, showing for platinum an orange colour and an R_f value 0·21, and for palladium a blue colour with R_f 0·70. For rhodium the spot was elongated with a red front and a yellow rear and an R_f spread from 0·13 to 0·56. Heating the solutions of the metal complexes had little effect on the chromatographic behaviour. Iridium formed two yellow-brown spots with R_f values of 0·18 and 0·78. Mixtures of ruthenium–palladium, osmium, ruthenium, platinum–palladium and platinum rhodium–palladium as the tin(II) bromide complexes in 3*M* hydrobromic acid were successfully separated with the solvent 0·5*M* tin(II) bromide in 3*M* hydrobromic acid. In the case of potassium chloroiridate(VI) dissolved in water or boiled with hydrobromic acid there were three spots, one red and two yellow with R_f values 0·19, 0·32, 0·87. If iridium(IV) was first heated with tin(II) bromide–hydrobromic acid mixture, four spots developed, one red and three yellow with R_f values 0·23, 0·37, 0·65 and 0·88. No explanation was offered for this phenomenon. The authors suggested that the complexes were similar in structure to heteropolyacids with the metal as the central atom surrounded by four or more tin chloro-complex groups. It was noted that the red tin(II) chloride–rhodium(III) complex could be converted into the yellow form by treatment with hydrochloric acid, by extraction with butanol, or by removing tin(II) during electromigration.

For the detection of gold, platinum, selenium and tellurium Larsen[2] evaporated the chloride solution with nitric acid to eliminate excess of hydrochloric acid, thus ensuring reduction of selenium and tellurium to the quadrivalent state. Ascending development was used with a solvent containing n-butanol, methanol and diethyl ether. The R_f values were: gold, 0·9–1·0: platinum, 0·0: selenium, 0·5: tellurium, 0·0. Platinum was detected with potassium iodide and gold with tin(II) chloride.

* For reprints of this review see advertisement at the front of this issue.
† Part II—*Talanta*, 1967, **14**, 991.

A chromatographic separation of gold, palladium, platinum and ruthenium was described by Vassiliades and Manoussakis.[3] The solvent was isobutanol containing hydrochloric acid to prevent hydrolysis of the metal salts, and acetic acid to encourage clear separation of the zones. A solution of dianisidine hydrochloride was used for locating the zones, the colours and R_f values being; ruthenium, brown-yellow, 0·22: palladium, yellow, 0·51: platinum, dark-yellow, 0·62: gold, brown-red, 0·94. The metal chloride solution contained 150 mg of platinum, 50 mg of palladium, 150 mg of gold and 20 mg of ruthenium per 100 ml. The chromatogram was run for 21 hr at 26°, dried for 2 hr, and then sprayed with the reagent. Continued exposure to air or to hydrogen peroxide modified the colours. For determination of R_f values the solvent front was located by use of ultraviolet light.

A useful series of chromatographic separations for the seven noble metals was described by Blasius and Fischer.[4] Ascending and radial development were both applied and three solvents were used successively, each with some specific advantage. Thiourea was used to locate osmium and ruthenium, and tin(II) chloride and potassium iodide were used for other metals. Iridium was located with concentrated hydrochloric acid, producing a brown zone at the solvent front. Ammonium sulphide was also used for ruthenium. The butanol–hydrochloric acid solvent was recommended for the chloro-complexes of gold, platinum and palladium with either ruthenium or rhodium (the metals are in order of increasing R_f). Sodium nitrite solution was especially useful for the separation of the chloro-complexes of iridium and platinum with or without osmium: the R_f values increased in the order given. Sodium nitrite in ethanol and isopropanol was recommended for separation of the nitrito-complexes of ruthenium and rhodium with either palladium or platinum in nitrite solution. The solvent ethyl methyl ketone–hydrochloric acid was used for the chloro-complexes of rhodium and palladium and the nitroso-chloro-complexes of ruthenium in hydrochloric acid. A variety of combinations of noble metals was separated successfully, and it appeared that osmium and ruthenium could be separated with the butanol–hydrochloric acid solvent: the use of thiourea as locating agent is of special interest. The authors also described a variety of paper ionophoresis separations of the seven noble metals in various combinations. The electrolytes were hydrochloric acid solutions of sodium chloride or acetate; the noble metals were present as the chloro-complexes: potentials of 230 or 130 V were applied for 1 or 2 hr. The variation in bands resulting from sample applications to either the side or centre of the strip and the effect of hydrolysis of platinic acid solution were discussed. Again, there is particular interest in the clean separation of osmium and ruthenium in sodium acetate–hydrochloric acid medium, a potential of 230 V being applied for 1 hr.

For the determination of platinum and palladium James[5] applied the Kember and Wells technique[6] to silver assay beads obtained by the fire-assay of Merensky Reef ores. The bead was parted with nitric acid in a specially designed glass bulb with a closed tail calibrated to contain 1 ml, which allowed control of the evaporation and isolation from the silver chloride formed by treating the parting acid with hydrochloric acid and sodium chlorate solution, the latter ensuring the oxidation of any bivalent platinum: 0·05 ml of the resulting solution was used for the chromatogram. The spotted area was allowed to dry and then inserted into the jar containing the pentanol–hydrochloric acid–hexone solvent and the chromatogram was allowed to develop overnight. The dried strips were sprayed with tin(II) chloride solution, platinum appearing as a yellow band and palladium as a dark purple one. The corresponding areas from a duplicate strip were removed and extracted with 2·5*M* hydrochloric acid for platinum and 0·5*M* hydrochloric acid for palladium. The platinum portion of the stained strip could also be used for the determination. In the filtered extracts platinum was determined with tin(II) chloride and palladium with thioglycollic acid. The results indicate very satisfactory precision. The author stated that "Results obtained with only slight familiarity with the technique compare very favourably with those obtained by laboratories practised in and using standard fire assay methods."

"Capillary chromatography" or, more simply, "spot-testing" has been applied to the separation and detection of rhodium and iridium. Černý and Kubin[7] added an acidified solution of the two metals by capillary to a filter paper impregnated with aluminium hydroxide. Several capillary-loads of water were added to the spot, which was then dried, and sprayed with a solution of tin(II) chloride and potassium iodide. Rhodium appeared as a red ring and iridium as a light brown inner ring. The intensity could be increased by the addition of potassium iodide solution. There was interference from platinum, palladium and gold.

Filter papers impregnated with cadmium sulphide have been used for separation and approximate determination of platinum, palladium, gold, silver and mercury. Ćelap *et al.*[8] claimed that the movement of the products of the metathesis was a linear function of the amount of the ion present. Presumably the precision obtained was 2–5%, depending on the amount of ion present. Some additional evidence for the usefulness of methods such as these might be forthcoming if the technique could be applied successfully to noble metal alloys.

When investigating the paper chromatographic separation of the platinum metals Noddack and Sanir[9] were unable to separate each of the six metals on one chromatogram. The amounts of metals

applied were 20–30 μg and the ascending technique was used. With the solvent ethyl acetate–concentrated hydrochloric acid–acetic acid, the R_f values for ruthenium, rhodium, iridium, palladium, osmium and platinum were respectively 0·10, 0·18, 0·19, 0·42, 0·53 and 0·58. For rhodium and iridium R_f values of 0·49 and 0·88 respectively were obtained with the solvent methyl nitrite–concentrated hydrochloric acid–ethanol. For spot location tin(II) chloride was used for rhodium, palladium and platinum: bromine water for iridium: thiourea for ruthenium: tin(II) chloride with thiourea for osmium.

A potentially useful report on ascending chromatographic separations of the seven noble metals and copper and silver was recorded by Voicu and Nascutiu,[10] who reported the R_f values obtained with eighteen solvents consisting of 1:1 mixtures of various alcohols or ketones with various concentrations of hydrochloric acid. No overall pattern of change of R_f value with increasing acidity appeared. With certain solvents the R_f values decreased with increase in acidity: in several cases the R_f value increased to a maximum with about 4 or 6M hydrochloric acid then decreased at higher acidity: in others the R_f values increased with acidity. A highly acidic ketone–hydrochloric acid solvent separated a large and more varied number of metals. The C_1–C_3 alcohols showed maxima in the R_f values. The C_4–C_5 alcohols provided relatively varied separations. Detailed examination of the tables suggests a variety of chromatographic separations of noble metals which are frequently associated as groups in analytical separations or as predominant groups in natural deposits. In general, the solvents allowed good separations of gold and platinum or gold and palladium. On the other hand, with solutions of platinum and palladium in 1M acid the R_f values indicated considerable separational difficulty for all 18 solvents.

For the chromatographic separation of noble metal groups containing rhodium or platinum with palladium, ruthenium and gold, Kao and Yuan[11] used as solvent oxine dissolved in isobutanol–ethanol–water–acetic acid (60:57:80:3). The metal solutions were buffered at pH 1–2 with dichloroacetic acid.

Thiocyanate in hydrochloric acid solution was used as locating agent and ethyl methyl ketone as solvent to separate the platinum metals into the groups: iridium, rhodium–ruthenium, platinum–palladium and osmium. In a second method Kao and Sun[12] used benzene saturated with thiocyanate as the solvent and hydrochloric acid, potassium chloride and thiocyanate as locating agent. Gold, palladium and platinum–ruthenium–rhodium–iridium could be separated. The authors are continuing their work with a view to separating iridium from rhodium.

Filter paper impregnated with butyl phosphate was used by Hu and Shi[13] to separate the groups gold–platinum–palladium–rhodium and osmium–palladium–rhodium by reverse-phase paper chromatography. Hydrochloric acid was used as solvent, and increasing its concentration had little effect on the R_f values, which for gold, platinum, palladium, and rhodium were 0, 0·2, 0·4–0·6 and 0·9 respectively. With 2–10M hydrochloric acid, gold remained at the origin. With $>8M$ hydrochloric acid, silver migrated as $AgCl_3^-$. With $>2M$ hydrochloric acid selenium and tellurium could be separated. In a second paper Hu and Shi[14] added variations to the method. Mixtures of gold or silver with platinum–palladium–rhodium could be separated with hydrochloric acid that was $<6M$. The R_f value of palladium increased with increased acid concentration. With nitric acid as solvent the R_f values of rhodium, selenium, tellurium, silver and gold changed very little with increased concentration of acid while there was a slight increase in the case of ruthenium, palladium, osmium and platinum. Unfortunately the chromatographic behaviour of iridium was not indicated. The persistently high R_f value of about 0·93 for rhodium indicates a clear separation from the remaining noble metals.

Kertes and Beck[15] used ammonium thiocyanate and nitric acid solutions of some sixty ions including gold and platinum, and extracted with isoamyl alcohol, methyl isobutyl ether and di-isopropyl ether. The R_f values were recorded for all sixty ion species. The use of thiocyanic acid in paper partition chromatography was also discussed by Locke and Martin,[16] who determined the chromatographic properties of eight solvents. Of the noble metals, only gold was included among the 38 ions used. The solvents were n-butanol–water–perchloric acid and seven complexing solvents based on an n-butanol–water–thiocyanic acid mixture to which was added pyridine, aniline or quinoline. The authors discussed criteria of complexing properties.

For the analysis of platinum metals, Kao and Chang[17] used two solvents, n-amyl methyl ketone–hydrochloric acid and acetone–hydrochloric acid–acetophenone. Both solvents provided speed and stability. The locating reagents were tin(II) chloride for gold, platinum–palladium, rhodium and ruthenium: thiourea for osmium: chlorine water for iridium. With the first solvent the chromatogram was run for 1 hr at room temperature, for the other 3 hr at 9·5–10° was required. With both solvents silver remained at the start and the osmium spots were scattered. The acetone solvent could be used to separate rhodium from iridium. Large amounts of sulphate, nitrate, chloride, phosphate and perchlorate did not interfere. Perchlorate concentrated the platinum spots with the acetone solvent. The method was applied to determine gold in electrolytic slimes following the isolation of gold by hydrogen peroxide.

Variations in chromatographic methods are being proposed, some of which offer useful adaptations to analytical areas of wide interest. Photographic emulsions have been used in many methods to detect the presence of gold in solid materials. The autoradiographic plate was used by Shima[18] to trace the losses of radioactive gold to pot wall, cupel *etc.* during a fire assay. The technique involved cutting the used pot or cupel into two equal parts. The extent of the penetration of gold, and thus of the losses, was determined by pressing the thin vinyl membrane against the freshly cut areas for 3 days and then developing and fixing as usual. The results obtained were discussed in a recent review.[19]

To detect *in situ* the presence of gold minerals, Rao and Sagar[20] used gelatine-coated paper strips impregnated with *aqua regia* and pressed the paper against a surface of polished mineral sections for 20–30 sec. The paper was removed and treated with pyridine in hydrobromic acid. In the presence of gold, cherry-red spots appeared. Presumably, the associated constituents in minerals do not interfere. Photographic paper washed free from silver by thiosulphate and water may be used as the paper base.

A similar method for the detection of gold in ores was reported by Lever[21] some years earlier. The ore and paper were pressed between two glass plates and the gold was extracted by *aqua regia* onto the paper, treated with ethyl acetate–nitrate acid mixture and finally identified with tin(II) chloride. Applied to ores containing 0·05–0·15 troy oz of gold per ton the method gave uncertain results with some interference from iron. The author reported a more satisfactory semi-quantitative chromatographic method for estimating gold in the range from 25 to 250 μg per assay ton of ore. Six samples can be examined in 2 hr and the range of application can be extended by simple modifications. For siliceous ores a 100-mesh sample weighing 1·5 g was treated with *aqua regia* and the mixture was heated and filtered. Orthophosphoric acid was added to complex iron, and gold was extracted with ethyl acetate. The aqueous phase was removed and potassium chlorate added to the organic phase to remove residual water. The organic phase was transferred to chromatographic strips (pretreated with potassium chlorate solution) over an area previously marked between 1 and 5 in. from one end. The strip was dried and the end nearest the 1-in. mark was immersed in the developing solution (methanol–hydrobromic acid–potassium chlorate). When the solvent had travelled to the 5-in. mark the strip was removed and air-dried, and the zone at the 5-in. mark was sprayed with tin(II) chloride solution. The intensities of the stains at the 5-in. mark were then compared with standards similarly prepared from a gold solution. The stain could be treated with ammonia fumes to reduce fading. A method for treating sulphide ores was included, in which case potassium chlorate was added before *aqua regia* extraction. The results compared favourably with those of fire assay. Losses of gold in the *aqua regia* and extraction treatments were negligible. The report bears the marks of a carefully considered and precisely executed research project.

Paper chromatography was also used by Agrinier[22] to estimate gold in silicate rocks and minerals. *Aqua regia* extracts, made after roasting the minerals, were evaporated and the residue was taken up in nitric acid. The solvent was ethanol–ethyl acetate–water–nitric acid, and *p*-dimethylaminobenzylidenerhodanine was used as location reagent. R_f values were given for associated base and noble metals: gold appeared at the solvent front. The results for gold compared favourably with those obtained by fire assay.

Thin-layer chromatography was applied by Hranisavljević-Jakovljević *et al.*[23] to separate and then identify gold, with palladium and platinum present as chlorides and silver as acetate. Dithizone extracts in benzene were spotted on silica gel plates and chromatographed with benzene–methylene chloride as solvent. The R_f values and colours were; AgHDz, O, reddish-brown: $Au(HDz)_3$, 0·31, red: Au_2Dz_3, 0·20, lemon-yellow: $Pd(HDz)_2$, 0·43, dark green: $Pt(HDz)_2$, 0·38, yellow. Silver and gold dithizonates were selectively extracted at pH 7·5, palladium at pH 5·5, and platinum at pH 3 after reduction with tin(II) chloride.

Wu and Wu[25] used layers of silica gel mixed with sintered anhydrous calcium sulphate to give faster separation with better-defined spots. With acetone–hydrochloric acid–ethyl acetate or nitric acid–ethyl acetate as solvent separations into four groups were made; gold–osmium, ruthenium–palladium, platinum–rhodium, iridium. With increased proportions of concentrated nitric acid gold–osmium, platinum, ruthenium, palladium, iridium–rhodium could be separated. A potentially useful technique involved fixing the palladium spot at a suitable R_f value by the addition of oxine solution and then using a solvent such as n-butanol saturated with dilute sulphuric acid to separate gold, platinum, and palladium.

Paper electrophoresis was used by Been and Hoeye[26] to determine gold(III) associated with colloidally dispersed gold. Paper strips, wetted with 0·075*M* sodium thiosulphate, were used to provide a clear separation of the ions from the colloidal gold: 5 μl of the samples were streaked in the middle of the strips, and under a constant current of 2·5 mA/cm, the gold(III) ions migrated about 65 mm towards the anode after 1 hr: the gold particles moved 2–5 mm toward the anode. The potential dropped from 400 to 200 V. Gold-198 was used for the determination. For 1–2% of gold(III) the

method showed a deviation of 30% or less from values obtained by paper chromatography: precision was about 10%.

Dithizone[26] has been used for the isolation of platinum and of palladium by chromatography on an alumina column after preliminary extraction of platinum dithizonate from tin(II) chloride–hydrochloric acid solution. Chloroform was used as eluent and 0·2–4 ppm of platinum could be determined. For palladium[27] dithizone separations were made from 1–6*N* hydrochloric or sulphuric acid. Chloroform was again used as eluent. The method could be applied to less than 1 μg of palladium. About 0·01% of palladium could be determined in 1-mg samples of platinum in 30 min. There was no interference from copper, mercury and bismuth.

Ashizawa[28] also separated several new metal dithizonates in a pure state by chromatography with chloroform as the eluent. Absorption maxima were recorded for the dithizonates of cobalt, iron, nickel, palladium, gold, copper and platinum.

Ruthenium and osmium

One of the most useful solutions for the collection of the tetroxides of osmium and ruthenium is cold hydrogen peroxide. Complexing or reducing reagents are sometimes added and determination can be made without the contaminants which are present in such media as sodium hydroxide or sulphite solutions. Koch and Bruchertseifer[29] used paper electrophoresis to characterize the composition of the peroxide solution of the distillates. The tetroxide was distilled from phosphoric acid solution into cooled water. Addition of perchloric acid and hydrogen peroxide gives quantitative formation of ruthenium(IV). With sulphuric acid and hydrogen peroxide ruthenium (III) is formed. To depolymerize the ruthenium(IV) the solution was added to an exchange-resin, Wofatit KPS in the hydrogen form, which was then washed with acidified water and irrigated with perchloric acid.

The effect of aging a solution of $[Ru(H_2O)Cl_5]^{2-}$ in 0·1*M* hydrochloric acid was studied by Shukla,[30] by paper electrophoresis and spectrophotometry. It was shown that aging the complex resulted in gradual hydration involving progressive replacement of the chloro- group by an aquo-group. The absorption spectra of electrophoretically pure $[Ru(H_2O)Cl_5]^{2-}$ and $[Ru(H_2O)_6]^{4+}$ were also reported.

Chromatographic and solvent extraction methods have been described for the separation and determination of the ruthenium constituents in nitric acid solution, specifically in those "aqueous process solutions from chemical separation plants, designed to separate plutonium and fission products from irradiated uranium by solvent extraction." In general, these constituents are of two types, nitrato (non-nitro) and nitro complexes of nitrosylruthenium.[31–33] Fletcher *et al.*[31] suggested graphic formulae for eleven nitrato complexes classified according to the presence or absence of a nitrato group *trans* to the NO-group. Paper chromatograms of ruthenium solutions in 3–15*M* nitric acid, previously aged to reach equilibrium, indicated a division of the complexes into four groups. The R_f values were given for each group with isopropyl methyl ketone (IPMK) and dibutylcellolve (DBC) as solvent.

Brown and Naylor[32] dealing with "process solutions" stated that, in contrast to solvent extractive methods, paper chromatography allowed the characterization and determination of the nitric acid–ruthenium complexes, which were practically all in the stable nitrosylruthenium form and contained the nitrato and the nitro groups. The solvents used were IPMK and DBC, equilibrated with 3*M* nitric acid. With "process solutions" containing mixed fission products, there was some masking of ruthenium by zirconium-95 and niobium-95, which had R_f values of about 0·6. Brown and Naylor[32] determined the ruthenium distribution on the chromatograms by gamma spectrometry. Wain *et al.*[33] used the same solvents with 0·005 ml or less of ruthenium solution applied as a band at the base of the paper. The nitrosylruthenium nitro complexes remain at the start while the nitrato complexes, with a ratio of nitrate to ruthenium greater than 3 to 1 migrate, the R_f values being between 0·2 and 0·7. Points of technique for optimum separation were described and the R_f values for the various nitro and nitrato complexes were included. An empirical formula was given for calculation of the amounts of nitro and nitrate complexes in nitric acid solutions. Scargill and Lyon[34] found anomalous results when the method was applied to uranium solutions. The method indicated "up to 20% of nitro-complexes in solutions known to contain only nitrato-complexes, and also up to 25% of nitrato-complexes in solutions where complete conversion to the nitro-complexes had been obtained." The authors concluded that the Wain method[33] would only give accurate results with the use of a carefully defined technique and in the absence of uranyl nitrate. A revised formula was proposed for general application to irradiated uranium process solutions to determine the proportions of nitrato- and nitro-complexes. The dibutylcellosolve results were used and showed a higher proportion of nitro-complexes in process solutions than that found by the Wain[33] method.

Scargill[35] later provided methods for the separation of individual nitrato and dinitro-complexes of nitrosylruthenium(III) and a method for the determination of the extractable nitrato and dinitro complexes in nitric acid solutions. By reverse-phase chromatography at 0°, with nitric acid as the solvent on paper impregnated with tributyl phosphate, the author was able to obtain 5 groups of

nitrato-complexes, two major groups of nitro-complexes, and to separate mixtures of nitrato- and nitro-complexes into the solvent-extractable nitrato group, the dinitro-complex and the cationic nitro- and nitrato-complexes. By cation-exchange methods he identified the cationic dinitro-complex, $[RuNo(NO_2)_2(H_2O)_3]^+$ and an anionic or neutral complex, $[RuNO(NO_2)_3(NO_3)(H_2O)_2]$. The existence of a mononitro-mononitrato complex was also indicated.

The interesting reaction of osmium(VIII) oxide and potassium iodide, one of the earliest reactions applied volumetrically, was studied chromatographically by Rallo.[36] In hydrochloric acid medium the constituents OsI_6^{2-} and chloroiodo-osmates(IV) were indicated. All of the latter could be converted into the violet OsI_6^{2-} by evaporation on a steam-bath with an excess of iodide. Practically pure OsI_6^{2-} could be obtained by performing the reaction in perchloric acid with sodium iodide.

Rhodium

Electrophoresis and ion-exchange chromatography have been used to identify the dissolved constituents in aqueous acid solutions of rhodium. Shukla and Lederer[37] used paper electrophoresis to determine the conditions for the formation of the yellow and the red rhodium sulphates. In general, a potential of 250 V was applied for 45 min and tin(II) chloride–potassium iodide was used for detection. The authors state that the yellow rhodium sulphate, in which the Rh(III) is cationic can be prepared by dissolving freshly precipitated rhodium(III) hydroxide in *N* sulphuric acid and that in 0·5*N* sulphuric acid several, presumably hydroxo-complex, cations are formed. Heating or evaporating the *N* acid solution results in considerable complexation, yielding a mixture of cationic complexes. Solutions left at room temperature are stable for months. The red rhodium trisulphate could be obtained by heating to 250° but not by heating on the water-bath. In solution it initially forms a single species but on standing tends to form an equilibrium similar to that for aged solutions of the yellow form, with some persistence of the anionic form. The authors[38] also investigated rhodium(III) perchlorate solutions, reaching the conclusion, of some analytical significance, that the single constituent $Rh(H_2O)_6(ClO_4)_3$ could be prepared by precipitating rhodium hydroxide from an aqueous solution of Na_3RhCl_6 with a slight excess of sodium hydroxide, dissolving the precipitate in perchloric acid and re-precipitating until a solution was obtained that had a single absorbance maximum at 396 mμ or gave a single electrophoretic band. Electrophoretic evidence was obtained of the presence of a second constituent of unknown identity in solutions made by boiling chlororhodite with perchloric acid. Previous work by the authors[39,40] indicated that the removal of co-ordinated chlorine from rhodium chloro-salts was not complete in one hydroxide precipitation. This conclusion becomes significant in the analytical separation of rhodium.

Platinum

Paper chromatography has also been applied to separate noble metal complexes in studies of their structural and behavioural characteristics. Thus, Basolo *et al.*[41] separated *cis*- and *trans*-dihalogendiammineplatinum(II) complexes and stated that practically all mixtures of *cis*- and *trans*- as well as of dichloro-, dibromo-, di-iodo-, chloroiodo- and chlorobromo-complexes could be thus separated. Later[42] they made a chromatographic study of platinum metals halides on several resin papers. The R_f values obtained at various hydrochloric acid concentrations indicated that platinum(IV) and platinum(II) could be readily separated. The R_f values for H_2PdCl_4 and H_2PtCl_4 on weak anion-resin and Amberlite SB2 resin papers were closely similar. A cursory examination of platinum chloride solutions containing sulphur dioxide indicated the presence of H_2PtCl_4 and sulphite complexes. Data were provided to confirm the chromatographic separation of chloroammine, amminepyridine and chloropyridine platinum(II) complexes.

Rhodium, iridium, and platinum

Blasius and Preetz[43] used ionophoresis at 3000 V for the separation of aquo and hydroxychloro complexes of rhodium(III), iridium(III) and platinum(IV) in an acetic acid–acetate buffer. Tin(II) chloride was used as location reagent for the ionophoretograms of rhodium(III) and platinum(IV) and chlorine for iridium(III). The authors investigated the temperature dependence of the migration velocity and the effect of aging on the composition of the species. In the case of rhodium, in addition to the main zone, there were a number of intermediate zones which they interpreted to indicate very unstable hydroxy-complexes or higher aggregated ions. The chloroaquo-complexes of rhodium(III) and iridium(III) were isolated and their composition determined by reduction to the metal by zinc and by halogen determination in the filtrate. For rhodium and iridium the cationic zone was characterized by yellow $[MCl_2(H_2O)_4]^+$, the neutral, orange zone by $[MCl_3(H_2O)_3]$ and the anionic zone by rose $[MCl_4(H_2O)_2]^-$ and red $[MCl(H_2O)]^{-2}$.

PRECIPITATION

Gold

Procedures for the extraction of noble metals from ores by dissolution in acids have been described. A number of these methods have been discussed in a review of neutron activation methods.[19] For the determination of gold in sulphide ores, Assarsson *et al.*[44] selectively removed the associated base metals and silver by treatments in a specially designed apparatus with chlorine-free hydrochloric acid. The residue was treated with hydrochloric acid and a little nitric acid to remove the gold, which was finally precipitated by hydrazine sulphate and sodium sulphide in the presence of mercury(II) chloride. The precipitate was ignited, refined by cupellation and weighed. The results, compared with values obtained by fire assay, indicated excellent accuracy.

A method of gold separation from lead and copper concentrates, crude lead, high grade commercial matte and slags was described by Bukharin,[45] for concentrations of over 40 g of gold per ton. A method for silver was included. Initially, the gold and silver were separated by assay melting of the crude lead which was then treated with nitric acid to produce a gold residue. This was heated at 600°, then dissolved in *aqua regia*, and the solution was evaporated in the presence of hydrochloric acid and sodium chloride, then treated with potassium hydrogen fluoride and *o*-dianisidine, and the gold determined volumetrically with hydroquinone. The gold losses were 0·1–0·4%.

For the separation of gold from copper and lead Ujihira[46] precipitated gold from dilute nitric or hydrochloric acid with *p*-dimethylaminobenzylidenerhodamine, 2-mercaptobenzothiazole, thionalide and Methyl Violet. There was interference from iodide, bromide and cyanide.

Palladium

The red-brown precipitate obtained from palladium and Reinecke's salt was used by Voicu and Dema[47] to separate palladium from gold and platinum with reasonable accuracy. The data indicated results for separations from high proportions of rhodium and low values for separations from high proportions of copper, with some significant lack of precision for separations from high proportions of copper, iron, cobalt and nickel. The interferences from various other cations were examined. Recoveries from solutions containing 1–460 μg of palladium were very acceptable. The extractant was ethyl methyl ketone and the medium was 0·1–0·75*M* hydrochloric acid. Large excesses of Reinecke's salt gave more complete extraction.

Ruthenium

As part of an investigation of methods of separating and determining trace amounts of ruthenium, manganese, technetium, rhenium, molybdenum, Jasim *et al.*[48] isolated ruthenium together with manganese by treating the solution with 10% sodium hydroxide solution and heating in a sealed capillary. The centrifuged liquid containing manganese and ruthenium was treated with ammonium sulphide which isolated ruthenium.

The application of co-precipitated iron(III) hydroxide as a collecting reagent for a variety of cations was discussed by Morachevskii *et al.*[49] In the case of ruthenium, ruthenium hexachloride was completely separated at pH 5·4–8·5 whereas in the absence of the iron(III) hydroxide only 76% of the ruthenium was precipitated at pH 7·3 and less at higher pH values.

Palladium, platinum, rhodium and iridium

For the precipitation of palladium and platinum and their collective separation from rhodium and iridium, Ginzburg *et al.*[50] used a suspension of copper(I) chloride in hydrochloric acid that was $\leq 0{\cdot}15M$ and contained 0·5–0·7 g of sodium chloride per 100 ml. The extent to which rhodium was co-precipitated depended on the acidity and the chloride concentration, increasing rapidly with a decrease of sodium chloride concentration below 0·10*M*. Selenium was removed by evaporation from a bromate solution, then tellurium by a cation-exchange (KU-2) separation. The effluent containing platinum, palladium, rhodium and iridium was treated with suspended copper(I) chloride. The mixed precipitate was filtered off and washed with hydrochloric acid at pH 2, then with brine solution to remove the admixed copper chloride. The platinum and palladium were dissolved in *aqua regia* and palladium was determined by dimethylglyoxime and platinum by precipitation with mercury(I) chloride or spectrophotometrically. The filtrate from the copper(I) chloride together with a solution of any residue remaining after dissolution of the platinum and palladium on the filter paper was treated to determine iridium polarographically and rhodium spectrophotometrically. For relatively high rhodium contents, iridium was determined polarographically: a simultaneous precipitation of rhodium and iridium by thiourea was made and rhodium was determined by difference. The data recorded by the authors, all in the milligram ranges, indicated somewhat indifferent separation efficiency and accuracy. Mitigating against the method are factors such as reagent instability, the sensitivity of platinum–rhodium separations to the sodium chloride content, and the adverse effect of high proportions of rhodium.

Rhodium and iridium

For the separation of rhodium from iridium, Tertipis and Beamish[51] heated a 1·0*M* hydrochloric acid solution of the metals to 80–85° in the presence of freshly reduced copper powder. The precipitate of copper and rhodium was collected and treated with *aqua regia*, and any residue was chlorinated at 700° in the presence of sodium chloride. The solution of copper and rhodium salts was converted into a chloride solution and the pH adjusted to 1·3–1·5. Copper was selectively removed by the cation-exchanger Dowex 50W in the sodium form. Milligram amounts of rhodium were determined gravimetrically with thiobarbituric acid and microgram amounts spectrophotometrically with tin(II) chloride. The rhodium–copper filtrate was treated with the cation-exchanger to remove copper, and iridium was determined gravimetrically with 2-mercaptobenzothiazole or spectrophotometrically with tin(II) chloride. The method was applied successfully to the range of 5 mg to 50 μg of the two metals. Cross-contamination of the precipitates was negligible.

Formamidinesulphinic acid (thiourea dioxide) was used by Prokof'eva and Bukanova[52] to precipitate rhodium in the presence of iridium. The filtrate was treated to determine iridium gravimetrically, potentiometrically or polarographically. Following dissolution of the rhodium complex a tin(II) chloride spectrophotometric method was applied. The method was applied to amounts of 50–200 μg of rhodium and 50 μg to 23 mg of iridium in ratios from 1:10 to 1:100. The accuracy of recovery was about $\pm 4\%$ for rhodium and about $\pm 5\%$ for iridium: co-precipitation of iridium with rhodium increased with increasing iridium concentrations.

Multicomponent mixtures of the noble metals

A method of separating and and determining silver, ruthenium, rhodium and palladium, developed primarily for radiochemical separation, was recorded by Dehmlow and Preiss.[53] The procedure is classical in approach, with silver chloride precipitated first and purified by dissolution in ammonia. The combined filtrates were treated with sodium hydroxide and sodium hypochlorite and the ruthenium tetroxide was extracted with carbon tetrachloride and subsequently back-extracted into sodium hydroxide containing sodium hydrogen sulphite. Palladium was removed from the aqueous phase dimethylglyoxime and then rhodium by reduction with titanium(III) chloride. The authors considered the method suitable for semi-microquantitative applications, and 10–12 min sufficed to give reproducible quantitative separations of high chemical yield and high purity. The authors' conjoint use of the terms quantitative and high chemical yield is questionable and the data recorded do not support the claim for quantitative recovery, though recoveries should be quantitative if the time taken were extended.

Very few reagents provide a greater separational potential than sulphide salts or acids. On the other hand the resulting sulphide precipitates are seldom satisfactory weighing forms. Despite this fact, analytical recipes claiming success with the sulphides of noble metals continue to appear in current literature. Salaria[54] recorded procedures for the separation and determination of platinum in the presence of rhenium or zirconium and for gold in the presence of zirconium by a separational precipitation with sodium sulphide followed by adjustment of the hydrochloric acid concentration to 6*M* for platinum and to 1*M* for gold. In each case the noble metal sulphide was used as the weighing form. An error of 0·0–0·15% was claimed for 15–30 mg of platinum and 0·0–0·13% for 20–40 mg of gold. These methods were discussed in an earlier review.[55] It is emphasized again that the accuracy claimed requires verification by independent investigators.

Thermolysis curves for the sulphides of gold, platinum, ruthenium and palladium have been recorded by Taimni and Tandon.[56] Oven-dried gold sulphide gave a horizontal up to 220°, being converted into metal at 280°. In the case of platinum, Taimni and Salaria[57] had recorded previously that drying *in vacuo* at room temperature produced $PtS_2 \cdot 5H_2O$, and that at 130–135° the constant weight corresponded to $PtS_2 \cdot 2H_2O$. The later thermogram by Taimni and Salaria indicated that the air-dried pentahydrate lost water and sulphur from 50° to 310° at which temperature the metal was formed. The trihydrate behaved in exactly the same way. In the case of ruthenium the earlier work indicated the formula $Ru_2S_3.2H_2O$ for the product obtained by drying *in vacuo* to constant weight at room temperature. The later thermolysis curve indicated a loss of weight from 60° to 180° with a horizontal at 180–240° corresponding to an uncertain composition, then a gain in weight to 340° with a horizontal at 340–410°, again without a stated composition, then a loss of weight until the metal was obtained at 500°. In the case of palladium the earlier work[57] indicated a constant composition of $PdS.2H_2O$ after drying *in vacuo* at room temperature. The later thermogram[56] indicated a loss of weight by the air-dried precipitate from 50° to 420° with subsequent increases and decreases. From 800–840° the horizontal corresponded to PdO, the metal being formed at 890°. From the earlier work of Taimni and Salaria[57] the precipitate of $Ir_2S_3.10H_2O$ could be heated to 85° with the weight remaining constant. Although these authors did not record thermograms of this precipitate, Duval[58] recorded his failure to find any level of constant composition over the range 44–842°, which suggests that no iridium compound is formed that is suitable as a weighing form. The thermolysis curves provided

by Taimni and Tandon[56] do not provide evidence for the acceptability of the weighing forms recommended by Salaria and this failure does not encourage confidence in the sulphide methods described by Salaria.

A method of isolating platinum metals from partially refined concentrates was discussed by Zachariasen and Beamish.[59] The technique was designed to provide a method of dissolution of platinum metal concentrates which could be applied both to large scale operations and to analytical processes. Methods of isolation were included which would lend themselves to the precipitation of both large and small amounts of platinum metals. The concentrate used contained some 25 elements in addition to about 25% of platinum metals (including traces of osmium). Ths principal base metals included nickel, tin, copper, lead, chromium and iron, and silica was also present. Standard methods of dissolution, such as fusion with lead or zinc followed by treatment with acids, fusion with sodium peroxide, or chlorination with or without a sealed tube, were rejected for various practical reasons. The process finally accepted involved an intimate mixing of concentrate and sodium carbonate, sintering at 700° and leaching with water and acid. The dissolution resulted in a residue containng silica and a very small proportion of platinum metals, amounting to a total of about 2–3% of the original sample. The residue was readily fused with sodium peroxide. This sintering method resulted in very little corrosion of the container and could be made in a silica vessel. The sintered mass was coherent and could be taken from the vessel as a solid, dry body. In general, subsequent treatments involved classical separations which would lend themselves to large scale treatments. One distinct innovation involved a new method of separating rhodium from iridium, developed by Tertipis and discussed above. The results compared favourably with those obtained by spectrophotometric and spectrographic methods.

FIRE ASSAY

Although reports of solvent extraction separation of noble metals from aqueous media are numerous, relatively little has been recorded concerning the no less important solvent extraction by metals or alloys from fused media. Practically no data are available on distribution coefficients, stability constants of the dissolved constituents *etc.*, which would allow prediction of the effectiveness of extraction from the associated base metals, even for classical extractants such as lead. The phase diagrams for these alloys are of very limited assistance because the collecting alloy invariably requires a very high weight ratio of collector to noble metal. Furthermore, with the present very limited knowledge of the identity of the noble metal species in aqueous solutions of complex noble metal–base metal alloys, one must rely to a considerable degree on empirical approaches for the development of improved methods of separating noble metals from one another and particularly from high proportions of base metals. Very little progress in investigation of fire assay treatments has been recorded in English-speaking countries. On the other hand, such assay problems have received incomparably more attention in Russian laboratories. Recently, Shlenskaya[60] reviewed some of the Russian developments in noble metal analysis and stated that "conferences on the analysis of noble metals, in which workers from research institutes and plant laboratories participate, are regularly held in the Soviet Union." The present author has made a considerable effort to secure copies of the original Russian publications which deal with the separation and determination of the noble metals but with little overall success. Wherever possible, however, pertinent material in the various abstracts has been included.

An excellent general discussion of the problems associated with each stage of the fire assay processes was recorded by Britten.[61] His comment on the future status of fire assay is of some interest; "In common with gold assaying elsewhere the classical methods of fire assay have continued to withstand all competition from the new methods of chemical analysis which have been adopted as standard practice in other fields." He outlined the steps which are being taken to reduce the various errors caused by pulverizing, cupellation, parting *etc.* It was considered that for existing processes of cupellation "The absorbed gold under good conditions of assay varies from about 0·5 to over 2% being inversely proportional to the weight of the final bead" and under specific conditions the oven assay is reasonably in balance with the measured losses of gold in the cupellation stages. The author concluded that a rise in the price of gold would encourage researches designed to produce increased accuracy of determination.

In an interesting paper, Hanrahan[62] stated that the results from two streams of assaying showed that the maximum differences in results were 2 parts per 10000. In discussion of the optimum gold–silver ratio for cupellation he stated that the absorption of gold by the cupel tended to decrease with increasing proportions of silver. The ratio of silver to gold of 2·5 represented the highest concentration of silver which could safely be subjected to normal acid parting.

Among the reports which deal with the losses of gold during the various stages of a fire assay, Coxon, Verwey and Lock[63] have shown that routine mine assays give values about 2% too low, the losses being made up as follows; 0·5% of gold to crucibles, slags, and button dressing, 0·7% to cupel, 1·2% dilution by iron during pulverizing. These losses are partially compensated for by the 0·4%

of silver retained from the bead after parting. Sinclair[64] pointed out that for samples which require little or no pulverizing the 1·2% loss can be neglected and for those cases where the silver retention by the gold is higher there may be a compensation of errors. Sinclair also reported on the amount of gold lost to slags and cupels and compared these losses with the silver content retained after parting. To determine the slag losses he made 132 residue fusions, the slags from which were remelted and re-assayed without crushing: the loss to slags was 2·20%. Losses to the slags and cupels, determined from 44 residue fusions without crushing, were 2·59 and 0·52% respectively. In the latter case, drillings with ¼-in. drill to a depth of ⅜ in. were used. The actual loss was reduced by 1·91% because of silver retention in the parting acid. The gold content of the litharge averaged 0·0036 mg for 4·3 g. Experiments with crushed slags and cupels which showed a nett loss of 12·82% indicated an appreciable contamination from the manganese-steel jaw-plates, and a direct determination on 8·12 g of skimmings from the latter yielded 0·041 g of gold. The nett loss on large composite samples of residues averaged 1·27% the slags from the fusions were not crushed. In a similar experiment in which the slags were crushed the apparent nett loss of gold was 9·35%. Salted composite samples, for crucibles washed with litharge, yielded results 2·23% low and for unwashed crucibles 1·36%: salted barren silicate samples yielded corresponding values low by 2·24% and 1·25%.

For the determination of gold in ores, concentrates and cyanide eluates, Linhart[65] rejected the polarographic determination because of losses of up to 50% caused by adsorption on voluminous precipitates such as silver chloride and iron hydroxide. He calcined the samples and formed a lead–gold button by fusion at 800–900° in the presence of borax and sodium chloride The lead was cupelled to form a silver bead which was parted in nitric acid. The parting acid was drawn off by suction and the gold dissolved and determined polarographically. To determine gold in biological material the latter was ignited and treated as described above.

For the determination of gold in ores, Bagdasaryn[66] used a wet extraction of 50–100 g with nitric acid, leaching 7–8 times. The dried residue was treated with *aqua regia*; the mixture was evaporated and treated with hydrochloric acid. The chloride filtrate was evaporated to small volume and neutralized to litmus. Gold was precipitated by excess of standardized iron(II) sulphate, the excess being back-titrated with potassium dichromate with *N*-phenylanthranilic acid as indicator.

Aluminium–gold alloys cannot be cupelled directly because of the oxidation to aluminium oxide. Scherfaufer[67] selectively dissolved the aluminium with 5*M* sodium hydroxide and filtered the gold. The paper was ashed in lead foil which was then fused to produce a lead button. Gold was then determined conventionally by cupellation.

An assay method for the determination of gold in materials containing high proportions of iron or chromium was recorded by Maslenitskii *et al.*[68] Iron oxide was removed by dissolution in hydrochloric acid and chromium oxide by *aqua regia*. Gold was then determined by precipitation and cupellation.

One of the most exhaustive examinations of the fire assay process for the collection of nanogram amounts of the noble metals was described by Beyermann.[69] The fusion technique was varied somewhat in that a little flour and lead granules were added subsequent to the fusion at 900°. The fusion mixture contained litharge, borax, silica, sodium carbonate and flour. Re-fusions of the slag were also made and the lead buttons were then combined. Standard cupels as well as some prepared from bonemeal and Portland cement were used for cupellation after preheating at 900°. In general, the noble metal content was about 1 ppm. The samples analysed were galena, feldspar, roasted ore and a synthetic galena. The author's results agreed with previous findings that collection by silver beads was ineffective for nanogram amounts of iridium, ruthenium and rhodium but relatively complete for gold, palladium and platinum.

Losses of radioactive palladium, platinum and gold during the parting process with either concentrated sulphuric acid or 50% v/v nitric acid were investigated. The parted residue was filtered through media with 1-μ pores and the radioactivity of the filtrate was measured. For 10-mg beads and platinum contents ranging from 0·02 to 1·8% the relative losses after parting with nitric acid ranged from 19 to 2% respectively for these extremes. In the case of sulphuric acid the relative losses were 0·04% for 0·1% of platinum and 6% for 0·003% of platinum. For 0·01% of rhodium, with sulphuric acid the relative loss was 81%, slightly reduced when small amounts of platinum were associated with the rhodium. Parting gold–silver beads with sulphuric acid resulted in a relative loss of 0·4% for 1·0% of gold and for 0·005% a loss of 0·8%.

Investigations were made of losses to the container wall during evaporation of aqueous solutions of rhodium, ruthenium and gold and subsequent heating of the residues to 120° and 400°. Solutions of 50 and of 2 ng of rhodium, gold and ruthenium were evaporated in such a way that the residue covered an area of 1–2 cm^2. Following evaporation the residue was heated for 10 min. After cooling the area was rinsed twice with 1*M* hydrochloric acid and the activity was then measured. With the residue heated at 120°, the losses of rhodium, ruthenium and gold to glass were respectively 0·8, 0·7 and 9·5%. At 300° the losses were appreciably higher. With quartz, the corresponding losses were

appreciably smaller. The activities retained in the container were not significantly removed by treatment with hydrochloric acid: chlorine and bromine were without effect, but short treatments with hydrofluoric acid eliminated the activities.

The effects of associated metal constituents on the efficiency of various extractions of each noble metal were examined. The noble metal was present in concentrated hydrochloric acid or ammonia solution. In each case 2-ng, 50-ng and 2-mg amounts of noble metal were used along with the associated metals, including silver and lead. The extractants for which there was no appreciable influence from associated metals were tributyl phosphate in benzene (10 mg of associated metal): n-octylamine and tri-n-octylamine in chloroform (50 mg of associated metal): butylamine in chloroform (from ammoniacal media): the extraction of 50 ng of rhodium, ruthenium and iridium with sodium diethyldithiocarbamate in chloroform from sodium carbonate or ammonical media was not affected by 10 mg of platinum, palladium or gold: 2 μg of rhodium could be extracted in the presence of uranium or thorium. Special precautions were necessary for the separation of rhodium, iridium and ruthenium from ammoniacal solutions of platinum, palladium and gold. Extraction of 10 ng of gold from hydrobromic acid was 99·8% complete: furthermore, in the presence of 50 mg of platinum, palladium rhodium and iridium and 50 mg of gold, only traces of the platinum metals were co-extracted. With dimethylglyoxime in ethanol and chloroform 50 ng to 1 mg of palladium could be extracted from solutions containing platinum, rhodium, iridium, calcium or aluminium chloride: only 1–2% of the noble metals were found in the chloroform layer.

The efficiency of co-precipitation of 2 and 50 mg of noble metals with the common precipitants and collectors was investigated. These were lead and rhenium sulphides, mercury mixed with mercury(I) chloride, selenium silver and lead chlorides, and various hydrous oxides. In the case of lead sulphide, additions of 10 g of nickel, aluminium, calcium and sodium were without adverse influence. Co-precipitations of the sulphides of rhodium, iridium and ruthenium with rhenium sulphide required the application of pressure. With selenium, co-precipitation was accomplished by sodium sulphite in sulphuric acid medium. In the presence of 50 mg of silver and 2 ng of the noble metals 24% of the silver was co-precipitated, and if 0·1 mg of silver was present, 80% of it was co-precipitated. Co-precipitation of the platinum metals with a mixture of mercury and mercury(I) chloride was unaffected by high proportions of iron, nickel and gold. Co-precipitation of palladium with silver chloride has been a consistent problem in the parting of noble metal–silver assay beads. Beyermann found that dissolution of the silver chloride in ammonia and reprecipitation of the silver chloride removed two-thirds of the co-precipitated palladium: the results for a solution containing 2 μg of the noble metal and 10 mg of silver are of some significance—the amounts of iridium(IV) palladium(II), gold(III), platinum(IV) and rhodium(III) co-precipitated were 95, 19, 9, 3 and 2% respectively. In the case of 1 g of lead as the chloride in the presence of 2 and 50 ng of rhodium, 2 and 4% respectively of the latter were co-precipitated.

He also dealt with co-precipitation of the noble metals with iron hydroxide from various aqueous media. From 2*M* ammonia solution containing 50 ng of rhodium(III), gold(III), platinum(IV), iridium(IV) and palladium(II) the recoveries were 59, 35, 45, 24 and 3% respectively. Results were given for solutions of sodium acetate and concentrated ammonia. In the case of the potassium bromate hydrolytic method of Gilchrist and Wichers[70] it is noted that in the presence of 5 mg of nickel, iron, palladium or rhodium the amount of platinum(IV) co-precipitated from a total of 50 ng was 2, 4, 4 and 5 ng respectively. Similarly, small amounts of gold were also co-precipitated, particularly in the case of 50 ng of palladium. About 2 ng of platinum(IV) were co-precipitated in solutions containing 25 mg of rhodium, palladium or iridium and 50 ng of platinum(IV).

The author's investigation of the separation by ion-exchange resulted in some unexpected conclusions. Dowex 1 was used to adsorb gold, platinum and palladium in 6*M* hydrochloric acid. Only 5–15% of the anions could be eluted with concentrated hydrochloric acid. Continued treatment removed two-thirds of the metals, and eluting media such as 2*M* ammonia were less effective. Recovery was accomplished sucking the resin dry, mixing it with litharge and fusing. Treatment of the lead regulus resulted in complete recovery of either 10 μg or 50 ng of rhodium. In the case of 50 ng of rhodium along with 50 mg of palladium, iridium or platinum, the recoveries of rhodium were 92, 100 and 97% respectively, the other three metals remaining adsorbed. In the present author's opinion, these results require some confirmation.

The author's results dealing with losses by evaporation were significant. Solutions containing 5 ng to 2 mg of ruthenium could be fumed with hydrochloric or nitric acid or *aqua regia* without loss, but in the presence of 25 mg of osmium and 10 ng of ruthenium 1% of the latter was lost on fuming with concentrated nitric acid. For the volatilization of 10 ng to 5 mg of ruthenium the author preferred sulphuric acid–bromate, hypochlorite (chlorine in alkaline solution), and perchloric acid to the sulphuric acid–dichromate oxidation. In contrast to other oxidizing media, perchloric acid avoided the introduction of oxidizing media into the receiving solutions and thus losses of ruthenium. Nitric acid was an effective oxidant for osmium but the receiving liquid of hydrochloric acid required

saturation with sulphur dioxide, and losses of osmium resulted from boiling off the hydrochloric acid.

Beyermann proposed three methods of treating silver beads. One applied to beads containing no more than 10 μg of gold or platinum. A second was intended for the determination of gold and palladium only. These two procedures involved combinations of standard treatments such as parting with sulphuric acid. Techniques were included for the recovery of palladium adsorbed by the silver chloride and for the isolation of palladium by extraction of the dimethylglyoximate by chloroform. Palladium was finally determined amperometrically. The "insoluble" residue of gold or platinum from the parting treatment was treated with *aqua regia* and fumed with perchloric acid, and gold was extracted as the bromide by diethyl ether and finally determined amperometrically. Platinum in the aqueous phase was also determined amperometrically.

The third method involved parting the bead with sulphuric acid, then adding selenium dioxide and sodium sulphite to the mixture. The residue, of gold, platinum, palladium and part of the silver, was dissolved in *aqua regia* and fumed to remove the selenium. Gold as the bromide was extracted by ether, followed by extraction of palladium dimethylglyoximate from the aqueous phase by ether, and then platinum was determined as in the first two methods. The results recorded for salted solutions indicated good recoveries of gold, palladium and platinum in microgram and submicrogram amounts. In each case, the solutions contained a second noble metal from which there was no significant interference. The methods were also applied to a variety of noble metal products such as roasted ore, iron ore, slags, silver coins and lead, generally with an accuracy acceptable in comparison with other methods. For the iron ore the values obtained by a spectrochemical method for gold, platinum and palladium were 0·09, 0·24 and 0·4 respectively as compared with the author's values of 0·13, 0·10, 0·21.

The present author's efforts to secure copies of original Russian publications dealing with the fire assay for noble metals met with little success. Consequently, most of the information included below has been obtained from various abstracts and thus details of significance may be lacking.

In order to ensure thorough mixing of the pot charge during the assay procedure for noble metals Anisimov *et al.*[71] arranged for mechanical mixing during the smelting process: the initial heating procedure was slow and super-heating was applied at the conclusion of the fusion. An excess of reducing reagent was required with a limited amount of litharge, part of which was added as a solution of lead acetate in order to secure uniform distribution and intimate contact with the noble metals. One may assume that the moistening process involves wetting the whole of the pot charge. Light and fluid slags were obtained with the ores used and the acidity of the charge varied between 1 and 1·5. The authors noted that impurities collected by the lead button assisted in the extraction of the platinum metals. In the case of noble metal concentrates, the accuracy of recovery was increased by resmelting the slag and the cupel.

Anisimov and his co-authors made several reports dealing with the fire assay of the noble metals. The losses of platinum metals at each stage of the assay of concentrates was studied.[72] The techniques included the preparation of a silver–lead button, scorification, reassay of slags and cupels, and the analysis of the silver bead. The ratio of noble metals to silver in the bead was 1:15 or 1:20, but in the case of high iridium was made 1:40. The fusion was carried out at 1000–1050° for 1·5 hr. The 40-g lead buttons were scorified to 18·25 g. The cupellation temperature was 900–950°. The authors included the losses to slags and cupels for platinum, palladium, rhodium, iridium and ruthenium. The amounts recovered from two silver beads were respectively 100·0 and 100·0, 99·9 and 100·0, 99·5 and 99·7, 98·3 and 100·0, 99·2 and 99·9%. Small amounts of selenium or tellurium were without effect. A separate lead button was used for ruthenium. The authors found that reassay of the first pot slag, and of the cupel, was required for good accuracy. To combine two silver beads, fusion was made in a chamotte crucible under a layer of soda, borax, and wood charcoal. Anisimov *et al.*[73] also provided a detailed description of a method for treating silver assay beads. These were parted with nitric acid and the residues were treated with *aqua regia* to dissolve the gold and platinum. The former was finally precipitated with sulphur dioxide and the latter as ammonium chloroplatinate. The residue from the *aqua regia* treatment was sintered with barium oxide, the sinter was treated with hydrochloric and sulphuric acids and the barium sulphate was removed. The filtrate was evaporated to fumes and sodium bromate was added to produce ruthenium tetroxide which was distilled and determined by potentiometric titration. The pot-liquid was boiled with hydrochloric acid to destroy the bromate, and sodium nitrate free from ammonium or potassium ion was added. Sodium sulphide was added to precipitate the rhodium and any residual platinum. The precipitate was dissolved in *aqua regia*, and later evaporated with hydrochloric acid. Platinum was again precipitated as ammonium chloroplatinate. The filtrate was treated with zinc to precipitate the rhodium, which was purified by fusion with silver under borax to remove contaminants. Iridium in the filtrate from the sulphide precipitation was finally determined potentiometrically.

For the determination of gold and silver in ores, Anisimov *et al.*[74] prepared a second lead button from the scorification and crucible slags and scorified the two buttons. Gold was determined by a potentiometric titration with hydroquinone.

The techniques and principles involved in fire assay methods were reviewed by Anisimov.[75] The function cupellation and scorification was outlined and methods for determining osmium and ruthenium were discussed. In particular, the author included a description of the wet methods of parting and determining the constituents in a noble metal–silver bead.

Methods of preparing ore concentrates for the assay of platinum metals were discussed by Anisimov *et al.*[76] The concentrates included copper–nickel ores, mattes, cementates, and other products containing large amounts of selenium, tellurium, arsenic, and antimony. The finely ground product was mixed with sawdust, sulphur and concentrated sulphuric acid, and was heated first at 240–300° and then at 375° for 2 hr. The powdered sinter was mixed with aqueous starch, dried, and again heated at 375° for 1–2 hr. The sinter was leached with water and the residue was fused. If appreciable selenium, tellurium, arsenic, tin and antimony were present the sample was chlorinated after mixing with sodium chloride and charcoal and wetting with starch to form granules: these were dried in a desiccator and heated in a tubular oven for 4 hr at 500–550° in a chlorine current. A single treatment removed up to 95% of the selenium and tellurium. If the sample contained iridium or ruthenium as well as copper the residue was subjected to two sulphuric acid treatments. The presence of copper in the lead assay button encouraged dissolution of ruthenium and iridium by the nitric acid parting solution.

Anisimov *et al.*[77] found that a spectral analysis of assay beads obtained from low-grade products increased the overall sensitivity of determinations relative to classical methods and thus permitted the use of smaller weights of samples than those normally used for fire assay: 50-mg silver–rhodium and copper–ruthenium–iridium beads were used. These were obtained from the residue of the lead parted with dilute nitric acid. The authors stated that when the weight ratio of platinum and palladium to ruthenium and iridium was less than 100, the latter two metals could be determined spectrochemically, without a separation of platinum and palladium. When the weight ratio was 200, the residue from the silver bead could be treated with *aqua regia*. It is most unfortunate that the details of the spectrochemical methods were not available. Normally, one of the most important problems is the necessity of achieving homogeneity in the beads or residues used by these authors. They stressed again the influence of copper and nickel which caused some dissolution of iridium and ruthenium in the button parting acid. A scheme of analysis of ores and their concentrates for rhodium, ruthenium and iridium was included.

For almost a century following the discovery of the platinum metals the only effective general method for the determination of these metals in ores involved a collection by molten lead from fused media of suitable composition. Furthermore, there can be little doubt that this method suggested itself through the similarity in properties of the platinum metals and gold, for which the assay-metallurgical method had been an ancient procedure. It is only within the past few years that organized investigations have been made to determine the effectiveness of lead as a collector for each of the six platinum metals and indeed even for gold. The results of these investigations, made in various parts of the world, are in approximate agreement that for such metals as gold, platinum, palladium, ruthenium, osmium and perhaps for rhodium the lead collection is effective for amounts of the order of small fractions of a milligram. Thus the classical fire assay will reveal commerically valuable noble metal values for all ores and concentrates although quantitative success will depend upon the assayer's experience and wisdom in the choice of technical conditions. Much of the early work which was concerned with the examination of the efficiency of classical fire assay has been reviewed.[78] Results were obtained which indicated some lack of efficiency of the fire assay for iridium. Because of this and the desirability of having available alternative assay methods for noble metals, various researchers developed procedures which involved collectors other than lead.

Tin has been used as one alternative. In a series of papers Faye and co-workers[79–87] have developed a scheme of separation of noble metals incorporating spectrophotometric methods of determination. The various steps in the method were each carefully proved and the method as a whole was applied with success to copper–nickel matte, precious metal concentrates, meteorites, and iridosmine. Although Faye provided a procedure for the continuous determination of the seven noble metals from a single sample, variations in procedure allowed for simplified determinations of certain noble metals in the absence of others. If the ore contains much sulphur or arsenic it is roasted at 750–800° to avoid the formation of a matte or speiss. For samples containing high proportions of copper and nickel a leaching process is recommended. In general, the precious metals are collected in molten tin when the sample is fused at 1200–1250° with a flux containing tin(IV) oxide, sodium carbonate, silica, borax and powdered coke. The resulting tin alloy is placed in a graphite crucible and melted at 600–700° in an atmosphere of nitrogen and then poured into a gallon of water to disintegrate the button. The liquid is decanted and the particles of noble metal–tin alloy are dried. These are parted in concentrated hydrochloric acid and if osmium is present the tetroxide is distilled in the presence of hydrogen peroxide, collected in hydrobromic acid[79] and determined with pyrogallol.[80] The pot residue is treated with hydrochloric and hydrobromic acids to volatilize the tin. In the absence of

osmium this treatment is applied directly to the solution of the noble metal residue produced by adding tin to the hydrochloric parting acid.

The mixed halide solution is treated to remove gold by extraction with diethyl ether and determined with *o*-tolidene.[81] At this stage, if more than 2 g of base metals are present they are removed by cation-exchange, and then the acid solution of the remaining noble metals is treated with perchloric acid to volatilize the ruthenium tetroxide which is collected in concentrated hydrobromic acid and determined spectrophotometrically.[79] The perchloric acid in the pot solution is removed by evaporation with hydrochloric acid* and with *aqua regia*, and further evaporations with hydrochloric acid. The chloride solution is treated with sodium iodide, and rhodium and iridium are extracted with tri-n-butyl phosphate (TBP) in hexane.[82–85] These metals may be separated by a modification of the method of Yoe and Kirkland,[88] in which case the palladium *p*-nitrosodimethylaniline complex is extracted from the aqueous phase by chloroform. The aqueous phase is treated with sulphuric and perchloric acids and platinum is determined with tin(II) chloride. The TBP–hexane phase is evaporated nearly to dryness and nitric acid is added to destroy the iodides. The metal salts are then converted into chlorides and hydrogen peroxide is added to ensure oxidation to iridium(IV) which is extracted by TBP–hexane, stripped by hydrochloric acid and finally determined with tin(II) chloride in hydrobromic acid. Rhodium in the aqueous phase is reconverted into the chloride complex and the solution is evaporated to dryness. The metal is determined with tin(II) bromide in perchloric acid.

The complete procedure, including a number of variations, depending upon the number of metals present and their proportions, was recorded by Faye.[86,87] The reports bear the marks of carefully applied techniques and the results are excellent.

Recent researches, reviewed earlier by the present author,[78] have indicated that the composition of the flux used for the classical assay may affect the recovery of iridium, basic slags producing relatively high losses. High losses also occur in the presence of much copper and nickel. To explain these losses it was suggested that the lead collector, which has a minimum crystal size factor of 3·00 Å, is above the theoretical size required for a good solvent of precious metals. Thus, the collection of iridium by lead is probably achieved largely through mechanical processes. This and other deficiencies in the quantitative collection of iridium by classical fire assay led to the investigation of other approaches. Because of the regular occurrence of copper, nickel and iron with the platinum metals it seemed probably that these metals could serve as collectors in a fire assay. One would guess too that the disintegration of the base metal silicates and the noble metal constituents would occur simultaneously and that their juxtaposition would thus encourage the efficiency of collection. The base metal buttons were prepared by reduction with mechanically mixed graphite, soda ash, borax, and ore with base metals added if required. The buttons were placed in standard distilling equipment together with hydrochloric acid (3 + 1) and a stream of nitrogen was passed through.[89] Heat was applied to accomplish dissolution Any small amount of osmium tetroxide developed during this treatment was collected in a receiver trap containing hydrochloric acid into which sulphur dioxide was bubbled. The content of the distillation flask was heated to yield a moist chloride cake which was moistened with water and allowed to stand overnight exposed to the atomsphere. The mixture was then diluted with water and filtered. The filter paper and residue were treated in the distillation flask with sodium hydroxide solution, chlorine was passed through and any osmium and ruthenium tetroxide were collected in hydrogen peroxide. This solution was added to the pot-liquid as indicated below. The filtrate from the pot-liquid was diluted with water, the pH adjusted to 0·9–1·5 and the base metals selectively removed by a cation-exchanger which was then washed with hydrochloric acid at pH 1 (see also reference 90). The effluent was treated with a stream of sulphur dioxide for 1 hr followed by a 6-hr standing period. The solution was evaporated to 500 ml on a hot-plate and subsequently to 15 ml in the distillation flask under an atmosphere of sulphur dioxide.

This solution was combined with the osmium and ruthenium from the filter paper and residue as indicated above, and then treated as described by Westland and Beamish[91] to remove osmium, and the pot-liquid containing the remaining platinum metals was also treated by Westland's procedure to remove ruthenium.

The pot-liquid now contained all of the platinum, palladium, iridium and rhodium. Rhodium and iridium may be separated and determined as described by Tertipis and Beamish[51,92] or by Sant and Beamish[93] and also by the various other methods recorded above. Platinum and palladium may be separated and determined as described by Coburn *et al.*[94] and by Plummer.[95]

The physical characteristics of the iron–copper–nickel–noble metal alloys were described by Plummer *et al.*[95] It was concluded that palladium and probably some of the other platinum metals form solid solutions with the alloy.

* Recent researches by the author have shown that though perchloric acid is removed by evaporations with hydrochloric acid and/or treatment with *aqua regia*, the removal is not sufficiently complete to allow the subsequent use of a cation-exchanger for the separation of decagram amounts of base metals.

The iron–copper–nickel collection was applied to determine the composition of iridosmines. Sen Gupta and Beamish[97] found that the fusion allowed the dissolution of even such resistant alloys as Tasmanian iridosmines. The results obtained by the method agreed with those from a chlorination of the iridosmines.

The iron–copper–nickel collection was used by Kavanagh and Beamish[98] to collect osmium and ruthenium quantitatively from roasted sulphide ores. The method involved parting of the alloy and distillation of the tetroxides of osmium and ruthenium from perchloric acid. Thiourea in 6*M* hydrochloric acid was used as the collecting liquid when both metals were distilled simultaneously, and hydrobromic acid when ruthenium only was distilled. The metals were precipitated as the thionalide complexes. Perchloric acid was also used for the dissolution of siderite meteorites.[99] The platinum metals were separated and determined as in the case of the iron–copper–nickel assay button.

This fire assay for osmium was extended to apply to sulphide concentrates. This adaption avoided the oxidation previously used by Kavanagh to eliminate sulphur, a process which could cause the loss of osmium. Van Loon and Beamish[100] used hydrogen to reduce the sulphur content to a level which allowed a clear fusion. For flotation concentrates, salted with 16–805 μg of osmium per assay ton, only microgram losses were found.

Because of the high temperature required for the fusion of iron–nickel–copper buttons an effort was made to reduce the required temperature by the addition of copper to the ore. Banbury and Beamish[101] collected platinum and palladium quantitatively in this way. Buttons of 25–40 g in weight were prepared from a roasted artificial sulphide containing 81·5 g of copper sulphide. The palladium content varied from 40 μg to 10 mg: the platinum content from 50 μg to 10 mg. Recoveries were acceptable in all cases. Initial furnace temperatures were 1100° and were raised to 1200° over a period of 1·5 hr. The chemical treatment involved the removal of copper by cation-exchange from the parting solution adjusted to pH 1·0 $\pm$ 0·1. By a similar process, Banbury[102] collected rhodium by means of copper. As in the case of platinum and palladium, losses to siliceous residue, slag, pot-wall, and ion-exchange resin were found to be negligible. Copper was also used as a collector or iridium. Agrawal and Beamish[103] considered copper superior to lead for the collection of iridium in that it can be applied successfully in the presence of the commonly associated transition metals. It was superior to copper–iron–nickel in that comparable collections could be made at lower temperatures. Maximum recovery was achieved with acid slags of 3·0 silicate degree.

Despite the availability of new collectors for the noble metals, the classical lead collector remains clearly superior for the determination of platinum, palladium, gold and perhaps rhodium. The device of cupellation to remove the lead selectively requires very little attention and it is a reasonably rapid process compared to the methods required for the removal of copper, nickel, iron or tin. Furthermore, the ease of forming a silver–noble metal alloy by cupellation allows use of a variety of potentially useful methods of separation and determination. It should be noted that though osmium is collected quantitatively by lead, cupellation is not acceptable because of losses of osmium tetroxide, and any attempt to form a silver bead will increase the osmium losses. On the other hand, the removal of both osmium and ruthenium from lead by a parting distillation with perchloric acid is accomplished with ease.

For those analytical consultants who frequently must deal with the claim that the classical lead collection will sometimes fail to reveal noble metal values of commercial importance, the present author emphasizes the fact that no valid support has ever been recorded for this claim and one cannot doubt that the classical method used by competent assayers will invariably indicate whether a noble metal content is of commercial value.

Zusammenfassung—Diese Übersicht handelt von den Trennungen der sieben Edelmetalle durch Chromatographie, Fällung oder Schmelzverfahren, die zwischen den früheren Übersichten und Januar 1966 publiziert wurden. Die in Lösung vorliegenden Edelmetallspezies werden diskutiert, sofern sie zur Trennung und Bestimmung in Beziehung stehen.

Résumé—Cette revue traite des méthodes de séparation des sept métaux nobles par chromatographie, précipitation et voie sèche, publiées ultérieurement aux précédentes revues et antérieurement à janvier 1966. On discute des espèces chimiques sous lesquelles les métaux nobles sont présents en solution dans la mesure où elles sont reliées à la séparation et au dosage.

STUDIES IN ATOMIC-FLUORESCENCE SPECTROSCOPY—V*

THE FLUORESCENCE CHARACTERISTICS AND DETERMINATION OF ANTIMONY

R. M. DAGNALL, K. C. THOMPSON and T. S. WEST
Chemistry Department, Imperial College, London S.W.7, England

(*Received* 21 *March* 1967. *Accepted* 25 *April* 1967)

Summary—Atomic-fluorescence of antimony may be generated in an air-propane flame by nebulizing aqueous solutions of antimony salts whilst irradiating the flame by means of a microwave-excited electrodeless discharge tube operating at 30 W. The strongest fluorescence is exhibited by the $^4S_{1\frac{1}{2}} \rightarrow {}^4P_{\frac{1}{2}}$ 2311 Å resonance line and weaker signals are observed at the 2068 and 2176 Å resonance lines and at four intercombination lines, at 2598, 2671, 2770 and 2878 Å. A process of thermally assisted direct-line fluorescence is postulated to account for the otherwise inexplicable intensity of the 2598 Å line emission. Atomic-fluorescence spectroscopy at 2176 Å permits the determination of antimony in the range 0·1–120 ppm with a detection limit of 0·05 ppm. With the same equipment and source, the range of measurement for atomic-absorption was 6–120 ppm and the detection limit was 1 ppm. No interferences were observed from 100-fold molar amounts of Cd, Co, Cu, Fe, Hg, K, Mg, Mn, Mo, Na, NH_4, Pb and Zn or from arsenate, chloride, nitrate, phosphate and sulphate.

THE determination of antimony by flame emission methods presents numerous problems. The ground state atoms of antimony are difficult to excite by thermal means and the only emission studies to date[1,2] have been carried out by using the inner cone of an oxy-acetylene flame in conjunction with nebulized organic solvents. The principal resonance lines at 2068, 2176 and 2311 Å lie in the far ultraviolet and give rise to low sensitivities because of the poor response of most photomultipliers in this region. In addition, antimony hollow-cathode lamps give a low radiation output at the resonance wavelengths. In spite of this, successful atomic-absorption measurements have been made by Gatehouse and Willis, using a hollow-cathode lamp at 3211 Å.[3] The 2176 Å resonance line gave the strongest absorption, but there was less noise at the 2311 Å resonance line because of its higher intensity as detected by the photomultiplier. The limit of detection was given as 1·5 ppm. Atomic-absorption studies have also been made with a continuous source[4] and photographic recording of line intensities. The limit of detection of this method was estimated to be 0·5 ppm.

The following communication reports some of our more recent observations with antimony in the development of atomic-fluorescence spectroscopy as an analytical technique.

* Part IV—*Talanta*, 1967, **14**, 557.

EXPERIMENTAL

Apparatus

The apparatus for exciting the discharge tube and recording the fluorescence has been described previously.[5,6]

Preparation of discharge tube. Quartz tubes 3–4 cm long and 0·8 cm in internal diameter, prepared as previously described,[6] were heated to redness with an oxy-propane blow-torch and subjected to evacuation for about 10 min, during which argon was periodically flushed through the system to sweep away any impurities liberated from the walls of the tubes. The tubes were cooled under vacuum and then removed from the vacuum line, and about 10 mg of electrolytic antimony were added to each. The tubes were then evacuated, heated so that the antimony just melted, and flushed three times with argon to remove any occluded gases or volatile impurities in the antimony. After cooling, 10 mg of iodine were introduced and the tubes were evacuated and periodically flushed with argon for about 5 min to remove any moisture liberated from the added iodine (heat cannot be used because of the volatility of iodine). The tubes were finally sealed under an argon pressure of 0·5–5 mm Hg. An excess of antimony over that required for the formation of antimony(III) iodide was maintained to eliminate free iodine, the intense spectrum of which would otherwise have been emitted.

Reagents

Antimony solution, $10^{-3}M$. Dissolve 0·3249 g of potassium antimony tartrate in distilled water and dilute to 1 litre; 1 ml ≡ 121·8 μg of Sb.

Atomic-fluorescence measurements

Flame conditions. A non-luminous, fuel-rich, air–propane flame was obtained with a propane jet in the standard burner base together with the circular propane emission burner-head, the air pressure being 15 psi and the propane pressure 12 cm on the di-n-butyl phthalate filled manometer. The top of the burner-head was set 3 cm below the centre of the monochromator slit. The SP900A is used in its "emission" mode for atomic-fluorescence measurements.

Source conditions. An antimony microwave discharge tube was operated at 30 W with the end-cap off the cavity and with a moderate degree of cooling applied by blowing compressed air through the cooling aperture. The source was placed *ca.* 8 cm from the centre of the burner-head, at right-angles to the line between the flame and the monochromator slit. A 5-mm slit was cut in the burner-housing to allow irradiation of the flame.

Procedure for 1·2–12 ppm of Sb. Transfer by pipette 1–10 ml portions of $10^{-3}M$ antimony solution into a series of 100-ml volumetric flasks and dilute to volume with distilled water. Nebulize the solutions into the air–propane flame and, using a slitwidth of 0·3 mm, a gain of 3,1, and bandwidth 3, measure the fluorescence signal at 2176 Å.

Other concentration ranges, *i.e.*, 10^{-4}–$10^{-3}M$ and 10^{-6}–$10^{-5}M$, may be measured by suitable dilution of the stock solution and adjustment of the slitwidth and gain controls.

Atomic-absorption measurements

Flame conditions. A non-luminous fuel-rich air–acetylene flame was obtained with an acetylene jet in the burner base and the 7-cm long acetylene burner-head, the air pressure being 15 psi and the acetylene pressure 9 cm on the di-n-butyl phthalate filled manometer. The top of the burner head was set 1 mm above the bottom of the monochromator slit.

Source conditions. An antimony microwave discharge tube was operated at 20 W with the end-cap off the cavity and with only slight cooling applied as described above. The source was placed in the usual position for atomic-absorption measurements on the SP900A, but slightly out of focus to prevent too much light reaching the photomultiplier. The SP900A was used in its "absorption" mode.

Procedure for 6–122 ppm of Sb. Transfer by pipette 2·5–50 ml portions of $10^{-3}M$ antimony solution into a series of 50 ml volumetric flasks and dilute to volume with distilled water. Nebulize into the air–acetylene flame and, using a slitwidth of *ca.* 0·01 mm, gain 2,3 and bandwidth 3, measure the absorption at 2176 Å.

RESULTS AND DISCUSSION

Characteristics of discharge tube.

The ground state of the antimony atom[7] is $^4S_{1\frac{1}{2}}$ and a simplified Grotrian diagram is shown in Fig. 1. All the lines shown in this diagram were observed as well as higher state lines which are accounted for by Brode.[8] In addition, the 2062 Å iodine line was very prominent, but the continuum associated with tubes containing free iodine was absent.

The tube was run at 30 W and the resonant cavity was air-cooled by forced draught. Tuning was very critical and there were two modes of tuning. The first was obtained by screwing the larger of the two coupling probes fully into the cavity; the discharge obtained rapidly reverted to an argon discharge. The other was obtained by unscrewing the large probe about three complete turns. This gave an intense stable output. The variation in response was $\pm 1\%$ over a period of 1 hr.

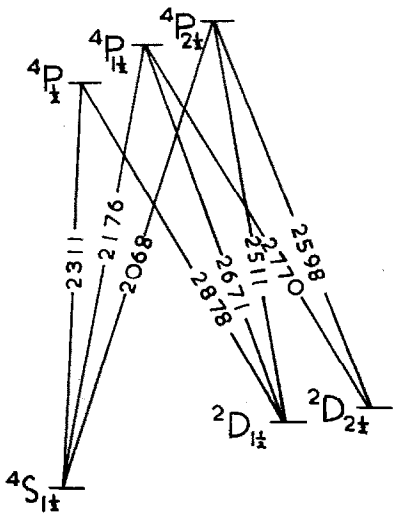

FIG. 1.—Simplified Grotrian diagram for antimony.

Close to the 2176 Å resonance line there is a non-resonance line at 2179 Å which, according to Brode,[8] is slightly more intense in the spark than in the arc spectrum. The 2176 Å resonance line however, is, only an eighth as intense in the spark as in the arc spectrum. Both lines are equal in intensity in the spark spectrum and the photomultiplier response over such a small range in this region can be considered to be constant. Hence, from the relative intensities of these two lines at various operating power ratings and rates of cooling, the exact type of discharge can be evaluated.

It was found that with the microwave-excited source the ratio of the line intensities (2176:2179 Å) decreased with increasing power ratings. At 15 W the ratio was *ca.* 3, whilst at 50 W the ratio was *ca.* 0.7. The ratio increased rapidly with increased cooling, but the absolute line intensities decreased. At relatively high power ratings ($>$ 30 W), the change of intensity (I) with power (p) (*i.e.*, dI/dp) fell to *ca.* 0·3 for the resonance line, but was approximately unity for the non-resonance line. It would appear from this that at these higher operating powers self-reversal (and possibly self-absorption) occurs. The optimum power for operation was considered to be about 30 W for a tube containing an argon pressure of *ca.* 1 mm Hg and about 35 W for a pressure of *ca.* 5 mm Hg. The argon lines were quite weak in intensity and the argon:antimony line intensity ratio decreased with increasing power ratings.

Atomic-fluorescence measurements

A $10^{-3}M$ solution of antimony was nebulized into both air–acetylene and air–propane flames. Under optimum conditions both flames gave similar fluorescence

signals, but because of its much lower background radiation the air–propane flame was selected for more detailed study (both background and fluorescence signals are recorded together under the conditions of measurements[5]). The fluorescence readings shown in Table I were obtained under the optimum conditions. As can be seen the "forbidden" intercombination lines ($^4P \rightarrow {}^2D$ transitions) fluoresce relatively strongly.

TABLE I.—ATOMIC-FLUORESCENCE MEASUREMENTS AT 0·05 mm SLITWIDTH

Spectral line, Å	Transition	Relative fluorescence signal
2068	$^4S_{1\frac{1}{2}} \rightarrow {}^4P_{2\frac{1}{2}}$	57
2176	$^4S_{1\frac{1}{2}} \rightarrow {}^4P_{1\frac{1}{2}}$	80
2311	$^4S_{1\frac{1}{2}} \rightarrow {}^4P_{\frac{1}{2}}$	108
2511	$^4P_{2\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}$	0
2598	$^4P_{2\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}$	52
2671	$^4P_{1\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}$	10
2770	$^4P_{1\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}$	25
2878	$^4P_{\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}$	35

This effect was not so marked in our previous study of selenium and tellurium,[9] probably because with antimony the absorption process is by an "allowed" line, but with selenium and tellurium both absorption and fluorescence are "forbidden". This type of fluorescence can be used with advantage to eliminate flame and particle light-scattering if it occurs, *e.g.*, with a total-consumption aspirator-burner. If a filter which transmits radiation only below *ca.* 2400 Å is placed between the source of excitation and the flame and fluorescence measurements are made at 2598, 2671, 2770, or 2878 Å, then light-scattering interference cannot occur.

The fluorescence intensity at the 2598·09 Å line ($^4P_{2\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}$) is considerably greater than that at the 2671 Å ($^4P_{1\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}$), 2770 Å ($^4P_{1\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}$) and the 2878 Å ($^4P_{\frac{1}{2}} \rightarrow {}^4D_{1\frac{1}{2}}$) lines (*cf.* Table I). This was unexpected as the wavelength for excitation, 2068 Å ($^4S_{1\frac{1}{2}} \rightarrow {}^4P_{2\frac{1}{2}}$), is not the strongest line for absorption. In addition, from Sommerfield's intensity rule, the $^4P_{2\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}$ transition intensity would be expected to be less than that of the $^4P_{1\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}$ and $^4P_{\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}$ transitions, and also the photomultiplier response is more sensitive at the longer wavelengths. This implies that the fluorescence signal given at 2598 Å is due to an effect other than, or in addition to, "direct-line" fluorescence. This can be explained if it is assumed that the fluorescence signal given at 2598 Å is "direct-line" fluorescence from the 2598·09 Å line ($^4P_{2\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}$) plus a fluorescence signal from the nearby, unresolved, 2598·05 Å line ($^2P_{\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}$). The $^2P_{\frac{1}{2}}$ state lies only 0·13 eV above the $^4P_{1\frac{1}{2}}$ state (the $^4S_{1\frac{1}{2}} \rightarrow {}^4P_{1\frac{1}{2}}$ transition line gives the greatest absorption) and some of the excited atoms in the $^4P_{1\frac{1}{2}}$ state could be thermally excited to the $^2P_{\frac{1}{2}}$ state. This is a radiationless transition and the $^2P_{\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}$ transition is a spin-allowed transition favoured by Sommerfield's intensity rule.

This type of fluorescence, which can be called thermally-assisted direct line fluorescence, does not appear to have been reported before. In this particular instance, because of the nearness of the two lines, it was not possible for us to come to a more definite conclusion. However, we have observed the same effect in studying the fluorescence of bismuth atoms and in this instance the effect has been proved conclusively. These results will be reported at a later date.

Linear calibration curves were obtained for aqueous solutions of antimony over the range 10^{-6}–10^{-3}M (*ca.* 0·1–120 ppm), the 2176 Å resonance line being used. The limit of detection in water (signal:noise ratio = 1) was 5×10^{-7} *M* (0·05 ppm). The sensitivity can be increased substantially by nebulizing with organic solvents to increase the volume of solution reaching the flame[9] (*ca.* 5-fold increase) and by modulating the light source to eliminate all background radiation. Greater sensitivity may be obtained at 2311 Å, but this wavelength was not used in this study because of a "light leak" in the monochromator at *ca.* 2300 Å and because it was desired to make a direct comparison with atomic-absorption measurements with the same source. The 2176 Å resonance line gives the strongest absorption signal and in theory should, therefore, give the strongest fluorescence signal. This does not happen here because the photomultiplier (EMI 9601B) is less sensitive at 2176 Å than at 2311 Å. The limit of detection quoted could therefore be considerably improved with better instrumentation.

The variation in the fluorescence signal of an acidic 10^{-4} *M* antimony solution caused by 10^{-2} *M* Cd, Co(II), Cu(II) Fe(II), Hg(II), K, Mg, Mn(II), Mo(VI), Na, NH_4, Pb, Zn, arsenate, chloride, nitrate, phosphate and sulphate was less than 5%. The interference of other ions was not examined, but there is no reason to suppose that they would interfere.[5,10]

Atomic-absorption measurements

An air–acetylene flame was used as it gave a more stable flame than air–propane on the 7-cm burner supplied with the instrument. Also, the background is relatively unimportant in these measurements as the source is placed in the usual position for absorption on the SP900A and is therefore mechanically modulated.[5] The source was placed slightly out of focus to prevent too much light reaching the photomultiplier. As with fluorescence measurements, the optimum flame verged on luminosity. The optimum burner height was with the top of the burner head approximately 1 mm above the bottom of the monochromator slit. Table II shows the absorbance measurements obtained at the three resonance lines with 10^{-3} *M* antimony.

TABLE II.—ATOMIC-ABSORPTION MEASUREMENTS AT ~0·005 mm SLITWIDTH

Spectral line, Å	Signal absorbance
2068	0·368
2176	0·515
2311	0·247

The 2176 Å line gave the strongest absorption, and linear calibration curves over the range 5×10^{-5}–10^{-3} *M* (6—120 ppm) antimony were obtained at this wavelength. The limit of detection (1% absorbance) was 10^{-5}*M* (1·2 ppm)

The non-resonance line at 2179 Å was completely resolved from the 2176 Å line at these small slitwidths and was found not to absorb. This illustrates one of the great advantages of using an electrodeless discharge tube instead of a hollow-cathode lamp. With the latter, large slitwidths must be used because of the weak intensity of the 2176 Å line, resulting in non-resolution of the 2176 and 2179 Å lines and hence non-linear calibration curves, narrow working range, low limits of sensitivity, noise, *etc.*

As observed in our former studies[9] the atomic-fluorescence sensitivities are at least an order of magnitude better than those obtained by atomic-absorption.

Acknowledgements—One of us (K. C. T.) wishes to thank the Science Research Council for the provision of a Research Studentship. We are also grateful to I.C.I. Ltd. for the provision of a grant for the purchase of the SP900A spectrophotometer.

Zusammenfassung—Die Atomfluoreszenz von Antimon kann man in einer Luft-Propan-Flamme erzeugen, in der wäßrige Lösungen von Antimonsalzen versprüht sind, indem man die Flamme mit einer durch Mikrowellen erregten elektrodenlosen 30 W-Entladungsröhre bestrahlt. Die stärkste Fluoreszenz zeigt die Resonanzlinie $^4S_{1\frac{1}{2}} \rightarrow {}^4P_{1/2}$ bei 2311 Å; schwächere Signale beobachtet man bei den Resonanzlinien 2068 und 2176 Å sowie bei vier Interkombinationslinien bei 2598, 2671, 2770 und 2878 Å. Um die sonst unerklärliche Intensität der Emission bei 2598 Å zu erklären, wird eine thermisch unterstützte direkte Fluoreszenz postuliert. Atomfluoreszenz-Spektroskopie bei 2176 Å gestattet die Bestimmung von Antimon von 0,1–120 ppm mit einer Nachweisgrenze von 0,05 ppm. Mit derselben Apparatur und Lichtquelle war der Meßbereich bei Atomabsorption 6–120 ppm und die Nachweisgrenze 1 ppm. 100-fache molare Überschüsse von Cd, Co, Cu, Fe, Hg, K, Mg, Mn, Mo, Na, NH_4, Pb, Zn, Arsenat, Chlorid, Nitrat, Phosphat und Sulfat störten nicht merklich.

Résumé—On peut engendrer la fluorescence atomique de l'antimoine dans une flamme air-propane en nébulisant des solutions aqueuses de sels d'antimoine pendant qu'on irradie la flamme au moyen d'un tube à décharge sans électrode excité par ondes courtes et opérant à 30 W. La plus forte fluorescence est manifestée par la raie de résonance $^4S_{1\frac{1}{2}} \rightarrow {}^4P_{\frac{1}{2}}$ 2311 Å et des signaux plus faibles sont observés aux raies de résonance 2068 et 2176 Å et à quatre raies d'intercombinaison, à 2598, 2671, 2770 et 2878 Å. On admet un processus de fluorescence de raie directe thermiquement assisté pour interpréter l'intensité autrement inexplicable de la raie d'émission 2598 Å. La spectroscopie de fluorescence atomique à 2176 Å permet le dosage de l'antimoine dans le domaine 0,1–120 p.p.m. avec une limite de détection de 0,05 p.p.m. Avec les mêmes équipement et source, le domaine de mesure pour l'absorption atomique a été de 6–120 p.p.m. et la limite de détection de 1 p.p.m. On n'a pas observé d'interférences avec des quantités molaires 100 fois plus grandes de Cd, Co, Cu, Fe, Hg, K, Mg, Mn, Mo, Na, NH_4, Pb et Zn ou avec l'arséniate, le chlorure, le nitrate, le phosphate et le sulfate.

EIN SCHNELLVERFAHREN ZUR RHENIUMBESTIMMUNG IN MOLYBDÄNIT

L. BALABANOFF,® F. BERNASCONI, H. LARA und R. WOERNER
Abteilung für Analytische Chemie und Physikalisch-Chemische Untersuchsmethoden, Universität von Concepcion, Chile

(*Eingegangen* 25 *November* 1966. *Angenommen* 14 *Februar* 1967)

Zusammenfassung—Es wird eine neue Methode für die Bestimmung des Rheniums in Molybdänit beschrieben. Es wird eine Extinktions-Verhältnis-Methode angewendet, durch die das Rhenium als Thiocyanatokomplex, auch bei Anwesenheit von Molydbän ohne vollständige Trennung, bestimmt werden kann.

DIE spektralphotometrische Bestimmung von Rhenium in Erzen wird durch die Anwesenheit von Molybdän stark gestört, besonders die sehr genaue und empfindliche Bestimmung als Thiocyanatokomplex. Bei allen herkömmlichen spektralphotometrischen Methoden muß deshalb diese Störung durch geeignete Trennverfahren ausgeschaltet werden. Durch den hierfür nötigen Aufwand ist diese Methode nicht für schnelle, serienmässige Bestimmungen geeignet.[1–6]

GRUNDLAGEN

Aus dem Vergleich der Absorptionspektren der Thiocyanatokomplexe von Rhenium und Molybdän[7,8] geht hervor, daß die "Extinktions Verhältnis-Methode"[9] anwendbar ist.

Die Konzentration C an Rhenium in einer Lösung die Rhenium und Molybdän enthält, läßt sich durch folgende Formel berechnen:

$$C = \frac{E' - RE''}{B} \tag{1}$$

E' = Summenextinktion bei der Wellenlänge λ', E'' = Summenextinktion bei der Wellenlänge λ'', die Konstante R wird an einer reinen Molybdänlösung ermittelt:

$$R = E_{Mo}'/E_{Mo}'' \tag{2}$$

Hier E_{Mo}' bzw. E_{Mo}'' = Extinktion bei der Wellenlängen λ', λ''. Die Konstante B ergibt sich durch Umformung von (1):

$$B = \frac{E' - RE''}{C} \tag{3}$$

Sie läßt sich aus einer Lösung mit bekannter Rhenium-Konzentration C bestimmen.

Bei dieser Extinktions-Verhältnis-Methode ist eine vollständige Trennung von Rhenium und Molybdän nicht erforderlich. Man muß lediglich den Molybdängehalt der Lösung auf eine gewisse Grenze herabsetzen und anschließend die Extinktionen bei zwei geeigneten Wellenlängen ermitteln. Nach (1) läßt sich der Rheniumgehalt der Lösung berechnen. Die Konstanten R und B müssen vorher experimentell bestimmt werden.

EXPERIMENTELLER TEIL

Apparate

Beckman Spektralphotometer, Modell DU Tpy 2400 mit SEV-Zusatz. Schüttelapparat (Eigenfabrikat), 4 Pulsschläge pro Sekunde.

Reagenzien

Alle Reagenzien *p.a.* der Firm Hopkin and Williams, oder Merck AG.

Rhenium, 1 mg/ml:[5] 100 mg Metallpulver werden in 50 ml Wasser suspendiert und mit Chlorgas oxydiert. Überschüssiges Chlor wird durch Kochen ausgetrieben und nach Abkühlen wird die Lösung mit Wasser auf 100 ml aufgefüllt.

Molybdän, 1 mg/ml: 1,500 g Molybdäntrioxyd werden in 100 ml 5% iger Natronlauge gelöst und auf 1000 ml aufgefüllt.

Wolfram, 1 mg/ml: 1,794 g Natriumwolframat (Na_2WO_4) werden in 500 ml Wasser gelöst und auf 1000 ml aufgefüllt.

TPA, 0,05*M*: 21,0 g Tetraphenylarsoniumchlorid (TPA) werden in Wasser gelöst, und auf 1000 ml aufgefällt.

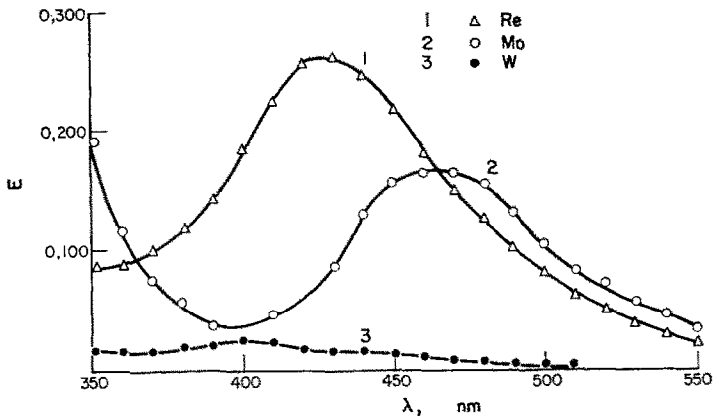

ABB. 1.—Absorptionsspektren der Thiocyanatokomplexe von Re bzw. Mo bzw. W in Isoamylalkohol.

Absorptionsspektren

Für die Auswahl der beiden Meßwellenlängen werden die Absorptionsspektren von Isoamylalkohol Extrakten ermittelt, die je 2 μg Rhenium bzw. Molybdän bzw. Wolfram pro ml enthalten. Das zuletzt genannte Metall ist meistens neben Rhenium in den Erzen enthalten und bildet auch gefärbte Thiocyanatokomplexe.

Arbeitsmethode

Zehn ml einer Lösung, die jeweils 50 μg Rhenium bzw. Molybdän bzw. Wolfram enthält, werden in einem 50-ml Scheidetrichter mit 0,5 ml 20%iger Natriumthiocyanat und 0,2 ml 35%iger Zinn(II)chlorid in konzentrierter Salzsäure versetzt und gut gemischt. Darauf gibt man 10 ml Isoamylalkohol hinzu, schüttelt 1 Minute im Schüttelapparat und trennt nach 2–3 Minuten Stehenlassen die wässrige Lösung in einen zweiten Scheidetrichter ab. Die organische Phase wird in einen Meßkolben von 25 ml Inhalt überführt. Der wässrige Teil wird nochmals mit 5 ml Isoamylalkohol ausgeschüttelt. Alle Extrakte werden im Meßkolben vereinigt und mit Isoamylalkohol auf 25 ml ergänzt. Die Absorptionsspektren der auf diese Weise erhaltenen Lösungen werden gegen Isoamylalkohol als Blindlösung aufgenommen und sind in Abb. 1 gegeben.

Die ausgewählte Wellenlängen sind $\lambda' = 430$ mμ (Max. für Rhenium) und $\lambda'' = 470$ mμ (Max. für Molybdän). Die Extinction von Wolfram kann im Vergleich zu den anderen beiden Elementen vernachlässigt werden, zumal der Gehalt an Wolfram in Molybdänit-Konzentration geringer als der an Rhenium ist. Ist der Gehalt an Wolfram wesentlich größer, kann die gleiche Methode für drei Komponenten[8] angewendet werden.

ERGEBNISSE

Ermittlung der Konstante R

Nach dem beschriebenen Verfahren wurden drei Extrakte des Molybdänkomplexes in Isoamylalkohol hergestellt und ihre Extinktion bei den ausgewählten Wellenlängen in Küvetten von 1 cm Schichtdicke gegen Isoamylalkohol gemessen (Tabelle I). Die Konstante R wird mittels Gleichung (2) berechnet.

TABELLE I.—BESTIMMUNG DER KONSTANTE R

Mo in Isoamylalkohol, *mg/ml*	E'_{Mo}, 430 *mμ*	E''_{Mo}, 470 *mμ*	R
2	0,117	0,234	$0{,}50_0$
6	0,230	0,455	$0{,}50_5$
9	0,333	0,635	$0{,}52_5$
			Mittelwert $0{,}51_0$

Ermittlung der Konstante B

Nach demselben Verfahren wurden Lösungen mit verschiedenem Gehalt an Rhenium- und Molybdän-Thiocyanatokomplex hergestellt. Der Gehalt an jedem Element im organischen Extrakt ergibt sich aus der gegebenen Menge in der wässrigen Lösung und dem Volumen an Isoamylalkohol. Die Extinktionen dieser Extrakte wurden bei den ausgewählten Wellenlängen in Küvetten von 1 cm Schichtdicke gegen Isoamylalkohol gemessen (Tabelle II). Die Konstante B läßt sich mittels Gleichung (3) berechnen.

TABELLE II.—BESTIMMUNG DER KONSTANTE B

Re in Isoamylalkohol *μg/ml*	Mo in Isoamylalkohol *μg/ml*	E' 430 *mμ*	E'' 470 *mμ*	B
1	3	0,207	0,280	0,064
1	6	0,317	0,504	0,060
1	9	0,422	0,692	0,069
2	3	0,312	0,358	0,065
2	9	0,510	0,733	0,068
3	3	0,375	0,356	0,065
			Mittelwert	0,065

Nach Einsetzen der beiden Konstanten in Gleichung (1) erhält man die Konzentration C des Rheniums im Isoamylalkohol in μg/ml:

$$C = \frac{E' - 0{\cdot}51E''}{0{\cdot}065}. \qquad (4)$$

Trennung des Rheniums von Molybdän

In einer vorliegenden Lösung von Rhenium und Molybdän kann der größte Teil des Molybdäns durch folgendes Verfahren entfernt werden: 10 ml der Versuchslösung werden in einem 50-ml Scheidetrichter mit 0,5 ml 0,05*M* TPA-Lösung versetzt und zweimal mit 10 ml Chloroform extrahiert, nachdem jeweils 2 Minuten im Schüttelapparat geschüttelt wurde. Zu den gesammelten Chloroformextrakten, die das

Rhenium enthalten, gibt man 20 ml Wasser, 0,5 ml einer 6*M* Natriumhydroxidlösung, und verdampft das Chloroform auf dem Wasserbad. Die zurückbleibende wässrige Lösung wird mit 2 ml konzentrierter Salzsäure versetzt. Neben dem Rhenium ist ein kleiner Anteil des Molybdäns in der Lösung enthalten, da etwas Molybdän-TPA-Komplex im Chloroform gelöst wird. Auch die Bildung von Emulsionen, die nur schwer zu trennen sind, trägt hierzu bei.

Spektralphotometrische Bestimmung

Die gesamte Lösung die von der Molybdän-Trennung erhalten worden ist, wird in einen 50-ml Scheidetrichter überführt und mit 0,5 ml 20% iger Natriumthiocyanatlösung und 0,2 ml 35%iger Zinn(II)chlorid in konzentrierter Salzsäure versetzt. Die Thiocyanatokomplexe werden mit Isoamylalkohol extrahiert und auf 25 ml ergänzt. Manchmal entsteht eine Trübung durch mitgeschleppter überschüssiges TPA, die durch Filtration beseitigt wird. Die Extinktionen dieser Lösung werden nun bei 430 und 470 mμ in 1-cm Küvetten gegen Isoamylalkohol als Blindlösung gemessen und der Gehalt an Rhenium nach Gleichung (4) berechnet. In der Tabelle III sind die Ergebnisse einer Reihe von Testlösungen zusammengestellt. Der Gehalt an Molybdän war allemal 1 mg/ml.

Anwendung der Methode zur Analyse von Molybdänit-Konzentraten

In einem 250-ml Becherglas werden 1,000 g Molybdänit mit 10 ml rauchender Salpetersäure versezt, mit einem Uhrglas abgedeckt und auf dem Wasserbad solange

TABELLE III.—ANALYSE VON GEMISCHEN VON RHENIUM UND MOLYBDÄN

erwärmt, bis keine schwarzen Teilchen übrigbleiben. Durch Zusatz von konzentrierter Salzsäure und Eindampfen auf etwa 2 ml wird die überschüssige Salpetersäure entfernt, mit 6*M* Natriumhydroxidlösung neutralisiert und mit festem Natriumhydrogenkarbonat behandelt bis die Lösung ein pH von 8–9 aufweist. Die Lösung wird in einen 100-ml Meßkolben überführt und dieser mit Wasser aufgefüllt. Dann werden 10 ml der so erhaltenen Lösung in einen 50-ml Scheidetrichter pipettiert und die spektralphotometrische Bestimmung dazu angewandt. In Tabelle IV sind die Ergebnisse zusammengestellt.

SCHLUSSFOLGERUNGEN

Die vorgeschlagene Bestimmungsmethode für Rhenium ist schneller und sicherer als die herkömmlichen und kann daher für Serienbestimmungen empfohlen werden. Die Genauigkeit der vorliegenden Methode liegt innerhalb der Grenzen einer photometrischen Bestimmung.

Summary—A new procedure is described for the spectrophotometric determination of rhenium in molybdenite. It entails the use of an absorbance-ratio method and allows the determination of rhenium in the presence of molybdenum. A great advantage over previous procedures is that it is not necessary to separate the molybdenum completely. Loss of rhenium during evaporations is prevented by use of an alkaline medium.

Résumé—On décrit une nouvelle technique de dosage spectrophotométrique du rhénium dans la molybdénite. Elle comporte l'emploi d'une méthode de rapport d'absorbance et permet le dosage de rhénium en présence de molybdène. Un grand avantage par rapport aux techniques antérieures réside dans le fait qu'il n'est pas nécessaire de séparer complètement le molybdène. On évite les pertes en rhénium durant les évaporations par l'emploi d'un milieu alcalin.

SUR LA DÉTERMINATION DES CHALEURS DE NEUTRALISATION DE QUELQUES AMINES ALIPHATIQUES PAR LE TITRAGE ENTHALPIMÉTRIQUE

E. POPPER, L. ROMAN et P. MARCU
Laboratoire de Chimie Analytique de l'Institut de Médicine et de Pharmacie, Cluj, Roumanie

(*Reçu* 14 *Novembre* 1966. *Accepté* 1 *Mai* 1967)

Résumé—Dans ce travail on a effectué le titrage enthalpimétrique de quelques amines aliphatiques. On a calculé les chaleurs de neutralisation respectives à partir des données expérimentales et on a étudié la variation de la basicité de ces amines en fonction de l'accumulation des groupes alcoyles, —OH, —NH_2. Dans chaque cas on a tracé des courbes de titrage en coordonnées droites, et en coordonnées obliques pour l'élimination des effets thermiques secondaires. On constate de la sorte que l'éthylamine est plus basique que l'éthanolamine, et que la diéthylamine est une base plus forte que l'éthylamine et la triéthylamine parce que, dans ce dernier cas, intervient un facteur stérique qui entraîne une baisse de la basicité de l'amine tertiaire. La baisse de la basicité de l'éthanolamine par rapport à l'éthylamine s'explique par la présence du groupe —OH qui attire les électrons et provoque une baisse de la densité électronique dans l'atome d'azote. Bien que l'éthylènediamine contienne deux groupes —NH_2, l'un d'eux est hydraté dans la solution et l'autre protonisé. L'existence dans la molécule de l'amine protonisée du groupe —OH détermine, de par son influence négativante, une baisse de la dissociation au deuxième palier. Les éthanolamines sont des bases plus faibles que les diéthyl- et triéthylamine, par suite de la présence du groupe —OH, qui amène une diminution de la basicité de celles-ci. L'influence du facteur stérique se manifeste aussi dans le cas de la triéthanolamine; aussi celle-ci a-t-elle une basicité plus réduite que la diéthanolamine. Ces faits sont confirmés par les chaleurs de neutralisation calculées expérimentalement.

DANS un travail précédent,[1] nous avons publié les résultats du titrage enthalpimétrique de quelques amines aromatiques (les *o*-, *m*- et *p*-phénylènediamines), en étudiant l'influence réciproque de la position des deux fonctions aminées sur la basicité des trois amines.

En ce qui concerne la technique de travail, nous apportions des améliorations en utilisant, pour la détermination de la variation de température pendant la réaction, un thermistor en pont, dont la précision est de 0.001°.

Certains auteurs[2] recommandent d'utiliser une burette automatique à piston, avec écoulement continu et rapide de l'agent de titrage, et de mesurer la variation de la température, au cours du processus étudié, avec un thermistor en pont. Il semble que par l'utilisation de la burette automatique à écoulement continu et rapide, la mise en thermostat de la solution que l'on titre n'est pas nécessaire, parce que la titrage dure 10 à 20 secondes, de sorte que les effets thermiques secondaires ne sont plus enregistrés. A cet égard, nous nous permettons de considérer qu'un écoulement lent de l'agent de titrage permet de déterminer (dans le cas de réactions de neutralisation) plusiers

TABLEAU I

No.	Substance	Q	N_{m_1}	N_{m_2}	ΔT_1, °C	ΔT_2, °C
1.	Ethylamine	$0{,}304_6$	0,003712	—	0,1386	—
2.	Ethanolamine	$0{,}334_9$	0,004778	—	0,117	—
3.	Ethylènedi-amine	$0{,}334_9$	0,01125	0,01125	0,407	0,391
4.	Diéthylamine	$0{,}334_9$	0,002316	—	0,0807	—
5.	Diéthanol-amine	$0{,}334_9$	0,01206	—	0,3865	—
6.	Triéthylamine	$0{,}304_6$	0,01244	—	0,34	—
7.	Triéthanol-amine	$0{,}334_9$	0,02737	—	0,645	—

points d'équivalence, avec une précision meilleure, ce qui, du point de vue théorique et pratique, est souvent très important. Par ailleurs, l'élimination des effets thermiques secondaires, par le passage des coordonnées droites à des coordonnées obliques, est plus sûr, en particulier dans les cas où la chaleur de réaction est plus faible. Il est probable que, si l'on pouvait réaliser une amplification électronique de signal émis par le thermistor, ces précautions seraient superflues.

En outre, il convient de tenir compte du fait que dans les titrages enthalpimétriques le solvant joue un rôle important.[3] Ainsi, dans des solvants organiques, dont les chaleurs spécifiques sont basses, à de petits changements d'énergie correspondent de grandes variations de température.

Dans ce travail nous présentons et discutons les résultats obtenus lors de la neutralisation de quelques amines aliphatiques primaires, secondaires ou tertiaires. Nous y étudions l'influence qu'exercent sur la basicité de ces amines certains substituants, à savoir: —OH et $—NH_2$.

PARTIE EXPERIMENTELLE

Détermination de la constante enthalpimétrique de la cellule de titrage

La détermination de cette constante se fait par titrage enthalpimétrique d'une solution $10^{-2}M$ de l'acide chlorhydrique par une solution $10^{-1}M$ de soude. Nous avons utilisé la relation:

$$Q = N_m \frac{\Delta H}{\Delta T_Q} = 0{,}002874 \cdot \frac{13{,}4}{0{,}115} = 0{,}336 \qquad (1)$$

où:

Q est la constante enthalpimétrique de la cellule de titrage,
N_m est le nombre de moles de chlorure de sodium formés,
$\Delta H = 13{,}4$ kcal/mole,
ΔT_Q est la variation totale de température à la neutralisation de 250 ml de l'acide chlorhydrique $10^{-2}M$ par soude $10^{-1}M$.

Cette valeur de Q a été utilisée seulement pour les titrages de l'éthanolamine, de l'éthylènediamine, de la diéthylamine, de la diéthanolamine et de la triéthanolamine.

Pour les titrages de l'éthylamine et de la triéthylamine nous avons été dans l'obligation d'utiliser une autre cellule de titrage, dont la constante enthalpimétrique Q_1 a la valeur:

$$Q_1 = N_m \frac{\Delta H}{\Delta T_Q} = 0{,}002842 \cdot \frac{13{,}4}{0{,}125} = 0{,}304_6$$

TABLEAU II

No.	Substance	ΔH_1 *kcal/mole*	ΔH_2 *kcal/mole*	C, M	C_{HCl}, M
1.	Ethylamine	−11,37	—	$3 \cdot 10^{-2}$	1

6.	Triéthylamine	−8,32	—	$4{,}987 \cdot 10^{-2}$	1
7.	Triéthanol-amine	−7,89	—	10^{-1}	1

Titrage enthalpimétrique des amines étudiées

Pour le titrages de ces amines, tants primaires que secondaires ou tertiaires, on a préparé des solutions de concentrations comprises entre $10^{-1}M$ et $10^{-2}M$, Tableau II, que l'on a titrées par l'acide chlorhydrique $1M$, en étudiant la variation de la température pendant la neutralisation. Les données obtenues ainsi que les chaleurs de neutralisation calculées à l'aide de la relation:

$$\Delta H = \frac{Q}{N_m} \cdot \Delta T_Q \tag{2}$$

où:

ΔH est la chaleur de réaction,
Q est la constante enthalpimétrique de la cellule,
N_m est le nombre de moles de produit formé,
QT_Q est la variation de température pendant le titrage, sont consignées au tableau I,
où Q, N_{m1}, N_{m2}, ΔT_1, ΔT_2, ΔH_1, ΔH_2 ont les mêmes significations que les termes de la relation (2), C est la concentration molaire de la substance et C_{HCl} la concentration molaire de l'acide chlorhydrique employé pour le titrage.

Pour écarter les effets thermiques secondaires on a appliqué dans tous les cas une transformation des coordonnées droites en coordonnées obliques, en utilisant les relations:

$$X_{B'} = x\sqrt{1+p^2} = x \cdot \varepsilon \tag{3}$$

$$Y_{B'} = y - p \cdot x \tag{4}$$

où:

x et y sont les coordonnées droites des points B (et du point C dans le cas de l'éthylènediamine),
X et Y sont les coordonnées obliques des points B' (et du point C' pour l'éthylènediamine),
p est la pente de la dernière portion des courbes de neutralisation (les segments BC, et pour l'éthylènediamine le segment CD), en coordonnées droites. On calcule la pente au moyen de la relation:

$$p = \frac{\Delta T}{\Delta n}$$

Δn étant le volume d'acide chlorhydrique correspondant au segment BC (pour l'éthylènediamine CD), et ΔT la variation de température correspondante.

Les valeurs de ces grandeurs sont reportées au Tableau II et Tableau IV.

Dans la relation (3) on remarque que $X_{B'} = x \cdot \varepsilon$. La grandeur $\varepsilon = \sqrt{1+p^2}$ a une valeur pratiquement égale à l'unité, parce que p^2 est très petit et que, par conséquent, on peut le négliger dans tous les cas.

Afin d'expliciter les différences entre les courbes en coordonnées droites et obliques nous avons choisi les cas de l'éthanolamine (Fig. 1) et de l'éthylènediamine (Fig. 2). Dans le second la courbe révèle les deux points d'équivalence qui apparaissent lors de la neutralisation.

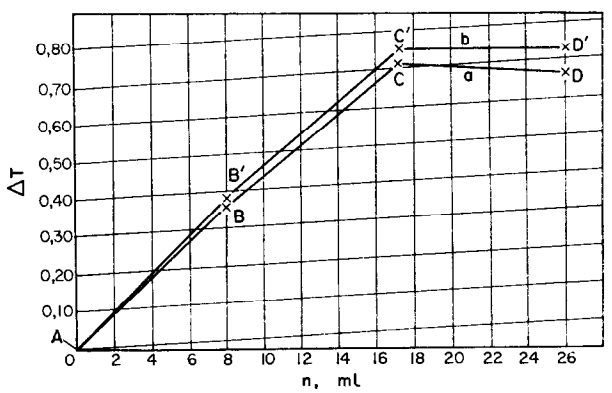

FIG. 2.

DISCUSSION

On sait que les amines aliphatiques[4] ont une basicité plus grande que l'ammoniac, par suite de leur capacité plus grande à fixer un proton. Cette capacité est due à l'effet inductif repousseur d'électrons des radicaux alcoyles,[5] qui amène un déplacement de la densité électronique vers l'azote, lorsque la mobilité du doublet libre de l'azote augmente. La chaleur de neutralisation plus grande de l'éthylamine ($\Delta H = -11{,}36$

TABLEAU IV

No.	Substance	x_C	y_C	$X_{C'}$	$Y_{C'}$
3.	Ethylènediamine	17,1	0,76	17,1	0,798

kcal/mole) confirme la basicité plus grande de celle-ci ($K_{25°} = 3{,}18 \cdot 10^{-4}$) que de l'ammoniac.

Cependant l'éthanolamine ($K_{25°} = 3{,}18 \cdot 10^{-5}$), bien que plus basique que l'ammoniac, est moins basique que l'éthylamine, ce qui ressort aussi sa chaleur de neutralisation moindre ($\Delta H = -8{,}20$ kcal/mole). Cette baisse de la basicité est due au groupe HO (attracheur d'ions), qui amène une baisse de la densité électronique à l'azote, diminuant sensiblement l'éffet inductif repousseur d'électrons du radical éthyle.

L'éthylendiamine est une base plus faible que l'éthylamine ($K_{1_{22°}} = 7{,}9 \cdot 10^{-5}$ et $K_{2_{22°}} = 7{,}9 \cdot 10^{-8}$). Dans ce cas a lieu la solvatation de l'une des fonctions amino et la protonisation de la deuxième:

$$H_2N—CH_2—CH_2—NH_2 + 2H_2O \rightarrow (HONH_3—CH_2—CH_2—NH_3)^+ + HO^-$$

La neutralisation aux deux paliers a lieu comme suit au premier palier, ou neutralise l'ion HO^-, résultant de la protonation de la base:

$$(HONH_3—CH_2—CH_2—NH_3)^+ + HO^- + (H^+ + Cl^-) = (HONH_3—CH_2—CH_2—NH_3)^+ + Cl^- + H_2O$$

et au second palier l'hydroxyle de la fonction amino solvatée:

$$(HONH_3—CH_2—CH_2—NH_3)^+ + Cl^- + (H^+ + Cl^-) = (NH_3—CH_2—CH_2—NH_3)^{2+} + 2Cl^- + H_2O$$

La dissociation au deuxième palier est diminuée par la présence de l'ion HO^- dans la molécule de l'amine protonisée. Mais au cours du titrage du deuxième palier, par la fixation de l'ion HO^- de la fonction amino solvatée sous forme de molécule d'eau non dissociée, l'équilibre de dissociation se déplace vers la droite, ce qui explique la chaleur de neutralisation également importante au deuxième palier ($\Delta H_1 = -12{,}1$ kcal/mole et $\Delta H_2 = -11{,}6$ kcal/mole). La différence entre les chaleurs de neutralisation aux deux paliers confirme la différence de basicité des deux fonctions amino.

Dans le cas des amines secondaires et tertiaires, la basicité croît avec l'augmentation du nombre et de la grandeur des substituants. C'est ce qui explique pourquoi la diéthylamine ($K_{25°} = 8{,}57 \cdot 10^{-4}$) et la triéthylamine ($K_{25°} = 5{,}66 \cdot 10^{-4}$) sont plus basiques que l'éthylamine. Par ailleurs, la diéthylamine ($\Delta H = -11{,}7$ kcal/mole) est une base plus forte que la triéthylamine ($\Delta H = -8{,}3$ kcal/mole). Cette baisse de la basicité des amines tertiaires par rapport aux amines secondaires est due tant à un effet stérique,[6] qui s'oppose à la formation de l'ion d'ammonium (en diminuant la basicité de l'amine tertiaire), qu'à la diminution de la capacité de solvatation, laquelle, comme on le sait déjà est moindre chez les amines tertiaires que chez les amines secondaires. La baisse de la capacité de solvatation de l'ion d'ammonium amène une baisse de la stabilité de celui-ci et inversement.

Enfin, les diéthanolamines et les triéthanolamines sont des bases plus faibles que

les diéthyl et triéthylamines correspondantes en raison de l'accumulation des groupements hydroxylés et des causes mentionnées ci-dessus. D'ailleurs les chaleurs de neutralisation de la diéthanolamine ($\Delta H = -10{,}72$ kcal/mole) et de la triéthanolamine ($\Delta H = -7{,}88$ kcal/mole) confirment ce fait.

Summary—Some aliphatic amines have been titrated enthalpimetrically. The heats of neutralization have been calculated from the results and correlated with the basicity of the amines and the number of hydroxyl and amine groups present. The titration curves were all plotted on Cartesian coordinates and again on oblique coordinates to eliminate secondary thermal effects. The order of basicity is ethylamine < ethanolamine, and ethylamine < diethylamine > triethylamine, the last because of steric factors reducing the basicity of the tertiary amine. The low basicity of ethanolamine relative to ethylamine is atttributed to the inductive effect of the hydroxyl group. Ethylenediamine contains two amino groups, one of which is hydrated in solution and the other protonated; the existence of the protonated group together with the electron-withdrawing power of the hydroxyl group accounts for the lower second dissociation. The ethanolamines are more feeble bases than di- and triethylamine, because of the presence of the hydroxyl group. A steric factor further reduces the basicity of triethanolamine. These facts are confirmed by the experimental heats of neutralization.

Zusammenfassung—Einige aliphatische Amine wurden enthalpimetrisch titriert. Aus den Ergebnissen wurden die Neutralisationswärmen berechnet und die Anzahl der anwesenden Hydroxyl- und Aminogruppen sowie die Basizität der Amine damit in Beziehung gesetzt. Die Titrationskurven wurden alle auf cartesischen und auf schiefen Koordinaten gezeichnet, um sekundäre thermische Effekte auszuschalten. Die Basizitätsreihenfolge ist Äthylamin > Ätholamin und Äthylamin < Diäthylamin > Triäthylamin, das letzte, da sterische Faktoren die Basizität des tertiären Amins reduzieren. Die niedrige Basizität von Äthanolamin gegenüber Äthylamin wird dem induktiven Effekt der Hydroxylgruppe zugeschrieben. Äthylendiamin enthält zwei Aminogruppen, von denen die eine in Lösung hydratisiert und die andere protoniert ist; die Existenz der protonierten Gruppe zusammen mit der elektronensaugenden Hydroxylgruppe erklärt die schwache Dissoziation in zweiter Stufe. Die Äthanolamine sind schwächere Basen als Di- und Triäthylamin wegen der Hydroxylgruppe. Ein sterischer Einfluß reduziert die Basizität von Triäthanolamin weiter, was durch die gemessenen Neutralisationswärmen bestätigt wird.

CHROMATOGRAPHIC LOCATION AND COLORIMETRIC DETERMINATION OF MERCAPTANS, PROLINES AND FREE RADICAL PRECURSORS

E. SAWICKI, C. R. ENGEL and W. C. ELBERT
Bureau of Disease Prevention and Environmental Control, National Center for Air Pollution Control, U.S. Department of Health, Education, and Welfare, Public Health Service, 4676 Columbia Parkway, Cincinnati, Ohio 45226, U.S.A.

(*Received* 23 *March* 1967. *Accepted* 28 *April* 1967)

Summary—A new reagent, 7, 7, 8, 8-tetracyanoquinodimethan (TCNQ), is introduced for the colorimetric determination of free radical precursors, such as cysteine, proline, hydroxyproline, the phenoxazine family and mercaptans. TCNQ is also useful in the location and characterization on paper or thin-layer chromatograms of proline, hydroxyproline, cysteine, polynuclear compounds, mercaptans, thiocarbonyl amides and thiosemicarbazones. In addition, amino-acid derivatives, such as the *N*-(phenylthiocarbamyl) amino-acids and the 3-phenylthiodantoins, can be located and characterized on chromatograms. TCNQ has been applied to the location and characterization of atmospheric proline, carbazole and 11*H*-benzo[*a*]carbazole. For characterization purposes absorption spectra were obtained directly from glass-fibre, paper, or thin-layer chromatograms from about 300 to 900 mμ.

7,7,8,8-TETRACYANOQUINODIMETHAN is known to react readily with inorganic and organic bases to form free radicals and with polynuclear compounds to form π complexes.[1,2] Because of this reactivity we believed that this reagent could be used to analyse mixtures for compounds from which a free electron could be readily extracted, *i.e.*, free radical precursors. Thus, in this type of reaction three analytically useful phenomena could take place. A cationic free radical (from the test substance) and an anionic one (from the reagent) could be formed. The cationic free radical could dimerize, leaving the anionic free radical in solution. The third possibility would be the combination of the cationic and anionic free radicals followed by subtraction of hydrogen cyanide from the molecule to give a highly coloured zwitterion resonance structure. In addition, the test substance and the reagent could combine to form a π complex.

Examples of all these types are discussed. The application of some of the techniques to air pollution studies is described.

EXPERIMENTAL*

Reagents and apparatus

All standards were obtained in the purest form available from commercial sources and were crystallized to give a constant melting point if their physical properties indicated they were impure. 7,7,8,8-Tetracyanoquinodimethan (TCNQ) was obtained from E. I. DuPont de Nemours and Co., Wilmington, Delaware. Pyridine and 2-butanone were obtained in chemically pure form and used directly. 2,4,7-Trinitrofluoren-$\Delta^{9,\alpha}$-malononitrile was prepared by a known procedure[3] and crystallized from toluene.

* Mention of commercial products does not constitute endorsement by the Public Health Service.

Location reagent I: 0·3% TCNQ in acetone; location reagent II: 0·3% TCNQ in pyridine-acetone (1:1).

Colorimetric reagent: 0·02% TCNQ in 2-butanone. This reagent was stable for 3–4 hr.

Colorimetric analyses were accomplished with a Cary Model 11 recording spectrophotometer with 1-cm path-length cells. Direct spectrophotometric examinations of coloured spots on various adsorbents, on glass-fibre papers, and on paper and thin-layer chromatograms were performed with a Model 1411 diffuse reflectance accessory with integrating sphere mounted on a Model 14 Cary recording spectrophotometer.

Location procedure for various chemicals on a chromatogram

Spray the chromatogram with either location reagent I or II. Place the chromatogram on a heated metal surface kept at a temperature of ~60°. Observe the colour changes (see Table I). For some of the compounds, especially the sulphur compounds, heat is not necessary. In some cases, the colours are different according to whether the plate is heated or not. For example, *N,N'*-tetramethylbenzidine gives a violet colour changing to blue; when the spot is warmed, immediately after spraying, the violet colour changes quickly to a dark green.

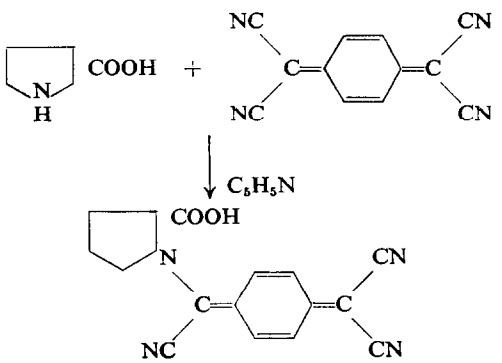
Colorimetric procedure

To 2 ml of a water–pyridine (1:1) test solution add 2 ml of 0·02% TCNQ solution in 2-butanone. Heat for 3 min at 60°. Cool under the tap and read the absorbance at 756 or 848 mμ within 3 min (see Table II).

DISCUSSION

Mechanism

Comparison of the colours obtained in location and in colorimetric analysis indicates that the predominant chromogen formed in location methods is a brilliantly coloured zwitterion resonance structure. Thus, proline reacts with TCNQ on a chromatogram in the following manner.



Purple, λ_{max} 565, 612 s

This reaction is compatible with the known reaction of pyrrolidine with TCNQ to form purple solutions of 7-pyrrolidino-7,8,8-tricyanoquinodimethan, λ_{max} 532, 567, and 613 mμ with the prominent band at 567 mμ.[2]

In the colorimetric method free radicals are formed as shown by the visible absorption spectrum obtained in the determination of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine, Fig. 1. In this case, since $Me_2N\text{-}C_6H_4\text{-}\dot{N}Me_2^+$ absorbs at 610 mμ with a molar absorptivity of 11,500,[4] and $TCNQ^{\cdot-}$ absorbs at 842 mμ with a molar absorptivity of 43,300,[1] almost quantitative yields of these radicals are obtained. Examples of many other compounds that can be determined because of their ability to donate an electron to TCNQ are given in Table II. The two bands in the near-infrared region show the approximate relation $A_{847} = 1{\cdot}86\,A_{748}$ for the absorbances.

† Procedure is to spray the chromatogram and then to observe development of colour. Spray reagent contained 0·3% of 7,7,8,8-tetracyanoquinodimethan (TCNQ) in acetone. In the columns labelled "cellulose (TLC)" and "paper" the spray reagent contained 0·3% of TCNQ in acetone–pyridine (1:1).

‡ Negative results were obtained on alumina with 10 μg of adenine, 1,3-diphenyl-1,3-propanedione, glucose, malathion, parathion, 2,4-pentanedione. The following compounds (10 μg) gave negative colour reactions but had a green-yellow fluorescence under ultraviolet light: δ-amino-butyric acid, n-butylamine, histidine, leucine, serine, and tryptophan.

¶ Negative at 10 μg. With cellulose and paper read colour immediately and after 5 min at 60°.

** Negative at 20 μg.

†† Polynuclear compounds form colours more quickly than proline does but also fade much more quickly.

For most of the compounds the reaction is not as simple as shown in Fig. 1. For example, while the molar absorptivity of $TCNQ^{\cdot-}$ is reported as 43,300 at 842 mμ, quite a few compounds in Table II gave higher molar absorptivities at this wavelength. Phenothiazine gave a value approximately 4 times as high as the theoretical value, apparently an indication of an autocatalytic effect. In this type of molecule the NH

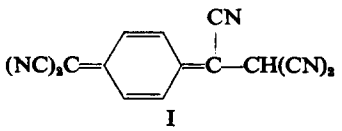
‡ Aniline, adenine, benzo[*a*]pyrene, n-butylamine, carbazole, cytosine, 2-deoxy-D-ribose, formaldehyde, β-D-fructose, L-fucose, β-D-glucose, 9-(3-indolyl)-thioxanthene, melizitose, *o*-mercaptoaniline, *N*-phenylphenothiazine, phenyl sulphoxide, pipecolic acid, piperidine, pyrrolidine, D-ribose, D-sorbitol, *N,N,N′,N′*-tetramethylbenzidine, triethylamine, and tryptophan.

group seems to be necessary for the reaction, since *N*-phenylphenothiazine did not react.

Some of the interesting spectral results are shown in Table III. Occasionally with 3-phenylthiohydantoin a broad strong band was obtained at 630 mμ after spraying. Spectra of the coloured spots obtained from benzo[*a*]pyrene and dibenz[*a,j*]acridine were apparently derived from π complexes. With malononitrile, TCNQ reacts in solution to form a strong acid, I.[5] This compound, pK_a 0·60, ionizes readily to form a brilliantly coloured anion, λ_{max} 625 mμ, ε 52200.



I

The purple spot, λ_{max} 600 mμ, obtained on glass-fibre paper (Table III) is probably due to the coloured anion.

Location and characterization methods

Most of the methods involving the formation of π complexes with polynuclear compounds are much less sensitive than those involving the natural fluorescence of the

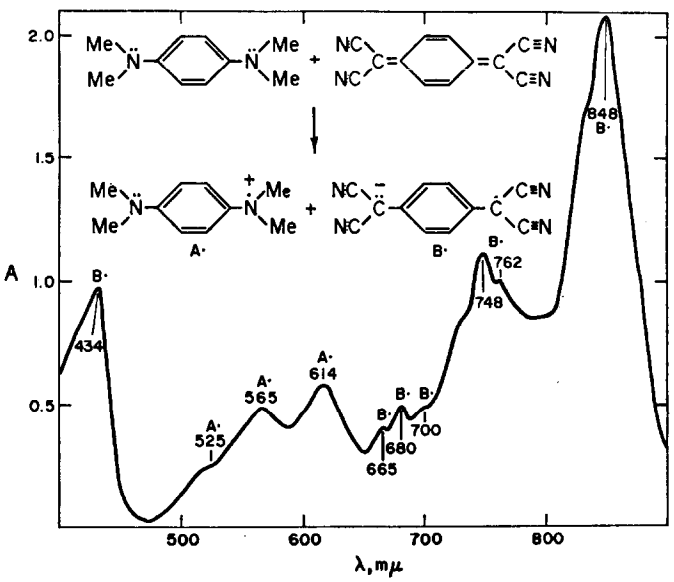


FIG. 1.—Absorption spectrum obtained in the colorimetric determination of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine ($5 \times 10^{-5}M$) with TCNQ but without heat.

molecules. Thus polynuclear compounds can be located by fluorescence on a thin-layer chromatogram in nanogram amounts[6,7] but only in microgram amounts with TCNQ. In the analysis of airborne particulates sensitivity is of vital importance. Only a few cubic metres of air are needed when it is possible to analyse for nanogram amounts of pollutant; when the method can determine only microgram amounts, then several thousand cubic metres of air are needed. Thus, the time required to collect a particulate sample for the latter type of analysis would be 100 to 1000 times as long as for a nanogram method. In many cases the colour methods are used either because the method is better or because nothing as sensitive is available.

Saturated heterocyclic imino-acids are readily located on alumina, cellulose, or paper with the help of TCNQ. The presence of pyridine in the reagent is of value in neutralizing the acidic substances present in the cellulosic absorbents. Sensitivity is better than that obtained without the pyridine. As Table I shows, brilliant colours are obtained with these compounds. Warming for about 3 min was required to develop the colours obtained with proline and hydroxyproline.

Compounds with very active hydrogen can be located readily with the reagent,

even if the hydrogen is on a carbon atom. For example, the compound obtained from malononitrile readily ionizes to give a brilliantly coloured anion, as shown by the purple to green spots obtained on the various adsorbents. Treatment of the coloured spot with trifluoroacetic acid fumes decreases the intensity of the colour, but warming the spot brings the colour back. With this treatment the dibenz[*a,j*]acridine spot loses its colour, whereas the proline spot changes from purple to a lighter red-orange.

Mercaptans can also be readily located on chromatograms. For example, cysteine gives an emerald green colour on the plate quickly and without heat.

‡ Similar spectra of $TCNQ^-$ on alumina thin-layer plate.
¶ Pure benzo[*a*]pyrene gave a doublet at 367 and 385 mμ.

Compounds containing the —C(=S)—NH— group also react with the reagent, *e.g.*, thiourea, dithio-oxamide, thiobarbituric acid, dithiobiuret, and thiosemicarbazide. Thiosemicarbazones of aldehydes and ketones give brilliant colours with TCNQ on chromatograms and thus can be located in this manner. Since methods are available for the paper chromatographic separation of the thiosemicarbazones of aldehydes and ketones,[8] TCNQ could be of value in locating these derivatives. In addition the separated spots can be characterized or estimated through direct spectrophotometric examination.

Phenylthiocarbamylamino acids and phenylthiohydantoins are readily prepared from amino-acids.[9,10] These derivatives have been separated by paper[11] and thin-layer chromatography.[12] The derivatives from glycine gave positive results with the location method. Consequently, TCNQ could be used to locate and characterize these two types of amino-acid derivative on the chromatogram or phoretogram.

Substituting 2,4,7-trinitrofluoren-$\Delta^{9,\alpha}$-malononitrile for TCNQ in the location reagent presented no advantage for the location of prolines or mercaptans. This reagent was better suited for the location of polynuclear compounds through π complex formation. Thus, the following location limits and colours were obtained: dibenz[*a,j*]acridine, 2 μg, red-orange; benz[*a*]acridine, 2 μg, orange: benz[*c*]acridine, 2 μg, purple; benzo[*a*]pyrene, 2·5 μg, brown; benzo[*e*]pyrene, 2 μg, black.

Results obtained with the diffuse reflectance accessory were checked by examining the purple spot obtained when a paper chromatogram containing 1 μg of leucine was sprayed with ninhydrin. Prominent absorption maxima were obtained at 407 and 570 mμ. The same bands were obtained when an aqueous solution of leucine reacted with a ninhydrin reagent solution.

Absorption spectra obtained on glass-fibre paper from various compounds sprayed with TCNQ are shown in Table III. We found that thin-layer or paper chromatograms could also be used in direct spectral investigations. Our investigations

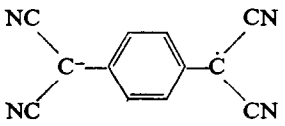
have convinced us that this technique is desirable and useful in characterizing and estimating the types of compounds studied in this paper. Examples of the spectra obtained after spraying with TCNQ are given in Fig. 2. The sensitivity could be considerably improved since only the surface of the glass fibre was stained and most of the compound was present in the sub-surface area.

Colorimetric analysis

The variables were investigated with proline as the test substance. Various solvents were tried. An aqueous pyridine mixture gave satisfactory results in dissolving a large variety of test substances and in assisting the reaction of the test substance with the reagent. Since the reagent was not readily soluble in a large variety of solvents, many solvents were investigated. 2-Butanone was satisfactory in its solvation of the reagent, its miscibility with the test solution, and its favourable influence on the test reaction. Of the various concentrations of reagent tried, 0·02% gave optimum results with the blank and the test mixture. Some heat was needed for the reaction to take place. With temperatures near 100°, the blank became too dark. Optimum results were obtained by heating at 60° for 3 min.

Conformance with Beer's law was observed from 0·8 to 12 μg of proline. The standard deviation of 11 determinations was $\pm 1{\cdot}6\%$. The colour was stable for about 10 min. In a duplicate determination average absorbances of 1·33 and 1·30 were obtained at 747 mμ when measured 3 and 20 min respectively after completion of the test.

The main chromogen formed in the determination of the compounds in Table II is the free radical anion, II.



II

The phenoxazine family of compounds gives better than theoretical (based on a 1:1 reaction) yields. Thus, the molar absorptivity obtained for phenothiazine is 4 times as great as the theoretical molar absorptivity obtained for II. These compounds can also be determined without the use of heat. Substitution of a phenyl group on the nitrogen atom of phenothiazine inhibits the reaction. As expected, the determination of phenothiazine did not conform with Beer's law.

Proline can be determined by reaction with ninhydrin;[13] hydroxyproline is usually determined by oxidation followed by reaction with *p*-dimethylaminobenzaldehyde.[14] The present procedure for these amino-acids is simpler and more sensitive but is less selective than the usual methods. Proline and hydroxyproline react well in the procedure. Except for cysteine, the other amino-acids do not react as well.

Mercaptans have usually been determined by reaction with 2,4-dinitrochlorobenzene,[15] 1,1-diphenyl-2-picrylhydrazine,[16] *N*-ethylmaleimide,[17] or bis(*p*-nitrophenyl) disulphide.[18] The present method is simpler and more sensitive for most of the compounds but is less selective. The reaction with cysteine is especially sensitive. Other types of compounds can also react, such as those with strongly active hydrogen, *e.g.*, malononitrile, and basic free radical precursors such as *N,N,N',N'*-tetramethyl-*p*-phenylenediamine.

These various reactions are complex: many compounds that react well in the location method give poor results in the colorimetric method. In addition, the type of reaction that takes place on the chromatogram is usually different from the reaction in the colorimetric procedure.

Applications

In preliminary work with this reagent we investigated some of the possibilities of its use. An urban air sample, in which coal-tar pitch fumes were the main contaminant, was separated on alumina by two-dimensional thin-layer chromatography. The location method indicated that carbazole and 11*H*-benzo[*a*]carbazole were present, Fig. 3.

A sample of airborne particulates was hydrolysed with hydrochloric acid[19] and the amino-acid fraction was then separated on a two-dimensional cellulose thin-layer plate. Spraying the chromatogram with a ninhydrin solution (0·2% in acetone containing 2% of pyridine) gave a series of violet, yellow, and orange spots (Fig. 4). The yellow spot was identified as proline on the basis of its R_f values in two different

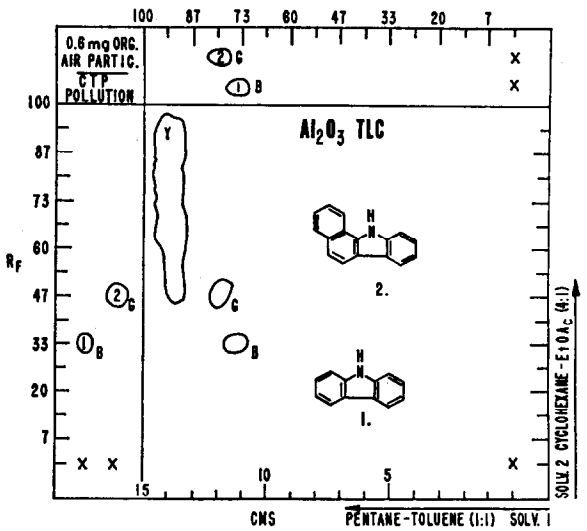


FIG. 3.—Two-dimensional alumina thin-layer chromatogram of urban airborne particulates contaminated with coal-tar pitch fumes and one-dimensional chromatograms of carbazole and 11*H*-benzo[*a*]carbazole sprayed with TCNQ location reagent.

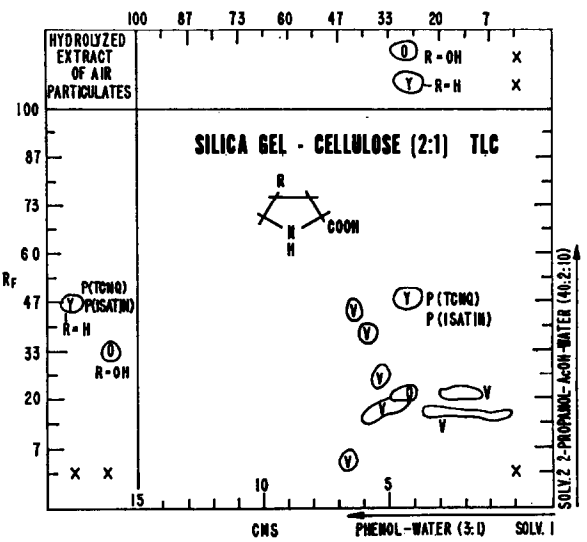

FIG. 4.—Two-dimensional silica gel–cellulose thin-layer chromatogram of an aqueous hydrolysed extract of urban airborne particulates and one-dimensional thin-layer chromatograms of proline and hydroxyproline sprayed with ninhydrin reagent.

solvent systems and its change to purple when sprayed with isatin (0·2% in acetone containing 2% of pyridine) and with TCNQ.

The amino-acid fraction was also separated on a cellulose thin-layer plate with 2-propanol–acetic acid–water (40:2:10) as the developer. Development (15-cm run) took about 3 hr. Spraying with ninhydrin gave six spots; spraying with TCNQ gave the purple spot of proline and a large emerald green spot with an R_f value close to that of cysteine. The emerald green spot has not yet been identified.

An urban airborne particulate sample was extracted with boiling water. The extract was then analysed by the colorimetric method. Based on the molar absorptivity of TCNQ $\bar{\cdot}$, 8·4 μmole of free radical precursors were found per gram of particulates.

Zusammenfassung—Zur kolorimetrischen Bestimmung von Vorläufern freier Radikale wie Cystein, Prolin, Hydroxyprolin, den Phenoxazinabkömmlingen und Mercaptanen wird ein neues Reagens, 7,7,8,8-Tetracyanochinodimethan (TCNQ) eingeführt. TCNQ ist auch von Nutzen bei Nachweis und Charakterisierung von Prolin, Hydroxyprolin, Cystein, mehrkernigen Verbindungen, Mercaptanen, Thiocarbonsäureamiden und Thiosemicarbazonen auf Papier- oder Dünnschichtchromatogrammen. Dazuhin können Aminosäurederivate wie N-(phenylthiocarbamyl)aminosäuren und 3-Phenylthiodantoine auf Chromatogrammen 10-kalisiert und charakterisiert werden. TCNQ wurde bei Nachweis und Charakterisierung von atmosphärischem Prolin, Carbazol und 11 H-benzo[*a*]carbazol verwendet. Zu Charakterisierungszwecken wurden Absorptionsspektren direkt von Glasfaser-, Papier- oder Dünnschichtchromatogrammen zwischen 300 und 900 nm aufgenommen.

Résumé—On présente un nouveau réactif, le 7,7,8,8-tétracyanoquinodiméthane (TCNQ) pour la détermination colorimétrique de précurseurs de radicaux libres comme la cystéine, la proline, l'hydroxyproline, la famille de la phénoxazine et les mercaptans. Le TCNQ est aussi utile dans la localisation et la caractérisation, sur chromatogrammes sur papier ou couche mince, de la proline, de l'hydroxyproline, de la cystéine, des composés polynucléaires, des mercaptans, des thiocarbonylamides et des thiosemicarbazones. En outre, des dérivés d'amino-acides comme les N-(phénylthiocarbamyl) amino-acides et les 3-phénylthiohydantoïnes peuvent être localisés et caractérisés sur les chromatogrammes. On a appliqué le TCNQ à la localisation et la caractérisation de la proline, du carbazole et du 11 H-benzo[*a*]carbazole dans l'atmosphère. A des fins de caractérisation, on a obtenu des spectres d'absorption directement des chromatogrammes sur fibre de verre, papier ou couche mince, d'environ 300 à 900 mμ.

DETERMINATION OF RADIOACTIVE COBALT IN REACTOR COOLANT WATER BY SOLVENT EXTRACTION

KENJI MOTOJIMA, SHOJI BANDO and NORI TAMURA
Japan Atomic Energy Research Institute, Tokaimura, Ibaraki-ken, Japan

(*Received* 30 *January* 1967. *Accepted* 15 *May* 1967)

Summary—A rapid extraction separation method is described for the radiochemical determination of cobalt-58 and cobalt-60 in reactor coolant water. After adjustment of the pH of the sample water to 5·0–5·5, cobalt diethyldithiocarbamate is extracted with benzene. Other nuclides, *e.g.*, manganese-54 and -56, copper-64 and iron-59, which are usually present in reactor coolant water, are also extracted together with cobalt. However, they can be readily removed by washing the extract with mercury(II) chloride solution. The cobalt-58 and -60 activities are measured by gamma counting of an aliquot of the washed extract. Trace amounts of radioactive cobalt in 500 ml of sample water can be quantitatively extracted without the use of carrier. The separation could be finished in 15 min and an average recovery of 99·5% was obtained, with a relative standard deviation of 1·4% (25 experiments).

THE analysis of radioactive nuclides in the coolant water of a large power reactor is very important in many respects. It provides, for example, considerable information on the behaviour of corrosion products in the coolant, and seems to be one of the most basic means for investigating the corrosion of fuel-cladding or reactor materials. It also serves for safety monitoring of a power reactor. In the normal operation of a reactor, cobalt-58 arising from the (n, p) reaction on nickel-58 and cobalt-60 from the (n, γ) reaction on cobalt-59 are the major long-lived activities in the coolant water. A rapid and reliable method of determination of radioactive cobalt in the coolant water is therefore needed.

The standard method[1] for determination of radioactive cobalt is based on precipitation of potassium cobaltinitrite. Although this method is accurate, it is troublesome and time-consuming.

Bode *et al.*[2,3] have reported studies on the extraction of metal diethyldithiocarbamates. In their experiments, the behaviour of cobalt was found to be exceptional in that cobalt diethyldithiocarbamate is very stable. Přibil *et al.*[4] and Stolyarov[5] used this property in the photometric determination of microgram quantities of cobalt with sodium diethyldithiocarbamate; interfering metals were exchanged with mercury(II) ion, which has the highest affinity for diethyldithiocarbamate.

In the present paper, a new method based on the solvent extraction of cobalt diethyldithiocarbamate is proposed for the determination of radioactive cobalt. By this method, radioactive cobalt can be separated quantitatively, without use of a carrier, from even 500 ml of water sample containing other radioactive nuclides, and the separated cobalt nuclides are found to be radiochemically pure.

EXPERIMENTAL

Apparatus

Gamma-ray scintillation counter and spectrometer. A gamma-ray scintillation counter with a 256 channel pulse-height analyser and a well-type NaI(Tl) crystal 1¾ in. × 2 in. was used.

Reagents

Cobalt-60 tracer solution. One mg of cobalt metal, irradiated for 130 hr with about 2×10^{13} n/cm²/sec in a reactor (JRR-2), was dissolved in hydrochloric acid and the solution was diluted with water to give an activity of about 1 μCi/ml.

Standard cobalt-60 solution. Cobalt(II) chloride solution (ORNL, U.S.A.) with a certified specific activity of 54545 mCi/g of cobalt, was diluted to give a solution containing $1{\cdot}87 \times 10^{-11}$ g of cobalt per ml.

Other radioactive nuclide solutions. Each metal was irradiated in JRR-2 then dissolved in an appropriate acid: the solutions were suitably diluted with water.

Buffer, pH 5·3. About 800 ml of 1*M* ammonium acetate mixed with 200 ml of 1*M* acetic acid.

Sodium diethyldithiocarbamate solution 2%. The solution was prepared fresh daily and filtered if necessary.

Mercury(II) chloride solution, 0·05*M*. The pH of this solution was adjusted to about 3·5 with ammonium acetate.

Procedure

A sample of coolant water was filtered under suction through a Millipore filter (pores 0·45 μ). The solid remaining on the filter was ashed along with the filter in a platinum crucible; the ash was fused with 0·5 g of potassium bisulphate, and the cooled melt was dissolved in 2 ml of 6*M* hydrochloric acid and the solution was diluted to 50 ml with water.

Appropriate aliquots of the filtrate and of the residue solution were taken in separatory funnels. Up to 500 ml of sample filtrate could be used when the sample contained small amounts of radioactive cobalt. The pH of the filtrate sample was adjusted to 5·0–5·5 by addition of buffer solution (the volume usually needed was about 1/50 of the sample volume). The pH of the residue solution was adjusted to 5·0–5·5 with 5 ml of 1*M* ammonium acetate and some dilute ammonia solution.

Then 5 ml of 2% sodium diethyldithiocarbamate solution were added to the solution and the mixtures was shaken for 2 min with exactly 10 ml of benzene. The aqueous layer was discarded, 20 ml of mercury(II) chloride solution were added, and the mixture was shaken for 2 min. An exact 5-ml portion of the benzene layer was taken in a polyethylene tube, and its gamma activity was measured.

A gamma-ray scintillation spectrometer was used to resolve the 0·51-MeV positron annihilation radiation from cobalt-58 and the 1·17- and 1·33-MeV gamma rays from cobalt-60. A peak-integration technique or a spectrum stripping technique was used to estimate the amount of each isotope.

RESULTS AND DISCUSSION

Selection of organic solvent

Cobalt(III) diethyldithiocarbamate can be extracted by many organic solvents such as chloroform, carbon tetrachloride and benzene. In the procedure described above, benzene was used as the solvent for the following reasons: the specific gravity of benzene is lower than that of water, so extraction and washing can be done in the same separatory funnel; its solubility in water is very low; the volume change of benzene after equilibration is negligible even when the extraction is made from 500 ml of sample water.

Effects of pH

In the extraction of cobalt diethyldithiocarbamate and the washing to remove diverse radioactive metals, the effects of the pH of the aqueous phases were examined by the radiochemical technique with cobalt-60 tracer solution.

The range of pH for quantitative extraction of cobalt was 4·8–8·0, as shown in Fig. 1. This range is somewhat different from the value 4–11 quoted[2] for the extraction with carbon tetrachloride. The mid-range (pH 5–5·5) was chosen for use. The cobalt diethyldithiocarbamate, extracted into benzene, is very stable and is not affected by washing even with mercuric chloride solution at pH 2, as shown in Fig. 1. The pH of the washing solution used was adjusted to 3·5–4·0, but should be no higher than 5, since mercury(II) tends to hydrolyse.

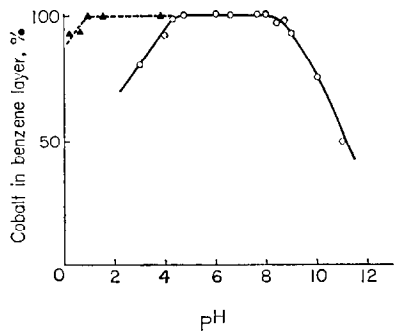

FIG. 1.—Effect of pH.
——○—— on the extraction of cobalt
- - -▲- - - of the washing solution on the extraction
Cobalt-60 tracer solution (54400 ± 150 cpm/ml) was used.

Amount of sodium diethyldithiocarbamate

Even when the extraction was made from 500 ml of sample water containing a few mg of diverse metal ions, 5 ml of 2% sodium diethyldithiocarbamate solution were sufficient for the quantitative extraction of cobalt. A large excess of the reagent did not affect the extraction. Since sodium diethyldithiocarbamate decomposes rapidly in acidic solution of pH below 6, the reagent solution should be added after the pH is adjusted to 5·0–5·5.

Volume of aqueous solution, addition of carrier, and time of shaking

The same results were obtained irrespective of the volume of aqueous phase, up to 500 ml. In the determination of trace amounts of radioactive cobalt (less than 10^{-9} g/ml), the addition of 25 μg of stable cobalt had no effect (Table I). Therefore, the addition of a carrier, used generally in the separation and determination of trace radioactive

TABLE I.—EFFECTS OF THE VOLUME OF SAMPLE SOLUTION AND ADDITION OF CARRIER

500	$3{\cdot}74 \times 10^{-14}$	650, 660, 660	101, 102, 102

* Cobalt-60 tracer solution containing 643 ± 12 gamma cpm/$1{\cdot}87 \times 10^{-11}$ g Co was used.

Washing solution

If the extract was washed with 20 ml of 0·05*M* mercury(II) chloride at pH 3·5–4·5, up to 5 mg of metals such as iron(III), nickel, manganese(II) and (III), and zinc were removed completely, while the trace amounts of cobalt-60 in the benzene remained there quantitatively.

Effects of foreign nuclides

The effects of various elements on the determination of cobalt were examined by the use of radioactive isotopes. Iron, copper, nickel, silver and zinc were extracted into benzene together with cobalt as the diethyldithiocarbamates. With the exception of palladium and platinum, the interferences of nuclides could be removed completely by washing the extract with mercury(II) chloride solution. Since mercury diethyldithiocarbamate is highly stable, the metals in other diethyldithiocarbamates are displaced by the mercury(II). The results obtained are shown in Table III.

TABLE III.—EFFECT OF FOREIGN NUCLIDES

Nuclides that do not form an extractable complex	Na-24, K-42, Cs-134m, Sr-89m, Ba-139, Sc-46, Zr-95, Hf-181, Sb-124, Ta-182, Ce-141, -144, Cl-38
Nuclides that form extractable complexes. These complexes are removed by washing	Ag-110m, Fe-59, Ni-65, Cu-64, Zn-65, Nb-95, Mo-99, Mn-54, Ga-72, In-114m, Tl-204, As-76, Sb-124, Bi-210, Se-75 (incompletely), Te-129
Nuclides that are not removed by washing	Pd-109, Pt-193, Se-75 (slightly)

In a reactor coolant water, the presence of palladium, platinum and mercury is rather unusual. If the coolant water contains such radioactive metals, they can be identified and their effects eliminated by gamma-ray spectrometry, because the gamma-ray energies and half-lives of these metals are different from those of cobalt-58 and -60.

Recovery and application

An average recovery of 99·5% was obtained from a cobalt-60 tracer solution. The relative standard deviation in the 25 determinations was 1·4%. The separation took 15 min.

Radioactive cobalt in the reactor coolant water of the Japan Power Demonstration

Reactor was determined by the procedure. A sample taken 13 hr after the initiation of the reactor operation at 16 MW contained long-lived nuclides such as manganese-54, chromium-51, iron-59 and zinc-65. A multichannel gamma spectrometer was used to identify the activities and to examine the purity of the separated fraction of cobalt-58 and -60.

The results obtained (cobalt-58 $1{\cdot}5 \times 10^{-2}$ μC/l and cobalt-60 $5{\cdot}0 \times 10^{-3}$ μC/l in the filtrate; cobalt-58 $2{\cdot}8 \times 10^{-3}$ μC/l and cobalt-60 $9{\cdot}0 \times 10^{-4}$ μC/l in the residue) agreed with those obtained by the standard method[1] and corresponded to less than 10^{-9} g of cobalt per ml.

Acknowledgement—The authors wish to thank Dr. T. Ishimori for useful comments on gamma spectrometry.

Zusammenfassung—Eine Trennung durch schnelle Extraktion zur radiochemischen Bestimmung von Kobalt-58 und Kobalt-60 in Reaktorkühlwasser wird beschrieben. Nach Einstellung des pH der Wasserprobe auf 5,0–5,5 wird Kobaltdiäthyldithiocarbamat mit Benzol extrahiert. Andere gewöhnlich im Reaktorkühlwasser vorhandene Nuklide wie Mangan-54 und -56, Kupfer-64 und Eisen-59 werden zusammen mit Kobalt extrahiert. Sie lassen sich jedoch leicht entfernen durch Waschen des Extrakts mit Quecksilber(II)chloridlösung. Die Kobalt-58- und -60-Aktivitäten werden durch Gammazählung eines Teiles vom gewaschenen Extrakt gemessen. Spuren von Radiokobalt in 500 ml Wasser konnen quantitativ ohne Träger extrahiert werden. Die Trennung ließ sich in 15 Minuten beenden, es wurde eine durchschnittliche Ausbeute von 99,5% mit einer relativen Standardabweichung von 1,4% in 25 Versuchen erzielt.

Résumé—On décrit une méthode de séparation rapide par extraction pour la détermination radiochimique du cobalt-58 et du cobalt-60 dans l'eau de réfrigération d'un réacteur. Après avoir ajusté le pH de l'échantillon d'eau à 5,0–5,5, on extrait le diéthyldithiocarbamate de cobalt au benzène. D'autres nucléides, par exemple manganèse-54 et -56, cuivre-64 et fer-59, qui sont habituellement présents dans l'eau de réfrigération du réacteur, sont également extraits en même temps que le cobalt. Toutefois, on peut aisément les éliminer par lavage de l'extrait avec une solution de chlorure de mercure (II). On mesure les activités des cobalt-58 et -60 par comptage gamma d'une partie aliquote de l'extrait lavé. On peut extraire quantitativement des traces de cobalt radioactif d'un échantillon d'eau de 500 ml sans emploi d'entraîneur. On peut achever la séparation en 15 mn, et l'on a obtenu une récupération moyenne de 99,5%, avec un écart type relatif de 1,4% (25 expériences).

ION-EXCHANGE BEHAVIOUR OF SEVERAL ELEMENTS IN MIXED SOLVENTS

T. CUMMINGS* and J. KORKISCH†
Analytical Institute, University of Vienna, IX. Währingerstrasse 38, Austria

(*Received* 30 *March* 1967. *Accepted* 16 *May* 1967)

Summary—The distribution coefficients between the cation- and anion-exchangers Dowex 50 and Dowex 1, and aqueous solutions containing nitric or hydrochloric acid and organic solvents with or without amines or complexing agents, have been obtained for a number of metals including uranium, thorium, cerium, iron, copper, and nickel. The organic solvents were methanol, acetone and dimethylformamide; the amines were tributylamine and tribenzylamine, and the complexing agents EDTA and citric acid. Both batch and column methods were used.

THOUGH data pertaining to the ion-exchange characteristics of various elements in mixed aqueous–organic solvents containing mineral acids are relatively numerous[1–3] no attempts have yet been made to investigate systems which also contain amines and/or organic complexing agents in addition to organic solvents and mineral acids. In order to obtain some information on the adsorption behaviour and separation possibilities of elements in the latter media, the research work presented in this paper was performed, with the widely used cation- and anion-exchange resins Dowex 50 and Dowex 1 in mixtures of three organic solvents with either hydrochloric or nitric acid, in the absence or presence of amines and/or organic complexing agents

EXPERIMENTAL

Reagents

Ion-exchange resins. The air-dried strongly acidic and basic, cation- and anion-exchangers, Dowex 50-X8 (100–200 mesh, hydrogen form) and Dowex 1-X8 (100–200 mesh: chloride or nitrate forms) were used for the batch and column experiments.

Standard solutions. Exactly weighed amounts of UO_2(II), Th, Ce(III), Fe(III), Co, Ni, Mg, Ca, Al, Cr(III), Cu(II), Mn(II), Mo(VI), Sr and Zr as chlorides or nitrates were dissolved in 6*M* or 12*M* hydrochloric or nitric acid to give concentrations of the ions of about 10 mg/ml.

Solvents. The reagent-grade organic solvents used were methanol, acetone and dimethylformamide (DMF).

Amines and complexing agents. These were tributylamine (TBA), tribenzylamine (TBeA), EDTA (disodium salt) and citric acid.

Determination of the various elements

Most of the elements investigated (in amounts exceeding *ca.* 100 μg) were determined titrimetrically with EDTA. Microgram quantities of the metal ions were determined spectrophotometrically,[4] or fluorometrically in the case of uranium.[5]

Determination of distribution coefficients

The weight distribution coefficients of the elements were determined by using either the batch equilibrium method (batch method) or the column method. Because details of these methods have already been reported[3] no further description will be given here.

RESULTS AND DISCUSSION

In Table I are shown the distribution coefficients of several elements on Dowex 50, measured in a medium consisting of 90% DMF and 10% 6*M* hydrochloric acid (v/v).

* On leave from Bradley University, Peoria, Illinois, U.S.A.

<1*	15*	2·2	<1*	<1*
Th(IV)	UO_2(II)	Zr(IV)	Ni(II)	Sr(II)
>10^3	<1*	18	4·6	39

* Column method; other results by batch method.

The distribution values with an asterisk were determined by the column method with 1 mg of the metal ion per gram of resin. The other values were determined by the batch method with a load of 50 mg of metal ion per gram of resin except for aluminium of which 10 mg were taken. From these results it is seen that all those metal ions that form relatively strong anionic chloro-complexes are virtually not retained by the resin, *i.e.*, they show distribution coefficients which are less than unity. An exception is chromium which is known to form no anionic complexes of this kind. The extraordinary behaviour of this element may, however, be attributed to its strong tendency to form complexes with DMF so that chromium is not retained by the cation-exchanger.

The effect of changing the concentrations of DMF and hydrochloric acid was investigated for several of the strongly adsorbed elements listed in Table I. The results are listed in Table II from which it is seen that in some cases the distribution coefficients of the elements decrease with an increase of the concentration of DMF. This is

TABLE II.—VARIATION OF CATION-EXCHANGE DISTRIBUTION COEFFICIENTS WITH CHANGING CONCENTRATIONS OF DMF AND HCl

Ion	Overall [HCl], *M*	DMF, %											
		95	90	80	70	60	50	40	30	20	10	5	0

* 10 mg of ion per gram of resin, batch method.
† 50 mg of ion per gram of resin, batch method.

especially notable in the case of cerium and zirconium at 0·6*M* overall hydrochloric acid concentration. This effect is probably due to increased anionic complex formation in the DMF phase with increasing concentration of this solvent. Irregular variations which cannot be accounted for are also observed with other elements, *e.g.*, aluminium.

In Table III is shown the effect of changing concentrations of DMF, acetone and hydrochloric acid on the distribution coefficients of cerium and thorium. At the concentrations of hydrochloric acid marked *a–g* the sum of the DMF and acetone concentrations are, respectively, 90, 80, 78, 74, 70, 88 and 68%. From the data shown in Table III it is seen that the distribution coefficient of cerium at overall acid concentrations from 1·2 to 3·6*M* decreases with an increase of the DMF concentration.

TABLE III.—VARIATION OF CATION-EXCHANGE DISTRIBUTION COEFFICIENTS OF Ce AND Th WITH CHANGING CONCENTRATIONS OF DMF, ACETONE AND HCl

Ion	Overall [HCl], *M*	DMF, %										
		95	90	80	70	60	50	40	30	20	10	0
Ce*	0·6	200	—	—	—	—	—	—	—	—	—	—
	1·2[a]	—	53	62	70	170	230	$>10^3$	$>10^3$	$>10^3$	$>10^3$	$>10^3$
	2·4[b]	—	—	20	27	45	85	185	$>10^3$	$>10^3$	$>10^3$	$>10^3$
	2·6[c]	—	—	21	29	36	—	—	—	—	—	—
	3·1[d]	—	—	13	17	31	37	146	470	$>10^3$	$>10^3$	$>10^3$
	3·6[e]	—	—	—	17	24	52	110	370	$>10^3$	$>10^3$	$>10^3$

	1·3[f]	—	$>10^3$	at all concentrations								
	2·5[c]	—	—	32	$>10^3$	at all other concentrations						
	3·0[d]	—	—	24	—	54	117	210	$>10^3$	—	—	$>10^3$
	3·7[g]	—	—	—	33	53	83	122	—	—	—	$>10^3$

* 8 mg Ce per gram resin, batch method.
† 10 mg Th per gram resin, batch method.

This is in accordance with the data presented in Table II and may be attributed to increased anionic complex formation with an increase in the concentration of the organic solvents. In the case of thorium this decrease of adsorption can be observed only at high concentrations of hydrochloric acid and organic solvents.

In Table IV are listed several solvent systems in which the distribution coefficients of iron, nickel and copper have been measured on Dowex 50. All of the distribution

TABLE IV.—CATION-EXCHANGE DISTRIBUTION COEFFICIENTS OF Fe(III), Ni(II) AND Cu(II) IN VARIOUS SOLVENT SYSTEMS

Solvent system composition	Fe	Ni	Cu
90% Methanol 0·6*M* in HCl and 0·1*M* in TBeA	1	$>10^2$	6
90% Methanol 0·6*M* in HCl	5	$>10^2$	8
90% Methanol 0·6*M* in HCl and 0·02*M* in EDTA	4	30	1
90% DMF 0·6*M* in HNO_3	100	65	8
90% Methanol 0·6*M* in HNO_3 and 0·01*M* in EDTA	>500	150	110
90% Methanol 0·6*M* in HNO_3	>500	400	250
90% Acetone 0·6*M* in HNO_3	>500	>500	>500
75% Acetone 0·6*M* in HNO_3	>500	>500	>500
90% Acetone 0·6*M* in HNO_3 and 0·5*M* in citric acid	>500	>500	>500
90% Acetone 0·6*M* in HNO_3 and 1·25*M* in citric acid	>500	>500	>500
75% Acetone 0·6*M* in HNO_3 and 0·025*M* in EDTA	21	21	21
72% Acetone 1·2*M* in HNO_3 and 0·04*M* in EDTA	17	25	9
72% Acetone 1·2*M* in HNO_3	>500	400	>500

values were determined by the column method with 1 mg of metal ion per gram of the resin. From these distribution data it is evident that in the hydrochloric acid media the distribution coefficients of nickel are invariably higher than those of the other two elements. This is due to the fact that iron and copper form anionic complexes which prevent the adsorption of these two elements on the resin. In the medium that is 0·1*M* in TBeA the distribution coefficients of iron and copper are lower than they are if the TBeA is omitted. This is very probably due to the CIESE-effect observed earlier.[6] A similar observation, although much less pronounced in the case of iron adsorption, was made for the hydrochloric acid system containing EDTA. Because

the distribution coefficient of nickel in this system also has a much lower value, the decrease in the distribution coefficients can very probably be attributed to the formation of EDTA-complexes which reduce the adsorbability of these elements on the resin. This effect of EDTA is rather small, however, because of the relatively high acidities involved.

In the methanol and acetone systems containing nitric acid alone or with EDTA or citric acid, the values of the distribution coefficients of iron, copper and nickel are generally much the same as each other (see Table IV). The coefficient for copper is, however, in several cases lower than that of the other two elements. This may be due to anionic nitrate complex formation. A similar observation has been made earlier[3] in studies involving the change of its distribution value on the same resin with variation of the nitric acid concentration.

Batch-method investigations of the anion-exchange behaviour of several metal ions in a mixture consisting of 90% DMF and 10% 6*M* hydrochloric acid (v/v) showed that in this medium the distribution coefficients of aluminium, cerium(III), cobalt, copper(II), iron(III), manganese(II), nickel, and thorium have values of <1, <1, 29, 29, <1, 18, <1, and <1 respectively. In the case of aluminium the loading was 10 mg/g of Dowex 1. All other loadings were 50 mg/g. These results show that the elements which are not adsorbed on strongly basic resins from any concentration of pure aqueous hydrochloric acid solutions (Al, Ce, Ni and Th) are also not retained on Dowex 1 from the DMF medium. On the other hand iron(III), which is strongly retained from pure aqueous hydrochloric acid solutions, is also not adsorbed from this organic solvent medium. This is very probably due to the influence of DMF which like acetone or tetrahydrofuran causes the CIESE-principle[6] to become effective.

It was also found that the distribution values of aluminium, cerium and thorium on Dowex 1 did not change when the DMF and hydrochloric acid concentrations were varied from 0 to 90% and 0·6 to 1·2*M* respectively.

In hydrochloric acid media containing both DMF and acetone, with the compositions listed in Table III, cerium and thorium were also not retained on Dowex 1 except at low concentrations of DMF (0 to 10%), for which the distribution coefficients were of the order of <100.

In Table V are shown the distribution coefficients of iron, nickel and copper on Dowex 1 for media of various compositions.

From the acetone–hydrochloric acid media in the presence or absence of TBA, iron is not retained by Dowex 1 owing to the CIESE-effect caused by the presence of acetone.[6] On the other hand from the methanol–hydrochloric acid media (see Table V) the adsorption of iron is high but decreases with increasing concentration of tertiary amine so that in this case the CIESE-effect is due to the presence of these amines. The CIESE-effect is not active in pure methanol–hydrochloric acid systems.[6]

In the nitric acid media only relatively small variations in the distribution coefficients of iron, nickel and copper are observed (see Table V). All of the distribution values listed in Table V were determined by the column method using 1 mg of metal ion per gram of Dowex 1.

By the use of one or the other of the media shown in Tables I–V several possibilities exist for analytical separations of the elements. Thus in 90% DMF–10% 6*M* hydrochloric acid, iron together with other elements can be separated on Dowex 50 from

TABLE V.—ANION-EXCHANGE DISTRIBUTION COEFFICIENTS OF Fe(III), Ni(II) AND Cu(II) IN VARIOUS SOLVENT SYSTEMS

Solvent system composition	Fe	Ni	Cu
90% Acetone 0·6*M* in HCl and 0·1*M* in TBA	<1	21	50
90% Acetone 0·6*M* in HCl	<1	21	50
90% Methanol 0·6*M* in HCl and 0·1*M* in TBA	>300	1	>300
90% Methanol 0·6*M* in HCl and 0·5*M* in TBA	80	—	150
90% Methanol 0·6*M* in HCl	300	1	400
90% Methanol 1·2*N* in HCl and 1*M* in TBA	35	—	—

90% Methanol 0·6*M* in HCl and 0·25*M* in TBeA	100	1	150
90% Methanol 0·6*M* in HCl and 0·02*M* in EDTA	>200	1	60
90% Methanol 0·6*M* in HNO_3 and 0·01*M* in EDTA	<1	1	1
90% Methanol 0·6*M* in HNO_3	1	1	1
90% Acetone 0·6*M* in HNO_3	9	8	11
90% Acetone 0·6*M* in HNO_3 and 0·5*M* in citric acid	1	1	4
90% Acetone 0·6*M* in HNO_3 and 1·25*M* in citric acid	<1	<1	—
75% Acetone 0·6*M* in HNO_3 and 0·025*M* in EDTA	3	1	1
75% Acetone 0·6*M* in HNO_3	<1	1	1
72% Acetone 1·2*M* in HNO_3 and 0·04*M* in EDTA	1	1	1
72% Acetone 1·2*M* in HNO_3	1	1	2

the alkaline earth metals, cerium, *etc.* (see Table I). Another example for a separation possibility is that of iron from nickel and copper on Dowex 1 with 90% acetone that is 0·6*M* in hydrochloric acid.

Zusammenfassung—Die Verteilungskoeffizienten zwischen den Kation- und Anionenaustauschern Dowex 50 und Dowex 1 und wäßrigen Lösungen, die Salpeter- oder Salzsäure enthalten, sowie organischen Lösungsmitteln mit oder ohne Amine oder Komplexbildner wurden für eine Anzahl Metalle bestimmt, darunter Uran, Thorium, Cer, Eisen, Kupfer und Nickel. Die organischen Lösungsmittel waren Methanol, Aceton und Dimethylformamid; die Amine waren Tributylamin und Tribenzylamin und die Komplexbildner EDTA und Zitronensäure. Die Austauscher wurden sowohl portionsweise als auch in Säulen verwendet.

Résumé—On a obtenu les coefficients de partage entre les échangeurs cationique et anionique Dowex 50 et Dowex 1, et des solutions aqueuses contenant les acides nitrique ou chlorhydrique et des solvants organiques avec ou sans amines ou agents complexants, pour un certain nombre de métaux comprenant l'uranium, le thorium, le cérium, le fer, le cuivre et le nickel. Les solvants organiques sont le méthanol, l'acétone et le diméthylformamide; les amines sont la tributylamine et la tribenzylamine, et les agents complexants l'EDTA et l'acide citrique. Les méthodes discontinue et sur colonne ont toutes deux été utilisées.

SHORT COMMUNICATION

A novel multi-column gas chromatographic system

(*Received* 27 *April* 1967. *Accepted* 15 *May* 1967)

IN THE course of an investigation into the mechanism of the pyrolysis of propylene it was necessary to analyse quantitatively mixtures of some 25 products, each present in the sample at below the 0·1 μmole level. The products ranged from hydrogen to toluene and included a number of linear and cyclic olefins and dienes. The analysis of such complex mixtures presents two main difficulties. First, with any given column, co-elution of two or more components is a commonplace event. Secondly, the boiling point range is frequently so wide that complete analysis in one operation is lengthy and, additionally, leads to very low sensitivities for the high boiling components. In principle, the first of these difficulties might be overcome by using a capillary column of sufficient length but the sensitivity of such an arrangement would be very low. The alternative approach of temperature programming would overcome problems of sensitivity but would not, because of thermal inertia effects, allow the speed of analysis which is essential for our kinetic investigations.

These problems can, however, readily be solved by means of a suitable multi-column arrangement. The various possible systems have been discussed at length elsewhere.[1] In the present instance the simplest approach, in which all columns are operated individually but in parallel with a single injector, was found to be adequate. With this arrangement only one detector need be employed, but in the present work the nature of the sample made it necessary to use two, and these were connected in series (see Fig. 1). Thus, the column effluent, in nitrogen carrier gas, passed first to a katharometer where hydrogen was determined. Thereafter, the emergent gas stream joined a controlled flow of hydrogen, and the mixed gases passed to a flame ionization detector, where all other materials were determined.

The hub of the multi-column system is a novel rotary column-selector valve operating on the sloping O-ring principle first utilized in gas chromatography by Pratt and Purnell.[2] This valve consists of two identical sloping O-ring valves ganged to operate on a common axis. Each half-valve, and hence the valve as a whole, has four positions, one per column. In each of these positions the selector valve connects the inlet and the outlet of a single column to the injection line and to the detector respectively. Thus, four samples can be analysed in sequence on the four columns by operating the sampling valve in each of the four positions of the column-selector valve.

Figure 2 shows the selector valve with the key in position for operating a column connected across ports 1*a* and 2*a*. In this position the sample enters port 1, passes through the 0·003-in. space between key and barrel, leaves the valve at port 1*a* and enters the column. On leaving the column it follows a similar path in the other half of the valve, entering at port 2*a* and passing on the detector through port 2.

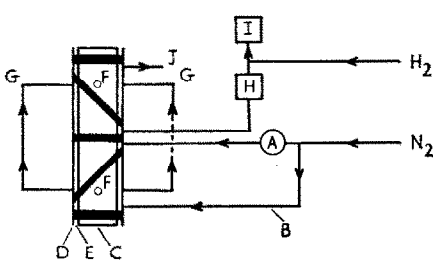

FIG. 1.—Flow diagram
(A) sampling valve; (B) flushing gas stream; (C) key of, and (D) barrel of column-selector valve; (E) clearance of 0·003 in, between key and barrel; (F) ports for connection to columns; (G) connected columns; (H) katharometer; (I) hydrogen flame ionization detector; (J) vent to atmosphere.

The *modus operandi* is the same for all other positions since the placing of ports 1 and 2 is arranged so that, independent of the orientation of the key, they always communicate with the appropriate annular space enclosed by the central and sloping O-rings. Similarly, ports 3 and 4 always communicate with the annular space enclosed by the *terminal* and sloping O-rings. Furthermore, the inlets of the three columns not in use, and also the outlets, are in communication *via* the terminal annular spaces, so that

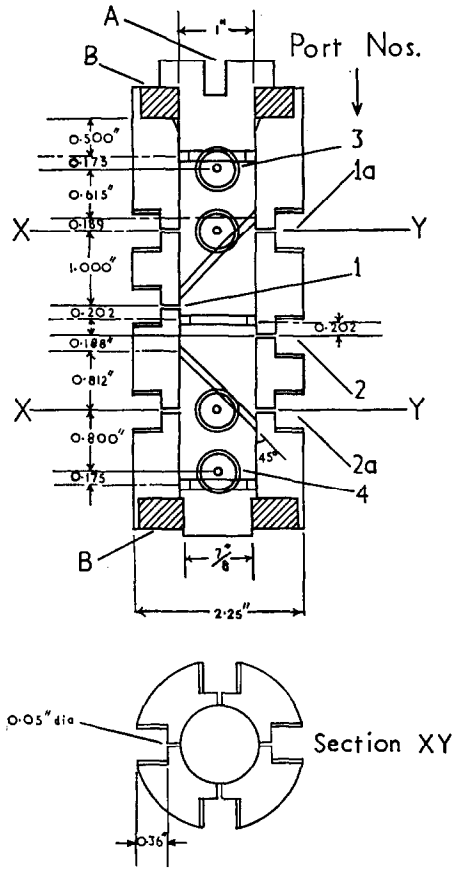

FIG. 2.—Longitudinal (top) and cross-sectional drawings of column-selector valve. Ports 3 and 4 have been projected down on to the plane of the longitudinal section: (A) slot for handle; (B) ball-race. The ports for connection to the four columns appear in the sections XY.

NOTES ON CONSTRUCTION

(1) The barrel was drilled for a diameter of 1 in. and the key was then machined to clear the barrel by 0·003 in.

(2) The dimensions of the grooves in the key are as follows;

sloping grooves: width = 0·125 in.; depth = 0·105 in.
straight grooves: width = 0·150 in.; depth = 0·115 in.

These grooves were designed to take neoprene O-rings with an internal diameter of 0·734 in. and a cross-sectional diameter of 0·139 in. (James Walker Ltd., Woking, England: PB 80/OS 15).

(3) The ports were drilled and tapped to take a ¼-in. B.S.P. fitting, but any convenient connection could be made. Great care was taken in deburring the 0·05-in. diameter holes (see Section XY) where they emerged into the barrel.

TABLE I.—DETAILS OF CHROMATOGRAPHIC COLUMNS

Column No.	Length, *cm*	Solvent	Solid support	Solvent–support ratio, % *w/w*
1	85	silicone oil	120/140 ASTM alumina	2·9
2	340	β,β'-oxydipropionitrile	100/120 ASTM sil-o-cel	15

4	75	squalane	120/140 ASTM sil-o-cel	6

these three columns are connected in parallel across ports 3 and 4 thereby enabling these ports to be used as entry and exit for a flushing gas stream.

Figure 1 illustrates a flow chart of the whole system. Since all columns are, in effect, in parallel and operate from a single back-pressure, the flow-rate through any given column is the same whether it is in use or not. This arrangement minimizes disturbances to the system caused by changing columns. Hence, after switching of columns the katharometer baseline rapidly took up a steady position while simple experiments with a soap bubble flow-meter showed that a stable flow-rate was attained almost immediately. Column switching could, therefore, be achieved in a matter of seconds merely by rotating the key of the valve through 90°.

The provision of flushing has the useful advantage that if the particular column in use is designed to deal with low boiling eluates there is no need to wait for the higher boiling point materials to be eluted before switching over to another column.

The use of several columns with different liquid phases is already a well-known and much-practised procedure for coping with multi-component peaks and no further elaboration of this theme will be undertaken here. The use of several columns with the *same* liquid phase is, however, not generally practised but it is clearly an approach which can be used to cope with mixtures which exhibit a wide range of boiling points, the objective being to adjust the length and solvent–support ratio of each column to deal with a given boiling point range. This expedient provides for faster and more

sensitive chromatography by reducing the retention volumes of the higher boiling materials. The columns used in this work, details of which are shown in Table I, were designed on this basis.

Analysis of the products of reaction from propylene pyrolysis was achieved as follows (see Fig. 3). First, hydrogen and the lower hydrocarbons up to propane were determined on column 1, the columns being switched before the emergence of the very large propylene peak. Then followed the elution on column 2 of a variety of hydrocarbons from 1,3-butadiene through 3-methylcyclopentene to 1,3-cyclopentadiene after which column 3 was engaged. This column was used to analyse cyclopentene and isoprene, and diallyl and *trans*-1,3-pentadiene, pairs of products which were simultaneously eluted on column 2. Finally, column 4, a shorter version of column 3, was used to analyse the higher products such as benzene and toluene.

This arrangement was found to be highly satisfactory for analysis of the products of propylene pyrolysis. However, with other mixtures it might be more convenient to utilize the presently described arrangement in other ways whilst still maintaining the economy of a single detector read-out system. For example, the use of phased injections may be advantageous for relatively simple mixtures. Then, by suitable adjustment of the phasing, the combined effluent from all columns would enable a chromatogram to be obtained in which all components are resolved at least once. The appearance of certain components more than once might be expected, and indeed this situation can be used as means of obtaining a double check of the determination of these components.

To take a different hypothetical example we may suppose that columns 1, 2 and 3 entail 5-min analyses and that the first eluate to be determined on column 4 does not emerge until 20 min after injection. Under these circumstances the present system can be used to inject a sample onto column 4 and then to conduct analyses, in turn, on columns 1, 2 and 3. Column 4 is then re-engaged and the total analysis completed. By this means the analysis time is virtually halved.

Summary—Constructional and operating details are given of a special valve permitting selection of any one of four columns for connection to the detection system of a gas chromatograph, all four columns being connected to the carrier gas stream. If the retention times permit it, the columns may be used simultaneously for chromatographic separations and switched in turn into series with the detector for determination of the eluted components.

Zusammenfassung—Konstruktions- und Bedienungseinzelheiten eines Spezialventils werden angegeben, das die Auswahl einer von vier Säulen zur Verbindung mit dem Detektorsystem eines Gaschromatographen gestattet, wobei alle vier Säulen an den Trägergasstrom angeschlossen sind. Wenn es die Rententionszeiten erlauben, können die Säulen gleichzeitig zu chromatographischen Trennungen verwendet und nacheinander vor den Detektor geschaltet werden, um die eluierten Komponenten zu bestimmen.

Résumé—On donne des détails sur la construction et la manipulation d'une valve spéciale permettant la sélection de n'importe laquelle parmi quatre colonnes, afin de la relier au système de détection d'un chromatographe en phase vapeur, les quatre colonnes étant toutes reliées au courant de gaz porteur. Si les temps de rétention le permettent, on peut utiliser les colonnes simultanément pour les séparations chromatographiques et les relier successivement en série avec le détecteur pour la détermination des composants élués.

PRELIMINARY COMMUNICATION

Fluorescent aluminium indicators derived from substituted coumarins

(*Received* 14 *April* 1967. *Accepted* 25 *May* 1967)

DYES that function as metalfluorechromic indicators, containing the *o,o'*-dihydroxyazo group, have been prepared by coupling the diazonium salt of 1-amino-2-naphthol-4-sulphonic acid with the following fluorescent compounds: umbelliferone, 4-methylumbelliferone, 7-hydroxy-4-phenylcoumarin and 7-hydroxy-4-(4-methoxyphenyl)coumarin. The reaction was carried out under red light in a dark-room, at about 0°. The coumarin derivatives were dissolved in sodium hydroxide solution at pH 10, and a dilute solution of the diazonium hydrochloride was added slowly, the pH not being allowed to fall below 10 until the reaction was complete as shown by the Lindstrom and Diehl test.[1] From the products it was possible to isolate compounds which, though themselves non-fluorescent, gave an intense pink fluorescence with aluminium. The fluorescence developed slowly at room temperature but rapidly at 50–60°.

The fraction that was reactive towards aluminium was separated by ascending paper chromatography at 0° for 12 hr on Whatman No. 1 paper with ethanol–butanol–water–ammonia–0·2*M* EDTA (16:4:2:1:1) as solvent. These fractions all gave blue stains, the R_f values being 0·20 (umbelliferone derivative), 0·27 (4-methylumbelliferone), 0·38 (7-hydroxy-4-phenylcoumarin), 0·24 [7-hydroxy-4-(4-methoxyphenyl)coumarin]. On electrophoresis on Whatman No. 3MM paper, with a borax buffer at pH 9·8, at a potential of 180–220 V and current of 9–10 mA, the reactive species moved 1–2 mm in 90 min and were well separated from the other fractions obtained in the syntheses.

The reactive fractions were separated on the preparative scale by partition chromatography on a 40 × 5 cm column containing 150 g of standard grade Whatman Cellulose Powder or Whatman CF 11 Fibrous Cellulose Powder slurried in 600 ml of the solvent mixture used for the paper chromatography. The separations were made at about 0° in a refrigerated dark-room. The fractions obtained were dialysed to remove electrolytes, and the products were dried by freeze-drying.

The 4-methylumbelliferone derivative has been studied the most extensively. When 3–5 drops of a 1% solution of it in 50% aqueous ethanol are added to 2–100 μg of aluminium in 10 ml of solution at pH 4–5, a red-pink fluorescence is observed when the solution is exposed to ultraviolet light. The excitation spectrum has a maximum at 540 mμ and the emission spectrum has a maximum at 590 mμ. Under the conditions specified, Be, Mg, Zn, Cu, Fe, Co, Ni, UO_2, Ce, Cr, Na, K, Ca and Li ions do not give a fluorescence. At pH 3, In and Tl give a weak fluorescence. At the excitation maximum (440 mμ), 4-methylumbelliferone is not excited, so the products need not be purified before use in this reaction.

At pH 10 the dye has a violet-blue colour which changes to red-pink when a trace of metal ion is added. Calcium and magnesium form this red colour, which is reversibly discharged on addition of EDTA, suggesting that the compound may have an *o,o'*-dihydroxyazo structure.[2,3]

The purification and identification of these compounds are being studied, and methods developed for the determination of aluminium in biological materials.

J. F. AGUILÁ

Summary—Metalfluorechromic indicators, containing the *o,o'*-dihydroxyazo group, have been prepared from a number of coumarin derivatives. The dye obtained from 4-methylumbelliferone reacts with 0·2–10 ppm of aluminium at pH 4–5 to give a pink fluorescence with an excitation peak at 540 mμ and an emission peak at 590 mμ.

Zusammenfassung—Aus einer Anzahl von Cumarinderivaten wurden die o,o'-Dihydroxyazogruppierung enthaltende Metall-Fluoreszenzindikatoren hergestellt. Der Farbstoff aus 4-Methylumbelliferon reagiert bei pH 4–5 mit 0,2–10 ppm Aluminium. Es resultiert eine rosa Fluoreszenz mit Anregungsmaximum bie 540 nm und Emissionsmaximum bei 590 nm.

Résumé—On a préparé des indicateurs métallofluorochromes contenant le groupe *o, o'*-dihydroxyazo à partir d'un certain nombre de dérivés de la coumarine. Le colorant obtenu à partir de la 4-méthylombelliférone réagit avec 0,2–10 p.p.m. d'aluminium à pH 4–5 en donnant une fluorescence rose avec un pic d'excitation à 540 mμ et un pic d'émission à 590 mμ.

LETTER TO THE EDITOR

Identification of electrolysis products at the dropping mercury electrode by submicro-analysis and flame-ionization detection

SIR,

To elucidate the processes at the dropping mercury electrode it is essential to identify the electrolysis products and to determine, if possible, their yields. Generally, the mercury pool electrode has been used for this purpose. Although the products formed at the pool electrode and at the dropping electrode are often identical, exceptions have been reported recently;[1,2] hence it is always preferable to use a dropping mercury electrode for all preparative electrolyses aimed at elucidation of the electrode processes at it. To maintain a reasonable time-period it is then necessary to use small volumes (0·1–1·0 ml) of the solution for electrolysis. To exclude the effects of adsorption phenomena and of higher order reactions, it has proved in many instances preferable to keep the concentration of the electroactive substance below $2 \times 10^{-3}M$. Under such conditions the electrolysis product is obtained in about 0·5 ml of a millimolar solution, and it is impossible to use many of the isolation and identification techniques which are applied in preparative controlled potential electrolysis with a mercury pool electrode. Recently we have had some success in applying two techniques (in addition to ultraviolet spectroscopy and electrochemical techniques previously used for such purposes) namely submicro methods and gas–liquid chromatography with flame ionization detectors.

A 70% complete electrolysis of 1 ml of a $0{\cdot}001M$ solution of a compound with molecular weight about 100, yields about 70 μg of the electrolysis product. The solution can be analysed by conventional submicro procedures.[3] For example, in the one-electron electrolytic reduction of cinnamaldehyde in acid media it was possible to determine the pinacol yield by periodate oxidation[4] and the double-bond content by the bromine monochloride method.[5] The results enabled the dependence of the yields on electrolysis conditions[6] to be properly evaluated.

Although the dilution of the sample was too high to allow the application of conventional gas–liquid chromatography, flame-ionization detectors for gas–liquid chromatography have been successfully applied. When 0·5 ml of the electrolysed solution was extracted with 0·5 ml of ether, the volume reduced to 0·1 ml and a few microlitres injected on to a polyethylene glycol adipate column, good separation and peak shape were obtained for the electrolysis products of the two-electron reduction wave of cinnamaldehyde. Evaluation was carried out with a standard solution. Gas–liquid chromatography combined with mass spectrometry can be applied in a similar way. Further applications of these techniques are to be examined.

One of us (P. Z.) expresses his thanks to the Scientific Research Council and another (D. B.) to J. Lyons and Co. Ltd. for the grants that made this study possible.

THE DETERMINATION OF TERVALENT CHROMIUM AND IRON IN CHROMIC ACID

D. L. FUHRMAN and G. W. LATIMER, JR.
PPG Industries, Chemical Division, P.O. Box 4026,
Corpus Christi, Texas, U.S.A.

(*Received* 22 *May* 1967. *Accepted* 29 *June* 1967)

Summary—Chromic acid is analysed for tervalent chromium by separation of Cr(III) from Cr(VI) by precipitation as the hydrous oxide, with $Zn(OH)_3$ as a carrier. The hydrous oxide is collected by centrifugation and dissolved in perchloric acid, then Cr(III) is complexed with 1,2-diaminocyclohexanetetra-acetic acid and measured spectrophotometrically at 540 mμ. Repetitive analysis of a sample of chromic acid showed 93 ppm of Cr(III) ($s = 13$, $n = 9$). Iron in chromic acid is also separated as the hydrous oxide, then dissolved in HCl, reduced to Fe(II) with hydroxylamine hydrochloride, complexed with bathophenanthroline disulphonic acid and measured spectrophotometrically at 533 mμ. Repetitive analyses of a sample of chromic acid showed 2·6 ppm of iron ($s = 0{\cdot}35$, $n = 8$).

A NUMBER of papers have appeared describing the titrimetric determination of tervalent chromium in the presence or absence of sexivalent chromium by use of ethylenediaminetetra-acetic acid (EDTA).[1–4] Another paper describes the use, for spectrophotometric measurements, of the coloured species formed between chromium(III) and EDTA.[5] Titrimetric determination of chromium(III) with 1,2-diaminocyclohexanetetra-acetic acid (CDTA)[6] and its colorimetric determination with CDTA have also been described.[6,7]

Several techniques have been reported for the colorimetric determination of iron in the presence of chromium; these include use of 8-hydroxyquinoline,[8] 1,10-phenanthroline,[9,10] bathophenanthroline,[11,12] and thiocyanate.[13]

An EDTA titration was used in most of these methods in order to determine chromium(III) in the presence of chromium(VI). None of them was concerned with determination of micro quantities of chromium(III) and iron in "pure" chromic acid.

As a result of studies completed in our laboratory, new techniques were devised for the determination of these species in high-purity chromic acid.

EXPERIMENTAL

Reagents

All reagents were of highest purity. Distilled or demineralized water was used throughout.

Iron standard, 1 g/l. Iron wire was dissolved in hydrochloric acid and the solution diluted to volume. Appropriate dilutions were prepared as needed.

Chromium(III) solution, 1 g/l. Primary standard potassium dichromate (2·827 g) was reduced with hydrogen peroxide (acid solution), excess of hydrogen peroxide was removed by boiling, and the resultant solution was diluted to 1000 ml.

1,2-Diaminocyclohexanetetra-acetic acid (CDTA), 4% w/v. Sufficient sodium hydroxide was added to effect solution.

Bathophenanthroline disulphonic acid (disodium salt), 0·4% w/v aqueous solution.

Procedure for chromium(III)

Samples of chromic acid were dissolved in distilled water and transferred to a centrifuge tube, then 1 ml of 1% w/v zinc chloride solution was added followed by 6*M* sodium hydroxide added

dropwise until the colour of the solution changed from orange to yellow. The samples were centrifuged to collect the precipitate and the supernatant liquid was withdrawn by water-aspiration through a fine-tipped pipette. The hydrous oxides were washed twice with hot water (adjusted to pH 10 with sodium hydroxide) and centrifuged, and then the supernatant liquid was withdrawn as before. The hydrous oxides were then dissolved by adding 10% v/v perchloric acid, reprecipitated with sodium hydroxide, centrifuged, and the supernatant liquid was again withdrawn. Perchloric acid (10 ml, 10% v/v), was added, the centrifuge tube was heated, if necessary, to dissolve the hydrous oxides,

TABLE III.—EFFECT OF IRON ON THE DETERMINATION OF Cr(III)

Cr(III) taken, *mg*	Fe, *mg*	Cr(III) found, *mg*	% Recovery
1	1	1·0	100
1	5	1·1	110
1	10	1·1	110

and 4 ml of CDTA were added. The pH was adjusted to 3·0 with 1*M* sodium hydroxide and the solutions were boiled for 20 min, cooled, transferred to 100-ml volumetric flasks, and diluted to volume. The absorbance of the solutions was read at 540 mμ, distilled water being used as reference. A standard calibration curve was prepared by placing various quantities of the chromium(III) solution in beakers, adjusting the pH, adding CDTA and completing as above. The effect of pH on the precipitation of hydrous chromic oxide in the absence of chromium(VI) was investigated with the chromium(III) standard (1 g/l) as the source of chromium. The results are shown in Table I.

To 10-ml aliquots of the chromium(III) standard solution (1 g/l) were added various amounts of reagent-grade sodium chromate solution (1 g/l) and then chromium(III) was determined as before. The results are shown in Table II.

The effect of iron on the determination of chromium(III) was investigated by mixing standard solutions of chromium(III) and iron and determining chromium(III) as before. The results are shown in Table III.

Repetitive analyses by this technique, completed by three analysts, of a sample of chromic acid showed it to contain 93 ppm of chromium(III) (9 variates, standard deviation 12 ppm).

Procedure for iron

Chromic acid solutions containing iron were treated as before, except that the precipitate was dissolved in 5 ml of dilute hydrochloric acid (1 + 4), 10 ml of absolute ethanol were added, and the solution was heated to reduce any chromium(VI) present. The solution was transferred to a 100-ml volumetric flask, 3 ml of 45% w/v sodium acetate trihydrate solution, 10 ml of 20% w/v hydroxylamine hydrochloride solution, another 5 ml of sodium acetate solution and 4 ml of bathophenanthroline disulphonic acid reagent were added. The solutions were diluted to volume and allowed to stand for 15 min, and the absorbance was measured at 533 mμ against a distilled water blank carried through the entire procedure. A standard calibration curve was prepared by placing various quantities of a diluted iron standard in 100-ml volumetric flasks, adding 5 ml of hydrochloric acid (1 + 4) and completing as above. The effect of chromium(III) on the iron determination was investigated by mixing standard solutions of each cation. The results are shown in Table IV.

The method of standard addition of iron to a chromic acid solution was used to test the accuracy of the iron determination. The results are shown in Table V.

Repetitive iron determinations on the sample of chromic acid used to establish the precision of the chromium(III) method showed 2·6 ppm of iron (8 variates, standard deviation 0·35 ppm).

DISCUSSION

Studies showed that the chromium(III)–CDTA complex is equally well developed at pH 4·8 (recommended by Verma[7]) and pH 3·0; however, colour development is more rapid at pH 3·0. The boiling time was extended from 10 min (recommended by Verma) to 20 min because results obtained after boiling for only 10 min were erratic and did not conform to the Beer-Lambert law. Additional studies showed the colour of the chromium(III)–CDTA complex was stable for at least 60 hr when developed at pH 4·8. The colour developed at pH 3·0 reaches a maximum in less than 1 hr. The complex is formed more slowly at pH 4·8 and a 40-min heating time is necessary to ensure stable absorbances.

Although magnesium had been successfully used as a carrier for routine analyses of chromic acid for chromium(III) and iron, zinc was used when the effect of pH on the precipitation of chromium(III) was investigated (magnesium hydroxide is not significantly precipitated below pH 10). A further advantage was that zinc formed a less flocculent precipitate than magnesium did.

The study of the effect of pH on the precipitation of $Cr(OH)_3$ showed essentially no change in the range 9–12, but results were about 15% lower at pH 13. These results are not surprising, as chromium(III) is slightly amphoteric whereas zinc is very amphoteric. Thus, at pH 13, a large portion of the $Zn(OH)_2$ would dissolve, probably along with some of the $Cr(OH)_3$.

Although the chromium(III)–CDTA complex ion has an absorptivity only 1/10 to 1/100 that of many organometallic species used in spectrophotometry, its absorbance is linear over a wide concentration range (0·2–8 mg/100 ml). The relative insensitivity of the colorimetric determination of Cr(III)—a reproducibility of 0·005 absorbance units on the spectrophotometer is equivalent to 25 μg of chromium(III)—limits the expected accuracy of the procedure to 2·5% relative at the 1000-μg level. The relative precision of 4% commonly found for tervalent chromium(III) standards in the absence of chromium(VI) might reflect anomalies inherent in the precipitation and separation of chromium(III) as the hydrous oxide.

The extraction of the iron–bathophenanthroline complex (not the disulphonic acid) with chloroform yielded a linear calibration curve with standards (10–40 μg of iron), but the procedure gave erratic results when applied to samples of chromic acid. The reason for its failure is not clear since less chromium was present in this study than that reported in the literature.[12]

Iron values obtained by application of the thioglycollic acid procedure[16] tend to be higher than those found by use of bathophenanthroline disulphonic acid. Under the ammoniacal conditions used for completion of the thioglycollic acid method, a colloidal precipitate was formed. The nature of this precipitate was not established, but the higher iron result found was probably due to scattering of light by the precipitate.

Other techniques for the colorimetric determination of chromium(III) include use of Chromeazurol S[14] and diphenylcarbazide[15] [after separation of chromium(III) from chromium(VI)]; a titrimetric procedure using mercury(I) and permanganate is also reported.[17] Iron has been separated from chromium by extraction of iron(III) chloride into isopropyl ether,[18] by ion-exchange,[19,20] and with 8-hydroxyquinoline prior to an EDTA titration.[21] None of these procedures was evaluated in our studies.

Zusammenfassung—Chromsäure wird auf dreiwertiges Chrom analysiert, indem Cr(III) von Cr(VI) durch Fällung als Oxidhydrat mit $Zn(OH)_2$ als Träger abgetrennt wird. Das Oxidhydrat wird durch Zentrifugieren gesammelt, in Überchlorsäure gelöst, Chrom(III) mit 1,2-Diaminocyclohexantetraessigsäure in den Komplex überführt und bei 540 nm spektrophotometrisch gemessen. Wiederholte Analysen einer Probe von Chromsäure ergaben 93 ppm Cr(III) ($s = 13$, $n = 9$). Eisen in Chromsäure wird ebenfalls als Oxidhydrat abgetrennt, in HCl gelöst, mit Hydroxylaminhydrochlorid zu Eisen(II) reduziert, mit Bathophenanthrolindisulfonsäure komplex gebunden und spektrophotometrisch bei 533 nm gemessen. Mehrfachanalysen einer Chromsäureprobe ergaben 2,6 ppm Eisen ($s = 0{,}35$, $n = 8$).

Résumé—On analyse l'acide chromique pour le chrome trivalent par séparation de Cr(III) de Cr(VI) par précipitation à l'état d'oxyde hydraté, avec $Zn(OH)_2$ comme entraîneur. L'oxyde hydraté est recueilli par centrifugation et dissous en acide perchlorique, puis Cr (III) est complexé avec l'acide 1,2-diaminocyclohexanetétracétique et dosé spectrophotométriquement à 540 mμ. Des analyses répétées d'un échantillon d'acide chromique ont montré 93 p.p.m. de Cr(III) ($s = 13$, $n = 9$). Le fer dans l'acide chromique est aussi séparé à l'état d'oxyde hydraté, puis dissous en HCl, réduit en Fe(II) par le chlorhydrate d'hydroxylamine, compléxé avec l'acide bathoplénanthroline disulfonique et dosé spectrophotométriquement à 533 mμ. Des analyses répétées d'un échantillon d'acide chromique ont montré 2,6 p.p.m. de fer ($s = 0{,}35$, $n = 8$).

MULTI-SPOT PAPER CHROMATOGRAMS OF SODIUM ORTHOPHOSPHATE

MARJORIE A. ROMMEL* and ROY A. KELLER
Department of Chemistry, University of Arizona, Tucson, Arizona, U.S.A.

(*Received* 23 *February* 1966. *Revised* 1 *June* 1967. *Accepted* 26 *June* 1967)

Summary—The formation of two zones on paper chromatograms was investigated by chromatographing orthophosphoric acid and the primary, secondary and tertiary sodium salts, using pyridine–ethyl acetate/water as mobile phase. Movement of the species from the origin depends on washing the paper with acid and suggests an exchange of protons for sodium as a prerequisite condition. Washing with EDTA does not alter this requirement. Zone movement and multi-spot formation require that the forming solvent contain at least 5% of water (v/v). Between this value and saturation, increasing water content enhances zone disengagement. A solute spot of a sodium salt exchanges with the protons to produce a fast-migrating protonated phosphate species. If the solute sample has a sodium content less than the amount of exchangeable protons, a single fast spot is produced; if the concentration exceeds this capacity, a second slower spot results.

OCCASIONALLY, when a compound normally considered to be a single molecular species is chromatographed on paper, two or more distinct zones appear on the final chromatogram. The normal practice is to interpret this as an indication of two species. This exceptional behaviour has been termed multi-zoning or multi-spotting of a single species. Pollard *et al.*[1] summarized the origins of multi-spots as: (1) the alkaline-earth and heavy metal impurities in the paper;[2–4] (2) the water content of partially miscible solvent mixtures; (3) solute reaction with the mobile phase to form "solvated complexes"; (4) acidity; (5) anions which compete for the cation. The character of the multi-spot chromatogram depends upon the relative anion affinities for the cation and their concentrations. Specifically, Curry[5] investigated the chromatographic separation of phosphate species which are in equilibrium in aqueous solutions of sodium orthophosphates, *e.g.*,

$$H_2PO_4^- + B^{n-} = HPO_4^{2-} + HB^{(n-1)-} \quad (1)$$

where B^{n-} is some proton acceptor. He found that the number, position, and relative size of the spots, proposed to be $H_2PO_4^-$ and HPO_4^{2-}, were related to the concentrations of the different species in the sample solutions, these concentrations being determined by the solution acidity and the identity of the solute. Erdem[6] employed the suggestion to explain the identical phenomena for the sodium orthoarsenates. Pollard, Nickless, and Bigwood[7] observed multiple zones for orthophosphate in chromatographic systems employing anion-exchangers. Their zones were not as distinctly separated as those reported here, nor did these authors comment on the phenomenon or establish the identity of the species in these zones. Efforts to explain these observations generally propose the separation of species in equilibrium with

* Koppers Company Fellow, 1963; Continental Oil Company Research Fellow, 1964; present address, Rocketdyne, Analytical Research Laboratory, Canoga Park, California.

each other [equation (1)]. Indeed Keller and Giddings[8] did conclude that multiple zones of a single solute on chromatograms can result from a slow transition between solute species. However, theory demonstrates that for multi-spotting by transition between species, the transition time, *i.e.*, the half-life, must be of the same magnitude as the time of formation of the chromatogram. The transition in equation (1) is a proton transfer and these tend to be very fast, *e.g.*, the half-life[9] for hydronium ion reacting with hydroxyl ion is about 10^{-8} sec. Equation (1) does not describe strictly the same situation, but other proton transfers would need to differ from this one by a factor of 10^{13} in order that the transition time and the period of chromatography be comparable. Thus the simple equilibrium of equation (1) seemed inadequate as an explanation because slow kinetic steps are required and are unlikely. The mechanism proposed here involves an ion-exchange process.

The first step in the problem was the verification that the separated spots obtained with phosphate salts are different phosphate species. Rommel and Keller[10,11] irradiated the completed chromatograms *in situ* with thermal neutrons to produce radioactive ^{24}Na and ^{32}P. Resolution of the activity *vs.* time curve of each zone gave the Na/P ratio. When double spots were produced with pyridine–ethyl acetate/water, the fast spot had Na/P ratios of 0·03–0·19 for the ortho-acid and any of its sodium salts, while the slow spot had Na/P = 0·75 for Na_2HPO_4 and 1·2 for Na_3PO_4. Similar phenomena were observed with a mobile phase of butanol/water, *e.g.*, with NaH_2PO_4, Na/P was 0·38 for the fast spot. Sodium was found in the fast zone for a sample of orthophosphoric acid.

EXPERIMENTAL

The glass chromatographic chamber for descending technique was that pictured by Macek.[12] The chromatograms were performed on 55 × 2·8 cm strips cut from sheets of Whatman No. 1 filter paper, acid washed. The start was always 8·6 cm from the end of the paper. Prior to chromatography the chamber was saturated with vapours of water containing the organic phase of the forming solvent. The sample was delivered to the dry paper by a 10-μl pipette to give a spot 1·5 cm in diameter, and the solvent was evaporated off. The sample-laden paper was placed in the vaporous atmosphere of the tank for at least 8 hr prior to chromatography. The sample solutions contained at least the minimum amount for detection by the colour reagent, *i.e.*, $10^{-3}M$ in phosphate. Completed chromatograms were air-dried and scanned for radioactivity, or the zones were revealed with the molybdate reagent.[13] Radiocounting procedures and equipment are described elsewhere.[11]

Pretreatment of the paper

Papers were washed and rinsed consecutively with (*a*) 2*M* acetic acid and 0·1*M* EDTA (*b*) 2*M* acetic acid, 0·1*M* EDTA and 2*M* acetic acid, (*c*) 2*M* acetic acid, (*d*) 2*M* hydrochloric acid, or (*e*) water. The acetic acid prewash was selected on the recommendation of Hanes and Isherwood[3] as sufficient to meet Pollard's first point. Each paper was immersed in the wash liquids for 5 min and rinsed by transfer through a series of immersions in distilled water until the acidity of the rinse remained that of distilled water. This rinse preceded the next wash solution. Finally the paper was rinsed with 20 ml of 95% ethanol (reported by Hettler[14] to prevent shrinkage of the paper) followed by 20 ml of ethyl acetate. The papers were dried in a fume-hood and stored. Storage did not change the chromatographic behaviour. Analyses by neutron activation[10,11] indicated that acid washing reduces the sodium content by a factor of 7 to 8. Some labile sodium still remains, however, since chromatography reduced the sodium content by a factor of 12 below that of the acid washed paper.

The solute for one set of these papers was 0·01*M* sodium dihydrogen phosphate and for the other 0·01*M* sodium dihydrogen phosphate plus 0·01*M* sodium acetate; both sets were formed with pyridine–ethyl acetate/water. Papers washed exclusively with water or not washed at all gave little or no movement of either solute solution; the spot "smeared out" from the origin. The sodium dihydrogen phosphate, when alone, gave a single spot of identical shape and R_f for all pre-washed papers. This salt combined with sodium acetate gave identical double spots, similar to those shown in Fig. 1, for all pre-washed papers. When only EDTA was used, *i.e.*, no acid wash, the phosphate

Na_3PO_4	1-10	0·01	0·03	0·01	3	2 spots, $R_f = \begin{cases} 0·64 \\ 0·40 \end{cases}$

remained at the origin with a forming solvent of butanol/water and gave an elongated smear with pyridine–ethyl acetate/water.

Papers washed with 2*M* acetic acid were used throughout the study of other variables.

Composition of the developer

The forming solvent routinely used was the 0·45:1 (v/v) pyridine–ethyl acetate combination, containing water.[8] Initial vagaries led to an investigation of the effect of water content of the forming solvent. The solvents used to prepare the mobile phase were analysed for water by titration with Karl Fischer reagent. Once the water content of the reagents was known, water could be added to produce a desired composition.

The solution chromatographed in these studies was one of radioactive 0·01*M* disodium hydrogen phosphate adjusted to pH 8·5 with dilute sodium hydroxide. The chromatograms were formed for identical time periods with pyridine–ethyl acetate mixtures of known but varying water content. Figure 2 is a plot of the radioactivity measured by the techniques described elsewhere.[11] With up to 5% of water in the mobile phase, there is only one zone, which essentially does not migrate. As the water content increases, more phosphate appears in a fast zone and there is increased separation of the zones. The saturation composition of 24% was determined by titration of the non-aqueous components to an opalescence with water. This water-saturated pyridine–ethyl acetate mixture gave only the fast spot. The 15% aqueous solution was used throughout the work unless otherwise noted.

Total solute concentration

Table I indicates the dependence of double zoning on the total solute concentration. The concentrations of sodium and *total* phosphate species, disregarding the particular ionic species involved, are shown along with the Na/P ratios. The R_f-values are reported where they were observed. In most cases, clear separations were produced only after mobile phase ran from the end of the paper. No attempt was made to control the acidity of the solution applied.

TABLE II.—EFFECT OF THE Na/P RATIO ON RELATIVE SPOT SIZE OF DOUBLE SPOTS FROM 0·01*M* TERTIARY SODIUM ORTHOPHOSPHATE

No.	Additive	[Na], *M*	[Total phosphate species] *M*	Na/P	Result
2-1		0·03	0·01	3	Two spots, slow spot ¼ the size of the fast spot
2-2	0·01*M* NaOH	0·04	0·01	4	Two spots, slow spot ½ the size of the fast spot
2-3	0·01*M* NaOAc	0·04	0·01	4	Two spots, slow spot ½ the size of the fast spot
2-4	0·01*M* NaOH + 0·01*M* NaOAc	0·05	0·01	5	Two spots of about equal size

Sodium to phosphorus ratio

Table II presents the results of the chromatography of 0·01*M* trisodium phosphate with the additives listed. Table III shows the results for various ratios and concentrations of sodium and phosphate for solutions prepared from sodium dihydrogen orthophosphate and sodium acetate.

TABLE III.—EFFECT OF THE SODIUM/PHOSPHORUS RATIO AND THE SALT CONCENTRATION ON THE APPEARANCE OF DOUBLE SPOTS

No.	[Total phosphate species], *M*	[Na], *M*	Na/P	Result

* F—fast spot, *i.e.*, large R_f.
S—slow spot, *i.e.*, small R_f.
t—threshold, *i.e.*, barely discernible separation.

chromatograms for any one phosphate solute were executed simultaneously in the same chamber with identical forming solvents for the same period of time.

Addition of sample to the paper at the instant the solvent reached or had just passed the origin resulted in smeared zones from which it was impossible to conclude anything.

Pyrophosphate as solute

The possibility that one of the spots was a condensed phosphate formed during the experiments seemed extremely remote, *e.g.*, Steinman, Lemmon and Calvin[15] found that a solution of phosphoric acid would not yield pyrophosphoric acid in the absence of a catalyst. Nonetheless, 0·1*M* primary and 0·1*M* secondary sodium orthophosphates were chromatographed simultaneously with 0·01*M* sodium pyrophosphate ($Na_4P_2O_7$). With 26·4% pyridine, 58·6% ethyl acetate, 15% water (v/v) as mobile phase, both the disodium orthophosphate and the pyrophosphate gave double spots but the zone locations and intensities were dramatically different and it seemed clear that very different ionic species were involved. With 24·8% pyridine, 55·2% ethyl acetate, 20% water (v/v), these salts formed single spots only, again at different positions.

DISCUSSION

Multi-zoning of a single species due to reversible transition between equilibrium forms is only possible with relatively slow kinetics. Therefore the multi-spots which occur with protonated phosphate must have some other explanation.

Acid washing is necessary to produce migration of the phosphate, and single and double spots can still be produced after this wash, even though this wash should have removed the heavy metals deemed necessary for multi-zones. EDTA, an excellent chelating agent for alkaline earths,[16] when used alone in neutral water as a pre-wash, led to retention at the origin and smeared chromatograms, but no multi-spots. When it was followed by acid, multi-spots resulted. The key to multi-spotting does not seem to be the removal of alkaline earths, but this removal followed by an acid wash.

Table IV shows that trisodium orthophosphate forms double spots in a range of pH values from acidic to basic. Multiple spotting seems to be independent of total salt content (Nos. 4-1 and 4-2) at the same pH (NH_4Cl present) and is identical for the same Na/P ratio and phosphate salt concentration at different acidities. The situation with secondary sodium orthophosphate probably represents threshold conditions for double spot formation and the system is highly sensitive to even minor differences in the solution applied. Double spots occur in Nos. 4-7, 4-8 and 4-10. The situation for 4-7 is identical with that of the entry for secondary sodium orthophosphate in Table I (single spot). We have no explanation for this except these sensitive threshold conditions. It is instructive that the double spots of Nos. 4-8 and 4-10 are nearly identical even though 4-8 is basic relative to the pure salt (4-7) while 4-10 is acidic. Table II reports chromatograms with 0·01*M* sodium hydroxide (2-2) and 0·01*M* sodium acetate (2-3) which were virtually identical. (Note that the concentrations of sodium ion are identical.) The result for the mixture of sodium hydroxide and sodium acetate was twice that of either one alone. If the relative size of the spots had depended on the presence of the basic hydroxyl ion, cases 2-2 and 2-4 would have been similar. The chromatograms are identical for primary sodium orthophosphate and represent the extreme situation of single spots only. For us, these results are a convincing argument that the acidity of the solution *applied* has little or nothing to do with the phenomenon, *e.g.*, Nos. 4-6, 4-12 and 4-18 vary by 0·1 pH unit and yet pass from a single to a double spot. To fully complete the theme, phosphoric acid was used as the starting material with acid, base (ammonia), or both added to cover a pH range of 2·2 to 12·0.

We propose that an ion-exchange mechanism is responsible for multi-spots and

that these appear at a particular concentration of sodium ion in the solution applied. Neutron-activation studies indicate that sodium occupies some or all of the exchange sites, and is not exchanged for protons when the paper is washed with EDTA alone or water alone. The solute zone, potentially the slow spot, "smears out" from the origin or does not move at all. Once the paper is acid-washed, most of the sodium is replaced by protons. Sodium ions in the solution applied can replace these protons. So long as the sodium content does not exceed the proton concentration available from the paper, and the Na/P ratio of the solute spot remains less than unity, a single fast spot appears (Na/P 0·03–0·19 for pyridine–ethyl acetate/water; 0·38 for butanol/water). If, however, the sodium content of the solution applied exceeds the capacity of the paper so that the solute spot has a Na/P ratio greater than unity, two spots appear, the usual fast spot of composition stoichiometrically near H_3PO_4 and a slow one of composition nearly that of NaH_2PO_4. If one takes the exchange capacity of paper to be the 0·008 mequiv/g given by Ultee and Hartel[17] (see Rommel and Keller[11]) and assumes complete protonation by prewashing, then the amount of hydrogen ions available is $6{\cdot}6 \times 10^{-5}$ mequiv/cm^2. The 10-μl sample covers 1·8 cm^2. The concentration of sodium needed to just replace this amount of hydrogen and have no excess of sodium remaining in the solute spot is 0·012*M*. Tables I–IV show that this is exactly the threshold concentration above which multiple spotting occurs.

The amount of fast and slow species is determined by the sodium ion removed by the paper, not by the acidity of the solution applied. As the fast spot moves out from the origin it retains its integrity because it encounters protonated paper. Some sodium ion is encountered since proton exchange is not complete. As the slow spot moves on, it enters proton-rich paper and exchanges sodium for hydrogen, but since it does not move very far (Fig. 1) there is not much conversion. The formation of a protonated species may also be retarded by a relatively large number of sodium ions by some sort of competition, *e.g.*,

$$HPO_4^{2-} + Na^+{\cdot}H_2O = NaPO_4^{2-} + H_3O^+$$

or if not by compound formation, then at least by some kind of ion-pair association. Proton exchanges between phosphate species in solution are probably fast, so that a single solute zone, characteristic of the equilibrium mixture, results.[8] This is very likely the reason for the spot moving at all. Since the mechanism is a cation–proton exchange, one may well wonder why ammonium ion, added to adjust the pH, does not introduce vagaries. Bark, Graham, and McCormick have shown that ammonium ion does not exchange with cellulosic protons.[8]

The dependence of multi-spots on the water content of the developer may be because a proton acceptor, a Brønsted base, must be present before the sodium can displace the protons. Sjövall Haahti, and Nyström[19,20] remark that the chromatographic behaviour of the sodium or potassium salt of dehydroepiandrosterone sulphate on a polar gel is completely altered when the water content of the developer is 3% or greater. They take this as evidence of dissociation of the salt in the more aqueous developer.

Acknowledgements—The authors are indebted to the National Institutes of Health, RG-7046-Bio(Cl) and the National Science Foundation G-14216 for financial support of this work and to Drs. E. N. Wise and J. T. Yoke, III, of the Chemistry Department for their guidance while the principal investigator was truant in Europe enjoying a sabbatical leave. We are particularly indebted to Dr. Graham of the University of Salford. His suggestions were a real contribution to the content of the paper in its final form and did much to alter some of our previous contentions.

Zusammenfassung—Die Bildung zweier Zonen auf Papierchromatogrammen wurde durch Chromatographieren von Orthophosphorsäure und ihren primären, sekundären und tertiären Natriumsalzen mit Pyridin/Äthylacetat/Wasser als mobiler Phase untersucht. Die Fortbewegung der Spezies vom Anfangspunkt hängt vom Waschen des Papiers mit Säure ab und deutet auf einen Austausch von Protonen für Natrium als Vorbedingung hin. Waschen mit EDTA ändert daran nichts. Die Zonenfortbewegung und die Bildung mehrerer Flecken erfordern einen Volumenanteil von mindestens 5% Wasser in der Entwicklungsflüssigkeit. Zwischen diesem und dem Sättigungswert fördert zunehmender Wassergehalt die Trennung der Zonen voneinander. Ein Fleck von einem gelösten Natriumsalz tauscht mit den Protonen aus und bildet eine schnell wandernde protonierte Phosphatspezies. Hat die gelöste Probe einen Natriumgehalt, der geringer ist als die Menge an austauschbaren Protonen, so wird nur ein schnell wandernder Fleck gebildet; steigt die Konzentration über diesen Wert hinaus, so entsteht ein zweiter, langsamer wandernder Fleck.

Résumé—On a étudié la formation de deux zones sur chromatogrammes de papier en chromatographiant l'acide orthophosphorique et les sels de sodium primaire, secondaire et tertiaire, utilisant comme phase mobile le mélange pyridine-acétate d'éthyle-eau. Le mouvement des espèces à partir de l'origine dépend du lavage du papier à l'acide et suggère un échange du sodium par des protons comme condition préalable nécessaire. Le lavage à L'EDTA ne change pas cette condition. Le mouvement de zone et la formation de taches multiples nécessitent que le solvant contienne au moins 5% d'eau (v/v). Entre cette valeur et la saturation, l'augmentation de la teneur en eau accroît la séparation de zone. Une tache d'un soluté d'un sel de sodium donne lieu à échange avec les protons pour produire un phosphate protoné migrant rapidement. Si l'échantillon dissous a une teneur en sodium inférieure à la quantité de protons échangeables, il se produit une seule tache rapide; si la concentration excède cette capacité, une seconde tache plus lente en résulte.

THE MASS SPECTROMETRY OF METAL CHELATES—II

OXINATES OF COMMON METALS

A. E. JENKINS, J. R. MAJER and M. J. A. READE
Department of Chemistry, P.O. Box No. 363, The University, Birmingham 15, U.K.

(*Received* 24 *April* 1967. *Accepted* 9 *May* 1967)

Summary—The mass spectra of the oxinates of zinc, iron(III), manganese(II), nickel, cobalt, aluminium, copper and magnesium have been measured. Concentrations of several of these chelates have been related to the integrated ion currents recorded at a significant *m/e* value during evaporation of the sample in the source of an A.E.I. M.S.9 mass spectrometer. The structural significance of some of the mass spectra is discussed.

IN a previous paper[1] a method was described for the detection and estimation of amounts of nickel dimethylglyoximate down to 10^{-12} g. In this method, a small sample of the chelate was evaporated into the source of an A.E.I. M.S.9 mass spectrometer. The ion current at *m/e* 288 corresponding to the ion $C_8H_{14}N_4O_4{}^{58}Ni^+$ was recorded continuously during the evaporation of the sample. The integrated ion current was then shown to be proportional to the amount of metal chelate evaporated. It is the purpose of the present paper to extend this method to the oxinates of a number of metals in order to investigate the suitability of oxine as a ligand for this specific purpose. At the same time, it is possible to obtain structural information on these metal chelates from an examination of their mass spectra.

EXPERIMENTAL

Reagents

The oxinates of zinc, iron(III), manganese(II), nickel, cobalt, aluminium, copper and magnesium were prepared by the methods described in "Oxine and its Derivatives".[2] Stock solutions of copper, aluminium and zinc oxinates were prepared by dissolving 10 mg of the chelate in 100 ml of chloroform.

The complete mass spectra were recorded by evaporating small solid samples of the chelates in the source of the mass spectrometer.

The method described previously was used to record the ion currents at significant *m/e* values during evaporation of samples introduced (in the form of their solutions in chloroform or dioxan) into the probe with the aid of a Hamilton syringe.

All measurements were made with an A.E.I. M.S.9 mass spectrometer fitted with a direct evaporation probe.

RESULTS AND DISCUSSION

Copper oxinate

The mass spectrum of copper oxinate is illustrated in Fig. 1. The spectrum is in accord with a metal : ligand ratio of 1 : 2 and there is an intense mass peak at *m/e* = 351 corresponding to the molecular ion $C_{18}H_{12}N_2O_2{}^{63}Cu^+$. The current from this ion was recorded in further quantitative measurements because it was characteristic of the molecule.

* Part I—*Talanta*, 1967, **14**, 777.

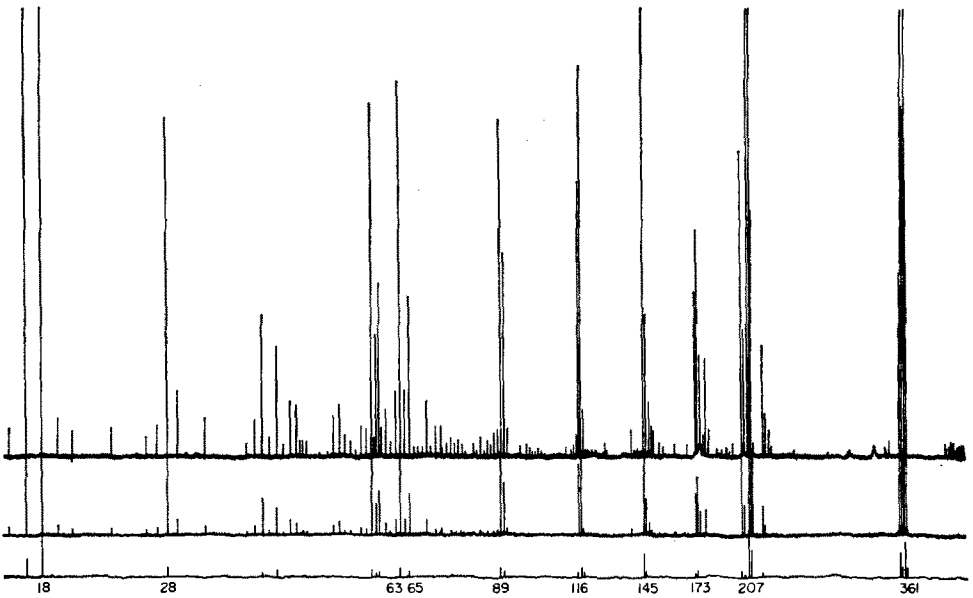

FIG. 1.—Mass spectrum of copper oxinate.

Using as reference peak the signal at *m/e* 219 obtained by admitting a measured pressure of heptacosafluoro tri-n-butylamine to the source, the integrated ion currents at *m/e* 351 were recorded when a range of measured samples of copper oxinate was evaporated into the ion source. The samples were introduced in the form of a chloroform solution from a Hamilton syringe, the stock solution being diluted stepwise immediately before introduction. The integrated ion current as measured by the area under the envelope of the peaks at *m/e* 351 was plotted against sample size and a straight line graph was obtained (Fig. 2). The limit of useful measurement was once again of the order of 10^{-12} g. For all measurements the source temperature was 255°.

Copper oxinate exists in an anhydrous form and as a dihydrate which is stable up to a temperature of 60°. The sample examined had previously been dried at a temperature of 110° and was in the anhydrous form. The mass spectrum showed no peaks which

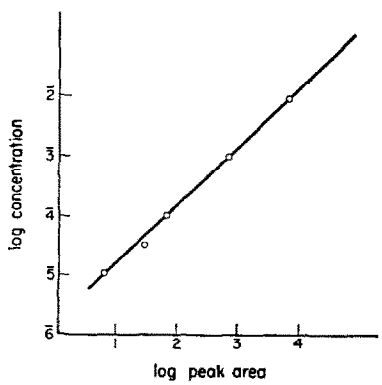

FIG. 2.—Variation of integrated ion current with weight of copper oxinate.

could have been derived from the evaporation of the copper oxinate as its dihydrate. The anhydrous form is reported to be stable up to a temperature of 300° which is nearly 50° above the temperature at which evaporation took place.

Zinc oxinate

The mass spectrum of zinc oxinate is illustrated in Fig. 3. There is an intense mass peak at *m/e* 352 corresponding to a metal:ligand ratio of 1:2. Although it is not visible in the figure, on close examination of the original record a smaller peak is revealed at *m/e* 560 corresponding to a metal:ligand ratio of 2:3. There is thus some evidence for the existence of more than one zinc oxinate species and it would be

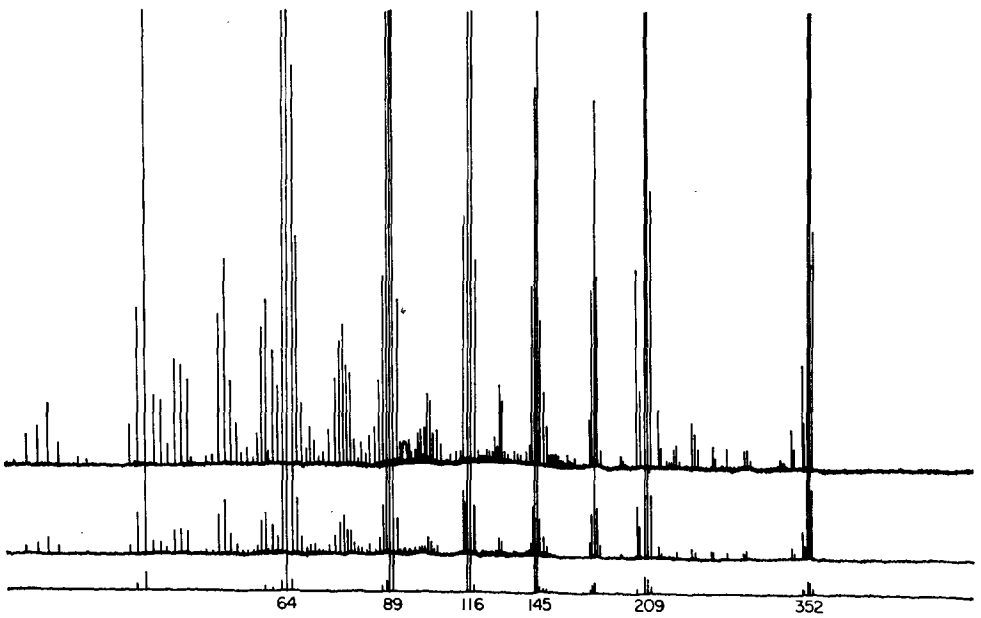

FIG. 3.—Mass spectrum of zinc oxinate.

expected that the two chelates would evaporate at different rates. It is not therefore possible to make a direct correlation between the integrated ion current at *m/e* 352 and zinc content in a sample. The envelope of the peaks at *m/e* 352 does in fact show two separate maxima the first of which may correspond to the molecule ion containing two oxinate residues and the second to a fragment ion of the same composition derived from decomposition products of higher molecular weight such as that containing three oxinate residues (Fig. 4). The sensitivity obtained as expressed by the peak area for a given weight of zinc oxinate was much lower than that found for other metal chelates and the smallest sample size examined was 5×10^{-8} g. This low sensitivity may be due to the complication of the existence of more than one metal chelate species or may be due to incomplete evaporation or to evaporation with decomposition. It is significant that no ion current at *m/e* 352 is recorded below a source temperature of 380°.

The sample was dried at 100° and the composition at this temperature is reported to be $ZnOx_2.1\frac{1}{2}H_2O$. The compound becomes anhydrous at 160° and the mass

spectrum reveals no peaks which could be attributed to the hydrated form. It is significant that the anhydrous form is reported to decompose at 300°, and evaporation was not observed by us until a temperature of 380° was reached. Thus, the low sensitivity and the appearance of mass peaks due to ions containing more than one zinc atom may be due to a polymerization process.

Aluminium oxinate

The mass spectrum of aluminium oxinate was recorded by evaporation of a solid sample at a temperature of 400°. The spectrum illustrated in Fig. 5 shows an intense

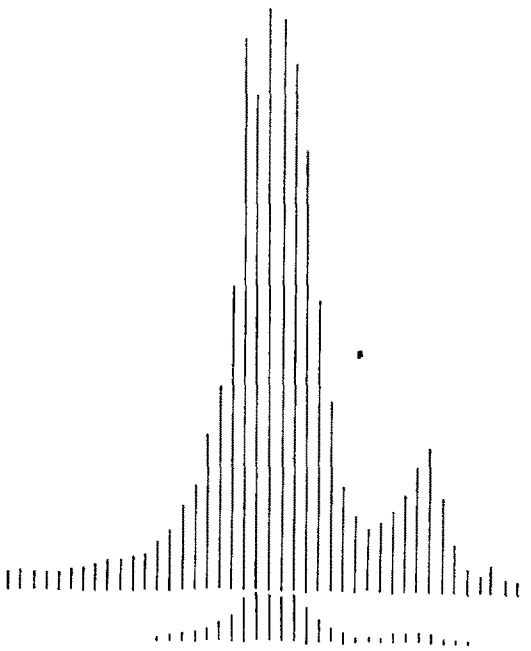

FIG. 4.—Integrated ion current curve for zinc oxinate.

peak at *m/e* 459 corresponding to the molecule ion $Al(Ox)_3^+$ but as there was no convenient reference peak close to this *m/e* value, the peak corresponding to the fragment ion $Al(Ox)_2^+$ was selected for quantitative study. The integrated ion current curves were recorded for a series of sample sizes and the limit of detection was found to be 10^{-10} g. It is possible that some decomposition may occur at the high source temperature used. The sample used was dried at 110° and was anhydrous, but this form is reported to begin to decompose at 375° and to form alumina at 700°. However, no mass peaks corresponding to ions containing more than one aluminium atom were observed.

Iron(III) oxinate

Under the conditions used for the precipitation of iron oxinate it has been suggested[2] that both iron(II) and iron(III) oxinates are produced. The mass spectrum illustrated in Fig. 6, recorded for evaporation of the solid sample at a temperature of 405°, contains an intense peak at *m/e* 344 corresponding to the ion $^{56}Fe(Ox)_2^+$ and

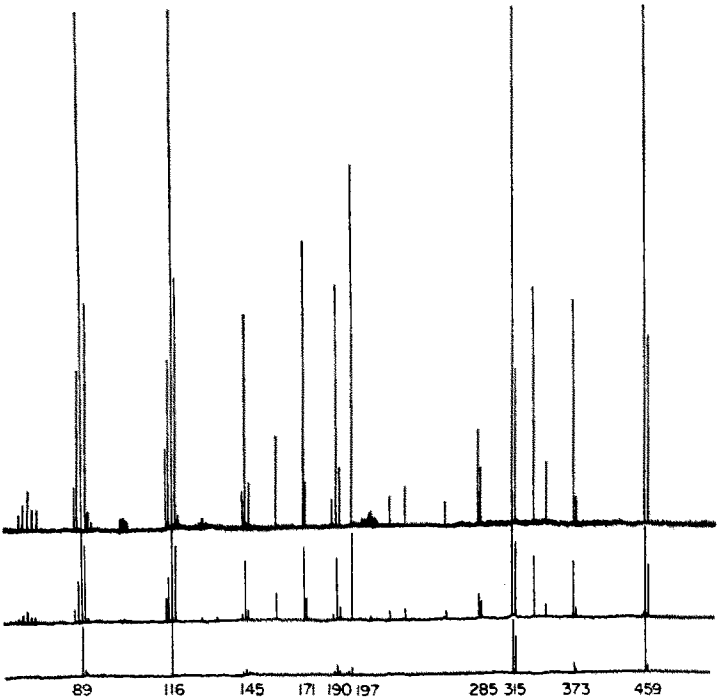

FIG. 5.—Mass spectrum of aluminium oxinate.

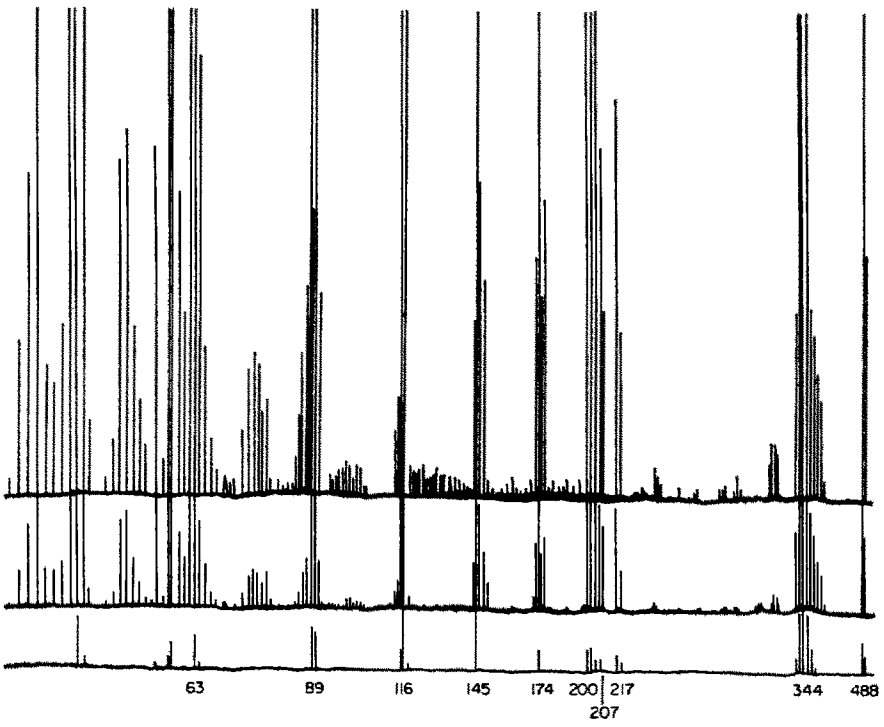

FIG. 6.—Mass spectrum of iron oxinate.

a smaller peak at *m/e* 488 corresponding to the ion $^{56}Fe(Ox)_3^+$. The relative proportions of the two species were not determined because of the intractable nature of the precipitate, which was fairly insoluble. A very dilute solution in dioxan could be prepared and 1 μl of this solution gave a small integrated ion current curve on evaporation in the instrument. It was estimated that the concentration in dioxan was of the order of a few ppm.

At the temperature used to dry the sample, iron(III) oxinate is reported to be anhydrous, but it appears certain that substantial decomposition was taking place at the evaporation temperature of 405°, as the upper limit of stability of the anhydrous form is given as 284°.

Other metals

The oxinates of nickel, manganese and cobalt are not soluble in the solvents used for the other metal chelates but are soluble in dimethyl sulphoxide. Despite the fact that the solid samples of the three metal chelates gave on evaporation mass spectra which could be readily interpreted, when dimethyl sulphoxide solutions were used in the manner described above not only could no integrated ion current curves be obtained but the normal mass spectra were not exhibited on evaporation. The spectrum recorded showed no peaks due to ions containing metal atoms, this observation being confirmed by high resolution mass measurement. It appears that there is some strong interaction or chemical change on dissolution in dimethyl sulphoxide. It was not possible, therefore, to carry out quantitative studies on these metal oxinates, but their mass spectra were recorded by the evaporation of small solid samples. The sample of nickel oxinate used was partly hydrated, having been dried at 110°. The anhydrous form is reported to be stable between 130° and 340°. The mass spectrum which was recorded at an evaporation temperature of 370° exhibits an intense mass peak corresponding to the ion $Ni(Ox)_2^+$.

The sample of cobalt oxinate was dried at 100°. At room temperature cobalt oxinate dihydrate is stable, but at temperatures below 130° the composition is closer to $Co(Ox)_2.1\frac{1}{2}H_2O$. Decomposition occurs above 306° but evaporation was not observed until the source temperature was raised to 370°. The mass spectrum is illustrated in Fig. 7 and in addition to an intense peak at *m/e* 347 corresponding to the molecule ion $^{59}Co(Ox)_2^+$, there was a smaller peak at *m/e* 406 corresponding to the ion $^{59}Co_2(Ox)_2^+$.

The sample of manganese oxinate used was dried at 110° and was most probably the dihydrate, which is reported to be stable up to a temperature of 150°. The anhydrous form decomposes at 250° but evaporation was not observed until 360°. The mass spectrum (Fig. 8) was complicated, showing peaks at *m/e* 542 and 487 which corresponded to the ions $^{55}Mn_2(Ox)_3^+$ and $^{55}Mn(Ox)_3^+$, in addition to a large peak at *m/e* 343 corresponding to the molecule ion $^{55}Mn(Ox)_2^+$.

Magnesium oxinate exists as the dihydrate at the temperature of drying (100°) but becomes anhydrous between 160° and 200°. The anhydrous form begins to decompose at 345°. Evaporation begins at 370°, when the mass spectrum reveals a peak at *m/e* 312 corresponding to the ion $^{24}Mg(Ox)_2^+$ and two unidentified peaks at *m/e* 343 and 346 which do not appear to be due to the dihydrate. On raising the temperature to 400° the peak at *m/e* 312 becomes more intense and a new peak appears

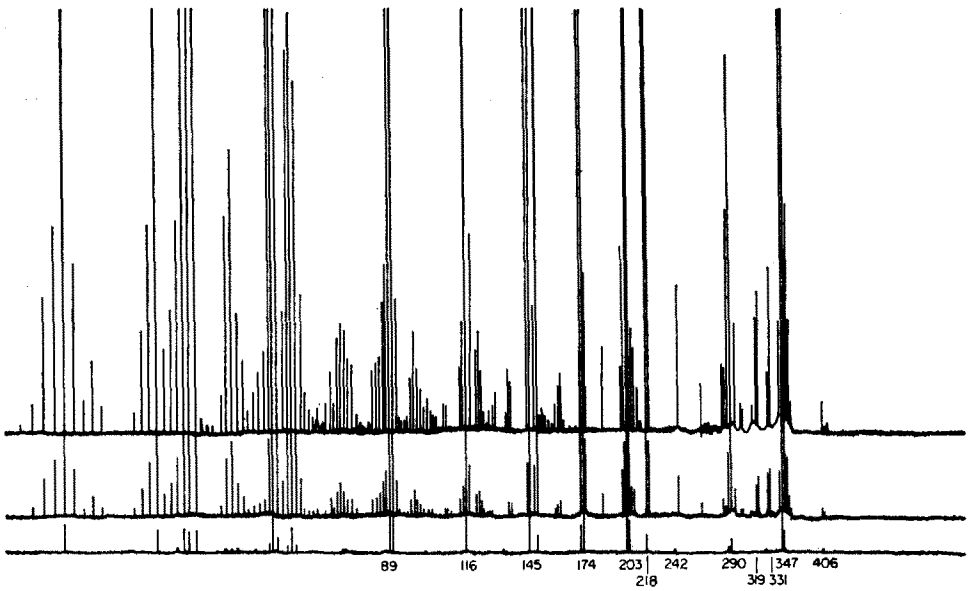

FIG. 7.—Mass spectrum of cobalt oxinate.

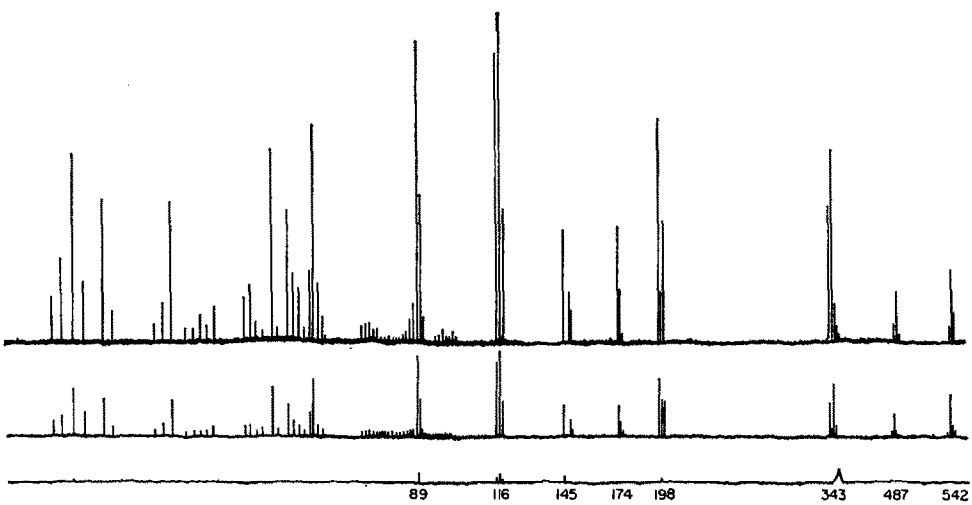

FIG. 8.—Mass spectrum of manganese oxinate.

at *m/e* 480 corresponding to the ion $^{24}Mg_2(Ox)_3^+$. It seems probable that this is due to a decomposition process taking place in the solid phase.

Determination of mixtures

Because of the differences between the molecular weights of the metal complexes it should be possible to record the integrated ion current curve corresponding to one metal chelate in the presence of others. In fact the molecule ion peak in the mass spectrum is the most specific detectable physical property. In mixtures of metal chelates, therefore, it should be possible to determine each component in a mixture by

making a separate introduction and recording. A further possibility was the determination of the components of the mixture in a single introduction by making use of the difference in the temperature of evaporation. To test this possibility 1 μl of each of the standard 0·01% solutions of copper and aluminium oxinates were introduced simultaneously. When the temperature was raised to 255° the integrated ion current at *m/e* 351 corresponding to the ion $^{63}Cu(Ox)_2^+$ could be recorded. When however the temperature was raised to 400° no signal could be recorded at *m/e* 315 corresponding to the ion^{27} $Al(Ox)_2^+$. If however the sample mixture was introduced and the source temperature raised directly to 400° then the integrated ion current could be recorded normally at *m/e* 315. This phenomenon may be explained by assuming that the instrument detects only the rapid evaporation of the sample and that slow evaporation of the less volatile sample occurs undetected at the lower temperature. There are some preliminary indications that the sensitivity also changes when a second metal chelate is present but further work is required to assess the extent of this interaction between the components of the mixture.

CONCLUSIONS

1. The oxinates of copper, aluminium, zinc, iron, cobalt, manganese, nickel and magnesium are sufficiently volatile at temperatures between 255° and 405° for their mass spectra to be recorded.

2. In all spectra recorded, the peak corresponding to the expected molecule ion was sufficiently intense to permit its use in quantitative determination. In some cases, however, it was more convenient to use a fragment peak at a lower *m/e* value.

3. There was evidence for the existence of ions of the type $M_2(Ox)_3^+$ (where M is a bivalent metal) where the vaporization temperature is higher than the decomposition temperature. It is suggested that these peaks result from a polymerization process taking place in the solid phase.

4. The technique may be applied successfully to the estimation of submicrogram quantities of copper and aluminium oxinates. While each metal may be detected separately, in a mixture of the two, there is evidence of mutual interference in the determination of the two chelates.

Zusammenfassung—Die Massenspektren der Oxinate von Zink, Eisen(III), Mangan(II), Nickel, Kobalt, Aluminium, Kupfer und Magnesium wurden gemessen. Die Konzentrationen mehrerer dieser Chelate wurden zu den integrierten Ionenströmen in Beziehung gesetzt, die bei einem charakteristischen *m/e*-Wert während des Verdampfens der Probe in der Ionenquelle eines M.S. 9-Massenspektrometers von A.E.I. registriert wurden. Diestrukturelle Bedeutung einiger der Massenspektren wird diskutiert.

Résumé—On a mesuré les spectres de masse des oxinates de zinc, fer(III), manganèse(II), nickel, cobalt, aluminium, cuivre et magnésium. On a établi un rapport entre les concentrations de plusieurs de ces chélates et les courants d'ions intégrés enregistrés à une valeur *m/e* significative durant l'évaporation de l'échantillon dans la source d'un spectromètre de masse A.E.I. M.S.9. On discute de la signification structurale de quelques-uns des spectres de masse.

CO-ORDINATING PROPERTIES OF SOME LIGAND SYSTEMS RELATED TO 4-(2-PYRIDYLAZO)RESORCINOL

R. G. ANDERSON* and G. NICKLESS
Department of Inorganic Chemistry, School of Chemistry, The University, Bristol 8, U.K.

(*Received* 19 *April* 1967. *Accepted* 25 *May* 1967)

Summary—The metal-complexing properties of 2-(8-quinolylazo)-1-naphthol-4-sulphonic acid and the 2-pyridyl-, 2-pyrimidyl- and 8-quinolylhydrazones of salicylaldehyde have been described and compared with those of 4-(2-pyridylazo)resorcinol and related dyes. The sensitive chromophoric action of metal ions on the latter group of dyes is thought to be due to the formation of a resonance-stabilized anion in which the heterocyclic nitrogen atom plays an important part. Ligands capable of forming chelates containing larger rings give on reaction with metals less sensitive colour reactions but more stable complexes.

THE use of azo dyestuffs containing a heterocyclic nitrogen atom and hydroxyl group *o-o'* to the azo group is now very familiar in analytical chemistry.[1] Of such dyes, 1-(2-pyridylazo)-2-naphthol (PAN) and 4-(2-pyridylazo)resorcinol (PAR) are by far the most important. Certain other azo dyes of pyridine and a wide range of the easily prepared thiazolylazo dyestuffs have also been studied as analytical reagents, but more briefly.[1] We have made a critical comparison of the analytical potentials of pyridineazo and pyrimidineazo dyestuffs,[2,3] and have shown that the latter dyes possess several advantages over the former as analytical reagents.

The two main features of the PAR or PAN chelating system are the wide range of metals capable of being complexed by these dyes and the large and characteristic bathochromic shifts accompanying this complex formation.

We have studied the metal-complexing properties of a series of compounds related to PAR.[4–6] However, in each compound, one or more of the potential co-ordinating groups of PAR has been blocked out. We have thus been able to show that dyes of this type act as tridentate chelating agents, mainly through the heterocyclic nitrogen atom, the azo nitrogen atom nearest to the phenol ring, and the *o*-hydroxyl group. In this way, the ligands form two five-membered rings on chelation.

We now report the preparation and metal-complexing properties of a new series of ligands capable of forming metal chelates in the same manner as PAR, but owing to the geometry of the ligand molecules, forming either a six-membered and a five-membered or two six-membered ring systems on chelation. The systems studied include an 8-quinolylazo derivative and some heterocyclic hydrazones of salicylaldehyde (see formulae at top of next page).

EXPERIMENTAL

Spectroscopic and potentiometric measurements

The techniques used to measure the stability constants and electronic spectra of the dyes and their complexes have been described previously.[6] The potentiometric titration technique was based on that of Irving and Rossotti.[7] All measurements were made in 50% aqueous methanolic solutions at an overall ionic strength of 0·1 (adjusted with sodium perchlorate) and a temperature of 25° (potentiometric) or 20 ± 2° (spectrophotometric).

2-(8-*Quinolylazo*)-1-*naphthol*-4-*sulphonic acid* (*QAN*α*4S*)

Sodium 1,2-naphthoquinone-4-sulphonate (2·6 g) was dissolved in 1*M* hydrochloric acid (100 ml), to which was added a solution of 8-hydrazinoquinoline (1·6 g; prepared by the method of Krasavin *et al.*[8]) in ethanol (25 ml). The crude dye that was precipitated was purified by dissolving it in sodium hydroxide solution and reprecipitating with hydrochloric acid. The dye thus obtained was found to be homogeneous by thin-layer chromatography[9] and was assumed to be the 2-azo-1-naphthol isomer (*cf.* reference 2). Found: C, 53·4%; H, 4·3%; N, 9·6%. Calc. for $C_{19}H_{13}N_3O_4S.2\frac{1}{2}H_2O$: C, 53·7%; H, 4·2%; N, 9·9%.

Salicylaldehyde-2-pyridylhydrazone (*SAPH*)

Salicylaldehyde (5·1 ml) was added to a solution of 2-hydrazinopyridine (4·1 g; prepared by the method of Fargher and Furness[10]) in ethanol (25 ml). The solid formed was recrystallized from ethanol to give slightly off-white needles, m.p. 217·5–218·5°. Found: C, 67·7%; H, 5·4%; N, 19·8%. Calc. for $C_{13}H_{11}N_3O$: C, 67·6%; H, 5·2%; N, 19·7%.

Salicylaldehyde-2-pyrimidylhydrazone (*SAMH*)

Salicylaldehyde (2 ml) in ethanol (10 ml) was added to a solution of 2-hydrazinopyrimidine (1·1 g; prepared by the method of Shirakawa *et al.*[11]) in ethanol (15 ml). The solid formed was recrystallized from ethanol to give slightly off-white platelets, m.p. 213–4° (lit. 213–5°).[12] Found: C, 61·9%; H, 5·4%; N, 26·4%. Calc. for $C_{11}H_{10}N_4O$: C, 61·7%; H, 4·7%; N, 26·2%.

Salicylaldehyde-8-quinolylhydrazone (*SAQH*)

Salicylaldehyde (4 ml) in ethanol (20 ml) was added to 8-hydrazinoquinoline (3·3 g) in ethanol (40 ml). The solid formed was recrystallized from ethanol to give cream platelets, m.p. 150–1°, that slowly turned pink on exposure to light. Found: C, 74·0%; H, 5·5%; N, 16·1%. Calc. for $C_{16}H_{13}N_3O$: C, 73·0%; H, 4·9%; N, 16·0%.

Metal complexes of SAPH

These were prepared by mixing together alcoholic solutions of SAPH and a metal salt, from which the complex was precipitated without difficulty (see Table I).

RESULTS AND DISCUSSION

These ligands have been reported previously as chromatographic spray reagents.[13] The most striking difference between these new compounds and the ligands forming

TABLE I.—THE SOLID METAL COMPLEXES OF SAPH

Ion	Preparation		Found			Calculated			Formula L = $C_{12}H_{10}N_3O$	Colour

two five-membered chelate rings (*e.g.*, PAR and PAN) is the very much smaller colour change produced on chelate formation by the former. QANα4S itself has a pink colour and its complexes are coloured blue, green and brown, but the contrast is poor. The dye, however, shows up most metals under ultraviolet light, and for this reason it is believed that QANα4S, like PAR and PAN, is non-selective in its reactions with metals. SAPH and SAMH have very similar properties to each other as chromatographic spray reagents. The backgrounds are colourless and the metal complexes stand out with varying shades of yellow. The vanadium complex is orange and the iron and ruthenium complexes are brown. The reagents appear to react with a wide range of metals, although the sensitivity is low for metals in groups Ia, IIa and IIIa. SAQH produces a cream background and very weak maroon to brown spots with only a limited number of metals in group VIII. It also produces a strong maroon colour with copper.

Tables II and III contain data relating to the electronic absorption spectra and acid dissociation constants of the ligands. All the hydrazone derivatives show bathochromic shifts on both protonation and ionization. Only with protonation of SAQH, however, is there a marked colour change (from pale cream to orange). QANα4S is interesting in that it shows small hypsochromic shifts on both protonation and ionization.

The SAPH molecule may be compared with the 2-(2-pyridylazo)phenol molecule[6] in which the azo group has been replaced with the hydrazone group. Apart from increasing the chelate ring size, this group decreases the conjugation in the molecule, thus destroying its properties as a dye. Furthermore, SAPH may be considered as a simple derivative of 2-aminopyridine, which has a very high pK_{NH} value (6·86) because of resonance stabilization.[14] In the same way, the pK_{NH} of SAPH has a very much higher value than that of 2-(2-pyridylazo)phenol[6] (1·85). Owing to the increased basicity of the hydrazone link the phenolic proton is more strongly hydrogen-bonded, thus its pK_{OH} value is raised from 9·42 for 2-(2-pyridylazo)phenol[6] to 10·87 for SAPH. The behaviour of SAMH is similar [pK_{NH} and pK_{OH} of 2-(2-pyrimidylazo)phenol being 0·0 and 8·66 respectively[15]]. SAQH also has a high pK_{OH} value, presumably because of the existence of a strong internal hydrogen bond. Its pK_{NH} value, however, is low and this is probably due to the so-called "ortho-effect" (*cf.* the pK_{NH} of 8-aminoquinoline[14]).

Tables IV and V present data pertinent to the metal complexes of these four ligands. Some data collected under the same conditions are also included for 2-(2-pyridylazo)-phenol (*o*-PAP)[6], 2-(2-pyrimidylazo)phenol (*o*-MAP)[15] and 2-(2-pyridylazo)-1-naphthol-4-sulphonic acid (PANα4S)[2] for comparison purposes. No data could be obtained concerning the copper complexes of QANα4S or SAQH as these are completely insoluble in aqueous solvents. However, the precipitates of the copper complexes showed a metal-to-ligand ratio of 1:1 for both ligands. Precipitation also prevented log K_2 from being obtained for the zinc and cobalt complexes of SAPH. The log K_1 values for the iron(II) and nickel complexes of QANα4S were too large to be obtained by the Irving and Rossotti[7] technique. In fact, all that was seen from the titration was the formation of a 1:2 complex from a 1:1 complex. With cobalt(II) and QANα4S there was evidence of 1:1 chelate formation only. This is somewhat surprising, since the iron(II) and nickel complexes have 1:2 stoichiometry. If, in fact cobalt(II) does form a 1:2 complex and is then oxidized to cobalt(III), with the subsequent reduction of hydrogen ions, the net result on the titration figures would be the release of one proton only per cobalt atom, or apparently 1:1 complex formation.

Comparison of the spectra and stability constants of the complexes with the corresponding 5-5 ring complexes shows clearly two facts.

1. The large and characteristic bathochromic shifts associated with the formation of the 5-5 ring complexes are lost when the ring size is increased. QANα4S produces small bathochromic shifts with most metals, but the colour changes are clear to see with iron(II) and cobalt ions only. The bathochromic shift on the formation of the copper SAPH complex is about 50 mμ, as opposed to about 180 mμ for the corresponding *o*-PAP complex. Solubility problems restricted the data obtained for the metal complexes of the hydrazones, however, and the small colour changes associated with these ligands are best appreciated in a qualitative way when they are used as spray reagents. The small bathochromic shifts of the hydrazone complexes are probably due in part to the different chromophoric properties of the non-conjugated hydrazone link and to the non-planar nature of the ligand. This is not so, however, for the complexes of QANα4S, which contain the same chromophoric groups as do the PANα4S complexes.

2. The stabilities of the 5-6 ring complexes are considerably higher than those of the corresponding 5-5 ring complexes. This is clearly evident from the log K_1 values,

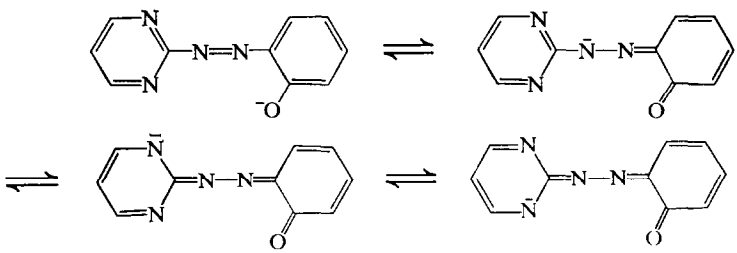
but is not quite so evident from the log K_2 values. From stereochemical considerations it can be seen that the increased stabilities of the 1:1 complexes do not arise from the shapes of the molecules. However, the gaps between the log K_1 and log K_2 values are larger for the new ligands and are thought to be evidence of the greater difficulty in packing two of these larger and more awkwardly shaped molecules around a metal atom. These two facts can be appreciated better when models of the ligands are studied.

It is seen that the Irving-Williams order of stabilities[16] is obeyed by these ligands with respect to log K_1. The order fails for log K_2 because of the reluctance of copper to form a 1:2 complex with tridentate ligands. The order for log K_1 holds even for the iron(II) complex. This is not so in the case of 2-(2-pyridylazo)phenol[6] which with iron(II) forms an abnormally stable, presumably low spin, complex. The nickel complex of SAMH appears to possess lower stability than would be expected by comparison with the other complexes. There is at present no satisfactory explanation of this fact.

Potentiometric titrations with iron(II)–SAQH and zinc–SAQH failed owing to the fact that hydrolysis of the metal ion occurred before complex formation. Although no

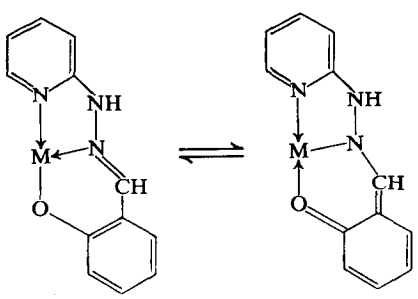
stability constants were thus obtained, it must be assumed from this fact that the complexes of SAQH, which will contain two six-membered chelate rings, are very much less stable than those of SAPH or 2-(2-pyridylazo)phenol. This is certainly so for the nickel and cobalt complexes for which some stability constants were obtained. SAQH possesses a very awkward shape for complex formation, the rings being bent almost at right angles to one another in the final complex. This fact must outweigh any other in determining the stability of the complexes of this ligand.

The greater stability of the 5-6 ring complexes, together with the small bathochromic shifts produced on their formation is thought to be caused directly by the ionization of the phenol group. The Irving-Rossotti theory assumes that it is the anion so produced that is in fact the chelating species and will therefore be mainly responsible for the properties of the complex. If the negative charge on this anion is delocalized over the whole molecule, then this will stabilize the anion and reduce its tendency either to protonate or form complexes. At the same time, the absorption peak of the resonance-stabilized anion is likely to move to longer wavelengths with respect to the neutral molecule if the resonance is more efficient. This resonance can take place in the anion and the complex but not in the neutral molecule, because of the unique properties of the unshielded proton. Very favourable canonical forms can be written for the 2-(2-pyridylazo)phenol anion and its pyrimidyl analogue:



With QANα4S and the hydrazones it is not possible for the negative charge to be delocalized onto the electronegative heterocyclic nitrogen atoms. It will therefore remain more closely associated with the oxygen atom and give rise to more stable complexes. The perturbation of the molecule being less, however, the bathochromic shifts involved will also be smaller.

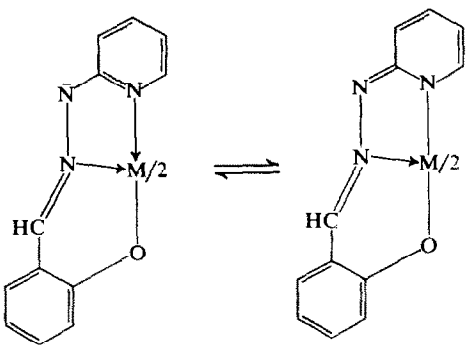
Another factor that may be responsible for the higher stabilities of these complexes is the possibility of resonance in the six-membered chelate ring. For example, with a chelate of SAPH, the following canonical forms are possible:



Ring stabilization through resonance of this kind is not possible for the complexes of PAN-type ligands, since they do not contain six-membered chelate rings. There are

two objections to this picture, however: (*i*) if the *o*-quinonoid structure played any significant role in the overall structure of the hydrazone chelates, then we would expect a deeper colour due to the presence of the *o*-quinone chromophore, but (*ii*) this explanation cannot be extended to account for the difference in pK_{OH} values between the two types of ligands, since the hydroxyl proton can be hydrogen-bonded into a six-membered ring with equal felicity in all the ligands studied.

The solid metal complexes of SAPH show some interesting properties in strongly alkaline medium. Normally the action of alkali on a metal complex of a heterocyclic azo dyestuff is to cause it to dissociate into the ligand anion and the metal hydroxide. The action of alkali on the complexes of SAPH is shown in Table VI. With the exception of zinc, all the complexes form strongly coloured water-soluble species. This is thought to be due to the removal of the hydrazine proton, which acquires acid properties on chelate formation. The resulting anion is capable of resonance stabilization involving a planar form of the ligand:



Similar behaviour to this is well known for pyridine-2-aldehyde-2-pyridylhydrazone and related ligands.[17]

In conclusion, it thus appears that the very sensitive chromophoric action of metals on dyes related to PAR and PAN is due to the formation of a resonance-stabilized anion in which the charge is partly located on the electronegative heterocyclic nitrogen atom. This is only possible in ligands forming five membered ring systems on chelation. Expansion of one of the chelate rings to six atoms increases the stability of the complexes because of the resultant greater localization of charge and the possible introduction of resonance into the six-membered chelate ring.

TABLE VI.—ACTION OF ALKALI ON THE CHELATES OF SAPH

Metal	Before the addition of sodium hydroxide		After the addition of sodium hydroxide	
	Soln. colour	Water solubility	Soln. colour	Water solubility
Zinc	Pale yellow	Insoluble	Pale yellow	Insoluble
Copper	Pale green	Slightly soluble	Orange yellow	Soluble
Cobalt	Yellow	Soluble	Brown	Soluble

Zusammenfassung—Die Komplexbildungseigenschaften von 2-(8-chinolylazo)-1-naphthol-4-sulfonsäure und den 2-Pyridyl, 2-Pyrimidyl- und 8-Chinolylhydrazonen von Salicylaldehyd werden beschrieben und mit denen von 4-(2-pyridylazo)resorcin und verwandten Farbstoffen verglichen. Die empfindliche Chromophorwirkung von Metallionen bei der zultzt genannten Gruppe von Farbstoffen wird auf Bildung eines resonanzstabilisierten Anions zurückgeführt, in dem der heterocyckische Stickstoff eine wichtige Rolle spielt. Zur Chelatbildung befähigte Liganden mit großeren Ringen geben mit Metallen weniger empfindliche Farbreaktionen, aber stabilere Komplexe.

Résumé—On a décrit les propriétés complexantes vis-à-vis des métaux de l'acide 2-(8-quinolylazo)1-naphtol 4-sulfonique et des 2-pyridyl-, 2-pyrimidyl- et 8-quinolylhydrazones du salicylaldéhyde et les a comparées à celles du 4 (2-pyridylazo) résorcinol et des colorants apparentés. On pense que l'action chromophorique sensible des ions métalliques sur le dernier groupe de colorants est due à la formation d'un anion stabilisé par résonance dans lequel l'atome d'azote hétérocyclique joue un rôle important. Les ligands capables de former des chélates contenant de plus grands cycles donnent par réaction avec les métaux des réactions colorées moins sensibles mais des complexes plus stables.

(*Received* 5 *May* 1967. *Accepted* 12 *June* 1967)

Summary—Ruthenium(III) and rhodium(III) form stable coloured complexes in ethanolic solution with oximidobenzotetronic acid (OBTA). Ruthenium forms a purple-violet $Ru(OBTA)_3$ complex at pH 1·1–3·5, which is stable over the pH range 1·1–11·3. Rhodium(III) forms a yellowish-brown complex, $RhCl_3(OBTA)_2$, at pH 2–8; at higher pH (11·5 and above) the complex is reddish-brown, but has the same Rh:OBTA ratio. A method for the simultaneous determination of these two metals is proposed, and the interference by commonly occurring ions has been investigated.

THE red colour produced by the addition of tin(II) chloride forms the basis of the best method available for the colorimetric determination of rhodium;[1] thiourea and its derivatives[2] have been recommended for the colorimetric determination of ruthenium(III). Critical reviews on the use of these and other reagents, along with their modifications and extensions, for the colorimetric determination of rhodium(III) and ruthenium(III) have been given by Beamish.[3–5] More recently, nitroso-R-salt[6] and trifluorothenoylacetone[7] have been suggested for the colorimetric estimation of rhodium, and salicylic acid,[8] sulphosalicylic acid[8] and nitroso-R-salt[9] have been proposed for the spectrophotometric determination of ruthenium.

Oximidobenzotetronic acid (OBTA), α-isonitrosobenzotetronic acid or 3-nitroso-4-hydroxy-5,6-benzopyrone-2, has already been used for the spectrophotometric determination of cobalt[10] and iron,[11] and for the gravimetric determination of cobalt[12] and palladium.[13] During the course of the present investigations, it was found that an ethanolic solution of this reagent instantaneously forms a blue-black water-soluble complex with aqueous ruthenium(III) chloride solution, slowly changed at room temperature to purple-violet. This change is more rapid at 90–100°, being then complete in about 25 min. The purple-violet solution has an absorption maximum at 520 mμ, obeys the Beer-Lambert law over the concentration range 0·4–20·2 ppm of ruthenium(III), is formed over the pH range 2·0–5·5 and is stable for 48 hr. The molar composition of the complex is 1:3 (metal:ligand).

No colour change is noticeable when ethanolic OBTA solution is added to rhodium(III) solution [taken as chlororhodate(III)] at room temperature. On heating the solution in a boiling water-bath, however, a yellow-brown complex is slowly formed, which on addition of potassium hydroxide solution instantaneously becomes red-brown. The red-brown complex at pH 12·0 shows absorption maxima at 410 mμ and 475 mμ, while the yellow-brown solution formed at pH 5·0 has only one maximum at 385 mμ. The complex at pH 12·0 obeys the Beer-Lambert law at 475 mμ over the

concentration range 0·7–15·7 ppm of rhodium(III), its absorbance remaining unchanged for 4 hr. The metal to ligand ratio at both the wavelengths is 1:2. Ruthenium(IV) gives a colour reaction with OBTA only on prolonged heating, presumably by reduction to ruthenium(III) by the alcohol present.

Because the ruthenium(III) and rhodium(III) complexes with OBTA form at different pH values and have different absorption maxima, this reagent can be used for the simultaneous spectrophotometric determination of rhodium(III) and ruthenium(III).

EXPERIMENTAL

Reagents

Oximidobenzotetronic acid (OBTA). Prepared by the method described earlier[11] and used in freshly prepared ethanolic solution.

Rhodium(III) and ruthenium(III). Stock solutions were prepared by using potassium chlororhodite

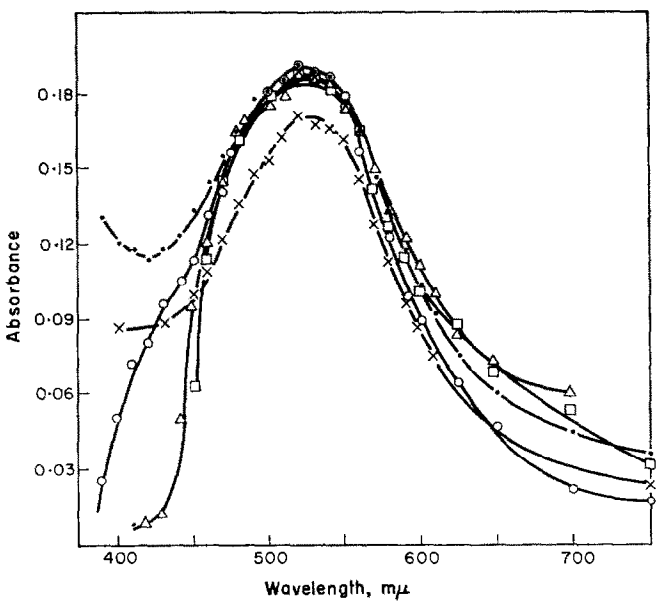

FIG. 1.—Absorption spectra of ruthenium(III)–OBTA complex at different pH values. Ru(III) 2·7 μg/ml; —×— pH; 1·1; —·— pH 2·0; —○— pH 3·5; —Δ— pH 10·1; —□— pH 11·8.

and ruthenium trichloride respectively (Johnson Matthey). They were standardized by spectrophotometric[1,3] and gravimetric methods.[14]

All other chemicals used were either from Johnson Matthey, or of B.D.H. AnalaR or Merck *pro analysi* quality.

Absorption spectra of ruthenium(III) and rhodium(III) complexes with OBTA

Ruthenium(III)–OBTA complex. A tenfold excess of reagent was added to ruthenium trichloride solution and the solution thus obtained was heated in a boiling water-bath for 25 min. This resulted in the formation of a purple-violet solution. The absorption spectrum of this complex, after adjustment of pH, was measured against reagent as blank in 1-cm² cross-section cylindrical tubes in a Unicam SP600. Within the pH range 1·1–11·3, the complex exhibited a single absorption maximum at 520 mμ (Fig. 1). As the reagent has negligible absorbance at this wavelength, all subsequent measurements were made at it.

Rhodium(III)–OBTA complex. Absorption spectra of the rhodium(III)–OBTA complex, obtained

by heating a tenfold excess of reagent with potassium chlororhodate(III) solution on a boiling water-bath for 45 min, were taken within the pH range 5·0–12·3, with the reagent solution as blank. At pH 5·0 the yellow-brown solution showed a single absorption peak at 385 mμ with negligible absorption at 475 mμ, (Fig. 2), while at pH 11·5 to 12·3, the red-brown solution showed two maxima, at 410 mμ and 475 mμ. For analytical determinations the wavelength 475 mμ was selected because at this wavelength both the reagent and rhodium(III) solutions have negligible absorbance.

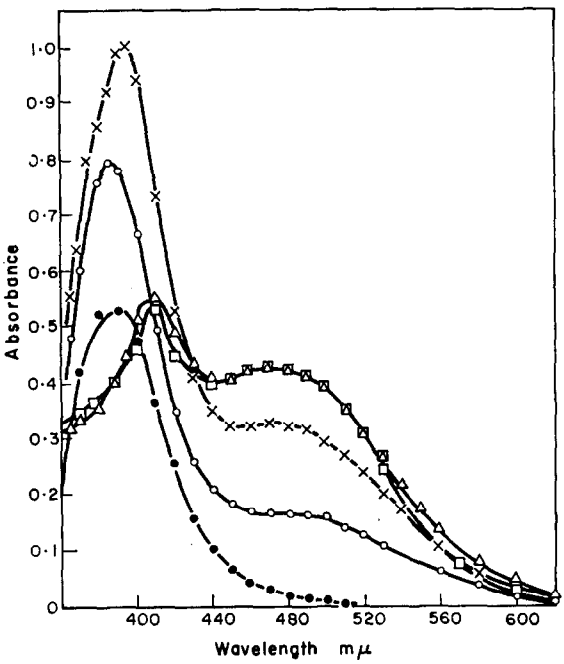

FIG. 2.—Absorption spectra of rhodium(III)–OBTA complex at different pH values Rh(III) 6·25 μg/ml —·— pH 5·0 —○— pH 9·4 —×— pH 10·0 —△— pH 11·6; —□— pH 12·4.

RESULTS AND DISCUSSION

Effect of time

Formation of the complexes. The colour development of the complexes is slow for both metals. The heating times required in a boiling water-bath for obtaining stable ruthenium(III) and rhodium(III) complexes were found to be 25 and 35 min respectively.

Stability of the complexes. At pH 3·5 the ruthenium(III)–OBTA complex formed as above does not show any significant change in its absorbance for up to 48 hr; the rhodium(III)–OBTA complex at pH 12·0 is stable for 4 hr at room temperature (≈30°). Eventually the solutions became opalascent.

Amount of reagent needed

It was observed that for ruthenium(III) the minimum ratio of reagent to metal required for full colour development is 5 and for rhodium(III) it is 3 (see Fig. 3). In the determinations, however, the ratio OBTA:metal was maintained at 10, as the excess of reagent has no significant effect on the absorbance of the complexes.

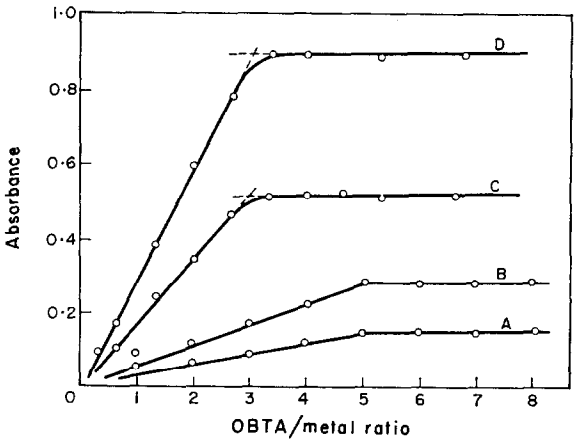

FIG. 3.—Effect of reagent concentration on the formation of Ru(III)- and Rh(III)-OBTA complexes.
A: Ru(III) 2·0 μg/ml *B*: Ru(III) 4·0 μg/ml *C*: Rh(III) 5·78 μg/ml; *D*: Rh(III) 12·49 μg/ml.

pH Effect

It was observed that the absorbance of the ruthenium(III)–OBTA complex at 520 mμ does not change over the pH range 1·3–11·7 (Table I), whereas for the rhodium(III)–OBTA complex at 475 mμ the optical density increases up to pH 11·5 and remains constant thereafter (Table II).

TABLE I.—EFFECT OF pH ON Ru–OBTA COMPLEX

pH	0·9	1·3	1·9	2·8	4·0	5·9	7·2	11·7	12·5
Absorbance at 520 mμ	0·133	0·138	0·140	0·139	0·138	0·140	0·139	0·140	0·126

Concentration of Ru(III) = 2·0 ppm.

TABLE II.—EFFECT OF pH ON Rh(III)–OBTA COMPLEX

pH	6·3	8·5	10·5	11·0	11·5	11·7	12·1	12·7
Absorbance at 475 mμ	0·005	0·013	0·043	0·055	0·065	0·066	0·066	0·065

Concentration of Rh(III) = 0·96 ppm.

Beer-Lambert law

The purple-violet ruthenium(III)–OBTA complex obeys the Beer-Lambert law at 520 mμ over the range 0·45–20·25 ppm ruthenium(III) with a molar absorptivity of $7·08 \times 10^3$; the sensitivity (Sandell) is 0·07 μg cm^{-2} for an absorbance of 0·005.

The red-brown rhodium(III)–OBTA complex obeys the Beer-Lambert law at 475 mμ, over the range 0·7–15·7 ppm rhodium(III) at pH > 11·5, the molar absorptivity being $7·06 \times 10^3$ and the sensitivity 0·07 μg cm^{-2}.

Extractability

The purple-violet Ru(III)–OBTA complex is not extracted from aqueous solutions by ether, benzene, toluene or nitrobenzene, but is partially extracted by chloroform

or cyclohexanol. The red-brown rhodium(III) complex at pH 12·0 is not extracted by any of the solvents mentioned.

Interference by foreign ions

It was found that oxalate, tartrate, citrate, borate, fluoride, phosphate, acetate and nitrite when present in quantities 100 times that of rhodium or ruthenium, and sulphate, nitrate or chloride in quantities up to 1000 times the amount of metal do not interfere. The limit of tolerance for cations commonly associated with these metals was determined and is in Table III.

TABLE III.—INTERFERENCE DUE TO FOREIGN IONS

Foreign ion	Ru(III)	Rh(III)	Pd(II)	Os(IV)	Ir(IV)	Pt(IV)	Fe(II)	Co(II)	Ni(II)
Maximum, *ppm*, tolerated for 1·4 ppm Ru(III)	—	50	4·8	2·2	2·1	11·0	0·5	0·05	112
Maximum, *ppm*, tolerated for 1·6 ppm Rh(III)		—	4·6	7·5		9·5			
2·0 ppm Rh(III)	0·02				0·8		11·2	0·05	112

Simultaneous determination of ruthenium(III) and rhodium(III)

Solutions containing various quantities of rhodium(III) and ruthenium(III) were mixed with excess of ethanolic OBTA solution and heated in a water-bath for 45 min. The absorbance of the solution at pH 3·5 was measured at 475 mμ and 520 mμ against a reagent blank; and again at pH 12·0 and 475 mμ.

The absorbance at 520 mμ and pH 3·5 was taken to be due to ruthenium(III) only, while the increase in the absorbance at 475 mμ on raising the pH of the solution to ~12 was attributed to rhodium(III) only. Some results are given in Table IV.

Molar composition

The composition of the Ru–OBTA complex was determined by Job's method of continuous variations[15] as modified by Vosburgh and Cooper,[16] with water as blank.

TABLE IV.—SIMULTANEOUS DETERMINATION OF RUTHENIUM(III) AND RHODIUM(III)

Taken, *ppm*		Absorbance at pH 3·5		Absorbance at pH 12	Diff. at 475mμ	Found, *ppm*		Error, *ppm*

3·39	6·36	0·235	0·257	0·698	0·441	3·36	6·36	−0·03	±0·0

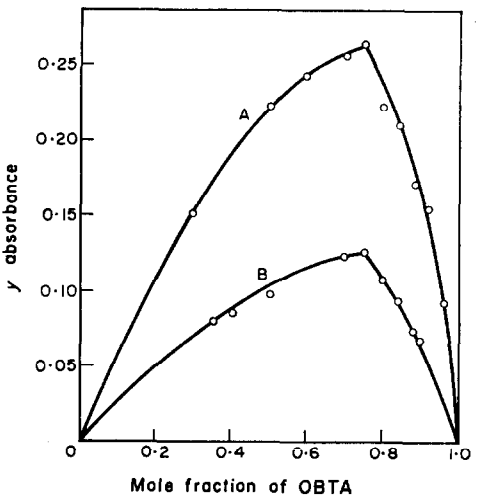

FIG. 4.—Job's curves for Ru(III)–OBTA system at pH 3·5 and wavelength 520 mμ. Total concentration of Ru(III) and OBTA for curve $A = 3{\cdot}64 \times 10^{-4}M$ and for curve $B = 2{\cdot}18 \times 10^{-4}M$.

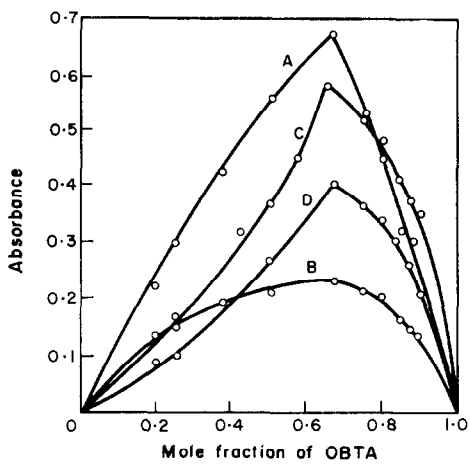

FIG. 5.—Job's curves for Rh(III)–OBTA system. Curves *A* and *B* are at pH 5·0 and wavelength 410 mμ; *C* and *D* at pH 12·0 and wavelength 475 mμ. Total concentration of Rh(III) and OBTA for curves *A* and *C* is $3{\cdot}07 \times 10^{-4}M$ and for *B* and *D* $1{\cdot}53 \times 10^{-4}M$.

The absorbance at 520 mμ due to the reagent is negligible, but that due to metal solution being significant, the function y, defined as the difference between the absorbance observed for a given mixture of metal and reagent after they have reacted, and the corresponding absorbance of the respective constituents for no reaction, was plotted against the mole fraction of the reagent (Fig. 4). The metal:ligand was found to be 1:3. The molar composition of the complex was also verified by the slope-ratio method of Harvey and Manning,[17] the ratio of the slopes of the straight line portions of the curves *A* and *B* (Fig. 6) being 2·8.

In order to determine the nature of the charge on the purple-violet complex, an aqueous ethanolic solution of the complex was passed through columns containing

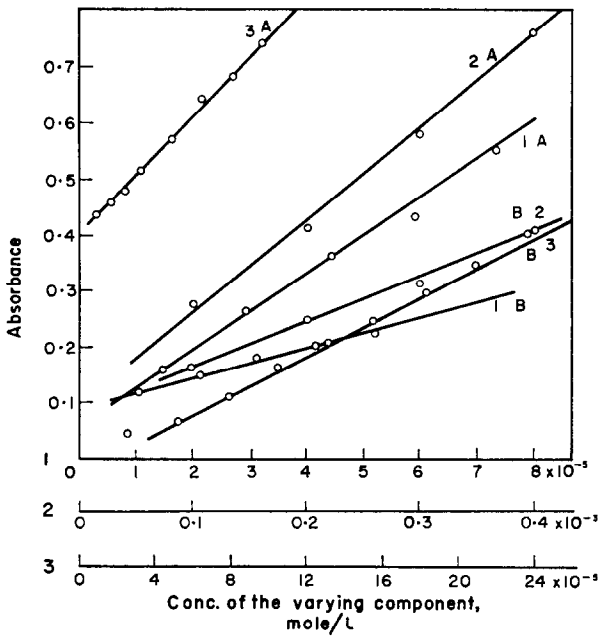

FIG. 6.—Slope-ratio method for composition of Ru and Rh complexes with OBTA. *1.* Ru(III)–OBTA complex, pH 3·5, $\lambda = 520$ mμ; *2.* Rh(III)–OBTA complex, pH 5·0, $\lambda = 410$ mμ; *3.* Rh(III)–OBTA complex, pH 12, $\lambda = 475$ mμ. In all cases, *A* corresponds to variation of metal concentration and *B* to variation of OBTA concentration.

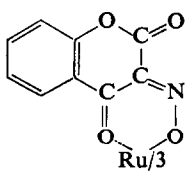
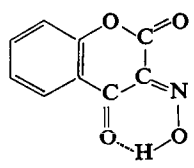
Amberlite ion-exchange resins IRA-401(OH) (B.D.H.) and Ionenaustaucher-I (Merck's cation-exchange resin). It was observed that the complex was not exchanged by either of the two ion-exchangers, thus showing the neutral character of the complex.

Based on these facts, the tentative structure of the complex may be put down as (I), derived from the structure (II) for the reagent, given earlier by Bhat and Jain.[10]



(I)



(II)

The compositions of the two Rh–OBTA complexes were determined by the method of continuous variation at pH 5·0, $\lambda = 410$ mμ and at pH 12·0, $\lambda = 475$ mμ. For both the complexes, the metal:ligand ratio was found to be 1:2 (Fig. 5). This composition was confirmed by the slope-ratio method[17] at these wavelengths (Fig. 6).

The composition of the complex formed at lower pH was confirmed by gravimetry. Assuming a $1:n$ composition of the complex, the reaction can be written as:

$$RhCl_6^{3-} + nHL \rightarrow RhCl_{6-2n}L_n^{-(3-n)} + 2nCl^- + nH^+$$

where HL represents the ligand. The amount of chloride ions liberated was determined gravimetrically as silver chloride. An average of 4 Cl^- ions was found to be liberated per atom of rhodium.

The nature of the charge on the complex was determined by ion-exchange. It was observed that both the yellow-brown and the red brown complexes are completely exchanged by the anion-exchanger and not by the cation-exchanger, so the complexes are anionic.

Recommended procedure for the determination of rhodium(III) and ruthenium(III)

To 5 ml of solution containing 5–40 ppm of ruthenium(III) and/or 3–35 ppm of rhodium(III), add a tenfold excess of reagent solution in ethanol and heat in a boiling water-bath for 25 min if only ruthenium(III) is present, and for 45 min if rhodium is also to be determined. Cool, dilute to a known volume (10–25 ml) after bringing the pH to 1·5–5·0, and measure the absorbance against a reagent blank at 520 mμ to determine ruthenium. If rhodium is also present, measure the absorbance at 475 mμ as well; raise the pH to about 12·0 and again measure the absorbance at 475 mμ. The difference in absorbance at 475 mμ is due to rhodium(III). If only rhodium is present, then after heating for 45 min, cool, raise the pH to nearly 12, dilute to known volume (10–25 ml) and measure the absorbance at 475 mμ against a corresponding reagent blank.

Zusammenfassung—Ruthenium(III) und Rhodium(III) bilden in äthanolischer Lösung mit Oximidobenzotetronsäure (OBTA) stabile farbige Komplexe. Ruthenium bildet einen purpurvioletten $Ru(OBTA)_3$-Komplex bei pH 1,1–3,5, der im pH-Bereich 1,1–11,3 stabil ist. Rhodium(III) bildet einen gelblichbraunen Komplex $RhCl_3(OBTA)_2$ bei pH 2–8; bei höherem pH (über 11,5) ist der Komplex rötlichbraun, zeigt aber dasselbe Verhältnis Rh: OBTA. Eine Methode zur gleichzeitigen Bestimmung dieser zwei Metalle wird vorgeschlagen; die Störungen durch häufig vorkommende Ionen wurden untersucht.

Résumé—Le ruthénium (III) et le rhodium (III) forment des complexes colorés stables en solution éthanolique avec l'acide oximidobenzotétronique (OBTA). Le ruthénium forme un complexe pourpre-violet $Ru(OBTA)_3$ à pH 1,1–3,5, qui est stable entre pH 1,1 et 11,3. Le rhodium (III) forme un complexe brun jaunâtre, $RhCl_3(OBTA)_2$, à pH 2–8; aux pH plus élèves (11,5 et au-dessus) le complexe est brun rougeâtre, mais a le même rapport Rh:OBTA. On propose une méthode pour le dosage simultané de ces deux métaux, et l'on a étudié les interférences des ions communément présents.

SPECTROPHOTOMETRIC INVESTIGATION OF ASCORBINATE COMPLEXES OF METALS

K. P. STOLYAROV and I. A. AMANTOVA
Chemistry Department, A. A. Zhdanov State University, Leningrad, U.S.S.R.

(*Received* 28 *October* 1966. *Accepted* 1 *June* 1967)

Summary—It has been shown that ascorbic acid forms metal complexes of the types ML and MHL, depending on the pH used, and that the complexes are relatively unstable, especially those of type MHL. Their absorption spectra have no maxima but have a steep slope at 320–380 mμ and are displaced to longer wavelengths relative to the absorption spectrum of ascorbic acid. A bigger shift occurs for elements of variable valency, and the spectra move to longer wavelengths as the pH is raised; at pH 7–9 a new maximum appears at 380–420 mμ, indicating a change of structure of the ascorbinate ion, probably with a lactone. Metals can be determined spectrophotometrically as their ascorbinates, at concentrations down to $10^{-5}M$ for Ti, U, Os, V, Cr, Nb, Ta, Zr, Mo, W, Sn, Pb and Th, and $10^{-4}M$ for lanthanides, Sc, Hf and Sb.

ALTHOUGH ascorbic acid is well-known as a reductant, there are only scattered references in the literature to its use as a complexing agent, mainly for the yellow complexes formed by titanium and uranium. We have made a thorough spectrophotometric study of the ascorbinate complexes of metals in most groups of the periodic table. The alkali metals were not investigated because the spectrophotometric method was not applicable, and no investigation was made of systems in which ascorbic acid was known to act as a reductant.

EXPERIMENTAL

l-Ascorbic acid[1] is 2,3-endiol-*l*-gulono-1,4-lactone. The value of pK_1, for the 3-hydroxy group, is 4·2, and pK_2, for the 2-hydroxy group, is 11·6. The reducing properties are due to the grouping —C(OH)=C(OH)—C=O with two conjugated double bonds, and the complexing properties arise from the 2,3-endiol configuration. Both properties sometimes operate simultaneously. The absorption spectrum of ascorbic acid shows a maximum at 245 mμ in acidic media and at 265 mμ in alkaline media. Ascorbic acid should not be used as a complexing agent at very high pH (where it will undergo hydrolytic and oxidative reactions).

Reagents and apparatus

Freshly prepared solutions of ascorbic acid were used throughout, and stabilizers, which might have interfered with the study of complex formation, were omitted. Any buffering action needed was supplied by the reagent and its salts. A large excess of reagent was added to make complex formation as complete as possible. Spectra were recorded on SF-4 and SF-5 spectrophotometers against a reagent blank. A pH meter and glass electrode were used for pH measurements. Because of the strong absorption of light below 300–320 mμ by ascorbic acid, the reagent could be used as a compensatory blank only at wavelengths longer than this, and 320 mμ was taken as the lower boundary for absorption spectra. Solutions of the metal chlorides were generally used.

Absorption spectra of the complexes

Absorption spectra were recorded for the ascorbinate complexes of the elements listed in Tables I and II and for thallium(I), ytterbium, germanium, arsenic, antimony, selenium, tellurium, rhenium and platinum(II). The general features were that the spectra of simple salts showed an increase in absorbance in the 320–380 mμ region, or a displacement to longer wavelengths in the presence of ascorbic acid (Table I). As the pH was increased the absorption bands shifted to longer wavelengths,

TABLE I.—THE MAJOR CHANGES IN ABSORPTION SPECTRA WHEN ASCORBINATE COMPLEXES ARE FORMED

* Peak affected by high absorbance of reagent in the ultraviolet region.

and then above a certain critical pH the reverse shift occurred. If measurements were made at a single wavelength, then the pH producing maximum absorbance varied with the electrovalency of the ion. For tervalent elements it was 5·5, for quadrivalent 4·5–5·5, for quinquevalent 4·0 and for sexivalent 3·5. The reason for this is the effect of the charge on the metal ion on the pH at which hydrolysis begins.

The molar absorptivities at 320, 330 and 380 mμ and the pH of maximum absorbance were calculated in order to provide a comparison of the sensitivity available in spectrophotometric determination of metals as ascorbinates, and are shown in Fig. 1.

The biggest spectral shift was observed with highly charged ions which are capable of reduction to a lower oxidation state. This does not mean that they are reduced by ascorbic acid, but rather that the reducing properties of ascorbic acid are manifested in charge transfer complex formation. For example, the molar absorptivity of the titanium complex (7000 at 380 mμ) is much greater than that of zirconium (100) or hafnium (50) at the same wavelength. Similarly that for niobium (1100) is higher than that for tantalum (250), and europium (which can form Eu^{2+}) gives the highest value for the lanthanide complexes. The determination of europium in mixtures of lanthanides by this method seems very promising, the only serious interference coming from lutetium.

The spectra of the complexes of bivalent ions (Mg, Ca, Sr, Ba, Zn, Cd, Sn, Pb, Mn, Co, Ni and Fe) have a maximum at 380–420 mμ and pH 7–9 (Table II). Tervalent ions do not show this maximum, with the exception of europium and samarium, which may be reduced to the bivalent state by the reagent. For Ti, Zr, Nb and U this maximum does not stand out against the general background of intense absorption.

The ascorbinate complexes of metals with variable valences and maximum oxidation states ranging from III to VI [Eu, Ho, Er, Zr, Hf, Nb, Ta, V(IV), Mo and W] were examined in more detail, the composition, instability constants and molar absorptivities being obtained.

RESULTS AND DISCUSSION

Calculation of constants for the complexes

We assumed that metal ions and ascorbic acid reacted to form complexes of the type $M(HA)_n$ and MA_n where HA and A are the singly and doubly dissociated ions

of ascorbic acid, charges being omitted for the sake of simplicity. We further supposed that in defined conditions only one product exists, *i.e.*,

$$M^{z+} + nH_2A \rightleftharpoons [M(H_mA)_n]^{[z-(2-m)n]+} + (2-m)nH^+. \quad (1)$$

Then the equilibrium constant, K, is given quite generally by

$$K = \frac{[M(H_mA)_n][H]^{n(2-m)}}{[M][H_2A]^n} \quad (2)$$

where m is 0 or 1. This equation gives the ratio of the concentrations of the complex

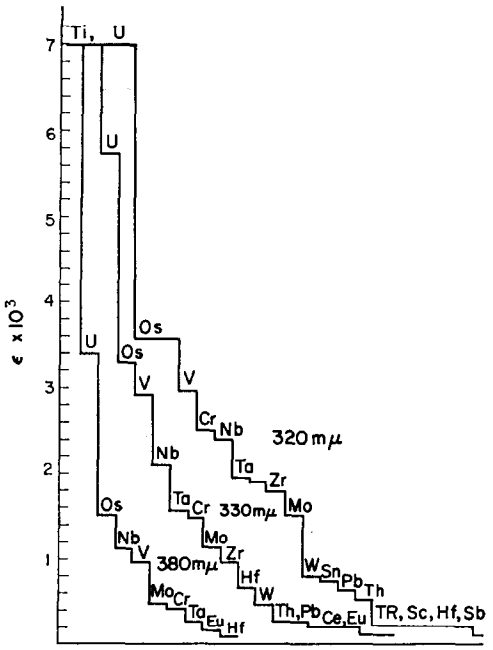

FIG. 1.—Molar absorptivities of ascorbinate complexes at wavelengths shown.

and the free metal ion. If the dissociation constant pK_1 for the first dissociation of ascorbic acid is taken into account together with the relationship of the absorbance, A, of the solution to the concentration of the complex, then

$$A = \varepsilon d[M(H_mA)_n] \tag{3}$$

where ε is the molar absorptivity of the complex and d is the length of the light-path in the cuvette, and we have

$$\frac{[M(H_mA)_n]}{[M]} = K' \frac{[HA]^n}{[H]^{n(1-m)}} = \frac{A}{\varepsilon d(C_M - A/\varepsilon d)} \tag{4}$$

where C_M is the total concentration of all the metal species, and $K' = K/K_1^n$.

If a maximum occurs in a plot of absorbance *vs.* ligand concentration it is a simple matter to calculate ε and the other quantities, but if no maximum appears then we use the expression

$$\frac{1}{E} = \frac{1}{C_M\varepsilon} + \frac{[H]^{n(1-m)}}{C_M\varepsilon K'[HA]^n} \tag{5}$$

where E, the extinction modulus, is given by A/d. Sommer used a similar expression in his investigation of the ascorbinate complexes of titanium.[2]

From this equation it follows that for complexes of the type $M(HA)_n$ the magnitude of $1/E$, and hence of A, is independent of pH if the ligand concentration is constant, but that for MA_n complexes there will be a pH-dependence. For a particular value of n (and at constant pH in the case of MA_n complexes) a plot of $1/E = f(1/[HA]^n)$ will yield a straight line with an intercept at $1/C_M\varepsilon$ on the y axis, from which ε can be determined. The slope of the line will be $1/C_M\varepsilon K'$, and K' can be

determined from it, and hence the instability constant K_{mn} of the complex can be calculated.

$$K_{mn} = \frac{[M][H_mA]^n}{[M(H_mA)_n]} = \frac{[H]^{n(1-m)}[H_mA]^n}{K'[HA]^n}. \quad (6)$$

For $m = 1$, $K_{1n} = 1/K'$ or $pK_{1n} = \log K'$, and for $m = 0$, $K_{0n} = K_2^n/K'$ or $pK_{0n} = npK_2 + \log K'$, where K_2 is the second dissociation constant for ascorbic acid.

The concentration of HA was calculated from the total ascorbic acid concentration, C_{H_2A}, and the pH, taking into account the degree of dissociation[3] of the sodium ascorbinate produced in adjusting the pH. This was done on the basis of the equations

$$C_{H_2A} = [H_2A] + [HA] + [NaHA] \quad (7)$$

$$K_1 = [H][HA]/[H_2A] = 10^{-4\cdot2} \quad (8)$$

$$K_{NaHA} = \frac{[Na][HA]}{[NaHA]} \sim 1\cdot5 \times 10^{-2} \quad (9)$$

$$C_{Na} = [Na] + [NaHA] \quad (10)$$

$$[HA] = \left\{\left[\frac{K_{NaHA} + C_{Na} - C_{H_2A} + [H]K_{NaHA}/K_1}{2(1 + [H]/K_1)}\right]^2 + \frac{C_{H_2A}K_{NaHA}}{1 + [H]/K_1}\right\}^{1/2} - \frac{K_{NaHA} + C_{Na} - C_{H_2A} + [H]K_{NaHA}/K_1}{2(1 + [H]/K_1)}. \quad (11)$$

It should be noted that the HA concentration will be maximal at pH 4·2, the half-neutralization point.

Plots were made for a fixed total concentration of metal and several different concentrations of ascorbic acid, as shown in Fig. 2 for neodymium. The absorbances were measured at the appropriate wavelength of maximum absorption (580, 380, 450 and 378 mμ for Nd, Eu, Ho and Er respectively) or on the short-wave side of an

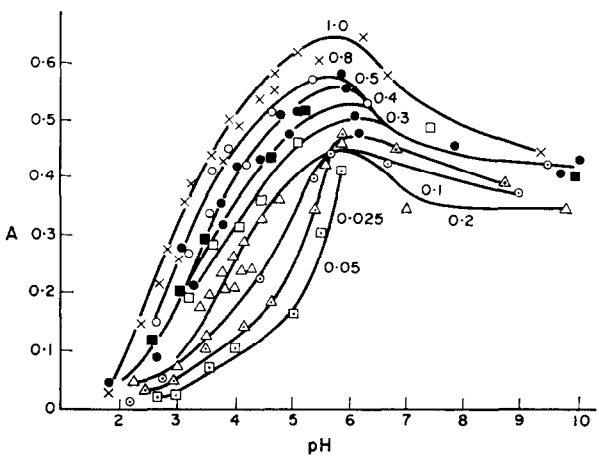

FIG. 2.—Variation in absorbance at 583 mμ of 0·0084M neodymium as a function of pH, in 0·025–1·00M ascorbic acid.

absorption peak (at 330 mμ for Zr, Hf, Nb, Ta, V, Mo and W). Plots of absorbance *vs.* concentration of HA were then made for each pH, as shown for neodymium in Fig. 3.

The results show that complexes of the type $M(HA)_n$ are formed at pH 2–4 with tervalent metals, 0–1 with quadrivalent metals, 0–0·5 with quinquevalent, and less than 0 with sexivalent metals. The pH of formation of this type of complex decreases with increase in the formal charge on the ion and is lower for the lower members of a particular group in the periodic classification.

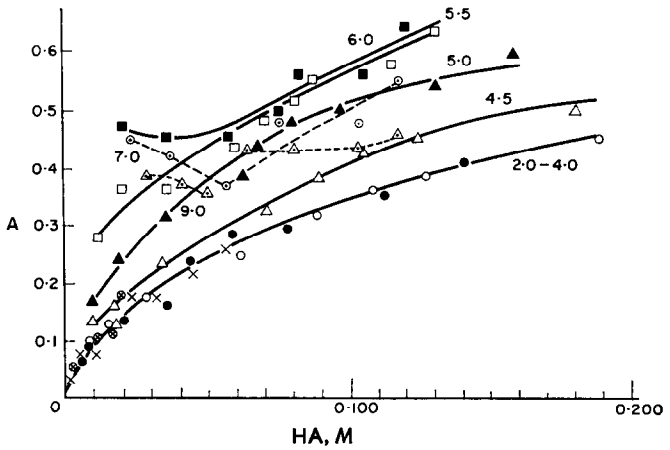

FIG. 3.—Variation in absorbance at 583 mμ of 0·0084*M* neodymium as a function of ascorbic acid concentration, at pH 2–9.

Complexes of the type MA_n are formed with tervalent metals at pH values above 4, but above pH 6 hydrolysis of the metal ion begins, especially if the concentration of ascorbic acid is low . For ions of oxidation state greater than IV, MA_n complexes are formed at pH values ranging up to 4 from the upper limit for formation of $M(HA)_n$ complexes, and hydrolysis sets in above this level.

The plots of $1/E$ *vs.* $f(1/[HA]^n)$ all gave values of unity for n, showing that all the complexes are either MA or MHA. The values calculated for the molar absorptivities and the instability constants are shown in Table III. Some of the instability constants were calculated for pH 2·5–4·0 from the relationship

$$K_{mn} = \frac{C'C''(A'' - A')}{A'C'' - A''C'} \tag{12}$$

where A' and A'' are the absorbances for a fixed concentration of metal and concentrations C' and C'' of ligand, and are given in Table IV. The ionic strength in the systems examined was varied from 0·1 to 0·3.

It is evident from the results that the stability of the complexes increases with the oxidation number of the metal ion, *e.g.*, Nb > Zr > Y, and with increasing atomic number within a group, *e.g.*, Hf > Zr > Ti (3.1[2]).

Considerably fewer facts are available about the MA_n complexes, but they are much more stable than the $M(HA)_n$ complexes, and are much more useful analytically,

TABLE III.—INSTABILITY CONSTANTS AND MOLAR ABSORPTIVITIES OF MHA ASCORBINATE COMPLEXES

Sa	1·2		

in terms of the colour developed. In no case has a complex been obtained containing more than one ascorbinate group per metal ion. The occurrence of negatively charged ascorbinates of zirconium, vanadium, molybdenum and tungsten[4] may be ascribed to addition of hydroxyl groups, as for instance in the uranyl compound[5] $[UO_2(C_6H_7)_6(OH)_2]^{-}$.

It was found that vanadium(IV) was reduced to vanadium(III) by ascorbic acid as well as being complexed. Similar effects were observed with tungsten and the MA complex of molybdenum, and it was impossible to obtain any quantitative information about these systems. The optimum conditions for reduction of tungsten were to start at pH 1·6 and end at pH 11·0. The colour was stable for at least an hour, and the absorption maximum was at 760 mμ for pH 5·5–5·9, shifting to 660 mμ for alkaline conditions. A 100-fold molar excess of ascorbic acid gave the best results.

The complexes formed in alkaline media were kinetically unstable. The absorbance obtained depends on the temperature, degree of exposure to light, and the rate of mixing of the solutions. Adjustment of the pH also presents problems, since addition of buffer causes a sharp decrease in the absorbance. The reagent is not self-buffering in the alkaline region.

When the europium system was examined more closely it was found that EuHA is formed at pH 3·0–4·5, with $\varepsilon_{380} = 300$ and $pK_{11} = 0{\cdot}8$. At pH values above 5 the

absorption maximum increases with pH and shifts to longer wavelengths, reaching a maximum absorbance at pH 9 and 390 mμ. Some evidence was found that the complex Eu_2A is formed at this pH (molar absorptivity 3250). It seems likely that the lactone ring of ascorbic acid is broken in forming this complex.

Quantitative applications

It was found that Beer's law was obeyed over the metal ion concentration range 10^{-3}–$10^{-4}M$. Spectrophotometric determinations in the visible region can be made with a limiting lower concentration of $10^{-5}M$ for osmium (420 mμ), iron(II) (500 mμ), and tungsten (660 mμ), $10^{-4}M$ for chromium(III) (600 mμ), and $10^{-3}M$ for holmium (450 mμ), cobalt (540 mμ) and neodymium (575 mμ).

The instability constants reported are regarded by us as tentative since no allowance is made in the calculations for hydrolysis or reduction reactions. Some applications of the reagent have been reported elsewhere.[6–9]

Zusammenfassung—Es wurde gezeigt, daß Ascorbinsäure je nach pH Metallkomplexe der Typen ML und MHL bildet und daß die Komplexe, besonders die vom MHL-Typ, relativ instabil sind. Ihre Absorptionsspektren haben keine Maxima, sondern einen steilen Anstieg bei 320–380 nm und sind relativz um Absorptionsspektrum der Ascorbinsäure langwellit verschoben. Die Verschiebung ist gröber bei Elementen von variabler Wertigkeit; die Spektren wandern bei steigendem pH zu längeren Wellen. Bei pH 7–9 erscheint ein neues Maximum bei 380–420 nm, das auf eine Strukturänderung im Ascorbinat-Ion deutet, möglicherweise zu einem Lacton. Metalle konnen als Ascorbinate spektrophotometrisch bestimmt werden, Ti, U, Os, V, Cr, Nb, Ta, Zr, Mo, W, Sn, Pb und Th bei Konzentrationen bis herunter zu 10^{-5}M, Lanthaniden, Sc, Hf und Sb bis 10^{-4}M.

Résumé—On a montré que l'acide ascorbique forme des complexes métalliques des types ML et MHL, selon le pH utilisé, et que le complexes sont relativement instables, particulièrement ceux du type MHL. Leurs spectres d'absorption n'ont pas de maximum mais ont une pente très marquées à 320–380 mμ et sont déplacés vers les plus grandes longueurs d'onde par rapport au spectre d'absorption de l'acide ascorbique. Un plus grand déplacement se produit avec les éléments de valence variable, et les spectres se déplacent vers les plus grandes longeurs d'onde lorsqu'on élève le pH; à pH 7–9, il apparaît un nouveau maximum à 380–420 mμ indiquant un changement de structure de l'ion ascorbinate, probablement en une lactone. On peut doser spectrophotométriquement les métaux à l'état d'ascorbinates, à des concentrations descendant jusqu'à 10^{-5} *M* pour Ti, U, Os, V, Cr, Nb, Ta, Zr, Mo, W, Sn, Pb et Th et 10^{-4} *M* pour les lanthanides, Sc, Hf et Sb.

REDOX REACTIONS ON COLUMNS

R. BELCHER, J. R. MAJER and G. A. H. ROBERTS
Department of Chemistry, The University, P.O. Box 363, Birmingham 15, U.K.

(*Received* 8 *May* 1967. *Accepted* 30 *May* 1967)

Summary—In a study of redox reactions on columns, the work of Cerrai and Testa has been extended. It has been shown that insolubility of the redox compound is the most important factor and that adsorptive forces play little or no part. A useful redox column method for the determination of iron and vanadium, which compares favourably with that using a Jones reductor column, has been developed. The redox potentials of several substituted hydroquinones have been measured.

METAL reductor columns have been used widely since the last century, but it is well-known that they are not completely satisfactory for all purposes. For example, there is still some uncertainty about the formation of hydrogen peroxide and the literature contains many conflicting statements.[1] In our own experience hydrogen peroxide is always formed with all types of metal reductor unless atmospheric oxygen is rigorously excluded from the system.[2]

As long ago as 1949, Cassidy[3] prepared "redox" or electron-exchange polymers consisting of vinyl polymers with pendant dihydroxyphenyl groups. Although the results obtained on columns packed with these polymers were promising, little attempt has been made to apply the technique. This may be due to the slow reactions and the comparative chemical instability of many of the products. Several reviews have been published on this topic and other types of electron-exchangers have also been described.[4]

Cerrai and Testa[5] recognized these shortcomings and attempted to prepare simpler systems; "the desired characteristics were that the organic solutions (of a simple redox compound) should be absorbed by the porous support in such a way that the redox molecules would be stably fixed to the surface and ready to react". Cerrai and Testa finally recommended columns packed with tetrachlorohydroquinone supported on Kel-F powder (polytrifluorochloroethylene).

The results obtained with these columns were very promising; Cerrai and Testa were able to effect redox reactions with a variety of compounds and of especial value was the use of the "memory" of the column, which enabled indirect determinations to be made, so preserving the uncontaminated effluent for other purposes.

It is not altogether clear from Cerrai and Testa's paper, whether the system depends entirely on water-insolubility or that weak adsorptive forces are involved; Betteridge[4] certainly considers that the latter play some part. A considerable amount of further experimentation is also necessary to establish the life of the columns after extended usage; comparison of the determinations against well-established methods and determinations at varying levels are also required. There is also the possibility that the same principle might be used for chelating systems. The present paper describes further studies on these factors. Other substrates and compounds having

redox properties have been examined; the formal potentials of the compounds have been determined.

Preparation of redox columns

The Kel-F powder was passed through a 14-mesh sieve to remove the larger particles. It was then coated with 30% w/w tetrachlorohydroquinone according to the method of Cerrai and Testa[5] by evaporating the solvent from the slurry of the powder and an ether solution of the tetrachlorohydroquinone. The resulting powder was made into a smooth paste with dilute hydrochloric acid and poured into a 1-cm diameter glass column fitted with a sintered disc and tap.

Determination of permanence of columns

Columns (8 cm long) were alternately completely oxidized and reduced by passage of an excess of oxidant or reductant solution, the column capacity being measured by back-titration of the eluate. The oxidant solution was 0·1*M* iron(III) chloride in 0·03*M* hydrochloric acid. Three reductant solutions were used: 0·1*M* iron(II) sulphate in 8*M* hydrochloric acid, 0·1*N* tin(II) chloride in 2*M* hydrochloric acid and 0·1*N* ascorbic acid in water. Of these three solutions, the ascorbic acid was the most stable.

Reduction of ferric chloride solution

A column (21 cm long) of 10 g of coated Kel-F powder was washed with 0·3*M* hydrochloric acid and 25 ml of iron(III) chloride solution in 0·03*M* hydrochloric acid were allowed to pass through the column during 1 hr. The column was then washed with 50 ml of 0·03*M* hydrochloric acid and the combined eluate was titrated with 0·1*N* potassium dichromate in the presence of phosphoric acid, diphenylamine being used as indicator.

Portions of the same iron(III) chloride solution were standardized volumetrically by reduction with sulphur dioxide and titration with cerium(IV) sulphate.

Reduction of ammonium vanadate solution

A column containing 5 g of 20% w/w tetrachlorohydroquinone on Kel-F powder was washed with 1*M* sulphuric acid, and 25 ml of ammonium vanadate solution in 1*M* sulphuric acid were passed through. The column was then washed with 25 ml of water and the combined eluate titrated with 0·1*M* potassium permanganate.

The amount of tetrachloroquinone produced on the column was determined by passing 25 ml of 0·2*N* ascorbic acid through the column, washing with 25 ml of water, and titrating the combined eluate with standard iodine solution. Portions of the same ammonium vanadate solution were also standardized by reduction with sulphur dioxide followed by titration with standard potassium permanganate solution.

Liquid electron-exchange systems

Portions (10 or 25 ml) of 0·100*M* iron(III) chloride in 0·3*M* hydrochloric acid were shaken with a solution of 0·5 g of tetrachlorohydroquinone in 50 ml of organic solvent (xylene–lauryl alcohol 90:10). Shaking times of 5–30 min were used. The aqueous layer was run off and the organic layer extracted with two 10-ml lots of water for 1 min each. The three aqueous layers were combined and titrated with 0·1*N* potassium dichromate. The partially-oxidized tetrachlorohydroquinone solution was reduced with excess of ascorbic acid solution, and 0·1*N* iodine was used to determine the amount of unreacted ascorbic acid.

Formal redox potential measurements

A 50-ml portion of a solution of the redox compound and hydrochloric acid in water or an ethanol-water mixture was placed in a 100-ml beaker, and stirred by a magnetic stirrer. A platinum foil electrode and a saturated calomel electrode in conjunction with a Pye pH meter were used to measure the potential. The oxidizing or reducing solution was added in small amounts at a time from a burette. To match the column conditions as closely as possible, an inert atmosphere was not used.

The point at which the redox compound had reacted completely was denoted by a rapid increase or decrease in potential for a small addition of titrant. This was preceded by a relatively flat portion of the potential–volume curve, the point of inflexion of which gave the formal redox potential, *i.e.*, the potential at which the redox compound is half-oxidized and half-reduced.

RESULTS AND DISCUSSION

Organic polymers such as polytetrafluoroethylene (PTFE), polyethylene, polyvinyl chloride and polyacrylonitrile retained tetrachlorohydroquinone to the same extent as Kel-F, no polymer possessing any markedly better retentive properties. Polystyrene presented preparative difficulties because it was soluble in the solvents used to deposit the tetrachlorohydroquinone. The permanence of such columns was checked by submitting two PTFE and two Kel-F columns to nine successive oxidation-reduction cycles each. After an initial 4–10% loss in capacity, all of the four columns settled down to a loss of only 0·1–1·2% per oxidation or reduction stage, compared with the 2% obtained by Cerrai and Testa.[6]

The permanence of the tetrachlorohydroquinone so obtained prompted an investigation of other reactants for use on columns. Alternative redox agents examined were alloxan, anthraquinone, t-butylcatechol, *p*-aminophenol, vanadium(II) 1,10-phenanthrolinate[7] and iron(II) 1,10-phenanthrolinate. In no case, except with anthraquinone, was the redox compound retained on the columns. Anthraquinone, which is water-insoluble like the other compounds reported by Cerrai and Testa,[5] was retained, but its standard redox potential[8] of 0·15 V is so low that the number of systems that could be oxidized by it is very limited.

Chelation reactions of nickel and cobalt with dimethylglyoxime and α-benzildioxime were studied on columns. Chelation was rapid with the former reagent, but the chelate was washed from the column. The second reagent, though more insoluble, reacted too slowly to be useful.

These redox and chelation results suggested that the reason for reasonable permanence on a column is that the compound is insoluble in the solvents, usually water, passed through the column. The alternatives are that there is adsorption due to a chemisorptive effect or to van der Waals forces. To eliminate these latter possibilities, the behaviour of other types of substrate with tetrachlorohydroquinone was

studied and also redox compounds of similar chemical structure but of greater solubility were used.

Inorganic substrates such as kieselguhr and diatomaceous earth (Celite) behaved as well as organic polymers in giving columns of satisfactory permanence, the capacity losses per oxidation or reduction step being 0·2–0·35%.

Tetrafluorohydroquinone and hydroquinone were tested as redox compounds that were water-soluble and of similar chemical structure to tetrachlorohydroquinone. However, they were not retained by columns of either inorganic or organic substrates. Especially in the case of tetrafluorohydroquinone does this point towards the insolubility effect being the all-important factor. The tetrafluorohydroquinone and tetrachlorohydroquinone are as chemically alike as is possible, so that any chemical bonding to the substrate should be just as probable with one as with the other. The outstanding difference between them is in their water-solubilities and it was therefore concluded that the tetrachlorohydroquinone remains on the column because of its insolubility. The substrate serves to hold the redox compound in a finely-divided state and so increases its efficiency.

The practical possibilities of using a redox column as a laboratory tool were evaluated. Blank runs, in which solvents only were passed through the columns gave very small or negligible corrections, equivalent to a loss per cycle of only 0·2% of the column capacity. Through-put rates could be increased from 30 ml/hr for a 1-cm diameter column to 180 ml/hr for a 3-cm diameter column, and still allow complete reaction of the material passed through the column.

The accuracy of the determination of solutions of iron(III) chloride in 0·03*M* hydrochloric acid was checked by comparison with reduction by sulphur dioxide followed by titration with cerium(IV) sulphate. The results are presented in Table I, and it can be seen that agreement is excellent.

A similar comparison was made for the reduction of ammonium vanadate solution by the column and by sulphur dioxide. In each case the reduced solution was titrated with standard potassium permanganate solution. It was also possible to make a further measurement of the amount of ammonium vanadate reduced, by determining the amount of tetrachlorohydroquinone oxidized on the column. This was achieved by passing a standard solution of ascorbic acid through the column and titrating the effluent with standard iodine solution. The results of this comparison are given in Table II, and it can be seen that there is agreement between results obtained by column and by sulphur dioxide reduction, but that results using the column "memory"

TABLE I.—DETERMINATION OF IRON(III) CHLORIDE SOLUTION IN 0·03*M* HYDROCHLORIC ACID SOLUTION

are up to 1% low. Similar results were obtained with iron(III). These slightly low results may be due to tetrachloroquinone being slightly more soluble than the hydroquinone; possibly the effect could be overcome by incorporating a short section of untreated substrate at the bottom of the column.

The liquid electron-exchange systems described by Danesi *et al.* have been evaluated and found to offer no advantages over redox columns. They claimed that electron-exchange at a liquid-liquid interface between tetrachlorohydroquinone in an organic solvent and an aqueous solution of metal ions could be expected to be faster than on columns, because there would be no slow diffusion of the ions through the resin as the rate-determining step. However, the redox reaction is an equilibrium and the two-phase liquid method does not readily give a complete reaction, as shown in Tables III and IV. On the other hand, the use of a column pushes the reaction to completion, because the column product is left behind in the upper part and fresh reactant is presented to the test solution as it descends.

Formal redox potentials were measured for tetrachlorohydroquinone, tetrafluorohydroquinone and hydroquinone. Because of the insolubility of the first of these, ethanol–water mixtures were used as solvent. Conant and Fieser[10] have reported that potentials are not highly dependent upon the solvent and this is also demonstrated by the values obtained for hydroquinone (Table V). The results in

Table V show that the presence of chlorine or fluorine as substituents in the nucleus has little effect on the value of the potential. The results in Table VI show that the redox potentials are dependent on the acidity. This is in agreement with the report of Cerrai and Testa[5] that iron(III) is reduced to iron(II) in 0·03*M* hydrochloric acid whereas in 8*M* hydrochloric acid, iron(II) is oxidized to iron(III) by tetrachloroquinone, though it must be remembered that the iron(II)/iron(III) couple has a potential dependent on the chloride concentration.

Conclusions

Redox or electron-exchange columns may be rapidly and simply prepared. They maintain their redox capacity effectively and have been shown to give reliable results in the determination of iron(III) and vanadium(V). However, it would be necessary to test them thoroughly in the presence of other metals and under routine conditions before they could replace metal reductor-columns for the determination of iron and vanadium.

Acknowledgements—One of us (G. A. H. R.) wishes to express his thanks to his employers, Esso Research Ltd., for the granting of a year's study leave at Birmingham University, during which time this work was carried out. We are grateful to Monsanto Ltd., and Bakelite Xylonite Ltd., for gifts of materials.

Zusammenfassung—In einer Untersuchung über Redoxreaktionen an Säulen wurde die Arbeit von Cerrai und Testa erweitert. Es wurde gezeigt, daß die Unlöslichkeit der Redoxverbindung der wichtigste Faktor ist und adsorptive Kräfte wenig oder keine Rolle spielen. Ein nützliches Säulenredoxverfahren zur Bestimmung von Eisen und Vanadium wurde entwickelt, das beim Vergleich mit einer Jones-Reduktorsäule gut abschneidet. Die Redoxpotentiale mehrerer substituierter Hydrochinone wurden gemessen.

Résumé—Dans une étude des réactions redox sur colonnes, on a développé le travail de Cerrai et Testa. On a montré que l'insolubilité du composé redox est le facteur le plus important et que les forces d'adsorption ne jouent qu'un rôle faible ou nul. On a élaboré une méthode de colonne redox utile pour le dosage du fer et du vanadium, qui est favorablement comparable à celle utilisant une colonne de réducteur de Jones. On a mesuré les potentiels redox de plusieurs hydroquinones substituées.

INTERACTION OF DOWEX A-1 CHELATING RESIN WITH SPARINGLY SOLUBLE CALCIUM SALTS

E. SEGALL and G. SCHMUCKLER
Department of Chemistry, Technion—Israel Institute of Technology, Haifa, Israel

(*Received* 4 *April* 1967. *Accepted* 15 *May* 1967)

Summary—The interaction between Dowex A-1 and sparingly soluble salts obeys the mass action law if no other salts are present in the solution. Increasing the total amount of charged species in the solution causes a decrease in the distribution coefficients of calcium, the decrease being in accordance with a simple function of the concentrations of the sodium ion and the precipitating anion in solution. The relations between the adsorbability and the solubility products have also been derived.

THE possibility of dissolving sparingly soluble substances with the aid of Dowex A-1, the chelating ion-exchanger, has already been dealt with by Rich[1] in 1963. Rich showed that sparingly soluble salts of the alkaline earth metals, the heavy metals (Ag, Hg) and transition metals may be dissolved by this means within a relatively short time. In the present work this interaction was studied quantitatively and the connection between the solubility product of the salts and their adsorbability on the chelating ion-exchanger investigated. Such a system is difficult to evaluate because the equilibria have to be measured between two solid phases that are by no means easy to separate. On the other hand this system has distinct advantages in that over a certain range the composition of the solid species investigated is known and constant, as distinct from the equilibria in salt solutions in which there is invariably more than one species, a fact that complicates the equilibrium systems. The system resin–sparingly soluble salt–water has a favourable property from the point of view of kinetics, in that the concentration of metal ions is constant because it is controlled by the solubility product of the salt. In other words there is no concentration gradient, except perhaps in a very thin layer in the vicinity of the resin beads.

More recently[2] the influence of pH and ionic strength on the distribution coefficients of alkaline earths was investigated, and there the great reduction in metal ion adsorption at relatively low ionic strengths was stressed. In the present work the same effect was encountered, at yet smaller ionic strengths ($\mu = 0{\cdot}1$), and it was found that this reduction is proportional to $\sqrt{(Na^+)/(A^{2-})}$ (where A^{2-} = the precipitating anion). This mathematical relationship is not accidental; it is directly connected with the solubility products of calcium carbonate and oxalate.

EXPERIMENTAL

Reagents

Dowex A-1 chelating resin was purified by treatment with 2*M* hydrochloric acid and 2*M* sodium hydroxide, repeated three times. The end product, in its sodium form, was rinsed with demineralized water.

All other reagents were reagent-grade chemicals.

Equilibrium measurements

Portions (20 ml) of a solution containing 0·20 mmole of sodium hydroxide, 50 mg of calcium carbonate or oxalate, and varying quantities of the ligands (carbonate or oxalate) were added to 100-mg portions of the dried sodium form of the resin and placed in 100-ml Erlenmayer flasks. In a subsequent series of experiments the same batches were prepared but with the addition of varying quantities of sodium nitrate. All the solutions were shaken for a week at a temperature of 25°, after which the composition of the solution was found to remain unchanged. Resin and solution were then separated by passing them through a 200-mesh sieve which, however, also passed the small particles of the sparingly soluble salt present. Thorough rinsing in distilled water adequately separated the resin particles from those of the salts. The two phases were then examined as follows.

Resin phase. Calcium was extracted from the resin by four treatments with 5*N* hydrochloric acid at 70° and the excess of acid was removed by evaporation. Calcium was determined by titration with EDTA at pH 10, Erio-T being used as indicator in the presence of Mg-EDTA. Traces of heavy metals were apparently present in the resin, since it was necessary to add masking reagents, such as potassium cyanide and hydroxylamine, in order to obtain a sharp end-point.

The solutions from the EDTA titrations were evaporated to a small volume, organic matter was oxidized with sulphuric and nitric acids, and the mixed metal sulphates were obtained by evaporation and then weighed. Since the concentrations of magnesium, calcium, and the sodium from the EDTA were all known, the concentration of sodium was easily determined by subtraction.

The water content and swelling of the resin were determined. The bottoms of 7-ml polypropylene test-tubes were cut off and replaced by 200-mesh stainless steel sieves. These modified test-tubes were encased in normal glass test-tubes, filled with the resin and a quantity of the solution, and finally sealed in order to prevent evaporation. The liquid was centrifuged off and the resin washed with the solutions with which it had been in contact. A small portion of the resin beads was set aside for microscopic examination of size; the rest was dried and weighed.

Aqueous phase. The hydroxide and carbonate content were determined by potentiometric microtitration with hydrochloric acid and oxalate was determined by titration with potassium permanganate in acidic medium.

DISCUSSION AND RESULTS

Theoretical considerations

The reaction between Dowex A–1 and calcium carbonate or oxalate at high pH may be represented as a stoichiometric reaction of the type

$$2\overline{Na}^+ + \overline{R}^{2-} + \underline{CaA} \rightarrow \overline{CaR} + 2Na^+ + A^{2-} \qquad (1)$$

in which

R^{2-} = the resin anion (which includes iminodiacetic acid groups) of Dowex A–1 resin;
$A^{2-} = CO_3^{2-}$ or $C_2O_4^{2-}$.

The upper bars denote a species in the resin, and underlining signifies a precipitate.

If the experiment is repeated with constant quantities of resin and CaA, and varying quantities of the ligand A^{2-}, all being left for 7 days for equilibrium to be reached, the selectivity coefficient may be found. It may be also shown in this manner under which conditions a constant value, which is related to the composition of the system, can be obtained.

The thermodynamic equilibrium of reaction (1) is

$$E = \frac{(\overline{CaR})(Na^+)^2(A^{2-})}{(R^{2-})(\overline{Na}^+)^2} \qquad (2)$$

but because it is possible only to measure the mole fractions of the metals in the resin

and not the activities of the various components in it, a modified equilibrium coefficient must be defined:

$$E_{\text{mod}} = \frac{[\overline{\text{CaR}}](\text{Na}^+)^2(\text{A}^{2-})}{[\text{R}^{2-}][\overline{\text{Na}^+}]^2} = E\frac{f_{\text{R}^{2-}} f^2_{\text{Na}^+}}{f_{\text{CaR}}}.$$

From Table I it is clear that E_{mod} is not a constant, but increases to 2–3 times its initial value. This increase may be tentatively explained by the change occurring in the ratio $\frac{f_{\text{R}^{2-}} f^2_{\text{Na}^+}}{f_{\text{CaR}}}$ as the ligand concentration increases, and by changes in swelling.

Reaction (1) actually consists of three stages:

Dissolution: $$\text{CaA} \rightleftharpoons \text{Ca}^{2+} + \text{A}^{2-} \tag{3}$$

Chelation inside the resin: $$\overline{\text{Ca}^{2+}} + \overline{\text{R}^{2-}} \rightleftharpoons \overline{\text{CaR}} \tag{4}$$

Ion-exchange: $$2\overline{\text{Na}^+} + \text{Ca}^{2+} \rightleftharpoons 2\text{Na}^+ + \overline{\text{Ca}^{2+}}. \tag{5}$$

Reaction (3) may be controlled through the solubility product, although this is based on the assumption that no ion-pairs are formed—an assumption that has recently[3] been shown not to be always correct. Reaction (4) has without doubt an influence on $\frac{f_{\text{R}^{2-}} f^2_{\text{Na}^+}}{f_{\text{CaR}}}$ with the decrease of the adsorption of calcium by the resin. Reaction (5) is connected with the swelling and the contraction of the resin; its value may be estimated with the aid of Donnan's equation:[4]

$$E_{\text{Don}} = \frac{1}{Z_i F}\left(RT \ln \frac{(a_i)}{(\bar{a}_i)} - \Pi v_i\right) \tag{6}$$

in which

Z_i = charge on species i

F = the Faraday

a_i = activity of species i

Π = swelling pressure

v_i = partial molar volume of species i.

Substituting the activities of the two ions gives, in the present case:

$$\frac{(\text{Na}^+)^2\overline{(\text{Ca}^{2+})}}{(\overline{\text{Na}^+})^2(\text{Ca}^{2+})} = \exp\{\pi(2v_{\text{Na}^+} - v_{\text{Ca}^{2+}})/RT\} \tag{7}$$

and substituting (7) in the expression for E_{mod} produces

$$E_{\text{mod}} = \frac{f^2_{\text{Na}^+} f_{\text{R}^{2-}}}{f_{\text{CaR}}} \frac{K_{\text{CaA}}}{K_{\text{CaR}}} \exp\{\pi(2v_{\text{Na}^+} - v_{\text{Ca}^{2+}})/RT\}. \tag{8}$$

The partial molar volume of two sodium ions being larger than that of one calcium ion, the increasing sodium concentration inside the resin—as illustrated in Table I

(samples 1–5 and 6–10)—will cause a rise in the "osmotic" pressure difference, and E_{mod} will therefore also increase. A rough calculation shows that in these systems swelling effects change E_{mod} by only about 10%, so that it may be assumed to be influenced mainly by the changes in $\frac{f_{R^{2-}} f_{Na^+}^2}{f_{CaR}}$. The term f_{CaR} would be expected to be nearly constant, while the product of the activity coefficients of the "salt" Na_2R ($f_{R^{2-}} f_{Na^+}^2$) should principally express ion-association of sodium ions with the fixed groups of the resin. These interactions would become stronger with decreasing dielectric constant (*i.e.*, with increasing CaR concentration). From experiment 1 to experiment 5 CaR concentration decreases, so that $f_{Na^+}^2 f_{R^{2-}}$ should increase.

Another phenomenon which may be involved in this effect is the possibility of the formation of CaR_2. The first samples are strongly contracted, and each R^{2-} group is closely surrounded by CaR; CaR_2 may certainly form. Sides and Kenner[2] in some cases (alkaline earths) also found a molar ratio of 1:2.

Empirical constants

Consider the equilibrium between two "precipitates":

$$R^{2-} + \underline{CaA} \rightleftharpoons \overline{CaR} + A^{2-} \tag{9}$$

(In other words the standard state is defined as that in which the activity of sodium ions in the solution equals that in the resin.) $\underline{CaA}$ has a constant density; $\overline{CaR}$ is part of a solid solution; by using concentrations, the constancy of the selectivity coefficient E_s may be checked:

$$E_s = \frac{[\overline{CaR}][A^{2-}]}{[\overline{R}^{2-}]} = \frac{N_{CaR}[A^{2-}]}{N_{R^{2-}}} \tag{10}$$

Mole fractions (N_{CaR} and $N_{R^{2-}}$) can be used in this case instead of concentrations, because CaR and R^{2-} are always in the same volume of resin.

Again Table I shows a fairly good constancy of E_s with respect both to calcium carbonate (mean value 0·0367 mole l^{-1}) and to calcium oxalate (mean value 0·0319 mole l^{-1}), although the ionic strength in these systems varied from 0·033 to 0·11.

When the same experiments were attempted at a constant ionic strength of 0·11, obtained by adding the required amount of sodium nitrate, a sharp drop was seen to occur in the adsorption of calcium ions by the resin, while E_s was reduced to half the value shown in Table I. It was also seen that this drop was lessened with increasing A^{2-} concentration in the solution in equilibrium with the resin. Qualitatively these effects may be explained by the thermodynamic interdependence of E_s and E expressed by the formula

$$E_s = E \frac{f_{R^{2-}}(\overline{Na^+})^2}{f_{CaR} f_{A^{2-}}(Na^+)^2} \tag{11}$$

Increasing the activity of the sodium ions in the solution will not raise the activity of the sodium ion in the resin in the same proportion, since the concentration of sodium ions in the resin is large from the outset, so that any further increase is limited by electrolyte exclusion. An increase in sodium ion activity therefore reduces E_s. A

similar consideration applies to the activity of carbonate or oxalate in the solution, which controls the amount of calcium ions in the solution. The visible effect is that an increase in (A^{2-}), or decrease in (Ca^{2+}), raises E_s. The two effects cancel each other if the system contains only CaA with no excess of A^{2-}.

The results obtained from these experiments are best expressed as a function of $([Na^+]/[CO_3^{2-}])^n$, for which n was determined experimentally as $n = 1/2$. The results are summarized in Fig. 1.

The lines obtained in Fig. 1 are straight, with a slope of 1/2. Their intercept with the y-axis gives a new constant, E_A, which is characteristic of the anion concerned.

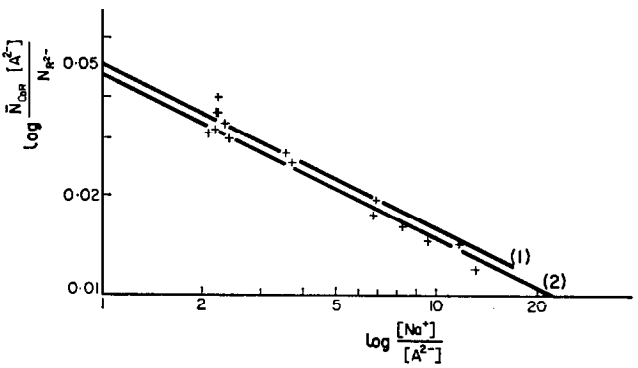

FIG. 1.—The influence of solution composition on the adsorbability of calcium on Dowex A-1.
(1) Calcium in the presence of carbonate ions.
(2) Calcium in the presence of oxalate ions.

$$E_A = E_s \left(\frac{[Na^+]}{[CO_3^{2-}]}\right)^{1/2} = \frac{N_{CaR}}{N_{R^{2-}}} \sqrt{[Na^+][CO_3^{2-}]}. \tag{12}$$

In practice the following values were obtained:

$$E_{CO_3^{2-}} = 0{\cdot}0518 \text{ mole } l^{-1}$$
$$E_{C_2O_4^{2-}} = 0{\cdot}0457 \text{ mole } l^{-1}$$

These values remain constant over a wide range of A^{2-} and sodium nitrate concentrations, as can be seen from Table I and was found in all the experiments done.

The connection between E_A and the solubility product

The connection between the mole fractions of the components in the resin and E_A was determined in equation (12). We may therefore write

$$\frac{E_{CO_3^{2-}}}{\sqrt{[Na^+][CO_3^{2-}]}} = \frac{N_{CaR}}{N_{R^{2-}}} = \frac{E_{C_2O_4^{2-}}}{\sqrt{[Na^+][C_2O_4^{2-}]}}. \tag{13}$$

In dilute solutions $f_{CO_3^{2-}} = f_{C_2O_4^{2-}}$ and therefore:

$$\frac{K_{spCaCO_3}}{K_{spCaC_2O_4}} = \left(\frac{E_{CO_3^{2-}}}{E_{C_2O_4^{2-}}}\right)^2. \tag{14}$$

The substitution of the numerical values obtained for $E_{CO_3^{2-}}$ and $E_{C_2O_4^{2-}}$ gives 1·28; Meites[6] gives 1·20 as the ratio between the solubility products—a reasonably good fit between a relatively involved experiment and a theoretical value.

CONCLUSIONS

Dowex A–1 is a chelating resin of low cross-linking in which the functional groups are fairly evenly distributed throughout the polymeric matrix. In view of this the resin may well be used in a way analogous to a chelating ligand in a solution, when the measure of similarity between two kinds of ligands is to be established.

In the present work it was shown that a connection exists between the stoichiometric reactions in the solution and the adsorbability on Dowex A–1. The connection between the overall concentration of electrolytes in the solution and the constants $E_{CO_3^{2-}}$ and $E_{C_2O_4^{2-}}$ is not haphazard, and many points over a wide range show the reliability of these values.

Experimental results from previous work,[5] carried out with soluble complexes with the purpose of examining the competition between copper glycinate and Dowex A–1 at pH 7 in the presence of varying quantities of potassium nitrate, may now be expressed by the reaction

$$H^+ + CuL_2 + R^{2-} \rightleftharpoons CuLR^- + HL \tag{15}$$

where HL is glycine.

The relationship found is

$$\frac{N_{CuLR}\sqrt{[K^+][HL]}}{N_{R^{2-}}[CuL_2]} = 116. \tag{16}$$

Here again the value remains constant over a wide range of concentrations.

Zusammenfassung—Die Wechselwirkung zwischen Dowex A–1 und schwer löslichen Salzen gehorcht dem Massenwirkungsgesetz, wenn keine anderen Salze in der Lösung vorhanden sind. Wächst die Gesamtmenge an geladenen Spezies in der Lösung, so fällt der Verteilungskoeffizient von Calcium; die Abnahme entspricht einer einfachen Funktion der Konzentrationen von Natrium und dem fällenden Anion in der Lösung. Auch die Beziehungen zwischen Adsorbierbarkeit und Löslichkeitsprodukten wurden abgeleitet.

Résumé—L'interaction entre la résine Dowex A–1 et des sels faiblement solubles obéit à la loi d'action de masse si d'autres sels ne sont pas présents dans la solution. Un accroissement de la quantité totale de l'espèce dont est chargée la solution cause une diminution des coefficients de partage du calcium, la diminution étant en accord avec une fonction simple des concentrations de l'ion sodium et de l'anion precipitant en solution. On a également calculé les relations entre l'adsorbabilité et les produits de solubilité.

HIGH-SPEED COMPUTERS AS A SUPPLEMENT TO GRAPHICAL METHODS—V*

HALTAFALL, A GENERAL PROGRAM FOR CALCULATING THE COMPOSITION OF EQUILIBRIUM MIXTURES

NILS INGRI†, WŁADYSŁAW KAKOŁOWICZ‡, LARS GUNNAR SILLÉN and BJÖRN WARNQVIST
Department of Inorganic Chemistry, Royal Institute of Technology (KTH), Stockholm 70, Sweden

(*Received* 1 *May* 1967. *Accepted* 31 *May* 1967)

Summary—A computer program, HALTAFALL, is described which calculates the equilibrium concentrations of the species in mixtures of any number of components, which can form any number of complexes and solid phases, provided concentrations (or partial pressures) can be used in the equilibrium calculations. Of course, the equilibrium constants must be known and enough data be given about the gross composition. Some applications are indicated. The flexible input rules make it applicable to a variety of problems. From the input information, the program itself devises an efficient plan for solving the simultaneous equations. The program also provides an efficient means of finding out which of many possible solid phases can actually appear in a certain equilibrium mixture.

THE main task of "equilibrium analysis" is the study of *unknown* equilibria. One starts with a number of reagents, not knowing for sure what the main reactions between them are, and tries to design experiments and treat the results in such a way that one may deduce the main reactions, and their equilibrium constants. The earlier papers of this series,[1–4] and in the series on graphical methods,[5–8] have been devoted to problems with unknown equilibria.

However, even assuming that one *knows* what the main reactions and their equilibrium constants are, it is not always an easy task to calculate the concentrations of the various species in an equilibrium mixture with many interacting reactions. Traditionally, many chemists consider this type of calculation very difficult.

Graphical methods, especially logarithmic plots,[9,10] can give a good survey of even quite complicated systems, provided the equilibrium ratios between various species can be expressed as functions of one or two master variables, such as $\log\{H^+\}$, $\log\{e^-\}$, or $\log p(O_2)$. If a numerical computation is necessary, however, one would like to take advantage of the capacity of high-speed computers.

In part II of this series,[2] two computer programs, KUSKA and HALTA, were described for equilibrium calculations that could be reduced to solving equations for

* Part IV—*Arkiv Kemi*, 1964, **23**, 97; for comment on spelling "program" see *Talanta*, 1967, **14**, 833.

† Present address: Department of Inorganic Chemistry, Umeå University, Sweden.

‡ Present address: Department of Inorganic Chemistry, The University, Wrocław, Poland.

one or two unknown master variables. Later on, we wrote similar programs for cases with a larger number of unknowns or other types of concentration conditions.

After some experience, however, we decided that we would rather have *one general program* for "known" equilibria than an increasing number of separate programs each for a special type of problem. A general program may not be quite as efficient as a program tailor-made for a special case, and hence may easily use more computer time. On the other hand, the general program saves the time otherwise needed for writing special programs, and computer time is getting less and less expensive in comparison with human time.

The first draft of this general ALGOL program—the new HALTA—was written by one of us (LGS) in late 1964, after discussions with NI on the types of equilibrium problems of interest to chemists. By the collaboration of NI and LGS improved editions were made to work on the computer BESK in Stockholm. WK took part in the work for three months in early 1965. When, in April 1965, NI and BW were to give a computer course for chemists at Göteborg University, they and LGS prepared an ALGOL version for SAAB D21. This program was then applied extensively to analytical problems by Professor David Dyrssen and his co-workers. Thanks to their work, some possible misbehaviours of the program were detected and corrected.

The first HALTA treated equilibria with only one fluid (liquid or gaseous) phase, but in 1965 it was extended to treat equilibria with one fluid and several solid phases. This revised program was called HALTAFALL, from the Swedish "halt" = concentration and "falla" = precipitate; a Scandinavian reader may find other associations as well. Starting with a draft by LGS the program was worked out on CD 3600 and CD 3200 by NI, BW and LGS. At the request of Dr Hay Liem, in December 1965 BW and LGS made additions so that HALTAFALL could also deal with distribution equilibria involving two fluid phases. Facilities for treating a gas phase at constant pressure were added as the need arose.

Many computer programs have been published for treating systems with "known" equilibria, and programs are still being published for surprisingly simple cases such as calculation of titration curves.

Most of the programs* of general interest that have been published are mainly designed and used for equilibria in a gas phase.[12–23] As will be discussed below, if condensed phases can be present, and the equilibrium conditions are known, one difficulty is to make the program deduce the correct set of condensed phases at equilibrium. This difficulty is avoided in most programs, either by considering only a gas phase, or by assuming that one has guessed the correct set; if the results are unreasonable, one may feed a new guess to the computer.[12–14] Villars's program[15] can decide whether or not solid carbon is present in a flame. Rosén[17] devised a more general method, and his special program decided which of three solid phases are present. Boll,[16] Cruise[21] and Shapiro[22] also handle cases with several condensed phases. The equilibrium conditions may either be set by minimizing the free energy (F or G) of the system,[11–13] or by applying equilibrium constant expressions.[14–23] A brief review of some important papers, including the iteration methods used, is given by Piehler.[18]

* Brinkley's procedure[14] was originally designed for computation by hand.

Programs for equilibria in a single liquid solution phase have been described by Anderegg,[24] Ropars and Viovy[25] and recently by Perrin.[26] The two first papers are in practice limited to three components, whereas the latter allows for an unlimited number of components. They all use equilibrium constants, and do not consider solid phases.

In comparison with other programs, it seems to us that HALTAFALL is very general and flexible, and is also adapted to the traditional ways of thought used by equilibrium chemists. It may be said to use the master variable approach (*cf.* ref. 9) like Ingri and Sillén[2] and Rosén,[17] and seems to converge reliably and quite rapidly even with very bad initial guesses for the master variables. We publish it here in the hope that it may be of some help to other chemists.

THE PROGRAM

Arrangement and Notation

Table I gives the present HALTAFALL program in ALGOL 60 with input/output orders mainly according to the ACM standard;[27] Table II explains the symbols used. Figures 3 and 4 are flow-sheets for essential parts of the program. The explanation of the principles in the text is mainly self-consistent but it may be advisable to glance occasionally at these tables and diagrams, even if explicit reference is not made to them.

The section on "input" is written in a manual style, and illustrated by the examples in Table III. For those who wish to test the program, the first output lines from the calculations are given.

The symbols in the text are partly defined as they appear and partly the same as in the ALGOL program (explained in Table II), where a quantity is often symbolized by a group of letters such as *Totbe*. The indices for a member of an array are sometimes given within square brackets, *pf*[*ia,if*] as in ALGOL, sometimes as a subscript, $pf_{ia,if}$. As usual, subscripts may mean things other than array numbers, but we trust there will be no misunderstanding. Matrices are denoted by bold-face letters; for a vector, an arrow may indicate whether it is horizontal or vertical.

Reference is sometimes made to Boolean (logical) variables (such as *Bra* below); as is well known, a Boolean variable has either of the values **true** or **false**.

One Fluid Phase

Species and equilibrium conditions

Let us start with a single fluid phase which may be a solution or a gas phase. Our system can be described with N_a *components* A_1, $A_2 \ldots A_{N_a}$, which can react to form N_X different products, *complexes*: $X_1, X_2 \ldots X_{NX}$.

In general it is convenient to choose as components well-defined species such as Ag^+, H^+, NH_3, $EDTA^{4-}$ in an aqueous solution, or $H_2(g)$, $CO(g)$, $O_2(g)$ in a gas phase. Sometimes it may prove practical to choose a component that does not correspond to a species present in measurable concentrations: e^-, H^+ in super-acidic solutions, C(s) or O(g) for a gas phase, *etc.* (for these, the Boolean *Noll*[*ia*] is set **true**).

We shall use the index *ia* to denote a component, and *ix* to denote a complex. By *p*[*ia*, *ix*] we mean the number of formula units of the component A_{ia} that are contained in the complex X_{ix}. Hence the composition of X_{ix} is

$$X_{ix} = (A_1)_{p[1,ix]}(A_2)_{p]2,ix]} \ldots . (A_{N_a})_{p[Na,ix]} \tag{1}$$

The numbers *p*[*ia*, *ix*] may be positive, zero, or negative; they are usually integers, but fractional numbers may appear. For instance, if Fe^{3+} and H^+ are among the components, a complex $Fe_2(OH)_2^{4+}$ in an aqueous solution is treated as $(Fe^{3+})_2(H^+)_{-2}$. If C(s) and $O_2(g)$ are components, CO(g) is $(C)_1(O_2)_{0.5}$. The activity of A_{ia}

$$\{A_{ia}\} = a_{ia} \tag{2}$$

is defined so that its ratio to the concentration $[A_{ia}]$ approaches indefinitely to unity when the composition of a solution approaches that of the solvent (or when the total pressure of a gas phase approaches zero). For components with *Noll*[*ia*], the ratio $\{A_{ia}\}/[A_{ia}]$ approaches instead an unknown constant $\gg 1$.

We shall assume that we can apply the law of ideality (activity = concentration) to all component species A_{ia} (if not *Noll*[*ia*]) and to all complexes X_{ix}. This assumption is usually permissible when

dealing with dilute gases, dilute solutions, or solutions in an ionic medium, and for approximate calculations. Provided one is consistent, the concentrations may be expressed in any convenient unit: mole fraction, mole/l, mole/kg or some pressure unit.

For the concentration of X_{ix}

$$c_{ix} = [X_{ix}], \tag{3}$$

the equilibrium law gives

$$\ln c_{ix} = \ln K_{ix} + p_{1,ix} \ln a_1 + \ldots p_{Na,ix} \ln a_{Na} = \ln K_{ix} + \sum_{ia} p_{ia,ix} \ln a_{ia} \tag{4}$$

where K_{ix} is the equilibrium constant for the formation of X_{ix} from the component species A_{ia}. Equation (4) uses natural logarithms as does the computer; for manual calculations, decadic logarithms are of course more convenient.

Mass balance equations

If the total concentration of each component is T_{ia} (in the program, *Tot*[*ia*]), the mass balance equations give

$$T_{ia} = a_{ia} + \sum_{ix} p_{ia,ix} c_{ix} \tag{5}$$

For components with *Noll*[*ia*], such as e^-, the activity a_{ia} may be well-defined, but does not correspond to the concentration of any component species, so that the term a_{ia} must be left out from (5). In either case, if the expressions for c_{ix} are inserted from (4), equation (5) gives each total concentration T_{ia} as a function of one, several, or all a_{ia}. The information on T_{ia} and a_{ia} may be given in various ways (input III). Often all one knows is the total concentration T_{ia} for each of the N_s components. One then has N_s equations (5), one for each component, from which the N_s unknown a_{ia} values can be deduced. For some purposes, *e.g.*, constructing survey graphs, it may be practical to consider a series of round values for some of the a_{ia} or log a_{ia} values. This reduces the number, N_{vs} of unknown a_{ia}, to be solved from equations (5) for each mixture considered.

Solving the equations (5)

So as not to overburden the reader with subscripts we shall change notation for a moment and denote the components by A, B, C . . . . their total concentrations by A, B, C . . . and the concentrations of the free component species by a, b, c . . . . Omitting the subscripts for p_i, q_i, *etc.*, we write any complex as

$$X_i = A_p B_q C_r \ldots \tag{1a}$$

Equations (4) and (5) take the forms

$$c_i = K_i a^p b^q c^r \ldots \tag{4a}$$

$$A = a + \sum p K_i a^p b^q c^r \ldots \tag{5a}$$

$$B = b + \sum q K_i a^p b^q c^r \ldots \tag{5b}$$

$$C = c + \sum r K_i a^p b^q c^r \ldots \tag{5c}$$

First let us consider how to solve the *equation for one component*, say (5*b*) for b, keeping a, c, *etc.* constant. On the right in equation (5*b*) is a monotonically rising function $B(b)$ since terms with positive or negative q all make B increase with increasing b. Here, then, is a special case of the general problem of finding the value for x that gives the value y_0 to a monotonically rising function $y(x)$. To solve it, HALTAFALL uses—in the switch ADA—the same operations as found after "Slinga" in Part IV of this series[4] (procedure Kålle in recent LETAGROP versions). For the same practical reasons as in Part IV, the $\ln a_{ia}$ are used as master variables rather than the a_{ia} themselves.

The computer starts with a first guess for $x(= \ln b)$, calculates $y(x)$ $[= B(b)]$ in procedure Totber and compares it with y_0 $(= B_{\text{given}})$. Then in successive passes through ADA series of systematic changes in x (symbolized here by Δx) and comparisons of the corresponding $y(x)$ with y_0 are performed. First, x is shifted by steps of 2 until one has one value for x that is too small and one that is too large. Then the computer interpolates, first by halving the interval of x, until it is smaller than a given value, "*stegbyt*", and finally by chords ("secant method") until the calculated y agrees with the given y_0 within the given tolerance limit *toly*. We have used this method extensively: it is reliable,

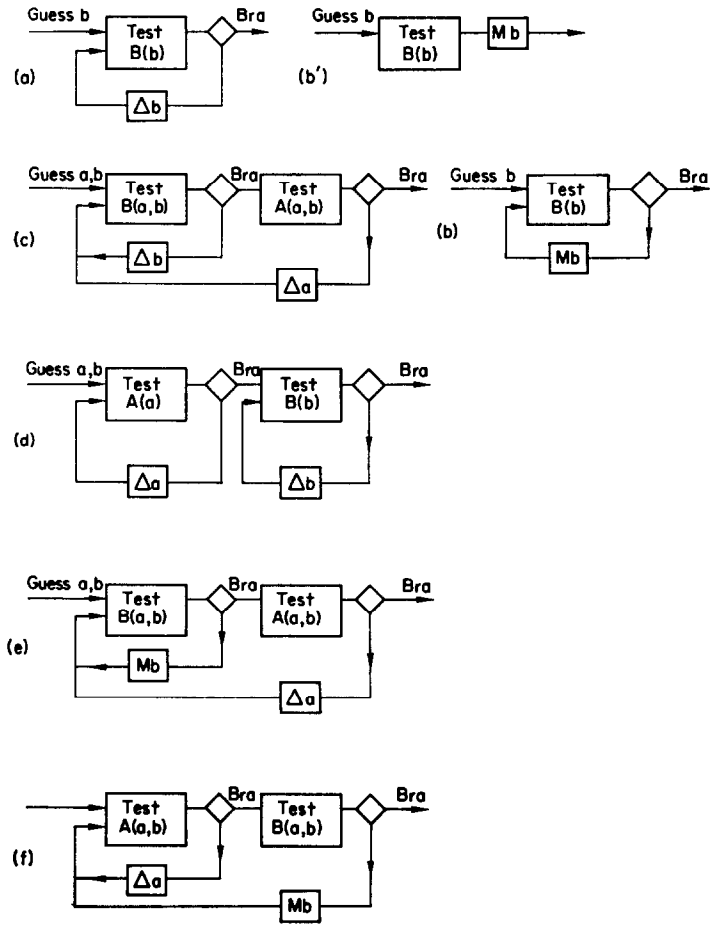

FIG. 1.—Some possible plans for solving equations (5) in equilibrium problems with one or two component concentrations (a, b) to be calculated from equilibrium conditions and total concentrations (A, B). See text for details; Δb stands for systematic variation by means of ADA, Mb for single step proportional adjustment in mononuclear cases.

general and quite fast, even with bad initial guesses, which we think makes it preferable to Newton-Raphson's method for the present case. We see no strong reason to change it, even if some economy of computer time might sometimes be achieved.

A special case occurs when B forms *only mononuclear* complexes (all q values are either 1 or 0) Then (5*b*) takes the form B = constant . b, and can be solved in one step, by a multiplication of the guessed value for b by the ratio $B_{\text{given}}/B_{\text{calculated}}$; this operation is symbolized here by Mb, or in general Mx.

Figure 1 symbolizes the method for the general case (Fig. 1*a*) and the mononuclear case (Fig. 1*b* and 1*b'*). We enter at the left with a guessed value for ln b. In the upper rectangle, $B(b)$ is calculated and tested for agreement of B_{calc} with B_{given}, within the tolerance limit. If there is agreement equation (5*b*) is satisfied, the Boolean *Bra* (Swedish = OK) is set *true*, and we proceed along the horizontal arrow to the right. Otherwise, in the general case ln b is changed (Δb), and $B(b)$ again calculated and tested (Fig. 1*a*). In the mononuclear case one might rely on the operation Mb to give immediately a correct result (Fig. 1*b'*). As it is, the program really makes one test (Fig. 1*b*) after making the operation Mb.

In a general case with *two unknowns*, a and b, and two functions, $A(a,b)$ and $B(a,b)$ to be adjusted to given values A_0 and B_0, Fig. 1*c* indicates a convenient method of solution. After ln b has been adjusted to make $B = B_0$, for a given ln$a$, a test is made for A, and ln$a$ is changed according to

whether A is found to be too small or too large. Then ln b is adjusted to make $B(a,b) = B_0$ with the new a value *etc.*, until both $A = A_0$ and $B = B_0$, within the given tolerance limits. At the end, ln a will have made a single cycle through ADA, whereas ln$b$ will have made many cycles. Permutation of A and B would give a schedule of the same type, and there is no *a priori* reason to prefer one or the other.

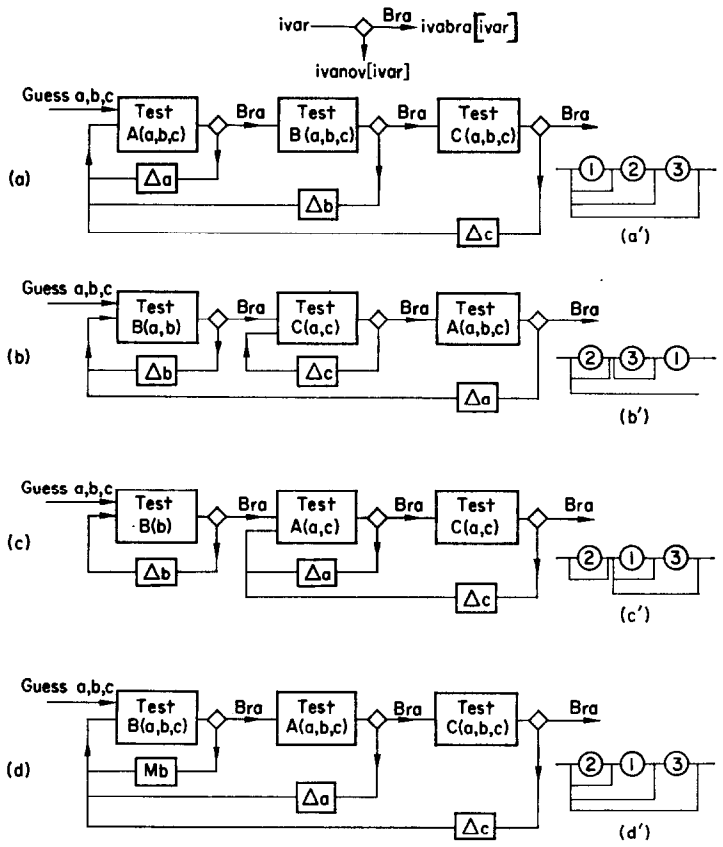

FIG. 2.—Possible plans for solving equilibrium problems with three component activities (a, b, c) to be determined from total concentrations A, B, and C and equilibrium conditions. M and Δ have the same significance as in Fig. 1. See text for details.

If the functions have the forms $A(a)$ and $B(b)$, then a and b are independent, and may be solved independently (Fig. 1*d*).

If B forms only mononuclear complexes, one might choose between the two schemes, Fig. 1*e* and Fig. 1*f*. The scheme in Fig. 1*e* requires only one ADA cycle for A and is hence preferred.

Figures 2*a*–2*d* similarly show convenient ways of solving the equations for cases with three components: a general case (Fig. 2*a*), no reaction B–C (no term containing both b and c, Fig. 2*b*), no reaction B–A or B–C (Fig. 2*c*), only mononuclear complexes with B (Fig. 2*d*). Permutation of A, B and C in Fig. 2*a*, of B and C in Fig. 2*b*, or of A and C in Fig. 2*c* or 2*d* would make no *a priori* difference.

If a mononuclear component is the first one to be tested, one may trust that the operation Mx will be successful. On the other hand, assume *e.g.*, that A in Fig. 2*b* is a mononuclear function. Then Δa will be replaced by Ma which like Δa affects B and C so that they have to be tested again. Hence the scheme in Fig. 2*b* will otherwise be the same, but it will work much faster if Ma can be used instead of Δa. A test is now made regularly after an M operation even if it happens to be the first.

In conclusion, one might attempt to set the general rules (1) that equations involving a smaller number of component activities should be tested before those with a larger number, and (2) that, everything else being equal, "mononuclear" equations should be tested before others.

Making the plan

Let us now return to the symbols A_1, A_2, A_3 etc for the components (A, B, C); T_1, T_2, T_3 for the total concentrations (A, B, C) and a_1, a_2, a_3 for the activities (free concentrations a, b, c), and remember that for practical reasons the computer treats the $\ln a_{ia}$ values as the unknowns in the equations. In the program, the symbol *ivar* is used for the *ia* number of the T_{ia} equation being tested, and hence of the $\ln a_{ia}$ that may as a result be varied; *e.g.*, if $ivar = 2$, T_2 is tested and $\ln a_2$ may be varied.

A plan like that in Fig. 1 or Fig. 2 may then be drawn in a still simpler form, giving the successive *ivar* numbers (Fig. 2*a'*–*d'*). The plan may be defined by two sets of numbers: (1) *iva*[1] to *iva*[*Nva*] are the *ivar* numbers in the order they should be tested; *Nva* is the number of unknowns. We set *iva*[*Nva* + 1] = 0, which serves as a signal that all equations (5) are satisfied; (2) *ivanov*[*ivar*] names the next *ivar* to be tested when the equation for T_{ivar} is not satisfied (*Bra* = **false**), so that $\ln a_{ivar}$ is adjusted by the operation Δ or M.

It is convenient to introduce also *ivabra*[*ivar*], the next *ivar* to be tested in case *Bra* = **true**. For instance, the plans in Fig. 2 (with *Nva* = 3) are described as follows. The numbers are *ia* numbers, *e.g.*, in Fig. 2*b*, *iva*[2] = 3, *ivabra*[2] = 3, and *ivanov*[2] = 2. Note that the index has a different meaning for *iva* on the one hand, and for *ivabra* and *ivanov* on the other. The statement *ivabra*[2] = 3 means that if the equation has been tested for *ivar* = 2 (thus the T_2 equation) and *Bra* found to be **true**, the next *ivar* to be tested is *ivar* = 3.

	iva[1 → 4]	*ivabra*[1 → 3]	*ivanov*[1 → 3]
Fig. 2*a*	1 2 3 0	2 3 0	1 1 1
Fig. 2*b*	2 3 1 0	0 3 1	2 2 3
Fig. 2*c*	2 1 3 0	3 1 0	1 2 1
Fig. 2*d*	2 1 3 0	3 1 0	2 2 2

(6)

Once the equations (5) are solved, the computer has the concentrations of all species and it is a trivial matter to ask it to print whatever quantities one wants to know: concentrations, logarithms of concentrations, average number of one component bound to another, *etc.*

The computer devises the plan of calculation from the information it has obtained on the *p*[*ia*,*ix*] for the various complexes. It uses two Boolean arrays, *Mono*[*ia*] which is **true** if A_{ia} takes part only in mononuclear complexes, and *Ober*[*i*,*j*] which is **true** if no complex contains both A_i and A_j, and hence a_i and a_j are "independent". For each component it calculates *Nober*[*ia*], the number of other components of which it is independent.

If there are N_{va} mass balance equations of type (5) to be solved, the computer arranges (after the label PLAN) the *ia* numbers of the corresponding components in the order, *iva*[1], *iva*[2] . . . *iva*[*Nva*], beginning with the *ia* that has the highest *Nober*, and for equal *Nober* beginning with those with *Mono*[*ia*] **true**; if *Nober* and *Mono* are equal, the lowest *ia* comes first. The *ivabra*[*ivar*] follow immediately from the *iva* series.

To find *ivanov*[*ivar*], the computer starts with *iva*[1], but if *iva*[1] is not connected with *ivar* (as seen from *Ober*), *ivanov* is shifted to *iva*[2], and so on.

After the plan has thus been laid out (and the necessary concentration data given) the computer can proceed to solve the equations for each "point", *i.e.*, equilibrium mixture. In Fig. 3, the full lines show the course of the calculation, from SLINGOR, the label where the first guesses for the $\ln a_{ia}$ are given, to the exit at FALLPROV, where all equations (5) are fulfilled. The broken lines refer to systems with solid phases present, which need not be considered until later.

To avoid unnecessary repetition, the calculation is made in three steps, using the procedures Lnbas, Cber and Totber. Lnbas calculates those parts of $\ln c_{ia}$ that are independent of $\ln a_{ivar}$, the $\ln a_{ia}$ to be varied. Cber calculates the concentrations c_{ia}. Totber combines the c_{ia} to give a calculated value y and compares it with the given $y_0 = Tot[ivar] = T_{ivar}$. If A_{ivar} is "mononuclear", Totber changes $\ln a_{ivar}$ by the operation we have denoted by M*x*.

Two Fluid Phases

If there are two fluid phases present—two liquids, or a gas and a liquid—the Boolean *Fas2* is set **true**. We can still use equilibrium conditions of the form (4) but if a certain chemical species occurs in both phases, we must treat it as a separate species in each phase. For each component A_{ia} we must hence decide in which phase to count it as a component species, with activity (concentration) a_{ia}; in the other phase, it is then treated as a complex with formation constant equal to its distribution constant.

Sometimes it may be practical to define the component species so that they are all in one phase, sometimes not. Suppose for instance that we are studying equilibria of a metal ion M^{s+}, a ligand acid HA (say dibutylphosphate—DBP), an uncharged ligand B (say tributylphosphate—TBP) and an

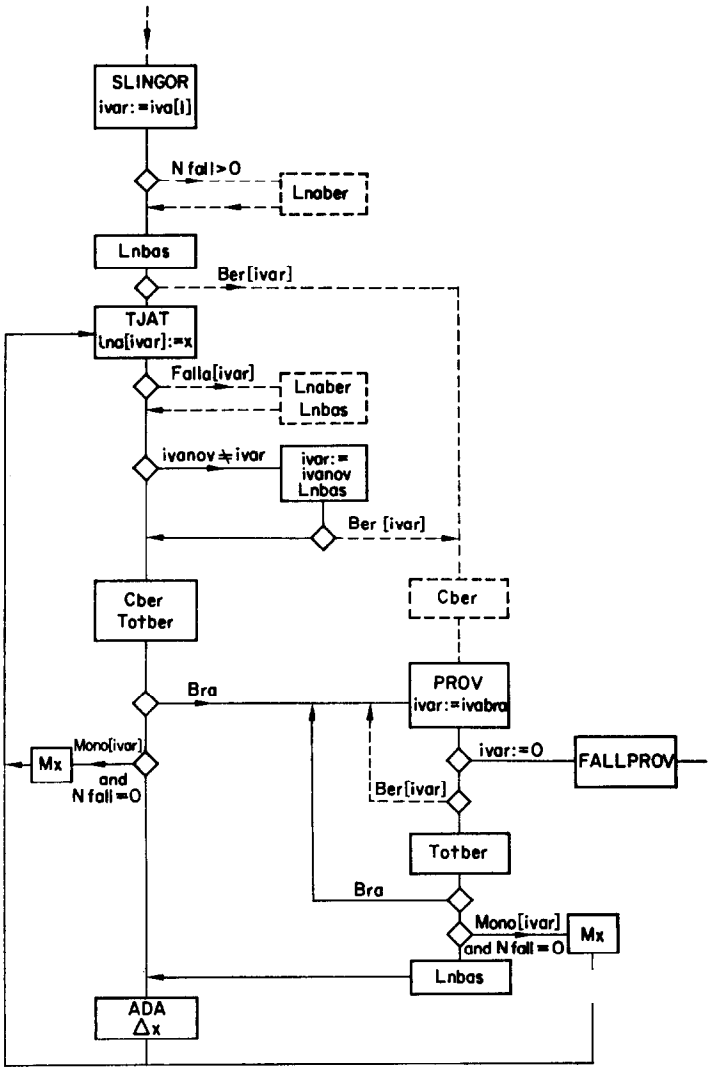

FIG. 3.—Flow sheet for solving the mass balance equations (5) or (16): enter at SLINGOR, exit at FALLPROV. The dotted lines are valid only in the presence of solid phases. Labels are written with capitals (SLINGOR, TJAT). The Boolean expression at a branching path such as *Nfall* > 0, *Bra*, or *Falla*[*ivar*] means that this path is taken if these Booleans are **true**. *Mx* stands for the "mononuclear" adjustment and Δx for the stepwise ADA adjustment, as in Figs. 1 and 2. The two branching points after **Totber** are inside the procedure Totber. In Lnbas one sets $x := lna[ivar]$.

inorganic anion X^- (say nitrate) in an aqueous phase and an organic phase. It may then be convenient to choose as component species: M^{s+}, H^+ and X^- in the aqueous phase, B in the organic phase, and HA in either the organic or the aqueous phase.

In the mass balance equations (5) we must consider the volumes of the two phases, V and V'. The total concentration T_{ia} may be defined as the amount of the component per unit volume of one phase (say the "unprimed" one) so that the total amount in the system is VT_{ia}. (Corresponding expressions are valid for concentration units other than mole/l.) On the other hand, the total amount of the component is obtained by multiplying each term to the right in equation (5) by V or V', depending on the phase in which the species occurs, and adding the products. If we finally divide this

expression by V, the resulting equation has the form (5) except that those concentration terms to the right that refer to the "primed" phase are multiplied by the volume ratio ϕ:

$$\phi = V'/V \tag{7}$$

The present program HALTAFALL is written for the case of equal volumes, $\phi = 1$. If ϕ is constant but differs from unity, one may simply, for all species in the primed phase, replace their K_{ix} by ϕK_{ix} and can then use (4) and (5) as before. By trivial changes in the program it could be adapted also to cases with varying volume ratio ϕ.

For calculating distribution ratios *etc.*, it is necessary to know in which phase each species occurs. For species in the "second" phase, the Boolean *Kifas2*[*ia*] (for A_{ia}) and *ifas2*[*ix*] (for X_{ix}) are **true**.

Gas Phase

Constant volume

For a single gas phase at constant volume, we may use the program in the same way as for a liquid solution provided we are careful with the concentration units. If the equilibrium constants are expressed in concentration units such as mole/l, then a_{ia}, c_{ix} and T_{ia} should be expressed in the same units. If one uses equilibrium constants with pressure units ("K_p"), then a_{ia}, c_{ix} and T_{ia} must be expressed in the same units, say bar, atm or possibly torr. Then a_{ia} and c_{ix} are the partial pressures, and T_{ia} is the pressure the component would have exerted if present alone, and in the form of the component species. (As is well known, to translate molar concentrations into pressures one multiplies by RT, being careful with the dimension of R.)

For the combination of a liquid phase and a gas phase at constant volume, again we may apply the program (setting *Fas2* **true**) but must be careful to make the dimensions of the K_{ix}, a_{ix} and c_{ix} consistent with the mass balance (5).

Constant pressure

For equilibria with a gas phase, it is often a practical condition that the total gas pressure be kept at a constant value, P_{tot}. In this case the Boolean *Pegas* is set **true**. The a_{ia}, c_{ix}, K_{ix} and T_{ia} are conveniently expressed in *pressure units*, as described for "constant volume".

The mass balance is usually defined by giving the mole ratios between the components (equivalent to the numbers of moles) *Ntot*[*ia*] $= n_{ia}$ in an initially unknown volume V of gas phase. The relationship is (note that T_{ia} is expressed in pressure units):

$$T_{ia} = n_{ia} * \left(\frac{RT}{V}\right) = n_{ia} * F. \tag{8}\dagger$$

F is an unknown, the same for all components. In the program, $\ln F$ is treated as another unknown, $\ln a[Na + 1]$, which is adjusted by means of an ADA cycle so as to satisfy, within the tolerance $\pm$ *tolp*, the total pressure condition

$$\sum a_{ia} + \sum c_{ix} = P_{\text{tot}}. \tag{9}$$

The test for (9) is made in the procedure Sump, after FALLPROV and NOG; if need be, F is changed, and the program returns to SLINGOR. This corresponds to another loop in Fig. 2, making in all $(N_{\text{va}} + 1)$ unknowns and is indicated in Fig. 4. The combination of a gas phase of constant pressure and variable volume, and a liquid phase, could be treated by trivial changes in the program, but no need has been seen for it as yet.

Ideal Liquid Mixture

For an ideal liquid mixture, one might use mole fraction units in a_{ia}, c_{ix}, T_{ia} and K_{ix}. We have an extra condition that the sum of all mole fractions = 1, which corresponds to (9) with $P_{\text{tot}} = 1$. Hence, the same treatment could be applied as for a gas at constant pressure.

Solid Phases Present

Up till now we have considered a single fluid phase, or possibly two, with variable concentrations of the species. Let us now assume that in addition a number N_f of solid phases are known, one or more of which might appear in our system at equilibrium. Each solid phase F_{if} is characterized by the coefficients *pf*[*ia*,*if*] of the components in its formula:

$$F_{if} = (A_1)_{pf[1,if]}\,(A_2)_{pf[2,if]} \ldots (A_{Na})_{pf[Na,if]}. \tag{10}$$

† The symbol * written on the line is ALGOL for *multiply*.

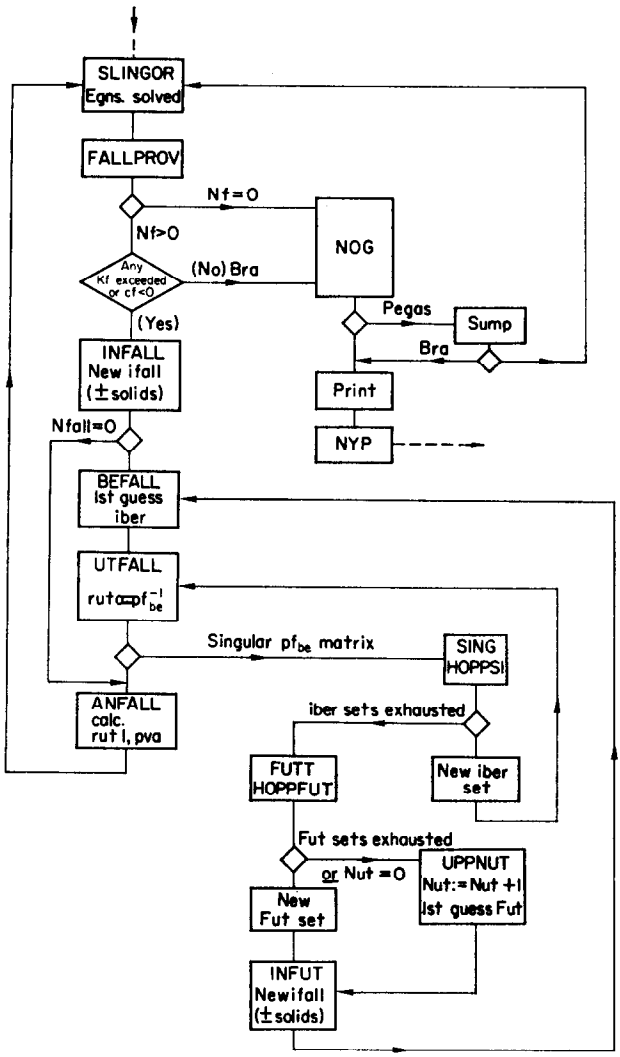

FIG. 4.—Plan for finding out which solids are present at equilibrium.

The coefficients *pf* may be positive or negative, integers or fractions. If Kf_{if} is the equilibrium constant (solubility product) for the dissolution of solid F_{if} to form the components, then the condition for F_{if} to be at equilibrium with the solution is

$$\ln Kf_{if} = pf_{1,if} \ln a_1 + \ldots + pf_{Na,if} \ln a_{Na} = \sum_{ia} pf_{ia,if} \ln a_{ia}. \tag{11}$$

These equations may give some new interdependences between components, which must be considered when calculating *Ober*[*i*, *j*].

The mass balance equations (5) are replaced by a set of equations (12), containing the formal concentrations cf_{if}, meaning the number of moles of solid F_{if} present per litre of solution (or correspondingly for other concentration units):

$$T_{ia} = a_{ia} + \sum_{ix} p_{ia,ix} c_{ix} + \sum_{if} pf_{ia,if} cf_{if}. \tag{12}$$

For the c_{ix}, (4) is valid as before.

Suppose that we know which solid phases are present, altogether N_{fall} phases, with the *if* numbers

ifall[1] to *ifall*[*Nfall*]. To find the a_{ia}, we have N_{fall} equations (11), one for each solid, and N_a equations (12), one for each component. The values of the N_{fall} formal concentrations cf_{if} are usually not interesting (as long as they are positive), and they may be eliminated from (12), leaving N_{fall} equations (11) and N_{vaf} reduced equations (16) (see below) of the same type as (5) where

$$(N_{vaf} = N_{va} - N_{fall}). \tag{13}$$

In other words, only N_{vaf} of the a_{ia} need to be calculated by solving equations of type (5) whereas the others can be found by applying (11). We may then divide the a_{ia} into three classes.

I. As before, $(N_a - N_{va})$ of the a_{ia} values are known from the onset.

II. N_{vaf} of the a_{ia} values are to be calculated from reduced mass balance equations of type (5); their *ia* numbers will be denoted by *ivaf*[1] to *ivaf*[*Nvaf*], in the order in which they will be solved.

III. N_{fall} of the a_{ia} values will be calculated from equilibrium conditions of type (11). Their *a*] numbers will be denoted by *ibe*[1] to *ibe*[*Nfall*], and for these *ia* (but no others) the Boolean *Ber*[*iia* is **true**.

The equations we need are perhaps best deduced in matrix form. The N_{fall} equations (11) and the N_a equations (12) may be written

$$\vec{\mathbf{ln\ Kf}} = \vec{\mathbf{ln\ a}} * \mathbf{pf} \tag{11m}$$

$$\underset{\downarrow}{\mathbf{T}} = \underset{\downarrow}{\mathbf{a}} + \mathbf{p} * \underset{\downarrow}{\mathbf{c}} + \mathbf{pf} * \underset{\downarrow}{\mathbf{cf}} \tag{12m}$$

The dimensions (rows, columns) of the matrices above are: $\mathbf{ln\ Kf}(1, N_{fall})$, $\mathbf{ln\ a}(1, N_a)$, $\mathbf{pf}(N_a\ N_{fall})$, $\mathbf{T}$ and $\mathbf{a}(N_a, 1)$, $\mathbf{p}(N_a, N_x)$, $\mathbf{c}(N_x, 1)$, $\mathbf{cf}(N_{fall}, 1)$.

We may divide (11*m*) into two parts, "be" corresponding to the ln a_{ia} of class III above, and "not-be" corresponding to classes I + II.

$$\vec{\mathbf{ln\ Kf}} = \vec{\mathbf{ln\ a}}_{\mathbf{be}} * \mathbf{pf}_{\mathbf{be}} + \vec{\mathbf{ln\ a}}_{\mathbf{not\text{-}be}} * \mathbf{pf}_{\mathbf{not\text{-}be}} \tag{11m'}$$

In the dimensions of the matrices, N_a is replaced by N_{fall} for "be" and by $(N_a - N_{fall})$ for "not-be". It follows from (11*m*') that we may calculate $\mathbf{ln\ a_{be}}$ from

$$\vec{\mathbf{ln\ a}}_{\mathbf{be}} = \vec{\mathbf{ln\ Kf'}} * \mathbf{pf}^{-1}{}_{\mathbf{be}} \tag{14}$$

where $\mathbf{lnKf'}$ is a reduced vector (*ln Kmi* in Lnaber).

$$\vec{\mathbf{ln\ Kf'}} = \vec{\mathbf{ln\ Kf}} - \vec{\mathbf{ln\ a}}_{\mathbf{not\text{-}be}} * \mathbf{pf}_{\mathbf{not\text{-}be}} \tag{14a}$$

Equations (14*a*) and (14) are used in the first part of the procedure Lnaber, and $\mathbf{pf}_{be}^{-1} = ruta$ is calculated after UTFALL.

The mass balance equations (12*m*) may be written separately for the N_{fall} "be" components (class III) and for the N_{vaf} "vaf" components (class II)

$$\mathbf{T}_{be} = \mathbf{a}_{be} + \mathbf{p}_{be} * \mathbf{c} + \mathbf{pf}_{be} * \mathbf{cf} \tag{12a}$$

$$\mathbf{T}_{vaf} = \mathbf{a}_{vaf} + \mathbf{p}_{vaf} * \mathbf{c} + \mathbf{pf}_{vaf} * \mathbf{cf}. \tag{12b}$$

Eliminating **cf** from (12*a*) we find

$$\mathbf{cf} = \mathbf{pf}_{be}^{-1} * (\mathbf{T}_{be} - \mathbf{a}_{be} - \mathbf{p}_{be} * \mathbf{c}) \tag{15}$$

Introducing (15) into (12*b*) we get a matrix equation, equivalent to N_{vaf} equations of the same type as (5).

$$\underset{\downarrow}{\mathbf{T'}_{vaf}} = \underset{\downarrow}{\mathbf{a}_{vaf}} + \underset{\downarrow}{\mathbf{p'}_{vaf}} * \mathbf{c} \tag{16}$$

where the reduced $\mathbf{T}$ and $\mathbf{p}$ may be calculated from

$$\mathbf{T'}_{vaf} = \mathbf{T}_{vaf} - \mathbf{pf}_{vaf} * \mathbf{pf}_{be}^{-1} * (\mathbf{T}_{be} - \mathbf{a}_{be}) \tag{16a}$$

$$\mathbf{p'}_{vaf} = \mathbf{p}_{vaf} - \mathbf{pf}_{vaf} * \mathbf{pf}_{be}^{-1} * \mathbf{p}_{be}. \tag{16b}$$

The N_{vaf} reduced mass balance equations (16) and the N_{fall} reduced equilibrium equations (14) should suffice for calculating the N_{va} unknown a_{ia}.

The "be" components can often be selected in several ways. Obviously, one cannot allow a selection that would give a zero determinant to $\mathbf{pf}_{be}$ since then it could not be inverted as required by (14), (16*a*) and (16*b*).

At present the program is based on the plan (= the set of *iva, ivanov* and *ivabra*) devised for the absence of solid phases. At first it is assumed (at BEFALL) that the first N_{fall} of the *iva* are the *ibe* to be calculated. If the determinant of $\mathbf{pf}_{be}$ is found to be zero at UTFALL, the *ibe*'s are changed systematically (at SING-HOPPSI), by means of the array *iber*, until a non-zero determinant is found. Then, at ANFALL, $\mathbf{pf}_{vaf} * \mathbf{pf}_{be}^{-1}$ (= *rut*1) and $\mathbf{p}'_{vaf}$[= "*pva*", equation (16*b*)] are calculated.

The course of the following calculations is shown by the diagram, Fig. 3, this time including the broken lines. Whenever a $\ln a_{ia}$ from the "vaf" class has been changed, all those of the "be" class are recalculated, using Lnaber [equation (14)], which also recalculates the T'_{vaf} ("*Totva*") since they contain a_{be} [equation (16*a*)]. The right hand side of (16) is compared with T'_{vaf} in Totber. On the other hand, if a new *ivar* belongs to the "be" class, one just passes to *ivabra*[*ivar*].

Possibly the most rapid procedure for some case may differ from the one now taken; at any rate, the equations are in general solved much faster in the presence of solid phases than without them.

Test for consistency

After a set of $\ln a_{ia}$ have been found that satisfy equations (14) and (16), one must test that they are consistent with the assumptions made as to which phases are present. Hence, (1) the solubility product *Kf* (11) must not be exceeded for any phase assumed to be absent, (2) the "formal concentration" *cf*, calculated by (15), must not be negative for any solid phase assumed to be present. These two tests are made after the label FALLPROV. (See the plan in Fig. 4.)

If the set of $\ln a_{ia}$ proves consistent, *Bra* comes out **true**, and the computer proceeds to NOG (= enough), otherwise it passes the labels INFALL, BEFALL and UTFALL, where it adds or subtracts solids as indicated by FALLPROV, and tries various sets of *iber*. When it has found a $\mathbf{pf}_{be}$ that can be inverted it goes to ANFALL, calculates the matrices *ruta* = $\mathbf{pf}_{be}^{-1}$, *rut*1 = $\mathbf{pf}_{vaf} * \mathbf{pf}_{be}^{-1}$ and *pva* = $\mathbf{p}'_{vaf}$ (16*b*), after which it goes back to SLINGOR.

At NYKO where K_{ix} and K_{if} are given it is assumed that no solid is formed. For the first point the equations (5) are solved (SLINGOR) and the set of $\ln a_{ia}$ tested for consistency. If necessary, solid phases are added and subtracted until a consistent set is obtained. For the next point in the series one starts by assuming that the same solid phases are present as at the preceding point, *etc.*

For instance, if we start with a solution containing Cl^-, Br^- and I^-, and add a small amount of Ag^+, the first hypothesis "no solid phase" gives ln a_{ia} values which exceed the solubility products of AgCl, AgBr and AgI. The second hypothesis, that these three solids are present, gives a negative formal concentration *cf* of AgCl. This is easily understood: at equilibrium with these three phases, $[Cl^-]:[Br^-]:[I^-] \approx 360:1:0{\cdot}0002$ so that most Br^- and I^- must be precipitated as AgBr and AgI. This would require the addition of a large amount of AgCl(s) from the outside, hence a negative *cf* for AgCl.

In the next cycle, AgCl is hence struck out. The third hypothesis, AgBr and AgI present, gives a negative *cf* for AgBr, and we are left with only AgI(s), which gives a consistent set of ln a_{ia}. If enough Ag^+ is added, however, AgBr(s) and AgCl(s) will also appear at equilibrium.

Provision has also been made for the more complicated case where FALLPROV indicates a set of solid phases which are not compatible at all. This may occur if there are two solid phases of the same composition, with different solubility products, or more generally if there is a linear relationship between the composition of a group of solid phases, or if more solids are indicated than there are ln a_{ia} values to vary. In such cases it proves impossible to pick out a group of N_{fall} components "*ibe*" such that $\mathbf{pf}_{be}$ has a non-zero determinant. When this has been found, one must try systematically combinations of a smaller number ($N_{fall} - N_{ut}$) of solid phases, until a consistent solution is found. This is done at FUTT, INFUT and UPPNUT, using the array *Fut*. To avoid going into a loop, the computer sets the Boolean *Singfall* **true** and remembers the first set of solids (*ifspar*[1] to *ifspar*[*Nfspar*]) which gave only zero determinants; it then automatically returns to "striking out" solids systematically until a consistent solution of the problem is found.

INPUT

O. Optional

(0:1) Orders for printing text, *e.g.*, characterizing the problem: 0, 0, followed by card with text. This may be repeated: 0,0,/text/0,0,/text/*etc.* For tape input, this can be done in other ways, depending on the computer.

(0:2) Ending the calculation: −1, −1,

I. Equilibrium data

(I:1) Number of components: *Na*, (if there are two fluid phases, give instead *Na* + 1).

(I:2) Data on soluble complexes: Nx, (*kbas, pot*, $(p[ia, ix])_{Na})_{Nx}$,†

† The subscript outside a parenthesis states how many such quantities or sets of quantities must be given.

The equilibrium constants are given by $K_{ix} = kbas*10^{pot}$. If there are two fluid phases, give $-Nx$ instead of Nx, and for each species add $p[Na + 1, ix]$, which is 1 if the species is in the second phase, otherwise 0.

(I:2a) If there are two fluid phases, add, immediately after Nx: m, $(ia)_m$, where m is the number of components with activities set equal to their concentrations in the second phase, and after m their ia numbers are given.

(I:3) Data on solid phases: Nf, $(kbas, pot, (pf[ia, ix])_{Na})_{Nf}$.

Again, the solubility product is given as $Kf = kbas*10^{pot}$. If no solid phase:0.

II. Printing orders

$Npri$, $(prix_1, prix_2)_{Npri}$,

Each of the N_{pri} printing orders consists of two integers, $prix_1$ and $prix_2$, which have the following significance:

$prix_1$	$prix_2$	quantity to be printed
ix	1	c_{ix}
ix	2	log c_{ix}
ix	$-ia$	$p_{ia,ix}*c_{ix}/T_{ia}$, fraction of A_{ia} present in complex X_{ix}
0	0	V_T, volume added in titration
$-ia$	1	a_{ia}
$-ia$	2	log a_{ia}
$-ia$	3	log (T_{ia}/a_{ia})
$-ia$	4	T_{ia}
$-ia$	5	a_{ia}/T_{ia}
$-ia$	6	log D_{ia}, log of distribution ratio for component A_{ia}
$-ia$	7	$D_{ia}/(1 + D_{ia})$
$-ia$	$-m$	average number of A_{ia} bound per A_m

III. Concentration data

These data are given as follows: III:1, (III:2, (III:3)$_{Np}$)$_{Ns}$.

The task to be carried out is divided into Ns groups. Each group contains a certain number Np of points, each of which corresponds to an equilibrium mixture. The type of concentration data may be different in different groups, but throughout the Ns groups the same equilibrium data and the same printing orders are valid.

(III:1) Common data: Ns, *stegbyt*.

Stegbyt is the value for *steg* in ADA at which "chord shooting" should replace binary approach. It may conveniently be set equal to the reciprocal value of the highest $p[ia, ix]$ value represented.

(III:2) Group data: Np, (*hur*[*ia*] + 0–4 numbers, see list below)$_{Na}$, (*Ptot*, *tolp*)(if *Pegas*), V_0 (if *Titer*).

Instead of Np, the number of points, $-Np$ is given if we treat a gas mixture at constant pressure. *Pegas* is then set **true**.

The series of numbers, *hur*[1] to *hur*[*Na*] tells what type of concentration data will be given for the corresponding component A_{ia}. After each *hur*[*ia*] come 0–4 numbers, as follows, with notations as in the program:

1, *start*[*ia*], *tol*[*ia*], *Tot*[*ia*]; for *hur* = 1, T_{ia} = *Tot*[*ia*] is constant throughout the group, and is to be printed.

2, *start*[*ia*], *tol*[*ia*], *Tot*[*ia*], *step*[*ia*]; for *hur* = 2, *Tot*[*ia*] starts at the given value and is then varied by steps, *step*[*ia*].

3, *start*[*ia*], *tol*[*ia*]; then *Tot*[*ia*] will be given for each point separately.

4, *start*[*ia*], *tol*[*ia*], A_0[*ia*], *AT*[*ia*]; titration—to V_0 ml of solution with $T_{ia} = A_0$[*ia*] one adds V_T ml of a solution with $T_{ia} = A_T$[*ia*] so that *Tot*[*ia*] = $(A_0*V_0 + A_T*V_T)/(V_0 + V_T)$.

5, log a_{ia}; then log a_{ia} is constant throughout group, to be printed.

6, log a_{ia}, step log$_{ia}$; then log a_{ia} starts as log a_{ia} and is then varied by steps, steplog $_{ia}$.

7, then log a_{ia} will be given at each point.

For *hur*[*ia*] < 5 only the total concentration *Tot*[*ia*] is known so that a_{ia} must be calculated from equation (5). One must then also give *start*[*ia*], which is the first guess for ln a_{ia}, and *tol*[*ia*] which indicates the deviation in T_{ia} (calculated), "*toly*", that we may tolerate when solving equation (5). If *tol*[*ia*] is given as a positive number, *toly*[*ia*]: =*tol*[*ia*]; if *tol*[*ia*] < 0, *toly*[*ia*]: =abs(*tol*[*ia*]*Tot*[*ia*]). If T_{ia} may be zero or negative, a positive *tol*[*ia*] must be used since one may otherwise soon get stuck in a loop.

Hur[*ia*] is set negative (for instance, −6, *loga*[*ia*], *steplog*[*ia*]) if *Noll*[*ia*] is **true**, hence the term a_{ia} is to be excluded from the expression (5) for the total concentration T_{ia}.

If *Pegas* is **true** (gas at constant pressure), one gives P_{tot} and the tolerance *tolp* for solving (9).

If at least some *hur*[*ia*] = 4, then a titration is considered, *Titer* is **true** and V_0 is given.

(III:3). Point data: V_T (if *Titer*), *Tot*[*ia*] (if *hur* = 3), *loga*[*ia*] (if *hur* = 7). If *hur* was 3 or 7 for some components, the promised values for *Tot*[*ia*] or *loga*[*ia*] are given, in the order of increasing *ia*. If not, and if in addition *Titer* is **false**, no point data are needed.

After I + II + III have been given, one may either start a new equilibrium problem with 0:1 and I, or finish the calculation by 0:2.

EXTENDING OR REDUCING THE PROGRAM

By changing the dimensions of the arrays, one may allow a practically unlimited number of reagents and complexes, although the amount of calculation may increase very much with increasing N_a and N_x.

The program—as far as we know—can handle the equilibria in systems that follow the ideal laws for dilute gases or solutions, that involve any number of solids and in addition one or two fluid phases at constant volume, a gas phase at constant pressure, or an ideal fluid mixture.

To adapt the program to other combinations, *e.g.*, more than two fluids with varying volume, solid solutions, *etc.*, one would have to make changes in the input and the calculation of the T_{ia}, but no new principal difficulties are expected. Likewise, by trivial changes one may ask for additional quantities to be printed, such as the *cf.*

Bringing variable activity factors into the picture would, of course, necessitate new loops.

The present program may also be abbreviated. Those who know that they will never want to study problems with solid phases, or with two fluid phases, or to have certain types of quantities printed, may remove the corresponding parts of the program. The exclusion of solid phases especially will make it considerably shorter.

TABLE II.—EXPLANATIONS OF SYMBOLS IN HALTAFALL (TABLE I)

real

det = determinant in Invert; *F* = factor for conversion from n_{ia}(*Ntot*[*ia*]) to T_{ia} (*Tot*) (8); *kbas* = factor in K_{ix} (or K_{if}) = *kbas*$*10^{pot}$; *lnc* = $\ln c_{ix}$; *ln*10=ln 10; *Ptot* = total gas pressure (9); *stegbyt* = see "input,III:1"; *tolp* = tolerance in solving (9) for *Ptot*; *VO* = original volume in titration; *VT* = added volume in titration; *Vtot* = total volume in titration; *x* = independent variable in $y(x)=y_0$(ADA); *y* = dependent variable; *y*0 = value for *y* aimed at in $y(x)=y_0$; *w*, *w1* = numerical values in general.

integer (nr = number)

i = integer in general; *ia* = serial nr of component A_{ia} (1→*Na*); *if* = serial nr of solid F_{if} (1→*Nf*); *ivar* = *ia* nr of component for which T_{ivar} (5) is being tested, and a_{ivar} adjusted (varied); *ix* = serial nr of complex X_{ix} (1→*Nx*); *j*,*m* = integer in general; *Na* = nr of components; *Nf* = nr of possible solid phases; *Nfall* = nr of solids present at equilibrium; *Nfspar* = nr of solids indicated at FALLPROV; *Np* = nr of points in group treated; *Npri* = nr of printing orders; *Ns* = nr of groups; *Nut* = nr of solids systematically eliminated at some stage while *Singfall* is **true**; *Nva* = nr of equations for T_{ivar} to be tested (a_{ivar} to be varied) in absence of solids; *Nvaf* = nr of equations to be tested in presence of solids (13); *Nx* = nr of complexes; *Nyfall* = number of new solids indicated at FALLPROV; *pot* = exponent in K_{ix} = *kbas*$*10^{pot}$; *Rp* = serial number of point treated; *Rs* serial nr of group treated; *Rva* = serial number of *iva*[*Rva*] treated.

Boolean

Bra = **true** if equation fulfilled within tolerance limits, or solution found consistent in FALLPROV; *Fas2* = **true** if second fluid phase exists; *Pegas* = **true** if gas at constant pressure is treated; *Singfall* = **true** if the first matrix $\mathbf{pf}_{be}$ tried has come out singular.
Titer = **true** if titration is treated.

arrays

usually *ia* can have values from 1 to *Na*, *if* from 1 to *Nf*, *ix* from 1 to *Nx*, *ivar* from *iva*[1] to *iva*[*Nva*+1]. Dimensions are given only where important and not obvious.
AO[*ia*], *AT*[*ia*] = total concentration of A_{ia} in original and added solutions at titration; *lna*[*ia*] = natural logarithm of activity a_{ia} of component A_{ia} (2); *Ntot*[*ia*] = number of moles of A_{ia} in portion considered, if *Pegas* (8); *start*[*ia*] = first guess for *lna*[*ia*] in solving (5); *steg*[*ia*] = step for adjusting *lna*[*ia*] in ADA; *step*[*ia*] = spacing between constant ln a_{ia} or *Tot*[*ia*] values to be considered; *tol*[*ia*] = *toly*[*ia*] = tolerance input (see input III:2), and absolute tolerance in solving equation (5) or (16) for *Tot*[*ia*]; *Tot*[*ia*] = T_{ia}, total concentration of component A_{ia} (5); *Totbe*[*i*] = term for *ia*=*ibe*[*i*] in $T_{be} - a_{be} - p_{be} * c$ [equation (15)], used for calculating *cf* (after FALLPROV); *Totmi*[*i*] = term in $T_{ia} - a_{ia}$ (or T_{ia}, if *Noll*[*ia*]) where *ia*=*ibe*[*i*], *i*=1→*Nfall* (Lnaber); *Totva*[*ia*] = term in T_{vaf} reduced total concentration in presence of solids (16*a*, Lnaber); *x1*[*ia*], *x2*[*ia*] = values for *x* below and above right value in ADA; *y1*[*ia*], *y2*[*ia*] = values for *y* corresponding to *x*1 and *x*2; *lnKf*[*if*] = ln *Kf*, where *Kf* = equilibrium constant for dissolution of solid F_{if} to form components (11); *lnKmi*[*if*] = term in **lnKf′**, reduced ln*Kf* (14*a*, Lnaber).
pf[*ia*,*if*] = number of formula units of component A_{ia} in formula unit of solid F_{if} (10); *p*[*ia*,*ix*] = number of formula units of component A_{ia} in complex X_{ix} (1); *pva*[*ia*,*ix*] = term in $\mathbf{p}'_{vaf}$, reduced **p** (16*b*, ANFALL); *ruta*[*i*,*j*] = term in $\mathbf{pf}_{be}^{-1}$ (11m′; 14,15, UTFALL); *rut1*[*i*,*j*] = term in $\mathbf{pf}_{vaf} * \mathbf{pf}_{be}^{-1}$ (16*a*,16*b*,ANFALL); *skriv*[*j*] = *j*'th quantity to be printed;
c[*ix*] = concentration of complex X_{ix} (3); *lnba*[*ix*] = part of ln(*c*[*ix*]) independent of *lna*[*ivar*] (4, Lnbas); *lnbeta*[*ix*] = ln K_{ix} where K_{ix} is the equilibrium constant for formation of complex X_{ix} from components (4).

Integer array

Fut[*i*] = *ifspar* number of *i*'th solid to be eliminated at some stage in systematic variation during *Singfall*; *Hur*[*ia*] = number characterizing type of information given on T_{ia} or lna_{ia} (input III:2); *ibe*[*m*] = *ia* number for m'th a_{ia} to be calculated by means of (14) (*m* = 1→*Nfall*); *iber*[*j*] = *j*'th of *iva* numbers to be an *ibe* (*ibe*[*j*] = *iva*[*iber*[*j*]]), *j* = 1→*Nfall*; *ifall*[*m*] = *if* number of *m*'th solid F_{if} present at equilibrium, *m*=1→*Nfall*; *ifspar*[*m*] = *if* number of *m*'th solid indicated as possible after FALLPROV (saved during Singfall); *iva*[*m*] = *ia* number for *m*'th T_{ia} to be tested in absence of solids (*m*=1→N_{va}); *ivabra*[*ivar*] = *ivar* to be tested after *ivar*, if (5) [or (16)] is satisfied (*Bra* **true**); *ivaf*[*m*] = *ia* number for *m*'th T_{ia} to be tested in presence of solids (*m*=1→N_{vaf}); *ivanov*[*ivar*] = *ia* to be tested after *ivar*, if equation (5) [or (16)] is not satisfied; *Karl*[*ia*] = control number for solving the equations (5) [or (16)] using switch ADA[*Karl*]; *Nober*[*ia*] = number of other components, which are independent of A_{ia} (compare Boolean array *Ober*); *prix*[*l*→N_{pri},1→2]=number indicating printing orders; *tryn*[*j*] = number indicating heading of *j*'th column in output table.

Boolean array

Ber[*ia*] = **true** if *lna*[*ia*] is calculated by means of (14); *Fall*[*if*] = **true** if F_{if} is assumed present at equilibrium; *Falla*[*ia*] = **true** if A_{ia} is assumed to occur in one or more solids at equilibrium; *Kifas2*[*ia*] = **true** if component A_{ia} is defined so that its a_{ia} = [A_{ia}] in the second phase; *Mono*[*ia*] = **true** if A_{ia} only takes part in mononuclear complexes (*p*[*ia*,*ix*]=0 or 1 for all *ix*); *Noll*[*ia*] = **true** if a_{ia} does not give a concentration term in T_{ia} (5); *ifas2*[*ix*] = **true** if complex X_{ix} occurs in the second phase; *Ober*[*i*,*j*] = **true** if a_i and a_j are "independent" (no complex or solid contains both A_i and A_j, hence *p*[*i*,*ix*]∗*p*[*j*,*ix*] =0 for all *ix*, and *pf*[*i*,*if*]∗*pf*[*j*,*if*]=0 for all *if*).

TABLE III.—EXAMPLES OF INPUT FOR HALTAFALL. EXPLANATIONS WITHIN PARANTHESES ARE, OF COURSE, NOT GIVEN AS INPUT

(3*a*) Components: Cu^{2+}, H^+, NH_3. Complexes: $Cu(NH_3)_n^{2+}$ (*n*=1,2,3,4,5), NH_4^+, OH^-, Solids: none. Printing orders: the log a_{ia} for Cu^{2+} and H^+, c_{ix} for $Cu(NH_3)_n^{2+}$ with *n*=0,1,2,3,4,5.
Group 1: $[Cu]_{tot}$ = 0·1*M*, $[NH_3]_{tot}$ = 0·5*M*, log $[H^+]$ varied from −11 to −1·5 in steps of 0·5.
Group 2: Titration. To 50 ml of solution with 0·10*M* Cu^{2+}, 0*M* excess of H^+ and 0·5*M* NH_3, increasing amounts of solution with 0*M* Cu^{2+}, 0*M* NH_3 and 1·0*M* H^+ are added.

```
   Input:

We are also indebted to Dr Hay Liem for help and valuable discussions in developing the "Fas2" part of the program, and to Dr George Baldwin for reading the manuscript, correcting the English and making helpful comments. This work has been supported by Statens Naturvetenskapliga Forskningsråd (The Swedish Natural Science Research Council) and by the United States Air Force, European Council of Aerospace Research, under its grants EO 65-22 and 63-8. We are also indebted to His Majesty the King of Sweden, who through various channels has given us free computer time.

Zusammenfassung—Das Rechenprogramm HALTAFALL wird beschrieben, das die Gleichgewichtskonzentrationen der Spezies in Gemischen aus jeder Zahl von Komponenten berechnet, die jede Anzahl von Komplexen und festen Reaktionsprodukten bilden können, sofern bei den Gleichgewichtsberechnungen Konzentrationen (oder Partialdrucke) benutzt werden können. Selbstverständlich müssen die Gleichgewichtskonstanten und genügend Daten über die analytische Zusammensetzung bekannt sein. Auf einige Anwendungen wird hingewiesen. Die flexiblen Eingangsregeln machen seine Anwendung auf ein breites Spektrum von Fragestellungen möglich. Aus der eingegebenen Information ermittelt das Programm selbst einen wirksamen Plan zur

Lösung der simultanen Gleichungen. Das Programm enthält auch die Möglichkeit, herauszufinden, welche unter vielen möglichen festen Phasen in einer gegebenen Gleichgewichtsmischung wirklich erscheint.

Résumé—On décrit un programme de computation, HALTAFALL, qui calcule les concentrations à l'équilibre des espèces dans des mélanges à n'importe quel nombre de composants, qui peuvent former n'importe quel nombre de complexes et de phases solides, en admettant qu'on peut utiliser les concentrations (ou les pressions partielles) dans les calculs d'équilibre. Evidemment, les constantes d'équilibre doivent être connues et l'on doit fournir suffisamment de données sur la composition brute. On indique quelques applications. Les règles souples d'admission le rendent applicable à des problèmes variés. A partir de l'information de départ, le programme lui-même établit un plan convenable pour la résolution des équations simultanées. Le programme fournit aussi un moyen efficace pour trouver laquelle des nombreuses phases solides possibles peut réellement apparaître dans un certain mélange en équilibre.

DETERMINATION OF TRACES OF ORGANIC FLUORINE IN HYDROCARBONS*

MARILYN MILLER and D. A. KEYWORTH
Universal Oil Products Company, Des Plaines, Illinois, U.S.A.

(*Received* 26 *April* 1967. *Accepted* 9 *June* 1967)

Summary—Organic samples containing down to 0·2 ppm of fluorine may be analysed by first converting the organic fluorine into inorganic fluoride by treatment with sodium biphenyl, followed by removal of diverse cations with a cation-exchanger before conductometric titration with lanthanum acetate. Effect of variables, sources of error, and control of reagent blanks are evaluated. For the 0·2–1 ppm organic fluorine level in synthetic blends made from 1-fluoronaphthalene, the relative estimated standard deviation was 7·8%; the mean relative error was 6·2%. Based on the mean range from duplicate analyses of catalytically processed samples in the C_{12} boiling range, at the 1 ppm fluorine level the estimated standard deviation was 0·087 ppm of fluorine. One analyst can determine the fluorine content of about 12 samples in 8 hr.

TRACES of organic fluorine can be produced in fluoride-catalysed petrochemical processes, and may adversely affect subsequent catalytic operations. Quality control may sometimes require determination of 1 ppm of fluoride.

Determination of traces of organic fluorine generally requires conversion of the fluorine in a large hydrocarbon sample into inorganic fluoride, followed by separation and determination. This carbon-fluorine bond cleavage is normally accomplished either by oxidation of all organic matter, or by reductive cleavage.[1] Attempts to oxidize the sample and recover all the fluoride at these low levels by using a quartz Wickbold burner[2] resulted in low recoveries. Use of sodium biphenyl[3] to accomplish the cleavage for traces of bromides, iodides and chlorides has been described.[4,5] Liggett[6] has reported the use of sodium biphenyl for reductive cleavage of organic fluorides where the organic fluoride was the major constituent. The rapid cleavage at room-temperature and the commercial availability of the reagent make this approach for the conversion of organic fluorine into fluoride ion an attractive one for control work.

Once the organic fluoride has been cleaved, there are several methods for determination of traces of inorganic fluoride that might be applied.[7] Attempts to use spectrophotometric methods employing either thorium chloranilate[8] or SPADNS [4,5-dihydroxy-3-(*p*-sulphophenylazo)-2,7-naphthalenedisulphonic acid, trisodium salt][9] after the sodium biphenyl treatment and hydrolysis were not successful; the blanks and recoveries were erratic, and seemed to be affected by traces of organic material from the biphenyl reagent.

Dowdall[9] has compared conductometric methods for determining traces of

* Presented to the American Chemical Society Division of Petroleum Chemistry, Miami Beach, Fla., 9–14 April 1967. Published by permission of American Chemical Society, owner of copyright of paper presented.

fluoride and recommends titration of 200–500 μg of fluoride in 0·01*M* acetic acid with lanthanum acetate. Experimentation with various titrants in our laboratories corroborates his findings. Kubota[10] has described a conductometric lanthanum acetate method for determination of down to 0·095 mg of fluoride as hydrofluorosilicic acid, obtained by the Willard and Winter[11] distillation, with a relative standard deviation of 9%.

Because of the exploratory laboratory results, and the literature cited, attention was directed toward combining the sodium biphenyl treatment and the conductometric titration. In such an approach about 100 g of hydrocarbon sample containing about 0·5 ppm of organic fluorine would be taken, so that about 50 μg of inorganic fluoride would be available for titration.

EXPERIMENTAL

Apparatus

Titrator. Conductometric titrations were performed with a recording potentiograph (Metrohm, Model E 336) with conductometric titration attachment (Metrohm, Model E 365). An immersion cell (Type 608) with a cell constant of 0·695 cm^{-1} and a 1-ml gear-driven microburette were employed, and each chart-paper division corresponded to 10 μg of fluoride.

Cation-exchange column. A 1·5-cm diameter column, 10 cm long, was flanged out at the top into a reservoir 10 cm × 3·0 cm diameter and equipped with a Teflon stop-cock at the bottom. The column was filled with 50 ml of Dowex 50W-X8 resin supported on a cotton wad (glass wool is unsatisfactory and causes erratic recoveries) and prepared for use by washing with four equal portions of a mixture of 70 ml of water and 30 ml of concentrated hydrochloric acid, followed by washing with 400 ml of demineralized water.

Reagents

Sodium biphenyl in 15-ml vials, and fluorine-free toluene (Southwestern Analytical Chemicals, Austin, Texas).

Lanthanum acetate titrant (0·15*N* La^{3+}) was prepared by dissolving about 16 g of lanthanum acetate and 1 ml of glacial acetic acid in 700 ml of demineralized water, heating to boiling, cooling, filtering, adding 1 ml of glacial acetic acid, diluting to 1 l. with demineralized water, and standardizing against sodium fluoride by conductometric titration.

Procedure

Add three vials of sodium biphenyl slowly to 100 ml of toluene in a 500-ml separatory-funnel, rotating the funnel continuously during the addition. The stop-cock and stopper of the separatory-funnel should be lightly greased with a fluorine-free lubricant; Teflon stop-cocks cannot be used in this part of the procedure. Add 100–200 ml of sample, mixing continuously with a gentle swirling motion throughout the addition. Let the mixture stand in the stoppered funnel for 10 min. Add 15 ml of demineralized water, shake, vent the funnel while it is inverted, and draw off and collect the aqueous lower phase. Repeat this three times more. Boil the combined aqueous extracts in a Vycor beaker until traces of hydrocarbon are no longer evident. Cool the boiled extract and pass it through the ion-exchange column. Wash the column with four separate 25-ml portions of 50% aqueous ethanol, collecting the effluent and the washings in a tall-form 250-ml beaker. Purge the combined effluent and washings for about 15 min with nitrogen to remove carbon dioxide. Titrate conductometrically with 0·15*N* lanthanum, using a 1-ml microburette. Obtain a reagent blank by substituting for the sample a fluoride-free solvent of similar hydrocarbon type.

RESULTS AND DISCUSSION

Standardization

Sodium fluoride was dried at 110° for 2 hr, and dissolved to produce a solution containing 0·1000 mg of fluoride per ml. Aliquots of this solution were diluted with 1*M* sodium hydroxide to 50 ml, to give roughly the conditions obtained after hydrolysis of the sodium biphenyl used in the procedure. Neither this solution nor a portion

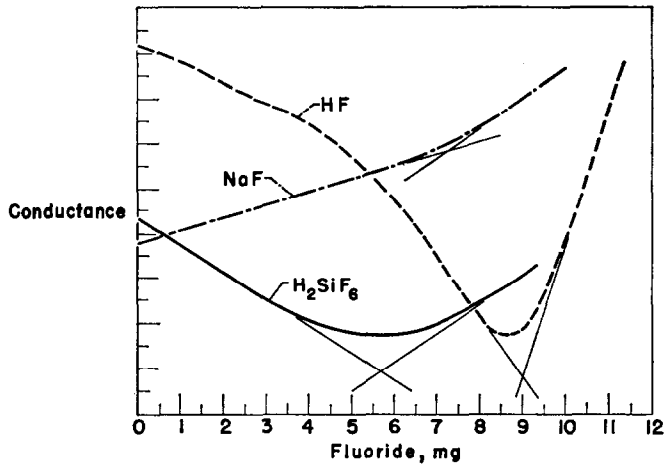

FIG. 1.—Conductometric end-points in presence of large amounts of sodium ions.

neutralized with acetic acid is suitable for titration directly, because the conductance of the large concentration of sodium ions causes an ill-defined end-point (Fig. 1). A satisfactory end-point is obtained with down to 1 mg of fluoride (Fig. 2) if the solution is neutralized by passing it through the cation-exchange column, and the carbon dioxide in the effluent and washings is removed by nitrogen stripping. The time required for removal of carbon dioxide by nitrogen stripping is determined experimentally (Table I), and for our apparatus was about 15 min. Recovery experiments showed that as little as 0·2 mg of fluoride may be determined conductometrically in this way, and that the estimated standard deviation is 0·007 mg for the range 0·2–1·0 mg (Table II).

Because the Willard and Winter distillation is commonly used to separate inorganic fluoride from many interfering substances, aliquots of standard hydrofluorosilicic acid were distilled to determine whether the conductometric titration could be used to titrate the fluoride present as SiF_6^{2-} in the distillate. The relative error for 0·1–0·4 mg of fluoride was 4%; for 0·5–1·0 mg of fluoride in the ion-exchange effluent, the relative

Pyrex (new)	0·205 0·256
Pyrex (old)	0·815 0·977

error was 5% (Table II). Either the ion-exchange separation or the Willard and Winter distillation is therefore an acceptable pretreatment to the conductometric titration of fluoride. Irrespective of which pretreatment is used, if the temperature of the solution being titrated is allowed to drift more than $\pm 0{\cdot}5°$ during the titration, the end-point will be less clearly defined. Because of its simplicity, the ion-exchange separation was preferred. The column is regenerated with hydrochloric acid after each sample and washed with water, according to the procedure given for preparation of the column. Care must be taken to avoid any leakage of resin past the cotton plug support into the effluent, since the presence of even small amounts of resin in the titration vessel causes excessive titrant consumption (Table III). Before the sample

is passed through the column, any organic solvent left over from the extraction should be removed by boiling in a Vycor or metal beaker. The blanks from such beakers are reproducible whereas higher blanks are obtained if Pyrex is used, particularly if it is old and scratched, when the blanks are very variable, presumably due to leaching of fluoride from Pyrex by the alkali produced from the hydrolysis of the sodium biphenyl (Table IV).

In order to evaluate the proposed procedure, standard blends of 1-fluoronaphthalene in iso-octane and in n-dodecane were prepared. The 1-fluoronaphthalene

TABLE VI.—DUPLICATE ANALYSES OF DODECANE SAMPLES CONTAINING FLUORIDE FROM CATALYTIC PROCESSING

Sample No.	Trial 1, *ppm* F	Trial 2, *ppm* F	Range, *ppm* F
1	1·08	1·22	0·14
2	0·54	0·64	0·10
3	0·87	0·80	0·07
4	0·88	0·77	0·11
5	0·67	0·56	0·11
6	0·33	0·23	0·10

used was analysed by two independent methods and found to have a purity of 98·3%. For the 0·2–1·0 ppm organic fluorine level in the synthetic blends with 1-fluoronaphthalene (Table V), the relative estimated standard deviation was 7·8%; the mean relative error was 6·2%. From these data the method is judged to be able to determine $0{\cdot}2 \pm 0{\cdot}1$ ppm of fluorine. The estimated standard deviation calculated from the mean range of duplicate analyses of catalytically processed samples in the C_{12} boiling

range, at the 1-ppm fluorine level (Table VI), was 0·087 ppm of fluorine. One analyst can determine fluorine in about 12 samples in 8 hr.

It is expected that there will be very few serious interferences since either the Willard and Winter distillation or the ion-exchange separation will remove most of them. The main limitation to further improvement in detection limits results from the sodium biphenyl reagent blank. The conductometric titration is capable of quantitatively determining fluoride even at levels below 0·1 ppm.

Zusammenfassung—Organische Proben mit bis zu 0,2 ppm Fluor lassen sich analysieren durch Umwandeln des organischen Fluors in anorganisches durch Behandlung mit Diphenylnatrium, nachfolgende Entfernung verschiedener Kationen mit einem Kationenaustauscher und konduktometrische Titration mit Lanthanacetat. Der Einfluß variabler Größen, Fehlerquellen und Kontrolle der Blindwerte wurden verfolgt. Bei Testmischungen aus 1-Fluornaphthalin mit 0,2–1 ppm organischem Fluor war die relative Standardabweichung 7,8%, der mittlere relative Fehler 6,2%. Beruhend auf dem Mittelwert von Doppelanalysen katalytisch behandelter Proben im C_{12}-Siedebereich war die Standardabweichung im 1 ppm-Bereich 0,087 ppm Fluor. Ein Analytiker kann den Fluorgehalt von etwa 12 Proben in 8 Stunden bestimmen.

Résumé—On peut analyser des échantillons organiques contenant seulement 0,2 p.p.m. de fluor en transformant d'abord le fluor organique en fluorure inorganique par traitement au biphénylsodium, puis en éliminant divers cations par un échangeur de cations avant titrage conductimétrique à l'acétate de lanthane. On a estimé l'influence des variables, des sources d'erreurs et du contrôle des témoins de réactifs. Pour les teneurs 0,2–1 p.p.m. en fluor organique dans des mélanges synthétiques faits à partir du 1-fluoronaphtalène, l'écart type relatif estimé a été de 7,8%; l'erreur relative moyenne a été 6,2%. En se basant sur l'intervalle moyen à partir d'analyses en double d'échantillons réalisés catalytiquement dans le domaine d'ébullition C_{12}, à la teneur en fluor de 1 p.p.m., l'écart type estimé a été de 0,087 p.p.m. de fluor. Un analyste peut déterminer la teneur en fluor d'environ 12 échantillons en 8 h.

SEPARATION AND ACID EQUILIBRIA OF XYLENOL ORANGE AND SEMI-XYLENOL ORANGE

MITSUMASA MURAKAMI, TAKASHI YOSHINO and SHIRO HARASAWA
Department of Chemical Technology, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube, Japan

(*Received* 15 *February* 1967. *Accepted* 29 *March* 1967)

Summary—A mixture of Xylenol Orange (XO) and Semi-Xylenol Orange (SXO) was chromatographed on a cellulose column and ion-exchanged with Diaion SK-1 resin. XO and SXO in the acidic forms were titrated with sodium hydroxide to determine the basicities and the acid formation constants. The absorption spectra of XO and SXO were measured over a wide pH range, and were used for the calculation of acid formation constants, molar absorptivities, and the effect of ionic strength on the activity of XO. The purity of a commercial XO was measured by absorption spectroscopy, and it was found that the sample contained 36·3% of XO and 17·2% of SXO. Pure XO and SXO form a 1:2 and a 1:1 complex respectively with Zn(II). On the basis of these data the ionic structure of XO and SXO have been compared with those of Cresol Red and iminodiacetic acid, and discussed.

AS PART of an investigation on the chelates formed between sulphonphthalein derivatives and metal ions, the purification and some physico-chemical properties of Xylenol Orange (XO) and Semi-Xylenol Orange (SXO) were studied, and the structures were confirmed. Previous workers[1–3] have reported that XO has been synthesized from Cresol Red, iminodiacetic acid and formaldehyde by the Mannich condensation, and the structure was supposed to be 3,3′-bis[*N*,*N*′-di(carboxymethyl)aminomethyl]-*o*-cresolsulphonphthalein. So far as is known, however, the purification of this compound has never been successful, so that the mole ratio, suitable pH range, wavelength of maximum absorption, molar absorptivity and stability constant have been uncertain in the case of the chelate of XO and a metal ion such as Zr(IV),[4–7] Th(IV),[8,9] or Fe(III).[10–11]

Olson and Margerum have pointed out that SXO could be isolated from a mixture with XO by paper chromatography.[3] In the present work cellulose column chromatography and ion-exchange were used for separation of XO and SXO. The purity of XO and SXO separated by these methods was nearly 100% and the purity of each XO used in other work[4,8,12–23] could be evaluated by comparison of the data.

EXPERIMENTAL

Apparatus

A Toadenpa pH meter, Model HM-5A, was used. Standard buffer solutions (phthalate, phosphate, borate, 0·1*M* hydrochloric acid and 0·1*M* sodium hydroxide) were used for calibration.

All the absorption measurements were made with a Shimadzu Model SV-50AL spectrophotometer, with a 1-cm cell.

Toyo Roshi No. 52 paper was used for paper and cellulose column chromatography. Metals contained as impurity in the paper were almost all removed by developing with a hydrochloric acid–acetone solution. The cellulose column was prepared by shaking the paper with hot 1*M* nitric acid and packing the slurry.

Reagents

Sodium hydroxide solution, 0·1*M*. Carbonate free.

Buffer solutions. The following buffer solutions were used, adjusted to the value required.

pH 9·5–14: potassium hydroxide solution
pH 8–11: 1*M* ammonia–1*M* ammonium nitrate
pH 3–9·5: 1*M* veronal–1*M* acetic acid–1*M* potassium hydroxide
pH 3–6·5: 1*M* hexamine–1*M* nitric acid
pH 1–3: nitric acid
pH (H_0) 0·5: sulphuric acid

The reagents were analytical grade materials.

Synthesis of XO and SXO

These were synthesized by the Mannich condensation.[1-3] *o*-Cresol Red (1·91 g; 5×10^{-3} mole), 37% formaldehyde (1·00 ml; $1{\cdot}2 \times 10^{-2}$ mole), iminodiacetic acid (1·33 g; 1×10^{-2} mole), and sodium hydroxide (1 g) were dissolved in glacial acetic acid (50 ml). The mixture was heated at 63–65°. After 10 hr, the solvent was distilled off under reduced pressure.

Recrystallization from a polar solvent

Recrystallization of XO and SXO from alcohol, ketones, and esters was unsuccessful. From ethanol–sodium acetate solution, XO was precipitated, but part of it was decomposed to a red compound which formed no chelates with metal ions.

Separation by column chromatography and ion-exchange

The synthesized XO was chromatographed on alumina, silica gel, cation-exchange resin, and cellulose. On alumina and silica gel XO was decomposed, and from the ion-exchange resin a part of the XO could not be eluted. The mixture of XO and SXO was completely separated on a cellulose column by butanol saturated with 10% acetic acid. The elution order was: an unknown white compound, Cresol Red, sodium ions, SXO, XO, and iminodiacetic acid. The solvent was distilled off from each fraction under reduced pressure. The SXO and XO were the disodium and trisodium salt respectively. The SXO (1 g) was run through a column of Diaion SK-1 100-mesh cation-exchange resin (10–20 mequiv). The effluent solvent was distilled under reduced pressure and the residue was dried in a vacuum desiccator for two weeks. The compound was the free acid form of SXO, m.p. 201–204° (decomp.). Found: C, 57·6%; H, 5·0%; N, 2·6%; $C_{26}H_{25}O_9NS.H_2O$ requires: C, 57·24%; H, 4·99%; N, 2·57%.

The ion-exchange method used for XO containing sodium ions was virtually identical with that described for SXO, but the acid form of XO was again chromatographed and ion-exchanged to remove iminodiacetic acid completely. The product had m.p. 274–277° (decomp.). Found: C, 52·3%; H, 5·2%; N, 4·1%. $C_{31}H_{33}O_{18}N_2S.2H_2O$ requires: C, 52·54%; H, 5·11%; N, 3·95%.

Potentiometric titration

The acid form of XO (67·3 mg) was dissolved in 45 ml of water and 5 ml of 1*M* potassium nitrate, and the solution was titrated with 0·1*M* sodium hydroxide at 25 ± 0·1°, under nitrogen. Similar titrations were performed with the acid form of SXO and a commercial XO (Dotite XO).

Absorption spectra

To a 25-ml volumetric flask, 1 ml of 1–2·5 × 10^{-4}*M* XO or SXO solution, 0·5 ml of the buffer solution, and 2 ml of 1*M* potassium nitrate were added and diluted to the mark with water. The absorption spectrum of the solution was measured at room temperature. When the solution had only a small buffer action, it was measured under nitrogen so that the pH error might be below 0·03 within the range of pH 2–10.

RESULTS AND DISCUSSION

The synthesis and separation of XO and SXO

The removal of iminodiacetic acid and SXO from impure XO is difficult by means of recrystallization, and what is worse, iminodiacetic acid and SXO form chelates with many metal ions. Table I shows that XO is decomposed by methanol, ethanol and propanol and that the R_f value on a cellulose column is related to the number of

* Samples in the free acid form.

carboxyl groups in the molecule and to the number of sodium ions. Cresol Red and SXO were separated on a cellulose column from the sodium salts of XO, and XO and iminodiacetic acid were separated from the acid form of SXO. The purities of the products were established by elemental analysis, titration, paper chromatography, and absorption spectra.

SXO was easily synthesized at 55° with the theoretical amount of starting materials.

Calculation of acid formation constants from the pH titration curve

The acid formation constant is more suitable than the acid dissociation constant for discussion over a wide pH range. The constants are calculated by the methods of Bjerrum[24] and Block *et al.*[25] As the acid is of the H_NI type, then

$$H^+ + I^{N-} \rightleftharpoons HI^{(N-1)-},\ H^+ + HI^{(N-1)-} \rightleftharpoons H_2I^{(N-2)-},\ \ldots,\ H^+ + H_{(N-1)}I^- \rightleftharpoons H_NI \quad (1)$$

$$k_1 = [HI^{(N-1)}]/[H^+][I^{N-}],\ k_2 = [H_2I^{(N-2)-}]/[H^+][HI^{(N-1)-}],\ \ldots,\ k_N = [H_NI]/[H^+][H_{(N-1)}I^-] \quad (2)$$

$$C_S = \sum_{n=0}^{N} [H_nI^{(N-n)-}] \quad (3)$$

$$\bar{n} = C_H - [H^+] + [OH^-]/C_S = \sum_{n=1}^{N} J_nK_n \quad (4)$$

$$J_n = (n - \bar{n})[H^+]^n \quad (5)$$

C_S = Total concentration of the acid

C_H = Total concentration of protons

$\bar{n}$ = Mean number of protons in the acid

$k_1, k_2, \ldots, k_N$ = Acid formation constants

$K_n = k_1k_2 \ldots k_N$

$[H^+]$ is measured potentiometrically, C_S and C_H are calculated from the pH titration curve, and then the acid formation constants are calculated from equations (4) and (5). The concentration of free protons is corrected for the activity coefficient, which is measured by pH titration of nitric acid under the same conditions.

The pH titration curves of XO and SXO are shown in Fig. 1. The curves show the acid forms of XO and SXO to be H_6XO and H_4SXO as might be expected. Within the titration range 0–3 ml, the equilibria of XO are those of a strong acid corresponding to H_3I. From equations (3) and (4), an initial value of 1·092 was obtained for $\bar{n}$

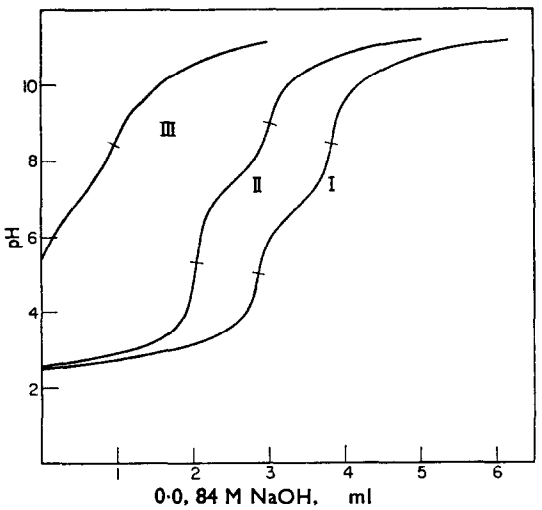

FIG. 1.—pH titration curves, at 25·0 ± 0·1°C.
I—67·3 mg of $H_6XO.2H_2O$; II—52·8 mg of $H_4XO.H_2O$; III—71·7 mg of Dotite XO; each in 50 ml of 0·1*M* KNO_3.

(*i.e.*, for an untitrated solution), which showed the existence of H_3XO^{3-}, H_4XO^{2-}, and H_5XO^-. From equations (4) and (5), $\log k_4 = 2{\cdot}85 \pm 0{\cdot}06$ and $\log k_5 = 2{\cdot}32 \pm 0{\cdot}15$ were calculated. Over the titration range 3–5 ml the solution will contain HXO^{5-}, H_2XO^{4-}, and H_3XO^{3-}. The equilibria correspond to those of H_2I and at 4·30 ml titration $\bar{n} = 0{\cdot}606$, which shows the existence of HXO^{5-}. For the equilibria, $\log k_2 = 10{\cdot}39 \pm 0{\cdot}05$ and $\log k_3 = 6{\cdot}67 \pm 0{\cdot}03$ were calculated.

The calculation of the acid formation constants of SXO is virtually identical with that of XO. $\log k_1 = 10{\cdot}90 \pm 0{\cdot}15$, $\log k_2 = 7{\cdot}44 \pm 0{\cdot}03$, and $\log k_3 = 2{\cdot}60 \pm 0{\cdot}06$ were calculated for the equilibria between SXO^{4-}, $HSXO^{3-}$, H_2SXO^{2-}, and H_3SXO^-. In this report all the constants are mixed constants and the accuracy of each was estimated by considering the accuracy of the pH titration and the absorption measurements.

Calculation of acid formation constants from absorption spectra

Both XO and SXO have a variation in colour over a wide pH range. The concentration of each species is determined from its absorbance. Between pH 2 and 5, however, XO or SXO have identical absorption curves, so the pH method is used for this region. When the equilibria shown in equations (1), (2) and (3) are in existence,

the absorbances should be in accordance with the equation (6).

$$A = \sum_{n=0}^{N} \varepsilon_{H_nI}[H_nI^{(N-n)-}] \tag{6}$$

From equations (2), (3) and (6) we obtain

$$A - C_s\varepsilon_I = \sum_{n=1}^{N} J_n' k_1 k_2 \ldots . k_N \tag{7}$$

$$J_n' = (C_s\varepsilon_{H_nI} - A)[H^+]^n \tag{8}$$

A = Absorbance

ε = Molar absorptivity

J_n' = A parameter used to calculate the acid formation constant.

Acid formation constants are calculated from equations (4), (7) and (8) used as simultaneous equations. The calculation does not necessitate knowledge of C_s and $[H_nI^{(N-n)-}]$, but A, $[H^+]$, and $C_s\varepsilon_{H_nI}$ will suffice so long as C_s is constant. If $C_s\varepsilon_{H_nI}$ cannot be measured, the constants containing it are calculated for many values of A and $[H^+]$, and $C_s\varepsilon_{H_nI}$ and the acid formation constants are derived from them by iterative calculation.

The absorption spectra of $1{\cdot}001 \times 10^{-5}M$ SXO and $8{\cdot}05 \times 10^{-6}M$ XO below pH 2 are shown in Figs. 2, 3 and 4. Figure 4 also shows the curves calculated from the constants determined in the course of this work. Acidity below pH 1 is indicated by the Hammett function H_0.[26,27] From pH 2 to H_0 0·35 the absorption of SXO gradually increases at 510 mμ and below H_0 0·35 SXO has strong absorption at 510 mμ and an isosbestic point at 470 mμ. The equilibria may be among H_4SXO, H_5SXO^+, and H_6SXO^{2+}. From the equations above, $\varepsilon_{H_5SXO} = 1{\cdot}54 \times 10^4$, $\log k_5 = 0{\cdot}53 \pm 0{\cdot}03$, and $\log k_6 = -0{\cdot}65 \pm 0{\cdot}05$ were calculated, using $C_s\varepsilon_{H_4SXO} = 0{\cdot}050$, $C_s\varepsilon_{H_6SXO} = 0{\cdot}670$, and $A = 0{\cdot}105$ (H_0 0·67), 0·201 (H_0 0·045), and 0·565 (H_0 −1·24) at 510 mμ. On the other hand the absorption spectra of XO show three equilibria below H_0 0·5. The absorbance increases at 450–490 mμ in regard to the first equilibrium and at 515 mμ in regard to the second equilibrium near H_0 −1. At 480 mμ, $\varepsilon_{H_7XO} = 1{\cdot}78 \times 10^4$, $\log k_7 = -1{\cdot}04 \pm 0{\cdot}05$, and $\log k_8 = -2{\cdot}29 \pm 0{\cdot}08$ were calculated for the equilibria between H_6XO, H_7XO^+, and H_8XO^{2+}. The absorbances between H_0 −0·86 and −5 were corrected by means of k_7 and k_8. By using the corrected values, $\varepsilon_{H_8XO} = 6{\cdot}45 \times 10^4$, $\log k_6 = -1{\cdot}83 \pm 0{\cdot}06$, and $\log k_9 = -3{\cdot}32 \pm 0{\cdot}08$ were obtained for the equilibria of H_7XO^+, H_8XO^{2+}, and H_9XO^{3+}.

The absorption spectra of SXO between pH 3·7 and 14 are shown in Fig. 5. Near pH 7, $\varepsilon_{HSXO} = 5{\cdot}58 \times 10^4$ and $\log k_2 = 7{\cdot}47 \pm 0{\cdot}03$ were obtained from the pH value corresponding to the mid-point of the absorbance increase at 573 mμ as the pH was raised. Above pH 9 the absorption increases gradually with the addition of alkali, and $\log k_1 = 10{\cdot}90 \pm 0{\cdot}15$ was obtained from the pH value of the mid-point of the absorbances corrected for ε_{HSXO} and k_2.

The absorption spectra of XO between pH 1 and 14 shown in Figs. 6 and 7 are similar to those obtained by Řehák and Körbl[28] but the absorbances are about one and a half times as large. The calculations for XO were carried out as described above, and the results are shown in Table I.

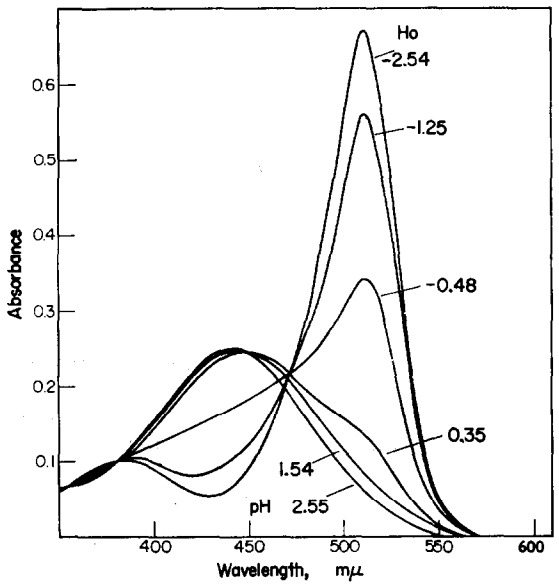

FIG. 2.—Absorption spectra of SXO ($1{\cdot}001 \times 10^{-5}M$ in 1-cm cells, from $H_0 = -2{\cdot}54$ to pH = 2·55).

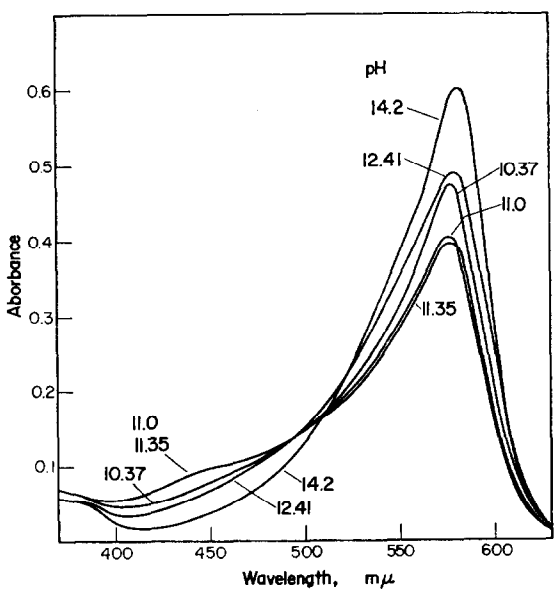

FIG. 7.—Absorption spectra of XO from pH 10·37 to 14·2 (conditions as in Fig. 6).

Effect of ionic strength on the activity of XO

If the equilibrium between red XO and orange XO is that between H_2XO^{2-} and H_3XO^{3-}, the equation will be described[29] by

$$\Delta \log k_3 = \log (\gamma_{H_2XO}/\gamma_{H_3XO})_x - \log (\gamma_{H_2XO}/\gamma_{H_3XO})_o. \quad (9)$$

γ = Activity coefficient of the ion indicated by subscript

$\Delta \log k_3$ = Difference between the apparent and true acid formation constant

Subscripts x and o = Actual and infinitely dilute solution respectively.

When the Debye-Hückel limiting law holds good ($\mu < 0{\cdot}01$), equation (9) becomes

$$\Delta \log k_3 = (3^2 - 4^2) \times 0{\cdot}509 \sqrt{\mu} = -3{\cdot}5 \sqrt{\mu}. \quad (10)$$

The acid formation constants were obtained spectrophotometrically in this way. The results, and data for Cresol Red for comparison,[29] are shown in Fig. 8. The slope is similar to that of equation (10). Cresol Red is a dibasic acid, and gives a slope of $-1{\cdot}5$. This shows that the activity coefficient of XO ion can be calculated from the Debye-Hückel equation, that the equilibrium near pH 7 is between H_2XO^{4-} and H_3XO^{3-}, and that the formation constants of XO-metal chelates are affected by the ionic strength.[30]

The equilibria of SXO

The wavelengths of absorption maxima and the formation constants of XO, SXO, Cresol Red and iminodiacetic acid are shown in Table II. On the alkaline side the equilibrium between the red SXO and yellow SXO corresponds to the dissociation of the hydroxyl group.[31] Above pH 10 the molar absorption of SXO increases gradually, but not that of Cresol Red, so that $\log k_1$ corresponds to $\log k = 9{\cdot}65$ for iminodiacetic acid. Between pH 2 and 5 the colour of the solution has not changed, and $\log k_3$ and $\log k_4$ are similar to those of the carboxyl groups. Below pH 2 the two constants corresponding to those of the quinone and sulphonic acid groups[32] are lower than the constants for Cresol Red ($\log k = 1{\cdot}00$). The constant observed by Olsen and Margerum[3] is compared with $\log k_5$ and $\log k_6$ calculated by us. All the equilibria of SXO are shown in Fig. 9.

The equilibria of XO

The equilibrium constants of XO obtained by Řehák and Körbl[28] are different from ours on the acidic side but similar on the alkaline side. This shows that their sample might have contained about 30% of iminodiacetic acid and a small amount of SXO. The three constants obtained in strongly acidic solution are based on the protonations of the carboxyl, quinone, and sulphonic acid groups, and correspond to the three constants of SXO (k_4, k_5 and k_6).[31,32]

In view of the facts it seems most reasonable to conclude as follows. (1) SXO and XO have one and two di(carboxymethyl)aminomethyl groups respectively. (2) The acid formation constants of SXO and XO are similar to those of Cresol Red and iminodiacetic acid. (3) The protonations of the sulphonic acid and quinone group of

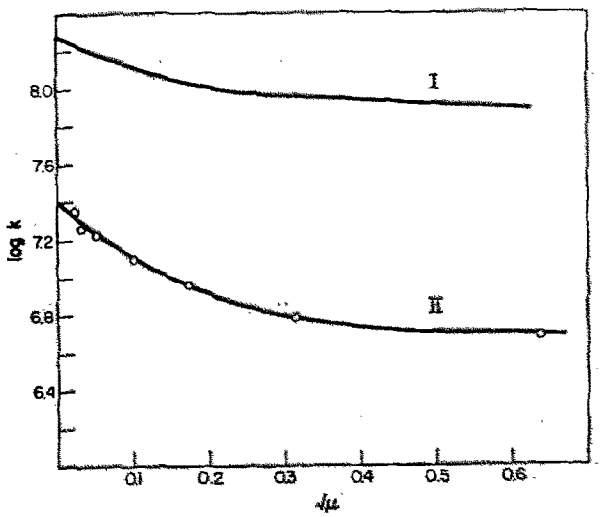

FIG. 8.—Effect of ionic strength on acid formation constants.

Salt used—KNO_3; I—$H^+ + CR^{2-} \rightleftharpoons HCR^-$; II—$H^+ + H_2XO^{4-} \rightleftharpoons H_2XO^{3-}$ (CR = Cresol Red).

SXO and XO are separately observed in strongly acidic medium. (4) The di(carboxymethyl)aminomethyl group is as weakly bathochromic as the methyl group and increases the molar absorptivity; it also influences slightly the non-localized electron of the sulphonphthalein group. As a final check, the curve for *n vs.* pH, calculated from the constants obtained in this work, was compared with the experimentally observed values. The results in Fig. 10 show excellent agreement.

The purity of a commercial XO reagent

From Fig. 1 the molecular weights of XO and SXO were calculated to be 705 ± 5 and 547 ± 3, which agreed well with the theoretical weights of 708·7 for $C_{31}H_{32}O_{13}N_2S.2H_2O$ and 545·5 for $C_{26}H_{25}O_9NS.H_2O$ respectively. The pH titration curve of a commercial XO (Dotite XO) is also shown in Fig. 1. The curve shows the commercial XO to be the trisodium salt with an apparent purity of 109%, but chromatography showed the reagent contained SXO. The absorption curves of pure XO, pure SXO, and the Dotite reagent are shown in Fig. 11. From the absorbances A_{435} at 435 mμ (pH 3·11) and A_{510} at 510 mμ (1·44*M* H_2SO_4) the purity of a sample of XO reagent can be calculated by means of the equations

$$A_{435} = 2{\cdot}62 \times 10^4 C_{XO} + 2{\cdot}52 \times 10^4 C_{SXO} \quad (11)$$

$$A_{510} = 0{\cdot}472 \times 10^4 C_{XO} + 3{\cdot}21 \times 10^4 C_{SXO} \quad (12)$$

where C_{XO} and C_{SXO} = concentrations of XO and SXO respectively, in the reagent solution. From the equations, 36·3% of XO and 17·2% of SXO were found for this trisodium salt. From the reports dealing with the XO–metal chelates, 30–40% of XO and 10–15% of SXO[19,33,34] or 40–50% total of XO and SXO[4,5,12–18,20–23] in the reagents used were calculated from the data of the absorption spectra. The molecular weight of SXO was measured by Olson and Margerum,[3] but the molar absorptivity

used was only 66% of that found by us. Impure XO and SXO may contain 30–50% of iminodiacetic acid which is difficult to remove by means of recrystallization. Figure 12 shows that XO and SXO form 1:2 and 1:1 chelates respectively with Zn(II) (*i.e.*, $XOZn_2$ and SXOZn), but Šťudlar and Janoušek's curve[20] shows a 1:1 chelate.

Although many papers have claimed that Methylthymol Blue[35–38] and XO[7,10,14–20,23,30,34,39–41] form 1:1 chelates with many metals, it now seems that XO forms at least some 1:2 chelates.

Résumé—On a chromatographié un mélange de Xylénol Orangé (XO) et de Semi-Xylénol Orangé (SXO) sur une colonne de cellulose puis procédé à l'échange d'ions avec la résine Diaion SK-1. On a titré XO et SXO sous formes acides par la soude pour déterminer les basicités et les constantes de formation d'acide. On a mesuré les spectres d'absorption de XO et SXO dans un large domaine de pH et les a utilisés pour le calcul des constantes de formation d'acide, des absorptions moléculaires et de l'effet de la force ionique sur l'activité de XO. On a mesuré la pureté d'un XO commercial par spectroscopie d'absorption et a trouvé que l'échantillon contenait 36,3% de XO et 17,2% de SXO. XO et SXO purs forment des complexes 1:2 et 1:1 respectivement avec Zn (II). Sur la base de ces données, on a comparé la structure ionique de XO et SXO à celles du Rouge de Crésol et de l'acide iminodiacétique et en discute.

Zusammenfassung—Ein Gemisch von Xylenolorange (XO) und Semi-Xylenolorange (SXO) wurde an einer Cellulosesäule chromatographiert und mit Diaion SK-1 dem Ionenaustausch unterworfen. XO und SXO wurden in saurer Form mit Natriumhydroxid titriert, um Basizitäten und Dissoziationskonstanten zu bestimmen. Die Absorptionsspektren von XO und SXO wurden in einem großen pH-Bereich gemessen und zur Berechnung der Dissoziationskonstanten, der molaren Extinktionskoeffizienten und des Einflusses der Ionenstärke auf die Aktivität von XO herangezogen. Die Reinheit von käuflichem XO wurde durch Absorptionsspektrometrie geprüft; die Probe enthielt 36,3% XO und 17,2% SXO. Reines XO und SXO bilden einen 1:2- bzw. 1:1- Komplex mit Zink(II). Auf Grund dieser Daten wurde die Ionenstruktur von XO und SXO mit der von Kresolrot und Iminodiessigsäure verglichen und diskutiert.

DIRECT TITRATION OF GLYCEROL BY CONSTANT CURRENT POTENTIOMETRY

J. R. SAND and C. O. HUBER
Department of Chemistry, University of Wisconsin–Milwaukee, Wisconsin 53201, U.S.A.

(*Received* 13 *April* 1967. *Accepted* 8 *June* 1967)

Summary—A direct, constant-current potentiometric titration method allows quantitative determination of 0·50–5·00 mg samples of glycerol in aqueous solution with errors ranging from 0·2% for the large samples to 2·0% for the smaller samples. Perchloratocerate is used as the standard oxidant and pyrolytic graphite as the electrode material. A direct determination is made possible by elevated temperatures, high acidity, and a relatively large constant current. Sources of error and possible interferences are discussed.

BECAUSE of its wide use and natural occurrence many methods have been devised for the determination of glycerol in aqueous solution. The convenience and simplicity of the "wet" volumetric methods account for their continued importance. The most common of these are esterification to the triacetate followed by hydrolysis and an acid–base titration, and oxidation by excess of chromate, periodate or cerate followed by back-titration of the excess oxidant. The indirect cerate titration was first described by Smith and Duke,[6] who showed that the reaction rate in perchloric acid was definitely higher than in sulphuric acid solution. The equation indicating the stoichiometry is as follows:

$$8Ce^{4+} + C_3H_5(OH)_3 + 3H_2O \rightarrow 3HCOOH + 8Ce^{3+} + 8H^+$$

The work presented here describes the direct titration of glycerol in perchloric acid solution by constant-current potentiometry[4] with pyrolytic graphite electrodes (PGE). Miller and Zittel[2] have shown the apparent reversibility of the cerate–cerous system at a pyrolytic graphite cathode.

EXPERIMENTAL

The electrodes used were two $\frac{1}{4} \times \frac{1}{4} \times \frac{1}{4}$ in. rods of pyrolytic graphite with the higher conductivity along the rod axis. The sides of the cathode were covered with a mixture of 80% Epolene C-10® (Eastman-Tennessee) and 20% high-melting paraffin wax, leaving only the end of the cathode exposed. The constant current in the system was maintained by a 90-V battery in series with a 900,000 ohm resistor. A commercially available pH meter with 0–1400 mV scale, or a digital vacuum tube voltmeter, was used to measure the potential difference between the two pyrolytic graphite electrodes.

Titrations were carried out in 150-ml beakers. A combination heater–magnetic stirrer was used to heat and stir the titration solutions. A heat reservoir in the form of a water-bath or an aluminium block maintained the temperature sufficiently constant during the titration.

Reagents

All chemicals were reagent grade and used as supplied. The perchloratocerate was prepared by mixing ammonium hexanitratocerate with enough concentrated perchloric acid to give a solution 2*F* in perchloric acid when diluted. Any hydrolysis precipitates were removed before the solution was standardized and used.

Procedure

Two pyrolytic graphite electrodes polarized by a 100-μA constant current, were immersed in a stirred solution of 2*F* perchloric acid which was heated to 80°. The glycerol sample was then added

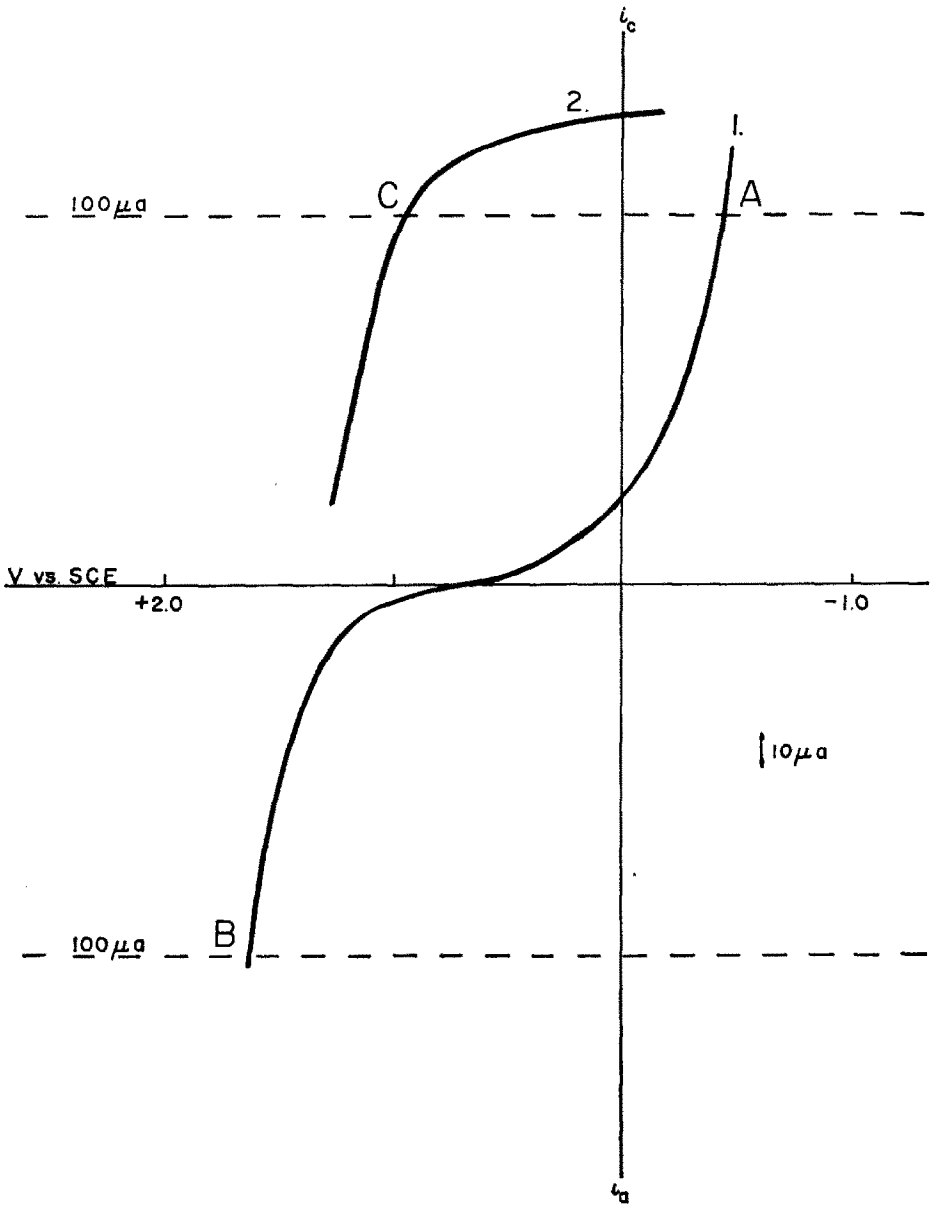

FIG. 1.—Current–voltage curves in 2*F* $HClO_4$ at 25°C.
1. Residual current. 2. Cerate reduction.

to the heated solution. The resulting solution was titrated with the perchloratocerate until the voltage between the electrodes changed to 0·3 V from initially high values of about 1·6 V. The end-point was defined as the volume at which a one-drop increment of titrant caused the potential to remain at or below 0·3 V for 30 sec. A blank was determined.

RESULTS AND DISCUSSION

The accuracy and precision of the proposed method were established by comparing the volume of titrant used for several direct titrations of 5-ml aliquots of 0·01114*M* glycerol solution with the volume used in a well-established indirect cerate oxidation method.[5] The results of this comparison are summarized in Table I. This table

TABLE I

Direct determination of 5·13 mg of glycerol		Indirect determination of 5·13 mg of glycerol	
Found, *mg*	Error, *mg*	Found, *mg*	Error, *mg*
5·12	−0·01	5·28	+0·15
5·12	−0·01	5·14	+0·28
5·05	−0·08	5·32	+0·19
5·20	+0·07	4·88	−0·25
5·19	+0·06	5·12	−0·01
5·17	+0·04	5·04	−0·09
5·10	−0·03	4·89	−0·24

illustrates the agreement between the indirect and direct methods in the 5·00-mg range. Greater precision was obtained for the direct method. This was presumably a result of the fewer manipulations needed in it.

Observation of the current–voltage curves for the perchloratocerate ion in acid solution at a pyrolytic graphite electrode (Fig. 1) indicates nearly reversible behaviour of the cerate-cerous system in the vicinity of 0·90 V (*vs.* S.C.E.). This is in distinct contrast to the highly irreversible reduction of cerate which occurs at other common electrodes. The titration curve of glycerol (Fig. 2) can be interpreted in terms of the current–voltage curves shown in Fig. 1. The potential at the beginning of the titration is determined by the intersection of the 100-μA constant current lines with current–voltage curve 1. The potential difference is indicated by the two points *A* and *B*. With the exception of a slight increase at the beginning of the titration, the voltage remains constant across the electrodes until an excess of cerate in the solution causes a shift in the cathode reaction from curve 1 to curve 2, and a corresponding potential drop from *AB* to *CB* which indicates the end-point of the titration.

The faster reaction rate needed for a direct determination was obtained by using elevated temperatures, high acid concentration, and a relatively large constant current (100 μA).

At temperatures below 70° the reaction is slow enough to make direct titration impractical. At the recommended temperatures delays due to slow reaction rate are still perceptible, but a titration can easily be performed in less than 10 min.

A 2*F* mineral acid solution was used as the solvent for the titration because the reaction rate is favoured by high acidity.[1] Perchloric acid was selected as the most suitable of the strong mineral acids. Nitric acid can be used, but the reaction is

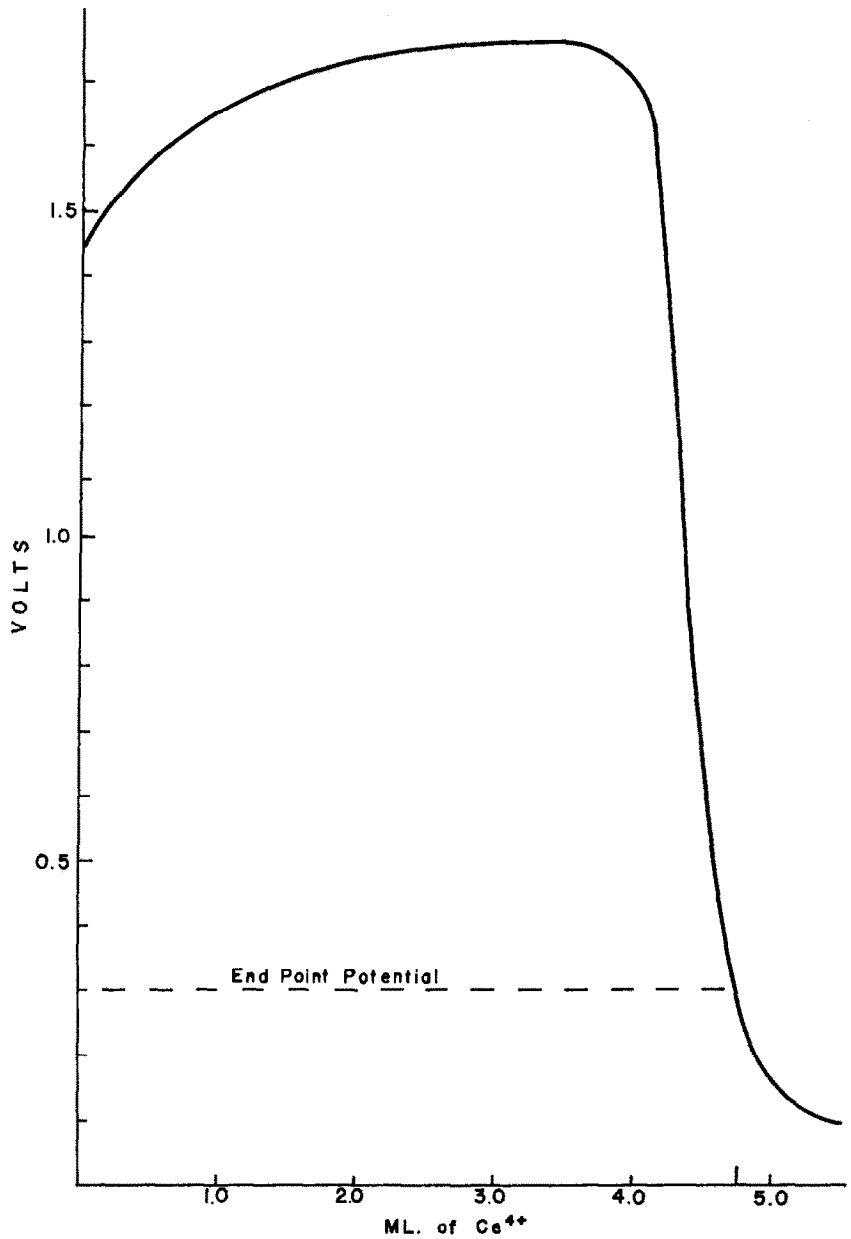

FIG. 2.—Titration curve for glycerol with perchloratocerate.

slightly slower. Guilbault and McCurdy[1] have shown that sulphate and bisulphate ions affect the reaction rate adversely. Chloride is oxidized under these conditions.

Titration at the relatively large constant current of 100 μA provides for a definite excess of titrant at the end-point, and thus a significant decrease in reaction time. Positive error is avoided by use of a blank titration at the same current. Figure 2 indicates also that the voltage change at the end-point is quite large and unmistakable

when this current is used. When a thermostatically controlled combination heater–stirrer is used, current drain by the heater coils may cause fluctuations in the stirring rate. Turning the heater coils off prior to reading the end-point potentials prevents such fluctuations. The stirring rate at the blank end-point and the end-point of the actual glycerol determinations must be the same in order to maintain the accuracy and the precision of the proposed method.

Sample loss due to evaporation was estimated, using Raoult's law. Such computations indicated that less than 0·1 % of a 5-mg sample volatilized during a 10-min titration. As an experimental check, several titrations were carried out in an Erlenmeyer flask fitted with a water-cooled condenser. These titrations showed no significant deviation from those performed in open beakers.

The large shift toward more positive cathode potentials at the end-point was quite definite, but somewhat slow. This is evidence to support the formation of an electrode film as suggested by Miller and Zittel.[3] Slow potential increases at the beginning of the titration were found to be anodic and are presumably due to electrochemical oxidation of the anode, or to film formation at the surface of the anode by temporary local concentrations of cerate. Neither of these effects significantly affects titration accuracy or convenience.

Reference to Fig. 2 indicates that in principle any potential along the relatively large potential shift could be selected for end-point indication. Titrating to 0·3 V allows the major portion of the potential shift to provide a convenient anticipation of the end-point. In addition, this potential is positive relative to the region where film formation occurs,[3] thereby eliminating spurious potentials resulting from alternate formation and reduction of the film.

Several titrations were carried out with more dilute solutions of glycerol and/or cerate to test the sensitivity limits of the method. Table II shows that less than 1 mg

TABLE II.—TITRATION SENSITIVITY

Sample number*	Cerate concentration, *M*	Glycerol present, *mg*	Glycerol found, *mg*	Relative error, %
1	0·09629	5·29	5·30	+0·2
2	0·09629	2·64	2·61	−0·8
3	0·09629	0·53	0·54	+1·9
4	0·04814	5·29	5·27	−0·4
5	0·00963	5·29	5·27†	−0·4
6	0·00963	2·64	2·60†	−1·5
7	0·00963	0·53	0·52†	−1·9

* Each individually listed result is an average of several results.
† These values were corrected for dilution caused by the addition of titrant.

of glycerol could be determined accurately by this method. When dilute perchloratocerate solutions (approx 0·01*M*) were used, corrections were made for the relatively large increases in the volume of titration solution. The negative errors found for the most dilute solutions may be due to anodic reoxidation of cerium(III). Titrations at greater dilutions than those presented here would be inconveniently slow.

Cerate solubility limits the titrant concentration to about 0·1*M*. Thus titration of samples larger than about 5·0 mg is not feasible unless rather large dilution corrections are applied.

Since no electrode which was sensitive to glycerol concentration was known, the major requirement for a suitable anode was that it should keep at constant potential in the vicinity of the end-point. Copper, platinum, gold, pyrolytic graphite, and a saturated calomel electrode were tested as possible anodes. The last was rejected because of the difficulties with the salt bridge at the temperatures used. Pyrolytic graphite was selected as the most suitable of the solid anode materials because it provided the most stable anode potentials under these conditions.

A study was conducted to see what interferences could be tolerated in the determination. As expected, easily oxidized or hydrolysed organic compounds interfere. Such interferences are less severe in the direct method than in the indirect method, because direct titration minimizes the concentrations of excess titrant. Neither saturated acids nor alcohols interfere significantly at concentrations up to $\frac{1}{10}$ that of the glycerol.

Acknowledgement—Mr. Gerald Nelesen obtained the current–voltage plots.

Zusammenfassung—Ein direktes potentiometrisches Titrationsverfahren bei konstanter Stromstärke erlaubt die quantitative Bestimmung von 0,50–5,00 mg-Proben Glycerin in wäßriger Lösung mit Fehlern von 0,2% bei den großen und 2,0% bei den kleineren Probemengen. Perchloratocerat wird als eingestelltes Oxidationsmittel verwandt und pyrolytischer Graphit als Electrodenmaterial. Die direkte Bestimmung wird ermöglicht durch erhöhte Temperatur, hohe Acidität und eine relativ große konstante Stromstärke. Fehlerquellen und mögliche Störungen werden diskutiert.

Résumé—Une méthode directe de titrage par potentiométrie à courant constant permet le dosage quantitatif d'échantillons de glycérol de 0,50 à 5,00 mg en solution aqueuse avec des erreurs comprises entre 0,2% pour les gros échantillons et 2,0% pour les échantillons les plus petits. On utilise le perchloratocérate comme oxydant standard et le graphite pyrolytique comme matière d'électrode. Une détermination directe est rendue possible aux températures élevées, forte acidité et courant constant relativement fort. On discute des sources d'erreur et des interférences possibles.

ALGOL-PROZEDUREN ZUR KORRELATIONSRECHNUNG

G. GOTTSCHALK
OSRAM Studiengesellschaft Berlin, Technische Universität,
1 Berlin 10, Helmhottzstr. 2–9, Berlin

(*Eingegangen* 7 *März* 1967. *Angenommen* 30 *April* 1967)

Zusammenfassung—An gleichartigen Objekten oder Vorgängen gemessene variable Merkmalsgrößen können nach zunächst unbekannten Gesetzen miteinander verknüpft sein. Realität und Straffheit des Zusammenhanges der Datenreihen im Rahmen vorgegebener Korrelationsfunktionen sind durch die mathematisch-statistische Auswertemethode der Korrelationsrechnung überprüfbar. Im folgenden werden die mathematische Struktur der erforderlichen Rechenprozesse beschrieben und in der problemorientierten Sprache ALGOL als universell verwendbare Prozeduren (Unterprogramme) KORR und TEST formuliert. Es wird gezeigt, daß derartige Universal-Prozeduren SCHWARZE KÄSTEN im Sinne der kybernetischen Terminologie darstellen, die als Bausteine ohne Kenntnis des mathematischen Inhaltes verwendet werden können. Das Schreiben eines Rahmenprogrammes für spezielle Problemstellungen wird dadurch so wesentlich vereinfacht, daß dies nach kurzer Schulung auch ohne mathematische Vorbildung einwandfrei durchgeführt werden kann. An einem praktischen Beispiel wird demonstriert, wie insgesamt 6 Korrelationsansätze und 9 Vergleiche von Korrelationskoeffizienten programmiert und in 9 min elektronisch ausgewertet werden. Der Zeitbedarf bei konventioneller Rechentechnik ist mehr als 100-fach größer.

EINFÜHRUNG

Problemstellung

Liegen für n gleichartige Objekte oder Vorgänge chemische, physikalische oder sonstige variable Merkmalsgrößen vor, so bildet der eindeutige Nachweis eines Zusammenhanges—einer KORRELATION—zwischen den einzelnen Merkmalen oft die Basis wertvoller neuer Erkenntnisse. Im einfachsten Falle wird eine Korrelation zwischem einem

Hauptmerkmal mit n Merkmalsgrößen y_1

und einem

Nebenmerkmal mit n Merkmalsgrößen x_1

hinsichtlich Realtität und Straffheit zu beurteilen sein, wobei eine geeignet erscheinende Korrelationsfunktion $y = F(x)$ vorzugeben ist. Bei mehreren Nebenmerkmalen $x(1)_1, x(2)_1, \ldots, x(J)_1, \ldots$ resultiert als Korrelationsfunktion:

$$y = F\{x(1), x(2), \ldots, x(J), \ldots\} \tag{1}$$

Die einfachste Form der korrelativen Datenauswertung ist die EINFACHE LINEARE KORRELATIONSRECHNUNG bei der die Größen des Hauptmerkmals und des Nebenmerkmals bzw. der Nebenmerkmale zunächst durch Substitution so umgeformt werden müssen, daß eine Linearfunktion (REGRESSIONSGERADE)

$$Y = [U] + [V] \cdot X \tag{2}$$

erhalten wird. Sowohl für die „formalen Parameter" Y als auch für X können beliebige Funktionen der „aktuellen Parameter" y, x oder y, $x(1)$, $x(2), \ldots, x(J), \ldots$ eingesetzt werden, wie z.B.

$$\text{für } Y\text{: } \ln y \text{ oder } \sin y \text{ oder } y^2 \text{ oder } y/x \text{ oder } y \cdot \sqrt{x}$$

$$\text{für } X\text{: } e^{-x} \text{ oder } \ln(1 + x^3) \text{ oder } x(1) - x(2) \text{ oder } \cos\left\{\frac{x(3)}{x(1)}\right\}.$$

Weitere Beispiele siehe Gottschalk.[1] Bei mehreren Merkmalen besteht prinzipiell die Möglichkeit, die Auswertung des Datenmaterials durch eine MEHRFACHE LINEARE KORRELATIONSRECHNUNG zu erweitern und zu verfeinern. Hierauf wird in dieser Arbeit nicht eingegangen.

Das Ziel einer Korrelationsrechnung ist zunächst die Ermittlung der Korrelationsgrößen

r_{xy} = Korrelationskoeffizient

B = Bestimmtheitsmaß

τ_r = Prüfgröße für Realität und Straffheit der Korrelation

Danach ist τ_r mit den Integralgrenzen t_1, t_2, t_3 der t-Verteilung zu vergleichen.

Wird keine Korrelation ($\tau_r < t_1$) gefunden, so entfallen weitere Rechnungen. Bei zumindest wahrscheinlicher Korrelation ($\tau_r \geqq t_1$) sind in einer weiteren Auswertungsstufe die Regressionsgrößen

$[U]$, $[V]$ = Konstanten der Regressionsgeraden

$[s_K]$ = Standardabweichung in Y-Einheiten

$[s_U]$, $[s_V]$ = „mittlerer" Fehler von $[U]$ bzw. $[V]$

zu berechnen.

Unterschiede in den Korrelationskoeffizienten für Funktionen, die gleichartige Objekte oder Vorgänge mathematisch beschreiben sollen, können über den λ-TEST beurteilt werden.

Es muß hier ausdrücklich darauf hingewiesen werden, daß der formal gesicherte Nachweis einer Korrelation keinesfalls besagt, daß der durch die vorgegebene Korrelationsfunktion beschriebene Zusammenhang von Größen in jedem Falle sinnvoll ist. Eine sinnlose Ausgangs-Fragestellung—etwa nach dem Zusammenhang zwischen dem stündlichen Wasserverbrauch und der Zahl der stündlich eingehenden Analysenproben in einem Laboratorium—erhält nicht dadurch einen Sinn, daß vielleicht formal mathematisch ein Zusammenhang nachweisbar ist. Bevor man eine oder mehrere Korrelationsfunktionen aufstellt und rechnerisch verarbeitet, muß sehr sorgfältig geprüft werden, ob eine logische Verknüpfung überhaupt vorhanden oder zumindest denkbar ist. Bei zeit- oder mengensynchronen Meßdaten an EINEM Objekt oder Vorgang kann dies jedoch fast immer vorausgesetzt werden. Ein anderes Problem stellt die Auffindung einer optimalen Korrelationsfunktion dar. Unter einer Reihe rechnerisch verarbeiteter Funktionsansätze zeichnet sich die Optimalfunktion dadurch aus, daß sie MÖGLICHST EINFACH ist und unter ähnlichen Ansätzen den höchsten Korrelationskoeffizienten r_{xy} und damit auch die kleinste Standardabweichung $[s_K]$ besitzt. Die Verbal-Aussage „einfach" bedeutet eine Dateninterpretation durch Funktionen mit einer kleinen Anzahl k an Funktionskonstanten, d.h. einem großen Freiheitsgrad $f = n - k$. Darüber hinaus ist der wissenschaftliche Erkenntniswert eines Ansatzes häufig erst dann ausreichend belegt, wenn er aus bekannten, chemischen, physikalischen oder sonstigen Gesetzen synthetisch aufgebaut oder abgeleitet werden kann.

Die Durchführung von Korrelationsrechnungen für eine Vielzahl denktheoretisch möglicher Funktionen ist bei Anwendung konventioneller Rechenmethoden eine zeitraubende und fehleranfällige Routinearbeit, die mit Recht gescheut wird, da sie das schöpferisch wissenschaftliche Arbeiten für Tage oder sogar Wochen blockiert. Im folgenden wird gezeigt, daß es neuartige Programmier- und Rechentechniken im Rahmen der elektronischen Informationsverarbeitung gibt, die in wenigen Minuten zu zuverlässigen Resultaten und Urteilen führen.

Elektronische Datenverarbeitung

Wie in den Arbeiten I (Modellanalysen)[2] und II (Varianzanalyse)[3] werden nachfolgend die Programme in der problemorientierten Sprache ALGOL (ALGO-rithmic L-anguage) unter Verwendung der für das Codesystem ALCOR CCIT zulässigen Zeichen formuliert.

Die formalen Parameter Y und X der Korrelationsfunktion (2) können, wie bereits ausgeführt wurde, beliebige arithmetische Ausdrücke aus parallel ermittelten Merkmalsgrößen beinhalten. Bei n Datengruppen ist eine n-fache gleichartige Überführung der ermittelten Meßdaten in Y- bzw. X-Größen erforderlich, was bei 5 verschiedenen Ansätzen von Korrelationsfunktionen immerhin die Durchführung von $5.n$ Rechenoperationen von oft komplizierter Natur bedeutet. Es wäre bei diesem Tatbestand umständlich und zeitraubend, wenn für jeden Korrelationsansatz ein spezielles Programm erstellt, erprobt und gerechnet werden müßte. Hier bietet ALGOL mit den als PROZEDUR bezeichneten Unterprogrammen einen Ausweg. Eine Prozedur braucht nur einmalig mit FORMALEN PARAMETERN formuliert und

kann sodann nach Vereinbarung in einem RAHMENPROGRAMM beliebig oft unter Ersatz der formalen durch AKTUELLE PARAMETER aufgerufen werden. Bei jedem Aufruf wird das formale mathematische Modell der Prozedur aktuell durchgerechnet.

Die nachfolgend aufgeführte Prozedur TEST zum Vergleich von Korrelationskoeffizienten ist sehr einfach aufgebaut. Die entsprechende Vereinbarung beginnt mit

'PROCEDURE' TEST (N1, N2, R1, R2); ....

Nach dem Vereinbarungs-Wortsymbol 'PROCEDURE' folgt der gewählte Prozedurname TEST und danach die in runde Klammern eingeschlossene Liste der formalen Parameter, die aus den Datenumfängen $n_1 =$ N1 und $n_2 =$ N2 sowie aus den zugehörigen Korrelationskoeffizienten $r_{xy}(1) =$ R1 und $r_{xy}(2) =$ R2 der zu vergleichenden Korrelationsansätze besteht. Der weitere Inhalt der Prozedur an Vereinbarungen und Anweisungen braucht hier nicht diskutiert zu werden. Sind nun in einem Rahmenprogramm 3 Korrelationsrechnungen mit Resultaten

$r_{11} =$ R11 aus $n_{11} =$ N11 Daten
$r_{12} =$ R12 aus $n_{12} =$ N12 Daten
$r_{13} =$ R13 aus $n_{13} =$ N13 Daten

erhalten worden, so genügen zur Durchführung der $\binom{3}{2} = 3$ möglichen Vergleiche r_{11} mit r_{12}, r_{11} mit r_{13}, r_{12} mit r_{13} lediglich die Aufrufe:

TEST (N11, N12, R11, R12);
TEST (N11, N13, R11, R13);
TEST (N12, N13, R12, R13);

im Anweisungsteil des Rahmenprogrammes.

Es liegt nahe, auch die Korrelationsrechnung selbst als Prozedur zu formulieren, etwa mit den formalen Eingangsparametern $n =$ N,X,Y,$t_1 =$ T1, $t_2 =$ T2 und $t_3 =$ T3 und dem für Vergleiche benötigten formalen Ausgangsparameter $r_{xy} =$ R. In einer gewöhnlichen Prozedur wären X und Y als Felder zu vereinbaren, da sie stellvertretend für jeweils n Größen mit der Laufzahl $i =$ I $= 1$ bis n stehen. Durch eine von dem dänischem Mathematiker Jensen endeckte und an einfachen Beispielen[4] beschriebene Variante der ALGOL-Prozedur wird es jedoch möglich, X und Y als gewöhnliche Variable einzuführen, wenn zusätzlich die Laufzahl $i =$ I als formaler Parameter aufgelistet wird. Die Vereinbarung einer Jensen-Prozedur beginnt mit

'PROCEDURE' KORR (N, I, Y, X, T1, T2, T3, R); ....

Im Gegensatz zur gewöhnlichen Prozedur mit X- und Y-Feldern, dürfen in der Jensen-Prozedur die X- und Y-Variablen in Aufrufen durch arithmetische Ausdrücke ersetzt werden, die mit aktuellen Feldgrößen formuliert sind. Damit können beliebige Korrelationsansätze unmittelbar in Prozeduraufruf realisiert und spezielle Substitutionsrechnungen im Rahmenprogramm erspart werden. Mögliche Zusammenhänge z.B. zwischen einer Konzentration C und Meßgröße W mit Ansätzen

$$C = [A1] + [B1] \,.\, W^2$$
$$C = [A2] \,.\, W + [B2] \,.\, W^2 \quad \text{umgeformt zu} \quad \frac{C}{W} = [A2] + [B2] \,.\, W$$
$$C = [A3] + [B3] \,.\, \exp\left(\tfrac{1}{2}W\right)$$

lassen sich mit den aktuellen Feldgrößen C[I] und W[I] im Rahmenprogramm direkt als Rechenanweisungen

KORR (N, I, C[I], W[I] × W[I], T1, T2, T3, T4, R1);

KORR (N, I, C[I]/W[I], W[I], T1, T2, T3, T4, R2);

KORR (N, I, C[I], EXP (W[I]/2), T1, T2, T3, T4, R3);

aufrufen.

Im Sinne der kybernetischen Terminologie stellen die Prozeduren SCHWARZE KÄSTEN (black boxes) dar. Es sind dies in sich geschlossene universelle Bausteine, die innerhalb eines Rahmensprogrammes beliebig oft verwendet werden können und zwar auch von solchen Mitarbeitern, die den im Inneren des Schwarzen Kastens konservierten mathematischen Mechanismus gar nicht verstehen oder bereits wieder vergessen haben. Mit wenigen genau festgelegten aktuellen EINGANGS-Informationen werden automatisch ganz bestimmte vorher bekannte aktuelle AUSGANGS-Informationen erhalten. Dieser reine INPUT/OUTPUT-Prozeß unterscheidet sich grundsätzlich nicht von der selbstverständlichen Bedienung zahlreicher schwarzer Kästen, die die technische Entwicklung uns zur Verfügung gestellt hat. Auch bei Gebrauch etwa eines Radioapparates wird ein Input in Form des Einschaltens, der Senderwahl sowie der Lautstärke- und Tonhöheneinstellung nach einem uns zumeist unbekannten Mechanismus in ein Output von Tönen oder Sprachsendungen umgesetzt, wobei der Benutzer es als höchst überflüssig erachtet, vorher das komplizierte Schaltschema und die physikalischen Grundlagen des Sende- und Empfangprozesses verstehen zu wollen.

Die außerordentlichen Vorteile einer solchen Auswertetechnik hinsichtlich Einfachheit, Schnelligkeit und Zuverlässigkeit brauchen nicht besonders hervorgehoben zu werden. Nach diesem Prinzip können bestimmte Wissenskomplexe, wie mathematische Modelle, vom Fachspezialisten optimal programmiert und danach mit einem Minimum an Vorbildung von Wissenschaftlern und Hilfskräften anderer Fachgebiete als geschlossene Bausteine verwendet werden. Die Prozeduren KORR und TEST sind universelle mathematische Modelle, die ein Biologe, Soziologe, Betriebswirtschaftler oder ein beliebig anderer Fachwissenschaftler ebenso wie ein Chemiker anwenden kann. Speziell ist allein die jeweilige Problemstellung und das danach gestaltete zumeist sehr einfache Rahmenprogramm.

Zusammenfassend zeigen die Abb. 1 und 2 nochmals wesentliche Teile der vorstehenden Gedankengänge.

MATHEMATISCHE STRUKTUR

Grundgrößen und Varianzen

Der Rechengang beginnt mit einer einfachen Summierung der formalen Parameter X und Y, die entsprechend den Funktionsansätzen aus den primären Eingangsgrößen y_i, x_i gebildet werden. Mit den formalen Mittelwerten $\bar{X}$ und $\bar{Y}$ werden danach die n Abweichungen $X - \bar{X}$ und $Y - \bar{Y}$ gebildet und zu varianzähnlichen Ausdrücken VX, VY und VXY aufsummiert.

Tabelle 1 gibt unter [1] und [2] eine Zusammenstellung der Rechenprozesse. Man beachte, daß X und Y keine einfachen Variablen, sondern Felder (Vektoren) aus jeweils n Einzelgrößen bzw. n Kombinationen aus mehreren Einzelgrößen sind.

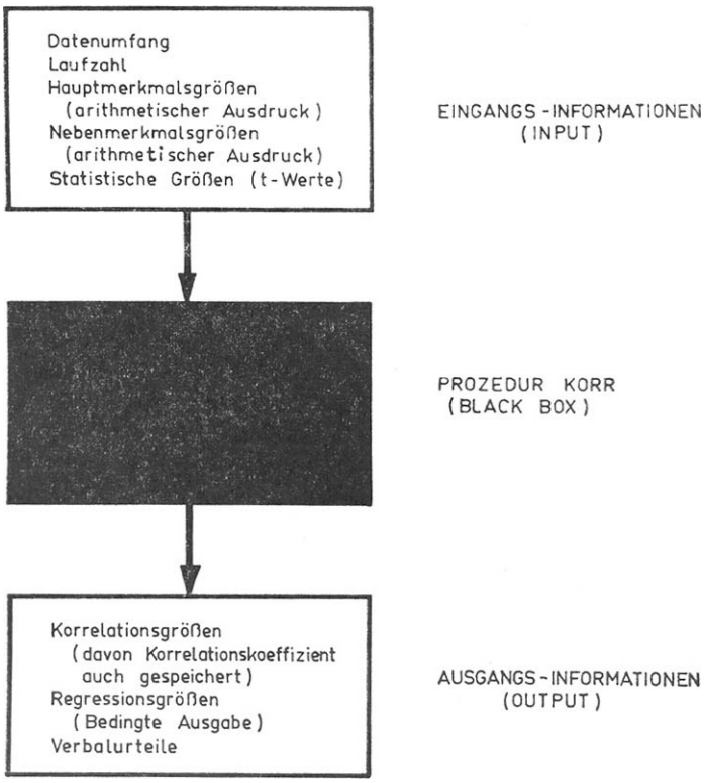

ABB. 1.—INPUT/OUTPUT-System der Prozedur KORR.

ABB. 2.—Programm-Schema zur Durchführung von Korrelationsrechnungen und *r*-Vergleichen für 3 Korrelationsfunktionen.

TABELLE I.—MATHEMATISCHE STRUKTUR DER LINEAREN KORRELATIONSRECHNUNG (FETT GEDRUCKTE SYMBOLE = ALGOL-NAMEN)

1 Grundgrößen	2 Varianzen
$\mathbf{S1} = \frac{1}{n}\sum_1^n \mathrm{X} = \overline{\mathrm{X}}$	$\mathbf{VX} = (n-2)\cdot s_x^2 = \sum_1^n \mathbf{S4} \times \mathbf{S4}$
$\mathbf{S2} = \frac{1}{n}\sum_1^n \mathrm{Y} = \overline{\mathrm{Y}}$	$\mathbf{VY} = (n-2)\cdot s_y^2 = \sum_1^n \mathbf{S5} \times \mathbf{S5}$
$\mathbf{S3} = \frac{1}{n}\sum_1^n \mathrm{X}\cdot\mathrm{X}$	
$\mathbf{S4} = \mathrm{X} - \overline{\mathrm{X}} = \mathrm{X} - \mathbf{S1}$	$\mathbf{VXY} = (n-2)\cdot s_{xy} = \sum_1^n \mathbf{S4} \times \mathbf{S5}$
$\mathbf{S5} = \mathrm{Y} - \overline{\mathrm{Y}} = \mathrm{Y} - \mathbf{S2}$	

3 Korrelationsgrößen
Korrelationskoeffizient: $\mathbf{R} = r_{xy} = \frac{s_{xy}}{s_x \cdot s_y} = \mathrm{VXY}/\sqrt{\mathrm{VX} \times \mathrm{VY}}$
Bestimmtheitsmaß: $\mathbf{B} = r_{xy}^2 = \mathrm{VXY} \times \mathrm{VXY}/(\mathrm{VX} \times \mathrm{VY})$
Prüfgröße: $\mathbf{TAU} = \tau_r = \sqrt{(N-2) \times B/(1-B)}$

4 Regressionsgrößen
Berechnung erfolgt nur für $\tau_r \geqq t_1 \cdot$ (V1 WAHR)
Konstanten: $\mathbf{V} = [V] = \frac{s_{xy}}{s_x^2} = \mathrm{VXY}/\mathrm{VX}$ und $\mathbf{U} = [U] = \overline{\mathrm{Y}} - [V]\cdot\overline{\mathrm{X}} = \mathbf{S2} - \mathrm{V} \times \mathbf{S1}$
Abweichungen: $\mathbf{SK} = [s_K] = s_y \cdot \sqrt{1-B} = \sqrt{\mathrm{VY} \times (1-B)/(N-2)}$
$\mathbf{SV} = [s_V] = \lvert V\rvert/\mathrm{TAU}$ und $\mathbf{SU} - [s_U] = \mathrm{SV} \times \sqrt{\mathbf{S3}}$

5 Boole'sche Variable			6 Urteile
Vergleiche mit t-Werten der t-Verteilung für $f = n-2$ und den Sicherheiten $S = 95\%$: $\mathbf{T1} = t_1$; $S = 99\%$: $\mathbf{T2} = t_2$; $S = 99{,}9\%$: $\mathbf{T3} = t_3$			Wenn V1 nicht wahr: KEINE KORRELATION NACHWEISBAR
V1	WAHR	für $\tau_r \geqq t_1$	Wenn V2 nicht wahr UND V1 wahr: KORRELATION NUR WAHRSCHEINLICH
	NICHT WAHR	für $\tau_r < t_1$	
V2	WAHR	für $\tau_r \geqq t_2$	Wenn V3 nicht wahr UND V2 wahr: KORRELATION SIGNIFIKANT NACHGEWIESEN
	NICHT WAHR	für $\tau_r < t_2$	
V3	WAHR	für $\tau_r \geqq t_3$	Wenn V3 wahr: KORRELATION HOCHSIGNIFIKANT NACHGEWIESEN
	NICHT WAHR	für $\tau_r < t_3$	

Korrelationsgrößen und Regressionsgrößen

Aus den Varianzen folgen unmittelbar der Korrelationskoeffizient r_{xy}, das Bestimmtheitsmaß B und die Prüfgröße τ_r nach den Rechenformeln, die in [3] der Tab. 1 aufgeführt sind.

Sofern überhaupt eine Korrelation nachweisbar ist, werden die Konstanten $[U]$ und $[V]$ der Regressionsgeraden (2) und die Abweichungen $[s_K]$, $[s_U]$, $[s_V]$ nach den

Formeln in [4] der Tab. I berechnet, die aus dem Minimumsansatz

$$\sum_1^n \{[U] + [V] \,.\, X - Y\}^2 = \sum_1^n \nu_i^2 = \text{MINIMUM} \tag{3}$$

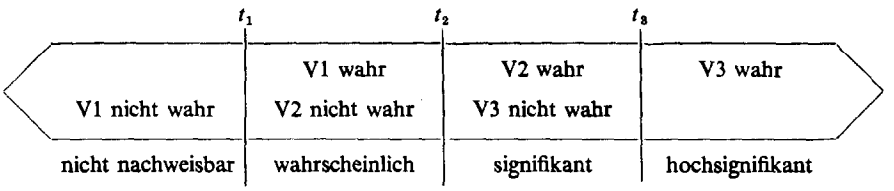
abgeleitet werden können. Einzelheiten siehe Gottschalk.[1]

Boole'sche Variable und Urteile

Der numerische Wert der Prüfgröße τ_r wird mit Werten t der t-Verteilung verglichen, wobei diese Vergleiche durch Zuordnung Boole'scher Variabler in einfache JA/NEIN- oder WAHR/NICHT WAHR-Entscheidungen überführt werden können.

Zur Beurteilung der Realität und Straffheit des Zusammenhanges ist es zweckmäßig, eine vierstufige Urteilsskala heranzuziehen, die sich aus Vergleichen von τ_r mit den Werten t_1; t_2; t_3 für Statistische Aussage-Sicherheiten $S = 95$; 99; 99,9% (level of significance 0,05; 0,01; 0,001) und dem Korrelationsfreiheitsgrad $f = n - 2$ (2 Konstanten) ergeben. Die Integralgrenzen t der t-Verteilung sind in statistischen Tabellenwerken oder Lehrbüchern tabelliert.

In [5] und [6] der Tab. I sind die Boole'schen Variablen und die Urteile formuliert, während nachfolgende Skizze die „Wahrheitstafel" zu [6] verdeutlicht.



Vergleich von Korrelationskoeffizienten

Zum Vergleich von 2 Korrelationskoeffizienten ist eine Prüfgröße λ_r zu bilden und mit den Integralgrenzen λ der Normalverteilung für die Statistischen Sicherheiten $S = 95$; 99; 99,9% (level of significance 0,05; 0,01; 0,001) zu vergleichen. Für die Beurteilung der Unterschiede wird auch hier eine vierstufige Urteilsskala definiert. Die Unterschieds-Wahrheitstafel hat die gleiche Struktur wie die Korrelations-Wahrheitstafel. Einzelheiten der sehr einfachen mathematischen Struktur des λ-Testes sind der Abb. 5 zu entnehmen.

Theoretisch können bei der Durchrechnung von α Korrelationsfunktionen insgesamt

$$\binom{\alpha}{2} = \frac{\alpha!}{2!\,(\alpha - 2)!} = \tfrac{1}{2}\alpha \,.\, (\alpha - 1).$$

verschiedene λ-TESTS durchgeführt werden, sofern dies in jedem Fall sinnvoll erscheint. Ein zumindest wahrscheinlich größerer Korrelationskoeffizient gibt dem betreffenden Funktionsansatz Priorität vor dem anderen Ansatz. Eine solche Priorität ist jedoch problematisch, wenn sie mit einer komplizierten oder gesetzmäßig nicht aufschlüsselbaren Funktion erzielt wird.

PROGRAMMIERUNG

Flußdiagramm

Abbildung 3 zeigt das vollständige Ablaufschema der Prozedur KORR. Die Prozedur TEST ist so einfach, daß ein Flußdiagramm überflüssig ist.

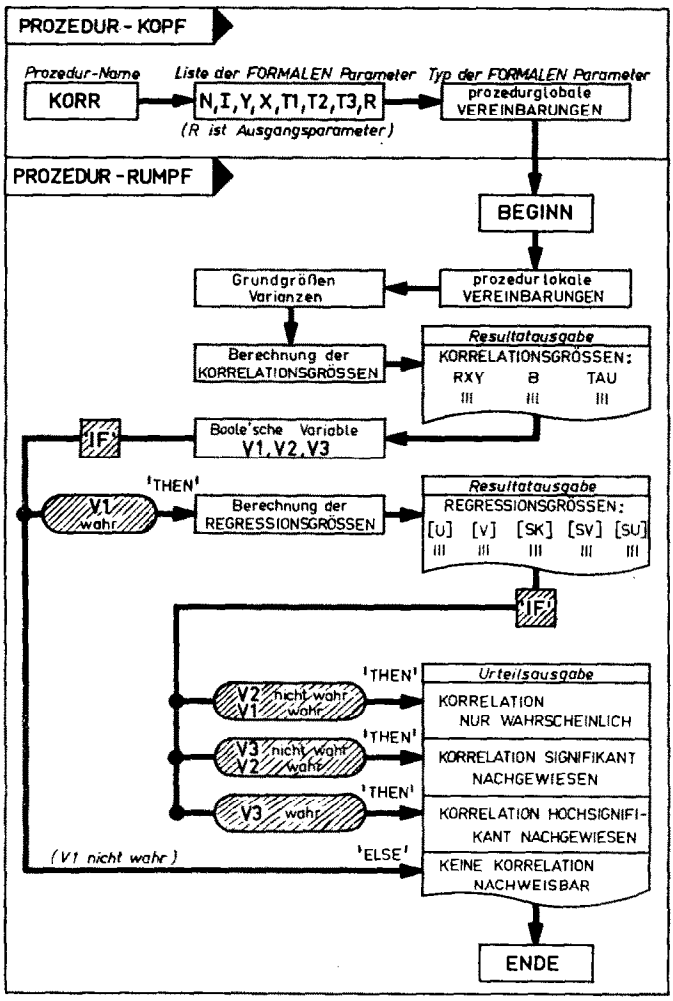


ABB. 3.—Flußdiagramm der ALGOL-Prozedur KORR.

ALGOL-Prozeduren und Rahmenprogramm

Abbildung 4 bringt die ALGOL-Formulierung der Prozedur KORR, während Abb. 5 die mathematische Struktur und die ALGOL-Formulierung der einfachen Prozedur TEST enthält.

Die Prozeduren sind erprobt und brauchen von einem Benutzer nur sorgfältig abgeschrieben und an ein Rechenzentrum gegeben zu werden. Die zukünftige Arbeit besteht im Schreiben eines Rahmenprogrammes, in das die Prozeduren durch Nennung ihres Kenn-Namens im Vereinbarungsteil eingeführt und durch Aufrufe im Anweisungsteil rechnerisch aktiviert werden. Die Schwarzen Kästen der beiden Prozeduren bestehen im ALGOL aus separaten Lochstreifen-Rollen (in Sonderfällen Lochkartenstapel), die im Gegensatz etwa zum Radiogerät sehr schnell vervielfältigt und an andere Interessenten weitergegeben werden können. Bei Schreiben des Datenstreifens mit aktuellen Daten ist lediglich zu beachten, daß die Reihenfolge der Daten mit der Reihenfolge in der Leseanweisung übereinstimmt.

$10^3 \cdot C2_i$	25,00	8,85	9,10	7,10	4,20	4,76	3,83	2,49	2,40	2,58	2,03

ABB. 6.—Cl und C2 als Funktion von G (aktuelle Eingangsinformationen).

Problemstellung

In jeweils 10 Untersuchungen wurde die Brauchbarkeit von 2 verschiedenen Adsorptionsmitteln ① und ② zur selektiven Entfernung eines störenden Bestandteiles aus einer Lösung getestet.

Hauptmerkmal (vorgegeben) = Menge G an Adsorptionsmittel ① bzw. ② in Gramm
Merkmalsgrößen $y_i = G_i$ = G[I]

Nebenmerkmal (gefunden) = Restkonzentration C in mMol/ml in der Lösung nach definierter Behandlung von Lösungen mit der Anfangskonzentration $C_0 = 2{,}50 \cdot 10^{-2}$ mMol/ml.

Merkmalsgrößen für ①: $x(1)_i = C1_i$ = C1[I]
②: $x(2)_i = C2_i$ = C2[I]

Abbildung 6 bringt die graphische Darstellung und die Tabelle der aktuellen Daten.

Mathematische Rahmenstruktur

Bei Einbeziehung der Anfangskonzentration $C_0 = C1[1] = C2[1]$ liegen insgesamt $n = N = 11$ Daten mit $i = I = 1, 2, 3, \ldots, 11$ für jede Merkmalsreihe vor.

'END' RAHMENPROGRAMM
```

ABB. 7.—ALGOL-Rahmenprogramm des Beispieles.

Nach dem graphischen Bild ist ein nichtlinearer Zusammenhang zwischen G und C zu erwarten. Die formale Korrelationsfunktion

$$Y = [U] + [V] \times X$$

soll auf folgende aktuelle Funktionen angewendet werden:

Adsorptionsmittel ①	[11]	$G[I] = [U] + [V] \times (1/C1[I])$	mit R11
	[12]	$G[I] = [U] + [V] \times C1[I] \times C1[I]$	mit R12
	[13]	$C1[I]/G[I] = [U] + [V] \times C1[I]$	mit R13

Adsorptionsmittel ② [21] G[I] = [U] + [V] × (1/C2[I]) mit R21

[22] G[I] = [U] + [V] × C2[I] × C2[I] mit R22

[23] C2[I]/G[I] = [U] + [V] × C2[I] mit R23

Die Beziehungen [13] und [23] lassen sich leicht in die Langmuir'sche Adsorptionsisotherme überführen. Durch Umformung folgt:

$$G = \frac{C}{[U] + [V] \cdot C} \sim CO \qquad \text{(Oberflächenkonzentration)}$$

Von den 15 möglichen Vergleichen der 6 Korrelationskoeffizienten sind 9 Vergleiche sinnvoll und zwar:

R11 mit R12	R21 mit R22	R11 mit R21
R11 mit R13	R21 mit R23	R12 mit R22
R12 mit R13	R22 mit R23	R13 mit R23

Als t-Werte entnimmt man für $f = n - 2 = 9$ den Tabellen:

$$t_1 = T1 = 2{,}26 \quad (95\%)$$
$$t_2 = T2 = 3{,}25 \quad (99\%)$$
$$t_3 = T3 = 4{,}78 \quad (99{,}9\%)$$

ALGOL-Rahmenprogramm

Im Rahmenprogramm werden namentlich nur die aktuellen Größen

T1, T2, T3, R11, R12, R13, R21, R22, R23, I, G[I], C1[I], C2[I]

vereinbart und soweit sie Eingangs-Informationen darstellen auch eingelesen; n = N = 11 wird direkt numerisch eingesetzt.

Abbildung 7 zeigt das Rahmenprogramm mit den einmaligen Prozedurvereinbarungen, den schriftlichen Erläuterungen durch WRITE-Anweisungen und den insgesamt 15 Prozeduraufrufen. Entsprechend den formulierten Leseanweisungen sind die aktuellen Eingangsdaten in der Reihenfolge

$$\langle t_1, t_2, t_3, G_1, C1_1, C2_1, G_2, C1_2, C2_2, \ldots G_{11}, C1_{11}, C2_{11} \rangle$$

im Datenstreifen numerisch aufzulisten.

Resultate, Urteile, Bearbeitungszeiten

Tabelle 2 gibt eine Zusammenstellung der gerundeten Resultate, während Abb. 8 Anfang, Mittelteil und Ende des von einer Rechenanlage ZUSE Z23 ausgedruckten Ergebnis-Bogens zeigt. Die Durchrechnung des Beispieles erfolgte mit einer relativ

Daten-Einlesezeit DEZ	:	16 sec	
Rechenzeit (Schnell-Locher-Ausgabe) RZ	: 3 min	26 sec	(bei Direktausgabe aber 9 min 44 sec)
ELEKTRONISCHE BEARBEITUNGSZEIT EBZ:	3 min	42 sec	
GESAMTZEIT für das Beispiel	: 8 min	58 sec	

Für die vollständige Durchrechnung und Beurteilung von nur einer der 6 Korrelationsfunktionen werden nur etwa 30 sec RZ benötigt. Die Ausgabe über

Schnell-Locher liefert einen Ergebnis-Lochstreifen, der mit jedem ALGOL-Schreiber beliebig oft in Klarschrift-Bögen nach Abb. 8 umgesetzt werden kann. Die Umsetzungszeit beträgt 5 min 42 sec. Dieses Vorgehen bietet gegenüber der langsamen direkten Klarschrift-Ausgabe den Vorteil einen wesentlichen Verkürzung der Maschinen-Belegungszeit, da in der Z23-Anlage die Rechenprozesse während des Druckvorganges unterbrochen werden.

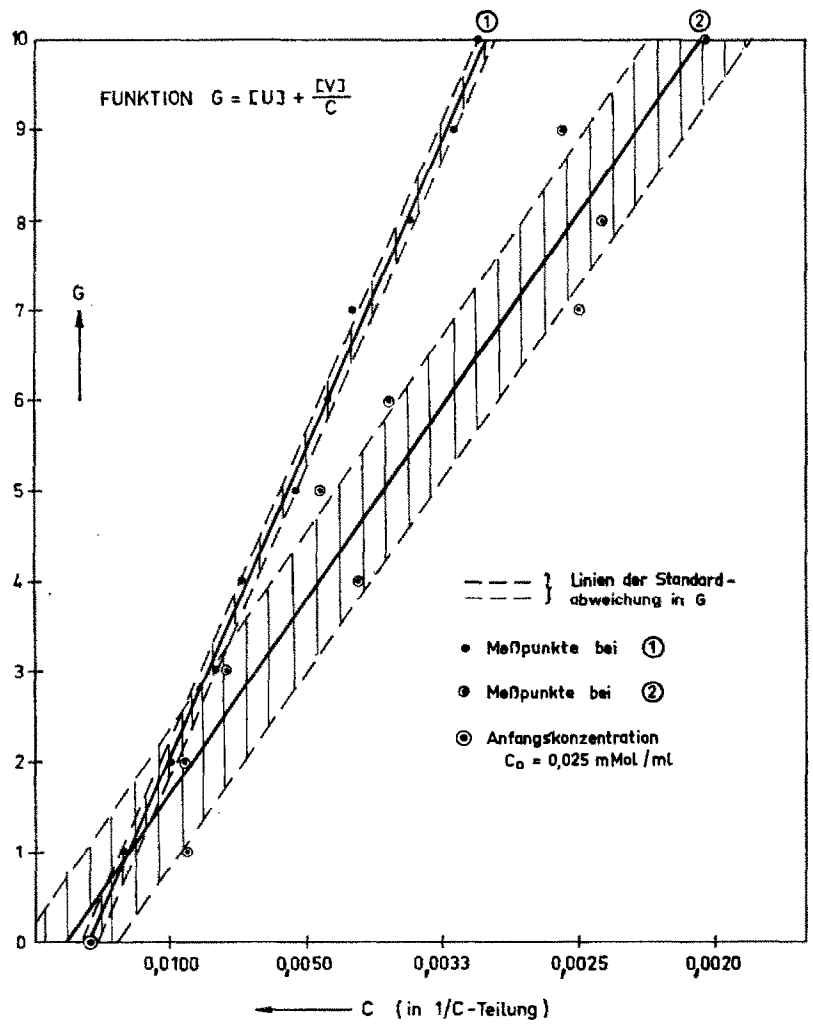

ABB. 9—Regressionsgeraden und Meßpunkte.

Bei konventioneller Rechentechnik mit Tischrechnern benötigt auch ein geübter menschlicher Rechner für das Beispiel mindestens 15 Stunden = 900 min (2 bis 3 Arbeitstage) zu einer gleichartigen Durchrechnung und Urteilsbildung, was einem Zeitfaktor von über 100 entspricht. Es sei erwähnt, daß bereits mit neueren mittelgroßen Rechenanlagen die Gesamtzeit durchaus auf weniger als 1 min vermindert werden kann.

Diskussion der Ergebnisse

Die aktuellen Daten werden am besten durch die strukturell gleichartigen Funktionen [11] und [21]

$$G = [U] + \frac{[V]}{C}$$

beschrieben, wobei die Standardabweichung in G bei [11] mit $[s_K] = \pm 0{,}19$ g wesentlich kleiner als bei [21] mit $[s_K] = \pm 0{,}83$ g ist. Die Konstante $[V]$ (Steigung der Regressionsgeraden) stellt ein Maß des Adsorptionsvermögens A dar. A ist umso größer je kleiner $[V]$ ist.

$$A = \frac{1}{[V]} \qquad \text{in } g^{-1}.\ (\text{mMol/ml})^{-1}$$

Im vorliegenden Beispiel besitzt das Adsorptionsmittel ② mit $A2 = 46{,}5$ ein höheres Absorptionsvermögen als ① mit $A2 = 29{,}2$. Wegen der in $[s_K]$ erkennbaren sehr viel größeren „Dosier-Streuung" von ② gegenüber ① wird man aber dem Adsorptionsmittel ① wegen „besserer Gleichmäßigkeit" zumeist den Vorzug geben. Der Vergleich von R11 mit R21 ergibt, daß das Datenmaterial von ① signifikant besser als dasjenige von ② korreliert ist. Abbildung 9 zeigt im 1/C; G-Diagramm die beiden Regressionsgeraden und die gefundenen Meßpunkte.

Für die Funktionen [12] und [22] vom Typ

$$G = [U] + [V] \cdot C^2$$

ist eine Korrelation nur wahrscheinlich. Wie auch die extrem großen Standardabweichungen $[s_K]$ zeigen, sind sie ungeeignet zur Interpretation des vorliegenden Datenmaterials. Die Unterschiede von R11 zu R12 bzw. von R21 zu R22 sind zudem hochsignifikant. Die Langmuir-ähnlichen Funktionen [13] und [23] vom Typ

$$\frac{C}{G} = [U] + [V] \cdot C \qquad \text{bzw. umgeformt} \qquad G = \frac{C}{[U] + [V] \cdot C}$$

ergeben zwar eine signifikante bzw. hochsignifikante Korrelation, besitzen aber gegenüber den Funktionen [11] und [21] einen kleineren Korrelationskoeffizienten. Zwischen R11 und R13 ist der Unterschied hochsignifikant, während zwischen R21 und R23 ein solcher nicht nachweisbar ist. Auf weitere Analysen der Auswertungsergebnisse kann hier nicht eingegangen werden. Die Ergebnisse der Korrelationsrechungen bilden die Planungsgrundlage für weitere gezielte Untersuchungen. Die sodann anfallenden Resultate werden zweckmäßig nach verfeinerten Methoden, insbesondere Ausgleichsrechnungen, aufgeschlüsselt, wie in nachfolgenden Arbeiten gezeigt werden soll.

Summary—The variable experimental parameters for similar objects or processes can be connected by means of relationships that in the first instance may be unknown. The reality and rigour of the connection of data series in the framework of given correlation functions can be checked by the statistical methods of interpreting correlations. In this paper the mathematical details of the necessary calculations are given and formulated in ALGOL language as universally applicable subprogramme procedures called KORR and TEST. It is shown that such universal procedures correspond to "black boxes" in cybernetic terminology, and can be used as building blocks, without knowledge

of their mathematical content. The writing of an overall programme for special problems is thereby so essentially simplified that it can be done satisfactorily after a short training without a mathematical background. As a practical example, 6 correlation equations and 9 sets of correlation coefficients can be programmed and solved electronically in 9 min. The time taken by conventional methods is 100 times as great.

Résumé—On peut relier les paramètres expérimentaux variables pour des objets ou des procédés similaires au moyen de relations qui, en première instance, peuvent être inconnues. La réalité et la rigueur de la liaison entre des séries de données dans le cadre de fonctions de corrélation données peuvent être contrôlées par les méthodes statistiques d'interprétation de corrélations. Dans ce mémoire on donne les détails mathématiques des calculs nécessaires, et les formule en langage ALGOL à l'état de techniques de sub-programme universellement applicables, appelées KORR et TEST. On montre que de telles techniques universelles correspondent aux "boîtes noires" en terminologie cybernétique et peuvent être utilisées comme des blocs de construction, sans connaissance de leur contenu mathématique. L'écriture d'un programme global pour des problèmes spéciaux est de ce fait tellement simplifiée qu'elle peut être faite de façon satisfaisante après un court entraînement sans un fond de connaissances mathématiques. A titre d'exemple pratique, 6 équations de corrélation et 9 ensembles de coefficients de corrélation peuvent être programmés et résolus électroniquement en 9 mn. Le temps nécessité par les méthodes ordinaires est 100 fois plus long.

The platinum–20% rhodium electrode in potentiometry

(*Received* 19 *January* 1967. *Accepted* 2 *June* 1967)

POTENTIOMETRIC technique with metal/metal oxide electrodes has been developed in great detail, but alloy electrodes have not been so thoroughly studied. The platinum–rhodium alloy electrode (10–40% Rh) has attracted some attention,[1,2] but complete information is not available. Potentials are taken with a stainless steel electrode in some solutions,[3] though mostly in the study of corrosion.[4] With a view to studying the effect of alloying on the electrode potential, we used the platinum–rhodium electrode in various redox and acid–base titrations.

EXPERIMENTAL

The vernier potientiometer used was manufactured by the Oriental Science Apparatus Workshop, Ambala, India and was capable of measuring 10^{-7} V. Platinum and platinum–20% rhodium electrodes were prepared by fusing the 19 s.w.g. wires into 5-mm bore soft glass tubing. A dip-type

saturated calomel electrode (S.C.E.) was used. The metal electrodes were cleaned cathodically by electrolysis of 50% v/v sulphuric acid at 0·2 A for 20 min with a platinum anode and the electrode as cathode.

All the chemicals used were either Merck G.R. grade or B.D.H. AnalaR grade. Approximately 0·1*N* solutions of iron(II) ammonium sulphate, potassium permanganate, cerium(IV) sulphate, sodium hydroxide and sulphuric acid were prepared, standardized in the usual way, suitably diluted, and used in suitable combination for titrations.

RESULTS AND DISCUSSION

Redox titrations

Malmstadt and Fett used a Pt–10% Rh electrode for 0·1*N* iron(II)–dichromate and iron(II)–cerium(IV) titrations.[1] They reported good results, though the end-point obtained with the alloy electrode was always later than that with the platinum electrode, by 0·866 and 0·822 ml respectively.

We performed a wide range of redox titrations at various concentrations for the Pt/S.C.E. and Pt–20%(Rh)/S.C.E. systems, as shown in Table I. For 0·1, 0·01 and 0·001*N* iron(II)–cerium(IV) titrations, the end-points with the alloy electrode were always later than with the platinum electrode. Deformities occur in the lower concentration curves for the alloy electrode, and the potential breaks obtained are also less than with the conventional electrode, the difference being 33, 72 and 207 mV for 0·1, 0·01 and 0·001*N* concentrations respectively.

For 0·1 and 0·01*N* dichromate–iron(II) titrations, the end-points are nearly the same for both the electrodes, but the potential breaks for the alloy electrode are smaller than those for platinum by 549 and 323 mV. For 0·1, 0·01 and 0·001*N* iron(II)–permanganate titrations, a similar trend of progressive diminution in potential breaks and of deformities in the lower concentration curves (Fig. 1) is obtained.

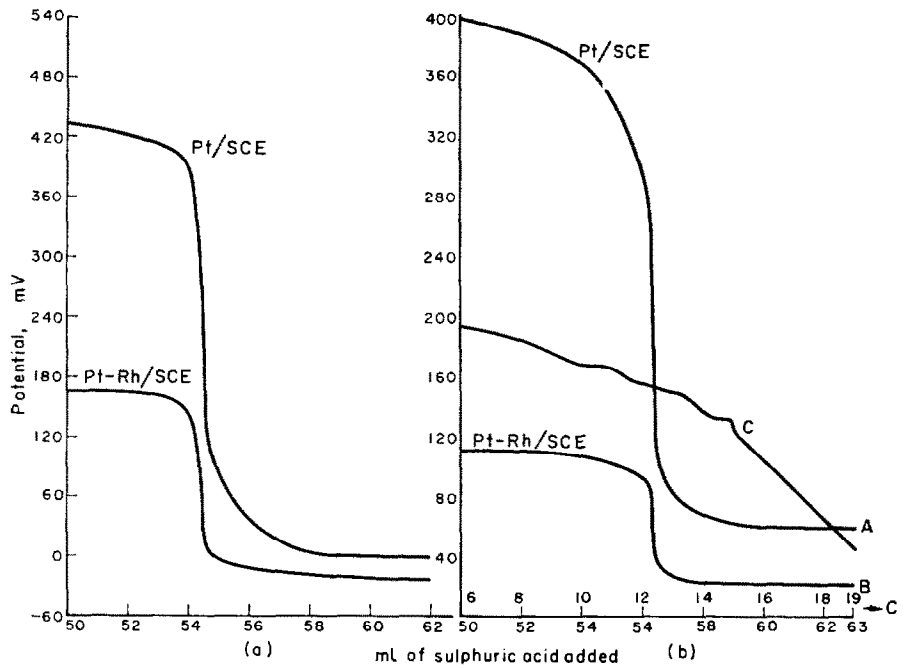

FIG. 2.—Potentiometric acid–base titrations, with Pt/S.C.E. and Pt–Rh/S.C.E. electrode systems.

(*a*) 0·1*M* NaOH *vs.* 0·1*N* H_2SO_4.

(*b*) 0·01*M* NaOH *vs.* 0·01*N* H_2SO_4; curve C is for 0·001*M* NaOH *vs.* 0·001*N* H_2SO_4, with the glass electrode–calomel electrode system.

Acid–base titrations

Strong acid–strong base titrations using the Pt/S.C.E. system have been reported,[5] and the Pt–Rh/S.C.E. system[3] for higher concentrations. The end-points obtained with the alloy electrode are earlier than those with the platinum electrode (Table I). The potential breaks are smaller for the alloy electrodes as usual. No good curves were obtained for any electrode system for concentrations below 0·01*N*. Figure 2 shows the curves for 0·1 and 0·01*N* sodium hydroxide–sulphuric acid titrations for both the electrode systems; results are more reproducible with the platinum electrode than with the alloy electrode.

Bimetallic electrode system

The alloy electrode is, however, found to be very useful in redox and acid–base titrations if used in combination with a platinum electrode. This combination gives peaks which are similar to the first differential peak of the zero current potentiometric curve because the potential breaks obtained at the end-points with these two electrodes, used separately, are different. The peaks could also be calculated from the difference of potential for each point in the iron(II)–permanganate curves shown in Fig. 1. The peaks thus calculated, as well as those actually obtained by using the bimetallic electrode system, are shown in Fig. 3.

Calculated and experimental results obtained for 0·1, 0·01 and 0·001*N* iron(II)–permanganate titrations, with the bimetallic electrode system, are given in Table II. The end-points obtained from the peaks coincide with the true end-points and are exactly the same for all the titrations. As the concentration decreases, the peaks become broader (the observed peaks are much broader than the calculated ones). The increase in peak height with decreasing concentration is greater for the observed

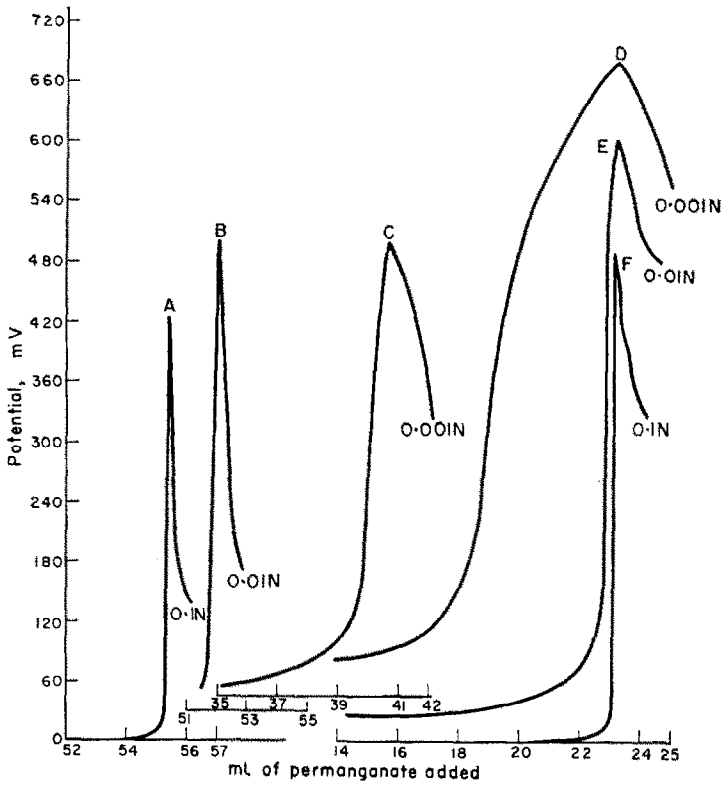

FIG. 3.—Bimetallic electrodes (Pt and Pt–Rh) in the potentiometric titration of iron(II) with permanganate.
Curves A, B, C are calculated from the curves in Fig. 1; curves D, E, F are those observed experimentally.

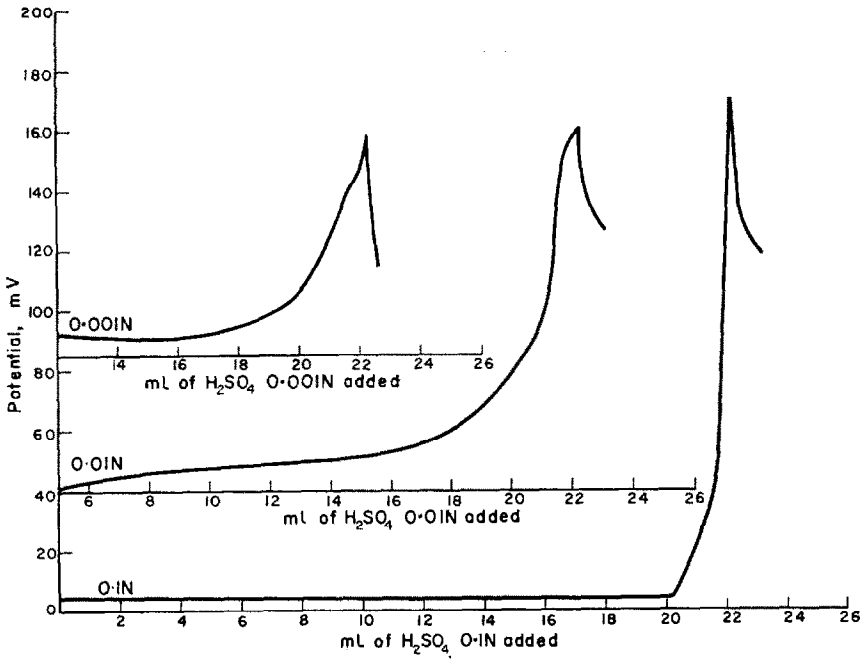

FIG. 4.—Bimetallic electrodes (Pt and Pt–Rh) in the potentiometric titration of NaOH with H_2SO_4.

peaks than for the calculated peaks. This difference in behaviour may be ascribed to meter-induced polarization of the metal and alloy electrodes.[6]

For acid–base titrations however (Fig. 4, Table II) the peak heights decrease with decreasing concentration; the end-points are the true end-points. Excellent peaks were obtained for 0·001*N* solutions, where the Pt/S.C.E., Pt–Rh/S.C.E. or glass/S.C.E. systems fail.

Unlike some bimetallic electrode systems with which an S-shaped curve is obtained,[7,8] this electrode system gives high peaks even at low concentrations, enabling easier true end-point detection.

Smaller potential breaks are obtained with the alloy electrode. Sometimes the end-points are later than the true end-points. In this respect, the alloy electrode is comparable to unclean and untreated metal electrodes which always show a response lag.[9,10] The alloyed and unalloyed bimetallic

TABLE II.—PERFORMANCE OF THE BIMETALLIC ELECTRODE SYSTEM

Titration	Reagent concentration, *N*	Peak height, *mV*		End-point, *ml*		
		Calculated	Observed	True	Calculated	Observed

Summary—The performance of a platinum–20% rhodium alloy indicator electrode is studied in a number of potentiometric redox and acid–base titrations and compared with that of the conventional platinum electrode. The potential breaks obtained with the alloy electrode are always smaller than those obtained with the platinum electrode. The end-points are also usually indicated later than the true end-points. The bimetallic electrode system comprising platinum and platinum–rhodium electrodes gives a peak at the correct end-point even with 0·001*N* concentration titrations, where the ordinary potentiometric systems do not always give good results.

Zusammenfassung—Das Verhalten einer Indikatorelektrode aus einer Legierung von Platin mit 20% Rhodium wird bei einer Anzahl potentiometrischer Redox- und Säure–Basen-Titrationen untersucht und mit dem der gebräuchlichen Platinelektroden verglichen. Die Potentialsprünge mit der legierten Elektrode sind stets kleiner als die mit der Platinelektrode erhaltenen. Die Endpunkte werden gewöhnlich später angezeigt als die wahren Endpunkte. Das Zwei-Metall-Elektrodensystem aus Platin- und Platin-Rhodium-Elektroden gibt am richtigen Endpunkt selbst bei Titrationen mit der Konzentration 0,001*N* eine Spitze, wo die gewönnlichen potentiometrischen Systeme nicht immer gute Ergebnisse zeigen.

Résumé—On a étudié le fonctionnement d'une électrode indicatrice en alliage platine-20% rhodium pour un certain nombre de titrages potentiométirques redox et acide–base et l'a comparé à celui de l'électrode de platine usuelle. Les brisures de potentiel obtenues avec l'électrode en alliage sont toujours plus petites que celles obtenues avec l'électrode de platine. Les points de fin de dosage sont aussi indiqués habituellement plus tard que les points de fin de dosage vrais. Le système d'électrodes bimétallique comprenant des électrodes en platine et platine-rhodium donne un pic au point de fin de dosage correct même avec des titrages à la concentration 0,001*N*, ou les systèmes potentiométriques ordinaires ne donnent pas toujours de bons résultats.

Neutron-activation analysis of manganese in polysulphide materials*

(*Received* 24 *April* 1967. *Accepted* 1 *June* 1967)

As a result of our continuing efforts to apply neutron-activation analysis (NAA) to various matrices containing a variety of elements which are not easily determined by other techniques, we have developed a method for determining manganese in polysulphide adhesives. Manganese, as manganese dioxide, is added to these adhesives as a catalyst, and the "curing rate" is dependent on its concentration. Wet chemical determination of manganese in these samples can be tedious and time-consuming, whereas neutron-activation analysis provides speed and sensitivity, and is non-destructive.

The use of neutron-activation analysis to determine manganese in various materials has been reported by other authors.[1,2] The cross-section (13 barns) and the half-life (2·58 hr) are an ideal combination for analysis in the absence of interfering elements.

EXPERIMENTAL

Apparatus

γ-counting. TMC 400-channel analyser with 3 × 3 in. sodium iodide crystal (T1 activated)

Reactor. The Sandia Engineering Reactor Facility (SERF), with a thermal flux of approximately 2×10^{12} n cm^{-2} sec^{-1}.

Polyethylene rabbits.

Reagents

Manganese metal. United Mineral & Chemical Corp.

Manganese dioxide, C. P. grade.

Coast Pro Seal 890 *polysulphide adhesive.*

Compounded polysulphide standard (2·56% *Mn*). Add a known amount of MnO_2 to pure polysulphide material, mix well and allow to harden.

Procedure

Samples of the standard material, pure manganese metal, and manganese dioxide were irradiated in SERF for times ranging from 5 min to 2 hr and then allowed to "cool" for approximately 30 min. The nuclear reaction used was $^{55}Mn(n, \gamma)^{56}Mn$. Manganese-56 has a half-life of 2·58 hr and decays with emission of 0·845, 1·81, and 2·12-MeV gamma rays. To obtain analytical information, the net counts for the 0·845-MeV photopeaks of the standard material, the manganese metal, and the manganese dioxide were intercompared. No differences were found and any of these three materials could therefore be used as standards. These results were verified by intercomparing the net counts for both the 1·81- and 2·12-MeV photopeaks of these three materials. All three were used as standards for manganese polysulphide unknowns and no significant difference was found in the final results. An irradiation time of 20 min was found to be quite sufficient for determining manganese in the unknowns.

RESULTS AND DISCUSSION

The gamma-ray spectra for our irradiated samples were identical with the standard spectra for ^{56}Mn presented by Heath.[3]

The accuracy and precision of this method were determined by doing two sets of 56 analyses of the standard material (2·56% Mn). The results showed the standard material contained 2·56% of manganese (standard deviations 0·07% and 0·08% Mn). The 0·845-MeV photopeak of ^{56}Mn was used in all cases.

As noted previously, the cross-section of ^{55}Mn and the half-life of ^{56}Mn make an ideal combination for analysis in the absence of interfering elements. However, the application of this method to less favourable sample systems would require the analyst to determine whether there were any serious interferences from radionuclides of other elements in the sample.

* This paper was presented at the Southwest Regional American Chemical Society Meeting, Nuclear and Radiochemistry Section, Albuquerque, New Mexico, 30 November–2 December 1966.

With the irradiation conditions used (20-min irradiation at 2×10^{10} n cm^{-2} sec^{-1}, 30-min preliminary decay time), 1 μg of manganese can be determined. With a 24-hr irradiation and other irradiation conditions remaining constant, 80 ng of manganese could, theoretically, be determined.

Summary—A fast non-destructive neutron-activation analysis method has been developed for manganese in polysulphide adhesives. Samples are irradiated for 20 min at a thermal flux of 2×10^{10} n cm^{-2} sec^{-1}. The net activity in the 0·845-MeV gamma peak of ^{56}Mn produced by the (n, γ) reaction in the sample is compared with the activity obtained from a weighed amount of pure manganese irradiated at the same time. Samples containing 2–3% of manganese have been analysed with a relative standard deviation of 2·9%.

Zussamenfassung—Eine schnelle zerstörungsfreie neutronenaktivierungsanalytische Methode zur Bestimmung von Mangan in Polysulfidklebern wurde entwickelt. Die Proben werden 20 min bei einem thermischen Fluß von $2 \cdot 10^{10}$ n cm^{-2} sec^{-1} bestrahlt. Die Nettoaktivität im 0,845 MeV-Gammapeak des durch die (n,γ)-Reaktion in der Probe gebildeten ^{56}Mn wird mit der Aktivität verglichen, die man in einer gleichzeitig bestrahlten gewogenen Menge reinen Mangans erhält. 2–3% Mangan enthaltende Proben wurden mit einer relativen Standardabweichung von 2,9% analysiert.

Résumé—On a élaboré une méthode rapide non destructive d'analyse par activation de neutrons pour le manganèse dans des adhésifs polysulfures. Les échantillons sont irradiés pendant 20 mn à un flux thermique de 2×10^{10} n cm^{-2} sec^{-1} On compare l'activité globale du pic gamma 0,845-MeV du ^{56}Mn produit par la réaction (n, γ) dans l'échantillon à l'activité obtenue à partir d'une quantité pesée de manganèse pur irradié au même moment. On a analysé des échantillons contenant 2–3% de manganèse avec un écart type relatif de 2,9%.

Amperometric titrations of cobalt(II) with hexacyanoferrate(III) in ammonium citrate and glycine media

(*Received* 30 *March* 1966. *Revised* 5 *May* 1967. *Accepted* 22 *June* 1967)

THE potentiometric titration of cobalt(II) with hexacyanoferrate(III) in the presence of complexing agents such as ammonia, ethylenediamine, triethylenetetramine, tetraethylenepentamine, glycine, and mixtures of alanine or phenylalanine with glutamic acid, has been described by a number of workers,[1–14] but polarographic studies have not so far been made. In the present communication amperometric titrations of cobalt(II) with hexacyanoferrate(III) in aqueous ammonium citrate and glycine media are reported.

Reagents

Cobalt(II), hexacyanoferrate(III), and other electrolyte solutions were prepared in doubly distilled water. Their strengths were determined by the usual methods.

Ammonium citrate buffer, pH 9·8, was prepared by adding 150 ml of 14·0*M* ammonia to 50 g of citric acid and diluting to one litre.

Glycine buffer was prepared from a 2·8*M* solution of the reagent adjusted to pH 8·0 with potassium hydroxide.

Apparatus

A Heyrovsky Lp-55A manually operated polarograph was used with a Pye Scalamp galvanometer. The capillary characteristics in closed circuit at 0·0 V *vs.* the S.C.E. were $m = 0{\cdot}0035$ g/sec, $t = 4{\cdot}30$ sec per drop.

Procedure

Amperometric titrations in ammonium citrate medium (pH 9·8) were carried out at −0·30 V and −1·55 V (lying on the plateaux of the polarograms of 0·005*M* hexacyanoferrate(III) and 0·005*M* cobalt chloride respectively, both in 0·05*M* potassium chloride). In the glycine medium (pH 8·0) the corresponding potentials used were −0·55 V and −1·5 V.

Both direct (0·2–29·5 mg of cobalt(II) in the cell) and reverse titrations (0·2 to 29·4 mg of hexacyanoferrate(III) in the cell) were performed, the titrant being added from a micro-burette. Nitrogen was passed to stir the solutions, and the current was recorded after elapse of about 2 min. Suitable quantities of metal ions were added for the investigation of interferences.

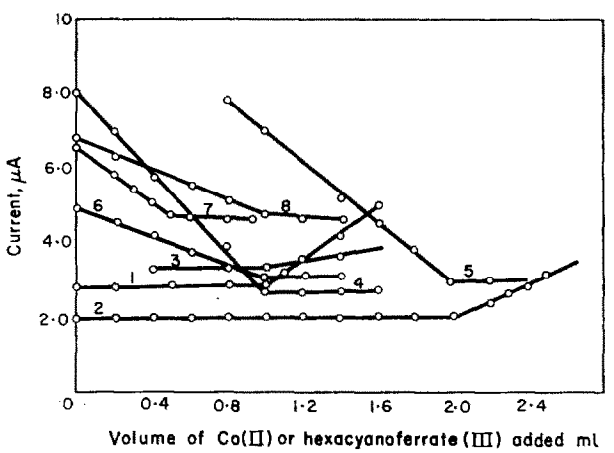

FIG. 1.—Amperometric titration curves at −0·3 V in ammonium citrate buffer at pH 9·8.
Direct titration of Co: *1*—$5 \times 10^{-4}M$; *2*—$10^{-3}M$; *3*—$5 \times 10^{-5}M$.
Reverse titration (Co as titrant): *4*—$5 \times 10^{-4}M$ Fe and Co; *5*—$10^{-3}M$ Fe and Co; *6*—$10^{-4}M$ Fe, $10^{-3}M$ Co; *7*—$5 \times 10^{-5}M$ Fe and Co; *8*—$2{\cdot}5 \times 10^{-5}M$ Fe, $5 \times 10^{-5}M$ Co (Fe = $[Fe(CN)_6]^{3-}$).

RESULTS AND DISCUSSION

The results of amperometric titrations are given in Tables I and II. Typical curves are shown in Fig. 1. From Table I it is evident that these titrations may be carried out successfully with fairly dilute solutions of cobalt(II). Errors of 1·0–1·8% were observed when $10^{-3}M$ solutions were titrated. In the ammonium citrate medium titrations could be carried out at potentials corresponding to the plateaux of cobalt(II) and hexacyanoferrate(III) but in the glycine buffer they were successful only at a potential on the hexacyanoferrate(III) wave (−0·55 V). Separate experiments showed that the binuclear complex formed in the glycine medium was reduced in the vicinity of the other potential (−1·50 V). This might be one of the reasons for the failure of the titrations at −1·5 V in this medium.

In ammonium citrate no interference was observed from copper(II), nickel(II), chromium(III) and vanadium(V), except that reverse titrations could not be successfully carried out in presence of chromium(III). This might be attributed to the oxidation of chromium(III) to chromate. Nickel(II) and vanadium(V) in up to 100-fold amounts did not interfere in the reverse titrations. Determinations were not possible in presence of cerium(III) and iron(III), owing to oxidation to cerium(IV) and precipitation of hydrous iron(III) oxide respectively.

In glycine medium both copper(II) and vanadium(V) interfered even when present in traces, and cerium(III) and chromium(III) when present in more than 10-fold amounts.

Summary—An amperometric titration of cobalt(II) with hexacyanoferrate(III) in aqueous ammonium citrate or aqueous glycine solution at pH 9·8 or pH 8·0 respectively, is reported. Cobalt concentrations of 2–30 mg/l were successfully determined. In citrate solutions cerium(III) and iron(III) interfered, and in glycine solutions, copper(II) and vanadium(V).

Zusammenfassung—Es wird über eine amperometrische Titration von Kobalt(II) mit Hexacyanoferrat(III) in wäßriger Ammoncitrat- oder Glycinlösung bei pH 9,8 bzw. 8,0 berichtet. Kobaltkonzentrationen von 2–30 mg/l wurden mit Erfogl bestimmt. In Citratlösungen störten Cer(III) und Eisen(III), in Glycinlösungen Kupfer(II) und Vanadium(V).

Résumé—On décrit un titrage ampérométrique du cobalt(II) au moyen d'hexacyanoferrate(III) en citrate d'ammonium aqueux ou en solution aqueuse de glycine à pH 9,8 ou pH 8,0 respectivement. On a dosé avec succès des concentrations en cobalt de 2–30 mg/l. En solutions de citrate, le cérium(III) et le fer(III) gênent; le cuivre(II) et le vanadium(V) interfèrent en solutions de glycine.

Selective spot test for hydrazine*

(*Received* 31 *March* 1967. *Accepted* 24 *May* 1967)

KUL'BERG and Cherkesov[1] described a sensitive assay and spot test for hydrazine based on its reaction with picryl chloride to form intensely violet hexanitrohydrazobenzene. However, this assay is not readily applicable to aqueous solutions of hydrazine, since the picryl chloride precipitates from solution and is partly hydrolysed to picric acid.[2]

We have found that trinitrobenzene sulphonic acid (TNBS), a stable water-soluble reagent, reacts with hydrazine to form violet hexanitrohydrazobenzene in weakly alkaline solutions. Monosubstituted hydrazines and primary amines combine with TNBS to form yellow, orange or pink *N*-picryl derivatives. *N,N'*-disubstituted hydrazines do not react. Typical reactons are shown in Fig. 1.

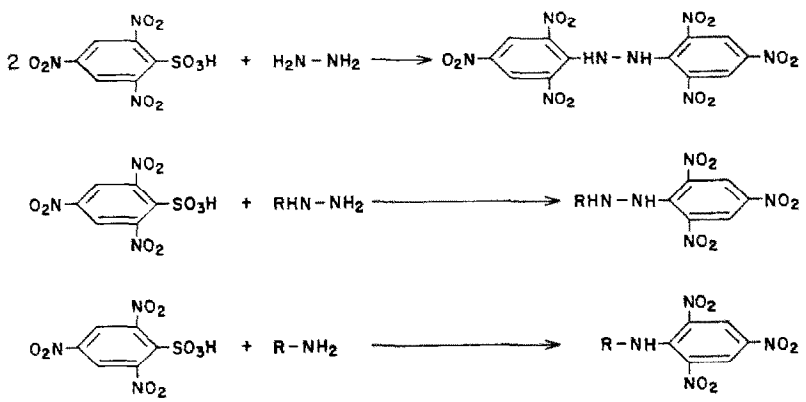

FIG. 1

Serial dilutions of hydrazine and its derivatives were tested with alkaline TNBS. At high concentrations, most gave a dark cherry red colour. Table I lists the identification limits and the colour at the identification limit. The violet colour from hydrazine was unmistakably different from the colour obtained from the hydrazine derivatives. Moreover the violet colour was readily observed when the test was conducted on samples containing equimolar amounts of hydrazine and methylhydrazine, propylhydrazine or phenylhydrazine.

N,N'-dimethylhydrazine, *N,N'*-dicarbethoxyhydrazine, *N,N'*-diacetylhydrazine, 1-acetyl-2-phenyl hydrazine, isonicotinylhydrazone of pyruvic acid, phthalic hydrazide, maleic hydrazide, citraconic hydrazide and luminol did not react with TNBS under the conditions described.

Reagents

Trinitrobenzene sulphonic acid reagent: 0·2% solution in water.
Sodium carbonate, 0·2*M*.

Procedure

To one drop of the test solution in a micro test-tube or on a spot-plate add one drop of trinitrobenzene sulphonic acid reagent and one drop of sodium carbonate solution. A violet colour appearing within 2 min is a positive test for hydrazine. If the colour is a dark red, dilute the test solution 10-fold and repeat the procedure.

Limit of identification 0·02 μg of hydrazine
Concentration limit $1:2{\cdot}5 \times 10^6$

* Issued as N.R.C. No. 9756.

TABLE I.—COMPOUNDS REACTING WITH TRINITROBENZENE SULPHONIC ACID

Compound	Colour	Limit of identification, μg
Hydrazine	Violet	0·02
Methylhydrazine	Orange	0·2
2-Hydroxyethylhydrazine	Orange	0·5
Propylhydrazine	Pink-orange	0·5
Isopropylhydrazine	Pink-orange	0·5
Phenylhydrazine	Pink-orange	1
p-Carboxyphenylhydrazine	Orange	1
2,4-Dinitrophenylhydrazine	Orange	4
Naphthylhydrazine	Yellow-brown	4
Aminoguanidine	Pink-orange	1
Triaminoguanidine	Brown-red	1
Carbohydrazide	Pink-brown	0·5
Butyric hydrazide	Pink	0·5
β-Hydroxybutyric hydrazide	Pink-orange	0·5
Lactic hydrazide	Orange-brown	1
Capric hydrazide	Orange	1
Aspartic acid β-hydrazide	Yellow	0·5
Glutamic acid γ-hydrazide	Yellow-orange	1·0
Oxalic dihydrazide	Orange	0·5
Malonic dihydrazide	Pink	1
Succinic dihydrazide	Pink	0·5
Glutaric dihydrazide	Pink	1
Adipic dihydrazide	Orange	0·5
Pimelic dihydrazide	Orange	0·5
Suberic dihydrazide	Orange	0·5
Cyclopropane carboxylic hydrazide	Pink	0·5
Benzoic hydrazide	Orange	0·5
Salicyclic hydrazide	Orange-brown	0·5
m-Nitrobenzoic hydrazide	Orange	0·2
p-Nitrobenzoic hydrazide	Orange-brown	0·1
p-Aminobenzoic hydrazide	Orange	1
4-Toluic hydrazide	Orange	1
Syringic hydrazide	Orange-pink	0·5
3,4,5-Trimethoxybenzoic hydrazide	Yellow	0·5
Benzilic hydrazide	Yellow	2
Mandelic hydrazide	Orange-pink	2
Phenylacetic hydrazide	Orange-pink	2
Indole-3-acetic hydrazide	Orange-pink	1
Indole-3-propionic hydrazide	Orange	1
Isonicotinic hydrazide	Orange	0·5
Ammonium chloride	Yellow	4
Hydroxylamine	Red-orange	2
DL-Alanine	Yellow	2
Albumin	Yellow	30
Aniline	Yellow	2

The concentration limit is dependent on the method of dilution. Aqueous solutions of hydrazine are unstable and dilutions should be made carefully in clean acid-rinsed glass-ware in a stepwise manner.

Determination of micro-amounts of beryllium in urine

(*Received* 1 *May* 1967. *Accepted* 24 *May* 1967)

A NUMBER of methods have been reported for the determination of microgram amounts of beryllium in urine.[1–8] A combination of steps such as precipitation with inorganic carrier, ion-exchange separation, solvent extraction and mercury cathode electrolysis is involved in these methods for the concentration and separation of beryllium prior to its determination. In continuation of our earlier studies,[9] we have used organic co-precipitants for the concentration and separation of beryllium from urine. The co-precipitation of beryllium with Methylene Blue and tannin is carried out directly on the urine sample, and there is no need to destroy the organic matter present in the urine or to remove the inorganic constituents.

EXPERIMENTAL

Reagents

Standard beryllium solution containing 5·0 μg/ml was prepared as recommended by Sandell.[10] Working solutions containing 1·0, 0·2 and 0·02 μg of beryllium per ml were prepared by suitable dilutions of the standard.

Stock Morin solution, 0·05% w/v in ethyl alcohol, was diluted 10-fold with distilled water for use.

Triethanolamine solution 3% v/v in water.

Tetrasodium ethylenediaminetetra-acetate solution (Na_4Y). A suspension of 25 g of disodium EDTA was dissolved by the slow addition of 134 ml of 1·0*M* sodium hydroxide and diluted to 500 ml with distilled water.

Quinine sulphate reference solution (1×10^{-4}% in 0·1*N* sulphuric acid) was prepared by proper dilution of a 0·1% solution in 0·1*N* sulphuric acid.

Methylene Blue solution, 1% w/v in water.

Tannin solution, 10% w/v in water.

Disodium EDTA solution (Na_2H_2Y), saturated.

Apparatus

Jarrell-Ash GM Fluorimeter Mark V with solution attachment.

Procedure for the fluorimetric determination of beryllium

The procedure followed for the determination of beryllium in the range 0·1–1·0 μg was the same as that given by Sandell,[10] except that the addition of stannite was not found necessary and that 1 ml of triethanolamine solution was added to complex heavy metals.

TABLE I.—RECOVERY OF BERYLLIUM FROM URINE

Sample volume, *ml*	Be taken, *μg*	Be recovered, *μg*
200	5·0, 5·0	4·7, 4·8
100	1·0	1·0
100	0·10	0·103 ± 0·009*
100	0·020	0·021 ± 0·004†
1000	Carrier-free ^{7}Be (4300 ± 65 cpm)	4224 ± 65 cpm

* Standard deviation (9 variates).
† Standard deviation (7 variates).

For the range 0·01–0·1 μg of beryllium, sample aliquots were taken in 10-ml Pyrex beakers, 2·5 ml of Na_4Y solution and 1 ml of triethanolamine solution were added to each of the beakers, and the pH of the solutions was adjusted to 11·6–11·9 with sodium hydroxide. The solutions were cooled in an ice-bath for 10 min. Then 0·2 ml of the working solution of Morin was added to each of them and mixed well. The solutions were transferred to 10-ml volumetric flasks and made up to volume with distilled water. The flasks were kept in the ice-bath for a further 10 min, and then 5-ml portions were transferred to clean fluorimetric tubes, the temperature was allowed to rise to 15 ± 1°, and the fluorescence was measured immediately.

Procedure for the co-precipitation of beryllium

To a suitable volume of urine sample (100–1000 ml), add 10 ml of Na_2H_2Y solution and adjust the pH to 8 with sodium hydroxide. Add a few drops of tannin solution followed by 20 ml of Methylene Blue solution and stir well. Add 7 ml more of tannin solution and stir again. Allow the precipitate to settle, filter it off on Whatman No. 540 paper and wash it several times with 0·5% ammonium chloride solution adjusted to pH 8. Dry the precipitate under an infrared lamp, and ignite it in a platinum crucible at 500°. Treat the residue with a drop or two of hydrofluoric acid and 2 ml of perchloric acid and heat almost to dryness on a sand-bath. Add small portions of 5% v/v hydrochloric acid and transfer the solution to a volumetric flask and make up to the mark. Take suitable aliquots of this solution for the fluorimetric determination already described. If the amount of beryllium is less than 0·1 μg use all the residue solution for the fluorimetric determination. Recoveries from urine to which known amounts of beryllium had been added are given in Table I.

Co-precipitation of other ions

A number of cations were studied for their co-precipitation behaviour under the conditions used for beryllium in pure solution.[9] The results are given in Table II.

RESULTS AND DISCUSSION

In the fluorimetric procedure given above for the determination of beryllium in the range 0·1–1·0 μg, it was found that the fluorescence was stable for more than 3 hr if the solutions were not continuously exposed to ultraviolet light. This is in agreement with Sill's findings.[11] In the lower range of 0·01–0·1 μg of beryllium, though the fluorescence was stable in pure solutions it faded rapidly in sample solutions. However, the fluorescence could be stabilized for up to 8 hr by keeping the solutions below 15°. Moreover, it was observed that the sensitivity was then about 25% greater than for measurements made at room temperature. Laitinen[5] has reported a similar increase in the intensity of beryllium–Morin fluorescence at low temperatures.

It can be seen from Table II that though a number of cations accompany beryllium, the co-precipitation of alkali and alkaline earth metals is poor. The precipitation of calcium phosphate in the urine sample at the pH used is prevented by adding EDTA. Thus it is possible by this method to collect beryllium in a single step free from any of the major inorganic constituents present in urine. No prior treatment of the sample is required either to destroy the organic matter or to remove the inorganic constituents present in it. The only other step required before the fluorimetric determination of beryllium is simple ignition of the organic matrix (the precipitate of tannin and Methylene Blue).

The results in Table I show that the reagents used in this method are efficient in collecting micro and sub-micro amounts of beryllium from urine samples. The relative standard deviations at concentrations of beryllium of 0·1 and 0·02 μg/100 ml of urine sample were 9% and 19% respectively.

TABLE II.—BEHAVIOUR OF OTHER CATIONS IN THE PRECIPITATION OF METHYLENE BLUE AND TANNIN

Ion	Amount taken μg	Recovery %
Sm(III)	10	100
La(III)	10	103
Y(III)	10	93
Zn(II)	10	100
Co(II)	10	95
Th(IV)	10	100
Sc(III)	10	100
Pb(II)	10	91
Hf(IV)	10	102

Summary—Methylene Blue and tannin are used to collect beryllium from urine by co-precipitation. After ignition the beryllium is brought into solution and determined fluorimetrically with Morin. When the amount of beryllium is less than 0·1 μg, measurements are carried out at low temperature to prevent fading of the fluorescence. In this method beryllium is collected and separated in a single step and no prior treatment of the urine sample is required either to destroy the organic matter or to remove the inorganic constituents present in it. The relative standard deviations for the determination of 0·1 and 0·02 μg of Be/100 ml of urine sample were 9 and 19% respectively.

Zusammenfassung—Zur Anreicherung von Beryllium aus Urin durch Mitfällung werden Methylenblau und Tannin verwendet. Nach Verglühen wird das Beryllium in Lösung gebracht und fluorimetrisch mit Morin bestimmt. Bei kleineren Berylliummengen als 0,1 μg werden

die Messungen bei tiefer Temperature ausgeführt, um Nachlassen der Fluoreszenz zu vermeiden. Bei dieser Vorschrift wird Beryllium in einem einzigen Arbeitsgang gesammelt und abgetrennt, ohne daß der Urin zur Zerstörung des organischen Materials oder der anorganischen Bestandteile einer Vorbehandlung bedürfte. Die relativen Standardabweichungen bei der Bestimmung von 0,1 und 0,02 μg Beryllium in 100 ml Urinprobe waren 9 und 19%.

Résumé—On utilise le bleu de méthylène et le tannin pour recueillir le béryllium de l'urine par coprécipitation. Après calcination, le béryllium est mis en solution et dosé par fluorimétrie au morin. Lorsque la quantité de béryllium est inférieure à 0,1 μg, les mesures sont menées à basse température pour éviter l'affaiblissement de la fluorescence. Dans cette méthode, le béryllium est recueilli et séparé en un seul stade et aucun traitement préalable de l'urine n'est necessité, soit pour détruire la matière organique, soit pour éliminer les constituants inorganiques qu'elle renferme. Les écarts types relatifs pour le dosage de 0,1 et 0,02 μg de Be/100 ml d'échantillon d'urine sont de 9 et 19% respectivement.

Homogeneous precipitation of basic aluminium benzoate with a buffer solution

(*Received* 19 *April* 1967. *Accepted* 6 *May* 1967)

It has been shown that homogeneous precipitation by addition of a buffer solution of pH just sufficient to precipitate the required hydroxide produces an easily filterable precipitate and is more easily controlled than by the urea hydrolysis method.

Britton[2] gives the following values for the pH at which metal sulphates just start to precipitate as hydroxides; iron(III), 2: aluminium, 4·1: chromium(III), 5·3: copper(II), 5·3: iron(II), 5·5; beryllium, 5·7: nickel, 6·7: cadmium, 6·7: cobalt(II), 6·8: zinc, 7·0: manganese(II), 8·6: magnesium, 10·5.

Replacing sulphate by benzoate should not change this order but separate experiments have shown that aluminium solutions first appear cloudy at pH 3·1 in the presence of benzoic acid and one might expect a comparable lowering for other metal hydroxides. The basic aluminium benzoate is completely precipitated at pH 3·7, just below the pH of maximum buffer capacity of the benzoic acid benzoate system (pK, 4·2). The quantitative precipitation of aluminium can be achieved in the presence of a large excess of cadmium, calcium, cobalt, copper, manganese, nickel and zinc.

die Messungen bei tiefer Temperature ausgeführt, um Nachlassen der Fluoreszenz zu vermeiden. Bei dieser Vorschrift wird Beryllium in einem einzigen Arbeitsgang gesammelt und abgetrennt, ohne daß der Urin zur Zerstörung des organischen Materials oder der anorganischen Bestandteile einer Vorbehandlung bedürfte. Die relativen Standardabweichungen bei der Bestimmung von 0,1 und 0,02 μg Beryllium in 100 ml Urinprobe waren 9 und 19%.

Résumé—On utilise le bleu de méthylène et le tannin pour recueillir le béryllium de l'urine par coprécipitation. Après calcination, le béryllium est mis en solution et dosé par fluorimétrie au morin. Lorsque la quantité de béryllium est inférieure à 0,1 μg, les mesures sont menées à basse température pour éviter l'affaiblissement de la fluorescence. Dans cette méthode, le béryllium est recueilli et séparé en un seul stade et aucun traitement préalable de l'urine n'est necessité, soit pour détruire la matière organique, soit pour éliminer les constituants inorganiques qu'elle renferme. Les écarts types relatifs pour le dosage de 0,1 et 0,02 μg de Be/100 ml d'échantillon d'urine sont de 9 et 19% respectivement.

Homogeneous precipitation of basic aluminium benzoate with a buffer solution

(*Received* 19 *April* 1967. *Accepted* 6 *May* 1967)

It has been shown that homogeneous precipitation by addition of a buffer solution of pH just sufficient to precipitate the required hydroxide produces an easily filterable precipitate and is more easily controlled than by the urea hydrolysis method.

Britton[2] gives the following values for the pH at which metal sulphates just start to precipitate as hydroxides; iron(III), 2: aluminium, 4·1: chromium(III), 5·3: copper(II), 5·3: iron(II), 5·5; beryllium, 5·7: nickel, 6·7: cadmium, 6·7: cobalt(II), 6·8: zinc, 7·0: manganese(II), 8·6: magnesium, 10·5.

Replacing sulphate by benzoate should not change this order but separate experiments have shown that aluminium solutions first appear cloudy at pH 3·1 in the presence of benzoic acid and one might expect a comparable lowering for other metal hydroxides. The basic aluminium benzoate is completely precipitated at pH 3·7, just below the pH of maximum buffer capacity of the benzoic acid benzoate system (pK, 4·2). The quantitative precipitation of aluminium can be achieved in the presence of a large excess of cadmium, calcium, cobalt, copper, manganese, nickel and zinc.

EXPERIMENTAL

Reagents

Buffer, pH 4·25–4·35. Dissolve 45 g of ammonium chloride, 5 g of benzoic acid and 15 g of ammonium benzoate in 2 l. of water.

Ammonium benzoate. Add excess of ammonia to a solution of recrystallized benzoic acid. Concentrate the solution to incipient crystallization, making sure that ammonia is present in slight excess, then cool rapidly, and dry at 90° the crystals which separate.

Standard aluminium solution, 1 *g/l*. Dissolve about 1 g of pure aluminium (accurately weighed) in dilute hydrochloric acid and dilute to 1 l.

Stock solutions of other metals were prepared by dissolving the appropriate amounts of the chlorides in water. These solutions were not standardized.

Procedure

To 350 ml of the benzoate buffer add 50 ml of standard aluminium solution which has been treated first with enough aqueous ammonia to give a faint permanent cloudiness and then by careful addition of dilute hydrochloric acid until the solution is clear.

Boil the solution for 2 min, allow it to stand for 30 min and filter off the precipitate on a retentive paper. The pH of the filtrate is typically 3·98, well above the pH at which all the aluminium is precipitated.

Wash the precipitate with 2% ammonium benzoate solution adjusted to pH 4·2 (Bromocresol Green indicator) and ignite to Al_2O_3 at 1250°.

RESULTS AND DISCUSSION

Typical results for 0·0854 g of Al_2O_3 taken are 0·0853, 0·0855, 0·0852 g by the ammonia method[a] and 0·0854, 0·0853, 0·0854 g by the proposed method.

Filtration is rapid and the determination can be carried out very much faster than by the standard ammonia method. Washing the precipitate with 1% ammonium chloride led to low results, owing to dissolution of the precipitate, even though the pH of the wash solution had been adjusted to pH 4·2; it had dropped to 3·2 by the end of the washing. Ammonium benzoate wash solution adjusted to pH 4·2 did not change in pH on passing through the filter.

The procedure was used to determine aluminium in the presence of other metal ions, and the results are given in Table I.

TABLE I.—DETERMINATION OF ALUMINIUM IN THE PRESENCE OF OTHER METAL IONS

Al_2O_3 taken, *g*	Other metal ion present, *g*	Al_2O_3 found, *g*
0·0853	0·24 Mn	0·0854
	0·36 Mn	0·0855
0·0853	0·41 Ca	0·0854
	0·67 Ca	0·0853
0·0853	0·18 Cd	0·0852
	0·25 Cd	0·0852
0·0853	0·42 Ni	0·0856
	0·52 Ni	0·0855
0·0855	0·40 Co	0·0856
	0·50 Co	0·0855
0·0855	0·31 Cu*	0·0854
0·0855	0·75 Cu*	0·0853
0·0853	0·21 Zn	0·0852†
0·0853	0·45 Zn	0·0853‡

* Reduced to copper(I) with $NH_2OH.HCl$ before the precipitation.

† Reprecipitation: 0·8 mg of Zn accompanied the aluminium in the first precipitation.

‡ Reprecipitation: 1·7 mg of Zn accompanied the aluminium in the first precipitation.

These results show that aluminium can be satisfactorily determined in the presence of a large excess of manganese, calcium, cadmium, nickel and cobalt without any complications. In the case of copper it was found that a small amount of copper(II) benzoate precipitated with the aluminium hydroxide, but this interference could be satisfactorily overcome by previous reduction to copper(I) with hydroxylamine hydrochloride or by double precipitation without the reduction. Similarly with zinc there is appreciable coprecipitation which can be overcome by a second precipitation.

Chromium, iron and beryllium all caused difficulties which necessitates a preliminary separation of these elements. Reduction of iron to iron(II) did not prove to be feasible as it was impossible to prevent aerial oxidation at the surface of the liquid. Chromium and beryllium both coprecipitated extensively with aluminium at pH 4 even though one would not expect their hydroxides to form at pH values below 5·3 and 5·7 respectively.

Zincon and its mercury and zinc complexes as indicators in EDTA titrations

(*Received* 8 *May* 1967. *Accepted* 30 *June* 1967)

ZINCON (2-carboxy-2′-hydroxy-5′-sulphoformazylbenzene), a well known colorimetric reagent for copper, zinc and mercury,[1–3] was introduced in chelometry for the direct EDTA titration of zinc and the indirect titrations of copper(II), nickel, cobalt(II), iron(III), manganese(II), cadmium, lead, cerium(III), indium, calcium, chromium and aluminium *via* back-titration of excess of EDTA with a

standard solution of zinc in alkaline medium by Kinnunen and Merikanto.[4] Ringbom[5] and Reilley[6] have used the Zn–Zincon complex as indicator for the direct titration of calcium with EGTA in presence of magnesium. In the present investigation it has been observed that Zincon is a very suitable indicator for the direct titration of mercury(II) in slightly acidic medium (pH 5·5–7). In this pH range the Hg(II)–Zincon complex also acts as a suitable indicator for the direct titration of lead and cadmium. It has been further observed that lead and cadmium can be directly titrated with EDTA, the indicator being the Zn–Zincon complex in ammoniacal buffer (pH 9·5). Reilley[6] mentioned that in the EGTA titration of calcium by this method, use of too high a concentration (0·1*M*) of ammonia in the buffer causes competition between the various zinc-complexing agents and leads to unsharp end-points. This disadvantage is obviated in our method, where the titration is carried out with EDTA instead of EGTA, because the Zn–EDTA complex has a higher stability constant ($\log K = 16{\cdot}5$) than that of the Zn–EGTA complex ($\log K = 13{\cdot}0$). However, EDTA could not be used for the titration of calcium in the presence of magnesium, with which EDTA reacted completely, whereas EGTA did not.

The stability and colour intensity of the Hg–Zincon complex is maximum at pH 7, but the indicator can be used for titration of mercury(II) with EDTA at pH 5·5–7 in acetate buffer, there being a sharp colour change from blue to pale red at the end-point. The titration can be carried out even in the presence of equivalent concentrations of chloride and bromide. The method gave accurate results, error not exceeding 0·3%, when mercury(II) solutions, concentration 10–40 mg/50 ml, were titrated.

The titrations of lead and cadmium with EDTA, using Hg–Zincon complex as indicator in acetate buffer (pH 5·5–7) or Zn–Zincon indicator in ammoniacal buffer (pH 9·5) were found to have an experimental error of 0·3%. The titration with Hg–Zincon complex has the advantage that alkaline earths do not interfere.

EXPERIMENTAL

Reagents

Standard EDTA solution, 0·1*M*. Prepared from analytical reagent grade disodium salt.

Mercury(II), 0·1*M*. Prepared from analytical grade mercury(II) chloride and standardized.[7–8]

Standard lead, calcium and cadmium solutions, 0·1*M*. Prepared from the analytical grade nitrates and standardized by EDTA titration.

Solutions of other metal ions. Prepared from analytical grade salts.

All these solutions were prepared in conductivity water and were diluted to the desired molarities.

Zincon indicator solution. Prepared by dissolving 0·13 g of Zincon indicator (Light-Koch) in 2 ml of 1*M* sodium hydroxide and diluting to 100 ml.

Mercury(II)–EDTA complex solution. Prepared by mixing equal volumes of 0·1*M* EDTA and 0·1*M* mercury(II) solutions.

Zinc–EDTA complex solutions. Prepared by mixing equal volumes of 0·1*M* EDTA and 0·1*M* zinc solutions.

Buffer solutions. Buffer solutions of pH ranging from 4·5 to 7·0 were prepared by mixing appropriate volumes of 0·2*M* sodium acetate and 0·2*M* acetic acid, and of pH 9·5 and 10 by mixing appropriate volumes of 1*M* ammonium chloride and 1*M* ammonia. Final pH of the buffer solutions was checked with pH meter and adjusted.

Direct titration of Hg(II) with EDTA, with Zincon as indicator

Mercury(II) solution (50 ml containing 10 mg of mercury) was mixed with an equal volume of acetate buffer, pH 6, and 5–6 drops of Zincon indicator solution. The pH of the solution was adjusted to 6 with 0·2*M* sodium acetate, and checked with pH meter. The blue solution was titrated with 0·02*M* EDTA until the colour changed abruptly to pale red at the equivalence point. The titration was carried out with constant shaking. The colour change at the end-point was very sharp and reversible. In this titration Cu^{2+}, Ni^{2+}, Co^{2+}, VO^{2+}, Fe^{3+}, Ga^{3+}, In^{3+}, Tl^{3+}, Al^{3+}, La^{3+} and Sm^{3+} caused interference even when present in traces, by blocking the indicator. Pb^{2+}, Cd^{2+}, Zn^{2+} and Mn^{2+} were co-titrated and when present in appreciable amounts gave a titration value which corresponded to the sum of the metal ions, except for Zn^{2+} and Mn^{2+} where it was always found to be less. Mercury could be accurately titrated even in the presence of tenfold amounts of alkaline earths. Chloride and bromide did not interfere when present in up to equivalent proportions but only traces of iodide could be tolerated. Other anions such as sulphate, acetate, nitrate did not interfere but phosphate, oxalate, citrate and tartrate did.

Direct titration of Pb^{2+} or Cd^{2+} with EDTA, with Hg(II)–Zincon as indicator

Ten ml of the metal ion solution (0·02*M*) were mixed with an equal volume of acetate buffer, pH 6, and 5–6 drops of the Zincon solution. When 1 ml of 0·1*M* Hg(II)–EDTA complex solution

was added to it a blue colour developed. The solution was titrated with 0·02*M* EDTA with constant shaking. At the equivalence point the colour changed to pale red. The colour change was sharp and reversible. In this titration Cu^{2+}, Ni^{2+}, Co^{2+}, VO^{2+}, Fe^{3+}, Ga^{3+}, In^{3+}, Tl^{3+}, Al^{3+}, La^{3+} and Sm^{3+} caused interference even when present in traces, by blocking the indicator. The alkaline earths did not interfere and traces of Zn^{2+} and Mn^{2+} could be tolerated.

Direct titration of Pb^{2+}, Cd^{2+} or Ca^{2+} ions with EDTA, using Zn–Zincon indication

The metal solution was mixed with an equal volume of ammoniacal buffer, pH 9·5 or 10 (about 0·1 g of solid sodium tartrate was also added to the lead solution), 3–4 drops of Zincon solution, and 1 ml of Zn–EDTA complex solution. The same titration procedure was used. In this titration Cu^{2+}, Ni^{2+}, Co^{2+}, VO^{2+}, Fe^{3+}, Ga^{3+}, In^{3+}, Tl^{3+}, Al^{3+}, La^{3+} and Sm^{3+}, even when present in traces, blocked the indicator. The alkaline earths, Zn^{2+} and Mn^{2+} were cotitrated.

Summary—Zincon has been found to be an excellent indicator in the titration of mercury(II) with EDTA at pH 5·5–7. Moreover the mercury(II)–Zincon and zinc–Zincon systems have been found to be suitable indicators in the direct EDTA titrations of Pb^{2+}, Cd^{2+} and Ca^{2+}. Interference studies of a number of cations and anions have been made. Chloride and bromide can be tolerated in the titration of mercury(II), up to equivalent concentrations.

Résumé—On a trouvé que le Zincon est un excellent indicateur pour le dosage du mercure(II) à l'EDTA à pH 5,5–7. En outre, on a trouvé que les systèmes mercure (II)–Zincon et zinc–Zincon sont des indicateurs convenables pour les titrages directs à l'EDTA de Pb^{2+}, Cd^{2+} et Ca^{2+}. On a fait une étude sur les interférences d'un certain nombre de cations et d'anions. On peut tolérer le chlorure et le bromure dans le dosage du mercure(II) jusqu'à des concentrations équivalentes.

Zusammenfassung—Zincon ist ein ausgezeichneter Indikator bei der Titration von Quecksilber(II) mit EDTA bei pH 5,5–7. Darüber hinaus sind die Systeme Quecksilber(II)–Zincon und Zink–Zincon geeignete Indikatoren bei der direkten EDTA-Titration von Pb^{2+}, Cd^{2+} und Ca^{2+}. Die Störung von einer Anzahl Kat- und Anionen wurde untersucht. Chlorid und Bromid können bis zu äquimolaren Mengen bei der Titration von Quecksilber(II) anwesend sein.

Successive chelatometric titration of calcium and magnesium

(*Received* 3 *March* 1967. *Accepted* 28 *June* 1967)

3′,3″-BIS(2-HYDROXY-3-CARBOXY-NAPHTHALENEAZO)PHENOLPHTHALEIN (BNP)[1] can be used as a metallochromic indicator for the alkaline earths. At pH 10 the colour of the reagent is red-violet and that of the chelate is blue, whereas above pH 12 the colours are blue-violet and red respectively. Thus the reagent can be used as an indicator for the successive chelatometric titration of calcium and magnesium in natural waters, by a simple procedure; calcium is titrated at pH 13, the end-point colour change being from red to blue-violet, and then after adjustment of the pH to 10 the magnesium is titrated, with a colour change from blue to red-violet at the end-point.

This procedure is reliable and is simpler than that due to Patton and Reeder.[2]

EXPERIMENTAL

Reagents

EDTA solution, 0·01M. Standardized with standard 0·01*M* zinc solution prepared from zinc that is 99·999% pure.

Calcium solution, 0·01M. Dissolve calcium carbonate in hydrochloric acid, dilute to volume and standardize with EDTA.

Magnesium sulphate solution, 0·01M. Standardized with EDTA.

BNP, 0·1% aqueous solution. Prepare BNP by the published procedure[1] and dissolve it in a small amount of acetone before diluting with water.

Other reagents are of analytical grade.

Procedures

Determination of calcium. Add to 100 ml of calcium solution (~0·001*M*) 0·2–0·5 g of potassium hydroxide and a few drops of the indicator solution. Titrate with 0·01*M* EDTA till the colour turns from red to blue-violet. The colour change is improved by addition of 10 ml of acetone to the solution, but the acetone must be omitted if magnesium is to be titrated subsequently, as it makes that end-point indistinct.

Determination of magnesium. Magnesium is titrated by the same method as calcium but at pH 10. At the end-point the colour changes from blue to red-violet, but it is somewhat difficult to detect the end-point, because the colour change proceeds slowly.

Successive titration for calcium and magnesium. Add, to 50 ml of sample solution containing calcium and magnesium, a few drops of the indicator and 0·3 g of potassium hydroxide to adjust the pH to 13. Titrate with 0·01*M* EDTA till the colour changes from red to blue-violet.

Acidify with 0·3 ml of concentrated hydrochloric acid and dissolve the magnesium hydroxide precipitate completely. Add a few drops of 3*M* ammonia till the colour becomes blue. Add 5 ml of ammonia-ammonium chloride buffer solution (pH 10) and a few more drops of the indicator if the colour has faded.

Continue the titration till the colour turns from blue to red-violet.

RESULTS AND DISCUSSION

The colour of the indicator when free or complexed is greatly affected by pH (Table I). Results of typical titrations of calcium, magnesium and mixtures of the two ions are shown in Tables II, III and IV respectively. Iron(III) interferes but can be effectively masked with triethanolamine. If a large amount of magnesium is present there will be the usual risk of coprecipitation of calcium on the magnesium hydroxide precipitate.

* Patton–Reeder indicator.[2]
† Eriochrome Black T.

Calcium and magnesium in river water and underground water have been determined by this method, and the results compared with the ordinary method in which the indicators were Patton and Reeder's for calcium, and Eriochrome Black T for magnesium (Table V).

This method was more convenient and faster than the ordinary chelatometric method for calcium and magnesium in water.

Controlled potential coulometric determination of uranium and neptunium in uranium–neptunium alloys*

THE need for an analytical method for the determination of uranium and neptunium in the presence of each other arose when our Metallurgical Laboratory prepared a uranium-neptunium alloy. It appeared obvious that these two elements could not be determined by the normal analytical procedures if the necessary precision and accuracy were to be attained. Controlled potential coulometry, however, seemed to offer the necessary precision, accuracy, and freedom from interference. It would also eliminate the necessity of a separation of these elements before an analysis could be performed.

The controlled potential coulometric determination of uranium has been widely investigated, as can be seen from the numerous papers on the subject.[1–4] Stromatt[5] has reported the successful controlled potential coulometric determination of neptunium. There is, however, no report of these elements being determined in the presence of each other.

EXPERIMENTAL

Apparatus

A Numec Model 6000 controlled potential coulometric titrator, described by Jones *et al.*,[6,7] and manufactured by Nuclear Materials and Equipment Corporation of Apollo, Pennsylvania, was used for this investigation. The titration cell and assembly have been described.[5]

* Work Performed Under U.S. Atomic Energy Commission Contract AT(29-1)-1106.

Controlled potential coulometric determination of uranium and neptunium in uranium–neptunium alloys*

THE need for an analytical method for the determination of uranium and neptunium in the presence of each other arose when our Metallurgical Laboratory prepared a uranium-neptunium alloy. It appeared obvious that these two elements could not be determined by the normal analytical procedures if the necessary precision and accuracy were to be attained. Controlled potential coulometry, however, seemed to offer the necessary precision, accuracy, and freedom from interference. It would also eliminate the necessity of a separation of these elements before an analysis could be performed.

The controlled potential coulometric determination of uranium has been widely investigated, as can be seen from the numerous papers on the subject.[1–4] Stromatt[5] has reported the successful controlled potential coulometric determination of neptunium. There is, however, no report of these elements being determined in the presence of each other.

EXPERIMENTAL

Apparatus

A Numec Model 6000 controlled potential coulometric titrator, described by Jones *et al.*,[6,7] and manufactured by Nuclear Materials and Equipment Corporation of Apollo, Pennsylvania, was used for this investigation. The titration cell and assembly have been described.[5]

* Work Performed Under U.S. Atomic Energy Commission Contract AT(29-1)-1106.

Reagents

Stock solutions of uranium were prepared from standard sample 950a, U_3O_8, obtained from the U.S. National Bureau of Standards. Neptunium stock solutions were prepared by dissolving neptunium dioxide, 99·74% NpO_2, in concentrated nitric acid with heating. All other chemicals were reagent grade.

Neptunium procedure

A cell with a platinum gauze working electrode was used. A 15-ml volume of 0·5*M* sulphuric acid supporting electrolyte solution was placed in this titration cell and deaerated for 3 min with a stream of argon. The solution was prereduced at 0·66 V *vs.* the saturated calomel electrode (SCE) under an argon blanket until the cell current had decreased to 30 μA, and was then preoxidized at 1·02 V *vs.* SCE until the cell current had again decreased to 30 μA. An aliquot, containing from 0·5 to 5·0 mg of neptunium, was transferred to the titration cell, followed by 0·25 ml of 0·05*M* cerium(IV) sulphate solution and 0·5 ml of a saturated solution of sulphamic acid. The solution was reduced at 0·66 V *vs* SCE under a blanket of argon gas until the cell current had decreased to 30 μA. The solution was then oxidized at 1·02 V *vs.* SCE until the cell current had decreased to 30 μA. By using the integrated current consumed during the oxidation, the amount of neptunium titrated was calculated by Faraday's law for a one-electron oxidation.

Uranium procedure

A 7-ml volume of mercury was used as the working electrode, and 10 ml of 0·5*M* sulphuric acid supporting electrolyte were transferred to the titration cell. The solution was deaerated for 3 min with a stream of argon gas. The solution was prereduced at 0·085 V *vs.* SCE under an argon blanket until the cell current had decreased to 50 μA, and was then reduced at −0·325 V *vs.* SCE until the cell current had again decreased to 50 μA. The integrated current consumed during the reduction was recorded as the background. An aliquot containing from 1·0 to 6·0 mg of uranium, was transferred to the titration cell, followed by 0·25 ml of 0·05*M* cerium(IV) sulphate solution. The solution was again prereduced at 0·085 V *vs.* SCE under a blanket of argon until the cell current had decreased to 50 μA. The solution was then reduced at −0·325 V *vs.* SCE until the cell current had decreased to 50 μA. The uranium content was calculated from the integrated current consumed during the last reduction. A correction for the background current was applied.

Calibration

The coulometer was calibrated absolutely[6] for neptunium titrations and relatively[8] for uranium titrations with a 5·014 mg/ml uranium standard solution. Five aliquots were titrated coulometrically, and a relative standard deviation (RSD) of 0·15% was obtained.

DISCUSSION

Neptunium

To be certain that the system was operating properly for the neptunium determination, a 5·344 mg/ml neptunium nitrate solution was titrated. Five titrations were made by the procedure above. The average relative error was +0·07%, and the RSD was 0·21%.

It appeared from a study of the uranium and neptunium potentials that uranium should not interfere with the neptunium determination. Six titrations, by the neptunium procedure described, were then made to determine whether uranium would interfere. Various ratios (1:1 to 100:1) of uranium to neptunium were titrated, and the results are shown in Table I. The average relative error

TABLE I.—RECOVERY OF NEPTUNIUM IN THE PRESENCE OF URANIUM

U present *mg*	Np, *mg*		Relative error %
	Present	Found	
4·761	5·344	5·354	+0·19
4·761	5·344	5·335	−0·17
4·761	0·534	0·532	−0·37
4·761	0·534	0·535	+0·19
47·61	0·534	0·535	+0·19
47·61	0·534	0·537	+0·56

was +0·10%, and the RSD was 0·32%. These results indicate that neptunium can be titrated successfully in the presence of uranium and are in good agreement with previously published results.[5]

Uranium

After the coulometer had been calibrated, a second uranium standard solution was titrated to check the calibration. This second uranium standard solution had a value of 4·763 mg/ml. Five titrations were made by the uranium procedure described. The average relative error was −0·02%, and the RSD was 0·22%.

A study of the uranium and neptunium potentials indicated that if any neptunium(IV) or neptunium(VI) were present during the uranium titration, the neptunium would interfere with the uranium determination. The neptunium(VI) interference can be eliminated by a prereduction titration. The neptunium(IV) interference was eliminated by the addition of cerium(IV) sulphate solution which oxidizes the neptunium to neptunium(VI). The interference which would be caused by the neptunium(VI) and the excess of cerium(IV) is eliminated by the prereduction titration.

The neptunium solution used in this investigation was titrated according to the procedure of Stromatt[5] to determine which neptunium oxidation states were present. It was found that the neptunium was 93·56% (VI), 4·98% (V), and 1·46% (IV).

Five uranium titrations were made in the presence of neptunium by the procedure above except that no cerium(IV) sulphate solution was added. The average relative error was +0·26% (Table II). Five additional uranium titrations were made following the uranium procedure including the addition of the cerium(IV) sulphate. The average relative error for these five titrations was +0·03% (Table III).

TABLE II.—RECOVERY OF URANIUM STANDARDS IN THE PRESENCE OF NEPTUNIUM WITHOUT THE CERIUM(IV) SULPHATE ADDITION

Np present, *mg*	U, *mg*		Relative error %
	Present	Found	
5·344	4·763	4·775	+0·25
5·344	4·763	4·785	+0·46
5·344	4·763	4·771	+0·17
5·344	4·763	4·777	+0·29
5·344	4·763	4·770	+0·15
		Average	+0·26%

TABLE III.—RECOVERY OF URANIUM STANDARDS IN THE PRESENCE OF NEPTUNIUM WITH THE CERIUM(IV) SULPHATE ADDITION

Np present, *mg*	U, *mg*		Relative error %
	Present	Found	
5·344	4·763	4·760	−0·06
5·344	4·763	4·775	+0·25
5·344	4·763	4·763	±0·00
5·344	4·763	4·760	−0·06
5·344	4·763	4·765	+0·04
		Average	+0·03%

It is apparent from these results that cerium(IV) sulphate must be added to the uranium sample to oxidize any neptunium(IV) which may be present. This step has been incorporated into the uranium procedure.

Interferences

There are only a few ions which will significantly interfere with the neptunium titration. These

TABLE IV.—RESULTS OF CONTROLLED POTENTIAL COULOMETRIC TITRATION OF URANIUM–NEPTUNIUM ALLOYS

0·825	0·824	99·1	99·1

are gold, platinum, mercury, thallium, and chloride at concentrations of 0·1*M* or greater. Plutonium and palladium will cause only slight interference.

The number of ions which would interfere with the uranium titration is greatly reduced by the prereduction step. This step will eliminate the interference from the more electropositive ions, such as iron(III), neptunium(VI), plutonium(IV), and cerium(IV). Ions that are more electronegative than uranium will not cause interference. The ions which will interfere are those which will react at the cathode during the uranium titration, namely antimony(III), bismuth(III), copper(I), and molybdenum(VI).

CONCLUSIONS

The results have shown that neptunium and uranium can be determined by controlled potential coulometry in the presence of each other. The procedures outlined above have been used to determine the concentrations of uranium and neptunium in uranium–neptunium alloys. The results of these titrations are presented in Table IV.

Summary—A controlled potential coulometric titration method has been developed for the determination of neptunium and uranium in the presence of each other. The recovery of a neptunium standard in the presence of uranium was 100·02% with a relative standard deviation of 0·13%, and the recovery of a uranium standard in the presence of neptunium was 100·03% with a relative standard deviation of 0·13%.

Zusammenfassung—Eine coulometrische Titrationsmethode bei konstanter Spannung wurde zur Bestimmung von Neptunium und Uran nebeneinander entwickelt. Die Ausbeute bei einem Neptuniumstandard neben Uran war 100,02% mit einer relativen Standardabweichung von 0,13%, die Ausbeute bei einem Uranstandard neben Neptunium 100,03% mit einer relativen Standardabweichung von 0,13%.

Résumé—On a élaboré une méthode de titrage coulométrique à à potentiel contrôlé pour le dosage du neptunium et de l'uranium en présence l'un de l'autre. Le rendement d'un étalon de neptunium en présence d'uranium a été de 100,02 pour cent avec un écart type relatif de 0,13 pour cent et le rendement d'un étalon d'uranium en présence de neptunium a été de 100,03 pour cent avec un écart type relatif de 0,13 pour cent.

Application of isotopic exchange for the determination of tin in nickel

(*Received* 20 *March* 1967. *Accepted* 11 *July* 1967)

RECENTLY a method was described for the determination of several impurities, namely copper, arsenic, antimony, bismuth and zinc, in nickel cathodes.[1,2] In further experiments the possibility of separating tin from the nickel matrix by isotopic exchange has been investigated.

The principle of radiochemical separation by isotopic exchange is based on the well-known fact that the exchange taking place between the dissolved radioactive ions of an element and its fairly insoluble precipitate is such that the major fraction of the radioactive ions will be eventually bound in the precipitate. In spite of the simple technique and speed of the process, isotopic exchange has seldom been applied in activation analysis for the separation of the components of the irradiated sample. Its application in connection with activation analysis was tried first by Sunderman and Meinke[3] who studied the isotopic exchange between radioactive silver ions and inactive silver chloride. Recently Qureshi and Shabbir[4,5] performed experiments on the radiochemical recovery of cobalt and antimony by means of isotopic exchange.

Isotopic exchange seemed for several reasons to be particularly convenient for the separation of tin from irradiated nickel samples. It was found to be more effective, the lower the solubility of the inactive precipitate used for the exchange. In the case of tin, tin(IV) oxide seemed to be the most suitable precipitate. Metallic nickel dissolves rapidly in nitric acid, taking only 1–2 min in hot nitric acid, while in hydrochloric or sulphuric acid a long time is required for dissolution. On the other hand the solubility of tin(IV) oxide in nitric acid is sufficiently low to obviate precise neutralization of the solution or removal of nitrate ions, and because the metals which form hydroxide precipitates are less likely to be bound on its surface good selectivity can be achieved.

EXPERIMENTAL

The experiments were performed with the ^{125m}Sn isotope (9·5 min half-life).

The irradiations were carried out in the pneumatic facility built into the core of the VVR-S reactor. The stoppered small danamid capsule containing the sample was put into an outer danamid ampoule, then irradiated for 3 min. After irradiation, conveying the sample to the laboratory and unpacking it took about 45–60 sec.

^{125m}Sn was quantitatively determined by measuring the 0·33 MeV photopeak intensity. For the measurements a 3 in. × 3 in. Tl-activated NaI crystal and 256-channel pulse-height analyser were used.

Application of isotopic exchange for the determination of tin in nickel

(*Received* 20 *March* 1967. *Accepted* 11 *July* 1967)

RECENTLY a method was described for the determination of several impurities, namely copper, arsenic, antimony, bismuth and zinc, in nickel cathodes.[1,2] In further experiments the possibility of separating tin from the nickel matrix by isotopic exchange has been investigated.

The principle of radiochemical separation by isotopic exchange is based on the well-known fact that the exchange taking place between the dissolved radioactive ions of an element and its fairly insoluble precipitate is such that the major fraction of the radioactive ions will be eventually bound in the precipitate. In spite of the simple technique and speed of the process, isotopic exchange has seldom been applied in activation analysis for the separation of the components of the irradiated sample. Its application in connection with activation analysis was tried first by Sunderman and Meinke[3] who studied the isotopic exchange between radioactive silver ions and inactive silver chloride. Recently Qureshi and Shabbir[4,5] performed experiments on the radiochemical recovery of cobalt and antimony by means of isotopic exchange.

Isotopic exchange seemed for several reasons to be particularly convenient for the separation of tin from irradiated nickel samples. It was found to be more effective, the lower the solubility of the inactive precipitate used for the exchange. In the case of tin, tin(IV) oxide seemed to be the most suitable precipitate. Metallic nickel dissolves rapidly in nitric acid, taking only 1–2 min in hot nitric acid, while in hydrochloric or sulphuric acid a long time is required for dissolution. On the other hand the solubility of tin(IV) oxide in nitric acid is sufficiently low to obviate precise neutralization of the solution or removal of nitrate ions, and because the metals which form hydroxide precipitates are less likely to be bound on its surface good selectivity can be achieved.

EXPERIMENTAL

The experiments were performed with the ^{125m}Sn isotope (9·5 min half-life).

The irradiations were carried out in the pneumatic facility built into the core of the VVR-S reactor. The stoppered small danamid capsule containing the sample was put into an outer danamid ampoule, then irradiated for 3 min. After irradiation, conveying the sample to the laboratory and unpacking it took about 45–60 sec.

^{125m}Sn was quantitatively determined by measuring the 0·33 MeV photopeak intensity. For the measurements a 3 in. × 3 in. Tl-activated NaI crystal and 256-channel pulse-height analyser were used.

The isotopic exchange technique was as follows: solid tin(IV) oxide was added to the hot tin solution, then boiled for 1 min. The solution was cooled rapidly and filtered through a G4 glass filter. After washing, the activity of the precipitate was measured on the filter.

Because the way in which the tin(IV) oxide is prepared may influence the effectiveness of the isotopic exchange, it is described: 10 ml of tin(IV) chloride were diluted to 100 ml with water and cooled in ice, then concentrated ammonia was added until a bulky precipitate of hydrated tin(IV) oxide was formed. Subsequently it was heated on a water-bath for 1 hr, then left standing overnight. The precipitate was filtered off, washed with water, dried and ignited for 1 hr at 800°. The cooled product was suspended in water, filtered off on a G3 glass filter and washed with water to remove the very tiny particles. The tin(IV) oxide remaining on the filter was dried, and portions of it were used for experiments.

To determine the most favourable conditions for the separation of tin by isotopic exchange the following experiments were carried out.

Effect of nitric acid concentration. Runs were performed in 4 + 1, 1 + 1, 1 + 4 and 1 + 9 dilutions of nitric acid with water and also with distilled water alone. About 10^4-cpm tin activity was added to 10-ml fractions of these solutions, and then 200 mg of tin(IV) oxide were used for isotopic exchange. The experimental results are summarized in Table I. As can be seen from the table, the 1 + 9 dilution seems to be the most suitable, the recovery of the radioactive tin being almost complete, while at the same time the slight acidity of the solution is favourable for the selectivity of the separation.

Minimum amount of tin(IV) oxide necessary. About 10^4-cpm ^{125m}Sn activity was added to 10 ml of hot nitric acid solution (1 + 9) and the isotopic exchange was performed with 5, 10, 100, 200 and 300 mg of tin(IV) oxide. The experimental results are summarized in Table II. Although with 50 mg of tin(IV) oxide almost complete recovery of radioactivity can be achieved, in the following experiments 200-mg portions were used to minimize the error due to losses during the filtration.

TABLE I.—VARIATION OF RECOVERY OF ^{125m}Sn WITH HNO_3 CONCENTRATION

200	99
500	99

* The results given in the tables are reproducible to 2–3% for the same preparation of SnO_2.

Selectivity. About 50 mg of nickel were irradiated for 3 min and dissolved, and the isotopic exchange was performed. The activity of the tin(IV) oxide precipitate differed only to a small extent from the background activity, proving the separation for nickel to be satisfactorily selective.

The selectivity of the method for some trace components has been investigated. For this purpose an experimental run was performed in each case in the presence of about 10^4-cpm activity of the element investigated. Tin(IV) oxide was not contaminated by Co, Mg, Zn, Na, K and Cl ions; Mn and Cu showed a contaminating effect of less than 1% of the original amounts. Arsenic, in the absence of carrier, was adsorbed to the extent of 50–60 %, and in the presence of a carrier the extent of adsorption decreased (in the presence of 3, 7 and 15 mg of arsenic carrier the amounts of adsorbed arsenic were 5–6%, 3% and 2–2·5% respectively).

An error can be introduced by titanium when present in amounts equal to or greater than that of the tin, since it is partly adsorbed on tin(IV) oxide and its γ-ray energy is very close to that of tin ($E = 0{\cdot}32$ MeV, $t_{\frac{1}{2}} = 5{\cdot}8$ min). Titanium, in the absence of carrier, was adsorbed to the extent of more than 10% but in the presence of carrier the adsorption decreased (in the presence of 4 mg and 11 mg of carrier 6–8% and 4–5% respectively was adsorbed).

Calibration curve. When known quantities of labelled tin from 10 μg to 100 μg were isotopically exchanged in 10 ml of nitric acid (1 + 9) with 200 mg of tin(IV) oxide, 30 ml of water, being used for washing, the experimental points exhibited ± 3% deviation from a straight line calibration curve.

Reproducibility. A nickel sample containing a known amount of tin was analysed as follows: 50 mg of nickel containing 80 μg of tin were irradiated for 3 min, then dissolved by heating in 2 ml of nitric acid (1 + 1) and diluted to 10 ml with hot water. Then 200 mg of tin(IV) oxide were added to the boiling solution, the boiling was continued for 1 min, and the solution was cooled in ice. After filtering the precipitate was washed with 30 ml of cold water and then counted. About 7–8 min elapsed from the end of the irradiation to the beginning of the counting. For three parallel determinations the deviations from the actual value were ± 3%.

CONCLUSION

Isotopic exchange between solid tin(IV) oxide and dissolved radioactive tin ions seems to be suitable for the separation of tin from a nickel matrix. By this method the recovery of radioactive tin is more than 99% complete, which is adequate for activation-analysis.

Hungary

M. CSAJKA

Summary—A method for the determination of tin in nickel by activation analysis is described. Isotopic exchange is used for the separation of tin from nickel. The most favourable conditions for the separation have been determined, under which more than 99% of the tin can be recovered in 7–8 min.

Zussamenfassung—Eine aktivierungsanalytische Methode zur Bestimmung von Zinn in Nickel wird beschrieben. Zur Zinn-Nickel-Trennung wird der Isotopenaustausch angewandt. Die vorteilhaftesten Bedingungen zur Trennung wurden ermittelt; mit ihnen können mehr als 99% des Zinns in 7–8 Minuten abgetrennt werden.

Résumé—On décrit une méthode pour le dosage de l'étain dans le nickel par analyse par activation. On utilise l'échange isotopique pour séparer l'étain du nickel. On a déterminé les conditions les plus favorables pour la séparation, dans lesquelles plus de 99 pour cent de l'étain peuvent être récupérés en 7–8 mn.

ANNOTATION

The meaning of "sensitivity" in trace analysis

(*Received* 9 *March* 1967. *Accepted* 30 *June* 1967)

IN CHOOSING a method for trace analysis, if elements or compounds that could interfere are absent or can be removed or masked, if the species to be determined can be concentrated to only a limited degree or not at all, and if a reasonably wide selection of analytical tools is available, then the choice of method is usually best made by deciding which analytical method will detect the least amount of the species. This decision is seldom easy, principally because trace methods for most materials except the elements[1] have not been critically compared. Even so, when the chemist attempts, by studying the literature, to find the method that will detect the least amount, he is discouraged by the fact that various terms are used for expressing how little material an analytical method will detect.

It is the purpose of this paper to explore the expressions for "sensitivity" and related terms, and to attempt to establish a common ground on which analytical methods can be compared. It has not proved possible to devise a universal definition. Rather, generalized definitions are proposed, which, though not universal, can be modified to fit the particular requirements of each method.

Fundamental concepts

Critical examination of the literature of analytical chemistry reveals a confusion not only of terms, but also of concepts, regarding "sensitivity." Most elementary textbooks of analytical chemistry do not treat the subject at all, while the specialized reference texts on colorimetry, electrochemistry, spectroscopy, chromatography, and trace analysis seldom devote more than a few lines to a definition of terms. In general, recent textbooks of gas–liquid chromatography provide the most satisfactory discussions.[2]

In the texts and papers that were examined,[1-18] the authors did not agree on the nomenclature describing "sensitivity," but they did generally agree on basic concepts. Two concepts seem to be necessary and sufficient:

(1) the ratio of the change in the output signal produced by an increment of the material to be determined to that increment, and

(2) the smallest quantity of material that can be detected "with certainty."

A definition of the term "with certainty" will be presented later in this paper. The two concepts are inter-related in that (2) cannot be stated without first defining (1).

General definitions

In naming concepts (1) and (2), the choice of terms should be made after considering two factors: scientific accuracy, and most common current usage. When most chemists speak of the "sensitivity" of a chemical method, they usually mean "How small an amount can be determined?" This is very similar to concept (2). However, in most recent textbooks, concept (1) is called "sensitivity", while concept (2) is assigned the name "lower limit of detection", "smallest detectable quantity", "limit of detection", "detectable limit", or some similar term.

It is proposed then, to call concept (1) "sensitivity", and concept (2) "detectability", the first on the basis of current usage in recognized reference texts, and the second on etymological grounds [Latin *detectus*, past participle of *detegere*, to detect, and old French from Latin *habilitas*, aptness (later, state of being able)]. It remains, however, to express these terms in precise mathematical language so that they may be useful to chemists.

Chemists have used a variety of definitions of terms relating to sensitivity and detectability. Morrison[1] describes two approaches. One was devised by Kaiser and Specker[18] in which the "minimum detectable difference" between a reading and a blank is given by

$$I_s - I_b = ks_b\sqrt{2} \qquad (1)$$

where k = constant determined by the degree of confidence required
s_b = standard deviation of the blank output signal
I_s and I_b = output signals for the sample and blank, respectively.

They recommend that k should be $2\sqrt{2}$ which corresponds to confidence limits above 99%, whereas the ASTM[10] has recently proposed that a signal difference of one standard deviation is sufficient [equivalent to $k = 1/\sqrt{2}$ in equation (1)].

In Morrison's other approach, suitable for smaller numbers of observations, the blank and sample signals are treated as pairs, and the standard deviation s_d is calculated from a suitable statistical relationship.

Wilson[11] also assumed that two readings were taken, one of the sample and one of the blank. By assuming that the standard deviations of the sample and blank readings are the same, he arrived at a "criterion of detection" (detectability) of $1{\cdot}645S_0$ for confidence limits of 95%, where S_0 is the standard deviation of the difference between the sample and blank readings (and corresponds to $s_b\sqrt{2}$).

Roos[12] proposed the concepts of "Criterion of Detection" and "Limit of Detection." He also pointed out that two concepts are involved, "error of the first kind" that is met by Wilson's criterion, and an "error of the second kind" that is met by the criterion of $3{\cdot}390S_0$. The error of the first kind entails the risk of assuming that the material is present when it is not, and the error of the second kind entails the risk of assuming that the material is absent when it is not.

The difference in readings between a sample and a blank is a useful concept for many analytical methods, such as colorimetry, but not for others, such as gas chromatography. Different theoretical approaches to the problem yield slightly different factors that relate the standard deviation and the degree of confidence to the detectability. Some approaches utilize the standard deviation of the blank while others use the standard deviation of the sample. Different confidence limits are used, but most agree on the 95% confidence limits, or 1·96 times the standard deviation.

Sensitivity

A precise definition of sensitivity is relatively easy to produce. We may write

$$S_n = \left(\frac{\Delta I}{\Delta Q}\right)_{Q_n} \tag{2}$$

where S = sensitivity
ΔI = the change in the output signal, I, in suitable units
ΔQ = the increment of material, in suitable units, that produced ΔI

$$Q_n = \frac{Q_2 + Q_1}{2} \text{ where } Q_2 - Q_1 = \Delta Q.$$

The units of sensitivity will be determined by the units in which ΔI and ΔQ are expressed. It follows, therefore, that the sensitivities of two different analytical methods cannot be compared unless ΔI and ΔQ are expressed in the same or related units for the two methods. Defining measurement of S at $Q = Q_n$ is necessary in the event that I is not linearly related to Q.

Another important concept is the "limiting sensitivity", S_0;

$$S_0 = \lim_{Q \to 0} \left(\frac{\Delta I}{\Delta Q}\right). \tag{3}$$

This quantity may be evaluated by calculating ΔI as a function of ΔQ, and extrapolating to $Q = 0$ graphically, or by fitting the data to an equation and solving it for $Q = 0$. The limiting sensitivity is required for defining the detectability.

Detectability

Translation of concept (2), now called "detectability", into mathematical language, is difficult because of the ambiguity implicit in the term "with certainty." Chemists have used a variety of definitions of this concept. Consideration of the approaches that have been taken by others suggests that the most useful definition of detectability is

$$D = \lim_{Q \to 0} \left[\frac{2s_I}{\left(\frac{\Delta I}{\Delta Q}\right)}\right] \tag{4}$$

where s_I = standard deviation of I at $Q = Q_n$.
If s_I is independent of I, then equation (4) becomes

$$D = \frac{2s_I}{S_0}. \tag{5}$$

The factor "2" in the equation actually has no theoretical significance; it is similar in magnitude to the various factors that have been used. No theoretically derived factor can be more useful because the difficulty inherent in measuring s_I for some systems may require that this quantity be estimated from other independent measurements.

Equation (5) is nearly the inverse of the relationship used by Mandel and Stiehler[13–15] in their "sensitivity criterion"; it differs in that $2s_I$ is used in place of s_I. Because it has the units of "amount" rather than "amount^{-1}", as in the Mandel–Stiehler relationship, it has more practical meaning to the analytical chemist. Equation (5) is also very similar to the expression for "limit of detection" as derived by Dal Nogare and Juvet,[2] who assumed a linear relationship between the output signal and the concentration, and used R_n, the peak-to-peak noise level, instead of s_I. In gas chromatography, R_n is certainly easier to measure than s_I because the signal is displayed on a recorder as a function of time. In general, however, R_n will be smaller than s_I; it will approach s_I as the time interval is extended.

Applications

These criteria will prove useful to analytical chemists only if they can be meaningfully used in defining the limitations of most analytical methods. Consequently, they have been applied to spectrophotometry and to gas–liquid chromatography, in order to demonstrate how two different analytical methods can be compared. A similar approach can be taken for other methods.

In spectrophotometry, it is convenient to express the sensitivity, S, in absorbance units per milligram, or A mg^{-1}. In gas–liquid chromatography, however, S is usually stated in the units mV ml mg^{-1}. Dimbat, Stross, and Porter[17] have proposed an expression for evaluating S directly from the chromatogram. As the units for I are different in the two cases, it is not possible to compare the sensitivities of the two methods directly. It should be noted that in evaluating S for the two methods, studies should be made to determine whether the relationship between I and Q is linear.

To compare the two methods directly, we must use the detectability criterion, as expressed in equations (4) and (5), and hence, the standard deviation, s. As stated previously, in gas–liquid chromatography the peak-to-peak signal-to-noise value approaches s as the time increases. Any deviations produced by non-reproducible introduction of the sample into the column are not included in this correlation, but in practice these are usually very small compared to other deviations. The standard deviation of a spectrophotometric method is usually obtained by making repeated measurements on a standard sample. Care must be taken to include or minimize errors due to mechanical positioning of the cell, differences between cells, volumetric errors, *etc.*

Assume then that a spectrophotometric method for methanol has a limiting sensitivity $S_0 = 0{\cdot}010\ A$ mg^{-1}, while for a particular gas chromatographic method, $S_0 = 0{\cdot}02$ mV ml mg^{-1}. Assume also that the standard deviation for the spectrophotometric method is $0{\cdot}005\ A$, while for the gas chromatographic method $R_n = 2\ \mu$V ml. Then $D_{spect.} = 1$ mg, while $D_{glc} = 0{\cdot}2$ mg. Hence, the gas–liquid chromatographic method will detect "with certainty" one-fifth the quantity of methanol that is detected by the spectrophotometric method.

The detectability criterion for the comparison of analytical methods must be applied with care because the limiting sensitivity may depend on the volume of sample that can be analysed, *e.g.*, the analysis of solutions by spectrophotometry, or it may depend on the rate at which the material passes through the transducer, *e.g.*, thermal conductivity cells in gas chromatography. Morrison[1] has discussed this problem for liquids, while Halasz[20] has discussed it for gas chromatographic detectors. In the example, the limiting sensitivity of the spectrophotometric method should have been qualified by stating the volume for which it was determined, and that for the gas chromatographic method should have included complementary information regarding the mass and flow conditions under which the detector was operated.

Conclusion

This treatment indicates that while the sensitivities of analytical methods cannot usually be compared, the detectability as defined in this paper can be used to determine which analytical method will detect with certainty the smallest amount of a material.

In order to permit the comparison of the detectabilities of analytical methods, authors should report the limiting sensitivity and the standard deviation of a single measurement. The experimental conditions that restrict the limiting sensitivity, and consequently the detectability, should be clearly stated. If the standard deviation of a single measurement cannot be measured, information regarding the noise level should be reported.

Summary—The concepts of the ratio of the change in output signal produced by an increment of a material to be determined to that increment, and the smallest quantity of a material that can be detected "with certainty" are examined. The name "sensitivity" is suggested for the former, and "detectability" for the latter. Mathematical relationships are proposed that will permit the comparison of the detectability of two different analytical methods.

Zusammenfassung—Die Begriffe "Verhältnis der Signaländerung am Ausgang, die durch eine Vergrößerung der Menge des zu bestimmenden Stoffes hervorgerufen wird, zu der Mengendifferenz" und "kleinste Menge eines Stoffes, die mit Sicherheit nachgewiesen werden kann" werden untersucht. Der Name "Empfindlichkeit" wird für den ersten, "Nachweisbarkeit" für den zweiten Begriff vorgeschlagen. Es werden mathematische Beziehungen angegeben, die den Vergleich der Nachweisbarkeit bei zwei verschiedenen analytischen Methoden gestatten.

Résumé—On a examiné les concepts du rapport du changement dans le signal de rendement produit par un incrément d'une substance à doser à cet incrément, et de la plus petite quantité d'une substance que l'on peut détecter "avec certitude". On suggère le nom "sensitivité" pour le premier et "détectabilité" pour le second. On propose des relations mathématiques qui permettront la comparaison de la détectabilité pour deux méthodes analytiques différentes.

LETTER TO THE EDITOR

Remarks on hexamminecobalt(III)carbonatoberyllate

SIR,

The letter of Vinagradov[1] on this subject requires a number of comments from me.

Because of the large proportion of water in the compound the avoidance of a dehydrating agent—even as mild a one as absolute ethanol—as a wash liquor seemed to us to be a minimum reasonable precaution in preparing samples for analysis. We therefore used 60% ethanol and, as noted in the paper,[2] dried the precipitate by suction. In all cases constant weight was reached in 15–20 minutes and the material was in equilibrium with atmospheric water vapour, as was indicated by the subsequent very small weight changes when exposed to atmospheres of controlled humidity. Generally, the observations indicated that the atmospheric humidity was between 32 and 80%, but on one occasion the air must have been drier than usual as the compound gained 0·1% after exposure to 32% relative humidity. It is therefore clear that there is no substance in Vinagradov's suggestion that the wash-liquor was not removed in these experiments. This fact is also evident from the close agreement between the cobalt contents of the four precipitates prepared on different occasions. Subsequent experience with acetone, or 95% ethanol followed by ether, has shown that these are also valid (and quicker) methods of drying the precipitate; this could not be assumed in our work.

Vinagradov criticises our procedure of conditioning to a definite humidity as being likely to be protracted. Since the humidity suggested would be one within the normal atmospheric range, and the samples would be in equilibrium with the prevailing atmospheric humidity, the time required for reaching constant weight would be expected to be quite short. In our experiments speed was not important and the samples were generally left overnight. In practice the time could be minimized by the use of reduced pressure. On general grounds it is desirable that a gravimetric precipitate should be exposed to an atmosphere with humidity controlled at a value appropriate to the particular compound. The use of an empty desiccator under reduced pressure, as described by Vinagradov, is open to criticism because the compound supposedly being conditioned has, in fact, to supply the water vapour in the enclosed volume. In the present instance this treatment would be expected to give an atmosphere drier than those used in our experiments (32–80% relative humidity). As we showed that the water content of the compound varies continuously between 10·8 and 11·1 molecules (per formula unit) within these humidity limits it might be expected that Vinagradov's treatment would dry the compound to a water content of less than 10·8 molecules. Nevertheless his assertion that the compound contains 10 molecules of water, seeming to imply that it is a definite hydrate, needs more convincing experimental evidence than has so far been forthcoming. (It should also be noted that if it were a precise decahydrate the factor for conversion to beryllium would be 0·03942, not 0·0395 as stated by Vinagradov.)

Table I shows the results of various analyses of the compound by Vinagradov *et al.*[3] Sen Gupta,[4,5] and Monk and Exelby.[2] The number of water molecules per formula unit has been calculated, in each case, from the result of the determination of a particular element or group. The uncertainty limits have been calculated from the limits of error quoted by the authors where available. In the case of Monk and Exelby the results of only the cobalt analyses have been quoted as this determination was specifically chosen for the purpose because of its high accuracy. The limits of error here correspond to the standard deviation of the mean. The table includes data from Sen Gupta's second paper[5] in which his methods of preparation of three varieties of the compound, (*a*) needle-shaped crystals, (*b*) tetrahedral crystals and (*c*) polyhedral crystals, are described. On the basis of the analytical results for Be, N, C and H, Sen Gupta claims that (*a*) contains 11, and (*b*) and (*c*) 10 molecules of water. In his original paper[4] (*a*)-type crystals are referred to as "feather-like" and stated to contain 12 molecules of water. Analytical results from both papers are given in Table I.

None of these results can be considered to provide evidence of a definite hydrate under any of the conditions of preparation. Vinagradov's results considered altogether provide as much evidence for a water content of about 11 molecules as they do for the 10 molecules he claims; this is true for his cobalt determination, which has the smallest relative error of his four sets of analyses and which gives a mean result quite close to ours.

TABLE I.—WATER CONTENT OF PRECIPITATE, CALCULATED FROM PUBLISHED DATA

Author	Method of treating precipitate	Number of molecules of water per formula $[Co(NH_3)_6]_3[Be_4O(CO_3)_6]$								Remarks
		Calculated from determination of								
		Claimed	Co	Be	N	C	CO_3	H	H_2O	
Vinagradov, Apirina and Cherstvenkova[3]	Alcohol, ether suction and 15 mins in moderate vacuum with no desiccant	10	10·9 ± 0·4	$10·0^{+0·7}_{-0·6}$	—	—	$10·8^{+1·1}_{-1·0}$	—	10·1 ± 0·5	Be-content of precipitate was estimated from the original weight of beryllium and final weight of precipitate.
Sen Gupta[4,5]	Alcohol and air-drying	10	—	10·4	10·3	10·7	—	9·8	—	Precipitated from potassium bicarbonate solution. Types (*b*) and (*c*).
		12	—	12·2	12·3	12·9	—	10·6	—	Precipitated from ammonium carbonate solution. Type (*a*).
		11	—	12·2	11·4	11·1	—	10·1	—	
Monk and Exelby[2]	60 % alcohol, suction to constant weight. Constant weight at:									
	32% R.H.	10·8	10·77 ± 0·01	—	—	—	—	—	—	
	55% R.H.	11·0								
	80% R.H.	11·1								

Sen Gupta's preparations were air-dried and would therefore be expected to reflect the atmospheric humidity at the time of preparation but the variation in his results is much greater than would be expected from this cause alone. While it might appear that precipitation from potassium bicarbonate gives a product containing less water than precipitation from ammonium carbonate the figures are hardly sufficiently accurate to substantiate any definite hydrate. Our tentative suggestion that the variation in water content with humidity might be accounted for by varying proportions of two hydrates does not now seem very plausible. An alternative explanation is that the compound has a zeolite structure.

TALANTA REVIEW*

COMPLEXATION REACTIONS OF DITHIOCARBAMATES

ADAM HULANICKI
Department of Inorganic Chemistry, University of Warsaw, Poland

(*Received* 22 *March* 1967. *Accepted* 24 *May* 1967)

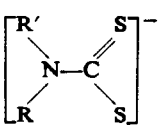
Summary—The complexation reactions of various disubstituted dithiocarbamates are discussed. Special attention is paid to studies of composition and stability of various metal complexes. The conditions of complex formation in solution are treated in terms of side-reaction coefficients. The properties of metal–dithiocarbamate complexes are presented as a function of the nature of the substituents in the ligand molecule.

THE analytical applications of dithiocarbamates have been discussed in several textbooks and monographs on trace analysis,[1] colorimetry,[2] organic reagents,[3,4] extraction,[5] and in special papers,[6] but there is no comprehensive treatment of the properties of various complexes and their composition and stability, although numerous analytical methods are based on these reagents. A large amount of information is contained in an excellent monograph on dithiocarbamates[7] published in 1962, but the analytical aspects are not sufficiently emphasized.

The purpose of this review is to discuss critically the complexing properties of various dithiocarbamates and the composition and stability of the complexes formed, in relation to their analytical application. No attempt has been made to include all references which deal with analytical application of dithiocarbamates, but attention has been focused on those which contribute some new information on the problem of dithiocarbamate complexes.

GENERAL REMARKS ON DITHIOCARBAMATES

The complexing properties of dithiocarbamates are directly connected with the presence of two donor sulphur atoms, which primarily determine the nature of the metals that can be bound, and the strength of the complexes formed. In the dithiocarbamate ion



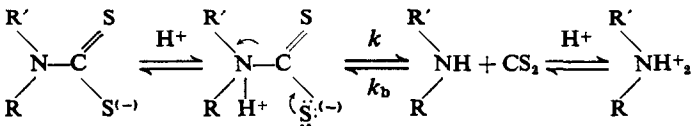
R′ and R denote various organic substituents, which do not influence significantly the metal–sulphur bonding, but may determine some analytical properties of the

* For copies of this Review see Publisher's advertisement near the end of this issue.

complexes. Most of the analytically interesting properties occur with disubstituted dithiocarbamates. Monosubstituted compounds are less useful because of their stronger reducing properties and tendency to decompose to hydrogen sulphide.[8]

The general method of preparation of dithiocarbamates from carbon disulphide and amines in alkaline medium is probably one of the reasons for the widespread incorrect nomenclature of these compounds. Thus a compound obtained from pyrrolidine and carbon disulphide is frequently named as pyrrolidinedithiocarbamate, whereas it is more correctly named pyrrolidine-*N*-carbodithioate, *N*-dithiocarboxy-pyrrolidine or *C*-tetramethylenedithiocarbamate.[9] The first two correct names do not emphasize the presence of the most characteristic complexing group. The third name, in spite of the lack of direct connection with the amine used in the synthesis, seems to be the most useful. In this review this nomenclature will be used, abbreviated where necessary to the symbol DTC as a general symbol for dithiocarbamates in cases where no confusion may occur.*

For the analyst, the most important property of the dithiocarbamate ion is its protonation in acidic solution and the subsequent decomposition into carbon disulphide and the protonated amine. Several authors report the values of pK_a of various dithiocarbamic acids, and those which correspond to aqueous solutions are given in Table I. From the kinetic and dissociation constants it follows[10,11] that the decomposition proceeds through the dipolar ion according to the scheme:



and is favoured when the pH of the medium is lower than pK_a for the $R'RNH_2^+$ ion. The rate-limiting step of this reaction is the decomposition of the dipolar ion. Contrary to these observations Soni and Trivedi[12] found the diethyldithiocarbamate ion to be a diacidic base. However, their results significantly differ for data calculated previously on the assumption that the ion is a monoacidic base. In non-aqueous solutions the dithiocarbamic acids are generally soluble and much more stable,[16,17] which has led to numerous applications in the extraction of metal chelates from acid solutions.

The rate of decomposition of dithiocarbamates in acid solution has been studied polarographically[10,14,18] by measuring the decrease of the anodic wave of dithiocarbamate. Similar results may be obtained spectrophotometrically[19–22] by measuring the absorbance of the dithiocarbamate at 360 mμ or that of the cobalt complexes at 650 mμ. In the range where pH $\gg pK_a$ of the DTC acid, the decomposition proceeds according to the equation $V = -k[H^+]C_{DTC}/K_a$ where k is the true rate constant, V the velocity, and C_{DTC} the total DTC concentration. When pH $\ll pK_a$ the decomposition rate is independent of the pH of the solution and $V = -kC_{DTC}$. The former equation is usually valid in the range over which measurements are performed and therefore the apparent rate constant k/K_a is usually given as a measure of the decomposition rate. Often for characterization of the acid the pH value is given at which the half-life of the DTC is 10 hr. Both methods should give consistent results

* The older German name is *Carbaminat* (*e.g.*, in Malissa and Gomišček[99]) and the new nomenclature uses *Carbamidat* (*e.g.*, in Bode *et al.*[16,20]).

TABLE I.—pK_a VALUES OF SOME DITHIOCARBAMIC ACIDS IN AQUEOUS SOLUTIONS

Acid derived from	pK_a	Reference
Dimethylamine	3·66	11
Diethylamine	4·04	11
	3·95	10
	7·5 (pK_{a_1})?	12
	8·4 (pK_{a_2})?	
Di-n-propylamine	4·79	11
Di-n-butylamine	5·19	11
Pyrrolidine	2·95	10
Morpholine	5·2	10
	5·19	15
Aminoacetic acid	4·57	14
	3·12 (pK_{a_1})*	13
	3·84 (pK_{a_1})	

* One of the pK_a values corresponds to the carboxyl group.

when over the range investigated and discussed the decomposition proceeds according to the same equation. Data given in Table II were recalculated in both ways. In certain cases they exhibit significant discrepancies, probably because of differences in ionic strength, temperature, *etc.*

The decomposition of dithiocarbamates in acid solution, a drawback in most analytical procedures, has been exploited for the determination of these compounds.[7,23–26] The most rapid procedures are based on acid and alkaline titration of the sample.[27,28]

TABLE II.—APPARENT RATE CONSTANTS k' FOR DITHIOCARBAMATE DECOMPOSITION, AND pH VALUES FOR HALF-LIFE TIMES $\tau_{1/2} = 10$ hr (AT ~20°C)

Dithiocarbamate derived from	k' $l\ mole^{-1}\ min^{-1}$	pH (for $\tau_{1/2} = 10$ hr)	Ref.
Dimethylamine	2000	6·24*	10
Diethylamine	8000	6·84*	10
	10,200*	6·95	20
Di-n-propylamine	110	4·98*	10

Pyrrolidine-2-carboxylic acid	160*	5·15	20
Iminodiacetic acid	1200	6·03*	21
Diethanolamine	11,800	7·01*	22
Aminoacetic acid	7·2*	3·8	20
	34	4·8*	14
Sodium cyanamide	41,000*	7·55	20

* Values calculated from data given in the reference.

COMPLEX FORMATION WITH DIFFERENT METALS

The dithiocarbamate ligands have two donor sulphur atoms able to react with those metals[29] which form insoluble sulphides. This general statement is only approximately true because chelate and steric effects also influence the reaction.

The water-insoluble metal dithiocarbamates, and aqueous solutions of many soluble ones, have characteristic colours, which are widely used for analytical purposes. The colours depend only slightly on the nature of the substituents in the disubstituted dithiocarbamate,[21,30–33] and may be different for monosubstituted ligands[34–37] or dithiocarbamates derived from acid amines.[38] This is probably due to the possibility of thiono-thiolo-tautomerism or the presence of other reactive donor groups in the ligand molecule. The absorption spectra of water-insoluble dithiocarbamate–metal complexes in organic solvents such as chloroform have been studied.[39,40]

Most metal complexes may be represented by the formula $M(DTC)_n$ where n is equal to the charge of the metal ion. If the co-ordination number of the metal is twice its charge such complexes are neutral molecules. The bidentate ligand forms a four-membered chelate ring, as shown by X-ray measurements.[41–43]

The composition $M(DTC)_n$ was established by special studies[6,44–48] and confirmed by numerous applications in titrimetric and gravimetric methods. The same component ratio has also been found for soluble complexes.[49] The dithiocarbamates are monomeric, except for the copper(I) complexes of diethyl and dipropyl derivatives, where tri- and tetrameric structures respectively, have been demonstrated.[50,51] Polymeric chelates of another type were found for the piperazine derivative, which contains two CS_2 groups, at two ends of the heterocyclic ring.[52]

A more complicated situation exists when complexes are formed with metal ions which have different oxidation states and/or do not form simple solvated ions in aqueous solutions. Among these are Ti, V, Nb, Cr, Mo, W, U, Re, Pt-metals, As, Sb, Sn, Se and Te.

According to some investigators[32,53–55] titanium forms a yellow complex of unknown structure, but others do not support this observation.[30,40]

The vanadium complex has the peculiar property of being extracted with methyl isobutyl ketone at pH 2 or 6, with an intermediate range where no extraction occurs.[56] This suggests that the oxo-cations VO_2^+ or VO^{3+} react with the ligand,[17] but reduction to lower oxidation states is also possible, taking into account that both vanadium(IV) and (V) react with dithiocarbamate.

Of the proposed[57,58] formulae of the niobium complex, $NbO(DTC)_3$ and $Nb(DTC)_3$, the former has been shown correct.[59–61] Data on the tantalum complexes are very scarce[62] and do not allow conclusions be made about their structure.

In the case of chromium(III) the inertness of its compounds affects its reactivity. DTC complex formation is achieved by reduction of chromium(VI)[54] or at elevated temperature.[30] For the diethyl derivative the formula is $Cr(DTC)_3$,[57,63] which confirms the older studies of Malatesta.[64]

The reactivity of 16 various dithiocarbamates towards molybdenum was studied by Kulberg and Kovaleva,[65] who found that in faintly acid and neutral solution a yellow compound is precipitated, and a violet one from warm 1*M* hydrochloric acid solution. To both groups of compounds the composition $MoO_3(HDTC)_2$ was ascribed. The yellow form has been found by many authors[30,31,40,38] but there is only one other report of the formation of the violet form,[66] and it has been argued that

the yellow form, in the case of pyrrolidine derivative, has the composition $Mo(DTC)_3$.[57] The recent extraction experiments of Shustova[67] indicate that the Mo:DTC ratio is 1:2 and on this basis the formula $MoO_2(DTC)_2$ was proposed. It differs from $MoO_3(HDTC)_2$[65] by one water molecule, which may be ascribed to the uncertainty of elemental analysis. A similar composition was found by Byrko[62] for the pyrazoline derivative.

There are only incomplete data available about the yellowish tungsten complex.[31,53]

The uranium(VI) complexes of dithiocarbamates which do not contain hydrophilic groups differ from other complexes of these ligands by their solubility in water. Malatesta[64] reported the formula as $UO_2(DTC)_2$ while Zingaro[68] stated the existence of the ion $UO_2(DTC)_4^{2-}$ in solution, and the compound $UO_2(DTC)_2 \cdot K_2UO_2(DTC)_4$ in the solid state.

In these compounds the diethyldithiocarbamate ion may function as a mono- and a bidentate ligand. For the hexamethylenedithiocarbamate Prodinger[69] found the metal–reagent ratio 1:3; Malissa and Kolbe-Rohde,[57] however, report the ratio 1:6.

Some controversies exist about the complexes of rhenium. Probably in strongly acid solutions of perrhenates the extractable dithiocarbamate complexes are formed.[53,62]

For the platinum metals the existence of various oxidation states and the formation of many stable and often inert complexes interfere with the study of dithiocarbamate compounds. Unquestionable is the formation of the yellow $Pd(DTC)_2$ complexes.[30,31,40,46,70,71] Platinum(II) forms in acid solution easily extractable complexes,[30,40,71] but platinum(IV) reacts incompletely,[30,31,40] possibly with partial reduction to the bivalent state. Heterometric studies[72] indicate the presence of platinum complexes having the metal to ligand ratios 1:1, 2:3, 1:2 and 1:3. Those complexes probably also contain chloride ions. The yellow rhodium(III) complex $Rh(DTC)_3$[73] may be extracted with dichloroethane[71,74] or 4-methyl-2-pentanone.[75] Even less is known about ruthenium, which probably forms $Ru(DTC)_2$,[70] and iridium reactions, which are slow and need special precautions.[30,31,40]

Many authors[30,31,34,40] indicate the formation of yellow–brown complexes of gold(III), the composition of which was established heterometrically as corresponding to metal–reagent ratios 1:1, 2:3 and 1:2.[46] However Tulupa and Usatenko[76] report reduction to gold(I), which subsequently forms a 1:1 complex.

Arsenic, antimony and tin in their lower oxidation states give relatively stable complexes,[30,77] but except for the reaction of arsenic(V) with the morpholine derivative[31] no compounds are reported for arsenic(V) and antimony(V). This is presumably because of the high stability of the oxy-anions over a wide pH range and the instability of dithiocarbamates in very acid solution. For tin, beside the yellow[39,40,78] or white[30] complex of tin(II) formed at $pH < 9$, a complex of tin(IV) is formed at $pH < 6$. A more detailed study should indicate whether there exist DTC compounds of arsenic, antimony and tin in their higher oxidation states, or whether reduction occurs.[48]

From weakly acidic solutions of selenium(IV) a dithiocarbamate is precipitated[30,31,38,40,44] but no details of its structure are given. Its formula is proposed as $Se(DTC)_2$.[79–81] A similar compound was found for tellurium,[79] when the relatively stable $Te(DTC)_4$[44,82] was reduced with thallium(I).[83] In alkaline solutions this

complex $Te(DTC)_2$ (which is intensely orange in carbon tetrachloride solution) disproportionates into Te(O) and Te(IV).

Information about the composition of various metal dithiocarbamates may presumably be found in the patent literature, but in general is of limited analytical interest.

In the case of several metals which have different oxidation states the formation of dithiocarbamate complexes is accompanied by redox reactions. The best known examples are manganese(II), iron(II) and cobalt(II) which undergo oxidation to the tervalent state[30,31,33,34,40,62] or even for manganese to the quadrivalent state.[84] This behaviour is connected with the high polarizability of the dithiocarbamate ligands. In strongly reducing media it is sometimes possible to obtain less strongly coloured compounds of bivalent ions. Gleu and Schwab[30] indicate that for the dithiocarbamate derivatives of diethylamine, piperidine, thiazane, dimethylamine, pyrrolidine, morpholine and piperazine the ability to stabilize higher oxidation states decreases in the order given. Some exceptions to this order may be attributed to differences in the physical structures of the precipitates.

In contrast the thallium(III) compounds are easily reduced to thallium(I) complexes,[85] indicating the low stability of complexes of 18-electron type ions.

The reducing properties of dithiocarbamates cause several ions (e.g. permanganate and dichromate) to be readily reduced to lower oxidation states.[7] Presumably such reactions interfere with the formation of complexes of molybdenum(VI),[20,67] vanadium(V), niobium(V),[58] platinum metals and tin(IV). Bode *et al.*[20] have stated that reduction may also interfere in the complexation of silver, gold, mercury, thallium, selenium, tellurium and iron. The reduction rate depends on pH and the nature of the substituents in the ligand molecule. The strongest reducing properties are associated with monosubstituted derivatives and the disubstituted derivative of *N*-methylglucosamine.

From these data it follows that dithiocarbamate ligands complex metal ions having partly filled *d* orbitals, ions with filled *d* orbitals but low positive charge, and ions with an 18+2 electronic structure. Thus they react with the elements from titanium to selenium (except germanium), niobium to tellurium and tungsten to bismuth.

THE EFFECT OF SUBSTITUENTS IN THE LIGAND MOLECULE

For many years after the early work of Delepine[86] only the dimethyl and diethyldithiocarbamates were used in chemical analysis. They form complexes with many metals, insoluble in water but soluble in organic solvents. To widen the applicability of these reagents attempts have been made to introduce new substituents with better analytical properties. Taking into account the properties of the complexes formed, it is possible to divide the dithiocarbamate reagents into three groups:

(*i*) dithiocarbamates having hydrophobic substituents, which give water-insoluble complexes, extractable with organic solvents;

(*ii*) dithiocarbamates containing hydrophilic groups, *i.e.*, OH^- or COOH, which form metal complexes soluble in water but insoluble in organic solvents and therefore not extractable;

(*iii*) dithiocarbamates containing two donor CS_2^- groups, which form polymeric chelates insoluble in all solvents.

This classification deals primarily with disubstituted compounds but may be extended to monosubstituted derivatives.

The first group includes a great number of studied compounds. The analytical applications of the dithiocarbamates—derivatives of dimethylamine and diethylamine[1–3,6]—have been described in several hundreds of papers. The derivatives of dipropylamine[30,87–90] and dibutylamine[91] have also been studied. Derivatives of aromatic and heterocyclic amines such as dibenzylamine,[71,92–95] diphenylamine,[71] cyclohexylethylamine,[96] pyrrolidine,[30,38,54,56–59,71,97–99] piperidine,[30,32,59,71,73,74,100] hexamethyleneamine,[69,85,100–102] morpholine,[30,31] thiazane,[30] indole[103] and substituted pyrrolidines[62,104] have similar properties. There are no significant differences in the chelating properties of these compounds. Comparative studies indicate small differences in the logarithms of the copper chelate stability constants[89,90] (less than 2 log units) wavelength of the absorption maximum (432–435 mμ) and molar absorptivity of these chelates[105] (12·1–13·4 $\times$ 10^3). Also the character of the precipitate,[30] rate of precipitation or dissolution in organic solvents[98] and the completeness of extraction[71] do not differ greatly.

Substituents exert a significant effect on the rate and degree of oxidation of metals forming dithiocarbamate complexes.[30] For example diethyldithiocarbamate strongly promotes manganese oxidation, whereas the thiazane derivative precipitates manganese(II) in the presence of even weak reducing agents.

For a particular analytical purpose a given ligand is preferred, but other properties of the reagent such as ease of synthesis and purification, stability both in the solid and in solution, must be taken into account. Therefore, for example, the pyrrolidine derivative is widely used when acidic media are recommended.

Dithiocarbamates of this group are mostly used as the sodium or ammonium salts, but in extraction methods the compounds soluble in organic solvents are often used, *e.g.*, diethylammonium diethyldithiocarbamate or zinc dibenzyldithiocarbamate. The first of these two reagents was introduced by Wyatt[106,107] and investigated in detail by Bode and Neumann.[16,17] These studies have shown its advantages over the sodium salt in extraction from acid solutions.[108,111] The second reagent[71,92,93,95,112] is also soluble in organic solvents and the low thermodynamic stability of the zinc complex enables fast and complete metal exchange reactions with other metals forming more stable complexes.

The second group of dithiocarbamates having hydrophilic substituents has not been investigated so thoroughly. Because of the presence of OH or COOH groups the metal complexes are soluble in water and do not dissolve readily in organic solvents. Because of steric factors and the rather weak complexing properties of the OH and COOH groups compared with those of the CS_2^- group it follows that the complexes formed have similar structure and properties to those of the first group. However, the complexation occurs in one phase and therefore the presence of successive complexes is easily observed.

Diethanoldithiocarbamate was introduced by Serfass *et al.*,[113,114] who, like others,[115,116] used it for masking several metals in the determination of zinc, or stripping of mercury into the aqueous phase.[117] This reagent was also found useful for direct colorimetric determination of cobalt,[118] molybdenum and uranium,[33] copper,[119] and nickel, cobalt and copper mixtures,[120,121] and for indirect determination of

mercury and cyanides.[122–124] With TBP the complexes of bismuth, copper and nickel and tellurium may be extracted.[125]

At higher concentrations the solubility of the complex is too low, and so Bode *et al.*[20] have also investigated dithiocarbamates synthesized from pyrrolidine-2-carboxylic acid, *N*-methylglucosamine, sodium cyanamide and aminoacetic acid (monosubstituted DTC). In all cases the solubility was good but the first-mentioned reagent seems to be the most advantageous because its reducing ability is low and stability in acidic solutions rather high. In spite of their reducing properties the monosubstituted dithiocarbamates have found several analytical applications in the colorimetric determination of bismuth and copper,[34] nickel and cobalt[126] and masking in complexometric titrations.[127] These ligands are more resistant to acids but at low pH values where the carboxylic group is undissociated the metal complexes may precipitate.

To this group also belongs bis(carboxymethyl)dithiocarbamate, investigated by Hulanicki *et al.*[21,49] This reagent is less susceptible to oxidation than the diethanolamine derivative and is quite stable in acidic solution. It is used for colorimetric determination of copper, nickel and cobalt[22] and masking of various metals in the dithizone determination of zinc.

Malissa and Miller[103] have investigated dithiocarbamates containing sulphonate groups, derivatives of diphenylamino-4,4′-disulphonic acid and *p*-aminosulphonic acid but report that the metal chelates are not readily soluble in aqueous media.

The third group of dithiocarbamates is represented by the piperazine derivative,[30,105] which contains two CS_2^- groups. This reagent was investigated by Hulanicki and Shishkova,[52] who found that its chelates are insoluble in water and numerous organic solvents. This suggests a polymeric structure of the chelates, which probably form chains with not more than 10 members. Other bis-dithiocarbamates were also prepared (*e.g.*, from polymethylenediamines[128]) but nothing is known about their complexing properties and analytical applications.

On the basis of these observations it may be stated that each of these groups of dithiocarbamate reagents finds its special analytical application. The first group of dithiocarbamates without hydrophilic substituents is applicable in colorimetric determinations where the coloured complex is extracted by organic solvents. Nevertheless many determinations may also be carried out in aqueous pseudo-solutions stabilized with protective colloids. In trace analysis these reagents are used for concentration of small amounts of metals by extraction or precipitation before their determination by various instrumental methods. Because dithiocarbamates are "wide spectrum" reagents this procedure is often used when numerous trace elements are to be determined in a material which does not contain heavy metals as main components.

The second group of hydrophilic reagents may find applications in direct colorimetry in aqueous solutions and for masking metals, for example in extraction or precipitation. In these methods the complexation with dithiocarbamate proceeds in homogeneous conditions. Therefore a relatively greater excess of the reagent is needed. It is obvious that they may be used only in alkaline, neutral and slightly acidic solutions.

The bis-dithiocarbamates, which form the last group, can be used in colorimetry in pseudo-solutions, and in the concentration of metals by precipitation.

As already mentioned, the monosubstituted dithiocarbamates may find their place in any of these groups, depending on the characteristics of their complexes, but their application is severely limited by their reducing properties and tendency to precipitate metal sulphides.[8,129]

THE EFFECT OF SOLUTION COMPOSITION ON COMPLEXATION

Numerous experimental data on the formation of dithiocarbamate complexes enable a clear picture to be obtained of conditions under which these complexes may be formed. Nevertheless in order to understand the nature of these reactions several factors must be separately discussed:

(*i*) formation of hydroxo-complexes of metals with increasing pH;
(*ii*) formation of metal complexes with ligands added as buffers, to prevent precipitation of hydroxides or to increase selectivity;
(*iii*) protonation of dithiocarbamate ions, which leads finally to decomposition of the ligand.

In most cases stepwise formation of dithiocarbamate complexes may be neglected, owing to a rather drastic shift of the equilibrium towards precipitation or extraction of the metal chelate.

In a simple case of a precipitated 1:1 complex, Ringbom's expression[130] for the conditional solubility product

$$K_{so}' = [M'][DTC']^n = [M][DTC]^n \cdot \alpha_M \alpha_{DTC}^n$$

(where α_M and α_{DTC} are the side-reaction coefficients) gives a straightforward answer, that precipitation occurs quantitatively when $K_{so}' < 10^{-7}$, and the reaction is masked when $K_{so}' > 10^{-2}$. For more complicated cases the masking coefficient[131] may be a useful concept. Its most general form[197], for the compound M_jA_i, is

$$pM' = \frac{1}{j} pK_{so} - \log \alpha_M + \frac{i}{j} (\log[A'] - \log \alpha_A)$$

and gives the relationship between the solubility product K_{so}, concentration of the precipitating anion [A'], and the side-reaction coefficients $\alpha_M = [M']/[M]$, $\alpha_A = [A']/[A]$ for the cation and anion, respectively. [M'] denotes the total concentration of all species of M in solution, and [M] the concentration of the free ion; [A'] and [A] have corresponding meanings. When this equation is used under the condition that

$$[A'] = \frac{i}{j} [M']$$

a simpler expression is obtained:

$$pM = \frac{1}{j+i} [pK_{so} - i \log j/i] - \frac{j}{j+i} \log \alpha_M - \frac{i}{j+i} \log \alpha_A$$

which was discussed in detail previously.[131] The conclusion follows that $pM' > 6$ represents complete precipitation, $pM' < 3$ represents masking.

To characterize the systems in which precipitation of metal dithiocarbamates may or may not occur the changes of individual coefficients should be considered.

The coefficient $\alpha_A = \alpha_{DTC}$ depends mainly on protonation of basic groups. As the dithiocarbamic acids are in general not very weak acids, in the pH range 6–14 $\alpha_{DTC} = 1$. In more acidic media the kinetic factors of dithiocarbamate decomposition play a significant role.

The coefficient α_M is the sum of all coefficients for different side-reactions of the metal ion. The principal interfering reactions are formation of hydroxo-complexes, and formation of other complexes with buffer or masking substances. The coefficient $\alpha_{M(OH)} = \sum_0^f \beta_f[OH]^f$ is a function of [OH] only (for mononuclear complexes), and therefore strongly increases with increasing pH. The coefficient $\alpha_{M(X)} = \sum_0^g \beta_g[X]^g$ is constant as long as the concentration [X], of free ligand additionally complexing the metal ion, is constant. However, in the case of complexing agents having basic properties, when the pH decreases the concentration of the free ligand decreases very significantly, causing a decrease in $\alpha_{M(X)}$. Thus, independent of the relative values of $\alpha_{M(X)}$ and $\alpha_{M(OH)}$, the pH increase over a broad range is responsible for the increase of the conditional solubility product of metal dithiocarbamates. This is the opposite of the general rule for organic precipitants, which are stronger bases than dithiocarbamates and hence the change in α_A predominates over the changes in α_M.

This conclusion is in agreement with the experimental observation that at higher pH values only those dithiocarbamate complexes which have extremely small molar solubility are precipitated, *i.e.*, those of mercury, silver, copper, cadmium, lead and nickel. On this basis Gleu and Schwab[30] have described a metal separation scheme based on precipitation of diethyldithiocarbamates at different pH values (Table III).

Extraction of dithiocarbamate complexes with organic solvents proceeds according to the equation

$$M^{n+} + n\,DTC^- \rightleftharpoons \{M(DTC)_n\}_O$$

where the subscript O denotes species in the organic phase. The extraction constant K_e of this reaction is equal to the product of the complex formation constant β_n in the aqueous phase and the partition constant $P_{M(DTC)_n}$

$$K_e = \beta_n \cdot P_{M(DTC)n} = \frac{[M(DTC)_n]}{[M][DTC]^n} \cdot \frac{[M(DTC)_n]_O}{[M(DTC)_n]} = \frac{[M(DTC)_n]_O}{[M][DTC]^n}$$

From the analytical point of view it is convenient to consider the total concentrations of metal-containing species in both phases and therefore the introduction of conditional constants is advantageous. The extraction coefficient E_M of the metal, expressed with the aid of the corresponding side-reaction coefficients,[22] is given by the equation

$$\log E_M = \log K_e + \log \alpha_{MR_n} - \log \alpha_M + n(\log [R'] - \log \alpha_R)$$

where α_{MR_n} represents the side-reaction coefficient of the complex (here of the $M(DTC)_n$ complex) in the organic phase, α_M is, as before, the side-reaction coefficient of the metal ion in the aqueous phase, [R'] the total concentration of unbound ligand (*i.e.*, DTC) and α_R its side-reaction coefficient. When $\log E_M > 3$ the extraction is practically complete, when $\log E_M < -2$ the metal is practically completely masked.

In this equation, which has a similar form to that for precipitation reactions, the first term corresponds to the true equilibrium constant of the reaction, and the

second ($\alpha_{M(DTC)_n}$) may be assumed to be unity, though in fact its value is unknown, and presumably it may be included in the numerical value of the extraction constant. The coefficient α_M is exactly the same as before, with $n = i/j$, but α_R—beside the $\alpha_{R(H)}$ component—contains an additional term $\alpha_{R(org)}$ which describes the extraction of the ligand itself. Its value is usually greater than that of $\alpha_{R(H)}$ and therefore plays a decisive role in the whole equilibrium. In the case of diethyldithiocarbamic acid, from the data of Bode[19] it follows that

$$\alpha_{DTC(CCl_4)} = 1 + \frac{V_{CCl_4}}{V_{H_2O}} [H^+] \times 1{\cdot}6 \times 10^6.$$

Thus at pH > 7·5 its value is practically equal to 1.

From these considerations it is seen that the effect of side-reactions on both precipitation and extraction is similar. These conclusions are experimentally confirmed by the similarity of the conditions in which both processes occur and therefore the scheme of separation by extraction closely resembles that for precipitation

TABLE III.—METAL IONS REACTING WITH DITHIOCARBAMATES IN VARIOUS MEDIA[30,38,44,133,156]

Complexing agent	pH ~ 5–6	pH ~ 9	pH > 11
Tartrate	Ag, As, Bi, Cd, Co, Cu, Fe, Hg, In, Mn, Ni, Pb, Pd, Sb, Se, Sn, Te, Tl, Zn	Ag, Bi, Cd, Co, Cu, Fe, Hg, In, Mn, Ni, Pb, Pd, Sb, Te, Tl, Zn	Ag, Bi, Cd, Co, Cu, Hg, Ni, Pb, Pd, Tl, Zn
EDTA	Ag, As, Bi, Cd, Cu, Fe, Hg, In, Mn, Pb, Pd, Sb, Se, Sn, Te, Tl	Ag, Bi, Cu, Fe, Hg, Pd, Sb, Te, Tl	Ag, Bi, Cu, Hg, Pd, Tl
KCN	—	Bi, Cd, Fe, In, Mn, Pb, Sb, Te, Tl	Bi, Cd, Pb, Tl
Citrate + EDTA	—	Ag, Bi, Cu, Hg, Sb, Te, Tl	—

(Table III). In this table some other common complexing media are also included to give a more complete picture of the analytical possibilities of separation with dithiocarbamates. Chalmers and Dick[132] suggest extraction of dithiocarbamates in the group separation of cations by extraction.

Several other complexing and masking solutions should also be mentioned. Ammonium citrate seems promising for the masking of iron, indium and manganese.[133–135] Iron(III) may also be masked by pyrophosphate,[6,135] sodium sulphosalicylate[136–138] and hydrofluoric acid,[108] whereas the fluoride ions at pH 6 mask the extraction of niobium but do not interfere with the iron(III) reaction.[59,139] In weakly acidic solutions oxalates prevent the reaction of gallium[140] and titanium.[55] Tiron (disodium pyrocatechol-3,5-disulphonate)[141] has interesting complexing properties in respect to iron and manganese, making it possible to separate these elements from bismuth, cadmium, cobalt, copper, nickel, lead and zinc. 1-(2-Pyridylazo)-2-naphthol masks zinc perfectly and does not influence the reaction of cadmium.[142] 1,10-Phenanthroline, however, masks iron, manganese, nickel and zinc, making possible the determination of lead.[143]

A separate problem is presented by reactions in acid solution. In these conditions the α_A coefficient has the most significant effect, indicating the protonation of the ligand and its subsequent decomposition. The kinetics of this latter process seem to be most important in the formation and decomposition of the complexes in acid solution. While in such media precipitation is rarely used, several authors apply extraction from acid solution,[17,53,97,99] using the diethylamine and pyrrolidine derivatives.

A very important parameter in these extractions, *e.g.*, from 10*N* sulphuric acid,[17] 6*M* hydrochloric acid,[97,99] 10*M* hydrochloric acid,[144] is the choice of the proper organic solvent, which influences the partition of the dithiocarbamic acid and its stability.[16] To decrease the rate of ligand decomposition it is often advantageous to replace the sodium or ammonium salts of dithiocarbamates by salts soluble in organic solvents, *e.g.*, diethylamine diethyldithiocarbamate.[16,17,110] Good results may also be obtained when the diethyldithiocarbamate is replaced by tetramethylenedithiocarbamate,[97,99] which is decomposed more slowly in acids. Usatenko and Tulupa[144] give the order of diethyldithiocarbamate complex decomposition with increasing acid concentration as zinc, cadmium, lead, bismuth, iron, nickel, copper (cobalt does not decompose). This indicates that the path of decomposition is not only a dissociation of complex followed by acid decomposition of free ligand.

Various solvents have been examined, *e.g.*, ethers, alcohols, esters, pyridine, hydrocarbons and halogenated hydrocarbons.[98,145,146] The most advantageous are halogenated hydrocarbons and aliphatic esters. Šedivec and Flek[145] indicate that the usefulness of solvents increases in the series: benzene, carbon tetrachloride, chloroform, ether, butyl acetate and ethyl acetate, but this sequence does not correspond to the increasing solubility of metal chelates.[98,146]

The solubility is usually greatest in chloroform and pyridine and much smaller in benzene, toluene, carbon tetrachloride and ethyl acetate. The polar halogenated hydrocarbons (ethylene chloride, 1,2-dichloroethylene, trichloroethylene, chlorobenzene and chloroform) are better than the non-polar (carbon tetrachloride, perchloroethylene).[147]

The choice of the solvent to some extent depends on the nature of the metal complex. The water-soluble uranyl complex is extracted with n-butanol,[148] methyl ethyl ketone,[149] isopentanol or ethyl ether, but not with chloroform or carbon tetrachloride.[40] The general rule for complexes of oxo-cations is to extract them with ketonic solvents.[56] Obviously when the ligand molecule contains hydrophilic groups extraction occurs only slightly or not at all, unless special solvents, such as acetate esters[149] or tributyl phosphate[125] are used.

In analytical practice several other properties of solvents are of importance (density, emulsion formation, purity, chemical inertness, *etc.*) and therefore ethyl acetate,[53] chloroform[39] and carbon tetrachloride[44,150] are widely used.

A detailed study of several parameters which do not enter into the equilibrium equations was performed by Šedivec and Flek.[145] They confirmed the previously observed fact[157] that in the presence of an excess of the ligand the extraction is not complete. This was especially observed for chloroform, carbon tetrachloride and benzene extractions and presumably is connected with stabilization of dispersed colloid particles by the dithiocarbamate anion, in a way similar to that observed for gelatin or soap. This effect may be suppressed by addition of neutral salts, which

increase the effectiveness of extraction.[145,152,153] Probably the increase of the extraction rate in acid solutions is connected with decomposition of the stabilizing anion adsorbed on the surface of the chelate particles.[145] Nevertheless the data given by different authors for the extractions often disagree.

STABILITY SERIES OF CHELATES

Difficulties in the determination of absolute values of stability constants of dithiocarbamate complexes stimulated several authors to establish the stability series based on solubility or extraction. Malatesta[154] found the solubility of diethyldithiocarbamates decreased in the order Tl(I), As(III), Zn, Fe(III), Ni, Cd, Pb, Co(III), Cu(II), Ag(I), Hg(II). This corresponds approximately to the solubilities of the sulphides. A similar series was given by Podtchainova[6] but neither of these authors indicates clearly the conditions of formation of the chelates. Potentiometric titration of metal ions with diethyldithiocarbamate[155] has given a similar series—Zn, Cd, Pb, Ni, Cu, Ag—but with an indication that this corresponds to non-complexing media, so this sequence may be closely related to the real solubilities of the complexes.

Wickbold[156] has shown that the presence of weak complexing agents—tartrate and ammonia (pH 9) or tartrate at pH 12—does not alter significantly the sequence [except for the strongly complexed iron(III)] namely, Fe(III), Mn(II), Zn, Sb(III), Tl(III), Cd, Bi, Pb, Co, Ni, Cu, Ag, Hg. The order of the first four relates to pH 9 only.

These relative solubilities agree well with the solubility products determined by Kemula and Hulanicki[22,143,157,158] and Starościk and Siagło.[159]

There is a similar lack of data for extraction procedures. The metal ion replacement in non-aqueous solutions of dithiocarbamate proceeds quantitatively if

$$\{K'_{e[M(DTC)_n]}\}^m \gg \{K'_{e[M'(DTC)_m]}\}^n$$

where K_e' represents the conditional extraction constant of the complex indicated. Eckert[160] established the replacement series of ions ("*Verdrängungsreihe*") valid in strictly defined solution conditions (pH 5·6, chloroform). However, this series, Mn, [As(III), Zn], [Sn(II), Fe(III)], Cd, Pb, Bi, [Ni, Co(II)], Cu, Ag, Hg, may be applied to diethyl- and tetramethylenedithiocarbamates and does not depend on the solvent (chloroform, carbon tetrachloride).

The experiments of Bode and Tusche[150] with precipitated metal hydroxides or carbonates at pH 8·5 or 11 were performed in easily reproducible conditions, at a constant metal ion concentration defined by their solubility products. With carbon tetrachloride as solvent they obtained the sequence Mn, Te(IV), Fe(III), Sb(III), In, Zn, Tl(I), Cd, Co(III), Pb, Bi, Ni, Tl(III), Cu, Ag, Pd(II), Hg(II), in which the ions up to indium react only at pH 8·5, whereas the others also react at pH 11.

A slightly different sequence was given by Tulupa *et al.*[149] for diethanoldithiocarbamates extracted with ethyl acetate: Mn(II), Zn, Ni, Co, Cd, Fe(III), Pb, Bi, Cu, Ag, Hg, Au(III). The differences may be attributed to the effect of the hydroxyl group in the ligand.

In all equilibria between dithiocarbamates and metal ions, especially in heterogeneous systems, the slow attainment of equilibrium plays an important role. This is particularly true for reactions of iron(III), nickel, cadmium and other ions.[150,160] The presence of various complexing agents has a significant influence on the rate of exchange reactions.

Another important factor in these processes is the possibility of a redox reaction

TABLE IV.—ANALYTICAL APPLICATIONS OF METAL EXCHANGE REACTIONS OF DITHIOCARBAMATE COMPLEXES, ACCORDING TO THE EQUATION $nM + mM'(DTC)_n \rightleftharpoons nM(DTC)_m + mM'$

M	M'(DTC)$_n$	Solvent	Medium	Application	Reference

Abbreviations: col.—colorimetric, compl.—complexometric, detn.—determination, extr.—extractive, iodom.—iodometric, merc.—mercurometric, polar.—polarographic, pur.—purification, radiom.—radiometric, separ.—separation, substoich.—substoichiometric, titr.—titration, ppt.—reaction involves the precipitate of dithiocarbamate, aq.—reaction in homogeneous aqueous phase.

Methods based on two reactions are indicated by the same letter in the last column.

of the metal ion. A well-known example[133] is the cobalt(III) complex, which is so stable that after its formation no exchange occurs with other ions, even mercury(II), whereas cobalt(II) ions in the aqueous phase react with the weakest complexes such as those of indium or zinc only. The same is true when the action of complexing agents on cobalt(II) ions or cobalt(III) complexes is considered.[120]

The rate of metal ion exchange in a homogeneous system (water-acetone solution, di-n-propyldithiocarbamate complexes) has been studied by Regenass *et al.*[88] They give the stability sequence Zn, Ni, Co, Cu and emphasize the effect of oxidation of cobalt(II) by oxygen. Nickel exchange in a methylcellosolve solution of dithiocarbamates is slow[161] but replacement of nickel by copper is on the contrary a rather rapid reaction, suggested to be S_E2 in type.[87]

In spite of the incomplete data on extractability and stability of complexes, numerous analytical methods are based on metal replacement between a complex of a metal M′ and solvated M ions. These procedures indicate the relative stabilities of the complexes of both metals and from the analytical point of view are of special interest because in combination with a suitable choice of medium they offer excellent methods of selective and specific determination of a particular ion. In Table IV such methods are listed, together with an indication of the reaction conditions for the replacement.

INVESTIGATION OF DITHIOCARBAMATE COMPLEXES IN SOLUTION

The study of dithiocarbamate complex stabilities must take into account some peculiar properties of the ligand and of the complexes formed, namely the possibility of decomposition of the ligand in acidic solution.

Concentrations of the species involved in complexation reactions may be measured directly only in a few cases, where the complexes are substantially dissociated. This procedure was successfully used by Budevsky *et al.*[187] in the study of carboxymethyldithiocarbamate complexes of cobalt by the spectrophotometric method of corresponding solutions. Spectrophotometry was also applied by Usatenko and Fedash[84] in the investigation of manganese(III) complexes, which may be considered as rather weak.

The evaluation of the thermodynamic stabilities of stable complexes in solution may be performed by direct potentiometric determination of metal ion concentration in equilibrium with the complex. This method is, however, restricted to those metals which form sufficiently reversible and reproducible electrodes in solutions of their ions, so is limited to silver and mercury.[143,158]

The most important methods of investigation of stable complexes are based on shifting the main complexation equilibrium by means of some competition reaction. The competition between metal ion and proton for the ligand is often used, but this relatively simple method fails in the case of dithiocarbamate ligands because of the unfavourable nature of the proton–dithiocarbamate reaction. Therefore the following competition methods should be used:

(*i*) competition of two metals for a ligand, one of them forming complexes of known characteristics

(*ii*) competition of two ligands for a metal ion, one being the dithiocarbamate and the other forming complexes of known stability.

The first group of methods includes potentiometric measurements on the system with the indicator electrode working as a third kind of electrode. With a similar electrode Hulanicki[22,143] determined the solubility products of copper, nickel, cadmium, lead, zinc and thallium diethyldithiocarbamates, and Starościk and Siagło[159] that of indium diethyldithiocarbamate. In all these experiments (except that for thallium) additional complexing agents were used to prevent hydrolysis of the excess of metal ions, so the systems involved two competition reactions.

With the second group of competition methods Janssen[89,90,188] determined the complex stabilities in the system dithiocarbamate–copper ions–8-hydroxyquinoline (or 8-hydroxyquinoline-5-sulphonic acid). The results obtained in homogeneous water–ethanol media were extrapolated to purely aqueous solutions. With a heterogeneous system containing a precipitate of the dithiocarbamate copper chelate, Kemula and Hulanicki[157] determined the solubility products of copper, lead and zinc diethyldithiocarbamates, using ethylenediamine, EDTA and NTA, and NTA as competing ligands for copper, lead, and zinc respectively.

A different kind of competition method should be used when the dithiocarbamate complexes are soluble in aqueous media. Hulanicki and Minczewska[49] used dithizone (diphenylthiocarbazone) as a competing ligand and determined the shift of $pH_{1/2}$ for the dithizone extraction of copper, lead, cadmium and nickel, caused by the formation of bis(carboxymethyl)dithiocarbamate complexes in the aqueous phase. The stability of the complexes in this system enabled all experiments to be performed in solutions of sufficiently high pH, so the total concentration of unbound dithiocarbamate could be assumed equal to the free ligand concentration. In this study the excess of the ligand shifted the equilibrium towards the complex with maximum co-ordination number. The stepwise formation of complexes may be indicated spectrophotometrically if smaller concentrations of the ligand are used.[22] The stability constants in these experiments could only be approximately evaluated ($\beta_1 \sim 10^{14}$, $\beta_2 \sim 10^{21}$).

The existence of such successive complexes for ligands having hydrophilic groups was also mentioned by other authors.[20,98,188] For other ligands the presence of such complexes was shown by Janssen,[89,188] working with homogeneous water-ethanol solutions. However in heterogeneous systems (precipitation and liquid-liquid extraction) the equilibrium is so strongly shifted in the direction of the complex having the maximum number of attached ligands that only in special systems can the presence of successive complexes be shown. Usatenko *et al.*[100,189,190,195] have determined amperometrically the equilibrium constant of the reaction

$$2M(DTC)^{+} \rightleftharpoons M(DTC)_2 + M^{2+}$$

using the oxidation current of the $M(DTC)^{+}$ complex as indicator current; they studied the lead, cadmium and zinc complexes of diethyl-, pentamethylene- and hexamethylenedithiocarbamates. The equilibrium constant of the reaction is shifted significantly to the left only for mercury(II). Therefore in non-complexing solutions, unless an equimolar amount of the ligand is exceeded, no mercury–dithiocarbamate precipitates. Using the combined potentiometric (mercury electrode) and solubility methods Kemula *et al.*[158] studied the formation of 1:1, 1:2 and 1:3 complexes. With a similar indicator electrode and procedure the thallium(I) complexes were studied.[22]

The formation of intermediate complexes was demonstrated heterometrically by Bobtelsky *et al.*[45,46,72] in the case of mercury, gold and platinum, but not for lead,

TABLE V.—EQUILIBRIUM CONSTANTS IN THE METAL–DITHIOCARBAMATE SYSTEMS

Metal ion	Method	Temp., °C	Medium	Log of the constant	Ref.
			$C_3H_7NS_2$ Dimethyldithiocarbamic acid

cadmium, bismuth and copper.[191–194] Nevertheless, heterometry does not seem to be a precise method for such investigations. The breaks on the heterometric curves may correspond not only to changes of chemical composition, but also to changes in the physical structure of the precipitate.

The equilibrium constants for different metal–dithiocarbamate systems are collected in Table V, presented in the manner used in the Stability Constant Tables.[196] These data are in good agreement with the previously established stability series or with empirically developed analytical procedures based on relative stabilities of complexes.

Acknowledgement—The author is greatly indebted to Professor Dr. W. Kemula, the Head of the Department, for his constant encouragement, help and stimulating discussions in the course of preparation of this paper.

Zusammenfassung—Die Komplexbildungsreaktionen mehrerer disubstituierter Dithiocarbamate werden diskutiert. Besondere Aufmerksamkeit wird Untersuchungen der Zusammensetzung und Stabilität verschiedener Metallkomplexe geschenkt. Die Bedingungen der Komplexbildung in Lösung werden an Hand von Nebenreaktionskoeffizienten abgehandelt. Die Eigenschaften von Metall-Dithiocarbamatkomplexen werden als Funktionen der Natur der Substituenten im Ligandenmolekül angegeben.

Résumé—On discute des réactions de complexation de divers dithiocarbamates disubstitués. On porte une attention particulière aux études relatives à la composition et à la stabilité de divers complexes métalliques. Les conditions de formation de complexes en solution sont traitées en fonction de coefficients de réaction secondaire. On présente les propriétés des complexes métal-dithiocarbamate en fonction de la nature des substituants dans la molécule de ligand.

DETERMINATION OF POTASSIUM BY AN AUTOMATIC ULTRAVIOLET ABSORPTIOMETRIC METHOD

J. M. SKINNER and A. C. DOCHERTY
Imperial Chemical Industries Limited, Agricultural Division Research and Development Department, Billingham, Co. Durham

(*Received* 26 *June* 1967. *Accepted* 26 *July* 1967)

Summary—An automatic ultraviolet absorptiometric method has been developed for the determination of potassium. The method involves precipitation of potassium by addition of a known excess of sodium tetraphenylborate, removal of the potassium tetraphenylborate precipitate by filtration, and measurement of the excess of sodium tetraphenylborate in the filtrate by means of its absorbance at 254 mμ. Most of the apparatus, including a continuous filter, is standard AutoAnalyzer equipment but a Uvicord ultraviolet absorptiometer replaces the conventional colorimeter. Build-up of precipitate in the system is eliminated by immersing the mixing coils in an ultrasonic bath which is actuated intermittently by a simple timing mechanism. The method is especially suitable for potassium analysis in production plant where flame photometer results are sometimes affected by fertilizer dust in the air surrounding the burner.

A FULLY automatic laboratory method[1] for the simultaneous determination of ammoniacal nitrogen, nitrate nitrogen, phosphate and potassium in fertilizer solutions has been in use for four years in the laboratories of the Agricultural Division of Imperial Chemical Industries Ltd. and has been found to be satisfactory and reliable. However, attempts to move this equipment into the production plant with the intention of using it for fully automatic control have given rise to various difficulties: the one dealt with in this paper arises from the fact that although a flame photometer provides a simple and convenient method for the determination of potassium when used in a laboratory, its use in the plant has the following disadvantages.

1. Fertilizer dust suspended in the plant atmosphere contaminates the flame and introduces errors.
2. The presence of a naked flame is undesirable in some plant areas.
3. The continuous supply of oxygen and propane is not always convenient to arrange.

The approach to this problem described here involves the determination of potassium by mixing the fertilizer solution with excess of sodium tetraphenylborate, filtering off the potassium tetraphenylborate precipitated, and measuring the excess of reagent by its absorbance at 254 mμ.

A survey of available methods for the quantitative determination of potassium indicated that either a colorimetric or a turbidimetric procedure would be the most suitable replacement for the flame photometric method usually adopted in the Auto-Analyzer system. Many methods,[2] with a variety of reagents, have been described for the colorimetric or turbidimetric determination of potassium but, taking low

solubility of the final potassium salt as a criterion, either sodium cobaltinitrite or sodium tetraphenylborate is the most suitable. With the cobaltinitrite reagent used in the presence of silver nitrate, the precipitated potassium silver cobaltinitrite has a solubility in water of $1{\cdot}64 \times 10^{-2}$ g/l at 25° and in aqueous media is the least soluble of all the potassium salts; potassium tetraphenylborate is only slightly more soluble in water—$3{\cdot}6 \times 10^{-2}$ g/l at 25°. However, the cobaltinitrite reagent is somewhat unstable and for this reason it was decided to use sodium tetraphenylborate as reagent.

The use of sodium tetraphenylborate (STPB) to precipitate potassium is already well-established although the reaction was first described by Wittig[3] only as recently as 1949. Subsequent work[4,5,6] has shown that it can be used for the quantitative precipitation of potassium from solution and Ford[7] successfully used the reagent for the gravimetric determination of potassium in fertilizers. For fertilizer analysis, however, a more attractive procedure is to add excess of STPB and determine the excess volumetrically by titration with a quaternary ammonium salt. A method[8] based on this principle has been adopted by the Association of Official Analytical Chemists (A.O.A.C.) Washington, D.C., and recent check analyses[9] have shown that it is accurate and precise. In Europe also a similar method is being used on an increasing scale. Since there is widespread acceptance of STPB as a reagent for the determination of potassium it was concluded that the investigation should aim to develop a spectrophotometric version of the method, which could be used with the AutoAnalyzer system and might replace the flame photometric method for analysis in a works.

A spectrophotometric method for the determination of potassium has been described by Pflaum and Howick[10] but this involves redissolving the potassium tetraphenylborate precipitate in an acetonitrile–water mixture (3 + 1) and measuring the absorbance at 266 mμ. It was considered preferable, if possible, to work with the visible region of the spectrum, and a method[11] in which the solution containing potassium is treated with excess of STPB and the excess is precipitated with *p*-rosaniline, was therefore examined. The excess of *p*-rosaniline can be measured in the visible region of the spectrum. Considerable difficulty was experienced with this method and it was finally abandoned. Attempts were then made to measure the turbidity produced by the potassium tetraphenylborate precipitate but it was found impossible to control the particle size of the suspension of potassium tetraphenylborate and it was decided to measure the excess of STPB directly by taking advantage of the absorbance bands of this substance in the ultraviolet region at 250–265 mμ.

EXPERIMENTAL

Apparatus

The apparatus used is shown diagrammatically in Fig. 1. Most of the items of equipment are standard AutoAnalyzer (Technicon Instruments Corp., Research Park, Chauncey, N.Y., U.S.A.) components and only the other items required are described in detail below.

Ultrasonic bath

The equipment was supplied by Kerry's (Ultrasonics) Ltd., Warton Road, London, E.15, and consists of a bath, a transducer and a power supply. The bath, Type KB 80/1, is constructed of 18-gauge cold-rolled steel 6 in. × 4 in. × 6 in. with a working capacity of 3 pints. Power is supplied by a Kerry "Pulsatron" Ultrasonic generator type KG 80/1, 200/240 V single phase 50 c/s, with a power consumption of 100 W and an output of 160 W peak and 40 W average, at a frequency of 80 kc/s. The power is fed to a specially designed barium titanate transducer unit permanently attached beneath the floor of the bath.

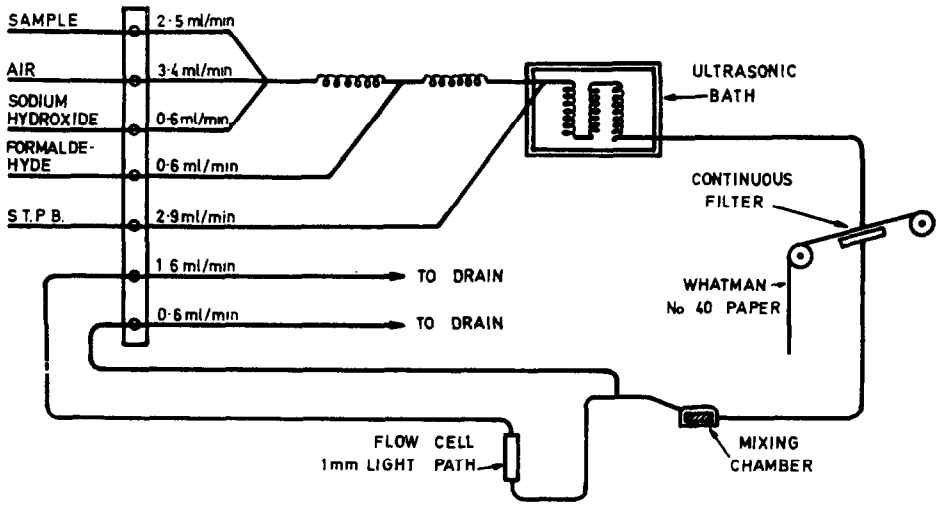

FIG. 1.—Flow system.

Filtrate mixing chamber

A drawing of the filtrate mixing chamber is shown in Fig. 2. The body of the chamber is made by sealing and flattening the end of a piece of glass tubing, 17 mm bore, and adding the inlet and outlet tubes as shown in the drawing. The outlet tube is offset to avoid trapping air bubbles. The main tubing is then cut and the ends ground level to an internal length of 8 mm. A glass disc 20 mm in diameter and 1·75 mm thick is prepared and ground flat with a 2-mm diameter depression drilled centrally to a depth slightly less than 1 mm to accommodate the spigot of the magnet follower.

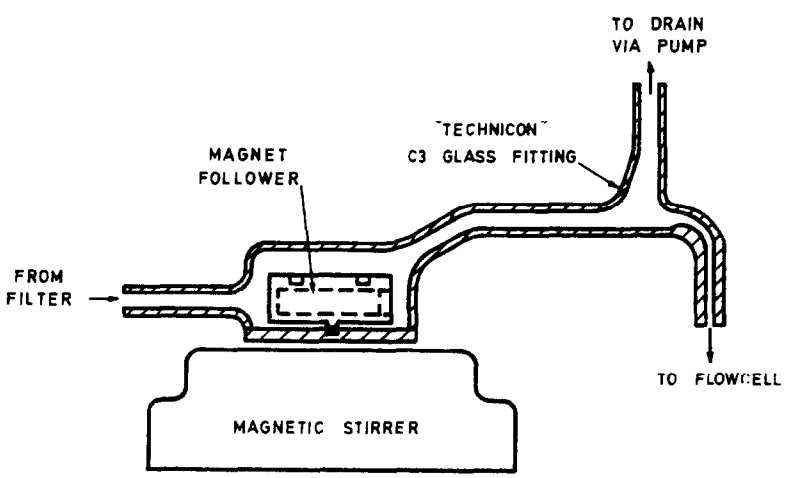

FIG. 2.—Detail of mixing chamber assembly.

The magnet follower, Fig. 3, is made from PTFE bar, 15-mm diameter, with a 5-mm diameter hole drilled through the side to a depth of 13 mm. A length of $\frac{3}{16}$ in. square cross-section "FERROBA" (Grant Instruments, Cambridge, England) is turned to just less than 5 mm in diameter, and an 11-mm length is cut and inserted into the hole, which is then sealed with a PTFE plug. The PTFE bar is then machined so that the top surface is 0·5 mm from the inner surface of the hole. Four slots 2 mm × 2 mm × 1 mm deep, set at 90° intervals, are cut on the circumference of this surface, clear of the FERROBA. The lower surface of the bar is now machined to within 0·5 mm of the inner surface of the hole but in this case a 1-mm diameter spigot 1 mm long is left to permit the correct

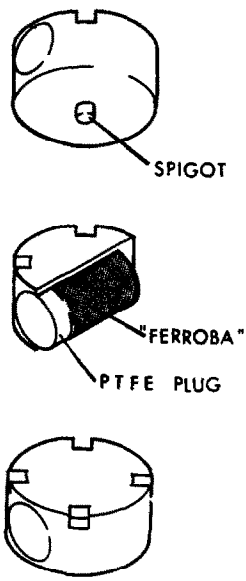

FIG. 3.—Detail of magnet follower.

positioning of the magnet follower in the base of the mixing chamber. Finally, the magnet follower is placed in the body of the chamber and the disc cemented in position with "ARALDITE" resin.

L.K.B. Uvicord ultraviolet absorptiometer

In this apparatus (L.K.B. Instruments, Inc., Washington 14, D.C., U.S.A.) ultraviolet light from a mercury vapour lamp passes through an adjustable slit. A liquid filter (nickel sulphate solution) on the other side of the slit absorbs most of the unwanted radiation at 312·6 mμ and 313·2 mμ and light which is essentially monochromatic (253·7 mμ) then passes through the measuring cell. The light is absorbed in the cell to an extent characteristic of the solution flowing through it. Unabsorbed ultraviolet light continues through a black glass filter and on to a phototube detector. The black glass filter absorbs any visible light coming from the mercury vapour lamp or from external sources. In the experiments described in this paper a quartz cell with a 1-mm optical path and volume of 0·05 ml was used.

Reagents

Formaldehyde solution 10% *w/v*. Dilute 275 ml of formaldehyde solution, analytical reagent grade 36% w/v, to 1 litre.

Sodium hydroxide solution 5% *w/v*.

Sodium tetraphenylborate solution, 0·2%. The solution may occasionally be cloudy and should be filtered through a Whatman No. 40 paper.

Procedure

Transfer the appropriate weight (1·5 g for 20% K_2O, 3·0 g for 10% K_2O) of the prepared sample (ground to pass a 0·152-mm aperture sieve) to a suitable beaker, add 200 ml of water and heat to boiling. Cover with a clock glass, continue to boil gently for 15 min, then cool and dilute with water to 1 litre in a volumetric flask. Filter sufficient solution for test through a Whatman No. 40 paper.

Set up the manifold system as shown in Fig. 1. With distilled water passing through the sample and reagent lines and with the slit fully closed, adjust the zero controls on the absorptiometric control unit until the recorder pen indicates zero transmission. The system is now ready for introduction of the reagent solutions; when a steady base line has been obtained introduce bracketing standards appropriate to the level of potassium expected, using an AutoAnalyzer Mark II sampler with a 2-min water wash and 4-min sample aspiration time. Aspirate the filtered sample solution immediately after the standards.

RESULTS AND DISCUSSION

Experiments in the visible region

As mentioned above, it was decided to concentrate initially on a spectrophotometric method in which potassium is precipitated with STPB and the excess of tetraphenylborate (TPB) ion is precipitated by the addition of excess of *p*-rosaniline. The precipitates can be filtered off and the excess of *p*-rosaniline in the filtrate measured spectrophotometrically at 525 mμ. Standard AutoAnalyzer equipment was used, comprising a sampler, pump, 2 dialysers, colorimeter and recorder.

The potassium-bearing solution was mixed with a stream of STPB reagent which precipitated potassium tetraphenylborate, and part of the excess of TPB ion was dialysed—a process which also separated the potassium precipitate. The dialysed TPB ions were then mixed with excess of *p*-rosaniline and the precipitated *p*-rosaniline TPB was removed by passage through a second dialyser. Some *p*-rosaniline dialysed into the recipient stream and the concentration was measured absorptiometrically at 525 mμ. As might have been expected, a number of difficulties were experienced with this complicated system. Foremost of these was the trouble caused by deposition of potassium TPB and *p*-rosaniline TPB on the walls of the transmission tubing. Moreover, *p*-rosaniline appeared to be absorbed into the transmission tubing and there were memory effects in the dialyser possibly due to variations in the dialysis process caused by blockage of the membrane with precipitate. Further work on this method was, therefore, abandoned.

It was next decided to ascertain whether or not a simple turbidimetric method might be possible, analogous to the standard AutoAnalyzer method for determination of sulphate. Although the investigation of this method was not exhaustive it did appear that the particle size of the precipitate was too large; with concentrated solutions the mean diameter of the potassium TPB precipitate was 20 μ and although this could be reduced by using more dilute solutions, these small crystals quickly formed aggregates of about 20 μ diameter. As a consequence of the large particle or aggregate size of the precipitate the recorder traces were very irregular. For comparison, a barium sulphate precipitate formed under conditions suitable for turbidimetric measurement was also examined, and found to have a mean particle size of 1 μ. The effect of temperature was also investigated and found to cause some slight increase in particle size. Several anticoagulants were also tried without success.

At this point it was decided to use a method in which the potassium TPB was filtered off and the concentration of the residual TPB ion was measured in the ultraviolet region of the spectrum.

Experiments in the ultraviolet region

Preliminary experiments using a solution of STPB to obtain an absorbance trace on a Unicam SP 800 indicated that the appropriate wavelength for measurement of absorption by the TPB ion was 266 mμ; this is in accord with the findings of Pflaum and Howick.[10] A typical trace is shown in Fig. 4 from which it may be seen that there are two shoulders on the absorbance curve, one at 273 mμ and one at 266 mμ. The latter was chosen since it is the more sensitive. A continuous flow system was therefore set up incorporating a standard AutoAnalyzer sampler, pump and continuous filter, followed by a Beckman DB spectrophotometer and recorder. The spectrophotometer was fitted with a flow-through cell with a small volume of about 0·2 ml,

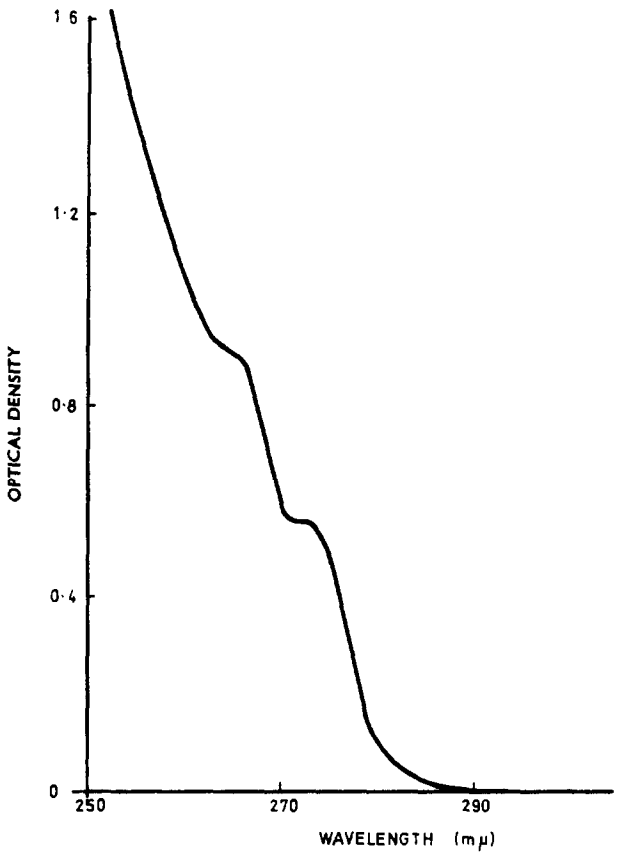

FIG. 4.—Absorption spectrum of sodium tetraphenylborate solution (0·01% w/v in water; 1-cm cuvette).

which minimized the response time of the system. It was also necessary to make provision in the manifold system for a preliminary treatment of the sample solution with 10% formaldehyde solution to destroy any ammonium ions present. After mixing with a 0·20% STPB solution the sample stream was passed through three mixing coils to ensure complete precipitation before passing to the continuous filter and thence to the spectrophotometer. A plot of absorbance against concentration gave a linear calibration graph for concentrations of K_2O up to 300 mg/l in the sample solution. At higher concentrations solubility effects caused slight deviation from linearity. The principle of the method is thus shown to be sound but it was considered preferable for routine use to employ a simple type of filter absorptiometer rather than the Beckman monochromator. An L.K.B. Uvicord absorptiometer was therefore substituted for the Beckman instrument.

Initially it was found that irregular recorder traces were obtained when using the absorptiometer and it was apparent that the principal cause of this was variations in the concentration of STPB from segment to segment in the flow system. Normally such variations are not troublesome but when the extremely small volume (0·05 ml) flow-cell in the Uvicord absorptiometer is used the effect is magnified and must be

eliminated. This was achieved by inserting a small reservoir (about 2 ml in volume) in the system to collect the filtrate from the continuous filter. A small magnetic stirrer was also included to ensure thorough mixing of the filtrate. For the correct functioning of the chamber, it was necessary to make provision for a de-bubbling step on the outlet line to prevent air bubbles, which occasionally pass through the filter, from being drawn through the flow-cell.

This manifold system gave excellent results when tested with standard fertilizer samples but could not be operated for more than about 4 hr owing to the build-up of precipitate in the mixing coils. It thus became necessary to immerse these coils in the ultrasonic bath shown in the manifold diagram. This was actuated by a timing mechanism which enabled the precipitate to be removed by switching on the generator for 1 min every hour. No further difficulty was experienced with this system.

A series of samples was examined, using as standards fertilizer samples analysed by the potassium chloroplatinate method described in the Fertilisers and Feeding Stuffs Regulations 1960, Section 5.2, Statutory Instrument 1165 published by Her Majesty's Stationery Office, London. Simultaneously, the same samples were analysed for potassium with a Technicon AutoAnalyzer flame photometer; in this instance also the bracketing standards used were analysed by the potassium chloroplatinate method previously mentioned. The results obtained by both techniques are given in Table I.

Both sets of results are the average of 3 independent determinations on each sample and it can be seen that the results are in close agreement. Statistical analysis of the individual determinations by the *F*-test indicated that there is a significant difference in the precision of the two procedures, the STPB method being more precise than the flame photometer method. Application of the *t*-test gave no evidence of a bias between the two methods. These results clearly indicate that this automatic absorptiometric procedure is capable of giving acceptable results for the determination of potash in fertilizers. Certain anomalies were observed from time to time with respect to the nature of the precipitated potassium TPB, which varied from a granular crystalline precipitate to a finely divided suspension. Various authors[5,6,12,13,14] have discussed the optimum conditions for the precipitation of potassium TPB but it was impractical to apply their findings to a continuous system. Moreover, the form of the precipitate did not affect the results obtained so it was considered unnecessary to investigate this aspect any further. If required, the sodium tetraphenylborate reagent may be purified, since there is evidence that trace impurities can affect the absorbance of the solution, but here again the results are not invalidated, the effect being merely to alter the absolute value of the absorbance and the slope of the calibration curve.

An automatic absorptiometric method for the determination of potassium in fertilizers has been developed which gives results at least as reliable as those obtained by standard procedures. The method is free from most of the disadvantages of the flame photometric method, and is generally applicable to the determination of potassium.

Using the manifold and flow system described above, the annual running cost in the U.K. for chemicals only, on a 24-hr, 350-day basis is £820. The main item in these costs is the price of the STPB and any significant reduction in this resulting from using a commercial grade would reduce the cost of operating the system by an almost proportionate amount. For comparison on the same basis, the continuous

operation of the flame photometer for the determination of potassium costs about £420 per annum for the oxygen and propane gases alone. The absorptiometric method is therefore more expensive to run and in one year the extra cost totals approximately £400. However, the advantages attendant on its use far outweigh the disadvantage of increased cost.

This work has shown that a reliable continuous method for the determination of potassium can be obtained based on the ultraviolet spectrophotometry of tetraphenylborate solutions. It is of interest to note that some years ago Cooper[15] claimed

to have developed a satisfactory laboratory procedure for the quantitative determination of potassium ion, based on this principle, but gave no details. The automatic method described in this paper can also be used manually and under standard laboratory conditions has given excellent results.

Acknowledgements—This work extended over a period of two years and during this time several people made valuable contributions, but we are especially indebted to Mr. S. G. Farrow and Mr. S. R. Hill whose assistance enabled us to bring the work to a successful conclusion.

Zusammenfassung—Ein automatisches Verfahren zur Bestimmung von Kalium durch UV-Absorptionsmessung wurde entwickelt. Dabei wird Kalium durch Zugabe eines bekannten Überschusses von Natriumtetraphenyloborat gefällt, der Niederschlag von Kaliumtetraphenyloborat durch Filtration entfernt und der Überschuß von Natriumtetraphenyloborat im Filtrat über seine Absorption bei 254 nm gemessen. Der größte Teil der Apparatur, darunter auch ein kontinuierlich arbeitendes Filter, ist normales AutoAnalyzer-Gerät; das übliche Kolorimeter wird jedoch durch ein Uvicord-Absorptiometer ersetzt. Ein Ausfallen von Niederschlag im System wird verhindert, indem die Misch-Schlangen in ein Ultraschallbad getaucht werden, das von Zeit zu Zeit durch einen einfachen Zeitgebermechanismus in Betrieb gesetzt wird. Die Methode eignet sich zur Kaliumbestimmung im Produktionsbetrieb, wo Ergebnisse vom Flammenphotometer zuweilen durch Düngemittelstaub in der Luft um den Brenner beeinträchtigt werden.

Résumé—On a élaboré une méthode absorptionmétrique ultraviolette automatique pour le dosage du potassium. La méthode comprend une précipitation du potassium par addition d'un excès connu de tétraphénylborate de sodium, l'élimination du précipité de tétraphénylborate de potassium par filtration et la mesure de l'excès de tétraphénylborate de sodium dans le filtrat au moyen de son absorption à 254 mμ. La majeure partie de l'appareil, comprenant un filtre continu, est l'équipment standard AutoAnalyzer, mais un absorptionmètre ultraviolet Uvicord remplace le colorimètre habituel. On élimine l'établissement de précipité dans le système en immergeant les serpentins de mélange dans un bain ultrasonique qui est actionné de façon intermittente par un simple mécanisme de minuterie. La méthode convient spécialement à l'analyse du potassium dans une plante industrielle où les résultats du spectrophotomètre de flamme sont parfois affectés par le poussière d'engrais dans l'air entourant le brûleur.

APPLICATION OF THE ZONE MELTING TECHNIQUE TO METAL CHELATE SYSTEMS—II*

CONCENTRATION OF A TRACE AMOUNT OF METAL ACETYLACETONATE IN CHROMIUM(III) ACETYLACETONATE†

HISAMITSU KANEKO‡, HIROSHI KOBAYASHI and KEIHEI UENO
Department of Organic Synthesis, Faculty of Engineering,

(*Received* 4 *May* 1967. *Accepted* 5 *June* 1967)

Summary—The zone melting process was applied to tris(acetylacetonato)chromium(III) which contained a trace amount of aluminium(III), iron(III), copper(II), manganese(III), nickel(II) cobalt(III) and rhodium(III) in the forms of their acetylacetonates, and the highly purified chromium chelate was found in the top portion of a column, while the minor components except the rhodium chelate were concentrated in the bottom portion. The rhodium chelate was concentrated in the top portion. Ease of migration of the minor components during the zone melting process decreased in the order Cu, Fe, Mn, Co, Ni, Al and Rh, and was accounted for in terms of their crystal structures. Extremely slow speed of zone travel caused an increase of the distribution coefficient; this was due to back diffusion of minor components into a congealed solid phase from a molten zone.

WE have been successful in applying the zone melting technique to systems containing metal chelates.[1,2] Results were previously reported for a system consisting of tris(acetylacetonato)chromium(III) (main component) and tris(acetylacetonato)aluminium(III) (minor component).[3] The distribution coefficient (k) of the aluminium chelate in the chromium chelate was examined and was found to reach a minimum value at a certain speed of zone travel, and to increase towards unity for faster and slower speeds. This phenomenon was presumed to be due to back-diffusion of the minor component into a congealed solid from a molten zone. Experimental proof that the presumption was correct is shown in the present paper.

This paper is also concerned with an investigation on the behaviour of various metal acetylacetonates in tris(acetylacetonato)chromium(III) during the zone melting process. The results suggest that the acetylacetonate from crude chromium(III) salts could be highly purified from impurities such as iron(III), copper(III), manganese(III), cobalt(III), aluminium(III), nickel(II) and rhodium(III) acetylacetonates, and these impurities could be concentrated and separated.

In the course of the study, phase diagrams were constructed for the tris(acetylacetonato)aluminium(III)–tris(acetylacetonato)chromium(III) and tris(acetylacetonato)rhodium(III)–tris(acetylacetonato)chromium(III) systems, in order to

establish the relationship between the phase diagram and the distribution coefficient, since these two systems represent the cases where the distribution coefficients are smaller and larger than unity respectively.

EXPERIMENTAL

Reagents

Metal acetylacetonates, prepared by standard procedures,[4] were purified by repeated recrystallization. Their melting points and analytical results are summarized in Table I.

TABLE I.—PROPERTIES OF METAL CHELATES

Chelate*	m.p., °C	Analyses Found, %	Calc., %

		H, 5·3	H, 5·29

* AA stands for a univalent acetylacetonate ion.

Procedure

The general procedure is that given previously.[3] Aluminium(III), iron(III), manganese(III), copper(II), cobalt(III) and nickel(II) in chromium(III) were determined by emission spectrography. Analytical line pairs selected for the determination of the metals are shown in Table II.

TABLE II.—LINE PAIRS FOR EMISSION SPECTROGRAPHIC ANALYSIS

Metal ion	Line pair, Å	
Al	Al 3082·155	Cr 3084·56
Fe	Fe 2599·396	Cr 2603·570
Mn	Mn 2593·729	Cr 2596·173
Cu	Cu 3273·962	Cr 3264·264
Co	Co 3412·339	Cr 3411·080
Ni	Ni 3002·491	Cr 3011·09

Rhodium(III) was determined by atomic absorption spectrophotometry on the rhodium absorption line at 3435 Å. The instrument was a Jarrel-Ash Model AA-1 and the solvent was a mixture of methanol and benzene (1:1).

Diffusion experiments

Tris(acetylacetonato)aluminium(III) was packed tightly on a column of tris(acetylacetonato)-chromium(III) which was cast into a teflon tube (9 mm inner diameter). The tube was stoppered at both ends with glass plugs and inverted, then heated at a temperature below the melting points of both components (166°). It was then cut into pieces 2 mm long and a sample from each piece was analysed for aluminium by emission spectrography.

Phase diagrams

The melting points of binary mixtures of various compositions were determined by differential thermal analysis.

RESULTS AND DISCUSSION

The distribution coefficient was found to increase towards unity when the speed of zone travel was too slow, and this phenomenon was due to back-diffusion of the minor component into the solid matrix from the melt. The diffusion experiment with aluminium(III) and chromium(III) acetylacetonates in contact at a boundary plane showed that the aluminium chelate migrated into the chromium chelate as far as 10 mm from the boundary plane at 166° (Fig. 1), at which temperature the whole system was solid over the entire range of composition (Fig. 2). The result seemed to be

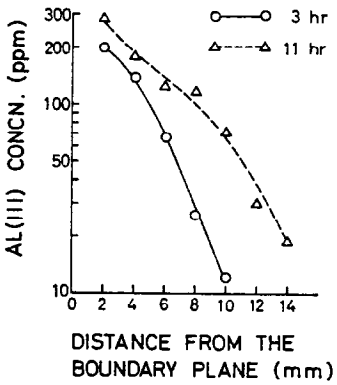

FIG. 1.—Diffusion of $Al(AA)_3$ in solid $Cr(AA)_3$ when heated at 166°C for 3 hr and 11 hr respectively.

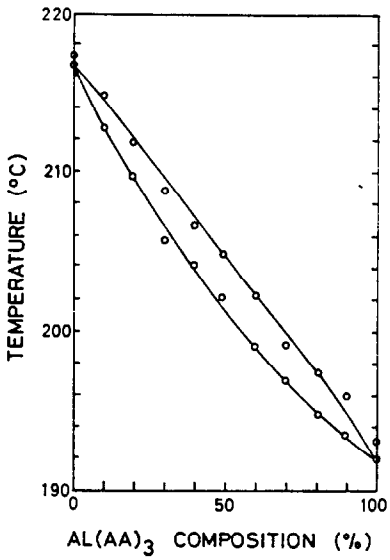

FIG. 2.—Phase diagram of the binary system $Al(AA)_3$–$Cr(AA)_3$.

indicative of the diffusion of the aluminium chelate through the solid chromium chelate. When a zone travels at an extremely slow speed, the neighbourhood of a boundary plane between a congealed solid and a molten zone will be subjected to a temperature just below the melting point for a considerable period of time. Under these conditions, the impurities in the molten zone may diffuse back into the congealed solid.

In addition to back-diffusion, the crystals in their melt, when cooled very slowly, tend to grow arborescently and become intertwined holding the melt, which solidifies as an inclusion. This causes less effective separation and hence an increased distribution coefficient.

Figures 3–8 show the results of the zone melting experiments on the binary systems with the chromium(III) chelate as the main component. The concentration of the minor component is plotted against the distance in zone lengths, x/l, where x is the distance from the top to the point where the sample was cut out for the determination, and l is the length of the molten zone.

As shown in Figs. 3 and 4, iron(III) and and copper(II) chelates are so easily concentrated at the bottom of the column that their concentrations in the top portion

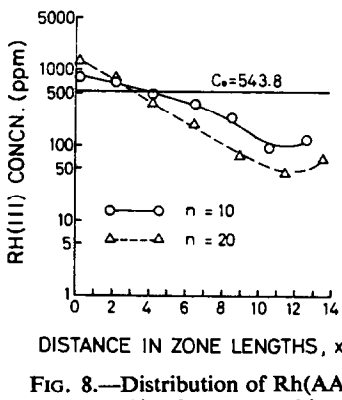

FIG. 8.—Distribution of $Rh(AA)_3$ in $Cr(AA)_3$ after zone melting.

are reduced far below the analytical sensitivities of the instruments, after only 10 passages.

In the determination of the distribution coefficients of the iron and copper chelates in the chromium chelate, the larger part of each had migrated to the bottom portion after a single passage of a molten zone at a speed of 15, 27 or 40 mm/hr. Since the Sorensen[5] method could therefore not be applied, the distribution coefficients were determined, for the last case only, by Sue's method.[6] The approximate values were 0·37 and 0·43 for copper and iron respectively.

Study of the binary systems indicates that the chelates of aluminium, nickel, manganese and cobalt were all concentrated at the bottom, but the concentration effect was poor for aluminium and intermediate for the rest. In contrast, the rhodium chelate was concentrated at the top of the column, indicating that the distribution coefficient is higher than unity, and this was proved by examination of the phase diagram of the system (Fig. 9).

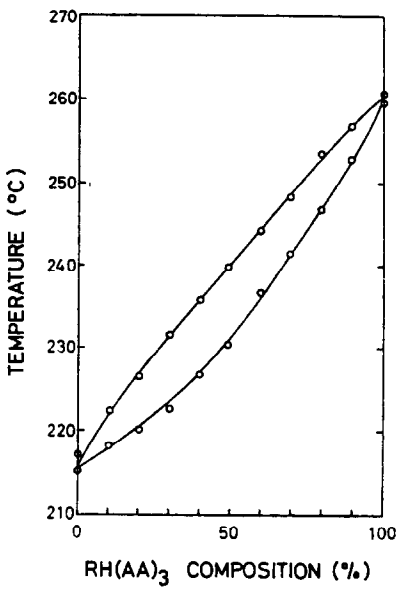

FIG. 9.—Phase diagram of the binary system $Rh(AA)_3$–$Cr(AA)_3$.

It is likely that the crystal structure of the metal chelates plays an important role in the difference in their mobilities in the matrix during the zone melting process. The trisacetylacetonates of chromium(III), aluminium(III), manganese(III), cobalt(III) and rhodium(III) are known to form a monoclinic isomorphic set, with a similar size of unit cell and the same space group C_{2h}^5,[7] whereas the iron(III)[8] and copper(II)[9] chelates are orthorhombic and monoclinic respectively and their cell dimensions are different from those of the chromium chelate.

The binary systems of aluminium(III) and chromium(III) chelates (Fig. 2) and of rhodium(III) and chromium(III) chelates (Fig. 9) each form a complete solution in both solid and liquid phase over the entire range of composition; aluminium and

rhodium chelates, therefore, seem to be more soluble in the solid chromium chelate than the rest. Formation of complete solid solution of any composition is encountered very often in systems of components having similarities in crystal structure as well as in molecular structure.

Thus, it is likely that metal chelates with different crystal structures segregate more easily than those with similar ones.

To investigate mutual interaction among the minor components present, multi-component systems (aluminium(III), copper(II) and iron(III) chelates in the chromium chelate; aluminium(III), manganese(III) and cobalt(III) chelates in the chromium chelate) were studied. The first system consists of chelates of different crystal structures, and the second of chelates forming a monoclinic isomorphic set. Their distribution in the chromium chelate is shown in Figs. 10 and 11, indicating that the

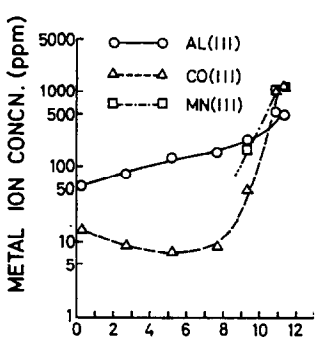

FIG. 11.—Distribution of the metal acetylacetonates in $Cr(AA)_3$ after zone melting.
$n = 20$; C_0 for Al, Co and Mn is 157·2, 157·5 and 150·5 ppm respectively

efficiency of concentrating each component is nearly equal to that for each binary system, and that there is no interaction.

Our results afforded an experimental foundation for the possibility of zone refining purification of acetylacetonates obtained from crude chromium salts. The zone refining of metallic chromium is known to be difficult because of its high volatility at the melting point, so this new process seems to be a useful method of obtaining highly purified chromium compounds. It also promises to be a useful method for the preconcentration of trace foreign components in a metal chelate.

Acknowledgements—The authors are indebted to the Ministry of Education, Japanese Government for the financial support of this work. They also gratefully acknowledge the valuable advice and the use of facilities for emission spectrographic analysis afforded by Dr. Hisashi Itoh, Professor of Metallurgy. Finally they wish to thank Mr. Kenjiro Yanagase of the Research Institute, Kyushu Electric Power Co. Ltd., and Miss Shin Kunitake of the Department of Metallurgy for their valuable advice on emission spectrography.

Zusammenfassung—Das Zonenschmelzverfahren wurde auf Tris-acetylacetonatochrom(III) angewandt, das Spurenmengen Aluminium (III), Eisen(III), Kupfer(II), Mangan(III), Nickel(II), Kobalt(III) und Rhodium(III) in Form ihrer Acetylacetonate enthielt; das hochgereinigte Chromchelat fand sich im oberen Teil der Säule, während die

Nebenbestandteile außer dem Rhodiumchelat im unteren Teil angereichert waren. Das Rhodiumchelat war im oberen Teil angereichert. Die Leichtigkeit der Wanderung der Nebenbestandteile während des Zonenschmelzprozesses nahm ab in der Reihenfolge Cu, Fe, Mn, Co, Ni, Al und Rh; dieser Gang wird mit den Kristallstrukturen erklärt. Extrem langsame Zonenverschiebung ließ den Verteilungskoeffizienten ansteigen; dies rührt von der Rückdiffusion von Nebenbestandteilen aus einer geschmolzenen in eine wieder erstarrte Zone.

Résumé—On a appliqué la méthode par fusion de zone au tris (acétylacétonato)chrome(III))contenant des traces d'aluminium(III), fer(III), cuivre(II), manganèse(III), nickel(II), cobalt(III) et rhodium(III) sous forme de leurs acétylacétonates et l'on a trouvé le chélate de chrome hautement purifié dans la partie supérieure d'une colonne, alors que les constituants mineurs à l'exception du chélate de rhodium ont été concentrés dans la partie inférieure. Le chélate de rhodium a été concentré dans la partie supérieure. La facilité de migration des constituants mineurs durant le processus de fusion de zone décroît dans l'ordre Cu, Fe, Mn, Co, Ni, Al et Rh et a été interprétée en fonction de leur structure cristalline. Une vitesse extrêmement faible du cheminement de la zone a causé un accorissement du coefficient de distribution; ceci était dû à une diffusion en retour des constituants mineurs dans une phase solide congelée à partir d'une zone fondue.

APPLICATION OF THE ZONE MELTING TECHNIQUE TO METAL CHELATE SYSTEMS—IV*

CONCENTRATION OF METAL-8-HYDROXYQUINOLINE CHELATES IN 8-HYDROXYQUINOLINE

HISAMITSU KANEKO†, HIROSHI KANAGAWA‡, HIROSHI KOBAYASHI and KEIHEI UENO
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka, Japan

(*Received* 4 *May* 1967. *Accepted* 2 *June* 1967)

Summary—The zone melting technique has been applied to 8-hydroxyquinoline containing trace amounts of various metal 8-hydroxyquinolates such as the nickel(II), cobalt(II), zinc(II) and copper(II) chelates. The metal chelate in each system was concentrated in the direction of zone travel. The highest concentrating effect was observed in the copper(II) chelate system. The concentration ratio, defined as the fraction of the metal chelate concentrated in the bottom 15% of the column, was determined after the 30th passage. A trace amount of copper ion extracted with a large excess of 8-hydroxyquinoline, was concentrated by means of the zone melting technique. The concentration ratio was 96%.

THE zone melting technique has been applied to the purification of metals and compounds. Modifications of the method have been employed to obtain a mixture of uniform composition. On the same basis, this method is applicable to concentration of trace impurities.

We have been successful in applying a zone melting technique to systems containing metal chelates. Characteristics of the technique were discussed in a previous paper.[1]

Our preliminary investigation[2] on the system of a free ligand containing trace amounts of its metal chelates, showed that trace metal ions could be concentrated at one end of the column. Thus, a zone melting process could be useful for the concentration of trace metal ions which were extracted in the form of metal chelates together with a large excess of the free ligand.

In these systems, the ligand must melt at a lower temperature than the chelates and solidify easily at its melting point (under forced cooling, if necessary). The metal chelates need not be stable at higher temperatures because the samples are processed near the melting point of the ligand, which is generally much lower than the decomposition temperatures of the chelates. The melting point of the free ligand should be low enough for the metal chelate to dissolve without thermal decomposition, but not so low that forced cooling is necessary as this may cause peritectism, and less effective separation.

* Part III—*Mikrochem. J.*, 1966, **10**, 244. Contribution No. 122 from the Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka, Japan.

† Present address: Mitsui Petrochemical Industries, Ltd., Iwakuni-Otake Works, Research and Development Department, Iwakuni-shi, Japan.

‡ Present address: Esso Standard Sekiyu K.K. TBS Bldg., Akasaka, Minato-ku, Tokyo, Japan.

The present paper is concerned with a detailed investigation on the binary systems of 8-hydroxyquinoline (oxine) with its nickel(II), cobalt(II), zinc(II), copper(II) and iron(III) chelates. In order to discuss the effectiveness of concentrating a minor component, we have introduced a quantitative measure "concentration ratio". This value is the fraction of the minor component concentrated in the bottom 15% of the total column length.

In most analytical procedures, a large excess of chelating agent need not be used for the extraction of metal ions in an aqueous solution. However, when the extraction has to be carried out under very mild conditions without destroying the matrix material, then the samples may have to be extracted repeatedly with a large excess of chelating agent. Zone melting concentration procedures may then be useful for isolating the metal chelates.

EXPERIMENTAL

Materials

The 8-hydroxyquinoline (analytical grade) was purified by distillation, and the metal chelates, which were prepared by standard procedures, were purified by washing with hot water. Analyses of these materials were satisfactory.

Found: Zn, 18·44; $Zn(C_9H_6NO)_2$ requires Zn, 18·49%.
Found: Cu, 18·11; $Cu(C_9H_6NO)_2$ requires Cu, 18·06%.
Found: Ni, 16·85; $Ni(C_9H_6NO)_2$ requires Ni, 16·92%.
Found: Co, 16·90; $Co(C_9H_6NO)_2$ requires Co, 16·97%.

Apparatus and procedures

The apparatus consisted of devices pulling upwards 8 glass tubes simultaneously at a speed of 28 mm/hr, with a two-stage nichrome heater for each glass tube; the tubes were 4 mm bore and each contained 2·50 g of sample.

Determination of metal ions. After the requisite number of passages, the sample column was cut into pieces 20–25 mm long. The sample from each piece was weighed and then dissolved in chloroform, and the amount of metal chelate was determined spectrophotometrically against a reagent blank. The absorption maxima of $Cu(Ox)_2$, $Zn(Ox)_2$, $Ni(Ox)_2$ and $Co(Ox)_2$ in chloroform were 410, 380, 380 and 420 mμ respectively. Amounts of copper lower than the photometric determination range were determined by atomic absorption spectrophotometry with a Jarrel-Ash Model AA-1 instrument.

Preparation of test sample and model extraction of copper ion. The 8-hydroxyquinoline solution was prepared by dissolving 2·7 g of 8-hydroxyquinoline in 7 ml of glacial acetic acid, then diluting with demineralized water to 100 ml. A 5-ml aliquot of copper acetate solution containing 2·397 μg of copper/ml, was treated with 5 ml of the 8-hydroxyquinoline solution at pH 3–4 (ammonium acetate buffer). The precipitate was extracted with chloroform. The aqueous layer was again treated with the rest of the 8-hydroxyquinoline solution at pH 7 (ammonia buffer). The precipitate was extracted with another lot of chloroform. The chloroform solutions were combined, dried over sodium sulphate, and evaporated to dryness. The residual solid was subjected to the zone melting process. After the 30th zone passage, a test piece 30 mm long, cut out of the column at the bottom, was dissolved in isobutyl methyl ketone and the amount of copper ion was determined by atomic absorption spectrophotometry at 3247 Å.

RESULTS AND DISCUSSION

The distributions of the metal ions after the zone melting process are shown in Figs. 1–4. The metal concentration is plotted against the distance in zone lengths, x/l, where x is the distance from the top to the point at which the sample was cut out for the determination, and l is the length of the molten zone. The chelate in every system was concentrated at the bottom. The concentrating effect decreased in the order Cu, Zn, Fe, Co and Ni. For the copper(II) system, an average of 30·7 μg of the 31·8 μg of copper taken was found to be concentrated in the bottom 15% of the column. The concentration ratio of 97% had a relative standard deviation of 2% (8 runs) and was in a good agreement with the calculated value (Table I).

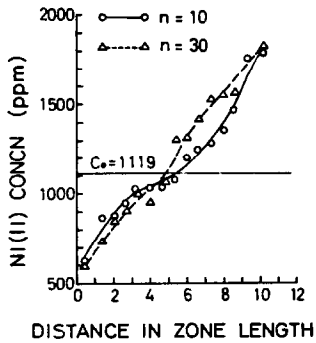

FIG. 1.—Distribution of metal ion concentration after zone melting the system bis(8-hydroxyquinolino)nickel(II) and 8-hydroxyquinoline.
C_0—initial concentration of the metal ion;
n—number of passages of molten zone.

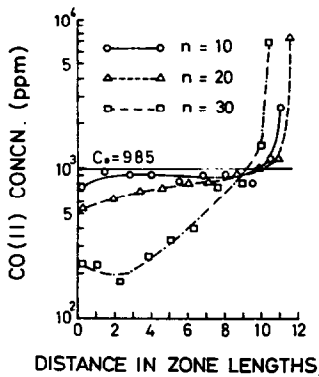

FIG. 2.—Distribution of metal ion concentration after zone melting the system bis(8-hydroxyquinolino)cobalt(II) and 8-hydroxyquinoline.

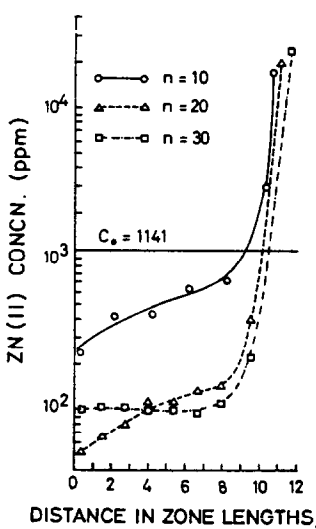

FIG. 3.—Distribution of metal ion concentration after zone melting the system bis(8-hydroxyquinolino)zinc(II) and 8-hydroxyquinoline.

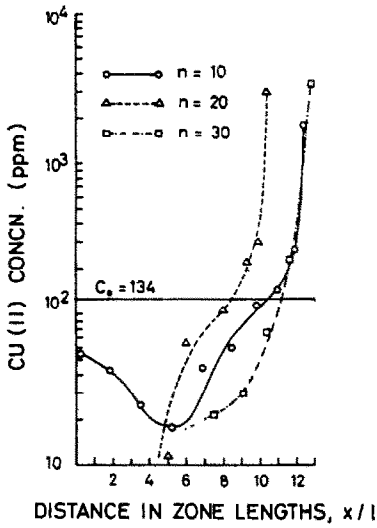

FIG. 4.—Distribution of metal ion concentration after zone melting the system of bis(8-hydroxyquinolino)copper(II) and 8-hydroxyquinoline.

TABLE I.—COMPARISONS OF THE CONCENTRATION RATIO AFTER THE 30TH ZONE PASSAGE

l/L	Concentration ratio, %		
	Calc.		Found
	$k = 0{\cdot}40$	$k = 0{\cdot}50$	$k = 0{\cdot}45$*
0·07	97·3	93·0	
0·08	96·3	91·5	96·6†
0·09	94·7	89·7	

k—distribution coefficient.
l—length of the molten zone.
L—total length of the column.

* Estimated by Sorensen's method.[8]
† The l/L value in the experimental work was nearly 0·08.

TABLE II.—EFFECT OF SPEED OF ZONE TRAVEL ON THE CONCENTRATION RATIO

Speed of zone travel, *mm/hr*	No. of zone passes	Concn. ratio
5·4	10	76·6%
15	10	88·5
15	20	89·5
28	30	96·6
40	30	60·2

The speed of zone travel affected the concentration ratio. The experimental results are summarized in Table II.

For efficiency of concentration of trace metal ions, the highest concentration ratio in the shortest time is desirable, and a zone travelling speed of 28 mm/hr was optimum for the conditions investigated.

The results of the model experiments on the extraction of copper with 8-hydroxyquinoline and the subsequent concentration of the extract by zone melting are summarized in Table III.

TABLE III.—COMPARISONS OF CONCENTRATION RATIOS OF COPPER ION AFTER ZONE MELTING

No. of zone passes	No. of runs	Average amount of Cu(II) in the bottom 15 % region, μg	Concn. ratios, %
30	3	11·0	91
40	3	11·5	96

Zone length about 15 mm; initial amount of Cu(II) in the sample solution, 12·0 μg.

After the zone melting process, the lower two thirds of the column was still yellow. The concentration ratio, however, was not affected, being satisfactorily high and in good agreement with the results described in Table I in spite of the different experimental conditions.

Acknowledgement—The authors wish to thank the Ministry of Education, Japanese Government, for financial support of this work.

Zusammenfassung—Das Zonenschmelzverfahren wurde auf 8-Hydroxychinolin angewandt, das Spuren verschiedener Metall-8-hydroxychinolate, wie z.B. die Chelate von Nickel(II), Kobalt(II), Zink(II) und Kupfer(II), enthielt. Das Metallchelat wurde in jedem System in Richtung der Zonenwanderung angereichert. Der höchste Anreicherungseffekt wurde beim Kupfer(II)-chelatsystem gefunden. Das Konzentrationsverhältnis, definiert als der Bruchteil an Metallchelat, der in den unteren 15% der Säule angereichert wird, wurde nach dem 30. Durchgang bestimmt. Eine mit einem großen Uberschuß an 8-Hydroxychinolin extrahierte Spurenmenge Kupfer wurde mit dem Zonenschmelzverfahren angereichert. Das Konzentrationsverhältnis war 96%.

Résumé—La technique de fusion de zone a été appliquée à la 8-hydroxyquinoléine contenant des traces de 8-hydroxyquinoléinates de divers métaux tels que les chélates de nickel(II), cobalt(II), aine(II) et cuivre(II). Dans chaque système, le chélate métallique a été concentré dans la direction du déplacement de la zone. L'effet de concentration le plus élevé a été observé dans le système chélate cuivre(II). Le rapport de concentration, défini par la fraction de chélate métallique concentrée dans les 15% inférieurs de la colonne, a été déterminé après le 30e passage. Une trace d'ion cuivre extraite avec un grand excès de 8-hydroxyquinoléine a été concentrée par la technique de fusion de zone. Le rapport de concentration a été de 96%.

APPLICATION OF UREASE FOR THE PRECIPITATION OF NICKEL DIMETHYLGLYOXIMATE BY UREA FROM HOMOGENEOUS SOLUTION

SEIICHIRO HIKIME, HITOSHI YOSHIDA and MITSUHIKO TAGA
Department of Chemistry, Faculty of Science,
Hokkaido University, Sapporo, Japan

(*Received* 31 *March* 1967. *Accepted* 30 *June* 1967)

Summary—Urease can be used to decompose urea for the precipitation of nickel dimethylglyoximate from homogeneous solution. Optimum experimental conditions, and a procedure giving good separations from other ions, are described.

PRECIPITATION of nickel dimethylglyoximate from homogeneous solution was developed by Bickerdike and Willard[1] in 1952, and further, by Salesin, Abrahamson and Gordon[2] in 1962. The former utilized the pH change produced by hydrolysis of urea, and the latter the formation of dimethylglyoxime by the reaction of hydroxylamine and biacetyl.

Precipitation from homogeneous solution (PFHS) has been used widely since then as an effective means for improving the separation of ions. There are, however, still some difficulties associated with the method; for example, urea is decomposed so rapidly when heated that the pH of the solution is raised too fast and an incomplete separation of the ions results. This paper concerns a proposal[3] to use urease to decompose urea, and thus to control the pH of the solution. Experimental conditions are examined in order to achieve optimum conditions for smooth and steady precipitation from homogeneous solution.

EXPERIMENTAL

Reagents

Stock nickel solution. A 0·05*M* nickel solution was prepared by dissolving 10·00 g of nickel in 6*M* hydrochloric acid. A standard solution containing 2·5 mg of nickel per ml was prepared by further dilution.

Dimethylglyoxime, 1% ethanolic solution.

Urease, 0·01% aqueous solution prepared just before use.

Citric acid, 20% aqueous solution.

All chemicals used, except the nickel, were analytical-reagent grade.

Procedure

Transfer a known volume of nickel solution to a wide-necked 250-ml bottle, add 5 ml of citric acid solution and 50 ml of urea solution, and dilute to about 200 ml. Adjust the pH to 4·4 with ammonia solution, add 15 ml of dimethylglyoxime solution and 20 ml of urease solution, dilute to about 250 ml, stopper, and keep at 35°. Collect the nickel dimethylglyoximate by filtration on a porosity-4 sintered glass crucible, dry at 120°, cool and weigh.

RESULTS AND DISCUSSION

It was hoped that the use of urease to bring about the change in pH of the solution would enable good separations of nickel from other ions to be obtained by PFHS without heating. However, as the activity of enzymes is inhibited by the presence

of metal ions, the optimum conditions had to be established for the decomposition of urea to be carried out smoothly in the presence of nickel ions.

Urease activity

Nickel (25 mg) was found to have no measurable effect on the activity of urease for the hydrolysis of urea.

Effect of citric acid concentration

The addition of citric acid as a buffering and complexing agent is recommended for the precipitation of nickel from homogeneous solution. However, if a large amount is added, the buffering effect is too strong and the pH change is not sufficient to allow precipitation to take place. On the other hand, when insufficient is added, the pH change of the solution is not controlled smoothly, and nickel dimethylglyoximate precipitates too rapidly.

As seen in Table I, from 3 to 7 ml of a 20% citric acid solution are sufficient for satisfactory recovery of the nickel.

TABLE I.—EFFECT OF CITRIC ACID CONCENTRATION

20% citric acid added, *ml*	Nickel		Difference, *mg*

* Precipitate appears rapidly.
Urea: 10 g, initial pH 4·4, dimethylglyoxime 15 ml, urease 20 ml, temperature 35°C, time 13–15 hr.

Effect of initial pH

The activity of urease is greatest at 35–40°, and decreases rapidly with increasing acidity of the solution. As the precipitation of nickel dimethylglyoximate is influenced by the presence of other ions, the exact pH of initial precipitation cannot be exactly stated, but precipitation usually begins at about pH 5·3 and is complete by about pH 7·1. Hence initial conditions are required under which nickel ions will remain in solution, and yet the urease will retain its activity and cause precipitation to take place.

Figure 1 shows the results of an experiment from which it can be seen that the activity of urease is inhibited in a solution with an initial pH of 4·1, the pH remaining almost unchanged for 15 hr, whereas in a solution starting at pH 4·5, slow decomposition of the urea by urease is indicated by the gradual increase in pH.

When urease is added to a nickel solution with an initial pH of 4·4–5·0, containing dimethylglyoxime and urea, dense crystalline nickel dimethylglyoximate precipitates quantitatively (see Table II). When the initial pH is greater than 5·0, precipitation

* Ni-DMG precipitates rapidly.

† Precipitate grows before addition of urease and the precipitate is similar to that by the conventional method.

is rapid, and the product has an appearance similar to that of precipitates obtained by the usual methods.

Dependence on the concentration of urea and urease

As shown in Table III, satisfactory results are obtained when 10 g of urea are added to 250 ml of solution containing 20 ml of urease solution.

When 5 g of urea are added per 250 ml of the solution, the increase of pH of the solution is not sufficient for the quantitative precipitation of nickel dimethylglyoximate. When 40 g of urea are added not only are the results unsatisfactory, but the precipitate is flocculent, like those obtained by the usual procedures. It is not known whether this is due to the urea raising the pH by acting as a weak base, or to a decrease in the urease activity when the urea concentration is high; the results in Table II indicate that the former is the more likely explanation.

A certain amount of urease is necessary to give satisfactory decomposition of urea (Fig. 2 and Table IV). For 10 g of urea, at least 20 ml of 0·01 % urease solution should be added.

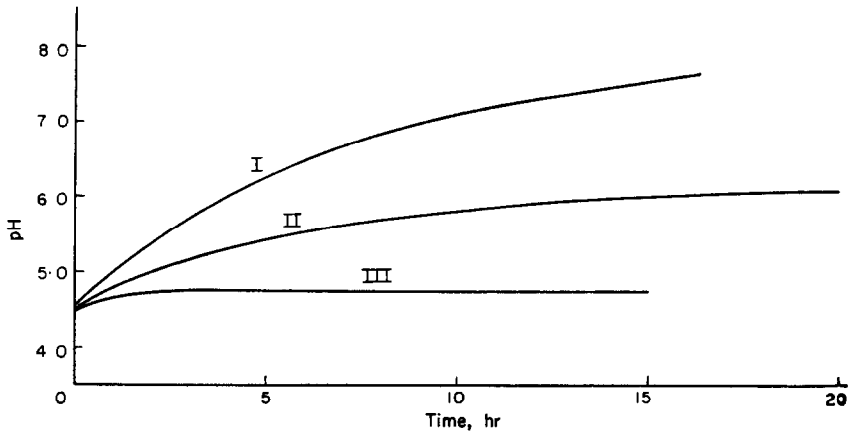

FIG. 2.—Effect of amount of urease on hydrolysis of 10 g of urea.

10	25·00	24·49	−0·51
20	25·00	24·99	−0·01

Effect of temperature

The optimum temperature for the hydrolysis of urea by urease is 35–40°. This was confirmed by following the change of pH at different temperatures, Fig. 3. When the precipitation is carried out from solution at 35–40°, the recovery of nickel ion as dimethylglyoximate is complete, as shown in Table V.

Effect of the concentration of dimethylglyoxime

From 13 to 20 ml of 1 % dimethylglyoxime solution is sufficient for the quantitative precipitation of 25 mg of nickel as nickel dimethylglyoximate (Table VI).

Determination of nickel

Table VII shows that satisfactory results are obtained for the precipitation of 5–25 mg of nickel by the procedure developed.

* Nickel taken, 12·56 mg.

Effect of other ions

The effect of the presence of a number of other ions on the determination of 12·56 mg of nickel by the proposed procedure was examined. The results are summarized in Table VIII. Cobalt (5 mg), mercury (10 mg), platinum (10 mg) and tellurium (5 mg) inhibit the hydrolysis of urea and the precipitation of nickel dimethylglyoximate becomes incomplete. Arsenic, cadmium, iron, and lead do not affect the urease. Chloride, nitrate and sulphate do not interfere, but the pH of the solution does not increase in the presence of a large amount of acetate owing to its buffering action.

Acknowledgement—The authors wish to acknowledge the partial assistance of the Ministry of Education, Japan, in supporting the investigation described herein.

Zusammenfassung—Zur Harnstoffzersetzung bei der Fällung von Dimethylglyoximnickel aus homogener Lösung kann Urease verwendet werden. Die optimalen Versuchsbedingungen und eine Vorschrift, die gute Trennungen von anderen Ionen liefert, werden angegeben.

Résumé—On peut utiliser l'uréase pour décomposer l'urée dans la précipitation du diméthyglyoximate de nickel à partir d'une solution homogène. On décrit les conditions expérimentales optimales et une technique donnant de bonnes séparations à partir d'autres ions.

ELEMENTAL ANALYSIS OF ORGANO-METALLIC COMPOUNDS

THE SIMULTANEOUS DETERMINATION OF CARBON, HYDROGEN AND OTHER ELEMENTS IN ONE WEIGHED SAMPLE

N. E. GEL'MAN
Institute of Elemental Organic Compounds, Academy of Sciences, Moscow, U.S.S.R.

(*Received* 2 *September* 1966. *Accepted* 20 *November* 1966)

Summary—A method is described for simultaneous gravimetric microdetermination of carbon, hydrogen and one or more hetero-elements in one weighed sample of organic substances. The method is based on pyrolytic combustion of the sample in a quartz container placed in an empty combustion tube. The carbon and hydrogen determination is completed as usual. Hetero-elements, in the form of volatile compounds, are retained in special previously weighed tubes inside the combustion tube. Hetero-elements forming non-volatile residues can be determined by the change in weight of the quartz sample-container. Volatile elements or compounds are determined by weighing the quartz insert tube. More than 40 elements in various combinations can be determined simultaneously with carbon and hydrogen.

THE number of elements which may be introduced into organic compounds has rapidly increased, and it is no exaggeration to say that almost all elements found in nature give a form of interaction (bonding) with organic compounds. This situation arises on the one hand from the extensive development of organo-metallic chemistry and on the other from the widespread use of organic reagents in inorganic chemistry, and has led to the need to determine quantitatively a wide variety of elements in organic compounds. In doing so it has given prominence to the methods of simultaneous determination of several elements in one weighed sample.

This paper deals with the most important type of simultaneous determination, the gravimetric determination of carbon, hydrogen, and some other elements in one weighed sample. The carbon and hydrogen determination itself is a classical example of the simultaneous determination of two elements, and early on, many attempts were made to determine a third element simultaneously as well.[1–4] In elemental microanalysis this has been achieved by M. O. Korshun and her coworkers[5–18] during the past two decades and later by others.[17,19–22] The purpose of this paper is to report on the general principles of this type of elemental analysis in its present state, to report the results achieved in our laboratory, and to describe briefly the main modes of operation.

So-called "pyrolytic combustion"[6,17,23,24] and gravimetric determination of the combustion products represents a general method of analysis accepted by us for simultaneous determination of carbon, hydrogen, and other elements (called hereafter "hetero-elements"). The reliability and universality of this combustion method in the determination of carbon and hydrogen have been confirmed by its application during many years. Its specific features, that no catalysts or oxidative packings are used in the combustion tube and that the substance is burned in a quartz container (Fig. 1)

past which flows a rapid stream of oxygen, offer great possibilities for simultaneous determinations. The main condition for simultaneous determinations, that the combustion is carried out in a container, seems to an uninformed analyst to be difficult, but in fact is an easy operation, which can be accomplished with simple manipulation for almost any organic compounds other than gaseous and highly explosive substances. It should be emphasized that pyrolytic combustion is the only method which provides

simultaneous determination of several elements in a number of compounds that are difficult to analyse, such as substances that spray particles when they burn (ferrocene, carborane, *etc.*), volatile compounds (metal carbonyls, *etc.*) and materials inflammable in air. As a rule in simultaneous determination the combustion cannot be carried out as rapidly (3–5 min) as in simple carbon and hydrogen determinations.[25] Nevertheless, the possibility of determining from three to five elements by one combustion makes the slower procedure worthwhile.

Depending on the elemental composition of the substance, the combustion in oxygen can lead to formation of oxides, salts, solid solutions, molecular compounds, or elements in the free state, the products being both volatile and non-volatile compounds. The non-volatile, non-burning residue is most frequently an oxide, sometimes a sulphate, phosphate, borate or silicate, and more seldom an element in the free state. Volatile compounds liberated include halogens, mercury, and certain oxides (of sulphur, arsenic, rhenium, *etc.*).

The products of decomposition (oxidation) of organic compounds can be quantitatively separated and collected within the combustion tube* in several particular

* The absorption outside the combustion tube of volatile products containing hetero-elements has some disadvantages and is not used.

"zones to be weighed" (Fig. 1). These zones are a quartz container for combustion of samples, and quartz tubes, called insert tubes. The container is used for determining a non-burning non-volatile residue, and the insert tubes (over-lapping as shown in Fig. 1) contain suitable reagents (*e.g.*, metallic silver) for absorption of volatile combustion products, or are used to condense sublimates or to retain particles mechanically removed by the gas stream, and so on. Depending on its purpose the zone can be empty or filled, cooled or heated. As we have established earlier,[12] the presence of cooled zones in the combustion tubes does not interfere with the determination of carbon and hydrogen. The use of several "zones to be weighed" makes it possible to increase the number of hetero-elements to be determined simultaneously with carbon and hydrogen in one weighed sample, and in some cases (for antimony, manganese, *etc.*) to increase the accuracy of determination.

EXPERIMENTAL

Apparatus and reagents

The apparatus consists of an oxygen source, absorption tubes containing ascarite and anhydrone for preliminary drying and purification of oxygen, a combustion tube, quartz insert tubes and containers, Pregl absorption tubes for water, nitrogen oxides and carbon dioxide, filled with anhydrone, silica gel impregnated with saturated potassium dichromate solution in concentrated sulphuric acid, and ascarite and anhydrone respectively, and an aspirator. The quartz combustion tube has an enlarged section, into which the insert tube or tubes and the quartz sample-container are placed (Fig. 1).

The filling and temperature of the insert tube for various purposes are given in Table I. The insert tube and its filling will last for several determinations. For example, 30–50 halogen or sulphur determinations can be done with 1–1·5 g of silver gauze (0·1-mm wire) as absorbent. Separate tubes

TABLE I.—CONDITIONS FOR DETERMINATION OF HETERO-ELEMENTS FROM THE CHANGE IN WEIGHT OF THE INSERT TUBE

Elements to be determined	The insert tube	
	Temperature, °C	Filling
Chlorine, bromine, iodine	575°	silver gauze or foil
Chlorine, bromine, iodine	425°	silver-plated pumice
Sulphur	750°	silver gauze or foil
Rhenium	450°	silver gauze or foil
Arsenic, molybdenum, antimony or manganese traces	room temp.	none (or quartz wool)
Mercury	0° (cool in ice)	gold (or silver) gauze or foil

should be used for halogens and sulphur. If silvered pumice is used, one filling will do for 80–100 analyses, and the corrosion of the walls of the insert tube will be negligible, so the tube can be refilled and used again. An empty insert tube or one containing a filling that is not heated, *e.g.*, quartz wool or gold, will last for a long time (at least a year) and so will the filling. Containers of various lengths (60–90 mm) are used for the sample. They can be used repeatedly. A container can be used for as many as 12–15 residue determinations, being cleaned after each (cleaning with cotton wool, followed by ignition, or treatment with acid and washing with water usually suffices). Weight constancy of the container serves as a criterion for its continued use, but old containers can be used if a residue determination is not necessary. For heating the oxidation and absorption zones and for combustion of the sample, split-type furnaces, 60 mm long, are used.

The sample

Solids are weighed in the quartz sample-containers, which can be hung horizontally on the hooks of the balance pan. If the substance decomposes violently it is necessary to distribute it on a layer of crushed quartz; the sample can be spread over the quartz by tapping it after weighing it. In phosphorus determinations and analyses of substances which spray particles on combustion, it is advisable to cover the sample with another portion of the quartz and to weigh the container and contents again.

Samples of liquids are taken in a glass capillary, or better in a quartz capillary, which is usually weighed together with the container. The capillary with sample is placed, open end down, in the container. Sticky substances are introduced into the container by means of a thin quartz stick, which is weighed together with the container. If necessary, crushed quartz is added to liquid or sticky samples.

Combustion

At the beginning of the day's work a few mg (unweighed) of any standard substance should be burned to condition the apparatus. Then the first sample is burned off after the absorption tubes and insert tube have been weighed. The sample-container is placed 30 mm inside the insert tube and put together with it into the combustion tube. Oxygen is passed through the tube for 1–2 min and then the tube is connected to the Pregl tubes and the aspirator. The narrow part of the insert tube is heated (or cooled) to the proper temperature (see Table I), the movable furnace is set so that the open end of the container is 10–15 mm inside it, and is then moved over the container at a rate dictated by the behaviour of the sample. The burning of the substances is accompanied either by the appearance of red-hot carbon particles moving towards the container outlet, or by tongues of flame, or by carbonization of the substance without visible indications of burning. The combustion tempo can be controlled by moving the heater backwards and forwards. The open end of the container must be in the heated zone all the time and the combustion must proceed within the container. In the determination of hetero-elements which form readily condensed sublimates (As_2O_3, MoO_3, Re_2O_7) the combustion is carried out in an empty container, 60 mm long, which must be completely heated with the movable furnace, thus providing rapid and complete transport of the volatile oxide into the insert tube. For this purpose it is better to heat the container, after combustion, with two split-type funances, each 60 mm long. If after combustion a carbonaceous residue remains in the container, it is cooled for 1–2 min and then heated again until the carbon is all burned off. The combustion time usually varies from 15 to 30 min. If a rapid oxygen stream is used, it is not necessary to sweep out the products after combustion is complete. After combustion the absorption tubes are removed first, and the container and insert tube are allowed to cool in the combustion tube and then are taken out, "flamed" to remove any electrostatic charge, conditioned on a metal block, and weighed. A fresh portion of crushed quartz is used for each combustion. Insert tubes are given fresh filling or the old one is freed from sublimates as far as possible. Blank tests should not give weight changes of more than 10 and 20 μg for container and insert tube respectively. When certain elements (*e.g.*, antimony and manganese) are determined, the completeness of retention of the oxides in the container should be checked by weighing the empty insert tube. If the insert tube gains weight, this may be due to carry over of finely dispersed particles or by volatilization of the residue in the container at high temperatures. If the element is determined as a sublimate precipitated on the cold walls of the insert tube (*e.g.*, As_2O_3 or MoO_3), it is best to put a loose piece of quartz wool or other non-hygroscopic fibrous material in the insert tube outlet.

DISCUSSION AND RESULTS

The question of the weighing form for the various hetero-elements in some cases needs thorough study. In critical comparisons of the thermal, chemical and other properties of the proposed weighing forms with data obtained in gravimetric analysis, there are observed some discrepancies which can be explained by the variation in experimental conditions. Thus, almost all the gravimetric data[26] have been obtained by heating the substances in air. Under these conditions a reducing atmosphere can arise during ignition of the substances. The combustion in elemental analysis proceeds in an oxygen atmosphere, which may lead to predominant formation of the higher oxides if the element has a variable valency. At the temperatures of 950–1000° frequently used in the combustion of organo-metallic compounds, the possible formation of solid solutions, molecular compounds and silicates should also be taken into account, as the combustion takes place on the surface of quartz particles. For instance, in the determination of manganese, according to thermogravimetric data only Mn_3O_4 is expected to be formed above 950°, but X-ray analysis of the residue formed after combustion of organo-manganese compounds on quartz chips reveals the presence of either Mn_2O_3 or $Mn_7O_{10}.SiO_2$.[27] From the results of more than 50 analyses we are satisfied that the formula $Mn_7O_{10}.SiO_2$ gave the best agreement with the

analytical results for all three elements—carbon, hydrogen and manganese. The formation of compounds of silicate type is also observed with thallium, which gives a yellowish non-hygroscopic residue, whereas the oxide of thallium(I) must be gray or black. Sometimes the temperature used can be of decisive importance in a successful analysis. For example, to isolate palladium as metal it is necessary to carry out the combustion at 1050°, because at lower temperatures (900–950°) palladium is present partly as oxide.

The hygroscopicity of oxides under the conditions used for weighing them in elemental analysis should be studied in view of possible errors. Most of these errors are negligible, as they lie within the error limits permissible for the elemental analysis. In some cases, for instance in determination of aluminium or boron, errors due to the hygroscopicity of the oxides were studied in detail and eliminated during development of the analysis conditions.[15,18]

Over a period of about 10 years our laboratory has carried out thousands of simultaneous determinations of carbon, hydrogen and other elements. This type of analysis is a reliable well-developed method for the elements B, Al, Si, P, S, Cl, Ti, Cr, Mn, Fe, Ge, Br, Zr, Pd, Sn, Sb, I, W, Pt, Hg, Tl and Pb. Elements such as Be, Mg, As, Se, Co, Ni, Cu, Nb, Mo, Zn, Au, Ag, Cd, Hf, Ta and Bi are seldom met with, but there is no doubt as to the possibility of their determination by this method.

Analysis of substances containing halogen combined with either the organic part of the molecule or the hetero-element, gives another interesting possibility of simultaneous determination. In this case the combustion in the container has a remarkable advantage over that in a direct oxygen stream. Because of the high combustion temperature in the container (900–1000°), many halides, even volatile ones (iron(III), palladium, *etc.*) either decompose quantitatively within the heated container during combustion of the sample, or simply do not form, especially if the halogen is combined with the organic part of the molecule. Therefore, it is now possible to determine halogen and hetero-elements simultaneously with carbon and hydrogen for a large number of organo-metallic compounds. Simultaneous determination of carbon, hydrogen, halogen and another hetero-element in organic compounds of B, P, Ti, Si, Fe, Zr, Pt, Hg and Pd may be considered to be a standard method. There have been few simultaneous determinations applied to compounds of Pb, Ge, Cr, Cu, Co, Mo, W, *etc.*, and the field of application is therefore not yet well defined. Carbon, hydrogen, sulphur, and a hetero-element are determined in a similar manner, but there are somewhat fewer possibilities, as sulphates are usually more refractory than halides. There are, however, other specific possibilities of simultaneous determination. For example, in salts of organic sulphonic acids with alkali or alkaline earth metals, half of the sulphur is determined in the insert tube as silver sulphate and the other half in the container as metal sulphate. The amount of metal in the sample is calculated from the weight of the metal sulphate. With three "zones to be weighed", *i.e.*, the container and two insert tubes, it is possible to determine four or even five elements from one weighed sample. For example, in organo-mercury compounds it may be possible to determine carbon, hydrogen, halogen or sulphur, mercury, and one other element (B, P, Fe, *etc.*) as non-burning residue.

The weighing forms for hetero-elements are given in Table II. From Tables III and IV can be seen which element combinations are possible for simultaneous determinations, though these examples are far from exhausting the possibilities.

TABLE II.—HETERO-ELEMENTS AND THEIR WEIGHING FORMS

Element	Weighing form in the container	Weighing form in the insert tube
Pd, Ag, Pt, Au	Pd, Ag, Pt, Au	
Hg		Hg (gold amalgam)
Tl	Tl_2O SiO_2	
Be, Mg, Zn, Cd, Pb, Ni	BeO, MgO, ZnO, CdO, PbO, NiO

ERRORS IN SIMULTANEOUS DETERMINATIONS

In the gravimetric determination of those elements that have a weighing form with a favourable conversion factor, the absolute error does not exceed the ±0·3% accepted in microanalysis. If the factor is near to unity (determination of rhenium, tungsten, bismuth and other heavy elements) or equal to it (determination of elements in the free state, *e.g.*, mercury and palladium), the permissible errors may be as great as 0·7–1%, but such large deviations are seldom found in practice.

To obtain correct results for carbon and hydrogen, empirical corrections are made to the weights of carbon dioxide and water. They may be calculated from the results obtained for combustion of standard substances under similar conditions. These corrections are necessary because of (*a*) the large volume of oxygen (500–1000 ml) used, (*b*) the use of open Pregl tubes, and (*c*) temperature differences between laboratory and balance room. The corrections are well reproducible and do not usually exceed 70 μg for carbon dioxide and 150 μg for water. Corrections for hetero-elements are not made, except for silicon compounds, where they are necessitated by the particular properties of the residue.

It is evident that the simultaneous determinations of element gives wide and accurate information about the elemental composition of a substance without much expenditure of work and time by the analyst, and, which is particularly valuable, requires only a few mg of substance. Simultaneous determinations are especially useful in analysis of compounds containing several hetero-elements, which occur more and more frequently in organo-metallic chemistry.

Zusammenfassung—Eine Methode zur gleichzeitigen gravimetrischen Mikrobestimmung von Kohlenstoff, Wasserstoff und einem oder mehreren Heteroelementen in einer Einwaage von organischen Substanzen wird beschrieben. Die Methode beruht auf pyrolytischem Aufschluß der Probe in einem Quarzbehälter, der in einem leeren Verbrennungsrohr untergebracht wird. Heteroelemente werden als flüchtige oder nichtflüchtige Verbindungen in besonderen, vorher gewogenen Röhrchen im Verbrennungsrohr gesammelt. Die Kohlenstoff- und Wasserstoffbestimmung wird wie üblich erledigt. Nichtflüchtige Rückstände bildende Heteroelemente können durch die Gewichtsänderung des Quarz-Cehälter bestimmt werden. Mehr als 40 Elemente können in verschiedenen Kombinationen zusammen mit Kohlenstoff und Wasserstoff bestimmt werden.

Résumé—On décrit une méthode de microdétermination gravimétrique simultanée du carbone, de l'hydrogène et d'un ou plusieurs hétéro-éléments dans une pesée d'échantillon de substance organique. La méthode est basée sur la combustion pyrolytique de l'échantillon dans un récipient en quartz placé dans un tube à combustion vide. Les hétéro-éléments, sous forme de composés volatils ou non, sont retenus à l'intérieur du tube à combustion par des tubes spéciaux préalablement pesés. Le dosage du carbone et de l'hydrogène est achevé comme d'habitude. On peut doser les hétéro-éléments formant des résidus non volatils par la variation de poids du récipient en quartz contenant l'échantillon. On peut doser plus de 40 éléments dans des combinaisons diverses simultanément avec le carbone et l'hydrogène.

APPLICATION OF THERMOELECTRIC POTENTIAL MEASUREMENTS IN CHEMICAL ANALYSIS—II*

DETERMINATION OF ALUMINIUM IN IRON ALLOYS

(*Received* 13 *February* 1967. *Accepted* 7 *June* 1967)

Summary—A method is proposed for the rapid determination of aluminium in iron alloys by means of thermoelectric potential measurement. An instrument has been modified, and a method devised for thermoelectro-analytical measurements. The thermoelectric potential of iron–germanium and iron–zinc alloys has been measured, and an attempt made at a theoretical explanation of the influence of alloying elements on the thermoelectric properties of transition metals.

THERMOELECTRIC POTENTIAL (TEP) measurements may be used in analysis for sorting materials differing in chemical composition, without determining any one of the components,[1–9] for determining alterations in the metallographic composition,[10–15] or determining one of the components of the sample.

The quantitative determination of a sample component by TEP measurement has up to now been limited to the determination of silicon or carbon in iron alloys.[16–20]

Since, after several years of practical use, the thermoelectric method has been found to be very advantageous because of its speed, precision and reliability, it has been further studied to find other applications and to establish the theoretical fundamentals for the elucidation of the influence of alloying elements on the thermoelectric properties of the alloy.

EXPERIMENTAL

Apparatus

The assembly used has been described earlier.[16] Only the arrangement of the hot electrode (Fig. 1), the manner of measuring its temperature and the measuring assembly proper have been modified. The hot electrode is located in a metal mantle which is movable vertically on a support (Fig. 2). The tempered cold electrode is located in the base of this support. The temperature of the silver point of the hot electrode is measured by a silver–constantan thermocouple with its hot junction pressed into the silver electrode point. The sensitivity of temperature measurement has been enhanced by using a galvanometer with compensation wiring (Fig. 3).

The resistance R_2 is placed in series with the temperature-measuring galvanometer: a d.c. voltage, opposed to the TEP of the silver–constantan thermocouple, is applied to this resistance (position 1—*measurement*—on switch K_2). The galvanometer G_2 then measures the difference of the two voltages. In this way the full sensitivity of the galvanometer can be utilized. To check the compensation voltage during measurement the two-pole switch K_2K_3 is used. In the instrument designed, *e.g.*, for industrial routine checking of the silicon or aluminium content of steel, compensation wiring is also used in the TEP-measuring circuit. The compensation voltage is then selected so that zero on the galvanometer corresponds to the minimum content of the element being determined, and the temperature difference

* Part I—*Talanta*, 1964, **11**, 1127.

between the electrodes is chosen, for a given galvanometer sensitivity, so the the maximum content of the element determined gives full-scale deflection on the galvanometer. In this way the sensitivity of the determination can be increased.

Alloys

Iron–aluminium alloy. Samples (300 g) were melted down in a vacuum arc furnace (Heraeus L 200 H) in an argon atmosphere, with a tungsten electrode. To achieve good homogeneity of the casting, the sample was turned and remelted several times.

Iron–germanium alloy. Samples were prepared in the same way as iron–aluminium samples, but the argon used was repurified by passage over red-hot calcium.

Zinc–iron alloy. Samples were melted down in an electric induction furnace (type ACES) in a normal atmosphere and cast immediately from the furnace at 1550° into a metal mould.

The raw materials used for the alloys mentioned were Arema-type iron (Czechoslovak Standard ČSN 12013: Mn 0·27–0·33%, C 0·02–0·07%, P max. 0·03%, Si max. 0·01%, Cr, Ni max. 0·01%), aluminium of technical purity, electrolytic zinc and germanium (99·9% purity). After grinding with a disc-type grinding machine, the side of the samples which was to come into contact with the hot electrode was fine-ground with abrasive paper.

Procedure

Set on the contact thermometer a temperature about 2° higher (for iron alloys) than the temperature at which it is wished to read the TEP value of the sample to be tested. Temper the sample to 20° on the electrode E_1 and then apply electrode E_2. The TEP value on galvanometer G_1 must always be read at the same deflection of galvanometer G_2 used to measure the temperature. When compensation wiring is used in the circuit of the temperature-measuring thermocouple, there is no need to correct for the error caused by an incorrect temperature difference between the electrodes. If a thermostat

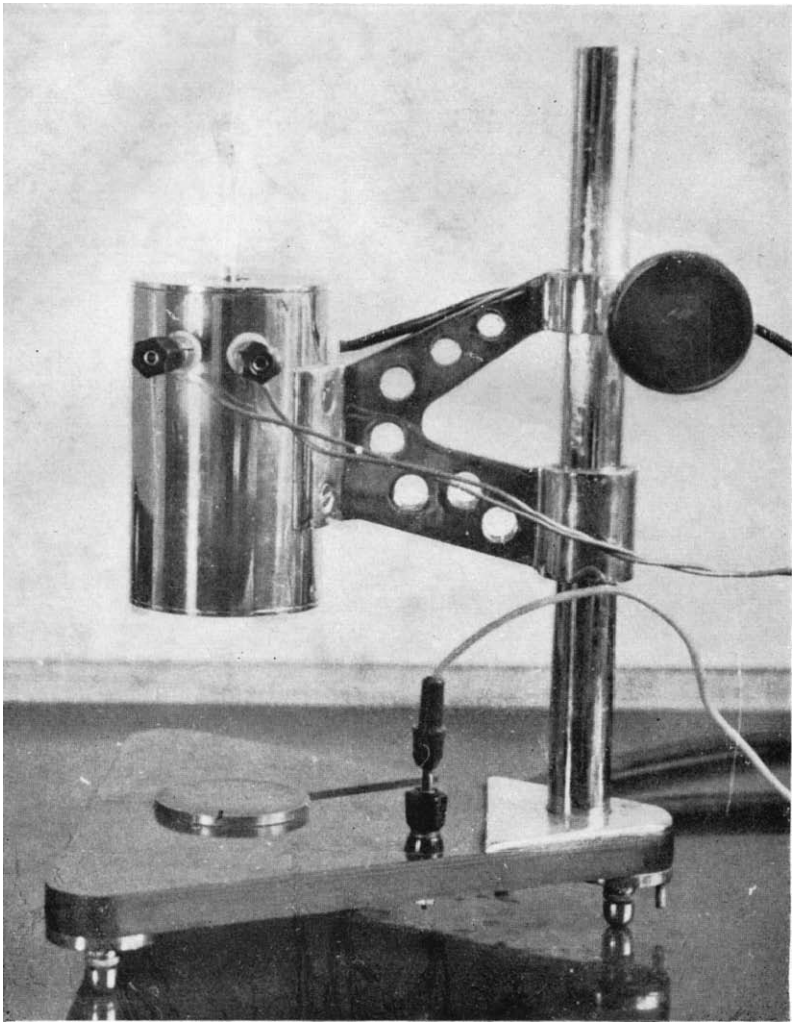

FIG. 2.—Support with the hot and cold electrodes.

is used and measurement on small samples is not repeated too quickly, the cold electrode will be sufficiently tempered and its temperature will not vary during the measurement. The TEP values mentioned in the following are always the mean of three values. According to convention, the TEP is taken as positive if the cooler electrode (E_1) is positive.

RESULTS AND DISCUSSION

We have mainly studied aluminium and its influence on the TEP of iron. It was found that aluminium shifts the TEP value of iron towards negative values more than silicon does (Fig. 4). Thus aluminium would interfere in the thermoelectric determination of silicon (positive error) in iron alloys. On the other hand, the exceptional influence of aluminium may be utilized for its sensitive thermoelectric determination in iron in the absence of silicon or with a constant amount of it present. The optimum range of Δt values for this determination is 200–260°. The calibration curve for the determination of aluminium, constructed for $\Delta t = 200°$ is shown in Fig. 7.

The thermoelectric method of aluminium determination has been applied to samples of different chemical composition and prepared in different ways. The results are given in Table I. As expected, larger chromium contents (samples 2K, 3K) interfere in the determination of aluminium (as they do in the determination of silicon in iron alloys) causing a negative error. For the other alloys the precision of the determination is satisfactory and the results are reproducible.

Among the other elements forming solid solutions with iron, germanium (Fig. 5) and zinc (Fig. 6) were studied. These metals also decrease the TEP value of iron. However, the influence of germanium is far smaller than that of silicon (Fig. 7). The influence of zinc on the TEP value is slight even with high concentrations (3·5%) (Fig. 7).

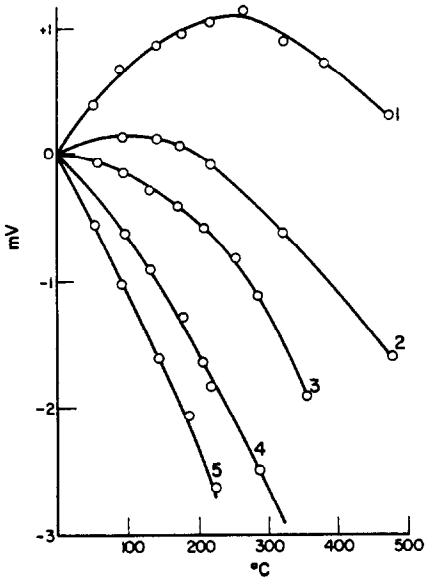

FIG. 4.—Dependence of the thermoelectric potential of iron with varying aluminium content, on the temperature difference between the hot and cold contact (Δt).

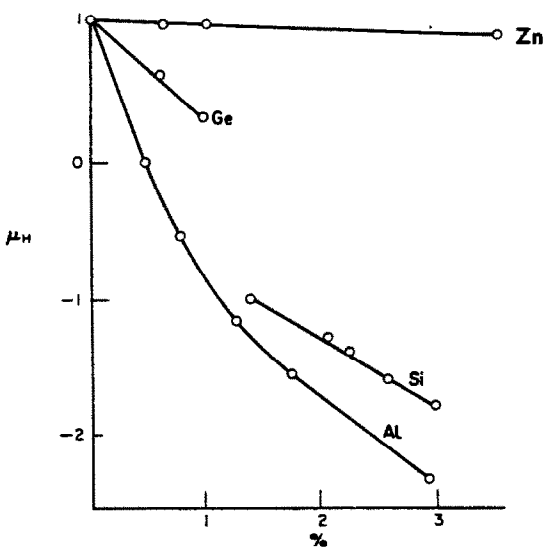

FIG. 7.—Dependence of the TEP value of iron on the content of Zn, Ge, Si and Al at $\Delta t = 200°C$.

The influence of carbon, manganese, phosphorus and sulphur on the TEP of iron has already been discussed.[16] The TEP value of iron alloys, moreover, is influenced to a small degree[31] by molybdenum (up to 5% w/w), vanadium (up to 18% w/w), nickel (up to 2·5% w/w) and tungsten (up to 5% w/w). These elements, therefore, will not interfere in the thermoelectric determination of aluminium or silicon in iron. On the other hand, chromium shifts the TEP value of iron distinctly toward positive values. Thus chromium in the range 0–1% interferes, but more than 1% of chromium does not have such a marked influence.[31] The influence of chromium may be eliminated by constructing a calibration curve by means of standards with about the same chromium content as that expected in the samples.

Existing data on the influence of germanium on the TEP value of iron[32,33] concerned alloys with compositions outside the solid solution range. The TEP values of iron–germanium alloys with germanium contents up to 1% were measured. The influence of germanium on the TEP value of iron is less than that of silicon.

It has already been stated[16] that the extraordinary influence of silicon on the TEP value of iron alloys cannot be explained by the high thermoelectric potential of silicon alone. That such a hypothesis[20,34–36] is incorrect has also been confirmed by TEP measurements on iron–aluminium and iron–germanium alloys. The explanation of the influence of alloying elements on the thermoelectric properties of the alloy, within the limits of solid-state solubility, must take into account the electron structure of the alloying elements and of the base metal. The theory of thermoelectric phenomena for metals is somewhat different from that used for semiconductors, *e.g.*, by Tauc.[21] The fundamental factors have been presented by Wilson,[22] Mott and Jones,[23] MacDonald[24] and others.[25–30]

Mott and Jones[23] show that the thermoelectric potential for a transition metal alloy is dependent on the extent to which the conducting *d*-band is filled with electrons. Iron has a partially filled *d*-band; if it is mixed with an element capable of filling the band, large negative values of the thermoelectric potential result. If the alloying element has a prevailing positive hole configuration the thermoelectric potential is either unaffected or becomes positive. Aluminium is effective in filling the band, and the thermoelectric potential for iron-aluminium alloys is strongly dependent on the composition. Zinc (Fig. 7), nickel, tungsten, vanadium and molybdenum have little effect, but chromium brings about a shift to more positive values. Silicon and germanium give rise to a negative shift, presumably because some of their *s* electrons contribute to the filling of the iron *d*-band.

The thermoelectric effect is also dependent on other factors besides chemical composition, *e.g.*, the structure of the sample, deformations and lattice defects, rate of cooling, and subsequent mechanical treatment. The method is therefore most suitable if molten samples can be taken and treated identically by the analyst. Of other electron transport effects, the Hall effect may be applied to chemical analysis.[37,38]

Zusammenfassung—Eine Methode zur raschen Bestimmung von Aluminium in Eisenlegierungen durch Thermokraftmessungen wird beschrieben. Ein Meßinstrument wurde umgestaltet und ein Verfahren für thermoelektrisch-analytische Messungen entwickelt. Die Thermokraft von Eisen-Germanium- und Eisen-Zink-Legierungen wurde gemessen und versucht, den Einfluß zulegierter Elemente auf die thermoelektrischen Eigenschaften von Übergangsmetallen theoretisch zu erklären.

Résumé—On propose une méthode pour le dosage rapide de l'aluminium dans les alliages de fer au moyen de mesures de potentiel thermoélectrique. On a modifié un instrument et élaboré une méthode pour les mesures thermo-électro-analytiques. On a mesuré le potentiel thermoélectrique d'alliages fer-germanium et fer-zinc et tenté une explication théorique de l'influence des éléments alliés sur les propriétés thermoélectriques des métaux de transition.

MICRODETERMINATION OF THE AZIDE GROUP IN ORGANIC COMPOUNDS

W. I. AWAD, Y. A. GAWARGIOUS and S. S. M. HASSAN
Chemistry Department, Faculty of Science, A'in Shams University, and Microanalytical Chemistry Unit, National Research Centre, Dokki, Cairo, U.A.R.

(*Received* 3 *May* 1967. *Accepted* 2 *June* 1967)

Summary—A simple, rapid and accurate micro-method for the analysis of mono- and diazide organic compounds is described. It is based on the Curtius rearrangement reaction. Glacial acetic acid is found to be the best decomposition medium. The acyl azide function yields two nitrogen atoms per azide group, but the diazides investigated ultimately give five nitrogen atoms per group on oxidation of their decomposition products, with acidified cerium(IV) sulphate solution. The decomposition time varies from 10 min for monoazides to 20 min for diazides. Accurate results were obtained for a representative series of 18 mono- and diazides.

RELATIVELY few methods have been reported for the determination of the azide group in organic compounds, and none is available on the micro scale. A method based on the reduction of azides by arsenite,[1] and another involving decomposition followed by Kjeldahl nitrogen determination on the residue,[2] have been reported. The latter method, though successful, is time-consuming and tedious. None of these methods has so far been applied on the micro scale.

The recently growing interest, in this department, in the synthesis of organic azides, necessitated the development of an accurate and rapid method for the determination of the azide group in such unstable compounds. The Curtius rearrangement reaction,[3] known to be specific for the azide group, appeared to suit our purpose, and had occasionally been used for the analysis of azide compounds on the macro scale.[4,5] Therefore the present work was undertaken to develop a micro method for the analysis of organic azides. The effect of the decomposition medium, the decomposition time, and some possible interferences were studied in order to establish the optimum procedural conditions.

EXPERIMENTAL

Reagents

Glacial acetic acid, 50% potassium hydroxide, 1*M* cerium(IV) sulphate in 20% sulphuric acid, solid carbon dioxide; all reagents were of analytical grade unless otherwise specified.

Apparatus

A diagram of the apparatus used is shown in Fig. 1. It consists of decomposition (A) and oxidation (B) vessels (10 × 2 cm), a trap (C), a small glass funnel (D), a Dewar flask (containing solid carbon dioxide), a micro burner and a micro nitrometer (1·50-ml capacity with 0·01-ml divisions). All the connections are Quickfit except those to the Dewar flask and the nitrometer, which were made of polythene tubing.

Procedure

Assemble the clean apparatus as shown in Fig. 1. Introduce not more than 5 mg of the sample into the decomposition vessel. Displace the air in the system with carbon dioxide. Introduce 2 ml of glacial acetic acid into the decomposition vessel through the funnel. Gently heat the reaction

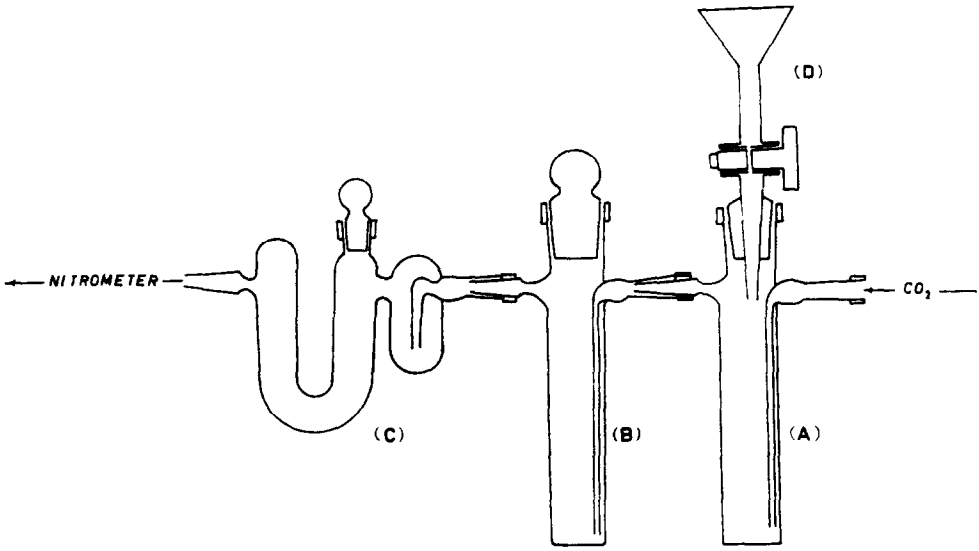

FIG. 1.—Apparatus for azide determination.
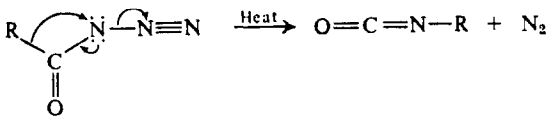
(A) Decomposition vessel; (B) oxidation vessel; (C) trap; (D) funnel.

mixture, for 10 min in the case of monoazides and 20 min for diazides, using a micro burner. Add one drop of cerium(IV) sulphate solution to the reaction mixture. Sweep the decomposition gases (for 5 min at a rate of 100 bubbles/min) through the oxidation vessel containing 5 ml of cerium(IV) sulphate solution. Collect the nitrogen gas produced, over concentrated potassium hydroxide solution in a micro nitrometer. Carry out a blank experiment under identical conditions.

RESULTS AND DISCUSSION

Decomposition medium

The Curtius rearrangement reaction[3,6] is essentially the decomposition of azide in acid medium to yield an isocyanate and nitrogen by thermolysis as follows:



The isocyanate is either isolated as such in inert solvents, *e.g.*, benzene and chloroform, or as derivatives, depending on the medium (*e.g.*, in alcohol, urethane or urea is obtained). This rearrangement is highly hazardous in the absence of solvents. In sulphuric acid medium the rearrangement sometimes takes place with partial decarbonylation to give a mixture of carbon monoxide and nitrogen.[7]

A decomposition medium in which the azide decomposes to liberate only two-thirds of its nitrogen content is a desideratum. The decomposition of some test compounds by heating in different media (basic, neutral and acidic) has thus been studied to determine the most suitable medium.

Decomposition in a basic medium. A 20% aqueous sodium hydroxide solution was tried, but no nitrogen was evolved. This may be attributed to the formation of sodium azide according to the reaction

$$RCON_3 + 2NaOH \rightarrow RCOONa + H_2O + NaN_3.$$

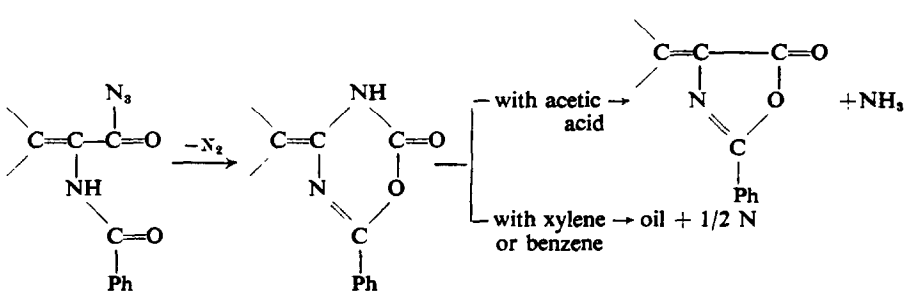
It was then thought to exploit this displacement reaction to produce sodium azide and then oxidize it to elementary nitrogen with cerium(IV) sulphate. The volume of nitrogen liberated was, however, more than the value calculated for two nitrogen atoms per azide group and less than that for three atoms per group. These invariably low values for nitrogen are attributed to incomplete hydrolysis rather than to the incomplete oxidation of sodium azide with cerium(IV) sulphate, which is shown to proceed quantitatively on the micro scale (*vide infra*). On the addition of the oxidizing agent, the unhydrolysed azide undergoes normal decomposition (loss of 2 nitrogen atoms/azide group) along with the oxidation of the sodium azide produced (loss of 3 nitrogen atoms/azide group). This assumption is in agreement with the finding of Forster and Van Gelderen[8] that the attack on α-azido carbonyl compounds by hydroxyl ions results in small amounts of displacement.

Organic bases such as aliphatic and aromatic amines were next tried as decomposition media. With aliphatic amines (*e.g.*, n-propylamine) no nitrogen was evolved. It seems that the basicity of such an aliphatic amine leads to the following reaction competing successfully with the azide decomposition.[9]

$$RCON_3 + R'NH_2 \rightarrow RCONHR' + HN_3$$
$$R'NH_2 + HN_3 \rightarrow [R'NH_3]^+N_3^-$$
$$(R' = -C_3H_7)$$

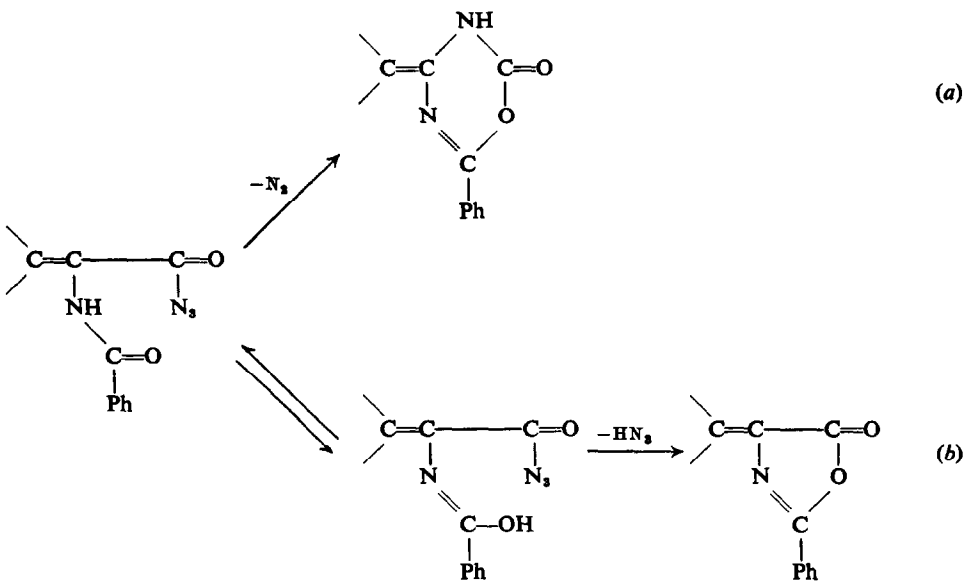
With aromatic amines (*e.g.*, aniline) nitrogen was liberated, but still the recoveries were low by 4–7%.

Decomposition in a neutral medium. When water was used as the decomposition medium, the recovery obtained was about 50%. No improvement was noticed even on increasing the boiling time up to 1 hr. If benzene or xylene was used as solvent, the recoveries obtained were high by 15–25%, corresponding to about 2·5 nitrogen atoms/azide group, instead of the expected 2 nitrogen atoms. Similarly, Smith and Hall[10] reported in their kinetic study that aryl azides decompose in decalin solution to give 1·32 mole of nitrogen instead of the expected one mole per mole of azide, but did not account for the source of the extra nitrogen. In the present work, however, the source of this extra nitrogen was found to be partial decomposition of the intermediate rearrangement product. When this product was isolated and boiled in either benzene or xylene, about 1 nitrogen atom per 2 azide groups was liberated. When the product was boiled with acetic acid no nitrogen was evolved, but ammonium acetate was detected. This can be represented as follows.



This suggested the use of acetic acid as the decomposition medium.

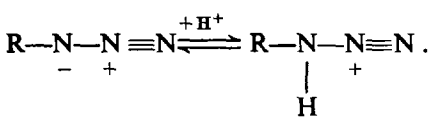
Decomposition in an acid medium. The use of dilute acetic acid (5*M*) as a decomposition medium gave invariably low recoveries varying between 83 and 90%. These low recoveries are thought to be due to the partial formation of hydrazoic acid. This assumption was tested by passing the decomposition products of isopropylidene hippuric azide through a small trap containing iron(III) nitrate solution in one experiment and silver nitrate solution in another. The formation of a deep red colour with iron(III) nitrate and a white precipitate with silver nitrate was a confirmation for this assumption.[11] Therefore, when dilute acetic acid is used, the decomposition of the azide generally proceeds *via* either of the following routes.



Route (*a*) is predominating since the average recovery is 83–90%; the remainder (*i.e.*, 10–17%) is lost owing to the formation of hydrazoic acid *via* route (*b*). When glacial acetic acid was used, the test azide compound decomposed completely *via* route (*a*).

Decomposition time

The time required for full decomposition in glacial acetic medium (*i.e.*, the time required until a constant volume of nitrogen was obtained) was recorded for the monoazide samples. The decomposition *vs.* time diagrams show that 10 min are enough for complete decomposition (*cf.* Fig. 2). The fast rate of nitrogen liberation confirms the favourable catalytic effect of the acidic medium, since the protonation of the azide group could reasonably lead to nitrogen liberation:[12]



Interferences

The nitro, nitroso, azoxy, azo, hydrazo, cyano, amido, imido, amino and ammonium compounds show no interference with the proposed procedure for azide

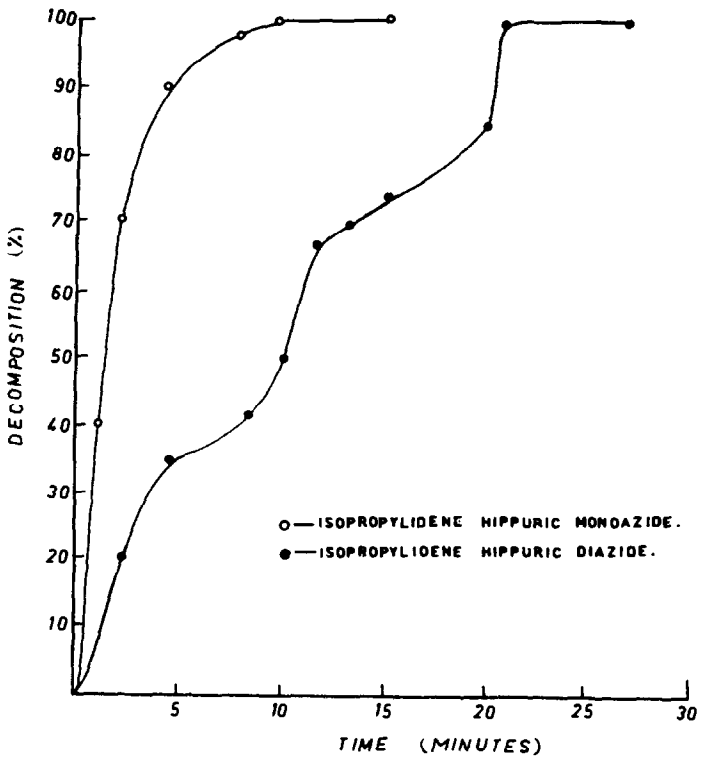


FIG. 2.—Decomposition of isopropylidene hippuric mono- and diazides in glacial acetic acid.

group determination, but diazo, diazonium and *N*-nitroso compounds seriously interfere. The first two of these interfering groups readily give off nitrogen, even on treatment with acetic acid at room temperature. The *N*-nitroso compounds (*e.g.*, cupferron) liberate nitric oxide. High recoveries were obtained for the azide group, even after the elimination of nitric oxide through oxidation with suitable reagents. The high recoveries are presumably due to gaseous products other than nitric oxide.

Determination of monoazides

Good results were obtained for the analysis of a representative series of 15 acyl azides. These azides are characterized by having an enolized γ-hydroxyl group, known to promote cyclization with subsequent loss of some hydrazoic acid,[6] and possess various substituents. The use of glacial acetic acid as a decomposition medium completely hindered this cyclization. The results obtained (Table I) show a total average recovery of 99·3% with an average absolute error of $\pm$0·13%, the maximum absolute error being $\pm$0·25%.

Determination of diazides

When diazides having both alkyl and acyl azide groups in the same molecule decompose in glacial acetic acid the nitrogen recovery corresponds approximately to one azide group; a large proportion of hydrazoic acid is also detected. This shows

TABLE I.—MICRODETERMINATION OF AZIDE GROUP IN SOME ACYL MONOAZIDES BY DECOMPOSITION IN GLACIAL ACETIC ACID

Sample	% Azide nitrogen, %		Error, %	Recovery, %

* The final structure of these samples is still under investigation but they show the characteristic band for the azide group in the infrared spectrum.

that the alkyl azide group is lost (in the form of hydrazoic acid) through decomposition, whereas the acyl azide group rearranges normally to give two-thirds of its nitrogen. It was thus thought possible to determine both nitrogen and hydrazoic acid produced from such compounds by oxidizing the hydrazoic acid quantitatively[13] in acid medium.

Recoveries corresponding to 5 nitrogen atoms/molecule of diazide were obtained when these compounds were decomposed in glacial acetic acid and the decomposition products passed through a trap containing an acidic solution of the oxidant. Both cerium(IV) sulphate and potassium permanganate were used as oxidants but the former is to be recommended. The time needed for the complete decomposition of these diazides is found to be double that required for the monoazides (*cf.* Fig. 2). Figure 2 also shows that the decomposition curve of diazides is not as smooth as that of monoazides.

More accurate results were obtained by adding one drop of the oxidant to the decomposition solution. The five nitrogen atoms obviously correspond to both the acyl azide group nitrogen (2 atoms/molecule) and that resulting from hydrazoic acid

oxidation (3 atoms/molecule; equivalent to the alkyl azide group). The results obtained (Table II) show an average recovery of 100·6% with an average absolute error of ±0·28%, the maximum error being ±0·45%.

Zusammenfassung—Eine einfache, schnelle und genaue Mikromethode zur Analyse organischer Mono- und Diazide wird beschrieben. Sie beruht auf der Curtius-Umlagerung. Eisessig erweist sich als bestes Reaktionsmedium. Die Acylazidfunktion ergibt zwei Stickstoffatome pro Azidgruppe, die untersuchten Diazide geben jedoch letzten Endes fünf Stickstoffatome pro Gruppe, wenn man ihre Zersetzungsprodukte mit saurer Cer(IV) sulfatlösung oxidiert. Die Reaktionszeit reicht von 10 min für Monoazide bis 20 min für Diazide. Für eine typische Reine von 18 Mono- und Diaziden wurden genaue Ergebnisse erhalten.

Résumé—On décrit une microméthode simple, rapide et précise pour l'analyse des composés organiques mono-et diazides. Elle est basée sur la réaction de réarrangement de Curtius. On a trouvé que l'acide acetique cristallisable est le meilleur milieu de décomposition. La fonction acyl azide donne deux atomes d'azote par groupement azide mais les diazides étudiés en dernier donnent cinq atomes d'azote par groupe par oxydation de leurs produits de décomposition avec une solution acidifiée de sulfate de cérium(IV). Le temps de décomposition varie de 10 mn pour les monoazides à 20 mn pour les diazides. On a obtenu des résultats exacts pour une série représentative de 18 mono-et diazides.

STUDIES ON VANADIUM(IV) COMPLEXES OF AZOXINE S DYES

S. S. GOYAL and J. P. TANDON
Chemical Laboratories, University of Rajasthan, Jaipur, India

(*Received* 30 *March* 1967. *Accepted* 28 *June* 1967)

Summary—Comparative studies of the reaction of 7-arylazo-8-hydroxyquinoline-5-sulphonic acid (Azoxine S) dyes with vanadium(IV), show that 2:1 yellow, water-soluble complexes are formed over the pH range 2·5–6, and that the phenyl derivative is the most suitable for spectrophotometric determination of 0·2–1·4 ppm of vanadium(IV). The colour is formed instantaneously and is stable for about 8 hr. The molar absorptivity at λ_{max}, 400 mμ, is $1{\cdot}15 \times 10^4$, and the equilibrium constant for complex formation is of the order of 10^9. These dyes can also be used as indicators in the direct complexometric determination of vanadium(IV). The interference of a number of anions and cations is reported.

AZOXINE S (7-arylazo-8-hydroxyquinoline-5-sulphonic acid) dyes have been mainly used as metal ion indicators,[1–7] but Uusitalo and a few other workers[8–11] have carried out potentiometric and spectrophotometric studies of the complexes of bivalent metals with such dyes. In our laboratories the reactions of Azoxine S dyes with vanadium(IV) have been studied. Yellow, water-soluble, 1:2 vanadium(IV)–dye complexes are formed over the pH range 2·5–6 with all the dyes examined (Table I), but 7-phenylazo-8-hydroxyquinoline-5-sulphonic acid is the best reagent for the microdetermination of vanadium(IV). This communication reports detailed spectrophotometric studies of vanadium(IV) complexes with 7-phenylazo-8-hydroxyquinoline-5-sulphonic acid (A) and 7-(4-sulphophenylazo)-8-hydroxyquinoline-5-sulphonic acid (B).

The dyes can be used as indicators for the direct complexometric determination of vanadium(IV), the best being those derived from aniline, *o*-, *m*- and *p*-nitroanilines, *m*- and *p*-toluidines, *m*- and *p*-anisidines, *p*-phenetidine, sulphanilic acid and *p*-aminobenzoic acid. Only a few other reagents are known to perform satisfactorily in this role.[12–15]

EXPERIMENTAL

Reagents

Vanadyl solution. A solution of vanadyl sulphate in doubly-distilled water containing a small amount of sulphuric acid, was standardized with permanganate.

EDTA solution, 0·05*M*. A solution of disodium EDTA standardized against zinc solution.

Buffer solutions. Stock solutions of 1*M* sodium acetate and 1*M* acetic acid were prepared and mixed in appropriate proportions when required.

Dye solutions. All the dyes were prepared and purified by the method of Uusitalo,[8] and the purity was confirmed by elemental analysis and potentiometric titrations against standard alkali solution. The dyes were dissolved in doubly-distilled water containing the requisite amount of sodium hydroxide to effect solution. The solutions were diluted to $5{\cdot}0 \times 10^{-4}M$ for spectrophotometric studies, and used as 0·1% solutions for titrimetry.

Ionic strength. In the spectrophotometric studies an appropriate amount of potassium nitrate solution was used for maintaining constant ionic strength ($\mu = 0{\cdot}1$).

Procedure for complexometric titrations

Place an aliquot of vanadyl solution, containing 5–35 mg of vanadium, in a conical flask and buffer it to pH ~ 4, add 2 ml of 1% ascorbic acid and 2–4 drops of indicator solution. Titrate with EDTA. The end-point is marked by a sharp change in colour from green to wine-red or reddish-violet. A few results obtained with dye (A) are given in Table III.

The alternative procedure used in presence of foreign ions is as follows: take the sample solution, containing interfering ions, and add about 1 g of potassium cyanide or about 0·2 g of sodium fluoride, (depending on the nature of the ion present); this increases the pH to about 9·5. Adjust the pH with dilute sulphuric acid to ~5 and then buffer the solution to pH ~ 4. Add 5 ml of ascorbic acid solution and 4 drops of indicator and complete the titration as described above.

RESULTS AND DISCUSSION

Spectra

The absorption spectra of the dyes and vanadium complexes were measured at the optimum pH and ionic strength of 0·10; the concentrations of dye and vanadium in the final solution were both $1{\cdot}20 \times 10^{-5}M$ (Fig. 1). The results (Table I) show that (A) and (B) are superior to the other dyes studied.

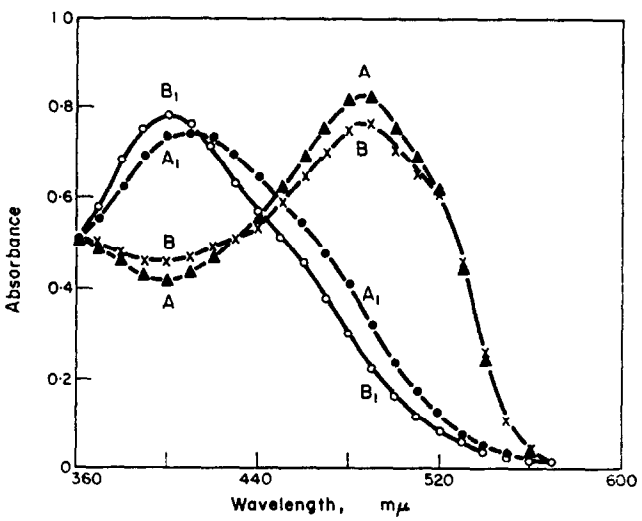

FIG. 1.—Absorption spectra for dyes (A) and (B) and their vanadium(IV) complexes. *A*—dye (A); A_1—dye (A) and vanadium(IV); *B*—dye (B); B_1—dye (B) and vanadium(IV). Final reagent concentrations were $1{\cdot}2 \times 10^{-5}M$.

Effect of pH

Optimum pH ranges were determined by plotting the absorbance at λ_{max} as a function of pH.

The effect of pH on the complexometric titrations was determined from titrations at different pH values with dyes (A) and (B) as indicators; the optimum pH range is 3·5–4·5.

Effect of time and temperature

The absorbance of the system was found to be constant for about 8 hr and the optimum temperature range was found to be 10–50°. It was noted that the titrations could be carried out satisfactorily over the temperature range 20–50°.

TABLE I.—PROPERTIES OF AZOXINE S DYES AND THEIR VANADIUM(IV) COMPLEXES

Dye		Absorption maxima, mμ		Colour of V(IV) complex	Optimum pH range	Optimum wavelength, mμ	Molar absorptivity at optimum wavelength		Isosbestic point, mμ
		Dye	Complex				Dye	Complex	
1. 	(A)	490	400	Yellow	3·6–4·3	400	$6·5 \times 10^3$	$11·5 \times 10^3$	443
2.	(B)	490	410	Yellow	3·7–4·3	410	$6·2 \times 10^3$	$8·5 \times 10^3$	449

Adherence to Beer's law

Beer's law is obeyed between 0·2 and 1·4 ppm of vanadium with (A) and from 0·2 to 1·6 ppm with (B). The molar absorptivities with different dyes are given in Table I.

Nature and composition of complex

The standard spectrophotometric methods[16–19] indicated that a 1:2 metal:reagent complex was formed but no others (Figs. 2 and 3). The isosbestic points obtained for the different dyes are given in Table I. The equilibrium constants were calculated,[16,19] the results being given in Table II.

64·34	29·10	28·20	−2·8

Effect of foreign ions

The interference due to several anions and cations was studied in detail. In spectrophotometric determination of 1 ppm of vanadium(IV), double the amount of alkaline earths and 10 mg of phosphate and fluoride ions did not interfere. The interference due to equal amounts of Cu(II), Cd(II), Co(II) and Ni(II) could be avoided by masking these ions with potassium cyanide and that of Al(III), Ti(IV) and Th(IV) with sodium fluoride. However, Hg(II), Mn(II), U(VI), Fe(III), Ga(III), In(III), V(V), Mo(VI), W(VI), oxalate, tartrate and citrate ions interfered.

In complexometric titration of 22 mg of vanadium, 20 mg of alkaline earths and 100 mg of phosphate and fluoride ions did not interfere. The interference due to equal amounts of Cu(II), Cd(II), Hg(II), Mn(II), Co(II) and Ni(II) was

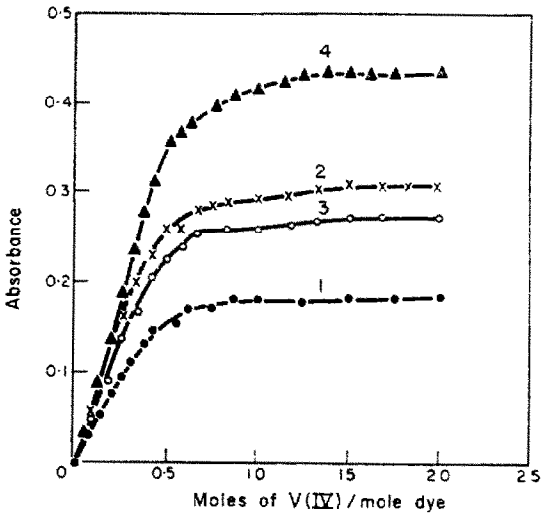

FIG. 4.—Mole-ratio curves.
1 — 4 × $10^{-5}M$ V(IV) and dye (A); *2* — 6 × $10^{-5}M$ V(IV) and dye (A);

overcome by masking with potassium cyanide and that of Al(III), Ti(IV) and Th(IV) with sodium fluoride. However, U(VI), Fe(III), In(III), Ga(III), Tl(III), V(V), Mo(VI), W(VI), oxalate, tartrate and citrate ions interfered in this case also.

Zusammenfassung—Vergleichende Untersuchungen der Reaktion von 7-Arylazo-8-hydroxychinolin-5-sulfonsäure- (Azoxin S-)farbstoffen mit Vanadium(IV) zeigen, daß sich gelbe wasserlösliche 2:1-Komplexe im pH-Bereich 2,5–6 bilden und daß das Phenylderivat zur spektrophotometrischen Bestimmung von 0,2–1,4 ppm Vanadium(IV) am besten geeignet ist. Die Farbe wird sofort gebildet und ist etwa 8 Stunden stabil. Der molare Extinktionskoeffizient beim Maximum 400 nm beträgt $1{,}15 \cdot 10^4$ und die Gleichgewichtskonstante für die Komplexbildung liegt in der Größenordnung von 10^9. Diese Farbstoffe können auch als Indikatoren bei der direkten komplexometrischen Bestimmung von Vanadium(IV) verwendet werden. Über die Störung durch eine Anzahl von An- und Kationen wird berichtet.

Résumé—Des études comparatives sur la réaction de colorants acides 7-arylazo 8-hydroxyquinoléine 5-sulfoniques (Azoxine S) avec le vanadium(IV) montrent qu'il se forme des complexes jaunes 2:1, hydrosolubles, dans le domaine de pH 2,5–6 et que le dérivé phénylé convient le mieux au dosage spectrophotométrique de 0,2–1,4 p.p.m. de vanadium(IV). La coloration se forme instantanément et est stable pendant 8 h environ. L'absorption molaire à λ_{max} 400 mμ est de $1{,}15 \times 10^4$ et la constante d'équilibre pour la formation du complexe est de l'ordre de 10^9. Ces colorants peuvent aussi être utilisés comme indicateurs pour le dosage complexométrique direct du vanadium(IV). On mentionne l'interférence d'un certain nombre d'anions et de cations.

CONTINUOUS SUBSTOICHIOMETRIC DETERMINATION OF TRACES OF MERCURY BY RADIOACTIVE ISOTOPE-DILUTION ANALYSIS*

G. B. BRISCOE, B. G. COOKSEY, J. RŮŽIČKA† and M. WILLIAMS‡
Department of Chemistry, The University of Aston in Birmingham, Birmingham 4, England

(*Received* 22 *May* 1967. *Accepted* 26 *June* 1967)

Summary—The possibility of automating substoichiometric analysis by isotope dilution has been proposed previously. Automation where the analysis is based on solvent extraction has now been carried out experimentally. Preliminary experiments are described by means of which optimum conditions for this type of automated determination can be chosen and its reproducibility and selectivity checked. As an example traces of mercury down to 5×10^{-8} g are determined and the method is applied to the analysis of low-grade cinnabar ores.

IN recent years the substoichiometric determination of a number of metals by radioactive isotope dilution has been developed.[1] This method has attracted interest because though its sensitivity can be comparable with that of neutron-activation analysis, it eliminates the use of a nuclear reactor and the need for special handling facilities. In a preliminary communication,[2] the possibility of carrying out continuous substoichiometric analysis by isotope dilution was recently discussed. This procedure would have several advantages.

1. Safety precautions in a radiochemical laboratory aim to restrict radioactive contamination to a minimum. This is more easily achieved when the radioactive solutions are processed automatically by a machine.

2. In many methods of trace metal analysis the accuracy is limited at low metal concentrations (below about $10^{-6}M$) by the reproducibility of the blanks. In an automatic process every sample is treated identically so that reproducibility of blanks and calibration is guaranteed.

3. Preparation of the radioactive samples for counting is time-consuming and may lead to errors, especially when β-active samples are measured after evaporation on planchets. These difficulties are avoided in continuous analysis where flow-counters can be used.

It was pointed out[2] that continuous substoichiometry might be based on precipitation, complexation followed by ion-exchange, or solvent extraction. The present paper describes the experimental verification of the last possibility. Trace amounts of mercury have been determined by continuous isotope dilution with mercury-203, a substoichiometric amount of zinc dithizonate in carbon tetrachloride being used as the extraction reagent.

* Presented at XXIst International Congress of Pure and Applied Chemistry, Paper A-27, Prague, Czechoslovakia, 7th September, 1967.

‡ Present address: Learned Journals Division, Pergamon Press Ltd., Headington Hill Hall, Oxford, England.

EXPERIMENTAL

Reagents

These were prepared from analytical reagent grade chemicals.

Radioisotope. The isotope used was mercury-203, as the acetate, with a specific activity of 500 mc/g (Radiochemical Centre, Amersham, England). The material received from Amersham was diluted to give a mercury isotope solution of 500 μg/ml.

Standard labelled mercury solutions. Prepared by dilution of the mercury isotope solution with 1*M* nitric acid. Various concentrations were used according to the range of calibration required (*e.g.*, a 1-ppm standard gave a calibration graph covering the range 0·2–4·0 ppm of mercury).

Urea solutions, 1%. In water or $10^{-4}M$ sodium chloride.

Standard inactive mercury solutions. An approximately 0·05*M* solution of mercury(II) nitrate was prepared and standardized by Volhard's method.[3] This stock solution was diluted appropriately with 1*M* nitric acid.

Zinc dithizonate stock reagent. Prepared by dissolving 0·05 g of dithizone in 10 ml of ammonia solution (s.g. 0·880) and diluting to 100 ml, then extracting with carbon tetrachloride until the colour of the organic phase changed from brown to pale green. This purified aqueous solution (free from carbodiazone) was mixed with a solution of 0·05 g of zinc sulphate (heptahydrate) in 90 ml of water and 10 ml of glacial acetic acid, then extracted with 100 ml of carbon tetrachloride. The organic layer was filtered through a dry No. 41 Whatman paper and the zinc dithizonate concentration (*ca.* $5 \times 10^{-4}M$) determined (after 100-fold dilution) from its absorbance[4] at 538 mμ ($\varepsilon = 9{\cdot}2 \times 10^4$). The working solution was prepared by appropriate dilution of this stock reagent. A $2 \times 10^{-5}M$ solution is suitable for determination of mercury in the range 0·4–4 ppm.

Apparatus

Technicon AutoAnalyzer (Technicon Instruments Company Ltd., Hanworth Lane, Chertsey, Surrey, England). The system used comprised, as its main items, a two-speed proportioning pump, a sampler (Model II) and a strip-chart recorder (Bristol Dynamaster Model 570 single point, as supplied by Technicon).

Scintillation counter. The detector used was a 2 × 2 in. NaI(Tl) well-type crystal: well-diameter 1 in., volume 20 ml. This was associated with a single channel gamma-ray spectrometer (9000 Series, Research Electronics Ltd., Cleckheaton, Yorkshire, England). In all experiments a setting of discriminator voltage corresponding to 50 keV was used. This gave a background counting rate of 10 cps. The output from the ratemeter (Model 9030) was fed into the strip-chart recorder. Satisfactory results were obtained with this combination only when no earth connection was used in the recorder; otherwise the recorder pen oscillated violently. If a matched ratemeter/recorder combination is used, this difficulty should not arise.

Flow-cell. Made from 32 cm of 3·5-mm outside diameter soda glass tubing, wound into a coil, 2·2 cm in diameter and 2 cm high, which fitted into the well of our scintillation counter.

The arrangement of apparatus shown in the flow diagram (Fig. 1) resulted from all our investigations on continuous substoichiometry and was that used for the final analytical procedure. During the development of the method there was no dilution, *in situ*, of a more stable concentrated zinc dithizonate working solution with carbon tetrachloride: zinc dithizonate reagents of appropriate strength (see Figs. 2–5) were used directly.

Sampler II is programmed to deliver alternately samples (for 5 min) and 1*M* nitric acid wash-solution (for 1 min). The samples (or nitric acid wash solution) and standard labelled mercury solutions were driven by the proportioning pump (A) into the first single mixing coil (B) where isotopic exchange occurred. Urea solution, added to prevent oxidation of the organic reagent by nitrous fumes, was mixed with the solution from B in the second single mixing coil (C). The zinc dithizonate reagent was now added and this final mixture passed through the special extraction coil (D),[5] where solvent extraction took place. The two phases were separated in the electrolyte trap (E), the activity of the organic phase being continuously measured in the flow-cell (F) and recorded by the strip-chart recorder.

Development of Method

The determination of mercury with dithizone was chosen for this work because a manual substoichiometric method by isotope dilution had previously been developed.[6] Otherwise it would have been necessary, with the aid of the theory of substoichiometry,[1] to select a suitable extraction reagent and to investigate the influence of pH and time of extraction. In either case the following routine tests must be carried out whenever a substoichiometric determination by solvent extraction is being automated.

Choice of reagent concentration

The apparatus is set up as in Fig. 1 but with 1*M* nitric acid replacing the samples. During this experiment the concentration of the zinc dithizonate reagent is increased in a series of steps, from pure solvent to excess of reagent relative to the concentration of mercury in the labelled standard solution (Fig. 2).

The pumping action is started and the first level of activity registered (Fig. 2, plateau *c*) represents the quantity of mercury extracted by pure solvent. For successful substoichiometry this level must not be different from that of plateau *b*. As the concentration of reagent is increased, increasing amounts of activity are extracted (plateaux *d*, *e*, *f*, *g*) from the labelled standard solution until an

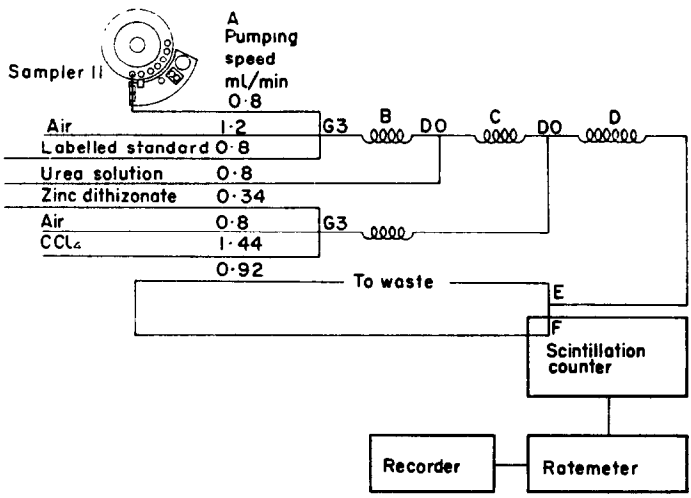

FIG. 1.—Flow diagram for continuous substoichiometric determination of mercury with the Technicon AutoAnalyzer.

excess of reagent extracts all the mercury and no further increase in activity is possible (*g*, *h*). For a substoichiometric separation any concentration of reagent could be used (*d*, *e*, *f*) which is below this limit. However, the concentration chosen (*f*) should be as high as possible so that the amount of mercury extracted minimizes statistical variations in the counting procedure. There is no need to repeat this experiment every time new reagents are prepared. The concentration of the proposed reagent should merely be checked by ensuring that it extracts less activity from the standard labelled mercury solution than is extracted by a solution of zinc dithizonate concentrated enough to give an excess of reagent with certainty.

Adsorption problems. The difference between plateaux *a* (background of the scintillation counter alone) and *b* (background of scintillation counter with flow-cell in the well), both recorded before any liquid is introduced into the apparatus, is caused by contamination of the flow cell from previous experiments. This is small for a glass flow-cell (negligible at first, but building up slowly over *ca.* 1 month, after which it is best to replace the cell and allow its activity to decay before reuse) but is important when plastic cells are used: most plastics strongly adsorb metal dithizonates (Tygon, Solvaflex, Acidflex and polythene were all useless in practice). Because of this adsorption it is necessary to use Acidflex tubing instead of the Solvaflex tubing normally recommended for pumping organic solvents (both tubings available from Technicon). Solvaflex tubing will remove all the zinc dithizonate from the reagent for several hours after pumping has started; even with Acidflex it is necessary to wait a short time (*ca.* 10 min) for adsorption losses to come to equilibrium and a constant activity to be registered. The time needed to register plateaux *a*, *b* and *c* is, however, very short (*ca.* 30 sec).

Stability of reagent

Very dilute (10^{-6} to $10^{-8}M$) solutions of organic reagents are often unstable. For automated substoichiometry the stability of such reagents is more critical than in the corresponding manual methods, because standards and samples are not processed simultaneously.

To test for reagent stability in the determination of mercury, the apparatus was arranged to deliver a substoichiometric reagent concentration. If the reagent is stable there should be no observable decrease, even after several hours, in the activity extracted. Figure 3 shows such a test with dithizone or zinc dithizonate as the extraction reagent. Clearly, zinc dithizonate is much more stable than dithizone and so it was used in all subsequent experiments.

In the present case the stability of the extraction reagent limits the sensitivity of the method and in order to determine 5×10^{-8} g of mercury it is necessary to dilute, *in situ*, a more stable concentrated zinc dithizonate working solution with carbon tetrachloride as shown in Fig. 1.

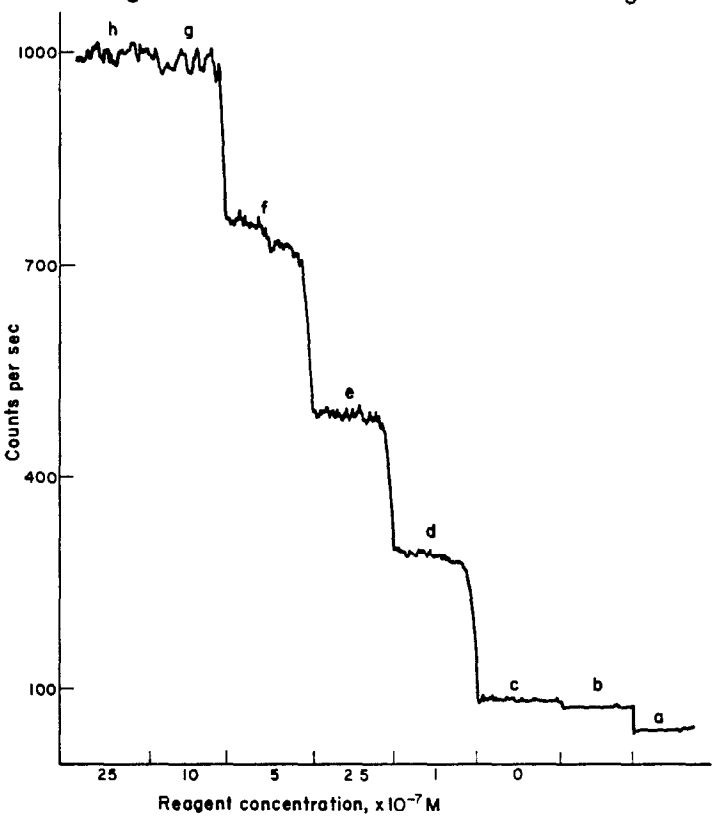

FIG. 2.—Extraction plateaux obtained with different concentrations of zinc dithizonate solution (standard labelled mercury solution: $3 \times 10^{-7}M$).

Time of extraction

It is important to check that extraction is complete in the time allowed by the AutoAnalyzer system. This is easily done by inserting a second extraction coil and seeing if there is any change in the activity extracted. It is particularly important to check this when a metal complex is used as the extraction reagent.

Choice of sampling rate

The maximum sampling rate depends primarily on the time required to replace with new solution all the old solution in the flow-cell and the electrolyte trap. This can be determined by measuring the time necessary (t_b min) for 95% of the maximum deflection to be registered on the strip-chart recorder. The maximum sampling rate is then $60/t_b$ samples/hr. For the arrangement shown in Fig. 1, t_b is 6 min, giving a maximum sampling rate of 10 samples/hr.

The sampling rate can be increased in two ways.

1. By increasing the rate at which the organic phase is pumped; however, if the sensitivity is to be maintained under such conditions, a more dilute extraction reagent would have to be used and this might be unstable. For a given sensitivity the stability of the extraction reagent limits the maximum sampling rate that can be used.

2. By reducing the size of the flow-cell, but this would reduce the counting efficiency and hence the sensitivity.

The compromise represented by Fig. 1 gives a high sensitivity but a low sampling rate.

Interferences

The effect of interferences on the extraction was investigated by using solutions of various cations (as their nitrates or sulphates), anions (as their potassium, sodium or ammonium salts) and other substances (*e.g.*, hydrogen peroxide) in the cups of Sampler II. Figure 4 shows the results of some of these studies. An interference is represented by any change in the otherwise constant activity extracted

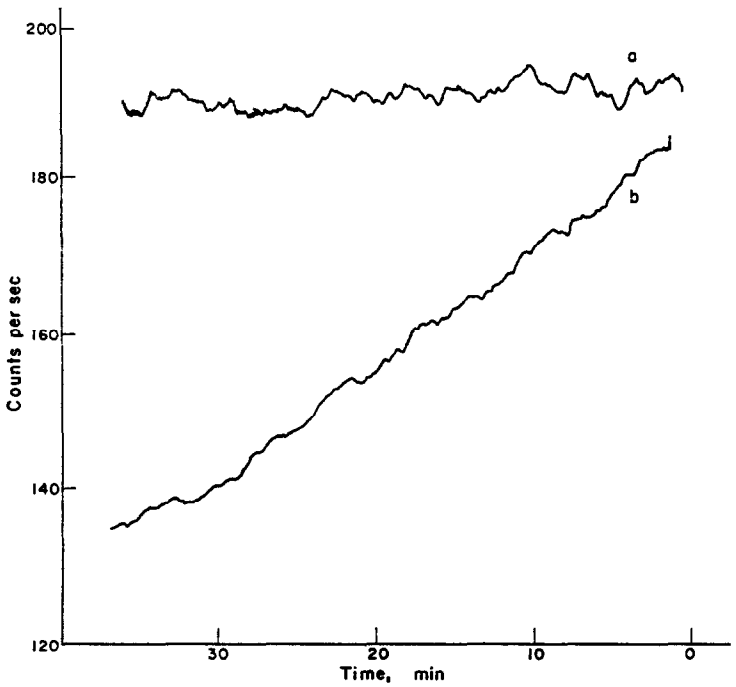

FIG. 3.—Stability of extraction reagent.
a—Zinc dithizonate ($1 \times 10^{-6}M$).

(Standard labelled mercury solution: $2 \times 10^{-5}M$).

from the standard labelled mercury solution (*e.g.*, palladium and chloride in Fig. 4). Table I summarizes the results for 58 ions and compounds.

It should be possible to overcome most interferences fairly easily and, for routine analysis, automatically. Cations can be masked with a suitable reagent; oxidizing and reducing agents can be destroyed with say hydrogen peroxide. Thus, silver and bismuth should be complexed with chloride and EDTA. Permanganate, dichromate and chlorate should be reduced with hydrogen peroxide or iron(II) sulphate. Tin(II), platinum(II), sulphite and hypophosphite should all be oxidized by hydrogen peroxide.

The anions in the last column of Table I present a more serious difficulty, particularly chloride, which is almost impossible to remove at the very low concentrations where interference is still encountered (calculated to be down to about 0·001 ppm). These anions appear to form ternary complexes of the type Cl·Hg·HDz' (H_2Dz = dithizone) so that a given amount of zinc dithizonate could extract twice as much mercury from solutions containing them as from solutions in which mercury is extracted as the primary dithizonate, $Hg(HDz)_2$. This will lead to an increase in the activity extracted, in contrast with other interferences (*e.g.*, palladium in Fig. 4) which cause a decrease.

It can be predicted theoretically that interference from chloride will be overcome if its concentration is between 6×10^{-5} and $6 \times 10^{-3}M$, under which condition all mercury is present as mercury(II) chloride. This has been confirmed experimentally and we recommend the use under all circumstances

of a 1% urea solution in $10^{-4}M$ sodium chloride. This method is, of course, only satisfactory if an empirical calibration graph is constructed. The chemistry of the reactions is being investigated more fully and will be reported at a later date.

Calibration graph

The calibration graph (Fig. 5) was prepared by using standard inactive mercury solutions in the cups of Sampler II. A fresh calibration graph should be prepared whenever new reagents are made up, particularly when the method given above to overcome interference from chloride is used. If a very large amount (*ca.* $1M$) of bisulphate or nitrate is present, a similar amount should be added to the standard inactive mercury solution to compensate for their small but noticeable interference.

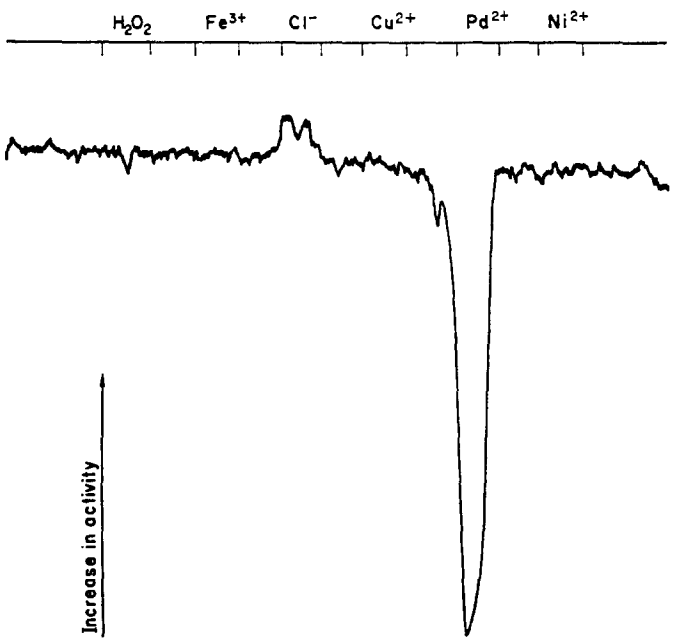

FIG. 4.—Effect of foreign ions (conditions as detailed in Table I).

As can be seen from Fig. 5, as little as $2{\cdot}5 \times 10^{-7}$ g of mercury in 5 ml of solution (0·05 ppm) can be determined (in a 6-min run 4·8 ml of sample solution are consumed). The lowest amount of mercury we have determined by this method is 5×10^{-8} g in 5 ml (0·01 ppm).

Analysis of Test Samples

In order to demonstrate the usefulness of the method, we analysed several samples of low-grade cinnabar ore which had previously been analysed spectrophotometrically for mercury at the Warren Spring Laboratory.

One g of ore (received as fine powder and used directly) was refluxed for 30 min with 25 ml of sulphuric acid (s.g. 1·84) and 1 g of potassium nitrate. After cooling and dilution, 1 g of urea was added, the mixture filtered through a No. 42 Whatman paper, and the filtrate diluted to 250 ml in a calibrated flask.

The solution was analysed with the apparatus as shown in Fig. 1, using the following solutions: standard labelled mercury solution—$5 \times 10^{-6}M$; urea solution—1% in $10^{-4}M$ sodium chloride; zinc dithizonate working solution—$5 \times 10^{-6}M$. The AutoAnalyzer was run at a rate of 5 samples/hr, and gave the results shown in Table II.

DISCUSSION

Our results for the determination of mercury in the low-grade cinnabar ores (Table II) by continuous substoichiometry are in good agreement with the spectrophotometric results, though for Sample 3 there was disagreement with the spectrophotometric values reported by Warren Spring Laboratory. For the determination

of traces of mercury with dithizone, continuous substoichiometry is more sensitive by an order of magnitude than spectrophotometry as judged by comparing Fig. 5 with spectrophotometric data.[8]

The advantages of the automatic method mentioned earlier should be weighed against the disadvantages which are now evident. First, there is a slow contamination of parts of the instrument (tubing, nipples, glass coils, *etc.*) by adsorption of radiomercury. Secondly, the automatic method is less sensitive than manual substoichiometry (by about one order of magnitude in the case of mercury) because the flow-cell is small and the organic phase passes rapidly through it. Fortunately radioisotopes of other metals are available with higher specific activities than that of mercury-203, many of them as carrier-free isotopes. This should permit determination of these metals at even lower concentrations than in the case of mercury.

¶ Using dithizone screened with EDTA and KSCN; sample dissolution as for continuous substoichiometry.

Because the volume which can be sampled by the AutoAnalyzer is small (maximum of 10 ml), an increase in sensitivity by increasing the sample volume would entail a preliminary extraction. However, this disadvantage could be outweighed by introduction of the radioisotope before the preliminary extraction. Because isotope-dilution analysis is being used, this preliminary separation need not then be quantitative. As the radioisotope is not being introduced into the AutoAnalyzer continuously, the strip-chart records and their evaluation would differ from those discussed above.

Zusammenfassung—Vor kurzem wurde die Möglichkeit angegeben, die unterstochiometrische Analysenmethode durch Isotopenverdünnung zu automatisieren. Bei einer auf flüssig-flüssig-Extraktion beruhenden Analyse wurde die Automation jetzt experimentell verifiziert. Es werden Vorversuche angegeben, durch die die optimalen Bedingungen für diese Art automatischer Analyse ausgewählt und deren Reproduzierbarkeit und Selektivität geprüft werden können. Als Beispiel werden Quecksilbermengen bis herunter zu 5×10^{-8} g bestimmt und die Methode auf die Analyse geringwertiger Zinnober-Erze angewandt.

Résumé—On a proposé antérieurement la possibilité d'automatiser l'analyse substoechiométrique par dilution isotopique. On a maintenant réalisé expérimentalement l'automatisation pour les cas où l'analyse est basée sur une extraction par solvant. On décrit des expériences préliminaires au moyen desquelles on peut choisir les conditions optimales pour ce type de détermination automatisée et vérifier la reproductibilité et la sélectivité. A titre d'exemple, on dose des traces de mercure pouvant descendre jusqu'à 5×10^{-8} g et applique la méthode à l'analyse de minerais de cinabre pauvres.

STUDIES IN ATOMIC-FLUORESCENCE SPECTROSCOPY—VI*

THE FLUORESCENCE CHARACTERISTICS AND ANALYTICAL DETERMINATION OF BISMUTH WITH AN IODINE ELECTRODELESS DISCHARGE TUBE AS SOURCE

R. M. DAGNALL, K. C. THOMPSON and T. S. WEST®
Chemistry Department, Imperial College, London S.W.7, England

(*Received* 14 *June* 1967. *Accepted* 7 *July* 1967)

Summary—The atomic-fluorescence characteristics of bismuth atoms in cool nitrogen–hydrogen and argon–hydrogen diffusion flames burning in air are described. Excitation is obtained from the non-resonance iodine line at 2061·63 Å emitted by a microwave-excited electrodeless discharge tube operating at 2450 Mc/s. Fluorescence of the bismuth resonance line at 2061·70 Å is observed and also direct-line fluorescence at 2697 and 3025 Å. In addition thirteen other much weaker lines were observed and two unidentified lines at 2880 and 2680 Å. The emissions at 2628 and 2938 Å appear to arise from "thermally assisted direct line fluorescence". The most intense line at 3025 Å permits linear-dependence analytical atomic-fluorescence measurements to be made in the range 0·1–200 ppm with a detection limit of 0·05 ppm and with no problems of source scatter. No interference was observed from hundred-fold concentrations of fourteen ions. Matrix effects from aluminium and magnesium were overcome by raising the temperature of the cool diffusion flames. A bismuth microwave-excited electrodeless discharge tube was used as a source for atomic-absorption measurement in air–hydrogen and air–propane flames at 2231 Å with a detection limit of 1 ppm and a linear-dependence analytical range of 10–100 ppm. With the iodine microwave-excited electrodeless discharge tube the detection limit for atomic absorption was 10 ppm at 2062 Å.

THE determination of bismuth by flame emission spectrophotometry is difficult because the main resonance line at 3068 Å lies in the middle of the hydroxyl band emission region and hence excessive background radiation is present. In addition, Gilbert[1] has noted absorption by bismuth atoms of the radiation from a hydroxyl band at 3068 Å in an oxy-hydrogen flame, thereby introducing more problems. The other bismuth resonance lines lie in the far ultraviolet and are in consequence difficult to excite thermally. At present, the most sensitive emission studies have been made in the inner cone of an oxy-acetylene flame in conjunction with nebulized organic solvents. Dean[2] gives a limit of detection of 6·4 ppm for bismuth under these most favourable conditions at 2231 Å.

Atomic-absorption measurements have been made at 3068 Å by Gatehouse and Willis,[3] who used a hollow-cathode lamp giving a limit of detection of 2 ppm. They stated that a line at 2320 Å, which we have been unable to detect, gave the strongest absorption, but because of the nearness of another line (at 2319·8 Å, which they attributed to nickel) the calibration curve became flattened above 50 ppm. This is a

* Part V—*Talanta*, 1967, **14**, 1151.

direct consequence of the low intensity output of some hollow-cathode lamps. A similar observation on the use of a conventional hollow-cathode lamp for iron has been made recently by Marshall and West.[4] Absorption studies have also been made with the continuum from a hydrogen lamp as source and with photographic recording of line intensities.[5] The integrated limits of detection in this instance were estimated to be 0·5–1·0 ppm for the 2062, 2231 and 3068 Å lines and 4·0 ppm for the 2228 Å line.

This communication deals with further developments in atomic-fluorescence spectroscopy and the use of microwave-excited electrodeless discharge tubes as spectral sources for atomic-absorption as well as atomic-fluorescence. It also describes the use of cool diffusion flames as atom reservoirs for atomic-fluorescence spectroscopy.

In this investigation the bismuth atoms were excited by the iodine line at 2061·63 Å (corresponding to the $5s^25p^4\ ^3P_2s \rightarrow 5s^25p^5\ ^2P^0_{1/2}$ transition)[6] from an iodine electrodeless discharge tube. This iodine line, which coincides almost exactly with a bismuth resonance line at 2061·70 Å (corresponding to the $^4P_{2\frac{1}{2}} \rightarrow {}^4S^0_{1\frac{1}{2}}$ transition), results from a non-ground-state transition and is hence not subject to self-reversal effects, even when the source is operated at high power ratings. In addition, an iodine discharge tube is as stable and easy to operate as that of an inert gas such as argon. Moreover, the iodine discharge tube does not emit radiation which is concident with the direct-line fluorescence signal from the bismuth atoms at 3025 Å and so scattering from the source is completely eliminated. This latter consideration is of considerable importance because scattering is potentially one of the most serious limitations in atomic-fluorescence spectroscopy. We have not found this to be so in practice.

EXPERIMENTAL

Preparation of electrodeless discharge tubes

Iodine. Quartz tubes between 6 and 7 cm in length and 8 mm internal diameter were prepared as described in previous communications.[7,8,9] The empty tube was heated to red heat with an oxy-propane blow torch and subjected to evacuation for about 10 min. During this time, argon was periodically flushed through the system to sweep away any impurities desorbed from the walls of the tube. After cooling under vacuum, the tube was removed from the vacuum line and a small amount (*ca.* 10 mg) of iodine was added. The tube was then evacuated and as much of it as possible was immersed in a beaker of water at *ca.* 40°. The system was flushed three times with argon to remove any occluded gases or moisture in the iodine. The iodine should not be heated directly with a flame because of its volatility. The tube was finally sealed under an argon pressure of *ca.* 1 mm Hg.

Bismuth. These tubes were prepared in a manner exactly similar to that described previously for antimony,[9] *i.e.*, with *ca.* 10 mg each of bismuth and iodine. A tube 3–4 cm in length, sealed under a final argon pressure of 1·0 mm Hg was found to be most suitable. Tubes containing only bismuth metal were not used, because of its involatility.

Spectral characteristics of discharge tubes

Iodine. These tubes were operated on the lower (0–25 W) range of the generator at 12–15 W with the upper portion of the tube within the cavity. The most stable and intense discharge was obtained by strongly cooling the lower portion (*ca.* 4 cm) of the tube protruding below the cavity, with a stream of air from a compressor. This prevents an undue increase in the vapour pressure of iodine and consequent unstable emission.

The only iodine line observed was the extremely intense one due to the $5s^25p^4\ ^3P_2s \rightarrow 5s^25p^5\ ^2P^0_{1\frac{1}{2}}$ transition at 2061·63 Å *cf.* Fig. 1. The remainder of the spectrum was a broad, low intensity, continuum extending from *ca.* 2400 Å into the visible region. Under optimized conditions of tuning and cooling, the iodine discharge occupied about two-thirds of the tube and in a period of over an hour showed a 1% maximum variation in response (see Fig. 1).

Bismuth. A stable, but low intensity, discharge was obtained by operating the tube at 40 W with only slight cooling. Under these conditions all the spectral lines shown in the Grotrian diagram given by Candler[6] were observed. In addition, a line at 2228 Å, not shown by Candler, was also observed

This line is, however, recorded by Brode[10] and it can be predicted indirectly from the energy difference between the $^4S_{1\frac{1}{2}}$ and $^4P_{1\frac{1}{2}}$ states. It has also been used elsewhere in the atomic-absorption of bismuth.[5] The low intensity of the observed lines is thought to be due to the involatility of bismuth tri-iodide (m.p. 409°). The intensity increased at higher operating power (60–70 W) and the colour of the discharge changed from red-pink to white-blue. An even brighter discharge was obtained without cooling, but under these conditions the tubes became overheated, with eventual loss of stability. The most intense emission obtained in all the various types of discharge was at 3068 Å.

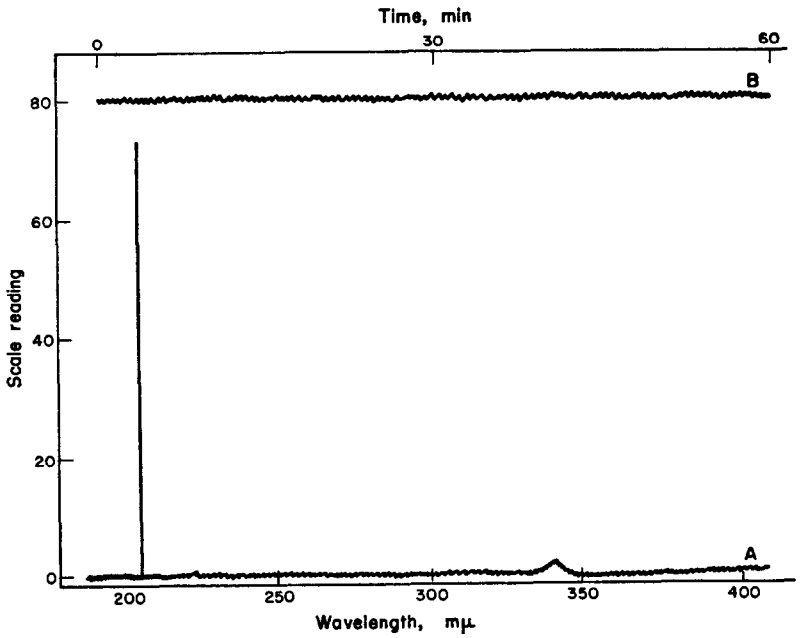

FIG. 1.—(A) Emission spectrum of iodine microwave-excited electrodeless discharge tube at 2450 Mc/s and 12 W.
(B) Stability plot of iodine tube at 2062 Å.

Atomic-fluorescence measurements

Source. The bismuth discharge tubes were examined as sources of excitation, but they were found to be either of rather low intensity or else somewhat unstable. Also, the most intense resonance line present in the discharge, at 3067·72 Å, coincides with a hydroxyl band emission from the flame in this region. In our arrangement[11] both the flame background and fluorescence emission signals are amplified by the a.c. detection system of the Unicam 900A because the source is not modulated. However, even with modulation it would be unwise to measure at this wavelength (*i.e.*, 3067·72 Å) because of variations in the intense flame background.

In consequence, the iodine discharge tube was selected as the most suitable source of excitation because the extremely intense non-resonance iodine line emission at 2061·63 Å is sufficiently close to the 2061·70 Å bismuth resonance line for some absorption by bismuth atoms to occur. The cross-matching of iodine and bismuth spectra does not appear to have been reported previously in the literature, although many instances are known to exist between iron and other elements.[12]

Another unreported instance of cross-matching which we have recently noted in these studies is that between the non-resonance line of arsenic at 2288·12 Å and the cadmium resonance line at 2288·02 Å. It is possible that many other instances exist which can be used with advantage, particularly in atomic-fluorescence spectroscopy, where it is not necessary to have the absorption line profile completely encompass the source line. Under these conditions absorption of the iodine line at 2062 Å would be expected with fluorescence emission from the bismuth resonance line at 2062 Å and direct-line emission at 2697 and 3025 Å.

Flame. Because of its low background a special type of diffusion flame, which has been fairly fully discussed by us elsewhere[13] in a communication concerned with molecular emission spectroscopy in cool flames, was used in these studies. These cool diffusion flames have several advantages over

the hot premixed flames commonly used in atomic-absorption spectroscopy. For comparison, a $10^{-3}M$ solution of bismuth nitrate was nebulized into low background flames and the fluorescence emission was measured at 3025 Å (see below): the flames used were air–propane and air–hydrogen premixed flames and nitrogen–hydrogen and argon–hydrogen diffusion flames. The diffusion flames were obtained with the same burner-head and gas jets as used for the air–hydrogen flame, and the nitrogen or argon was used as the nebulizing gas.

The optimized fluorescence signal was exactly the same in the two premixed flames and in the nitrogen–hydrogen diffusion flame, but was twice as large in the argon–hydrogen diffusion flame. We attribute this difference to the fact that in a collisional encounter the diatomic nitrogen molecules would be expected to absorb energy from the excited bismuth atoms more efficiently than argon atoms, *i.e.*, they would exhibit greater quenching action. The rate of sample uptake was similar (±1%) for all gases and was 1·72 ml/min.

Although diffusion flames are very cool[13] in comparison with the premixed flames which are normally used in thermal-emission and atomic-absorption spectroscopy, and may in consequence be more prone to show matrix effects, they also have considerable advantages. For example, the air–ground radiation propane flame back at 3025 Å is *ca.* 100 times as high as that of the diffusion flames; that of the air–hydrogen flame is *ca.* 25 times as high. This permits lower limits of detection and increased precision in both atomic-absorption and atomic-fluorescence spectroscopy. Because of the low temperatures of diffusion flames, thermal-emission from the alkali and alkaline earth elements is considerably reduced. In the atomic-fluorescence of bismuth no interference was observed from a 100-fold molar excess of sodium and potassium (see below) in a diffusion flame. The transparency of these flames is also of very great significance, especially when dealing with elements which have resonance lines in the far ultraviolet region of the spectrum, *e.g.*, arsenic.[14] This again results in a considerable lowering of detection limits and often a much wider working range becomes available. This is particularly important if an inefficient source is used, *e.g.*, a conventional arsenic hollow-cathode lamp.

Wavelength of measurement. A 200-ppm bismuth solution was nebulized with argon into an argon–hydrogen diffusion flame which was irradiated by an iodine electrodeless discharge tube. The essential optimum conditions of operation were found to be: hydrogen pressure corresponding to a reading of 16 cm on a di-n-butyl phthalate manometer gauge (flame near lift-off point); argon pressure 15 psi; top of the burner head *ca.* 3 cm below the bottom of the analysing monochromator slit. The fluorescence response was found to be rather dependent on the hydrogen pressure and burner head height. Optimized signals were obtained with a hydrogen pressure slightly more than sufficient to prevent flame lift-off and with fluorescence measurements made half way up the flame. The most intense fluorescence signals obtained under these conditions are shown in Table I. A comparison is also made with the less sensitive nitrogen–hydrogen diffusion flame.

TABLE I.—MAJOR ATOMIC-FLUORESCENCE WAVELENGTHS

Spectral line, Å	Fluorescence transition	Slitwidth, mm	Relative fluorescence signal*	
			N_2/H_2	Ar/H_2
2062	$^4P_{2\frac{1}{2}} \rightarrow {}^4S_{1\frac{1}{2}}{}^0$	0·017	6·5	12
2697	$^4P_{2\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}{}^0$	0·017	3	6
3025	$^4P_{2\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}{}^0$	0·017	50	100
3068	$^4P_{\frac{1}{2}} \rightarrow {}^4S_{1\frac{1}{2}}{}^0$	0·017	28	54

* Identical gain for both flames.

As expected, the three fluorescence signals were obtained from the $^4P_{2\frac{1}{2}}$ state. The additional intense signal at 3068 Å must be due to deactivation of the excited $^4P_{2\frac{1}{2}}$ state atom by radiationless transitions to the $^4P_{\frac{1}{2}}$ excited state. The high intensity of the emission at 3068 Å arises because the $^4P_{\frac{1}{2}}$ is the lowest lying excited state and it may be populated by radiationless transfers from other excited states. Moreover, it is the only line other than the 4722 Å ($^4P_{\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}{}^0$ transition), which can be emitted from this state. The analogous behaviour of the $^3P_1{}^0 \rightarrow {}^1S_0$, 2537 Å mercury line can be explained similarly.

In addition to the more intense fluorescence signals shown in Table I, many unexpected and much weaker signals were recorded. These are shown in Table II and are compared to the weakest signal shown in Table I (at 2697 Å), *cf.* Fig. 2. The two lines at 2989 and 2993 Å could not be resolved at the slitwidths used. In addition to these emissions, two unidentified peaks were obtained at 2880 and

TABLE II.—MINOR ATOMIC-FLUORESCENCE WAVELENGTHS

Spectral line, Å	Transition	Relative fluorescence signal N_2/H_2*	Relative fluorescence signal Ar/H_2†

3511	$^2D_{1\frac{1}{2}} \rightarrow {}^2D_{2\frac{1}{2}}{}^0$	6·5	11
4722($6s^26p^27s$)	$^4P_{\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}{}^0$	47	49
2781($6s^26p^28s$)	$^4P_{\frac{1}{2}} \rightarrow {}^2D_{1\frac{1}{2}}{}^0$	4	6·5

* Slitwidth 0·06 mm.
† Slitwidth 0·04 mm. Gain adjusted to give 100 divisions scale reading at 2697 Å in each flame.

2680 Å, and with an increased gain and slitwidth a slight fluorescence signal was obtained at 2110 Å, corresponding to the $6s^26p^28s\ ^4P_{\frac{1}{2}} \rightarrow {}^4S_{1\frac{1}{2}}{}^0$ transition. The 1954, 1959, 2524 and 2810 Å lines from the $6s^26p^27d\ ^2D$ states lie *ca.* 0·3 eV above the $^4P_{2\frac{1}{2}}$ and could not be detected. Also no fluorescence signal was observed from the 2021 Å line ($^2P_{1\frac{1}{2}} \rightarrow {}^4S_{1\frac{1}{2}}$ transition), but this is a very low intensity transition and lies at a wavelength at which the sensitivity of the photomultiplier becomes vanishingly small.

Table I indicates that the ground state bismuth atom can absorb energy from the iodine discharge tube at 2062 Å, be excited to the $^4P_{2\frac{1}{2}}$ state and then give rise to resonance fluorescence at 2062 Å,

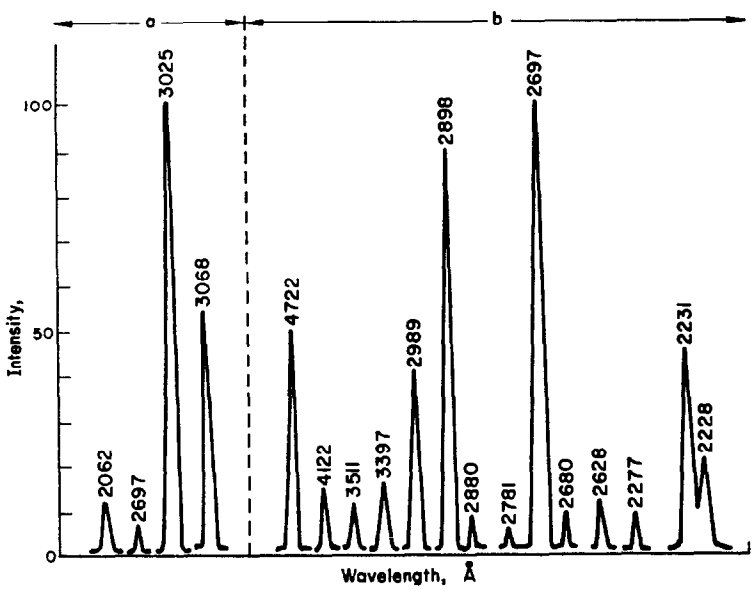

FIG. 2.—Fluorescence emission spectra of bismuth in the argon–hydrogen diffusion flame with iodine microwave tube as source.
(*a*) *cf.* Table I; (*b*) *cf.* Table II.

direct-line fluorescence at 2697 and 3025 Å and multiple stepwise fluorescence at 3068 Å. Although the absolute intensities of these lines vary in the two flames examined, their ratio is constant. This is to be expected because quenching of an excited state should not alter the ratio of line intensities emitted from that state. This effect is again observed for other states shown in Table II.

It is apparent from Tables I and II that not only are the readings obtained in the argon–hydrogen diffusion flame greater than those in the nitrogen–hydrogen diffusion flame under similar conditions, but that the ratio of a given line intensity to the 2697 Å line in the same flame is in general 50% more in the argon–hydrogen flame, for reasons which have already been explained. The fluorescence emissions shown in Table II are of no real analytical significance because their intensity is rather low, but they do give a good indication of the population of the various energy levels. The fluorescence emissions at 2628 and 2938 Å which originate from the $^3P_{1\frac{1}{2}}$ state are examples of *thermally assisted* direct-line fluorescence, which was first postulated in our previous communication on the atomic fluorescence characteristics of antimony.[9] In this instance there must be a radiationless promotion from the $^4P_{2\frac{1}{2}}$ to the $^3P_{1\frac{1}{2}}$ state (energy difference of only 0·12 eV). The other fluorescence emissions shown in Table II may be attributed to stepwise and/or direct-line fluorescence.

TABLE III.—ATOMIC-ABSORPTION MEASUREMENTS
(100 ppm OF BISMUTH)

Spectral line, *Å*	Slitwidth, *mm*	Absorbance
3068	0·003	0·130
2231	0·015	0·348
2228	0·018	0·162
2277	0·020	0·025
2062	0·001	0·028
3025	0·010	0·000

All the fluorescence signals obtained can be attributed to the initial absorption of the 2061·63 Å iodine line. This was verified by the introduction of suitable filters. For example, a 10% solution of acetone in distilled water, contained in a quartz cuvette (1-cm path length) and placed between the monochromator slit and the iodine source, shows complete absorption between 2220 and 3000 Å, with 23·5% and 3% transmittance at 2062 and 3025 Å respectively. These transmission readings are uncorrected for reflection and absorption by the walls of the quartz cuvette. When this filter was interposed between the source of excitation and the flame, the fluorescence signal at 3025 Å decreased from 100 to 24 divisions on the scale. This decrease corresponds almost exactly to the extent of the absorption of the 2061·63 Å iodine line by the acetone filter. Similarly a 0·1*M* nickel chloride filter gave 6 and 80% transmittance at 2062 and 3025 Å respectively. When this filter was placed between the source and flame, the fluorescence signal at 3025 Å decreased from 100 to 6 divisions. This again corresponds to the absorption of the 2061·63 Å iodine line by the filter. Finally, a Pyrex glass filter gave 0 and 50% transmittance at 2062 and 3025 Å and when placed between source and flame produced a fluorescence signal decrease at 3025 Å from 400 divisions to 1. These results prove conclusively that the initial absorption step in the whole fluorescence process is absorption of the 2061·63 Å iodine line.

The 3025 Å line exhibits the greatest sensitivity and there is negligible scattering from the source at this wavelength. Linear calibration curves have been obtained at 3025 Å over the range from $5 \times 10^{-7}M$ to $10^{-3}M$ solutions of bismuth (0·1–200 ppm) and the slope of the log-log curve was 0·93. The limit of detection (signal:noise ratio of 1) in aqueous solution was $2·5 \times 10^{-7}M$, *i.e.*, 0·05 ppm of bismuth, with a slitwidth of 0·2 mm. With the aspirator-nebulizer used in this work, these sensitivity limits can be improved substantially (*ca.* 5-fold) by nebulizing solutions containing solvents to increase the volume of liquid reaching the flame,[11] and possibly also by modulating the radiation from the source to minimize the effects of background radiation and thus permit the use of wider slitwidths (up to 2·0 mm).

Salts of the following selected ions, when present in a 100-fold molar excess over a $10^{-4}M$ bismuth nitrate solution in $4 \times 10^{-2}M$ nitric acid, did not produce a variation of more than 5% in the fluorescence signal; As(III), Cd, Fe(II), Fe(III), K, Na, NH_4, Sb(III) and Zn. Similarly, chloride, nitrate, phosphate, sulphate and tartrate did not interfere. Greater than a 100-fold molar excess of sulphuric acid produced a positive interference because of the strong blue S_2 emission in the diffusion flame.[12] This interference could be eliminated by bleeding a small amount of air into the flame to raise the temperature and oxidize the S_2 species. Aluminium and magnesium in a 100-fold molar excess produced, as expected, significant decreases in the fluorescence signal (40 and 20% respectively).

This interference may be attributed to the formation of oxide particles which "cage" the bismuth and which are not efficiently dissociated by the thermal energy available from the relatively cool diffusion flame. The magnesium suppression may be readily overcome by introducing a small amount of air into the diffusion flame *via* an auxiliary jet in the burner stem.[15] This results in only a slight loss in *overall* sensitivity. In the case of aluminium it was necessary to use an air–hydrogen premixed flame to overcome the interference; the overall sensitivity for bismuth was thereby reduced by *ca.* 50%. Alternatively it may be possible to use an argon–oxygen–hydrogen flame in which the sensitivity loss would not be expected to be so great. There is reason to suppose that many other matrix effects may be readily overcome in the same manner. A diffusion flame burning in oxygen might be equally effective.

Atomic-absorption measurements

Source. The low intensity bismuth electrodeless discharge tubes operated at 40 W with slight cooling were perfectly satisfactory. With the iodine discharge tube as source, a detection limit of 10 ppm was obtained at 2062 Å. This is comparable to the 5·5 ppm detection limit obtained by Manning, Volmer and Fernandez[16] when using a shielded bismuth hollow cathode lamp at the same wavelength.

Flame. The nitrogen–hydrogen and argon–hydrogen diffusion flames used in the fluorescence measurements gave higher (by *ca.* 30%) absorption figures for a given concentration of bismuth than the air–propane and air–acetylene premixed flames when burning on the 7-cm long burner supplied with the instrument. Since background radiation is relatively unimportant in atomic-absorption measurements because the source is modulated (the Unicam SP 900A is operated in its "absorption" mode), the air–propane and air–acetylene flames are recommended to minimize matrix effects. The optimum position for the burner-head was with its top level with the bottom of the monochromator slit.

Table III shows the absorbance measurements obtained at the five resonance lines for a 100-ppm solution of bismuth nebulized into an air–propane flame. The non-resonance line at 3025 Å is included only because of its use in atomic-fluorescence measurements.

The strongest absorption was produced at 2231 Å. At the narrow slitwidths used, this line was completely resolved from the 2228 Å line. It is relevant to note that on this occasion the strongest absorption was not obtained at the same wavelength as the strongest fluorescence signal. The detection limit for bismuth in the present study of atomic-absorbance was found to be 1 ppm and the analytical range 10–100 ppm.

Preparation of calibration curve for atomic-fluorescence

Bismuth solution, 1000-ppm. Dissolve 1·00 g of bismuth metal in 20 ml of concentrated nitric acid and dilute to 1 l. Dilute this solution as required.

Apparatus. The Unicam SP 900A flame spectrophotometer, coupled to a 10-mV Servoscribe recorder, was operated in its "emission" mode. The normal EMI 9529B photomultiplier was replaced by a more ultraviolet-sensitive EMI 9601B photomultiplier.

A "Microtron 200" microwave generator (2450 ± 25 Mc/s) and a model 214L resonant cavity (Electromedical Supplies Limited) were used. Initiation of the discharge was obtained with a simple high-frequency 'Tesla' vacuum-tester.

Flame conditions. A nitrogen–hydrogen diffusion flame was obtained with an acetylene jet in the standard burner base, and the 1·8 × 7·5 cm air–acetylene emission head supplied with the SP 900A (this head is perforated at one end with 13 holes in a 1-cm square). The nitrogen pressure was set at 15 psi and the hydrogen pressure corresponded to 8 cm on the di-n-butyl phthalate manometer gauge. The top of the burner-head was set 3 cm below the bottom of the monochromator slit.

Source conditions. An iodine microwave discharge tube, prepared as described previously, was operated at a power rating of 12 W with a 0·5 cm of the tube extending above and *ca.* 4 cm below the cavity. A moderate degree of cooling was applied by blowing compressed air on the lower 1 cm of tube (the cooling apertures on the cavity were not used). The source was placed *ca.* 8 cm from the centre of the burner-head at right angles to the line from flame to monochromator slit. A 5-mm slit was cut in the burner housing to allow irradiation of the flame.

Procedure. Transfer by pipette 1–10 ml of a 100-ppm bismuth solution into a series of volumetric flasks and dilute to volume with distilled water. Mix and nebulize into the nitrogen–hydrogen flame; use a slitwidth of 0·1 mm, gain 3·1, bandwidth 3, and measure the fluorescence signal at 3025 Å.

Zusammenfassung—Das Atomfluoreszenzverhalten von Wismutatomen in kalten Stickstoff-Wasserstoff- und Argon-Wasserstoff-Diffusionsflammen, die in Luft brennen, wird beschrieben. Angeregt wird mit der Jodlinie (keine Resonanzlinie) bei 2061,63 Å, die von einer elektrodenlosen, mit Mikrowellen erregten Entladungsröhre emittiert wird, die bei 2450 MHz arbeitet. Man beobachtet die Fluoreszenz der Wismut-Resonanzlinie bei 2061,70 Å sowie direkte Fluoreszenz bei 2697 und 3025 Å. Dazuhin wurden dreizehn andere, viel schwächere Linien beobachtet, sowie zwei nicht identifizierte Linien bei 2880 und 2680 Å. Die Emissionen bei 2628 und 2938 Å rühren offenbar von "thermisch unterstützter direkter Fluoreszenz." Die intensivste Linie bei 3025 Å erlaubt analytische Atomfluoreszenzmessungen mit linearer Anzeige im Bereich 0,1–200 ppm mit einer Nachweisgrenze von 0,05 ppm und keinen Problemen durch Streuung von der Lichtquelle. Hundertfache Konzentrationen von 14 Ionen störten nicht. Matrixeffekte von Aluminium und Magnesium wurden durch Erhöhung der Temperatur der kalten Diffusionsflammen überwunden.

Eine mikrowellenerregte elektrodenlose Wismut-Entladungsröhre wurde als Lichtquelle zur Atomabsorptionsmessung in Luft-Wasserstoff- und Luft-Propan-Flammen bei 2231 Å mit einer Nachweisgrenze von 1 ppm und einem linearen analytischen Bereich von 10–100 ppm verwendet. Mit der Jod-Entladungsröhre war die Nachweisgrenze bei Atomabsorption 10 ppm bei 2062 Å.

Résumé—On décrit les caractéristiques de fluorescence atomique des atomes de bismuth dans les flammes de diffusion froides azote-hydrogène et argon-hydrogène brûlant dans l'air. L'excitation est obtenue par la raie de non résonance de l'iode à 2061,63 Å émise par un tube à décharge sans électrode excité par microndes, opérant à 2450 Mc/s On observe la fluorescence de la raie de résonance du bismuth à 2061,70 Å ainsi que la raie directe de fluorescence à 2697 et 3025 Å. En outre, on a observé treize autres raies beaucoup plus faibles et deux raies non identifiées à 2880 et 2680 Å. Les émissions à 2628 et 2938 Å paraissent provenir de la "fluorescence de raie directe thermiquement assistée". La raie la plus intense à 3025 Å permet des mesures analytiques de fluorescence atomique à fonction linéaire dans le domaine 0,1–200 p.p.m. avec une limite de détection de 0.05 p.p.m. et sans problèmes de diffusion de source.

On n'a pas observé d'interférences pour des concentrations cent fois supérieures de quatorze ions. Les effets de matrice de l'aluminium et du magnésium ont été surmontés en élevant la température des flammes de diffusion froides.

On a utilisé un tube à décharge au bismuth sans électrode excité par micro-ondes comme source pour la mesure d'absorption atomique dans des flammes air-hydrogène et air-propane à 2231 Å avec une limite de détection de 1 p.p.m. et un domaine analytique de relation linéaire de 10–100 p.p.m. Avec le tube à décharge à iode sans électrode excité par micro-ondes, la limite de détection pour l'absorpton atomique a été de 10 p.p.m. à 2062 Å.

(*Received* 2 *May* 1967. *Accepted* 16 *June* 1967)

Summary—The oxidation of the redox indicator Variamine Blue in an aqueous medium has been studied by the ESR method. The optimum conditions for the formation of the radical have been determined. The spectra have in some cases shown hyperfine splitting, from which conclusions could be drawn for the nature of the oxidation reaction and structure of the oxidized product. The coupling constants have also been determined for the radicals. The correctness of the assumptions for the structure of the radicals has been supported by the simulation of spectra and the investigation of deuterated derivatives.

VARIAMINE Blue [*N*-(*p*-methoxyphenyl)phenylenediamine] is a redox indicator used in analytical chemistry.[1] Its oxidation mechanism has been investigated by different methods.[2] The potentiometric titration curves obtained for Variamine Blue have shown that relatively stable intermediates are formed during its oxidation. The paramagnetic properties of the intermediates have earlier been proved[3] by ESR analysis. These measurements have been carried out partly on the solid oxidation product isolated from benzene and partly on the aqueous suspension of the product. Owing to the experimental techniques used, no hyperfine splitting could be observed. Therefore the structure of the radical or radical ion could not be studied in detail.

In the present experiments water was used as solvent, both the original compound and its oxidation products being soluble in it; moreover, water is used as the solvent in practice when Variamine Blue is used as an indicator. The high dielectric constant of water, however, is disadvantageous in an ESR investigation, and makes necessary the tedious removal of oxygen by freezing out. The application of capillary cuvettes, however, enabled us to produce spectra which gave information on the structure of radicals formed during the oxidation of Variamine Blue.

EXPERIMENTAL

Variamine Blue and its derivatives used for the investigations were prepared in our laboratories. The compounds were of analytical purity. ESR measurements were carried out with a JES-P-10 type ESR spectrometer. The oxidation products were separated by thin-layer chromatography.

The influence of the pH of the solution, of the stoichiometry of the oxidation reaction, of the nature of the oxidizing agent and of the concentration of the dyestuff have been studied. The change of radical ion concentration has also been measured as a function of time. All measurements were made at room temperature.

The concentration of the radical ion was supposed to be proportional to the height of the amplitude of the derivative curve. The simulated spectra were constructed on a JRA-1 "Spectrum Accumulator".

RESULTS AND DISCUSSION

pH-Dependence of the radical ion concentration

According to earlier measurements the indicator can be used in the pH range between 2 and 6.[4] The formation and concentration of the radical ion have therefore been investigated in our present experiments in the pH range between 0·5 and 5. The compound was oxidized with the Ag^+/Ag redox system, one mole of Variamine Blue being allowed to react with one mole of silver nitrate. The pH was checked in each determination. Figure 1 shows the pH-dependence of the relative radical

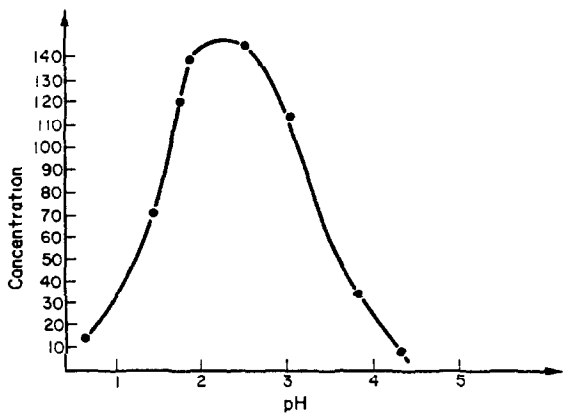

FIG. 1.—pH-Dependence of relative radical concentration.

concentration. The maximum radical ion concentration occurs between pH 2 and 3. As shown by Fig. 1, at pH 1 and pH $>$ 4 hardly any radical ion is present in the solution. Hence the indicator can be used in a wider pH range than that in which the radical ion can exist, and it seems likely that the colour of the oxidized form cannot be attributed to the radical ion.

Influence of the stoichiometry of the oxidation reaction on the radical ion concentration

When three different oxidizing agents were used in buffered solutions, in each case the maximum values of the radical ion concentration occurred at about $\tau = 1$ (Fig. 2). However, the presence of radical ions in small amounts, even at degree of oxidation corresponding to the transfer of two electrons, indicates that the oxidation reaction of the compound is more involved than that assumed to result in the quinone di-imine oxidized form *via* a semiquinone intermediate. It seems likely that the oxidation involves several reaction sequences proceeding in parallel. This assumption has been proved by thin-layer chromatographic separations.

Effect of the nature of the oxidizing agents

The normal redox potential has no influence on the character of the spectrum, but only on the concentration of the radical ion (Fig. 2). The Ce(IV)/Ce(III), Ag^+/Ag and Br_2/Br^- systems were investigated. According to the results of chromatographic separations, products obtained at different dyestuff to oxidant ratios are the same for both the Ag^+/Ag and Ce(IV)/Ce(III) systems, but some of the products obtained with an excess of oxidant are different.

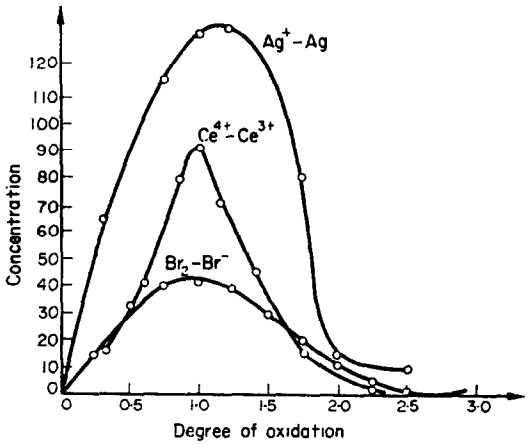

FIG. 2.—Dependence of relative radical concentration on the degree of oxidation.

The change of radical ion concentration with time

The initial period of decomposition has been found to be kinetically second-order (Fig. 3). The shapes of the curves obtained for oxidation with different oxidizing agents have been found to be the same. The reduction of radical ion concentration can be due to recombination or disproportionation. On the basis of experience

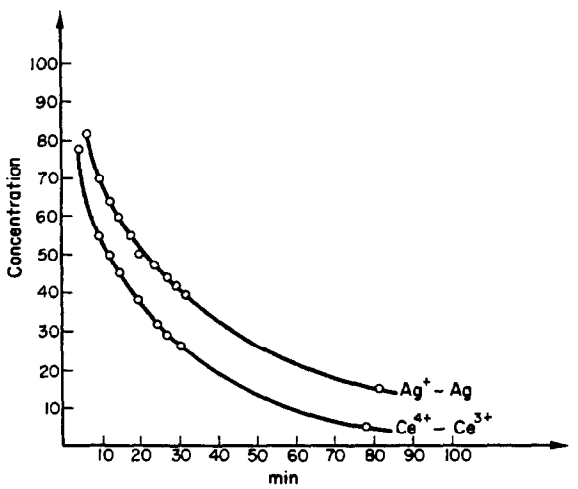

FIG. 3.—Dependence of relative radical concentration on time.

gained in earlier experiments, all concentration determinations were started at a fixed time after mixing the reagents. The amount of radical ion produced is proportional to the initial concentration of reagents. The relationship has been investigated in the concentration range between about 4×10^{-3} and $4 \times 10^{-2} M$; the limits are determined by the signal-to-noise ratio of the instrument and by the solubility of the compound.

Measurement of radical ion concentration

The ratio of radical ion concentration to the produced and initial Variamine Blue concentration has also been studied. Frémy's salt was used as standard. It has been

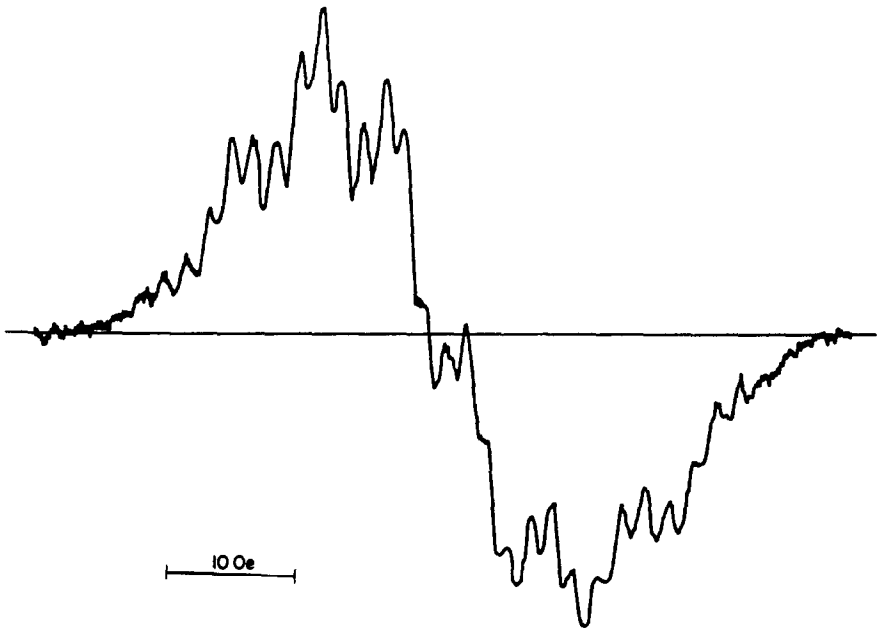

FIG. 4.—ESR spectrum of the radical ion of Variamine Blue.

found by comparing double integrals of the ESR signals that, even under optimal experimental conditions, the paramagnetic intermediate is only formed from 3% of the initial compound in aqueous medium.

Interpretation of the hyperfine splitting of the spectra

The ESR spectrum of oxidized Variamine Blue taken under oxygen-free conditions is shown in Fig. 4. The line diagram in Fig. 5a was drawn by a JRA-1 Spectrum Accumulator. The spectrum contains 8–9 groups of lines which are not well resolved, and 29 lines altogether. No spectrum with better separation could be obtained. In

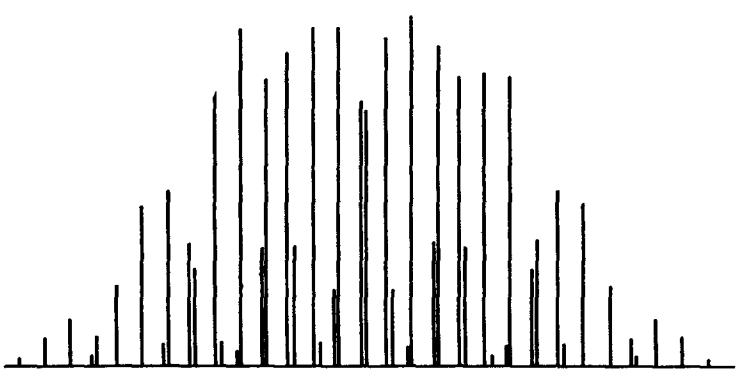

FIG. 5a.—Line diagram of the ESR spectrum of Variamine Blue.

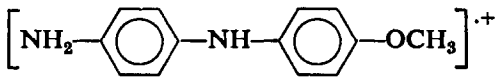
the interpretation of the spectra, literature data concerning the structure of Wurster-type radicals were used.

It has been assumed that the hyperfine splitting of the spectrum is due to the interactions between the two equivalent nitrogen atoms, the three hydrogen atoms attached to them, four further hydrogen atoms and an unshared electron. The radical ion can be assumed to be



The two nitrogen atoms are equivalent because, to a first approximation, the electrophile property of the phenyl group B can be considered as equivalent to the electron repelling effect of the methoxy group in the *para* position, and therefore no large electron shift is caused on the secondary nitrogen atom by the *p*-anisyl group. It also follows that the three hydrogen atoms attached to the two nitrogen atoms are also equivalent. The ratio of the coupling constants of nitrogen and hydrogen atoms can be taken as 3:4 on the basis of the spectra and also from literature data.[5,6,7] The coupling constant for the ring and the four equivalent hydrogen atoms attached to it has been found to be 1. On the basis of these considerations calculations have been made for the simulation of the experimental spectrum. According to these the best coincidence has been obtained with the following coupling constants: $a_N = 5{\cdot}6$ Oe (2N), $a_H = 7{\cdot}6$ Oe (3H), $a_H = 2{\cdot}0$ Oe (4H), and the line width measured between the maxima of the derivative curve was $\Delta H_m = 2{\cdot}3$ Oe. The Lorentz line-shape has been used in the simulation, and no attempt has been made to determine line width correctly. A line diagram and the spectrum calculated by means of the data above are shown in Figs. 5a and 5b respectively. The formation of a radical of the proposed

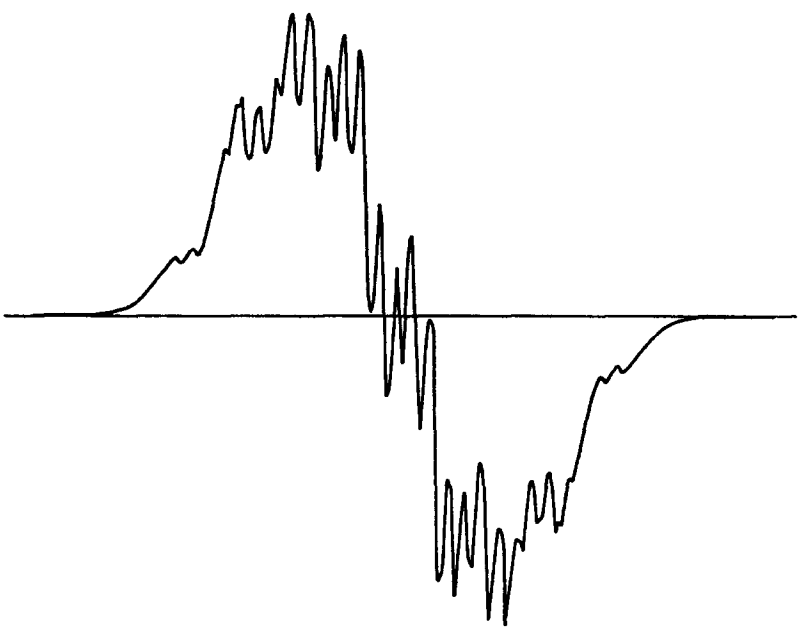


FIG. 5b.—Simulated ESR spectrum of the radical ion of Variamine Blue.

structure is in agreement with our earlier investigations and can be described as follows:

$$\text{Red} \overset{-H^+ \; -e}{\rightleftharpoons} \text{Sem} \rightleftharpoons \tfrac{1}{2}\,\text{Dim} \overset{-H^+ \; -e}{\rightleftharpoons} \text{Ox}$$

or

$$\text{Ox} + \text{Red} \rightleftharpoons 2\,\text{Sem} \rightleftharpoons \text{Dim}$$

where Sem = Semiquinone and Dim = dimer.

The existence of the reactions leading to equilibrium was established by thin-layer chromatographic measurements. If the amount of oxidizing agent corresponding to the transfer of one electron was added to the reduced form, and the mixture separated

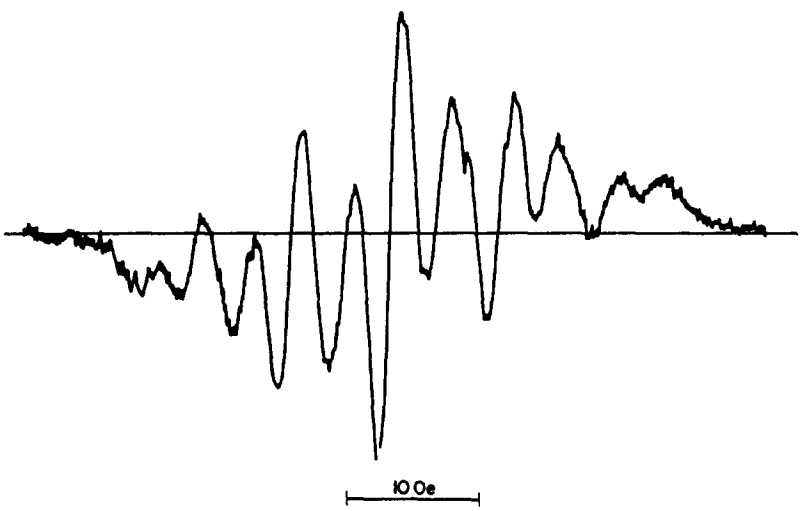

FIG. 6.—ESR spectrum of the *N*-acetyl derivative of Variamine Blue.

by thin-layer chromatography, the initial compound and the oxidized product corresponding to the transfer of two electrons could be found as well as the intermediate. Some unidentified polymeric material was also found. There was also evidence of the production of compounds from a further reaction of *p*-quinonedi-imine. As shown by the relatively small amount of radical ion, the equilibrium between semiquinone and dimer is shifted towards the formation of dimer.

Some derivatives (2-CH_3, 2-CH_3O, 2-COOH, 2-SO_3H and 2-SO_2NHPh) of Variamine Blue have also been studied. All produce an ESR signal, but the splitting in the spectra is not satisfactory. The ESR spectrum of the *N*-acetyl derivative gives good splitting, in which 11 relatively broad lines have been observed (see Fig. 6).

In spite of the fact that the spectrum shows relatively good splitting, two interpretations are possible. The spectrum is essentially a quintet, all the lines of which can be split (*a*) to a triplet with intensity ratios 1:2:1, or (*b*) to a quintet with intensity ratios 1:4:6:4:1. Since the lines partly coincide, only 11 lines can be observed, the widths of neighbouring lines being different because of the inaccuracy of coincidence.

The spectrum corresponding to assumption (b) should contain 13 lines, the two smallest of which (at the ends) overlap with their neighbours almost entirely. The spectra can be simulated by using the following parameters.

(*a*) $a_N = 7{\cdot}6$ Oe (2N), $a_H = 3{\cdot}1$ Oe (2H) and $\Delta H_m = 2{\cdot}1$ Oe

(*b*) $a_N = 7{\cdot}6$ Oe (2N), $a_H = 3{\cdot}0$ Oe (4H) and $\Delta H_m = 2{\cdot}1$ Oe

The simulated spectra are shown in Figs. 7a and 7b, respectively. Analogous reactions have been carried out in heavy water with the purpose of exchanging hydrogen atoms attached to the nitrogen atom for deuterium atoms. The spectra of the deuterated

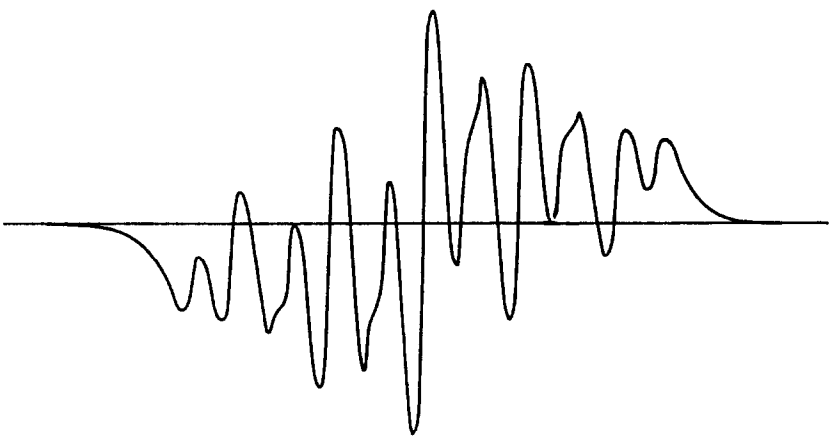

FIG. 7a.—Simulated ESR spectrum of the *N*-acetyl derivative in case (*a*).

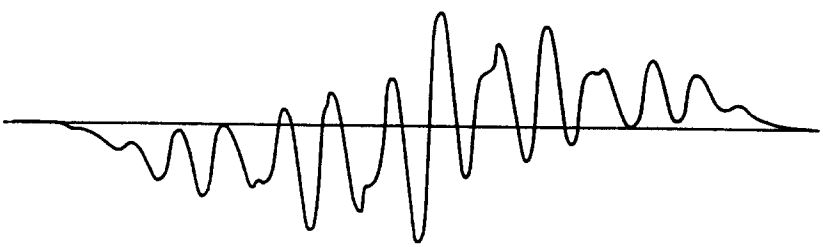

FIG. 7b.—Simulated ESR spectrum of the *N*-acetyl derivative in case (*b*).

products can be interpreted in agreement with the statements above and with the chemical properties of the compounds. The width of the spectrum of deuterated Veriamine Blue was found to be three-quarters that of the original, owing to the difference of the coupling constants for hydrogen and deuterium (Fig. 8). No splitting of the spectrum could be observed.

The simulated spectra show that these changes of the spectrum are to be expected (Figs. 9a and 9b). The $a_{D(N)}$ coupling constant has been calculated from the $a_{H(N)}$ coupling constant, taking the magnetic moments and nuclear spins into consideration

$$\left(a_D/a_H = \frac{\mu_D}{I_D} \cdot \frac{I_H}{\mu_H} = \frac{0{\cdot}8574}{1} \times \frac{1/2}{2{\cdot}7928} = 1/6{\cdot}51\right).$$

Because of this and the actual line-width the lines must coalesce.

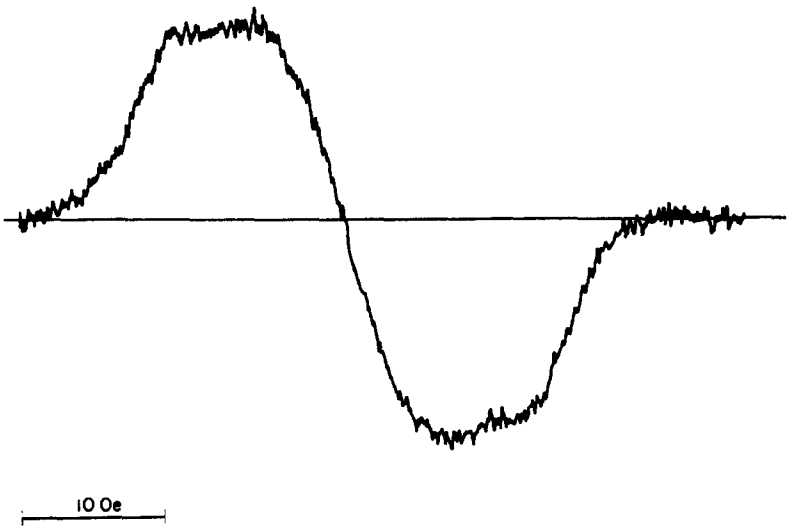

FIG. 8.—ESR spectrum of the radical ion of Variamine Blue in heavy water.

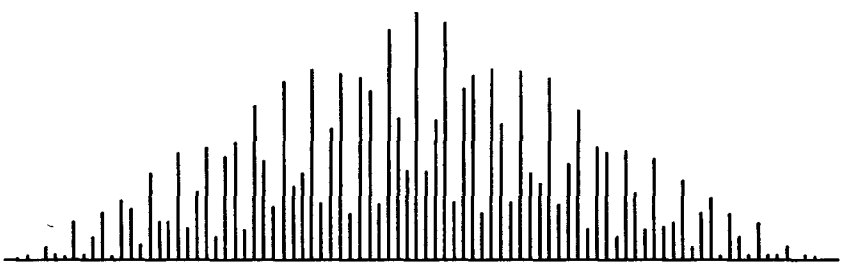

FIG. 9a.—Line diagram of the spectrum shown in Fig. 8.

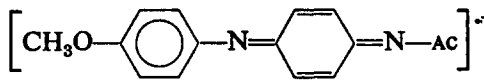
FIG. 9b.—Simulation of the spectrum shown in Fig. 8.

In contradiction to this, no change could be observed in the spectrum of the *N*-acetyl derivative under the given conditions, indicating that hydrogen–deuterium exchange has not taken place. This could be due to the reduced basicity of the *N*-acetyl derivative. One cannot, however, reasonably assume that this reduction in basicity would be large enough to make the exchange impossible even in strongly acidic solution. Therefore it seems more likely that the radical does not contain hydrogen atoms attached to nitrogen atoms, *i.e.*, its structure can be assumed to be



This structure corresponds to the transfer of three electrons but is in agreement with such facts as the low radical concentration. The ratio of coupling constants (a_H/a_N = 0·40) also suggests that the protons causing splitting are attached to the ring and not to nitrogen atoms (for Variamine Blue $a_{H(N)}/a_N$ = 1·36, and a_H/a_N = 0·36). The spectrum of the *N*-acetyl derivative can be therefore interpreted by assumption (b), and the structure described above.

Acknowledgement—We should like to thank B. Turcsányi and G. Koszterszitz for their help with the measurements and interpretation of spectra.

Zusammenfassung—Die Oxidation des Redoxindikators Variaminblau in wäßriger Lösung wurde mit der Elektronenspinresonanzmethode untersucht. Die optimalen Bedingungen zur Bildung des Radikals wurden ermittelt. Die Spektren zeigten in einigen Fällen Hyperfeinstrukturaufspaltung, aus der Schlüsse über die Natur der Oxidationsreaktion und die Struktur des oxidierten Produkts gezogen werden konnten. Die Kopplungskonstanten der Radikale wurden auch bestimmt. Die Richtigkeit der Annahmen über die Struktur der Radikale wurde bekraftigt durch die Simulierung von Spektren und die Untersuchung deuterierter Derivate.

Résumé—On a étudié l'oxydation de l'indicateur redox Bleu de Variamine en un milieu aqueux par la méthode RSE. On a déterminé les conditions optimales pour la formation du radical. Dans quelques cas, les spectres ont montré un dédoublement hyperfin, à partir duquel on a pu tirer des conclusions sur la nature de la réaction d'oxydation et la structure du produit oxydé. On a également déterminé les constantes de couplage pour les radicaux. L'exactitude des hypothèses pour la structure des radicaux a été étayée par la simulation de spectres et l'étude de dérivés deutérés.

PUBLICATIONS RECEIVED

Optical Rotatory Dispersion and Circular Dichroism in Organic Chemistry: Editor, G. SNATZKE Heyden, London, 1967. pp. 416. 96s.

This collection of invited lectures, given at the N.A.T.O. Summer School on Optical Rotatory Dispersion and Circular Dichroism, Bonn, 1965, although primarily devoted to applications in organic chemistry, also includes significant contributions on inorganic, biochemical and high polymer topics. The opening chapters, contributed by some of those most responsible for the recent widespread renewal of interest and activity in the subject, form an excellent introduction for those unfamiliar with O.R.D. and C.D. The succeeding chapters well illustrate the tremendous range of modern developments in the field, that on magnetically induced optical activity being particularly valuable. The volume is well produced and the text adequately illustrated with diagrams and formulae. Particularly useful as an introduction both to the phenomena of O.R.D. and C.D. and to current developments this book will appeal to those interested in optical activity at any level.

Reagent Chemicals and Standards, 5th Ed: JOSEPH ROSIN. Van Nostrand, Princeton, New Jersey, 1967. pp. vii + 641. 132s.

The most significant addition to the text in this latest edition is a section dealing with the technique of flame photometry. This has been necessitated by the wide application of this technique in the analysis of trace impurities and many methods based on flame photometry are described separately. Among the other additions are new reagents and dyes such as osmium tetroxide and Eriochromecyanine.

Progress in Nuclear Energy, Series IX, Analytical Chemistry, Vol. 8, Pt. 1: Editors, H. A. ELION and D. C. STEWART, Pergamon, Oxford, 1967. pp. 139. 45s.

This volume contains three well-grouped articles on the analytical chemistry of protactinium (D. Brown and A. G. Maddock) and actinium (H. W. Kirby) and analysis of essential nuclear reactor materials by extraction photometry with oxine and 2-methyloxine. All show evidence of practical experience, sometimes painfully gained, and this is reflected in a lively style. The sections on protactinium and actinium also contain much information of general chemical interest. The standard of production of the series is maintained; though flexi covers have replaced hard covers the price per page remains constant.

Methodes D'Analyse, CETAMA-1966, Methodes 151-200: Commissariat a L'Energie Atomique, Presses Universitaires de France, Paris, 1967. F 75.

This is a collection of tried and proven methods of analysis used in French atomic energy establishments. Each is laid out in an exemplary way, with extremely clear instructions on how to prepare for the analysis, how to execute it and how to treat the results. Although the methods are devised for materials of specialized interest, many would appear to have general applicability. Many approaches are used, *e.g.*, titrimetry, spectrophotometry, fluorimetry, neutron-activation, spectrography, polarography and radioactivity, and methods for thirty different elements are reported.

Use of submicroanalysis and flame ionization detecting gas–liquid chromatograph in the identification of electrolysis products at the dropping mercury electrode: D. BARNES, R. BELCHER and P. ZUMAN (21 *June* 1967)

Preliminary investigation of the application of electroluminescence techniques to the determination of aromatic hydrocarbons: B. FLEET, G. F. KIRKBRIGHT and C. J. PICKFORD (22 *June* 1967)

Spectroscopy in separated flames—II. The use of the separated air–acetylene flame in atomic absorption spectroscopy: D. N. HINGLE, G. F. KIRKBRIGHT and T. S. WEST (22 *June* 1967)

Studies in imidazole derivatives as chelating agents—IV. Stability constants of the metal chelates of azomidazoles: OSAMU YAMAUCHI, HISASHI TANAKA and TOYOZO UNO (22 *June* 1967)

Studies on imidazole derivatives as chelating agents—V. Investigations of the applicabilities of the azomidazoles as metallochromic indicators: OSAMU YAMAUCHI, HISASHI TANAKA and TOYOZO UNO (22 *June* 1967)

Determination of potassium in fertilizers and related materials by an automatic UV absorption method: J. M. SKINNER and A. C. DOCHERTY (26 *June* 1967)

Comparisons of metal bath techniques in vacuum fusion analysis by an isotope dilution method: H. KAMADA and K. FURUYA (27 *June* 1967)

Spectrophotometric study of the mercury(II)–Xylenol Orange chelate: H. H. WALKER and J. A. POOLE (28 *June* 1967)

Cation-exchange behaviour of several elements in hydrofluoric acid-organic solvent media: J. KORKISCH and A. HUBER (3 *July* 1967)

Gravimetric determination of perchlorate ion as tetraphenylarsonium perchlorate: TEIJI OKUBO and FUMIO AOKI (3 *July* 1967)

Spectrophotometric determination of ferric ions with *o*-hydroxybutyrophenone oxime: M. H. GANDHI and MAHENDRA N. DESAI (3 *July* 1967)

Spectrophotometric determination of iron with 2,4-dihydroxybutyrophenone oxime: M. H. GANDHI and MAHENDRA N. DESAI (3 *July* 1967)

Flavones as analytical reagents—A review: MOHAN KATYAL (4 *July* 1967)

Spectrophotometric study and micro-determination of copper by the pyridine-phenylpyruvic acid oxime system: MOHAN KATYAL, K. C. TRIKHA and R. P. SINGH (4 *July* 1967)

Precipitation of beryllium in presence of succinate by the urea hydrolysis technique: T. P. PRASAD and M. N. SASTRI (4 *July* 1967)

Extraction of titanium(IV) gallate into tri-isoctylamine and its spectrophotometric determination: KULUMANI R. KRISHNAMURTHY and CH. VENKATESWARLU (5 *July* 1967)

Use of 1-phenyl-3-methyl-4-capryl-pyrazolone-5 in the liquid-liquid extraction method for the carrier free production of ^{115m}In: M. Y. MIRZA (10 *July* 1967)

Volumetric determination of the U/O-ratio in uranium oxides: J. J. ENGLEMAN, J. KNAAPE and J. VISSER (10 *July* 1967)

Determination of palladium, platinum and rhodium in geologic materials by fire assay and emission spectrography: JOSEPH HAFFTY and LEONARD B. RILEY (14 *July* 1967)

Kinetic titration with thermometric determination of the end-point: I. SAJÓ (14 *July* 1967)

Spectrophotometric determination of aluminium with Eriochrome Azurol B: HIRAKO KANEKO and KEIJI KANEKO (18 *July* 1967)

Metal chelates of uranium(VI) and thorium(IV) with ammonium aurintricarboxylate: a potentiometric study: AMITAV BANERJEE and ARUN. K. DEY (18 *July* 1967)

Metal chelate exchange in the organic phase—II. Extraction and exchange constants of dithizonates and diethyldithiocarbamates: J. STARÝ and J. RŮŽIĆKA (18 *July* 1967)

Talanta, 1967, Vol. 14, p. i. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

Elektronisches Rechnen in den Analytischen Chemie—IV. Algol-Prozedur für Ausgleichsfunktionen mit zwei Konstanten: G. GOTTSCHALK (26 *April* 1967)

Gravimetric and spectrophotometric determination of hexafluoroantimonate utilizing tetraphenylarsonium chloride, nitron and ferroin: VERNON S. ARCHER and RONALD B. TWELVES (19 *May* 1967)

Continuous substoichiometric determination of traces of mercury by radioactive isotope-dilution analysis: G. B. BRISCOE, B. G. COOKSEY, J. RŮŽIČKA and M. WILLIAMS (22 *May* 1967)

Determination of tervalent chromium and iron in chromic acid: D.L. FUHRMAN and G. W. LATIMER, JR. (22 *May* 1967)

Controlled potential coulometric determination of uranium and neptunium in uranium-neptunium alloys: C. E. PLOCK and W. S. POLKINGHORNE (25 *May* 1967)

Studies of current-time curves of mature polarized mercury drops: S. LAL, P. S. JAIN and S. N. SRIVASTAVA (26 *May* 1967)

Analytical applications of ternary complexes—V. Indirect spectrophotometric determination of cyanide: R. M. DAGNALL, M. T. EL-GHARMY and T. S. WEST (29 *May* 1967)

Spektrophotometrische Bestimmung von Kupfer mit 2.3.8.9-dibenzo-4,7-dimethyl-5.6-dihydro-1.10-phenanthrolin (Cuprotest): G. ACKERMANN and W. ANGERMANN (29 *May* 1967)

Neutron-activation analysis by standard addition and solvent extraction. Determination of traces of antimony: A. ALIAN, B. ALIAN and H. KHALIFA (31 *May* 1967)

Polarographic currents in potassium peroxydisulphate—alkali systems and the analysis of peroxydisulphate ion: E. HAKOILA (5 *June* 1967)

Remarks on hexaminecobalt(III)carbonatoberyllate: R. G. MONK (5 *June* 1967)

Investigation of magnesium ammonium phosphate by derivatography: F. PAULIK, E. BUZÁGH-GERE and L. ERDEY (5 *June* 1967)

Replacement substoichiometry and its application in activation analysis: IVAN OBRUSNÍK and ARNOLD ADÁMEK (6 *June* 1967)

Switching valves for use in multi-column gas chromatography: J. R. CONDER, J. H. PURNELL and R. WALSH (12 *June* 1967)

Identification of thiols by means of mercurated fluorescein: MIECZYSLAW WRONSKI (13 *June* 1967)

Note on the various methods of ion separation by electrolytic migration in a counter-current solution: D. BEHNE, B. A. BILAL, H. D. FREYER and W. THIEMANN (14 *June* 1967)

Studies in atomic-fluorescence spectroscopy—VI. The fluorescence characteristics and analytical determination of bismuth, using an iodine electrodeless discharge tube as source: R. M. DAGNALL, K. C. THOMPSON and T. S. WEST (14 *June* 1967)

Talanta, 1967, Vol. 14, p. i. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

Mass spectrometry of metal chelates—II. Oxinates of common metals: A. E. JENKINS, J. R. MAJER and M. J. READE (24 *April* 1967)

Neutron-activation analysis of manganese in polysulphide materials: F. J. CONRAD and B. T. KENNA (24 *April* 1967)

Determination of organic fluoride down to 0·2 ppm in hydrocarbons: M. MILLER and D. A. KEYWORTH (26 *April* 1967)

Determination of stable strontium environmental media: A. B. STRONG, G. L. REHNBERG and U. R. MOSS (27 *April* 1967)

High-speed computers as a supplement to graphical methods. HALTAFALL, a general program for calculating the composition of equilibrium mixtures: NILS INGRI, WŁAYYSŁAW KAKOŁOWICZ, LARS GUNNAR SILLÉN and BJÖRN WARNQVIST (27 *April* 1967)

A novel multi-column gas chromatograph system: J. H. PURNELL and B. C. SHURLOCK (27 *April* 1967)

Determination of microamounts of beryllium in urine: S. R. DESAI and KUM. K. SUDHALATHA (1 *May* 1967)

Microdetermination of the azide group in organic compounds: W. I. AWAD, Y. A. GAWARGIOUS and S. S. M. HASSAN (2 *May* 1967)

Electron spin resonance analysis of the redox indicator Variamine Blue—II: L. ERDEY, T. MEISEL, B. MOHOS and F. TUDOS (2 *May* 1967)

Application of zone-melting technique to metal chelate systems—II. Concentration of a trace amount of metal acetylacetonate in chromium(III) acetylacetonate: HISAMITSU KANEKO, HIROSHI KOBAYASHI and KEIHEI UENO (4 *May* 1967)

Application of zone melting technique to metal chelate systems—IV. Concentration of metal-8-hydroxyquinoline chelates in 8-hydroxyquinoline: HISAMITSU KANEKO, HIROSHI KANAGAWA, HIROSHI KOBAYASHI and KEIHEI UENO (4 *May* 1967)

Spectrophotometric studies of ruthenium(III) and rhodium(III)-oximidobenzotetronic acid complexes and the simultaneous determinations of the two metals: G. S. MANKU, A. N. BHAT and D. B. JAIN (5 *May* 1967)

Redox reactions of columns: R. BELCHER, R. J. MAJER and G. A. H. ROBERTS (8 *May* 1967)

Studies on metallochromic indicators—II. Zincon and some of its metal derivatives: G. L. SINGHAL and K. N. TANDON (8 *May* 1967)

Separation and identification of some naturally occurring alkylphenanthrenes: ROLF JÖNSSON (15 *May* 1967)

LOUIS GORDON MEMORIAL AWARD

To commemorate the late Professor Louis Gordon, who was closely associated with TALANTA from its inception, the Publisher and the Editorial Board have instituted an annual Memorial Award. In view of Professor Gordon's deep interest in analytical chemistry and the presentation of scientific reports, the Award will be made to the author (or authors) of the TALANTA paper adjudged to be the best-written, stylistically, of the year. All full papers in English, French or German will be considered. The Award will take the form of a specially bound copy of the volume of TALANTA containing the paper chosen.

The Award for 1966 has been made to FOLKE INGMAN and EBBE STILL for their paper "Graphic Method for the Determination of Titration End-points" in *Talanta*, 1966, **14**, 1431.

Talanta, 1967, Vol. 14, p. i. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

Photometrische Bestimmung von Kupfer mit Polyäthylenimin: MAX ZIEGLER and LÜDER ZIEGELER (6 March 1967)

Die Anwendung von Komplexbildnern in der polarographischen Analyse anorganischer Verbindungen—XIII. Polarographisches Verhalten der Komplexverbindungen des Mangans mit Mannit: JAN DOLEŽAL and OSWALD GÜRTLER (20 March 1967)

Application of isotopic exchange for the activation analytical determination of tin in nickel: M. CSAJKA (20 March 1967)

Studies in atomic fluorescence spectroscopy—V. The fluorescence characteristics and analytical determination of antimony: R. M. DAGNALL, K. O. THOMPSON and T. S. WEST (21 March 1967)

Complexation reactions of dithiocarbamates: ADAM HULANICKI (22 March 1967)

Chromatographic location and colorimetric determination of mercaptans, prolines, and free radical precursors: E. SAWICKI, C. R. ENGEL and W. C. ELBERT (23 March 1967)

Use of complex forming substances in polarographic analysis of inorganic compounds: Polarographic determination of manganese in minerals: OSWALD GÜRTLER and JAN DOLEŽAL (30 March 1967)

Mass spectrometric analysis of high purity helium and hydrogen, using a dynamic sampling and calibration system: R. T. PARKINSON (30 March 1967)

Ion-exchange behaviour of several elements in mixed solvents: T. CUMMINGS and J. KORKISCH (30 March 1967)

New titrimetric microdetermination of lanthanum: J. D. PANDEY and O. C. SAXENA (30 March 1967)

Gravimetric determination of copper(II) with *p*-amino benzoic acid: L. ERDEY, P. MARIK-KORDA and G. LIPTAY (30 March 1967)

Application of ion-associates of tris(1,10-phenanthroline)iron(II) with anions of organic dyes for sensitivity improvement of photometric iron determination: M. KNIŽEK and M. MUSILOVÁ (30 March 1967)

Polarographic behaviour of metal chelates of *o,o'*-dihydroxyazo dyes: GEORGE W. LATIMER, JR. (30 March 1967)

Successive chelatometric titration for calcium and magnesium in water with BNP: K. TÔEI and T. KOBATAKE (30 March 1967)

Studies in vanadium(IV) complexes of Azoxine S dyes: S. S. GOYAL and J. P. TANDON (30 March 1967)

Polarographic microdetermination of halogens in organic compounds after oxygen flask combustion: F. M. HABASHY, Y. A. GAWARGIOUS and B. N. FALTAOOS (30 March 1967)

Application of urease for the precipitation of nickel dimethylglyoximate by urea from homogeneous solution: SEIICHIRO HIKIME, HITOSHI YOSHIDA and MITSUHIKO TAGA (31 March 1967)

On amino-acid chromatograms obtained through development by means of ninhydrin, later studied in a hydrochloric acid medium: J. SZÁNTAY and P. SZABÓ (31 March 1967)

Oxalato compounds of tervalent thallium: A potentiometric study: S. R. SAGI and V. RAMANAK (31 March 1967)

Spectroscopic studies on scandium 8-hydroxyquinolates: TERENCE J. CARDWELL and ROBERT J. MAGEE (31 March 1967)

Selective spot test for hydrazine: T. A. LARUE (31 March 1967)

Oxidation of some sugars with copper(III): S. CHANDRA and K. L. YADAVA (1 April 1967)

Interaction of Dowex A-1 chelating resin with sparingly soluble calcium salts: E. SEGALL and G. SCHMUCKLER (4 April 1967)

Amperometric determination of neodymium(III) as tungstate: M. P. JOSHI and C. M. GUPTA (7 April 1967)

Neutron activation analysis by standard addition and solvent extraction. Determination of certain impurities in thorium and iron: A. ALIAN and R. SHABANA (12 April 1967)

New spectrophotometric method for the estimation of bismuth with EDTA: N. A. RAMAIAH, G. D. TEWARI, S. R. TRIVEDI and SARVAGYA S. KATIYAR (12 April 1967)

Studies on uranyl complexes—II. Uranyl complexes of EDTA: J. J. R. FRAÚSTO DA SILVA and M. LOURDES SADLER SIMÕES (13 April 1967)

Direct titration of glycerol by constant current potentiometry: J. R. SAND and C. O. HUBER (13 April 1967)

Fluorescent aluminium indicators derived from substituted coumarins: J. F. AGUILÁ (14 April 1967)

Co-ordinating properties of some ligand systems related to 4-(2-pyridylazo)-resorcinol: R. G. ANDERSON and G. NICKLESS (19 April 1967)

Homogeneous precipitation of basic aluminium benzoate using a buffer solution: R. J. IRVING (19 April 1967)

TALANTA MEDAL

PROFESSOR EGON STAHL

The Editorial Board of *Talanta*, has pleasure in announcing that, with the approval of the Advisory Board, the Fourth Award of the Talanta Medal (see *Talanta*, 1966, **13**, 1052) has been made to

PROFESSOR EGON STAHL

of the Institute for Pharmacognosy and Analytical Phytochemistry, University of Saarland, German Federal Republic.

Thin-layer chromatography (TLC) is simple, rapid, relatively inexpensive, versatile, and it requires very little working material. Today its use is almost routine in many organic laboratories (natural product, pharmaceutical, lipid) and the technique is becoming increasingly applied to more polar molecules. However, application of TLC mushroomed only after 1958.

Chromatography on thin layers of adsorbent was conceived as early as 1938, but its development and adoption were slow because equipment and reagents were not available commercially. These obstacles were removed by Egon Stahl, who devised a system involving standard-size glass plates, a new apparatus for preparation of thin layers, and a standard adsorbent (silica-gel-gypsum); these were presented to ACHEMA in 1958. The apparatus became commercially available from Desaga (Heidelberg) and the adsorbent from Merck (Darmstadt). Variables of the technique were studied systematically by Professor Stahl and his co-workers; they applied it to many new types of organic compound and pioneered the use of new adsorbents, which immediately became available commercially. Stahl called the method "Dünnschicht Chromatographie" or "thin-layer chromatography", which remains the most widely accepted name. His further contributions to TLC since 1958 have ensured that he remains constantly at the frontiers of its development.

Talanta, 1967, Vol. 14, p 1 Pergamon Press Ltd Printed in Northern Ireland

PUBLICATIONS RECEIVED

Laboratory Handbook of Chromatographic Methods: Editor O. MIKEŠ. Van Nostrand, London, 1966. Pp. 434. 75*s*.

An interesting book which collects together a large amount of information on all chromatographic techniques and electrophoresis. The material has been supplied by Czech authors with great experience in the field and the translation is excellent. The treatment is practical and the book will be valuable to third year students and research workers, particularly those associated with the medical and biological sciences.

Advances in Chromatography, Vols. 1, 2 and 3: Editors J. CALVIN GIDDINGS and ROY A. KELLER, Arnold, London, 1965 and 1966. Pp. XV + 392, XVI + 377 and XIII + 271. £6, £6 and 95*s*.

Each volume of this series contains a group of surveys on paper and thin-layer chromatography, electrophoresis and gas chromatography. The contributors are themselves well known workers in the fields which they discuss and their contributions contain more experimental detail than that normally found in a competent literature survey. In sections where checking was possible, the coverage was found to be complete. The series will be useful to the research worker in most fundamental and applied disciplines.

XXth International Congress of Pure and Applied Chemistry. Butterworths, London, 1965. Pp. v + 365. 75*s*.

The Congress Lectures presented in Moscow, 12–18 July 1965.

Index to Reviews, Symposia Volumes and Monographs in Organic Chemistry for the Period 1963–1964: NORMAN KHARASCH and WALTER WOLF. Pergamon, Oxford, 1966. Pp. x + 326. 105*s*.

Dynamics of Chromatography. Part 1: Principles and Theory: J. CALVIN GIDDINGS. Arnold, London, 1965. Pp. xii + 323. 90*s*.

This is a useful addition to the extensive range of books on chromatography in that it deals with the fundamental theory of the chromatographic process rather than its application. There is a very interesting section in which the "random walk" concept is applied to the theory of zone spreading. The book can be recommended to final year and post-graduate science students.

Handbuch der mikrochemischen Methoden, Vol. IV: Electronenstrahl-Mikroanalyse: HANNS MALISSA. Springer, Vienna, 1966. Pp. 154. 49 DM.

This is a comprehensive and most readable introduction to a rather new branch of analytical chemistry, and is especially welcome as the first in its field in the German language. The book is well illustrated, and has an up to date bibliography. There are chapters on Theoretical Principles of Electron Probe Microanalysis, Equipment and Applications, Measurement Techniques and Practical Examples.

NOTICE

U.S.A.

9–11 *August* 1967: **Denver X-Ray Conference on Applications of X-ray Analysis.** In or Near Denver, Colorado.

Papers are now invited on fundamental and practical applications of X-ray analysis. Technical emphasis this year is to be placed on the subject of quantitative chemical analysis by X-ray fluorescence. Titles and abstracts are due 10 April 1967 (*two* copies, please). Abstracts should be between 200 and 400 words in length. Final manuscripts (also two copies) are due 10 July. The author's written consent to publish in the copyrighted proceedings of the conference are also required at this time.

OBITUARY

It is with regret that we announce the death in Prague, on 27th March 1967 at the age of 76, of JAROSLAV HEYROVSKÝ. Formerly Head of the Division of Physical Chemistry of Charles University in Prague, Professor Heyrovský is well known for his invention and pioneer development of polarography and polarographic analysis, for which he was awarded the Nobel Prize in 1959.

Readers of *Talanta* will recall that Professor Heyrovský's seventy-fifth birthday (December 1965) was honoured by publication of a special issue of the journal, comprized entirely of invited contributions from his former students and associates

The Czechoslovak Academy of Sciences has lost one of its best members, and the Polarographic Institute in Prague its first (and eponymous) director

ADVISORY BOARD OF TALANTA

The Editorial Board and Publishers of *Talanta* take pleasure in welcoming the following new members to the Advisory Board of the journal

T. HADJIIOANNOU G. TÖLG

THEMISTOCLES HADJIIOANNOU (Greece) was born in 1927 and studied at University of Thessaloniki. In 1960 he received his Ph.D. at University of Illinois, where he subsequently became Assistant Professor. He is currently Director of the Laboratory of Analytical Chemistry at University of Athens. His research interests include spectrophotometric titrations, isomation techniques, ion specific transducers, complexometry, and trace analysis by catalytic methods.

Born in 1929, GÜNTHER TÖLG (German Federal Republic) received his education in chemistry at Johannes Gutenberg-University in Mainz. He became Diplomchemiker in 1956 and Dr. rer. nat. in 1959 under Professor W. Geilmann. Since 1965 he has been Dozent of Analytical Chemistry at Mainz. His research activities are in organic and inorganic trace- and ultramicroanalysis, especially development of accurate methods for determination of extremely small amounts of elements in organic compounds and materials and investigation of the animal metabolism of pesticides.

PAPERS RECEIVED

Ein Schnellverfahren zur Rheniumbestimmung in Molybdänit: L. BALABANOFF, F. BERNASCONI H. LARA and R. WOERNER. (25 *November* 1966)

Determination of uranium in electro-refined plutonium by a combined ion-exchange X-ray fluorescenc e technique: J. A. HAYDEN (18 *January* 1967)

A high-speed micro-vacuum fusion apparatus: M. T. LILBURNE (23 *January* 1967)

Present state of complexometry—IV. Determination of rare earths: RUDOLF PRIBIL (23 *January* 1967)

End-point sharpness in thermometric titrimetry: H. J. V. TYRRELL (23 *January* 1967)

Determination of trace amounts of sulphur in selenium: BRITT-LOUISE SJÖBORG (24 *January* 1967)

Critical micelle concentration determination of non-ionic surfactants by electrocapillary curves: WAHID U. MALIK, PURAN CHAND and S. M. SALEEM (26 *January* 1967)

Polarographic reduction behaviour of clay minerals: WAHID U. MALIK and G. C. GUPTA (26 *January* 1967)

Aspects of the precipitation of nickel dimethylglyoximate: S. J. LYLE and R. MAGHZIAN (27 *January* 1967)

Determination of radioactive cobalt in reactor coolant water by solvent extraction: KENJI MOTOJIMA, SHOJI BANDO and NORI TAMURA (30 *January* 1967)

Separation of copper and iron in their different valency states by paper chromatography: P. B. JANARDHAN and AGNES PAUL (31 *January* 1967)

Reactions of Eriochrome Blue Black R: G. L. SILVER and R. C. BOWMAN (2 *February* 1967)

Polarographic behaviour of Mo(VI) in aspartic acid and its determination: C. M. GUPTA and J. K. GUPTA (2 *February* 1967)

Spectrophotometric determination of chromium with Xylenol Orange and Methylthymol Blue: K. L. CHENG (3 *February* 1967)

Analytical method for the determination of ^{3}H and ^{85}Kr in aqueous samples by liquid scintillation techniques: J. B. COHEN, J. L. SETSER, W. D. KELLEY and S. D. SHEARER, JR. (4 *February* 1967)

Decomposition of thiosulphate in acidified oxidants: G. W. LATIMER, JR. and ELAINE I. STETEKO (4 *February* 1967)

Determination of barium in sea water by a cation-exchange concentration procedure: BARNEY J. SZABO and OIVA JOENSUU (4 *February* 1967)

Microchemical detection of isocyanides: E. V. CRABTREE, E. J. POZIOMEK and D. J. HOY (4 *February* 1967)

Gas-chromatographic examination of organophosphorous pesticides and their oxidation products: J.RUZICKA, J. THOMSON and B. B. WHEALS (6 *February* 1967)

Solvent extraction of amine complexes: M. KYRŠ and M. PIVŮNKOVÁ (8 *February* 1967)

APDC-MIBK extraction system for the determination of trace elements in saline waters by atomic-absorption spectrophotometry: ROBERT R. BROOKS, BOB J. PRESLEY and ISAAC R. KAPLAN (8 *February* 1967)

Promethazine hydrochloride as a new redox indicator in vanadametry: H. SANKE GOWDA, R. SHAKUNTHALA and P. G. RAMAPPA (8 *February* 1967)

Titrimetric, coulometric and spectrophotometric determination of manganese following perchloric acid oxidation in the presence of pyrophosphate: JOHN KNOECK and HARVEY DIEHL (9 *February* 1967)

Some solvent effects on the solvent extraction of 8-quinolinol: HORACIO A. MOTTOLA and HENRY FREISER (9 *February* 1967)

Determination of molybdenum in the soil solution by neutron-activation method: W. ŻMIJEWSKA and J. MINCZEWSKI (10 *February* 1967)

Application of thermoelectric potential measurements in chemical analysis—II. Determination of aluminium in iron alloys: A. KRAJINI and J. DOLEŽAL (13 *February* 1967)

Polarographic study of inhibitors and catalysts for the reaction of dissolved oxygen with sulphite ion: Y. ISRAEL, A. VROMEN and B. PASCHKES (13 *February* 1967)

Separation and acid equilibria of Xylenol Orange and Semixylenol Orange: MITSUMASA MURAKAMI, TAKASHI YOSHINO and SHIRO HARASAWA (15 *February* 1967)

Talanta, 1967, Vol. 14, p. i. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

Study of iron(II)–iron(III) behaviour during iron(II) oxide determinations: J. C. VAN LOON. (16 *December* 1966)

Anion-exchange separation of cobalt from nickel and its electro-deposition: O. G. BALAKRISHNAN NAMBIER and P. R. SUBBARAMAN. (23 *December* 1966)

Oxidimetric determination of indigo with iron(III) and hexacyanoferrate(III): G. GOPALA RAO and V. RUKMINI. (23 *December* 1966)

A new reductimetric reagent: iron(II) in a strong phosphoric acid medium—V: G. GOPALA RAO and V. RUKMINI. (23 *December* 1966)

A new oxidimetric reagent: Potassium dichromate in a strong phosphoric acid medium—VIII. Potentiometric determination of molybdenum(VI) and vanadium(V): G. GOPALA RAO and U. MURALIKRISHNA. (23 *December* 1966)

Reduction of iridium after oxidation in fuming perchloric acid: E. JACKSON and D. A. PANTONY. (23 *December* 1966)

Studies in atomic-fluorescence spectroscopy—III. Microwave electrodeless discharge tubes as spectral sources for atomic-fluorescence and atomic-absorption spectroscopy: R. M. DAGNALL, K. C. THOMPSON and T. S. WEST. (23 *December* 1966)

Studies in atomic-fluorescence spectroscopy—IV. The atomic-fluorescence spectroscopic determination of selenium and tellerium: R. M. DAGNALL, K. C. THOMPSON and T. S. WEST. (23 *December* 1966)

Separation of ions by alteration of the concentration of the ligand in a discontinuous countercurrent extraction system: C. R. BOSWELL and R. R. BROOKS. (29 *December* 1966)

Mass spectrometry of metal chelates—I. Detection on the picogram scale: A. E. JENKINS and J. R. MAJER. (5 *January* 1967)

Spectrophotometric extractive titrations—IV. Determination of zinc in germanium dioxide and in germanium chloride: AFTANAS GALÍK. (5 *January* 1967)

Precipitation of bismuth basic acetate from homogeneous solution: P. F. S. CARTWRIGHT. (5 *January* 1967)

Metal chelate exchange in the organic phase—I. Theory. Application in spectrophotometry and complex chemistry: JAROMÍR RŮŽIČKA and JIŘÍ STARÝ. (5 *January* 1967)

Spectrophotometric determination of osmium with ammonium thiocyanate: MOHSIN QURESHI and KISHORE N. MATHUR. (5 *January* 1967)

Solvent extraction of indium with 1-(2-pyridylazo)-2-naphthol. The formation of mixed complexes: YU. A. ZOLOTOV, I. V. SERYAKOVA and G. A. VOROBYEVA. (10 *January* 1967)

Some vanadium(V) complexes as reagents for the photometric determination of alcohols: MOTOHARU TANAKA and ISAO KOJIMA. (11 *January* 1967)

Polarographic study of bis-(2-pyridyl)-disulphide di-*N*-oxide and bis(2-quinolyl)-disulphide di-*N*-oxide in aqueous ethanol: I. EL-KHIAMI and R. M. JOHNSON. (11 *January* 1967)

Alloy electrodes in potentiometry—I. Study of platinum—20% rhodium electrode in redox and acid-base titrations: V. T. ATHAVALE, R. G. DHANESHWAR and D. A. SARANG. (19 *January* 1967)

Sorption of hydrolytic products of iron(III), aluminium(III) and chromium(III) on the silica column, and its analytical use: F. VYDRA and J. GALBA. (19 *January* 1967)

Talanta, 1967, Vol. 14, p. i. Pergamon Press Ltd. Printed in Northern Ireland

PAPERS RECEIVED

Radiochemische Trennungen mit Hilfe der Ringofenmethode II: Das System $^{99}Mo/^{99}Tc$: D. KLOCKOW (10 *November* 1966)

Determination of microgram quantities of tin(IV) by a combined ion-exchange/X-ray fluorescence technique: B. R. CHAMBERLAIN and R. J. LEECH (21 *November* 1966)

Separation of tin from other elements by partition chromatography: J. S. FRITZ and G. L. LATWESEN (21 *November* 1966)

1-Hydroxy-ethylidene-1,1-diphosphonic acid as a volumetric and masking agent: R. PŘIBIL and V. VESELÝ (22 *November* 1966)

Separation of As(V) and As(III) by thin-layer chromatography: K. OGUMA (23 *November* 1966)

Instrumental activation analysis of vegetable tissue: E. STEINNES (23 *November* 1966)

Estimation of the minimum detectable concentration and optimum instrumental conditions in precison absorption spectrophotometry of molecules in the condensed phase: J. J. CETORELLI and J. D. WINEFORDNER (23 *November* 1966)

Fluorimetric determination of sebacic acids: ZBIGNIEW GREGOROWICZ and PIOTR GÓRKA (25 *November* 1966)

Kinetics of the precipitation of palladium dimethylglyoximate from homogeneous solution: PAUL R. ELLEFSEN and LOUIS GORDON (1 *December* 1966)

Computer calculation of equilibrium concentrations in mixtures of metal ions and complexing species: D. D. PERRIN and I. G. SAYCE (2 *December* 1966)

Substoichiometric determination of traces of gold by radioactive isotope-dilution analysis: D. A. BEARDSLEY, G. B. BRISCOE, J. RŮŽIČKA and M. WILLIAMS (2 *December* 1966)

Spectrophotometric determination of cobalt using phenanthrenequinone monoxime as analytical reagen t K. C. TRIKHA, MOHAN KATYAL and R. P. SINGH (6 *December* 1966)

Some aspects of the reactions between selenium-containing ligands and platinum group metals: L. S BARK and D. BRANDON (6 *December* 1966)

Physico-chemical and analytical study of thallous chelates with hydroxy-phenols: O. S. TOMAR and P. D. BRATTACHARYA (6 *December* 1966)

Inorganic polarography in organic solvents—III. Analytical applications of metal–acetylacetone complexes in toluene: B. K. AFGHAN, R. M. DAGNALL and K. C. THOMPSON (6 *December* 1966)

Extractive photometric determination of lanthanides and yttrium with chlorophosphonazo DAL: BŘETISLAV BUDĚŠINSKÝ and BLANKA MENCLOVÁ (6 *December* 1966)

Complexometric determination of iron (III) with 2-hydroxy-1-naphthaldoxime as indicator: V. B. S. CHAUHAN (7 *December* 1966)

Emission spectra of nitrous oxide supported acetylene flames at atmospheric pressure: G. F. KIRKBRIGHT M. K. PETERS and T. S. WEST (8 *December* 1966)

New method for the determination of sorbic acid: P. SPACU and H. DUMITRESCU (8 *December* 1966)

New method for the determination of pentachlorophenol by atomic absorption spectrophotometry: Y. YAMAMOTO, T. KAMAMARU and Y. HAYASHI (9 *December* 1966)

Determination of calcium by atomic-absorption spectrophotometry combined with extraction: MASAAKI YANAGISAWA, MASAMI SUZUKI and TSUGIO TAKEUCHI (13 *December* 1966)

Determination of selenium snf tellurium in silver chloride and uranium oxide: B. G. RUSSELL W. V. LUBBE, ANITA WILSON, ELAINE JONES, J. D. TAYLOR and T. W. STEELE (20 *December* 1966)

Electron microscopy and diffraction studies on coprecipitation—I. Morphological study on coprecipitation: KAZUYOSHI TAKIYAMA and LOUIS GORDON (20 *December* 1966)

Talanta, 1967, Vol. 14, p. i. Pergamon Press Ltd. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Purification of Laboratory Chemicals: D. D. PERRIN, W. L. F. AMAREGO and DAWN R. PERRIN. Pergamon, Oxford, 1966. Pp. viii + 362. 70*s*.

An account is given of the techniques available for purification of chemical compounds, and this is followed by a collection of instructions for purifying individual compounds (arranged alphabetically and classified as organic and inorganic). The last chapter deals with purification of classes of compounds.

History of Analytical Chemistry: FERENC SZABADVÁRY. Pergamon, Oxford, 1966. Pp. ix + 419. £6.

This volume will prove invaluable to historians of science and to all chemists interested in the origins of analytical chemistry and the lives of the great analysts of the past. It would not be surprising if it germinated fresh ideas in the minds of modern analysts.

Spot Tests in Organic Analysis: FRITZ FEIGL. Elsevier, Amsterdam, 7th Ed., 1966. Pp. XXIII + 772. 170*s*.

The latest edition of this well-known work is a completely revised and reorganised text, containing substantially more material than the last edition, much of it being work published for the first time. New features are sections on the differentiation of isomers and the detection of particular structures or types of compound.

Progress in Nuclear Energy, Series IX—Analytical Chemistry, Vol. 4: Eds. C. E. CROUTHAMEL, D. C. STEWART and H. A. ELION. Pergamon, Oxford, 1966. Pp. v+ 166. 70*s*.

This volume of the series is mainly concerned with developments in nuclear methods of analysis that are more physical than chemical. It contains reviews of solid state charged particle detectors (N. J. Hansen), advances in neutron activation analysis (V. P. Guinn), slow electron interaction with adsorbed gases (D. Lichtman and R. B. McQuistan) and the use of neutron generators in activation analysis (J. E. Strain). The reviews provide critical surveys of their subject until 1964 and some of the references are usefully annotated.

Progress in Nuclear Energy, Series IX—Analytical Chemistry, Vol. 6: Eds. D. C. STEWART and H. A. ELION. Pergamon, Oxford, 1966. Pp. v + 260. 90*s*.

This volume contains reviews of ion-exchange in mixed and non-aqueous media (J. Korkisch), neutral bifunctional organophosphorus compounds as solvent extractants (J. W. O'Laughlin), anion-exchange in nitrate solutions (J. Faris and R. F. Buchanan), and the analytical chemistry of neptunium (G. A. Burney, E. K. Dukes and H. J. Groh) and polonium (R. C. Lange). The articles are critical, contain a lot of useful data and complement each other to a fair degree. The typographical standard of the series is maintained.

No. 20 in the 'Incidental Information' Series

INCIDENTAL INFORMATION ON

REAGENTS...

REAGENTS FOR CLINICAL ANALYSIS

We supply a range of solutions as required by automated analytical machines that use standard methods.
Please write for brochure.

"INSTANT" FLUORIDE REAGENT

Alizarin fluorine blue, the first direct colorimetric reagent for fluoride is now widely used, but involves several ancillary reagents. The composite "*Alizarin fluorine blue lanthanum complex preparation*" requires only solution in water and addition to the nearly neutral test solution before spectrophotometric measurement.

Alizarin fluorine blue lanthanum complex preparation.
Code No. 1156.7 price 5g 17/6.
Leaflet available on request.

EXTRACTANT FOR HEAVY METALS

Ammonium pyrrolidinedithiocarbamate (APDC) sequesters Bi, Co, Cu, Fe, Hg, Mn, Ni, Pb, Sb, Zn and other metal ions in aqueous acid solution to form complexes that can be solvent-extracted, e.g. for atomic absorption spectroscopy.

Ammonium pyrrolidinedithiocarbamate
Code No. 1537 price 5g 13/6, 25g 55/-
100g 202/6. Leaflet available on request.

MODIFIED COLOUR REAGENT FOR IRON

4,7-Diphenyl-1,10-phenanthroline-disulphonic acid disodium salt can be used in more alkaline solutions than can the unsulphonated reagent (Bathophenanthroline) and is more convenient to use in many applications where solvent extraction is not required. The ferrous complex can serve as a redox indicator even in the presence of perchlorate.
See Talanta 7, 163 (1961)
4,7-Diphenyl-1,10-phenanthroline-disulphonic acid disodium salt,
Code No. 4004.35.
Price—0.1 g 16/8d. 1 g 110/0d.

Available from stock.
Manufactured and tested by chemists for chemists.

TAS/HW.39A

Talanta, 1967, Vol. 14, p. ii. Pergamon Press Ltd. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Electronic Electrochemical Measuring Instruments: D. DOBOS, TERRA, Budapest, 1966. Pp. 449. 105*s*.

This is a readable and valuable reference book, half of which covers the theory of basic electronics and the design of the most important circuit elements, with notes on their application in methods of measurement. The design of pH meters, conductometers, h.f. oscillometers, polarographs and coulometers is discussed with reference to commercially available equipment. A useful few pages on care of electronic instruments should be compulsory reading for all students. The second half of the book is an international compendium of electronic electrochemical measuring instruments, with many photographs, diagrams and technical details. The information here should be of considerable interest to anyone faced with the problem of choosing new laboratory equipment.

Protides of the Biological Fluids: Vol. 14 of a Series on Proteins and Related Subjects: Proceedings of the 14th Colloquium at Bruges in 1966: Editor, H. PEETERS. Elsevier, 1967. Pp. xiii + 734. £12.

The subject matter falls into four divisions, namely, metal-binding proteins (26 papers), protein level and turnover (30 papers), determination of protein structure by physical methods (6 papers), separation techniques (31 papers) and, in addition to an introductory lecture by E. F. Lüscher on "The Biochemical Properties and the Biological Function of Fibrinogen", there are six other papers. Most papers are in English but there are a few in German and French. In the section on separation techniques particular emphasis, not surprisingly, is on the use of gel-filtration. The book is well-produced, with many illustrations and tables, and the editor is to be congratulated on the speed with which the papers have been published. While primarily the book is of value to those working in the protein field there are details of methods of value to other research workers.

NOTICE

16–18 *September* 1968

Fifth International Symposium on Chromatography and Electrophorese. Organized by the Belgian Society of Pharmaceutical Sciences, Brussels.

The official languages will be French, Dutch, English and German, and a scientific exhibition will be held during the Symposium.

Further information from: The Secretary's Office, The Belgian Society of Pharmaceutical Sciences, 11 rue Archimede, Brussels 4.

PAPERS RECEIVED

Le dosage du plomb dans les eaux alimentaires par trois methodes polarographiques: M. DEVALERIOLA and P. NANGNIOT. (4 *July* 1967)

Polarographische Bestimmung des Schwefels in Benzin: H. HOLZAPFEL and K. SCHÖNE. (3 *August* 1967)

Determination of moisture on thorium dioxide by a coulometric electrolytic measurement with electronic integration: E. A. SCHAFFER and J. O. HIBBITS. (11 *August* 1967)

Chromatographic separation of diastereoisomeric esters. II. Mandelates and lactates of 2-methylbutanol-1, 3-methylbutanol-2, pentanol-2 and hexanol-2: R. E. LEITCH, H. L. ROTHBART and WILLIAM RIEMAN III. (15 *August* 1967)

Metal ion separations using cellulose phosphate as an ion-exchanger: DONALD H. SCHMITT and JAMES S. FRITZ. (21 *August* 1967)

Application of 2-diphenylacetyl-1,3-indandione chemistry in the identification of organic compounds: W. A. MOSHER, E. J. POZIOMEK and I. S. BECHARA. (22 *August* 1967)

Improved method for the simultaneous absorptiometric determination of cobalt and nickel with quinoxaline-2,3-dithiol: J. A. W. DALZIEL and A. K. SLAWINSKI. (25 *August* 1967)

Note on the separation and determination of certain 17-ketosteroids from human urine: S. K. WAHBA, S. W. AMIN, M. HASSAN and A. A. EL-DAMATY. (25 *August* 1967)

Studies on Methymol Blue—I. Separation and purification of Methylthymol Blue and Semi-Methylthymol Blue: TAKASHI YOSHINO, HARUMI IMADA, TADAYOSHI KUWANO and KATSUYA IWASA. (25 *August* 1967)

Studies on metallochromic indicators—III. Hematoxylin and hematein as metallochromic indicators: G. K. SINGHAL and K. N. TANDON. (29 *August* 1967)

The masking coefficient in precipitation reactions: D. E. RYAN. (29 *August* 1967)

Substoichiometric determination of tungsten in steel by neutron-activation analysis: R. A. NADKARNI and B. C. HALDAR. (30 *August* 1967)

Anion-exchange separation of metal ions in dimethyl sulphoxide-methanol-hydrochloric acid: JAMES S. FRITZ and MARCIA LEHOCZKY GILLETTE. (31 *August* 1967)

Application of polarography and related electroanalytical techniques to the determination of derivatives of dithiocarbamic acid—I. Sodium diethyldithiocarbamate: M. J. D. BRAND and B. FLEET. (1 *September* 1967)

Application of polarography and related electroanalytical techniques to the determination of derivatives of dithiocarbamic acid—II. Tetramethylthiuram disulphide: M. J. D. BRAND and B. FLEET. (1 *September* 1967)

Application of polarography and related electroanalytical techniques to the determination of derivatives of dithiocarbamic acid—III. Ethylene *bis*dithiocarbamates: M. J. D. BRAND and B. FLEET. (1 *September* 1967)

Arsenazo III and analogues—I. Concerning the electronic structure of arsenazo III in various acidic media: S. B. SAVVIN and E. W. KUZIN. (4 *September* 1967)

Arsenazo III and analogues—II. Concerning the complexing of niobium with reagents containing the *o*, *o*-dioxyazo grouping: T. P. ALIMARIN, S. B. SAVVIN and L. A. OCHANOVA. (4 *September* 1967)

α-Oximinoacetoacetarylamides as analytical reagents for palladium: S. B. PATEL, M. R. PATEL and B. N. MANKAD. (4 *September* 1967)

A new concept of automated radiochemical analysis based on substoichiometric separation: J. RŮŽIČKA and C. G. LAMM. (4 *September* 1967)

Determination of nitrogen in an aluminium-killed steel by an isotope dilution method using $Al^{15}N$: KEIICHI FURUYA, SHOICHIRO OKUYAMA, SATOSHI TACHIKAWA and HITOSHI KAMADA. (5 *September* 1967)

The role of 70–80% perchloric acid as oxygen donor and determination of oxidation potentials made available: G. FREDERICK SMITH. (8 *September* 1967)

Extraction of radiogold and radiomercury and some other radioisotopes with mesityl oxide: A. ALIAN. (12 *September* 1967)

Solvent extraction of chromium(III), molybdenum(VI) and tungsten(VI) with thenoyltrifluoroacetone: ANIL K. DE and CHITTARANJAN SAHU. (12 *September* 1967)

Solvent extraction and photometric determination of molybdenum: A. I. BUSEV and T. V. RODIONOVA. (15 *September* 1967)

Exchange reactions on volumes: G. A. H. ROBERTS. (20 *September* 1967)

Photometric and spectrochemical determination of gold in copper, lead, and iron pyrites concentrates, after preliminary separation by extraction: N. JORDANOV, ST. MAREVA, N. KRASNOBAEVA and N. NEDYALKOVA. (21 *September* 1967)

Zur polarographie der n-Butyl-zinnchloride: K. ISSLEIB, H. MATSCHINER and S. NAUMANN. (15 *September* 1967)

Talanta, 1967, Vol. 14, p. ii. Pergamon Press Ltd. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Flame Photometry Theory: E. PUNGOR. Van Nostrand, London, 1967. Pp. xi + 200. 60s.

This monograph gives a concise survey of the theories of flame velocity and propagation, reactions in the flame, and atomization. The problems of temperature measurement are also dealt with. There are a large number of graphs which complement the many equations and illustrate clearly the principles expounded. The analytical chemist will benefit greatly by studying the work.

Tungsten and its Compounds: G. D. RIECK. Pergamon, Oxford, 1967. Pp. 138. 45s.

In spite of the vast quantity of information presented, the book is readable. The references cited are adequate to provide an intending researcher with a modern basis for a literature search. At the same time this neat monograph provides an excellent introduction to a broad area of investigation, and interest is added by the author's references to the applications and uses of various compounds.

Lyuminestsentnii Analiz Neorganicheskikh Veshchestv: E. A. BOZHEVOLNOV. Izdat. "Khimia", Moscow, 1966. Pp. 416. 1 Rb. 89 Kop.

This book contains an account of the theory and practice of luminescent analysis of inorganic substances. The apparatus and techniques are described, and available reagents and the development of new ones are discussed. Detailed methods are given for elements in groups I–VIII of the periodic table.

Khemilyuminestsentnii Analiz: A. K. BABKO, L. I. DUBOVENKO and N. M. LUKOVSKAYA. Izdat. "Tekhnika", Kiev, 1966. Pp. 250. 96 Kop.

The fundamentals of the phenomenon of chemiluminescence are expounded, and the properties of the most important components of chemiluminescent reactions are described. An account is given of the use of chemiluminescence for the titrimetric determination of 10^{-6}–10^{-9} g of substances, on the basis of their catalytic or inhibiting capacity. The use of this method for the analysis of several ultra-pure materials is described.

Arsenazo III: Metodi fotometricheskogo opredelenya redkikh i aktinidnikh elementov: S. B. SAVVIN. Atomizdat, Moscow, 1966. Pp. 256. 93 Kop.

The theory and practice of the use of Arsenazo III and its analogues for the determination of Th, U, Zr, Hf, Sc, Ce, La, Nb, Sr, Ba, S, lanthanides and actinides are described. The mechanism of the complex formation and the nature of the colour reactions, the composition and structure of the complexes, and the selectivity and other properties of the reagents in this series are all discussed. Full details are given of the methods of determining elements in various materials by this method.

Radiometric Titrations: T. BRAUN and J. TÖLGYESSY. Pergamon, Oxford, 1967. Pp. x + 168 55s.

The monograph is a very clear and comprehensive account of the subject. The exposition is greatly enhanced by the frequent use of diagrams and photos, which show titration curves and apparati. The method, which holds out the possibility of determining microgram amounts of many ions with a relative precision of 1% is of considerable interest. The interest, modest price and quality of production should make it popular with many analysts.

Chromatographic Reviews, Volume 8: Ed. MICHAEL LEDERER, Elsevier, Amsterdam, 1966. Pp. viii + 298. £5. 10s.

This volume continues the task of its predecessors by providing competent and detailed reviews in various aspects of chromatography. The first three articles are on gas chromatography and deal with the flow of gases in porous media, the study of pyrolysis products and trace analysis. An interesting article outlines chromatography and electrophoretic techniques for the separation of denaturation and degraded fibrous proteins. Elsewhere there are reviews on the chromatography of triglycerides, lipids and co-ordination compounds and one on the use of papers impregnated with ion exchangers. This is the last annual volume to appear, henceforth it is the intention of the editor to publish the review twice or thrice a year.

Talanta, 1967, Vol. 14, p. ii. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

POLAND

10–15 *September* 1968: **Third Polish Analytical Conference,** Warsaw Polytechnic, Warsaw.

The main subjects to be dealt with are: basic problems of analytical chemistry, analytical methods in organic and inorganic industry, and technique of analytical chemistry. Papers on these subjects (in English, French, German or Russian) may be submitted not later than 30 September 1967. Address all correspondence to Dr. A. Hulanicki, Warszawa 22, ul. Pasteura 1, Poland.

U.S.A.

8–10 *November* 1967: **The 9th Eastern Analytical Symposium,** Statler-Hilton Hotel, New York City. (Sponsored by the Analytical Groups of the New York and North Jersey Sections of the American Chemical Society; the Baltimore-Washington, Delaware Valley, New York, and New England Sections of the Society for Applied Spectroscopy; and the American Microchemical Society).

For further information contact Mr G. L. Davis, Dalare Associates, 2300 Locust Street, Philadelphia, Pa. 19103, U.S.A.

3–8 *March* 1968: **The Nineteenth Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy,** Penn-Sheraton Hotel, Pittsburgh, Pennsylvania, U.S.A.

An estimated 300 papers on all phases of Analytical Chemistry and Spectroscopy will be presented. The theme will be Analytical Chemistry and Spectroscopy for the Future. Symposia on 11 other subjects are now being arranged. Papers are not restricted to the symposium subjects and original papers on all phases of analytical chemistry and spectroscopy are invited. Prospective authors should submit three copies of a 150 word abstract to: Dr. John O. Frohliger, Department of Occupational Health, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, 15213, U.S.A. by 15 October 1967. In addition to the programme of technical papers, there will be an exhibition of the newest analytical instrumentation.

ERRATUM

D. BETTERIDGE: Extractive indicators in complex-formation titrations—theory and practice. *Talanta* 1966, **13**, 1497.

Equation (12) on p. 1500 should read:

$$\alpha_{2(D)} = K_{a1} \cdot K_{a2} / \left\{ [H^+]^2 + [H^+]K_{a1}\left(1 + K_{DR}\frac{V_{org}}{V_{aq}}\right) + K_{a1}K_{a2} \right\}.$$

Talanta, 1967, Vol. 14, p. ii. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

POLAND

10–15 *September* 1968: **Third Polish Analytical Conference,** Warsaw Polytechnic, Warsaw.

The main subjects to be dealt with are: basic problems of analytical chemistry, analytical methods in organic and inorganic industry, and technique of analytical chemistry. Papers on these subjects (in English, French, German or Russian) may be submitted not later than 30 September 1967. Address all correspondence to Dr. A. Hulanicki, Warszawa 22, ul. Pasteura 1, Poland.

U.S.A.

PUBLICATIONS RECEIVED

Instrument and Chemical Analysis Aspects of Electron Microanalysis and Macroanalysis: H. A. ELION. Pergamon, Oxford, 1966. Pp. 252. 90*s*.

This is a useful review, more suited to the worker with some experience in the field, though the attempt to cover every possibility and aspect of the topic renders the book rather heavy reading. A useful set of tables and list of original references will be of value to the researcher. There are chapters on Electron Optics, X-Ray Optics, X-Ray Detectors and Detection, Specimen Preparation and Observation, Quantitative X-Ray Emission Analysis, and Future Developments.

Pharmaceutical Analysis, Vol. 1, Theory and Application: ed. L. G. CHATTEN. Arnold, London, 1966. Pp. xii + 504. 115*s*.

This is the first of two volumes and deals with the theory and practice of the more common non-instrumental techniques of pharmaceutical analysis, each section being compiled by an expert in the field. The theoretical treatment is reasonably limited and is supported by adequate practical detail, especially of technique, and by comprehensive lists of references to applications. The very full index to analytical procedures for a large number of compounds will be extremely useful to students, professional pharmaceutical analysts and research workers alike.

Rapid Methods of Trace Analysis for Geochemical Application: R. E. STANTON. Arnold, London, 1966. Pp. vii + 96. 25*s*.

This little book is a compilation of the methods that have been found to give rapid trouble-free estimation of traces of elements in geochemical survey work. The methods are designed for use in the field and permit the completion of as many as 100 determinations a day. The precision ranges from 10 to 25%, depending on the method and on the skill of the operator, but this is acceptable for the type of work. There are useful sections on reagents, statistics, and decomposition of samples, as well as the main section on the procedures themselves.

Atomic-Absorption Spectrophotometry, 2nd (revised) edition: W. T. ELWELL and J. A. F. GIDLEY. Pergamon, Oxford, 1966. Pp. ix + 140. 42*s*.

This book has been thoroughly brought up to date and fully maintains the standard set by its first edition. It is an essential in the library of anyone working in this field, and can strongly be recommended to students and those contemplating the use of atomic-absorption methods.

In Table I on p. 105, the limits of detection (L. of D.) should be expressed in *μg/ml*, and not in *mg/ml*.

EDITORIAL NOTICE

Authors in United States and Canada

SINCE Professor Gordon's untimely death robbed this journal of one of its most devoted servants, Mr. HOWARD FRANCIS JR. has carried on as sole Regional Editor for the Western Hemisphere and has joined the Editorial Board. We are glad to announce that Professor J. S. FRITZ has accepted our invitation to collaborate with Mr. Francis in this work. We take the opportunity to remind authors that because of the large number of papers submitted to *Talanta* from the United States and Canada, publication will be facilitated if manuscripts are sent direct to either of these two Regional Editors, who will arrange for rapid refereeing within the Western Hemisphere. Responsibility for final acceptance and editing remains, of course, with the Editor-in-Chief and the Editorial Board.

PUBLICATIONS RECEIVED

The Analysis of Nickel: C. L. LEWIS, W. L. OTT and N. M. SINE. Pergamon, Oxford, 1966. Pp. x + 214. 55*s*.

This book gives a thorough account of the classical and instrumental methods available for the determination of impurities in nickel metal. Some of the methods are also applicable to the analysis of nickel alloys, but only if the alloy is almost all nickel. The standards of this series are fully maintained.

Handbook of Physical Constants: SYDNEY P. CLARK, JR., Editor. Revised Edition, Geological Society of America, New York, 1966. Pp. vii + 587. $8.75.

This reference book is a compilation of the physical constants required by geologists, geophysicists and geochemists. The material presented in the first edition in 1942 has been thoroughly brought up to date and has been considerably expanded. Analysts working in the ceramic, cement and silicate industries or in geological and geochemical exploration, may find it very useful.

Elementary Practical Organic Chemistry, Part 2: Qualitative Organic Analysis: ARTHUR I. VOGEL. 2nd Edition, Longmans, London, 1966. Pp. xv + 431. 35*s*.

The most important change from the first edition is the inclusion of a chapter on spectroscopic methods of identification. This chapter covers the use of ultraviolet, visible and infrared spectroscopy, mass spectrometry, and nuclear magnetic resonance, and in the present state of development of analysis is undoubtedly the most useful and timely section of the book. The use of quantitative information as an aid to qualitative identification is also a feature that commends the book for student use.

Mass Spectrometric Analysis of Solids: ARTHUR J. AHEARN, Editor. Elsevier, Amsterdam, 1966. Pp.175. 60*s*.

An excellent review of the present state of spark source mass spectrography, written by experts in the field. The uncertainties in the interpretation of results are discussed and the most modern techniques in the examination of very small samples are described.

Progress in Nuclear Energy Series IX, Analytical Chemistry, Volume 7: H. A. ELION and D. C. STEWART, Eds. Pergamon, Oxford, 1966. Pp.v +288. £4 10*s*.

This volume maintains the high standard of the series. The main emphasis is on instrumental methods particularly those connected with surface studies, with articles on electron diffraction (R. K. Hart), ion microprobe mass spectrometer (A. E. Barrington, R. F. K. Herzog and W. P. Poschenrieder) and a table of coefficients for microprobe analysis (R. D. Dewey), which is coupled with tables of X-ray data (R. D. Dewey, R. S. Mapes and T. W. Reynolds). A long, 90-page, article on liquid scintillator solutions (D. L. Horrocks) and a comprehensive review of in-line analytical instrumentation of nuclear fuel processing plants (C. R. McGowan and J. K. Foreman) complete the volume. Only a few references are to articles printed later than 1964.

Talanta, 1967, Vol. 14, pp. ii to iii. Pergamon Press Ltd. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Progress in the Science and Technology of the Rare Earths, Vol. 2: Ed. LE ROY EYRING. Pergamon, Oxford, 1966. Pp. 366. 105*s*.

This is a well produced volume exactly described by its title. For some of the articles "progress" refers to advances made since the writing of Vol. 1 in 1960. The length of the articles ranges from 12 to 108 pages. The subject matter includes, in decreasing order of length, uses (H. H. and R. M. Mandle, over 1300 references), mixed cation oxides (W. Low), chalcogenides and pnictides (E. F. Westrum, over 400 references), halides (R. E. Thoma), solid-state chemistry of pure oxides (G. Brauer), the molecular-field model of exchange coupling (J. H. van Vleck), metal complexes (D. I. Ryabchikov and E. K. Korchemnaya), and preparation of pure metals (A. H. Daane). Emphasis is placed on thermodynamic and magnetic properties. The personal style of the authors, retained by the editor, results in some of the articles being very readable.

Reinststoffprobleme: I—Reinststoffdarstellung, II—Reinststoffanalytik: Eds. J. BARTHEL, G. GÜNZLER and G. EHRLICH. Akademie-Verlag, Berlin, 1966. Pp. XII + 599; XI + 707. 55 DDM each.

These are the first two of the three volumes of the proceedings of the 2nd International Symposium "Reinststoffe in Wissenschaft und Technik" held in Dresden, 28 September–2 October 1965. Practically every aspect of the problems of producing and analysing high-purity and ultrahigh-purity materials is covered in these two volumes, and the papers presented at the symposium should prove highly stimulating to chemists in general as well as to workers active in this field. A very useful feature is the provision of summaries in English, German and Russian. The editors are to be congratulated on being able to get the work out so quickly; events move so rapidly that reports of symposia are often well out of date by the time they appear.

Organicheskii Analyz (in Russian): A. P. TERENT'EV. Izdat Moscow University, Moscow, 1966. Pp. 408. 2 Rb 51 Kop.

This book contains the collected works of the author in the field of identification of organic substances and of elemental and functional group analysis. The main topics covered are elemental analysis, the "wet-combustion" methods, functional group analysis, identification, gasometric methods, the analytical reactions of double bonds, sulphonic acids and the use of sulphur trioxide, use of diazo compounds in analysis, polarimetric analysis, organic reagents, and molecular weight determination. Special apparatus and experimental techniques are described. The book should be of general interest to analytical chemists engaged in research and control work, and also to organic chemists.

Analysis of Copper and its Alloys: W. T. ELWELL and I. R. SCHOLES. Pergamon, Oxford, 1967. Pp. xiii + 183. 50*s*.

This book gives a selection of methods, both chemical and instrumental, for the determination of 30 elements in copper and its alloys. The methods have all been tested and assessed in the authors' laboratories, and a particularly useful feature of the book is the quotation of the precision to be expected when these methods are used. The scope and limitations of the methods are also discussed, and reference is made to many of the other methods that are available but are not discussed in detail in the book.

Chromatographic Methods, 2nd Edition: R. STOCK and C. B. F. RICE. Chapman and Hall, London, 1967. Pp. viii + 256. 42*s*.

The second edition of this useful handbook contains an expanded section on the more recent thin-layer chromatographic technique, and additional material on gel-filtration. There are many useful table summarizing experimental details.

Polarographie: J. PROSZT, V. CIELESZKY and K. GYÖRBIRÓ. Akadémiai Kiadó, Budapest, 1967. Pp. 587. £7.

This book (written in German) is a useful compendium of polaragraphic methods. The theoretical section describes classical polarography and its modern developments, and is followed by sections on inorganic and organic applications of the polarographic method. These sections take the form of reviews of the literature, and there are working details given for selected inorganic methods.

A Generalized Outline of the Metabolism of Steroid Hormones: DINESH C. SHARMA and RALPH I. DORFMAN. Holden-Day, 500 Sansome St., San Francisco, 1966. $8.50.

A wall-chart showing the biosynthesis and catabolism of these hormones.

Chemie in unserer Zeit. Verlag Chemie GmbH, Weinheim. DM 18 per annum.

A new journal (written in German) of general chemical interest, appearing 6 times in the year. It is intended for the intelligent layman, schools, and scientists with a non-specialized interest in chemistry, and is produced under the auspices of the Gesellschaft Deutscher Chemiker.

Chemical Analysis of Radioactive Materials: A. K. LAVRUKHINA, T. V. MALYSHEVA and F. I. PAVLOTSKAYA. Iliffe, London, 1967. Pp. 10 + 386. 50*s*.

This translation from the Russian is divided into five sections dealing with behaviour of radioactive species in solution, the theory of radiochemical analysis, methods of identification of radioisotopes, isolation and concentration of radioactive species, and methods of obtaining radioactively pure species. There do not appear to be any references later than 1963, though the literature up to that date seems to be well covered.

Advances in Inorganic Chemistry and Radiochemistry, Vol. 9: H. J. EMÈLEUS and A. G. SHARPE, Editors. Academic Press, New York, 1966. Pp. xiii + 386. 124*s*.

This volume keeps up to standard of its predecessors and contains articles on liquid-liquid extraction of metal ions, nitrides of metals of the first transition series, pseudohalides of Group IIIB and IVB elements, stereoselectivity in coordination compounds, heterocations, and the inorganic chemistry of tungsten.

Talanta, 1967, Vol. 14, p. iii. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

POLAND

10–15 *September* 1968: **Third Polish Analytical Conference.** Organized by the Commission of Analytical Chemistry of the Polish Academy of Sciences under the auspices of the International Union of Pure and Applied Chemistry. To be held in Warsaw.

The main subjects to be dealt with are basic problems of analytical chemistry (new reagents, new reactions, ionic equilibria, accuracy and precision, etc.), analytical methods in inorganic and organic industry and technique of analytical chemistry (new apparatus, automation, standards, sampling, etc.). Abstracts of papers for the conference are required by 15 January 1968. Further details from: Dr Adam Hulanicki, Warszawa 22, ul. Pasteura 1, Poland.

U.S.A.

18–23 *August* 1968: **Second International Conference on Thermal Analysis,** Holy Cross College, Worcester, Massachusetts, U.S.A.

Further details from Dr. J. P. Redfern (U.K. ICTA Liaison Officer) Stanton Instruments Ltd., Copper Mill Lane, London, S.W.17 (Tel. 01-946 7731).

Talanta, 1967, Vol. 14, p. iii. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

The XXIst International Congress of Pure and Applied Chemistry will be held in Prague, 4–10 September 1967. Three topical subjects have been selected which will be dealt with in three sections:

Automation in Analytical Chemistry

Toxicological Chemistry

Chemistry of Nucleic Acid Components.

The Second Circular of the Congress, with full information, may be obtained on request from:

Organizing Committee XXIst International Congress of Pure and Applied Chemistry, P.O.B. 139, Praha 6-Dejvice, Czechoslovakia.

The time-limit for application for participants who intend to present a paper terminates on 1 March 1967 and for other participants on 31 May 1967.

GERMANY

The Analytical Chemistry Group of the German Chemical Society will hold a meeting on "Methods of Structure Analysis of Organic Compounds" in Berlin, 21–23 September 1967. Plenary lectures will be given on "Methods of Structure Analysis", "Structure Analysis by Mass Spectrometry", Optical Rotation and Circular Dichroism Applied to Conformational Analysis" and "Characterization of High Polymers". Intending contributors should send 5 copies of a 200-word abstract of their paper not later than 17 February 1967 to Geschäftsstelle der Gesellschaft Deutscher Chemiker, Herrn Dr. Fritsche, 6 Frankfurt/Main 9, Postfach 9075, from whom further particulars may be obtained.

The Group will also hold a meeting on "Analysis and Chemistry of Enamels" in Freudenstadt (Schwarzwald), 9–11 May 1967. Abstracts of papers (which may be in English, French or German) should be sent (5 copies, 200 words) not later than 15 February 1967 to Prof. Dr. W. BUES, Laboratorium für anorganische und analytische Chemie der Universität Tübingen, 74 Tübingen, Wilhelmstraße 33, from whom further details may be obtained.

UNITED KINGDOM

Solvent Extraction Group

This group has recently been formed (details from the Secretary, Mr. A. A. North, Warren Spring Laboratory, Gunnels Wood Road, Stevenage, Herts., U.K.) to foster interest in the technique of solvent extraction. Its immediate aims are to outline the existing state of knolwedge and demonstrate the possibilities of the technique, and to indicate some of the problems involved in its technical application. A half-day meeting on the theme "Principles of Industrial Solvent Extraction" will be held in four centres in different parts of the country in order to introduce the Group and its aims to as wide an audience as possible. The meetings will begin at 2.30 p.m. on the following dates:

23 January 1967, at 14 Belgrave Squate, London S.W.1.

15 February 1967, at the Houldsworth School of Applied Science, The University, Leeds.

1 March 1967, at the Technical College, Falkirk.

12 April 1967, at the University of Technology, Loughborough.

Papers will be given on "The Chemistry of Solvent Extraction", "Process Design" and "Industrial Contacting Equipment".

ERRATUM

G. GOPALA RAO: Potassium dichromate as an oxidimetric reagent, *Talanta*, 1966, **13**, 1473–1495.

On p. 1476 of the November issue and the 10th line under the heading "Species present at high acid concentration", the sentence beginning "The presence of . . ." should read:

The presence of $(CrSO_7^{2-})$,[14] (CrO_2^{+})[19] and $HOCrO_2(OSO_3H)$[17,20] in sulphuric acid solutions has been reported.

G. GOPALA RAO: Potassium dichromate as an oxidimetric reagent, *Talanta*, 1966, **13**, 1473–1495.

On p. 1476 of the November issue and the 10th line under the heading "Species present at high acid concentration", the sentence beginning "The presence of . . ." should read:

The presence of $(CrSO_7^{2-})$,[14] (CrO_2^{+})[19] and $HOCrO_2(OSO_3H)$[17,20] in sulphuric acid solutions has been reported.

Variamine Blue as a gravimetric reagent. Determination of tungsten: L. ERDEY, I. BUZÁS and K. VIGH, *Talanta*, 1967, **14**, 515 (Institute for General Chemistry, Technical University, Budapest XI, Hungary).

Summary—Tungsten can be precipitated by a solution of Variamine Blue at pH 5. The precipitate is ignited to constant weight at a temperature above 600° and weighed as tungsten trioxide. The method can be used for the determination of tungsten in alloy steels.

Radiometric determination of submicrogram amounts of mercury: JIŘÍ STARÝ and RADULE MILOŠEVIĆ, *Talanta*, 1967, **14**, 521 (Department of Nuclear Chemistry, Faculty of Technical and Nuclear Physics, Prague, Czechoslovakia).

Summary—A radiometric method for the determination of submicrogram amounts of mercury (down to 5×10^{-10} g/ml) is described. The method is based on the exchange reaction between mercury and silver–110m dithizonate. Only palladium, gold, silver, and large amounts of copper and bismuth interfere in the determination, and must be removed.

Extractive photometric determination of thorium with arsenazo DAL: BŘETISLAV BUDĚŠÍNSKÝ and BLANKA MENCLOVÁ, *Talanta*, 1967, **14**, 523 (Nuclear Research Institute, Czechoslovak Academy of Sciences, Řež near Prague, Czechoslovakia).

Summary—Arsenazo DAL, the dianilide of 3,6-bis(2′-arsonophenylazo)-4,5-dihydroxy-2,7-naphthalenedisulphonic acid, is proposed as an extractive photometric reagent for the highly selective determination of trace amounts of thorium.

The stability constants of TAR and PAR complexes: ROBERT A. CHALMERS, *Talanta*, 1967, **14**, 527 (Chemistry Department, University of Aberdeen, Old Aberdeen, Scotland).

Summary—A discussion is given of the problem of ascribing dissociation constants in the hypothetical situation in which the protons of the hydroxy groups of TAR and PAR dissociate in the reverse of the normal order, and it is suggested that the *o*-hydroxy group should be regarded as intrinsically as acidic as the *p*-hydroxy group, and that the change in p*K* due to the internal hydrogen bonding is probably less than one unit.

SUMMARIES FOR CARD INDEXES

Separation of tin from other elements by partition chromatography: JAMES S. FRITZ and GARY L. LATWESEN, *Talanta*, 1967, **14**, 529. (Institute for Atomic Research and Department of Chemistry, Iowa State University, Ames, Iowa, U.S.A.)

Summary—Tin(IV) is separated quantitatively from many other metal ions by reversed-phase chromatography on a column of solid support impregnated with an organic liquid. When aqueous 8*M* hydrochloric acid is used as the eluent, tin(IV) is retained on a column impregnated with methyl isobutyl ketone and is separated quantitatively from bismuth(III), cadmium(II), copper(II), lead(II), mercury(II) and zinc(II). For the separation of tin(IV) and molybdenum(VI) the aqueous eluting phase is 1*M* hydrochloric acid–3*M* sulphuric acid. A column impregnated with isopropyl ether quantitatively retains antimony(V) from 8*M* hydrochloric acid and permits tin(IV) to be eluted rapidly.

Steric hindrance effects in the use of heterocyclic azodyestuffs as spectrophotometric reagents: W. J. GEARY and F. BOTTOMLEY, *Talanta*, 1967, **14**, 537 (Department of Chemistry and Metallurgy, Lanchester College of Technology, Coventry, England).

Summary—The heterocyclic azo dyestuffs 4-(*n*-methyl-2′-pyridylazo)-resorcinol (where $n = 3'$, $4'$, $5'$, $6'$) have been prepared, and their possible use as spectrophotometric reagents investigated. The dyestuffs are shown to function analogously to the parent ligand 4-(2′-pyridylazo) resorcinol (PAR) in giving red complexes with the ions Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+} and UO_2^{2+}. Steric effects resulting from the position of the methyl group in the heterocyclic ring are shown to occur in relation both to the spectra of the dyestuffs themselves and to the sensitivity of their reactions with the metal ions.

Extraction of reduced molybdosilicic acid and its application to the determination of traces of silicon: YACHIYO KAKITA and HIDEHIRO GOTO, *Talanta*, 1967, **14**, 543 (Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan.)

Summary—It is difficult to find satisfactory organic solvents for the extraction of reduced molybdosilicic acid, but extraction is possible with isoamyl or isobutyl alcohol if the acid concentration of the aqueous solution is increased before the extraction, the best results being obtained by extraction with isoamyl alcohol from 3·5–4·5*N* sulphuric acid medium. This makes the reduced molybdosilicic acid method much more sensitive and permits the determination of microgram amounts of silicon in various kinds of high-purity metals.

ОТДЕЛЕНИЕ ОЛОВА ОТ ДРУГИХ ЭЛЕМЕНТОВ МЕТОДОМ РАСПРЕДЕЛИТЕЛЬНОЙ ХРОМАТОГРАФИИ:

JAMES S. FRITZ and GARY L. LATWESEN, *Talanta*, 1967, **14**, 529.

Резюме—Олово(IV) отделяется количественно от числа других ионов металлов методом хроматографии на обратной фазе, пользуясь колонкой наполненой твердым носителем, пропитанным органической жидкостью. В случае использования 8*M* соляной кислоты в качестве элюента, олово(IV) задерживается на колонке пропитанной метилизобутилкетоном и этим образом отделяется количественно от висмута(III), кадмия(II), меди(II), свинца(II), ртути(II) и цинка(II). Для разделения олова(IV) и молибдена(VI) пользуются смесью 1*M* соляной кислоты и 3*M* серной кислоты в качестве водяного элюента. Пропитанная изопропиловым эфиром колонка задерживает количественно сурьму(V) из раствора 8*M* соляной кислоты и позволяет быстрое элюирование олова(IV).

ВЛИЯНИЕ ПРОСТРАНСТВЕННОГО ЗАТРУДНЕНИЯ НА ИСПОЛЬЗОВАНИЕ ГЕТЕРОЦИКЛИЧЕСКИХ АЗОКРАСИТЕЛЕЙ В КАЧЕСТВЕ СПЕКТРОФОТОМЕТРИЧЕСКИХ РЕАГЕНТОВ:

W. J. GEARY and F. BOTTOMLEY, *Talanta*, 1967, **14**, 537.

Резюме—Приготовлены гетероциклические азокрасители типа 4-(н-метил-2 -пиридилазо)резорцина (где н = 3′, 4′, 5′, 6′) и изучена их применимость в качестве спектрофоторетрических реагентов. По аналогии с основным лигандом 4-(2 -пиридилазо)резорцином (ПАР) красители дают красные комплексы с ионами Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, и VO_2^{2+}. Вызванные положением метилгруппы в гетероциклическом кольце пространственные эффекты показывают их влияние на спектры самых красителей и на чувствительность их реакций с ионами металлов.

ИЗВЛЕЧЕНИЕ ВОССТАНОВЛЕННОЙ КРЕМНЕМОЛИБДЕНОВОЙ КИСЛОТЫ И ЕГО ИСПОЛЬЗОВАНИЕ ДЛЯ ОПРЕДЕЛЕНИЯ СЛЕДОВ КРЕМНИЯ:

YACHIYO KAKITA and HIDEHIRO GOTO, *Talanta*, 1967, **14**, 543.

Резюме—Трудно найти удовлетворительные органические растворители для извлечения восстановленной кремнемолибденовой кислоты, но извлечение можно провести изоамиловым или изобутиловым спиртами если повышается кислотность водяного раствора пред извлечением; самые лучшие результаты получаются экстрагированием изоамиловым спиртом из 3,5–4,5*N* сернокислой среды. Метод пользующийся восстановленной кремнемолибденовой кислоты гораздо больше чувствительний и позволяет определение микрограммовых количеств кремния в различных высокочистотных металлах.

Studies in atomic-fluorescence spectroscopy—III. Microwave-excited electrodeless discharge tubes as spectral sources for atomic-fluorescence and atomic-absorption spectroscopy: R. M. DAGNALL, K. C. THOMPSON and T. S. WEST, *Talanta*, 1967, **14**, 551 (Chemistry Department, Imperial College, London S.W.7, England.)

Summary—Details are given for the production and operation of microwave-excited electrodeless discharge tubes for use as sources in atomic-fluorescence and atomic-absorption spectroscopy. Special reference is made to the tubes for selenium and tellurium and their spectral characteristics are fully discussed. Optimum conditions are given for producing suitably intense and stable sources.

Studies in atomic-fluorescence spectroscopy—IV. The atomic-fluorescence spectroscopic determination of selenium and tellurium: R. M. DAGNALL, K. C. THOMPSON and T. S. WEST, *Talanta*, 1967, **14**, 557 (Chemistry Department, Imperial College, London S.W.7, England.)

Summary—Selenium and tellurium are determined down to 0·25 and 0·12 ppm respectively by measuring the atomic-fluorescence signals at 2040 Å and 2143 Å respectively. Other possible wavelengths of measurement are considered in detail and the effects of some extraneous ions are examined. Microwave-excited electrodeless discharge tubes are used as spectral sources and intensity measurements are made with a Unicam SP 900A atomic-absorption/flame-emission spectrophotometer. Atomic-absorption measurements are also made with the same sources and spectrophotometer. The advantages of atomic-fluorescence methods and the use of electrodeless discharge tubes are discussed.

Photon-activation analysis of caesium: C. PERSIANI, J. SPIRA and R. BASTIAN, *Talanta*, 1967, **14**, 565 (Republic Aviation Corp., Farmingdale, N.Y., U.S.A.)

Summary—The corrosive behaviour of caesium has been attributed in part to the presence of a non-metallic impurity such as oxygen. A photon-activation method for determining oxygen and carbon in caesium is described. Scintillation coincidence-counting and pulse-height discrimination are used to count the gamma-ray activity resulting from annihilation of the positrons emitted. Variation of beam energy has been investigated in order to obtain optimum irradiation conditions. In the samples analysed and under the conditions used, less than 100 ppm of oxygen and carbon can be detected. Results are compared with those from other methods.

ИЗУЧЕНИЕ АТОМНО-ФЛУОРЕСЦЕНТНОЙ СПЕКТРОСКОПИИ—III. ВОЗБУЖДЕННЫЕ МИКРОВОЛНАМИ БЕЗЭЛЕКТРОДНЫЕ РАЗРЯДНЫЕ ЛАМПЫ КАК СПЕКТРАЛЬНЫЕ ИСТОЧНИКИ ДЛЯ АТОМНО-ФЛУОРЕСЦЕНТНОЙ И АТОМНО-АБСОРБЦИОННОЙ СПЕКТРОСКОПИИ:

R. M. Dagnall, K. C. Thompson and T. S. West, *Talanta*, 1967, **14**, 551.

Резюме—Приведены детали изготовления и использования возбужденных микроволнами безэлектродных разрядных ламп в качестве источников в атомно-флуоресцентной и атомно-абсорбционной спектроскопиях. Авторы особенно отсыляются к лампами для селена и теллура и обсуждают их спектральные характеристики. Приведены оптимальные условия для произведения интенсивных и устойчивых источников.

ИЗУЧЕНИЕ АТОМНО-ФЛУОРЕСЦЕНТНО Й СПЕКТРОСКОПИИ—IV. ОПРЕДЕЛЕНИЕ СЕЛЕНА И ТЕЛЛУРА МЕТОДОМ АТОМНО-ФЛУОРЕСЦЕНТНОЙ СПЕКТРОСКОПИИ:

R. M. Dagnall, K. C. Thompson and T. S. West, *Talanta*, 1967, **14**, 557.

Резюме—Селен и теллур определили все до 0,25 и 0,12 частей на миллион соответственно, измерением сигналей атомной флуоресценции при 2040 Å и 2143 Å соответственно. Детально обсуждены другие используемые длины волн и испытано влияние некоторых чуждых ионов. Возбужденные микроволнами безэлектродные разрядные лампы использовали в качестве спектральных источников а измерение интенсивности проводили на спектрофототометре Юникам SP 900A для атомной абсорбции и пламенной емиссии. Измерения атомной абсорбции проведены на том же самои спектрометре и пользуясь тем же самим источниками. Обсуждены преимущества методов атомной флуоресценции и безэлектродных разрядных ламп.

ФОТОННЫЙ АКТИВАЦИОННЫЙ АНАЛИЗ ЦЕЗИЯ:

C. Persiani, J. Spira and R. Bastian, *Talanta*, 1967, **14**, 565.

Резюме—Коррозионная характеристика цезия приписана частью присутствии неметаллических примесей, как на пример кислорода. Описан метод фотонноактивационного анализа для определения кислорода и углерода в цезии. Сцинтиллационный счетчик и анализатор импульсов использованы для измерения активности гамма лучей, образующихся в результате уничтожения вылетающих позитронов. Изучено влияние изменения энергии пучка с целью определения оптимальных условий облучения. В исследованных образцах и условиях опыта удалось обнаружить меньше чем 100 частей на миллион кислорода и углерода. Полученные этим методом результаты сравнены с результатами других методов.

Rapid microchemical method for the determination of magnesium in biological fluids: U. P. S. CHAUHAN and P. C. PANDE, *Talanta*, 1967, **14**, 575 (Institute of Nuclear Medicine and Allied Sciences, Delhi-7, India.)

Summary—A photometric method for the determination of magnesium in the presence of up to 50-fold excess of calcium is described. A magnesium–Azovan Blue lake is formed, stabilized with polyvinyl alcohol, and the absorbance is measured (Kodak No. 7 filter). The method has been used to determine magnesium in sera.

Applicability of the quasi-adiabatic enthalpimetric method for the study of chemical kinetics: PAOLO PAPOFF and PIER GIORGIO ZAMBONIN, *Talanta*, 1967, **14**, 581 (Istituto Chimica Analitica, Universita di Bari, Italy.)

Summary—The thermal quasi-adiabatic method and the non-adiabatic one are compared for the study of chemical kinetics. With thermistors as temperature-sensitive elements, and a very simple apparatus, moderately fast reactions (with $t_{1/2}$ down to 2 sec) and consecutive reactions can be followed, and mixtures analysed with good accuracy. The reproducibility is satisfactory over a wide range of experimental conditions. The calculation of the kinetic parameters, for both first- and second-order kinetics is very simple and requires no calibration of the system. Application of the technique to the study of the alkaline hydrolysis of some alkyl acetates is described.

1-Hydroxy-ethylidene-1,1-diphosphonic acid as a titrimetric agent: R. PŘIBIL and V. VESELÝ, *Talanta*, 1967, **14**, 591 (Laboratory for Analytical Chemistry, J. Heyrovský Polarographic Institute, Czechoslovak Academy of Sciences, Prague 1, Jilská 16, Czechoslovakia.)

Summary—1-Hydroxy-ethylidene-1,1-diphosphonic acid (HEDPHA) has been proposed as a highly selective titrimetric reagent for thorium. In the presence of 1,2-diaminocyclohexanetetra-acetic acid (DCTA) a soluble binuclear ternary complex, $Th_2(DCTA)_2(HEDPHA)$, is formed. The determination of thorium is carried out in a slightly acidic medium, buffered with urotropine, with 0·025*M* HEDPHA, and Xylenol Orange as indicator. DCTA masks all bivalent metals, rare earths, scandium, yttrium, bismuth, iron, gallium and indium. Only zirconium, titanium, aluminium and large amounts of thallium(III) interfere.

БЫСТРЫЙ МИКРОХИМИЧЕСКИЙ МЕТОД ОПРЕДЕЛЕНИЯ МАГНИЯ В БИОЛОГИЧЕСКИХ ЖИДКОСТЯХ:

U. P. S. Chauhan and P. C. Pande, *Talanta*, 1967, **14**, 575.

Резюме—Описан фотометрический метод определения магния в присутствии 50 кратного избытка кальция. Образуется стабилизированный поливиниловым спиртом лак магния с азовансином, светопоглощение которого измеряют с использованием фильтра Кодак Но. 7. Метод применен в определении магния в сыворотке.

ПРИМЕНИМОСТЬ КВАЗИАДИАБАТИЧЕСКОГО ЭНТАЛЬПИМЕТРИЧЕСКОГО МЕТОДА ДЛЯ ИЗУЧЕНИЯ КИНЕТИКИ ХИМИЧЕСКИХ РЕАКЦИЙ:

Paolo Papoff and Pier Giorgio Zambonin, *Talanta*, 1967, **14**, 581.

Резюме—Сравнена применимость квазиадиабатического и неадиабатического методов для изучения кинетики химических реакций. Пользуясь термисторами в качестве элементов для обнаружения температуры и весьма простой аппаратурой, можно следить умеренно быстрые реакции (имеющие $t_{1/2}$ выше 2 сек.) и последующие реакции, и анализировать смеси с довольном точностью. Воспроизводимость результатов удовлетворительна в широких пределах опытных условий. Вычисление кинетических параметров для реакций первого и второго порядка весьма простое и не требует калибровку системы. Описано применение процедуры на изучение щелочного гидролиза некоторых алкилацетатов.

1-ОКСИЭТИЛИДЕН-1,1-ДИФОСФОНОВАЯ КИСЛОТА КАК ТИТРИМЕТРИЧЕСКИЙ АГЕНТ:

R. Přibil and V. Veselý, *Talanta*, 1967, **14**, 591.

Резюме—1-оксиэтилиден-1,1-дифосфоновая кислота(ОЭДФК) предложена в качестве высокоизбирательного титримет рического агента для тория. В присутствии 1,2-диаминоциклогексантетрауксусной кислоты (ДЦТА) образуется растворимый бинуклеарный третичный комплекс Th_2(ДЦТА)$_2$-логексантетрауксусной кислоты (ДЦТА) образуется раст-(ОЭДФК). Определение тория проводится в слабокислом, забуферированном уротропином растворе с 0,025*M* ОЭДФК и ксиленолоранжевым в качестве индикатора. ДЦТА маскирует все двувалентные металлы, редкоземельные элементы, скандий, иттрий, висмут, железо, галлий и индий. Только цирконий, титан, алюминий и большие количества таллия(III) мешают определению.

Determination of microgram quantities of tin(IV) by a combined ion-exchange/X-ray fluorescence technique: B. R. CHAMBERLAIN and R. J. LEECH, *Talanta*, 1967, **14**, 597. (Pilkington Brothers Limited, Research and Development Laboratory, Lathom, Ormskirk, Lancashire, U.K.)

Summary—A method is described for the analysis of microgram quantities of tin in dilute hydrofluoric acid. The tin is extracted onto anion-exchange resin loaded paper discs by a very simple technique and the papers are examined by X-ray fluorescence spectrography. The solutions are obtained by the dissolution of tin-containing glasses, and the normal glass-forming elements do not interfere. The method is intended for the determination of 1–20 μg of tin but may be used for up to at least 250 μg; 5 μg can be determined with a precision of $\pm 10\%$

Spectrophotometric determination of Channel Black in small arms propellants: MICHAEL GALAN and GEORGE NORWITZ; *Talanta*, 1967, **14**, 603 (Frankford Arsenal, Philadelphia, Pa., U.S.A.)

Summary—A spectrophotometric method is proposed for the determination of Channel Black in small arms propellants. The Channel Black is separated from the nitrocellulose and other organic compounds by dissolution of the propellant in morpholine and filtration through a sintered porcelain crucible containing an asbestos mat. The Channel Black is then dissolved by treating the mat and crucible with boiling nitric acid for 3 hr, the solution is filtered, and the yellow colour is measured. The colour is due to polycarboxylic acids with cyclic nuclei. The range of the method is from 0 to 0·5% of Channel Black.

Synthetic and analytical studies on colour reagents—IX. The reactions of phthaleinazo compounds with the alkaline earths: TOSHIKO KOBATAKE, TADASHI IWACHIDO and KYOJI TÔEI, *Talanta*, 1967, **14**, 607 (Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama-shi, Japan.)

Summary—Some new phthaleinazo compounds—*o,o'*-dihydroxyazo compounds—have been prepared by coupling chromotropic acid, R-acid, and 2-hydroxy-3-naphthoic acid with bis-diazotized diaminophthaleins. These compounds have been found to be very sensitive colour reagents for alkaline earths in alkaline media, and in particular, bis(chromotropeazo)phenolphthalein is the most sensitive yet found.

New method for the determination of pentachlorophenol by atomic absorption spectrophotometry: Y. YAMAMOTO, T. KUMAMARU and Y. HAYASHI, *Talanta*, 1967, **14**, 611 (Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima, Japan.)

Summary—A new application of atomic absorption is reported for the determination of pentachlorophenol. The method is based on solvent extraction into nitrobenzene of the ion-pair formed between tris(1,10-phenanthroline)iron(II) and the anion of pentachlorophenol, and the subsequent determination of the iron concentration in the extract by atomic absorption at the 2483 Å iron line.

ОПРЕДЕЛЕНИЕ МИКРОГРАММОВЫХ КОЛИЧЕСТВ ОЛОВА(IV) КОМБИНИРОВАННОЙ ПРОЦЕДУРОЙ ИОННОГО ОБМЕНА И ФЛУОРЕСЦЕНЦИИ РЕНТГЕНОВСКИХ ЛУЧЕЙ:

B. R. Chamberlain and R. J. Leech, *Talanta*, 1967, **14**, 597.

Резюме—Описан метод анализа микрограммовых количеств олова в разбавленной фтористоводородной кислоте. Олово концентрируют на пропытанных анионообменной смолой бумажных дисках, следуя весьма простую процедуру и диски испытывают методом флуоресценции рентгеновских лучей. Растворы получены растворением оловосодержающих стекл, а обыкновенные стеклообразующие элементы не мешают определению. Метод разработан для определения 1–20 мкг олова, нотможет применяться все до 250 мкг и выше; точность определения 5 мкг равна ±10%.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ КАНАЛЬНОЙ САЖИ В РЕАКТИВНЫХ ТОПЛИВАХ ДЛЯ МАЛЫХ ОРУЖИЯХ:

Michael Galan and George Norwitz, *Talanta*, 1967, **14**, 603.

Резюме—Предложен спектрофотометрический метод определения канальной сажи в топливах для малых оружиях. Канальную саж отделяют от нитроцеллюлозы и других органических веществ растворением топлива в морфолине и фильтрованием через спеченный фарфоровый тигель с вставкой из асбестовой ткани. Канальную сажу затем растворяют помещением асбестовой ткани и тигеля в кипящую азотную кислоту и обрабативанием в течение 3 часа; раствор фильтруют и измеряют его желтый цвет. Цвет вызван поликарбоновыми кислотами с циклическими ядрами. Метод применимый в пределах 0 до 0,5% канальной сажи.

СИНТЕТИЧЕСКОЕ И АНАЛИТЧЕСКОЕ ИЗУЧЕНИЕ ОКРАШИВАЮЩИХ РЕАГЕНТОВ—IX. РЕАКЦИИ ФТАЛЕИНАЗОСОЕДИНЕНИЙ С ЩЕЛОЧНОЗЕМЕЛЬНЫМИ ЭЛЕМЕНТАМИ:

Toshiko Kobatake, Tadashi Iwachido and Kyoji Tôei, *Talanta*, 1967, **14**, 607.

Резюме—Некоторые новые фталеиназосоединения—*o,o'*-диоксиазосоединения—приготовлены путем сочетания хромотроповой, Р—кислоты и 2-окси-3-нафтойной кислоты с бисдиазотированными диаминофталеинами. Эти соединения являются очень чувствительными окрашивающими реагентами для щелочноземельных элементов в щелочной среде; бис(хромотропазо)фенолфталени является наиболее чувствительным реагентом найденым до сих пор.

НОВЫЙ МЕТОД ОПРЕДЕЛЕНИЯ ПЕНТАХЛОРОФЕНОЛА МЕТОДОМ АТОМНО-АБСОРБЦИОННОЙ СПЕКТРОФОТОМЕТРИИ:

Y. Yamamoto, T. Kumamaru and Y. Hayashi, *Talanta*, 1967, **14**, 611.

Резюме—Сообщено применение метода атомно-абсорбционной спектрофотометрии для определения пентахлорофенола. Метод основывается на извлечении нитробензолом ионной пары образующейся между трис(1,10-фенантролин) железом(II) и анионом пентахлорофенола, с последовательным определением концентрации железа в екстракте методом атомно-абсорбционной спектрофотометрии, пользуясь линией железа при 2483 Å.

SUMMARIES FOR CARD INDEXES

A critical review of methods of isolating and separating the noble metals—II: Ion-exchange and solvent extraction: F. E. BEAMISH, *Talanta*, 1967, **14**, 991 (Department of Chemistry, University of Toronto, Toronto 5, Ontario, Canada.)

Summary—This review deals with ion-exchange and solvent extraction methods of separating the seven noble metals, published subsequent to the previous reviews and prior to January 1966. The noble metal species present in solution are discussed in so far as they relate to separation and determination.

Spectroscopy in separated flames—I. The use of the separated air–acetylene flame in thermal emission spectroscopy: G. F. KIRKBRIGHT, A. SEMB and T. S. WEST, *Talanta*, 1967, **14**, 1011 (Chemistry Department, Imperial College, London, S.W.7.)

Summary—The separation of a premixed air–acetylene flame is described. The interconal zone of this flame exhibits very low radiative background, and is only slightly cooler than that of a normal air–acetylene flame. The use of the separated flame in flame photometry, for which it has several pronounced advantages, has been investigated.

Precipitation of nickel dimethylglyoximate: S. J. LYLE and R. MAGHZIAN, *Talanta*, 1967, **14**, 1021 (The Chemical Laboratory, The University of Kent at Canterbury, Canterbury, Kent, U.K.)

Summary—The homogeneous precipitation method of Salesin and Gordon and the aqueous acetone precipitation described by Jones and Howick are examined for the determination of nickel as the dimethylglyoximate and where applicable comparisons are made with a direct (conventional) precipitation of this substance. The co-precipitation of iron and cobalt was studied radiometrically under various experimental conditions. Relevant solubility data are also presented. Application of the methods to the determination of nickel in alloy steels showed that in the absence of cobalt there is little to choose between them. For cobalt steels the method of Jones and Howick is more convenient than that of Salesin and Gordon and more satisfactory than a conventional precipitation and gravimetric finish.

КРИТИЧЕСКИЙ ОБЗОР МЕТОДОВ ВЫДЕЛЕНИЯ РАЗДЕЛЕНИЯ БЛАГОРОДНЫХ МЕТАЛЛОВ—II: ИОННЫЙ ОБМЕН И ЭКСТРАКЦИЯ РАСТВОРИТЕЛЯМИ:

F. E. Beamish, *Talanta*, 1967, **14**, 991.

Резюме—Приведен обзор методов ионного обмена и экстракции растворителями для разделения семи благородных металлов, опубликованных после предыдущих обзоров, а раньше января 1966. Обсуждены только те ионы благородных металлов в растворе, относящиеся на разделение и определение этих металлов.

СПЕКТРОСКОПИЯ В РАЗДЕЛЕННОМ ПЛАМЕНИ—I. ИСПОЛЬЗОВАНИЕ РАЗДЕЛЕННОЙ ПЛАМЕНИ ВОЗДУХ-АЦЕТИЛЕН В ТЕРМИЧЕСКОЙ ЭМИССИОННОЙ СПЕКТРОСКОПИИ:

G. F. Kirkbright, A. Semb and T. S. West, *Talanta*, 1967, **14**, 1011.

Резюме—Описано разделение пламени из заранее смешанной смеси воздуха и ацетилена. Межконусная зона этой пламени имеет весьма низкий излучáющий фон и она только незначительно холоднее чем зона в обыкновенной пламени воздуха и ацетилена. Изучено применение раделенной пламени в пламенной фотометрии, для которого метода это пламя имеет некоторые преимущества.

ОСАЖДЕНИЕ ДИМЕТИЛГЛИОКСИМАТА НИКЕЛЯ:

S. J. Lyle and R. Maghzian, *Talanta*, 1967, **14**, 1021.

Резюме—Метод гомогенного осаждения Салесина и Гордона и метод осаждения водным раствором ацетона Джонса и Гауика применены в определении никеля в форме диметилглиоксимата и сравнены в некоторых случаях с прямым обыкновенным осаждением этого вещества. Соосаждение железа и кобальта изучено радиометрическим методом в различных опытных условиях. Приведены относящиеся к этим условиям данные о растворимости. Применение методов в определении никеля в легированных сталях показало хорошую применимость обоих методов в отсутсвии кобальта. В случае кобальтовых сталях более пригодным является метод Джонса и Гауика чем метод Салесина и Гордона, и более пригодным чем обыкновенное осаждение с весовым определением никеля.

A high speed micro vacuum-fusion apparatus: M. T. LILBURNE, *Talanta* 1967, **14**, 1029 (National Physical Laboratory, Teddington, Middlesex, England).

Summary—A micro vacuum-fusion apparatus capable of extracting, collecting and examining volumes of gas of no more than 2×10^{-3} cm^3 at N.T.P. from metal samples is described. The resulting gas mixture is analysed by gas chromatography with helium as the carrier gas and with a highly sensitive ionization detector.

Mass spectrometric analysis of high-purity helium and hydrogen, using a dynamic sampling and calibration system: R. T. PARKINSON, *Talanta*, 1967, **14**, 1037 (Master General of Ordnance Inspectorates, Chemical Inspectorate, Royal Arsenal, Woolwich, London S.E. 18, U.K.)

Summary—A dynamic gas sampling system has been designed for use with a mass spectrometer (A.E.I. Model MS2G). It is capable of sampling directly from gas streams at pressures in the region of 800 torr and has been satisfactorily used for the analysis of high-purity helium and hydrogen containing less than 50 vpm total impurity. The overall sensitivity is 1 vpm or better. The design permits the mass spectrometer to be used with its normal gas sampling system when required. A dynamic gas blending rig, incorporating a recirculation and purification system, has been developed for the calibration of the mass spectrometer over the range 5–100 vpm of impurity content.

Radioactive substoichiometric isotope-dilution procedure for the determination of rare earth metals: G. B. BRISCOE and A. DODSON, *Talanta*, 1967, **14**, 1051 (Department of Chemistry, University of Aston in Birmingham, Birmingham 4, England.)

Summary—A theory is developed which describes the equilibrium conditions when solutions containing trace metals and substoichiometric amounts of EDTA are extracted with thenoyltrifluoroacetone. Experimental evidence is given to support the theory. A method for the determination of microgram quantities of rare earth metal is outlined as an application.

ПРИБОР ДЛЯ ПЛАВЛЕНИЯ В ВАКУУМЕ НА МИКРОШКАЛЕ:

M. T. Lilburne, *Talanta*, 1967, **14**, 1029.

Резюме—Описан прибор для плавления в вакууме образцов металлов, которым можно экстрагировать, собирать и анализировать объемы газов меньше чем 2×10^{-3} см³ при нормальной температуре и давлении. Экстрагированная смесь газов анализируется методом газовой хроматографии, пользуясь гелием в качестве газа носителя и высокочувствительным ионизационным детектором.

АНАЛИЗ ВЫСОКОЧИСТОТНОГО ГЕЛИЯ И ВОДОРОДА МЕТОДОМ МАССПЕКТРОМЕТРИИ С ИСПОЛЬЗОВАНИЕМ ДИНАМИЧЕСКОЙ СИСТЕМЫ ДЛЯ ОТБОРА ПРОБЫ И КАЛИБРОВКИ:

R. T. Parkinson, *Talanta*, 1967, **14**, 1037.

Резюме—Сконструирована динамическая система отбора пробы газа для масс-спектрометра A.E.I. типа MS2G. Этой системой удается отобрать пробы прямо из струи газа при давлении в пределе 800 торр; ей пользовались успешно в анализе высокочистотного гелия и водорода, содержащего меньше чем 50 частей на миллион (по объему) общих примесей. Общая чувствительность метода больше чем I часть на миллион (по объему). Конструкция этой системы позволяет использование масс-спектрометра с его нормальной системой отбора газовидных проб в случае желания этого. Также сконструирована система для динамического смешивания газов, включая систему рециркуляции и очистки, которой пользовались для калибровки масс-спектрометра в пределах 5–100 частей на миллион (по объему) примеси.

СУБСТЕХИОМЕТРИЧЕСКАЯ ПРОЦЕДУРА РАЗБАВЛЕНИЯ РАДИОАКТИВНЫХ ИЗОТОПОВ ДЛЯ ОПРЕДЕЛЕНИЯ РЕДКОЗЕМЕЛЬНЫХ ЭЛЕМЕНТОВ:

G. B. Briscoe and A. Dodson, *Talanta*, 1967, **14**, 1051.

Резюме—Разработана теория описывающая равновесные условия при экстрагировании теноилтрифторацетоном растворов, содержащих следы металлов и субстехиометрические количества ЭДТА. Приведены экспериментальные данные подкрепляющие теорию. Методом пользовались для определения микрограммовых количеств редкоземельных металлов.

Purity control of uranium by neutron activation assay—II. Determination of manganese, nickel and copper: A. A. ABDEL-RASSOUL and S. S. WAHBA, *Talanta*, 1967, **14**, 1061 (Nuclear Chemistry Department, Atomic Energy Establishment, Cairo, U.A.R.)

Summary—Activation analysis is applied for the simultaneous determination of manganese, nickel and copper in different uranium samples, including metallic uranium, uranium concentrates, oxide, acetate, nitrate and sodium uranate. The analytical scheme developed is based on separation of the uranium by paper chromatography and subsequent determination of these elements in the pile-irradiated residues by simple radiochemical operations. The reliability of the scheme proposed is tested, and the limits of sensitivity of the methods worked out are ascertained. Accordingly, microgram concentrations of the elements studied could be assayed in limited quantities of the samples analysed with a precision of $\pm 15\%$. Reagent-blank determinations are also considered.

Cation-exchange behaviour of several elements in nitric acid–organic solvent media: J. KORKISCH, F. FEIK and S. S. AHLUWALIA, *Talanta*, 1967, **14**, 1069 (Analytical Institute, University of Vienna IX, Währingerstrasse 38, Austria.)

Summary—The cation-exchange behaviour of 19 elements towards the strongly acidic cation-exchange resin Dowex 50-X8 in media containing varying concentrations of organic solvents and aqueous nitric acid is reported. Based on the determination of the distribution coefficients of these elements in the organic solvents methanol, ethanol, n-propanol, isopropanol, methyl glycol, acetone, tetrahydrofuran and acetic acid, the conditions most suitable for their quantitative separation are indicated and discussed.

Titrimetric, coulometric and spectrophotometric determination of manganese following perchloric acid oxidation in the presence of pyrophosphate: JOHN KNOECK and HARVEY DIEHL, *Talanta*, 1967, **14**, 1083 (Department of Chemistry, Iowa State University, Ames, Iowa, U.S.A.)

Summary—Manganese is oxidized quantitatively to a violet, tervalent pyrophosphate in a boiling mixture of equal parts of perchloric acid and phosphoric acid. This Mn(III) can be titrated potentiometrically or coulometrically with iron(II); it can also be measured spectrophotometrically. If the titrimetric method is carried out with titanium (III) or chromium(II), iron can also be titrated immediately after the manganese. The methods were applied to a new reference sample, ISU 600 Manganiferous Iron Ore, and to manganese ore, spiegeleisen, ferromanganese, and rail steel. Manganese(II) oxalate dihydrate has been reinvestigated as a primary standard and is highly recommended.

КОНТРОЛЬ ЧИСТОТЫ УРАНА МЕТОДОМ НЕЙТРОННО-АКТИВАЦИОННОГО АНАЛИЗА—II. ОПРЕДЕЛЕНИЕ МАРГАНЦА, НИКЕЛЯ И МЕДИ:

A. A. Abdel-Rassoul and S. S. Wahba, *Talanta*, 1967, **14**, 1061.

Резюме—Методом радиоактивационного анализа пользовались для одновременного определения марганца, никеля и меди в различных урансодержащих пробах, на пример в металлическом уране, концентратах урана, в окиси, ацетате, нитрате и в уранате натрия. Метод основывается на отделении урана методом бумажной хроматографии и последующем определении этих элементов в облученных в реакторе остатках применяя несложные радиохимические процедуры. Испытана надёжность предложенной схемы и определены пределы чувствительности методов. Этим образом удалось определить микрограммовые количества исследованных элементов точностью ±15% в ограниченных количествах анализируемых проб. Проведены также контрольные опыты для реагентов.

ИОНООБМЕННОЕ ПОВЕДЕНИЕ НЕКОТОРЫХ ЭЛЕМЕНТОВ В РАСТВОРАХ АЗОТНОЙ КИСЛОТЫ И ОРГАНИЧЕСКИХ РАСТВОРИТЕЛЯХ:

J. Korkisch, F. Feik and S. S. Ahluwalia, *Talanta*, 1967, **14**, 1069.

Резюме—Изучено катионообменное поведение 19 элементов на сильнокислой катионообменной смоле Дауекс 50-X8 в растворах, состоящихся из различных концентраций органических растворителей и водного раствора азотной кислоты. На основе коэффициентов распределения этих элементов в метиловом, этиловом, н-пропиловом и изопропиловом спиртах, метилгликоле, ацетоне, тетрагидрофуране и уксусной кислоте определены и обсуждены оптимальные условия для количественного выделения этих элементов.

ТИТРИМЕТРИЧЕСКОЕ, КУЛОНОМЕТРИЧЕСКОЕ И СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ МАРГАНЦА ПОСЛЕ ОКИСЛЕНИЯ ХЛОРНОЙ КИСЛОТОЙ В ПРИСУТСТВИИ ПИРОФОСФАТА:

John Knoeck and Harvey Diehl, *Talanta*, 1967, **14**, 1083.

Резюме—Марганец окисляется количественно до фиолетового трехвалентного пирофосфата в кипящей смеси, состоящейся из равных частей хлорной и фосфорной кислот. Mn(III) можно титровать потенциометрическим или кулонометрическим методом с железом(II) или определять спектрофотометрическим методом. Если титрование проводится с титаном(III) или хромом(II), дана возможность титрования железа непосредственно после марганца. Метод использован в анализе нового эталона—ISU 600, содержащей марганец руды железа—и в анализе руды марганца, зеркального чугуна, ферромарганца и рельсовой стали. Снова изучено и рекомендовано использование дигидрата оксалата марганца (II) в качестве первичного стандарта.

Eléments de fluorimétrie organique fonctionnelle: M. PESEZ and J. BARTOS, *Talanta*, 1967, **14**, 1097 (Centre de Recherches Roussel-Uclaf, 93-Romainville, France.)

Summary—By means of suitable chemical reactions, formaldehyde is obtained from 1,2-diols, hexitols, primary α-amino alcohols, 2-nitro-1-hydroxy aliphatic compounds, the methylene group in R—CH=CH_2 and 17-ketolsteroids, and converted into a dihydrolutidine derivative which is then determined by fluorimetry. The formation of dihydropyridine derivatives also allows the fluorimetric determination of primary alkylamines, nitriles and aliphatic aldehydes. Aldehydes with an α-methylene group and 2-deoxysugars can be determined by forming fluorescent quinaldines. The fluorescent compound obtained by condensing glyoxylic acid with resorcinol allows the determination of α,β-dihydroxy and hexuronic acids after a periodate oxidation. The fluorimetric determination of phenols is achieved by converting them into coumarins.

Neutron activation analysis by standard addition and solvent extraction. Determination of impurities in aluminium: A. ALIAN and A. HAGGAG, *Talanta*, 1967, **14**, 1109 (Nuclear Chemistry Department, Atomic Energy Establishment, Inshas, U.A.R.)

Summary—A separation scheme based on the selective extraction in conjunction with the standard addition technique has been developed for the determination of impurities in aluminium by neutron activation. Preliminary investigations have been carried out on the extractability of Sc, Co, Hf, Fe, Sn, Cd, Zn, Ag, Cr, Ce, Cs and Rb by TDA and TBP from acidic media. The best conditions are predicted for the separation of these elements into fractions suitable for analysis by gamma-ray spectrometry. Recovery values of ~90% were obtained for all the elements.

Photometrische Bestimmung von Kupfer mit Polyäthylenimin: MAX ZIEGLER and LÜDER ZIEGELER, *Talanta*, 1967, **14**, 1121 (Anorganisch-Chemischen Institut, Die Universität, Göttingen, Deutschland.)

Summary—Copper (0·3–10%) in light metal alloys can be determined spectrophotometrically at 635 mμ by means of the colour produced with polyethylene imines. The reactions of these reagents with HNO_2, CS_2, HgI_2 and As_2O_3 have also been investigated.

ОСНОВЫ ФЛУОРОМЕТРИИ ОРГАНИЧЕСКИХ ФУНКЦИОНАЛЬНЫХ ГРУПП:

M. Pesez and J. Bartos, *Talanta*, 1967, **14**, 1097.

Резюме—Подходящими химическими реакциями можно получать формальдегид из 1,2-диолов, гекситолов, первичных α-аминоспиртов, 2-нитро-1-оксиалифатических соединений, метиленовой группы R—CH=CH_2 и 17-кетостероидов, и превращать его в дериват дигидролутидина, который затем определяют флуорометрическим методом. Образование дериватов дигидропиридина позволяет флуорометрическое определение первичных алкиламинов, нитрилов и алифатических альдегидов. Содержащие α-метиленовую группу альдегиды и 2-дезоксисахары можно определять путем образования флуоресцирующих хиналдинов. Флуоресцирующее соединение, полученное конденсацией глиоксалевой кислоты с резорцином позволяет определение α,β-диоксикислот и гексуроновых кислот после окисления периодатом. Флуорометрическое определение фенолов можно после их превращения в кумарины.

НЕЙТРОННОАКТИВАЦИОННЫЙ АНАЛИЗ ПУТЕМ ДОБАВЛЕНИЯ СТАНДАРТОВ И ЭКСТРАГИРОВАНИЯ РАСТВОРИТЕЛЯМИ. ОПРЕДЕЛЕНИЕ ПРИМЕСЕЙ В АЛЮМИНИИ:

A. Alian and A. Haggag. *Talanta*, 1967, **14**, 1109.

Резюме—Разработана основывающаяся на селективном извлечении схема разделения в связи с методом добавления стандартов для определения примесей в алюминии методом нейтронной активации. Проведены предварительные исследования экстрагируемости Sc, Co, Hf, Fe, Sn, Cd, Zn, Ag, Cr, Ce, Cs, и Rb из кислих растворов при помощи ТДА и ТБФ. Предсказаны оптимальные условия разделения этих элементов в фракции, анализируемые методом спектрометрии гамма лучей. Выход ~90% получен для всех этих элементов.

ФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ МЕДИ ПОЛИЭТИЛЕНИМИНОМ:

Max Ziegler and Lüder Ziegeler, *Talanta*, 1967, **14**, 1121.

Резюме—Медь (0,3–10%) в сплавах лёгких металлов определяли спектрофотометрическим методом при 645 ммк, на основе окраски образованной с полиэтилениминами. Также изучены реакции этих реагентов с HIO_3, CS_2, HgI_2 и As_2O_3.

Synthesis and analytical applications of 2,4-dinitro-6-chlorophenylazothymol: S. K. MUKERJI and H. L. SHARMA, *Talanta*, 1967, **14**, 1123 (Geological Survey of India, Rajasthan Circle, Jaipur, India and Department of Pharmacology, S.M.S. Medical College, Jaipur, India.)

Summary—The newly synthesized 2,4-dinitro-6-chlorophenylazothymol, a weak acid with pK_a 8·33 ± 0·04 at 27°, is proposed as a sensitive spot reagent for magnesium, with an identification limit of 0·14 μg at pH 10·5–11·6. Silver and manganese(II) interfere but can be masked by means of cyanide and periodate respectively. There is little interference by anions. The reagent also serves as an acid–base indicator with a transition interval of pH 7–9, giving a sharp colour change at the equivalence point.

Studies on metallochromic indicators—I. Pyrocatecholphthalein as metallochromic indicator: G. K. SINGHAL and K. N. TANDON, *Talanta*, 1967, **14**, 1127 (Chemistry Department, Rajasthan University, Jaipur, India.)

Summary—Pyrocatecholphthalein has been used as a metallochromic indicator for the direct complexometric titrations of a number of metal ions with EDTA, both in acidic and in alkaline medium. Th, Bi(III), Ba, Sr, Ca, Mg, Mn(II), Pb(II), Cu(II), Cd, Ni, Co(II) and Zn have been successfully titrated. In comparison with Pyrocatechol Violet, this dyestuff gives sharper end-points when the titrations are done at high pH.

Interference of the ammonium ion in Mohr's method for the determination of chloride: JACOB BLOCK and OSCAR B. WATERS, JR., *Talanta*, 1967, **14**, 1130 (W. R. Grace and Co., Washington Research Center, Clarksville, Maryland 29029, U.S.A.)

Summary—The ammonium ion has been found to interfere in the Mohr method for the determination of chloride.

СИНТЕЗ И ПРИМЕНЕНИЕ В АНАЛИЗЕ 2,3-ДИНИТРО-6-ХЛОРОФЕНИЛАЗОТИМОЛА:

S. K. Mukerji and H. L. Sharma, *Talanta*, 1967, **14**, 1123.

Резюме—Недавно синтезированный 2,4-динитро-6-хлорофенилазотимол,—слабая кислота с pK_a 8,33 ± 0,04 при 27°—предложен в качестве чувствительного капельного реагента для магния, имеющий предел чувствительности 0,14 мкг при pH 10,5–11,6. Серебро и марганец(II) мешают, но их можно маскировать цианидом или периодатом, соответсвенно. Анионы почти не влияют на определение. Реагентом также можно пользоваться в качестве кислотно-щелочного индикатора, имеющим область перехода от pH 7–9, а дающим острую перемену цвета в точке еквиленватности.

ИЗУЧЕНИЕ МЕТАЛЛОХРОМНЫХ ИНДИКАТОРОВ—I. ПИРОКАТЕХИНФТАЛЕНИ В КАЧЕСТВЕ МЕТАЛЛОХРОМНОГО ИНДИКАТОРА:

G. K. Singhal and K. N. Tandon, *Talanta*, 1967, **14**, 1127.

Резюме—Пирокатехинфталеин использован в качестве металлохромного индикатора для прямого комплексонометрического титрования ряда ионов металлов с ЭДТА, в кислой и щелочной средах. Успешно титрованы Th, Bi(III), Ba, Sr, Ca, Mg, Mn(II), Pb(II), Cu(II), Cd, Ni, Co(II) и Zn. В сравнении с пирокатехинфиолетовым, этот краситель дает более острые конци титрования при высоких pH.

ВЛИЯНИЕ ИОНА АММОНИЯ НА ОПРЕДЕЛЕНИЕ ХЛОРИДА МАТОДОМ МОРА:

Jacob Block and Oscar B. Waters, Jr., *Talanta*, 1967, **14**, 1130.

Резюме—Установлено влияние иона аммония на определение хлорида методом Мора.

Substoichiometric determination of traces of gold by radioactive isotope-dilution analysis: D. A. BEARDSLEY, G. B. BRISCOE, J. RŮŽIČKA and M. WILLIAMS, *Talanta*, 1967, **14**, 879 (Department of Chemistry, The University of Aston in Birmingham, Birmingham 4, England).

Summary—A radioactive isotope-dilution method for the determination of traces of gold has been developed. It is based on the solvent extraction of gold diethyldithiocarbamate from 0·5*N* sulphuric acid containing ascorbic acid, by means of a substoichiometric amount of zinc diethyldithiocarbamate in chloroform. The separation has been applied to the analysis of gold-doped semiconductor-grade silicon and of gold-bearing ores. Amounts of gold down to 5×10^{-7} g/20 ml of test solution can be determined.

Study of the formation of dodecatungstates and the dosage of iso- and heterododecatungstates with the aid of chloride of tetraphenylphosphonium: RALUCA RIPAN and CLEOPATRA CALU, *Talanta*, 1967, **14**, 887 (Institut de chimie de l'Académie de la République Socialiste, Filiala Cluj Roumaine).

Summary—A physico-chemical study of the conditions of formation (pH, time, temperature) of dodecatungstates and of their separation with tetraphenylphosphonium chloride is presented. In the iso- and heteropolytungstate series only the anions of the form $XW_{12}O_{40}^{(8-n)-}$ (where n is the oxidation number of X) are precipitated by this reagent. The reaction is quantitative and can be used to separate the dodecatungstate from a mixture of tungstate anions. By using tetraphenylphosphonium chloride as a specific reagent for dodecatungstate it has been possible to show that in the condensation of sodium tungstate in high concentrations of acid the dodecatungstate begins to appear at pH $\sim$ 6 and all the tungstate is in this form at pH $\sim$ 2. Factors such as dilution, time and temperature also affect the formation of dodecatungstate over this pH range. The reaction is used for the determination of a series of dodecatungstates.

Reactions of Eriochrome Blue Black R: G. L. SILVER and R. C. BOWMAN, *Talanta*, 1967, **14**, 893 (Monsanto Research Corporation, Mound Laboratory, Miamisburg, Ohio, U.S.A.).

Summary—The reactions of Eriochrome Blue Black R with approximately 25 metals are tabulated. Photometric titrations of molybdenum and uranium are described, and a new method of titrating thulium with EDTA is presented.

Application of volatilazation-excitation curves to the determination of the conditions for spectrochemical analysis of tantalum oxide: J. BRIL and J. VINOT, *Talanta*, 1967, **14**, 897 (Cie Pechiney LRM-38- Grenoble, France).

Summary—The determination of the optimum conditions for the spectrographic analysis of tantalum oxide is facilitated by consideration of the volatilization curves for the elements sought. The method is applied for the estimation of Cr, Fe, Hf, Ni, Nb, Ti, Y and Zr at the 10–1000 ppm level.

СУБСТЕХИОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ СЛЕДОВ ЗОЛОТА МЕТОДОМ РАЗБАВЛЕНИЯ РАДИОАКТИВНЫХ ИЗОТОПОВ:

D. A. Beardsley, G. B. Briscoe, J. Růžička and M. Williams, *Talanta*, 1967, **14**, 879.

Резюме—Разработан метод определения следов золота разбавлением радиоактивных изотопов. Метод основывается на экстрагировании диэтилдитиокарбамината золота субстехиометрическим количеством диэтилдитиокарбамината цинка в хлороформе из содержхющей аскорбиновую кислоту 0,5 *N* серной кислоты. Метод выделения был применен в анализе зараженного золотом кремния для полупроводников и руд золота. Метод позволяет определить до 5×10^{-7} г золота/20 мл анализируемого раствора.

ИЗУЧЕНИЕ ОБРАЗОВАНИЯ ДОДЕКАВОЛЬФРАМАТОВ И ОПРЕДЕЛЕНИЕ ИЗО- И ГЕТЕРОПОЛИВОЛЬФРАМАТОВ ХЛОРИДОМ ТЕТРАФЕНИЛФОСФОНИЯ:

Raluca Ripan and Cleopatra Calu, *Talanta*, 1967, **14**, 887.

Резюме—Сообщены результаты физико-химического изучения условий (pH, времени, температуры) образования додекавельфраматов и их разделения хлоридом тетрафенилфосфония. В ряде изо- и гетерополивольфраматов только анионы формы $XW_{12}O_{40}^{(8-n)}O$ (где *n* окислительное число от X) осаждаются этим реагентом. Реакция количественная и ею можно пользоваться для выделения додекавольфрамата из смеси вольфраматанионов. Использованием хлорида тетрафенилфосфония в качестве специфического реагента для додекавольфрамата удалось показать что в конденсации вольфрамата натрия при высоких концентрациях кислоты додекавольфрамат появляется при pH $\sim$ 6 и что весь вольфрамат присутствует в этой форме при pH $\sim$ 2. Факторы как на пример разбавление, время и температура так же влияют на образование додекавольфрамата в этой области pH. Реакцией пользовались для определения ряда додекавольфраматов.

РЕАКЦИИ ЭРИОХРОМ СИНЕ-ЧЁРНОГО Я:

G. L. Silver and R. C. Bowman, *Talanta*, 1967, **14**, 893.

Резюме—Приведены в форме таблицм реакции эриохром сине-чёрного R с около 25 металлов. Описаны фотометрические титрации молибдена и урана и предложен новый метод титрования тулия с ЭДТА.

ПРИМЕНЕНИЕ КРИВЫХ ВОЗБУЖДЕНИЯ И УЛЕТУЧИВАНИЯ В РАЗРАБОТКЕ УСЛОВИЙ ДЛЯ СПЕКТРОХИМИЧЕСКОГО АНАЛИЗА ОКИСИ ТАНТАЛА:

J. Brll and J. Vinot, *Talanta*, 1967, **14**, 897.

Резюме—Определение оптимальных условий для спектрографического анализа окиси тантала облегчано рассмотрением кривых улетучивания анализируемых элементов. Методом пользовались для оценки Cr, Fe, Hf, Ni, Nb, Ti, Y и Zr в области 10–1000 частей на миллион.

Potentiometric study of complexes of lead(II) with dithiocarbaminoacetic acid: O. BUDEVSKY and E. PLATIKANOVA, *Talanta*, 1967, **14**, 901 (Bulgarian Academy of Sciences, Institute of General and Inorganic Chemistry, Sofia 13, Bulgaria).

Summary—A potentiometric determination of the stability constants of lead(II)–dithiocarbaminoacetic acid complexes has been made. Potentiometric data have been used for estimating the maximum number of co-ordinated ligands. After graphical solution of the Fronaeus integral, the relationship between the concentration variables has been found, and the curve-fitting method, in which both variables are normalised, has been used for determining the stability constants. The values found are $\log \beta_1 = 7{\cdot}32 \pm 0{\cdot}12$ and $\log \beta_2 = 13{\cdot}03 \pm 0{\cdot}20$ ($\mu = 0{\cdot}1$; 25°). From these data, the relationship between the conditional stability constant $\log \beta_2'$ and pH has been calculated, thus furnishing a full description of TCA as a masking agent for lead ions.

Metal chelate exchange in the organic phase—I. Theory: Application in spectrophotometry and complex chemistry: JAROMÍR RŮŽIČKA and JIŘÍ STARÝ, *Talanta*, 1967, **14**, 909 (Department of Nuclear Chemistry, Faculty of Technical and Nuclear Physics, Prague 1, Břehová 7, Czechoslovakia).

Summary—Metal chelates, extracted from an aqueous phase by organic solvents, can react with other chelating agents (or their metal chelates) dissolved in the same solvent. This exchange of metal chelates in the organic phase can be used for (1) investigation of the exchange equilibrium and composition of the metal chelates formed, (2) determination of the extraction constants, (3) preparation of new inner-complexes soluble in organic solvents, and (4) spectrophotometric determination of small amounts of metals. The theory and experimental verification of this phenomenon are given. The extraction constants of silver and zinc diethyldithiocarbamates in carbon tetrachloride have been determined by means of the extraction constants of the corresponding dithizonates. A mixed complex of arsenic(III) with dithizone and diethyldithiocarbamic acid has been prepared and its properties studied. A simple method for spectrophotometric determination of microgram quantities of arsenic is proposed.

Spectrophotometric determination of hexafluoroarsenate with ferroin: VERNON S. ARCHER and FRANKLIN G. DOOLITTLE, *Talanta*, 1967, **14**, 921 (Department of Chemistry, University of Wyoming, Laramie, Wyoming, U.S.A.).

Summary—A spectrophotometric method for the hexafluoroarsenate anion is described. The determination involves selective extraction of the tris(1,10-phenanthroline)iron(II) salt of the anion into n-butyronitrile, followed by measurement of the absorbance of the organic layer. The extracts give good Beer's law plots over a wide range of concentrations and more than 98% of the hexafluoroarsenate is removed in a single extraction. Interference studies were made on a number of anions.

ПОТЕНЦИОМЕТРИЧЕСКОЕ ИЗУЧЕНИЕ КОМПЛЕКСОВ СВИНЦА(II) И ДИТИОКАРБАМИНОУКСУСНОЙ КИСЛОТЫ:

O. Budevsky and E. Platikanova, *Talanta*, 1967, **14**, 901

Резюме—Определены потенциометрическим методом константы устойчивости комплексов свинца(II) и дитиокарбаминоуксусной кислоты. Потенциометрические данные использованы для определения максимального числа координированных лигандов. Отношение между переменными величинами концентрации получено на основе графического решения интеграла Фронеуса, а метод приспособления кривой—с нормализированными обеими переменными величинами—использован для определения констант устойчивости. Получены величины $\log \beta_1 = 7{,}32 \pm 0{,}12$ и $\log \beta_2 = 13{,}03 \pm 0{,}20$ ($\mu = 0{,}1$; 25°). На основе этих данных определена зависимость условной константы устойчивости $\log \beta_2'$ от pH, получая этим образом совершенное охарактеризование дитиокарбаминоуксусной кислоты в качестве маскирующего агента для ионов свинца.

ОБМЕН ХЕЛАТОВ МЕТАЛЛОВ В ОРГАНИЧЕСКОЙ ФАЗЕ—I. ТЕОРИЯ : ПРИМЕНЕНИЕ В СПЕКТРОФОТОМЕТРИИ И ХИМИИ КОМПЛЕКСНЫХ СОЕДИНЕНИЙ:

Jaromír Růžička and Jiří Starý, *Talanta*, 1967, **14**, 909.

Резюме—Экстрагированные органическим растворителем из водной фазы хелаты металлов могут реагировать с другими комплексообразующими агентами (или их хелатами металлов), растворенными в том же растворителе. Этим обменом хелатов металлов в органической фазе можно пользоваться для I) исследования равновесия обмена и состава образованных хелатов металлов, (2) определения констант экстракции, (3) приготовления новых растворимых в органических растворителях внутренных комплексов, и (4) спектрофотометрического определения небольших количеств металлов. Приведены теория и экспериментальная проверка этого явления. Константы экстракции диэтилдитиокарбаминатов серебра и цинка в четыреххлорцстои чллероче определены на основе констант экстракции их дитизонатов. Приготовлен смешанный комплекс мышьяка(III) с дитизоном и диэтилдитиокарбаминовой кислотой и исследованы его свойства. Предложен цростой метод спектрофотометрического определения микрограммовых количеств мышьяка.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ГЕКСАФТОРАРСЕНАТА ФЕРРОИНОМ:

Vernon S. Archer and Franklin G. Doolittle, *Talanta*, 1967, **14**, 921

Резюме—Описан спектрофотометрический метод определения гексафторарсенатаниона. Определение основывается на селективной экстракции соли аниона с трис(1,10-фенантролин)железом(II) н-бутиронитрилом и измерении светопоглощения органического слоя. Экстракты сохраняют закон Бера в широких пределах концентрации, а больше чем 98% гексафторарсената экстрагируется в одной экстракции. Изучено влияние ряда анионов на определение.

Polarographic study of inhibitors and catalysts for the reaction of dissolved oxygen with sulphite ion: YECHESKEL ISRAEL, AVRAHAM VROMEN and BRUNO PASCHKES, *Talanta*, 1967, **14**, 925 (Israel Mining Industries, Institute for Research and Development, P.O. Box 313, Haifa, Israel).

Summary—Oxygen reduction waves are utilized to determine the inhibition effect of some reagents commonly added in polarographic work, on the reaction of dissolved oxygen with sodium sulphite in neutral and alkaline supporting electrolytes. Alkali metal hydroxides, EDTA, TEA, ethanol and methyl cellosolve inhibited the reaction to various extents. In this work, it appeared that some metallic ions, such as cobalt(II) and manganese(II) can catalyse the oxygen–sulphite reaction, enabling wider application to be made of sodium sulphite for de-oxygenation of neutral and alkaline supporting electrolytes containing inhibitors.

Determination of traces of calcium in phosphoric acid and its salts by atomic-absorption spectrometry: MASAAKI YANAGISAWA, MASAMI SUZUKI and TSUGIO TAKEUCHI, *Talanta*, 1967, **14**, 933 (Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan).

Summary—A method for the determination of traces of calcium by atomic-absorption spectrometry after extraction into an organic solvent, has been investigated for the determination of traces of calcium in phosphoric acid and its salts. Calcium is extracted as the hydroxyquinolate complex, the extract is introduced into the flame, and the calcium atomic-absorption is measured. The effects of pH, concentration of reagent, and diverse ions on the calcium extraction were investigated.

Homogeneous nucleation of magnesium hydroxide: DAVID H. KLEIN, MELVIN D. SMITH and JAMES A. DRIY, *Talanta*, 1967, **14**, 937 (Department of Chemistry, Hope College, Holland, Michigan, U.S.A.).

Summary—The rate of homogeneous nucleation of magnesium hydroxide has been determined as a function of solution concentration, using a quasi-homogeneous precipitation technique and electronic particle counting. The nucleation rate becomes measurable at supersaturations of about 4, and is dependent on the 33rd power of the product $a_{Mg}a_{OH}^2$. The experimental results are consistent with nucleation theory. The nucleus–solution interfacial energy is calculated to be 115 erg/cm^2.

ПОЛЯРОГРАФИЧЕСКОЕ ИЗУЧЕНИЕ ИНГИБИТОРОВ И КАТАЛИЗАТОРОВ ДЛЯ РЕАКЦИИ РАСТВОРЕННОГО КИСЛОРОДА С СУЛЬФИТИОНОМ:

YECHESKEL ISRAEL, AVRAHAM VROMEN and BRUNO PASCHKES, *Talanta*, 1967, **14**, 925.

Резюме—Волны восстановления кислорода использованы в определении эффекта замедления некоторых реагентов, обычно добавленных в полярографической работе, на реакцию растворенного кислорода с сульфитом натрия в нейтральных и щелочных фоновых электролитах. Гидроокиси щелочных металлов, ЭДТА, ТЭА, этиловый спирт и метилцеллосолв замедляют реакцию в различной степени. В этой работе показано, что некоторые ионы металлов, на пример кобальт(II) и марганец(II) могут катализировать реакцию кислорода с сульфитионом; этим образом дана возможность использования в большой мере сульфита натрия для обескислорожи-вания содержающих ингибиторы нейтральных и щелочных фоновых электролитов.

ОПРЕДЕЛЕНИЕ СЛЕДОВ КАЛЬЦИЯ В ФОСФОРНОЙ КИСЛОТЕ И ЕЁ СОЛЯХ МЕТОДОМ АТОМНО-АБСОРБЦИОННОЙ СПЕКТРОМЕТРИИ:

MASAAKI YANAGISAWA, MASAMI SUZUKI and TSUGIO TAKEUCHI, *Talanta*, 1967, **14**, 933.

Резюме—Разработан метод определения следов кальция в фосфорной кислоте и её солях, основывающийся на атомно-абсорбционной спектрометрии после извлечения кальция органическим растворителем. Кальций экстрагируют в форме его комплекса с 8-оксихинолином, экстракт вводят в пламя и измеряют атомное поглощение. Изучено влияние pH, концентрации реагента и различных ионов на экстрагирование кальция.

ГОМОГЕННАЯ НУКЛЕАЦИЯ ГИДРООКИСИ МАГНИЯ:

DAVID H. KLEIN, MELVIN D. SMITH and JAMES A. DRIY, *Talanta*, 1967, **14**, 937.

Резюме—Определена скорость гомогенной нуклеации гидроокиси магния в зависимости от концентрации раствора, пользуясь квазигомогенным осаждением и электронным прибором для счета частиц. Скорость нуклеации становится измеримом при пересыщении раствора около 4 и зависит от 33 ей степени продукта $a_{Mg}a_{OH}^2$. Экспериментальные данные соглашаются с теорией нуклеации. Енергия межфазового взаимодействия между центром кристаллизации и раствором найдена 115 эрг/см^2.

Spectrophotometric determination of nitrate with *p*-diaminodiphenylsulphone and diphenylamine–*p*-diaminodiphenylsulphone: E. SZEKELY, *Talanta*, 1967, **14**, 941 (The Negev Institute for Arid Zone Research, Beer Sheva, Israel).

Summary—*p*-Diaminodiphenylsulphone is used in a new spectrophotometric method for the determination of nitrate. Factors affecting the colour development are given. The useful range for a 1-cm cell is 30–300 mg/l. In this range the coloured solutions are stable and obey Beer's law. The method is rapid and precise and is applicable to routine analysis of samples containing macro amounts of nitrates. For determination of micro amounts of nitrate the reagent is modified by addition of diphenylamine. The limit of determination is then 0·25 mg/l. at 15°. This method can be considered specific for nitrate and is applicable in the presence of nitrite.

Radiochemical separation of strontium by isotopic exchange: J. H. QURESHI, M. S. SHAHID and S. M. HASANY, *Talanta*, 1967, **14**, 951 (Atomic Energy Centre, Ferozepur Road, Lahore, Pakistan).

Summary—Isotopic exchange has been used for the rapid separation of minute quantities of radio-strontium. A number of variables such as agitation time, concentration of strontium in both phases, mode of preparation and aging of the precipitates, were studied and optimized. With an optimized procedure, exchange yields of 96% and 94% respectively were obtained when strontium sulphate and strontium oxalate precipitates were used for the exchange. Decontamination studies made with radioactive tracers of 15 elements showed that the sulphate precipitate is more selective than the oxalate, most of the elements showing <1% contamination except ^{140}Ba–^{140}La and ^{110}Ag which show high contamination. This simple procedure has also been applied for the determination of radioactive strontium in rain-water samples.

Determination of selenium and tellurium in silver chloride and uranium oxide: B. G. RUSSELL, W. V. LUBBE, ANITA WILSON, ELAINE JONES, J. D. TAYLOR and T. W. STEELE; *Talanta*, 1967, **14**, 957 (National Institute for Metallurgy, Yale Road, Milner Park, Johannesburg, South Africa).

Summary—Methods are described for the determination of selenium and tellurium in crude silver chloride produced as a by-product of the refining of gold, and in high-purity uranium oxide. Selenium and tellurium are separated from one another as well as from the numerous other substances in the sample before they are extracted into organic solvents and determined spectrophotometrically. For the determination of selenium 3,3′-diaminobenzidine is used and for tellurium, *sym*-diphenylthiourea. A minimum of 2 ppm of each element may be determined in silver chloride and 0·3 ppm in uranium oxide. Statistical data are given to show the precision and accuracy of the methods.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ НИТРАТА П-ДИАМИНОДИФЕНИЛСУЛЬФОНОМ И СМЕСЬЮ ДИФОНИЛАМИНА И П-ДИАМИНОДИФЕНИЛСУЛЬФОНА:

E. Szekely, *Talanta*, 1967, **14**, 941.

Резюме—п-Диаминодифенилсульфон применен в новом спектрофотометрическом методе определения нитрата. Приведены факторы влияющие на образование окраски. Кюветка толщины 1 см применима в пределах 30–300 мг/л. В этих пределах окрашенные растворы устойчивые и повинуются закону Бера. Метод является быстрым и точным и им можно пользоваться в серийном анализе проб, содержающих макроколичества нитратов. Для определения микроколичеств нитрата реагенту добавляют дифениламин. Предел определения в этом случае 0,25 мг/л при 15°. Этот метод можно считать специфическим для нитрата, им можно пользоваться в присутствии нитрита.

РАДИОХИМИЧЕСКОЕ ВЫДЕЛЕНИЕ СТРОНЦИЯ ИЗОТОПНЫМ ОБМЕНОМ:

I. H. Qureshi, M. S. Shahid and S. M. Hasany, *Talanta*, 1967, **14**, 951

Резюме—Изотопный обмен использован для быстрого выделения небольших количеств радиостронция. Изучено влияние и определены оптимальние условия для времени перемешивания, концентрации стронция в обеих фазах, метода получения и старения осадков. В отобранной процедуре получены обмены 96% и 94% в случае осадков сульфата стронция и оксалата стронция, соответственно. В изучении деконтаминации с использованием радиоактивных индикаторов 15 элементов, осадок сульфата оказался более селективным чем осадок оксалата: большинство элементов показали загрязнение $<1\%$, исключая ^{140}Ba, ^{140}La, и ^{110}Ag, которые элементы показали большое загрязнение. Эта несложная процедура использована для определения радиоактивного стронция в дождевой воде.

ОПРЕДЕЛЕНИЕ СЕЛЕНА И ТЕЛЛУРА В ХЛОРИДЕ СЕРЕБРА И ОКИСИ УРАНА:

B. G. Russell, W. V. Lubbe, Anita Wilson, Elaine Jones, J. D. Taylor and T. W. Steele; *Talanta*, 1967, **14**, 957.

Резюме—Описаны методы определения селена и теллура в сыром хлориде серебра, полученном в форме побочного продукта при очищении золота, и в высокочистотной окиси урана. Селен и теллур отделяют один от другого и от других веществ в образце, затем экстрагируют органическими растворителями и определяют спектрофотометрическим методом. Для определения селена пользуются 3,3′-диаминобензидином, для определения теллура—симдифенилтиомочевиной. До 2 мкг/г каждого элемента определяют в хлориде серебра, до 0,3 мкг/г в окиси урана. Точность и воспроизводимость методов показана на основе статистических данных, приведенных в стата.

Spektrophotometrische Bestimmung von Wolfram in Molybdän: B. NEEF and H.-G. DÖGE, *Talanta*, 1967, **14**, 967 (Institut für Metallphysik und Reinstmetalle der Deutschen Akademie der Wissenschaften zu Berlin, Dresden, Deutsche Demokratische Republik).

Summary—A procedure is described for the spectrophotometric determination of traces of tungsten in molybdenum. The separation is based on the different behaviour of both elements towards reduction reagents. First the molybdenum is reduced with thioglycollic acid and extracted as molybdenum(V) thiocyanate complex. After reduction with titanium(III) chloride, tungsten is extracted as tungsten(V) thiocyanate complex, which is determined spectrophotometrically. Amounts of 0·5 μg of tungsten can be determined in 0·1–0·5 g of molybdenum.

Reduction of iridium after oxidation in fuming perchloric acid: E. JACKSON and D. A. PANTONY, *Talanta*, 1967, **14**, 973 (Department of Metallurgy, Imperial College, London, S.W.7).

Summary—Evidence is given in support of the theory that high results obtained for reduction titrations of iridium solutions which have been fumed with perchloric acid are due to retention in solution of volatile reduction products of the acid.

Spectrophotometric determination of cobalt with phenanthrenequinone monoxime: K. C. TRIKHA, MOHAN KATYAL and R. P. SINGH, *Talanta*, 1967, **14**, 977 (Department of Chemistry, University of Delhi, Delhi-7, India).

Summary—Phenanthrenequinone monoxime reacts with cobalt to form a yellow–orange insoluble 1:3 (cobalt:ligand) complex which is extractable into chloroform in the pH range 4·45–8·0. The determination of cobalt is carried out at 470 mμ. Beer's law is obeyed over the concentration range 0–3·0 ppm of cobalt. The sensitivity is 0·00336 μg of Co/cm^2 for 0·001 absorbance. The effect of a number of foreign ions has been studied.

Determination of sorbic acid with sodium chlorite: P. SPACU and H. DUMITRESCU, *Talanta*, 1967, **14**, 981 (Department of Inorganic Chemistry, University of Bucharest, Splaiul Independentei 89, Bucharest, Rumania).

Summary—A new method for the determination of sorbic acid is proposed, using sodium chlorite in hydrochloric acid medium as reagent. In these conditions the hydrochloric acid is oxidized to chlorine which adds on to the double bonds of the sorbic acid. The addition is rapid (30–90 sec) and for this reason the determination is more rapid then others similar to it. Sorbic acid has been determined in foods by this method, after a preliminary solvent extraction or steam-distillation.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ВОЛЬФРАМА В МОЛИБДЕНЕ:

B. Neef and H.-G. Döge, *Talanta*, 1967, **14**, 967.

Резюме—Описан метод спектрофотометрического определения следов вольфрама в молибдене. Разделение основывается на различном поведении этих элементов в присутствии восстановителей. Сперва молибден восстанавливается тиогликолевой кислотой и экстрагируется в форме тиоцианата молибдена(V). После восстановления с хлоридом титана(III) вольфрам экстрагируют в форме комплекса тиоцианата вольфрама(V), который затем определяют спектрофотометрическим методом. Этим методом можно определять 0,5 мкг вольфрама в 0,1–0,5 г молибдена.

ВОССТАНОВЛЕНИЕ ИРИДИЯ ПОСЛЕ ОКИСЛЕНИЯ В ДЫМЯЩЕЙСЯ ХЛОРНОЙ КИСЛОТЕ:

E. Jackson and D. A. Pantony, *Talanta*, 1967, **14**, 973.

Резюме—Приведены данные, поддерживающие теорию что высокие результаты полученные в восстановительном титровании растворов иридия, обработанных дымящейся хлорной кислотой являются в результате удерживания в растворе летучих продуктов восстановления кислоты.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ КОБАЛЬТА ФЕНАНТРЕНХИНОНМОНОКСИМОМ:

K. C. Trikha, Mohan Katyal and R. P. Singh, *Talanta* 1967, **14**, 977.

Резюме—Фенантренхинонмоноксим реагирует с кобальтом образуя оранжевожёлтый 1 : 3 (кобальт : лиганд) комплекс, экстрагируемый хлороформом в области pH 4,45–8,0. Определение кобальта проводится при 470 ммк. Закон Бера почитается в области концентрации 0–3,0 мг/л. Чувствительность 0,00336 мкг кобальта/см^2 для поглощения 0,001. Изучено влияние ряда посторонных ионов.

ОПРЕДЕЛЕНИЕ СОРБИНОВОЙ КИСЛОТЫ ХЛОРИТОМ НАТРИЯ:

P. Spacu and H. Dumitrescu, *Talanta*, 1967, **14**, 981.

Резюме—Предложен новый метод определения сорбиновой кислоты с использованием хлорита натрия в солянокислом растворе в качестве реагента. В этих условиях соляная кислота окисляется в хлор, который присоединяется по месту двойных связей сорбиновой кислоты. Присоединение протекает быстро (30–90 сек.), поэтому определение быстрее чем остальные. Сорбиновую кислоту определяли этим методом в пищах, после предварительной экстракции или перегонки с водяным паром.

Decomposition of thiosulphate in acidified oxidants: G. W. LATIMER, JR. and ELAINE I. STEICKO, *Talanta*, 1967, **14**, 984 (Department of Chemistry, University of Utah, Salt Lake City, Utah 84112, U.S.A.).

Summary—The Wollack procedure has been used to study the competition between oxidant and acid for the thiosulphate ion. In concentrated hydrochloric acid solutions of iodine, iodate and chloramine-T, polythionates are the chief products, whereas in acid permanganate substantial amounts of other products occur. Both the concentration of the acid and the acid anion affect the course of the reaction in these solutions. Production of polythionate, an acid-decomposition product, suggests that acid decomposition successfully competes with oxidation.

Interfacial free energies of ionic crystals: G. CLEGG and T. P. MELIA, *Talanta*, 1967, **14**, 989 (Department of Chemistry and Applied Chemistry, University of Salford, Salford 5, U.K.).

Summary—Minimum values of the liquid–crystal interfacial free energy have been obtained from data on the maximum supercooling of small droplets of solutions of ionic crystals.

РАЗДОЖЕНИЕ ТИОСЧЛЬФАТА В КИСЛЫХ РАСТВОРАХ ОКИСЛИТЕЛЕЙ:

G. W. Latimer, Jr. and Elaine I. Stetcko, *Talanta*, 1967, **14**, 984.

Резюме—Процедура Воллака применена в изучении конкуренции окислителя и кислоты для тиосульфатиона. В сильно солянокислых растворах иода, иодата и хлорамина Т, главными продуктами являются политионаты, тогда как в кислом растворе перманганата образуются значительные количества других продуктов. Как концентрация кислоты так и анион кислоты влияют на течение реакции в этих растворах. Образование политионата—продукта разложения кислоты—указивает на успешную конкуренцию разложения кислоты с окислением.

МЕЖПОВЕРХНОСТНАЯ СВОБОДНАЯ ЭНЕРГИЯ ИОННЫХ КРИСТАЛЛОВ:

G. Clegg and T. P. Melia, *Talanta*, 1967, **14**, 989.

Резюме—Получены минимальные величны свободной энергии поверхности жидкость–кристалл на основе данных о максимальном переохлаждении маленких капелек растворов ионных кристаллов.

SUMMARIES FOR CARD INDEXES

A critical review of neutron activation and tracer methods for the determination of the noble metals: F. E. BEAMISH, K. S. CHUNG and A. CHOW, *Talanta*, 1967, **14**, 1. (Department of Chemistry, University of Toronto, Toronto 5, Canada).

Summary—Neutron activation methods for the seven noble metals are critically reviewed up to December, 1965. The methods deal with the determination of trace impurities in each noble metal as well as traces of noble metals in media such as organic material, fission product and other solutions, ores, alloys, minerals, silica and base metals. The need for confirmatory evidence in the case of such complex materials as ores is emphasized.

A new oxidimetric reagent: Potassium dichromate in a strong phosphoric acid medium—VI: Photometric titration of vanadium(IV) and of cerium(III) alone and in mixtures with iron(II): G. GOPALA RAO and P. KANTA RAO, *Talanta*, 1967, **14**, 33. (Department of Chemistry, Andhra University, Waltair, India).

Summary—Vanadium(IV) can be accurately titrated with potassium dichromate in media containing phosphoric acid of 3–12*M* concentration: the change in absorption of vanadium(IV) is followed in the region 660 mμ using a red filter. It is more convenient to carry out the titration in 3*M* phosphoric acid because at higher concentrations chloride, nitrate, cerium(III) and manganese(II) may interfere. Photometric titration is more convenient than potentiometric because the former can be made in a 3*M* phosphoric acid medium, whereas the latter is possible only in 12*M* phosphoric acid. The simultaneous differential photometric titration of iron(II) and vanadium(IV) is also possible. Conditions have been found for the photometric titration of cerium(III) and of cerium(III) plus iron(II). The titration is carried out (at 450 mμ or with a blue filter) in about 10.5*M* phosphoric acid. Application of the method to a cerium mineral is considered.

Separation of strontium from large amounts of calcium, with application to radiostrontium analysis: VICTOR E. NOSHKIN and NORMAN S. MOTT, *Talanta*, 1967, **14**, 45. (Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, U.S.A.).

Summary—The elution first of calcium and then of strontium by complex formation with cyclohexanediaminetetra-acetic acid (CyDTA) after sorption on ion-exchange columns, is shown to require careful control of pH and the concentrations of CyDTA and NH_4^+. A procedure is described for volumetric analysis of calcium and strontium, and for use of this separation procedure before determination of ^{90}Sr in sea-water. Careful choice of reagents and materials is shown to be necessary for use of such a method in determination of trace amounts of radiostrontium.

КРИТИЧЕСКИЙ ОБЗОР МЕТОДОВ НЕТЙРОННОГО АКТИВАЦИОННОГО АНАЛИЗА И ИНДИКАТОРНОГО АНАЛИЗА ДЛЯ ОПРЕДЕЛЕНИЯ БЛАГОРОДНЫХ МЕТАЛЛОВ:

F. E. Beamish, K. S. Chung and A. Chow, *Talanta*, 1967, **14**, 1.

Резюме—Критически обсуждаются опубликованные до декабря 1965 г. методы нейтронного активационного анализа для определения семь благородных металлов. Методы разработаны для определения следовых примес в каждом благородном металле и следов благородных металлов в органических материалах, продуктах расщепления и других растворах, рудах, сплавах, минералах, в кварце и простых металлах. Подчеркивается нужда подкрепляющих данных в случае сложных материалов, как на пример руд.

НОВЫЙ ОКСИДИМЕТРИЧЕСКИЙ РЕАГЕНТ: БИХРОМАТ КАЛИЯ В СИЛЬНО ФОСФОРНОКИСЛОЙ СРЕДЕ—VI: ФОТОМЕТРИЧЕСКОЕ ТИТРОВАНИЕ ВАНАДИЯ(IV), ТОЛЬКО ЦЕРИЯ(III) И ЦЕРИЯ(III) В СМЕСЯХ С ЖЕЛЕЗОМ(II):

G. Gopala Rao and P. Kanta Rao, *Talanta*, 1967, **14**, 33.

Резюме—Предложенный метод позволяет аккуратное титрование ванадия(IV) бихроматом калия в растворе содержащем фосфорную кислоту концентрации 3-12 М: перемену светопоглощения ванадия(IV) измеряют в области 660 ммк, с использованием красного фильтра. Удобнее провести титрование в 3М фосфорной кислоте, потому что при более высоких концентрациях ионы хлорида, нитрата, церия(III) и марганца(II) мешают определению. Фотометрическое титрование удобнее чем потенциометрическое потому что первое можно провести в 3М фосфорной кислоте, а второе только в 12М фосфорной кислоте. Также осуществымо одновременное дифференциальное фотометрическое титрование железа(II) и ванадия(IV). Разработаны условия для фотометрического титрования церия(III) и церия(III) в смеси с железом(II). Титрование проводится (при 450 ммк или пользуясь голубым фильтром) в 10,5М фосфорной кислоте. Предполагается использование метода в анализе руды церия.

ОТДЕЛЕНИЕ СТРОНЦИЯ ОТ БОЛЬШИХ КОЛИЧЕСТВ КАЛЬЦИЯ И ЕТО ИСПОЛЬЗОВАНИЕ В АНАЛИЗЕ РАДИОСТРОНЦИЯ:

Victor E. Noshkin and Norman S. Mott, *Talanta*, 1967, **14**, 45.

Резюме—Показано что элюирование кальция и после его стронция, путем образования комплексов с циклогексаминтетрадиаминтетрауксусной кислотой (ЦиДТА) и сорбирования на колонке ионообменника, требует тщательный контроль pH и концентраций ЦиДТА и ИН-0. Описывается процедура для обменного анализа кальция и стронция и ее использование для определения --00 в морской воде. Тщательнеый выбор реагентов и магериалов оказался необходимым при использвании этого метода для определения следовых количеств радиостронция.

Determination of rhenium in molybdenite by neutron-activation analysis: KIKUO TERADA, YUKIO YOSHIMURA, SUSUMU OSAKI and TOSHIYASU KIBA, *Talanta*, 1967, **14**, 53. (Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Japan.)

Summary—A neutron-activation method is described for the determination of rhenium in molybdenite. Radiochemical separation by a carrier technique was carried out very rapidly by means of successive liquid–liquid extraction processes. The recovery of rhenium, which was determined by a spectrophotometric method, was about 93%. About 10 samples could be analysed within 6 hr in parallel runs.

Electronic calculation in analytical chemistry—I: ALGOL programme for evaluation of model analyses: G. GOTTSCHALK, *Talanta*, 1967, **14**, 61. (OSRAM Studiengesellschaft Berlin, Technische Universität Berlin, Germany.)

Summary—The usual way of evaluating an analytical method is to carry out a series of model experiments. A comparison of the amount taken and the amount found gives objective numerical information about the random and systematic errors in the particular range studied. If conventional methods of calculation are used, the time needed and the difficulty are relatively large. A series of 24 tests may need 8 hr for the calculations, even if no human error in computation occurs. Experience shows that inexperienced operators may need several days for the calculations. Results free from error can be obtained in as little as 5 min by electronic computing. A calculation programme written in the universal logical language ALGOL is given. The preparatory operations are so simple that skilled assistance is not necessary.

Thermal standards in thermogravimetry: C. J. KEATTCH, *Talanta*, 1967, **14**, 77. (John Laing Research & Development Ltd., Boreham Wood, Hertfordshire, England.)

Summary—Comparisons of thermogravimetric data from different instruments have often led to controversy because of lack of appreciation that the values are influenced by the apparatus used. Consequently, it is suggested that various compounds be employed as thermal standards for comparing data from different sources. The paper also discusses the variables to be considered when attempting to devise such standards and includes a list of suggested thermal standards covering the ranges 100–400° and 1050–1060°.

ОПРЕДЕЛЕНИЕ РЕНИЯ В МОЛИБДЕНИТЕ МЕТОДОМ НЕЙТРОННОГО АКТИВАЦИОННОГО АНАЛИЗА:

Kikuo Terada, Yukio Yoshimura, Susumu Osaki and Toshiyasu Kiba, *Talanta*, 1967, **14**, 53.

Резюме—Описывается нейтронноактивационный метод для определения рения в молибдените. Радиохимическое выделение методом носителя производили очень быстро последовательным экстрагированием растворителями. Возврат рения, после определения спектрофотометрическим методом, был около 93%. В течение 6 часов можно анализировать около 10 образцов, двое по двое.

ИСПОЛЬЗОВАНИЕ ЕЛЕКТРОННОГО РАСЧЕТА В АНАЛИТИЧЕСКОЙ ХИМИИ—I: АЛГОЛ ПРОГРАММА В ОЦЕНКЕ МОДЕЛЬНЫХ АНАЛИЗОВ:

G. Gottschalk, *Talanta*, 1967, **14**, 61.

Резюме—Для оценки аналитического метода обыкновенно проводят ряд модельных опытов. Сравнение количеств взятых и полученных в анализе дает объективные численные данные о беспорядочных и систематических ошибках в исследованных пределах. Условные методы расчета трудны и требуют довольно много времени. Для расчета серии 24 опытов нужно 8 часов даже без появления ошибок в расчете. Знакомо что неопытному оператору нужно несколько дней для расчета. Методом электронного расчета получаются безошибочные результаты только через тять минут. Приведена программа расчета выраженная в универсальном логическом языке АЛГОЛ. Приготовительные работы так просты, что квалифицированная помощь не нужна.

ТЕРМИЧЕСКИЕ ЭталОНЫ В ТЕРМОГРАВИМЕТРИИ:

C. J. Keattch, *Talanta*, 1967, **14**, 77.

Резюме—Сравнение термогравиметрических данных, полученных различными приборами часто привело до дискуссии, потому что не принято во внимание что использованные приборы влияют на результаты. Ради этого предложено использование различных соединений в качестве термических эталонов для сравнения данных из различных источников. В статье тоже обсуждаются факторы влияющие на выбор таких эталонов и приводится список предложенных термических эталонов для областей 100–400° и 1050–1060°.

Application of radioisotopes in column chromatography on substituted celluloses—III: The separation of gold from silver, iron and other metals: R. A. A. MUZZARELLI, *Talanta*, 1967, **14**, 85. (Department of Chemistry, Faculty of Science, University of Sherbrooke, Sherbrooke, Québec, Canada).

Summary—The chromatographic behaviour of several metals has been studied on columns of natural and substituted celluloses, by using radioisotopes. It has been found that gram and nanogram amounts of gold are not adsorbed on natural cellulose, and consequently gold can be separated from nanogram amounts of silver, iron, zinc, cadmium, chromium, manganese and cobalt. Gold has a limited tendency to form complexes with the functional groups of the celluloses, but the other metals mentioned formed very stable complexes. The results have also been compared with those obtained for mercury.

Hydrolysis study of organic acid anhydrides by differential thermal analysis—II: Maleic anhydride and trimellitic anhydride: J. M. ROSENFELD and C. B. MURPHY, *Talanta*, 1967, **14**, 91. (General Electric Company, Schenectady, N.Y., U.S.A.).

Summary—Differential thermal analysis has been used to follow the hydrolysis of maleic anhydride (MA) and trimellitic anhydride (TMA). On exposure of MA to an atmosphere of 96% relative humidity maleic acid is produced, hydrolysis being complete in 21 hr at 22°, but no hydrolysis occurs at a relative humidity of 50%. When exposed to an atmosphere of 96% relative humidity, TMA is quite stable for short periods, but hydrolyses slowly, the production of trimellitic acid being complete in 113 hr at 22°.

Complexometric determination of gallium with Calcein Blue as indicator: H. N. ELSHEIMER, *Talanta*, 1967, **14**, 97 (U.S. Geological Survey, Menlo Park, California 94025, U.S.A.).

Summary—A metalfluorechromic indicator, Calcein Blue, has been used for the back-titration of milligram amounts of EDTA in presence of gallium complexes. The indicator was used in conjunction with an ultraviolet titration assembly equipped with a cadmium sulphide detector cell and a microammeter for enchanced end-point detection. The result is a convenient and rapid method with an accuracy approaching 0·1% and a relative standard deviation of about 0·4% for 10 mg of gallium.

ИСПОЛЬЗОВАНИЕ РАДИОИЗОТОПОВ В ХРОМАТОГРАФ́И НА КОЛОНКЕ ЗАМЕ0ОЕННЫХ ЦЕЛЛЮЛОЗ—III. ОТДЕЛЕНИЕ ЗОЛОТА ОТ СЕРЕБРА, И ДРУГИХ МЕТАЛЛОВ:

R. A. A. Muzzarelli, *Talanta*, 1966, **14**, 85.

Резюме—Определены хроматографические характеристики на колонках природной и замещенных целлюлоз ряда металлов, с использованием радиоизотопов. Результаты опытов показывают что граммовые и наногра́ммовые количества золота не адсорбиру ются на природной целлюлозе, поэтому этим методом можно пользоваться для отделения золота от наног раммовых количеств серебра, железа, цинка, кадмия, хрома, марганца и кобальта. Золото в ограниченной мере образует комплексы с функциональными группами целлюлозы, пока другие упомянутые металлы образуют очень устойчивые комплексы. Результаты опытов сравнены с полученными для ртути данными.

ИЗУЧЕНИЕ ГИДРОЛИЗА АНГИДРИДОВ ОРГА ОРГАНИЧЕСКИХ КИСЛОТ МЕТОДОМ ДИФФЕРЕНЦИАЛЬНОГО ТЕРМИЧЕСКОГО АНАЛИЗА —II: МАЛЕИНОВЫЙ АНГИДРИД И ГЕМЕЛЛИТО ВЫЙ АНГИДРИД:

J. M. Rosenfeld and C. B. Murphy, *Talanta*, 1967, **14**, 91.

Резюме—Метод дифференциального термического анали а исполь ован для и учения гидроли а малеинового (МА) и гемеллитового (ГА) ангидридов. При контакте МА с во - духом 96Ш относительной влажности обра уется малеиновая кислота, а гидроли окончен нере 21 час при 22°; гидроли не появляется при относительной влажности 50Ш. При контакте с во духом 96Ш тной относительной влажности ТА довольно устойчивый в коротком интервале времени, но постепенно гидроли ируется, а обра ование гемеллитовой кислоты окончано чере 113 часа.

КОМПЛЕКСОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ГАЛЛИЯ С ИСПОЛЬЗОВАНИЕМ КАЛЬЦЕИНОВОГО ГОЛУБОГО В КАЧЕСТВЕ ИНДИКАТОРА:

H. N. Elsheimer *Talanta*, 1967, **14**, 97.

Резюме—Автор пользовался металлофлуорохромным индикаторомкальцеиновым голубым—для титрования миллиграммовых количеств галлия в форме комплексов с ЭДТА. Индикатор использован на приборе для титрования в ультрафиолетовом свете, снабженному с детектором на основании сульфида кадмия и микро амперметром для улучшенного открития конца титрования. Разработанный подходящий и быстрый метод имеет точност около 0,1% и относительную стандартную ошибку 0,4% для 10 мг галлия.

Fluorescence and phosphorescence characteristics of anticoagulants: A new approach to direct measurement of drugs in whole blood: H. C. HOLLIFIELD and J. D. WINEFORDNER, *Talanta*, 1967, **14**, 103. (University of Florida, Department of Chemistry, Gainsville, Florida 32601, U.S.A.)

Summary—Fluorimetric and phosphorimetric excitation and emission peaks and limiting detectable concentrations and phosphorimetric decay times are given for warfarin, dicumarol, diphenandione, phenindione and tromexan. Known concentrations of warfarin, a highly fluorescent compound, and dicumarol, a highly phosphorescent compound, are directly measured in the complex biochemical system of whole blood. Excellent recoveries of warfarin and dicumarol in the concentration range of 0·1 to 10 mg% in whole blood were achieved.

Substoichiometric separation in activation analysis: Extraction of co-ordinatively-unsolvated salts: I. P. ALIMARIN and G. A. PEREZHOGIN, *Talanta*, 1967, **14**, 109. (V. I. Vernadsky Institute of Geochemistry and Analytical Chemistry, Academy of Sciences, Moscow, U.S.S.R.)

Summary—The necessary conditions have been examined for the use of extraction of coordinatively-unsolvated salts for substoichiometric separations in activation analysis, especially the influence of interfering ions and of the concentration of the carrier. A study has been made of the substoichiometric extraction of halide ions, oxyanions and anionic metal complexes by means of the tetraphenylarsonium ion into chloroform and dichloroethane, and of the extraction of alkali metal ions into nitrobenzene with tetraphenylborate. Substoichiometric extraction can be combined with neutron-activation analysis for the determination of traces of iodine, caesium, rubidium, manganese, rhenium, chromium, thallium, gold, gallium and tantalum.

Purification des colorants thiaziniques, Azur A, Azur B, Azur C, par une methode de partage: ROLAND BONNEAU, JEAN FAURE and JACQUES JOUSSOT-DUBIEN, *Talanta*, 1967, **14**, 121. (Département de Chimie-Physique, Faculté des Sciences de Bordeaux, France.)

Summary—Some *N*-methylated derivatives of thionine have been separated from thionine, Methylene Blue, and each other by solvent extraction into carbon tetrachloride from an aqueous solution buffered to the pH appropriate for each compound. The method can be used to purify the dyes.

ФЛУОРЕСЦЕНТНЫЕ И ФОСФОРЕСЦЕНТНЫЕ ХАРАКТЕРИСТИКИ ПРОТИВОСВЕРТЫВАЮЩИХ СРЕДСТВ: НОВЫЙ ПОДХОД К ПРЯМОМУ ОПРЕДЕЛЕНИЮ ЛЕКАРСТВЕННЫХ ПРЕПАРАТОВ В ЦЕЛЬНОЙ КРОВИ:

H. C. Hollifield and J. D. Winefordner, *Talanta*, 1967, **14**, 103.

Резюме—Приведены флуориметрические и фосфорометрические пики во буждения и змиссии, предельные концентрина, дикумарола, дифенандиона, фениндиона и тромексана. И вестные концентрации уорфарина—сильно флуоресцирующего соединения, и дикумарола—сильно фосфоресцирующего соединения определяют прямо в сложной биохимической системе цельной крови. Получены отличные выходы для уорфарина и дикумарола в пределах концентрации от 0,1 до 10 мг 00 в цельной.

СУБСТЕХИОМЕТРИЧЕСКОЕ РАЗАЕЛЕНИЕ В АКТИВАЦИОННОМ АНАЛИЗЕ ПУТЕМ ЭКСТРАКЦИИ КООРДИНАЦИОННО НЕСОЛЬВАТИРОВАННЫХ СОЛЕЙ

I. P. Alimarin and G. A. Perezhogin, *Talanta*, 1967, **14**, 109.

Резюме—Рассмотрены условия субстехиометрического разделения в активационном анализе путем экстракции координационно несольватированных солей, влияние концентрации носителя и мешающих ионов. Изучена субстехиометрическая экстракция галогенид-ионов, кислородсодержащих анионов и комплексных металлсодержащих анионов с тетрафениларсонием хлороформом или дихлорэтаном, а также катионов щелочных металлов с тетрафенилбораторм нитробензолом. Субстехиометрическое экстракционное разделение йода, цезия рубидия, марганца, рения, хрома, таллия, золота, галлия, тантала может быть использовано для нейтроноактивационного определения следов этих элементов.

ОЧИСТКА ТИАЗИНОВЫХ КРАСОК АЗУРА А, АЗУРА В И АЗУРА С МЕТОДОМ ЭКСТРАКЦИИ РАСТВОРИТЕЛЕМ:

Roland Bonneau, Jean Faure and Jacques Joussot-Dubien, *Talanta*, 1967, **14**, 121.

Резюме—Авторы отделили некоторые *N*-метилированные производные тионина от тионина, метиленового голубого и одного от другого экстрагированием тетрахлорметаном из водного раствора забуферированного до pH, ответствующем каждому соединению. Методом можно пользоваться для очистки красок.

Azo dyes from 2-amino-1,3,4-thiodiazole: F. H. POLLARD, G. NICKLESS and T. J. SAMUELSON, *Talanta*, 1967, **14**, 123. (Department of Inorganic Chemistry, School of Chemistry, The University, Bristol 8, England).

Summary—Thiodiazolyazo dyes from resorcinol, *p*-cresol and *β*-naphthol have been prepared. They are inferior to their thiazole and triazole analogues in their colour-forming reactions with metal ions.

Semimicro method for the determination of linalol in coriander oil: K. R. MANOLOV and E. V. GEORGIEV, *Talanta*, 1967, **14**, 124. (Higher Institute of Food Industry, Department of Inorganic and Analytical Chemistry, Plovdiv, Bulgaria).

Summary—Linalol has been determined colorimetrically in essential oils by means of the green colour developed in the presence of nitrous acid. Geraniol, dipentene, terpineol, citronellol and citral also give a green colour, and are therefore calculated as linalol by this method, but the error is small if they are present in small concentrations.

Photo-induced oxidation of some organic carbonyl compounds by vanadium(V): K. S. PANWAR and J. N. GAUR, *Talanta*, 1967, **14**, 127. (Department of Chemistry, University of Rajasthan, Jaipur, India).

Summary—The oxidation of pyruvic acid, levulinic acid, acetaldehyde, isobutyraldehyde, and acetylacetone by vanadium(V) in aqueous solution on illumination with visible light is described. Pyruvic acid undergoes oxidation much more rapidly than does levulinic acid; both give acetic acid. Acetaldehyde is more rapidly oxidized than is isobutyraldehyde, the former giving formic acid, and the latter, formic acid and acetone. Acetylacetone is converted into acetic acid. The oxidations are rapid and quantitative and may be used for the estimation of these carbonyl compounds.

Amalgam exchange separation of radiothallium: RICHARD B. HAHN and GEORGE M. KANAPILLY, *Talanta*, 1967, **14**, 129. (Chemistry Department, Wayne State University, Detroit, Michigan 48202, U.S.A.).

Summary—A method is presented for the rapid separation of radiothallium. The solution is made basic by addition of ammonia, then sodium fluoride and ethylenediamine are added and the mixture is shaken with 3% thallium amalgam. A rapid exchange takes place and the bulk of the activity is concentrated in the amalgam. The amalgam is diluted with clean mercury and shaken with acidic cobalt nitrate solution which back-extracts thallium. About 90% of the thallium activity is recovered.

АЗОКРАСИТЕЛИ НА ОСНОВЕ 2-АМИНО-1,3,4-ТИОДИАЗОЛА:

F. H. POLLARD, G. NICKLESS and T. J. SAMUELSON, 1967, **14**, 123.

Резюме—Приготовлены тиодиазолилазокрасители из резорцина, п-крезола и β-нафтола. Цветообразующие реакции этих красителей с ионами металлов не так успешны как аналогичных красителей на основе тиазола и триазола.

K. R. MANOLOV and E. V. GEORGIEV, *Talanta*, 1967, **14**, 124.

Резюме—Пиналоол в эфирных маслах определен колориметрическим методом, основывающимся на зеленой окраске которая образуется в присутствии азотистой кислоты. Гераниол, дипентен, терпинеол, цитронеллол и цитрал также дают зеленую окраску и поэтому в этом методе определяются вместе с линалоолом; однако, ошибка небольшая если эти соединения присутствуют только в небольших концентрациях

ФОТОИНДУКТИРОВАННОЕ ОКИСЛЕНИЕ ВАНАДИЕМ(V) НЕКОТОРЫХ ОРГАНИЧЕСКИХ КАРБОНИЛЬНЫХ СОЕДИНЕНИЙ:

K. S. PANWAR and J. N. GAUR, *Talanta*, 1967, **14**, 127.

Резюме—Описывается окисление пировиноградной, илевулиновой кислот, ацетальдегида, изомасляного альдегида и ацетилацетона в водном растворе, с использованием ванадия(V) и облучения видимым светом. Пировиноградная кислота окисляется гораздо быстрее чем левулиновая кислота; продуктом окисления в обоих случаях является уксусная кислота. Ацетальдегид окисляется быстрее чем изомасляный альдегид: первый дает муравьиную кислоту а второй—муравьиную кислоту и ацетон. Ацетилацетон превращается в уксусную кислоту. Эти процедуры показываются быстрыми и количественными, ими можно пользоваться для определения этих карбонильных соединений.

ВЫДЕЛЕНИЕ РАДИОТАЛЛИЯ С ИСПОЛЬЗОВАНИЕМ АМАЛЬГАМНОГО ОБМЕНА:

RICHARD B. HAHN and GEORGE M. KANAPILLY, *Talanta*, 1967, **14**, 129.

Резюме—Предложен метод для быстрого выделения радиоталлия. Раствору прибавляют аммиак до щелочной реакции, затем фторид натрия и этилендиамин и раствор встряхивают 3% тной амальгамой таллия. Происходит быстрый обмен и основная масса радиоталлия концентрируется в амальгаме. Амальгаму разбавляют чистой ртутью и встряхивают кислым раствором нитрата кобальта для экстрагирования. Выход радиоактивного таллия около 90%.

High frequency titration methods in the investigation of complex formation: D. I. RYABCHIKOV and V. A. ZARINSKY, *Talanta*, 1967, **14**, 133. (Vernadsky Institute of Geochemistry and Analytical Chemistry, Academy of Sciences, Moscow, U.S.S.R.)

Summary—High frequency titration is a valuable tool in the study of complex formation in solutions, and the breaks in the titration curves can be used, in conjunction with the results of other physical methods, to determine the composition of the complexes formed. High frequency titration and other methods have been used to study the complexes formed by thorium, indium, plutonium(V), and boron with various complexing agents, and to develop methods for the determination of thorium and yttrium in rare earth mixtures, and of indium in the presence of zinc, cadmium, aluminium, nickel and cobalt.

Application of the drop method to the study of nucleation of sparingly soluble chelates: S. THOMPSON and L. GORDON, *Talanta*, 1967, **14**, 137. (Department of Chemistry, Case Institute of Technology, Cleveland, Ohio 44106, U.S.A.)

Summary—The methods of producing supersaturated solutions of sparingly soluble chelates by precipitation from homogeneous solution have been combined with drop nucleation studies.

Precipitation from homogeneous solution applied to the drop technique for the study of nucleation: O. E. HILEMAN, JR., *Talanta*, 1967, **14**, 139. (Department of Chemistry, Burke Chemical Laboratories, McMaster University, Hamilton, Ontario, Canada.)

Summary—The technique of precipitation from homogeneous solution has been successfully coupled with the drop technique for study of the nucleation process.

ИСПОЛЬЗОВАНИЕ МЕТОДОВ ВЫСОКОЧАСТОТНОГО ТИТРОВАНИЯ ДЛЯ ИЗУЧЕНИЯ КОМПЛЕКСООБРАЗОВАНИЯ:

D. I. Ryabchikov and V. A. Zarinsky, *Talanta*, 1967, **14**, 133.

Резюме—Метод высокочастотного титрования является очень полезным в изучении образования комплексов в растворе; изломом кривой титрования можно пользоваться—вместе с результатами других физических методов—для определения состава образованных комплексов. Метод высокочастотного титрования и другие методы были использованы для изучения комплексов тория, индия, плутония(V) и бора с различными комплексообразующими агентами и для разработки методов для определения тория и иттрия в смесях редкоземельных элементов, и индия в присутствии цинка, кадмия, алюминия, никеля и кобальта.

ИСПОЛЬЗОВАНИЕ КАПЕЛЬНОГО МЕТОДА В ИЗУЧЕНИИ НУКЛЕАЦИИ УМЕРЕННО РАСТВОРИМЫХ ХЕЛАТОВ:

S. Thompson and L. Gordon, *Talanta*, 1967, **14**, 137.

Резюме—Исследовано приготовление пересыщенных растворов умеренно растворимых хелатов методом осаждения из гомогенного раствора, вместе с изучением нуклеации капельным методом.

ПРИМЕНЕНИЕ ОСАЖДЕНИЯ ИЗ ГОМОГЕННОГО РАСТВОРА НА КАПЕЛЬНЫЙ МЕТОД С ЦЕЛЬЮ ИЗУЧЕНИЯ НУКЛЕАЦИИ:

O. E. Hileman, *Talanta*, 1967, **14**, 139.

Резюме—Осаждение изгомогенного раствора успешно использовано вместе с капельным методом для изучения процесса нуклеации.

Determination of trace amounts of sulphur in selenium: BRITT-LOUISE SJÖBORG, *Talanta*, 1967, **14**, 693 (Department of Analytical Chemistry, University of Uppsala, Uppsala, Sweden).

Summary—Determination of trace amounts of sulphur as Methylene Blue after reduction of sulphate to sulphide by hydriodic and hypophosphorous acids in acetic acid solution is applied to the determination of trace amounts of sulphur in selenium after removal of the selenium by evaporation with hydrobromic acid. Samples of 100 mg or less of selenium are chosen if the sulphur content is greater than 5–10 ppm; the time required for the separation is about 1·5 hr; 100 ppm of sulphur has been determined with a coefficient of variation of 5·2%. If the sulphur content is less than 5 ppm, 1-g samples must be taken and the time required is then about 3 hr; 0·4 ppm of sulphur has been determined with a standard deviation of 0·13 ppm. The accuracy of the method seems to be well within the random error.

Tetrachlorogallate(III) complexes with basic triphenylmethane and diphenylnaphthylmethane dyestuffs: V. ARMEANU and P. COSTINESCU, *Talanta*, 1967, **14**, 699 (Chemistry and Physics Department, V. I. Lenin Institute for Economic Sciences, 6 Piaţa Romană, Bucharest, Romania, and Department of Inorganic and Analytical Chemistry, Institute for Petroleum, Gas and Geology, 6 Traian Vuia St., Bucharest).

Summary—A general survey is given of the properties of tetrachlorogallate(III) complexes with basic dyestuffs of the triphenylmethane and diphenylnaphthylmethane class; solvents for extraction, the absorption spectra and molar absorptivities, the optimum concentrations of the dyestuffs and of hydrochloric acid, the stability of the compounds and their composition are also described. Analytical methods for the determination of traces of gallium by means of many of these complexes are suggested.

Estimation of the minimum detectable concentration and optimum instrumental conditions in precision absorption spectrophotometry of substances in the condensed phase: J. J. CETORELLI and J. D. WINEFORDNER, *Talanta*, 1967, **14**, 705 (Department of Chemistry, University of Florida, Gainesville, Florida 32601, U.S.A.).

Summary—An expression for the signal-to-noise ratio in precision absorption spectrophotometry of molecules in the condensed phase is derived and used to calculate the theoretical minimum detectable sample concentration, C_{mt} and to predict the best instrumental conditions for measurement. Single-beam and double-beam instruments are considered. The theoretically calculated values of C_{mt} for several organic molecules are compared with the practical minimum detectable sample concentrations, C_{mp}, which are those concentrations giving an absorbance of 0·002. As long as the source of radiation is intense, and the root-mean-square noise-to-signal ratio for incident radiation passing through the blank is known, then the expression for C_{mt} is extremely simple and easy to evaluate for any given substance whose molar absorptivity is known. The influence of instrumental parameters on the value of C_{mt} is evaluated, and only the monochromator slitwidth, the number of combined blank and sample signal measurements, and the frequency response bandwidth of the electrometer-readout system have any significant effect on the value of C_{mt} (for any given wavelength setting of the monochromator).

ОПРЕДЕЛЕНИЕ СЛЕДОВЫХ КОЛИЧЕСТВ СЕРЫ В СЕЛЕНЕ:

BRITT-LOUISE SJÖBORG, *Talanta*, 1967, **14**, 693.

Резюме—Определение следовых количеств серы в форме метиленовой сини после восстановления сульфата до сульфида раствором иодстоводородной и гипофосфористой кислотах в уксусной кислоте, применено на определение следовых количеств серы в селене, после удаления селена выпариванием с бромистоводородной кислотой. Если содержание серы превышает 5–10 мкг/г, отбирают пробу селена 100 мг или менее; продолжительность отделения около полутора часов; 100 мкг/г серы определено с коэффициентом вариации 5,2%. Если содержание серы меньше чем 5 мкг/г, следует отбирать пробы 1 г, а продолжительность определения 3 часа; 0,4 мкг/г серы определено с стандартной ошибкой 0,13 мкг/г. Точность метода в границах беспорядочных ошибок.

КОМПЛЕКСЫ ТЕТРАХЛОРГАЛЛАТА(III) С ОСНОВНИМИ ТРИФЕНИЛМЕТАНОВЫМИ И ДИФЕНИЛНАФТИЛМЕТАНОВЫМИ КРАСИТЕЛЯМИ:

V. ARMEANU and P. COSTINESCU, *Talanta*, 1967, **14**, 699.

Резюме—Приведен общий обзор свойств комплексов тетрахлоргаллата(III) с основними красителями трифенилметанометанового дифенилнафтилметанового классов; описываются также растворители для извлечения, спектри светопоглощения и молярные поглощения, оптимальные концентрации красителей и соляной кислоты, устойчивость соединений и их состав. Предложены аналитические методы определения следов галлия с использованием ряда етих комплексов.

ОПРЕДЕЛЕНИЕ ПРЕДЕЛА ЧУВСТВИТЕЛЬНОСТИ И ОПТИМАЛЬНЫХ АППАРАТУРНЫХ УСЛОВИЙ ДЛЯ ПРЕЦИЗИОННОЙ АБСОРБЦИОННОЙ СПЕКТРОФОТОМЕТРИИ ВЕЩЕСТВ В КОНДЕНСИРОВАННОЙ ФАЗЕ:

J. J. CETORELLI and J. D. WINEFORDNER, *Talanta*, 1967, **14**, 705.

Резюме—Получено выражение для отношения сигнала к фону в методе прецизионной абсорбционной спектрофотометрии молекул в конденсированной фазе и использовано для вычисления теоретического предела чувствительности и для предсказания оптимальных условий измерения на приборе. Рассматриваются одполучевие и двухлучевие приборы. Вычисленные теоретически значения C_{mt} для ряда органических молекул сравниваются с практически определенными пределными концентрациями C_{mp}, представляющими концентрации дающие светопоглощение 0,002. В случае интенсивного источника радиации и известного среднеквадратичного отклонения отношения сигнала к фоне надающей радиации в контрольном растворе, выражение для C_{mt} весьма простое и может применяться для каждого вещества с известным молярным светопоглощением. Изучено влияние параметров прибора на значение C_{mt}: обнаружено что только ширина щели монохроматора, число измерений сигнала пробы и стандарта, и ширина полосы ответа частоты электрометра имеют влияние на значение C_{mt} (для данной длины волны на монохроматоре).

Inorganic polarography in organic solvents—III. Analytical applications of metal–acetylacetonate complexes in toluene: B. K. AFGHAN, R. M. DAGNALL and K. C. THOMPSON, *Talanta*, 1967, **14**, 715 (Chemistry Department, Imperial College, London, S.W.7).

Summary—Indium and palladium are determined polarographically with a dropping mercury electrode in a toluene phase, following extraction as the acetylacetonates from aqueous solutions containing 2–10 ppm of the metals (or 0·1–0·5 ppm with a greater ratio of sample volume to solvent volume). Of 31 elements examined, only Co(III), Cr(III), Cu(II), Fe(III), In, Mo(VI), Pd and Ti(IV) gave extractable complexes with reduction waves in the available potential range. Specificity for palladium is obtained by extraction at pH 0·5, and for indium at pH 9 in the presence of cyanide and ascorbic acid as masking agents.

Determination of uranium in electro-refined plutonium by a combined ion-exchange and X-ray fluorescence technique: J. A. HAYDEN, *Talanta*, 1967, **14**, 721 (Analytical Development Group, Rocky Flats Division, Dow Chemical Company, P.O. Box 888, Golden, Colorado 80401, U.S.A.).

Summary—Uranium is separated from plutonium by adsorption on an anion-exchange resin from a concentrated hydrochloric acid solution and is eluted from the resin, collected on a disc of cation-exchange paper, and determined by X-ray fluorescence. The lower limit of detection is 2 μg of uranium, and 50 μg may be determined with a recovery of 98% and a standard deviation of 3·2 μg. In plutonium metal, 19 ppm of uranium were found, with a standard deviation of 2 ppm (6 results).

Spectrophotometric extractive titrations—IV. Determination of zinc in germanium dioxide and germanium chloride: AFTANAS GALÍK, *Talanta*, 1967, **14**, 731 (Lachema, N. C., Kaznějov, Plzeň-North, Czechoslovakia).

Summary—A simple and selective determination of zinc in germanium chloride and germanium dioxide is described. The sample is dissolved in sodium potassium tartrate solution and zinc is titrated spectrophotometrically at 532 mμ with a dithizone solution in carbon tetrachloride without discarding the organic phase. Interfering ions such as Bi(III), Cu(II), Cd(II), Co(II), Ni(II), Pb(II), Sn(II), Fe(II), Fe(III), Mn(II) and Tl(I) are masked with bis(2-hydroxyethyl)dithiocarbamate. The detection limit is $3{\cdot}23 \times 10^{-5}$% of zinc and this may be lowered by taking a larger sample and by performing the analysis in a closed system. A simplified technique, consisting of the simultaneous titration of the sample and blank, is described.

НЕОРГАНИЧЕСКАЯ ПОЛЯРОГРАФИЯ В ОРГАНИЧЕСКИХ РАСТВОРИТЕЛЯХ—III. ПРИМЕНЕНИЕ В АНАЛИЗЕ КОМПЛЕКСОВ МЕТАЛЛОВ С АЦЕТИЛАЦЕТОНОМ В ТОЛУОЛЕ:

B. K. Afghan, R. M. Dagnall and K. C. Thompson, *Talanta*, 1967, **14**, 715.

Резюме—Индий и палладий определяют полярографическим методом в растворе толуола с использованием капельного ртутного электрода, после экстрагирования комплексов с ацетилацетоном из водного раствора металлов, содержащего 2–10 мг/л металла (или 0,1–0,5 мл/л в случае большего отношения объема пробы и объема растворителя). Из исследованных 31 элементов только Co(III), Cr(III), Cu(II), Fe(III), In, Mo(VI), Pd и Ti(IV) дали экстрагируемые комплексы, имеющие волны восстановления в доступной области потенциала. Метод является избирательным для палладия если экстрагирование проводится при pH 0,5 ,а избирательным для индил при pH 9 в присутствии цианида и аскорбиновой кислоты в качестве маскирующих агентов.

ОПРЕДЕЛЕНИЕ УРАНА В ЭЛЕКТРООЧИЩЕННОМ ПЛУТОНИИ КОМБИНИРОВАННЫМ МЕТОДОМ ИОННОГО ОБМЕНА И ФЛУОРЕСЦЕНЦИИ РЕНТГЕНОВСКИХ ЛУЧЕЙ:

J. A. Hayden, *Talanta*, 1967, **14**, 721.

Резюме—Уран отделяют от плутония адсорбированием на анионообменной смоле из раствора в концентрированной соляной кислоте, элюируют из смолы, собирают на диске катионообменной бумаги и определяют методом флуоресценции рентгеновских лучей. Предел чувствительности 2 мкг урана, а 50 мкг можно определить с выходом 98% и стандартной ошибкой 3,2 мкг. В металлическом плутонии определено 19 мкг/г, с стандартной ошибкой 2 мкг/г (6 результатов).

ЭКСТРАКЦИОННО-СПЕКТРОФОТОМЕТРИЧЕСКИЕ ТИТРАЦИИ—IV. ОПРЕДЕЛЕНИЕ ЦИНКА В ДВУОКИСИ ГЕРМАНИЯ И ХЛОРИДЕ ГЕРМАНИЯ:

Aftanas Galík, *Talanta*, 1967, **14**, 731.

Резюме—Описан несложный и избирательный метод определения цинка в двуокиси и хлориде германия. Пробу растворяют в растворе виннокислого натрия-калия, а цинк титруют спектрофотометрическим методом при 532 ммк раствором дитизона в тетрахлорметане без отбрасывания органической фазы. Мешающие ионы как например Bi(III), Cu(II), Cd(II), Co(II), Ni(II), Pb(II), Sn(II), Fe(II), Fe(III), Mn(II) и Tl(I) маскируют бис(2-оксиэтил)дитиокарбаминатом. Предел определения цинка $3{,}23 \times 10^{-5}\%$ можно снижать взятием большей пробы и выполнением анализа в закрытой системе. Описана упрощенная процедура основывающаяся на одновременном титровании пробы и контрольного раствора.

Formation of mixed complexes in the extraction of indium with 1-(2-pyridylazo)-2-naphthol: YU. A. ZOLOTOV, I. V. SERYAKOVA and G. A. VOROBYEVA, *Talanta*, 1967, **14**, 737 (Vernadsky Institute of Geochemistry and Analytical Chemistry, Academy of Sciences, Moscow, U.S.S.R.).

Summary—A detailed study has been made of the extraction of indium into chloroform by 1-(2-pyridylazo)-2-naphthol (PAN). The rate of extraction is maximal if the PAN is added to the aqueous phase and is not added as its chloroform solution. The ratio of indium to PAN is 1:1 and the cationic complex can be extracted only if a suitable anion is present, such as acetate or chloride.

Polarographic study of bis(2-pyridyl)disulphide di-*N*-oxide and bis(2-quinolyl)disulphide di-*N*-oxide in aqueous ethanol: I. EL-KHIAMI and R. M. JOHNSON, *Talanta*, 1967, **14**, 745 (Department of Chemistry, Chelsea College of Science and Technology, University of London, London, S.W.3).

Summary—The polarographic reduction of bis(2-pyridyl)- and of bis(2-quinolyl)disulphide di-*N*-oxide in aqueous alcohol yields aryl mercaptans. The electrode reaction is kinetically controlled by an initial one-electron transfer step, and values for the transfer coefficients and the specific heterogeneous rate constants for the forward reactions are presented. The polar *N*-oxide function in the α-position withdraws electrons from the disulphide bond, making the half-wave potential less negative than that of the diphenyl disulphide. The pK_a values of the mercapto compounds formed have been evaluated and the low values obtained for the heterocyclic *N*-oxides are further evidence for tautomerism in these compounds.

Instrumental activation analysis of vegetable tissue: E. STEINNES, *Talanta*, 1967, **14**, 753 (Isotope Laboratory, Institutt for Atomenergi, Kjeller, Norway).

Summary—A non-destructive method for the determination of bromine, manganese, phosphorus, potassium, sodium and zinc in plant tissue by neutron activation and gamma-ray spectrometry is described. Phosphorus and potassium have been determined also by beta-counting. The method should be especially attractive for analysis of manganese and zinc.

Some aspects of the reactions between selenium-containing ligands and platinum group metals: L. S. BARK and D. BRANDON, *Talanta*, 1967, **14**, 759 (Department of Chemistry and Applied Chemistry, University of Salford, Salford 5, U.K.).

Summary—2-(2-Pyridyl)benzo[*b*]selenophene has been investigated as a possible reagent for palladium. From a consideration of its reactions with diverse metal ions, and the probable structure of the complex formed between the compound and palladium(II) it is postulated that the group —Se···C···C···N— may be highly selective for palladium. From the experimental evidence it is suggested that the delocalization of the metal electron density by π-bond formation between the palladium and selenium atoms is a major factor in determining the stability of the chelated complex.

ОБРАЗОВАНИЕ СМЕШАННЫХ КОМПЛЕКСОВ ПРИ ЭКСТРАГИРОВАНИИ ИНДИЯ 1-(2-ПИРИДИЛАЗО)-2-НАФТОЛОМ:

Yu. A. Zolotov, I. V. Seryakova and G. A. Vorobyeva, *Talanta*, 1967, **14**, 737.

Резюме—Подробно изучено экстрагирование в хлороформ индия 1-(2-пиридилазо)-2-нафтолом (ПАН). Скорость экстрагирования максимальная, если ПАН добавляют водной фазе, а не в форме раствора в хлороформе. Отношение индия и ПАН 1:1, ц катионный комплекс экстрагируется только в присутствии подходящего аниона, как например ацетата или хлорида.

ПОЛЯРОГРАФИЧЕСКОЕ ИЗУЧЕНИЕ ДИ-*N*-ОКИСИ БИС(2-ПИРИДИЛ) ДИСУЛЬФИДА И ДИ-*N*-ОКИСИ БИС(2-ХИНОЛИЛ)ДИСУЛЬФИДА В ВОДНОМ РАСТВОРЕ ЭТИЛОВОГО СПИРТА:

I. El-Khami and R. M. Johnson, *Talanta*, 1967, **14**, 745.

Резюме—При полярографическом восстановлении ди-*N*-окисей бис(2-пиридил) дисульфида и бис(2-хинолил)дисульфида образуются арилмеркаптаны. Электродная реакция регулирована кинетически начальным переходом одного электрона; приведены величины коэффициента переноса и констант скорости гетерогенной реакции. Полярная функциональная группа *N*-окиси в положении альфа отнимает электроны из полосы дисульфида, в результате чего потенциал этой полуволны является менее отрицательным чем полуволны дифенилдисульфида. Определены величины pK_a образующихся меркаптосоединений: полученные для гетероциклических *N*-окисей визкие величины также свидетельствуют о таутомерии в этих соединениях.

ИНСТРУМЕНТАЛЬНЫЙ АКТИВАЦИОННЫЙ АНАЛИЗ РАСТИТЕЛЬНОЙ ТКАНИ:

E. Steinnes, *Talanta*, 1967, **14**, 753.

Резюме—Описан недеструктивный метод определения брома, марганца, фосфора, калия, натрия и цинка в растительной ткани, основывающийся на нейтронноактивационном анализе и спектрометрии гамма лучей. Фосфор и калий определялы также путем считания бета-частиц. Метод является особенно подходящим для анализа марганца и цинка.

НЕКОТОРЫЕ ВИДЫ РЕАЦИЙ МЕЖДУ СОДЕРЖАЮЩИМИ СЕЛКН ЛИГАНДАМИ И МЕТАЛЛАМИ ПЛАТИНОВОЙ ГЕРУППЫ:

L. S. Bark and D. Brandon, *Talanta*, 1967, **14**, 759.

Резюме—2-(2-Пиридил)бензо(*b*)селенофен был изучен в качестве реагента для палладия. На основании реакций этого реагента с различными ионами металлов и предполагаемого строения комплекса образующегося между реагентом и палладием(II) авторы считают группу —Se···C···C··· И—высокоизбирательной для палладия. На основании экспериментальных данных предложено, что делокализация плотности электронов металла образованием π-связи между атомами палладия и селена представляет собой главный фактор при определении устойчивости комплекса.

Kinetics of the precipitation of palladium dimethylglyoximate from homogeneous solution: PAUL R. ELLEFSEN and LOUIS GORDON, *Talanta*, 1967, **14**, 769 (Department of Chemistry, Case Institute of Technology, Cleveland, Ohio, U.S.A.).

Summary—The kinetics of formation of palladium dimethylglyoximate in the post-nucleation and pre-nucleation stages, and the effect of palladium on the reaction of biacetyl and hydroxylamine, have been studied.

Mass spectrometry of metal chelates—I. Detection on the picogram scale: A. E. JENKINS and J. R. MAJER, *Talanta*, 1967, **14**, 777 (Department of Chemistry, P.O. Box 363, The University, Birmingham, 15, U.K.).

Summary—A method has been developed for the detection and estimation of metals in the form of chelates in amounts down to 10^{-12} g. The chelate is evaporated into the source of a mass spectrometer and a continuous record of the ion current at a significant mass number is made. The integrated ion current is directly proportional to the concentration of metal chelate.

Anion-exchange separation of cobalt from nickel: O. G. BALAKRISHNAN NAMBIAR and P. R. SUBBARAMAN, *Talanta*, 1967, **14**, 785 (National Chemical Laboratory, Poona-8, India).

Summary—An anion-exchange method has been developed for the separation of cobalt from nickel, based on the observation that from a malonic acid solution containing sodium nitrite, cobalt is preferentially adsorbed by the exchanger but nickel passes through. The cobalt is eluted with 2*M* ammonium chloride in dilute ammonia solution. From an ammonium malonate solution containing chloride and nitrate, cobalt is quantitatively electro-deposited on a platinum cathode to give a bright, adherent deposit. Nickel is deposited from a solution of similar composition.

Emission spectra of nitrous oxide supported acetylene flames at atmospheric pressure: G. F. KIRKBRIGHT, M. K. PETERS and T. S. WEST, *Talanta*, 1967, **14**, 789 (Chemistry Department, Imperial College, London, S.W.7).

Summary—The emission spectra of a premixed flame of acetylene supported by nitrous oxide have been recorded under different fuel-gas mixture conditions. The emission spectra in these flames of a series of metals, for which it is difficult to obtain a significant population of ground state atoms for atomic absorption spectroscopy in more conventional flames, have also been studied. The red secondary zone which is present in the fuel-rich flames shows emission attributable to long-lived CN and NH species which form a strongly reducing atmosphere to inhibit refractory oxide formation from elements such as molybdenum, titanium and aluminium introduced into the flame. An attempt has also been made to explain some of the reactions which may occur between the flame species above the primary reaction zone.

КИНЕТИКА ОСАЖДЕНИЯ ДИМЕТИЛГЛИОКСИМАТА ПАЛЛАДИЯ ИЗ ГОМОГЕННОГО РАСТВОРА:

PAUL R. ELLEFSEN and LOUIS GORDON, *Talanta*, 1967, **14**, 769.

Резюме—Изучена кинетика образования диметилглиоксимата палладия в фазах после и пред образованием центров кристаллизации, и влияние палладия на реакцию диацетила с гидроксиламином.

МАСС-СПЕКТРОМЕТРИЯ ХЕЛАТОВ МЕТАЛЛОВ—I. ОТКРЫТИЕ ПИКОГРАММОВЫХ КОЛИЧЕСТВ:

A. E. JENKINS and J. R. MAJER, *Talanta*, 1967, **14**, 777.

Резюме—Разработан метод открытия и определения количеств металлов в форме их хелатов все до 10^{-12} г. Хелат испаривают в камеру масс-спектрометра и получают непрерывный запись ионного тока при знаменательном массовом числе. Интегрированный ионный ток прямо пропорционален концентрации хелата металла.

ОТДЕЛЕНИЕ КОБАЛЬТА ОТ НИКЕЛЯ МЕТОДОМ АНИОННОГО ОБМЕНА:

O. G. BALAKRISHNAN NAMBIAR and P. R. SUBBARAMAN, *Talanta*, 1967, **14**, 785.

Резюме—Разработан метод анионного обмена для отделения кобальта от никеля, основывающийся на наблюдении что из содержающего нитрит натрия малоновокислого раствора кобальт адсорбируется на ионообменнике в то время как никель не адсорбируется. Кобальт елюируют 2*M* хлоридом аммония в разбавленном аммиачном растворе. Из раствора малоната аммония, содержающего хлорид-и нитратионы, кобальт электроосаждается количественно на платиновом катоде, образуя блестящий, плотно пристающий к основе осадок. Никель осаждается из растовра подобного состава.

ЭМИССИОННЫЕ СПЕКТРИ СОДЕРЖАЩИХ ЗАКИСЬ АЗОТА ПЛАМЁН АЦЕТИЛЕНА ПРИ АТМОСФЕРНОМ ДАВЛЕНИИ:

G. F. KIRKBRIGHT, M. K. PETERS and T. S. WEST, *Talanta*, 1967, **14**, 789.

Резюме—Эмиссионные спектры предварительно смешанного пламени ацетилена и закиси азота записаны для различных отношений компонентов в смеси. Также были изучены эмиссионные спектры ряда металлов в этих пламенах, для которых трудно получить довольное число атомов в основном состоянии для атомно-абсорбционной спектрофотометрии в более обыкновенных пламенах. Красная вторичная зона, присутствующая в пламенах с высоким содержанием топлива показывает эмиссию, которую можно приписать группам долгой жизни CN и NH, образующим сильно восстанавливающую атмосферу что бы препятствовать образование огнестойких окисей из внесепных в пламя элементов, на пример молибдена, титана и алюминия. Авторы также пытались объяснить некоторые реакции, появляющиеся в пламени над первичной зоной.

Concentration and separation of indium, gallium, thallium, antimony and bismuth by extraction with alkylphosphoric acids: I. S. LEVIN, A. A. SHATALOVA, T. G. AZARENKO, I. A. VORSINA, N. A. BURTOVAYA-BALAKIREVA and T. F. RODINA, *Talanta*, 1967, **14**, 801 (Institute of Mineral Treatment, Derzhavina 18, Novosibirsk, U.S.S.R.).

Summary—The use of alkylphosphoric acids for solvent extraction separations is described, and the use of antisynergic agents for stripping is discussed.

APDC–MIBK extraction system for the determination of trace elements in saline waters by atomic-absorption spectrophotometry: ROBERT R. BROOKS, BOB J. PRESLEY and ISAAC R. KAPLAN, *Talanta*, 1967, **14**, 809 (Department of Geology and Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California, U.S.A.).

Summary—A technique has been developed for the determination of "soluble" cobalt, copper, iron, lead, nickel and zinc in saline waters by simultaneous extraction of their complexes with ammonium pyrollidine dithiocarbamate (APDC) into methyl isobutyl ketone (MIBK) and subsequent analysis by atomic-absorption spectrophotometry. Particulate matter is analysed separately by dissolving millipore filters in an acetone–hydrochloric acid mixture. Various analytical and instrumental parameters have been evaluated. The method is self-compensating in that it makes allowance for any incomplete extraction of the complexes. The technique has been applied to the determination of these elements in sea-water and saline lakes.

Radiochemical separations by the ring-oven method—II: The system ^{99}Mo/^{99m}Tc: D. KLOCKOW, *Talanta*, 1967, **14**, 817 (Chemistry Laboratory, The University, Freiburg i. Br., Germany).

Summary—The separation of ^{99}Mo and ^{99m}Tc by the ring-oven technique is described. The separation is best carried out on round papers impregnated with Prussian Blue or with manganese dioxide, when the molybdenum is fixed in the centre of the paper and the technetium is concentrated with 70–90% yield in the ring. Decontamination factors of $\geqslant 10^3$ were obtained. ^{99m}Tc formed after the separation can be further leached from the parent nuclide. The half-life of ^{99m}Tc was found to be 6·06 $\pm$ 0·05 hr.

КОНЦЕНТРИРОВАНИЕ И РАЗДЕЛЕНИЕ ИНДИЯ, ГАЛЛИЯ, ТАЛЛИЯ, СУРЬМЫ И ВИСМУТА ИЗВЛЕЧЕНИЕМ АЛКИЛФОСФОРНЫМИ КИСЛОТАМИ:

I. S. Levin, A. A. Shatalova, T. G. Azarenko, I. A. Vorsina, N. A. Burtova-Balakireva and T. F. Rodina, *Talanta*, 1967, **14**, 801.

Резюме—Обсуждается применение алкилфосфорных кислот в разделениях основывающихся на извлечении растворителями, и использование антисинергетических агентов для реэкстракцим.

СИСТЕМА ЭКСТРАКЦИИ АПДК–МИБК ДЛЯ ОПРЕДЕЛЕНИЯ СЛЕДОВЫХ ЭЛЕМЕНТОВ В СОЛЕНЫХ ВОДАХ МЕТОДОМ АТОМНО-АБСОРБЦИОННОЙ СПЕКТРОФОТОМЕТРИИ:

Robert R. Brooks, Bob J. Presley and Isaac R. Kaplan, *Talanta*, 1967, **14**, 809.

Резюме—Разработана процедура для определения «растворимого» кобальта, меди, железа, свинца, никеля и цинка в соленых водах одновременным экстрагированием их комплексов с пирролидиндитиокарбаминатом аммония (АПДК) метилизобутилкетоном (МИБК) и последовательным анализом методом атомно-абсорбционной спектрофотометрии. Частицы анализируют отдельно, растворением миллипорфильтров в смеси ацетона и соляной кислоты. Испытаны различные аналитические и аппаратные параметры. Метод самокомпенсирующий, потому что принимает во внимание неполную экстракцию комплексов. Процедурой пользовались для определения этих элементов в морской воде и соленых озерах.

РАДИОХИМИЧЕСКИЕ ВЫДЕЛЕНИЯ С ИСПОЛЬЗОВАНИЕМ КОЛЬЦЕВОЙ ПЕЧИ—II: СИСТЕМА ^{99}Mo/^{99m}Tc:

D. Klockow, *Talanta*, 1967, **14**, 817.

Резюме—Описано разделение ^{99}Mo и ^{99m}Tc методом кольцевой печи. Разделение лучше всего проводится на круглых бумажных дисках пропитанных берлинской лазурью или двуокисью марганца: молибден адсорбируется в центре диска, а технеций концентрируется в кольце с выходом 70–90%. Получены факторы деконтаминации $>10^3$. Образованный после разделения ^{99m}Tc можно элюировать от маточного нуклида. Полупериод ^{99m}Tc равен 6,06 ± 0,05 часов.

Determination of traces of calcium, magnesium, iron and nickel in aluminium salts by atomic-absorption spectrophotometry with a microwave-excited source and hollow-cathode lamps: G. B. MARSHALL and T. S. WEST, *Talanta*, 1967, **14**, 823 (Chemistry Department, Imperial College, London, S.W.7).

Summary—The determination of trace amounts of calcium and magnesium in solutions containing large concentrations of aluminium salts may be accomplished by co-precipitating their hydroxides on iron(III) hydroxide, dissolving the precipitate, and extracting the 8-hydroxyquinolates of calcium and magnesium into methyl isobutyl ketone at about pH 11. The extract may be sprayed into the air-propane flame of a simple unmodulated spectrophotometer and atomic-absorption measurements for calcium and magnesium made at 4227 and 2852 Å respectively. The limits of determination correspond to 10 and 1 ppm of calcium and magnesium in solid alumina. Iron and nickel may be co-precipitated on hydrated manganese(IV) oxide and their 8-hydroxyquinolates extracted at pH 4·5. Measurements of atomic absorption for these elements at 2483 and 2320 Å respectively yield limits of determination corresponding to 10 ppm in alumina. Hollow-cathode lamps may be used for calcium, magnesium and nickel, but a simple microwave-excited discharge tube gives much better sensitivity than a hollow-cathode lamp for iron.

Computer calculation of equilibrium concentrations in mixtures of metal ions and complexing species: D. D. PERRIN and I. G. SAYCE, *Talanta*, 1967, **14**, 833 (Department of Medical Chemistry, Australian National University, Canberra, Australia).

Summary—A method is described for calculating equilibrium concentrations of all species in multi-metal—multi-ligand mixtures from the pH of the solution, the total concentration of each metal and each complexing agent, and the relevant equilibrium constants (pK_a values and stability constants). No restriction is imposed on types of possible complexes, which can include mixed, hydrolysed, protonated and polynuclear species. Two examples are given. One of these comprises a 10-metal–10-ligand system (195 equilibrium constants). In the second system, mixed complex formation is important. The computer program is given.

End-point sharpness in thermometric titrimetry: H. J. V. TYRRELL, *Talanta*, 1967, **14**, 843 (Department of Chemistry, Chelsea College of Science and Technology, Manresa Road, London, S.W.3).

Summary—It is shown that the sharpness of an end-point in a thermometric titration where the simple reaction

$$A + B \rightleftharpoons AB$$

takes place, depends on Kc_A' where K is the equilibrium constant for the reaction, and c_A' is the total concentration of the titrand (A) in the reaction mixture. The end-point is sharp if, (*i*) the enthalpy change in the reaction is not negligible, and (*ii*) $Kc_A' > 10^3$. This shows that it should, for example, be possible to titrate 0·1*M* acid, $pK_A = 10$, using a thermometric end-point. Some aspects of thermometric titrimetry when $Kc_A' < 10^3$ are also considered.

ОПРЕДЕЛЕНИЕ СЛЕДОВ КАЛЬЦИЯ, МАГНИЯ, ЖЕЛЕЗА И НИКЕЛЯ В СОЛЯХ АЛЮМИНИЯ МЕТОДОМ АТОМНО-АБСОРБЦИОННОЙ СПЕКТРОФОТОМЕТРИИ С ИСПОЛЬЗОВАНИЕМ ВОЗБУЖДЕННОГО МИКРОВОЛНАМИ ИСТОЧНИКАИЛАМПС ПОЛЫМ КАТОДОМ:

G. B. Marshall and T. S. West, *Talanta*, 1967, **14**, 823.

Резюме—Определение следовых количеств кальция и магния в содержащих большие колвчества солей алюминия растворах осуществлено соосаждением их гидроокисей на гидроокиси железа(III), растворением осадка и экстрагированием 8-оксихинолинатов кальция и магния метилизобутилкетоном при pH II. Экстракт вводится в пламя пропана и воздуха простого вемодулированного спектрофотометра и измеряется атомное поглощение кальция и магния при 4227 и 2852 Å, соответсвенно. Предел определения в твердой окиси алюминия 10 мкг/г кальция и 1 мкг/г магния. Железо и никель соосаждаются на гидроокиси марганца(IV), а их 8-оксихинолинаты экстрагируются при pH 4,5. Измерение атомного поглощения этих элементов при 2483 и 2320 Å дает предел определения 10 мкт/г в окиси алюминия. Лампы с полым катодом пригодны для определения кальция, магния и никеля, но простой возбужденной микроволнами разрадной лампой получается значительно лучшая чувствительность для железа чем лампой с полым катодом.

ИСПОЛЬЗОВАНИЕ ЭЛЕКТРОННОВЫЧИСЛИТЕЛЯ ДЛЯ ВЫЧИСЛЕНИЯ РАВНОВЕСНЫХ КОНЦЕНТРАЦИЙ В СМЕСЯХ ИОНОВ МЕТАЛЛОВ И КОМПЛЕКСООБРАЗОВАТЕЛЕЙ:

D. D. Perrin and I. G. Sayce, *Talanta*, 1967, **14**, 833.

Резюме—Описан метод вычисления равновесных концентраций всех компонентов в содержащих ряд металлов и лигандов системах, па основе pH раствора, общей концентрации каждого металла и каждого лиганда и уместных констант равповесия (величин pK_a и констант устойчивости). Метод не ограничивается на известные типы комплексов, они могут включать смешанные, гидролизированные, протонованные и многоядерные комплексы. Приведены два примера. Один из них представляет систему 10 металлов и 10 лигандов (195 констант равновесня). В другой системе значительно образование смешанных комплексов. Сообщена программа для электронновычислительного прибора.

ОСТРОТА КОНЦА ТИТРОВАНИЯ В ТЕРМОМЕТРИЧЕСКОЙ ТИТРИМЕТРИИ:

H. J. V. Tyrrell, *Talanta*, 1967, **14**, 843.

Резюме—Показано что острота конца титрования при термометрической титрации, представленной простим уравнением

$$A + B \rightleftharpoons AB$$

зависит от Kc_A', где K константа равновесия реакции, а c_A' суммарная концентрация титранда (A) в реакционной смеси. Конец титрования острый, если (1) перемена энтальпии реакции значительна, а (2) $Kc_A' > 10^3$. На основании этого, на пример, можно титровать 0,1M раствор кислоты, $pK_A = 10$, с использованием термометрического конца титрования. Рассмотрены некоторые взгляды на термометрическую титрацию в случае $Kc_A' < 10^3$.

Oxidimetric determination of indigo with iron(III) and hexacyanoferrate-(III): G. GOPALA RAO and V. RUKMINI, *Talanta*, 1967, **14**, 849 (Andhra University, Waltair, India).

Summary—The use of iron(III) in sulphuric acid medium and of potassium hexacyanoferrate(III) in hydrochloric acid medium has been investigated for the oxidimetric determination of indigo and indigo sulphonic acid. Conditions have been established for the assay of the dye with iron(III) sulphate at 100° and with potassium hexacyanoferrate-(III) at room temperature.

Milligram determination of aromatic amines and phenols with *N*-bromosuccinimide: R. D. TIWARI, J. P. SHARMA and I. C. SHUKLA, *Talanta*, 1967, **14**, 853 (Department of Chemistry, University of Allahabad, Allahabad, India).

Summary—A simple and rapid method has been developed for the determination of milligram amounts of aromatic amines and phenols. An aliquot containing 2–4 mg of sample is dissolved in a mixture of hydrochloric and acetic acids and allowed to react with *N*-bromosuccinimide, the excess of which is determined iodometrically after the reaction is over. The reaction time varies from 1–10 min and the absolute error generally is negative, ranging from −1 to −4%.

Microchemical detection of isocyanides: E. V. CRABTREE, E. J. POZIOMEK and D. J. HOY, *Talanta*, 1967, **14**, 857 (Physical Research Laboratory, Edgewood Arsenal, Maryland 21010, U.S.A.).

Summary—Microgram quantities of isocyanides may be easily detected on filter paper or in tubes of silica gel by using benzidine acetate–copper(II) acetate or *p,p'*-tetramethyldiaminodiphenylmethane–copper(II) sulphate reagents. Interferences include those substances which are known to interfere in the use of the same reagents for the detection of hydrogen cyanide. The lowest amount of n-, s-, or t-butyl isocyanide detectable is approximately 0·1 μg.

***p*-Aminoacetophenone as a reagent for the colorimetric determination of cerium(IV):** G. SOMIDEVAMMA and M. S. SARMA, *Talanta*, 1967, **14**, 861 (Department of Chemistry, Andhra University Colleges, Waltair, India).

Summary—With a solution of *p*-aminoacetophenone, cerium(IV) gives a purple colour which can be used for its detection and determination. The limits of identification and dilution are 1·0 μg and 1 in 50000 respectively. Beer's law is obeyed in the range 14–350 μg. The colour is stable for only 5 min and measurements of absorbance must be made quickly. The interferences are fewer than with existing methods.

ОКСИДИМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ИНДИГО ЖЕЛЕЗОМ(III) И ГЕКСАЦИАНОФЕРРАТОМ(III):

G. Gopala Rao and V. Rukmini, *Talanta*, 1967, **14**, 849.

Резюме—Изучено использование железа(III) в сернокислой среде и гексацианоферрата(III) калия в солянокислой среде для оксидиметрического определения индиго и индигосульфокислоты. Установлены условия для анализа красителя сульфатом железа(III) при 100° и гексацианоферратом(III) калия при комнатной температуре.

ОПРЕДЕЛЕНИЕ АРОМАТИЧЕСКИХ АМИНОВ И ФЕНОЛОВ НА МИЛИГРАММОВОЙ ШКАЛЕ *N*-БРОМСУКЦИНИМИДОМ:

R. D. Tiwari, J. P. Sharma and I. C. Shukla, *Talanta*, 1967, **14**, 853.

Резюме—Разработан быстрый и несложный метод определения миллиграммовых количеств ароматических аминов и фенолов. Аликвотную часть, представляющую 2-4 мг пробы растворяют в смеси соляной и уксусной кислот и реагируют с N-бромсукцинимидом, избыток которого определяют иодометрическим методом после окончания реакции. Продолжительность реакции 1–10 мин, а абсолютная ошибка в большинстве случаев отрицательная, колеблющаяся от −1 до −4%.

МИКРОХИМИЧЕСКОЕ ОБНАРУЖЕНИЕ ИЗОНИТРИЛОВ:

E. V. Crabtree, E. J. Poziomek and D. J. Hoy, *Talanta*, 1967, **14**, 857.

Резюме—Микрограммовые количества изонитрилов могут обнаружится на фильтровальной бумаге или трубках силикагеля смесью ацетата бензидина и ацетата меди(II) или смесью п,п'-тетраметилдиаминодифенилметана и сульфата меди(II) в качестве реагентов. Определению мешают вещества, влияющие на определение цианистого водорода теми же реагентами. Метод позволяет обнаружение до 0,1 мкг н-, с- или н-бутилизонитрила.

П-АМИНОАЦЕТОФЕНОН КАК РЕАГЕНТ ДЛЯ КОЛОРИМЕТРИЧЕСКОГО ОПРЕДЕЛЕНИЯ ЦЕРИЯ(IV):

G. Somidevamma, and M. S. Sarma, *Talanta* 1967, **14**, 861.

Резюме—С раствором п-аминоацетофенона церий(IV) дает пурпурную окраску которой можно пользоваться для его обнаружения и определения. Пределы отождествления и разбавления 1,0 мкг и 1 в 50,000, соответственно. Закон Бера соблюдается в пределах 14–350 мкг. Окраска устойчивая только в течение 5 мин., потому измерение светопоглощения следует проводить быстро. Описанный метод меньше подлежает влиянию других ионов чем обыкновенные методы.

Some solvent effects on the solvent extraction of 8-quinolinol: HORACIO A. MOTTOLA and HENRY FREISER, *Talanta*, 1967, **14**, 864 (Department of Chemistry, University of Arizona, Tucson, Arizona 85721, U.S.A.).

Summary—The distribution constants of 8-quinolinol between water and a series of substituted aliphatic hydrocarbons, at 25°, are reported. The results are discussed in terms of dielectric constant and solubility parameter of the solvents. For 8-quinolinol, and possibly for its chelates, bromochloromethane, dibromomethane and chloroform seem to be about the best solvents, in that order. Among the solvents studied, chloroform shows significantly higher values than expected; the deviation may be explained by a specific interaction of the hydrogen-bonding type.

Explosion hazards with xenon trioxide solutions ("xenic acid"): JOHN H. HOLLOWAY, *Talanta*, 1967, **14**, 871 (Department of Chemistry, University of Aberdeen, Old Aberdeen, Scotland).

Summary—Attention is drawn to the explosion hazards associated with xenic acid (xenon trioxide solution) and hence all xenon compounds that can yield xenon trioxide by hydrolysis.

Spectrophotometric determination of chromium with Xylenol Orange and Methylthymol Blue: K. L. CHENG, *Talanta*, 1967, **14**, 875 (Department of Chemistry, University of Missouri at Kansas City, Kansas City, Missouri 64110, U.S.A.).

Summary—A new simple and sensitive method for determining traces of chromium is described. Xylenol Orange and chromium(III) form a red complex at pH 3 on heating in boiling water for 20 min. The molar absorptivity is $19{\cdot}0 \times 10^3$. No catalytic action of the bicarbonate ion, carbon dioxide, or chromium(II) generated by metallic zinc was observed. Methylthymol Blue is a less sensitive reagent for chromium, the molar absorptivity being $11{\cdot}5 \times 10^3$.

Solvent extraction of ammine complexes: M. KYRŠ and M. PIVOŇKOVÁ, *Talanta*, 1967, **14**, 877 (Nuclear Research Institute, Czechoslovak Academy of Sciences, Řež near Prague, Czechoslovakia).

Summary—The ammine complexes of zinc and of cobalt(II) can be extracted effectively as the dipicrylaminates or tetraphenylborates by using nitrobenzene as the solvent.

ВЛИЯНИЕ РАСТВОРИТЕЛЯ В ЭКСТРАКЦИИ РАСТВОРИТЕЛЯМИ 8-ХИНОЛИНОЛА:

HORACIO A. MOTTOLA and HENRY FREISER, *Talanta*, 1967, **14**, 864.

Резюме—Определены константы распределения 8-хинолинола между водой и рядом замещенных алифатических углеводородов при 25°. Результаты обсуждены ссиляясь на диэлектрическую постоянную и параметр растворимости растворителей. Для 8-хинолинола и—возможно—для его хелатов бромохлорметан, дибромметан и хлороформ представляют собой найуспешные растворители, в том же порядке. От исследованных растворителей, хлороформом получаются значителńо больше величины от ожиданых; эту неправильность можно объяспить на основе специфического взаймодейсвия типа водородной связи.

ОПАСНОСТЬ ВЗРЫВА РАСТВОРОВ ТРЁХОКИСИ КСЕНОНА ("КСЕНОНОВОЙ КИСЛОТЫ"):

JOHN H. HOLLOWAY, *Talanta*, 1967, **14**, 871.

Резюме—Обращастся внимание на опасность взрыва, связанную с ксеноновой кислотой (раствором трёхокиси ксенона) и со всеми соединениями ксепона, дающими трёхокис ксенона путем гидролиза.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ХРОМА КСИЛЕНОЛОРАНЖЕВЫМ И МЕТИЛТИМОЛСИНИМ:

K. L. CHENG, *Talanta*, 1967, **14**, 875.

Резюме—Описан новый несложный и чувствительный метод определения следов хрома. Ксиленолоранжевый образует с хромом(III) красный комплекс при pH 3, нагреванием в кипящей воде через 20 мин. Не обпаружено каталитическое действие бикарбонатиона, двуокиси углерода или хрома(II), генерированных металлическим цинком. Метилтимолсиний является менее чувствительным реагентом на хром, дающий молярное поглощение $11{,}5 \times 10^3$.

ЭКСТРАКЦИЯ РАСТВОРИТЕЛЯМИ АММИНОВЫХ КОМПЛЕКСОВ:

M. KYRŠ and M. PIVOŇKOVÁ, *Talanta*, 1967, **14**, 877.

Резюме—Амминовые комплексы цинка и кобальта(II) успешно экстрагируются нитробензолом в качестве растворителя в форме дипикриламинатов или тетрафенилборатов.

Talanta, 1967, Vol. 14, p. iv. Pergamon Press Ltd. Printed in Northern Ireland

NOTICES

PRAGUE

3–17 *September* 1967, **VI Internationaler Polarographischer Kursur.**

Dieser Kursus besteht aus Vorlesungen über die Grundlagen der Polarographie und Oszillopolarographie, und einem entsprechendem Praktikum. Der Lehrgang ist für Hochschulabsolventen gedacht, jedoch sind eingehende Kenntnisse der Polarographie nicht Vorbedingung. Die Zahl der Teilnehmer wurde auf 40 Personen begrenzt. Die Teilnehmer werden in zwei Gruppen eingeteilt. Die Vorlesungen und das Praktikum werden in deutscher Sprache abgehalten, aber falls eine ausreichende Anzahl der Teilnehmer es vorziehen sollte, wird die englische Sprache für eine der beiden Gruppen verwendet werden.

Der Lehrgang wurde unter Aufsicht des Herrn Professor Dr. J. Heyrovský zusammengestellt. Die Vorlesungen und das Praktikum werden von wissenschaftlichen Fachkräften der Karlsuniversität und des J. Heyrovský Polarographischen Institutes gehalten, resp. geleitet werden (Doz. J. Kůta, Prof. A. Vlček, Prof. P. Zuman und andere). Die Teilnahmegebühr beträgt Kčs 600,– –, einschliesslich der Kosten eines Ausfluges in die Umgebung von Prag und eines gemeinsamen Abendessens am letzten Tage des Lehrganges. Alle Teilnehmer erhalten eine vervielfältigte Anleitung zu den Laboratoriumsversuchen. Unterbringung in Studentenheimen zu mässigen Preisen wird gewährleistet.

Die Anmeldungen sind an das Institut für Physikalische Chemie der Karlsuniversität, Prag 2, Albertov 2030, Dozent V. Kalous, bis spätestens Ende Juni 1967 zu richten.

U.S.A.

14–18 *August* 1967, **Gordon Research Conference on Analytical Chemistry,** New Hampton School, New Hampton, New Hampshire. Chairman; C. W. Zuehlke; Vice Chairman; D. N. Hume. For further information write to: W. George Parks, Director University of Rhode Island Kingston, Rhode Island, U.S.A.

5–9 *September* 1967, **22nd annual Molecular Spectroscopy Symposium,** Columbus Ohio.

In addition to our usual programme of Invited Speakers and Contributed Papers, we will have three specially arranged seminars on Rapid Scanning Spectroscopy, Far Infrared Problems, and New Experiments with Molecular Beams. For further information write to: K. Narahari Rao, The Ohio State University, Dept. of Physics, 174 West 18th Avenue, Columbus, Ohio 43210, U.S.A.

10–12 *October* 1967, **Eleventh Conference on Analytical Chemistry in Nuclear Technology,** Mountain View Hotel, Gatlinburg, Tennessee sponsored by the Analytical Chemistry Division, Oak Ridge National Laboratory.

The theme of this years conference is "Instrumental Methods in Analytical Chemistry". Papers, up to 25 min in length, dealing with instrumentation and instrumental applications in areas such as radiochemistry electrochemistry, spectrophotometry, spectroscopy, chromatography, automated methods of analysis, and chemical separations, are solicited by the committee. Special symposia will be arranged by the committee as interest dictates.

SUMMARIES FOR CARD INDEXES

Countercurrent Ionophoresis—II. Practical Applications: W. PREETZ and H. L. PFEIFER, *Talanta*, 1967, **14**, 143 (Institute for Analytical Chemistry and Radiochemistry, University of Saarland, Saarbrücken, Germany).

Summary—By use of a new apparatus it has been possible to confirm the principle and course of countercurrent ionophoresis, by applying it to model anionic substances. Qualitative investigation showed that the anions were arranged between the anode and cathode according to their mobilities. For the formation of a stationary state the anions in the anode and countercurrent electrolytes must have greater mobility, and the anions of the effluent and cathode electrolytes a lower mobility, than the anions in the mixture to be separated. Field intensity measurements in a chamber with a capillary separation gap show that there is a sharpe change in the field intensity at the boundaries of the stationary zones, and this intensity profile is responsible for the sharp separations obtained. By comparison of field intensity factors and known mobilities it is possible to calculate other ionic mobilities. The concentrations of ions in the zones can be calculated from the ionic mobilities and the concentration of the countercurrent solution.

Cation-exchange behaviour of several elements in hydrochloric acid—organic solvent media: J. KORKISCH and S. S. AHLUWALIA, *Talanta*, 1967, **14**, 155 (Analytical Institute, University of Vienna IX, Währingerstrasse 38, Austria).

Summary—In the present paper the cation-exchange characteristics of 20 elements towards the strongly acidic cation-exchange resin Dowex 50X8 in media containing varying concentrations of organic solvents and aqueous hydrochloric acid were investigated. Based on the determination of the distribution coefficients of these elements in the organic solvents methanol, ethanol, n-propanol, isopropanol, methyl glycol, acetone, tetrahydrofuran and acetic acid, the conditions most suitable for their quantitative separation are indicated and discussed.

ПРОТИВОТОЧНЫЙ ИОНОФОРЕЗ—II: ПРАКТИЧЕСКИЕ ПРИМЕНЕНИЯ МЕТОДА:

W. Preetz and H. L. Pfeiffer, *Talanta*, 1967, **14**, 143.

Резюме—С помощью нового прибора удалось подтвердить принципы и течение противоточного ионофореза на основании применения метода на модельные анионные вещества. Качественные исследования показали распределение анионов между анодом и катодом в зависимости от их подвижностей. Для образования стационарного состояния анионы в аноде и противоточных электролитах надо быть более подвижны, а анионы в вытекающем растворе менее подвижны чем анионы в разделяемом растворе. Измерение напряжения поля в камере с капиллярным разделительным зазором показали существование острой перемены напряженности поля на границах стационарных зон; обнаруженные острые разделения получены на основе этого профиля напяжения. На основании сравнения факторов напряжения поля и известных подвижностей удалось вычислить подвижности других ионов. Концентрации ионов в зонах можно вычислить из подвижностей ионов и концентрации противоточного раствора.

КАТИОННЫЙ ОБМЕН НЕКОТОРЫХ ЭЛЕМЕНТОВ В РАСТВОРЕ СОЛЯНОЙ КИСЛОТЫ И ОРГАНИЧЕСКИХ РАСТВОРИТЕЛЕЙ:

J. Korisch and S. S. Ahluwalia, *Talanta*, 1967, **14**, 155.

Резюме—Исследованы катионообменные характеристики 20 элементов на сильнокислой катионообменной смоле Дауекс 50 × 8 в растворах, содержащих различные концентрации органических растворителей и соляной кислоты. Сообщены и обсуждены самые подходящие условия для количественного определения этих элементов, разработанные на основании их коэффициентов распределения в органических растворителях метиловом, этиловом, н-пропиловом и изопроплловом спиртах, метилгликоле, ацетоне, тетрагидрофуране и уксусной кислоте.

Spectrophotometric study of the reaction of the uranyl ion with 4-(2-thiazolylazo)resorcinol: L. SOMMER and V. M. IVANOV, *Talanta*, 1967, **14**, 171 (Department of Analytical Chemistry, J. E. Purkyně University, Brno, Czechoslovakia).

Summary—The uranyl ion forms only 1:1 chelates with 4-(2-thiazolylazo)resorcinol (TAR) in solution, $UO_2(TAR)H^+$ being formed below pH 3 and $UO_2(TAR)$ above pH 3·5. The latter complex may also be precipitated at pH > 3. The quantitative formation of $UO_2(TAR)$ at pH 7·5–7·8 in solutions containing a small excess of reagent and some triethanolamine as buffer can be used for the sensitive spectrophotometric determination of uranium. Several interfering ions can be masked with a mixture of sodium fluoride, cyclohexanediaminetetraacetic acid and 5-sulphosalicyclic acid. TAR is slightly less sensitive than 4-(2-pyridylazo)resorcinol as a reagent for uranium but is more selective.

Determination of alumina film thickness by alpha particle scattering: MAX PEISACH, DARRELL O. POOLE and HERMANN F. RÖHM, *Talanta*, 1967, **14**, 187 (Southern Universities Nuclear Institute, P.O. Box 17, Faure, C.P., South Africa).

Summary—The scattering of accelerated alpha particles has been used to determine the surface oxide film thickness of anodized aluminium. The measurements were based on determining the difference between the energy of an alpha particle scattered from the surface oxide layer and that from the underlying metal. Films ranging in thickness from 10 to 130 $\mu g/cm^2$ were analysed non-destructively with a relative standard deviation of 3·5%. The average time for an analysis was 30 min with an incident beam current of up to about 1 μA.

Analysis of zone-melted ultra-pure organic compounds: A new quantitative differential thermal analysis method: ROBERT FRIEDENBERG and PAUL J. JANNKE, *Talanta*, 1967, **14**, 195 (Department of Neurobiology in Psychiatry, University of Maryland, Baltimore, Maryland, U.S.A.)

Summary—A method for the rapid quantitative determination of impurities in ultra-pure organic compounds is described. It is based on the difference in slopes of the curves obtained when the difference in temperature between the sample and a reference shield is plotted against time. The results are compared with those obtained by thermal analysis.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ИЗУЧЕНИЕ РЕАКЦИИ УРАНИЛИОНА С 4-(2-ТИАЗОЛИЛАЗО)-РЕЗОРЦИНОМ:

L. Sommer and V. M. Ivanov, *Talanta*, 1967, **14**, 171.

Резюме—Уранилион образует только 1:1 хелаты с 4-(2-тиазолилазо)резорцином (TAR) в растворе, $UO_2(TAR)H^+$ образуясь ниже pH 3, а $UO_2(TAR)$ выше pH 3,5. Последный компдекс тоже осаждается при pH выше 3. Количественным образованием $UO_2(TAR)$ при pH 7,5–7,8 в растворах содержащих небольшой избыток реагента и триэтаноламин в качестве буффера можно пользоваться для чувствительного спектрофотометрического определения урана. Некоторые мешающие ионы можно маскировать смесью фторида натрия, циклогександиаминтетрауксусной кислоты и 5-сульфосалициловой кислоты. TAR является незначительно меньше чувствительным чем 4-(2-пиридилазо)резорцин в качестве реагента для урана, но является более избирательным.

ОПРЕДЕЛЕНИЕ ТОЛЩИНЫ ПЛЕНОК АЛЮМИНИЯ МЕТОДОМ РАССЕЯНИЯ АЛЬФА ЧАСТИЦ:

Max Peisach, Darrell O. Poole and Hermann F. Röhm, *Talanta*, 1967, **14**, 187.

Резюме—Рассеяние ускоренных альфа частиц использовано для определения толщины поверхностной пленки окиси анодированного алюминия. Определение основывается на измерении разници между энергией альфа частици рассеяной от поверхностной пленки окиси и альфа частици рассеяной от нижнего слоя металла. Относительная стандартная ошибка при анализе пленок толщины 10–130 мкг/см^2 была 3,5%. Средная продолжительность определения 30 мин. при токе падающего пучка около 1 мкамп.

АНАЛИЗ ОЧИЩЕННЫХ МЕТОДОМ ЗОНАЛЬНОГО ПЛАВЛЕНИЯ ВЫСОКОЧИСТЫХ ОРГАНИЧЕСКИХ СОЕДИНЕНИЙ. НОВЫЙ КОЛИЧЕСТВЕННЫЙ МЕТОД ДИФФЕРЕНЦИАЛЬНОГО ТЕРМИЧЕСКОГО АНАЛИЗА:

Robert Friedenberg and Paul J. Jannke, *Talanta*, 1967, **14**, 195.

Резюме—Описан метод для быстрого количественного определения примесей в высокочистых органических соединениях. Метод основывается на разници наклона кривых, представляющих разницу температуры между пробы и эталонного экрана в зависимости от времени. Результаты сравниваются с полученными термическим анализом данными.

Rapid analysis of plating baths by a direct-reading thermometric method: I. SAJÓ and B. SIPOS, *Talanta*, 1967, **14**, 203 (Research Institute for Ferrous Metallurgy, Budapest XI, Fehérvári út 130, Hungary).

Summary—Methods are described for the rapid analysis of plating baths by measurement of the heat evolved in a reaction between the reagent and the component to be determined. The novel feature of the method is the use of reagents which have zero heat of mixing, so that the temperature scale can be directly calibrated in concentration units for a particular determination. A determination takes only 5 min and the precision is equal to that of the classical methods. Procedures are given for the analysis of nickel and chromium plating baths.

Improved method for the constant-current potentiometric determination of plutonium: CHARLES E. PIETRI and ALBERT W. WENZEL, *Talanta*, 1967, **14**, 215 (U.S. Atomic Energy Commission, New Brunswick, N.J., U.S.A.)

Summary—A highly precise method is described for the determination of plutonium by constant-current potentiometric titration with primary standard potassium dichromate. The relative standard deviation is 0·04% or better.

An experimental evaluation of neutron activation, wet assay and fire assay methods of determining gold in ores: A. CHOW and F. E. BEAMISH, *Talanta*, 1967, **14**, 219 (Department of Chemistry, University of Toronto, Toronto 5, Canada).

Summary—The errors associated with fire assay, wet extraction and neutron activation methods are evaluated, the accuracy and precision of these methods are compared, and a method for determining the chemical recovery in the activation determination of gold in ores and concentrates is presented.

БЫСТРЫЙ АНАЛИЗ ГАЛЬВАНИЧЕСКИХ РАСТВОРОВ С ИСПОЛЬЗОВАНИЕМ ТЕРМОМЕТРИЧЕСКОГО МЕТОДА С ПРЯМЫМ ОТСЧЁТОМ:

I. Sajó and B. Sipos, *Talanta*, 1967, **14**, 203.

Резюме—Описаны методы для быстрого анализа гальванических растворов измерением теплоты, выделеной реакцией между реагентом и определяемым компонентом. Новое в этом методе использование реагентов имеющих теплоту смешения нуль, так что дана возможность директной калибровки температурной шкалы в единицах концентрации для определенного анализа. Одно определение требует только 5 минут, а точность метода равна точности классических методов. Приведены процедуры для анализа гальванических растворов никеля и хрома.

УЛУЧШЕННЫЙ МЕТОД ПОТЕНЦИОМЕТРИЧЕСКОГО ОПРЕДЕЛЕНИЯ ПЛУТОНИЯ ПРИ ПОСТОЯННОМ ТОКЕ:

Charles E. Pietri and Albert W. Wenzel, *Talanta*, 1967, **14**, 215.

Резюме—Описывается весьма аккуратный метод определения плутония основывающийся на потенциометрическом титровании стандартным раствором бихромата калия при постоянном токе. Относительная стандартная ошибка лучше чем 0,04%.

ОЦЕНКА МЕТОДОВ НЕЙТРОННОЙ АКТИВАЦИИ, МОКРОЙ ПРОБЫ И СУХОЙ ПРОБЫ ДЛЯ ОПРЕДЕЛЕНИЯ ЗОЛОТА В РУДАХ:

A. Chow and F. E. Beamish, *Talanta*, 1967, **14**, 219.

Резюме—Рассмотрены ошибки при определении золота сухим путем, экстрагированием и нейтроноактивационным методом. Сравнивается точность и воспроизводимость этих методов и предложен метод определения химического выхода при активационном определении золота в рудах.

Use of thenoyltrifluoroacetone for the determination of manganese by activation analysis: FRANTIŠEK KUKULA, BLAŽENA MUDROVÁ and MILOSLAV KŘIVÁNEK, *Talanta*, 1967, **14**, 233 (The Nuclear Research Institute, Czechoslovak Academy of Sciences, Řež by Prague, Czechoslovakia).

Summary—A new procedure for the substoichiometric extraction of bivalent manganese by thenoyltrifluoroacetone into ethyl acetate has been developed and used in activation analysis. The value of the extraction constant has been found to be $3{\cdot}1 \times 10^{-6}$; the pH range in which the extraction can be performed is 7·8–9·2. The influence of oxalate, citrate, tartrate, fluoride and cyanide ions has been studied. A selective substoichiometric extraction of manganese in the presence of Zr, Hf, Nb, Th, Fe and Sc is possible at pH 8–8·5, tartrate and fluoride being used as masking agents. Copper and cobalt can be screened by ammonia and cyanide respectively. The method has been used for the determination of manganese in biological materials, potassium fluoride and zirconium.

Inorganic polarography in organic solvents—II: Polarographic examination of the molybdenum(V) thiocyanate complex in diethyl ether: B. K. AFGHAN and R. M. DAGNALL, *Talanta*, 1967, **14**, 239 (Chemistry Department, Imperial College, London, S.W.7, England).

Summary—A procedure involving the solvent extraction of molybdenum(V) thiocyanate into diethyl ether followed by a direct polarographic examination of the organic phase offers a selective method for the determination of molybdenum down to 0·5 ppm. Only molybdenum, amongst 21 elements examined, is observed to give a reduction wave under the recommended conditions. The method is evaluated with respect to various experimental factors and is applied to the determination of molybdenum in mild and alloy steels.

Determination of low concentrations of hydrogen halides and halogens in the gas phase. Removal from a mixture of gases and quantitative estimation: LESLIE BATT and FRANK R. CRUICKSHANK, *Talanta*, 1967, **14**, 245 (Chemistry Department, University of Aberdeen, Old Aberdeen, Scotland).

Summary—A method has been developed for the removal of hydrogen chloride, and mixtures of bromine and hydrogen bromide, from gaseous mixtures by absorption on various solids. The efficiency of removal of bromine and hydrogen bromide has been determined and the substances have been estimated potentiometrically. The technique is extended to include the other halogens and hydrogen halides.

ИСПОЛЬЗОВАНИЕ ТЕНОИЛТРИФТОРАЦЕТОНА ДЛЯ ОПРЕДЕЛЕНИЯ МАРГАНЦА МЕТОДОМ АКТИВАЦИОННОГО АНАЛИЗА:

FRANTISEK KUKULA, BLAZENA MUDROVA and MILOSLAV KRIVANEK, *Talanta*, 1967, **14**, 233.

Резюме—Разработана и применена в активационном анализе новая процедура для извлечения двувалентного марганца теноилтрифторацетоном в растворе этилацетата. Константа экстракции равна $3{,}1 \times 10^{-6}$; извлечение проводится в области pH 7,9–9,2. Изучено влияние ионов оксалата, цитрата, тартрата, фторида и цианида. Можно провести селективное субстехиометрическое извлечение марганца в присутствии Zr, Hf, Nb, Th, Fe, и Sc при pH 8–8,5, с использованием тартрат—и фторидионов в качестве маскирующих агентов. Медь и кобальт можно маскировать аммиаком или цианидионом, соответственно. Методом пользовались для определения марганца в биологических веществах, в фториде калия и цирконии.

ИЕОРГАНИЧЕСКАЯ ПОЛЯРОГРАФИЯ В ОРГАНИЧЕСКИХ РАСТВОРИТЕЛЯХ—II. ПОЛЯРОГРАФИЧЕСКОЕ ИЗУЧЕНИЕ КОМПЛЕКСА ТИОЦИАНАТА МОЛИБДЕНА(V) В ЭТИЛОВОМ ЭФИРЕ:

B. K. AFGHAN and R. M. DAGNALL, *Talanta*, 1967, **14**, 239.

Резюме—Описывается избирательный метод определения молибдена все до 0,5 мг/л основывающийся на экстрагировании тиоцианата молибдена(V) этиловым эфиром и прямом исследовании органической фазы полярографическим методом. Среди 21 исследованных элементов только молибден дает волну восстановления в предложенных условиях. Исследованы различные экспериментальные факторы влияющие на метод, а методом пользовались для определения молибдена в мягких и легированных сталях.

ОПРЕДЕЛЕНИЕ НЕБОЛЬШИХ КОНЦЕНТРАЦИЙ ГАЛОИДОВОДОРОДОВ И ГАЛОИДОВ В ГАЗОВОЙ ФАЗЕ. УДАЛЕНИЕ ИЗ СМЕСИ ГАЗОВ И КОЛИЧЕСТВЕННОЕ ОПРЕДЕЛЕНИЕ:

LESLIE BATT and FRANK R. CRUICKSHANK, *Talanta*, 1967, **14**, 245.

Резюме—Разработан метод удаления хлороводорода и смесей брома и бромоводорода из смесей газов адсорбированием на различных твердых фазах. Определена эффективность удаления брома и бромоводорода и проведена оценка их концентраций потенциометрическим методом. Методом можно пользоваться и для определения других галоидов и галоидоводородов.

Polarography of lead itaconate complexes: TSAI-TEH LAI, SHOU-NAN CHEN and EYIH LIN, *Talanta*, 1967, **14**, 251 (Analytical Chemistry Laboratory, Cheng Kung University, Tainan, Taiwan, China).

Summary—The complexation of lead ions with itaconic acid (H_2A) has been studied polarographically at 30°. At $pH < pK_1$, the complex species $Pb(HA)^+$ was identified. At $pK_1 < pH < pK_2$ and $pH > pK_2$ the formation of Pb(A) and $Pb(A)_3^{4-}$ respectively, was confirmed. The dissociation constant of $Pb(A)_2^{2-}$ was found to be $8{\cdot}3 \times 10^{-6}$. The electrode reactions were established.

Free radical oxidation of dihydric phenols with diphenylpicrylhydrazyl: GEORGE H. SCHENK and DANIEL J. BROWN, *Talanta*, 1967, **14**, 257 (Department of Chemistry, Wayne State University, Detroit 2, Michigan, U.S.A.)

Summary—A spectrophotometric study has been made of the reactions between the free radical 2,2-diphenyl-1-picrylhydrazyl (DPPH) and the three dihydric phenols. It has been shown that water affects the rate of all three reactions and the stoichiometry of the DPPH-catechol (pyrocatechol) reaction. Because of the differences in the rate of oxidation in absolute ethanol, it is possible to determine selectively either hydroquinone or catechol in the presence of resorcinol.

Precise determination of uranium in pure uranium and uranium compounds by constant-current coulometric titration: JERZY MALINOWSKI, *Talanta*, 1967, **14**, 263 (International Atomic Energy Agency, Seibersdorf Laboratory, Seibersdorf, Niederösterreich, Austria).

Summary—A procedure is described for very precise determination of uranium in high-purity uranium and uranium compounds. Uranium(VI) is reduced in a concentrated hydrochloric acid solution by metallic aluminium in the presence of cadmium ions to uranium(III). This is oxidized to uranium(IV) by protons on addition of an excess of orthophosphoric acid, and then oxidized to uranium(VI) by adding a weighed quantity of potassium dichromate in small excess. The excess of potassium dichromate is determined by constant-current coulometry. The coefficient of variation does not exceed 0·003%.

Contributions to the basic problems of complexometry—XXII: Determination of thorium and scandium in the presence of each other: R. PŘIBIL, V. VESELÝ and J. HORÁČEK, *Talanta*, 1967, **14**, 266 (Analytical Laboratory, J. Heyrovský Polarographic Institute, ČSAV, Prague 1, Jilská 16, Czechoslovakia).

Summary—A new method for the determination of thorium and scandium in the presence of each other is presented. Two aliquots of the solution are necessary. In one the sum of thorium and scandium is determined by direct titration with DCTA. In the second, thorium and scandium are treated with an excess of TTHA, phosphate is added, and zinc is used to titrate the excess of TTHA and to displace the scandium from its TTHA complex.

ПОЛЯРОГРАФИЯ КОМПЛЕКСОВ СВИНЦА И ИТАКОНОВОЙ КИСЛОТЫ:

TSAI-TEH LAI, SHOU-NAN CHEN and EYIH LIN, *Talanta*, 1967, **14**, 251.

Резюме—Образование комплексов между ионами свинца и итаконовой кислоты (H_2A) изучено полярографическим методом при 30°. При $pH < pK_1$ обнаружен комплекс $Pb(HA)^+$. При $pK_1 < pH < pK_2$ и $pH > pK_2$ подтверждено образование комплексов $Pb(A)$ и $Pb(A)_2^{2-}$. Константа диссоциации комплекса $Pb(A)_2^{2-}$ равна $8{,}3 \times 10^{-5}$. Определены электродные реакции.

ОКИСЛЕНИЕ ПУТЕМ СВОБОДНЫХ РАДИКАЛОВ ДВУАТОМНЫХ ФЕНОЛОВ С ИСПОЛЬЗОВАНИЕМ ДИФЕНИЛПИКРИЛГИДРАЗИЛА:

GEORGE H. SCHENK and DANIEL J. BROWN, *Talanta*, 1967, **14**, 257.

Резюме—Изучены спектрофотометрическим методом реакции свободного радикала 2,2-дифенил-1-пикрилгидразила(ДФПГ) и трех двуатомных фенолов. Показано что вода влияет на скорость этих трех реакций и на реакцию ДФПГ с катехином (пирокатехином). На основании различных скоростей окисления в абсолютном спирте удается избирательно определять гидрохинон или катехин в присутствии резорцина.

АККУРАТНОЕ ОПРЕДЕЛЕНИЕ УРАНА В ЧИСТОМ УРАНЕ И В СОЕДИНЕНИЯХ УРАНА МЕТОДОМ КУЛОНОМЕТРИЧЕСКОГО ТИТРОВАНИЯ ПРИ ПОСТОЯННОМ ТОКЕ:

JERZY MALINOWSKI, *Talanta*, 1967, **14**, 263.

Резюме—Предложена процедура весьма аккуратного определения урана в высокочистом уране и в урановых соединениях. Уран(VI) восстанавливаю до урана(III) металлическим алюминием в растворе концентрированной соляной кислоты в присутствии ионов кадмия. Уран(III) окисляют до урана(IV) протонами добавлением избытка ортофосфорной кислоты, а затем окисляют до урана(VI) добавлением взвешенного количества бихромата калия в небольшем избытке. Этот избыток бихромата калия определяют кулонометрическим титрованием при константном токе. Коэффициент вариации не превосходит 0,003%.

ВКЛАД К ОСНОВНЫМ ПРОБЛЕМАМ КОМПЛЕКСОМЕТРИИ—XXIII: ОПРЕДЕЛЕНИЕ ТОРИЯ И СКАНДИЯ ОДНОГО В ПРИСУТСТВИИ ДРУГОТО:

R. PŘIBIL, V. VESELÝ and J. HORÁČEK, *Talanta*, 1967, **14**, 266.

Резюме—Сообщен новый метод определения тория и скандия одного в присутствии другого. Требуются две аликвотных части раствора. В одной части определяют сумму тория и скандия прямым титрованием с ДЦТА. Во второй части раствору добавляют избыток ТТХА и фосфатионы а затем оттитровывают избыток ТТХА и вытесняют скандий из его комплекса с ТТХА с раствором цинка.
